# Synthesis and Structural Characterization of Tetra- and Pentanuclear Lanthanide Hydroxido Clusters

Simmi Datta,[a] Viswanathan Baskar,[a] Henan Li,[a] and Peter W. Roesky*[a]

**Keywords:** Cage compounds / Cluster compounds / Coordination modes / Bridging ligands / Lanthanides

Tetra- and pentanuclear lanthanide clusters having dibenzoylmethanido and *o*-nitrophenolato as ligands in the coordination sphere were prepared. Treating [$LnCl_3 \cdot 6H_2O$] (Ln = Er, Tm) with dibenzoylmethane and *o*-nitrophenol in the presence of triethylamine yielded the pentanuclear lanthanide clusters $HNEt_3^+[Ln_5(\mu_3\text{-}OH)_4(\mu_4\text{-}OH)(Ph_2acac)_7(o\text{-}O_2NC_6H_4\text{-}O)_3Cl]^-$ (Ln = Er, Tm). Under the same reaction conditions but using Yb and Lu as center metals, tetranuclear lanthanide clusters $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_8(o\text{-}O_2NC_6H_4O)_2]$ (Ln = Yb, Lu) were obtained. The structures of all new compounds were confirmed by single-crystal X-ray diffraction. The anions of the pentanuclear lanthanide cores are square pyramidal. Each triangular face of the square pyramid is capped by one $\mu_3$-O moiety. In the square base, four lanthanide atoms are linked by one $\mu_4$-O atom. The formation of the hydroxido bridges can be explained by deprotonation of the coordinated water molecules.

## Introduction

Inorganic clusters continue to attract considerable attention, as they represent the bridge linking molecular and solid-state chemistry, and also because they act as useful tools to understand the size-dependent physical properties of electronic materials.[1] While the cluster chemistry of the d-block transition metals is now firmly established, and huge clusters (especially of molybdenum,[2] copper,[3] silver,[4] and gold[5]) have been isolated, the analogous chemistry of the lanthanides is virtually undeveloped.[6,7] This is even more surprising, since oligomeric lanthanide structures are proposed to play a key role in some catalytic transformations.[8,9] It is well known that the most stable lanthanide clusters are oxido/hydroxido clusters.[10] Recently, we, along with others, synthesized new tetradeca- and pentadecanuclear lanthanide oxido/hydroxido clusters.[7,11] Basically, two different approaches towards the preparation of oxido/hydroxido clusters were investigated. One way to obtain these compounds is the hydrolysis of moisture-sensitive starting material,[11,12] whereas the other approach is a hydrolytic one in which the water molecules are deprotonated in a controlled way.[13–18] Most of the oxido/hydroxido clusters are stabilized by ligands such as alkoxides,[19,20] phenoxides,[21] diketones,[22,23] and more recently amino acids[7,24] and the *o*-nitrophenolato ligand.[11]

In a recent communication, we reported the synthesis and structure of a pentanuclear yttrium cluster, $H_5[Y_5(\mu_4\text{-}O)(\mu_3\text{-}O)_4(\mu\text{-}\eta^2\text{-}Ph_2acac)_4\eta^2\text{-}(Ph_2acac)_6]$. It was obtained by treating [$YCl_3 \cdot 6H_2O$] with dibenzoylmethane ($Ph_2acacH$) in the presence of triethylamine.[14] The cluster was found to catalyze the oxidation of aldehydes to the corresponding carboxylic acids in the presence of air. An isostructural cluster having europium as the center metal was reported.[13] In contrast, by using the larger lanthanides, tetranuclear clusters of composition $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_{10}]$ (Ln = Pr, Nd, and Sm) were obtained in a similar manner.[15] Single-crystal X-ray analysis of these compounds revealed that each cluster consists of four lanthanide atoms, two $\mu_3$-oxygen atoms, and ten $Ph_2acac$ ligands, which make up the peripheral part of the cluster. Three types of coordination modes [$\eta^2$-, ($\mu$-O)-$\eta^2$-, and ($\mu$-O)$_2$-$\eta^2$] are observed for the ligation of $Ph_2acac$ to the metal centers.

The second ligand that we successfully introduced in the synthesis of lanthanide clusters is *o*-nitrophenolato.[11] Infinite chains of composition $[(thf)_4\{K(o\text{-}O_2NC_6H_4O)_4\text{-}Ln\}_4]_n$ (Ln = Y, Er, Lu), infinite layers of composition $[\{K_2(o\text{-}O_2NC_6H_4O)_5Tb\}_n]$ and $[\{K_2(o\text{-}O_2NC_6H_4O)_5Ln)\}_n]$ (Ln = Sm, Eu), as well as tetradecanuclear clusters of composition $H_{18}[Ln_{14}(\mu\text{-}\eta^2\text{-}o\text{-}O_2NC_6H_4O)_8(\eta^2\text{-}o\text{-}O_2NC_6H_4O)_{16}(\mu_4\text{-}O)_2(\mu_3\text{-}O)_{16}]$ (Ln = Dy, Er, Tm, Yb), were obtained by using *o*-nitrophenolato as a ligand under different reaction conditions. Thus, *o*-nitrophenolato is a ligand that features different coordination modes and is thus able to stabilize different sorts of coordination polymers and oligomers.

We are now interested in synthesizing lanthanide clusters having both the dibenzoylmethanido and *o*-nitrophenolato ligands in the coordination sphere. Herein, we report on the synthesis and structure of a series of novel tetra- and

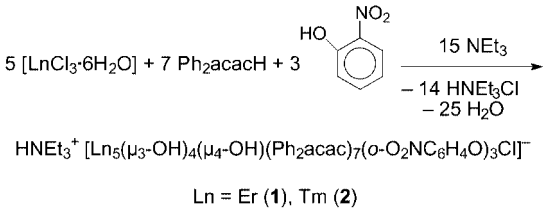
pentanuclear clusters of composition $HNEt_3^+[Ln_5(\mu_3\text{-}OH)_4(\mu_4\text{-}OH)(Ph_2acac)_7(o\text{-}O_2NC_6H_4O)_3Cl]^-$ (Ln = Er, Tm), and $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_8(o\text{-}O_2NC_6H_4O)_2]$ (Ln = Yb, Lu).

## Results and Discussion

Reaction of $[LnCl_3{\cdot}6H_2O]$[25] with dibenzoylmethane and *o*-nitrophenol in methanol, in the presence of triethylamine as a base, yielded the pentanuclear lanthanide clusters $HNEt_3^+[Ln_5(\mu_3\text{-}OH)_4(\mu_4\text{-}OH)(Ph_2acac)_7(o\text{-}O_2NC_6H_4O)_3Cl]^-$ [Ln = Er (**1**), Tm (**2**)] (Scheme 1). As the clusters were soluble in methanol, we used toluene to extract them from the reaction mixture. The clusters have been characterized by standard analytical and spectroscopic techniques. The solid-state structures of compounds **1** and **2** were established by single-crystal X-ray diffraction. They crystallize in the monoclinic space group $P2_1/c$ and have four molecules in the unit cell. Crystals of compounds **1** and **2** that consist of an ion pair composed of a $HNEt_3^+$ cation and a $[Ln_5(\mu_3\text{-}OH)_4(\mu_4\text{-}OH)(Ph_2acac)_7(o\text{-}O_2NC_6H_4O)_3Cl]^-$ anion are isomorphous (Figure 1). The anions consist of pentanuclear lanthanide cores in a square pyramidal arrangement. This pentanuclear arrangement of the Ln core in compounds **1** and **2** is a common structural motif for lanthanide oxido/hydroxido clusters[13,14,26] and is observed in compounds such as $[Y_9O_2(OH)_8(aacac)_{16}]^-$[10] (aacac = allylacetoacetate), $[Ln_9O_2(OH)_8(ba)_{16}]^-$[12] (ba = benzoylacetone and Ln = Sm, Eu, Gd, Dy, Er), $H_{18}[Ln_{14}(\mu\text{-}\eta^2\text{-}o\text{-}O_2NC_6H_4O)_8(\eta^2\text{-}o\text{-}O_2NC_6H_4O)_{16}(\mu_4\text{-}O)_2(\mu_3\text{-}O)_{16}]$ (Ln = Dy, Er, Tm, Yb), and related compounds.[11,13] In contrast to these neutral clusters, compounds **1** and **2** contain anionic species. Each triangular face of the square pyramid is capped by one $\mu_3$-O moiety. In the square base, four lanthanide atoms are linked by one $\mu_4$-O atom. The pentanuclear Ln core is surrounded by ten peripheral ligands and a chlorine atom. A comparison with the pure dibenzoylmethanido clusters $[Ln_5(OH)_5(Ph_2acac)_{10}]$ is quite interesting. In $[Ln_5(OH)_5(Ph_2acac)_{10}]$, six ligands are terminal chelates and four are bridging chelates bonding to two metal ions that belong to the base of the polyhedron. In compounds **1** and **2**, three of the four bridging dibenzoylmethanido ligands are formally substituted by *o*-nitrophenolato ligands. The phenolate oxygen atoms always bridge two lanthanide atoms. Two of the three *o*-nitrophenolato ligands also bind a lanthanide atom through one oxygen atom of the $NO_2$ group, whereas the $NO_2$ group of the third *o*-nitrophenolato ligand, located between Ln1 and Ln5, is turned away from the cluster core. This generates a free coordination site on Ln5, which is occupied by a chlorine atom, and results in a negatively charged cluster core.

The formation of the hydroxido bridges can be explained by the presence of water in the solvents[27] and by the six water molecules coordinated to the metal center through the oxygen atom in the starting material $[LnCl_3{\cdot}6H_2O]$.[25] Addition of base leads only to the deprotonation of the coordinated water molecules. The bridging oxygen atoms in the core of the cluster are parts of hydroxy groups; this is confirmed by a broad peak around 3425 $cm^{-1}$ in the IR spectra. The Ln–O bond lengths to the dibenzoylmethanido and to the *o*-nitrophenolato ligands are in the expected range of 222.8(2) to 246.2(2) pm for compound **1** and 223.63(11) to 247.13(13) pm for compound **2**. Each triangular face of the square pyramid is capped by one $\mu_3$-O group,



Scheme 1.

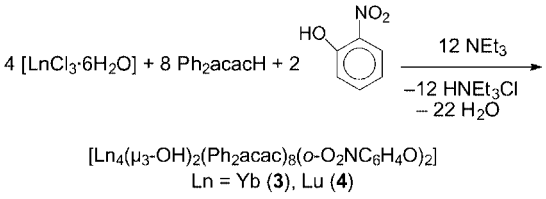
whereas the square plane is capped by one $\mu_4$-bonded oxygen atom. The Ln–O bond lengths of the $\mu_4$-oxygen atoms are in the range of 243.6(2) to 263.7(2) pm in **1** and 242.31(10) to 262.70(11) pm in **2**. The Ln–Cl bond lengths are 272.2(4) pm in **1** and 272.6(2) pm in **2**. Selected metric parameters are given in the caption of Figure 1.

Since it is well known that dramatic changes in the microstructure of lanthanide clusters are observed by altering the ionic radius of the center metal, we were also interested in using smaller lanthanides. Under the same reaction conditions as those used to prepare compounds **1** and **2**, but using Yb and Lu as center metals, tetranuclear lanthanide clusters of composition $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_8(o\text{-}O_2NC_6H_4O)_2]$ [Ln = Yb (**3**), Lu (**4**)] were obtained (Scheme 2). The solid-state structures of compounds **3** and **4** were established by single-crystal X-ray diffraction, which revealed that they are tetranuclear (Figure 2). A comparable $Ln_4$ core was observed earlier in $[Nd_4(\mu_3\text{-}OH)_2(\mu_2\text{-},\mu_1\text{-}acac)_6(acac)_4]$ (acac = acetylacetonate)[28] and $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_{10}]$ (Ln = Pr, Nd, and Sm).[15] Compounds **3** and **4** are pseudopolymorphic to each other, because the amount of noncoordinated solvent (toluene) in the unit cell differs for each compound. Two types of coordination modes are observed for the ligation of $Ph_2acac$ to the metal centers in the clusters. Of the eight $Ph_2acac$ ligands, six chelate the metal centers in $\eta^2$ fashion, and two more both chelate and bridge two metal centers, thus they are $(\mu\text{-}O)_2\text{-}\eta^2$-coordinating. The *o*-nitrophenolato ligands chelate one metal atom and bridge another metal atom through one oxygen atom, thus they are $(\mu\text{-}O)\text{-}\eta^2$-coordinating. A comparison with the pure dibenzoylmethanido clusters $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_{10}]$ (Ln = Pr, Nd, and Sm)[15] shows the same interesting features as those observed for compounds **1** and **2**. The tetranuclear Ln core in $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_{10}]$ is similar to that in compounds **3** and **4**. Moreover, the $Ph_2acac$ ligands coordinate in a similar $\eta^2$- and $(\mu\text{-}O)_2\text{-}\eta^2$ fashion. The only difference between compounds **3** and **4** and $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_{10}]$ is the presence of the two *o*-nitrophenolato ligands. In $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_{10}]$, the positions of the *o*-nitrophenolato ligands are formally replaced by two more $Ph_2acac$ ligands, which bind in the same arrangement $[(\mu\text{-}O)\text{-}\eta^2$-coordination]. A significant difference arises with respect to the ionic radius of the center metal. Whereas in the pure $Ph_2acac$ clusters the cluster size decreases from penta- to tetranuclear by increasing the ionic radius, the opposite trend is observed for the mixed $Ph_2acac$/*o*-nitrophenolato compounds. In compounds **3** and **4**, the two $\mu_3$-oxygen atoms in the core of the cluster are parts of hydroxy groups, as revealed by a broad peak around 3430 $cm^{-1}$ in the IR spectra. This is supported by the Ln–O12–Ln bond angles, which are close to tetrahedral (e.g. for compound **4**: Lu1–O12–Lu1′ 108.20(6)°, Lu1–O12–Lu2 108.75(8)°, and Lu1–O12–Lu2′ 103.54(7)°). Each metal is coordinated to eight oxygen atoms in a square antiprismatic arrangement. The metal-to-oxygen distances of the coordinated ligands range from 230.1(5) to 240.7(6) pm (**3**) and from 234.5(2) to 243.6(2) pm (**4**) for the *o*-nitrophenolato ligands; for the $Ph_2acac$ ligands, the distances range from 223.1(5) to 257.6(7) pm in **3** and from 222.8(2) to 272.0(2) pm in **4**. Selected metric parameters are given in the caption of Figure 2.



Scheme 2.

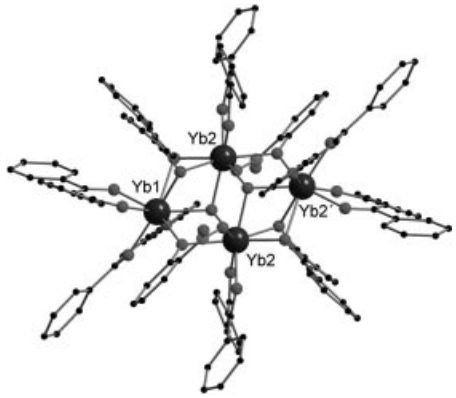


Figure 2. Solid-state structure of **3** showing the atom labeling scheme, with omission of hydrogen atoms. The small and larger dark spheres indicate carbon and oxygen atoms, respectively, and the lighter spheres stand for nitrogen atoms. ## Conclusion

In summary, a series of tetra- and pentanuclear lanthanide clusters having dibenzoylmethanido and *o*-nitrophenolato as ligands in the coordination sphere were synthesized. By using the larger lanthanides as center metals, ionic clusters of composition $HNEt_3^+[Ln_5(\mu_3\text{-}OH)_4(\mu_4\text{-}OH)(Ph_2acac)_7(o\text{-}O_2NC_6H_4O)_3Cl]^-$ (Ln = Er, Tm) were obtained. In contrast, by using the smaller center metals Yb and Lu, clusters of composition $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_8(o\text{-}O_2NC_6H_4O)_2]$ were isolated. The formation of the hydroxido bridges can be explained by the six water molecules, which are coordinated through the oxygen atom to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the metal center of the starting material, $[LnCl_3 \cdot 6H_2O]$. Addition of base leads only to deprotonation of the coordinated water molecules. The bridging oxygen atoms in the cores of the clusters are parts of hydroxy groups, as revealed by the broad band in the IR spectra.

A comparison of the new mixed dibenzoylmethanido/*o*-nitrophenolato clusters with pure dibenzoylmethanido clusters shows the relationship between the two classes of clusters. Formally, the dibenzoylmethanide groups, which act in the pure dibenzoylmethanido clusters as tridentate ligands and bind in a (μ-O)-$\eta^2$ mode, are replaced by *o*-nitrophenolato ligands.

## Experimental Section

**General Considerations:** Deuterated solvents were obtained from Chemotrade or Euriso-Top GmbH (99% D atoms). NMR spectra were recorded with a Jeol JNM-LA 400 FT-NMR spectrometer. Chemical shifts are referenced to internal solvent resonances and are reported relative to tetramethylsilane. Raman spectra were recorded with a Bruker RFS 100. IR spectra were recorded with a Shimadzu FTIR-8400s. Elemental analyses were carried out with an Elementar vario EL. The lanthanide starting materials were synthesized from the corresponding oxides by neutralizing with concentrated hydrochloric acid, followed by concentration to dryness. Dibenzoylmethane, triethylamine, and the solvents were used as purchased from commercial sources without further purification.

**General Procedure for the Preparation of $HNEt_3^+[Ln_5(\mu_3\text{-}OH)_4(\mu_4\text{-}OH)(Ph_2acac)_7(o\text{-}O_2NC_6H_4O)_3Cl]^-$ [Ln = Er (1), Tm(2)] and $[Ln_4(\mu_3\text{-}OH)_2(Ph_2acac)_8(o\text{-}O_2NC_6H_4O)_2]$ [Ln = Yb (3), Lu (4)]:** $Ph_2$acacH (292 mg, 1.30 mmol) and *ortho*-nitrophenol (181 mg, 1.30 mmol) were combined in methanol (20 mL). Excess triethylamine (5.20 mmol) was slowly added to the resulting solution, and the reaction mixture was stirred for 1 h at room temp. To this was added a solution of the corresponding lanthanide trichloride hydrate (1.30 mmol) in methanol (20 mL), and the resulting yellow solution was stirred overnight at room temp. A crimson–yellow precipitate formed and was filtered off before the solvent was removed in vacuo. The residue was dissolved in toluene (5 mL) and stirred for 2 h, at which point the solution was filtered. Slow evaporation of toluene at room temp. yielded yellow crystals.

**$HNEt_3^+[Ln_5(\mu_3\text{-}OH)_4(\mu_4\text{-}OH)(Ph_2acac)_7(o\text{-}O_2NC_6H_4O)_3Cl]^-$ [Ln = Er (1), Tm (2)]**

**X-ray Crystallographic Studies of 1–4:** Suitable crystals of **1**–**4** were covered in mineral oil (Aldrich) and mounted onto a glass fiber. The crystal was transferred directly to the cold (–73 °C or –100 °C) $N_2$ stream of a Stoe IPDS 2T or Bruker Smart 1000 CCD. Subsequent computations were carried out with an Intel Pentium IV PC.

**Data Collection and Refinement:** Data were processed with SHELXS-97[29] and SHELXL-97.[30]

**$HNEt_3^+[Er_5(\mu_3\text{-}OH)_4(\mu_4\text{-}OH)(Ph_2acac)_7(o\text{-}O_2NC_6H_4O)_3Cl]^-\cdot$ 2.5toluene (1):** Monoclinic, space group $P2_1/c$ (No. 14); lattice constants $a$ = 2165.5(9) pm, $b$ = 1976.2(6) pm, $c$ = 3312(3) pm, $\beta$ = 95.50(5)°, $V = 14109(13) \times 10^6$ pm$^3$, $Z$ = 4; $\mu$(Mo-$K_\alpha$) = 3.031 mm$^{-1}$; $2\theta_{max.}$ = 50.0°; 13128 ($R_{int}$ = 0.1037) independent reflections were measured, 13128 of which, observed with $I > 2\sigma(I)$, were considered; max. residual electron density 1.328 and –1.122 e/A$^{-3}$; 1385 parameters (all non-hydrogen atoms except those in the thf molecules were calculated anisotropically; for H atoms, the idealized positions were calculated) $R_1$ = 0.0592; $wR_2$ = 0.1637.

# Sterically Demanding Iminopyridine Ligands

**Torsten Irrgang,[a] Sandra Keller,[a] Heidi Maisel,[a] Winfried Kretschmer,[b] and Rhett Kempe*[a]**

**Keywords:** Ethylene polymerization / N ligands / Cobalt / Iron / Nickel / Palladium

Two sterically demanding iminopyridine ligands, (2,6-diisopropylphenyl)[6-(2,4,6-triisopropylphenyl)pyridin-2-ylmethylene]amine and (2,6-diisopropylphenyl)[6-(2,6-dimethylphenyl)pyridin-2-ylmethylene]amine, were prepared by a two-step process: first, condensation of 6-bromopyridine-2-carbaldehyde with an equimolecular amount of 2,6-diisopropylaniline, and second, Kumada-type coupling of in-situ-formed Grignard compounds of 1-bromo-2,6-dimethylphenyl and 1-bromo-2,4,6-triisopropylphenyl. Dichlorido complexes of the ligands were synthesized starting from $FeCl_2$, $[PdCl_2(cod)]$, $[NiCl_2(dme)]$, and $CoCl_2$ (cod = 1,5-cyclooctadiene, dme = dimethoxyethane). X-ray crystal structure analyses of a Fe, Pd, and Co complex were determined. Ethylene polymerization/oligomerization behavior of the dichlorido complexes after activation with methylaluminoxane or triethylaluminum was studied. Ethylene dimerization selectivity greater than 95 % was observed.

## Introduction

Olefin polymerization catalyzed by late-transition-metal complexes is an intensively explored area of research.[1] Out of the neutral N ligand environments studied so far, diimine group 10 (Scheme 1, left) and the pyridyl diimine Fe/Co catalysts (Scheme 1, right) have received most of the attention.[2] Remarkable changes in the polymerization behavior especially with regard to the obtained molecular weights of the polymers have been observed for these complexes if very bulky 2,6-diisopropylphenyl substituents were introduced.

Scheme 1. N-ligand-stabilized late-transition-metal olefin polymerization precatalysts (for instance: M = Ni, Pd; M′ = Fe, Co; X = Cl; R = H; $R^1 = CH_3$; Ar = 2,6-diisopropylphenyl).

Iminopyridine ligands (Scheme 2, right) might be considered to be structurally related to both of the above-mentioned ligand systems, and consequently, the olefin polymerization behavior of some of these complexes was investigated recently.[3–5] Sterically demanding examples bearing 2,6-diisopropylphenyl substituents in the pyridine ring are not known to the best of our knowledge.

Scheme 2. Sterically demanding aminopyridinato ligands (left) and iminopyridines [**3a**: $R^1 = CH_3$, $R^2$ = H; **3b**: $R^1 = R^2 = CH(CH_3)_2$].

Bianchini and coworkers for instance described phenyl and naphthalenyl substitution at the pyridine ring by Suzuki coupling.[4] It may not be possible to use such a protocol to cross couple sterically demanding phenyl derivatives like 2,6-diisopropylphenyl.[6] We recently described an efficient protocol to introduce 2,6-diisopropylphenyl substituents into pyridine rings by Kumada coupling. This chemistry was explored to synthesize sterically demanding aminopyridines[7] and to use them as aminopyridinato ligands (Scheme 2, left);[8] a class of ligands we investigated intensively in the past.[9]

Because of the importance of steric protection in late-metal-catalyzed olefin polymerization chemistry, as well as other areas of coordination chemistry, we became interested in the synthesis of bulky iminopyridines such as **3a**,**b** (Scheme 2, right). We felt that an approach we used to synthesize bulky aminopyridines might by suitable for the synthesis of ligands such as **3a**,**b** as well. The imine function that is usually sensitive towards the addition of Grignard reagents might be well enough protected due to the 2,6-diisopropylphenyl substituent at the imine N atom. Herein we report the synthesis of sterically demanding iminopyridine ligands, the syntheses and structures of Co, Ni, Fe,

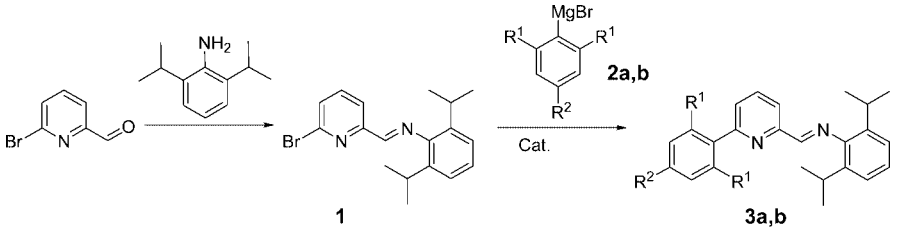


Scheme 3. Synthesis of **3** [$R^1$ = $CH_3$, $R^2$ = H (**2a/3a**); $R^1$ = $R^2$ = *i*Pr (**2b/3b**); cat for Kumada coupling is $FeCl_2$ or $MnCl_2$].

and Pd complexes stabilized by these ligands, and some aspects of the olefin polymerization/oligomerization behaviors of a few of these complexes.

## Results and Discussion

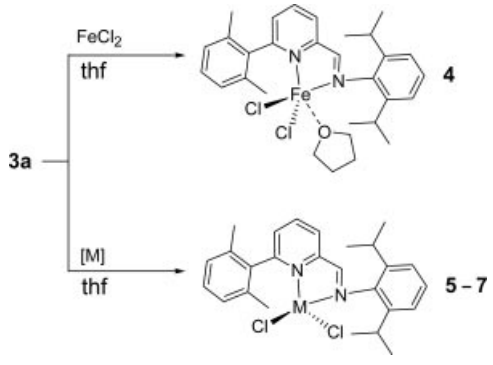
### Syntheses of the Ligands

The sterically demanding iminopyridine ligands **3a**,**b**[10] were prepared by the two-step process illustrated in Scheme 3. First, the convenient condensation of 6-bromopyridine-2-carbaldehyde with an equimolecular amount of 2,6-diisopropylaniline leads to **1**.[11] The reaction of in-situ-formed Grignard compounds **2a**,**b** of 1-bromo-2,6-dimethylphenyl and 1-bromo-2,4,6-triisopropylphenyl with **1** in the presence of a catalytic amount of $FeCl_2$ leads to iminopyridines **3a**,**b** (Scheme 3).[12] We observed similar results by using $MnCl_2$ as a catalyst. The catalyst was chosen on the basis of the results that were obtained from screening experiments with various transition-metal halogenides and N or P ligands. The 2,6-diisopropylphenyl group at the imine N atom protects the imine well enough if an efficient catalyst is added to accomplish biaryl formation.

Compounds **3a**,**b** were obtained as pale yellow crystalline materials. They differ in the steric demand ($R^1$ and $R^2$) of the phenyl substituent in the 6-position of the pyridine ring.

### Syntheses and Structures of the Complexes

Complexes **4**–**7** were obtained in high yields in the reaction of 1 equiv. of **3a** with anhydrous $FeCl_2$, [$PdCl_2$(cod)], [$NiCl_2$(dme)], and $CoCl_2$ (cod = 1,5-cyclooctadiene, dme = dimethoxyethane) in thf at 70 °C for 18 h (Scheme 4).



Scheme 4. Reaction of **3a** with late-transition-metal halogenides {[M] = [$PdCl_2$(cod)] (**5**); [$NiCl_2$(dme)] (**6**); $CoCl_2$ (**7**)}.

Single crystals of red paramagnetic complex **4** and yellow crystals of diamagnetic **5**[13] were grown from a concentrated thf solution at –25 °C. For both complexes, one uncoordinated thf molecule was found in the crystal lattice, and for **4**, one additional coordinated thf ligand was found. ORTEP drawings are reported in Figures 1 and 2 for **4** and **5**, respectively. Crystallographic details are summarized in Table 2. In **4**, the iron is five coordinate, and the coordination sphere is best described as distorted trigonal bipyramidal with the equatorial plane being occupied by the imino N atom and the two chlorine atoms. The axial positions are coordinated by the pyridine N atom and by the O atom of the coordinated thf ligand. A Cl–Fe–Cl angle of 131.81(6)° is observed within the equatorial plane and a "chelating" angle $N_{pyridine}$–Fe–$N_{imino}$ of 77.30(16)°. The Fe–O bond of the coordinated thf ligand is rather long [2.474(8) Å], which indicates a very weakly bound thf ligand. The Fe–O bond lengths of thf-coordinated iron chlorides range from 1.944 Å for [$FeCl_3$(thf)][14] to 2.181 Å for the [$Fe_2Cl_3$-$(thf)_6$]$^-$ anion.[15] The coordination of **5** is best described as square planar with a $N_{pyridine}$–Pd–$N_{imino}$ angle of 80.50(15)° and Cl–Pd–Cl angle of 88.84(5)°.

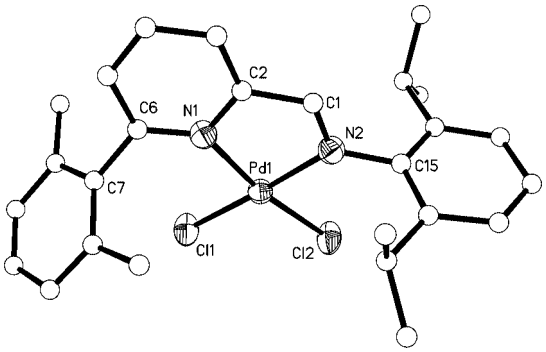

Figure 2. Molecular structure of **5**; selected bond lengths [Å] and angles [°]: Pd1–N2 2.012(4), Pd1–N1 2.090(4), Pd1–Cl1 2.273(13), Pd1–Cl2 2.2746(15), N2–C1 1.272(6), N2–C15 1.464(6), N1–C6 1.347(6), N1–C2 1.355(6), C1–C2 1.451(6), C6–C7 1.489(8); N2–Pd1–N1 80.50(15), N2–Pd1–Cl1 176.40(13), N1–Pd1–Cl1 99.43(10), N2–Pd1–Cl2 91.01(12), N1–Pd1–Cl2 170.89(11), Cl1–Pd1–Cl2 88.84(5), C1–N2–C15 117.9(4), C1–N2–Pd1 113.8(3), C15–N2–Pd1 128.2(3), C6–N1–C2 117.1(4), C6–N1–Pd1 132.8(3), C2–N1–Pd1 110.0(3), N2–C1–C2 119.1(4), N1–C2–C1 115.3(4), N1–C6–C7 121.2(4).

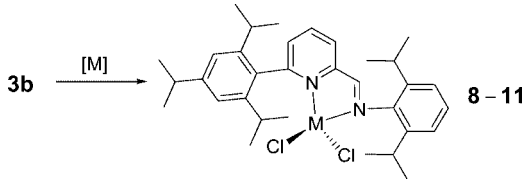
The reaction of sterically more demanding ligand **3b** with the anhydrous metal salts $FeCl_2$, $[PdCl_2(cod)]$, $[NiCl_2(dme)]$, and $CoCl_2$ leads to corresponding complexes **8**–**11** (Scheme 5). Compounds **8**, **10**, and **11** are paramagnetic.



Scheme 5. Synthesis of **8** (M = Fe), **9** (M = Pd), **10** (M = Ni), and **11** (M = Co).

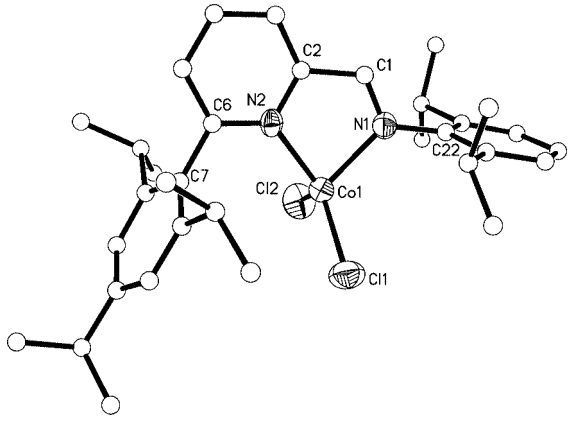


Figure 3. Molecular structure of **11**; selected bond lengths [Å] and angles [°]: Co1–N2 2.052(4), Co1–N1 2.057(4), Co1–Cl2 2.2023(16), Co1–Cl1 2.2007(15), N2–C2 1.346(6), N2–C6 1.353(6), N1–C1 1.267(6), N1–C22 1.453(6), C1–C2 1.477(7), C6–C7 1.479(7); N2–Co1–N1 80.23(16), N2–Co1–Cl2 111.01(11), N1–Co1–Cl2 109.89(12), N2–Co1–Cl1 125.20(12), N1–Co1–Cl1 113.17(22), Cl2–Co1–Cl1 112.60(7), C2–N2–C6 118.6(4), C2–N2–Co1 112.3(3), C6–N2–Co1 128.8(3), C1–N1–C22 120.1(4), C1–N1–Co1 113.2(3), C22–N1–Co1 126.7(3), N1–C1–C2 118.6(4), N2–C2–C1 114.7(4), N2–C6–C7 118.6(4).

The coordination of the cobalt centre of **11** is best described as slightly distorted tetrahedral. For the three structurally characterized metal complexes we observed three different coordination environments. The sterically demanding N ligands introduced here seem to be quite flexible with regard to the coordination they adopt with transition metals, and they do not force metals in energetically unfavored coordinations because of steric pressure. The chelating $N_{pyridine}$–Co–$N_{imino}$ angle of **11** is 80.24°. The bulky phenyl substituents in the 6-position of the pyridine and at the imino N atom are twisted relative to the pyridine ring with dihedral angles of 99.8° and 97.1°, respectively. The five-membered chelating $C_2CoN_2$ ring is nearly planar (0.0473 Å mean deviation). Details of the X-ray crystal structure analysis of **11** are summarized in Table 2. The molecular structure of **11** is shown in Figure 3.

## Olefin Polymerization/Oligomerization Behavior

Oligomerization results are summarized in Table 1. The investigated complexes mainly produce oligomeric materials. Nearly no activity is observed for the iron complexes. The highest activities are observed for the cobalt and nickel complexes. For both metals, Co and Ni, the changes in terms of activity and distribution of the oligomers are rather small. The sterically more demanding ligand shows essentially the same polymerization behavior, aside from a little enhanced activity. Noteworthy is that the selectivity for **6**, **7**, **10**, and **11** towards 1-butene is high. High ethylene dimerization selectivities were observed for iminopyridine complexes bearing sterically less-demanding substituents on the pyridine ring as well.[4] Activation with triethylaluminum (TEA), $Et_3Al$, instead of methylaluminoxane (MAO), leads to reduced activity but suppresses the formation of polymeric byproducts and increases the dimerization selectivity above 95%. The results obtained with our Co complexes are similar to (or nearly as good as) the results observed by Bianchini and coworkers.[4] They observed for iminopyridine Co complexes (activated with MAO) carrying a phenyl or naphthyl substituent on the pyridine ring the formation of oligomerization products and butenes, especially with conversions of 784 and 630 $kg_{product}mol_{cat}^{-1}h^{-1}bar^{-1}$, respectively. This comparison indicates that the introduction of steric bulk in the 6-position of the pyridine ring does not influence the nature of the products formed. It was recently demonstrated by these groups that their tetrahedral high-spin complexes react with MAO in toluene to give low-spin Co square-planar methyl complexes.[4e] This species, intercepted by EPR spectroscopy, inserts ethylene to form a cobalt–propyl intermediate that eliminates propene with the formation of a Co–H initiator. A similar mechanism is most likely in operation for our Co (and Ni) complexes; by ethylene insertion into a Co–H bond, an ethyl complex is formed. If this species undergoes β-H elimination/transfer we get back to the starting point (Co–H complex and ethylene). If a second insertion of ethylene takes place, a butyl complex is formed and

[a] The general procedure and conditions as described in the Experimental Section were followed by using the catalyst (10 μmol), the activator (500 equiv.), and toluene (260 mL) at 30 °C, 5 bar ethylene with a 15 min run time. [b] * Indicates the sterically more-demanding ligand. [c] MMAO-3A: Modified MAO $\{[Me_{0.7}iBu_{0.3}AlO]_n\}$. [d] >95% 1-Butene. [e] M/Al, 1:200. [f] Not determined, isoparaffinic solvent (b.p. 118 °C).

subsequently butene can be eliminated. It looks as though β-H elimination/transfer is very fast with regard to chain growth for our Co complexes and thus we preferentially obtain butenes. If we activate with TEA, β-H elimination/transfer may become enhanced because butene selectivity is increased. Alternatively, TEA may reduce the Co dichloride complexes followed by oxidative coupling of two ethylene molecules including the formation of a cobaltacyclopentene followed by β-H elimination, forming a butenyl hydride that undergoes reductive elimination, and butene is formed. The stability of the transient cobaltacyclopropene against further ethylene insertion may lead to the exclusive formation of the dimerization product. Interestingly, we are able to dimerize selectively with relatively low cocatalyst loadings and MAO was not needed. Mapolie and coworkers studied the formation of polymeric materials for Pd complexes.[5] Conversions up to 15 $kg_{product}\,mol_{cat}^{-1}\,h^{-1}\,bar^{-1}$ were observed, which again is in accordance with the results obtained for our Pd complexes. Once more, no dramatic influence is seen due to the introduction of the very bulky substituents on the pyridine ring. It is surprising that the electronic situation that the iminopyridines provide dominate the polymerization chemistry and that the bulkiness of the ligands on the pyridine ring is of minor relevance despite the difference in shielding at the metal center. The shielding is visualized in Figure 4.

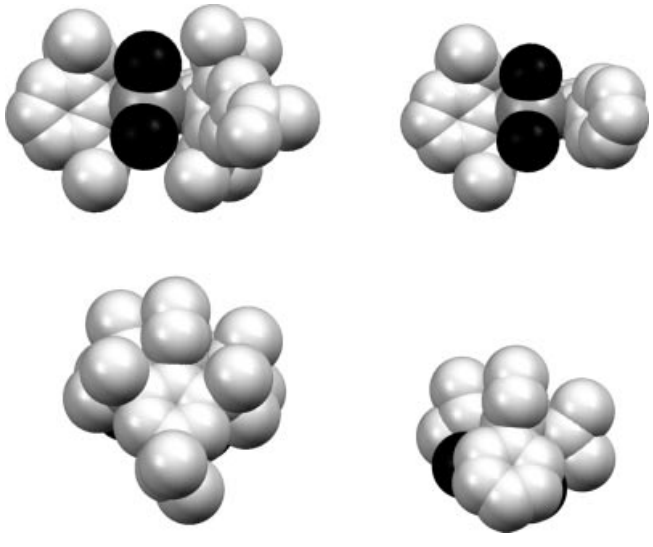

Figure 4. Visualization (space filling plot with C atoms light grey, Co atoms dark grey, Cl atoms black) of the steric protection of the 2,4,6-triisopropylphenyl substituent at the pyridine ring (right) versus shielding provided by a phenyl ring only (left).

## Conclusions

Four general conclusions can be drawn from the investigations discussed here. First, Kumada coupling is an efficient protocol to introduce sterically demanding substituents in the 6-position of the pyridyl ring of iminopyridines. Second, the sterically demanding ligands discussed here accomplish a variety of coordinations with late transition metals, such as trigonal bipyramidal, tetrahedral, and square planar. Third, the cobalt and nickel dichlorido complexes (if activated with MAO or TEA) dimerize ethylene rather than polymerize it and can show dimerization selectivities greater than 95%. Fourth, the introduction of the bulky 2,6-dialkylphenyl substituent in the pyridine moiety does not influence the polymerization behavior of the resulting late-transition-metal complexes (activation with MAO) tremendously relative to the significantly less bulky versions of those ligands.

## Experimental Section

### Polymerization Experiments

**General:** Toluene (Aldrich, anhydrous, 99.8%) was passed over columns of $Al_2O_3$ (Fluka), BASF R3–11 supported Cu oxygen scavenger and molecular sieves (Aldrich, 4 Å) prior to use. Ethylene (AGA polymer grade) was passed over BASF R3–11 supported Cu oxygen scavenger and molecular sieves (Aldrich, 4 Å) prior to use. TEA (1.6 M in toluene, Aldrich), PMAO (4.9 wt.-% in Al, toluene, Akzo), and MMAO-3A (2.1 wt.-% in Al; isoparaffinic solvent, b.p. 118 °C; Akzo) were used as received.

**Preparative Procedure:** The polymer samples were prepared by dissolving the polymer (15 mg) in $CD_2Cl_2$ (0.5 mL) at 100 °C for 3 h before measuring. Gel permeation chromatography (GPC) analysis was carried out with a Polymer Laboratories Ltd. (PL-GPC210) chromatograph, equipped with a capillary differential viscometer (Viscotek), a refractive index (RI) detector, and a two-angle (15 and 90°) light-scattering photometer at 150 °C by using 1,2,4-trichlorobenzene as the mobile phase. The samples were prepared by dissolving the polymer (0.1% weight/volume) in the mobile phase solvent in an external oven and were run without filtration. The molecular weight was referenced to polyethylene ($M_w$ = 50000 g mol$^{-1}$) and polystyrene ($M_w$ = 100000–500000 g mol$^{-1}$) standards. The reported values are the average of at least two independent determinations. GC analyses were performed with an HP 6890 instrument equipped with an HP-1 dimethylpolysiloxane column (19095 Z-123). GC–MS analyses were conducted with an HP 5973 mass-selective detector attached to an HP 6890 GC instrument.

**Polymethylaluminoxane (PMAO) Ethylene Conversion:** The catalytic ethylene conversion reactions were performed in a stainless steel 1-L autoclave (Medimex) in the semibatch mode (ethylene was added by replenishing flow to keep the pressure constant). The reactor was temperature, flow, and pressure controlled and equipped with separated toluene, catalyst, and cocatalyst injection systems and a sample outlet for continuous reaction monitoring. Up to 15 bar of ethylene pressure multiple injections of the catalyst with a pneumatically operated catalyst injection system were used. During a polymerization run, the pressure, the ethylene flow, the inner and the outer reactor temperature, and the stirrer speed were monitored continuously. In a typical semibatch experiment, the autoclave was evacuated and heated for 1 h at 125 °C prior to use. The reactor was then brought to the desired temperature, stirred at 600 rpm and charged with toluene (230 mL), PMAO (2.7 g of a toluene solution, 4.9 wt.-% Al, 5 mmol), and cyclohexane (10 g) as an internal standard. After pressurizing with ethylene to reach a total pressure of 5 bar, the autoclave was equilibrated for 5 min. Subsequently, the catalyst (10 μmol, M/Al, 1:500) suspended in toluene (30 mL) was injected to start the reaction. During the run the ethylene pressure was kept constant to within 0.2 bar of the initial pressure by replenishing flow. After a reaction time of 15 min, a sample of the reaction mixture was taken to analyze and quantify the soluble products before the reactor was vented and the residual aluminum alkyls were destroyed by the addition of ethanol (100 mL). The polymeric product was collected, stirred for 30 min in acidified ethanol, and rinsed with ethanol and acetone on a glass frit. The polymer was initially dried in air and subsequently in vacuo at 80 °C. The results are presented in Table 1.

**MMAO-3A Ethylene Conversion:** The general procedure and conditions as described above were followed with the use of MMAO-3A (6.4 g of an isoparaffinic solvent, b.p. 118 °C; 2.1 wt.-% Al, 5 mmol, M/Al, 1:500) instead of PMAO to charge the reactor. The results are presented in Table 1.

**TEA Ethylene Conversion:** The general procedure and conditions as described above were followed with the use of TEA (M/Al, 1:200) instead of PMAO to charge the reactor. The results are presented in Table 1.

### Syntheses and Structure Analyses

**General:** All reactions and manipulations with air-sensitive compounds were performed under an atmosphere of dry argon by using standard Schlenk and glove box techniques. Nonhalogenated solvents were distilled from sodium benzophenone ketyl and halogenated solvents from $P_2O_5$. Deuterated solvents were obtained from Cambridge Isotope Laboratories and were degassed, dried, and distilled prior to use. All other chemicals were purchased from commercial vendors and used without further purification. NMR spectra were obtained with a Bruker ARX 250 spectrometer. Chemical shifts are reported in ppm relative to the deuterated solvent. Elemental analyses were carried out with a Vario elementar EL III. Melting points were measured in sealed capillaries with a Stuart SMP3 apparatus. Magnetic moments were determined with a magnetic susceptibility balance Sherwood Mark 1 MSB at room temperature. X-ray crystal structure analyses were performed by with a STOE-IPDS II equipped with an Oxford Cryostream low-temperature unit. Structure solution and refinement were accomplished by using SIR97,[16] SHELXL-97,[17] and WinGX.[18] Crystallographic details are summarized in Table 2. CCDC-639686 (for **4**), -639684 (for **5**), and -639685 (for **11**) contain the supplementary crystallographic data for this publication. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

### Syntheses of the Ligands and Ligand Precursors

**1:** 6-Bromopyridine-2-carbaldehyde (2.0 g, 10.7 mmol) and 2,6-diisopropylaniline (2.03 mL, 1.91 g, 10.7 mmol) were dissolved in ethanol (30 mL), and the mixture was heated at reflux for 2 h. The solvent was removed under reduced pressure, and a pale yellow crystalline material was obtained and used without further purification. Yield: 3.59 (97%). M.p. 104 °C. $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 8.26–8.25 (d, $J$ = 1.0 Hz, 1 H, CH), 8.23 (s, 1 H, N=CH), 7.73–7.66 (t, $J$ = 7.8 Hz, 1 H, CH), 7.61–7.57 (dd, $J$ = 7.9, 1.0 Hz, 1 H, CH), 7.24–7.08 (m, 3 H, CH), 3.08–2.92 [sept, $J$ = 6.9 Hz, 2 H, 2 × C$H$(CH$_3$)$_2$], 1.16–1.13 [d, $J$ = 6.9 Hz, 12 H, 2 × CH(C$H_3$)$_2$] ppm. $^{13}$C NMR (62.90 MHz, $CDCl_3$): $\delta$ = 161.44 (N=CH), 155.40, 147.85, 141.81, 138.99, 136.99, 129.79, 124.66, 123.03 (C$_m$, C$_6$H$_3$), 119.86, 27.91 [2 × $C$H(CH$_3$)$_2$], 23.37 [2 × CH($C$H$_3$)$_2$] ppm. $C_{18}H_{21}BrN_2$ (345.28): calcd. C 62.61, H 6.13, N 8.11; found C 62.66, H 6.05, N 8.01.

**2a:** A solution of 2-bromo-*m*-xylene (1.39 mL, 1.93 g, 10.4 mmol) in thf (30 mL) was added to magnesium turnings (0.30 g, 12.5 mmol), and the resulting suspension was stirred and activated by the addition of 1,2-bromoethane (0.2 mL). An exothermic reaction took place, and an ice bath was used to cool the reaction mixture when the reaction became too vigorous. The reaction mixture was stirred at r.t. for 2 h and then filtered, and the filtrate was directly used.

**2b:** To a suspension of magnesium turnings (0.21 g, 8.69 mmol) in thf (100 mL) was added by syringe 1-bromo-2,4,6-triisopropylbenzol (1.82 mL, 7.24 mmol). The resulting suspension was stirred and activated by the addition of 1,2-bromoethane (0.2 mL). A low exothermic reaction took place. The reaction mixture was stirred at r.t. for 2 h and then filtered, and the filtrate was directly used.

**3a:** To a solution of **1** (3.0 g, 8.69 mmol) in dioxane (30 mL) was added a suspension of $FeCl_2$ (0.11 g, 0.87 mmol) in thf (10 mL). The Grignard solution **2a** was then slowly added to the stirred sus-

pension. The reaction mixture was heated to 70 °C for 48 h. Water (100 mL) and diethyl ether (80 mL) were added, and the resulting suspension was transferred to a 500-mL separatory funnel. The organic phase was collected, and the inorganic phase was washed twice with diethyl ether and extracted. The combined organic phases were washed with a saturated NaCl solution and dried with $Na_2SO_4$. The organic phase was concentrated to dryness under vacuum, resulting in a brown oily product. The oil was purified by silica chromatography (pentane) and then crystallized from pentane at –25 °C to afford a pale yellow crystalline material. Yield: 1.16 g (39%). M.p. 142.5 °C. $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 8.36 (s, 1 H, N=CH), 8.29–8.25 (dd, $J$ = 7.9, 1.1 Hz, 1 H, pyridine), 7.95–7.89 (t, $J$ = 7.7 Hz, 1 H, $4_{pyridine\text{-}H}$), 7.37–7.34 (dd, $J$ = 7.6, 1.1 Hz, 1 H, pyridine), 7.25–7.04 (m, 6 H, $2 \times C_6H_3$), 3.08–2.92 [sept, $J$ = 6.9 Hz, 2 H, $2 \times CH(CH_3)_2$], 2.12 (s, 6 H, $2 \times CH_3$), 1.20–1.17 [d, $J$ = 6.9 Hz, 12 H, $2 \times CH(CH_3)_2$] ppm. $^{13}$C NMR (62.90 MHz, $CDCl_3$): $\delta$ = 163.29 (N=CH), 159.76 (C), 154.31 (C), 148.35 (C), 139.73 (C), 137.13 ($2 \times$ C), 137.01 (CH), 135.84 ($2 \times$ C), 128.17 (CH), 127.79 ($2 \times$ CH), 126.21 (CH), 124.35 (CH), 122.96 ($2 \times$ CH), 119.08 (CH), 27.90 [$2 \times CH(CH_3)_2$], 23.41 [$2 \times$ CH-$(CH_3)_2$], 20.34 ($2 \times CH_3$) ppm. $C_{26}H_{30}N_2$ (370.54): calcd. C 84.28, H 8.16, N 7.56; found C 83.74, H 8.15, N 7.47.

**3b:** To a solution of **1** (2.5 g, 7.24 mmol) in dioxane (30 mL) at 70 °C was added a suspension of $FeCl_2$ (0.092 g, 0.72 mmol) in thf (30 mL). The Grignard solution **2b** was then slowly added to the stirred suspension. The reaction mixture was stirred at 70 °C for 48 h. Water (100 mL) and hexane (80 mL) were added, and the resulting suspension was transferred to a 500-mL separatory funnel. The organic phase was collected, and the inorganic phase was washed twice with hexane and extracted. The combined organic phases were washed with a saturated NaCl solution and dried with $Na_2SO_4$. The organic phase was concentrated under vacuum, and at –25 °C pale yellow crystals were obtained. Yield: 2.14 g (86%). M.p. 193.5 °C. $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 8.33 (s, 1 H, N=CH), 8.29–8.26 (dd, $J$ = 7.8, 0.9 Hz, 1 H, pyridine), 7.92–7.86 (t, $J$ = 7.7 Hz, 1 H, $4_{pyridine\text{-}H}$), 7.44–7.40 (dd, $J$ = 7.6, 0.9 Hz, 1 H, pyridine), 7.19–7.10 (m, 5 H, $C_6H_2/C_6H_3$), 3.07–2.90 [sept, $J$ = 6.8 Hz, 3 H, $3 \times (CH_3)_2CH\text{-}C_6H_2$], 2.63–2.46 [sept, $J$ = 6.8 Hz, 2 H, $2 \times (CH_3)_2CH\text{-}C_6H_3$], 1.28–1.26 [d, $J$ = 7.0 Hz, 12 H, $2 \times (CH_3)_2$-CH-$C_6H_3$], 1.18–1.12 [q, $J$ = 6.8 Hz, 18 H, $3 \times (CH_3)_2CH\text{-}C_6H_2$] ppm. $^{13}$C NMR (62.90 MHz, $CDCl_3$): $\delta$ = 163.61 (N=CH), 160.07 (C), 153.93 (C), 149.05 (C), 148.43 (C), 146.24 ($2 \times$ C), 137.22 ($2 \times$ C), 136.34 (CH), 135.71 (C), 126.60 (CH), 124.35 (CH), 122.99 ($2 \times$ CH), 120.96 ($2 \times$ CH), 118.87 (CH), 34.45 (CH), 30.48 (CH), 27.92 [$2 \times (CH_3)_2CH\text{-}C_6H_3$], 24.26 (CH), 24.09 (CH), 24.00 (CH), 23.49 [$2 \times (CH_3)_2CH\text{-}C_6H_3$] ppm. $C_{33}H_{44}N_2$ (468.72): calcd. C 84.56, H 9.46, N 5.46; found C 84.38, H 9.49, N 6.21.

**Syntheses of the Complexes**

**4:** A solution of **3a** (0.358 g, 0.97 mmol) and $FeCl_2$ (0.11 g, 0.86 mmol) in thf (30 mL) was heated at 70 °C whilst stirring for 18 h. The solvent was removed under vacuum, and the red residue was washed with hexane, dissolved in thf, and filtered through quartz. The filtrate was concentrated, and red crystals were grown at –25 °C. Yield: 0.434 g (90%). M.p. 240 °C. $\mu_{eff}$ = 4.44 BM (24.4 °C). $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 34.50, 30.98, 8.23, 7.63, 7.14, 5.90, 3.97, 2.89, 2.03, 1.74, 1.23, 1.14, 0.86, 0.05, –2.57 ppm. $C_{26}H_{30}Cl_2FeN_2$ (497.25): calcd. C 62.80, H 6.08, N 5.63; found C 63.26, H 6.05, N 5.24.

**5:** A stirred solution of **3a** (0.229 g, 0.81 mmol) and [$PdCl_2$(cod)] (0.223 g, 0.79 mmol) in thf (30 mL) was heated at 70 °C for 18 h. The solvent was removed under vacuum, and the residue was washed with hexane, dissolved in dichloromethane (50 mL), and filtered through quartz. The resulting orange solution was concentrated, and yellow-orange crystals (needles) were grown at –25 °C. Yield: 76%. M.p. 255 °C. $^1$H NMR (250.13 MHz, $CD_2Cl_2$): $\delta$ = 8.23–8.16 (t, $J$ = 7.5 Hz, 1 H, $4_{pyridine\text{-}H}$), 8.19 (s, 1 H, N=CH), 7.97–7.94 (dd, $J$ = 7.7, 1.5 Hz, 1 H, pyridine), 7.59–7.55 (dd, $J$ = 8.3, 1.5 Hz, 1 H, pyridine), 7.40–7.09 (m, 6 H, $2 \times C_6H_3$), 3.44–3.31 [sept, $J$ = 6.8 Hz, 2 H, $2 \times CH(CH_3)_2$], 2.30 (s, 6 H, $2 \times CH_3$), 1.40–1.37 (d, $J$ = 6.8 Hz, 6 H, $2 \times CH_3$, isopropyl), 1.19–1.16 (d, $J$ = 6.9 Hz, 6 H, $2 \times CH_3$, isopropyl) ppm. $^{13}$C NMR (62.90 MHz, $CD_2Cl_2$): $\delta$ = 170.22 (N=CH), 166.21 (C), 154.87 (C), 143.30 (C), 140.98 (C), 140.11 (CH), 138.40 (C), 135.93 (CH), 133.78 (CH), 129.55 (CH), 128.76 (CH), 127.59 (CH), 123.49 (CH), 28.97 [$2 \times CH(CH_3)_2$], 24.27 ($2 \times CH_3$, isopropyl), 22.93 ($2 \times CH_3$, isopropyl), 20.68 [$(CH_3)_2CH\text{-}C_6H_4$] ppm. $C_{26}H_{30}Cl_2N_2Pd \cdot 0.5CH_2Cl_2$ (590.29): calcd. C 53.92, H 5.29, N 4.75; found C 53.52, H 5.35, N 4.41.

**6:** Compound **3a** (0.25 g, 0.67 mmol), [$NiCl_2$(dme)] (0.145 g, 0.66 mmol), and thf (50 mL) were added together in a Schlenk flask under an atmosphere of nitrogen. The reaction mixture was stirred at 70 °C for 18 h. The solvent was removed under vacuum, and the red residue was washed with hexane, dissolved in thf, and filtered through quartz. The filtrate was concentrated, and orange crystals were grown at –25 °C. Yield: 0.256 g (59%). $\mu_{eff}$ = 2.99 BM (25.9 °C). $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 32.03, 24.09, 20.65, 10.74, 8.85, 8.34, 8.24, 7.92, 7.14, 5.48, 3.75, 2.99, 2.41, 2.10, 1.85, 1.18, 0.89, 0.06 ppm. $C_{26}H_{30}Cl_2N_2Ni{\cdot}2C_4H_8O$ (644.34): calcd. C 63.38, H 7.20, N 4.35; found C 63.04, H 7.57, N 4.54.

**7:** In a closed Schlenk flask, a stirred solution of **3a** (0.362 g, 0.98 mmol) and $CoCl_2$ (0.12 g, 0.92 mmol) in thf (30 mL) was heated at 70 °C for 18 h. The solvent was removed under vacuum, and the red residue was washed with hexane, dissolved in thf, and filtered through quartz. The filtrate was concentrated, and green needles were grown at –25 °C. Yield: 0.43 g (77%). M.p. 300 °C. $\mu_{eff}$ = 4.17 BM (25.9 °C). $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 34.70, 32.45, 19.13, 7.16, 5.21, 3.75, 3.34, 2.33, 2.15, 2.09, 1.80, 1.43, 1.22, 1.17, 1.14, 1.10, 0.85, 0.82, 0.04, –2.40, –3.37, –8.80 ppm. $C_{26}H_{30}Cl_2CoN_2{\cdot}C_4H_8O$ (572.47): calcd. C 62.94, H 6.69, N 4.89; found C 63.23, H 6.22, N 5.18.

**8:** In a dry box, **3b** (0.243 g, 0.52 mmol), $FeCl_2$ (0.066 g, 0.52 mmol), and thf (50 mL) were combined in a Schlenk flask under an atmosphere of nitrogen. The resulting solution was stirred at 60 °C for 48 h. The solvent was removed, and the precipitate was washed with hexane, dissolved in thf, and filtered through quartz. The filtrate was concentrated to dryness under vacuum, resulting in a dark red solid product. Yield: 0.11 g (32%). $\mu_{eff}$ = 6.16 BM (25.1 °C). $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 39.31, 8.23, 7.86, 7.09, 2.92, 2.50, 1.56, 1.13, 0.05 ppm. $C_{33}H_{44}Cl_2FeN_2{\cdot}C_4H_8O$ (667.57): calcd. C 66.57, H 7.85, N 4.20; found C 66.38, H 7.55, N 3.92.

**9:** A stirred solution of **3b** (0.252 g, 0.538 mmol) and [$PdCl_2$(cod)] (0.138 g, 0.483 mmol) in thf (50 mL) was heated at 60 °C for 72 h. The solvent was removed under vacuum, and the residue was washed with hexane, dissolved in toluene (50 mL), and filtered through quartz. The solvent was then removed, and the yellow product was dried under vacuum. Yield: 0.18 g (47%). M.p. 161 °C. $^1$H NMR (250.13 MHz, $CD_2Cl_2$): $\delta$ = 8.18 (s, 1 H, N=CH), 8.17–8.11 (t, $J$ = 8.0 Hz, 1 H, $4_{pyridine\text{-}H}$), 7.92–7.89 (d, $J$ = 7.5 Hz, 1 H, pyridine), 7.64–7.61 (d, $J$ = 7.9 Hz, 1 H, pyridine), 7.38–7.32 (t, $J$ = 7.2 Hz, 1 H, $p$-CH-$C_6H_3$), 7.22–7.18 (d, $J$ = 8.0 Hz, 2 H, 2 × $m$-CH-$C_6H_3$), 7.06 (s, 2 H, $C_6H_2$), 3.40–3.28 [sept, $J$ = 6.8 Hz, 2 H, 2 × C$H$($CH_3$)$_2$], 3.02–2.88 [sept, $J$ = 7.0 Hz, 1 H, $p$-C$H$($CH_3$)$_2$], 2.62–2.50 [sept, $J$ = 6.8 Hz, 2 H, 2 × C$H$($CH_3$)$_2$], 1.59–1.56 (d, $J$ = 6.8 Hz, 6 H, 2 × $CH_3$), 1.37–1.36 (d, $J$ = 6.8 Hz, 6 H, 2 × $CH_3$), 1.29–1.26 (d, $J$ = 6.9 Hz, 6 H, 2 × $CH_3$), 1.18–1.15 (d, $J$ = 6.9 Hz, 6 H, 2 × $CH_3$), 1.10–1.08 (d, $J$ = 6.8 Hz, 6 H, 2 × $CH_3$) ppm. $^{13}$C NMR (62.90 MHz, $CD_2Cl_2$): $\delta$ = 170.22 (N=CH), 166.71, 154.88, 151.11, 146.18, 143.42, 141.13, 139.20, 134.39, 134.16, 128.90, 127.70, 123.70, 121.24, 34.74, 31.72, 29.07, 25.18, 24.53, 24.18, 24.11, 23.18 ppm. $C_{33}H_{44}Cl_2N_2Pd{\cdot}C_4H_8O$ (718.15): calcd. C 61.88, H 7.30, N 3.90; found C 61.40, H 7.33, N 3.61.

**10:** Compound **3b** (0.24 g, 0.512 mmol), [$NiCl_2$(dme)] (0.113 g, 0.512 mmol), and thf (50 mL) were added together in a Schlenk flask under an atmosphere of nitrogen. The reaction mixture was stirred at 70 °C for 18 h. The solvent was removed, and the beige precipitate was washed with hexane, dissolved in thf, and filtered through quartz. After concentration, beige crystals were grown at –25 °C and dried under vacuum. Yield: 0.044 g (15%). $\mu_{eff}$ = 2.57 BM (26 °C). $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 39.53, 24.43, 17.49, 11.24, 5.51, 3.46, 2.78, 2.53, 2.16, 1.25, 1.17, 1.14, 0.03, –4.63 ppm. $C_{33}H_{44}Cl_2N_2Ni$ (598.32): calcd. C 66.24, H 7.41, N 4.68; found C 65.94, H 7.22, N 4.44.

**11:** Compound **3b** (0.283 g, 0.604 mmol) and $CoCl_2$ (0.08 g, 0.604 mmol) were dissolved in thf (40 mL). The resulting dark green reaction mixture was stirred for 20 h at 60 °C. The solvent was removed under vacuum. The product was washed with hexane, dissolved in thf, filtered through quartz, and concentrated. Green crystals were collected at –25 °C. Yield: 0.21 g (58%). M.p. 272 °C. $\mu_{eff}$ = 4.38 BM (26 °C). $^1$H NMR (250.13 MHz, $CDCl_3$): $\delta$ = 28.16, 21.32, 8.29, 8.20, 7.86, 7.12, 7.07, 6.88, 5.05, 3.72, 3.11, 2.93, 2.50, 1.62, 1.39, 1.23, 1.12, 0.82, 0.70, 0.35, 0.04, –1.56, –4.38, –5.26, –5.43 ppm. $C_{33}H_{44}Cl_2CoN_2$ (598.56): calcd. C 66.22, H 7.41, N 4.68; found C 65.89, H 7.62, N 4.51.

# Transition Metal(II)–Salen and –Salophen Macrocyclic Complexes for Rotaxane Formation: Syntheses and Crystal Structures

**Mamiko Narita,[a][‡] Il Yoon,[a][‡‡] Masaru Aoyagi,[a] Midori Goto,[a] Toshimi Shimizu,[a] and Masumi Asakawa*[a]**

*Dedicated to Professor J. Fraser Stoddart on the occasion of his 65th birthday*

**Keywords:** Rotaxanes / Ring opening / Ring closing / Transition metals / Porphyrinoids

We used a "threading-followed-by-shrinking" approach to prepare [2]rotaxanes possessing nickel(II)–salen and –salophen moieties. Reactions of macrocycles incorporating salen and salophen moieties with secondary dialkylammonium salts, followed by the addition of aqueous sodium sulfate, afforded the corresponding pseudorotaxanes; subsequent addition of nickel acetate shrank the effective size of the macrocycles to give the respective [2]rotaxanes. We obtained a [2]rotaxane possessing a salen unit in remarkably high yields − even in a polar solvent − indicating that the "threading-followed-by-shrinking" and "salen-ring-opening-and-closing" approaches occurred together. In addition, we expanded the "threading-followed-by-shrinking" approach to prepare a [2]rotaxane and a bis[2]rotaxane comprising two palladium(II)–salophen moieties linked in a bis-macrocycle and one and two secondary dialkylammonium salts, respectively. Furthermore, we prepared a tetraphenylporphyrin rhodium(III) chloride [Rh(TPP)Cl]-stoppered [2]rotaxane comprising a palladium(II)–salophen macrocycle and a pyridyl-terminated thread-like ion coordinated to the rhodium(III) center, which has potential as a next-generation molecular machine exhibiting catalytic function.

## Introduction

Interest in functionalized rotaxanes and their future potential as molecular machines in nanotechnology has increased in recent years.[1] Many template-directed methods for the preparation of rotaxanes have appeared in the literature; they generally involve clipping,[2] threading followed by stoppering,[3] and slipping[4] approaches. Functionalized rotaxanes can be immobilized onto solid surfaces through the use of self-assembled monolayers or Langmuir–Blodgett techniques.[5] We demonstrated − through molecularly resolved scanning tunneling microscopy (STM) images – that porphyrin and phthalocyanine derivatives self-assemble into ordered monolayer arrays on solid substrates.[6] Furthermore, we synthesized porphyrin-stoppered rotaxanes, explicitly pseudorotaxanes bound to the metal centers of metalloporphyrins through axial coordination, which suggest that such organic molecules can be immobilized onto two-dimensional arrays of metalloporphyrins on a solid substrate.[6a,6b,6d] Transition metals are often incorporated as templating or assembling centers for the formation of rotaxanes.[7] Previously, we demonstrated the synthesis of a [2]rotaxane incorporating a palladium(II)–salophen [*N*,*N*′-*o*-phenylenebis(salicylideneiminato) dianion] moiety by using a "threading-followed-by-shrinking" approach (Figure 1a) that involves threading a rod-like unit through a macrocycle and then shrinking the free space within the macrocycle through coordination of its salophen moiety to palladium metal; the rotaxane formation in this system occurs in a nonpolar solvent (dichloromethane) when a sodium(I)-complexed macrocycle possessing a salophen unit is used.[8] Furthermore, we reported the synthesis of monomeric and dimeric macrocycles incorporating salen [*N*,*N*′-ethylenebis(salicylideneiminato) dianion] moieties and a [2]-rotaxane formed by using a "ring-opening-and-closing" approach (Figure 1b) through the cleavage and formation of imino bonds of a salen moiety; the self-assembly of this macrocycle in the presence of a dumbbell-shaped rod-like component, followed by the addition of nickel acetate, af-

forded, after counterion exchange, a [2]rotaxane that was stabilized through coordination of the Ni ion to the macrocyclic salen moiety.[9]

In this paper, we describe a different synthetic system in which we combined both "threading-followed-by-shrinking"[8] and "ring-opening-and-closing"[9] approaches − and note the remarkably higher yield for the synthesis of a salen-based rotaxane relative to that of our previous approach[8] − for the formation of [2]rotaxanes **3a/b**-H·$PF_6$ (Scheme 1) from a precursor macrocycle [a barium(II)-complexed macrocycle possessing either a salen or salophen unit], a transition metal [nickel(II)], and a polar solvent (a mixture of water, methanol, and acetonitrile). Furthermore, we expanded the "threading-followed-by-shrinking" approach (Figure 2) to afford [2]rotaxane **5**-H·$ClO_4$ and bis[2]rotaxane **6**-2H·2$ClO_4$, which features two palladium(II)–salophen moieties linked in a bismacrocycle (Scheme 2). The transition metal(II)–salen or –salophen moiety, which behaves as the shrinking center, might also be of use for applications in areas related to, for example, metallocatalysis,[10] nonlinear optical response,[11] and electron transfer[12] when incorporated into rotaxane structures. In addition, we synthesized Rh(TPP)Cl-stoppered rotaxane **8**-H·Rh(TPP)Cl·$ClO_4$ (TPP = tetraphenylporphyrin; Scheme 3) by combining sequential "threading-followed-by-shrinking" and end-capping approaches, the latter through axial coordination of a pyridyl unit in the thread-like component and the rhodium(III) metal center. Such rotaxanes may allow the construction of catalytically active molecular machines on solid surfaces. We characterized rotaxanes **3a/b**-H·$PF_6$, **5**-H·$ClO_4$, **6**-2H·2$ClO_4$, and **8**-H·Rh(TPP)Cl·$ClO_4$ by using NMR and IR spectroscopy, mass spectrometry, elemental analysis, and X-ray crystallography (see the Supporting Information).

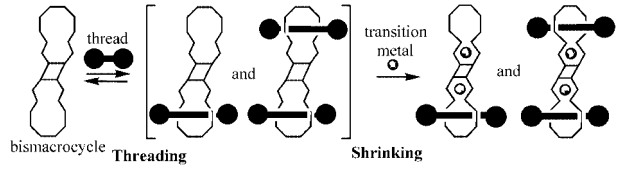

Figure 2. Graphical representation of the [2]rotaxane and bis[2]rotaxane when using the bismacrocycle and the "threading-followed-by-shrinking" approach.

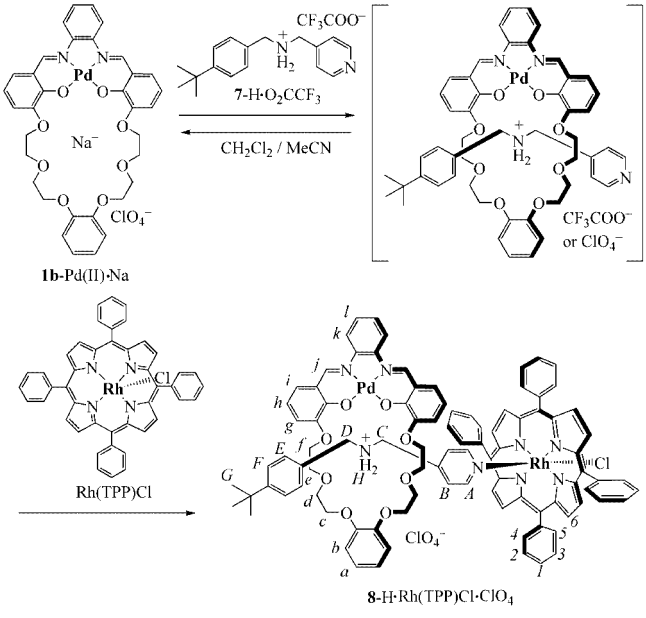

Scheme 3. Synthesis of tetraphenylporphyrin-stoppered [2]rotaxane **8**-H·Rh(TPP)Cl·$ClO_4$.

## Results and Discussion

As thread-like moieties, we used two types of the secondary dialkylammonium salt: **2**-H·$PF_6$,[4c] which contains two terminal *t*Bu groups, and **7**-H·$O_2CCF_3$,[13] which contains one *t*Bu group and one pyridyl unit as its termini. For the shrinking centers, we incorporated a salen moiety into macrocycle **1a**[9] and salophen moieties into macrocycle **1b**[12d] and bismacrocycle **4** (with each of these macrocycles prepared as a Ba complex). For end-capping, we used the rhodium(III) metal center of Rh(TPP)Cl. The reaction of **1a/b**-Ba and **2**-H·$PF_6$, followed by the addition of aqueous sodium sulfate, afforded the corresponding intermediate pseudorotaxanes, which could form free of macrocyclic and dumbbell components; the subsequent addition of nickel(II) acetate afforded [2]rotaxanes **3a/b**-H·$PF_6$ in yields of 55 and 20%, respectively (Scheme 1). The yield of rotaxane **3a**-H·$PF_6$, which incorporates the salen moiety, was remarkably high when considering that the use of polar solvents, which disrupt hydrogen bonding, was necessary because of the poor solubility of nickel(II) acetate in nonpolar solvents. Previously, we reported evidence for the "ring-opening-and-closing" approach occurring during the synthesis of a [2]rotaxane incorporating a salen moiety.[9] We believe that the unexpectedly high yield of **3a**-H·$PF_6$ relative to that of **3b**-H·$PF_6$ may be attributed to the different environments experienced by the salen and salophen moieties during their respective "ring-opening-and-closing" processes, which occurred through reactions at their imine bonds. The relatively low yield in the synthesis of **3b**-H·$PF_6$ may have arisen from the fact that ring opening and closing are very slow in the macrocycle incorporating the salophen moiety. In the case of salen rotaxane **3a**-H·$PF_6$, both "threading-followed-by-shrinking" and "ring-opening-and-closing" processes occurred together, whereas salophen rotaxane **3b**-H·$PF_6$ formed only through the "threading-followed-by-shrinking" process.

For the synthesis of an extended system, we used the "threading-followed-by-shrinking" approach[8] with bismacrocycle **4** possessing two macrocycle units linked through two salophen moieties (Figure 2). The reaction of two dialdehyde derivatives and 3,3′-diaminobenzidine afforded the barium(II)-complexed bismacrocycle possessing linked salophen moieties **4**-Ba (Scheme 2). The addition of aqueous potassium sulfate or aqueous sodium sulfate removed the coordinated barium(II) ions as precipitated

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$BaSO_4$ to afford **4**-K or **4**-Na, respectively. The self-assembly of **4**-K or **4**-Na with **2**-H·$PF_6$, followed by the addition of palladium(II) acetate and counterion exchange, afforded a mixture of [2]rotaxane **5**-H·$ClO_4$ (i.e. possessing one thread-like moiety; 3% yield) and bis[2]rotaxane **6**-2H·2$ClO_4$ (i.e. possessing two thread-like moieties; 20% yield).

Toward our goal of immobilizing catalytically active rotaxanes as molecular machines on solid substrates, we synthesized the Rh(TPP)Cl-stoppered [2]rotaxane **8**-H·Rh(TPP)Cl·$ClO_4$. The reaction of **1b**-$Pd^{II}$·Na and **7**-H·$O_2CCF_3$, followed by the addition of Rh(TPP)Cl and counterion exchange, afforded the Rh(TPP)Cl-stoppered [2]rotaxane **8**-H·Rh(TPP)Cl·$ClO_4$ in 40% yield (Scheme 3). The yield of this [2]rotaxane is lower than the one we achieved previously (75%)[6b] when using dibenzo[24]-crown-8 as the macrocycle, possibly because of an increased steric clash between the larger salophen-containing macrocycle and the Rh(TPP)Cl unit or because of relatively weaker interactions between the components of this pseudorotaxane.

Figure 3 displays representative $^1$H NMR spectra of [2]-rotaxane **3a**-H·$PF_6$, the salen-incorporating macrocycle bound with nickel(II) [**1a**-$Ni^{II}$·Na],[9] and thread-like salt **2**-H·$PF_6$. The $^1$H NMR spectrum of **3a**-H·$PF_6$ (Figure 3c), together with its 2D ROESY and COSY NMR spectra (see Supporting Information) provides evidence for the successful formation of the [2]rotaxane. The signal of the $CH_2N^+$ protons (*A*) in the rotaxane has shifted downfield significantly relative to that in the free thread (Figure 3a) as a result of the formation of [C–H···O] hydrogen bonds[14] (Figure 6). In addition, these protons (*A*) resonate as a triplet in the rotaxane (Figure 3c), whereas they appear as a singlet in the free thread (Figure 3a), which might be a result of the reduced exchange rates of the ammonium protons in the rotaxane structure owing to the hydrogen bonds.

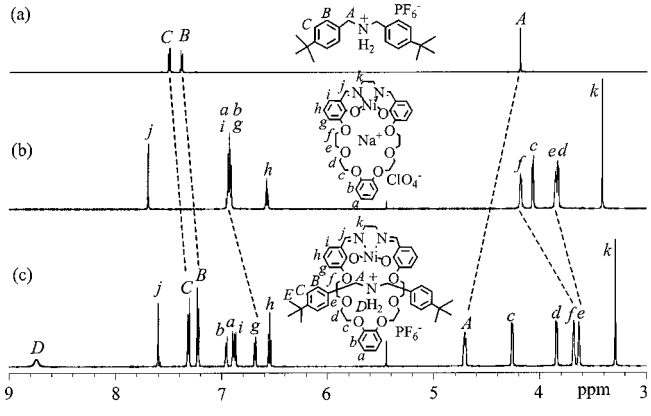

Figure 3. $^1$H NMR spectra (600 MHz, $CD_3CN$, 25 °C) of (a) **2**-H·$PF_6$, (b) **1a**-$Ni^{II}$·Na(I), and (c) **3a**-H·$PF_6$.

In contrast, two of the signals for the ether $CH_2O$ protons (*e* and *f*; Figure 3c) in the $Ni^{II}$-bound macrocycle of the rotaxane have shifted upfield relative to their location in the unthreaded $Ni^{II}$-complexed macrocycle (Figure 3b); we attribute this phenomenon to shielding by the aromatic units in the thread in bent conformations of the components (Figure 6). In addition, the signals of the protons of the aromatic groups in the salen moiety (*g*; Figure 3c) as well as in the thread (*B* and *C*; Figure 3c) have shifted upfield relative to their locations in the corresponding free components probably as a result of π–π stacking interactions.[15] As indicated in Figure 4, the $^1$H NMR spectrum of [2]rotaxane **3b**-H·$PF_6$ (Figure 4c) displays signals that are very similar to those observed for **3a**-H·$PF_6$, which provides good evidence of the successful formation of this rotaxane. Moreover, the ROESY NMR spectra (see Supporting Information) of both rotaxanes **3a/b**-H·$PF_6$ feature cross peaks between the signals of the protons of the ether units (*e* and *f*) in their respective macrocycles and the $CH_2N^+$ units (*A*) in their thread-like moieties.

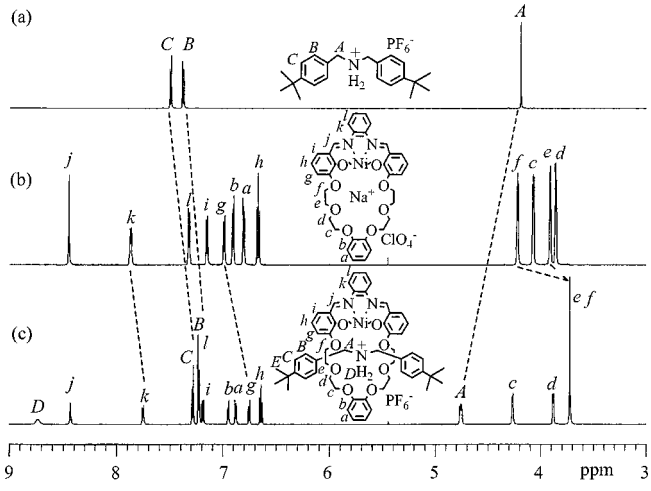

Figure 4. $^1$H NMR spectra (600 MHz, $CD_3CN$, 25 °C) of (a) **2**-H·$PF_6$, (b) **1b**-$Ni^{II}$·Na(I), and (c) **3b**-H·$PF_6$.

Figure 5 displays representative $^1$H NMR spectra of bis[2]rotaxane **6**-2H·2$ClO_4$, the salophen-incorporating bismacrocycle bound with palladium(II) [**4**-$Pd^{II}$·Na; for its synthesis, see the Supporting Information], and thread-like salt **2**-H·$PF_6$. Most of signals for the protons of bis[2]rotaxane **6**-2H·2$ClO_4$ (Figure 5c–e) are very similar to those observed for [2]rotaxanes **3a/b**-H·$PF_6$, which provides good evidence for the successful formation of this rotaxane and confirms its structure. At 25 °C (Figure 5c), the protons of the salophen and ether units in the bismacrocycle suggest that slow conformational changes occur on the $^1$H NMR spectroscopic timescale, which results in broadening and splitting (*e*, *h*, and *j*) of the signals for a few protons of the bismacrocycle. The spectrum became much simpler when the signals for these protons coalesced at higher temperatures (Figure 5d, e). In addition, the ROESY NMR spectrum (see Supporting Information) of this bis[2]rotaxane features cross peaks between the signals of the protons of the ether unit (*c* and *d*) in the bismacrocycle component and aromatic protons (*B* and *C*) in its two thread-like moieties.

The $^1$H NMR spectrum of the Rh(TPP)Cl-stoppered [2]-rotaxane **8**-H·Rh(TPP)Cl·$ClO_4$ (see Supporting Information) displays signals that are very similar to those that

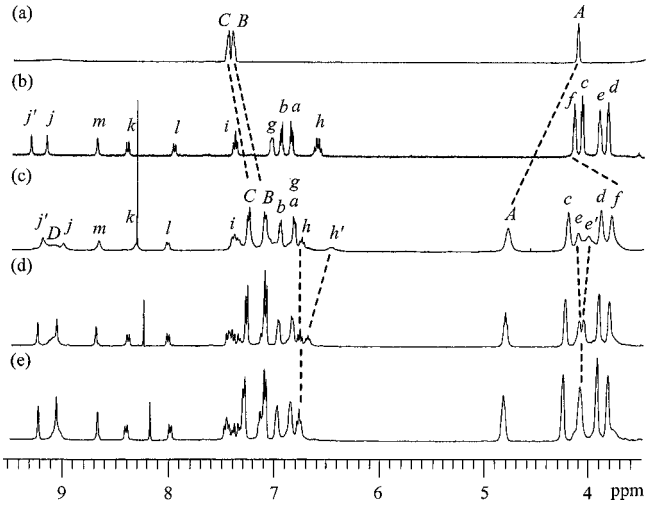

Figure 5. $^1$H NMR spectra (400 MHz, [$D_6$]DMSO) of (a) **2**-H·$PF_6$, (b) **4**-$Pd^{II}$·Na(I), and **6**-2H·2$ClO_4$ recorded at temperatures of (c) 298 K, (d) 323 K, and (e) 353 K.

we observed previously.[6a,6b,6d] In particular, the signal of the aromatic protons (*A*; Scheme 3) in the terminal pyridyl unit of the thread-like moiety is shifted upfield drastically relative to that in the free salt as a result of the shielding effect of the diamagnetic current of the porphyrin ring.[16]

We obtained dark-brown-colored single crystals of **3a**-H·$PF_6$ that were suitable for X-ray crystallographic analysis upon slow evaporation of a $CH_2Cl_2$/EtOAc solution of the [2]rotaxane; **3b**-H·$PF_6$ provided yellowish-brown-colored single crystals, also suitable for X-ray crystallographic analysis, upon vapor diffusion of diisopropyl ether into a $CH_2Cl_2$ solution of the [2]rotaxane. The crystal structures

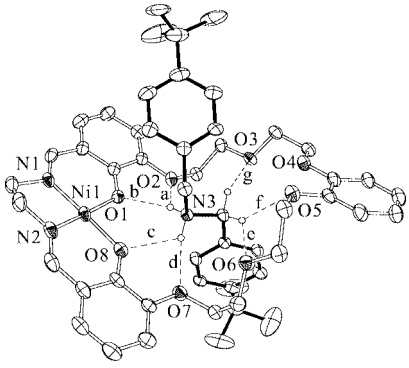

Figure 6. One molecular structure of **3a**-H·$PF_6$ that indicates the intercomponent [N+–H···O] and [C–H···O] hydrogen bonds. The other rotaxane molecule, the nonhydrogen-bonding hydrogen atoms, disordered carbon atoms, and the counter anion have been omitted for clarity. Hydrogen bonding geometries: [X···O], [H···O] distances [Å] and [X–H···O] angles [°] are (a) 3.067, 2.348, 136.8; (b) 2.840, 2.032, 148.6; (c) 2.737, 2.207, 117.1; (d) 2.892, 2.008, 166.8; (e) 3.264, 2.523, 134.0; (f) 3.429, 2.580, 147.6; (g) 3.185, 2.318, 149.9.

(Figures 6 and 7, respectively) confirm the proposed [2]rotaxane structures incorporating the nickel(II)–salen and –salophen moieties, respectively. Stabilization of these [2]-rotaxanes is achieved through a combination of (1) [$N^+$–H···O][17] and [C–H···O][17a,17c] hydrogen bonds involving $NH_2^+$ centers, their adjacent $CH_2$ groups, and the oxygen atoms in the macrocycles and (2) π–π stacking interactions[17] between aromatic rings (see Supporting Information). The packing arrays of both **3a/b**-H·$PF_6$ are stabilized by intra- and intermolecular [C–H···π] interactions.[17b,17d] The [$N^+$– H···O][17] and [C–H···O][17a,17c] hydrogen bonding distances (2.737–3.498 Å) are comparable to those found in a related [2]rotaxane incorporating a palladium(II)–salophen,[8] a nickel(II)–salen[9] moiety, and other[17] similar compounds. The nickel atom exists in a distorted square-planar array (see Supporting Information) that is very similar to the geometries we have observed previously for palladium atoms in related structures.[8,12d]

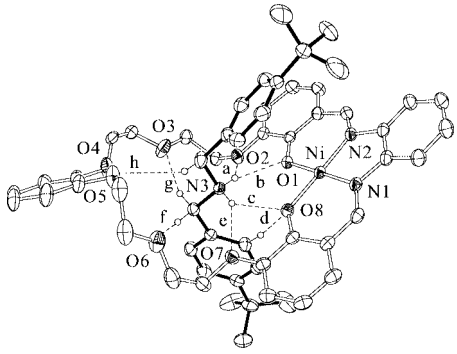

Figure 7. Molecular structure of **3b**-H·$PF_6$ that indicates the intercomponent [$N^+$–H···O] and [C–H···O] hydrogen bonds. The nonhydrogen-bonding hydrogen atoms, disordered carbon atoms, and the counter anion have been omitted for clarity. Hydrogen bonding geometries: [X···O], [H···O] distances [Å] and [X–H···O] angles [°] are (a) 2.906, 2.148, 141.5; (b) 2.829, 2.074, 140.7; (c) 2.858, 2.127, 137.8; (d) 3.498, 2.572, 162.1; (e) 2.920, 2.141, 144.4; (f) 3.408, 2.545, 149.7; (g) 3.259, 2.329, 162.8; (h) 3.323, 2.575, 134.9.

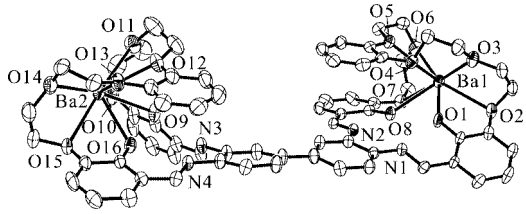

Figure 8. Molecular structure of **4**–Ba. Perchlorate anions, solvent molecules, and hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ba1–O1 2.745(5), Ba1–O2 3.001(5), Ba1–O3 2.975(5), Ba1–O4 2.934(5), Ba1–O5 3.010(5), Ba1–O6 2.965(5), Ba1–O7 2.903(5), Ba1–O8 2.786(5), Ba2–O9 2.828(5), Ba2–O10 3.046(6), Ba2–O11 2.945(6), Ba2–O12 2.932(6), Ba2–O13 2.956(5), Ba2–O14 2.984(6), Ba2–O15 2.995(6), Ba2–O16 2.816(5); O1–Ba1–O6 156.66(15), O8–Ba1–O3 116.71(14), O7–Ba1–O3 171.01(15), O4–Ba1–O2 98.17(14), O6–Ba1–O2 147.28(14), O2–Ba1–O5 149.92(14), O16–Ba2–O11 122.12(17), O9–Ba2–O14 154.50(16), O12–Ba2–O15 119.58(17), O11–Ba2–O15 175.73(17), O13–Ba2–O10 152.92(16), O14–Ba2–O10 150.05(16).

We obtained orange-colored single crystals of **4**-Ba suitable for X-ray crystallographic analysis upon the slow evaporation of a $CH_2Cl_2$/THF/MeOH solution of the $Ba^{II}$-coordinated bismacrocycle. The crystal structure (Figure 8) confirms that this bismacrocycle possesses two barium(II) ions; the two salophen macrocyclic units, which are attached through aromatic rings, are twisted at a dihedral angle of 14.8°. Each oligoether unit is folded completely to allow coordination of all of its oxygen atoms to the barium(II) ion.

## Conclusions

We synthesized [2]rotaxanes **3a**/**3b**-H·$PF_6$ that feature nickel(II)–salophen and –salen moieties, respectively. Both "ring-opening-and-closing" and "threading-followed-by-shrinking" processes occurred during the synthesis of the salen-based [2]rotaxane **3a**-H·$PF_6$, resulting in its remarkably higher yield than that of the salophen-based [2]rotaxane **3b**-H·$PF_6$, for which only a "threading-followed-by-shrinking" process occurs. During the formation of these [2]rotaxanes, the binding of nickel(II) ions to the salophen and salen moieties constitutes the shrinking event. Furthermore, we extended the synthetic system by using a "threading-followed-by-shrinking" approach to afforded [2]rotaxane **5**-H·$ClO_4$ and bis[2]rotaxane **6**-2H·2$ClO_4$, which both feature two palladium(II)–salophen moieties linked in a bismacrocycle. In addition, we synthesized the Rh(TPP)Cl-stoppered [2]rotaxane **8**-H·Rh(TPP)Cl·$ClO_4$ from salophen-based macrocycle **1b**-$Pd^{II}$·Na by using a combination of "threading-followed-by-shrinking" and end-capping through axial coordination between the pyridyl unit of the thread-like cationic component and the rhodium(III) center. We believe that these approaches will be useful for the construction of multifunctional rotaxanes and for the development of molecular devices as new tools. Such rotaxanes possessing salen and salophen moieties have the potential to behave as catalytically active molecular machines on solid surfaces.

## Experimental Section

**General Information:** Nickel(II) acetate tetrahydrate, 3,3′-diaminobenzidine, palladium(II) acetate, and tetracarbonyl-di-μ-chlororhodium(I) ($[Rh(CO)_2Cl]_2$) were purchased from Aldrich. Sodium sulfate, potassium sulfate, and barium perchlorate were purchased from Wako Pure Chemical Industries. **1a**-Ba[9] (Scheme 1), **1b**-Ba[12d] (Scheme 1), **1a**-$Ni^{II}$·Na,[9] **1b**-$Pd^{II}$·Na[12d] (Scheme 3), **2**-H·$PF_6$[4c] (Scheme 1), **7**-H·$CF_3COO$[13] (Scheme 3), and Rh(TPP)Cl[6b] (Scheme 3) were all prepared according to literature procedures. Solvents were purchased from commercial sources. Each reaction was performed under an anhydrous nitrogen atmosphere. Thin-layer chromatography (TLC) was performed by using aluminium sheets precoated with silica gel 60F (Merck 5554). The plates were inspected under UV light and developed in $I_2$ vapor. Column chromatography was conducted by using Wakogel C-400HG (Wako Pure Chemical Industries). $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker AVANCE 400 spectrometer (400 and 100 MHz for $^1H$ and $^{13}C$ NMR, respectively). All 2D NMR spectroscopy experiments were recorded by using 1 K data points and 256 time increments in phase-sensitive mode and were processed in a 1 K × 1 K matrix. The ROESY NMR spectroscopic experiment was performed with the use of a spin–lock mixing time of 200 ms and was processed using a forward linear prediction in the F1 dimension. Matrix-assisted laser-desorption/ionization time-off-light mass spectrometry (MALDI-TOF MS) was performed with a Shimazu Kratos Kompact-MALDI III with a 2,5-dihydroxybenzoic acid as the matrix. FAB mass spectra were recorded with an MS600H spectrometer. Infrared (IR) spectra were recorded by using a Jasco FTIR 620 spectrophotometer. Elemental analyses were performed with a CE Instruments EA1110. Gel permeation chromatography (GPC) separation was performed with an LC-918 (Japan Analytical Industry Co. Ltd.) equipped with JAIGL-1H and –2H columns; chloroform was used as the eluent.

**Macrocycle Coordinated to Both Nickel(II) and Sodium(I), 1b-$Ni^{II}$·Na:** A solution of sodium sulfate (2.00 g, 14.0 mmol) in water (20 mL) was added to a solution of **1b**-Ba (935 mg, 1.0 mmol) in MeCN (40 mL), and then the mixture was stirred at r.t. for 3 h. The reaction mixture was filtered to remove the precipitated barium sulfate. The filtrate was dried (anhydrous $Na_2SO_4$), the solvent was evaporated, and the residue was dried under high vacuum to yield **1b**-Na as an orange solid (801 mg, 95%). A solution of nickel(II) acetate tetrahydrate (274 mg, 1.1 mmol) in MeOH (12 mL) was added to a solution of **1b**-Na (616 mg, 0.73 mmol) in $CH_2Cl_2$ (40 mL), and then the mixture was stirred at r.t. for 2 h. The solvent was evaporated under reduced pressure. The residue was dissolved in a small amount of MeCN and purified by column chromatography ($SiO_2$; $CH_2Cl_2$/MeOH, 98:2). Fractions containing the product [$R_f$ = 0.42 for **1b**-$Ni^{II}$·Na; $CH_2Cl_2$/MeOH, 9:1] were combined, and the solvent was evaporated under reduced pressure to afford **1b**-$Ni^{II}$·Na (454 mg, 80%) as a brown solid. M.p. 141–142 °C. $^1H$ NMR (400 MHz, $CD_3CN$, 25 °C): $\delta$ = 8.00 (s, 2 H, *j*), 7.44 (br., 2 H, *k*), 6.89–6.86 (m, 2 H, *a*), 6.79–6.74 (m, 6 H, *b*, *i*, *l*), 6.61 (d, *J* = 7.8 Hz, 2 H, *g*), 6.40 (t, *J* = 7.8 Hz, 2 H, *h*), 4.13 (br., 4 H, *f*), 4.07 (br., 4 H, *c*), 3.86–3.85 (br., 8 H, *d*/*e*) ppm. $^{13}C$ NMR (100 MHz, $CD_3CN$, 25 °C): $\delta$ = 155.3, 154.1, 148.4, 147.3, 141.9, 127.4, 125.5, 121.7, 119.7, 115.4, 115.1, 114.7, 68.9, 68.2, 67.8, 67.0 ppm. IR (KBr): $\tilde{\nu}$ = 3504, 2920, 2874, 1707, 1610, 1543, 1503, 1450, 1254, 1202, 1100 ($ClO_4^-$), 936, 739 $cm^{-1}$. MS (MALDI-TOF): *m*/*z* = 678 (100) $[M + 1 - ClO_4]^+$. $C_{34}H_{32}ClN_2NaNiO_{12}$ (777.77): calcd. C 52.51, H 4.15, N 3.60; found C 52.58, H 4.28, N 3.51.

**3a/b-H·$PF_6$:** A solution of $Na_2SO_4$ (101 mg, 0.71 mmol) in $H_2O$ (2 mL) and MeCN (2 mL) was added to a solution of the relevant macrocycle–barium perchlorate complex (0.25 mmol; 222 mg for **1a**-Ba; 234 mg for **1b**-Ba) and **2**-H·$PF_6$ (229 mg, 0.50 mmol) in MeCN (20 mL), and then the mixture was stirred for 2 h. A solution of $Ni(OAc)_2·4H_2O$ (63.3 mg, 0.25 mmol) in MeOH (2 mL) and MeCN (2 mL) was added to the reaction mixture, which was stirred for 12 h. The solution was filtered, and then the solvent was evaporated under reduced pressure. The residue was dissolved in a small amount of MeCN and purified by column chromatography ($SiO_2$; $CH_2Cl_2$/MeOH, 9:1). Fractions containing the product ($R_f$ = 0.37 for **3a**-H·$PF_6$; $R_f$ = 0.33 for **3b**-H·$PF_6$; $CH_2Cl_2$/MeOH, 9:1) were combined, and the solvent was evaporated under reduced pressure to afford the [2]rotaxanes as either a yellow-green (**3a**-H·$PF_6$: 146 mg, 55%) or dark-brown solid (**3b**-H·$PF_6$: 56 mg, 20%). Selected data for **3a**-H·$PF_6$: M.p. 145–147 °C (decomp.). $^1H$ NMR (600 MHz, $CD_3CN$, 25 °C): $\delta$ = 8.74 (br., 2 H, *D*), 7.60 (s, 2 H, *j*), 7.31 (d, *J* = 8.4 Hz, 4 H, *C*), 7.23 (d, *J* = 8.4 Hz, 4 H, *B*), 6.95 (m, 2 H, *b*), 6.90 (m, 2 H, *a*), 6.88 (d, *J* = 7.8 Hz, 2 H, *i*), 6.68 (d, *J* = 7.8 Hz, 2 H, *g*), 6.55 (t, *J* = 7.8 Hz, 2 H, *h*), 4.71 (t, *J* = 6.6 Hz, 4 H, *A*), 4.25 (m, 4 H, *c*), 3.85 (m, 4 H, *d*), 3.68 (m, 4 H, *f*), 3.63 (m,

**4-Ba:** A solution of the dialdehyde-functionalized crown ether derivative (526.5 mg, 1.0 mmol) and 3,3′-diaminobenzidine (107.2 mg, 0.5 mmol) in dry THF (20 mL) was added over 2 h to a solution of barium perchlorate (336.3 mg, 1.0 mmol) heated under reflux in dry MeOH (100 mL). The mixture was heated under reflux for an additional 24 h. During the reaction, an orange-colored solid precipitated out. This solid was filtered off and washed with $CH_2Cl_2$ to afford the barium perchlorate–bismacrocycle complex **4**-Ba as an orange solid (691 mg, 74%). M.p. 221–226 °C. $^1$H NMR (400 MHz, $CD_3CN$, 25 °C): $\delta$ = 14.89–14.67 (m, 4 H, *OH*), 9.42 (br., 2 H, *j*′), 9.04 (br., 2 H, *j*), 8.02 (s, 2 H, *m*), 7.95–7.90 (m, 2 H, *k*), 7.74–7.69 (m, 2 H, *l*), 7.24 (m, 4 H, *i*), 7.08 (m, 4 H, *g*), 6.93–6.85 (m, 8 H, *a*, *b*), 6.61 (m, 4 H, *h*), 4.47 (m, 8 H, *f*), 3.97–3.82 (m, 24 H, *c*–*e*) ppm. IR (KBr): $\tilde{\nu}$ = 1080 ($ClO_4^-$) cm$^{-1}$. MS (FAB): *m*/*z* (%) = 1431 (10) [M – Ba – 3$ClO_4$]$^+$. $C_{68}H_{66}Ba_2Cl_4N_4O_{32}\cdot 3H_2O$ (1921.80): calcd. C 42.50, H 3.78, N 2.92; found C 42.23, H 3.92, N 2.69.

**4-K and 4-Na:** A solution of potassium sulfate (1 g, 5.7 mmol) or sodium sulfate (0.81 g, 5.7 mmol) in $H_2O$ (50 mL) was added to a solution of **4**-Ba (1.06 g, 0.57 mmol) in a solution of MeOH/THF/MeCN/$Me_2CO$ (4:4:1:1, 200 mL), and then the mixture was stirred at r.t. for 3 h. The reaction mixture was filtered to remove the precipitated barium sulfate. The solvent was evaporated, and the residue was dried under high vacuum to yield **4**-K as an orange solid (684 mg, 90%) or **4**-Na as an orange solid (683 mg, 91%). Selected data for **4**-K: $^1$H NMR (400 MHz, [$D_6$]DMSO, 25 °C): $\delta$ = 13.59–13.56 (m, 4 H, *OH*), 9.11–9.02 (m, 4 H, *j*, *j*′), 8.55 (s, 2 H, *m*), 7.99 (m, 2 H, *k*), 7.67 (m, 2 H, *l*), 7.29–7.26 (m, 4 H, *i*), 7.15–7.14 (m, 4 H, *g*), 6.98–6.91 (m, 8 H, *a*, *b*), 6.89–6.86 (m, 4 H, *h*), 4.17 (m, 8 H, *f*), 4.11 (m, 8 H, *c*), 3.86 (m, 8 H, *e*), 3.83–3.82 (m, 8 H, *d*) ppm. $^{13}$C NMR (100 MHz, [$D_6$]DMSO, 25 °C): $\delta$ = 192.3, 192.2, 150.9, 150.8, 150.3, 148.1, 147.7, 147.6, 146.8, 146.3, 146.0, 143.9, 124.2, 121.8, 121.7, 120.8, 120.6, 118.7, 118.6, 118.0, 114.3, 113.7, 98.7, 54.3, 52.6, 48.0, 30.0 ppm. IR (KBr): $\tilde{\nu}$ = 1100 ($ClO_4^-$) cm$^{-1}$. MS (FAB): *m*/*z* (%) = 1233 (10) [M – $ClO_4$]$^+$.

**4-Pd$^{II}$·Na:** Solid palladium(II) acetate (384 mg, 1.71 mmol) was added to a $CH_2Cl_2$/THF/MeOH (6:2:2, 200 mL) solution of **4**-Na (751 mg, 0.57 mmol), and then the mixture was stirred at r.t. for 2 h. The solvent was evaporated under reduced pressure. The residue was dissolved in a small amount of MeCN and purified by column chromatography ($SiO_2$; $CH_2Cl_2$/MeOH, 98:2) to afford **4**-Pd$^{II}$·Na (752 mg, 80%) as a orange solid. $^1$H NMR (400 MHz, [$D_6$]-DMSO, 25 °C): $\delta$ = 9.37 (s, 2 H, *j*′), 9.22 (s, 2 H, *j*), 8.74 (s, 2 H, *m*), 8.45 (d, *J* = 9 Hz, 2 H, *k*), 8.02 (d, *J* = 9 Hz, 2 H, *l*), 7.43 (m, 4 H, *i*), 7.08 (br., 4 H, *g*), 6.98 (m, 4 H, *b*), 6.91 (m, 4 H, *a*), 6.66 (m, 4 H, *h*), 4.21 (br., 8 H, *f*), 4.14 (br., 8 H, *c*), 3.97 (br., 8 H, *e*), 3.89 (br., 8 H, *d*) ppm. IR (KBr): $\tilde{\nu}$ = 3003, 2391, 1853, 1630, 1481, 1346, 1163, 1053 ($ClO_4^-$), 976 cm$^{-1}$. MS (MALDI-TOF): *m*/*z* (%) = 1428 (100) [M + 1 – Na – 2$ClO_4$]$^+$, 1548 (4) [M – 1 – $ClO_4$]$^+$.

**5-H·$ClO_4$ and 6-2H·2$ClO_4$:** A solution of **2**-H·$PF_6$ (592 mg, 1.3 mmol) in MeCN (20 mL) was added to a solution of the bismacrocycle with potassium(I) perchlorate **4**-K (173 mg, 0.13 mmol) in $CH_2Cl_2$ (20 mL) and stirred for 16 h at r.t. Then, solid Pd(OAc)$_2$ (87 mg, 0.39 mmol) was added, and the reaction mixture was stirred for 4 h. The solvent was evaporated under reduced pressure, and the residue was dissolved in $CH_2Cl_2$ and filtered through a column ($SiO_2$; $CH_2Cl_2$/MeOH, 98:2). The crude material was purified by GPC ($CHCl_3$) to afford **6**-2H·2$ClO_4$ as a red-orange solid (58 mg, 20%). Selected data for **5**-H·$ClO_4$: IR (KBr): $\tilde{\nu}$ = 1100 ($ClO_4^-$) cm$^{-1}$. MS (FAB): *m*/*z* (%) = 1715 (18) [M – $ClO_4$]$^+$. Selected data for **6**-2H·2$ClO_4$: M.p. 184–187 °C. $^1$H NMR (400 MHz, [$D_6$]-DMSO, 25 °C): $\delta$ = 9.22 (s, 2 H, *j*′), 9.06 (m, 4 H, *D*), 8.68 (s, 2 H, *j*), 8.33 (m, 2 H, *m*), 8.32 (s, 2 H, *k*), 8.03 (m, 2 H, *l*), 7.36 (m, 4 H, *i*), 7.25 (m, 8 H, *C*), 7.11 (m, 8 H, *B*), 6.95 (m, 4 H, *b*), 6.83 (m, 8 H, *g*, *a*), 6.75 (t, *J* = 8 Hz, 2 H, *h*), 6.47 (br., 2 H, *h*′), 4.79 (br., 8 H, *A*), 4.22 (m, 8 H, *c*), 4.12 (m, 4 H, *e*), 4.02 (m, 4 H, *e*′), 3.91 (br., 8 H, *d*), 3.81 (br., 8 H, *f*) ppm. IR (KBr): $\tilde{\nu}$ = 3181, 2060, 1856, 1525, 1488, 1382, 1090 ($ClO_4^-$), 989, 687 cm$^{-1}$. MS (FAB): *m*/*z* (%) = 2023 (6) [M – 1 – $ClO_4$]$^+$, 1012 (13) [M – 2 $ClO_4$]$^{2+}$.

**8-H·Rh(TPP)Cl·$ClO_4$:** The thread-like salt **7**-H·$O_2CCF_3$ (44 mg, 0.12 mmol) was added to a $CH_2Cl_2$/MeCN (10:1, 50 mL) solution of the salophen macrocycle with palladium(II)-sodium(I) **1b**-Pd$^{II}$·Na(I) (100 mg, 0.12 mmol) and stirred for 1 h at r.t. Then, solid Rh(TPP)Cl (90 mg, 0.12 mmol) was added, and the reaction mixture was stirred for 60 h. The solvent was evaporated under reduced pressure. The residue was dissolved in $CH_2Cl_2$ and chromatographed ($SiO_2$; $CH_2Cl_2$/MeOH, 98:2) to afford the **8**-H·Rh(TPP)Cl·$ClO_4$ as a violet solid (86 mg, 40%). $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 8.79 (s, 10 H, *j*, *6*), 8.35 (br., 2 H, *H*), 8.24 (m, 4 H, *5*), 8.04 (m, 2 H, *F*), 7.83 (d, *J* = 7 Hz, 4 H, *4*), 7.70 (m, 8 H, *1*, *3*), 7.52 (m, 4 H, *2*), 7.33 (m, 2 H, *k*), 7.11 (br., 2 H, *E*), 6.85 (m, 2 H, *b*), 6.70 (d, *J* = 8 Hz, 2 H, *g*), 6.65 (m, 2 H, *a*), 6.53 (d, *J* = 8 Hz, 2 H, *l*), 6.33 (m, 2 H, *i*), 6.17 (m, 2 H, *h*), 5.44 (m, 2 H, *B*), 4.13 (m, 4 H, *c*), 4.01 (m, 8 H, *f*, *e*), 3.95 (m, 4 H, *d*), 3.84 (m, 2 H, *C*), 3.75 (br., 2 H, *D*), 1.05 (d, *J* = 7 Hz, 2 H, *A*), 0.88 (s, 9 H, *G*) ppm. MS (MALDI-TOF): *m*/*z* (%) = 835 (4) [M – 1 – $ClO_4$ – Cl]$^{2+}$.

**X-ray Measurements**: X-ray data were obtained with a Bruker SMART-CCD diffractometer; structural determination and refinement were performed by using SAINT[18] and SHELXTL[19] software packages, and the empirical absorption correction was performed by using the SADABS[20] program. All structures were solved by direct methods and refined by a full-matrix least-squares method.

**Crystallographic Data**

**3a-H·$PF_6$:** [Ni($C_{30}H_{32}N_2O_8$)$C_{22}H_{32}N$]$_2$($PF_6$)$_2$·$CH_2Cl_2$·$C_4H_8O_2$, $C_{109}H_{138}Cl_2F_{12}N_6Ni_2O_{18}P_2$, *M* = 2298.51, monoclinic, space group *C*2/*c*, *a* = 67.469(4) Å, *b* = 13.7577(8) Å, *c* = 24.5387(14) Å, $\beta$ = 96.183(2)°, *V* = 22645(2) Å$^3$, *Z* = 8, $\rho_{calcd.}$ = 1.348 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 4.94 cm$^{-1}$, *T* = 183(2) K, yellow-brown plates, 0.20 × 0.15 × 0.10 mm, $R_1$ = 0.0819 [I > 2$\sigma$(*I*)], $wR_2$ = 0.2822 (all data), GOF = 0.940.

# Synthesis, Characterisation and Luminescent Properties of Lanthanide-Organic Polymers with Picolinic and Glutaric Acids

**Penka I. Girginova,[a] Filipe A. Almeida Paz,[a] Paula C. R. Soares-Santos,[a] R. A. Sá Ferreira,[b] Luís D. Carlos,[b] Vítor S. Amaral,[b] Jacek Klinowski,[c] Helena I. S. Nogueira,[a] and Tito Trindade*[a]**

**Keywords:** Lanthanide complexes / Picolinic acid / Glutaric acid / Luminescence

Three new lanthanide(III) complexes (Ln = Sm, Tb and Eu) of picolinic and glutaric acid were prepared and characterised. The crystal structure of the complex [Sm(glu)(pic)-$(H_2O)_2$] (where Hpic and $H_2$glu stand for picolinic and glutaric acid, respectively) was determined by single-crystal X-ray diffraction. All the Ln complexes were characterised by elemental analysis, infrared spectroscopy, X-ray powder diffraction and thermoanalytical measurements. The combined data show that these Ln complexes are isostructural. The effect of both organic ligands on the photoluminescent behaviour of the $Sm^{3+}$, $Eu^{3+}$ and $Tb^{3+}$ complexes is discussed and we anticipate the possibility of controlling the photoluminescence of picolinic-containing lanthanide compounds by systematically varying the length of the bridging ligand.

## Introduction

The design of functional units from the molecular scale to macroscopic assemblies has emerged as a new paradigm in materials synthesis resulting in an interplay between conventional molecular chemistry and conventional solid-state science. This has been particularly clear in the development of functional materials using coordination compounds such as in the field of semiconductors technology, supramolecular machinery, microporous and hybrid materials and catalysis.[1] In some cases, the development of these functional materials is based on the chemistry of well-known coordination compounds as illustrated by the assembly of inorganic-organic extended lattices[2] and in the thermolysis of metal thiolato compounds to produce thin films or nanoparticles.[3]

Metals coordinated to aromatic ambidentate ligands form a class of compounds with a wide variety of coordination modes which has long attracted the attention of chemists.[4] Griffith and co-workers extended this type of chemistry to the second row transition metals and, in particular, to their applications in catalysis.[5] More recently, as part of our own studies of metal complexes with aromatic ambidentate ligands,[6] we began to exploit the coordination chemistry of 3-hydroxypicolinic acid and its derivatives in the synthesis of a series of lanthanide complexes and we investigated the role of this ligand in the photoluminescence of such complexes.[7] Picolinic acid complexes of lanthanides, particularly those of $Eu^{3+}$ and $Tb^{3+}$, show interesting photoluminescent behaviour because energy transfer from the aromatic groups close to the lanthanide ions may enhance the luminescent efficiency of the ion.[8] Even dispersed in solid matrices they can produce efficient luminescent materials, such as those in $SiO_2$ nanoparticles obtained by the sol-gel method.[7] Therefore, in principle, it should be possible to fine tune the luminescence of such nanocomposites by working out the coordination chemistry of the Ln complexes. Lanthanide coordination polymers, including those synthesised in the presence of dicarboxylato ligands have attracted considerable interest and many examples can be found in the literature.[9] However, we could not find examples of Ln-containing coordination compounds with this type of ligand or an aromatic antenna. Consequently, we report here a distinct approach which involves the simultaneous use of a highly flexible bridging ligand (glutaric acid) with a chelating aromatic ligand (picolinic acid) which, on the one hand, might function as an antenna, efficiently transferring energy to the Ln centre or, on the other hand, may remove available coordination sites thus controlling to some extent the dimensionality of the final product.

## Results and Discussion

### Synthetic Aspects

Lanthanide-organic coordination polymers, with the general empirical formula [Ln(glu)(pic)($H_2O$)$_2$] (where $Ln^{3+}$ = $Sm^{3+}$, $Tb^{3+}$ and $Eu^{3+}$), have been prepared by reaction, in aqueous media, of the respective Ln nitrato salts with glutaric ($H_2$pic) and picolinic (Hpic) acids (see Exp. Sect.). Such a procedure invariably yielded microcrystalline powders. Thus, the reaction with $Sm^{3+}$ was allowed to proceed slowly in a silica gel matrix over a period of several months, leading to high-quality single-crystals suitable for a full structural determination using X-ray diffraction (see crystal description below). Phase identification of the $Tb^{3+}$ material was also performed using single-crystal X-ray diffraction whereas for the $Eu^{3+}$ complex only powder studies could be undertaken (see Exp. Sect. dedicated to X-ray crystallography and the Supporting Information). Crystal images of the $Sm^{3+}$ (SEM) and $Tb^{3+}$ (optical microscope) compounds are supplied as Supporting Information.

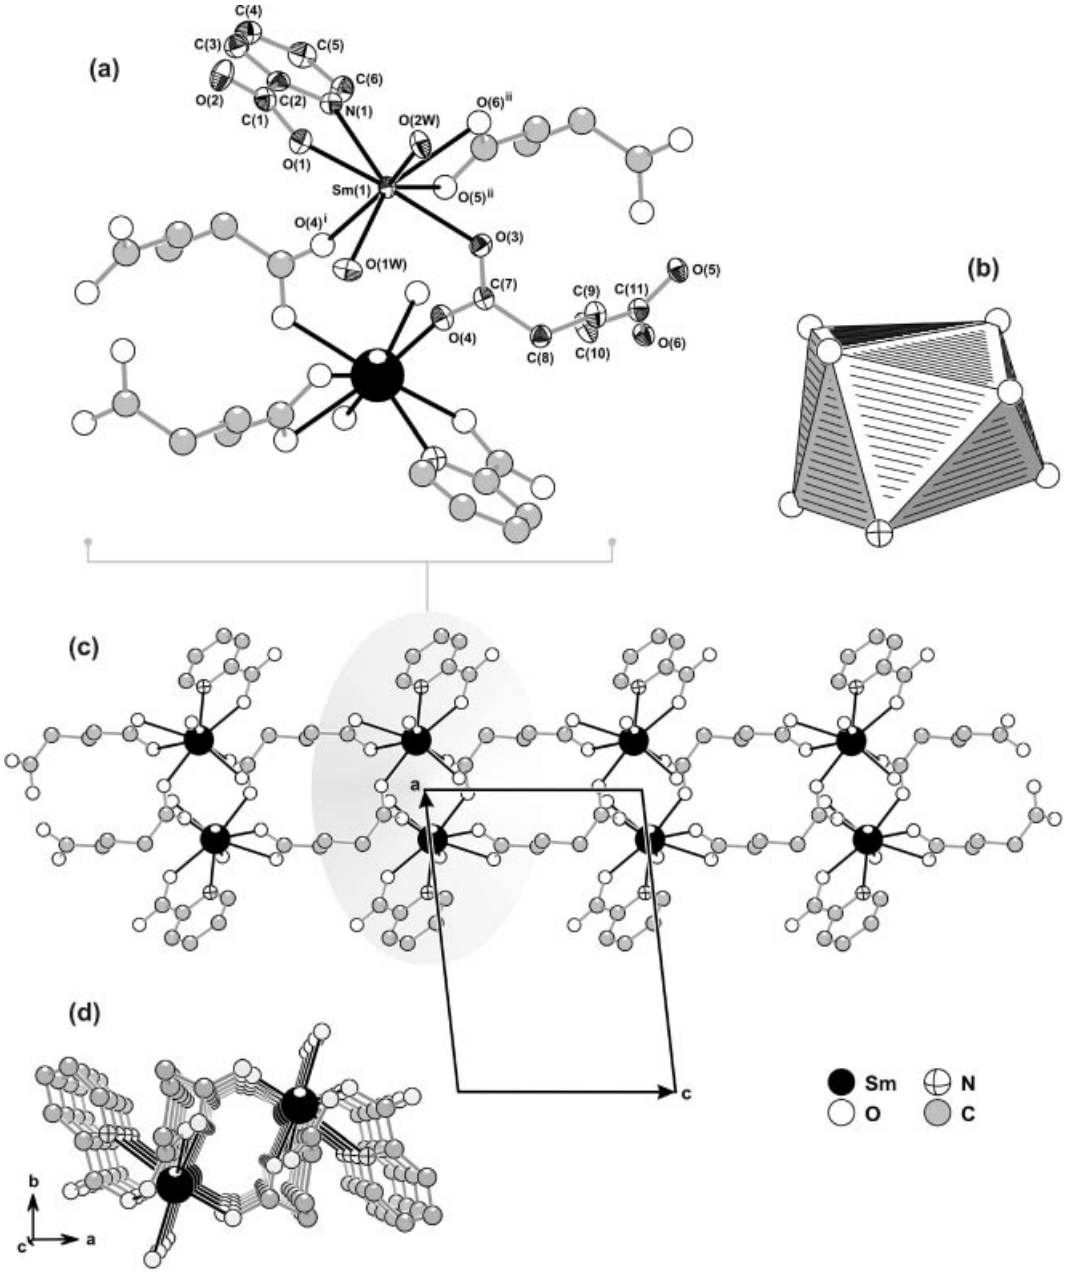

Figure 1. (a) Centrosymmetric binuclear secondary building unit of the coordination polymer, showing the labelling scheme for all non-hydrogen atoms belonging to the asymmetric unit. Thermal ellipsoids are shown at the 50% probability level. (b) Polyhedral representation of the coordination sphere of the $Sm^{3+}$ centre, {$SmNO_7$}, resembling a highly distorted dodecahedron. ### Crystal Structure Description of [Sm(glu)(pic)($H_2O$)$_2$]

When an aqueous solution containing $Sm^{3+}$ diffuses into a gel containing glutaric acid ($H_2glu$ = $C_5H_8O_4$) and picolinic acid (Hpic = $C_6H_5NO_2$) a crystalline material, which could be manually isolated in the form of large single-crystals, formed after a period of 4 months (see Exp. Sect.). The crystal structure of this material was elucidated by X-ray crystallography (see dedicated Exp. Sect.) and ultimately formulated as [Sm(glu)(pic)($H_2O$)$_2$]. The phase purity and homogeneity of the bulk sample were further confirmed using powder X-ray diffraction (not shown) and CHN elemental composition analyses.

The crystal structure contains a single crystallographically unique $Sm^{3+}$ metallic centre which appears coordinated to two water molecules, three glutarate anions ($glu^{2-}$) and one picolinic acid residue ($pic^-$) in a typical eight-coordination fashion (see part a of Figure 1, {$SmNO_7$}) best described as a highly distorted dodecahedron (Figure 1, b): while one trapezoid of this polyhedron is composed of two water molecules [O(1W) and O(2W)] and two oxygen atoms from distinct glutarato residues [O(4)$^{i}$ and O(6)$^{ii}$], the other is instead formed from the N,O-chelate of the picolinic acid moiety plus another two oxygen atoms from glutarate anions [O(3) and O(5)$^{ii}$] (Figure 1, a and b; symmetry codes: (i) 2 – *x*, 1 – *y*, –*z*; (ii) 2 – *x*, 1 – *y*, 1 – *z*). The Sm–O bond lengths for the coordinated water molecules and the carboxylato groups [found in the 2.407(3)–2.410(3) and 2.355(3)–2.508(3) Å ranges, respectively – see Table 1] are in good agreement with those typically found in related compounds, as revealed by a search of the Cambridge Structural Database (CSD, Version 5.27, November 2005),[10,11] while the typical Sm–$O_{water}$ distance can be found in the 2.32–2.89 Å range (from 41 entries with a median of 2.44 Å). The Sm–$O_{carboxylate}$ are instead in the 2.19–3.08 Å range (from 98 entries with a median of 2.41 Å). It is of considerable interest to mention that the lack of regularity in the dodecahedral coordination environment arises, mainly, because of the various binding modes of the ligands composing the first coordination sphere (details in the following paragraphs) which is directly reflected in the internal angles of the polyhedron (Table 1).

The compound contains a single crystallographically independent glutarato residue which appears with its two carboxylato groups having very distinct coordination modes (Scheme 1). On the one hand, the carboxylato group composed of O(5) and O(6) (Figure 1, a) coordinates to the $Sm^{3+}$ centre through a typical bidentate *syn*,*syn* chelating fashion with a bite angle of 52.33(9)° which is in good agreement with the values reported for analogous materials (from 35 entries in the CSD with a median of 51.2°). On the other hand, the opposite carboxylato group, composed of O(3) and O(4) (Figure 1, a), appears instead forming a *syn*,*anti* bridge with a neighbouring $Sm^{3+}$ cation, thus imposing a Sm(1)···Sm(1)$^{i}$ separation of 4.626(1) Å. This *syn*,*anti* bridge leads to the formation of a centrosymmetric binuclear moiety which can be further envisaged as the building block of the polymeric structure of the material (see below), a structural feature only found in a handful of other structures also containing lanthanide centres and glutarato anions, namely with $Nd^{3+}$,[12,13] $Ho^{3+}$ [13] and $Tb^{3+}$,[14] all of which are 1D materials. Interestingly, in those compounds, the glutarato anions exhibit markedly distinct coordination geometries compared with those recorded for our material. This is particularly notable for the bridging groups which appear as *syn*,*anti* bridges while in those related 1D compounds[12,13] one oxygen atom is simultaneously involved in a *syn*,*syn* chelate and in a *syn*,*anti* bridge. Moreover, this structural aspect exhibited by one carboxylato oxygen atom is repeatedly found in all the remaining known 2-[14] and 3D[15–21] lanthanide-organic materials containing glutaric acid residues, thus rendering the present compound the first example of a glutarato-lanthanide material in which an inter-lanthanide bridge via a carboxylato group is enforced by a *syn*,*anti* bridge. Apart from structurally creating the aforementioned bimetallic

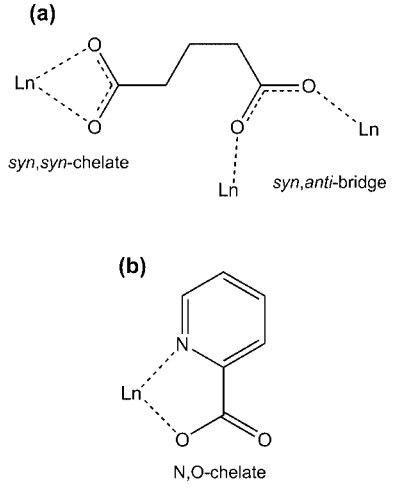
units, the glutarato anionic residues further establish physical links interconnecting the two $Sm^{3+}$ centres of one unit [Sm(1) plus $Sm(1)^{i}$ – Figure 1, a] with a third metallic centre of a neighbouring moiety [$Sm(1)^{iii}$], imposing Sm(1)···$Sm(1)^{iii}$ and $Sm(1)^{i}$···$Sm(1)^{iii}$ separations of 8.480(2) and 9.074(2) Å, respectively [symmetry code: (iii) $x$, $y$, $-1 + z$]. This leads to the formation of a 1D $_{\infty}^{1}$[Sm(glu)(pic)$(H_2O)_2$] molecular tape running parallel to the [001] direction of the unit cell (Figure 1, c and d).



Scheme 1. Coordination modes of the ligands present in [Sm(glu)(pic)$(H_2O)_2$]: (a) glutaric acid; (b) picolinic acid.

As reported by Zhang et al.[13] for the 1D $_{\infty}^{1}$[Ln(glu)(phen)Cl] (where $Ln^{3+}$ = $Tb^{3+}$ and $Ho^{3+}$, phen = 1,10-phenanthroline) materials, the $_{\infty}^{1}$[Sm(glu)(pic)$(H_2O)_2$] molecular tape present in the crystal structure also contains, external to the glu/Sm core, chelating aromatic organic ligands (picolinato residues) which seem to prevent the growth of the hybrid polymer in more than one direction by removing available coordination sites in the metallic centres (Figure 1). Indeed for all known and related compounds, when these chelating moieties are not present, 2-[14] and 3D[15–22] materials are typically isolated. The picolinic acid residues appear coordinated to the $Sm^{3+}$ metallic centres in a typical N,O-chelating fashion (Scheme 1) with a bite angle of 64.97(10)°, a value consistent with those reported for similar compounds[23–26] (10 entries in the CSD, with values spanning from 60.5 to 67.6°; median of 64.0°).

Individual neutral 1D $_{\infty}^{1}$[Sm(glu)(pic)$(H_2O)_2$] molecular tapes close-pack in the solid state, mediated by weak interactions such as homonuclear O–H···O hydrogen bonds and π-π stacking to form a 3D supramolecular structure. On the one hand, strong and highly directional [all interaction angles <(DHA) are well above 150° – see Table 2] O–H···O hydrogen bonds involving the coordinated water molecules and the carboxylato groups interconnect neighbouring tapes in the *bc* plane of the unit cell leading to a 2D supramolecular framework (Figure 2, a). One of these interactions is particularly important for the structural integrity of the binuclear secondary building unit of the molecular tape, as represented in Figure 2 (b). The coordinated O(1W) water molecule donates one hydrogen atom in a strong hydrogen bonding interaction with a neighbouring carboxylato group [D···A of 2.753(4) Å with <(DHA) of 175(4)°]. In fact, for all other closely related compounds, connections between adjacent lanthanide centres are usually assured by four carboxylato groups, either belonging to the glutarato[12–14,16,18–21] or oxalato[15,17] anions in a pseudo-paddlewheel motif. For the $_{\infty}^{1}$[Sm(glu)(pic)$(H_2O)_2$] molecular tape, only two carboxylato groups bridge the metallic centres (Figure 2, b) with structural stability being achieved

when the aforementioned hydrogen bonds are taken into account. Hydrogen-bonded supramolecular layers are in turn arranged in an orderly fashion along the [100] direction of the unit cell, mediated by offset π-π stacking interactions between neighbouring coordinated picolinic acid residues (Figure 3).

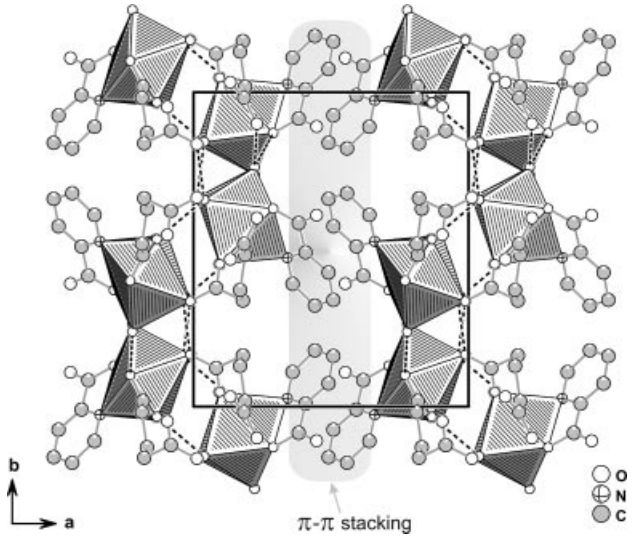

Figure 3. Mixed ball-and-stick and polyhedral (for the $\{SmNO_7\}$ coordination environments) representations of the crystal packing of $[Sm(glu)(pic)(H_2O)_2]$ viewed along [001] direction of the unit cell. Hydrogen atoms have been omitted for clarity and hydrogen bonds are represented as black-filled dashed lines.

## Spectroscopic and Thermoanalytical Results

The CHN elemental data for $[Ln(glu)(pic)(H_2O)_2]$ (where Ln = $Sm^{3+}$, $Tb^{3+}$ and $Eu^{3+}$) are summarised in Table 3 and agree well with the expected compositions based on the single-crystal X-ray studies performed (see above). Diagnostic FTIR and Raman spectroscopic data are also provided in Table 3. FTIR spectroscopy confirms the coordination of both ligands to the metal centres: $pic^-$ by means of the carboxylic group and the nitrogen atom from the aromatic ring and $glu^{2-}$ by its carboxylato groups. The asymmetric stretching $\nu_{asym}(-CO_2^-)$ mode shows shifts up to 33 $cm^{-1}$ (40 $cm^{-1}$ in the Raman spectra) to lower wavenumbers when compared with the values reported for the free picolinic acid. Furthermore, the measured values of $\Delta$ [$\nu_{asym}(-CO_2^-) - \nu_{sym}(-CO_2^-)$] for the Sm (281 $cm^{-1}$), Eu (283 $cm^{-1}$) and Tb (283 $cm^{-1}$) compounds are further evidence for the presence of carboxylato groups coordinated to the metal centres. The typical stretching $\nu$(C–N) vibrational mode of substituted pyridines appears for the uncoordinated picolinic acid at 1594 $cm^{-1}$ and shows small shifts (up to 13 $cm^{-1}$ in the FTIR spectra and up to 30 $cm^{-1}$ in the Raman spectra) for all compounds, in agreement with N,O-chelation involving the nitrogen atom of the $pic^-$ group. The typical stretching $\nu$(C–O) vibrational mode of the carboxylic group of glutaric acid at 1265 $cm^{-1}$ is shifted for all compounds by 26 $cm^{-1}$, confirming the bond formed between the deprotonated carboxylic group of glutaric acid and the lanthanide ion.

The thermal decomposition of $[Sm(glu)(pic)(H_2O)_2]$ occurs in a multi-step process from ambient temperature to 800 °C to yield $Sm_2O_3$ as the final residue (total weight loss: 57%; calculated: 60%). The first weight loss of ca. 8.4% occurs in the 57–230 °C temperature range (DTG peak at 182 °C) and can be attributed to the release of the two coordinated water molecules (calculated weight loss of 8.2%). Between 230 and 747 °C a total weight loss of ca. 49% corresponds to the thermal decomposition of the organic components (calculated 57%). The other Ln compounds exhibit similar thermal properties: for $[Tb(glu)(pic)(H_2O)_2]$ the total weight loss was 58% with a calculated value of 59% between 72 °C and 700 °C. For $[Eu(glu)(pic)(H_2O)_2]$ the total weight loss was 57% with a calculated value of 60% between 22 °C and 800 °C.

## Photoluminescence

The excitation spectra of the $Sm^{3+}$, $Eu^{3+}$ and $Tb^{3+}$ compounds represented in Figure 4 were monitored around the cation's more intense line which can be found at 597 nm for $Sm^{3+}$, 614 nm for $Eu^{3+}$ and 545 nm for $Tb^{3+}$. Each spectrum displays a large broad band in the range of 250–

340 nm and a series of sharp lines characteristic of the $Sm^{3+}$, $Eu^{3+}$ and $Tb^{3+}$ energy levels. The large broad bands can be ascribed to the excited levels of the ligands[24,26] and are mainly formed of two components, peaking around 275 and 295 nm, being most evident for the $Eu^{3+}$ and $Tb^{3+}$ compounds. The assignment of the intra-$4f^5$ transitions was based on the published literature.[27] Although the $^7F_1$ level of the $Eu^{3+}$ complex is populated at room-temperature, we have only explicitly assigned the $^7F_1 \rightarrow {}^5D_0$ transition. We also note that the intensity at lower wavelengths (250–260 nm) for the $Sm^{3+}$ complex is artificial due to the correction for the spectroscopic distribution of the lamp intensity (marked with an asterisk in Figure 4).

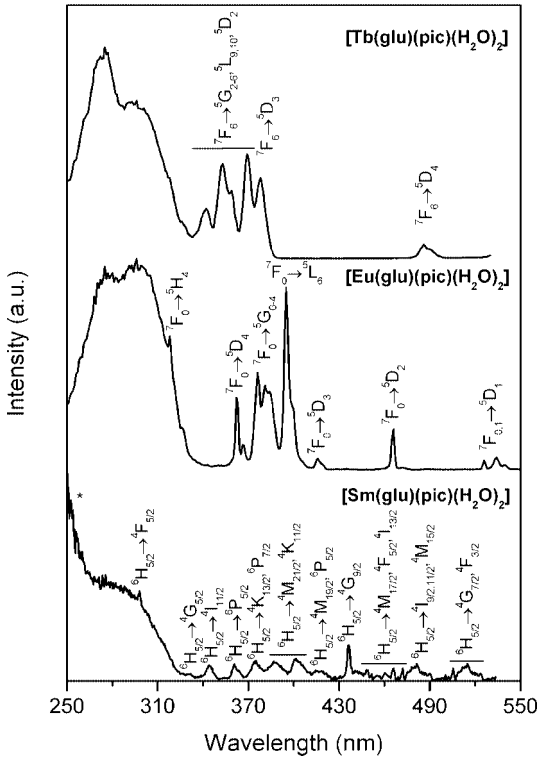

Figure 4. Excitation spectra of $[Ln(glu)(pic)(H_2O)_2]$ monitored at 597, 614, and 545 nm for the $Sm^{3+}$, $Eu^{3+}$ and $Tb^{3+}$ complexes, respectively.

Figure 5 shows the emission spectra of the $Sm^{3+}$, $Eu^{3+}$ and $Tb^{3+}$ compounds. No changes could be detected in the lines of the cations by varying the excitation wavelength, suggesting that the lanthanide centre has only one local environment. The emission spectra of the $Sm^{3+}$, $Eu^{3+}$ and $Tb^{3+}$ complexes are composed from the intra-$4f^5$ ($Sm^{3+}$), intra-$4f^6$ ($Eu^{3+}$) and intra-$4f^8$ ($Tb^{3+}$) transitions ($^4G_{5/2} \rightarrow {}^6H_{5/2,7/2,9/2}$, $^5D_0 \rightarrow {}^7F_{0-4}$, and $^5D_4 \rightarrow {}^7F_{6-3}$, respectively).

The $^5D_0$ ($Eu^{3+}$) and $^5D_4$ ($Tb^{3+}$) lifetimes were monitored within the more intense line of the $^5D_0 \rightarrow {}^7F_2$ and $^5D_4 \rightarrow {}^7F_5$ transitions, respectively, under the excitation which maximises the $Eu^{3+}$ and $Tb^{3+}$ emissions. The emission decay curves (not shown) reveal a single-exponential behaviour yielding lifetime values of $0.385 \pm 0.002$ ($^5D_0$) and $1.024 \pm 0.005$ ms ($^5D_4$). The quantum efficiency, $q$, of the emission arising from the $^5D_0$ level in the [Eu(glu)(pic)$(H_2O)_2$] complex has been estimated assuming that only nonradiative and radiative processes are essentially involved in the depopulation of the excited state, as already reported.[7,28] We obtained a $q$ value of ca. 10%, with a corresponding $k_r$ value of 0.253 $ms^{-1}$. These values, lifetimes and quantum efficiency values, although lower when compared with those obtained by Sendor et al. for the europium picolinato,[8] are of the same order of magnitude as those obtained for the $Eu^{3+}$ emission in the 3- hydroxypicolinato[7] and 2-hydroxynicotinato complexes.[29]

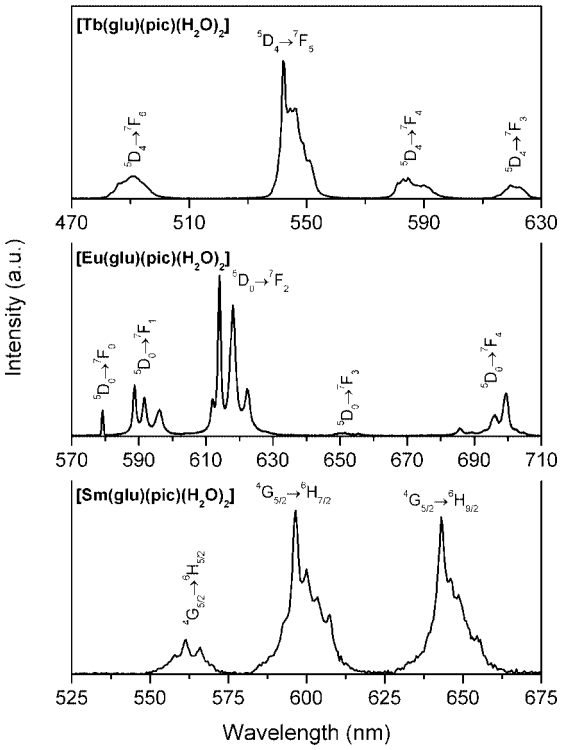

Figure 5. Emission spectra of $[Ln(glu)(pic)(H_2O)_2]$ (Ln = Sm, Eu, Tb), excited at 277, 305 and 277 nm for the $Sm^{3+}$, $Eu^{3+}$, and $Tb^{3+}$ complexes, respectively.

## Conclusions

A triad of isostructural lanthanide-organic 1D coordination polymers, $[Ln(glu)(pic)(H_2O)_2]$ (where Ln = $Sm^{3+}$, $Tb^{3+}$ and $Eu^{3+}$), were successfully isolated and characterised in the solid-state as homogeneous phase-pure materials. All these compounds share common structural features and show efficient intramolecular aromatic ligand-to-lanthanide energy transfer. These coordination polymers are composed of lanthanide dimers separated by long and flexible glutarato anions. The present results open up interesting prospects for future work concerning the investigation of the photoluminescent behaviour of other picolinic-containing lanthanide-organic polymers in which the length of the flexible ligand could be systematically varied.

## Experimental Section

**General Instrumentation:** Infrared spectra were recorded using KBr disks (Aldrich, 99%+, spectroscopic grade) with a Matson 7000 FTIR spectrometer. FT-Raman spectra were collected on a Bruker RFS 100 instrument with a Nd:YAG coherent laser ($\lambda$ = 1064 nm). Elemental analyses for C, H and N were performed using a CHNS-932 elemental analyser (at the Microanalysis Laboratory of the University of Aveiro) and also an Exeter Analytical CE 440 Elemental Analyser using helium as the purge gas (at the Department of Chemistry, University of Cambridge). Thermogravimetric analyses (TGA) were carried out using a Shimadzu TGA 50 instrument with a heating rate of 10 °C min$^{-1}$ under a continuous air stream with a flow rate of 10 cm$^3$ min$^{-1}$. Crystal photographs were taken using a Stemi 2000 stereomicroscope equipped with Carl Zeiss lenses and a high-resolution AxioCam MRc5 digital camera connected to a personal computer. Scanning Electron Microscopy (SEM) images were acquired using a Hitachi S-4100 field emission gun tungsten filament instrument working at 25 kV. Samples were prepared by deposition on aluminium sample holders and by carbon coating. The luminescence spectra were recorded at room temperature with a modular double grating excitation spectrofluorimeter with a TRIAX 320 emission monochromator (Fluorolog-3, Jobin Yvon-Spex) coupled to a R928 Hamamatsu photomultiplier by means of the front face acquisition mode. The excitation source was a 450 W Xe arc lamp. Excitation spectra were corrected from $\lambda$ = 240 to 600 nm for the spectral distribution of the lamp intensity using a photodiode reference detector. Emission spectra were also corrected for the spectral response of the monochromators and the detector by using typical correction spectra provided by the manufacturer. The lifetime measurements were acquired with the setup described for the luminescence spectra using a pulsed Xe-Hg lamp (6 μs pulse at half width and 20–30 μs tail).

**Syntheses:** Chemicals were obtained from commercial sources and used without further purification. Preparation of single crystals of [Sm(glu)(pic)($H_2O$)$_2$] of an appropriate size and stability for single-crystal X-ray diffraction studies was carried out in a gel formed from $Na_2SiO_3$·$H_2O$. A solution of $Na_2SiO_3$·5$H_2O$ (0.1 M, 5 mL) was added dropwise to an aqueous solution (10 mL, pH 4.3) containing glutaric acid and picolinic acid. The mixture was stirred and each test tube, with 5 mL of solution, was left for 24 h. Afterwards, $Sm(COO)_3$·$x$$H_2O$ (0.25 mmol) was added to the gel. White single crystals of [Sm(glu)(pic)($H_2O$)$_2$] were grown over a period of 4 months.

Isostructural materials, mainly isolated as microcrystalline powders, of picolinic acid and glutaric acid with $Tb^{3+}$ and $Eu^{3+}$ were synthesised by adding an aqueous solution of picolinic acid (1 mmol) to an aqueous solution containing glutaric acid (1 mmol) (pH 6.5, adjusted with KOH) and the corresponding lanthanide salt [Ln($NO_3$)$_3$·5$H_2O$, Ln = Tb and Eu] (0.25 mmol). For the compound [Tb(glu)(pic)($H_2O$)$_2$], small crystals could also be manually harvested which allowed unequivocal phase identification by means of the unit cell determination using single-crystal X-ray diffraction data. Phase identification of [Eu(glu)(pic)($H_2O$)$_2$] was performed by employing X-ray powder diffraction (see following sections).

**Single-Crystal X-ray Diffraction:** A suitable single-crystal of [Sm(glu)(pic)($H_2O$)$_2$] was mounted on a glass fibre using FOMBLIN Y perfluoropolyether vacuum oil (LVAC 25/6) purchased from Aldrich.[30] Data were collected at 180(2) K on a Nonius Kappa CCD area-detector diffractometer (Mo-$K_\alpha$ graphite-monochromated radiation, $\lambda$ = 0.7107 Å) equipped with an Oxford Cryosystems cryostream and controlled with the Collect software package.[31] Images were processed using the software packages Denzo and Scalepack[32] and data were corrected for absorption by the empirical method employed in Sortav.[33,34] The structure was solved by direct methods with SHELXS-97[35] and refined by full-matrix least-squares on $F^2$ using SHELXL-97.[36] All non-hydrogen atoms were directly located from difference Fourier maps and refined with anisotropic displacement parameters.

Even though the vast majority of the hydrogen atoms bound to carbon were markedly visible in the difference Fourier maps, they were instead located in their idealised positions using appropriate *HFIX* instructions in SHELXL (43 for the aromatic and 23 for the –$CH_2$– carbon atoms) and included in subsequent refinement cycles in riding-motion approximation with isotropic thermal displacements parameters ($U_{iso}$) fixed at 1.2 times $U_{eq}$ of the carbon atom to which they are each attached. Hydrogen atoms associated with the coordinated water molecules were directly located from difference Fourier maps and included in the final structural model with the O–H and H···H distances restrained to 0.95(1) Å and 1.55(1) Å, respectively (in order to ensure a chemically reasonable geometry for these molecules), and using a riding model with an isotropic displacement parameter fixed at *1.5* times $U_{eq}$ of the atom to which they are each attached. The last difference Fourier map synthesis showed the highest peak (0.892 e Å$^{-3}$) and deepest hole (–0.949 e Å$^{-3}$) located at 1.51 Å from C(5) and 0.82 Å from Sm(1), respectively.

A single-crystal of [Tb(glu)(pic)($H_2O$)$_2$] was also investigated using the same experimental conditions as for the $Sm^{3+}$ compound (see above). A full data set (data completeness 99.7%), collected in the 1.00° ≤ $\theta$ ≤ 32.03° range, consisted of 13480 integrated reflections ($R_{int}$ = 0.065 in $P2$ symmetry) of which 4800 are unique. A subset of 8701 reflections was used for unit cell refinement, with the final parameters converging to: $a$ = 8.4304(2) Å, $b$ = 13.3040(3) Å, $c$ =

11.9536(2) Å, $\beta$ = 96.4275(14)° and $V$ = 1332.27(5) Å$^3$ [crystal mosaicity of 0.500(2)°].

Information concerning crystallographic data collection and structure refinement details for [Sm(glu)(pic)$(H_2O)_2$] is summarised in Table 4. Selected bond lengths and angles for the $Sm^{3+}$ coordination environment are given in Table 1. Hydrogen bonding geometric details are provided in Table 2.

CCDC-611302 (for [Sm(glu)(pic)$(H_2O)_2$] contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Powder X-ray Diffraction:** Powder X-ray diffraction data were collected on a X'Pert MPD Philips diffractometer (Cu-$K_\alpha$ X-radiation, $\lambda$ = 1.54060 Å) equipped with an X'Celerator detector, graphite-monochromated radiation and a flat-plate sample holder in a Bragg–Brentano para-focusing optics configuration (40 kV, 50 mA). Intensity data were collected in a continuous scanning mode in the ca. 3° ≤ 2$\theta$ ≤ 70° angular range.

The collected powder X-ray diffraction pattern for [Eu(glu)(pic)$(H_2O)_2$] was indexed by means of the routines provided with the software program DICVOL04[37] and by employing the first 20 well-resolved reflections (located using the derivative-based peak search algorithm provided with Fullprof.2k)[38,39] and a fixed absolute error on each line of 0.03° 2$\theta$. Preliminary unit cell metrics were calculated with high figures-of-merit: $M(20)$[40] = 44.4 and $F(20)$[41] = 97.6; zero shift of 0.0246°.

A Le Bail[42] whole-powder-diffraction-pattern profile fitting in the space group $P2_1/c$ (systematic absences unequivocally identified using CHECKCELL[43]) was performed with the FullProf.2k software package. The fit provided as in Figure S1 in the Supporting Information was obtained by using a typical pseudo-Voigt peak-shape function and, in the last stages of the fitting process the unit cell parameters and typical profile parameters, such as scale factor, zero shift, Caglioti function values and two asymmetry parameters were allowed to refine. Fixed background points were used. Refined unit cell parameters: $a$ = 12.025(1) Å, $b$ = 13.376(1) Å, $c$ = 8.480(1) Å, $\beta$ = 96.862(5)° ($R_{Bragg}$ = 1.54% and $\chi^2$ = 6.81).

**Supporting Information** (see also the footnote on the first page of this article): Le Bail whole-powder-diffraction-pattern profile fitting in the $P2_1/c$ space group for compound [Eu(glu)(pic)$(H_2O)_2$]. Optical and SEM images of crystals belonging to the compounds containing $Tb^{3+}$ and $Sm^{3+}$.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** the reaction sequence of an $Ni^{II}$-assisted regiospecific *ortho*-aromatic hydroxylation. Sequential events of orthonickelation, oxygen insertion into the Ni−C bond induced by $H_2O_2$ and demetallation have been demonstrated to be involved in the aromatic hydroxylation in 2-(arylazo)aniline. The $H_2O_2$-induced O insertion into the Ni−C bond led to the formation of *metalloazosalophen* analogues of *metallosalophens* for the first time. Details are discussed in the article by S. Chattopadhyay et al. on p. 4263f.

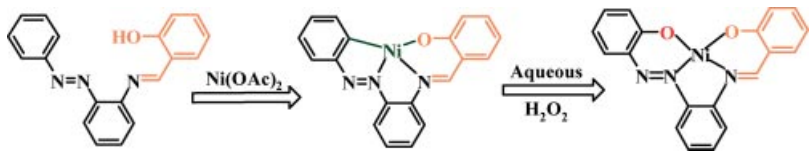
## FULL PAPERS

### Metal-Assisted Synthesis

**P. Pattanayak, J. Lal Pratihar, D. Patra, A. Burrows, M. Mohan, S. Chattopadhyay* ..... 4263–4271**

Regiospecific *ortho*-Aromatic Hydroxylation via Cyclonickelation Using Hydrogen Peroxide and Other Oxygen Donors: Synthesis of Metalloazosalophens



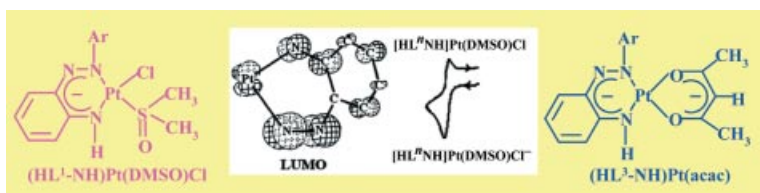
**Keywords:** Nickel / N,O ligands / Metallacycles / Oxygenation / Peroxo reagents / C–H activation

The first metalloazosalophen complexes, $(OL_{sal})Ni$, were prepared by a $Ni^{II}$-assisted route. Ni–C bond formation and subsequent facile oxygen insertion induced by peroxo reagents *m*CPBA, TBHP, or aqueous $H_2O_2$ were exploited for this purpose.

### $Pt^{II}$ and $Pd^{II}$ Chelates

**J. Lal Pratihar, B. Shee, P. Pattanayak, D. Patra, A. Bhattacharyya, V. G. Puranik, C. H. Hung, S. Chattopadhyay*..... 4272–4281**

Synthesis, Structure, and Reactivity of Diazoketiminato Complexes of Platinum(II) and Palladium(II): Cytotoxic Properties of a Platinum Complex



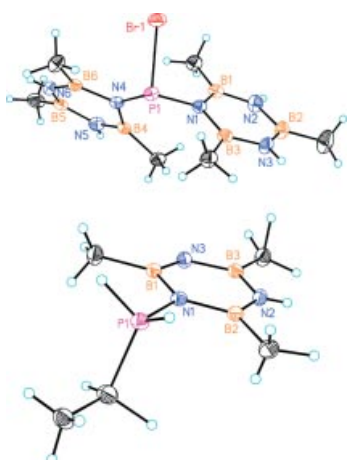
**Keywords:** Chelating ligands / Platinum / Palladium / Redox chemistry / Bioinorganic chemistry

New $Pt^{II}$ complexes incorporating delocalized diazoketimine ligands have been prepared and their chemical, electrochemical, and cytotoxic properties studied. A strategy to prepare an electroactive model $Pt^{II}$-based antitumor drug has emerged as a consequence.

### Phosphanes, Arsanes and Stibanes

**H. Nöth,* B. Gemünd, R. T. Paine ..... 4282–4297**

*N*-(2,4,6-Trimethylborazinyl)-Substituted Phosphanes, Arsanes, and Stibanes



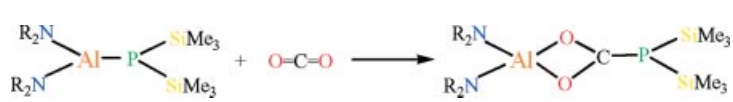
**Keywords:** Boron / Phosphanes / Arsenic / Antimony

*N*-Monolithio-*B*,*B*′,*B*′′-trimethylborazine reacts with $PX_3$, $AsX_3$, or $SbX_3$ (X = Cl, Br) to give the *N*-trimethylborazinyl-substituted phosphanes, arsanes, and stibanes $(Me_3B_3N_3H_2)_nEX_{3-n}$ (E = P, As, Sb; *n* = 1, 2, 3). Treatment of $(Me_3B_3N_3H_2)_2PCl$ with $LiAlH_4$ in diethyl ether gives the phosphane $(Me_3B_3N_3H_2)_2PH$, while $(Me_3B_3N_3H_2)PBr_2$ yields the zwitterionic compound $[Me_3B_3(NH)N(N^{-}\text{-}P^{+}H_2Et)]$. Dehalogenation of $(Me_3B_3N_3H_2)_2PBr$ with Na yields the corresponding diphosphane, and dehalogenation of $(Me_3B_3N_3H_2)PBr_2$ the corresponding cyclotetraphosphane.

### (Amino)(phosphanyl)alumane Chemistry

**T. Habereder, H. Nöth,* R. T. Paine* ..... 4298–4305**

Synthesis and Reactivity of New Bis(tetramethylpiperidino)(phosphanyl)alumanes



**Keywords:** Aminoalumanes / Phosphanylalumanes / Carbon dioxide insertion / Phosphanylcarbonate ligand / Structure elucidation

The bis(amino)(phosphanyl)alumane, $tmp_2AlP(SiMe_3)_2$, undergoes selective insertion in the Al–P bond, not the Al–N bonds, with $CO_2$, COS and $CS_2$.

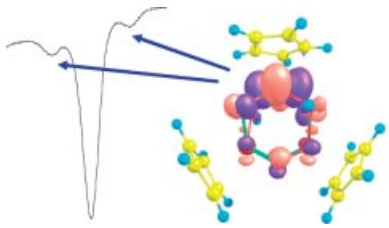
## Aqueous Reduction of $[Cp^*_2W_2O_5]$

Two related triangular tungsten clusters, 3-electron $[Cp^*_3W_3O_4(OH)_2]^{2+}$ and 2-electron $[Cp^*_3W_3O_6]^{+}$ obtained by aqueous reduction of $[Cp^*_2W_2O_5]$, are described.



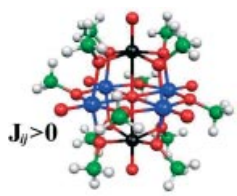
**C. Dinoi, P. Sözen, G. Taban, D. Demir, F. Demirhan,* P. Prikhodchenko, J. Gun, O. Lev, J.-C. Daran, R. Poli* ..... 4306–4316**

Aqueous Reduction of $[Cp^*_2W_2O_5]$: Characterization of the Triangular Clusters $[Cp^*_3W_3O_4(OH)_2]^{2+}$ and $[Cp^*_3W_3O_6]^{+}$ – Comparison with Molybdenum

**Keywords:** Tungsten / O ligands / Metal clusters / Density functional calculations

## Ferroexchange in Polyoxovanadates

DFT calculations suggest that the $V^{IV}/V^{V}$ mixed-valence alkoxo-polyoxovanadate $[4V^{IV} + 2V^{V}]$ is valence-trapped and characterized by ferromagnetic interactions between the vanadium(IV) centers.



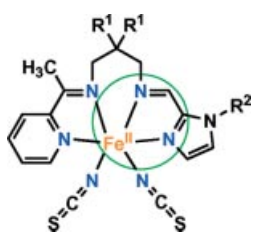
**E. M. Zueva,* S. A. Borshch,* M. M. Petrova, H. Chermette, A. M. Kuznetsov ..... 4317–4325**

Ferromagnetic Coupling in a Mixed-Valence Hexavanadate Core: Quantum-Chemical Forecast

**Keywords:** Mixed-valent compounds / Vanadates / Density functional calculations / Exchange interactions / Electron transfer

## $Fe^{II}$ Spin-Crossover Complexes

1-*N*-$R^2$-Imidazole-2-carboxaldehyde ($R^2$ = H, Me) was used as a carbonyl synthon for the synthesis of symmetrical and dissymmetrical tetradentate Schiff bases. In the symmetrical series the $NCS^-$ moieties are *trans* for $R^2$ = H and *cis* for $R^2$ = Me. In the dissymmetrical series the electronic behaviour evidences that the combination of pyridyl and imidazolyl rings allows the generation of an intermediate ligand field suitable for spin crossover.



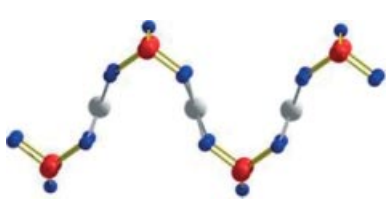
**N. Bréfuel,* S. Shova, J.-P. Tuchagues* ..... 4326–4334**

$Fe^{II}$ Bistable Materials with Dissymmetrical Ligands: Synthesis, Crystal Structure, Magnetic and Mössbauer Properties of $Fe^{II}$ Complexes Based on $N_4$ Schiff Bases Possessing 2-Pyridyl and 1-R-Imidazol-2-yl Rings

**Keywords:** Schiff bases / N ligands / Iron / Spin crossover / Magnetic properties / Mössbauer spectroscopy

## Oxoanionic Palladium Compounds

Elemental palladium can be oxidized by selenic acid at elevated temperatures to form $Pd(SeO_3)$, $Pd(SeO_4)$, or $Pd(Se_2O_5)$, depending on the reaction conditions. These compounds are the first oxoselenates of a platinum-group metal.



**A. Arndt, M. S. Wickleder* ... 4335–4339**

$Pd(SeO_3)$, $Pd(SeO_4)$, and $Pd(Se_2O_5)$: The First Palladium Oxoselenates

**Keywords:** Solid-state structures / Palladium / Selenium / Lone-pair effect / IR spectroscopy

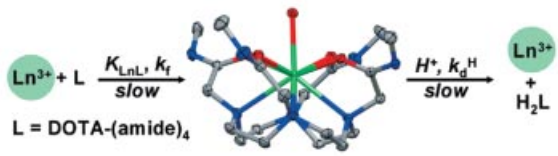
# CONTENTS

## Ln−DOTA Complexes

**A. Pasha, G. Tircsó,* E. Tircsóné Benyó, E. Brücher, A. D. Sherry* ..... 4340−4349**

Synthesis and Characterization of DOTA-(amide)$_4$ Derivatives: Equilibrium and Kinetic Behavior of Their Lanthanide(III) Complexes

**Keywords:** Magnetic resonance imaging / Contrast agents / Protonation constants / Stability constants / Kinetics



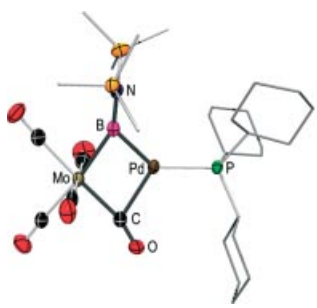
The stabilities of the lanthanide(III) DOTA-(amide)$_4$ complexes are several orders of magnitude lower than the stabilities of the corresponding $[Ln(DOTA)]^-$ complexes. The formation rates of the $[Ln\{DOTA\text{-}(MeAm)_4\}]^{3+}$ complexes proved to be slow, following second-order reaction kinetics. The rates of acid-catalyzed dissociation of $[Eu\{DOTA\text{-}(MeAm)_4\}]^{3+}$ complexes, however, are also quite slow, which suggests that these complexes may ultimately prove suitable for in vivo applications.

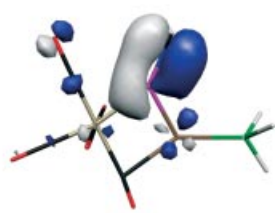
## Molybdenum Borylene Complexes

**H. Braunschweig,* K. Radacki, K. Uttinger ..... 4350−4356**

Synthesis and Characterisation of Semi-Bridging Molybdenum Borylene Complexes

**Keywords:** Boron / Borylene complexes / Molybdenum / Palladium / DFT calculations





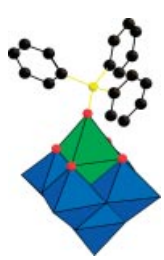
A variety of heterodinuclear borylene complexes was obtained from the reaction of $[(OC)_5Mo{=}B{=}N(SiMe_3)_2]$ with $[M(PCy_3)_2]$ (M = Pd, Pt). Structural studies and DFT computations revealed that the borylene ligand adopts a semi-bridging position.

## Functionalized Polyoxometalates

**F. Bannani, R. Thouvenot,* M. Debbabi* ..... 4357−4363**

Synthesis and Characterization of New Organosilyl Derivatives of Polyoxometalates $(n\text{Bu}_4\text{N})_2[\text{NbW}_5\text{O}_{19}\text{SiRR}'_2]$ (R = R′ = Et, *i*Pr, O*t*Bu, Ph; R = *t*Bu and R′ = Me) − The X-ray Crystal Structure of $(n\text{Bu}_4\text{N})_2[\text{NbW}_5\text{O}_{19}\text{SiPh}_3]$

**Keywords:** Polyoxometalates / Organic−inorganic hybrid / Multinuclear NMR spectroscopy



The selective coordination of electrophilic fragments $\{SiRR'_2\}^+$ to the terminal $O_t$(Nb) oxygen of the $NbW_5O_{19}^{3-}$ Lindqvist-type polyoxometalate leads to the formation of organic−inorganic hybrids. These species are characterized by multinuclear NMR, IR, and Raman spectroscopy. A single-crystal X-ray study of $(n\text{Bu}_4\text{N})_2[\text{NbW}_5\text{O}_{19}\text{SiPh}_2]$ supports the structure postulated on the basis of $^{183}$W NMR study.

## C=O Hydrogenation

# Regiospecific *ortho*-Aromatic Hydroxylation via Cyclonickelation Using Hydrogen Peroxide and Other Oxygen Donors: Synthesis of Metalloazosalophens

**Poulami Pattanayak,[a] Jahar Lal Pratihar,[a] Debprasad Patra,[a] Andrew Burrows,[b] Mary Mohan,[b] and Surajit Chattopadhyay*[a]**

**Keywords:** Nickel / N,O ligands / Metallacycles / Oxygenation / Peroxo reagents / C–H activation

The new ligands *N*-[2-(arylazo)phenyl]salicylideneamine, $H_2L_{sal}$ [where H represents the dissociable protons upon complexation and aryl groups of $H_2L_{sal}$ are phenyl for $H_2L^1{}_{sal}$, *p*-methylphenyl for $H_2L^2{}_{sal}$, and *p*-chlorophenyl for $H_2L^3{}_{sal}$], were prepared by the reaction of 2-(arylazo)aniline, $H_2L$, with salicylaldehyde. $H_2L_{sal}$ ligands afforded stable ortho-metalated complexes, $(L_{sal})Ni$, upon treatment with $Ni(CH_3COO)_2{\cdot}4H_2O$. The dianionic $(L_{sal})^{2-}$ ligands bind $Ni^{II}$ in tetradentate (C,N,N,O) fashion in distorted square-planar geometry. Reaction of $(L_{sal})Ni$ with *meta*-chloroperbenzoic acid, *tert*-butyl hydroperoxide, or hydrogen peroxide furnished the metalloazosalophens, $(OL_{sal})Ni$, as a result of oxygen insertion into the Ni–C bond. The X-ray structures of $(L^1{}_{sal})Ni$ and $(OL^1{}_{sal})Ni$ were determined as representatives for unequivocal characterization. Treatment of $(OL^1{}_{sal})Ni$ with dilute $HClO_4$ liberated 2-(2-aminophenylazo)phenol, $H_2L^1OH$, which is an *ortho*-hydroxylated derivative of $H_2L^1$. The cyclic voltammograms of $(OL_{sal})Ni$ complexes display a reversible reductive response near –1.06 V vs. SCE.

## Introduction

The rich chemistry and usefulness of transition-metal complexes incorporating tetradentate (O,N,N,O) *salen* and its derivatives (also termed *metallosalens*, in general), **I**, have drawn interest in the areas of coordination chemistry,[1] catalysis,[2] and biochemistry research.[3] The challenge of the design and synthesis of new analogues of metallosalens prompted us to investigate the synthesis of azo-aldimine complexes as shown in **II**. These new complexes of type **II** are termed *metalloazosalophens* in this paper, in analogy to *metallosalophens*.

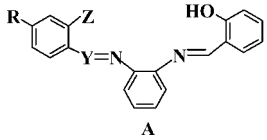
The preparation of metalloazosalophen complexes was contemplated after successful preparation of the new ligand, *N*-[2-(arylazo)phenyl]salicylideneamine, $H_2L_{sal}$, **1**, which comprises of two types of N-donor ligands: azo (–N=N–) and aldimine (–CH=N–). The $H_2L_{sal}$ ligand is similar to 1,2-*N*,*N*-disalicylidene phenylamine, **2** (commonly known as "salophen"), as shown in **A**, where Z = H and Y = N for $H_2L_{sal}$ while Z = OH and Y = CH for "salophen" ligands.



| No | Abbreviations of compounds | Y | Z |
|---|---|---|---|
| 1 | $H_2L_{sal}$ | N | H |
| 2 | salophen | CH | OH |
| 3 | $H_2OL_{sal}$ (azosalophen) | N | OH |

It was further realized that the substitution of Z (i.e., H) in $H_2L_{sal}$ by OH would afford the "azosalophen" analogue, $H_2OL_{sal}$, **3**, of "salophen" and the corresponding phenolato complex of this ligand would be the metalloazosalophens of type **II**.

Metal complexes incorporating azo ligands exhibited interesting electron-transfer properties, photophysical behavior, and biological activities.[4] Therefore, metalloazosalophens may not only possess the properties of enhanced performance compared with that of metallosalophens but also there are possibilities of new and interesting characteristics.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Metal-assisted chemical transformations have received attention in recent years because of their potential application in planned and directed organic synthesis for the preparation of target compounds which have not been prepared thus far by applying conventional synthetic protocols. Oxygenation (addition of an O atom in between a C–H bond) is highly desirable for functionalization of an aromatic ring. The regiospecificity of such an oxygenation has been appreciated for intended synthesis. One of the strategies towards regiospecific oxygenation is to activate a particular C–H bond through metal–carbon bond formation, followed by stoichiometric insertion of an oxygen atom within the metal–carbon bond. Therefore, the search for cheaper and easily available metal substrates and convenient reaction conditions to carry out such stoichiometric reactions, leading to the preparation of desired molecules, is important in terms of wide applicability and cost control. In this aspect it is worthwhile to mention that transition-metal-assisted aromatic hydroxylation has been recognized in essential biological reactions (e.g., oxygenase activity)[5] and in several complicated organic syntheses.[6]

Orthometalation is one of the processes of C–H bond cleavage (a precondition of C–H activation), which is reported amply in the cases of $Pd^{II}$ and $Pt^{II}$,[7] whereas it is scarce for $Ni^{II}$, the 3d congener of group 10 metals.[8] The usage of 3d metal ions in C–H activation has an edge over heavier members of group 10 metals in terms of cost effectiveness and availability.

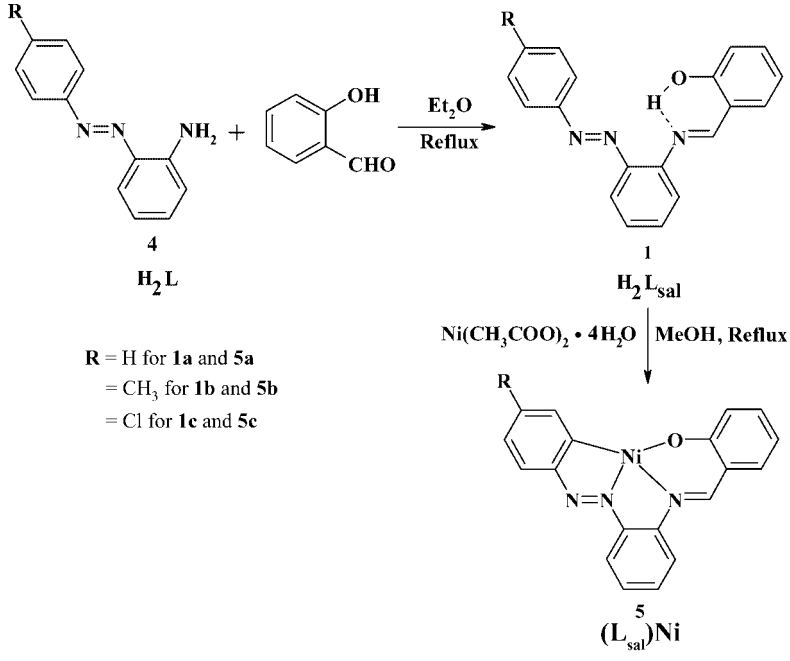
Studies on orthopalladation and orthoplatination in azobenzene-related ligands were initiated after the discovery of the "Cope complex".[9] Later, stoichiometric regiospecific *ortho*-hydroxylation of azobenzene derivatives by cyclopalladation were reported.[7c,7d] In contrast, the preparative method based on oxygen insertion into nickel–aryl bonds to give new aryl oxide compounds was reported to occur either with $N_2O$ or $O_2$.[10,11] This background information on metal-assisted routes to the oxy-functionalization of aryl rings provides a stimulus to contemplate the preparation of new metalloazosalophen complexes of type **II**.

Herein, we report the syntheses of new cyclometalated $Ni^{II}$ complexes incorporating the dianion of deprotonated $H_2L_{sal}$ and its conversion to the corresponding aryloxy form (metalloazosalophen complex of type **II**) by oxidation with *meta*-chloroperbenzoic acid (*m*CPBA), *tert*-butyl hydroperoxide (TBHP), or hydrogen peroxide ($H_2O_2$) by oxygen insertion into the nickel–carbon bond. TBHP and *m*CPBA are non-atom-efficient reagents as oxidants, whereas $H_2O_2$ is an atom-efficient oxidant since water is the sole by-product and it can therefore be classified as a green oxidant.[12] Furthermore, oxidation with aqueous $H_2O_2$ is cheap, safe, and easy to handle.[13] Also, this report may provide valuable information concerning the issue of organonickel-intermediate formation during the oxygenation of hydrocarbons on the nickel surface.[14] The synthesis of the specifically *ortho*-hydroxylated derivative 2-(2-aminophenylazo)phenol is also described.

## Results and Discussion

### Synthesis and Reactions

The strategy of the preparation of the target metalloazosalophen complexes of type **II** is based on three major steps: (i) synthesis of the precursor ligand, $H_2L_{sal}$, **1**, (ii) nickel–carbon bond formation by orthonickelation in $H_2L_{sal}$, and (iii) regiospecific oxygenation by way of oxygen insertion into the nickel–carbon bond of new orthonickelated complexes.



Scheme 1.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### *Syntheses of $H_2L_{sal}$ Ligands and Cyclonickelated ($L_{sal}$)Ni Complexes*

The azo-aldimine hybrid ligand *N*-[2-(arylazo)phenyl]salicylideneamine, $H_2L_{sal}$, **1**, was prepared by refluxing 2-(arylazo)aniline, $H_2L$, **4**, with salicylaldehyde in diethyl ether (Scheme 1). The solid, obtained upon evaporation of $Et_2O$, was used for further reactions without purification since the $^1$H NMR spectra (see later) exhibited good purity. The reaction of $H_2L_{sal}$ with nickel acetate tetrahydrate, $Ni(CH_3COO)_2{\cdot}4H_2O$, in refluxing methanol precipitated the orthonickelated green complex ($L_{sal}$)Ni, which was collected by filtration. The reaction is shown in Scheme 1. A further crop of product was isolated upon concentrating the filtrate. The total yield of ($L^1_{sal}$)Ni was 70%. Such a facile formation of cyclonickelated compounds upon treatment of $Ni(CH_3COO)_2{\cdot}4H_2O$ with tri- and bidentate azo ligands has not been reported so far.

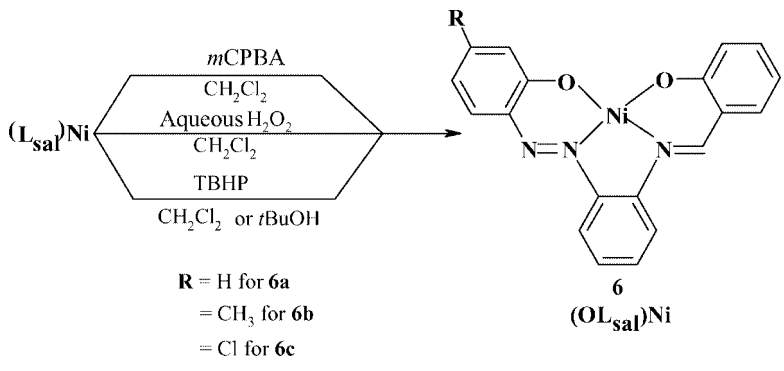
### *Synthesis of ($OL_{sal}$)Ni from ($L_{sal}$)Ni*

The new metalloazosalophen complexes, ($OL_{sal}$)Ni, were prepared by the highly selective metaloxylation[15] of ($L_{sal}$)Ni with the oxidants *m*CPBA, TBHP, or $H_2O_2$. The oxygen insertion into the Ni–C bond of ($L_{sal}$)Ni occurred upon treatment with *m*CPBA or TBHP in either aprotic (dichloromethane) or protic (*tert*-butyl alcohol) solvent at room temperature to afford the diamagnetic and electroneutral $Ni^{II}$ complex, ($OL_{sal}$)Ni (Scheme 2). Furthermore, the reaction of ($L_{sal}$)Ni in $CH_2Cl_2$ with aqueous $H_2O_2$ (a better choice of oxidant) furnished ($OL_{sal}$)Ni after stirring for a period longer than that of the reactions of *m*CPBA or TBHP with ($L_{sal}$)Ni. The formation of ($OL_{sal}$)Ni complexes from ($L_{sal}$)Ni was monitored spectrophotometrically up to the extent of 85% conversion for all the reactions. Considerable delay in metaloxylation with aqueous $H_2O_2$ can be attributed to the heterogeneous solvent mixture ($CH_2Cl_2/H_2O$). The $^1$H NMR spectrum of the crude product, as obtained after oxidation, exhibited good purity of ($OL_{sal}$)Ni indicating the likelihood of quantitative transformation [the spectrum of crude ($OL^1_{sal}$)Ni is available as Supporting Information, Figure S24]. Nevertheless, after every reaction, pure ($OL_{sal}$)Ni complexes were isolated in ca. 65% yield by employing a conventional purification procedure using the silica gel preparative TLC plate. Pure product separated well, leaving an unidentified material at the bottom. Since the $^1$H NMR spectrum of crude ($OL_{sal}$)Ni exhibited good purity,[16] the unidentified material was assumed to be the decomposition product of ($OL_{sal}$)Ni on the silica plate.

Oxygen insertions into Pd–C σ bonds of arylpalladium(II) complexes, induced by *m*CPBA, have been reported.[7c–7e] These reactions followed a straightforward second-order rate law (first order in both organopalladium substrate and in *m*CPBA).[7c–7e] The probable mechanism was proposed to follow a concerted one-step process leading to O insertion into the Pd–C bond on the basis of kinetic results.[7c–7e] Reaction of *m*CPBA with ($L_{sal}$)Ni was so fast that it could not be monitored spectrophotometrically for kinetic studies. The reaction completed to the extent of 86% within one minute. However, by analogy with the proposed mechanism of O insertion into the Pd–C bond,[7c–7e] the oxygen insertion into the Ni–C bond of ($L_{sal}$)Ni with *m*CPBA has been assumed to follow a similar concerted one-step process via formation of intermediate **I-A** as shown in Scheme 3.

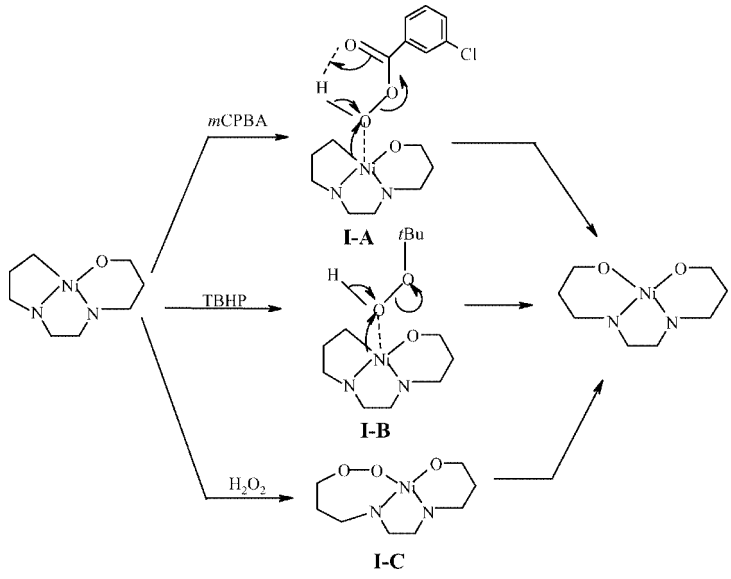
Realizing the fact that the Ni–C bond of ($L_{sal}$)Ni complexes is much more susceptible to metaloxylation compared with the Pd–C bond of orthopalladated complexes incorporating tridentate azo ligands,[7c–7e] oxidation was attempted with milder oxidizing agents such as TBHP or $H_2O_2$.

($L_{sal}$)Ni underwent oxygenation in the solvents *t*BuOH and $CH_2Cl_2$ with TBHP. The beneficial effect of protic solvents (*t*BuOH) in the metaloxylation of organopalladium complexes with TBHP has been reported.[17] Formation of alcohol oxide species (RHO–O) in protic solvents was believed to be the actual oxygen-donating agent in oxygen-transfer reactions by TBHP because the RHO–O species can provide an oxenoid oxygen atom and a neutral leaving group.[17] It is tempting to believe that TBHP reacts directly with ($L_{sal}$)Ni to afford ($OL_{sal}$)Ni, following a concerted one-step mechanism via formation of intermediate **I-B** as shown in Scheme 3. Nevertheless, formation of a ($L_{sal}$)$Ni^{IV}$=O intermediate[18] can not be excluded unequivocally though it is expected to be unstable for $Ni^{IV}$ ($d^n$ oxo system, $n > 4$),[19,7d] and a doubly bonded $Ni^{IV}$=O species is unlikely to be involved since it is better represented as either $Ni^{III}$–O· or $Ni^{IV}$–$O^-$.[18a]



Scheme 2.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3.

Interestingly, ($L_{sal}$)Ni could be oxidized to ($OL_{sal}$)Ni upon treatment with aqueous $H_2O_2$. Although there are studies on the formation of peroxo-bridged dinuclear nickel complexes upon treatment of square-planar $Ni^{II}$ with $H_2O_2$, to the best of our knowledge, there is no report on oxygen insertion into a Ni–aryl bond with $H_2O_2$.[20] It was demonstrated previously that the oxygen insertion into a Ni–aryl bond had taken place upon reaction with air (i.e., $O_2$), where formation of a peroxo–nickel(II) intermediate was postulated in the reaction trajectory.[10d] By analogy, a mechanism of O insertion into the Ni–aryl bond of ($L_{sal}$)-Ni with $H_2O_2$ has been proposed to proceed via formation of the peroxo–$Ni^{II}$ intermediate **I-C** as shown in Scheme 3. It is worthwhile to mention that the ($L_{sal}$)Ni did not undergo metaloxylation upon prolonged bubbling of air into an acetonitrile solution of the complex.

### *Synthesis of 2-(2-Aminophenylazo)phenol, $H_2L^1OH$*

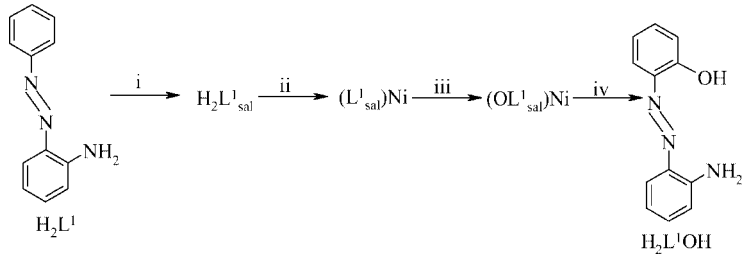
The new organic substrate $H_2L^1OH$ [a specifically *ortho*-hydroxylated phenyl derivative of 2-(phenylazo)aniline, $H_2L^1$] was obtained upon treatment of ($OL^1_{sal}$)Ni with dilute $HClO_4$ in acetonitrile solution. Demetalation and hydrolysis of the aldimine bond[21] occurred in acid medium, liberating the free 2-(2-aminophenylazo)phenol, $H_2L^1OH$, in good yield. Therefore in general, the new hydroxylated derivative, $H_2L^1OH$, was obtained in four steps as a result of regiospecific hydroxylation of 2-(phenylazo)aniline (Scheme 4). It is important to mention that the synthesis of authentic $H_2L^1OH$ has not been reported so far, so we cannot compare the merits of different procedures. It seems that the conventional synthetic protocol for the preparation of $H_2L^1OH$ would require carrying out several nonspecific reactions followed by careful work-up and separation of products after each step. The present reaction sequence is not associated with the formation of side products, and the chemicals used are cheap and easy to use.

## Spectral Characterization

The new ligands and complexes were characterized by UV/Vis, IR, $^1H$ NMR, and mass spectral studies.

### *UV/Vis and IR Spectra*

Dichloromethane solutions of $H_2L_{sal}$ ligands display an intense broad absorption near 316 nm in the UV/Vis spectra, characteristic of the overlapping n → π* transitions of azo (N=N) and aldimine (N=CH) functionalities.[22] The UV/Vis spectra of the green solutions of ($L_{sal}$)Ni in $CH_2Cl_2$ feature a relatively weak absorption band near 630 nm for



Scheme 4. (i) Salicylaldehyde in diethyl ether; (ii) $Ni(CH_3COO)_2{\cdot}4H_2O$ in refluxing methanol; (iii) *m*CPBA, TBHP, or $H_2O_2$ in $CH_2Cl_2$; (iv) dilute $HClO_4$ in $CH_3CN$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the d–d transition,[23] while four absorption bands in the range 315 to 460 nm are assigned to MLCT transitions (N=N and C=N).[22] The absorption for the d–d transition in ($OL_{sal}$)Ni occurs at lower energy (640 nm) than that of the parent complex ($L_{sal}$)Ni. In addition, there are five MLCT absorptions in the range 340 to 520 nm in the UV/Vis spectra. Representative spectra of $H_2L^1_{sal}$, ($L^1_{sal}$)Ni, and ($OL^1_{sal}$)Ni are shown in Figure 1. The UV/Vis spectrum of $H_2L^1OH$ is different from that of either $H_2L^1_{sal}$ or $H_2L^1$ with an intense absorption at 450 nm in addition to the absorption at 318 nm due to the n → π* transition for the N=N functionality.

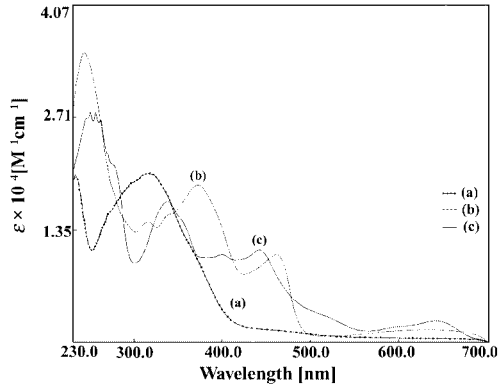


Figure 1. UV/Vis spectra of (a) $H_2L^1_{sal}$ ($C = 3.98 \times 10^{-5}$ M), (b) ($L^1_{sal}$)Ni ($C = 3.62 \times 10^{-5}$ M), and (c) ($OL^1_{sal}$)Ni ($C = 2.67 \times 10^{-5}$ M).

A sharp single band near 1614 $cm^{-1}$ in the IR spectra (KBr disc) of $H_2L_{sal}$ is characteristic of $\nu_{C=N}$.[22] The IR band near 1450 $cm^{-1}$ is assigned to $\nu_{N=N}$ by comparing the same band for other azo ligands and considering the extent of redshift upon coordination (see later).[23] The $\nu_{O-H}$ for the phenol OH of the salicylidene fragment is absent in conformity with the intramolecular hydrogen-bonded form of $H_2L_{sal}$. The $\nu_{C=N}$ and $\nu_{N=N}$ of ($L_{sal}$)Ni appear at slightly lower frequency (1605 and 1380 $cm^{-1}$, respectively) than those of the ligands, indicating coordination of aldimine (N=CH) and azo (N=N) nitrogen atoms. The $\nu_{C=N}$ and $\nu_{N=N}$ stretches of ($OL_{sal}$)Ni complexes appear near 1610 and 1375 $cm^{-1}$, respectively, consistent with azo (N=N) and aldimine (N=CH) coordination. The $\nu_{O-H}$ and $\nu_{NH_2}$ of $H_2L^1OH$ are observed at 3284 and 3407 $cm^{-1}$, respectively, in the IR spectrum while the $\nu_{N=N}$ appears at 1468 $cm^{-1}$.

### *$^1$H NMR Spectra*

The $H_2L_{sal}$ ligands display well-resolved $^1$H NMR spectra in $CDCl_3$, indicating good purity of products. The phenol OH of $H_2L_{sal}$ appears as a singlet near $\delta$ = 13.60 ppm which is absent in ($L_{sal}$)Ni and ($OL_{sal}$)Ni complexes, consistent with the phenolato coordination. The singlet resonance for the aldimine (N=CH) proton of the $H_2L_{sal}$ ligand near $\delta$ = 8.62 ppm is shifted marginally in the spectra of ($L_{sal}$)-Ni, observed in the range $\delta$ = 8.43 to 8.57 ppm. The resonance for the same aldimine proton of ($OL_{sal}$)Ni undergoes considerable upfield shift and appears within the range $\delta$ = 8.38 to 8.40 ppm. The $^1$H NMR spectral features for the aromatic protons of all the ligands and complexes are consistent with their structures. Data are collected in the Experimental Section.

The phenol OH proton and the $NH_2$ protons of $H_2L^1OH$ appear as singlets at $\delta$ = 12.84 and 6.19 ppm, respectively. Aromatic protons appear within the region $\delta$ = 6.75 to 7.76 ppm, in the sets of doublets at $\delta$ = 6.75, 7.67, and 7.76 ppm, triplets at $\delta$ = 6.83, 7.20, and 7.29 ppm, and a multiplet within the range $\delta$ = 6.99 to 7.04 ppm, with a total of eight equivalent protons. These spectral features are consistent with the structural formula. All the original $^1$H NMR spectra are given in the Supporting Information (Figures S18–S28).

### *Mass Spectra*

The electrospray mass spectrometry in $CH_2Cl_2$ solution (positive mode) was investigated for ($L^1_{sal}$)Ni and ($OL^1_{sal}$)-Ni as representatives. The mass spectra are consistent with the compositions and molecular masses. The major envelope, in each case, is satisfactorily simulated on the basis of formulae $C_{19}H_{13}N_3NiO$ and $C_{19}H_{13}N_3NiO_2$ for ($L^1_{sal}$)Ni and ($OL^1_{sal}$)Ni, respectively.

### X-ray Structures of ($L^1_{sal}$)Ni and ($OL^1_{sal}$)Ni

Unequivocal characterization of the cyclonickelated complex, ($L^1_{sal}$)Ni, and the corresponding oxygenated metalloazosalophen complex, ($OL^1_{sal}$)Ni, was performed by X-ray structure analysis. Figures 2 and 3 show the perspective views of ($L^1_{sal}$)Ni and ($OL^1_{sal}$)Ni molecules, respectively. Selected bond lengths and angles are collected in Tables 1 and 2. The dianions $(L^1_{sal})^{2-}$ and $(OL^1_{sal})^{2-}$ bind $Ni^{II}$ in distorted square-planar geometry in both complexes. The structure of the ($L^1_{sal}$)Ni crystal did not refine well ($R_w$ = 17%) because of bad quality but it could be characterized unequivocally (in combination with $^1$H NMR and mass spectral results, vide infra). The accuracy of bond lengths, angles, and anisotropic parameters were satisfactory after several full-matrix least-square refinements. The Ni($N_2OC$) and Ni($N_2O_2$) coordination spheres of ($L^1_{sal}$)Ni and ($OL^1_{sal}$)Ni are planar with mean deviations 0.006 and 0.003 Å, respectively. In the case of ($L^1_{sal}$)Ni, the Ni–C [1.984(10) Å] and Ni–O [1.820(6) Å] distances are comparable to reported values.[8d,22a]

The oxygen insertion into the nickel–carbon bond was confirmed as a result of the appearance of O2 in the molecular structure of ($OL^1_{sal}$)Ni. The Ni–N(azo) distance [Ni1–N2 1.8365(17) Å] of ($OL^1_{sal}$)Ni is shorter than the Ni–N-(aldimine) distance [Ni1–N3 1.8570(16) Å], indicating a stronger π-acidity of the azo (N=N) group relative to that of the aldimine (HC=N) group. Accordingly, the Ni1–O1 bond *trans* to N2 is longer [1.8420(15) Å] than the Ni1–O2 bond [1.8311(14) Å] *trans* to N1. However, the Ni–N and Ni–O distances are within the normal range.[22a] All the atoms in both the molecules ($L^1_{sal}$)Ni and ($OL^1_{sal}$)-Ni are coplanar with maximum deviations 0.08 and 0.75 Å, respectively, from the mean plane. Molecular stacking in

the crystal lattices exhibited that the planar molecules are held as *trans* pairs with Ni···Ni distances 3.199 and 3.136 Å in $(L^1_{sal})Ni$ and $(OL^1_{sal})Ni$, respectively. However, the crystal lattices feature slanted stacked arrangement of the *trans* pairs as shown in Figure 4 for $(L^1_{sal})Ni$. In contrast, the superposed molecules of Ni(salophen) are stacked infinitely in its crystal lattice,[24] unlike the Ni(azosalophen) analogue $(OL^1_{sal})Ni$.

## Electrochemistry

The cyclic voltammograms (Figure 5) of $(OL_{sal})Ni$ complexes display a reversible reductive response near –1.06 V vs. SCE in acetonitrile solution. This reductive response has been assigned to the $Ni^{II}/Ni^{I}$ couple according to Equation (1).

$$[(OL_{sal})Ni^{II}] + e^- \rightleftharpoons [(OL_{sal})Ni^{I}]^-$$

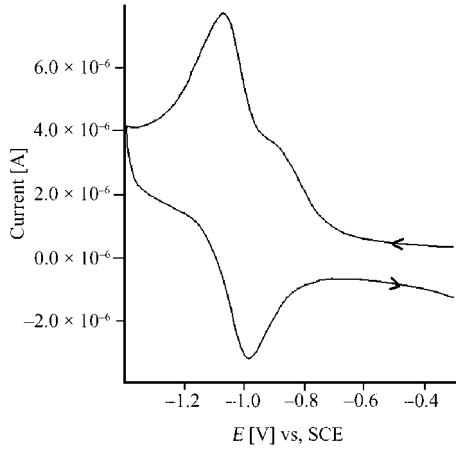

Figure 5. Cyclic voltammogram of $(OL^1_{sal})Ni$ in $CH_3CN$ and 0.1 M TEAP.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Similar reversible reduction for the [$Ni^{II}$(salen)] complex was reported to occur at –1.77 V vs. Ag/AgCl, and electrogenerated [Ni(salen)]$^-$ was demonstrated to be useful for the purpose of carrying out organic reactions.[25] Therefore, new electrogenerated [($OL_{sal}$)Ni]$^-$ may be active in a similar fashion as in the case of [Ni(salen)]$^-$.

## Conclusions

Unprecedented metalloazosalophen analogues of metallosalophens were prepared by way of oxygen insertion into the Ni–C bond of the precursor complex ($L_{sal}$)Ni. This facile Ni–C bond formation followed by oxygen insertion induced by peroxo reagents is a valuable report in terms of stoichiometric and catalytic oxo-functionalization of organic substrates. In addition to the synthesis of target metalloazosalophens, a synthetic procedure for the preparation of the regiospecifically hydroxylated derivative 2-(2-aminophenylazo)phenol, $H_2L^1OH$, has emerged to enhance the scope of further studies in this area. Although the O insertion into a Ni–C bond with $N_2O$[10a,10b] or $O_2$ (dioxygen)[10d] was documented previously, the use of peroxo reagents (especially $H_2O_2$) for O insertion into a Ni–C bond are described for the first time in this report. This information may provide important clues towards the design of appropriate organic substrates that are prone to form Ni–C σ bonds for oxygen insertion. The re-combination of $H_2L^1OH$ ($H_2LOH$, in general) with several other *ortho*-hydroxy aryl aldehydes are expected to afford a wide range of free azosalophen ligands. The metalloazosalophens derived from there may be useful for obtaining models of potential catalysts.

## Experimental Section

**Materials:** The solvents used in the reactions were of reagent grade obtained from E. Merck, Kolkata, India and were purified and dried by reported procedures.[26] Nickel acetate, salicylaldehyde, $HClO_4$, and $H_2O_2$ (6% in aqueous solution) were purchased from E. Merck, Kolkata, India. *m*CPBA (≈70%) and TBHP (≈70% in aqueous solution) were obtained from Aldrich, USA and were used as received (the activity of *m*CPBA was determined iodometrically before use). Silica gel G with binder was used for thin layer chromatography. 2-(Arylazo)aniline ligands were prepared according to the procedure described earlier.[23]

**Physical Measurements:** UV/Vis spectra were recorded with a Shimadzu UV-2401 PC spectrophotometer. IR spectra were obtained with a Perkin–Elmer L120–00A FTIR spectrophotometer (4000–225 $cm^{-1}$) using KBr pellets. Elemental analyses (C, H, N) were performed with a Perkin–Elmer 240C elemental analyzer. NMR spectra were recorded with Bruker Avance RPX 500 MHz and Bruker Avance DPX 300 spectrometers in $CDCl_3$ using TMS as the internal standard. Electrochemical measurements were made under dinitrogen using a PAR model VERSASTAT-II potentiostat. A glassy-carbon working electrode, platinum-wire auxiliary electrode, and standard saturated calomel electrode (SCE) were used in a three-electrode configuration. Tetraethyl perchlorate (0.1 M) was used as supporting electrolyte. All electrochemical data were collected at 298 K and are uncorrected for junction potentials. ESI mass spectra were recorded with a micromass Q-TOF mass spectrometer (serial no. YA 263).

**Syntheses of Ligands, $H_2L_{sal}$ (1)**

The three ligands $H_2L^1_{sal}$, $H_2L^2_{sal}$, and $H_2L^3_{sal}$ were prepared by a similar procedure. The detailed procedure for the preparation of $H_2L^1_{sal}$ is given.

***N*-[2-(Phenylazo)phenyl]salicylideneamine, $H_2L^1_{sal}$ (1a):** To a solution of 2-(phenylazo)aniline, $H_2L^1$, (100 mg, 0.50 mmol) in diethyl ether (40 mL) was added a little excess of salicylaldehyde (67 mg, 0.55 mmol). The resulting mixture was then heated to reflux for 8 h. The solvent was then evaporated in vacuo for 2 h to obtain the partially solid mass after removal of excess salicylaldehyde. It was further kept in a vacuum desiccator for 24 h to obtain the solid product of $H_2L_{sal}$. Isolated yield: 145 mg (95%). M.p.: 96 °C. $C_{19}H_{15}N_3O$ (301): calcd. C 75.74, H 4.98, N 13.95; found C 75.90, H 4.75, N 13.85. IR (KBr): $\tilde{\nu}$ = 1614 (C=N), 1450 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.91 (t, 1 H), 7.06 (d, 1 H), 7.33 (t, 1 H), 7.37 (d, 3 H), 7.46 (d, 1 H), 7.48–7.52 (m, 3 H), 7.78 (dd, 1 H), 7.92–7.95 (m, 2 H), 8.61 (s, 1 H), 13.59 (s, 1 H, OH) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 316 (18890), 232 (18750) nm.

***N*-[2-(*p*-Tolylazo)phenyl]salicylideneamine, $H_2L^2_{sal}$ (1b):** Isolated yield: 141 mg (95%). M.p.: 80 °C. $C_{20}H_{17}N_3O$ (315.37): calcd. C 76.19, H 5.39, N 13.33; found C 76.00, H 5.50, N 13.25. IR (KBr): $\tilde{\nu}$ = 1615 (C=N), 1452 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.42 (s, 3 H, *p*-$CH_3$), 6.93 (t, 1 H), 7.06 (d, 1 H), 7.31 (d, 2 H), 7.36 (t, 1 H), 7.46 (d, 1 H), 7.38–7.40 (m, 3 H), 7.51 (t, 1 H), 7.78 (d, 1 H), 7.85 (d, 2 H), 8.63 (s, 1 H), 13.59 (s, 1 H, OH) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 325 (26570), 233 (27114) nm.

***N*-[2-(*p*-Chlorophenylazo)phenyl]salicylideneamine, $H_2L^3_{sal}$ (1c):** Isolated yield: 137 mg (95%). M.p.: 92 °C. $C_{19}H_{14}ClN_3O$ (335.79): calcd. C 67.95, H 4.17, N 12.51; found C 67.80, H 4.15, N 13.90. IR (KBr): $\tilde{\nu}$ = 1617 (C=N), 1452 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.94 (t, 1 H), 7.07 (d, 1 H), 7.35 (t, 1 H), 7.40–7.42 (m, 3 H), 7.49 (d, 2 H), 7.57 (t, 1 H), 7.79 (d, 1 H), 7.90 (d, 2 H), 8.65 (s, 1 H), 13.58 (s, 1 H, OH) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 322 (24980), 233 (22250) nm.

**Syntheses of Complexes, ($L_{sal}$)Ni (5)**

All three complexes ($L^1_{sal}$)Ni, ($L^2_{sal}$)Ni, and ($L^3_{sal}$)Ni were prepared by a similar procedure. The detailed procedure for the preparation of ($L^1_{sal}$)Ni is given.

**($L^1_{sal}$)Ni (5a):** To $H_2L^1_{sal}$ (120 mg, 0.40 mmol) dissolved in methanol (40 mL) was added $Ni(OAc)_2{\cdot}4H_2O$ (100 mg, 0.40 mmol). The mixture was then heated to reflux for 12 h to obtain a green precipitate of ($L^1_{sal}$)Ni. The solid product was then filtered and washed with water and a little ethanol. The volume of the filtrate was reduced to ca. 20 mL and kept in a beaker covered with a watch glass. After 12 h a further crop of product was collected by filtration. All the product was taken together and recrystallized from dichloromethane/petroleum ether to obtain pure ($L^1_{sal}$)Ni. Yield: 99.82 mg (70%). $C_{19}H_{13}NiN_3O$ (358.04): calcd. C 63.74, H 3.63, N 11.74; found C 63.70, H 3.65, N 11.80. IR (KBr): $\tilde{\nu}$ = 1605 (C=N), 1389 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.57 (t, 1 H), 6.98 (d, 1 H), 7.12–7.14 (m, 1 H), 7.23–7.27 (m, 2 H), 7.39–7.43 (m, 3 H), 7.56 (d, 1 H), 7.67 (d, 1 H), 8.57 (s, 1 H) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 630 (1740), 460 (10867), 371 (19378), 341(15800), 315 (14820), 242 (35480) nm. ESI-MS: *m*/*z* = 358.

**($L^2_{sal}$)Ni (5b):** This complex was prepared by following a similar procedure as that described for ($L^1_{sal}$)Ni, using ligand $H_2L^2_{sal}$ in place of $H_2L^1_{sal}$. Yield: 89.91 mg (60%). $C_{20}H_{15}NiN_3O$ (372.07): calcd. C 64.59, H 4.03, N 11.29; found C 64.67, H 4.00, N 11.35.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

IR (KBr): $\tilde{\nu}$ = 1605 (C=N), 1374 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.31 (s, 3 H, *p*-$CH_3$), 6.57 (t, 1 H), 6.90 (d, 1 H), 7.02 (d, 1 H), 7.14–7.19 (m, 3 H), 7.24–7.27 (m, 1 H), 7.38 (t, 1 H), 7.56 (d, 2 H), 7.65 (d, 1 H), 8.57 (s, 1 H) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 631 (2829), 460 (19244), 378 (30420), 340 (24340), 319 (20690), 243 (58351) nm.

**($L^3_{sal}$)Ni (5c):** This complex was prepared by following a similar procedure as that described for ($L^1_{sal}$)Ni, using ligand $H_2L^3_{sal}$ in place of $H_2L^1_{sal}$. Yield: 97.84 mg (62%). $C_{19}H_{12}ClNiN_3O$ (392.49): calcd. C 58.13, H 3.05, N 10.70; found C 58.18, H 3.00, N 10.75. IR (KBr): $\tilde{\nu}$ = 1606 (C=N), 1372 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.55 (t, 1 H), 6.93 (d, 1 H), 7.05 (d, 1 H), 7.12 (d, 1 H), 7.15 (t, 1 H), 7.22–7.29 (m, 2 H), 7.43 (t, 1 H), 7.51 (d, 2 H), 7.62 (d, 1 H), 8.43 (s, 1 H) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 634 (1990), 455 (13413), 372 (24432), 338 (18393), 314 (17445), 243 (44052) nm.

**Syntheses of Complexes, ($OL_{sal}$)Ni (6)**

All complexes were prepared by a similar procedure. The details for the preparation of ($OL^1_{sal}$)Ni are given.

**($OL^1_{sal}$)Ni (6a):** A solution of *m*CPBA (143 mg, 0.824 mmol) in dichloromethane (5 mL) was added dropwise to a stirred solution of ($L^1_{sal}$)Ni (100 mg, 0.279 mmol) in dichloromethane (25 mL). Immediately the color of the solution began to change from deep green to olive green. The stirring was continued for 10 min. Evaporation of the solvent in vacuo afforded a greenish solid mass. The solid mass was washed with diethyl ether (3 × 5 mL). The product was then purified by preparative TLC using a benzene/acetonitrile (19:1) mixture as eluent. Upon evaporation of the solvent, the pure target complex ($OL^1_{sal}$)Ni was obtained. Isolated yield: 67.90 mg (65%). $C_{19}H_{13}NiN_3O_2$ (374.04): calcd. C 61.01, H 3.47, N 11.23; found C 60.95, H 3.43, N 11.20. IR (KBr): $\tilde{\nu}$ = 1614 (C=N), 1376 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.68 (t, 1 H), 6.84 (t, 1 H), 7.15 (d, 1 H), 7.24–7.27 (m, 3 H), 7.33–7.40 (m, 4 H), 7.76–7.72 (m, 2 H), 8.17 (d, 1 H), 8.40 (s, 1 H) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 640 (3846), 442 (15468), 399 (14715), 356 (19842), 340 (23520), 255 (38277) nm. ESI-MS: *m*/*z* = 374.

**($OL^2_{sal}$)Ni (6b):** Complex ($OL^2_{sal}$)Ni was prepared using ($L^2_{sal}$)Ni in place of ($L^1_{sal}$)Ni. Isolated yield: 68 mg (65%). $C_{20}H_{15}NiN_3O_2$ (388.07): calcd. C 61.90, H 3.86, N 11.00; found C 61.46, H 3.92, N 10.91. IR (KBr): $\tilde{\nu}$ = 1611 (C=N), 1376 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.28 (s, 3 H), 6.67 (t, 2 H), 7.07 (s, 1 H), 7.14 (d, 1 H), 7.37 (t, 4 H), 7.62 (d, 1 H), 7.72 (d, 1 H), 8.17 (d, 1 H), 8.40 (s, 1 H) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 631 (3101), 441 (12902), 402 (12603), 356 (15848), 340 (17860), 261 (29455) nm.

**($OL^3_{sal}$)Ni (6c):** Complex ($OL^3_{sal}$)Ni was prepared using ($L^3_{sal}$)Ni in place of ($L^1_{sal}$)Ni. Isolated yield: 63 mg (60%). $C_{19}H_{12}ClNiN_3O_2$ (408.49): calcd. C 58.13, H 2.93, N 10.28; found C 57.91, H 2.82, N 10.32. IR (KBr): $\tilde{\nu}$ = 1611 (C=N), 1374 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.70 (t, 1 H), 6.83 (d, 2 H), 7.12 (d, 2 H), 7.33–7.42 (m, 4 H), 7.73 (t, 2 H), 8.15 (d, 1 H), 8.38 (s, 1 H) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 638 (4209), 441 (7795), 350 (9110), 339 (10340), 2276 (11872), 248 (14061) nm.

**Reaction of ($L_{sal}$)Ni with TBHP:** The reaction of ($L^1_{sal}$)Ni is given in detail. To a stirred solution of ($L^1_{sal}$)Ni (50 mg, 0.140 mmol) in dichloromethane or *tert*-butanol (25 mL) was added dropwise TBHP (0.30 mL, 2.76 mmol). Immediately the color of the solution began to turn from deep green to olive green. The stirring was continued for 30 min. Evaporation of the solvent in vacuo afforded a greenish solid mass. The solid mass was washed with water and diethyl ether. The product was then purified by preparative TLC using a benzene/acetonitrile (19:1) mixture as eluent. Upon evaporation of the solvent, the pure target complex ($OL^1_{sal}$)Ni was obtained. Isolated yield: 34.14 mg (65%).

**Reaction of ($L_{sal}$)Ni with $H_2O_2$:** The reaction of ($L^1_{sal}$)Ni is given in detail. To a stirred solution of ($L^1_{sal}$)Ni (30 mg, 0.083 mmol) in dichloromethane (15 mL) was added dropwise 6% $H_2O_2$ (10 mL). The color of the organic layer began to turn from deep green to olive green after 20 min. The stirring was continued for 1.5 h. Evaporation of the organic solvent, after separation from the aqueous layer, in vacuo afforded a greenish solid mass. The solid mass was washed with water. The product was then purified by preparative TLC using a benzene/acetonitrile (19:1) mixture as eluent. Upon evaporation of the solvent, the pure target complex ($OL^1_{sal}$)Ni was obtained. Isolated yield: 20.5 mg (65%).

**Preparation of 2-(2-Aminophenylazo)phenol, $H_2L^1OH$, from ($OL^1_{sal}$)Ni:** To an acetonitrile solution (20 mL) of ($OL^1_{sal}$)Ni (200 mg, 0.534 mmol) was added dropwise 0.1 M $HClO_4$ (5 mL) with continuous stirring. The color of the solution changed from olive green to yellow. Evaporation of the solvent in vacuo afforded a yellow solid mass. The solid mass was washed (3×) with water and extracted with dichloromethane and purified by preparative TLC using petroleum benzene as eluent. Upon evaporation of the solvent, the pure target compound $H_2L^1OH$ was obtained. Yield: 56.5 mg (50%). $C_{12}H_{11}N_3O$ (213.24): calcd. C 67.60, H 5.16, N 19.71; found C 67.65, H 5.06, N 19.65. IR (KBr): $\tilde{\nu}$ = 3407 ($NH_2$), 3284 (OH), 1468 (N=N) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.19 (s, $NH_2$), 6.75 (d, 1 H), 6.83 (t, 1 H), 7.04–6.99 (m, 2 H), 7.20 (t, 1 H), 7.29 (t, 1 H), 7.67 (d, 1 H), 7.76 (d, 1 H), 12.84 (s, OH) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 450 (10566), 318 (13124), 230 (10646) nm.

**X-ray Crystallography:** Suitable X-ray-quality crystals of **5a** (0.08 × 0.23 × 0.25) and **6a** (0.13 × 0.13 × 0.20) for X-ray studies were grown by slow evaporation of a dichloromethane solution of **5a** and a dichloromethane/acetonitrile solution of **6a**. Data were collected with a Bruker SMART CCD diffractometer using a Mo-$K_\alpha$ monochromator ($\lambda$ = 0.71043). Structure solutions were performed using the SHELX-97 (PC version) program. The full-matrix least-square and anisotropic refinements were performed on all the atoms. Hydrogen atoms were included at calculated positions.

Table 3. Crystal data for complexes ($L^1_{sal}$)Ni and ($OL^1_{sal}$)Ni.

| Parameter | ($L^1_{sal}$)Ni | ($OL^1_{sal}$)Ni |
|---|---|---|
| Formula | $C_{19}H_{13}N_3ONi$ | $C_{19}H_{13}N_3NiO_2$ |

# Synthesis, Structure, and Reactivity of Diazoketiminato Complexes of Platinum(II) and Palladium(II): Cytotoxic Properties of a Platinum Complex

**Jahar Lal Pratihar,[a] Biswaranjan Shee,[a] Poulami Pattanayak,[a] Debprasad Patra,[a] Arindam Bhattacharyya,[b] Vedavati G. Puranik,[c] C. H. Hung,[d] and Surajit Chattopadhyay*[a]**

**Keywords:** Chelating ligands / Platinum / Palladium / Redox chemistry / Bioinorganic chemistry

Reaction of the 2-(arylazo)anilines Ar-N=N-$C_6H_4NH_2$ [$HL^nNH_2$; Ar = $C_6H_5$ ($HL^1$), *p*-$CH_3C_6H_4$ ($HL^2$), *p*-$ClC_6H_4$ ($HL^3$)] with $K_2PtCl_4$ in dmso affords the new $Pt^{II}$ azoimine complexes [($HL^n$NH)Pt(dmso)Cl] where the chloride and dmso ligands are mutually *cis*. In contrast, treatment of $Na_2PdCl_4$ with $HL^nNH_2$ in dmso gives the chloro-bridged palladium dimer [{($HL^n$NH)$PdCl$}$_2$] as the major product along with [($HL^n$NH)$_2$Pd] as the minor product. Further, the reaction of $HL^n$NH$CH_2$Ph with $K_2PtCl_4$ in dmso also gives [($HL^n$NH)Pt(dmso)Cl] whereas $Na_2PdCl_4$ affords the ortho-palladated complexes [($L^n$NH$CH_2$Ph)PdCl]. This means that the N–C($CH_2$Ph) bond is selectively cleaved by $K_2PtCl_4$. The reaction of [($HL^n$NH)Pt(dmso)Cl] with acetylacetone (acacH) gives the heteroleptic complex [($HL^n$NH)Pt(acac)]. [($HL^n$NH)-Pt(dmso)Cl] and [($HL^n$NH)Pt(acac)] display a reversible reductive response at –1.20 and –1.46 V vs. SCE, respectively, in their cyclic voltammograms. The nature of the redox orbitals has been determined semi-empirically employing the EHMO method. The cytotoxicity of [($HL^1$NH)Pt(dmso)Cl] has been examined with HeLa cells and the sub-lethal dose (8 μM) determined by dose-dependence studies. The relative degree of apoptotic and necrotic cell death using a sub-lethal dose were measured by flow cytometry.

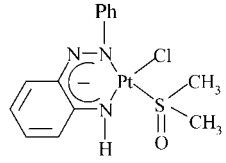
## Introduction

$Pt^{II}$ complexes have been known for a long time and their importance was enhanced with the discovery of cisplatin. Cisplatin and carboplatin are two widely used anticancer drugs although there are certain limitations in their therapeutic uses, therefore several appropriately designed models of $Pt^{II}$ complexes have been clinically tested in search of suitable alternatives.[1–9] One of the proposed models for $Pt^{II}$-based chemotherapeutic agents is [Pt(L)(dmso)Cl], where L is a bidentate anionic ligand and the anticipated labile ligands are dimethyl sulfoxide (dmso) and chloride.[10–13] These reports encouraged us to study the in vitro cytotoxic properties of our newly synthesized diazoketiminato complex [($HL^1$NH)Pt(dmso)Cl] in view of its importance as a potential model of anticancer agents.



[($HL^1$NH)Pt(dmso)CL]

The work reported here stems from our interest in the coordination chemistry of platinum complexes incorporating bidentate (N,N), anionic, and delocalized diazoketimine ligands **1**. We have previously reported the bis-chelate complexes of $Pd^{II}$ and $Pt^{II}$ incorporating **1**,[14,15] and herein we report the reactions of $Na_2PdCl_4$ and $K_2PtCl_4$ with the ligand precursors Ar-N=N-$C_6H_4NH_2$ [$HL^nNH_2$; Ar = $C_6H_5$ ($HL^1$), *p*-$CH_3C_6H_4$ ($HL^2$), *p*-$ClC_6H_4$ ($HL^3$)] and $HL^n$NH$CH_2$Ph in dmso. Aspects related to N–C(alkyl) bond cleavage with $K_2PtCl_4$, the redox properties of the new platinum complexes formed, and a comparison of the reactivities of $Pt^{II}$ and $Pd^{II}$ substrates toward similar ligands are also described in this paper.

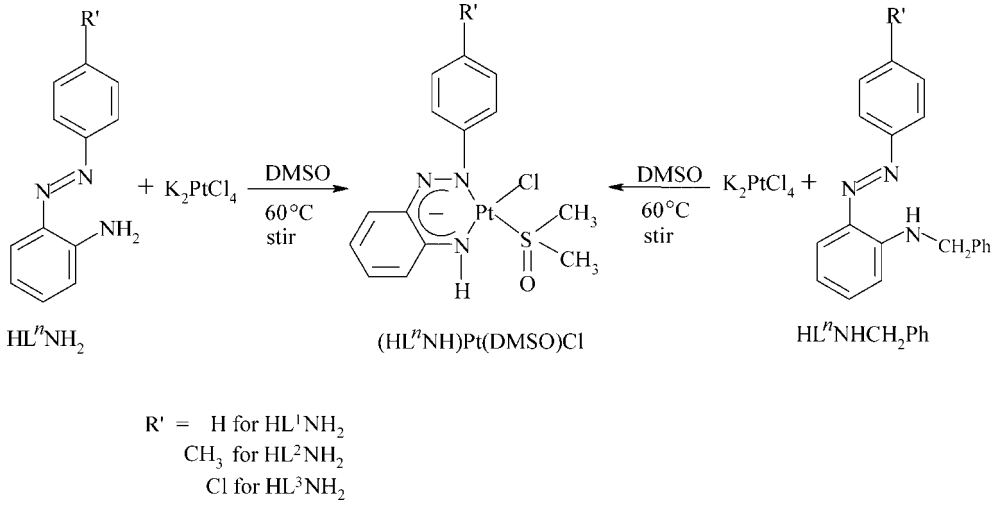
Reaction of the 2-(arylazo)anilines $HL^nNH_2$ or their *N*-benzylated derivative $HL^nNHCH_2Ph$ with $K_2PtCl_4$ affords the electroactive complexes of the desired composition, namely [$(HL^nNH)Pt(dmso)Cl$]. Reaction of the same ligands with $Na_2PdCl_4$ was also performed to confirm that cleavage of the N–C(benzyl) bond only occurs with $K_2PtCl_4$. The reactions of [$(HL^nNH)Pt(dmso)Cl$] with the bidentate ligand acacH to give the new heteroleptic bis complexes of composition [$(HL^nNH)Pt(acac)$] show the feasibility of substituting the $Cl^-$ and dmso ligands in this complex. All new complexes have been characterized unequivocally and their structures confirmed by X-ray crystallography. The electron-transfer properties of the $Pt^{II}$ complexes have been examined electrochemically and the results rationalized by employing semi-empirical EHMO calculations. The dose dependence and nature of cell (HeLa) death (apoptotic or necrotic) have also been studied for [$Pt(HL^1NH)(dmso)Cl$].

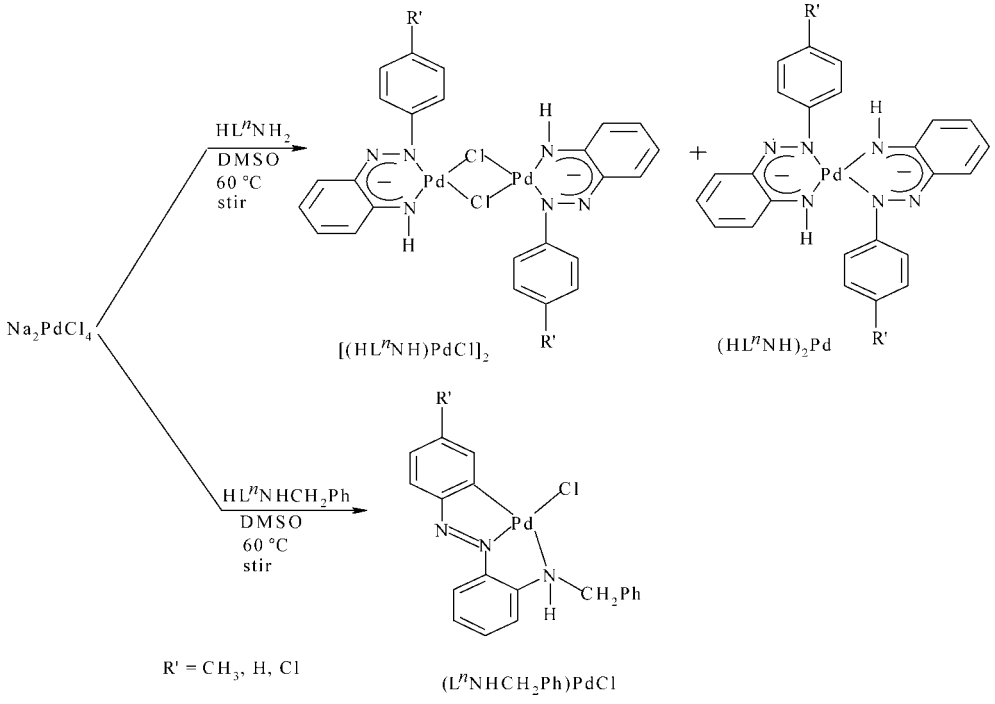
## Results and Discussion

### Syntheses and Reactions

The reaction of $HL^nNH_2$ or $HL^nNHCH_2Ph$ with $K_2PtCl_4$ in warm dmso affords the pink complexes [$(HL^nNH)Pt(dmso)Cl$] in good yield (Scheme 1). Addition



Scheme 1.



Scheme 2.

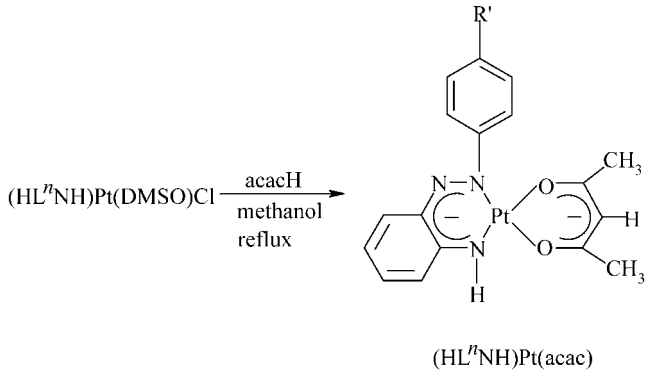
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of $K_2PtCl_4$ to warm dmso is excepted to form the dmso-coordinated $Pt^{II}$ complex, which is likely to be the actual metal substrate that reacts with the ligands.

The formation of [(HL$^n$NH)Pt(dmso)Cl] prompted us to examine the reactions of the same ligands with $Na_2PdCl_4$ in warm dmso. The results of these reactions are summarized in Scheme 2.

The minor product [Pd(HL$^n$NH)$_2$] has been prepared in good yield previously,[14] while the major product, [{(HL$^n$NH)PdCl}$_2$], is isolated here for the first time. Its structure was confirmed by X-ray crystallography (see below). The orthopalladated complex [(L$^n$NHCH$_2$Ph)PdCl] was obtained, as expected,[16] upon treatment of HL$^n$NHCH$_2$Ph with $Na_2PdCl_4$, whereas the same reaction with $K_2PtCl_4$ gives [(HL$^n$NH)Pt(dmso)Cl] by cleavage of the N–C(benzyl) bond of HL$^n$NHCH$_2$Ph. Subtle difference in the properties of $Pt^{II}$ and $Pd^{II}$ are likely to be the origin of this mismatch in reactivity between $Na_2PdCl_4$ and $K_2PtCl_4$.

Reaction of [(HL$^n$NH)Pt(dmso)Cl] with the bidentate ligand acetylacetone (acacH) was performed in boiling methanol to give the blue neutral heteroleptic bis complex [(HL$^n$NH)Pt(acac)] (Scheme 3). Substitution of the mutually *cis* dmso and Cl$^-$ ligands of [(HL$^n$NH)Pt(dmso)Cl] by acetylacetonate indicates the possibility of coordination of this complex with the nucleoside bases of nucleic acids.



Scheme 3.

## Spectroscopic Characterization

The complexes [(HL$^n$NH)Pt(dmso)Cl] and [(HL$^n$NH)-Pt(acac)] dissolve in common organic solvents to give pink and blue solutions, respectively, consistent with the relative energies of absorptions in the visible region {approx. 560 nm for [(HL$^n$NH)Pt(dmso)Cl] and approx. 600 nm for [(HL$^n$NH)Pt(acac)]}. The positions of other higher energy absorption bands for all the complexes are alike with characteristic shifts. The relevant data are collected in Table 1 and representative spectra of [(HL$^1$NH)Pt(dmso)Cl] and [(HL$^1$NH)Pt(acac)] are shown in Figure 1.

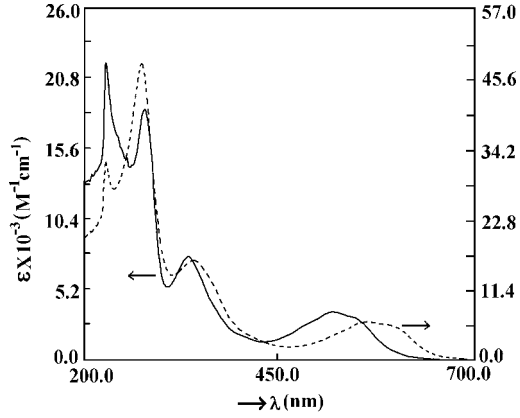


Figure 1. UV/Vis spectra of [(HL$^1$NH)Pt(dmso)Cl] (−) and [(HL$^1$NH)Pt(acac)] (---). The arrows indicate the scales of the corresponding spectrum.

The IR spectra of complexes [(HL$^n$NH)Pt(dmso)Cl] in solid KBr exhibit sharp $\nu_{N-H}$ absorptions in the range 3284–3291 cm$^{-1}$, thereby indicating the presence of one

amino proton. Surprisingly, the complexes [(HL$^n$NH)Pt(acac)] exhibit two overlapping $\nu_{N-H}$ absorptions in the range 3320–3350 cm$^{-1}$, which may be due to a site effect in the solid state.[17] The $\nu_{N=N}$ absorptions of both complexes are shifted to lower frequency (1340–1347 cm$^{-1}$) than in the free ligands HL$^n$NH$_2$ (approx. 1460 cm$^{-1}$).[14,15,18,19] The strong band observed at around 1617 cm$^{-1}$ which is absent in the free ligands can be assigned to the $\nu_{C=N}$ absorption.[14,15,18,19] The blue-shift of the $\nu_{S=O}$ absorption for complexes [(HL$^n$NH)Pt(dmso)Cl] (1112–1120 cm$^{-1}$) compared to free dmso (1050 cm$^{-1}$) indicates S-coordination. The $\nu_{Pt-Cl}$ absorption of [(HL$^n$NH)Pt(dmso)Cl] appears in the range 371–374 cm$^{-1}$. Relevant IR data are also collected in Table 1.

The $^1$H NMR spectra of complexes [(HL$^n$NH)Pt(dmso)Cl] display a resonance near $\delta$ = 3.5 ppm for coordinated dmso while the aromatic protons of the coordinated (HL$^n$NH)$^-$ ligands appear in the range $\delta$ = 6.58–7.75 ppm. The proton counts match well with the composition, thereby indicating no mismatch with the molecular structure in solution. The $^1$H NMR spectroscopic data are listed in Table 2. Although the spectrum of [(HL$^1$NH)Pt(dmso)Cl] is slightly more complicated in the aromatic region, the proton count is consistent with the composition. The spectra of [(HL$^2$NH)Pt(dmso)Cl] and [(HL$^3$NH)Pt(dmso)Cl] are well resolved in the aromatic region, where two doublets and two triplets, each integrating for one proton, appear for 2-H, 3-H, 4-H, and 5-H (the atom numbering scheme is shown in Figure 3, a). Two doublets, each integrating for two equivalent protons, are observed for 8,12-H and 9,11-H. A representative spectrum for [(HL$^2$NH)Pt(dmso)Cl] is shown in Figure 2. The N–H resonances for these complexes fall within the aromatic region and are overlapped by other resonances of the aromatic protons. However, the proton count matches the composition (HL$^n$NH)$^-$, thereby confirming the removal of one $NH_2$ proton upon complexation.

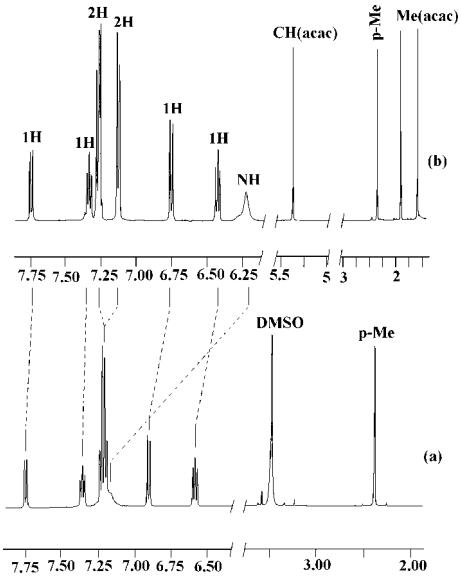

Figure 2. Correlation of aromatic proton resonances along with the proton count of [(HL$^2$NH)Pt(dmso)Cl] (a) and [(HL$^2$NH)Pt(acac)] (b).

The $^1$H NMR spectra of the [(HL$^n$NH)Pt(acac)] complexes exhibit the N–H resonance as a broad singlet in the range $\delta$ = 6.22–6.35 ppm, thereby confirming the (HL$^n$NH$_2$) → (HL$^n$NH)$^-$ transformation. The $^1$H NMR spectra of [(HL$^n$NH)Pt(acac)] are similar to those of [(HL$^n$NH)Pt(dmso)Cl] in the aromatic region but with slightly different chemical shift values. A one-to-one correlation of the aromatic protons is shown in Figure 2 for [(HL$^2$NH$_2$)Pt(acac)] and [(HL$^2$NH)Pt(dmso)Cl]. The coordinated acac ligand of [(HL$^n$NH)Pt(acac)] shows three sets of resonances, one for the methine proton ($\delta \approx$ 5.35 ppm) and two for the $CH_3$ groups ($\delta \approx$ 1.92 and 1.59 ppm),

Table 2. $^1$H NMR spectroscopic data for [(HL$^n$NH)Pt(dmso)Cl], [(HL$^n$NH)Pt(acac)], and [{(HL$^1$NH)PdCl}$_2$].

thereby indicating an unequal chemical environment about the two Me groups, consistent with the X-ray structure (see below).

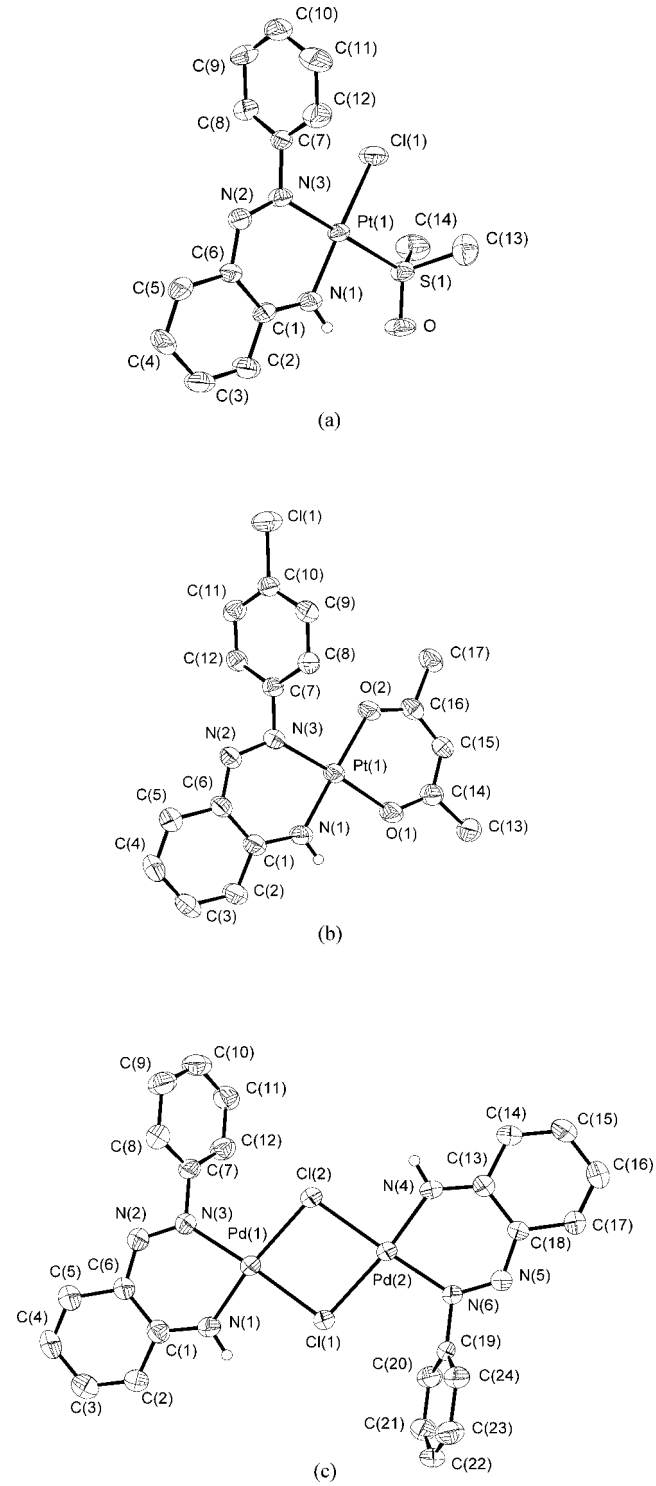

Figure 3. Perspective views of [(HL[1]NH)Pt(dmso)Cl] (a), [(HL[3]NH)Pt(acac)] (b), and [{(HL[1]NH)PdCl}$_2$] (c) with atom numbering scheme. Hydrogen atoms, except those on N1 in (a), (b), and (c) and N4 in (c), have been omitted for clarity.

## X-ray Structures

The crystal structures of [(HL[1]NH)Pt(dmso)Cl], [{(HL[1]NH)PdCl}$_2$], and [(HL[3]NH)Pt(acac)] were determined as representative examples of each type of complex. The (HL$^n$NH) ligands bind to the metals in an N,N-bidentate fashion in all three complexes. A chloride and a dmso ligand (coordinated to the Pt$^{II}$ through its S atom) are present in the coordination sphere of [(HL[1]NH)Pt(dmso)Cl], and the acac$^-$ ligand of [(HL[3]NH)Pt(acac)] binds Pt$^{II}$ in an O,O-bidentate fashion as expected. Two bridging chloride

ligands coordinate the $Pd^{II}$ apart from the bidentate $(HL^1NH)^-$ ligand in $[\{Pd(HL^1NH)Cl\}_2]$. The $(HL^1NH)^-$ ligands in this molecule are mutually *trans* with no substantial mismatch in the bond parameters. Perspective views of the molecules are shown in Figures 3 (a–c), and selected bond lengths and angles are collected in Table 3.

The geometries about the metal center are planar (mean deviations within 0.0216–0.0532 Å) for all three neutral molecules, thereby confirming the bivalent state of Pt and Pd and the formation of a mononegative anionic ligand $(HL^nNH)^-$ by dissociation of an amine proton from the precursor $HL^nNH_2$, consistent with the IR and $^1H$ NMR spectroscopic data (see above).[14,15,18,19] The equality in bond lengths within the chelate ring framework of coordinated acetylacetone of [(HL$^n$NH)Pt(acac)] signifies the expected delocalization upon deprotonation.[20] The C(1)–N(1) distances (approx. 1.324 Å) of all three molecules are much shorter than that of the C(7)–N(3) single bond (approx. 1.444 Å) in the same molecules. The C(1)–N(1) distances are, in fact, similar to that of an imine (approx. 1.34 Å).[14,15,18,19] The effect of delocalization within the chelate framework of $(HL^nNH)^-$ is further reflected by the adjacent phenyl ring [C(1)–C(6)], which has four long and two short bonds. The C(6)–N(2) bond length (approx. 1.35 Å) is shorter than the C(7)–N(3) single bond length as a consequence. These structural features allowed us to infer the formation of delocalized diazoketiminato chelates.[14,15,18,19]

The asymmetric unit of [(HL$^n$NH)Pt(acac)] contains two mutually *trans* molecules that are held together by a weak $Pt^{II}\cdots Pt^{II}$ interaction (3.898 Å). The stacking arrangement displayed by this weak dimer in the crystal lattice is shown in Figure 4 (inter dimer $Pt^{II}\cdots Pt^{II}$ distance is 4.320 Å). The $Pd^{II}\cdots Pd^{II}$ distance in the $[\{(HL^nNH)PdCl\}_2]$ dimer is 3.494 Å, which means that there is no Pd–Pd single bond formation and no possibility of forming a $Pd^I$–$Pd^I$ dimer.

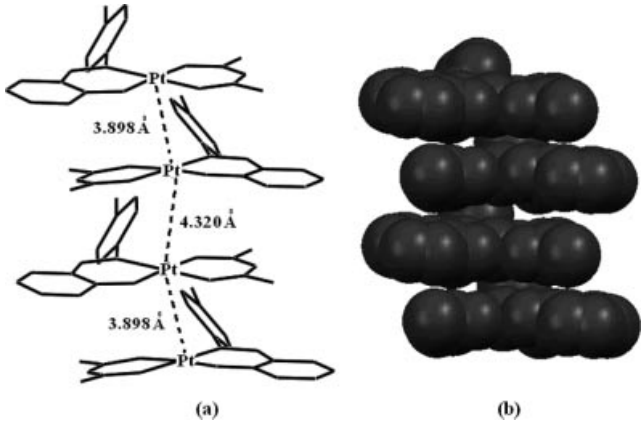

Figure 4. (a) Partial packing diagram and (b) stacking arrangement of [(HL$^3$NH)Pt(acac)].

## Electrochemistry

The cyclic voltammograms of complexes [(HL$^n$NH)Pt(dmso)Cl] display a quasi-reversible one-electron reduction (calibrated against the current height of the $Fc/Fc^+$ couple) in the range $E_{1/2} \approx -1.120$ to $-1.246$ V vs. SCE in acetonitrile. The voltammogram of [(HL$^1$NH)Pt(dmso)Cl] is shown in Figure 5 (a) as an example. The overall redox reactions are represented in Equation (1). The $E_{1/2}$ values vary systematically with R′ of the (HL$^n$NH) ligand, and a plot of $E_{1/2}$ vs. σ (the Hammett substituent constant) is linear (Figure 5, b).[21]

$$[(HL^nNH)Pt(DMSO)Cl]^- \xrightarrow[-e]{} [(HL^nNH)Pt(DMSO)Cl] \quad (1)$$

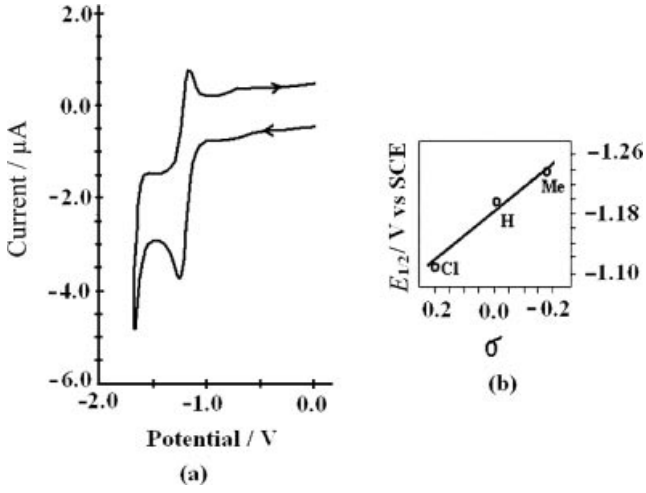

Figure 5. (a) Cyclic voltammogram of [(HL$^1$NH)Pt(dmso)Cl] in acetonitrile solution (0.1 M $NBu_4ClO_4$) vs. SCE. (b) A least-squares plot of $E_{1/2}$ values of [(HL$^n$NH)Pt(dmso)Cl] complexes vs. σ (Hammett substituent constant).

To gain an insight into the nature of the redox orbitals we performed EHMO calculations[22,23] using the crystallographic atomic coordinates of [(HL$^1$NH)Pt(dmso)Cl]. The energy level and interaction diagram was determined by FMO analysis, which showed that the LUMO is a nonbonding ligand group orbital (Figure 6). The contribution of an antibonding combination of azo (–N=N–) nitrogens to the LUMO is 50%, therefore the reductive response of [(HL$^n$NH)Pt(dmso)Cl] may be assigned to reduction of the azo function [Equation (2)].[24,25] The cyclic voltammogram of [(HL$^n$NH)Pt(acac)] is similar (see Figure S16) to that of the [(HL$^n$NH)Pt(dmso)Cl] complexes but with a characteristic shift of the $E_{1/2}$ values (–1.410 V to –1.510 V vs. SCE in acetonitrile). An EHMO calculation was also performed with the crystallographic atomic coordinates of [(HL$^3$NH)-Pt(acac)], and analysis of the LUMO showed a similar composition to that of [(HL$^n$NH)Pt(dmso)Cl], with a contribution from the azo-π* combination of also about 50%. The energy-level diagram with metal–ligand interactions and the orbital diagram of LUMO are given in Figure S1 (see Supporting Information).

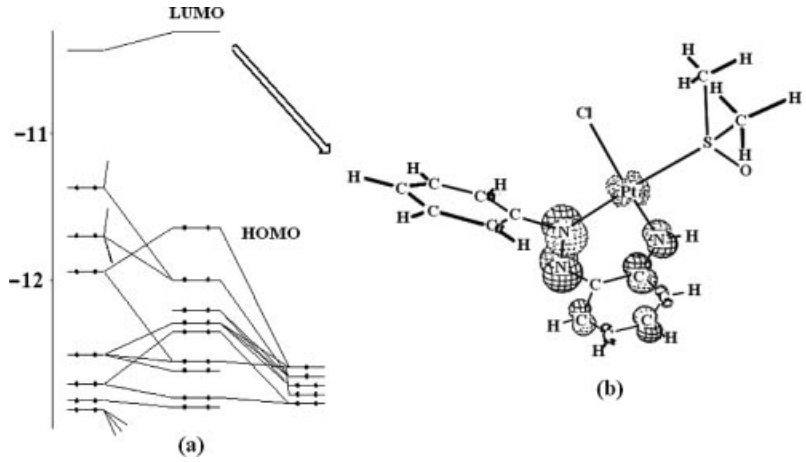

Figure 6. (a) Partial energy level and interaction diagram and (b) MO drawing of the LUMO of [(HL$^1$NH)Pt(dmso)Cl].

trypan blue dye exclusion assay is shown in Figure 7. The trypan blue assay showed that $ED_{75}$, which is the effective dose of [(HL$^1$NH)Pt(dmso)Cl] required to kill 75% of cells, is 12 μM for this complex. Around 50% of the cells were still viable after 5 h from the time of treatment of the cells with 8 μM [(HL$^1$NH)Pt(dmso)Cl], which is therefore the sub-lethal dose.[26] The pattern of cell death was studied by flow cytometric technique using appropriate dye stains. The apoptotic cell death was studied by the Annexin-V binding assay technique using a sub-lethal dose (8 μM) of [(HL$^1$NH)-Pt(dmso)Cl]. The cells were co-stained with propidium iodide (PI) in addition to Annexin V to distinguish between apoptotic and necrotic cell death.[27] Although the later stages of apoptosis cannot be distinguished from necrosis, the flipped-out phosphatidylserine residue selectively binds Annexin V-FITC on the cells' surface during the early stages of apoptosis. The results of the flow cytometric measurements are shown in Figure 8. Viable cells are negative to both dyes (PI and Annexin V-FITC), as shown in the bottom-left quadrant of Figure 8. The Annexin V conjugated cells appearing in the bottom-right quadrant of Figure 8 represent the apoptotic cells, and the upper-right quadrant represents the Annexin V and PI conjugated cells, which indicates late-stage apoptosis or necrosis.

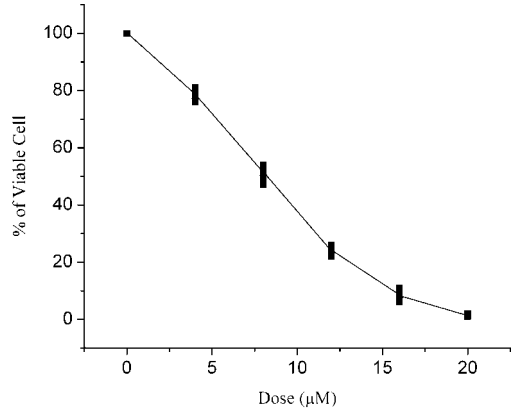

Figure 7. Plot of dose vs. viable cells to determine the sub-lethal dose.

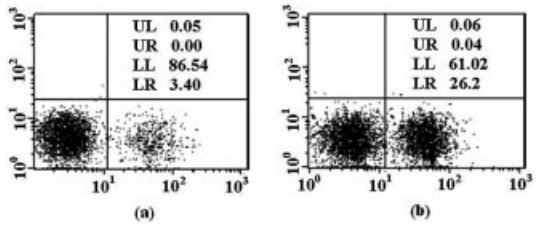

Figure 8. Flow cytometric measurements with HeLa cells using Annexin V-FITC/PI to distinguish between apoptosis and necrosis: (a) the plot for untreated cells; (b) the plot for cells treated with [(HL$^1$NH)Pt(dmso)Cl]. UL = upper left, UR = upper right, LL = lower left, LR = lower right.

These studies show the cytotoxic effects of this new class of platinum(II) chelate complexes [(HL$^1$NH)Pt(dmso)Cl] with mutually *cis*-coordinated dmso and chloride ligands. Although activation of apoptosis is a remarkable observation, a comparison of the results obtained with cisplatin is necessary and is currently underway.

## Concluding Remarks

The reactions of $K_2PtCl_4$ with HL$^n$NH$_2$ and HL$^n$NHCH$_2$Ph in refluxing dmso both afford the diazoketiminato complex [(HL$^n$NH)Pt(dmso)Cl] due to N–C(benzyl) bond cleavage in HL$^n$NHCH$_2$Ph. In contrast, $Na_2PdCl_4$ affords the orthopalladated complexes and chloro-bridged diazoketiminatodipalladium complexes upon reaction with HL$^n$NHCH$_2$Ph and HL$^n$NH$_2$, respectively. The reaction of [(HL$^n$NH)Pt(dmso)Cl] with acacH affords the new heteroleptic complex [(HL$^n$NH)Pt(acac)], thereby indicating the possibility of binding bioligands by substituting the chloride and/or dmso ligands of [(HL$^n$NH)Pt(dmso)Cl]. The crystal structure of [(HL$^n$NH)Pt(acac)] exhibits a stacked

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

arrangement with weak intermolecular interactions. Interestingly, the delocalized diazoketiminato chelates [(HL″NH)Pt(dmso)Cl] and [(HL″NH)Pt(acac)] exhibit reversible one-electron reductions in their cyclic voltammograms. This electron-transfer property has been attributed to a ligand-centered reversible azo (–N=N–) reduction by EHMO calculations. The results of an in vitro study of the cytotoxicity of [(HL$^1$NH)Pt(dmso)Cl] against the HeLa cell line are interesting in terms of dose dependence and apoptotic pattern of cell death. Further biological experiments are underway to compare the relative activities with cisplatin.

## Experimental Section

**Materials:** The solvents used in the reactions were of reagent grade (E. Merck, Kolkata, India) and were purified and dried by reported procedures.[14] Platinum chloride, dimethyl sulfoxide, and acetylacetone were purchased from the same company. Potassium tetrachloroplatinate and sodium tetrachloropalladate were prepared by a reported procedure. Trypan blue, propidium iodide, and Annexin V-FITC were obtained from Aldrich. HeLa cells were collected from NCCS, Pune, India. The ligands 2-(phenylazo)aniline (HL$^1$NH$_2$), 2-(*p*-tolylazo)aniline (HL$^2$NH$_2$), and 2-(*p*-chlorophenylazo)aniline (HL$^3$NH$_2$) were prepared following the reported procedures.[14,15,18]

**Physical Measurements:** Microanalysis (C,H,N) was performed using a Perkin–Elmer 240C elemental analyzer. Infrared spectra were recorded with a Perkin–Elmer L120-00A FT-IR spectrometer with the samples prepared as KBr pellets. Electronic spectra were recorded with a Shimadzu UV- 2401 PC spectrophotometer. $^1$H NMR spectra were obtained with Bruker 500 RPX and Bruker 300 DPX spectrometers in $CDCl_3$ using TMS as the internal standard. Electrochemical measurements were performed using a PAR Versastat II potentiostat with a platinum disk working electrode, a platinum wire auxiliary electrode, and an aqueous saturated calomel electrode (SCE) as reference, (0.1 M) $Bu_4NClO_4$ as supporting electrolyte, in acetonitrile. Electrochemical measurements were carried out under a dinitrogen atmosphere at 298 K and were uncorrected for junction potentials. Cytotoxicity was measured with a Fluorescence Microscope (Olympus BX40, Tokyo, Japan), FACS Calibur (BD Biosciences) and the Cell Quest (Bekton Dickinson) software package.

**Synthesis of [(HL$^1$NH)Pt(dmso)Cl]:** A solution of 2-(phenylazo)-aniline (HL$^1$NH$_2$; 100 mg, 0.5 mmol) in 5 mL of dmso was added to a solution of $K_2PtCl_4$ (207 mg, 0.5 mmol) in 5 mL of the same solvent. The mixture was stirred for 5 h at 60 °C and a dark pink solid was obtained upon evaporation of dmso. Pure [(HL$^1$NH)-Pt(dmso)Cl] was obtained from the pink solid by chromatography on a silica gel (60–120 mesh) column with toluene as the eluent. Solid [(HL$^1$NH)Pt(dmso)Cl] was obtained by evaporating the eluent. Yield: 115.25 mg (45%). $C_{14}H_{16}ClN_3OPtS$ (504.9): calcd. C 33.25, H 3.18, N 8.34; found C 33.27, H 3.16, N 8.31.

**[(HL$^2$NH)Pt(dmso)Cl] and [(HL$^3$NH)Pt(dmso)Cl]:** These complexes were prepared following the same procedure as for [(HL$^1$NH)Pt(dmso)Cl] but with HL$^2$NH$_2$ (106 mg, 0.5 mmol) and HL$^3$NH$_2$ (116 mg, 0.5 mmol). Yield: 104.27 mg (40%, for the HL$^2$NH$_2$ complex $C_{15}H_{18}ClN_3OPtS$) and 121.62 mg (45%, for the HL$^3$NH$_2$ complex $C_{14}H_{15}Cl_2N_3OPtS$). $C_{15}H_{18}ClN_3OPtS$ (518.9): calcd. C 34.71, H 3.41, N 8.12; found C 34.68, H 3.46, N 8.09. $C_{14}H_{15}Cl_2N_3OPtS$ (539.4): calcd. C 31.10, H 2.80, N 7.82; found C 31.14, H 2.78, N 7.78.

**[(HL$^1$NH)Pt(acac)]:** [(HL$^1$NH)Pt(dmso)Cl] (50 mg, 0.1 mmol) was dissolved in 40 mL of methanol and acetylacetone (10 mg, 0.38 mmol) was added. The mixture was then heated to reflux for 4 h to afford a blue solution. Evaporation of the solvent gave a dark blue residue, which was purified by chromatography on a silica gel (60–120 mesh) column with toluene as eluent. Evaporation of the solvent gave [(HL$^1$NH)Pt(acac)] as a dark blue solid. Yield: 32.10 mg (65%). $C_{17}H_{17}N_3O_2Pt$ (490.36): calcd. C 41.55, H 3.48, N 8.53; found C 41.60, H 3.46, N 8.56.

**[(HL$^2$NH)Pt(acac)] and [(HL$^3$NH)Pt(acac)]:** These compounds were prepared following the same procedure as for [(HL$^1$NH)Pt-(acac)] but with [(HL$^2$NH)Pt(dmso)Cl] (52 mg, 0.1 mmol) and [(HL$^3$NH)Pt(dmso)Cl] (54 mg, 0.1 mmol). Yield: 35.05 mg (70%, for the HL$^2$NH complex $C_{18}H_{19}N_3O_2Pt$) and 36.24 mg (70%, for the HL$^3$NH complex $C_{17}H_{16}ClN_3O_2Pt$).
$C_{18}H_{19}N_3O_2Pt$ (504.36): calcd. C 42.85, H 3.79, N 8.29; found C 42.82, H 3.76, N 8.32.
$C_{17}H_{16}ClN_3O_2Pt$ (524.86): calcd. C 38.83, H 3.08, N 8.05; found C 38.86, H 3.04, N 8.00.

**[(HL$^1$NH)PdCl]$_2$:** A solution of HL$^1$NH$_2$ (100 mg, 0.5 mmol) in 5 mL of dmso was added to a solution of $Na_2PdCl_4$ (150 mg, 0.5 mmol) in 5 mL of dmso. The mixture was stirred for 4 h at 60 °C and a dark pink solid was obtained upon evaporation of dmso. Pure [{(HL$^1$NH)PdCl}$_2$]was obtained from the pink solid by chromatography on a silica gel (60–120 mesh) column with toluene as the eluent. Solid [{(HL$^1$NH)PdCl}$_2$] was obtained upon evaporation of the eluent. Yield: 188.80 mg (55%). $C_{24}H_{20}Cl_2N_6Pd_2$ (1352.5): calcd. C 42.59, H 2.95, N 12.42; found C 42.54, H 3.01, N 12.38.

**Reaction of HL$^1$NHCH$_2$Ph with Na$_2$PdCl$_4$:** A solution of HL$^1$NHCH$_2$Ph (110 mg, 0.52 mmol) in 5 mL of dmso was added to a solution of $Na_2PdCl_4$ (150 mg, 0.52 mmol) in 5 mL of dmso. The mixture was stirred for 4 h at 60 °C and a dark brown solid was obtained upon evaporation of dmso. Pure [(HL$^1$NHCH$_2$Ph)-PdCl] was obtained from the brown solid by chromatography on a silica gel (60–120 mesh) column with a toluene/acetonitrile mixture (90:10 v/v) as eluent. Solid [(L$^1$NHCH$_2$Ph)PdCl] was obtained upon evaporation of the eluent. Yield: 119.99 (55%).

**Reaction of HL$^1$NHCH$_2$Ph with K$_2$PtCl$_4$:** A solution of HL$^1$NHCH$_2$Ph (110 mg, 0.52 mmol) in 5 mL of dmso was added to a solution of $K_2PtCl_4$ (215 mg, 0.52 mmol) in 5 mL of dmso. The mixture was stirred for 5 h at 60 °C and a dark pink solid was obtained upon evaporation of dmso. Pure [(HL$^1$NH)Pt(dmso)Cl] was isolated by chromatography on a silica gel (60–120 mesh) column with toluene as the eluent. Solid [(HL$^1$NH)Pt(dmso)Cl] was obtained upon evaporation of the eluent. Yield: 130.76 mg (50%).

**Viability Assay. Trypan Blue Exclusion Test:** HeLa cells were treated with 4, 8, 12, and 16 μM solutions of complex in dmso.[28] The cells (10 μL suspension) were then placed on cover slips at the required dilution and each cover slip was placed cell-side down onto a slide containing a drop of 0.125% Trypan Blue dye (wt/vol in sterile isotonic saline). The excess dye solution was removed by applying gentle pressure with gauze at the edges of the cover slip. The slides were viewed within ten minutes with a light microscope at a magnification of 40× and 50–100 cells counted. Viable cells remained unstained, while the nuclei of nonviable cells were stained blue.

**Differentiation Between Apoptosis and Necrosis by FACS:** To distinguish between apoptosis and necrosis treated or untreated cells ($1 \times 10^6$ in each case) were harvested, in a double labeling system, and PI and Annexin V Fluos (Boehringer Mannheim) added directly to the culture medium or to the cell suspension. The mixture

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = \Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]^{1/2}$ where $w = 1/\sigma^2(F_o^2) + (aP)^2 + bP$, $P = (F_o^2 + 2F_c^2)/3$. [c] GOF = $\Sigma[w(F_o^2 - F_c^2)^2]/(n - p)]^{1/2}$.

was then incubated for 15 min at 37 °C. Excess PI and Annexin V Fluos were washed off, and the cells were fixed and then analyzed with a FACS Calibur apparatus [quipped with a 488-nm argon laser light source, a 515-nm band pass filter (FL1-H), and a 623-nm band pass filter (FL2-H)] using the CellQuest program (Becton Dickinson). Electronic compensation of the instrument was done to exclude overlapping of the emission spectra. A total of 10,000 events were acquired, the cells were properly gated, and a dual parameter dot plot of FL1-H ($x$-axis; Fluos fluorescence) vs. FL2-H ($y$-axis; PI fluorescence) was produced in logarithmic fluorescence intensity.[29]

**X-ray Crystallography:** Crystals of [(HL$^1$NH)Pt(dmso)Cl], [(HL$^3$NH)Pt(acac)], and [{(HL$^1$NH)PdCl}$_2$] were grown by diffusion of hexane into a dichloromethane solution at 298 K. Data were collected with a Bruker SMART CCD diffractometer using Mo-$K_\alpha$-monochromated radiation ($\lambda$ = 0.71043 Å). Structure solutions were performed using the Shelx 97 program (PC version). Full-matrix least-squares and anisotropic refinements were performed on all the atoms. Hydrogen atoms were included at their calculated positions. The data collection parameters and relevant crystal data are collected in Table 4.

CCDC-283817 for [(HL$^1$NH)Pt(dmso)Cl], -283818 for [(HL$^3$NH)-Pt(acac)], and -283819 for [{(HL$^1$NH)PdCl}$_2$] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Figure S1 shows the EHMO diagrams for [(HL$^3$NH)-Pt(acac)]. Figures S2–S8 show the IR spectra and Figures S9–S15 the $^1$H NMR spectra of all the complexes; Figure S16 shows the cyclic voltammogram of [(HL$^1$NH)Pt(acac)].

## Acknowledgments

We are thankful to the Department of Science and Technology (DST), New Delhi for funding and a fellowship to J. P. under the DST-SERC project (no. SR/S1/IC-09/2003). We are also thankful to the Council of Scientific and Industrial Research for funding. The necessary laboratory and infrastructural facilities were provided by the Department of Chemistry, University of Kalyani. The support of DST under the FIST program to the Department of Chemistry, University of Kalyani is acknowledged. We acknowledge Prof. Jui-Hsien Huang, National Changhua University of Education, Changhua, Taiwan for performing the X-ray studies of [(HL$^3$NH)Pt(acac)].

# *N*-(2,4,6-Trimethylborazinyl)-Substituted Phosphanes, Arsanes, and Stibanes[‡]

Heinrich Nöth,*[a] Birgit Gemünd,[a] and Robert T. Paine[b]

**Keywords:** Boron / Phosphanes / Arsenic / Antimony

Reaction of the *N*-lithioborazine $LiH_2N_3B_3Me_3{\cdot}OEt_2$ (**2**) in diethyl ether with $PCl_3$ or $PBr_3$ leads to the borazinylphosphanes $(Me_3B_3N_3H_2)PX_2$, $(Me_3B_3N_3H_2)_2PX$ (X = Cl, Br), and $(Me_3B_3N_3H_2)_3P$, depending on the initial stoichiometry. The analogous arsane and stibane derivatives were obtained in a similar manner. While $(Me_3B_3N_3H_2)_2PBr$ is reduced by $LiAlH_4$ in diethyl ether/hexane to give the monophosphane $(Me_3B_3N_3H_2)_2PH$ (**13**), the reaction of $(Me_3B_3N_3H_2)PBr_2$ (**5**) with $LiAlH_4$ in diethyl ether/hexane produces the zwitterionic compound $[Me_3B_3N_2(HN)]^-P^+H_2Et$ (**14**). Dehalogenation of $(Me_3B_3N_3H_2)_2PBr$ (**6**) with Na yields the diphosphane $(Me_3B_3N_3H_2)_2PP(H_2N_3B_3Me_3)_2$ (**18**), while the mixed diphosphane $(Me_3B_3N_3H)_2PPmes_2$ (**17**) is obtained from **6** and $LiPmes_2$. Dehalogenation of $Me_3B_3N_3H_2PBr_2$ with Na results in the exclusive formation of $(Me_3B_3N_3H_2)_4P_4$ (**19**), while the reaction of **5** with $Li_2Pmes$ leads to a mixture of cyclotetraphosphanes $(mes)_{4-n}(Me_3B_3N_3H_2)_nP_4$ (**A**–**F**) along with bicyclic $P_4mes_2$. The new compounds have been characterized by NMR and IR spectroscopy and partly by mass spectrometry. X-ray structures for compounds, **4**, **5**, **6**, **9**, **13**, **14**, **17**, **18**, **19**, and **E** have been determined. All show different B–N bond lengths within the borazine rings, and some have borazine rings in a half-chair conformation.

## Introduction

The deprotonation of borazines $R_3B_3N_3H_3$ by organolithium reagents was first described by Wagner and Bradford,[2] although none of the resulting *N*-lithioborazines were isolated and characterized − their formation was based on the observation that the products reacted with alkyl halides (R′X) to generate borazines of the type $R_3B_3N_3H_{3-n}R'_n$ ($n$ = 1–3), thereby indicating that the lithiation is not specific and yields a mixture of *N*-lithioborazines. Recently, we reported the isolation and structural characterization of ligand-stabilized *N*-monolithioborazines $R_3B_3N_3H_2Li{\cdot}L$ (e.g. R = Me, *i*Pr, *t*Bu, Ph; L = $Et_2O$, thf, tmeda, pmtda).[3,4] These proved to be versatile reagents for the preparation of hitherto unknown borazine derivatives of, for example, B, Al, Ge, or Ti.[5,6] Here, we describe borazinyl-substituted phosphanes, arsanes, and stibanes. Known P-containing borazines are derivatives of phosphorus esters in which either $(RO)_2P(O)_2$ groups are bonded to the B atoms[7] or an $(RO)PO_3$ group connects two borazine units through a B–O–B bond.[8] Other P-containing borazine derivatives include the interesting borazine cations $[Cl_{3-n}B_3(N{=}PPh_3)_3]^{+n}(Cl^-)_n$ ($n$ = 1, 2, 3).[9,10] However, no borazine derivatives have been reported to date where $R_2P$ groups are bonded to either B or N. These may be interesting ligands for transition metal complexes, particularly those which act as catalysts, because they will change the catalytic properties of triarylphosphane-based catalysts. Here, we describe the synthesis, structures, and reactivity of some of the heavier group 15 element 2,4,6-trimethylborazinyl compounds, with an emphasis on phosphane derivatives.

## Results and Discussion

### (2,4,6-Trimethylborazinyl)-halogeno-phosphanes, -arsanes, and -stibanes

#### *Synthesis*

2,4,6-Trimethylborazine (**1**) does not react with $PCl_3$ or $PBr_3$ in the presence of triethylamine to form borazinyl-halogeno-phosphanes $(Me_3B_3N_3H_2)_nPX_{3-n}$ ($n$ = 1, 2, 3; X = Cl, Br) as the ring N atoms are not sufficiently nucleophilic to attack the P atoms of the halogenophosphanes to allow $NEt_3$-assisted HX elimination. This contrasts with the reactivity of dialkylamines with phosphorus halides.[11,12] We therefore studied the reactions of phosphorus trichloride and tribromide, and their arsenic and antimony analogs, with the diethyl ether adduct of 1-lithio-2,4,6-trimethylborazine (**2**) in diethyl ether solution. Depending on the molar ratios employed, we obtained the borazinyldihalogenophosphanes **3** and **5**, as well as the bis(borazinyl)-halogenophosphanes **4** and **6** in acceptable yields (>75%). The tris(borazinyl)phosphane **11** could, however, not be prepared in pure state; it was always slightly contaminated with **4**. The borazinyl-arsanes **7**, **8** and borazinyl-stibanes **9**, **10** were prepared analogously. The formation of

$(Me_3B_3N_3H_2)_3E$ (E = As, Sb) was observed only by NMR spectroscopy, and these compounds could not be isolated in pure state. Compounds **4**, **5**, **6**, and **9** were obtained as single crystals.

### *Spectra*

Table 1 lists the NMR spectroscopic data of compounds **3**–**11**. Each of these compounds is characterized by two $^{11}B$ NMR signals in a 2:1 ratio. The signal at lower field results from the B atoms adjacent to the N1(4) atom(s) carrying the P, As, or Sb atoms (see Figures 1 and 3 for the numbering). The signals at higher field result from the *para* boron atoms B2(5). The shielding is practically unaffected by the number of halogen atoms at P, As, or Sb. The replacement of P by As or Sb leads to an exceptionally small low-field shift of 1–1.5 ppm, which is only a little bit larger for the bromides **5** and **6** (approx. 2.6 ppm). This shows that the charge distribution within the borazine ring is negligibly affected by the *N*-substitution. Even the replacement of the $Li(OEt_2)$ group by $EX_2$ or EX groups has little effect. The $^{11}B$ NMR shift of compound **2**, for example, is $\delta$ = 35.4 ppm[3] and that of the parent borazine **1** is $\delta$ = 32.3 ppm.[13]

There is a $^{31}P$ chemical shift difference of only 8.6 ppm between the borazinyl-chloro-phosphanes **3** and **4**, whereas this difference is 54.7 ppm for **3** and **11**. Similarly, $\Delta\delta^{31}P$ for the bromides **5** and **6** is only 1.5 ppm but 69.0 ppm for **5** and **11**. The corresponding $\Delta\delta^{31}P$ data for the series $Ph_{3-n}PCl_n$ ($n$ = 0, 1, 2) are 64 and 91.2 ppm and in the $(Me_2N)_{3-n}PCl_n$ series they are 6.3 and 37 ppm, respectively.[14] These latter data are similar to those of the borazinyl-chloro-phosphanes.

While the shielding of the boron nuclei is only slightly affected by the $EX_{2-n}$ groups, the methyl protons in the *para* position of the borazine rings show differences of 0.06 and 0.09 ppm for **3** and **4** and for **5** and **6**, respectively, in contrast to a difference of only 0.01 ppm for the *ortho* methyl groups. This trend is also observed for the arsenic and antimony compounds **7**–**10**.

The proton of the *o*-Me groups of compounds **3** to **6** couples with the $^{31}P$ nucleus. The resulting $^4J_{^{31}P,^1H}$ coupling constants cover the range 3.3–5.7 Hz, with those of the dihalides being larger than those of the monohalide species. A similar coupling has been observed in borylamino phosphanes.[15]

Table 2 contains a selection of the typical strong IR bands recorded in Hostaflon/Nujol mulls. There are two $\nu$(NH) bands for compounds **3** and **5**, while three $\nu$(NH) bands are observed for **4** and **6**, although either two or four are to be expected. The two borazinyl groups of **4** and **6** are obviously not equivalent in the solid state. All of these bands are comparatively sharp, and the bands at highest

wavenumbers are almost the same for all four compounds, whereas the others are lower for the bromides than for the chlorides. BN ring vibrations are found in the regions from 1500 to 1490 $cm^{-1}$ and 1430 to 1380 $cm^{-1}$ as strong bands. Those of the chlorides are observed at somewhat higher wavenumbers than those of the bromides, which suggests an inductive effect of the halides. Only one $\nu$(PN) band is observed for compounds **3** and **5**. As expected, there are two $PN_2$ bands ($\nu_{sym}PN_2$ and $\nu_{asym}PN_2$) for compounds **4** and **6** and their values suggest that the PN bonds of the chlorides are stronger than those of the bromides. This conclusion is also supported by the PN bonds lengths of these compounds (see below).

### *X-ray Structures*

Single crystals suitable for X-ray structure determinations were obtained for compounds **4**, **5**, **6**, and **9**. The dibromoborazinylphosphane **5** crystallizes in the orthorhombic space group *Pnma* with $Z = 8$, which means that there are two independent molecules in the unit cell (see Figure 1a). As expected, the structural parameters of the two molecules do not differ much, but they are nevertheless significantly different (see Table 3). Both molecules show $C_s$ symmetry, with the P, N, B, C, and some of the H atoms occupying special positions on a mirror plane. The symmetry-related bromine atoms are perpendicularly oriented with respect to the ring plane.

The P1–N1–B3 and P2–N4–B4 angles [119.8(6)° and 112.7(5)°, respectively] of compound **5** demonstrate that the $PBr_2$ groups lie closer to atoms C3 and C6, respectively. The P–N bond lengths of molecules **5A** and **5B** are equal within standard deviations. The B–N bond lengths of the borazine units show distortions relative to the parent molecule $Me_3B_3N_3H_3$.[16] For example, the P substituent induces a significant B–N bond lengthening for the B–N bonds involving the P-bonded atoms N1 and N4. The remaining B–N bonds are shorter than those observed for borazines of the type $(RB{=}NH)_3$ (1.42–1.44 Å).[17] The B–N–B angles at atoms N1 and N4 [119.8(6)° and 118.6(6)°, respectively] are more acute than all other B–N–B bond angles [125.5(6)–126.7(6)°] while all N–B–N bond angles are smaller than 120° (by an average of 4°).

Figure 1 (b) shows a plot of the packing of the two independent molecules in the unit cell. This packing leads to an identical orientation of the bromine atoms of **5A** and **5B** in the stacks of packed borazine rings along the *b*-axis. These stacks are formed by alternating **5A** and **5B** molecules. The closest interatomic distances between the stacks are: B4–B3A = 3.971, B6A–B2A = 3.802, N5A–N3A = 3.940, and N2A–N6A = 3.714 Å. This leads to an average centroid–centroid distance of 3.87 Å, which is larger than the distance between the BN planes of hexagonal boron nitride (3.33 Å). There are no NH···Br interactions and no close Br···Br contacts.

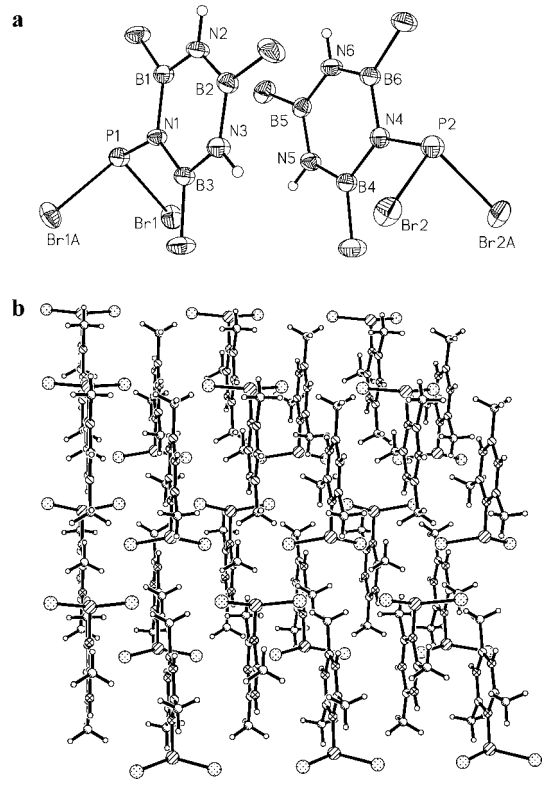

Figure 1. (a) Molecular structure of compound **5** showing the two independent molecules **5A** (left) and **5B** (right). CH hydrogen atoms have been omitted for clarity. The bonding parameters are listed in Table 3. (b) Packing of molecules **5A** and **5B**. These molecules are arranged in strings of alternating **5A** and **5B**.

The structure of **5** can best be compared with that of the dichlorostibane **9**, which crystallizes in the monoclinic system, space group $P2_1/n$, also with $Z = 8$. Relevant structural parameters are summarized in Table 3. The B–N bonds to the Sb-substituted atoms N1 and N4 are significantly longer than all other B–N bonds in the ring, and the B–N(1,4)–B bond angles are smaller (av. 120.95°) than all other B–N–B bond angles (av. 125.6°). The Cl–Sb–Cl bond angles of the two independent molecules differ by 4°, but the two pairs of Cl–Sb–N bond angles differ only by 2.7°.

The packing diagram of the molecules is depicted in part b of Figure 2, which reveals that the molecules are stacked on top of each other with the $SbCl_2$ groups oriented in opposite directions. The planar borazine rings are twisted against each other by 7° and are arranged perpendicularly to the respective $SbCl_2$ planes. Although the orientation of the Sb atoms with respect to the neighboring molecules suggests a higher coordination number than 3, the shortest intermolecular Sb–N distance is 3.693 Å, which is too long to be considered as a weak bond (sum of van der Waals radii: 3.8 Å). Even the intermolecular Sb–Cl interaction is weak because the respective Sb–Cl distance (3.310 Å) is only 0.05 Å shorter than the sum of the van der Waals radii.

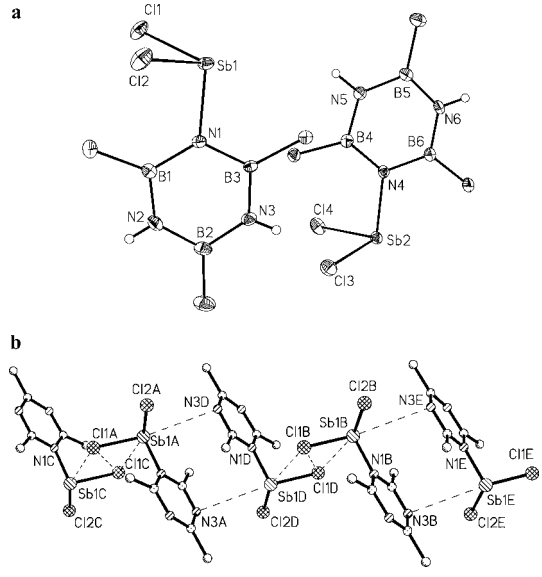

Figure 2. (a) The molecular structure of the two independent molecules in $(Me_3B_3N_3H_2)SbCl_2$ (**9**). Selected bonding parameters are listed in Table 3. CH hydrogen atoms have been omitted. (b) Interaction of one of the two independent molecules of **9**. Dotted lines represent the closests intermolecular interactions.

Figure 3 depicts the molecular structure of the bis(borazinyl)chlorophosphane **4**. This compound crystallizes with two molecules of toluene,[18] which are site disordered. The triclinic space group is $P\bar{1}$ with $Z = 2$. Relevant structural parameters are summarized in Table 4 together with the data for the corresponding bromide **6** (Figure 4). The configuration at the P atom is pyramidal (sum of bond angles: 303.5°). This represents partial $sp^3$ hybridization similar to that found in triaminophosphanes.[19] The P–Cl bond length [2.307(1) Å] of **4** is longer than that in $PCl_3$ [2.02(2) Å][20] and is also significantly longer than in most aminochlorophosphanes (2.109–2.197 Å).[21] The largest angle at the P1 atom is N1–P1–N4 (106.7°), while the angles N1–P1–Cl1 and N4–P1–Cl1 are only 100.3(1)° and 96.4(1)°, respectively. The opening of the N1–P1–N4 bond angle is most likely due to the steric demand of the trimethylborazinyl groups. The rings of these groups are not planar, as shown by the position of the atoms N1 and N4, which are bent out of the ring plane by 17° and 7°, respectively. The consequence of this ring distortion is that the methyl groups are also bent away from the ring plane in the opposite direction of the N1(4) atoms. Atoms C1 and C3 are more strongly affected, as shown by the value of 10° for

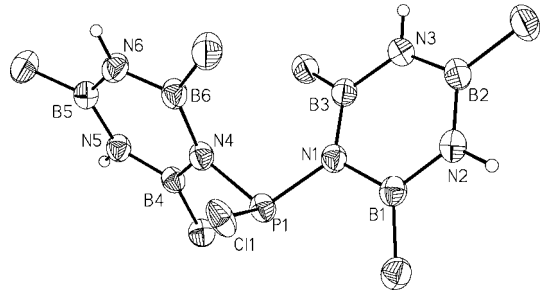

Figure 3. The molecular structure of compound $(Me_3P_3N_3H_2)_2PCl$ (**4**). Hydrogen atoms and the disordered toluene molecule have been omitted. See Table 4 for selected molecular parameters.

C1 and 13° for C3 (C4 and C6 are displaced only by 5° and 9°, respectively). Nevertheless, the sum of the bond angles at atoms N1 and N4 is 360°. It is also worthy to note that the B1–N1–P1 bond angle is 114.5(3)°, which contrasts with the value of 126.2° for the angle B3–N1–P1 [similarly B4–N3–P1 = 113.6(3)° and B6–N4–P1 = 125.7(3)°].

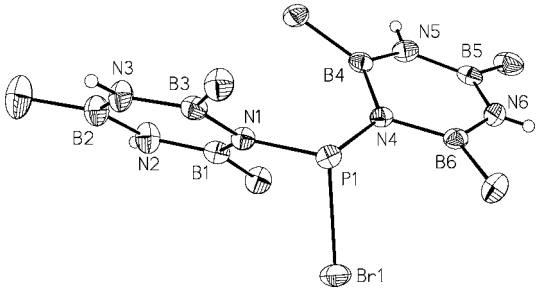

Figure 4. ORTEP plot of the molecular structure of $(Me_3B_3N_3H_2)_2$-PBr (**6**). Selected bonding parameters are listed in Table 4. CH hydrogen atoms have been omitted.

Amongst the B–N–B bond angles, those at atoms N1 and N4 are almost identical [119.1(4)° and 120.6(4)°, respectively]. The N–B–N bond angles to the B atoms opposite to N1 and N4 are only 114.7(4)° and 114.5(4)°, respectively, and are thus the smallest N–B–N bond angles of the two borazine moieties. In contrast, the B1–N2–B2 and B4–N5–B5 angles are quite wide [125.9(4)°]. The two borazine rings are twisted against each other by 56.6°.

Compound **6** crystallizes free of solvent molecules in the orthorhombic system, space group *Pbca*, with $Z = 8$. It is thus not isomorphous with **4** although the structural parameters of its trimethylborazinyl units are similar to those of **4**. This can readily be seen by comparing the data in Table 4. The sum of bond angles at the P1 atom is 306.4°, and, in analogy to **4**, the largest angle at the P atom is 106.2(1)° for N1–P1–N4.

The two borazine rings are twisted against each other by 51°. One of the borazine rings (N1 to B3) is planar, and the P1 atom is coplanar with this ring. The other borazine ring (N4 to B6) shows a half-chair conformation, with the plane B3–N4–B6 forming an angle of 15.9° with the B3–N5–B5–N6–B6 plane. Atoms C4 and C6 are placed below the plane of these five atoms. As observed in **4**, the N5–B4 and N6–B6 bonds are no longer parallel to one another, as would be expected for a planar borazine moiety, but are twisted against each other by 5°. This results in torsion angles of 7° for C6–B6–N5–P1 and 14° for C4–B4–N4–P1.

Once again, the B–N bonds to atoms N1 and N4 are longer [1.475(5) and 1.469(5)°] than all other B–N bonds in the rings. The shortest B–N bonds are B1–N2, B3–N3, B4–N5, and B6–N6, while those to the *p*-B atoms correspond best with those of symmetrically substituted borazines [1.418(6) Å].[17] The N–B–N bond angles vary from 113.9° to 115.8(3)°. While the bond angles B–N(1,4)–B are close to 120°, all other B–N–B bond angles are on average 126.7°. The P–Br bond length is 2.333(1) Å, which is 0.07 Å longer than in the dibromophosphane **5**.

### Reactions of the Bromo(trimethylborazinyl)phosphanes with Lithium Tetrahydridoaluminate

The reaction of the bromides **5** and **6** with $LiAlH_4$ should allow the synthesis of the corresponding phosphanes, $(Me_3B_3N_3H_2)PH_2$ and $(Me_3B_3N_3H_2)_2PH$, as shown in Equations (3) and (4), although it is known that aminophosphanes $(R_2N)_{2-n}PH_{n+1}$ are prone to undergo amine elimination.[22]

As shown in Equation (4), the reaction of **6** with $LiAlH_4$ in diethyl ether/hexane gives the compound bis(trimethylborazinyl)phosphane (**13**) in 75% yield. In contrast, the expected reaction [Equation (3)] between the dibromophosphane **5** and $LiAlH_4$ in the same solvents takes a different course. Thus, after removing the solid formed, the filtrate was found to be free of bromide. The crystals that separated from the concentrated filtrate within a week were found to exhibit three $^{11}B$ NMR signals at $\delta$ = 34.1, 35.3, and 36.8 ppm (in a ratio of about 1:1:1) but only a single $^{31}P$ NMR signal as a triplet at $\delta$ = 6.5 ppm ($^1J_{^{31}P,^1H}$ = 430 Hz) when dissolved in $C_6D_6$ (Figure 5, a). These data give evidence for the presence of a phosphonium $R(X)PH_2^+$ unit, and this was confirmed by the $^1H$ NMR spectrum, which shows two doublets (see Figure 5, b).

The signal of one of the doublets is further split into a triplet, while the other doublet is split into a quartet (see Figure 5, b). This gives convincing evidence that an ethyl group is attached to the P atom and that the solid is definitely not compound **12**, as would be expected from Equation (3). At this stage we assumed that the compound was most likely the zwitterionic phosphonium borazinate **14**. The $^1J_{^{31}P,^1H}$ coupling constant for the doublet of quartets is 380 Hz, while the $^1J_{^{31}P,^1H}$ coupling constant of the doublet of triplets is 370 Hz. Each of these resonances displays a further coupling of 7 Hz corresponding to $^3J_{^1H,^1H}$. Neither

**14**

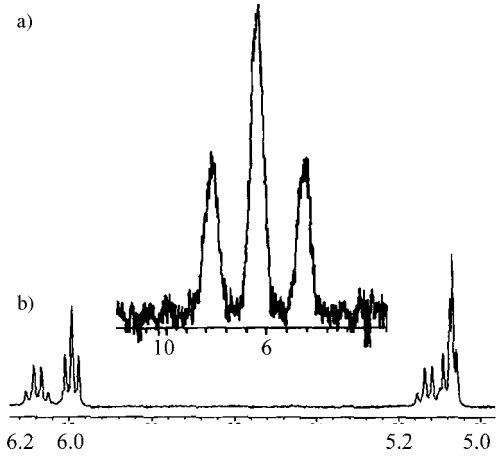

Figure 5. (a) $^{31}P$ NMR spectrum of **14**. (b) $^{1}H$ NMR spectrum of **14**.

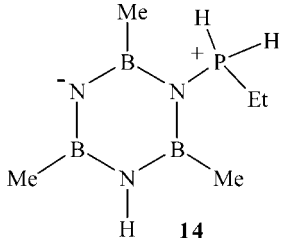
of the signals shows a roof effect. This assignment was verified by recording a two dimensional $^{1}H$-$^{31}P$ spectrum.[5] The structure of **14** was finally confirmed by an X-ray structure determination. The $^{11}B$ NMR spectrum, with its three $^{11}B$ NMR signals, is also in line with these arguments.



**14**

It is clear that the formation of **14** requires a number of steps. One hypothesis for its formation is summarized in Equations (5) to (8). The crucial step here is the formation of EtBr by an ether cleavage with $AlBr_3$, which is a well known process. EtBr is needed to form the phosphonium salt shown in Equation (7), which is the logical precursor to compound **14**. This reaction sequence is unique as no zwitterionic borazine is yet known and nor is a noncoordinated singly deprotonated borazine ring.

### *X-ray Structures*

The monophosphane **13** crystallizes from hexane as colorless needles (orthorhombic, space group *Pbca* with $Z = 8$). Its molecular structure is shown in Figure 6 and structural parameters are listed in Table 5. Its P–N bonds are significantly longer than those in compounds **4**, **5**, and **6**. The sum of bond angles at the P1 atom is 311°, which is a few degrees larger than in any of the borazinylphosphanes described previously. This results primarily from an N1–P1–H bond angle of 102.5(9)°. On the other hand, the N1–P1–N4 bond angle is 105.7(1)°, which corresponds with those found in **4** and **6**. The angles at the P1 atom are, in general, smaller than those found for aminophosphanes.[19]

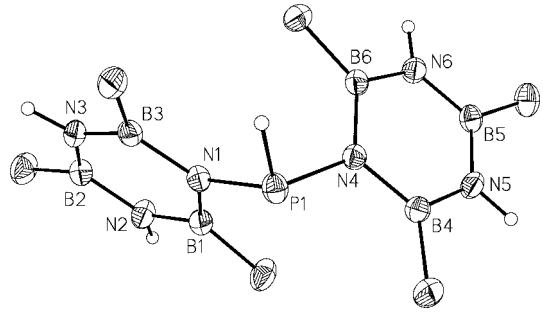


Figure 6. Molecular structure of the phosphane derivative **13**. Selected bonding parameters are listed in Table 5. CH hydrogen atoms have been omitted.

The two borazine units of **13** are almost planar and are twisted against each other by 84°, an angle that is significantly larger than in **4** or **6**, where the angle between the planes B1–N1–B3 and B1–B2–B3 is 5.2° and 8.0°, respectively. The exocyclic angles at N1 are 119.0(2)° for B1–N1–P1 and 120.0(2)° for B3–N1–P1, while the P1–N1–B2–C2 torsion angle is 177°. The B4–N4–P1 and B6–N4–P1 angles are 118.2(2)° and 121.7(2)°, respectively, whereas the P1–

N4–B5–C5 torsion angle is only 33°, which deviates significantly from the corresponding P1–N1–B2–C2 torsion angle. Once again, the B–N bonds to N1 and N4 are longer [1.452(4), 1.464(4), 1.454(4), and 1.460(4) Å] than all other B–N bonds (av. 1.43 Å).

Compound **14** crystallizes in the orthorhombic space group $Pca2_1$ with $Z = 8$. Its molecular structure, depicted in Figure 7, demonstrates the presence of a phosphonium group. The bond angles at the P1 atom range from 102.6(4)° (N1–P1–H2) to 114.53(9)° (N1–P1–C4). The two P–H bonds seem to be significantly different [1.32(4) and 1.23(4) Å] and the bond angle between them is 103.4°. The P–C bond [1.930(3) Å] is much longer than in other organophosphonium salts [d(PC) = 1.674 to 1.849 Å],[23] and this bond is still 0.1 Å longer than the "normal" P–C single bond length when an electronegativity correction is applied.[24]

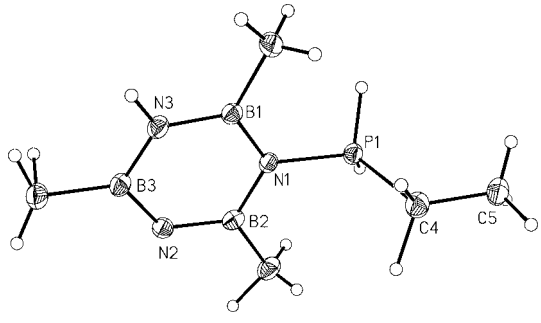

Figure 7. ORTEP plot of the molecular structure of the zwitterion **14**. Selected bonding parameters are listed in Table 5.

The borazine ring of **14** is planar and large B–N–B bond angles at atoms N2 and N3 [125.0(2)° and 125.3(2)°, respectively] are once again observed; the B1–N1–B2 bond angle is 121.3(2)°. The B1–N1–P1 and B2–N1–P1 bond angles are smaller than 120° [119.5(2)° and 119.0(2)°, respectively], and the N–B–N bond angles are also acute [114.9(2)–116.5(2)°]. Equivalent pairs of B–N bond lengths range from 1.462(3) and 1.459(3) Å (to N1) and include short [B1–N2 = 1.413(3), B3–N3 = 1.421(3) Å] and intermediate bond lengths [N2–B2 = 1.439(3), N3–B2 = 1.428(3) Å].

The difference Fourier analysis for NH hydrogen atoms revealed weak peaks on atoms N2 and N3. They refined best with a site occupation factor (SOF) of 0.5 as the $U_i$ values were not compatible with an SOF of 1. Figure 7 shows only one occupied NH position. The X-ray structure analysis excludes an Et/Me exchange between the P atom and a B atom.

### Trimethylborazinyldiphosphanes and Cyclotetraphosphanes

The trimethylborazinyl-halogeno-phosphanes appeared to be precursors for borazinyldiphosphanes and cyclophosphanes because it is well known that the dehalogenation of di- and monoorgano-halogeno-phosphanes leads to diphosphanes $P_2R_4$ and cyclophosphanes $(RP)_n$, respectively. Diphosphanes can also be prepared by the reaction of $R_2PX$ with $Me_3SiPR_2$. However, no reaction was observed on treating the bromide **6** with $Me_3SiPR_2$ [Equation (9)] even at reflux in toluene.

After replacement of $Me_3SiPR_2$ with $LiPmes_2$, however, good yields of the diphosphane **17** were obtained [Equation (10)]. The analogous reaction with $LiPPh_2$ generated **16**, although it could not be completely separated from accompanying $Ph_2PPPh_2$.

As the reaction shown in Equation (11) proceeded without problems, we also decided to treat the dibromide **5** with sodium in toluene. This reaction gave exclusively tetrakis(trimethylborazinyl)cyclotetraphosphane (**19**), as shown in Equation (12). This compound crystallized as strongly intergrown needles, which were also obtained by treating **5** with activated Mg or sodium naphthalide in thf.

While the crystal quality of **16** was insufficient for an X-ray structure determination, single crystals of **17** and **18** were obtained. However, those of **17** were quite small and did not diffract too well. Nevertheless, the refinement converged at $R_1 = 6.5\%$.

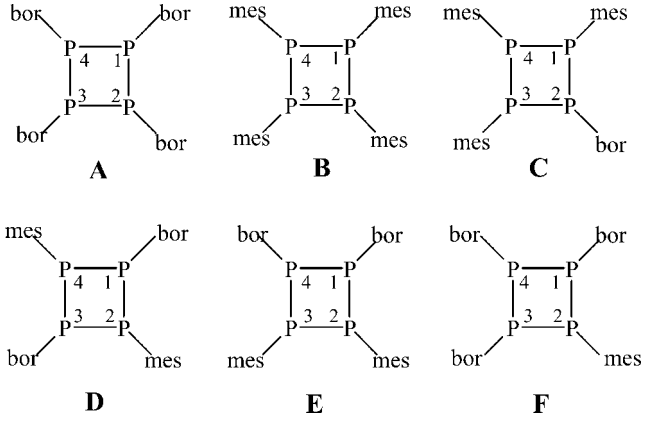
$$2\,(Me_3B_3N_3I_2)PBr_2 + 2\,Li_2Pmes \rightarrow (Me_3B_3N_3I_2)_2P_4(mes)_2 + 4\,LiBr \quad (13)$$

**A** – **E**

We expected that the reaction of **5** with $Li_2Pmes$ might yield the 2,4-bis(mesityl)-1,3-bis(trimethylborazinyl)cyclotetraphosphane **D**. However, the $^{31}P$ NMR spectroscopic data of the solution showed that this ideal composition is not achieved. Rather, a mixture of the cyclotetraphosphanes **A**–**F** (Scheme 1) is formed, with no evidence for cyclotriphosphanes or cyclopentaphosphanes. Isolated single crystals turned out to be the isomer 2,3-bis(mesityl)-1,4-bis(trimethylborazinyl)cyclotetraphosphane (**E**).



Scheme 1. Isomers of dimesitylbis(trimethylborazinyl)cyclotetraphosphane.

### *NMR Spectra*

Table 6 lists the chemical shifts and coupling constants of the nuclei $^1H$, $^{11}B$, and $^{31}P$ for the diphosphane derivatives. Surprisingly, both diphosphanes **17** and **18** show only a single but very broad $^{11}B$ resonance, which contrasts with the borazinyl-halogeno-phosphanes. As expected, **18** exhibits a single $^{31}P$ resonance signal at $\delta$ = 108.7 ppm, while there are two doublets at $\delta$ = 113.9 and –20.6 ppm for **17**, with a $^1J_{^{31}P,^{31}P}$ coupling constant of 223 Hz. Thus, the mesityl-bonded P nuclei are much better shielded than the P nuclei bearing borazine rings. Two sets of proton signals are observed for the BMe groups in **17** and **18**, with those of the *o*-BMe protons being better shielded than the *p*-BMe protons. The former appear as doublets due to $^4J_{^{31}P,^1H}$ coupling, whereas no such coupling is observed for the *o*-Me groups of the mesityl substituents.

The NMR spectra of compound **19** are rather simple, with only one signal appearing in each of the $^{11}B$ and $^{31}P$ NMR spectra. The $^{11}B$ NMR signal is rather broad. Since there are also single sets of $^1H$ NMR signals for the *o*-BMe and *p*-BMe groups, this suggests that the compound has an all-*trans* conformation. The *o*-BMe protons appear as doublets with a $^4J_{^{31}P,^1H}$ coupling constant of 5.2 Hz. These data also demonstrate that no cyclotriphosphane or cyclopentaphosphane is generated upon dehalogenation of **5**.

In contrast, the NMR spectra of the solution obtained by treating **5** with $Li_2Pmes$ are surprisingly complex. There are many $^{31}P$ NMR signals in the range from $\delta$ = –60 to –300 ppm, which indicates the presence of cyclotetraphosphanes. Most of these signals could be assigned. Thus, the weak triplets at $\delta$ = –171.2 and –299.0 ppm are due to the presence of *cis*-bis(mesityl)bicyclo[1.1.0]tetraphosphane,[24] which is also present as its *trans*-isomer ($\delta$ = –292.2 ppm (dd) and two triplets at $\delta$ = –155.7 and –161.2 ppm).[24]

Fractional crystallization provided crystals of the isomer **E**. A solution of these crystals shows a single but rather broad $^{11}B$ NMR signal with $h_{1/2}$ = 1300 Hz. This may well result from two overlapping $^{11}B$ signals because the $^{1}H$ NMR spectra clearly show the presence of two types of BMe, NH, CMe, and CH signals in the expected intensity ratios. Both the *o*-BMe and *o*-CMe protons appear as doublets due to $^{4}J_{^{31}P,^{1}H}$ coupling.

A two-dimensional $^{31}P$ NMR spectrum[5] and high-resolution $^{31}P$ NMR spectra of the reaction solution give evidence for the presence of all isomers of the cyclotetraphosphanes **A**–**F**. The rings **A** and **B** should lead to an $A_4$ spin system ($^{31}P$ singlet for the all-*trans* conformer). The singlet at $\delta$ = 63.0 ppm demonstrates the presence of isomer **A**, and another singlet at $\delta$ = –43.2 ppm stems from compound **B**. Ring **E** should be represented by an AA′XX′ spin system and should therefore show a higher order spectrum, which, in a first approximation, could appear as a doublet of doublets. This doublet of doublets can indeed be observed at $\delta$ = 60.9 and –49.2 ppm and these signals show additional signals at higher resolution to give a spectrum of higher order. Ring **D** should give a first-order spectrum, as expected for an $A_2X_2$ spin system. This is indeed observed, with two triplets at $\delta$ = 36.9 and –7.8 ppm ($^{1}J_{^{31}P,^{31}P}$ = 170 Hz). The P2 atom of ring **C** should give an $A_2X$ type spectrum, in other words a triplet, which is found at $\delta$ = 77.3 ppm. Another triplet at $\delta$ = 32.5 ppm, with a coupling constant of 232 Hz, can be assigned to the atom P4. Finally, a doublet of doublets is observed at $\delta$ = –26.4 ppm representing atoms P1 and P3. The same signal types should result from the presence of isomer **F**. The respective chemical shifts are: a triplet at $\delta$ = –30.5 ppm for P2, a doublet of doublets at $\delta$ = 41.4 ppm for P1 and P3, and a triplet at $\delta$ = 74.9 ppm for P4. The coupling constant is 168 Hz. Examples of the observed and calculated $^{31}P$ NMR spectra are displayed in Figure 8. The program NUTS[36] was used to obtain the calculated spectra.

The mes and borazinyl substituents (or PX groups) therefore appear to have exchanged during the course of reaction to give a more or less random distribution of the cyclotetraphosphanes.

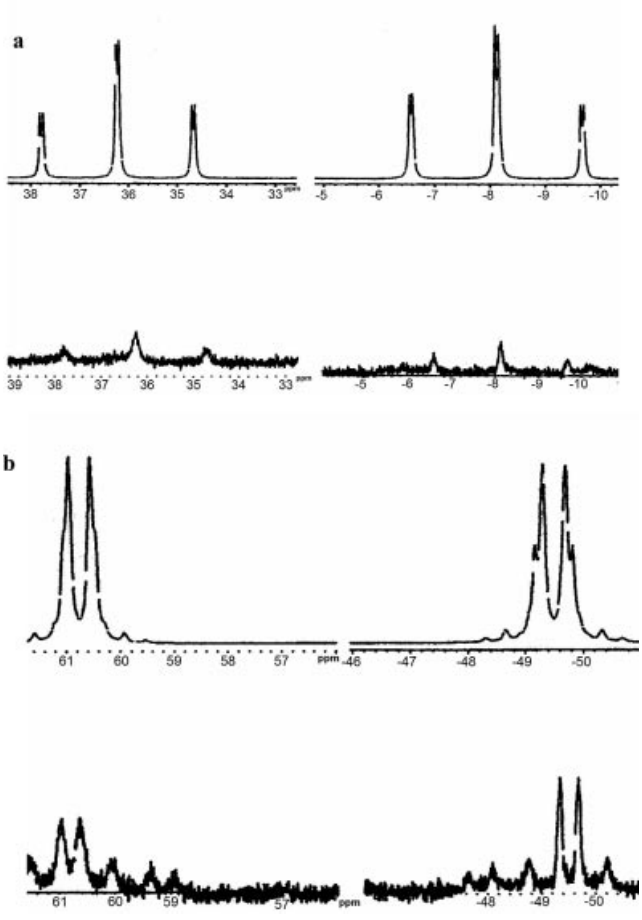

Figure 8. (a) Observed (bottom) and calculated (top) $^{31}P$ NMR spectra for the isomer 1,3-diborazinyl-2,4-dimesitylcyclotetraphosphane. (b) Observed (bottom) and calculated (top) $^{31}P$ NMR spectrum of the isomer 1,2-diborazinyl-3,4-dimesitylcyclotetraphosphane (**E**).

### *X-ray Structures*

The tetrakis(trimethylborazinyl)diphosphane **18** crystallizes from toluene as **18**$(C_6H_5Me)_2$ in the triclinic space group $P\bar{1}$; its molecular structure is depicted in Figure 9 and relevant bonding parameters are listed in Table 7. The borazinyl units in this compound are present in a staggered conformation. The dihedral angles of opposite rings are 164° for both ring pairs while the dihedral angles of adjacent rings differ by 30°. The N4–P1–P2 angle is 108.4(2)° while the N1–P1–P2 angle exceeds this angle by 7.8°. A twist of 32° is found for the borazinyl rings containing N1 and N7, and this value is even larger for N4 and N10 (97°). While the borazine rings containing N1 and N7 are planar, those including atoms N4 and N10 are slightly bent into a half-chair conformation, with N4 bent out of the plane by 11° and N10 by 9.2°. The BMe groups at the *ortho* positions are bent backwards, with the respective NBC angles ranging from 124.3(7)° to 127.4(7)°. Additional bonding parameters are listed in Table 7.

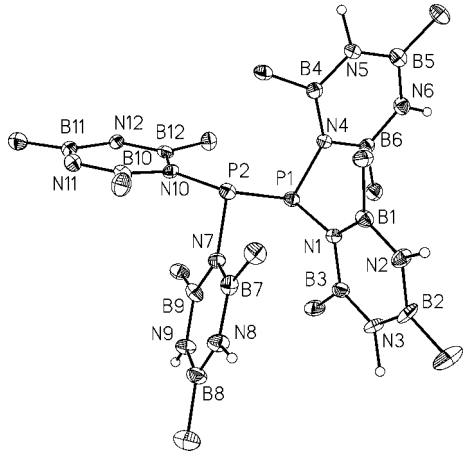

Figure 9. The molecular structure of tetrakis(trimethylborazinyl)diphosphane (**18**). The H atoms of the methyl groups are not shown. Selected bonding parameters are listed in Table 7.

Figure 10 shows the molecular structure of the "mixed" diphosphane **17**, and Table 8 contains its bonding parameters. The P–P bond in **18** [2.287(1) Å] is longer than in **17** [2.268(1) Å], which may be a steric effect because the P–N bond in **18** is about 0.03 Å shorter than in **17**.

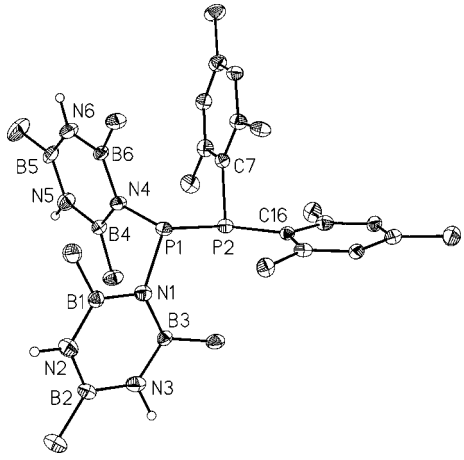

Figure 10. Molecular structure of *P*,*P*-dimesityl-*P'*,*P'*-bis(trimethylborazinyl)diphosphane (**17**). Hydrogen atoms, with the exception of the NH hydrogens, have been omitted. Selected bonding parameters are listed in Table 8.

The first fraction to crystallize from a hexane solution obtained by treating $Me_3B_3N_3H_2PBr_2$ with $Li_2Pmes$ proved to be uniform when inspected by microscopy. The crystals are monoclinic, space group $P\bar{1}$, with $Z = 2$. There is also one molecule of hexane in the unit cell. In a first attempt we solved the structure by assuming that the crystal might have the composition $P_4(H_2N_3B_3Me_3)_4$. The structure solution indeed revealed a cyclotetraphosphane ring, with each of the four P atoms carrying a six-membered ring. The structure refined to $R = 6.6\%$ with attached $B_3N_3$ rings. However, the thermal parameters and bond lengths clearly showed that this assumption was wrong as there are two long P–N bonds and two shorter ones, and the B–C bond lengths are also shorter for those rings with "long" P–N distances. This result suggests that these latter rings are mesityl rings rather than borazines. In this case the R value improved to $R_1 = 5.99\%$. The result of this latter refinement is shown in Figure 11, where it is clear that the crystal contains species **E**. Selected bonding parameters are summarized in Table 9.

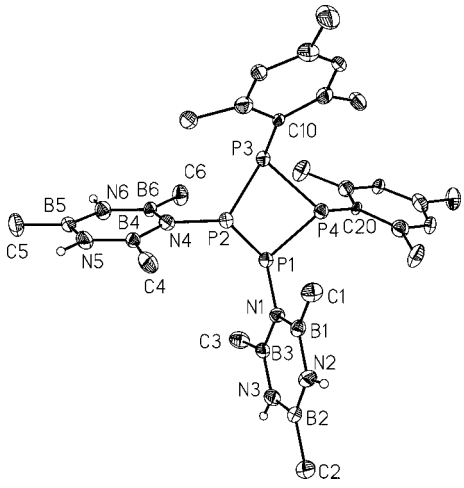

Figure 11. The molecular structure of 3,4-dimesityl-1,2-bis(trimethylborazinyl)cyclotetraphosphane (**E**). Hydrogen atoms at the methyl groups have been omitted. Selected bonding parameters are listed in Table 9.

The cyclotetraphosphane ring is folded, as expected, and it substituents are present in the *trans* orientation that is typical for other $P_4R_4$ rings.[25–28] The rings at atoms P1 and P3 are twisted against each other by 20° while those at atoms P2 and P4 make an angle of 93°. Amongst the P–P bonds, those to atom P4 are significantly longer than those to atom P2. The longer bonds match with those found for tetrakis(2,2,6,6-tetramethylpiperidino)cyclotetraphosphane or diphenylbis(tetramethylpiperidino)cyclotetraphosphane (2.245 Å).[26]

The endocyclic P–P–P angles span the range from 78.99(5)° (P4) to 84.35(5)° (P3) and are compatible with those of other cyclotetraphosphanes.[25–28] The four-membered ring is not uniformly bent, however, as the non-bonding P–P distances are 3.6 Å for P2–P4 and 2.8 Å for P1–P3.

## Discussion and Conclusion

The chemistry of borazines is well documented,[29–31] although neither *B*- nor *N*-phosphanylborazines have been reported. We now show that (2,4,6-trimethylborazinyl)-halogeno-phosphanes are readily available and may serve as starting materials for *N*-(diorganophosphanyl)borazines. *B*-Phosphanylborazines should also be accessible by treating *B*-haloborazines with alkali metal organophosphides.

Because halophosphanes do not react with borazines of the type $R_3B_3N_3H_3$, even in the presence of an HX acceptor, we have used the recently characterized *N*-monolithio-trimethylborazine (**2**) as a stronger nucleophile to bind the borazinyl unit to $P^{III}$, $As^{III}$, and $Sb^{III}$ centers. This gives access to all members of the series $(Me_3B_3N_3H_2)_n$-$EX_{3-n}$ (E = P, As, Sb), although the compounds with $n = 3$ were not obtained in pure state. We have also found that the borazinyl-halogeno-phosphanes are suitable reagents for preparing the corresponding bis(borazinyl)phosphane (**13**) as well as borazinyldiphosphanes or borazinylcyclotetraphosphanes. However, the reaction of $LiAlH_4$ with $Me_3B_3N_3H_2PBr_2$ in hexane/diethyl ether does not provide $Me_3B_3N_3H_2PH_2$; rather, this provides the zwitterionic phosphonium borazinate **14**, which shows that the P atom of $(Me_3B_3N_3H_2)PHEt$ is a stronger basic center than the ring N atoms because one of the NH atoms migrates to the P atom. This generates a new type of borazine derivative.[29–31] We are convinced that the reaction of $LiAlH_4$ with $Me_3B_3N_3H_2PBr_2$ in the absence of diethyl ether will lead to $Me_3B_3N_3H_2PH_2$, whose P atom should be less basic than that of the PHEt group.

The dehalogenation of organohalophosphanes with Na or other metals is often employed as a route to organodiphosphanes or organocyclophosphanes.[32] While the dehalogenation of **6** with Na or Mg produced the corresponding diphosphane derivative **18**, its reaction with $LiPmes_2$ gives access to the mixed substituted diphosphane **17**. However, in the case of $LiPPh_2$ the formation of $P_2Ph_4$ is also

Table 9. Selected bonding parameters for $(Me_3B_3N_3H_2)_2P_4mes_2$ (**E**).[a]

observed along with $(Me_3B_3N_3H_2)_2PPPh_2$ (**16**). This indicates that a Li/Br exchange occurs during the reaction, and this also occurs during the reaction of $Li_2Pmes$ with **4**, as shown by the formation of compounds **A**–**F**, which is also accompanied by the formation of small amounts of bicylo[1.1.0]tetraphosphanes. The tetra(borazinyl)cyclotetraphosphane (**19**) shows only one $^{31}P$ signal ($\delta$ = 63 ppm),which fits nicely with the other $^{31}P$ data recorded for cyclotetraphosphanes of the type $(R_2NP)_4$.[26] As far as we are aware the exchange of organo substituents in organophosphorus chemistry is not common, although the borazinyl group, with its P–N bond, is a species with higher bond polarity and is therefore more likely to be more reactive, similar to the aminophosphanes.

This higher reactivity of the borazinylphosphanes with respect to the *N*-unsubstituted borazines seems to be a consequence of the changes in the structures of the new compounds. As shown by X-ray structure determinations, the P atom induces asymmetry in the borazine ring as shown by the comparatively long B–N bonds to the P-carrying N atom. This weakens the B1–N2 and B3–N4 bonds to the neighboring boron atoms. Atoms B1(3), on the other hand, usually form the shortest B–N bonds to atoms N2(5), while the B–N bonds to B2(5) (*para*-position) show B–N bond lengths that correspond to those found in symmetrically substituted borazines $(RB{=}NH)_3$.[30,31] In contrast, the lithium borazine **2**·$OEt_2$, which is dimeric, shows a different distortion. Here, the bonds N1–B1(3) are the shortest bonds in the borazine ring while the B1–N2 and N3–B3 bonds are the longest.[3] This demonstrates that the P substituents have an opposite effect on the B1(3)–N1 bonds, and therefore on the electron distribution in the P-substituted borazine rings, to the Li atom. Moreover, although most of the borazine rings in the new compounds are planar, several show a semi-chair distortion. The distortion is only weak but is nevertheless significant. We assume that this might be a packing effect. We will report shortly on new boron-, aluminum-, and titanium-substituted borazines, the latter of which show the strongest BN bond differences to date, and we are continuing to explore further aspects of this new field of borazine chemistry.

## Experimental Section

All experiments were performed using inert gas techniques. Solvents were dried by conventional methods and distilled under an $N_2$ atmosphere. Compounds **1** and **2** were prepared as described in the literature,[2] as were $LiPmes_2$, LiPmes, and $LiPPh_2$.[32] All other reagents were commercially available. NMR spectroscopic data were recorded in $C_6D_6$ solutions with TMS (int.), 85% $H_3PO_4$, or $BF_3$·$OEt_2$ (external) as standards with Bruker ACP 200 or Jeol FX 400 instruments. IR spectra were recorded as Nujol/Hostaflon mulls. Mass spectroscopy was performed with a Varian Atlas CH-7 instrument. A Siemens P4 four-circle diffractometer equipped with an area detector and a low temperature device was used for recording X-ray reflection data. Elemental analyses were performed by the analytical laboratory of the department. C/N values often deviate by more than 1%, particularly when the compounds contain aryl groups. This is due to incomplete combustion due to boron carbide or nitride formation or to partial hydrolysis.

**Dichloro(2,4,6-trimethylborazinyl)phosphane (3):** A solution of **2** (0.60 g, 2.96 mmol) in a mixture of hexane (10 mL) and diethyl ether (5 mL) was slowly added to a solution of $PCl_3$ (0.26 mL, 2.96 mmol) in hexane (30 mL). LiCl precipitated rapidly. After stirring overnight the solid was removed by filtration (yield 95% of LiCl) and the solvents were evaporated from the filtrate in vacuo. The oil which remained was distilled at 55 °C/1 Torr to give pure **3**. Yield 0.56 g (85%). $C_3H_{11}B_3Cl_2N_3P$ (223.45): calcd. C 16.12, H 4.96, N 18.80; found C 16.40, H 5.03, N 18.40. IR: $\tilde{\nu}$ = 3428 s, 3377 m, 3243 w, 2960 s, 2491 w, 2293 w, 2227 w, 2190 w, 2000 w, 1955 w, 1898 w, 1499 s, 1402 s, 1321 s, 1295 s, 1179 m, 1147 m, 1083 m, 1040 w, 1006 m, 982 s, 891 s, 811 m, 729 m, 626 w, 587 m, 532 w, 500 m. 459 m, 426 w, 362 w $cm^{-1}$.

**Chlorobis(2,4,6-trimethylborazinyl)phosphane (4):** Prepared in analogy to **3** from $PCl_3$ (0.18 mL, 2.02 mmol) in hexane (30 mL) and **2** (0.82 g, 4.05 mmol) in hexane/diethyl ether (10:5 mL). The filtrate was reduced to a fifth of its original volume in vacuo and then kept at –25 °C. Yellowish crystals of **4** separated within 5 d. After drying they melted at 110 °C (b.p. 140 °C/1 Torr). Yield 0.50 g (80%). $C_6H_{22}B_6ClN_6P$ (309.57): calcd. C 23.28, H 7.16, N 27.15; found C 22.95, H 6.96, N 26.43. IR: $\tilde{\nu}$ = 3441 s, 3411 s, 3402 s, 2988 m, 2956 m, 2941 m, 2911 m, 1487 s, 1435 s, 1396 s, 1302 s, 1285 s, 1193 m, 1176 m, 1159 s, 1145 s, 1080 m, 1010 w, 973 s, 960 s, 891 s, 808 m, 751 m, 735 m, 721 m, 704 m, 640 w, 591 m, 578 m, 566 m, 539 w, 503 w, 493 w, 468 w, 446 w, 431 w, 405 w, 366 w, 320 w, 296 w $cm^{-1}$.

**Dibromo(2,4,6-trimethylborazinyl)phosphane (5):** Prepared in analogy to **3** from $PBr_3$ (0.17 mL, 1.78 mmol) in hexane (30 mL) and **2** (360 mg, 1.78 mmol) in hexane/diethyl ether (10 mL each). LiBr precipitated rapidly and the solution turned yellow. After stirring overnight, filtration and evaporation of the solvents from the filtrate left a yellow oil (b.p. 95 °C/1 Torr). Within a month the liquid turned into yellow needles (m.p. 50 °C). Yield 0.5 g (85%). $C_3H_{11}B_3Br_2N_3P$ (312.35): calcd. C 11.54, H 3.55, N 13.45; found C 11.50, H 3.62, N 13.47. IR: $\tilde{\nu}$ = 3423 s, 3414 s, 2950 m, 2856 w, 2284 w, 2218 w, 1993 w, 1947 w, 1859 w, 1867 w, 1487 s, 1432 s, 1394 s, 1369 m, 1355 m, 1320 m, 1290 s, 1191 s, 1176 s, 1144 s, 1079 s, 975 s, 940 m, 889 s, 809 s, 731 s, 687 s, 569 s, 480 w, 465 w, 436 m, 389 s, 351 s, 286 w, 258 m $cm^{-1}$.

**Bromobis(2,4,6-trimethylborazinyl)phosphane (6):** Prepared in analogy to **4** from $PBr_3$ (0.18 mL, 1.63 mmol) dissolved in hexane (30 mL) and **2** (0.66 g, 3.26 mmol) in hexane/diethyl ether (10 mL each). After stirring overnight the precipitate (LiBr, 90%) was removed by filtration and two thirds of the solvent was removed in vacuo. Colorless crystals of **6** separated from the slightly yellow solution at 5 °C within a week. Yield 0.40 g (80%), m.p. 145 °C. $C_6H_{22}B_6BrN_6P$ (354.03): calcd. C 20.36, H 6.26, N 23.74; found C 19.27, H 6.19, N 23.23. IR: $\tilde{\nu}$ = 3430 s, 3401 s, 3391 s, 3314 m, 3142 m, 2989 s, 2859 m, 2808 m, 2459 w, 2296 w, 2224 w, 1993 w, 1945 w, 1747 w, 1682 w, 1483 s, 1395 s, 1282 s, 1224 m, 1192 m, 1174 m, 1158 s, 1142 s, 1037 w, 1006 w, 962 s, 889 s, 806 m, 759 m, 741 m, 704 m, 624 m, 596 m, 689 m, 567 m, 493 w, 454 w, 439 w, 423 w, 384 w, 362 w, 309 w, 284 w $cm^{-1}$. MS (70 eV): *m*/*z* (%) 354 (20) [$M^+$], 339 (15) [$M^+$ – Me], 309 (10) [$M^+$ – 3Me], 274 (100) [$M^+$ – Br], 259 (55), [$M^+$ – Br – Me], 244 (15) [$M^+$ – Br – 2Me], 121 (20) [$B_3N_3Me_3H_2^+$], 111 (65) [$PBr^+$].

**Dichloro(2,4,6-trimethylborazinyl)arsane (7):** A toluene solution of **2** (0.58 g, 2.86 mmol in 20 mL) was added dropwise to a solution of $AsCl_3$ (0.24 mL, 2.86 mmol) in hexane (30 mL). A white precipitate formed immediately. After stirring overnight the solid was removed

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

by filtration and the solvents evaporated in vacuo. A slightly yellow oil (0.5 g) remained as residue which decomposed on attempted distillation. Yield 500 mg (65%). $^1$H NMR: $\delta$ = 0.15 (s, 3 H, BMe), 0.56 (s, 6 H, BMe), 4.42 ppm (br. s, 2 H, NH). $^{11}$B NMR: $\delta$ = 35.6, 37.9 ppm (1:2).

**Chlorobis(2,4,6-trimethylborazinyl)arsane (8):** Prepared in analogy to **4** from $AsCl_3$ (0.30 mL, 3.58 mmol) in hexane (30 mL) and **2** (1.45 g, 7.16 mmol) in toluene (20 mL). LiCl was recovered in 95% yield. The filtrate was concentrated and the white amorphous precipitate that formed within a week was isolated. Yield 0.9 g (75%), m.p. 64 °C. No single crystals were obtained from toluene, diethyl ether, or thf solutions. $C_6H_{22}AsB_6ClN_6$ (353.49): calcd. C 20.38, H 6.27, N 23.37; found C 20.81, H 6.09, N 22.96. IR: $\tilde{\nu}$ = 3445 m, 3419 s, 3411 s, 2942 s, 2951 s, 2909 s, 2858 m, 1478 s, 1397 s, 1303 s, 1285 s, 1193 m, 1177 m, 1161 m, 1154 m, 1118 w, 1083 m, 1045 w, 1026 w, 920 s, 889 s, 805 m, 753 w, 734 m, 717 s, 573 s, 539 m, 505 w, 485 w, 458 w, 430 w, 416 w, 344 m, 322 w, 288 w, 282 w, 274 w cm$^{-1}$.

**Dichloro(2,4,6-trimethylborazinyl)stibane (9):** Freshly sublimed $SbCl_3$ (0.60 g, 2.62 mmol) was suspended in hexane (30 mL) and a solution of **2** (0.53 g, 1.57 mmol) in hexane (20 mL) was added. After keeping the suspension at reflux overnight the insoluble white material was removed by filtration. The solvent was evaporated from the filtrate in vacuo and the residue dissolved in a small quantity of hexane. Colorless crystals separated from this solution at –5 °C within a week. Yield 0.62 g (75%), m.p. 148–149 °C. $C_3H_{11}B_3Cl_2N_3Sb$ (314.23): calcd. C 11.47, H 3.53, Cl 22.56, N 13.37; found C 12.86, H 3.84, Cl 22.34, N 12.48. IR: $\tilde{\nu}$ = 3448 w, 3421 s, 3406 s, 2964 s, 2964 m, 2946 m, 2910 w, 1474 s, 1407 s, 1332 m, 1317 s, 1303 s, 1292 s, 1262 s, 1191 m, 1172 m, 1153 m, 1082 s, 1020 m, 889 s, 802 s, 757 m, 740 m, 715 s, 661 w, 569 s, 531 m, 400 w, 392 w, 342 s, 331 s, 318 st cm$^{-1}$. MS (50 eV): *m*/*z* (%) 314 (5) [$M^+$], 299 (45) [$M^+$ – Me], 207 (20) [$MeSbCl_2^+$], 192 (100) [$SbCl_2^+$], 156 (65) [$SbCl^+$], 122 (80) [$Me_3B_3N_3H_2^+$].

**Tris(2,4,6-trimethylborazinyl)arsane** was obtained from **2** (0.96 g, 4.69 mmol) in a solution of hexane (30 mL) and $AsCl_3$ (0.11 mL, 1.56 mmol) in 10 mL of hexane. After keeping the mixture at reflux for 3 d the solid was filtered off and the filtrate reduced to one third of its original volume. The solution still contained small amounts of chloride. The $^{11}$B NMR spectrum showed the formation of $(Me_3B_3N_3H_2)_3As$. $^1$H NMR ($C_6D_6$): $\delta$ = 0.07 (s, 3 H, BMe), 0.61 (s, 6 H, BMe), 4.42 ppm (br. s, 2 H, NH) with some weak signals from impurities. $^{11}$B NMR ($C_6D_6$): $\delta$ = 35.5, 36.9 ppm.

**Chlorobis(2,4,6-trimethylborazinyl)stibane (10):** A suspension of $SbCl_3$ (0.37 g, 1.62 mmol) in hexane (30 mL) was allowed to react with a solution of **2** (0.657 g, 3.24 mmol) in hexane (20 mL). After refluxing overnight the solid was removed by filtration and the filtrate reduced in volume by 3/4. From the solution settled a white powder at –25 °C. Yield 0.50 g of **10** (75%), dec. > 200 °C. $C_6H_{22}B_6ClN_6Sb$ (400.36): calcd. C 17.99, H 5.53, N 20.99; found C 20.47, H 5.38, N 21.79. IR: $\tilde{\nu}$ = 3438 s, 3418 s, 2963 s, 2932 m, 2861 m, 2791 w, 1473 s, 1449 m, 1429 m, 1300 s, 1370 m, 1360 w, 1321 m, 1282 w, 1261 s, 1193 w, 1170 w, 1095 s, 1021 w, 956 w, 893 w, 833 w, 803 w, 755 w, 700 m, 670 m, 658 m, 614 s, 533 w, 528 w, 477 w, 404 w cm$^{-1}$.

**Tris(2,4,6-trimethylborazinyl)phosphane (11):** $PBr_3$ (1.64 mmol) dissolved in toluene (10 mL) was added to a solution of **2** (1.00 g, 4.93 mmol) in toluene (30 mL). A white precipitate formed rapidly. After keeping the mixture at reflux for one day the solid was removed by filtration. A $^{31}$P NMR spectrum showed the formation of **11** ($\delta$ = 120.3 ppm) along with minor amounts of **6** ($\delta$ = 191 ppm). The latter could not totally be removed from **6** despite repeated crystallization from toluene/hexane at –20 °C. $^1$H NMR ($C_6D_6$): $\delta$ = 0.18 (s, 3 H, BMe), 0.64 (d, 6 H, BMe), 4.55 ppm (br. s, NH) ppm. $^{11}$B NMR ($C_6D_6$): $\delta$ = 35.7, 39.5 ppm (2:1). $^{31}$P NMR ($C_6D_6$): $\delta$ = 120.3 ppm.

**Tris(2,4,6-trimethylborazinyl)stibane** (impure) was obtained as a white powder upon treatment of a suspension of $SbCl_3$ (0.488 g, 2.13 mmol) in hexane (20 mL) with a solution of **2** (1.30 g, 6.24 mmol) in hexane (30 mL). After heating the mixture overnight to reflux and removing the insoluble material a white powder remained after evaporation of the solvent. The product was characterized only by NMR spectroscopy. $^1$H NMR: $\delta$ = 0.19 (s, 9 H, Me), 0.52 (s, 18 H, Me), 4.31 ppm (s, 6 H, Me) and some additional weak signals. $^{11}$B NMR: $\delta$ = 35.1, 37.3 ppm (1:2).

**Bis(2,4,6-trimethylborazinyl)phosphane (13):** Compound **6** (1.65 g, 4.67 mmol) was dissolved in hexane (30 mL) and a solution of $LiAlH_4$ in diethyl ether (0.83 mL of a 1.3 M solution) was added to this stirred solution to give a white precipitate. After stirring overnight the solid was removed by filtration and three quarters of the solvents were evaporated from the filtrate in vacuo. Storing the solution at +5 °C gave platelets of **13** within two weeks (m.p. 82 °C). Yield 0.95 g (75%). $C_6H_{23}B_6N_6P$ (275.12): calcd. C 26.19, H 8.43, N 30.54; found C 26.69, H 9.01, N 29.96. IR: $\tilde{\nu}$ = 3424 s, 3402 s, 2958 s, 2942 s, 2932 s, 2846 w, 2489 w. 2293 s, 2254 s, 2175 w, 2122 w, 2080 w, 1980 w, 1915 w, 1901 w, 1879 w, 1483 s, 1397 s, 1371 m, 1316 s, 1291 s, 1206 m, 1196 m, 1186 w, 1163 s, 1143 w, 1105 w, 1093 w, 1065 m, 1040 w, 1021 w, 991 m, 962 s, 895 s, 834 w, 912 m, 785 w, 748 s, 725 w, 636 w. 605 m, 592 m, 572 m, 492 w, 479 w, 440 w, 394 w. 371 m, 356 w cm$^{-1}$.

**Zwitterionic Ethylphosphonium 2,4,6-Trimethylborazinate 14:** A diethyl ether solution of $LiAlH_4$ (0.29 mmol, 1.4 M) was added to a hexane solution (30 mL) of **5** (0.52 g, 1.66 mmol) with stirring. The solid formed was removed by filtration after stirring the mixture overnight. The volume of the filtrate was then reduced to one fifth. Crystals separated within a week on storing this solution at –5 °C. Yield 0.20 g (65%). $C_5H_{17}B_3N_3P$ (182.59): calcd. C 32.89, H 9.37, N 23.01; found C 32.19, H 9.12, N 22.54. IR: $\tilde{\nu}$ = 3443 s, 3407 s, 2950 s, 2911 s, 2900 s, 2853 s, 2332 s, 1490 s, 1407 s, 1370 s, 1360 s, 1262 s, 1199 s, 1183 s, 1166 s, 1144 s, 1098 s, 1059 s, 1021 s, 997 s, 943 s, 888 s, 806 s, 748 s, 730 m, 715 m, 676 m, 667 m, 649 m, 642 m, 603 m, 567 m, 546 w, 397 w, 378 m cm$^{-1}$. $^1$H NMR: $\delta$ = 0.14 (s, 3 H, BMe), 0.30 (m, 5 H, Et). 0.35–0.47 (m, 5 H, P*Me*, P*CH*$_2$), 0.54 (d, $^4J_{^{31}P,^1H}$ = 1.9 Hz, 6 H, BMe), 5.52 (dt, $^1J_{^{31}P,^1H}$ = 370, $^3J_{^{31}P,^1H}$ = 7 Hz, 2 H, $PH_2$), 5.59 ppm (dq, $^1J_{^{31}P,^1H}$ = 379, $^3J_{^1H,^1H}$ = 7 Hz, 2 H, P*H*$_2$). $^{11}$B NMR: $\delta$ = 34.1, 35.3 ppm. $^{31}$P NMR: $\delta$ = 5.5 ppm (t, $^1J_{^{31}P,^1H}$ = 430 Hz).

**Bis(mesityl)bis(2,4,6-trimethylborazinyl)diphosphane (17):** A solution of **6** (0.88 g, 25 mmol) in hexane (20 mL) was added slowly to a stirred suspension of $LiPmes_2$ (0.69 g, 2.5 mmol) in hexane (50 mL) at –78 °C. The mixture was then kept at reflux for 14 h. Insoluble material was removed by filtration and about half of the solvent was removed in vacuo. The filtrate was kept at –25 °C and the microcrystalline material recrystallized from toluene at –30 °C as colorless prisms. Two crystals were selected for the X-ray structure determination and proved to contain toluene. The crystals became opaque in vacuo. After keeping them in vacuo for 3 h the yield was 1.15 g (85%), m.p. 182 °C. $C_{24}H_{44}B_6N_6P_2$ (542.47): calcd. 53.04, H 8.16, N 15.46; found C 51.71, H 8.66, N 14.74. IR: $\tilde{\nu}$ = 3424 m, 3414 m, 3403 w, 3100 w, 3089 m, 3025 m, 2965 s, 2924 s, 2864 m, 2731 w, 1667 w, 1601 m, 1549 w, 1478 s, 1432 s, 1396 m, 1298 s, 1277 s, 1188 m, 1178 m, 1152 m, 1083 m, 1031 w, 1016 w, 930 m, 896 m, 953 m, 861 m, 807 m, 787 w, 734 m, 699 w, 602 w,

581 s, 568 m, 559 m, 546 w, 521 w, 499 w, 453 w, 375 m, 365 m $cm^{-1}$.

**Tetrakis(2,4,6-trimethylborazinyl)diphosphane (18):** Freshly cut pieces of elemental Na (300 mg) were added to a solution of **6** (1.61 g, 5.0 mmol) in toluene (50 mL). There was no reaction at ambient temperature. The mixture was then kept at reflux (about 3 d) until the $^{31}P$ NMR signal of the **6** could no longer be observed. The solid material was then removed by filtration. The filtrate was free of bromide. Two thirds of the toluene was then evaporated in vacuo and the remaining solution kept at –25 °C. Crystals of **18** separated within 10 d. Yield 1.02 g (70%). $C_{12}H_{44}B_{12}N_{12}P_2$ (548.24): calcd. C 26.29, H 8.09, N 30.66; found C 28.34, H 8.36, N 29.86. IR: $\tilde{\nu}$ = 3432 s, 3413 s, 2956 m, 2943 m, 2855 m, 1483 s, 1399 s, 1293 s, 1280 s, 1200 m, 1190 s, 1177 s, 1153 s, 1084 m, 1041 w, 1030 w, 1019 w, 933 s, 889 s, 808 m, 736 s, 727 s, 715 m, 649 m, 683 s, 563 m, 518 w, 491 w 431 w, 374 m, 358 m $cm^{-1}$. $^1H$ NMR: $\delta$ = 0.15 (s, 12 H, BMe), 0.84 (s, 24 H, BMe), 4.49 ppm (s, 8 H, NH). $^{11}B$ NMR: = 36.3 ppm (br., $h_{1/2}$ = 1260 Hz). $^{31}P$ NMR: = 108.7 ppm (s).

**Tetrakis(2,4,6-trimethylborazinyl)cyclotetraphosphane (19):** A solution of **5** (0.33 g, 1.04 mmol) in hexane (50 mL) was treated with a suspension of finely cut sodium chips (ca. 0.5 g). The reaction started after heating the mixture to reflux. After 3 d the $^{31}P$ NMR signal of **5** could no longer be detected. The insoluble material was removed by filtration. No bromide was found in the filtrate. After reducing the volume of the filtrate by about 60% slightly yellowish crystals separated within two weeks at –50 °C. Attempts to obtain single crystals from hexane, toluene, or thf were unsuccessful. Yield 0.18 g (60%), m.p. 200 °C. $C_{12}H_{44}B_{12}N_{12}P_4$ (610.18): calcd. C 23.62, H 7.26, N 27.55; found C 24.12, H 7.34, N 24.89. IR: $\tilde{\nu}$ = 3437 w, 3422 w, 2969 m, 2890 w, 1483 s, 1397 s, 1380 m, 1364 w, 1282 s, 1261 m, 1193 m, 1178 m, 1150 m, 1131 w, 1082 m, 939 s, 878 s, 850 m, 808 m, 701 wm, 613 w, 574 w, 351 w, 343 w $cm^{-1}$.

**Dimesitylbis(2,4,6-trimethylborazinyl)cyclotetraphosphane (A–F):** A solution of **4** (0.33 g, 1.04 mmol) in toluene (20 mL) was slowly added at –78 °C to a suspension of $mesPLi_2$ (0.17 g, 1.04 mmol) in the same solvent (20 mL). The stirred mixture was allowed to reach room temperature and stirring was continued overnight. The insoluble material was then removed by filtration. The filtrate contained no bromide and was investigated by NMR spectroscopy. The volume of the filtrate was further reduced to one fifth. Colorless, prismatic crystals were isolated after two weeks which proved to be compound **E**. Yield 0.27 g (45%), m.p. 189 °C. Further fractional crystallizations yielded no other pure product. $C_{24}H_{44}B_6N_6P_4$ (605.35): calcd. C 42.55, H 7.37, N 14.61; found C 44.46, H 7.63, N 13. 84. IR: $\tilde{\nu}$ = 3437 w, 3428 w, 3409 w, 3400 m, 3025 w, 2959 m, 2860 w, 1602 m, 1481 s, 1399 s, 1370 m, 1361 w, 1285 s, 1263 m, 1201 m, 1191 m, 1178 m, 1150 m, 1130 w, 1084 m, 1028 w, 939 s, 888 s, 850 m, 733 m, 701 m, 607 w, 571 m, 467 w, 353 w $cm^{-1}$. $^1H$ NMR: $\delta$ = 0.043 (s, 6 H, BMe), 0.99 (d, $^4J_{^{31}P,^1H}$ = 5.75 Hz, 12 H, BMe), 2.80 (d, $^4J_{^{31}P,^1H}$ = 3.57 Hz, 12 H, CMe), 2.82 (s, 6 H, CMe), 4.47 (s, 4 H, NH), 6.68 ppm (s, 4 H, CMe). $^{31}P$ NMR: $\delta$ = 74.9 (t, $^1J_{^{31}P,^{31}P}$ = 168.3 Hz), –30.5 (t, $^1J_{^{31}P,^{31}P}$ = 168.4 Hz), 48.6 (dd, $^1J_{^{31}P,^{31}P}$ = 168.2 Hz), 63.4 (s), 60.7 (dd, $^1J_{^{31}P,^{31}P}$ = 57.0 Hz), –49.5 (dd, $^1J_{^{31}P,^{31}P}$ = 57.0 Hz), 36.2 (t, $^1J_{^{31}P,^{31}P}$ = 171.7 Hz), –8.1 (t, $^1J_{^{31}P,^{31}P}$ = 168.4 Hz), 77.3 (t, $^1J_{^{31}P,^{31}P}$ = 170.2 Hz), –26.4 (dd, $^1J_{^{31}P,^{31}P}$ = 170.2 Hz), –32 ppm (t, $^1J_{^{31}P,^{31}P}$ = 170.2 Hz).

**X-ray Structure Determinations:** Single crystals were covered with perfluoro ether oil under dinitrogen and a specimen selected. The selected crystal was mounted on the top of a glass fiber and placed

on the goniometer head flushed with a cold stream of $N_2$. Data for the determination of the unit cell were colleted at –80 °C for a total of 75 frames. The unit cell was determined with the program SMART.[33] Data collection was performed in the hemisphere mode. After data reduction the model structure was determined with the program SAINT.[34] The structure determination package SHELXTL[35] was used to refine the data. Non-hydrogen atoms were refined anisotropically. Hydrogen atom positions were calculated and refined using a riding model. The NH hydrogen atoms were located in the difference Fourier map and their positions were refined with isotropic thermal parameters. The thermal ellipsoids in the figures are shown at the 25% probability level. Distances are given in Ångstroms and bond angles in degrees. Crystallographic data and data related to data collection and refinement are summarized in Tables 10 and 11.

CCDC-620997 to -621005 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

This work was supported by the Fond der Chemischen Industrie and Chemetall GmbH, Frankfurt/Main. We thank Mr. P. Mayer and Mrs. D. Ewald for the recording many of the NMR, IR, and mass spectra. We are also grateful to Dr. M. Suter, Dr. T. Seifert, and Dr. M. Warchhold for collecting the data sets for the X-ray structure determination. Finally, we would also like to thank Prof. Dr. K. Karaghiosoff for interesting discussions.

[18] Both toluene molecules are disordered with an SOF of close to 0.5. This value was fixed to 0.5 in the refinement. One toluene looks like a xylene whereas the other is more differently disordered: the benzene rings are shifted so that the *p*-C atoms are centered in the middle of the other six-membered ring. However, the C–C distances are not equal. No H atoms have been added to these disordered molecules.

# Synthesis and Reactivity of New Bis(tetramethylpiperidino)(phosphanyl)-alumanes

**Tassilo Habereder,[a,b] Heinrich Nöth,*[a] and Robert T. Paine*[b]**

*Dedicated in memory of Professor Robert W. Parry*

**Keywords:** Aminoalumanes / Phosphanylalumanes / Carbon dioxide insertion / Phosphanylcarbonate ligand / Structure elucidation

Syntheses for the new bis(2,2,6,6-tetramethylpiperidino)-(phosphanyl)alumanes, $tmp_2AlP(SiMe_3)_2$, $tmp_2AlP(SnMe_3)_2$ and $(tmp_2Al)_2PPh$ are described along with spectroscopic characterization and X-ray crystallographic structure determinations. In addition, the insertion reactions between $tmp_2AlP(SiMe_3)_2$ and $CO_2$, COS and $CS_2$ are described and compared with the outcomes for $CO_2$ insertion reactions with $tmp_2AlCl$ and $tmp_2AlMe$. In the case of the amino-phosphanyl-alumane, the Al–P bond undergoes the insertion chemistry in contrast to Al–N bond insertions observed with $tmp_2AlCl$ and $tmp_2AlMe$.

## Introduction

Since the initial report on the synthesis of $(tmp_2AlH)_2$ (tmp = 2,2,6,6-tetramethyl-piperidino)[1] steady development of the chemistry of the sterically congested $tmp_2Al$– fragment has led to the discovery of several structurally interesting compounds that are unique in comparison to other (alkylamido)alumanes as well as (alkylamido)boranes.[2–8] In particular, the bulky tmp group shows little tendency to participate in bridge bonding and the halide compounds, $tmp_2AlX$ [X = Cl (**1**), Br, I], are monomeric in the gas phase, in solutions and in the solid state.[2] The fluoride and hydride analogues, on the other hand, form dimers, $(tmp_2AlX)_2$ (X = F, H), through Al–F–Al and Al–H–Al bridge bonding. The halides undergo nucleophilic displacement forming a variety of $tmp_2AlX$ (X = OR, SR, $NR_2$, $PR_2$, $AsR_2$, $CR_3$ and $Si(SiMe_3)_3$) compounds all of which are monomeric.[5] Crystallographic structure studies and computational modelling indicate that these compounds develop little or no Al–N-pp(π) bonding interactions. Instead, the Al–N bonds can be considered to possess highly polar sigma-bond character.

As part of a continuing interest in the reactivity and utility of $tmp_2AlX$ reagents as synthons, we set out in this study to expand the available range of phosphanyl derivatives for this fragment. In the initial study mentioned above, only the formation of $tmp_2AlPPh_2$ was described.[5] As expected, this compound provides limited potential for use in, for example, N–Al–P ring or cage construction chemistry. In the current study, we directed attention to the synthesis of additional examples of (amino)(phosphanyl)alumanes and their reactivity.

### Synthesis and Reactions

Prior work in our group with (amino)(phosphanyl)boranes[9] suggested that the molecule $tmp_2AlPH_2$ might be an excellent building block for the construction of novel ring and cage compounds and this compound was the initial synthetic target. Numerous attempts to accomplish the 1:1 reaction of $tmp_2AlCl$ with $LiPH_2$·dme, as shown in Equation (1), were fruitless.

$$tmp_2AlCl + LiPH_2{\cdot}dme \xrightarrow[-LiCl]{hexane} tmp_2AlPH_2 \quad (1)$$

At 23 °C, the combination proved unreactive while under solvent reflux conditions tmpH formed along with insoluble solids some of which is LiCl. Efforts to employ $Me_3Si$-$PH_2$ directly in elimination chemistry with **1** or with strong base promotion also led to the formation of tmpH along with $(Me_3Si)_3P$ and slightly soluble, unidentified solids that may be oligomeric aminoalumane species. These results led to the subsequent studies of reactions between $tmp_2AlCl$ and $LiP(SiMe_3)_2$·$(thf)_2$, $LiP(SnMe_3)_2$ and $LiP(H)Ph$·$(thf)_n$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Combination of one equivalent of **1** with one equivalent of $LiP(SiMe_3)_2{\cdot}(thf)_2$ or $LiP(SnMe_3)_2$ in hexane gave the respective (amino)(phosphanyl)alumanes **2** and **3** according to Equation (2). The substitution reactions are quantitative as evidenced by NMR analysis.

$$tmp_2AlCl + LiPR_2 \xrightarrow[-LiCl]{\text{hexane}} tmp_2AlPR_2$$

**2**: R = $SiMe_3$

**3**: R = $SnMe_3$ (2)

Following recrystallization from cold hexane, the compounds are isolated as analytically pure, colorless crystalline solids in 65–70% yield. The compounds are stable indefinitely at 23 °C in the absence of moisture and oxygen.

In a similar fashion, the 1:1 combination of **1** with $LiP(H)Ph{\cdot}(thf)_n$ unexpectedly gave the (amino)(phosphanyl)alumane **4**, which likely forms in two steps summarized in Equations (3) and (4).

$$tmp_2AlCl + LiP(H)Ph \xrightarrow[-LiCl]{\text{hexane}} tmp_2AlP(H)Ph \quad (3)$$

$$tmp_2AlP(H)Ph + tmp_2AlCl \xrightarrow[-HCl]{\text{hexane}} (tmp_2Al)_2PPh$$

**4** (4)

The initial combination of reagents at –78 °C produced no reaction; however, warming the mixture to 23 °C with stirring resulted in sluggish elimination of LiCl and formation, in low yield, of the anticipated product, $tmp_2AlP(H)Ph$, with a $^{31}P$ NMR resonance at $\delta$ = –112 ppm. Efforts to isolate this compound in pure form were not successful and attempts to complete the substitution by solvent reflux led to three additional $^{31}P$ NMR resonances, $\delta$ = –51, –72 and –96 ppm. The last corresponds to **4** obtained in about 45% yield in the crude reaction mixture. Following separation and recrystallization from cold hexane, **4** was isolated as colorless crystals in 33% yield. The species responsible for the $^{31}P$ resonances at $\delta$ = –51 and –72 ppm remain unidentified at this time.

Thwarted in our attempts to form $tmp_2Al–PH_2$ or $tmp_2Al–P(H)R$ reagents for systematic ring and/or cage construction chemistry, attention was turned to examinations of $Me_3SiCl$ and $Me_3SnCl$ elimination chemistry of **2** and **3** that might support ring/cage assembly processess. Such elimination chemistry routes have been used previously by us with (amino)(halo)boranes to form (amino)(phosphanyl)borane rings and cages.[9–15] In the present cases, the 1:1 combinations of $BCl_3$, $AlCl_3$ and $GaCl_3$ with **2** or **3** in hexane at 23 °C led to the formation of **1** identified by $^1H$ NMR ($\delta$ = 1.29, 1.40, 1.57) and very likely the respective $[MCl_2P(SiMe_3)_2]_n$ and $[MCl_2P(SnMe_3)_2]_n$ (M = B, Al, Ga) compounds. Attempts to obtain analytically pure samples and/or single crystals of the latter compounds were unsuccessful. These results indicate that alternative approaches will be required in the pursuit of systematic synthetic pathways for the construction of new ring and cage compounds containing multiple N–Al–P components.

Historically, another reactivity pathway of interest in our group is that involving insertion reactions into P–N,[16] B–N[17] and Al–N[18] bonds. In the current context, we have previously reported the reactions of $Al(NMe_2)_3$ and $Al(Cl)(NMe_2)_2$ with $CO_2$[19] and $CS_2$.[18] Each Al–N bond undergoes insertion with the formation of the corresponding carbamate or dithiocarbamate compounds, $Al(X_2CNMe_2)_3$ and $Al(Cl)(X_2CNMe_2)_2$ (X = O or S). A single-crystal X-ray structure determination for $Al(S_2CNMe_2)_3$ confirmed the formation of an unusual six coordinate aluminum center with bidentate dithiocarbamate chelation.[18] In close parallel to the present study, we have also previously observed $CO_2$ insertion in Al–N bonds in tmpAl fragments.[5,8] With the (amino)(phosphanyl)alumane, **2**, the question of interest was: will this reagent, with both Al–N and Al–P bonds, undergo selective insertion or insertion in all Al–N and Al–P bonds?

For comparison, the reaction of **1** with $CO_2$ was examined first. Slow diffusion of $CO_2$ gas into a hexane solution of **1** held first at –78 °C and then at 23 °C led over several days to the formation of a brown oil as summarized in Equation (5).

$$tmp_2AlCl + CO_2 \xrightarrow[23\ ^\circ C]{\text{hexane}} (tmp)(tmpCO_2)AlCl$$

**5** (5)

The oil was extracted with hexane and concentration led to the isolation of **5** as a crystalline solid. Although excess $CO_2$ was present, no evidence for double insertion was obtained. However, it cannot be ruled out that such a product is present in the brown oil that resists crystallization.

The combinations of **2** with excess $CO_2$, COS and $CS_2$ led to complete conversion of **2** to the insertion products **6**–**8** as summarized in Equation (6).

$$tmp_2AlP(SiMe_3)_2 + CXX' \longrightarrow tmp_2Al\begin{matrix}X'\\ \diagup\ \diagdown\\ X\end{matrix}CP(SiMe_3)_2$$

**2**

**6**: X = X' = O

**8**: X = X' = S

**7**: X = O; X' = S (6)

The compounds **6** and **7** are obtained in high yield (90–95%) as colorless and faintly yellow crystals, respectively. Compound **8** was isolated as a red oil along with small amounts of tmpH and $(Me_3Si)_3P$. All attempts to isolate a crystalline sample of **8** for X-ray analysis failed.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### NMR Characterization

The $^{1}H$, $^{13}C\{^{1}H\}$, $^{31}P$, $^{27}Al$ and $^{119}Sn$ NMR spectra were recorded as appropriate for **2**–**8**. The spectra for **2**–**4** can be compared with data for **1** and $tmp_2AlPPh_2$,[5] and the spectra for **5**–**8** can be examined against data for $[MeAl(O_2Ctmp)_2]_2$,[5] $[(tBuAl)_2(O_2Ctmp)_3]^+[tBu_3AlBrAltBu_3]^-$[8] and $Al(S_2CNMe_2)_3$.[18] In each of the new compounds **2**–**8**, the $^{1}H$ and $^{13}C\{^{1}H\}$ spectra are consistent with a single tmp group environment with free rotation about the Al–N bonds and rapid ring inversion. These spectra also show a single $Me_3Si$ or $Me_3Sn$ environment. The $^{31}P$ NMR spectra for **2** and **3** display high field resonances ($\delta$ = –238 and –282) significantly upfield from the value observed for $tmp_2AlPPh_2$ ($\delta$ =–42.9 ppm). This observation is typical of silyl- and stannylphosphanes and these shifts are similar to those in (amino)(phosphanyl)boranes reported previously.[9] The $^{31}P$ chemical shift for the bis-alumane **4** is downfield compared to **2** and **3**, and the shift ($\delta$ – 96) is comparable to related (phosphanyl)boranes.[9] The $^{31}P$ NMR shifts for **6**–**8** are successively shifted downfield from the starting material **2**: $\delta$ = –121.8 ($CO_2$), –57.8 (COS) and –16 ($CS_2$). This observation provides solid evidence that insertion of the small molecules occurs in the Al–P bond instead of the Al–N bond.

The $^{27}Al$ NMR spectra for **2** and **3** display a broad singlet at $\delta$ = 78 ($h_{1/2}$ = 3500 Hz) and 73 ($h_{1/2}$ = 3300 Hz) ppm, respectively. These are upfield of the reported shifts in $tmp_2AlPPh_2$, $\delta$ = 110 ppm, but similar to the shifts in $tmp_2AlX$ $\delta$ = 74 ppm ($AsPh_2$), 75 (OPh) and 85 (Odipp) ppm.[5] The line widths are somewhat lower than in other $tmp_2AlX$ compounds (ca. 8000–14,000 Hz), but in all cases they are characteristic of asymmetric, lower coordination environments on $^{27}Al$. The $^{27}Al$ NMR spectra for the insertion products **5**–**8** are very similar. Each displays a broad single resonance in the range $\delta$ = 75–81 ppm with $h_{1/2}$ = 3400–3600 Hz. These can be compared to the $^{27}Al$ NMR spectrum for $[(tBuAl)_2(O_2Ctmp)_3]^+[tBu_3AlBrAltBu_3]^-$ that shows a single broad resonance for the Al in the cation at $\delta$ = 53 ppm ($h_{1/2}$ = 3500 Hz). As discussed in the next section, this cation contains two four coordinate *t*BuAl units bridged by three carbamate ligands.[8]

### Crystal Structure Analyses

Single crystal X-ray diffraction structure determinations were completed for **2**–**7**. As found for **1**[2] and $tmp_2AlPPh_2$,[5] the compounds **2**–**4** are monomeric in the solid state and views of the molecules are shown in Figures 1, 2, and 3. In **2** and **3**, the tri-coordinate Al atom and tmp N atoms are planar while the phosphorus atom is pyramidal (sum of angles: **2**, 335.5°; **3**, 326.3°). The same atom geometries exist in $tmp_2AlPPh_2$ although the sum of angles at the P atom (316.2°) is smaller in $tmp_2AlPPh_2$. The Al–P bond lengths [**2**, 2.361(2) Å; **3**, 2.334(2) Å] are slightly shorter than that found in $tmp_2AlPPh_2$ [2.377(1) Å] but slightly longer than that reported for $trip_2Al$–P(Ada)($SiPh_3$) [2.342(2) Å] (trip = 2, 4, 6-*i*$Pr_3C_6H_2$; Ada = adamantyl).[20] The Al–N bond lengths [**2**, 1.846(4) Å and 1.848(4) Å; **3**, 1.832(4) Å and 1.818(4) Å] are slightly longer or identical to the distances in $tmp_2AlPPh_2$ [1.819(2) Å], while the Al–N distances in **1** are 1.785(4) Å and 1.810(4) Å.[2] These parameters are consistent with sigma-only Al–P bonding and highly polar sigma-only Al–N bonding. The molecular structure of **4** is similar (planar N and Al atom environments) to **2** and **3**, but different in that the P atom is also flat with C(37)–P(1)–Al(1) 109.1(2)°, C(37)–P(1)–Al(2) 109.4(2)° and Al(1)–P(1)–Al(2) 141.4(1)° (sum = 359.9°). The Al–P bond lengths [Al(1)–P(1), 2.287(3) Å; Al(2)–P(1), 2.292(3) Å] are slightly shorter than in **2**, **3** and $tmp_2AlPPh_2$ while the Al–N bond lengths [Al(1)–N(1) 1.826(5) Å, Al(1)–N(2) 1.825(5) Å, Al(2)–N(3) 1.819(5) Å, Al(2)–N(4) 1.812(5) Å] are comparable to those in **2**, **3** and $tmp_2AlPPh_2$. The flattened P atom environment is probably a result of steric constraints imposed by the tmp and phenyl substituent groups rather than the operation of Al–P pp–π bonding contributions. Furthermore, the N–Al–N angles in all three compounds fall in a narrow range, 121.8–132.4°, observed in other $tmp_2AlX$ compounds: 126.6(2)° for **2**, 127.2(2)° for **3**, and 126.8(2)° for **4**.[5] These parameters are consistent with the observation that N–Al–N bond angles offer a gauge of Al–N bond polarity and large angles (> 122°) appear in compounds containing weakly basic substituents X and highly polar Al–N bonds.[5]

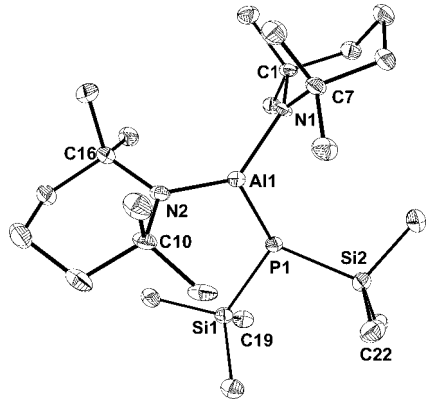

Figure 1. Molecular structure of **2**.

The core molecular structure for **5**, isolated from the reaction of **1** with $CO_2$, is shown in Figure 4 (tmp carbon atoms omitted for clarity). It is immediately apparent that **5** is dimeric. Furthermore, the structure reveals that $CO_2$ insertion takes place in only one of the two Al–N bonds and that the resulting carbamate acts as a bridging ligand toward a second Al(Cl)(tmp)(μ-$O_2$Ctmp) fragment. The resulting puckered eight-membered $[–Al–O–C–O–]_2$ ring has four coordinate Al atom environments with the terminal tmp groups and terminal Cl atoms in *cis* orientations across the ring. The terminal Al–Cl bond lengths [Al(1)–Cl(1) 2.164(2) Å and Al(2)–Cl(2) 2.159(1) Å] are slightly longer than the Al–Cl bond lengths in $tmp_2AlCl$, [2.144(2) Å] and in $(Me_2NAlCl_2)_2$ [2.088(3) Å and 2.123(3) Å].[21] The terminal Al–N bond lengths [Al(1)–N(2) 1.805(3) Å and Al(2)–N(4) 1.826(3) Å can be compared with the values in

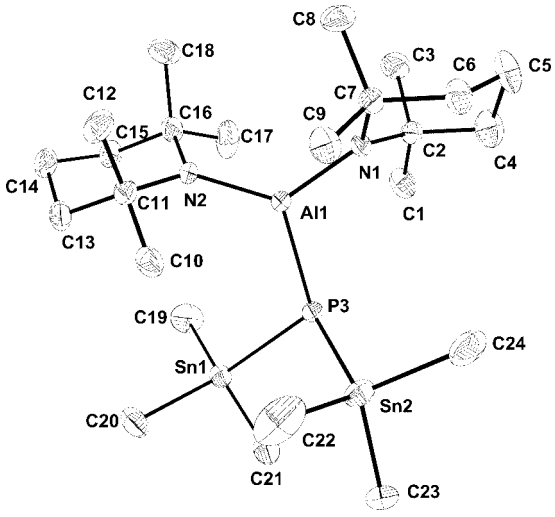

Figure 2. Molecular structure of **3**.

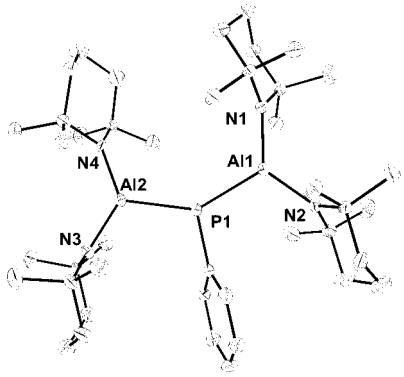

Figure 3. Molecular structure of **4**.

$tmp_2AlCl$ [1.785(4) and 1.810(4) Å]. The bonding parameters in the carbamate ligands are fairly symmetrical with N(1)–C(2) 1.328(4) Å, N(3)–C(1) 1.330(5) Å, O(1)–C(2) 1.289(4) Å O(4)–C(2) 1.275(4) Å, O(2)–C(1) 1.289(4) Å and O(3)–C(1) 1.271(4) Å. The carbamate bridging interactions with the two Al atoms are also relatively symmetrical with Al–O (avg) = 1.78(1) Å [Al(1)–O(1) 1.784(3) Å, Al(1)–O(2) 1.789(3) Å, Al(2)–O(3) 1.776(3) Å, Al(2)–O(4) 1.790(2) Å]. These Al–O bond lengths are significantly shorter than in the related but more fragile complex $[MeAl(O_2Ctmp)_2]_2$ whose four bridging bidentate carbamate ligands form a paddle-wheel structure with Al–O bond lengths in a range 1.863(3) to 1.880(3) Å.[5] On the other hand, the bonding parameters in **5** are similar to those in the cation $[(t\text{BuAl})_2(O_2Ctmp)_3]^+$: Al–O (avg) 1.763(4) Å, C–O (avg) 1.292(7) Å and C–N (avg) 1.308(6) Å.[8]

In direct contrast with **5**, the molecular structure determinations for **6** and **7** reveal that insertions of $CO_2$ and COS take place exclusively into the Al–P bond of **2** and the resulting compounds are monomeric in the solid state as shown in Figure 5 and Figure 6. The formal phosphanylcarbonate $(Me_3Si)_2PCO_2^{1-}$ and phosphanylthiocarbonate $(Me_3Si)_2PCOS^{1-}$ units are planar and they act as bidentate

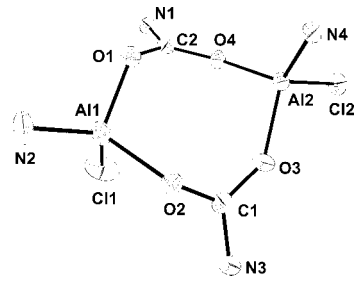

Figure 4. Molecular structure of **5** with tmp carbon atoms omitted for clarity.

chelating ligands toward tetrahedral Al centers in a formal $tmp_2Al$ cation. The Al–N bond lengths and internal N–Al–N bond angles in the two compounds are similar: **6**, Al(1)–N(1) 1.800(6) Å, Al(1)–N(2) 1.815(6) Å and N(1)–Al(1)–N(2) 129.8(3)°; **7**, Al(1)–N(1) 1.827(5) Å, Al(1)–N(2) 1.801(5) Å, and 128.2(2)°. In both compounds the N–Al–N angle is only slightly enlarged compared with the starting compound **2**. The phosphanylcarbonate, $(Me_3Si)_2PCO_2^{1-}$, unit is symmetrically bonded to the Al center in **6**: Al(1)–O(1) 1.921(5) Å, Al(1)–O(2) 1.918(4) Å, C(1)–O(1) 1.281(7) Å, C(1)–O(2) 1.285(7) Å and C(16)–P(1) 1.814(7) Å, with internal chelate ring angles O(1)–Al(1)–O(2) 68.4(2)°, Al(1)–O(1)–C(16) 88.1(4)°, Al(1)–O(2)–C(16) 88.2(4)° and O(1)–C(16)–O(2) 114.3(6)°. The $(Me_3Si)_2PCOS^{1-}$ unit of course forms a more asymmetric chelate ring in **7**: Al(1)–O(1) 1.887(3) Å, Al(1)–S(2) 2.422(2) Å, C(1)–O(1) 1.291(6) Å, C(1)–S(2) 1.708(5) Å and C(1)–P(1) 1.796(6) Å, with internal chelate ring angles O(1)–Al–S(2) 70.9(1)°, Al–O(1)–C(1) 101.6(3)°, Al–S(2)–C(1) 71.9(2)° and O(1)–C(1)–S(2) 114.8(4)°. It is notable that the Al–O bond lengths in **6** and **7** are significantly longer than in **5** [Al–O avg 1.78(1) Å] and in the cation $[(t\text{BuAl})_2(O_2Ctmp)_3]^+$ [Al–O (avg.) 1.763(7) Å]. The Al–O distances in **6** are, in fact, even significantly longer than the Al–O (avg.) in $[MeAl(O_2Ctmp)_3]_2$. Given these bonding parameters it is a little surprising that the complex is as stable as it appears to be where the carbonate ligands are bridging two Al atoms. It is also observed that the Al–S bond length in **7** is longer than the corresponding bond length in $Al(S_2CNMe_2)_3$ [Al–S avg 2.396(1) Å].[18]

## Conclusions

The nucleophilic substitution chemistry on $tmp_2AlCl$ described in part in a previous report,[5] has been extended further in the present study. The initial intent was to prepare (amino)(phosphanyl)alumanes, $tmp_2AlPR_2$, that might find use for the construction of Al–P cage compounds related to those discovered in our prior work with (amino)-(phosphanyl)boranes.[9] Unfortunately, the principle target compound, $tmp_2AlPH_2$, either does not form or is unstable under forcing reaction conditions. However, three new (amino)(phosphanyl)alumanes, $tmp_2AlPR_2$, R = $SiMe_3$ (**2**), $SnMe_3$ (**3**) and $(tmp_2Al)_2PPh$ (**4**) were obtained and characterized.

It had been previously noted that the polar Al–N bond in (amino)alumanes is susceptible to $CO_2$ bond insertion.[5,8,19] In particular, both Al–N bonds in $tmp_2AlCH_3$ have been observed to undergo $CO_2$ insertion with formation of $[MeAl(tmpCO_2)_2]_2$ in which the two Al atoms are bridged by four carbamate ligands.[5] In the present study, it was expected that similar Al–N bond insertion would occur in both tmp–Al bonds of $tmp_2AlCl$, **1**. However, under the conditions explored, only one tmp–Al bond undergoes $CO_2$ insertion with resulting formation of $[Al(Cl)(tmp)(tmpCO_2)]_2$ **5**, a dimer with *two* bridging carbamate ligands and two terminal tmp groups. In a sense, this can be considered an intermediate product on the way to the formation of the compound $[MeAl(tmpCO_2)]_2$ that utilizes four bridging carbamate ligands to form a dimeric structure. Perhaps the electronic difference between Me and Cl is responsible for shutting down the reactivity of the second Al–N bond in **1**. It is also worth reviewing that $[MeAl(tmpCO_2)]_2$ is thermally unstable above –10 °C,[5] so perhaps the full insertion product from **1** is simply too unstable to allow isolation.

Molecule **2** presents the additional option that insertion might occur in the Al–P bond as well as the Al–N bonds. However, under the conditions utilized, reactions of **2** with $CO_2$, COS and $CS_2$ result *only* in Al–P bond insertion. Furthermore, crystal structure analyses indicate that the resulting phosphanylcarbonate $(Me_3Si)_2PCO_2^-$ and phosphanylthiocarbonate $(Me_3Si)_2PCOS^-$ fragments act as terminal, bidentate chelating ligands toward aluminum. Spectroscopic data, suggest that the same coordination condition results with $CS_2$ insertion that produces only $tmp_2Al[S_2CP(SiMe_3)_2]$.

## Experimental Section

Standard inert-atmosphere techniques were used for the manipulation of all reagents and solvents were rigorously dried and distilled before use. NMR spectra were recorded on Bruker WP-250 and JEOL GSX-400 NMR spectrometers from samples flame sealed in evacuated NMR tubes containing appropriate lock solvents. Spectra were referenced with external $Me_4Si$ ($^1H$ and $^{13}C$), 85% $H_3PO_4$ ($^{31}P$), 1 M aqueous LiCl ($^7Li$), 1 M aqueous $HAlCl_4$ ($^{27}Al$) and $Me_4Sn$ ($^{119}Sn$). Downfield shifts relative to the reference were assigned positive $\delta$ values. CHN-Analytical data obtained for these compounds are low in comparison to the calculated values and this is consistent with incomplete combustion and formation of aluminum carbide or silicide residues.[22–24] X-ray diffraction: Siemens P4 four-circle diffractometer with a CCD area detector and LT2 device, Mo-$K_\alpha$ radiation, graphite monochromator.

**Bis(trimethylsilyl)phosphanyl-bis(2,2,6,6-tetramethylpiperidino)alumane (2):** A suspension of $LiP(SiMe_3)_2\cdot(thf)_2$[25] (1.3 g, 4.3 mmol) in hexane (50 mL) was slowly treated (–78 °C) with $tmp_2AlCl$ (**1**) (1.5 g, 4.3 mmol) in hexane (50 mL). The mixture was warmed slowly with stirring and then held at 23 °C (1 h). Volatile components were vacuum-evaporated, the solid residue treated with fresh hexane (50 mL) and filtered. The filtrate was concentrated to ca. 10 mL and cooled (–78 °C). After several days colorless crystals were collected. Yield: 1.34 g (66%) of **2**, m.p. 87 °C (dec.). $^1H$ NMR ($C_6D_6$): $\delta$ = 0.46 [d, $J_{HP}$ = 4.8 Hz, 18 H, $Si(CH_3)_3$], 1.39 [m, 8 H, $CCH_2$], 1.55 [s, 24 H, $CCH_3$], 1.62 [m, 4 H, $CCH_2CH_2$] ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 5.5 [d, $J_{CP}$ = 11.4 Hz, $SiCH_3$], 18.6 [$CCH_2CH_2$], 34.5 [$CH_3$], 40.7 [$CCH_2$], 52.7 [$C(CH_3)_2$] ppm. $^{27}Al$ NMR: $\delta$ = 78 ($h_{1/2}$ = 3500 Hz) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = –238 ppm. $C_{24}H_{54}AlN_2PSi_2$ (484.83): calcd. C 59.64, H 11.23, N 5.78; found C 57.70, H 9.42, N 6.80.

**Bis(trimethylstannyl)phosphanyl-bis(2,2,6,6-tetramethylpiperidino)-alumane (3):** A solution of $(Me_3Sn)_3P$[26] (2.91 g, 5.6 mmol) in THF (30 mL) was cooled (–78 °C) and *n*BuLi solution (3.5 mL, 5.6 mmol) in hexane was added with stirring. The mixture was warmed to 23 °C, stirred (1 h) and volatiles vacuum evaporated. The residue was treated with hexane (30 mL) and this suspension was cooled (–78 °C) and combined with $tmp_2AlCl$ (1.9 g, 5.5 mmol) in hexane (30 mL). The mixture was warmed to 23 °C and stirred (1 h). Volatile components were removed from the resulting mixture, the residue treated with hexane (50 mL) and filtered. The filtrate was concentrated (5 mL) and cooled (–20 °C). After several days, colorless crystals deposited. Yield: 1.84 g, 69% of **3**, m.p. 103–104 °C. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.46 [m, $J_{HP}$ = 4.8, $J_{HSn}$ = 52 Hz, 18 H, $Sn(CH_3)$], 1.36 [m, 8 H, $CCH_2$], 1.52 [s, 24 H, $CCH_3$], 1.63 [m, 4 H, $CCH_2CH_2$] ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = –3.0 [m, $J_{CP}$ = 6.6, $J_{CSn}$ = 295 Hz, $SnCH_3$], 18.5 [$CCH_2CH_2$], 34.7 [$CH_3$], 41.0 [$CCH_2$], 52.6 [$C(CH_3)_2$] ppm. $^{27}Al$ NMR: $\delta$ = 73 [$h_{1/2}$ = 3300 Hz] ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = –282 [m, $J_{PSn}$ = 754, 785 Hz] ppm. $^{119}Sn$ NMR: $\delta$ = 18.0 [d, $J_{SnP}$ = 785 Hz] ppm. $C_{24}H_{54}AlN_2PSn_2$ (666.04): calcd. C 43.28, H 8.17, N 4.21; found C 42.65, H 8.13, N 4.02.

**Phenyl-bis[bis(2,2,6,6-tetramethylpiperidino)alumanyl]phosphane (4):** A solution of $PhPH_2$ (0.55 g, 4.95 mmol) in THF (30 mL) was

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cooled to –78 °C and combined with *n*BuLi/hexane solution (5.0 mmol). The mixture was stirred, warmed to 23 °C and stirred further (2 h) leaving an orange suspension. The volatiles were vacuum evaporated and the solid residue suspended in hexane (30 mL). The mixture was cooled (–78 °C) and combined with $tmp_2AlCl$ (1.7 g, 5.0 mmol) and then warmed, stirred (2 h) at 23 °C and then refluxed (2 d). The crude reaction mixture displayed $^{31}P$ NMR resonances at $\delta$ = –51, –72, –96 (broad) and –112. The mixture was filtered, the filtrate concentrated and cooled (–20 °C) and colorless crystals deposited which were collected and washed with cold hexane. Yield: 0.66 g, 33% of **4**, m.p. 200 °C (dec.). $^1H$ NMR ($C_6D_6$): $\delta$ = 1.25 (m, 24 H, $C(CH_2)_2$ and $CCH_2CH_2$), 1.61 (s, 48 H, $CCH_3$), 7.15 (m, 3 H Ph), 7.81 (t, $J_{HH}$ = 6.8 Hz, 2 H, Ph) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = –96 ppm. $C_{42}H_{77}Al_2N_4P$ (722.55): calcd. C 69.77, H 10.73, N 7.75; found C 66.40, H 9.93, N 6.48.

**Reaction of 1 with $CO_2$:** Carbon dioxide gas was allowed to slowly diffuse into a sample of **1** (0.5 g, 1.5 mmol) in hexane (10 mL) held at –78 °C. The resulting mixture was allowed to stand for several days and a brownish oil formed. The oil was crystallized from a minimum of hexane at 23 °C over several weeks and a few colorless crystals of **5** were isolated. The oil was examined by NMR spectroscopy. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.23, 1.46, 1.52, 1.61 ppm. $^{27}Al$ NMR: $\delta$ = 81 ppm.

**Reaction of 2 with $CO_2$:** A sample of **2** (1.88 g, 4.0 mmol) in hexane (5 mL) was layered over dry-ice and allowed to stand at 23 °C for several days. Orange crystals deposited. Yield: 2.0 g, 95% of **6**, m.p. 109 °C (dec.). $^1H$ NMR ($C_6D_6$): $\delta$ = 0.46 [d, $J_{HP}$ = 5.5 Hz, 18 H, $SiCH_3$], 1.39 [m, 8 H, $CCH_2$], 1.51 [s, 24 H, $CCH_3$], 1.62 [m, 4 H, $CCH_2CH_2$] ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 1.6 [d, $J_{CP}$ = 12.5 Hz, $SiCH_3$], 18.7 [$CCH_2CH_2$], 34.3 [$CH_3$], 41.5 [$CCH_2$], 52.3 [$C(CH_3)_2$] ppm. $^{27}Al$ NMR: $\delta$ = 75 [$h_{1/2}$ = 3500 Hz] ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = –121.8 ppm. $C_{25}H_{54}AlN_2O_2PSi_2$ (528.84): calcd. C 56.78, H 10.29, N 5.30; found C 54.59, H 9.89, N 4.78.

**Reaction of 2 with COS:** A sample of **2** (1.0 g, 2.1 mmol) in hexane (40 mL) was frozen at –196 °C and COS gas (2.1 mmol) was measured volumetrically and condensed on the mixture. The combined mixture was warmed to –78 °C, stirred (2 h) and then warmed to 23 °C and stirred (12 h). The resulting cloudy orange solution was filtered and the filtrate concentrated (20 mL) and cooled (–20 °C). After several days, yellow crystals deposited. Yield: 0.95 g, 95% of **7**, m.p. 111–114 °C. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.37 [d, $J_{HP}$ = 5.0 Hz, 18 H, $SiCH_3$], 1.46 [m, 8 H, $CCH_2$], 1.58 [s, 24 H, $CCH_3$], 1.67 [m, 4 H, $CCH_2CH_2$] ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 1.7 [d, $J_{CP}$ = 12.1 Hz, $SiCH_3$], 18.6 [$CCH_2CH_2$], 34.5 [$CH_3$], 41.7 [$CCH_2$], 52.9 [$C(CH_3)_2$] ppm. $^{27}Al$ NMR: $\delta$ = 81 ppm [$h_{1/2}$ = 3400 Hz]. $^{31}P\{^1H\}$ NMR: $\delta$ = –57.8 ppm. $C_{25}H_{54}AlN_2OPSSi_2$ (544.90): calcd. C 55.64, H 9.99, N 5.14; found C 54.90, H 9.92, N 4.74.

**Reaction of 2 with $CS_2$:** A sample of **2** (0.85 g, 1.75 mmol) in hexane (20 mL) was treated with $CS_2$ (0.15 mL, 1.75 mmol). The reaction mixture was stirred at 23 °C and monitored by $^{31}P$ NMR spectroscopy. After 36 h, no resonance due to **2** was detected. The mixture was filtered leaving a bright red solution that was concentrated (10 mL) and cooled (–78 °C). A red oil, **8**, deposited. Efforts to purify **8** by crystallization were unsuccessful. The crude product contained small amounts of $P(SiMe_3)_3$ and tmpH that were not completely removed. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.40 [d, $J_{HP}$ = 5.4 Hz, 9 H, $SiCH_3$], 0.50 [d, $J_{HP}$ = 4.8 Hz, 9 H, $SiCH_3$], 1.2–1.5 [m, 12 H, $CCH_2CH_2$], 1.54 [s, 12 H, $CCH_3$], 1.63 [s, 12 H, $CCH_3$] ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 1.8 [d, $J_{CP}$ = 11.7 Hz, $SiCH_3$], 5.6 [d, $J_{CP}$ = 11.4 Hz, $SiCH_3$], 18.4 [$CCH_2CH_2$], 18.6 [$CCH_2CH_2$], 34.5

**X-Ray Structure Determinations:** Single crystals were covered with a polyfluoro ether oil and specimens mounted on the tip of glass fibers. After cooling the crystals on the goniometer head to –80 °C with the LT2 device, the unit cells were determined from reflections collected on 65 frames at five different settings of the $\omega$ and $\chi$ circles. Data collections were performed in the hemisphere mode (1200 frames) with programs implemented in SMART.[27] The program SAINT[28] was used for data reduction and absorption corrections were applied using SADABS.[29] The structures were solved by direct methods using SHELX97[30] and refined with the same package. Non-hydrogen atoms were refined with anisotropic thermal factors. Most hydrogen atoms were visible following anisotropic refinement but were placed in calculated positions and included in refinements by applying the riding model. Data related to the crystallography are summarized in Table 1 and Table 2.

CCDC-640019 to –640025 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Aqueous Reduction of $[Cp^*_2W_2O_5]$: Characterization of the Triangular Clusters $[Cp^*_3W_3O_4(OH)_2]^{2+}$ and $[Cp^*_3W_3O_6]^+$ – Comparison with Molybdenum

**Chiara Dinoi,[a] Pelin Sözen,[b] Gülnur Taban,[b] Deniz Demir,[b] Funda Demirhan,*[b] Petr Prikhodchenko,[c] Jenny Gun,[c] Ovadia Lev,[c] Jean-Claude Daran,[a] and Rinaldo Poli*[a]**

**Keywords:** Tungsten / O ligands / Metal clusters / Density functional calculations

Zinc reduction of $Cp^*_2W_2O_5$ in an acidified water–methanol medium affords the green 3-electron trinuclear cluster $[Cp^*_3W_3O_4(OH)_2]^{2+}$, isolated and crystallographically characterized as the triflate salt, **1**. Upon exposure to air, this complex is oxidized to a related 2-electron cluster, $[Cp^*_3W_3O_6]^+$, which was crystallized and characterized in three different salts, **2**–**4**. The 3-electron cluster exhibits a near-tetragonal frozen-glass EPR spectrum, and it shows evidence of coupling of the unpaired electron to only one of the three W atoms. The two-electron cluster is diamagnetic. An electrospray ionization $MS^n$ study revealed a stepwise expulsion of neutral $[Cp^*WO_2]$ units as the main fragmentation process. DFT calculations unveiled the intimate details of the electronic structures of these complexes and fully rationalized the structural and spectroscopic properties.

## Introduction

Aqueous organometallic chemistry is attracting growing interest because of its "green" impact[1–3] and because of its potential in catalytic[4,5] and biomedical applications.[6] Although this area is widely explored for low-valent systems, usually upon appending hydrophilic functionalities to the ligand periphery to increase solubility in an aqueous environment,[7–9] studies of high-oxidation organometallics are still rather scarce.[10–12] For redox-active metals, these studies are particularly interesting, as they may open the way to electrocatalytic applications.[12]

In a recent contribution,[13] we reported that the zinc reduction of $Cp^*_2Mo_2O_5$ in a strongly acidic ($CF_3COOH$ or $CF_3SO_3H$) mixed $H_2O$/MeOH medium affords the trinuclear mixed-valence ($Mo_3^{13+}$) cluster $[Cp^*_3Mo_3O_2(OH)_4]^{2+}$. The ion adopts a nearly equilateral triangular shape; each edge is bridged by two ligands. The distortion of the triangle is caused by one edge that is bridged by two OH groups, whereas the other two edges are bridged by one O atom and one OH group. As a consequence, the former edge is slightly longer than the latter ones. Although the number of bridging OH versus O groups was not revealed directly by the X-ray structural analysis, it was suggested indirectly by the same technique through the existence of short hydrogen-bonding contacts (or lack thereof) between the $Mo_3O_6$ core and the two $CF_3CO_2$ and $CF_3SO_3$ anions, and this was confirmed by comparison with a DFT geometry-optimized model, by EPR spectrometry, and by magnetic susceptibility measurements.

In this contribution, we examine the parallel behavior of the pentamethylcyclopentadienyltungsten system and report the isolation and characterization of two new redox-related tritungsten oxido clusters, $[Cp^*_3W_3O_6]^+$ and $[Cp^*_3W_3O_4(OH)_2]^{2+}$.

## Results and Discussion

### The $[Cp^*_3W_3O_4(OH)_2]^{2+}$ Cluster

The reduction of $[Cp^*_2W_2O_5]$ was carried out under the same conditions previously used for the reduction of $[Cp^*_2Mo_2O_5]$, namely by metallic zinc in an acidic $H_2O$/MeOH mixed solvent. MeOH is necessary to increase the solubility of the starting material. The reaction was carried out in the presence of two different acids, trifluoroacetic acid and trifluoromethylsulfonic (triflic) acid. As for the

Mo analogue, a series of color changes was observed over a period of three days, yielding a final green solution through an intermediate orange-red color. Crystallization of the final green product was successful in the case of the triflic acid reaction, revealing the nature of the compound as $[Cp^*_3W_3O_4(OH)_2](CF_3SO_3)_2{\cdot}2H_2O$ (**1**). Thus, the reaction stoichiometry is as shown in Equation (1). The oxidation state of tungsten in the final product is +5, yielding a 3-electron $W_3^{15+}$ cluster. Compound **1** is quite soluble in $CH_2Cl_2$ and its solutions are air sensitive, and they turn rapidly to orange when exposed to the atmosphere. The nature of the orange product is shown in the next section.

$$3[Cp^*_2W_2O_5] + 3Zn + 10H^+ \rightarrow 2[Cp^*_3W_3O_4(OH)_2]^{2+} + 3H_2O + 3Zn^{2+} \quad (1)$$

[a] CGn is the center of gravity of the Cp* ligand bonded to atom Wn. [b] This structure has a symmetry imposed $C_2$ axis passing through atoms W2 and the midpoint of the W1–W1$^i$ bond. Numbering scheme correspondence: W3=W1$^i$; O12 = O22$^i$; symmetry code: (i) –*x*, *y*, –*z* + 3/2.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The structure of the dication is shown in Figure 1, whereas Figure 2 illustrates the arrangement of the anions and the interstitial $H_2O$ molecules relative to the trimetallic cluster. Relevant bonding parameters are collected in Table 1. The H atoms on the bridging OH groups could not be directly located from the diffraction data, but their presence is clearly demonstrated by the H-bonding network. Hydrogen bond contacts for compound **1** are available in the Supporting Information. As shown in Figure 2, the bridging atoms O13 and O21 establish short contacts with atoms O100 and O200 of the interstitial water molecules. The latter, in turn, establish short contacts with two different atoms of triflate anions: O100 with O6 but also with O4 of a second asymmetric unit; O200 with O3 but also with O1 of a third asymmetric unit. Close inspection of the difference Fourier map obtained after refinement of all heavy atoms revealed in fact the position of the H atoms on the interstitial $H_2O$ molecules. This observation excludes the alternative formulation as a neutral $[Cp^*_3W_3O_6]$ complex with two interstitial $CF_3SO_3H$ molecules, because in the latter case only one of the two $H_2O$ protons would point towards an oxygen atom of the trifluoromethylsulfonate group, whereas the other one would point towards the bridging oxido group of the $W_3$ cluster. Although these considerations establish the presence of H atoms on O13 and O21, they provide no information on the absence or presence of H atoms on the other bridging O atoms, O11, O12, O22, and O23. This point will be addressed in further detail later by inspection of the spectroscopic properties and by comparison of the experimental (X-ray diffraction) and computed (DFT) bonding parameters.

A most informative structural feature is the variation of the W–W distances: the two bonds bridged by one O atom and one OH group, W1–W2 [2.7416(3) Å] and W2–W3 [2.7485(3) Å], are almost 0.1 Å longer than the bond bridged by two O groups, W1–W3 [2.6545(3) Å]. In addition, the W–OH distances [in the range 2.038–2.080 Å; average 2.06(2) Å] are statistically longer than the W–O distances [in the range 1.872–2.009 Å; average 1.94(6) Å]. Furthermore, the W–(μ–OH)–W angles [83.39(13) and 83.73(13)°] are smaller than the W–(μ-O)–W angles in the $W(\mu\text{-}O)_2W$ moiety [average 85.54(14)°]. The W–(μ-O)–W angles in the W(μ-O)(μ-OH)W moiety are even larger [average 90.40(15)°]. This is certainly a secondary effect related to the longer W–W distance.

## The $[Cp^*_3W_3O_6]^+$ Cluster

### *The Triflate Structure – Compound 2*

As stated above, exposure of solutions of compound **1** to air rapidly yields orange-red solutions. Crystallization from this oxidized solution yielded red crystals of compound **2**, which was shown by X-ray analysis to correspond to $[Cp^*_3W_3O_6](CF_3SO_3)$. This formulation is consistent with the spectroscopic properties and with a comparison between the experimental (X-ray diffraction) and computed (DFT) structural parameters, as shown in a later section. The cation is a mixed-valence $W_3^{V,V,VI}$ cluster, namely a 2-electron cluster. Thus, the transformation generating this cluster can be described as in Equation (2).

$$[Cp^*_3W_3O_4(OH)_2]^{2+} + [ox] \rightarrow [Cp^*_3W_3O_6]^+ + 2H^+ + [red] \quad (2)$$

Like compound **1**, compound **2** is soluble in $CH_2Cl_2$, but it is also fairly soluble in $MeOH/H_2O$ solvent mixtures. These solutions are relatively stable in air, but not indefinitely so, to ultimately yield colorless solutions, which apparently occurs faster at high pH values. $^1H$ NMR spectroscopic monitoring in $MeOD/D_2O$ reveals the formation of a single resonance ($\delta$ = 2.05 ppm) attributed to $[Cp^*WO_3]^-$[14] at neutral or basic pH, whereas several other products, yet to be identified, are obtained under strongly acidic conditions (pH 2: resonances at $\delta$ = 2.22, 2.19, 2.15).

The structure of **2** contains a simple anion and no interstitial solvent molecules, which firmly establishes the +1 charge of the cluster. However, the cation exhibits a symmetry-imposed disorder because of a twofold axis that

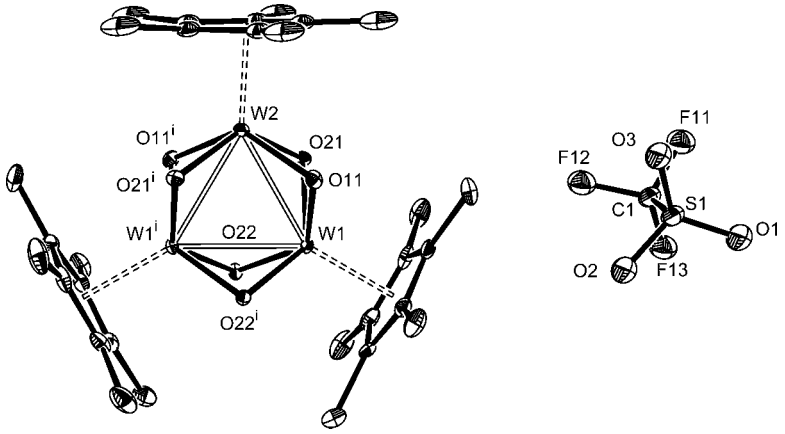

Figure 3. A view of the relative orientation of the cation and anion in the structure of $[Cp^*_3W_3O_6](CF_3SO_3)$ (**2**). Only one of the two symmetry-related orientations of the trifluoromethylsulfonate anion and of the Cp*(2) ligand are shown for the sake of clarity.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

passes through atom W2 and through the midpoint of the W1–W1$^{i}$ bond. Therefore, there is a 50:50 distribution of two symmetry-related orientations of the Cp* ligand bonded to atom W2. In addition, the triflate anion is also located on a special position (another $C_2$ axis, orthogonally cutting through the C–S bond), yielding again a 50:50 distribution of two symmetry-related orientations. In spite of this problem, the structural model refined to quite acceptable final residuals, yielding relatively precise bond lengths and angles.

The crucial question concerns the absence of H atoms on the bridging O atoms. No residual electron density that could be assigned to such atoms was visible from the final difference Fourier map. However, even more convincing is the absence of close contacts between the two ions. The anion is located on the same plane as the $W_3$ triangle, separated from it by one of the Cp* ligands, see Figure 3. Two of the Cp* methyl H atoms are in close contact with the anion: H11B···O2 2.448, H11B···F11 2.506, H12C···O11 2.428, H12C···F12 2.540 Å. It may be reasonably argued that, if any OH group was present on the triangular $W_3$ cluster, this would establish H-bonding contacts with the triflate anion, as observed for the reduced analogue **1** (see above). Rather, the space above and below the $W_3$ triangle, in close contact with the bridging O atoms, is occupied by $CH_3$ groups of the $[Cp^*_3W_3O_6]^+$ ions located in other asymmetric units.

### *Two Trifluoroacetate Structures – Compounds 3 and 4*

Before discussing the structural parameters within the $[Cp^*_3W_3O_6]^+$ ion in more detail, we introduce two additional compounds related to **2**. These were obtained from the same synthetic procedure shown above but by using $CF_3COOH$ in place of triflic acid. Although the green product could not be obtained in single crystalline form, red crystals of the oxidation product were obtained after exposure to air. From two batches, crystallized under slightly different conditions, two different crystals containing the same $[Cp^*_3W_3O_6]^+$ ion were obtained: $[Cp^*_3W_3O_6][Zn_3(\mu_3\text{-}O)(\mu\text{-}CF_3COO)_4(CF_3COO)(CF_3COOH)(H_2O)_3]\cdot CF_3COOH$ (**3**) and $[Cp^*_3W_3O_6]_2[Zn(H_2O)_6](CF_3COO)_2(CF_3COOHOOCCF_3)_2\cdot 4H_2O$ (**4**). The bonding parameters for the tritungsten cluster of each compound are collected in Table 1, together with those of compounds **1** and **2**.

Compound **3** contains a complex, apparently unprecedented trinuclear zinc anion, as well as an interstitial $CF_3COOH$ molecule as shown in Figure 4. The closest relatives appear to be $Zn_3(\mu_3\text{-}O)(\mu\text{-}CF_3COO)_x$ clusters with $x = 5$[15] or 6,[16] and with similar frameworks and geometries. The anion in compound **3** contains one four-coordinate (Zn2) and two six-coordinate (Zn1, Zn3) zinc ions joined together by a triply bridging ligand O4. One carboxylate ligand bridges atoms Zn1 and Zn2, a second one bridges atoms Zn2 and Zn3, two additional ones bridge atoms Zn2 and Zn3, and a fifth one is terminally bonded to the four-coordinate Zn2 atom. The latter one is disordered among two different positions, one of which features a H-bond to the aqua ligand identified by atom O2 [O71a···O2 = 2.70(2) Å]. The other position features two weaker H-bonding interactions, the first one with the same aqua ligand [O71···O2 = 3.11(3) Å] and the second one (not shown in Figure 4) with atom O92 of a coordinated acid ligand [O71···O92 = 3.02(2) Å]. The latter ligand is terminally bonded to atom Zn3 through the carbonyl oxygen atom O91, whereas the OH functionality of this ligand (O92) is engaged as a proton donor in H-bonding with the triply bridging oxygen atom O4. The most relevant H-bonding contacts in compound **3** are supplied in the Supporting Information. The coordination sphere of six-coordinate Zn1 is completed by two water molecules (O1 and O2), whereas that of six-coordinate Zn3 is completed by a third water molecule (O3). The interstitial acid is a proton donor to the OH group of the coordinated acid (O92) and an acceptor from one of the aqua ligands (O2). The anion also establishes H-bonding interactions, as a proton donor, with the $W_3$ cation: three stronger ones through the aqua ligands O1 and O3 (with atoms O21, O23, and O13$^{i}$), plus two weaker ones through the aqua ligands O3 (with atom O12$^{i}$) and O2 (with atom O22), see Figure 5. H-bonding interactions are established on both opposite sides of the triangular $W_3$ face, which results in zig–zag 1D H-bonded chains (see Figure S1, Supporting Information). The most significant bonding parameters of the $[Zn_3(\mu_3\text{-}O)(\mu\text{-}CF_3COO)_4(CF_3COO)(CF_3COOH)(H_2O)_3]^-$ anion are collected in Table 2.

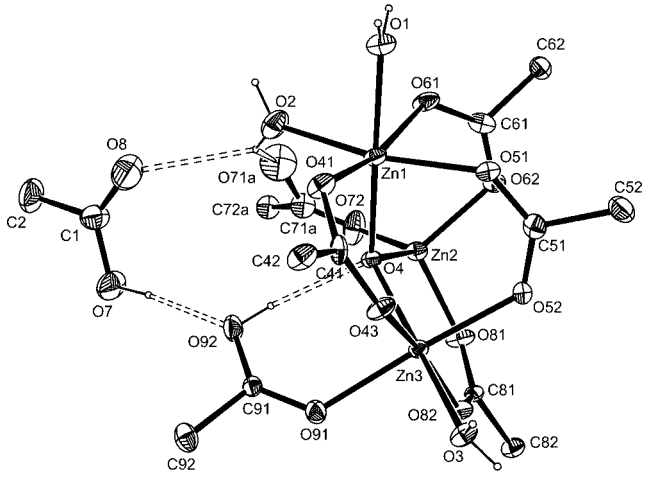

Figure 4. A view of the $[Zn_3(\mu_3\text{-}O)(\mu\text{-}CF_3COO)_4(CF_3COO)(CF_3COOH)(H_2O)_3]^-$ anion and the interstitial $CF_3COOH$ molecule in compound **3**. Only one component (C71a, C72a, and O71a) of the disordered $CF_3COO$ group is shown for the sake of clarity.

Compound **4** features a $[Zn(H_2O)_6]^{2+}$ ion sitting on an inversion center, plus an isolated $CF_3COO^-$ ion, a homoconjugate $CF_3COO\cdots H\cdots OOCCF_3^-$ ion, and two water molecules in general positions, in addition to the $[Cp^*W_3O_6]^+$ ion, also located in a general position. The three bridging O atoms on one face of the $W_3$ triangle (O21, O22, and O23) are acceptors for H-bonds with the aqua ligands of the $[Zn(H_2O)_6]^{2+}$ cation, see Figure 6. The opposite face of the $W_3$ triangle (atoms O11, O12, and O13) does not establish H-bonds. In addition, the aqua ligands of the

$[Zn(H_2O)_6]^{2+}$ cation are H-bond donors towards the interstitial water molecules ($O111^i$ to O2W and $O113^i$ to O1W) and to the free $CF_3COO^-$ ion (O112 to O51). The other O atom of the latter (O52) is a H-bond acceptor from O1W. The homoconjugate anion, $CF_3COOHOOCCF_3^-$, also establishes H-bonds as acceptor with both interstitial water molecules. The relevant H-bonding parameters are provided in the Supporting Information. The H-bonding network yields an arrangement of the structure in 2D layers (see Figure S2, Supporting Information).

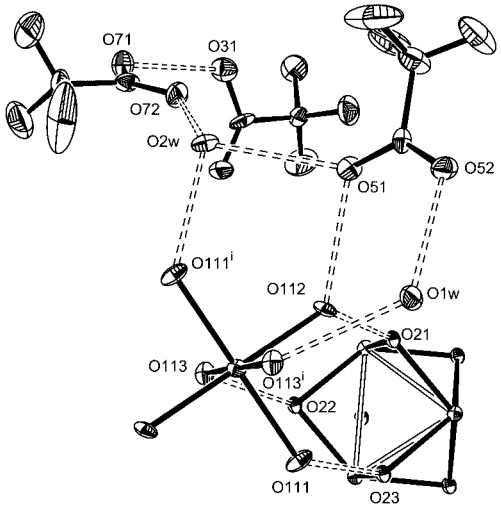

Figure 6. A view of the arrangement between the $[Cp^*_3W_3O_6]^+$, $[Zn(H_2O)_6]^{2+}$, $CF_3COO^-$, and $CF_3COO\cdots H\cdots OOCCF_3^-$ ions, and the two interstitial $H_2O$ molecules, in the structure of compound **4**. The cation Cp* ligands and all H atoms have been removed for clarity [symmetry code: (i) –*x*, –*y*, –*z*].

### *Description of the $[Cp^*_3W_3O_6]^+$ Structure*

The $[Cp^*_3W_3O_6]^+$ cluster has identical bonding parameters, within experimental error, in the structures of compounds **2**, **3**, and **4**, see Table 1. A representative view is shown in Figure 7. These parameters are significantly different from those of the dication of compound **1**. In particular, the three W–W distances are essentially equivalent, and they are placed in the narrow range 2.650–2.685 Å, with averages of 2.655(3) Å for **2**, 2.673(10) Å for **3**, and 2.662(2) Å for **4** or 2.663(10) Å for the entire set. This value is very close to the distance of the W–W bond bridged by

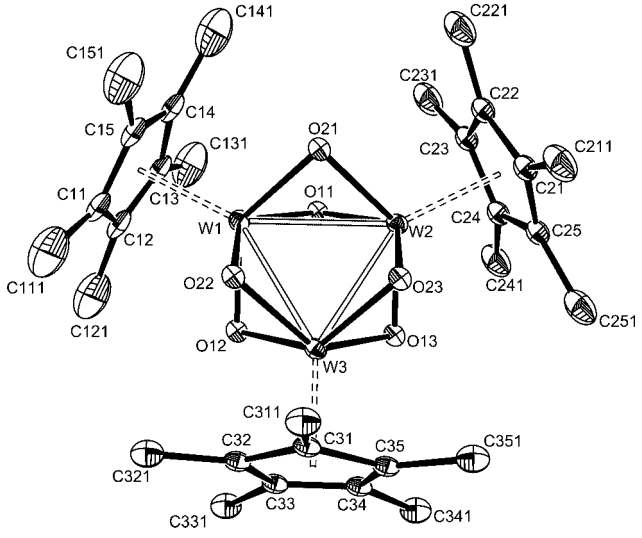

Figure 7. An ORTEP view of the $[Cp^*_3W_3O_6]^+$ ion from the structure of compound **3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

two O ligands in compound **1**. The higher symmetry of the $Cp^*_3W_3O_6$ scaffold in the monocation, approaching ideal $D_{3h}$ symmetry, is also revealed by the small spread of the W–O distances [range 1.918–1.998 Å; averages 1.960(10) Å for **2**, 1.964(16) Å for **3**, 1.948(17) Å for **4**; global average 1.957(16) Å] and W–O–W angles [range 84.9–87.5°; averages 85.2(4)° for **2**, 85.8(4)° for **3**, 86.2(8)° for **4**; global average 85.7(7)°]. These values are also close to those of the $W(\mu\text{-}O)_2W$ moiety in compound **1**.

### Spectroscopic Identification

According to the formulation of the two clusters, derived from the X-ray analyses shown above, as $[Cp^*_3W_3O_4(OH)_2]^{2+}$ for the green derivative and $[Cp^*_3W_3O_6]^+$ for the red-orange derivatives, the first cluster has three metal electrons and should therefore be paramagnetic, whereas the second one has only two, which should be located in a symmetric metal–metal bonding combination,[13] and should therefore be diamagnetic. These expectations are in agreement with the experiment.

Compound **1** does not exhibit any strong $^1H$ NMR spectroscopic signal. In contrast, it has an EPR resonance, although this is clearly visible only at low temperatures (<200 K). The frozen glass spectrum in $CH_2Cl_2$ solution is shown in Figure 8. The overall shape is close to that expected for tetragonal symmetry, though a slight splitting of the perpendicular component is clearly visible. This is in nice agreement with the asymmetry of the bridge system, which introduces a slight perturbation to the threefold symmetry of the $W_3$ triangle as also indicated by the W–W distances. The perpendicular component does not have sufficient resolution to reveal the $^{183}W$ satellites. The parallel component, conversely, shows them quite clearly (see enlargement in Figure 8b). This feature was satisfactorily simulated as the sum of three Lorentzians, plus a quadratic function to account for the baseline drift. The satellites correspond to ca. 15% of the total intensity, in agreement with coupling of the unpaired electron with only one of the three cluster W atoms (theoretical values of 14.4, 24.7, and 31.6% are expected for coupling to 1, 2, or 3 equiv. W atoms, respectively). This observation will be fully rationalized on the basis of the computational results (vide infra).

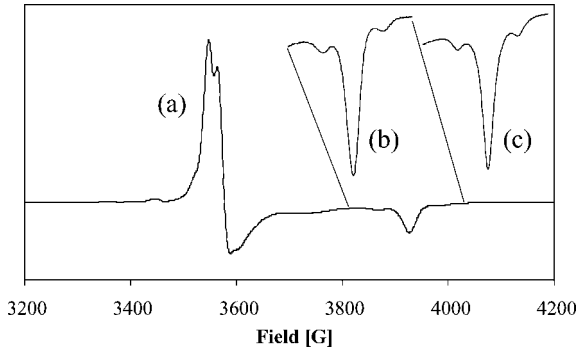

Figure 8. EPR spectrum of a frozen $CH_2Cl_2$ solution of compound **1** at 120 K: (a) experimental spectrum; (b) enlargement of the 3800–4050 G range; (c) simulation of (b), see text.

Contrary to compound **1**, compounds **2**–**4** do not show any EPR signal. They exhibit instead an NMR resonance at $\delta$ = 2.28 ppm in $CDCl_3$, consistent with the equivalence of the three Cp* ligands. Because this single $^1H$ NMR spectroscopic resonance is not conclusively proving the chemical constitution of the isolated bulk material, further characterization was sought by mass spectrometry (MS).

An electrospray ionization (ESI) MS study of compound **4** in $CH_2Cl_2$ gives a very clean isotopic cluster, which agrees with the theoretical isotopic distribution of $[Cp^*_3W_3O_6]^+$, see Figure 9. The same pattern is also observed in MeOH and in $MeOH/H_2O$ mixtures. Note the absence of fragmentation peaks, which reflects the robustness of the molecular

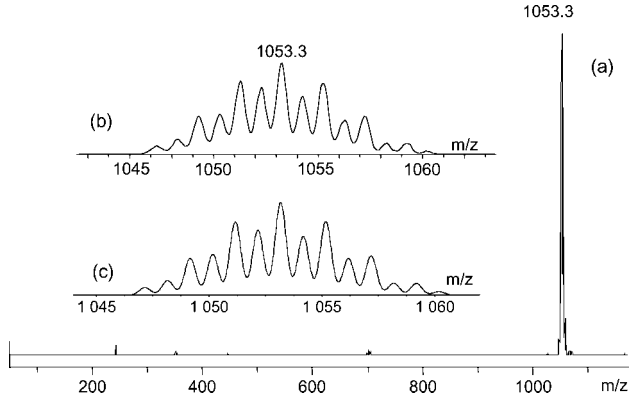

Figure 9. MS (ESI) of a $CH_2Cl_2$ solution of compound **4**. An expansion of the molecular ion isotopic cluster is shown in part (b) and the theoretical simulation in part (c).

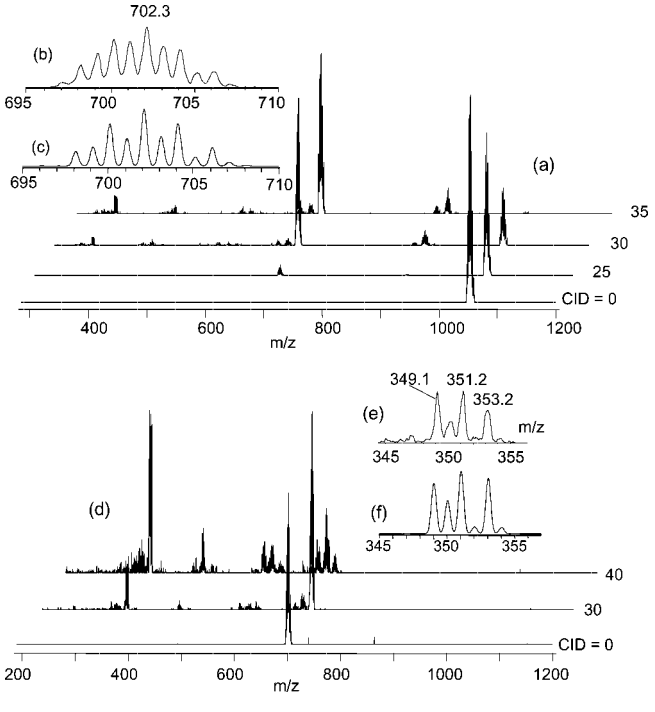

Figure 10. $MS^n$ studies of the $[Cp^*_3W_3O_6]^+$ ion: (a) MS–MS(1053) at increasing collision energies; (b) expansion; and (c) simulation of the product ion; (d) MS–MS(1053)–MS(702) at increasing collision energies; (e) expansion; and (f) simulation of the product ion.

scaffold. To learn about the fragmentation pattern, the collision-induced decay (CID) of this ion was investigated by $MS^n$. As shown in Figure 10(a), the ion displays a major decay pathway by expulsion of a $[Cp^*WO_2]$ fragment with transformation into $[Cp^*_2W_2O_4]^+$ (isotope cluster centered at $m/z$ = 702). However, the isotope pattern [Figure 10(b) with simulation in Figure 10(c)] reveals the presence of a second species one mass unit lighter. Therefore, elimination of a $[Cp^*WO_2H]$ unit, with the presumed involvement of a $CH_3$ group and generation of a tetramethylfulvene ligand, constitutes a competitive fragmentation pathway. Further trapping of these species and new CID in an $MS^3$ experiment, see Figure 10(d), is less selective but the major decay pathway is once again expulsion of a $[Cp^*WO_2]$ fragment from $[Cp^*_2W_2O_4]^+$, yielding $[Cp^*WO_2]^+$ (isotope cluster centered at $m/z$ = 351). The latter ion is not produced in a major pathway by direct expulsion of $[Cp^*_2W_2O_4]$ from the trinuclear species.

## DFT Calculations

Model compounds of the triangular $W_3$ clusters, obtained by replacing the Cp* ligands with the simpler Cp ring, i.e. $[Cp_3W_3O_4(OH)_2]^{2+}$ (**5**) for compound **1** and $[Cp_3W_3O_6]^+$ (**6**) for compounds **2**–**4**, were subjected to geometry optimization to find further supporting evidence for their stoichiometry (notably the number of OH vs. O groups) and to investigate their electronic structure. The calculations were run with no symmetry restrictions. Both calculations converged smoothly, giving final geometries in remarkably good agreement with the corresponding experimental ones for the Cp* derivatives (see Table 3). The only slight discrepancy consists of slightly longer bond lengths from the calculations relative to the experiment (W–O distances by 0.02–0.05 Å; W–W distances by 0.06–0.10 Å), as is typically observed for DFT calculations.

The geometrical trends for the less symmetric dihydroxido cluster **5** (see Scheme 1) are perfectly reproduced. Particularly notable is the difference between the W–W and W–W′ distances. The dioxido-bridged (W–W) bond is shorter than the two oxidohydroxido-bridged (W–W′) bonds by about 0.1 Å, like in the experimental structure. The lengths of different types of W–O bonds also have the same trend in the calculated and experimental structures (b > d > a > c, for the labeling, refer to Scheme 1), as do the different types of W–OH bonds (e > f). Finally, the two W–CG distances are longer than the W′–CG′ distance.

Excellent agreement is also found between the optimized geometry for the $[Cp_3W_3O_6]^+$ cluster and the experimentally observed structure for the Cp* analogue. In particular, the geometry is now close to the ideal $D_{3h}$ symmetry, with three very similar W–W distances. Note that the average optimized W–W distance in **6** is essentially identical to the shorter W–W distance for the dioxido-bridged bond in **5**. The same phenomenon is observed in the experimental structures. The three W–CG distances are also essentially equivalent.

Table 3. Comparison of the DFT optimized geometries (distances [Å], angles [°]) for the model $[Cp_3W_3O_4(OH)_2]^{2+}$ (**5**) and $[Cp_3W_3O_6]^+$ (**6**) complexes with the X-ray structures of the Cp* analogues.[a]

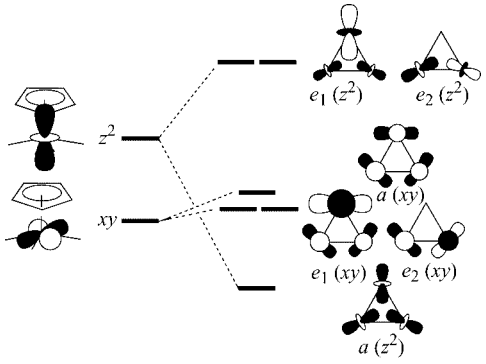
The electronic structure analysis is particularly interesting. The qualitative interaction diagram for the metal-based orbitals in this type of molecular scaffold was previously discussed[17,18] and is reproduced in Scheme 2 for convenience. The relevant metal-based molecular orbitals calculated for the two systems are shown in Figure 11, whereas more extensive data are available in the Supporting Information. For system **6** – a 2-electron $W_3^{V,V,VI}$ cluster – the two metal electrons are located in the $a(z^2)$ orbital, as expected. This orbital interaction insures the metal–metal attractive force. The additional electron in system **5** – a 3-electron $W_3^{V,V,V}$ cluster – is located in one of the two orbitals derived from the $e(xy)$ set. Because the ideal symmetry is reduced from $D_{3h}$ to $C_2$ by the addition of the two protons, the $e(xy)$ set splits ($e_1$ of $a$ type + $e_2$ of $b$ type) and the unpaired electron is located in the symmetric $a$ component. Note that, whereas the antisymmetric ($b$) component must be nil on the unique tungsten atom (W′) (see Supporting Information), there is no symmetry restriction for the composition of the $a$-type orbital. However, the composition of this orbital is such that the contribution from the two symmetry-equivalent W atoms is negligible, whereas atom W′ contributes greatly. Thus, the spin density is very much localized on the W′ atom (0.911), whereas it is negligible on the two W atoms (0.028 and 0.036), in perfect agreement with the measured relative intensity of the satellites in the EPR spectrum (vide supra). In this respect, it should be noted that the related molybdenum complex $[Cp^*_3Mo_3O_2(OH)_4]^{2+}$ – a 5-electron $Mo_3^{IV,IV,V}$ cluster – was shown to have the same ordering for the metal-based molecular orbitals.[13] Therefore, the unpaired electron for that complex is located in the antisymmetric $b$ orbital and couples to only two Mo nuclei, again consistent with the experimental evidence from EPR spectroscopy.



Scheme 2. Qualitative metal–metal orbital interactions for a $Cp_3M_3L_6$ molecule of ideal $D_{3h}$ symmetry.

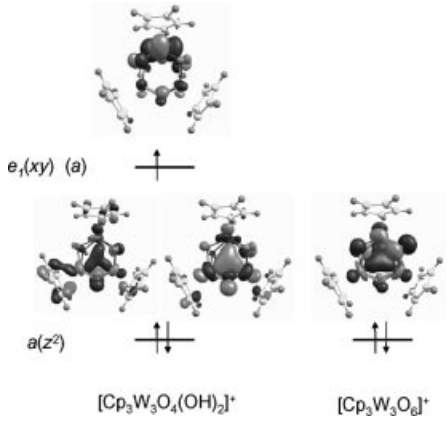


Figure 11. Filled metal-based molecular orbitals for systems **5** (left) and **6** (right). For the former, both spin orbitals resulting from the spin unrestricted calculation are shown.

## Comparison with Molybdenum and Redox Considerations

The reduction process reported here parallels that reported recently for the reduction of $Cp^*_2Mo_2O_5$.[13] However, the Mo system leads to a deeper reduction with generation of a 5-electron cluster, the trinuclear $Mo_3^{IV,IV,V}$ $[Cp^*_3Mo_3O_2(OH)_4]^{2+}$ complex. This product has the same molecular architecture as the two trinuclear W clusters described here, differing only by the number of protons and electrons. This difference agrees with the general trend of greater stability for higher oxidation states upon descending the same group of transition metals. It may be predicted that, by treatment with suitable oxidizing agents (or at a suitable electrochemical potential in an electrochemical experiment) the 5-electron Mo cluster could produce a 3-electron or a 2-electron cluster with the same structure found in the present study for the W system. Conversely, suitable reductive treatment of the W system could afford a 5-electron system such as the previously reported Mo cluster. Other electronic configurations such as 4-electron $M^{IV,V,V}$ could also exist. Given that proton gains/losses are associated with these transformations (at least between the two types of W clusters reported in the present contribution), it may also be expected that the redox potential is pH dependent in a protic environment. A detailed analysis of the electrochemical behavior of these clusters is beyond the scope of the present investigation and may be carried out at a later time.

Previous studies of the $Cp^*_2Mo_2O_5$ system by a coupled electrochemical–electrospray mass spectrometry methodology, by using a flow-through electrochemical cell,[19,20] revealed a very rich redox behavior, including the formation of trinuclear clusters that are related to the isolated cluster. We have now attempted to carry out a similar investigation for $Cp^*_2W_2O_5$, but no sufficient quantities of soluble products were revealed by the mass spectrometric analysis. At the potential at which the Mo system started to yield reductive processes, the W system showed no activity, whereas the rapid formation of a film on the surface of the electrode, which blocked any further electrochemical transformation, was observed at lower potentials. Therefore, it seems that the $Cp^*_2W_2O_5$ is more difficult to reduce than the Mo analogue and the primary reduction products (perhaps including the isolated trinuclear clusters described here) are unstable under these highly reducing conditions and proceed further to yield insoluble products.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

## Conclusions

Like its Mo analogue,[13] the compound $[Cp^*_2W_2O_5]$ can be reduced in an aqueous medium to a triangular metal–metal bonded cluster. However, only 2- and 3-electron clusters are obtained for W, whereas the Mo system undergoes a deeper reduction to yield a 5-electron cluster. Like for the Mo cluster, the oxido/hydroxido asymmetry in the bridge system splits the degeneracy of the "*e*"-type frontier orbitals, as indicated by the EPR spectrum of the 3-electron cluster and confirmed by the DFT calculations. The variability of the cluster electrons for this system will be further explored for applications in organometallic chemistry and catalysis.

## Experimental Section

**General Procedures:** All preparations and manipulations were carried out with Schlenk techniques under an oxygen-free argon atmosphere. All glassware was oven-dried at 120 °C. Solvents were dried by standard procedures and distilled under nitrogen prior to use. $^1$H NMR spectra were recorded with a Bruker AM 250. Chemical shifts are expressed in ppm downfield from $Me_4Si$. Coupling constants are given in Hertz. Mass spectra were recorded with a Finnigan (San Francisco, USA) LCQ quadrupole ion-trap mass spectrometer equipped with an electrospray-ionization (ESI) interface. The ESI was operated in the positive ion mode with a spray voltage of 4.5 kV. The capillary voltage was 20 V and the source temperature was 100 °C. Mass spectra were obtained by scanning the mass analyzer from *m*/*z* 100 to 2000 with 5 total microscans. Maximum inject time was 400 ms. The analyzer was operated at a background pressure of $2 \times 10^{-5}$ Torr. In all experiments, helium was introduced at an estimated pressure of 1 mTorr to improve the ion-trapping efficiency and as collision gas for the collision-induced dissociation events. The compounds were isolated in the ion trap with an isolation width of 12 *m*/*z* units and activated by using increased collision energy to obtain collision-energy-dissociation profiles. EPR measurements were carried out at the X-band microwave frequency with a Bruker ESP300 spectrometer. The spectrometer frequency was calibrated with diphenylpicrylhydrazyl (DPPH, $g = 2.0037$). The starting compound, $[Cp^*_2W_2O_5]$, was prepared as described in the literature.[14]

**Synthesis and Crystallization of $[Cp^*_3W_3O_4(OH)_2](CF_3SO_3)_2 \cdot 2H_2O$ (1):** Metallic zinc (20 mesh, 0.415 g, 6.34 mmol) was added to a solution of $[Cp^*_2W_2O_5]$ (50 mg, 0.070 mmol) in MeOH/$H_2O$ (1:1, 6 mL). The mixture was acidified with $CF_3SO_3H$ (10 drops) and stirred under an atmosphere of argon at r.t. for 3 d, during which time it changed from a yellow solution to a green suspension. The mixture was filtered, and the solid was extracted with THF (0.5 mL). The addition of $Et_2O$ (1.5 mL) to the filtrate yielded the product as a green precipitate (0.047 g, 72%). A single crystal for X-ray analysis was obtained by diffusion of an $Et_2O$ layer into a THF solution at r.t. EPR (X-band, $CH_2Cl_2$, 120 K): $g_\perp = 1.89$; $g_\parallel = 1.72$ ($a_{W\parallel} = 114$ G).

**Synthesis and Crystallization of $[Cp^*_3W_3O_6](CF_3SO_3)$ (2):** A sample of compound **1** (61 mg, 0.044 mmol) was dissolved in $CH_2Cl_2$ and stirred for 1 h at r.t. in open air. The color of the green solution turned orange. The solvent was evaporated to dryness to afford an orange power, which was recrystallized from $CH_2Cl_2$/pentane to give red crystals (25 mg, 47% yield). $^1$H NMR (250 MHz, $CDCl_3$): $\delta = 2.28$ ppm.

**Reduction of $[Cp^*_2W_2O_5]$ by Zinc in the Presence of $CF_3COOH$ – Formation of Compounds 3 and 4:** Metallic zinc (20 mesh, 0.415 g, 6.34 mmol) was added to a solution of $[Cp^*_2W_2O_5]$ (50 mg, 0.070 mmol) in MeOH/$H_2O$ (1:1, 6 mL). The mixture was acidified with $CF_3COOH$ (10 drops) and stirred under an atmosphere of argon at r.t. for 5 d during which time it changed from a yellow solution to a green suspension. The mixture was filtered, and the solid was dried under vacuum (31 mg). Attempts to produce single crystals from this material failed as only powdery precipitates were obtained. Red single crystals of compound **3** were eventually obtained from $CH_2Cl_2$/hexane after exposure of the solution to air. $^1$H NMR (250 MHz, $CD_2Cl_2$): $\delta = 2.26$ ppm.

In a parallel identical procedure, from one of the numerous attempts to crystallize the green solid, the yellow mother solution of the green powdery precipitate was recovered, dried, and the yellow-orange residue was set again for crystallization from THF/hexane to yield single crystals of compound **4**. $^1$H NMR (250 MHz, $CDCl_3$): $\delta = 2.28$ ppm. MS (ESI, $CH_2Cl_2$): $m/z = 1053$ (envelope) $[M]^+$ (see Results and Discussion section).

**X-Ray Diffraction Studies:** A single crystal of each compound was mounted under inert perfluoropolyether at the tip of a glass fiber and cooled in the cryostream of an Oxford-Diffraction XCALIBUR CCD diffractometer. Data were collected by using the monochromatic Mo$K_\alpha$ radiation ($\lambda = 0.71073$). The structures were solved by direct methods (SIR97)[21] and refined by least-squares procedures on $F^2$ by using SHELXL-97.[22] All H atoms attached to carbon were introduced at idealized positions and treated with the riding model. All H atoms attached to oxygen were either located on difference Fourier syntheses or their coordinates were calculated on the basis of hydrogen bonding geometry and energy considerations.[23] They were then treated as riding on their parent O atoms. In compound $Cp^*_3W_3O_6(CF_3SO_3)$, the cation, $Cp^*_3W_3O_6$, is arranged around a twofold axis resulting in one of the Cp* to be disordered over two positions. The $CF_3SO_3$ anion is also disordered and arranged around another twofold axis. For both the disordered parts, the atomic positions and anisotropic thermal parameters were restrained to reasonable values using the tools available within SHELXL-97.[22] The drawing of the molecules was realized with the help of ORTEP3.[24] Crystal data and refinement parameters are shown in Table 4. CCDC-643997 to -644000 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** The DFT calculations were carried out on model systems where the Cp* ligands were replaced on the simpler Cp rings. The starting geometries were based on the crystallographically determined structures and no symmetry restrictions were imposed. The geometries were fully optimized and the resulting minima of the potential energy surface (PES) were verified by the positive value of all second derivatives of the energy. The calculations were performed by using the B3LYP three-parameter hybrid density functional method of Becke[25] and the standard LANL2DZ basis set, which included the Hay and Wadt effective core potentials (ECP) for the tungsten atoms,[26] as implemented in the Gaussian03 suite of programs.[27] The calculation on the open-shell system **5** was carried out by using the spin-unrestricted formulation. The value of $<S^2>$ resulting from the calculation is 0.7575, indicating negligible spin contamination.

# Ferromagnetic Coupling in a Mixed-Valence Hexavanadate Core: Quantum-Chemical Forecast

**Ekaterina M. Zueva,*[a] Serguei A. Borshch,*[b] Maria M. Petrova,[a] Henry Chermette,[c] and Andrey M. Kuznetsov[a]**

**Keywords:** Mixed-valent compounds / Vanadates / Density functional calculations / Exchange interactions / Electron transfer

The electronic structure and magnetic properties of the recently synthesized $V^{IV}/V^{V}$ mixed-valence alkoxo-polyoxovanadate comprising a hexanuclear vanadium core with four unpaired electrons have been studied within the DFT framework. The results of calculations suggest that the d electrons are completely trapped within the hexavanadate core, in agreement with the experimental observations. The exchange coupling constants computed using the broken symmetry formalism appeared to be of a ferromagnetic nature. Such interactions are very rare in oxovanadium complexes and are a consequence of a specific core geometry imposed by the polyoxometalate architecture. It has been shown that the earlier proposed intramolecular electron transfer cannot change the ground spin-state multiplicity irrespective of the sign of the exchange parameters.

## Introduction

Polyoxometalates (POMs) constitute a large group of polynuclear metal–oxygen anionic species possessing interesting and potentially valuable physical, chemical, and electrochemical properties. The ability of some transition metals (e.g., V, Mo, W, etc.) in their high oxidation states (+5, +6) to form POMs in solution has inspired many studies on POMs, giving rise to a variety of POM derivatives with intriguing architectures. Because of their unique properties, these species have multiple applications in different disciplines, such as catalysis (both heterogeneous and homogeneous), medicine, and materials science.[1–4] It has been found that unstable POM architectures can be stabilized by the introduction of alkoxo ligands because of the charge compensation associated with formal substitution of peripheral oxo ligands.[5] Among many other alkoxo-polyoxometalates, the fully alkylated polyoxovanadate derivatives $[V^{IV}_{n}V^{V}_{6-n}O_7(OR)_{12}]^{(4-n)}$ (R = $CH_3$, $C_2H_5$) of the classical (Lindqvist) POM structure $[M_6O_{19}]^{n-}$, which as an entity is not known for vanadium, have been reported by Hartl et al.[6,7] In these complexes, the hexavanadate core contains an $OV_6$ unit in which the vanadium ions are arranged in an octahedral fashion; six oxo groups act as terminal ligands and twelve alkoxo groups act as bridging ligands. The chemical synthesis and crystal structures of such alkoxo-polyoxovanadium compounds differing in their $V^{IV}$ content ($n$ = 2, 3, 4, 5, 6) have been described (see Figure 1). Interestingly, the complexes with two, three, and four vanadium(IV) centers give rare examples of cationic and neutral POM species. With the exception of the isovalent systems comprising six unpaired electrons ($n$ = 6), the reported complexes are mixed-valent and, as such, are of great interest for studying the interplay between exchange coupling and electron transfer in the hexanuclear framework. For the neutral and positively charged redox isomers of the methoxo and ethoxo series, experimental studies (X-ray structural, IR spectroscopic, cyclovoltammetric) of electron delocalization between vanadium centers have been performed.[7] The results obtained from these investigations suggest that the hexavanadate core can display either trapped metal valences or partly and fully delocalized d electrons, depending on the state of the compound (solid or solution), the $V^{IV}/V^{V}$ ratio, the nature of the μ-bridging alkoxo ligands, and the temperature. The neutral methoxo and ethoxo species ($n$ = 4) seem to contain trapped vanadium valences in the solid state, the four vanadium(IV) centers being located in a planar $V_4O_4$ ring. This result has been obtained from valence sum calculations conducted on the X-ray structural data collected at 173 K. The same conclusion has been drawn from the IR spectra (KBr pellet, room

temperature), where the shape of the $O_b$–R absorption band is supposed to reflect the extent of trapped valence on the IR timescale. It should be mentioned, however, that the X-ray structure analysis conducted at room temperature yields, in the case of the ethoxo derivative, a structure displaying complete d-electron delocalization within the hexavanadate core. The phase transition[8] of the neutral ethoxo compound to the structure with completely detrapped vanadium valences is accompanied by disorder of the ethyl chains. It has been supposed that the latter is responsible for the delocalization of the unpaired electrons because it causes motion of the μ-bridging oxygen atoms. The event of valence detrapping at room temperature, which is revealed by valence sum calculations from crystallographic data, is not, however, manifested in the IR spectrum of the ethoxo derivative. As for the neutral methoxo species, the valence sums for its ambient-temperature X-ray structure still show the trapped vanadium valences, and differential scanning calorimetry measurements indicate no detectable phase transition in the temperature range 153–323 K. At the same time, the EPR-spectroscopic studies carried out for the $[V^{IV}_4V^{V}_2O_7(OCH_3)_{12}]$ single crystals[9] display the presence of an EPR signal, which has been attributed to a triplet ground state. As this observation does not agree with the expected antiferromagnetic interactions, active between four unpaired electrons, the results have been explained by introducing an internal dynamical process, namely, the intramolecular electron transfer. However, the attribution of the low-temperature signal to a triplet spin state is not unambiguous and, unfortunately, is not accompanied by thorough magnetic susceptibility measurements. Moreover, an abrupt transformation of the EPR spectrum discovered on cooling at about 190 K has been interpreted as a first-order phase transition. In the case of monocationic methoxo and ethoxo species containing three unpaired electrons ($n$ = 3), the X-ray structures obtained from hexachloroantimonate salts at 173 K comprise a highly symmetrical hexavanadate core, for which the valence sums indicate that all three d electrons are equally delocalized over the vanadium centers. In the dicationic ethoxo species ($n$ = 2), obtained again from its hexachloroantimonate salt, valence sum calculations conducted on the X-ray structure at 173 K indicate that the two unpaired electrons are located in a planar $V_4O_4$ ring, however it is not clear whether they are trapped or delocalized within the ring. The IR spectroscopic data (KBr pellet, room temperature) suggest that the monocationic derivatives exhibit a smaller degree of trapped valence than the neutral species, as well as the dicationic derivative in the ethoxo series, and are, therefore, in agreement with the solid-state results obtained by the X-ray structural analysis. We would also like to note that the earlier reported X-ray structural data for the methoxo compound series at 193 K[6] suggest that the monocationic derivative, if coupled with other counterions (e.g., polyhalide, $VOCl_4^-$), displays a distorted core and, apparently, a certain degree of trapped valence. Unfortunately, none of the mixed-valence alkoxo-polyoxovanadates have been studied using magnetic susceptibility measurements.

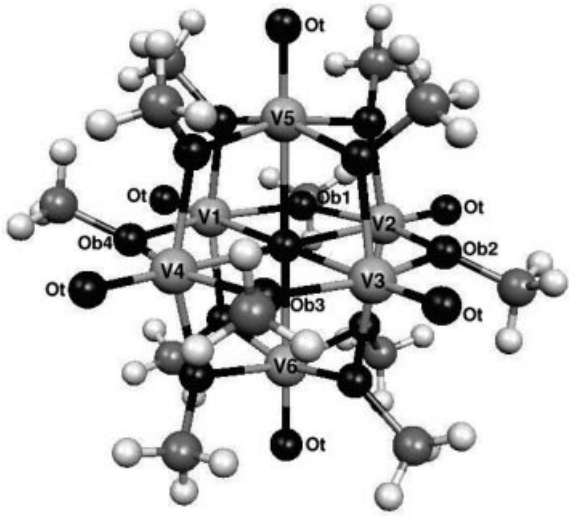

Figure 1. Crystal structure of the uncharged methoxo-bridged complex $[V^{IV}_4V^{V}_2O_7(OCH_3)_{12}]$ (ref.[6]).

The results of the cyclovoltammetric experiment carried out for the methoxo and ethoxo compound series are attributed to the solvated state of the redox isomers. Large potential separations $\Delta E^{o/}$ between successive one-electron redox processes have been observed in the cyclic voltammograms. Supposing that the stabilization energy imparted to the mixed-valence species by d-electron delocalization is the major factor influencing the splitting of the redox potentials, Hartl et al. have concluded that the unpaired electrons in redox isomers are significantly delocalized in the solvated state.[7] Interestingly, within any series of compounds (methoxo or ethoxo), the monocationic isomer displays a greater $\Delta E^{o/}$ value than the neutral complex (the $\Delta E^{o/}$ values for dicationic systems have not been determined yet).

On the basis of the obtained data, the given alkoxo-polyoxovanadium complexes have been classified as class II mixed-valence compounds. It has been assumed that the valence trapping found in the solid state is specifically linked to the cooperative effects encountered in the crystalline phase. However, the experimental results available to date are quite conflicting, especially for the $n$ = 4 member of the series, and are not conclusive for the reported compounds. Hartl et al. have pointed out that investigations by UV/Vis and NIR spectroscopy are imperative to the further understanding of these series of compounds, as well as EPR-spectroscopic studies and magnetic measurements. Herein, we present the results of a density functional theory (DFT) investigation carried out for the neutral species $[V^{IV}_4V^{V}_2O_7(OR)_{12}]$. Such a study provides an insight into mixed valency in the individual molecule or allows assessment of the electronic properties of the compound in its solid state (if calculations are performed on the X-ray molecular structure). On the basis of the results obtained from the quantum-chemical investigation, strong dynamical vibronic coupling has been assumed to be effective in a given species. The DFT calculations allowed evaluation of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

magnetic exchange constants which, contrary to widespread opinion, appeared to be of a ferromagnetic nature. Such interactions result in the magnetic ground state, whereas, as will be shown below, the intramolecular electron transfer, assumed in a previous publication,[9] cannot change the ground spin-state multiplicity and, consequently, cannot lead to a magnetic ground state in the presence of antiferromagnetic exchange.

## Computational Methodology

All DFT calculations reported in this paper were performed by means of the GAUSSIAN03 package[10] using the hybrid B3LYP exchange-correlation functional.[11–13] In some cases (see below), to simplify the calculations, we used hydroxo groups as μ-bridging ligands. In order to determine the extent of d-electron delocalization, we computed the electronic state with the highest total spin (S = 2) using the spin-unrestricted formalism. For both hydroxo- and methoxo-bridged complexes (**I** and **II** vide infra), the unrestricted high-spin (HS) solution obtained either on the optimized molecular structure or X-ray geometry (if available) is a good representation of the quintet state (the computed $<\mathbf{S}^2>$ values are close to 6.000, the expectation value for the pure S = 2 state, see Tables S1 and S2 in the electronic supporting information). The electronic states with lower spin multiplicity (three triplet and two singlet states) are not represented by a single-determinant wave function and can be described using sophisticated post-Hartree–Fock methods that take into account electron correlation effects (either only nondynamical correlation or both nondynamical and dynamical effects). However, such multideterminant approaches are very computationally demanding and have been applied so far only for small model systems.

As will be shown below, the unrestricted SCF calculations of the HS state resulted in the localization of four unpaired electrons on four vanadium centers. The magnetic properties of systems containing localized spins are generally interpreted using the Heisenberg–Dirac–van Vleck (HDVV) spin Hamiltonian

$$H = -\Sigma_{i>j} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j,$$

which introduces an isotropic interaction between the paramagnetic centers $i$ and $j$ described through the exchange coupling constant $J_{ij}$. In the above notation, the $J_{ij}$ value is positive if the spins $S_i$ and $S_j$ are coupled ferromagnetically; the negative $J_{ij}$ value means antiferromagnetic coupling. The eigenfunctions of the HDVV spin Hamiltonian are simply spin functions of the system $|S,M>$, constructed as linear combinations of the products of single-center spin functions $|S_1,M_1>|S_2,M_2>...|S_n,M_n>$ ($|S_i,M_i>$ vide infra). The eigenvalues of the above Hamiltonian represent the energies of the total spin states expressed as functions of $J_{ij}$. In isotropic systems, the energies of the electronic states with different total spin are related to the eigenvalues of the HDVV spin Hamiltonian. For a simple system, the energies of electronic states can be accurately computed at a high level of theory (i.e., within a multiconfigurational approach) and they can be used to obtain the $J_{ij}$ values. These values are directly comparable to those obtained by fitting the magnetic susceptibility data to the expression derived using the HDVV model Hamiltonian. For a system of chemical complexity, an accurate CI calculation becomes intractable. However, the exchange parameters can be estimated in the framework of a single-determinant method using the broken symmetry (BS) approach developed by Noodleman et al.,[14–17] as already described in the literature.[18–22] This method establishes the one-to-one matching between a diagonal element of the exact nonrelativistic Hamiltonian matrix computed in a basis set of single determinants (HS and so-called BS states) and the corresponding diagonal element of the HDVV spin Hamiltonian matrix computed in a basis set of products of single-center spin functions. It should be emphasized that the one-to-one matching is achieved provided that one deals with the orthogonal set of single determinants constructed from the same set of orthogonal space orbitals comprising doubly occupied closed-shell orbitals and singly occupied magnetic orbitals localized (not strictly) on the different spin centers. The set of $n$ different $J_{ij}$ values can be determined from the computed $n + 1$ single-determinant energies corresponding to different (nonequivalent) spin configurations. As these energies are related to the diagonal elements of the HDVV spin Hamiltonian matrix, the $J_{ij}$ values are obtained from a system of $n$ equations expressing the differences in energy between two single determinants as functions of $J_{ij}$. It is important to note that the HS and BS single determinants represent the wave functions related to one (ground) electronic configuration and, therefore, the BS approach neglects the dynamical correlation contribution to $J_{ij}$ (see Figure 2 illustrating the simplest case of two unpaired electrons on two centers A and B, where a and b are magnetic orbitals mainly localized on A and B, respectively).

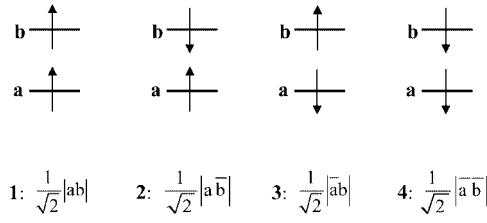

Figure 2. HS (**1** and **4**) and BS (**2** and **3**) single determinants for a dinuclear system with two unpaired electrons. **1** and **4** (S = 1, $M_S = \pm 1$) represent the equivalent spin configurations (degenerate states) and are related to $|\alpha\alpha>$ and $|\beta\beta>$ products of single-center spin functions; **2** and **3** ($M_S = 0$) also represent the equivalent spin configurations and are related to $|\alpha\beta>$ and $|\beta\alpha>$ products of single-center spin functions.

All SCF calculations presented here were carried out within the spin-unrestricted formalism using the tight SCF convergence criteria[10] to ensure sufficiently well converged values for the HS- and BS-state energies. The stability of all unrestricted SCF solutions was confirmed by means of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stability analysis of Seeger and Pople.[23] Full geometry optimizations were carried out without imposing symmetry constraints; tight convergence criteria[10] were employed. The contracted Gaussian basis sets reported by Ahlrichs et al.[24,25] were used throughout the calculations. These all-electron basis sets are commonly applied[19,21,26–33] in the framework of the UB3LYP-BS computational procedure. On the vanadium and oxygen atoms, the triple-ζ valence basis sets extended by one polarization function (p-function for V, d-function for O) were used (TZVP). The carbon and hydrogen atoms were described by slightly smaller basis sets (SVP) that are of double-ζ quality in the valence region and contain one polarization function (d-function for C, p-function for H).

## Results and Discussion

### Exchange Interactions between Localized Electrons

In all systems studied, the spin-density distribution computed from the unrestricted HS solution clearly indicates that all four d electrons are completely trapped (see Tables S1 and S2) and our next task was the evaluation of exchange interactions between localized electrons. Before presenting the results of the DFT calculations of the exchange parameters in complexes **I** and **II**, we would like to mention the two problems arising when the BS approach is employed using a standard quantum-chemical program package. In this case, the HS and BS single determinants and their energies are obtained by performing unrestricted SCF calculations. One of the problems associated with this computational procedure is that the single determinants are constructed from the spatially nonorthogonal α and β orbitals. Another problem is that the spin-polarized orbitals are determined for each single determinant from a separate SCF calculation and, strictly speaking, the orbital sets obtained for different single determinants are not equivalent to each other. As a result, the computed single determinants have nonzero overlap integrals. In such a case, the energies of single determinants are not directly related to the diagonal elements of the HDVV spin Hamiltonian matrix and the effect of nonorthogonality should be taken into account to derive the relationships between the computed single-determinant energies and the $J_{ij}$ values. Such a complex problem has been solved only for dinuclear systems, provided that all single determinants are built from the equivalent orbital sets, which causes the $M_S$ components of the total spin state (constructed from these single determinants) to be degenerate.[18–20] For more complex systems, the effect of nonorthogonality of the computed single determinants can hardly be explicitly considered and it is simply ignored. Herein, we judge the performance of the UB3LYP-BS computational procedure to describe the magnetic structure of a given species by using the following two criteria. The first one establishes whether the nonorthogonality problem affects the single-determinant $<\mathbf{S}^2>$ values. Comparison of the computed $<\mathbf{S}^2>_{HS}$ and $<\mathbf{S}^2>_{BS}$ values with those derived using the Clebsch–Gordan algebra answers this question.[34] The second criterion is the compatibility of the equations for $J_{ij}$ derived for the orthogonal single-determinant basis set with the computed HS- and BS-state energies. Apparently, this criterion can be employed if the number of $J_{ij}$ is less than the number of the nonequivalent BS states that could be generated for a system. In these cases, any set of equations should have the same solution if the influence of the nonorthogonality on the $J_{ij}$ values is negligible. The necessity of considering a complete set of BS single determinants has also been pointed out by Bencini et al.[22] However, in this work it was implicitly assumed that the computed $J_{ij}$ values are not affected by the nonorthogonality problem and the consistency of equations for $J_{ij}$ was tested to check the validity of the nearest-neighbors approximation.

For complex **I**, the UB3LYP-BS calculations were performed on the HS-state geometry. For complex **II**, besides its HS-state geometry, the X-ray molecular structure[6] was also used (see Figure 1). All three systems were found to possess $C_i$ symmetry; the structural parameters are collected in Table 1. In each system, the hexavanadate core has a significantly distorted geometry: for the equatorial metal centers ($V^{IV}$ sites, see the HS-state atomic spin densities in Tables S1 and S2), the $V–O_c$ bonds are significantly elongated, whereas the same bonds for the remaining axial metal ions ($V^V$ sites) appear to be relatively short. In other words, the hexavanadate core has a "short" $O_t–V^V–O_c–V^V–O_t$ axis and two "long" $O_t–V^{IV}–O_c–V^{IV}–O_t$ axes. These results suggest that electron transfer is suppressed in the individual and solid-state molecules of **I** and **II** and their magnetic properties can be analyzed using the HDVV spin Hamiltonian. For the given systems, this Hamiltonian contains four exchange parameters ($C_i$ symmetry) and reads

$$H(4) = -[J_{12}(\mathbf{S}_1\cdot\mathbf{S}_2 + \mathbf{S}_3\cdot\mathbf{S}_4) + J_{14}(\mathbf{S}_1\cdot\mathbf{S}_4 + \mathbf{S}_2\cdot\mathbf{S}_3) + J_{13}\mathbf{S}_1\cdot\mathbf{S}_3 + J_{24}\mathbf{S}_2\cdot\mathbf{S}_4] \quad (1)$$

where $S_i = 1/2$. Spins are indexed according to the numbering shown in Figure 1.

Table 1. Structural parameters for complexes **I** and **II** (bond lengths in Å, bond angles in °).

| Parameter | **I** (S = 2)[a] | **II** (S = 2)[a] | **II** (X-ray)[b] |
|---|---|---|---|
| $V_1–O_c$ | 2.37 | 2.33 | 2.280 |
| $V_2–O_c$ | 2.38 | 2.33 | 2.296 |
| $V_5–O_c$ | 2.32 | 2.31 | 2.266 |
| $V_1–V_2$ | 3.36 | 3.30 | 3.247 |
| $V_1–V_4$ | 3.36 | 3.30 | 3.224 |
| $V_1–O_{b1}$ | 2.01 | 2.01 | 1.955 |
| $V_1–O_{b4}$ | 2.01 | 2.00 | 1.965 |
| $V_2–O_{b1}$ | 2.01 | 2.00 | 1.991 |
| $V_2–O_{b2}$ | 2.01 | 2.01 | 1.979 |
| $V_1–O_{b1}–V_2$ | 113.4 | 110.6 | 110.8 |
| $V_1–O_{b4}–V_4$ | 113.0 | 110.5 | 109.7 |
| $V_1–O_c–V_2$ | 90.0 | 90.0 | 90.4 |
| $V_1–O_c–V_4$ | 90.0 | 90.0 | 89.6 |
| $V–O_t$ | <1.58> | <1.59> | <1.588> |

The eight SCF single determinants computed for **I** and **II** are reported in Tables S1 and S2, respectively. The products of single-center spin functions associated with the computed single determinants representing different spin configurations are shown in Table 2. For any system, the remaining eight microstates are simply spin-reversed analogues of those listed in the table. In order to check whether the SCF convergence criteria were strong enough, such spin-reversed counterparts were computed for BS1, BS2, and BS3 states. In all cases, the degeneracy of the single determinants representing the equivalent spin configurations was found. As can be expected for $C_i$ symmetry, BS4 and BS6 states, as well as BS5 and BS7 states, appear to be equivalent to each other (see Tables S1 and S2). From these tables it can also be seen that the single-determinant $<\mathbf{S}^2>$ values are not significantly affected by the nonorthogonality problem inherent in the computational procedure. The computed $<\mathbf{S}^2>_{BS}$ values are close to 2.000 and 3.000 expected for the pure BS states (which are eigenfunctions of $\mathbf{S}_z$) with $M_S = 0$ and $M_S = 1$, respectively; the computed $<\mathbf{S}^2>_{HS}$ values approach 6.000, the expectation value for the pure S = 2 state.

Table 2. Diagonal matrix elements of the model spin Hamiltonian H(4) [Equation (1)] associated with SCF energies corresponding to different spin configurations of the systems studied.

| SD: $\|S_i,M_i>$ | $E_{SD}$: $<S_i,M_i\|H(4)\|S_i,M_i>$ |
|---|---|
| HS: $\|\alpha\alpha\alpha\alpha>$, $M_S = 2$ | $E_{HS}$: $-\frac{J_{12}}{2} - \frac{J_{14}}{2} - \frac{J_{13}}{4} - \frac{J_{24}}{4}$ |
| BS1: $\|\alpha\beta\alpha\beta>$, $M_S = 0$ | $E_{BS1}$: $\frac{J_{12}}{2} + \frac{J_{14}}{2} - \frac{J_{13}}{4} - \frac{J_{24}}{4}$ |
| BS2: $\|\alpha\alpha\beta\beta>$, $M_S = 0$ | $E_{BS2}$: $-\frac{J_{12}}{2} + \frac{J_{14}}{2} + \frac{J_{13}}{4} + \frac{J_{24}}{4}$ |
| BS3: $\|\alpha\beta\beta\alpha>$, $M_S = 0$ | $E_{BS3}$: $\frac{J_{12}}{2} - \frac{J_{14}}{2} + \frac{J_{13}}{4} + \frac{J_{24}}{4}$ |
| BS4 (BS6): $\|\alpha\alpha\alpha\beta>$ ($\|\alpha\beta\alpha\alpha>$), $M_S = 1$ | $E_{BS4(BS6)}$: $-\frac{J_{13}}{4} + \frac{J_{24}}{4}$ |
| BS5 (BS7): $\|\alpha\alpha\beta\alpha>$ ($\|\beta\alpha\alpha\alpha>$), $M_S = 1$ | $E_{BS5(BS7)}$: $\frac{J_{13}}{4} - \frac{J_{24}}{4}$ |

The diagonal matrix elements of the model spin Hamiltonian H(4) [Equation (1)] associated with the computed single-determinant energies are listed in the second column of Table 2. From Table 2, 15 equations for $J_{ij}$ can be obtained (see Table S3 of supporting information). The consistency of these equations with the computed HS- and BS-state energies was tested by considering all possible sets of four equations. For any system, five noncoincident values were found for $J_{12}$ and $J_{14}$, and seven for $J_{13}$ and $J_{24}$. The average values and their standard deviations are reported in Table 3. According to these results, the influence of the single-determinant nonorthogonality on the $J_{ij}$ values can be considered negligible for the given systems. The energies of the total spin states (one quintet, three triplet, and two singlet levels) computed using the obtained $J_{ij}$ values are (in $cm^{-1}$):

Table 3. $J_{ij}$ means and their standard deviations (in parentheses) obtained for complexes **I** and **II** using the model spin Hamiltonians H(4) and H(2) containing four and two exchange parameters, respectively (in $cm^{-1}$).

| | $J_{ij}$ | Sample size | **I** (S = 2)[a] | **II** (S = 2)[a] | **II** (X-ray)[b] |
|---|---|---|---|---|---|
| H(4) | $J_{12}$ | $n = 5$ | 67.6 (0.3) | 10.9 (1.8) | 196.9 (1.6) |
| | $J_{14}$ | $n = 5$ | 51.4 (0.3) | 12.2 (1.8) | 193.2 (1.6) |
| | $J_{13}$ | $n = 7$ | 31.2 (0.7) | 21.6 (4.7) | 73.3 (4.1) |
| | $J_{24}$ | $n = 7$ | 16.7 (0.7) | 22.5 (4.7) | 55.3 (4.1) |
| H(2) | $J_{12}$ | $n = 5$ | 59.5 (0.3) | 11.5 (1.8) | 195.1 (1.6) |
| | $J_{13}$ | $n = 4$ | 24.0 (0.3) | 22.3 (2.0) | 64.1 (1.7) |

[a] The values computed on the HS-state geometry of a given complex. [b] The values computed for the X-ray structure (ref.[6]).

**I** (HS-state geometry): –71.5 (S = 2); 1.1, 22.8, 47.5 (S = 1); 33.2, 109.7 (S = 0);
**II** (HS-state geometry): –22.6 (S = 2); 0.5, 10.2, 11.8 (S = 1); 12.0, 33.1 (S = 0);
**II** (X-ray geometry): –227.2 (S = 2); 23.0, 41.3, 162.9 (S = 1); 96.4, 358.0 (S = 0).

Interestingly, reasonable $J_{ij}$ values can be obtained if the model spin Hamiltonian containing two $J_{ij}$ parameters [Equation (1) with $J_{14} = J_{12}$ and $J_{24} = J_{13}$] is used:

$$H(2) = -[J_{12}(\mathbf{S}_1\cdot\mathbf{S}_2 + \mathbf{S}_1\cdot\mathbf{S}_4 + \mathbf{S}_2\cdot\mathbf{S}_3 + \mathbf{S}_3\cdot\mathbf{S}_4) + J_{13}(\mathbf{S}_1\cdot\mathbf{S}_3 + \mathbf{S}_2\cdot\mathbf{S}_4)] \quad (2)$$

where $S_i = 1/2$. This Hamiltonian describes the total spin levels of a highly symmetrical system comprising the square $S_i = 1/2$ unit with the equivalent $|\alpha\alpha\beta\beta>$ and $|\alpha\beta\beta\alpha>$ states, as well as $|\alpha\alpha\alpha\beta>$ and $|\alpha\alpha\beta\alpha>$ ones. The diagonal matrix elements of such a Hamiltonian are equal to those listed in Table 2 provided that $J_{14} = J_{12}$ and $J_{24} = J_{13}$. From these expressions the following equations for $J_{ij}$ can be obtained:

$$E_{HS} - E_{BS1} = -2J_{12}$$
$$E_{HS} - E_{BS2} = -J_{12} - J_{13}$$
$$E_{HS} - E_{BS4} = -J_{12} - \frac{J_{13}}{2}$$
$$E_{BS1} - E_{BS2} = J_{12} - J_{13}$$
$$E_{BS1} - E_{BS4} = J_{12} - \frac{J_{13}}{2}$$
$$E_{BS2} - E_{BS4} = \frac{J_{13}}{2}$$

The systems studied have only $C_i$ symmetry and, thus, the computed BS2 and BS3 states, as well as BS4 and BS5 states, are not equivalent to each other (see Tables S1 and S2). From the above equations we obtained (for each system) the sets of noncoincident values for $J_{12}$ and $J_{13}$ using the average of BS2 and BS3 state energies for $E_{BS2}$ and the average of BS4 and BS5 state energies for $E_{BS4}$. The $J_{12}$ and $J_{13}$ means and their standard deviations are reported in Table 3. For each system, the obtained $J_{12}$ value coincides with the average of $J_{12}$ and $J_{14}$ values obtained using the model spin Hamiltonian H(4). Similarly, the $J_{13}$ value [for H(2)] is equal to the average of $J_{13}$ and $J_{24}$ values [for H(4)].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

We would like to stress that the one-to-one matching between the matrix elements of the electronic and spin Hamiltonians, being the basis of the BS approach, exists if all single-determinant states are constructed by assuming the same molecular geometry. Therefore, for the systems studied, we used the same structure (the HS-state or X-ray one) throughout the single-determinant calculations. We also did a series of test SCF calculations using the geometries optimized for all single-determinant states. As expected, the equations for $J_{ij}$ became inconsistent. The $J_{ij}$ values obtained from different sets of equations dramatically differ; the standard deviations were found to be twice as much as the mean values.

In the literature, the so-called nonprojected scheme[19] is often used for the estimation of the exchange coupling constant in dinuclear transition-metal complexes in the DFT framework.[19,26–29,32] Within this scheme, the single-determinant BS solution (associated with $|S_1,M_1 = S_1\rangle|S_2,M_2 = -S_2\rangle$ or $|S_1,M_1 = -S_1\rangle|S_2,M_2 = S_2\rangle$) is assumed to describe the electronic state with the lowest total spin $S = |S_1 - S_2|$, that is, the energy of the BS state is used as the energy of the pure $S = S_{min}$ state. Thus, the equation for J is obtained from the expressions for the eigenvalues of the HDVV spin Hamiltonian: $E(S_{max})$ and $E(S_{min})$. This scheme was found to give a better agreement between the computed and experimental exchange coupling constants in a number of dimers (especially when used with the B3LYP functional).[19,26,35] The success of the nonprojected approach was recently explained by a partial account of the nondynamical electron correlation in the DFT-BS solutions through the self-interaction error.[35] This statement was, however, questioned in the literature.[36] Such a technique may be adopted for a more complex system if its total spin states are described by the HDVV model Hamiltonian having the analytical solution. However, the use of this scheme in general cases of polynuclear systems is less straightforward. For example, in the case of the systems studied, the analytical expression for the energies of the total spin states is available only for the model spin Hamiltonian containing two $J_{ij}$ parameters [Equation (2)]. The solution of this Hamiltonian reads

$$E(S,S_{13},S_{24}) = -\frac{J_{13}}{2}[S_{13}(S_{13} + 1) + S_{24}(S_{24} + 1) - 3] - \frac{J_{12}}{2}[S(S + 1) - S_{13}(S_{13} + 1) - S_{24}(S_{24} + 1)],$$ where

$$S_{13} = S_1 + S_3, ..., |S_1 - S_3|$$
$$S_{24} = S_2 + S_4, ..., |S_2 - S_4|$$
$$S = S_{13} + S_{24}, ..., |S_{13} - S_{24}|.$$

The eigenvalues $E(S,S_{13},S_{24})$ and eigenfunctions $|S,S_{13},S_{24}\rangle$ of the Hamiltonian (2) when $S_i = 1/2$ can be easily obtained and they are presented in Table S4 of the electronic supporting information. The given total spin levels are associated to a highly symmetrical system comprising the square $S_i = 1/2$ unit with the equivalent $|\alpha\alpha\beta\beta\rangle$ (BS2) and $|\alpha\beta\beta\alpha\rangle$ (BS3) states, as well as $|\alpha\alpha\alpha\beta\rangle$ (BS4), $|\alpha\alpha\beta\alpha\rangle$ (BS5), $|\alpha\beta\alpha\alpha\rangle$ (BS6), and $|\beta\alpha\alpha\alpha\rangle$ (BS7) ones. The systems studied were found to possess $C_i$ symmetry and, therefore, the average of the computed BS-state energies may be used for the energy of the single-determinant states that should be degenerate in the idealized system having the square vanadium(IV) unit. Thus, there are three single-determinant energies, $E_1$ (for BS1), $E_2$ (for BS2 and BS3), and $E_3$ (for BS4, BS5, BS6, and BS7), to be associated with four pure-spin state energies, E(0,0,0), E(0,1,1), E(1,1,1), and E(1,1,0) = E(1,0,1). In the case of the singlet states, even if we suppose that E(0,0,0) can be approximated by $E_2$, the use of $E_1$ as E(0,1,1) is questionable (see the expressions for $|0,0,0\rangle$ and $|0,1,1\rangle$ in Table S4). As for the triplet states, it is not evident which of the two energies, E(1,1,1) or E(1,1,0) = E(1,0,1), can be approximated by $E_3$.

Table 3 shows that all $J_{ij}$ values obtained for **I** and **II** are positive, that is, paramagnetic centers are coupled ferromagnetically. The HS state was found to be the ground state of the systems. This implies that complexes **I** and **II** considered as individual molecules should possess ferromagnetic properties, as well as complex **II** in the solid state. This result is very intriguing, as most of the oxovanadium(IV) compounds reported so far display antiferromagnetic coupling in the vanadium pairs.[32,37] From the results obtained for the individual molecules of **I** and **II**, it is seen that the introduction of the methyl groups weakens the ferromagnetic coupling within the dimeric units comprising the μ-OR bridges. The coupling between the diagonal vanadium(IV) ions bridged by the central oxygen atom is not significantly affected. In the case of the methoxo-bridged complex, the two geometries studied display a sizeable difference in the strength of exchange. In the solid-state structure, because of the crystalline effects, the hexavanadate core is compressed along the $O_t$–V–$O_c$–V–$O_t$ axes. This results in smaller V–V distances (see Table 1). The decrease of the intermetal separations enhances the ferromagnetic interactions between the vanadium(IV) ions, especially within the dimeric units comprising the μ-methoxo bridges (the distance between the vanadium centers within the unit is reduced by 0.08 Å). In the diagonal vanadium(IV) pairs, where metal centers are separated by more than 4.5 Å, the coupling is not so sensitive to variations of the V–V distances.

The presence of ferromagnetic coupling in the alkoxo(hydroxo)-bridged dimeric units can be rationalized within the Kahn–Briat model, which relates the antiferromagnetic contribution of the exchange coupling constant between two paramagnetic centers (A and B) with the overlap between "magnetic orbitals", that is, the orbitals of the two localized A–X and X–B fragments (if a simple A–X–B system is considered) bearing the unpaired electrons.[38,39] In the systems studied, the V–$O_t$ bonds are directed along the mutually orthogonal axes (the V–$O_c$–V angles are equal to 90°), that is, the $d_{xy}$ orbitals[40] on the vanadium centers within an alkoxo(hydroxo)-bridged dimeric unit are orthogonal to each other (see Figure S1 in the supporting information presenting the HS-state spin density for the crystal structure of **II** as an example). Thus, the ferromagnetic coupling in the $V_1$–$V_2$ ($V_3$–$V_4$) and $V_1$–$V_4$ ($V_2$–$V_3$) pairs can

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

be expected as the antiferromagnetic term in the expression for $J_{ij}$ vanishes because of the orthogonality of the "magnetic orbitals" imposed by the POM architecture.

The given dimeric unit has syncoplanar configuration according to the classification proposed by Plass.[41] A DFT study of exchange coupling in alkoxo(hydroxo)-bridged dinuclear oxovanadium(IV) compounds with different core arrangements has been carried out by Ruiz et al.[32] In syncoplanar complexes, the antiferromagnetic interactions were found to be active between vanadium centers. It was shown that the coupling decreases from –94 to –43 $cm^{-1}$ (for hydroxo-bridged model structures) when the V–O–V angle becomes smaller (angle values between 108 and 100° were considered). However, the situation when the V–O–V angle is 90°, encountered in the systems studied here, was not examined. Only a few examples of ferromagnetic coupling between the vanadium(IV) sites in oxovanadium complexes are known in the literature.[41–43] Among them, the octanuclear vanadium complex with the ligand 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (taci) is the most exciting one.[43] The peculiar chelating properties of the ligand enforce a mutually orthogonal orientation of the V–$O_t$ bonds favoring ferromagnetic coupling between the vanadium(IV) centers.

### Possible Effects of d-Electron Delocalization

Until now we have considered the energy spectrum of magnetic levels resulting from the exchange interactions between localized magnetic electrons. Let us now consider what effects can be expected on the energy spectrum from the electron hopping between vanadium centers. For the sake of simplicity, we consider an idealized system of six V centers forming an octahedron and four magnetic electrons, which can be transferred between orbitals localized on these centers. There are two types of distribution of four electrons between six octahedron vertices: in one type four paramagnetic centers form a square and in another type they are arranged in a rhombic butterfly structure. Three square distributions and twelve butterfly distributions can be formed. The magnetic interactions in the first case are described by the Hamiltonian (2). For the rhombic distribution, a very similar Hamiltonian can be written

$$H_b = -[J_{12}(\mathbf{S}_1\cdot\mathbf{S}_2 + \mathbf{S}_1\cdot\mathbf{S}_4 + \mathbf{S}_2\cdot\mathbf{S}_3 + \mathbf{S}_3\cdot\mathbf{S}_4 + \mathbf{S}_2\cdot\mathbf{S}_4) + J_{13}\mathbf{S}_1\cdot\mathbf{S}_3]$$

with the following eigenvalues:

$$E(S,S_{13},S_{24}) = -\frac{J_{12}}{2}[S(S+1) - S_{13}(S_{13}+1) - \frac{3}{2}] - \frac{J_{13}}{2}[S_{13}(S_{13}+1) - \frac{3}{2}] \quad (3)$$

The eigenvalues of both Hamiltonians are characterized by the values of the total spin S and the intermediate spin $S_{13}$, but for the Hamiltonian (2) the energies also depend on $S_{24}$, whereas the eigenenergies of (3) are degenerate over this quantum number.

The electron transfer between different vanadium sites can be taken into account by the same procedure that has been used before for two-electron mixed-valence polyoxometalates.[44,45] We consider that the eigenfunctions of the Hamiltonians (2) and (3) are linear combinations of the Slater four-electron determinants composed from orthogonal s-type orbitals localized on different centers. If we take into account only the possibility of the electron transfer between nearest neighbors and suppose that the matrix element of the transfer operator on a one-electron localized wave function is equal to t, the total matrix of the electron Hamiltonian can be built on the multielectron wave functions, characterized by spin quantum numbers and different positions of magnetic electrons, using the common Clebsch–Gordan algebra. The analysis of these matrices shows that only the states characterized by the same spin quantum numbers are mixed through the electron transfer. For each set of spin quantum numbers, the electron transfer Hamiltonian can be represented as a $15 \times 15$ matrix, where the diagonal elements are the energies resulting from the Hamiltonians (2) and (3) and the nondiagonal elements are obtained from the electron transfer operator. It can be seen that the nondiagonal parts of all matrices are similar. If we neglect the difference between the two exchange Hamiltonians (2) and (3) (i.e., supposing $J_{12} = J_{13}$), the electron transfer leads to 15 repeated energy spectra of the unique exchange Hamiltonian, with the center of gravity at 4t (1), 2t (6), 0 (3), –2t (2), and –4t (3), where the numbers in parentheses give the degeneracy of transfer levels. However, if the difference between the two exchange Hamiltonians is taken into account, the electron energy spectrum will consist of

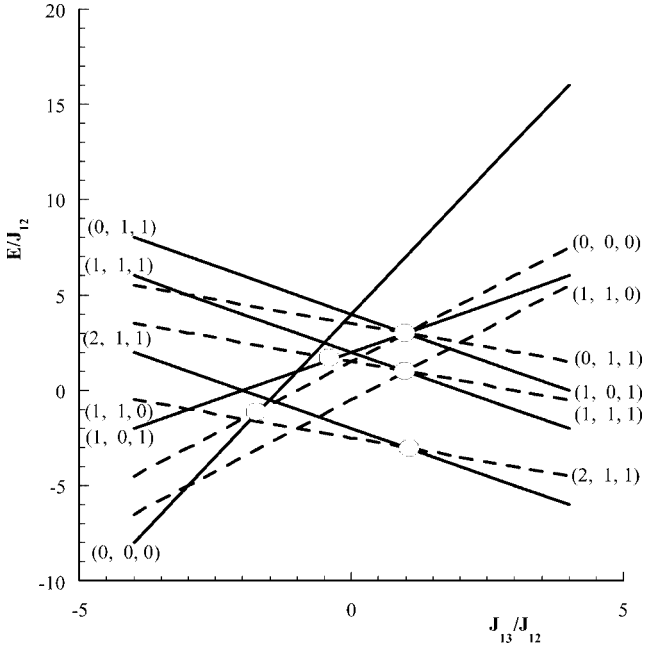

Figure 3. Spin levels of square (full lines) and rhombic four-nuclear complexes. The corresponding spin states (S, $S_{13}$, $S_{24}$) are indicated left and right for the square and rhombic configurations, respectively. The circles show the positions of avoided crossings resulting from the electron transfer.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

15 similar groups presenting the superposition of the energy spectra of the two exchange Hamiltonians. Within each group, the electron transfer results in avoided crossings in the crossing points of energy levels belonging to different Hamiltonians but characterized by the same total and intermediate spins (see Figure 3). Although these effects will modify the energies in the vicinity of the crossing point, they are not able to change the multiplicity of the ground state imposed by the "static" exchange interaction.

## Conclusions

The DFT results obtained for the neutral representative of the $[V^{IV}_{n}V^{V}_{6-n}O_7(OR)_{12}]^{(4-n)}$ series indicate that its individual molecule (because of internal vibronic interactions) does not possess octahedral symmetry within the hexavanadate core and comprises a slightly distorted square-bipyramidal $OV_6$ unit, which is characterized by localized spin-density distribution; the four vanadium(IV) centers are involved in ferromagnetic coupling. According to the available experimental data mentioned in the Introduction, the complex retains its structural features to a large extent in the crystal lattice and displays the trapped vanadium valences at least at low temperature. In solution, the experimental observations have been interpreted as arising from delocalization of the unpaired electrons, which has been associated with the intervalence electron transfer. However, it is improbable that interaction of the neutral species with the solvation sphere can result in significant changes in the core geometry enabling d-electron delocalization.

The results of the experimental studies could be explained without introducing the electron transfer process if the existence of strong dynamical vibronic coupling in a given species is proposed. Such coupling produces the three valence-trapped structures (states), which can be obtained from each other by changing the "short" axis, that is, the "short" and "long" axes in one structure change into the "long" and "short" axes in another structure, respectively. Apparently, one of these states is frozen (i.e., the transitions between the states are suppressed or their rates are very low) in the crystal lattice because of cooperative solid-state effects. Upon temperature increase, the rates of transitions increase and, on the timescale of the X-ray structural analysis, an averaged structure displaying a symmetrical octahedral vanadium framework and fully delocalized d electrons can be obtained. Such a structure has been obtained, for example, in the case of species with ethylated bridges, where the disorder of the ethyl groups apparently has a pronounced effect on the rates of transitions. Extensive d-electron delocalization detected by the cyclovoltammetric experiment implies the reduction of the barriers between the states in solution, that is, the electronic and molecular structure of the neutral complex in its solvated state can be assessed by taking a superposition of the three valence-trapped forms.

The most interesting feature of the systems studied is the ferromagnetic coupling in the vanadium(IV) pairs – a result obtained from the DFT calculations. Ferromagnetic interactions are very rare in oxovanadium complexes and are a consequence of a specific core geometry imposed by the POM architecture. The results described here present a step toward understanding the properties of a given alkoxo-polyoxovanadium compound series, however, magnetic susceptibility measurements and EPR-spectroscopic studies carried out on the freshly prepared samples are required to make final conclusions.

**Supporting Information** (see also the footnote on the first page of this article): Tables S1 and S2 deal with the SCF single determinants and present atomic spin densities, expectation values of $\mathbf{S}^2$, and energies (in a.u.) computed for complexes **I** and **II**. Table S3 shows the energy differences between the single-determinant states as functions of $J_{ij}$ obtained with the model spin Hamiltonian H(4) [Equation (1)]. Table S4 contains the eigenvalues and eigenfunctions of the model spin Hamiltonian H(2) with $S_i = 1/2$. Figure S1 presents the plot of the HS-state spin density for the crystal structure of complex **II**.

# $Fe^{II}$ Bistable Materials with Dissymmetrical Ligands: Synthesis, Crystal Structure, Magnetic and Mössbauer Properties of $Fe^{II}$ Complexes Based on $N_4$ Schiff Bases Possessing 2-Pyridyl and 1-R-Imidazol-2-yl Rings[‡]

**Nicolas Bréfuel,*[a] and Sergiu Shova,[a][‡‡] and Jean-Pierre Tuchagues*[a]**

**Keywords:** Schiff bases / N ligands / Iron / Spin crossover / Magnetic properties / Mössbauer spectroscopy

The synthesis and characterization of two symmetrical $Fe^{II}$ complexes, $[FeL^{B4}(NCS)_2]$, **1**, and $[FeL^{B5}(NCS)_2]$, **2** {$L^{Bx}$ = *N*,*N*′-bis[(2-*N*-R-imidazol-1-yl)methylene]-2,2-dimethylpropane-1,3-diamine ligands; **1**: *x* = 4, R = H; **2**: *x* = 5, R = Me} are reported. Whereas the tetradentate ligand $L^{B4}$ is planar in **1**, the X-ray structure of **2** illustrates the folded conformation of $L^{B5}$. Ferrous $[FeL^{Ex}(NCS)_2]$ complexes were synthesized {$L^{Ex}$ = *N*-[(1-*N*-$R^2$-imidazol-2-yl)methylene]-*N*′-(1-pyridin-2-yl-ethylidene)-2,2-$R^1$-propane-1,3-diamine; **3**: *x* = 1, $R^1$ = H, $R^2$ = H; **4**: *x* = 2, $R^1$ = H, $R^2$ = Me; **5**: *x* = 3, $R^1$ = Me, $R^2$ = H; **6**: *x* = 4, $R^1$ = Me, $R^2$ = Me}. These dissymmetrical Schiff bases, possessing pyridine and imidazole rings, are obtained through the reaction of 2-methyl-2-pyridin-2-yl-hexahydropyrimidine ($R^1$ = H; **3**, **4**) or 2,5,5-trimethyl-2-pyridin-2-yl-hexahydropyrimidine ($R^1$ = Me; **5**, **6**) aminals with imidazole-2-carboxaldehyde ($R^2$ = H: **3**, **5**) or 1-*N*-methylimidazole-2-carboxaldehyde ($R^2$ = Me: **4**, **6**) and iron(II) thiocyanate. Single-crystal X-ray structures were determined for $[FeL^{E1}(NCS)_2]$ **3** $[FeL^{E3}(NCS)_2]$ **5** and $[FeL^{E4}(NCS)_2]$ **6**; these complexes are in the low-spin state at 180 K. Magnetic susceptibility and Mössbauer measurements showed a smooth and incomplete spin crossover involving ca. 50 % of the iron centres between 200 and 400 K for **5** and **6**; **3** and **4** remain low spin up to 350 K; the slight $\chi_M T$ increase between 350 and 400 K results from the onset of spin crossover for **3** and **4**. The spin crossover properties in the $[FeL^{Ex}(NCS)_2]$ series may thus be tuned by the ligand substituents: by changing $R^1$ from H (for **3**, **4**) to Me (for **5**, **6**) the spin crossover is lowered from above 400 K to ca. 350 K; the effect of the imidazolyl substituent is weaker: by changing $R^2$ from H (for **5**) to Me (for **6**) the spin crossover temperature is lowered by ca. 35 K. The electronic effect of the highly conjugated Fe–N=C–C=N– imidazolyl fragment overpasses and qualitatively and quantitatively modifies the effects of $R^1$ and $R^2$.

## Introduction

Most iron(II) complexes have octahedral geometry, and depending on the strength of the ligand field, either the low-spin (LS) or the high-spin (HS) electronic configuration is observed. For some $Fe^{II}$ complexes, mainly those characterized by an $[FeN_6]$ core, the ligand field is intermediate and allows a LS ($S$ = 0, $^1A_{1g}$) ↔ HS ($S$ = 2, $^5T_{2g}$) spin crossover (SC) that may be induced by a variation in temperature, pressure or light irradiation.[1] Slight modifications to the ligand(s) may provide conditions that do or do not favour SC, depending on the balance between the ligand field and the mean spin-pairing energy. Whereas the phenomenon is mainly molecular in solution, intermolecular interactions, such as π–π staking or hydrogen bonds between complex molecules, are the key for observing cooperative transition in the solid state, as a result of the supramolecular structure.[2] Such a behaviour, evidenced by thermal hysteresis of the magnetic properties, is attractive owing to the potential technological applications of these materials in molecular electronics and memory devices.[3]

In previous studies, we showed that a rational approach for the design of SC materials allows tuning of the ligand field by combination, in a same tetradentate Schiff base ligand, of both the "strong ligand field" pyridine moiety and the "weak ligand field" imidazole ring.[4] Reaction between the isolated aminal-type ligands 2-methyl-2-pyridin-2-yl-hexahydropyrimidine ($R^1$ = H) or 2,5,5-trimethyl-2-pyridin-2-yl-hexahydropyrimidine ($R^1$ = Me) and 2-$R^2$-imidazole-4-carboxaldehyde, in the presence of iron(II) thiocyanate, led to the $[FeL^{Cx}(NCS)_2]$ complexes {$L^{Cx}$ = *N*-[(2-$R^2$-1H-imidazol-4-yl)methylene]-*N*′-(1-pyridin-2-ylethylidene)-2,2-$R^1$-propane-1,3-diamine ($R^1$ = H, Me; $R^2$ = H, Me, Ph)}.[4a] Because the complexes in the $[FeL^{Cx}(NCS)_2]$ family exhibit only partial SC in the 60–400 K temperature range, we explored the $[FeL^{Dx}(NCX)_2]$ (X = S, Se) series

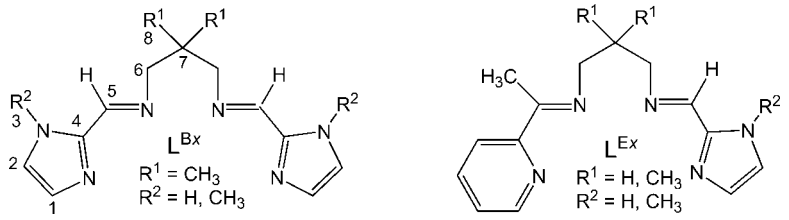

Figure 1. Schematic drawing of the $L^{Bx}$ and $L^{Ex}$ ligands ($R^1$ = H, Me; $R^2$ = H, Me).

where the terminal imidazolyl fragment of $L^{Dx}$ originates from 5-methyl-4-formylimidazole.[4b] The complexes in the corresponding $[FeL^{Dx}(NCX)_2]$ series exhibit steeper SC, with hysteresis or with two steps, depending on the pseudohalide ligands (NCS or NCSe) and on the $R^1$ substituent of the propyl chain. Detailed structural studies revealed the prominent role of the hydrogen bond network in the occurrence of steep SC, as underlined by the hysteresis evidenced through their magnetic study.[4b]

In this paper, we report the synthesis and characterization of six ferrous materials including: (1) two HS complexes of general formula $[FeL^{Bx}(NCS)_2]$ {$L^{Bx}$ = *N*,*N*′-bis-[(2-*N*-R-imidazol-1-yl)methylene]-2,2-dimethylpropane-1,3-diamine ligands (Figure 1); **1**: $x$ = 4, R = H; **2**: $x$ = 5, R = Me} and (2) a series of ferrous complexes $[FeL^{Ex}(NCS)_2]$ {$L^{Ex}$ = *N*-[(1-*N*-$R^2$-imidazol-2-yl)methylene]-*N*′-(1-pyridin-2-ylethylidene)-2,2-$R^1$-propane-1,3-diamine ligands (Figure 1); **3**: $x$ = 1, $R^1$ = H, $R^2$ = H; **4**: $x$ = 2, $R^1$ = H, $R^2$ = Me; **5**: $x$ = 3, $R^1$ = Me, $R^2$ = H; **6**: $x$ = 4, $R^1$ = Me, $R^2$ = Me}. The molecular structure of these materials was investigated by single-crystal X-ray diffraction, and their electronic properties were explored by variable-temperature magnetic susceptibility and Mössbauer studies.

## Results

### Description of the Structures

The molecular structures along with the main geometric characteristics of complexes **2**, **3**, **5** and **6** are presented in Figures 2, 4, 6 and 8, respectively.

The X-ray structural study of **2** reveals a highly distorted octahedral geometry with the thiocyanato ligands *cis* to each other and a folded conformation of the $L^{B5}$ tetradentate ligand (Figure 2). This strong deviation of the coordination site from the regular octahedron, suggested by the Fe–N distances and N–Fe–N angles, is associated with the HS electronic configuration.

The crystal packing of **2** is characterized by isolated dimeric units (Figure 3) formed through π–π stacking interactions between centrosymmetrically related $[FeL^{B5}(NCS)_2]$ molecules ($1-x$, $2-y$, $2-z$) with a centroid-to-centroid distance of 3.50 Å. Other intermolecular separations equal or exceed the sum of van der Waal radii.

The $Fe^{2+}$ ion in complex **3** (Figure 4) presents a slightly distorted $N_6$ octahedral environment constituted by four nitrogen atoms from the $L^{E1}$ tetradentate ligand (two $N_{imino}$, one $N_{pyridyl}$ and one $N_{imidazolyl}$) and two N donors from the *trans*-coordinated $NCS^-$ anions. The values of the Fe–N bond lengths are in the range 1.932–2.028 Å, and they are indicative of a LS state of $Fe^{II}$ in complex **3** at 180 K.

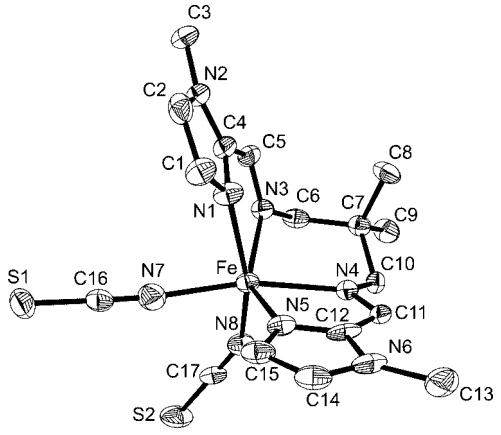

Figure 2. Molecular structure of $[FeL^{B5}(NCS)_2]$ (**2**). Thermal ellipsoids are drawn at the 40% probability level. H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe–N1 2.235(4), Fe–N3 2.185(4), Fe–N4 2.212(7), Fe–N5 2.144(5), Fe–N7 2.122(10), Fe–N8 2.119(5); N1–Fe–N3 73.49(16), N1–Fe–N4 107.9(2), N1–Fe–N5 87.79(18), N1–Fe–N7 81.7(3), N1–Fe–N8 158.2(2), N3–Fe–N4 79.8(2), N3–Fe–N5 142.8(3), N3–Fe–N7 112.1(2), N3–Fe–N8 93.15(16), N4–Fe–N5 75.8(3), N4–Fe–N7 166.86(16), N4–Fe–N8 85.9(2), N5–Fe–N7 96.0(3), N5–Fe–N8 112.37(16), N7–Fe–N8 87.9(3).

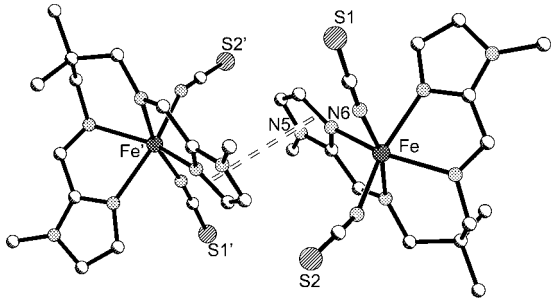

Figure 3. π–π stacking interactions in the crystal structure of $[FeL^{B5}(NCS)_2]$ (**2**).

Both H-bonds and π–π stacking interactions are responsible for the crystal packing of **3**. $[FeL^{E1}(NCS)_2]$ molecules are alternately associated into infinite chains through two N–H···S hydrogen bonds with the following parameters: N2···S1′ ($x$, $1-y$, $1+z$) = 3.330(2) Å, N2–H = 0.86 Å, ∠N2–H···S1′ = 160.0°. Interactions of the π–π type be-

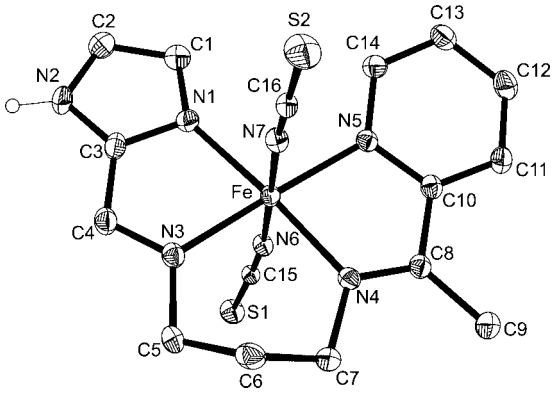

Figure 4. Molecular structure of $[FeL^{E1}(NCS)_2]$ (**3**). Thermal ellipsoids are drawn at the 40% probability level. H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe–N1 2.0277(17), Fe–N3 1.9618(17), Fe–N4 1.9493(17), Fe–N5 1.9692(17), Fe–N6 1.9391(18), Fe–N7 1.9324(18); N1–Fe–N3 80.67(7), N1–Fe–N4 174.76(7), N1–Fe–N5 101.71(7), N1–Fe–N6 87.95(7), N1–Fe–N7 91.52(7), N3–Fe–N4 96.80(7), N3–Fe–N5 177.25(7), N3–Fe–N6 88.82(7), N3–Fe–N7 90.45(7), N4–Fe–N5 80.94(7), N4–Fe–N6 87.41(7), N4–Fe–N7 93.09(7), N5–Fe–N6 92.62(7), N5–Fe–N7 88.13(7), N6–Fe–N7 179.15(7).

tween centrosymmetrically related $(1-x, -y, 1+z)$ pyridine rings with a centroid-to-centroid distance of 3.62 Å organize the chains into 2D layers, a fragment of which is shown in Figure 5.

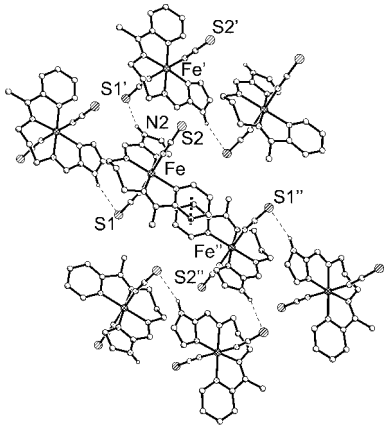

Figure 5. Fragment of a 2D layer of $[FeL^{E1}(NCS)_2]$ (**3**) that shows the H-bonds and π–π stacking interactions responsible for the crystal packing.

Solution and further refinement of the crystal structure of complex **5**, $[FeL^{E3}(NCS)_2]$, showed the presence of a statistical disorder of the external parts of the ligand. As a result, $L^{E3}$ occupies two distinct positions around Fe (Figure 6), related by C2 rotation through the Fe···C6 axis. The refined values of the site occupancy factors are equal to 0.74 and 0.26 for the major and minor (*) components, respectively. The average value of the Fe–N bond lengths, 1.969 Å, evidences the LS state of $Fe^{II}$ in **5** at 180 K.

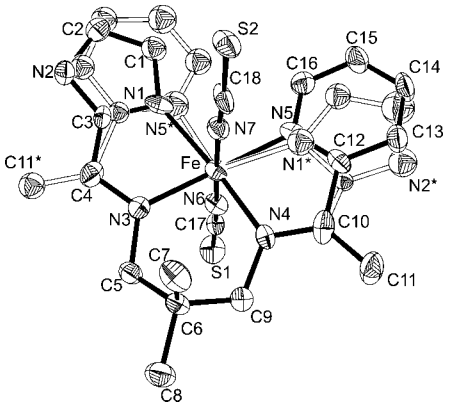

Figure 6. Molecular structure of $[FeL^{E3}(NCS)_2]$ (**5**). Thermal ellipsoids are drawn at the 40% probability level. H-atoms have been omitted for clarity. The minor location of $L^{E3}$ is drawn with thin lines. Selected bond lengths [Å] and angles [°]: Fe–N1 2.061(6), Fe–N1* 2.028(14), Fe–N3 1.946(4), Fe–N4, 1.939(4), Fe–N5 1.962(6), Fe–N5* 1.957(13), Fe–N6 1.928(4), Fe–N7 1.931(4); N1–Fe–N3 78.6(2), N1*–Fe–N3 171.7(7), N1–Fe–N4 173.0(3), N1*–Fe–N4 76.1(7), N1–Fe–N5 102.1(4), N1*–Fe–N5* 99.8(8), N1–Fe–N6 93.4(2), N1*–Fe–N6 90.8(8), N1–Fe–N7 85.2(2), N1*–Fe–N7 87.1(8), N3–Fe–N4 95.65(15), N3–Fe–N5 177.5(3), N3–Fe1–N5* 88.5(5), N3–Fe–N6 90.17(15), N3–Fe–N7 92.17(15), N4–Fe–N5 83.5(3), N4–Fe–N5* 174.6(5), N4–Fe–N6 90.56(16), N4–Fe–N7 91.11(15), N5–Fe–N6 92.1(3), N5*–Fe–N6 86.0(5), N5–Fe–N7 85.6(3), N5*–Fe–N7 92.2(5), N6–Fe–N7 176.98(16).

The crystal packing of **5** is essentially determined by the only possible N–H···S hydrogen bond [N2H···S2′ $(1+x, y, z)$ = 3.37 Å, H(N2)···S2′ = 2.52(4) Å, ∠N2HS2′ = 168.5°], which leads to the formation of infinite chains, as depicted in Figure 7. Further association of the components occurs through the short S2···S1′$(x-0.5, 0.5-y, 0.5+z)$ interchain contacts (3.38 Å), which result in 2D layers parallel to the [010] plane.

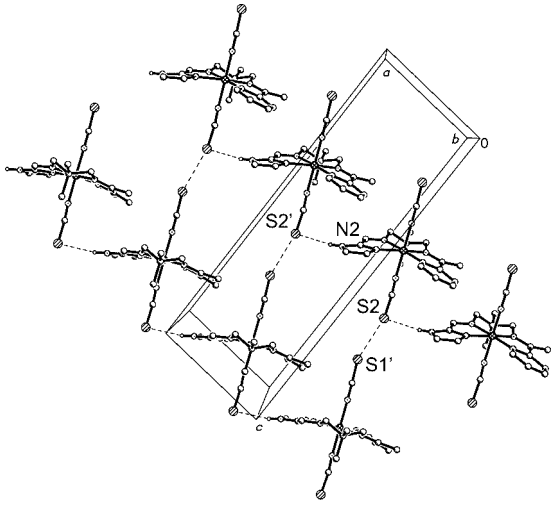

Figure 7. Fragment of a 1D chain of $[FeL^{E3}(NCS)_2]$ **5** that shows the H-bonds responsible for the crystal packing.

Complex **6** has a molecular structure that consists of neutral $[FeL^{E4}(NCS)_2]$ complex molecules as depicted in Figure 8. Geometrical parameters (Fe–N distances and N–

Fe–N angles) of the Fe $–N_6$ core at 180 K, close to those of a regular octahedron, indicate a LS electronic configuration of the $Fe^{2+}$ ions.

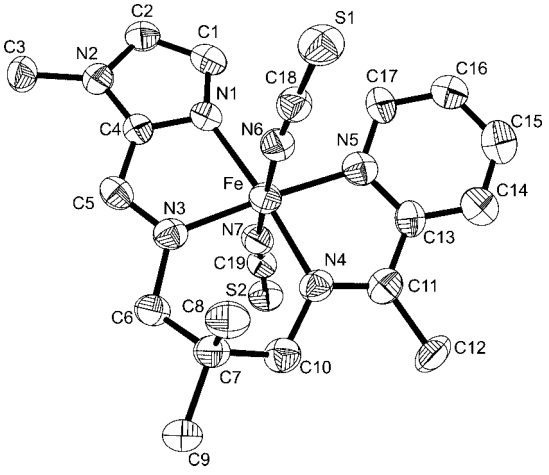

Figure 8. Molecular structure of $[FeL^{E4}(NCS)_2]$, the complex molecule of **6**. Thermal ellipsoids are drawn at the 40% probability level. H-atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe–N1 2.048(6), Fe–N3 1.945(6), Fe–N4 1.948(6), Fe–N5 1.946(7), Fe–N6 1.948(7), Fe–N7 1.944(7); N1–Fe–N3 81.4(3), N1–Fe–N4 174.0(2), N1–Fe–N5 102.7(3), N1–Fe–N6 88.0(3), N1–Fe–N7 89.6(3), N3–Fe–N4 94.8(3), N3–Fe–N5 175.8(3), N3–Fe–N6 92.0(3), N3–Fe–N7 91.6(3), N4–Fe–N5 81.2(3), N4–Fe–N6 96.8(3), N4–Fe–N7 85.8(3), N5–Fe–N6 87.1(3), N5–Fe–N7 89.5(3), N6–Fe–N7 175.3(3).

MeOH solvate molecules are associated to the $[FeL^{E4}(NCS)_2]$ complex molecules in the 1:1 ratio through O–H···S hydrogen bonds with distances O1–H = 1.03 Å, O1···S2 = 3.227(7) Å and O1–H···S2 = 2.30 Å and ∠O1HS2 = 149.9° (Figure 9). In addition, π–π stacking interactions between centrosymmetrically related ($–x$, $2–y$, $1–z$) imidazolyl rings are evidenced by the short interplanar (3.49 Å) and centroid-to-centroid (3.88 Å) distances. Centrosymmetric $\{[FeL^{E4}(NCS)_2]\cdot CH_3OH\}_2$ pairs are quite separated in the crystal space as a result of this π–π stacking interaction. In this respect, the crystal packing motif of **6** resembles that of **2**.

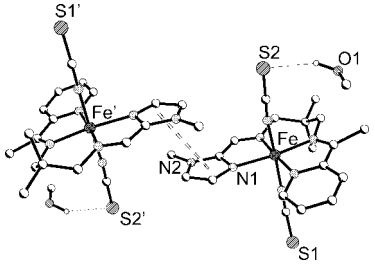

Figure 9. The dimeric association in $[FeL^{E4}(NCS)_2]\cdot CH_3OH$ (**6**) that shows the H-bonds and π–π stacking interactions responsible for the crystal packing.

## Magnetic Studies

The thermal variation of the magnetic susceptibility $\chi_M$ was explored for complexes **1** and **3**–**6**: the $\chi_M T$ data for selected temperatures ($T$) are collated in Table S1 (Supporting Information). The $\chi_M T$ vs. $T$ data are shown in Figure 10 for complexes **1** and **3**–**6**. It was not possible to study the magnetic properties of **2**, because this sample was obtained in very poor yield as a mixture with complex **6** (see Experimental Section).

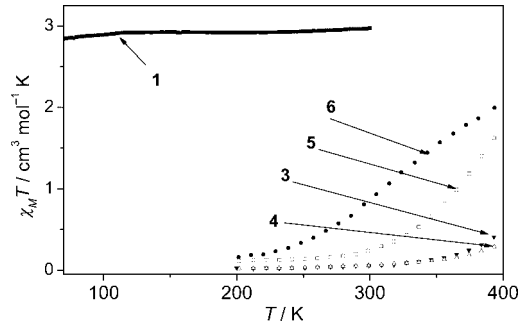

Figure 10. Thermal variation of the $\chi_M T$ product for complexes **1** and **3**–**6**.

The magnetic study of **1** shows that this complex is in the HS state between 70 and 300 K, with a $\chi_M T$ value close to 3 $cm^3 mol^{-1} K$. The $\chi_M T$ product for complexes $[FeL^{E1}(NCS)_2]$ (**3**; $R^1$ = H, $R^2$ = H) and $[FeL^{E2}(NCS)_2]$ (**4**; $R^1$ = H, $R^2$ = Me) is practically constant over the 200–350 K range and characteristic of LS $Fe^{II}$ $\chi_M T \approx 0$ $cm^3 mol^{-1} K$). The slight increase in $\chi_M T$ above 350 K ($\chi_M T$ = 0.4 $cm^3 mol^{-1} K$ at 400 K) may be considered as the onset of SC, with ca. 10% of HS sites at 400 K. Similarly, the $\chi_M T$ product for **5** ($R^1$ = Me, $R^2$ = H) is practically constant from 200 to 300 K and characteristic of LS $Fe^{II}$. Then, $\chi_M T$ increases from 0.2 $cm^3 mol^{-1} K$ at 300 K to 1.6 $cm^3 mol^{-1} K$ at 400 K, indicating LS→HS SC of ca. 50% $Fe^{II}$ centres at 400 K. Complex **6** ($R^1$ = Me, $R^2$ = Me) is essentially LS at 200 K ($\chi_M T$ = 0.4 $cm^3 mol^{-1} K$) and exhibits a smooth and incomplete SC upon heating with ca. 60% $Fe^{II}$ sites in the HS state at 400 K. Relative to that of complex **5**, the SC is smoother for **6**. The same behaviour is observed in the cooling mode, indicating the absence of hysteresis for these compounds.

## Mössbauer Spectroscopy

### *$[FeL^{Bx}(NCS)_2]$ Complexes*

Mössbauer spectra were recorded at selected temperatures in the 80–250 K range for complexes **1** and **2**. Values of the Mössbauer parameters (isomer shift $\delta$, quadrupole splitting $\Delta E_Q$ and line width $\Gamma/2$) resulting from fitting the spectra are collated in Table S2 (Supporting Information). The isomer shift values decrease slightly with increasing temperature, indicating the operation of second-order Doppler effect.[5]

The Mössbauer spectra of **1** evidence two HS doublets characteristic of slightly inequivalent Fe centres, $Fe^{II}$(A) and $Fe^{II}$(B) sites, as previously observed in related complexes.[4a] These doublets were fitted with similar isomer shift

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

values [1.098(2) and 1.120(2) mm s$^{-1}$ at 80 K, Table S2] as expected for identical $N_6$ donor sets around $Fe^{II}$(A) and $Fe^{II}$(B) and different $\Delta E_Q$ values [2.582(8) and 2.982(8) mm s$^{-1}$ at 80 K for $Fe^{II}$(A) and $Fe^{II}$(B), respectively], suggesting different low symmetry environments (Figure 11).[5]

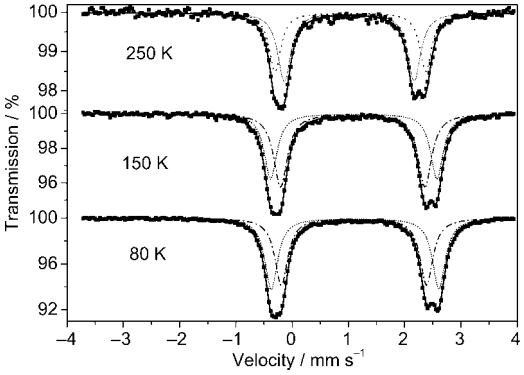

Figure 11. Representative least-squares-fitted Mössbauer spectra of [FeL$^{B4}$(NCS)$_2$] **1**. The solid line represents the fit of the data to two subspectra, the dash–dot line corresponds to site A and the dotted line to site B with the parameters given in the text and in Table S2.

In contrast, **2** is characterized by a unique quadrupole-split doublet [$\delta$ = 1.17(2) and $\Delta E_Q$ = 2.66(4) mm s$^{-1}$ at 80 K] typical of HS iron(II). The Mössbauer spectra of **2** were obtained from a sample resulting from the synthetic procedure described in the Experimental Section of **6**: this sample was the first solid obtained, specifically a mixture of **2** (red crystals) and **6** (dark-blue powder), because it was not possible to isolate enough red crystals of **2** in order to carry out Mössbauer measurements. The second solid (pure single crystals of **6**) were obtained in good yield through slow evaporation of the resulting filtrate; it was then possible to carry out Mössbauer measurements of **6** (pure) and thus to ascertain that the major doublet in the Mössbauer spectrum of the mixture was indeed that of **6**, and moreover to evaluate the relative ratio of **2** [11(2)%] in its mixture with **6**.

### *[FeL$^{Ex}$(NCS)$_2$] Complexes*

The Mössbauer spectra of complexes **3**–**6** confirm the spin states deduced from the magnetic data for these materials (Table S2, Supporting Information); however, as a result of poor counting statistics, high-temperature spectra (350–400 K) of complexes **3**, **4** and **5** could not be obtained in good quality. As an example for the materials in this series, we describe the study of complex **6** for which representative Mössbauer spectra recorded in the heating mode are shown in Figure 12. These spectra, measured in the 200–400 K range, confirm the partial SC deduced from the magnetic measurements. At 200 K, a unique LS doublet [$\delta$ = 0.417(4) and $\Delta E_Q$ = 0.787(8) mm s$^{-1}$] is observed;[4–7] at and above 300 K, the asymmetry of this doublet results from the presence of a growing HS component that is difficult to fit owing to the poor counting statistics. This Mössbauer behaviour confirms the SC observed by magnetic measurements. It is also worth mentioning that these high temperature spectra are very broad [$\Gamma_{1/2}$(LS) = 0.22 mm s$^{-1}$, $\Gamma_{1/2}$(HS) = 0.23 mm s$^{-1}$]. In the case of SC materials, observation of broadened Mössbauer spectra is usually related to dynamic phenomena: the interstate conversion rates $K_{LH}$ (LS→HS) and $K_{HL}$ (HS→LS) are comparable to the hyperfine frequency ($10^8$ s$^{-1}$).[8,9]

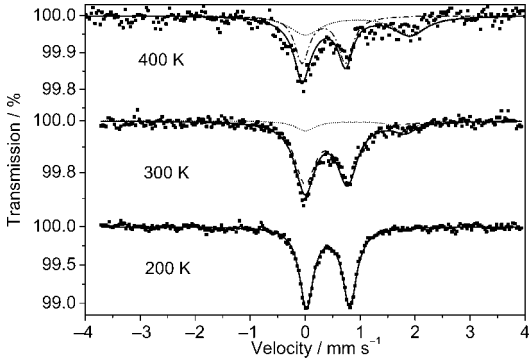

Figure 12. Representative least-squares-fitted Mössbauer spectra of [FeL$^{E4}$(NCS)$_2$] (**6**). The solid line represents the fit of the data to two subspectra, the dash–dot line corresponds to the LS site and the dotted line to the HS site with the parameters given in the text and in Table S2.

Mössbauer spectra of complexes **3**, **4** and **5** were recorded between 77 and 300 K. In agreement with the magnetic studies, all spectra show a unique doublet with parameters characteristic of the LS iron(II) state [$\delta$ = 0.376(1), $\Delta E_Q$ = 0.719(2) mm s$^{-1}$ for **3** at 293 K; $\delta$ = 0.357(4), $\Delta E_Q$ = 0.663(7) mm s$^{-1}$ for **4** at 293 K; $\delta$ = 0.377(4), $\Delta E_Q$ = 0.634(8) mm s$^{-1}$ for **5** at 300 K; Table S2).

### IR Spectroscopy

The IR spectroscopic study was focused on the NCS stretching absorptions (2000–2100 cm$^{-1}$ range), which serves as a good sensor for the *cis* or *trans* conformation of the coordinated thiocyanate anions. Usually, *trans* isomers exhibit a single absorption, whereas *cis* isomers are characterized by a splitting of the $\nu_{CN}$ absorption.[10] However, this criterion must be considered with much caution because the splitting of this band is very sensitive to slight deformations of the coordination sphere (in particular the N–M–N angle between the two thiocyanate ligands coordinated to the metal centre). The IR spectrum of [FeL$^{B4}$(NCS)$_2$] (**1**) shows two doublets (2081, 2070 and 2052, 2036 cm$^{-1}$), and this is similar to that of [FeL$^{B1}$(NCS)$_2$],[4a] which shows one doublet (2097, 2095 cm$^{-1}$) and one singlet (2025 cm$^{-1}$; Figure S1). The X-ray structure of [FeL$^{B1}$(NCS)$_2$] evidences two independent *trans* NCS molecules with strongly and differently distorted octahedral symmetries and its Mössbauer spectra confirm the presence of two HS $Fe^{II}$ sites.[4a] The presence of two HS $Fe^{II}$ sites {with $\delta$ and $\Delta E_Q$ parameters similar to those of [FeL$^{B1}$(NCS)$_2$]} in the Mössbauer spectra of **1**, together with the similarity of its IR spectrum to that of [FeL$^{B1}$(NCS)$_2$], strongly advocates to the similarity of their molecular structures with two independent *trans* NCS molecules with strongly and differently distorted octahedral

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

symmetry. As mentioned above, the splitting (or broadening) of the $\nu_{CN}$ absorptions is characteristic of a strong distortion of the octahedral symmetry. In contrast, the X-ray structure of $[FeL^{B2}(NCS)_2]$ evidences only one *trans* molecule with strongly distorted octahedral symmetry and the Mössbauer spectra of $[FeL^{B2}(NCS)_2]$ and $[FeL^{B3}(NCS)_2]$ show the presence of one HS $Fe^{II}$ site.[4a] The IR spectra of $[FeL^{B2}(NCS)_2]$ and $[FeL^{B3}(NCS)_2]$ show one doublet (2093, 2065 and 2082, 2018 $cm^{-1}$, respectively; Figure S1), and they are in agreement with the strong distortion of their unique *trans* NCS molecule. Consequently, the four bands between 2081 and 2036 $cm^{-1}$ observed for **1** confirm the presence of two distinct *trans* isomers as observed through Mössbauer spectroscopy, and in accordance with previous studies.[4]

## Discussion

As part of our systematic approach to generate new ferrous materials of the general formula $[FeL(NCS)_2]$ with predictable magnetic properties, in this contribution we report the results obtained when 1-*N*-$R^2$-imidazole-2-carboxaldehyde ($R^2$ = H, Me) is used as a carbonyl synthon in combination with 1,3-diaminopropane and 2,2-dimethyl-1,3-diaminopropane as diamino synthons for the synthesis of symmetrical $L^{Bx}$ and dissymmetrical $L^{Ex}$ tetradentate Schiff base ligands (Figures 1 and 13).

The change in carbonyl synthon from 2-$R^2$-imidazole-4-carboxaldehyde ($R^2$ = H, $CH_3$, $C_6H_5$)[4a] or 5-methylimidazole-4-carboxaldehyde[4b] to 1-*N*-$R^2$-imidazole-2-carboxaldehyde ($R^2$ = H, $CH_3$) involves minor structural modifications in the case of $[FeL^{B4}(NCS)_2]$ (**1**; $R^2$ = H), which is characterized by a *trans* coordination of the thiocyanato ligands and a planar conformation of $L^{B4}$, as suggested by comparison of the IR spectra and X-ray data of $[FeL^{B1}(NCS)_2]$, $[FeL^{B2}(NCS)_2]$ and **1**. These three complexes have the same coordination sphere and a very similar geometry around the metal centre with a planar conformation of $L^{Bx}$ (see above and ref.[4a]). However, in $[FeL^{B5}(NCS)_2]$ (**2**; $R^2$ = $CH_3$), which is characterized by a *cis* coordination of the thiocyanato ligands, $L^{B5}$ has a folded conformation, as demonstrated by X-ray analysis (see above). One plausible explanation for obtaining different isomers is the absence/presence of a methyl substituent at the 1-*N*-imidazole, which would allow/prevent the involvement of N–H hydrogen bonds as observed in the previous studies[4a,4b] and also for $[FeL^{Ex}(NCS)_2]$ complexes described in the present report. In the crystal structure of **2**, the *cis* arrangement of the thiocyanato anions associated to the folded conformation of the tetradentate ligand allows π–π stacking interactions between adjacent imidazolyl rings, which result in a crystal packing made of isolated dimeric associates. Although no structural data is available for **1**, the *trans* NCS coordination is likely to be promoted by N–H···S and/or N–H···N hydrogen bonds as observed in $[FeL^{B1}(NCS)_2]$,[4a] $[FeL^{B2}(NCS)_2]$,[4a] $[FeL^{D2}(NCS)_2]$,[4b] **3** and **5** (this work).

With regard to the series based on the disymmetrical $L^{Ex}$ ligands, we may establish a parallelism between the statistical disorder of $L^{E3}$ observed in **5**, which implies the presence of two configurations of the propylene fragment and the statistical disorder of the propylene fragment of $L^{D2}$ in $[FeL^{D2}(NCS)_2]$ at and below 300 K.[4b] Two conformers similarly distinguished by the configuration of one of the propylene fragments of $H_2L^{2-Me}$ were also observed in the crystal structure of $[FeH_2L^{2-Me}](ClO_4)_2$ ($H_2L^{2-Me}$ = bis{[(2-methylimidazol-4-yl)methylidene]-3-aminopropyl}ethylene diamine) at low temperature.[2k] Although no molecular structure is available, it is thus likely that the two-step SC of $[FeL^{D1}(NCS)_2]$, which is also characterized by two quadrupole-split LS doublets at low temperature,[4b] originates from the presence of two conformers distinguished by the configuration of the propylene fragment of $L^{D1}$.

Similar to the previously reported $[FeL^{Cx}(NCS)_2]$[4a] and $[FeL^{Dx}(NCS)_2]$[4b] series (Figure 14), the electronic behaviours of **3**–**6** evidences that a combination of pyridyl and imidazolyl rings to yield $Fe^{II}$ complexes that are based on a dissymmetrical tetradentate $L^{Ex}$ ligand allows the generation of an intermediate ligand field suitable for SC. In the absence of substituents on the central carbon atom of the propylene bridge of $L^{Ex}$ ($R^1$ = H, **3** and **4**), the onset of SC is above 350 K, regardless of the 1-*N*-$R^2$-imidazolyl substit-

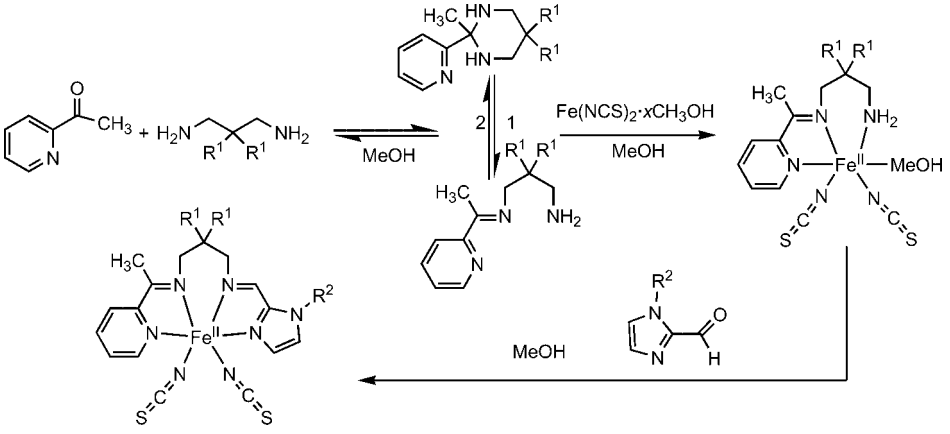

Figure 13. Synthetic pathway for the $[FeL^{Ex}(NCS)_2]$ ($R^1$ = H, Me; $R^2$ = H, Me).

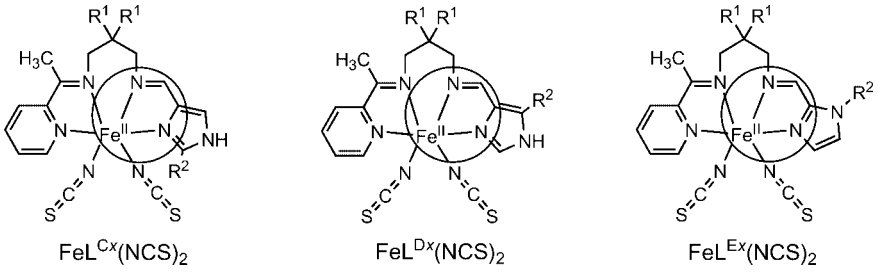

Figure 14. Compared schematic drawings of the $[FeL^{Cx}(NCS)_2]$,[4a] $[FeL^{Dx}(NCS)_2]$[4b] and $[FeL^{Ex}(NCS)_2]$ complexes (this work).

uent. Because the electronic properties of these materials cannot be evaluated above ca. 400 K, the effect of the 1-*N*-$R^2$-imidazolyl substituent on the compared SC behaviours of **3** and **4** cannot be appreciated. In the presence of substituents on the central carbon atom of the propylene bridge of $L^{Ex}$ ($R^1$ = Me, **5** and **6**), the SC is shifted towards lower temperatures. This down shift is modulated by the effect of the 1-*N*-$R^2$-imidazolyl substituent in two ways: (1) $T_{1/2}$ is higher for **5** ($R^2$ = H) than for **6** ($R^2$ = Me), ca. 390 vs. ca. 360 K and (2) the SC is much steeper for **5** than for **6**, indicating a more cooperative behaviour of **5** in line with the presence of extended intermolecular interactions in **5** versus isolated dimeric associates in **6**. The higher $T_{1/2}$ for **5** ($R^2$ = H) relative to that of **6** ($R^2$ = Me) is in line with our previous studies showing that the ligand fields exerted by $L^{C1}$ and $L^{C4}$ ($R^2$ = H) are weaker (higher $T_{1/2}$) than those exerted by the remaining $L^{Cx}$ ligands ($R^2$ = Me or Ph).[4a] However, the $R^2$ substituent is at the C2 imidazolyl in the $L^{Cx}$ series, whereas it is at the 1-*N*-imidazolyl in the present $L^{Ex}$ series (Figure 14); thus both the steric and inductive effects of $R^2$ are significantly different from one series to the other one, which prevents a more detailed comparison.

From our previous studies,[4a,4b] the role of $R^1$ in tuning the ligand field, as estimated through approximated $T_{1/2}$ values, was considered as more limited than that of $R^2$ and opposite in trend (lower $T_{1/2}$ associated with $R^1$ = H). It may thus seem striking to observe the opposite situation for the present series where the role of $R^1$ in tuning the ligand field is larger than (and similar in trend to) that of $R^2$. However, it must be underlined that the change in carbonyl synthon from 2-$R^2$-imidazole-4-carboxaldehyde[4a] or 5-methylimidazole-4-carboxaldehyde[4b] to 1-*N*-$R^2$-imidazole-2-carboxaldehyde (this work) moves the connection of the imidazolyl fragment (to the propyl chain) from the 4- to the 2-imidazolyl position: this change switches the orientation of the coordinated imidazolyl and the position of the imine imidazolyl nitrogen with respect to the adjacent Schiff base imine function (Figure 14). As a result, in the present $[FeL^{Ex}(NCS)_2]$ series the metallacycle involving the imidazolyl fragment is highly conjugated (Fe–N=C–C=N–) at variance with the corresponding metallacycle in the $[FeL^{Cx}(NCS)_2]$[4a] and $[FeL^{Dx}(NCS)_2]$[4b] series (Fe–N–C–C=N–), see Figure 14. It is then clear that this electronic effect not only largely overpasses but also qualitatively and quantitatively modifies the effects of $R^1$ and $R^2$.

As a final comment, we would like to stress the role of hydrogen bonds in the SC behaviour within this series of compounds: involvement of 1-*N*-Me-imidazole-2-carboxaldehyde for the synthesis of dissymmetrical ligands **4** and **6** prevents $NH_{imidazole}$···SCN interactions. Indeed, no weak interactions of this type are found in **6**, yielding isolated dimeric associates through π–π stacking interactions. As a consequence, **6** exhibits a very smooth SC that spreads over 200 K because of the lack of intermolecular interactions/cooperativity relative to its chemical isomer $[FeL^{D1}(NCS)_2]$ (including the 5-methyl-4-imidazolyl fragment), which exhibits a steep SC with a 5 K hysteresis.[4b]

## Experimental Section

**General:** All reagents and solvents are commercially available (Aldrich, Wako), and they were used without further purification. Elemental analyses were carried with a Perkin–Elmer 2400 series II device (C, H, N) at the Microanalytical Laboratory of the Laboratoire de Chimie de Coordination in Toulouse, and with a Maxim Thermoelectron device (S, Fe) at the Service Central de Microanalyses du CNRS in Vernaison, France. 1D $^1$H and 1D $^{13}$C NMR spectra were obtained with an AC 250 FT spectrometer (Bruker). Chemical shifts are given relative to tetramethylsilane by using $CDCl_3$ as the solvent. IR spectra were measured in the 400–4000 $cm^{-1}$ range with a 9800 FTIR spectrometer (Perkin–Elmer). Mössbauer spectra were recorded with a constant-acceleration conventional spectrometer with a 50 mCi source of $^{57}$Co (Rh matrix). The absorber was a powdered sample enclosed in a 20-mm diameter cylindrical plastic sample holder, the size of which was determined to optimize the absorption. Spectra were obtained in the 80–400 K range by using a MD306 Oxford cryostat (4–293 K) or an homemade vacuum oven (300–500 K), the thermal scanning being monitored by an Oxford ITC4 servo control device (± 0.1 K accuracy). A least square computer program[12] was used to fit the Mössbauer parameters and to determine their standard deviations of statistical origin (given in parentheses). Isomer shift values ($\delta$) are relative to iron foil at 293 K. Variable temperature magnetic susceptibility data were collected from powdered samples with a MPMS-55 Quantum design SQUID magnetometer or a Faraday type susceptometer under applied magnetic fields lower than 0.5 T. Diamagnetic corrections were applied by using Pascal's constants.[13]

### *Synthesis of Ligands*

**Symmetrical Ligands $L^{Bx}$:** 2,2-Dimethyl-1,3-diaminopropane (0.102 g, $10^{-3}$ mol) and imidazole-2-carboxaldehyde (0.192 g,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$2 \times 10^{-3}$ mol, for $L^{B4}$) or 1-methylimidazole-2-carboxaldehyde (0.220 g, $2 \times 10^{-3}$ mol, for $L^{B5}$) in methanol (20 mL) were stirred for 2 h at r.t. Slow evaporation of the solvent yielded brown-yellow oils. Yield: 0.190 g (74%) and 0.234 g (82%) for $L^{B4}$ and $L^{B5}$, respectively. Data for $L^{B4}$: $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 8.16 (s, 2 H, 4-H), 7.14 (s, 2 H + 2 H, 1-H + 2-H, NH proton exchange did not allow distinguishing the two types of protons), 3.43 (s, 4 H, 5-H5), 0.90 (s, 6 H, 7-H) ppm. Data for $L^{B5}$: $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 8.26 (s, 2 H, 4-H), 7.05–6.88 (2s, 2 H + 2 H, 1-H + 2-H), 3.956 (s, 6 H, 3-H), 3.42 (s, 4 H, 5-H), 0.97 (s, 6 H, 7-H).

**Synthesis of the Half-Units L and L′:** The synthetic pathway was adapted from ref.[4b]: 2-acetylpyridine and 1,3-diaminopropane (for L) or 2,2-dimethyl-1,3-diaminopropane (for L′) were mixed for 30 min in a 1:1 ratio (1 equiv. = $10^{-3}$ mol) in methanol (10 mL). The resulting pale yellow solution was used immediately for the preparation of complexes **3**–**6**.

***Synthesis of Complexes***

All complexation reactions and sample preparations for physical measurements were carried out under a purified nitrogen atmosphere within a glove box (Vacuum Atmospheres H.E.43.2) equipped with a dry train (Jahan EVAC 7).

**$Fe(NCS)_2 \cdot x$MeOH:** Prepared through the 1:2 reaction of $Fe(ClO_4)_2 \cdot xH_2O$ with potassium thiocyanate in MeOH.[11] After removal of potassium perchlorate through filtration, the freshly prepared $Fe(NCS)_2 \cdot x$MeOH was used immediately for the preparation of complexes **1**–**6**.

*Caution: Although no such behaviour was observed during the present work, perchlorate salts are potentially explosive and should be handled in small quantities and with much care.*

**General Procedure for 1 and 2:** A methanolic solution ($10^{-3}$ mol in 10 mL) of $[Fe(NCS)_2] \cdot x$MeOH was added slowly to a methanolic solution ($10^{-3}$ mol in 10 mL) of the ligand. The solution immediately changed from pale yellow to orange-yellow and was stirred for 30 min.

**$[FeL^{B4}(NCS)_2]$ (1):** Yield: 0.28 g, 65%, microcrystalline powder. IR: 2081, 2070, 2052, 2036 (NCS, 4 bands), 1619 (imine) $cm^{-1}$. $C_{15}H_{18}FeN_8S_2$ (430.3): calcd. C 41.87, H 4.22, N 26.04, S 14.90, Fe 12.98; found C 41.68, H 3.91, N 25.36, S 14.23, Fe 12.67.

**$[FeL^{B5}(NCS)_2]$ (2):** Could not be obtained as a pure species through the general method described above. However, during the synthesis of **6** with the dissymmetrical ligand $L^{E4}$, see below, we observed the systematic (and reproducible) formation of single crystals of red complex **2** in a poor yield, mixed with the desired dark-blue complex **6**. The amount of **2** in this mixture was evaluated by Mössbauer spectroscopy to 11(2)% (Table S2). The red single-crystal selected for X-ray data collection was picked from the mixture of **2** and **6**, see synthetic details for **6**, below.

**General Procedure for 3–6:** The synthetic pathway was adapted from the method previously described[4] (Figure 13). To a pale-yellow solution ($10^{-3}$ mol, 10 mL of methanol) of aminal L, **3** or **4**, or L′, **5** or **6**, was slowly added the freshly prepared $Fe(NCS)_2$ solution ($10^{-3}$ mol, 10 mL of methanol). The colour of the reaction mixture immediately turned to dark blue, and the mixture was stirred for 5 min. The appropriate 1-*N*-$R^1$-imidazole-2-carboxaldehyde ($10^{-3}$ mol, 10 mL of methanol) was then added (imidazole-2-carboxaldehyde for **3** and **5**, and 1-*N*-methyl-imidazole-2-carboxaldehyde for **4** and **6**). No further colour change was observed; the solution was stirred for another 30 min and then left undisturbed until a microcrystalline powder or crystals formed quantitatively.

**$[FeL^{E1}(NCS)_2]$ (3):** Yield: 0.32 g, 75%, dark-blue single crystals. IR (KBr): 2125, 2113 (NCS); 1645 (imine) $cm^{-1}$. $C_{16}H_{17}FeN_7S_2$ (427.3): calcd. C 44.97, H 4.01, N 22.94, S 15.01, Fe 13.07; found C 45.29, H 3.72, N 22.75, S 14.68, Fe 12.72.

**$[FeL^{E2}(NCS)_2]$ (4):** Yield: 0.32 g, 73%, dark-blue microcrystalline powder. IR (KBr): 2109, 2080 (NCS), 1647 (imine) $cm^{-1}$. $C_{17}H_{19}FeN_7S_2$ (441.4): calcd. C 46.26, H 4.34, N 22.22, S 14.53, Fe 12.65; found C 46.15, H 4.18, N 21.86, S 13.96, Fe 11.96.

**$[FeL^{E3}(NCS)_2]$ (5):** Yield: 0.31 g, 68%, dark-blue single crystals. IR (KBr): 2127, 2111 (NCS), 1656 (imine) $cm^{-1}$. $C_{18}H_{21}FeN_7S_2$ (455.4): calcd. C 47.48, H 4.65, N 21.53, S 14.08, Fe 12.26; found C 48.02, H 4.43, N 21.34, S 13.68, Fe 11.88.

**$[FeL^{E4}(NCS)_2] \cdot CH_3OH$ (6):** After removal of a small amount of a mixture of **2** and **6** by filtration, **6** was obtained from the resulting filtrate 2 d later. Yield: 0.36 g, 72%, dark-blue single crystals. IR (KBr): 2113, 2070 (NCS), 1635 (imine) $cm^{-1}$. $C_{20}H_{27}FeN_7OS_2$ (501.4): calcd. C 47.91, H 5.42, N 19.55, S 12.79, Fe 11.14; found C 47.69, H 4.92, N 20.13, S 12.43, Fe 10.86.

**Crystallographic Data Collection and Structure Determination for 2, 3, 5 and 6:** The X-ray data for compounds **2** and **6** were collected at 180 K with a Stoe Imaging Plate Diffractometer System (IPDS) equipped with an Oxford Cryosystems cooler device by using a graphite monochromator ($\lambda$ = 0.71073 Å). Data were collected[14] by using $f$ rotation movement with the crystal-to-detector distance equal to 80 mm (**2**), 70 (**6**) and $f$ = 0.0–250°, $\Delta f$ = 1.5° (**2**), $f$ = 0.0–200°, $\Delta f$ = 2.0° (**6**). Crystallographic measurements for **3** and **5** were carried out at 180 K with an Oxford-Diffraction XCALIBUR CCD diffractometer by using graphite-monochromated Mo-$K_\alpha$ radiation. The crystals were placed 50 mm from the CCD detector. More than the hemisphere of reciprocal space was covered by combination of four sets of exposures; each set had a different $f$-angle (0, 90, 180, 270°). The unit cell determination and data integration were carried out using the CrysAlis package of Oxford Diffraction.[15] All structures were solved by direct methods by using SHELXS-97[16] and refined by full-matrix least-squares on $F_o^2$ with SHELXL-97[17] with anisotropic displacement parameters for non-hydrogen atoms. All H atoms attached to carbon were introduced in idealized positions ($d_{CH}$ = 0.96 Å) by using the riding model with their isotropic displacement parameters fixed at 120% of their riding atom. Because of statistical disorder of the tetradentate ligand around Fe, the structure of **5** was refined by using a disordered approach in combination with the tools available from the SHELXL97 program package, yielding conformations with respective occupancy factors of 0.74(1) and 0.26(1)*. The molecular plots were obtained using the ZORTEP program.[18] The main crystallographic data together with refinement details are summarized in Table 1. CCDC-639917 for **2**, -639919 for **3**, -639918 for **5** and -639916 for **6**, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Table of the $\chi_M T$ data vs. temperature ($T$) for complexes **1** and **3**–**6**, Table of the Mössbauer parameters (isomer shift $\delta$, quadrupole splitting $\Delta E_Q$ and line width $\Gamma/2$) resulting from fitting the spectra of complexes **1**–**6** and the IR spectra of **1** and the three related complexes.

## Acknowledgments

# $Pd(SeO_3)$, $Pd(SeO_4)$, and $Pd(Se_2O_5)$: The First Palladium Oxoselenates

**Annika Arndt[a] and Mathias S. Wickleder*[a]**

**Keywords:** Solid-state structures / Palladium / Selenium / Lone-pair effect / IR spectroscopy

Depending on the reaction conditions, the reaction of elemental palladium with $H_2SeO_4$ in sealed glass tubes at 350 °C leads to red single crystals of $Pd(SeO_3)$ [$C2/m$, $Z = 4$, $a = 6.788(2)$, $b = 7.030(2)$, $c = 7.008(2)$ Å, $\beta = 118.09(3)°$] or to yellow-orange single crystals of $Pd(SeO_4)$ [$C2/c$, $Z = 4$, $a = 8.171(1)$, $b = 5.286(1)$, $c = 8.115(1)$ Å, $\beta = 94.54(1)°$]. Yellow-orange single crystals of $Pd(Se_2O_5)$ [$I2/a$, $Z = 4$, $a = 7.212(1)$, $b = 5.569(1)$, $c = 12.177(3)$ Å, $\beta = 106.84(2)°$] are obtained when $SeO_3$ is added to the reaction mixture. X-ray single-crystal diffraction shows that $Pd(SeO_3)$ consists of layers that are formed by square-planar coordinated $Pd^{2+}$ ions and pyramidal $SeO_3^{2-}$ groups. These layers are held together by weak interactions involving the lone electron pairs of the selenium atoms. The Se–O distances within the selenite ion are different (1.69 and 1.76 Å), in accordance with the different attachment of the oxygen atoms to the $Pd^{2+}$ ions. The square-planar $[PdO_4]$ units in the crystal structure of $Pd(SeO_4)$ are linked by tetrahedral $SeO_4^{2-}$ ions into a three-dimensional network. These anions act as monodentate ligands towards the $Pd^{2+}$ ions, with Se–O distances of around 1.65 Å. The $Pd^{2+}$ ions in the crystal structure of $Pd(Se_2O_5)$ are coordinated by two chelating diselenite ions. The $Se_2O_5^{2-}$ ions link the palladium ions into corrugated chains, which are held together by weak interactions only. The IR spectra of these compounds display the typical bands for oxoselenate anions.

## Introduction

Despite the vital importance of platinum group metals in various fields, complete classes of compounds of these elements are almost essentially unexplored. This is particularly true for those compounds containing complex oxo anions. To some degree this is astonishing as these compounds play a crucial role in various applications: the separation of platinum metals involves reactions with sulfuric acid, for example, and the rhodium sulfate $Rh_2(SO_4)_3 \cdot 12H_2O$ is used as a homogeneous catalyst, although its structure is not known.[1] Such compounds might also be important as precursors for the preparation of metal nanoparticles by thermolysis.[2] The investigation, and especially the structure elucidations, of these compounds are often difficult because single crystals are hard to obtain. Recently, we started to investigate compounds of precious metals with complex oxo anions in a systematic way and were able to develop suitable preparative routes for compounds of the elements gold and platinum. We found that the oxidation of gold with concentrated selenic acid and of platinum with sulfuric acid leads to gold selenites and platinum sulfates, respectively.[3,4] Surprisingly, in the case of platinum only platinum(III) sulfates were obtained. The extension of this chemistry to further platinum group metals has now afforded the selenite $Pd(SeO_3)$ by oxidation of elemental palladium with $H_2SeO_4$. Furthermore, the selenate $Pd(SeO_4)$ has been obtained by using $H_2SeO_4$ in excess, and $Pd(Se_2O_5)$ is formed when $SeO_3$ is added to the reaction mixture. $Pd(SeO_3)$, $Pd(SeO_4)$, and $Pd(Se_2O_5)$ are the first binary oxoselenates of a platinum group metal. Only two other structurally characterized palladium compounds with complex oxo anions have been reported to date, namely $Pd(SO_4)$, which has been prepared in a single crystalline form,[5] and $Pd(NO_3)_2 \cdot 2H_2O$, which has been characterized by powder diffraction data.[6] IR data are presented for a number of perchlorate salts.[7]

## Results and Discussion

### Crystal Structures

$Pd(SeO_3)$ crystallizes in the monoclinic space group $C2/m$. In the crystal structure the $Pd^{2+}$ ion is located at the special site 4*e* (site symmetry: $C_i$) and the selenium atom of the $SeO_3^{2-}$ group is placed at the position 4*i* (site symmetry: $C_s$) of that space group (Table 1). The $Pd^{2+}$ ion in square-planar coordination of four oxygen atoms ($2 \times O1$ and $2 \times O2$) from four monodentate selenite ions. The Pd–O distances are 2.01 and 2.02 Å, respectively, and a slight distortion of the square-planar coordination is found, with O1–Pd–O2 angles of 85.3° and 94.7° (Table 2). Two remarkably different distances are found within the $SeO_3^{2-}$ group, namely 1.69 Å for Se–O1 and 1.76 Å for Se–O2. The differ-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ence between these two can be attributed to the different coordination of the oxygen atoms by $Pd^{2+}$ ions: O1 is bonded to only one palladium ion while O2 has two neighbors. In this way the $SeO_3^{2-}$ ion is surrounded by four $Pd^{2+}$ ions, and this linkage leads to electronically neutral $^2_\infty[Pd(SeO_3)_{4/4}]$ layers that are stacked in the [102] direction of the monoclinic unit cell. The square-planar $[PdO_4]$ units within these layers join two *trans* vertices to each other to yield infinite $^1_\infty[PdO(1)_{2/1}O(2)_{2/2}]^{4+}$ chains (Figure 1). The $Pd^{2+}$–$Pd^{2+}$ distances are 3.52 Å within the chains and 3.39 Å between adjacent chains. The most remarkable feature of the crystal structure of $Pd(SeO_3)$ is that the neutral $^2_\infty[Pd(SeO_3)_{4/4}]$ layers are held together only by weak Van der Waals interactions with respect to the observed distances between the atoms of adjacent sheets (Figure 2). The selenium atoms of one layer and the oxygen atoms of the neighboring layer are separated by 3.15 Å, and the selenium atoms show a shortest distance of 3.70 Å from layer to layer. Thus, there is a large gap between the layers, which obviously contains the lone electron pairs of the selenium atoms. The layer type structure and the presence of only weak forces between the layers weakens the single crystals, which results in severe problems in finding a suitable single crystal for X-ray diffraction, as reflected by the rather high residual values (Table 4).

[a] $U_{eq} = 1/3[U_{22} + 1/\sin^2\beta(U_{11} + U_{33} + 2U_{13}\cos\beta)]$.

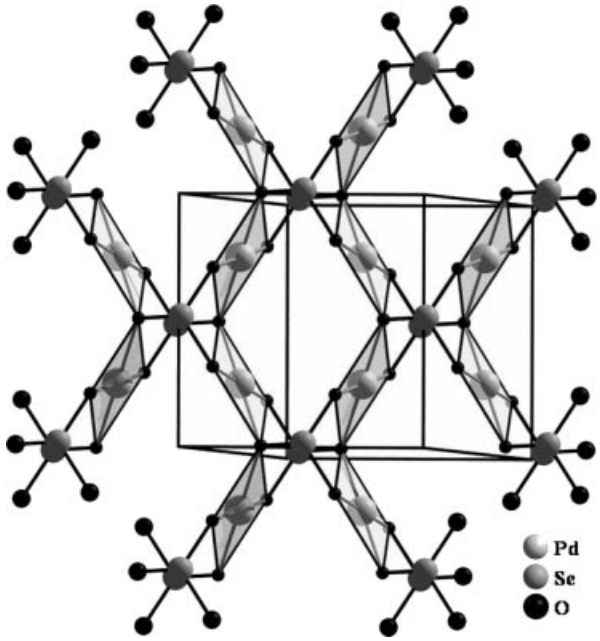

Figure 1. Linkage of the $[PdO_4]$ units according to $^1_\infty[PdO(1)_{2/1}O(2)_{2/2}]^{4+}$. The metal ions lie in a square plane of oxygen atoms and are connected via *trans* vertices into chains.

$Pd(SeO_4)$ also crystallizes monoclinically with a face centered unit cell (space group *C*2/*c*) and is isotypic with the recently reported $Pd(SO_4)$.[5] The palladium atoms are surrounded in a square-planar manner by oxygen atoms, and the selenium atoms are tetrahedrally coordinated by oxygen atoms. Both the palladium and the selenium atoms are located on special sites (4*c* and 4*e*, respectively), which implies $C_i$ symmetry for the $[PdO_4]$ units and $C_2$ symmetry for the $SeO_4^{2-}$ anions (Table 1). The Pd–O distances are in the same range as found for $Pd(SeO_3)$ and show values of 2.04 (O1) and 2.02 Å (O2; Table 2). This is also in good agreement with the findings reported for $Pd(SO_4)$.[5] Similarly to $Pd(SeO_3)$, a distortion of the $[PdO_4]$ unit has to be taken into account, with O1–Pd–O2 angles of 87.0 and 93.0°,

Table 2. Selected bond distances [Å] and angles [°] in $Pd(SeO_3)$, $Pd(SeO_4)$, and $Pd(Se_2O_5)$.

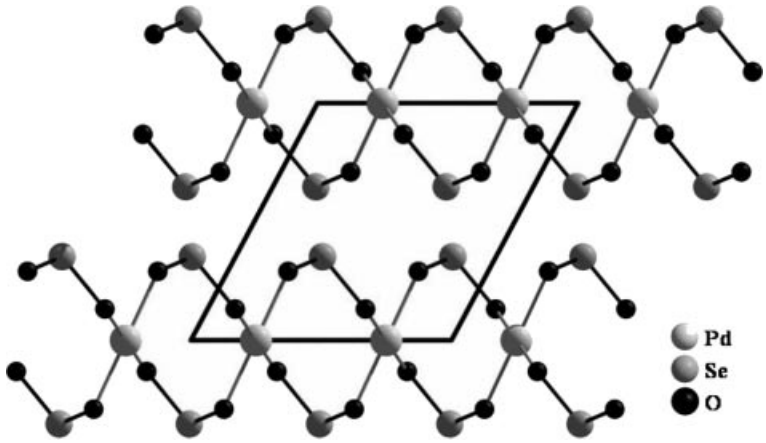

Figure 2. Stacking of electronically neutral $^{2}_{\infty}[Pd(SeO_3)_{4/4}]$ layers along the [102] direction of the unit cell.

respectively. The oxygen atoms of the $[PdO_4]$ groups ($2\times$O1, $2\times$O2) come from four monodentate $SeO_4^{2-}$ ions. Each of the latter must be connected to four $Pd^{2+}$ ions to achieve the composition $Pd(SeO_4)$. Thus, each of the oxygen atoms is connected to a $Pd^{2+}$ ion, which leads to uniform Se–O distances of about 1.65 Å within the anions. Judging from the O–Se–O angles within the anion (106.8–112.3°) a slight deviation of the ideal tetrahedral symmetry is observed. The connectivity of $Pd^{2+}$ and $SeO_4^{2-}$ ions leads to a three-dimensional network, as expressed by the Niggli formula $^{3}_{\infty}[Pd(SeO_4)_{4/4}]$ (Figure 3). The crystal structure of $Pd(SeO_4)$ is related to that of PdSe if the complex $SeO_4^{2-}$ ions are regarded as spheres.[8] The $Se^{2-}$ ions in PdSe have the same coordination as the $SeO_4^{2-}$ groups in $Pd(SeO_4)$.

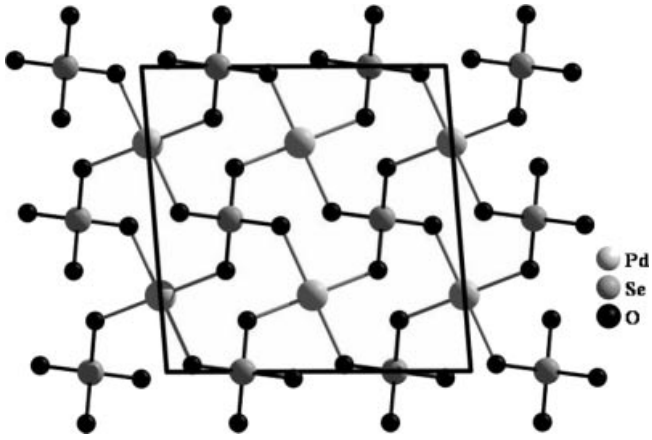

Figure 3. Perspective view of the crystal structure of $Pd(SeO_4)$ along the [010] direction of the unit cell.

The monoclinic structure of $Pd(Se_2O_5)$ (*I*2/*a*) contains the $Pd^{2+}$ ion (Wyckoff site 4*e*; site symmetry: $C_i$) in a square-planar environment of oxygen atoms ($2\times$O2 and $2\times$O3) with the Pd–O distances being essentially equal at 2.03 Å. The deviation of the $[PdO_4]$ unit from ideal $D_{4h}$ symmetry is again significant (Table 2). The four oxygen atoms belong to two $Se_2O_5^{2-}$ ions that act as chelating ligands (Figure 4). The distance between the bridging oxygen atom (O1) and the crystallographically equivalent selenium atoms is 1.793(3) Å, which matches the value that has been reported for other diselenites.[9] Furthermore, the Se–O1–Se angle of 131° lies within the range reported so far.[9] The oxygen atom O1 is located at the 4*e* site of space group

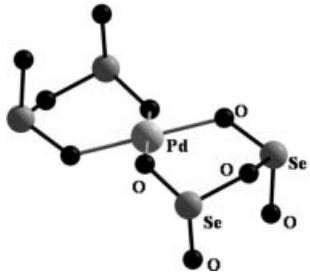

Figure 4.Coodination of the $Pd^{2+}$ ion by two chelating $Se_2O_5^{2-}$ groups in the crystal structure of $Pd(Se_2O_5)$.

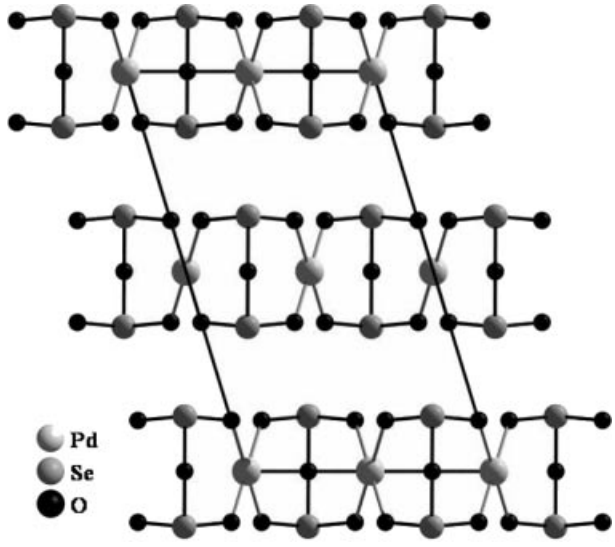

Figure 5. Perspective view of the crystal structure of $Pd(Se_2O_5)$ along the [010] direction of the unit cell.

*I*2/*a*, which yields $C_2$ symmetry for the $Se_2O_5^{2-}$ ion. According to the formulation $^1_\infty[Pd(Se_2O_5)_{2/2}]$, each $Se_2O_5^{2-}$ ion is coordinated to two $Pd^{2+}$ ions, which leads to the formation of infinite chains (Figure 5). These chains are strongly corrugated, as shown in Figure 6, and are stacked in the [010] direction. The Pd–Pd distance between adjacent $[PdO_4]$ units is 3.60 Å. The $^1_\infty[Pd(Se_2O_5)_{2/2}]$ chains are only held together by weak interactions and therefore, similarly to $Pd(SeO_3)$, single crystals of $Pd(Se_2O_5)$ suitable for X-ray diffraction were hard to obtain.

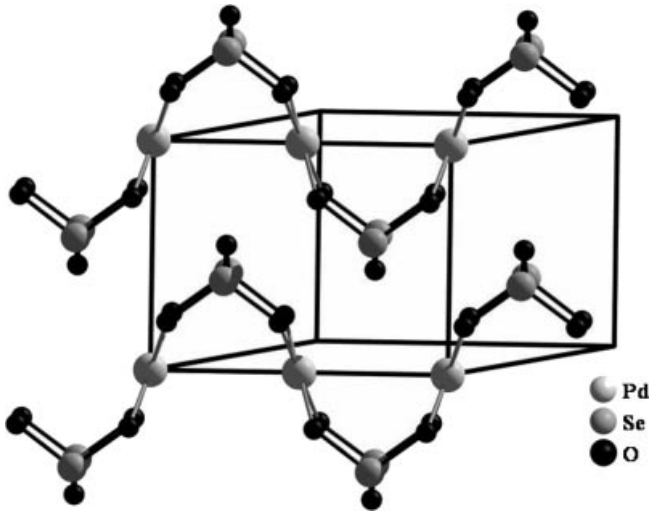

Figure 6. Stacking of the electronically neutral $^1_\infty[Pd(Se_2O_5)_{2/2}]$ chains in the crystal structure of $Pd(Se_2O_5)$.

### Vibrational Spectroscopy

The symmetry of the $SeO_3^{2-}$, $SeO_4^{2-}$, and $Se_2O_5^{2-}$ ions is remarkably lower in the compounds under discussion than in the free anions. Thus, the anion in $Pd(SeO_3)$ has $C_s$ symmetry, $SeO_4^{2-}$ shows $C_2$ symmetry in $Pd(SeO_4)$, and $C_2$ symmetry is also found for the $Se_2O_5^{2-}$ ion in $Pd(Se_2O_5)$. A number of bands are observed in the IR spectra between 400 and 4000 $cm^{-1}$. These are summarized in Table 3 and their assignment is straightforward by comparison with literature data.[9,10]

Table 3. IR data [$cm^{-1}$] for $Pd(SeO_3)$, $Pd(SeO_4)$, and $Pd(Se_2O_5)$.[a]

## Conclusions

As an extension of our work on direct oxidation of precious metals by mineral acids, we have shown in this paper that elemetal palladium can be oxidized by selenic acid under solvothermal conditions, which leads to $Pd(SeO_3)$ or $Pd(SeO_4)$, depending on the metal/acid ratio. Furthermore, the diselenite $Pd(Se_2O_5)$ is obtained if $SeO_3$ is added to the reaction mixture. The compounds were characterized by single-crystal X-ray diffraction and IR spectroscopy.

## Experimental Section

**Synthesis:** For the preparation of $Pd(SeO_3)$, 30 mg of palladium powder and 1 mL of $H_2SeO_4$, which was prepared from $H_2O_2$ and $SeO_2$ according to the literature procedure,[11] were sealed in a glass ampoule (length: 100 mm; width: 6 mm). This ampoule was heated to 350 °C for 72 h and then cooled slowly (3 °C/h). Plate-shaped and easily cleavable red crystals of $Pd(SeO_3)$ were recovered from the ampoule. Following the same procedure, lath-shaped yellow single crystals of $Pd(SeO_4)$ were obtained when only 15 mg of palladium powder was used in the reaction. Orange-yellow slightly needle shaped and cleavable single crystals of $Pd(Se_2O_5)$ were obtained upon treating 8 mg of palladium powder with 1 mL of $H_2SeO_4$ and 50 mg of $SeO_3$. This mixture was sealed in a glass ampoule, heated to 250 °C, and then slowly cooled (3 °C/h). The yields of the reactions were almost quantitative, and the samples were found to be single phase within the accuracy of X-ray powder diffraction.

**Caution:** All selenium-containing compounds are potentially poisonous. The glass ampoules are under considerable pressure after the reaction and should be handled with care and appropriate protection.

**X-ray Crystallography:** Crystals of $Pd(SeO_3)$, $Pd(SeO_4)$, or $Pd(Se_2O_5)$ were transferred into protecting oil and several specimens were glued on glass fibers and checked with the help of an image plate diffractometer (STOE IPDS). Reflection intensities for the best crystals were collected with the same diffractometer at 153 K. The crystal structures were solved by direct methods with the help of the program SHELXS97[12] assuming the space groups *C*2/*m* ($PdSeO_3$), *C*2/*c* ($PdSeO_4$), and *I*2/*a* $Pd(Se_2O_5)$. The latter setting of space group no. 15 was chosen in order to obtain a smaller monoclinic angle. Full-matrix least-squares refinements on $F^2$ were performed for all compounds using SHELXL97.[12] All atoms were refined anisotropically after applying numerical absorption corrections.[13] Details of the data collection are given in Table 4. Crystallographic and structural data are summarized in Tables 1 and 2, respectively. The final residuals for $Pd(SeO_3)$ and $Pd(Se_2O_5)$ are significantly higher than those for $Pd(SeO_4)$ due to the structural features of the former two compounds (extremely fragile crystals). Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen. These data

# Synthesis and Characterization of DOTA-(amide)$_4$ Derivatives: Equilibrium and Kinetic Behavior of Their Lanthanide(III) Complexes

**Azhar Pasha,[a] Gyula Tircsó,*[a] Enikő Tircsóné Benyó,[a] Ernő Brücher,[b] and A. Dean Sherry*[a,c]**

**Keywords:** Magnetic resonance imaging / Contrast agents / Protonation constants / Stability constants / Kinetics

Lanthanide complexes of tetraamide derivatives of DOTA are of interest today because of their application as chemical exchange saturation transfer (CEST) agents for magnetic resonance imaging (MRI). The protonation constants of some simple tetraamide derivatives of DOTA and the stability constants of the complexes formed with some endogenous metal ions, namely $Mg^{2+}$, $Ca^{2+}$, $Cu^{2+}$, $Zn^{2+}$, and lanthanide(III) ions, have been studied. These complexes were found to be considerably less stable than the corresponding $[M(DOTA)]^{2-}$ complexes, largely due to the lower basicity of the tetraamide ligands. The $Mg^{2+}$ and $Ca^{2+}$ complexes are well described by formation of only ML species at equilibrium while the $Zn^{2+}$ and $Cu^{2+}$ complexes exhibit one and two additional deprotonation steps above a pH of around 6, respectively. The extra deprotonation that occurs at high pH for the $[Zn\{DOTA\text{-}(amide)_4\}]^{2+}$ complexes has been assigned to an amide deprotonation by $^1H$ NMR spectroscopy. The first deprotonation step for the $Cu^{2+}$ complexes was traced to formation of the ternary hydroxo complexes ML(OH) (by UV/Vis spectrophotometry) while the second step corresponds to deprotonation of an amide group to form $ML(OH)H_{-1}$-type complexes. The trends in the stability constants of the $[Ln\{DOTA\text{-}(amide)_4\}]^{3+}$ complexes follow similar trends with respect to ion size as those reported previously for the corresponding $[Ln(DOTA)]^-$ complexes, but again, the stability constants are about 10–11 orders of magnitude lower. A kinetic analysis of complex formation has shown that complexes are directly formed between a $Ln^{3+}$ cation and fully deprotonated L without formation of a protonated intermediate. $[Ln\{DOTA\text{-}(MeAm)_4\}]^{3+}$ complex formation occurs at a rate that is two to three orders of magnitude slower than those of the corresponding $[Ln(DOTA)]^-$ complexes, while the variation in complex formation rates with $Ln^{3+}$ ion size is opposite to that observed for the corresponding $[Ln(DOTA)]^-$ complexes. The $Ce^{3+}$ and $Eu^{3+}$ complexes of DOTA-$(MeAm)_4$ are kinetically inert with respect to acid-catalyzed dissociation, which suggests that these complexes may potentially be safe for use in vivo.

## Introduction

Magnetic resonance imaging (MRI) is one of the most powerful and versatile techniques in modern medical diagnostics. Contrast agents (CA) are used to enhance MR contrast in 40–50% of all clinical MRI applications. The most common CAs are $Gd^{3+}$ complexes due to the high spin state (seven unpaired electrons) and favorable relaxation properties of the $Gd^{3+}$ ion.[1] The first contrast agent used in medical diagnosis was the $Gd^{3+}$ complex of diethylenetriamine-*N*,*N*,*N*′,*N*′′,*N*′′-pentaacetic acid ($H_5$DTPA), followed shortly thereafter by the $Gd^{3+}$ complex of 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid ($H_4$DOTA). These complexes are negatively charged and therefore must be formulated as salts. The next two approved agents, [Gd(DTPA-BMA)] and [Gd(HP-DO3A)], derived from an open-chain DTPA ligand and a macrocyclic DOTA ligand, respectively, are both neutral complexes.[2–4] All four of these systems are nonadentate, with one $Gd^{3+}$ coordination site occupied by a water molecule. Rapid relaxation of this inner-sphere water molecule by the paramagnetic $Gd^{3+}$ results in a shortening of the bulk water proton relaxation time ($T_1$) through the rapid exchange of an inner-sphere bound water molecule with tissue water. Lanthanide(III) complexes of some tetraamide derivatives of DOTA have been known for many years but were neglected as possible contrast agents due to the slow water-exchange rates exhibited by the $Ln^{III}$ complexes of these ligands and their less than favorable thermodynamic stablility.[5] However, a recent report by Balaban et al. describing the chemical exchange saturation transfer (CEST) mechanism for generating a negative image con-

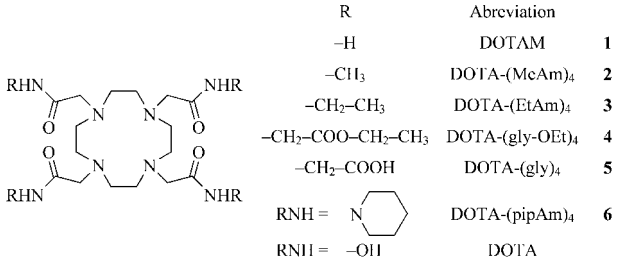
trast has renewed interest in these complexes.[6] CEST contrast begins with application of a presaturation RF pulse applied at the resonance freqnency of an exchangeable OH or NH proton on a CEST agent and this partially saturated spin then exchanges with the protons of bulk water. Given proper exchange kinetics and relaxation times, this results in a reduction in the bulk water signal intensity and negative contrast in an image. More recently, Sherry and co-workers discovered the CEST effect in [Eu{DOTA-(gly-OEt)$_4$}]$^{3+}$ (Scheme 1) and showed that a particularly useful exchange site for CEST activation is provided by the highly shifted (approx. 50 ppm), slow-exchanging water protons bound to a paramagnetic $Eu^{3+}$ ion in this complex.[7] Paramagnetic CEST (PARACEST) agents that contain a highly shifted CEST activation site offer some advantages over the diamagnetic agents proposed originally; most importantly, the large chemical-shift difference between the exchanging protons on the agent and the bulk water reduces the possibility of off-resonance saturation of the bulk water signal. This observation has catalyzed interest in the synthesis and design of new tetraamide derivatives of DOTA as potential CEST systems, and this potential new application makes it especially important to evaluate the thermodynamic and kinetic stability of these complexes in solution and in the presence of adventitious ions.



Scheme 1. Ligands investigated in this work.

Lanthanide(III) complexes of DOTA are among the most thermodynamically stable and kinetically inert complexes known to date.[8–10] A recently published report on the thermodynamic stability and kinetics of [Ln{DOTA-(gly)$_4$}]$^-$ complex formation demonstrated that both the basicity of the amide ligands and the stability of the complexes are several orders of magnitude lower than for their [Ln(DOTA)]$^-$ analogues.[11] It was also shown that spontaneous dissociation of [Eu{DOTA-(gly)$_4$}]$^-$ occurs somewhat faster than [Eu(DOTA)]$^-$, but that acid-catalyzed dissociation of the protonated intermediate [Eu{H$_4$DOTA-(gly)$_4$}]$^{3+}$ seems to occur more slowly than for its protonated [Eu(H$_2$DOTA)]$^+$ analog.[9,11] This suggests that these systems may in fact be suitable for in vivo imaging applications.

The stability constants of the $Ca^{2+}$, $Sr^{2+}$, $Ba^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Hg^{2+}$, $La^{3+}$, and $Gd^{3+}$ complexes of DOTAM have been reported by Maumela et al.[12] The authors also provided the lower limit for the stability constants of the $Cd^{2+}$ and $Pb^{2+}$ complexes ($\log K_{min}$ = 19.0), because these stabilities are too high to be measured experimentally.[12] A more detailed study involving eleven $Ln^{III}$ ions was published recently by Voss et al., who used competition reactions between various $Ln^{III}$ ions and $Eu^{III}$ and followed the competition by the measurement of the luminescence intensity to calculate the ratio of the stability constants $K_{Ln}^{III}/K_{Eu}^{III}$.[13] No information about possible hydroxo complex formation (or amide dissociation) for $Cu^{2+}$, $Zn^{2+}$, and $Ln^{III}$ complexes are available in these papers. The protonation constants of the ligand DOTA-(MeAm)$_4$ and the stability of the $Eu^{3+}$ and $Gd^{3+}$ complexes have also been reported by Virtuani and co-workers,[14] and the formation of MHL and ML [M(OH)L and M(OH)$_2$ for $Cu^{2+}$ and $Zn^{2+}$ ions] species in solution was subsequently reported.[15] The stability constants of metal ion complexes of DOTA-(EtAm)$_4$ and DOTA-(gly-OEt)$_4$ have not been reported previously.

These earlier reports leave the impression that these structurally similar ligand systems behave quite differently in solution, which led to the present investigation of detailed thermodynamic studies of the divalent ions $Mg^{2+}$, $Ca^{2+}$, $Cu^{2+}$, and $Zn^{2+}$ and the trivalent lanthanide(III) ions with the ligands shown in Scheme 1. The rates of complex formation and acid-catalyzed dissociation of some [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ complexes (where $Ln^{3+}$ = $Ce^{3+}$, $Eu^{3+}$, and $Lu^{3+}$ in the complex formation studies and $Ln^{3+}$ = $Ce^{3+}$ and $Eu^{3+}$ in the acid-catalyzed dissociation studies) have also been studied.

## Results and Discussion

The simple tetraamide ligands DOTAM (**1**), its *N*-methyl analog DOTA-(MeAm)$_4$ (**2**), the *N*-ethyl analog DOTA-(EtAm)$_4$ (**3**), and the glycinate ethyl ester analog DOTA-(gly-OEt)$_4$ (**4**) were prepared following established procedures by alkylation of 1,4,7,10-tetraazacyclododecane with the appropriate α-halo amide derivative.[12,15–18] The characteristics of these ligands were in a good agreement with those reported previously.

### Equilibrium Studies

The protonation constants of the ligands and stability constants of the complexes formed with the DOTA-(amide)$_4$ ligands were determined by pH-potentiometry. The protonation constants ($\log K_i^H$) of these tetraamide ligands are listed and compared to the literature values for DOTA and DOTA-(gly)$_4$ in Table 1 (the values shown in parentheses are the standard deviations).[11,19] Our data agree well with the published values except for the variation in the first p$K_a$ of the ligand DOTAM, where the difference is larger than one order of magnitude. This variation can be attributed to the different ionic strength used in the present study. The protonation constants of DOTAM have been determined in 0.1 M NaCl at 25 °C by Maumela et al.[12] The $Na^+$ ion is known to form more stable complexes with most of the ligands than the $K^+$ ion. For instance, the stability of [Na(DOTA)]$^{3-}$ is $\log K_{NaL}$ = 4.2 in contrast to

[a] Ref.[11] [b] Ref.[20] [c] Ref.[12] [d] Refs.[14,15]

[K(DOTA)]$^{3-}$, which is $\log K_{KL}$ = 1.6.[20] The stability of the $Na^+$ and $K^+$ complexes with DOTAM differ considerably from those reported for DOTA, so one can argue that measurements in a KCl background give more realistic p$K_a$ values than those measured in an NaCl background. Only two protonations were found for these ligands above a pH of about 1.8. The highest protonation constant was typically in the range 9.0–9.6, while the second protonation constant was in the range 5.4–6.5. The sum of these protonation constants (reflecting the total ligand basicity) is in the range 15.5–16.5 log $K$ units (Table 1). These values are around 50% of the total ligand basicity of DOTA, thus demonstrating the importance of the negatively charged acetate sidechains in DOTA in stabilizing the protonated ring nitrogen atoms of DOTA through hydrogen-bonding interactions. Similar variations in p$K_a$ values of DOTA-(MeAm)$_4$ to those reported by Virtuani and co-workers were found.[14,15]

The reaction between these ligands and different divalent endogenous metal ions was rapid enough to allow direct potentiometric titrations for stability determinations. However, under acidic conditions, where complex formation is slow, the interval between base additions was maintained at 30 minutes to ensure complete equilibrium complexation at each titration step. The time needed for the $Cu^{2+}$ complexes to reach equilibrium was verified by UV/Vis spectrophotometry. These stability constants are summarized and compared with previous literature values in Table 2.

The equilibria involving these ligands with $Mg^{2+}$ and $Ca^{2+}$ ions can be described by formation of ML-type complexes only; no protonated complexes or terniary hydroxo complexes [ML(OH)] were detected. The stability of the MgL complexes is so low that competition by hydrolysis of $Mg^{2+}$ at higher pH values was significant. Hydrolysis of $Ca^{2+}$, however, occurs at much higher pH values [$\log K_a(Ca^{2+})$ = 12.8] so formation of ML(OH)-type complexes was neither anticipated nor observed.[21] The titration curves measured for the CuL complexes show two extra deprotonation steps above the pH at which the complexes were fully formed. The absorption spectra of [Cu(DOTAM)]$^{2+}$ and [Cu{DOTA-(MeAm)$_4$}]$^{2+}$ are identical and addition of the first equivalent of base to form a CuL(OH) species resulted in no apparent change in the visible spectra of these complexes. However, addition of a second equivalent of base resulted in a significant blue shift in their

absorption maxima from 715 nm to about 650 nm (Figure 1). Such spectral changes are known to occur for $Cu^{2+}$-oligopeptide complexes, where deprotonation and coordination of an amide group to the $Cu^{2+}$ ion is known to occur. However, the terminal $NH_2$ group (anchor nitrogen atom) plays a critical role in the deprotonation and coordination of the adjacent amide moiety in the $Cu^{2+}$-polypeptide systems.[20]

The peptide hydrogen deprotonation in $Zn^{2+}$-oligopeptide systems is known to occur only above a pH of 10.[22] The titration curve of $[Zn\{DOTA\text{-}(amide)_4\}]^{2+}$ systems also reflects an extra deprotonation step after the protons associated with the ligand are neutralized (above pH > 10). Furthermore, the X-ray structure of $[Zn(DOTAM)]^{2+}$ shows a $Zn^{2+}$ ion coordinated by four nitrogen atoms of the cyclen ring and two oxygen atoms of the amide pendant arms, with no inner-sphere water molecule, so the extra deprotonation likely reflects an amide proton.[12] $^1$H NMR titrations of $[Zn(DOTAM)]^{2+}$ and $[Zn\{DOTA\text{-}(MeAm)_4\}]^{2+}$ complexes (Figure S2 in the Supporting Information and Figure 2) over the pH range 7–12 were consistent with this assignment.

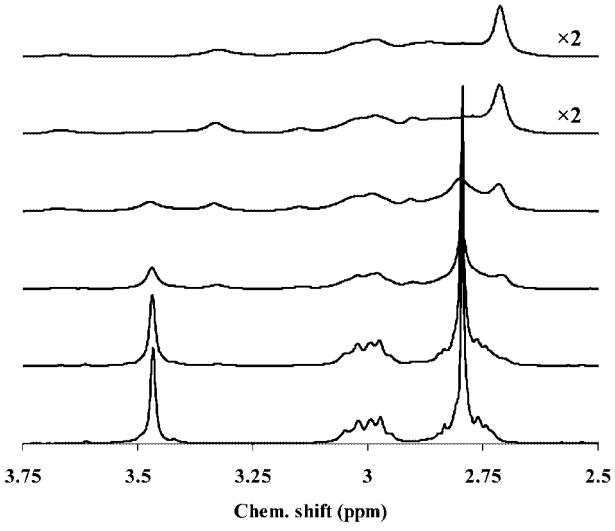

Figure 2. $^1$H NMR titration of the $[Zn\{DOTA\text{-}(MeAm)_4\}]^{2+}$ complex ($C_{Zn} = C_L = 3.0 \times 10^{-2}$ M). The pD of the samples are as follows (from top to bottom): 12.04 (the intensity of the spectra is doubled), 11.44 (the intensity of the spectra is doubled), 10.94, 10.49, 9.84 and 6.95.

Aqueous solutions of DOTA-(gly-OEt)$_4$ are unstable toward hydrolysis of the ester above a pH of around 5. When dissolved in 0.01 M acid, the ligand is stable enough to allow estimates of the stabilities of its $Mg^{2+}$, $Ca^{2+}$, $Cu^{2+}$, and $Zn^{2+}$ complexes (Table 2) using titration data up to pH 5. With further increases in pH, hydrolysis of the ester bonds was evident so this precluded an examination of whether $MLH_{-1}$ type complexes are formed with this ligand. Similarly, it was not possible to calculate the stabilities of the LnL complexes with this ligand because slow kinetics of complex formation dictated that the "out-of-cell" technique be used and this requires sample heating for an extended period to reach equilibrium; this favors ester hydrolysis which, in turn, distorts the pH-potentiometric data.

The stability constants of the complexes formed between several DOTA-(amide)$_4$ ligands and numerous $Ln^{3+}$ ions are summarized in Table 3. The values increase with a decrease in $Ln^{3+}$ ion size near the beginning of the lanthanide series, then remain relatively constant for the heavier ions until the very end of the series, where a decrease is noted. A similar trend has been noted by Voss et al. for the $[Ln(DOTAM)]^{3+}$ complexes, although the changes with lanthanide size differed somewhat.[13] The stability constants of the $[Ln\{DOTA\text{-}(EtAm)_4\}]^{3+}$ and $[Ln\{DOTA\text{-}(gly)_4\}]^{-}$ complexes are nearly identical for most lanthanides, as one would expect for systems with similar structures and ligand basicities.[11] The data also show that the stabilities are not influenced by the overall charge on these complexes and that the extended glycinate groups do not coordinate to the central metal ions in ML complexes.

The stabilities of $[Eu\{DOTA\text{-}(MeAm)_4\}]^{3+}$ and $[Gd\{DOTA\text{-}(MeAm)_4\}]^{3+}$ previously reported by Virtuani et al. are in good agreement with the current results; the deviation of about 0.5 log$K$ units in these two studies can be traced to differences in the $\log K_i^H$ values of the ligands themselves.[14,15] A noticeable difference in the equilibrium model is that we could find no evidence for formation of protonated (LnHL) complexes (either from "out-of-cell" data or from the titration data obtained for fully formed LnL complexes with HCl), while Virtuani et al. included protonated species in their model.[14,15]

An extra deprotonation was evident for all three $[Ln\{DOTA\text{-}(amide)_4\}]^{3+}$ complexes at pH values above 10.5. Virtuani, et al. have also reported formation of ternary hydroxo complexes $[Ln(OH)L^{2+}]$, although the pH

range for this deprotonation was much lower in their study (in the range pH 7–9).[14,15] These differences may be due to the presence of excess free metal ions in their study since our titration curves resemble the titration curve of a strong acid with a strong base (no buffering region is observed below pH 10.5, Figure S3). So, if one accepts that a deprotonated species does form in these complexes, does the site of deprotonation correspond to an amide deprotonation or does deprotonation of the coordinated water molecule occur in these complexes? To answer this question, several additional experiments were performed. First, high resolution $^1$H NMR spectra of the diamagnetic $Lu^{3+}$ complexes of DOTAM and DOTA-$(MeAm)_4$ showed no change in the chemical shift of the $CH_2$ protons of the amide side-arms (AB coupling pattern) upon addition of up to 2.5 equivalents of base (Figures S4 and S5 show the $^1$H NMR titrations of the $[Lu(DOTAM)]^{3+}$ and $[Lu(DOTA\text{-}(MeAm)_4\})]^{3+}$ complexes, respectively). This result is inconsistent with dissociation of an amide proton. The most convincing evidence that deprotonation occurs at the coordinated water molecule was obtained by luminescence studies with the $Eu^{3+}$ complexes. It is known from the literature that both $[Eu(DOTAM)]^{3+}$ and $[Eu\{DOTA\text{-}(MeAm)_4\}]^{3+}$ contain one inner-sphere coordinated water molecule ($q$ = 1).[23] This was verified by measuring the luminescence rate constants for depopulation of the $Eu^{3+}$ excited states in $H_2O$ vs. $D_2O$. At pH 7 and 25 °C, these lifetimes are 1.79 ($H_2O$)/0.44 $ms^{-1}$ ($D_2O$) and 1.96 ($H_2O$)/0.46 $ms^{-1}$ ($D_2O$) for $[Eu(DOTAM)]^{3+}$ and $[Eu\{DOTA\text{-}(MeAm)_4\}]^{3+}$, respectively. These values give an estimated $q$ of 1.02 and 1.20 for the two complexes.[23] With an increase in pH (pD) to 11.8, the measured $q$ values decrease to 0.47 and 0.52 for $[Eu(DOTAM)]^{3+}$ and $[Eu\{DOTA\text{-}(MeAm)_4\}]^{3+}$, respectively, consistent with deprotonation of the coordinated water molecule and a decrease in OH (OD) oscillators of about 50%. These data do not, however, rule out the possibility of amide deprotonation in these complexes at even higher pH values (>11.8) but it is not likely that amide deprotonation would lead to a change in the coordination environment around the chelated $Ln^{3+}$ ion. This is in good agreement with the results published previously by Aime et al.[24]

### Formation Kinetics of Some $[Ln\{DOTA\text{-}(MeAm)_4\}]^{3+}$ Complexes

The complexation reaction involving macrocyclic ligands is usually several orders of magnitude slower than that with linear polyamino-polycarboxylate type ligands.[25] It is now generally accepted that complex formation in LnDOTA-type systems takes place in several discrete steps.[26] First, an unusually stable intermediate where the $Ln^{3+}$ ion is positioned "out of cage" and one or two of the macrocyclic amino groups remain protonated, which has been detected by several spectroscopic techniques, is formed quickly. Subseqnent slow base-catalyzed deprotonation of those amines and rearrangement leads to the formation of a final $[Ln(DOTA)]^-$ complex where the $Ln^{3+}$ ion is trapped "in cage".[8–10,27] Evidence for a similar stable intermediate has been reported during formation of the $[Ln\{DOTA\text{-}(gly)_4\}]^-$ complexes as well.[11] Furthermore, an interesting structure that is thought to be the reactive intermediate in the formation of $[Ln(DOTAM)]^{3+}$ complexes was characterized recently by X-ray diffraction.[28]

The visible spectra of solutions recorded after mixing DOTA-$(MeAm)_4$ with $CeCl_3$ (both reagents were present at $5\times10^{-4}$ M) at pH 5.26 are shown in Figure 3. At this pH, the ligand is distributed between the forms $H_2L$ (80%) and HL (20%), both of which are favorable for formation of such an intermediate. With time, two new absorption bands, with $\lambda_{max}$ = 269 and 323 nm, respectively, appear in the spectra, the intensities of which increase with time as the "in cage" complex forms. The rate constants calculated from each absorption band agree with each other to within 3%, thereby indicating that both bands characterize the same reaction process. These changes are similar to those described for formation of $[Ce(DOTA)]^-$ except that the $\lambda_{max}$ of the $[Ce(H_2DOTA)]^+$ kinetic intermediate occurs at 297 nm. Another major difference is that the $[Ce\{DOTA\text{-}(MeAm)_4\}]^{3+}$ reaction requires about 8 hours to reach equilibrium at pH 5.26, which is considerably more than the time required for $[Ce(DOTA)]^-$ complexation to reach equilibrium at pH 4.45.[8] The presence of one isosbestic point at $\lambda$ = 260 nm indicates that only two absorbing components are present – the reactant ($Ce^{3+}$) and the product $[Ce\{DOTA\text{-}(MeAm)_4\}]^{3+}$.

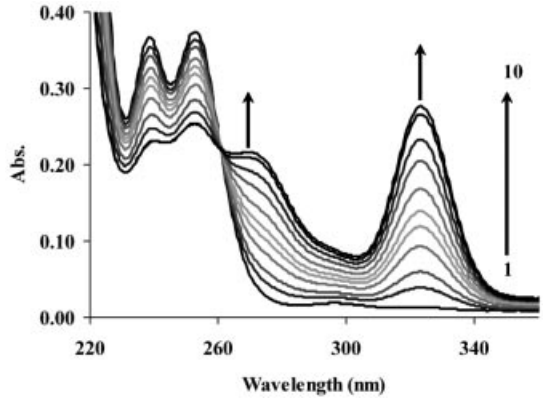

Figure 3. Formation of $[Ce\{DOTA\text{-}(MeAm)_4\}]^{3+}$ as a function of time. Absorption spectra were recorded (150 nm/min) at 1 (1), 9 (2), 17 (3), 33 (4), 49 (5), 65 (6), 97 (7), 161 (8), 241 (9), and 401 (10) minutes after the reaction was started and at equilibrium [$C_{Ce} = C_L = 5\times10^{-4}$ M in NMP buffer ($C_{NMP} = 2.5\times10^{-2}$ M) with pH 5.26].

It is also possible to follow the rate of $[Eu\{DOTA\text{-}(MeAm)_4\}]^{3+}$ complex formation by following changes in the $Eu^{3+}$ charge-transfer (CT) bands (broad "shoulder" between 240 and 305 nm, Figure S6). A wavelength of 255 nm was selected for these studies since the absorbance of $Eu^{3+}$ and ligand are not significant at this wavelength and $[Eu\{DOTA\text{-}(MeAm)_4\}]^{3+}$ is the only absorbing species (Figure S6).

Kasprzyk et al. have reported that the reaction between metal and ligand can proceed by three possible mechanisms,[29] one of which is a simple second-order reaction

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

where saturation kinetics is not observed and the rate constant is a linear function of the metal ion concentration. The linear variation of pseudo-first-order rate constants ($k_{obs}$) with analytical concentration of $Ln^{3+}$ at different pH values is displayed graphically in Figure 4 for $Ce^{3+}$ (similar data were also observed for $Eu^{3+}$ and $Lu^{3+}$, see Figures S7 and S8, respectively, in the Supporting Information). $k_{obs}$ was found to vary linearly with $Ln^{3+}$ concentration for all systems, and since [L] ≤ 10[M], these data may be described by Equation (1).

$$v = \frac{d[LnL]_t}{dt} = k_{obs}[L]_t \quad (1)$$

The rates of complex formation are pH-dependent, slowing considerably with increasing the acid concentrations. Based on this, one can assume that some protonated species may be involved in the formation reaction. Taking into account all possible pathways, the rate of complex formation may be described by Equation (2), where $k_0$, $k_1$, and $k_2$ are rate constants characterizing the reaction of the nonprotonated (L), monoprotonated ($HL^+$), and diprotonated ($H_2L^{2+}$) forms of the ligand, respectively.

$$v = k_0[M][L] + k_1[M][HL] + k_2[M][H_2L] \quad (2)$$

Given that the analytical concentration of the ligand is $[L]_t = [L] + [HL^+] + [H_2L^{2+}]$, and substituting the appropriate concentrations from the definition of the protonation constants of the ligand ($K_1^H = [HL^+]/[H^+][L]$ and $K_2^H = [H_2L^{2+}]/[H^+][HL^+]$), rearranging Equation (2) yields Equation (3).

$$k_{obs} = \frac{[M]\cdot(k_0 + k_1K_1^H[H^+] + k_2\cdot K_1^H\cdot K_2^H[H^+]^2)}{1 + K_1^H[H^+] + K_1^H\cdot K_2^H[H^+]^2} \quad (3)$$

The $k_{obs}$ values obtained at different metal concentrations for each pH were fitted to Equation (3) using the ligand protonation constants ($K_1^H$ and $K_2^H$, Table 1) to obtain $k_0$, $k_1$, and $k_2$ (Figure 4). The $k_2$ values were either negligible or negative for all metal ions examined here, and hence were ultimately omitted during final data refinement. This indicates that a diprotonated form of the ligand is not involved in this reaction. The fitting yielded positive $k_1$ values, although the errors in these values were about an order of magnitude higher than the rate constants themselves (for [Ce{DOTA-(MeAm)$_4$}]$^{3+}$ $k_1 = 0.0026 \pm 0.0146$ M$^{-1}$ s$^{-1}$; for [Eu{DOTA-(MeAm)$_4$}]$^{3+}$ $k_1 = 0.0025 \pm 0.0227$ M$^{-1}$ s$^{-1}$; for [Lu{DOTA-(MeAm)$_4$}]$^{3+}$ $k_1 = 0.081 \pm 0.184$ M$^{-1}$ s$^{-1}$). This result suggests that although the monoprotonated ligand may contribute somewhat to the reaction, the fully deprotonated ligand is clearly the most reactive species. This is a surprising conclusion because, over the pH range investigated, the concentration of HL is about four to five orders of magnitude higher than the concentration of L (the ratio [HL]/[L] decreases from $9 \times 10^5$ to $7 \times 10^4$). These combined data suggest that the pathway involving the monoprotonated ligand can also be ignored in the overall reaction and that formation of the [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ complexes occurs due to the direct encounter between the $Ln^{3+}$ ions and the fully deprotonated ligand. Thus, Equation (3) can be simplified to Equation (4).

$$k_{obs} = \frac{k_0[M]}{1 + K_1^H[H^+] + K_1^H\cdot K_2^H[H^+]^2} \quad (4)$$

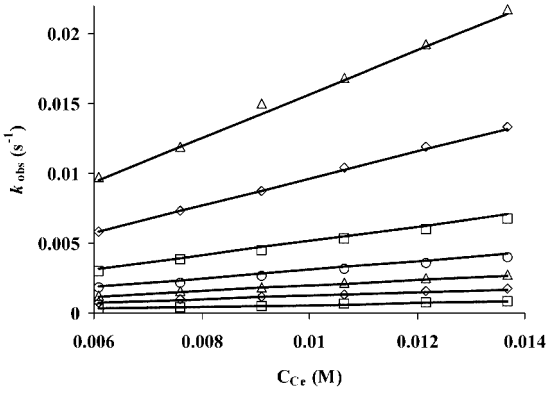

Figure 4. Dependence of $k_{obs}$ on metal concentration for formation of [Ce{DOTA-(MeAm)$_4$}]$^{3+}$ at different pH values (5.71, 5.59, 5.43, 5.31, 5.20, 5.09, and 4.92 from top to bottom).

The rate constants $k_0$ determined here for three [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ complexes and the rate constants characterizing the formation of the corresponding [Ln(DOTA)]$^-$ and [Ln(DOTAM)]$^{3+}$ complexes are compared in Table 4. These data show that formation of [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ occurs about two to three orders of magnitude slower than for the corresponding [Ln(DOTA)]$^-$ complexes. This may be partially attributed to differences in ligand charge since DOTA, in its active from, is negatively charged ([$H_2$DOTA]$^{2-}$ is the primary species in most cases) while the tetraamide ligand is neutral. Interestingly, the rates of [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ complex formation are somewhat slower than for formation of the [Ln(DOTAM)]$^{3+}$ complexes, likely due to the presence of the methyl group on the amide pendant arm.[30] The rates of complex formation can be altered further by increasing the bulkiness of the substituent on the amide pendant arms

Table 4. Comparison of the formation rate constants for [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ ($k_0$, M$^{-1}$ s$^{-1}$), [Ln(DOTAM)]$^{3+}$, and [Ln(DOTA)]$^-$ complexes.

| $Ln^{3+}$ | $Ce^{3+}$ | $Eu^{3+}$ | $Lu^{3+}$ |
|---|---|---|---|
| DOTAM[a] | $7.7 \times 10^3$ | $2.7 \times 10^4$ | $6.6 \times 10^3$ [d] |
| DOTA-(AmMe)$_4$ | $(3.0 \pm 0.1) \times 10^4$ | $(4.8 \pm 0.1) \times 10^4$ | $(6.5 \pm 0.7) \times 10^3$ |
| DOTA | $3.5 \times 10^6$ [b] | $1.1 \times 10^7$ | $4.1 \times 10^7$ [b,d] |
| | $2.7 \times 10^6$ [c] | | $9.3 \times 10^7$ [c,d] |

(formation of $[Ln\{DOTA\text{-}(pipAm)_4\}]^{3+}$ complexes).[31] The trends in formation rates across the lanthanide series follow a similar trend to that observed for $[Ln(DOTAM)]^{3+}$ complexes recently and opposite to that observed for $[Ln(DOTA)]^-$ complexes.[9,30] The water-exchange rates of $[Ln\{DOTA\text{-}(amide)_4\}]^{3+}$ complexes have been found to behave identically when they are plotted against the size of the $Ln^{3+}$ ions (maximum at $Eu^{3+}$).[32,33] This indicates that the water-exchange rates may influence the rates of complex formation of $[Ln\{DOTA\text{-}(amide)_4\}]^{3+}$ complexes and can be used to interpret the trends in the rates of complex formation. Similar phenomena have often been observed for the formation of lanthanide complexes of with mono- and multidentate ligands.[34]

### Acid-Catalyzed Dissociation of $[Ln\{DOTA\text{-}(MeAm)_4\}]^{3+}$ Complexes

Lanthanide complexes used for medical diagnosis must be kinetically stable because neither product of dissociation (the $Ln^{3+}$ aqua ions or the ligands) is well tolerated in vivo. Several groups have demonstrated that dissociation of $[Ln(DOTA)]^-$ and Ln(DOTA) derivatives takes place by a proton-assisted pathway and that endogenous metal ions such as $Cu^{2+}$ or $Zn^{2+}$ have little affect on the dissociation rates.[8–10,35] As the structures of the complexes examined here do not differ substantially from those of the $[Ln(DOTA)]^-$ complexes, one could anticipate a similar kinetic dissociation behavior for the LnDOTA-tetraamides. Acid-catalyzed dissociation of $[Ce\{DOTA\text{-}(MeAm)_4\}]^{3+}$ and $[Eu\{DOTA\text{-}(MeAm)_4\}]^{3+}$ was examined at a pH below 2, where one would predict complete dissociation of the complexes based upon the thermodynamic measurements. At pH 2, the complexes dissociate so slowly that it was difficult to collect kinetic data over a reasonable period of time. Ultimately, it was found that the kinetic measurements could be performed over the range $0.5 < [HClO_4] < 3.0$ M and by maintaining a constant ionic strength with addition of $NaClO_4$ when necessary $[(H^+ + Na^+)ClO_4^-$ constant at 3.0 M]. As the total acid concentration was more than two orders of magnitude greater than the complex concentration in all cases, the dissociation rates follow pseudo-first-order kinetics ($k_{obs} = k_d$) and can be described by Equation (5), where $[LnL]_t$ is the total complex concentration.

$$-\frac{d[LnL]_t}{dt} = k_d \cdot [LnL]_t \quad (5)$$

Plots of first-order dissociation rates vs. acid concentration were found to be similar for both complexes (Figure 5). Similar results have been obtained in a study of the dissociation rates of $[Gd(DOTA)]^-$ and $[Eu\{DOTA\text{-}(gly)_4\}]^-$.[10,11] It has been shown previously that dissociation of $[Ce(DOTA)]^-$ is second order with respect to $[H^+]$ while dissociation of $[Eu(DOTA)]^-$ shows saturation behaviour.[8,9] Like other complexes, dissociation of $[Ln\{DOTA\text{-}(MeAm)_4\}]^{3+}$ is initiated by protonation, probably at an amide pendant arm. This is in agreement with the observation that there is no change in the absorption spectrum of either complex immediately after mixing the complex with a strong acid. The proton must therefore be transferred to the ring nitrogen atom, after which the metal ion moves out from the "coordination cage" (rearrangement), since the "in cage" complexes cannot dissociate directly. A protonation constant of $K^H_{[Eu(DOTA)]^-} = 14$, which corresponds to the protonation of the acetate arm coordinated to the $Eu^{3+}$ in the complex, was found for $[Eu(DOTA)]^-$.[9] Complexes formed with extended phosphonate or glycinate pendant arms have even higher $\log K_i^H$ values. For example, three to four protonation steps can be measured for the $Ln^{III}$ complexes of DOTA-$(gly)_4$ ($\log K_i^H$ = 2–4) and four steps for the $[Ln(DOTP)]^{5-}$ complexes ($\log K_i^H$ = 4–8).[11,36] The protonation constants of the $[Ln\{DOTA\text{-}(MeAm)_4\}]^{3+}$ complexes are very low and no protonation constant can be obtained from the titration data of 0.01 M complex solutions with 0.1 M HCl. This can be explained by the large difference in basicity of the donor atoms in the pendant arms of the amides compared to acetates or phosphonates. This is easily understood if one compares $\log K^H$ values for aminomethanephosphonic acid, glycine, and glycine amide. The protonation constant of aminomethanephosphonic acid falls in the range 5.32–5.40 and the protonation constant of glycine is in the range 2.33–2.79, while the protonation of the amide nitrogen of glycine amide occurs only at high acid concentrations and $\log K^H$ can not be determined by pH-potentiometry.[20,37]

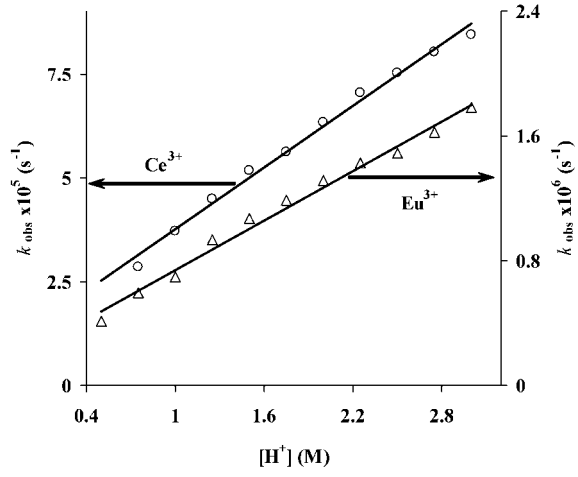

Figure 5. Rates of dissociation of $[Ln\{DOTA\text{-}(MeAm)_4\}]^{3+}$ {$Ln^{3+}$ = $Ce^{3+}$ (circles) and $Eu^{3+}$ (triangles)}. The solid line represents the fitted curves while the points are the measured values.

The data in Figure 5 demonstrate that the rates of dissociation of the complexes are linearly proportional to the acid concentration and are hence described by Equation (6), where $k_0$ corresponds to dissociation of the complex (most likely spontaneous) while $k_1$ corresponds to acid-catalyzed dissociation of the monoprotonated LnLH complex.

$$k_d = k_0 + k_1 \cdot [H^+] \quad (6)$$

The rate constants calculated from these data are listed in Table 5 along with comparative values for $[Ce(DOTA)]^-$ and $[Eu(DOTA)]^-$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 5. Proton-assisted dissociation rates for two [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ complexes.

| $Ln^{3+}$ | $k$ | DOTA | DOTA-(MeAm)$_4$ | DOTA-(gly)$_4$[a] |
|---|---|---|---|---|
| $Ce^{3+}$ | $k_0$ $s^{-1}$ | not observed | $(1.1 \pm 0.1) \times 10^{-5}$ | not studied |
| | $k_1$ $M^{-1} s^{-1}$ | $8 \times 10^{-4}$ [b] | $(2.6 \pm 0.1) \times 10^{-5}$ | not studied |
| $Eu^{3+}$ | $k_0$ $s^{-1}$ | not observed[c] | $(1.5 \pm 0.2) \times 10^{-7}$ | $7.3 \times 10^{-7}$ |
| | $k_1$ $M^{-1} s^{-1}$ | $1.4 \times 10^{-5}$ [d] | $(5.6 \pm 0.2) \times 10^{-7}$ | $8.1 \times 10^{-6}$ |

[a] Ref.[11] [b] Ref.[8], second-order dependence on $H^+$ ion concentration with a third-order rate constant of $2.0 \times 10^{-3}$ $M^{-2} s^{-1}$ was also observed. [c] For [Gd(DOTA)]$^-$, $k_0 = 5 \times 10^{-8}$ $s^{-1}$ and $k_1 = 5 \times 10^{-6}$ $M^{-1} s^{-1}$ from ref.[10] [d] Ref.[9]

Spontaneous dissociation of [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ ($k_0$) is somewhat faster than [Gd(DOTA)]$^-$ but the corresponding data ($k_0$) for [Ce(DOTA)]$^-$ and [Eu(DOTA)]$^-$ are not available. However, the acid-catalyzed rates of dissociation ($k_1$) are about 25–30-fold slower than the corresponding rates for the [Ln(DOTA)]$^-$ complexes, perhaps reflecting the ease of protonation of a charged carboxylate side-arm in [Ln(DOTA)]$^-$ compared to the difficulty of protonating a neutral amide side-arm in [Ln{DOTA-(MeAm)$_4$}]$^{3+}$. There is also a noticeable difference in the rates of acid-catalyzed dissociation of [Eu{DOTA-(MeAm)$_4$}]$^{3+}$ vs. [Eu{DOTA-(gly)$_4$}]$^-$ (both tetraamide complexes) − the latter complex dissociates about 15-fold faster than the former.[11] This likely reflects the greater overall positive charge on [Eu{DOTA-(MeAm)$_4$}]$^{3+}$ compared to [Eu{DOTA-(gly)$_4$}]$^-$. Thus, even though the LnDOTA-tetraamide complexes are thermodynamically considerably less stable than the corresponding [Ln(DOTA)]$^-$ complexes, it appears to be more difficult to protonate the neutral amide side-chains in these complexes and this ultimately limits their rates of acid-catalyzed dissociation. Similar conclusions have been reported previously for some phosphinate and phosphonate ester derivatives of DOTA.[38,39] This suggests that the kinetic inertness of the LnDOTA-tetraamide complexes may ultimately allow for their use as imaging agents in vivo.

## Conclusions

The protonation constants of several tetraamide derivatives of DOTA show similar $\log K_i^H$, values with the highest protonation constant falling in the range 9.0–9.6 and the lowest in the range 5.5–6.5. In comparison to DOTA, the basicity ($\Sigma \log K_i^H$) of the tetraamide ligands is about 15–16 orders of magnitude less than that of DOTA. This indicates that the DOTA-tetraamide ligands have a greatly reduced ability to bind $H^+$ and metal ions. Only ML type complexes are formed between these ligands and $Mg^{2+}$ or $Ca^{2+}$ ions while complexes formed with $Zn^{2+}$ and $Cu^{2+}$ undergo additional deprotonation steps either at a bound water molecule (first deprotonation step) or an amide side-chain (first deprotonation step for $Zn^{2+}$ and second deprotonation step for $Cu^{2+}$ complexes). The thermodynamic stability constants of several LnL complexes determined using the "out-of-cell" technique show an unusual trend in that they increase between $Sm^{3+}$ and $Eu^{3+}$ then remain relatively constant with further decreases in $Ln^{3+}$ size until the very end of the lanthanide series. The thermodynamic constants are about 10–11 orders of magnitude lower than the corresponding [Ln(DOTA)]$^-$ complexes. The [Ln{DOTA-(amide)$_4$}]$^{3+}$ complexes also undergo an additional deprotonation above pH 10.5 which is accompanied by formation of the ternary Ln(OH)L complex, with the deprotonation likely occurring at the coordinated water molecule in these systems.

The rates of [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ complex formation are about two to three orders of magnitude slower than those of the corresponding [Ln(DOTA)]$^-$ complexes. The variation of the formation rates with $Ln^{3+}$ ion size is the opposite of that observed for the [Ln(DOTA)]$^-$ complexes. This is most likely due to the higher positive charge density of the heavier $Ln^{3+}$ ions resulting in greater repulsion between the positively charged $Ln^{3+}$ ions and the ligand. [Ce{DOTA-(MeAm)$_4$}]$^{3+}$ and [Eu{DOTA-(MeAm)$_4$}]$^{3+}$ are kinetically inert toward acid-catalyzed dissociation due to the unfavorable acid-base properties of the uncharged amide pendant arms in these complexes. Based on the slow rates of acid-catalyzed dissociation, LnDOTA-(amide)$_4$ systems may prove safe for in vivo imaging applications.

## Experimental Section

**Synthesis of the Ligands:** The tetraamide ligands DOTAM (**1**),[12] DOTA-(MeAm)$_4$ (**2**)[15,16] DOTA-(EtAm)$_4$ (**3**),[16,17] and DOTA-(gly-OEt)$_4$ (**4**)[18] were prepared by established procedures and their purity established by $^1H$ and $^{13}C$ NMR spectroscopy, EI mass spectrometry, elemental analysis, and melting point determinations for all solids.

**Potentiometric Measurements:** The pH-potentiometric titrations were carried out with a Thermo Orion expandable ion analyzer EA940 pH meter using Thermo Orion semi-micro combination electrode 8103BN in a mixing vessel thermostatted at 25.0 °C. A Metrohm DOSIMATE 665 autoburette (5 mL capacity) was used for base additions and 1.0 M KCl was used to maintain the ionic strength. All equilibrium measurements (direct titrations) were carried out in 10.00 mL sample volumes with magnetic stirring. Argon was passed over the top of the sample during the titrations to maintain the cell free of $CO_2$. Standard buffers (Borax: 0.01 M, pH 9.180 and KH-phthalate 0.05 M, pH 4.005) were used to calibrate the electrode. The titrant, a carbonate-free KOH solution, was standardized against 0.05 M KH-phthalate solution by pH-potentiometry. A standard solution of hydrochloric acid was prepared using doubly distilled water and the concentration was determined by pH-potentiometry with standard KOH solution. A method proposed by Irving et al. was used to obtain $H^+$ ion concentrations from the measured pH values.[40] The $pK_w$ of water was also calculated from these titration data and was found to be 13.845. The protonation constants ($\log K_i^H$) and stability constants were evaluated from the potentiometric data by using the PSEQUAD computer program.[41]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Stock Solutions:** Stock solutions of metal ions (prepared from chloride salts) at about 0.02–0.06 M were calibrated by complexometric titration against standardized [$Na_2(H_2EDTA)$] using the appropriate end-point indicator.[42] [$Na_2(H_2EDTA)$] was purchased from Alfa-Aesar and standardized by a pH-potentiometric titration using standardized KOH. Stock solutions of the ligands synthesized in this work (0.02–0.05 M) were prepared in deionized water maintaining the pH in the range 3–4 with acid (HCl). It was found important to maintain the stock solution of DOTA-(gly-OEt)$_4$ somewhat acidic (pH ≤ 3) due to slow hydrolysis of the ester bonds. The concentrations of stock solutions of these ligands were determined by pH-potentiometry from the titration data obtained in the absence and in the presence of an approximately 50-fold excess of $CaCl_2$.

**Protonation and Metal Binding (Stability) Constants:** The protonation constants of the ligands were calculated from the data obtained by titrating 2 and 5 mM samples (180–268 data points) with standardized KOH solution (0.18 M) in the absence of $Ca^{2+}$ over the pH range 1.8–12.0. The protonation constants of the ligand ($\log K_i^H$) are defined according to Equation (7), where $i$ = 1, 2, and 3 and [$H_{i-1}L$] and [$H^+$] are the equilibrium concentrations of the ligand ($i$ = 1), protonated forms of the ligand ($i$ = 2 or 3) and hydrogen ions, respectively.

$$K_i^H = \frac{[H_iL]}{[H_{i-1}L][H^+]} \quad (7)$$

Relatively rapid equilibrium was observed in the systems containing $Mg^{2+}$, $Ca^{2+}$, $Zn^{2+}$, or $Cu^{2+}$. This proved fast enough to be able to use a direct titration method for stability constant determinations. In these measurements, a time period of 900–1200 seconds was allowed between each addition of KOH to ensure equilibrium before the sample pH was read. The next addition of base was made only when four consecutive pH readings collected over 60 seconds were identical within ±0.0006 pH units. The titrations were carried out at 1:1 and 2:1 metal to ligand concentration ratios and the concentration of the ligands was maintained at around 2 mM. These combined titration data were fitted simultaneously and the thermodynamic stability constants ($K_{ML}$) were evaluated and reported based on Equations (8) and (9).

$$K_{ML} = \frac{[ML]}{[M][L]} \quad (8)$$

$$K_{MLH_{-1}} = \frac{[MLH_{-1}][H^+]}{[ML]} \text{ and } K_{MLH_{-2}} = \frac{[MLH_{-2}][H^+]}{[MLH_{-1}]} \quad (9)$$

The complexation of lanthanide(III) ions with macrocyclic ligands is very slow (about four to five weeks are required to achieve equilibrium at room temperature), so "out-of-cell" experiments (also known as the batch method) were performed instead of direct titrations. Typically, 25.0 mL of a mixture of $Ln^{3+}$ and ligand each at 2–2.5 mM was prepared and divided into 16 individual solutions (1.5 mL each). The pH of the samples was adjusted with HCl or KOH to span the range pH 2.5–4.5 (where complex formation is ongoing but not complete). The samples were sealed and placed in a 45 °C incubator for 21 days followed by an additional 28 days at room temperature to re-equilibrate the mixtures. The pH of each individual sample was then measured. Acid/base titrations were also performed under identical conditions before and after measuring the pH of the samples. The average of these measurements was used to correct the pH of the samples for the difference between the measured and calculated pH by following the method proposed by Irving et al.[40] This difference was usually greater than the one obtained in the stirred samples and can be attributed to the difference in the diffusion of the ions in the samples not being stirred.

**Formation and Dissociation Kinetics of the [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ Complexes:** The formation rates of [Ce{DOTA-(MeAm)$_4$}]$^{3+}$ ($\lambda_{max}$ = 323 nm) and [Eu{DOTA-(MeAm)$_4$}]$^{3+}$ ($\lambda_{max}$ = 255 nm) were studied at 25 °C and 1.0 M KCl ionic strength by spectrophotometry using a Cary 300 Bio UV/Vis spectrophotometer equipped with thermostatted cell holders and semi-micro quartz cells (Starna, optical path length 1 cm). All the reactions were performed under pseudo-first-order conditions where the metal ions were in 10–25-fold excess. The concentration of the ligand in the formation reactions of $Ce^{3+}$, $Eu^{3+}$,and $Lu^{3+}$ complexes was set to $5.62 \times 10^{-4}$, $9.83 \times 10^{-4}$, and $1.12 \times 10^{-3}$ M, respectively. Since $Lu^{3+}$ ions do not absorb in the UV/Vis region, the indicator method proposed by Kasprzyk et al. using indicators bromocresol green (pH 4.0–5.6) and bromocresol purple (pH 5.2–6.8) was used to record the absorbance change at a wavelength of 615 nm.[29] An appropriate concentration of indicator and buffer at different pH values was established experimentally to allow slight pH change in these systems (ΔpH ≤ 0.1). The pH of each sample was re-measured after the equilibrium was reached (usually the next day) and any samples with a pH change greater than 0.1 pH units were either excluded from the calculations or the process was repeated at a higher buffer concentration. Formation kinetic studies were carried out with the non-coordinating buffers *N*-methylpiperazine (NMP, $\log K_2^H$ = 4.83) at a concentration of 0.05 M for $Ce^{3+}$ and $Eu^{3+}$ and dimethylpiperazine (DMP, $\log K_2^H$ = 4.18) at 0.025–0.05 M for $Lu^{3+}$ to maintain constant pH.[20]

Absorbance data recorded as a function of time were fitted to Equation (10) to evaluate the first-order rate constants, where $A_0$, $A_e$, and $A_t$ are the absorbance values measured at the start of the reaction ($t$ = 0), at equilibrium, and at time $t$, respectively. These data were fitted to Equation (10) with the Scientist® (Micromath) software using a standard least-squares procedure.[43]

$$A_t = A_e + (A_0 - A_e)\cdot e^{(-k_{obs}\cdot t)} \quad (10)$$

Proton-assisted dissociation of the complexes takes place slowly after addition of excess strong acid. The dissociation kinetics were studied in 0.5–3.0 M $HClO_4$ acidic solutions at 25 °C and 3.0 M ionic strength provided by ($Na^+ + H^+$)$ClO_4$ in samples where the concentration of complexes was 1 mM. The decrease in absorbance was measured periodically at 323 nm for [Ce{DOTA-(MeAm)$_4$}]$^{3+}$ and at 255 nm for [Eu{DOTA-(MeAm)$_4$}]$^{3+}$. The complete kinetics curve was registered for the $Ce^{3+}$ complex and used for the fitting procedure, whereas the dissociation curves for the $Eu^{3+}$ complex were followed until 60–70% conversion was reached.

**Supporting Information** (see also the footnote on the first page of this article): Visible spectra of the [Cu(DOTAM)]$^{2+}$ complex as a function of pH (Figure S1); $^1$H NMR titration of the [Zn(DOTAM)]$^{2+}$ complex (Figure S2); titration curves obtained for some [Ln{DOTA-(MeAm)$_4$}]$^{3+}$ complexes ($Ln^{3+}$ = $Ce^{3+}$, $Eu^{3+}$, and $Lu^{3+}$; Figure S3); $^1$H NMR titration of the [Lu(DOTAM)]$^{3+}$ complex (Figure S4); $^1$H NMR titration of the [Lu{DOTA-(MeAm)$_4$}]$^{3+}$ complex (Figure S5); formation of [Eu{DOTA-(MeAm)$_4$}]$^{3+}$ with time (Figure S6); dependence of $k_{obs}$ on the $Eu^{3+}$ concentration for the formation of [Eu{DOTA-(MeAm)$_4$}]$^{3+}$ at different pH values (Figure S7); dependence of $k_{obs}$ on the $Lu^{3+}$ concentration for the formation of [Lu{DOTA-(MeAm)$_4$}]$^{3+}$ at different pH.

# Synthesis and Characterisation of Semi-Bridging Molybdenum Borylene Complexes

**Holger Braunschweig,*[a] Krzysztof Radacki,[a] and Katharina Uttinger[a]**

**Keywords:** Boron / Borylene complexes / Molybdenum / Palladium / DFT calculations

Investigation of the reactivity of the molybdenum borylene complex $[(OC)_5Mo{=}B{=}N(SiMe_3)_2]$ towards the late transition metal complexes $[M(PCy_3)_2]$ (M = Pd, Pt) indicated the formation of $[(OC)_4Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ and $[(Cy_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pt(PCy_3)]$, respectively, as the first Mo-based semi-bridging borylene complexes. The new complexes were fully characterised spectroscopically and analysed by X-ray diffraction. The conclusions drawn from the experimental data for the ligand-metal interactions for this particular coordination mode of a borylene group were supported by DFT computations.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

Transition metal boryl complexes have attracted significant interest due to their role as key intermediates in catalysed hydro-[1] and diboration reactions[2] as well as in C–H bond activation of organic compounds.[3] Borylene complexes as another type of metal-boron compound are also in the focus of research[4] because of their close relationship to carbonyl complexes and due to their propensity to effectively stabilise[4g,5] elusive borylenes[6] in the coordination sphere of a metal. In particular, group 6 transition metal carbonyl fragments have been shown to possess good stabilising properties resulting in the formation, by means of a salt elimination reaction, of $[(OC)_5M{=}B{=}N(SiMe_3)_2]$ (M = Cr, **1**; W, **2**) which are the first two-coordinate borylene complexes.[7] Unfortunately, this method of preparation is limited in scope and, hence, the borylene transfer under thermal[8] or photochemical conditions[9] has become established as a highly useful alternative for the synthesis of borylene complexes and borylene functionalised main group element substrates.[10]

Very recently, it was demonstrated that borylene ligands (Figure 1) can adopt rather unusual coordination modes beyond the common scope of mononuclear neutral (e.g. **1**, **2** and **3**)[7,9,11] and cationic (e.g. **4**)[12] or symmetrically bridged homodinuclear species (e.g. **5** and **6**).[9a,13] Important examples include heterodinuclear borylene complexes (e.g. **7**),[14] metalloborylenes (e.g. **8**)[8d,15] (Figure 1) and dinuclear compounds with semi-bridging borylene ligands.[8a,8b]

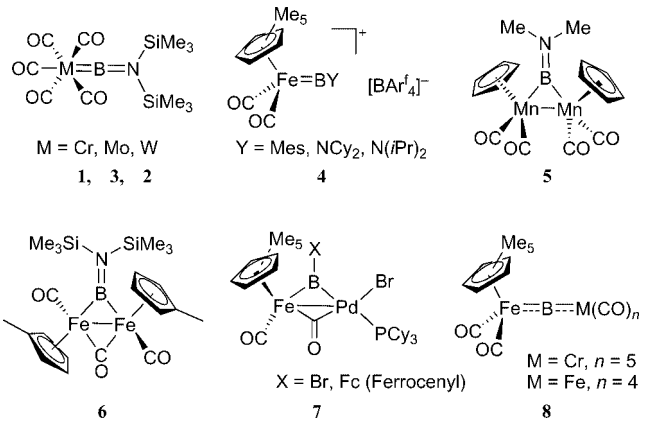

Figure 1. Different coordination modes for borylene ligands: terminal **1**,[7,9a] **2**[7] and **3**,[11b] cationic **4**,[12a,12b,12c] symmetrically bridging homodinuclear **5**[13a] and **6**,[13b] symmetrically bridging heterdionuclear **7**[14] and metalloborylene **8**.[15]

In the case of the group 6 transition metals, several boryl and borylene complexes of tungsten are known for example $[L(OC)_4W{=}B{=}N(SiMe_3)_2]$ (L = CO, **2**; $PCy_3$)[7,11b] and $[(\eta^5\text{-}C_5H_5)_2WXBR_2]$ (X = H, $R_2$ = $Ph_2$, 1,2-$O_2$-$C_6H_4$; X = Cl, $R_2$ = 1,2-$O_2$-$C_6H_4$),[16] $[(\eta^5\text{-}C_5H_5)_2W(BR_2)_2]$ [$R_2$ = (1,2-$O_2$-4-*t*Bu$C_6H_3$), (1,2-$O_2$-3,5-*t*$Bu_2C_6H_2$)][16b,17] or $[(\eta^5\text{-}C_5H_5)\text{-}W(CO)_3\{B(NMe_2)B(NMe_2)X\}]$ (X = Cl, Br, I),[18] most of them being fully characterised including crystallographic data. Likewise, a variety of chromium borylene complexes were reported, e.g. $[L(OC)_4Cr{=}B{=}N(SiMe_3)_2]$ (L = CO, **1**; $PCy_3$, **10**),[7,8a,9a,11b] $[(OC)_5Cr{=}B{-}Si(SiMe_3)_3]$[11a] and $[(OC)_5\text{-}Cr{=}B{-}Fe(\eta^5\text{-}C_5H_5)(CO)_2]$ (**8**)[15] and in addition, one boryl complex $[Cr(\eta^6\text{-}C_6H_6)(CO)_2(\eta^2\text{-}tmp'BCR_2)]$ [$tmp'BCR_2$ = ($\eta^2$-9-fluorenylidene)(2,2,6,6-tertramethylpiperidino)-borane].[19] In the case of molybdenum, however, only few boryl complexes of molybdenum are known, e.g.

[Mo(tpb′)(CO)$_2${B(Et)CH$_2$-*p*-tolyl}] [tpb′ = tris(3,5-dimethylpyrazol-1-yl)hydroborate][20] or the diborane(4)yl complex [($\eta^5$-C$_5$H$_5$)Mo(CO)$_3${B(NMe$_2$)B(NMe$_2$)X}] (X = Br, I)[18b,18c,18d] and only very recently we contributed the first Mo borylene complex [(OC)$_5$Mo=B=N(SiMe$_3$)$_2$] (**3**) and reported its conversion to *trans*-[(Cy$_3$P)(OC)$_4$-Mo=B=N(SiMe$_3$)$_2$] (**11**).[11b] Presumably, the relative scarcity of Mo–boron complexes can be attributed to the enhanced lability of 4d transition metal complexes with respect to their corresponding 3d and 5d analogues.[21]

Recent studies have shown that metal coordinated borylene and, albeit to a lesser extent, boryl ligands[22] are highly susceptible to the addition of transition metal bases, leading in the case of the former to novel heterodi- and trinuclear borylene species.[8c,8d]

In this paper we report on the reactivity of [(OC)$_5$-Mo=B=N(SiMe$_3$)$_2$] (**3**)[11b] towards the late transition metal complexes [M(PCy$_3$)$_2$] (M = Pd, **12**; Pt, **13**)[23] which leads to the first Mo-species comprised of a semi-bridging borylene ligand. In addition, we provide detailed results of DFT studies which have elucidated the electronic structures of the title compounds.

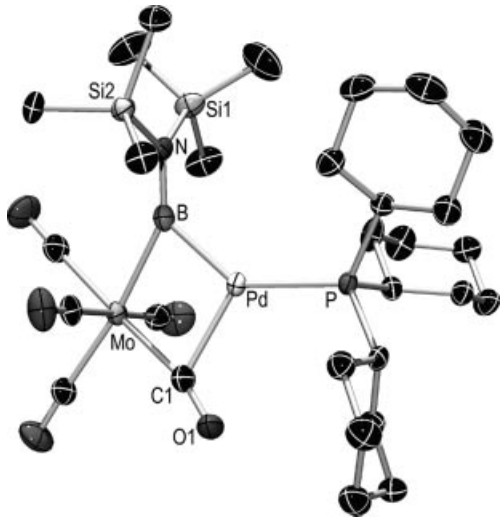

Figure 2. Molecular structure of [(OC)$_4$Mo(μ-CO){μ-BN(SiMe$_3$)$_2$}Pd(PCy$_3$)] (**16**). Thermal ellipsoids are set at the 50% probability level. Selected bond lengths [Å] and angles [°]: Mo–B 2.235(4), Pd–B 2.065(4), B–N 1.376(5), Pd–P 2.3764(9), Pd–Mo–C1 51.74(10), Mo–C1–O1 164.3(3), Pd–Mo–B 47.59(10), Mo–B–N 150.7(3), Si1–N–B–Pd 86.1(3).

## Results and Discussion

Equimolar amounts of [(OC)$_5$Mo=B=N(SiMe$_3$)$_2$] (**3**) and [Pd(PCy$_3$)$_2$] (**12**) were mixed in C$_6$D$_6$ at room temperature. The progress of the reaction was monitored by multinuclear NMR spectroscopy and, after 30 min, complete conversion of the starting materials, formation of a new compound and liberation of PCy$_3$ [$\delta$ ($^{31}$P) = 10.0 ppm] was observed. The product was isolated as orange crystals in 53% yield by layering a toluene solution with hexane and storing at –35 °C overnight. The $^{11}$B{$^1$H} NMR spectrum shows a broad signal at $\delta$ = 99 ppm which is downfield shifted with respect to that in the precursor **3** ($\delta$ = 89.7 ppm).[11b] A sharp resonance at $\delta$ = 35.1 ppm in the $^{31}$P{$^1$H} NMR spectrum can be observed for the metal coordinated phosphane ligand indicating the presence of only one tricyclohexylphosphane unit in the molecule. The $^1$H NMR spectrum features one singlet for both trimethylsilyl groups at $\delta$ = 0.41 ppm which is deshielded with respect to that of the borylene precursor **3** ($\delta$ = 0.15 ppm)[11b] but comparable to those of the Cr and W analogues ([(OC)$_4$-M(μ-CO){μ-BN(SiMe$_3$)$_2$}Pd(PCy$_3$)], M = Cr, **14**; M = W, **15**; $\delta$ = 0.42 ppm).[10a]

The result of a single-crystal X-ray diffraction study of [(OC)$_4$Mo(μ-CO){μ-BN(SiMe$_3$)$_2$}Pd(PCy$_3$)] (**16**) is shown in Figure 2.

Compound **16** crystallises in the orthorhombic space group *Pna*2$_1$ with the two metal fragments [Mo(CO)$_4$] and [Pd(PCy$_3$)] linked by a bridging CO and a –BN(SiMe$_3$)$_2$ group. The latter is oriented almost perpendicular with respect to the plane containing Mo, B and Pd as indicated by the dihedral angle Si1–N–B–Pd of 86.1(3)°. The Mo–B bond [2.235(4) Å] is elongated by 8 pm when compared with the terminal Mo-borylene complex **3** [2.1519(15) Å][11b] and this is due to the increased coordination number of the boron centre in the former. However, it is still shorter (10 pm) than the distance in the only structurally characterised complex with a Mo–B–bond [($\eta^5$-C$_5$H$_5$)Mo(CO)$_2$-COB(NMe$_2$)B(NMe$_2$)Mo(CO)$_3$] [Mo–B 2.348(4) Å].[18b,18c] Likewise, the Pd–B bond length [2.065(4) Å] lies within the expected range for three-coordinate boron linked to a palladium centre [2.006(9)–2.077(6) Å].[24] The relatively short B–N distance of 1.376(5) Å, which is only marginally longer than in the corresponding borylene complex **3** [1.3549(18) Å], indicates significant double bond character in the B–N linkage.[11b] In contrast, the homodinuclear bridged aminoborylene species [{($\eta^5$-C$_5$H$_5$)Mn(CO)$_2$}$_2${μ-BNMe$_2$}] (**5**)[13a] and [{($\eta^5$-C$_5$H$_4$Me)Fe(CO)}$_2$(μ-CO){μ-BN(SiMe$_3$)$_2$}] (**6**),[13b] in which the boron centres possess formal sp$^2$ hybridisation, display a different arrangement. In **5** the B–N distance of 1.39(1) Å is also in agreement with the formulation of a B=N double bond, the plane of the BNMe$_2$ substituent, however, is arranged almost coplanar [8(3)°] with respect to the Mn$_2$B plane[13a] whereas in **6** the BN(SiMe$_3$)$_2$ plane is twisted by 53(1)° with respect to the Fe$_2$B plane resulting in less effective N–B π bonding and, hence, an elongation of the B–N bond [1.412(4) Å].[13b] The perpendicular disposition of the two respective planes in **16** in combination with a typical B–N double bond length disagrees with the description of a formally sp$^2$ hybridised boron centre. More appropriate is the description of the overall bonding situation in terms of a terminal borylene centre being stabilised by a metal base. The Lewis-basic [(Cy$_3$P)Pd] fragment releases electron density into the empty orbitals of CO and the borylene moiety (vide infra). Thus, the π acceptor fragments CO and BN(SiMe$_3$)$_2$ form a pair of two noncompensating, semi-bridging ligands. The classification scheme for semi-bridging carbonyl ligands de-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

veloped by Crabtree[25] is applicable to the relevant bond angles [Pd–Mo–C1 51.74(10)°; Mo–C1–O1 164.3(3)°]. The corresponding angles for the semi-bridging B–R moiety [Pd–Mo–B 47.59(10)°; Mo–B–N 150.7(3)°] lie clearly between those typically found for terminal and symmetrically bridging ligands and are similar to their semi-bridging Cr and W analogues **14** and **15**.[10a]

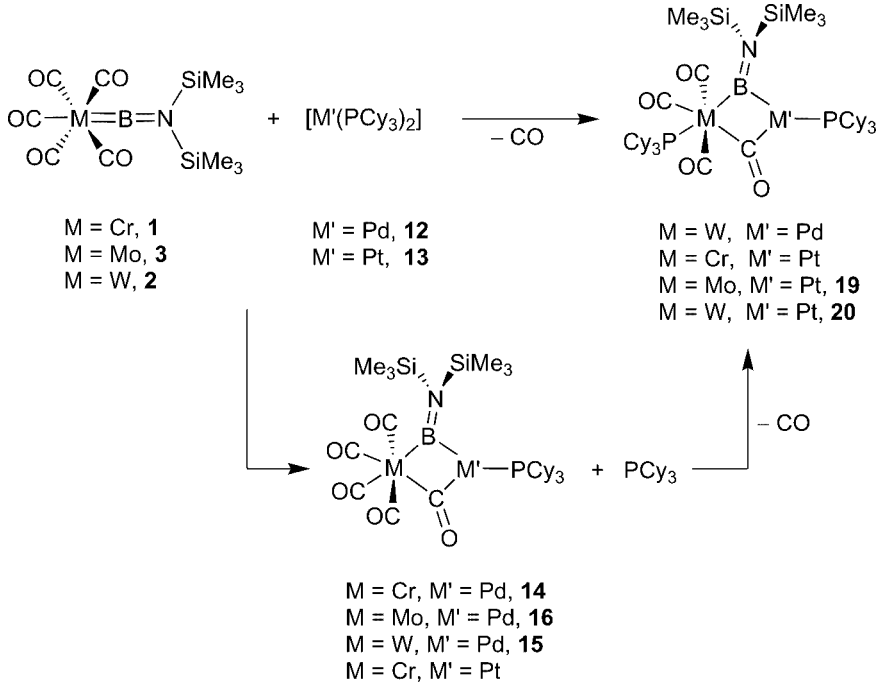
For the synthesis of **16**, it is important to restrict the reaction time to a minimum since liberated phosphane tends to substitute a carbonyl group at Mo which subsequently leads to formation of a variety of degradation products as indicated by $^{31}P\{^1H\}$ NMR spectroscopic data: $[(Cy_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (**17**) [$\delta$ ($^{31}P$) = 50.7 ppm (d, $^4J_{P,P}$ = 12 Hz, $P_{Mo}$), 33.9 ppm (d, $^4J_{P,P}$ = 12 Hz, $P_{Pd}$); $\delta$ ($^1H$) = 0.63 ppm (s, $SiMe_3$)], *trans*-$[(Cy_3P)(OC)_4Mo{=}BN(SiMe_3)_2]$ (**11**) [$\delta$ ($^{31}P$) = 51.2 ppm (s); $\delta$ ($^1H$) = 0.37 ppm (s, $SiMe_3$)],[11b] and $[(OC)_5Mo(PCy_3)]$ (**18**) [$\delta$ ($^{31}P$) = 47.8 ppm(s)]. In a typical experiment, a ratio of 9:1 for $[(OC)_4Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (**16**) to $[(Cy_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (**17**) was observed after 30 min which decreased after 1 d to 3:1 and, in addition, *trans*-$[(Cy_3P)(OC)_4Mo{=}BN(SiMe_3)_2]$ (**11**) started to be formed. Finally, after 4 d the ratio was approximately 4:3:3 according to the $^1H$ NMR spectra.

In order to study whether *trans*-$[(Cy_3P)(OC)_4Mo{=}BN(SiMe_3)_2]$ (**11**) is available in an analogous manner to the Cr complex **10** by irradiation of the heterodinuclear complex **14**,[10a] $[(OC)_4Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (**16**) was photolysed. According to the $^{31}P\{^1H\}$ NMR spectra, however, the aforementioned product mixture of **16**, **17**, **11** and **18** was already obtained after 30 min but now with a ratio of 5:4:6:14.

In order to complete the series of semi-bridging group 6 borylene complexes with Pd- and Pt-base stabilisation, $[(OC)_5Mo = BN(SiMe_3)_2]$ (**3**) was treated with $[Pt(PCy_3)_2]$ (**13**) in $C_6D_6$ under identical conditions. The reaction mixture showed several compounds, from which $[(Cy_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pt(PCy_3)]$ (**19**), *trans*-$[(Cy_3P)(OC)_4Mo{=}BN(SiMe_3)_2$ (**11**), $[(OC)_5Mo(PCy_3)]$ (**18**) and $PCy_3$ could be identified by $^{31}P\{^1H\}$ NMR spectroscopy. The dinuclear complex **19** was isolated by layering a toluene solution with hexane and slow evaporation of the solvent.

The $^{31}P\{^1H\}$ NMR spectrum of the isolated compound **19** showed two doublets [$\delta$ = 70 ppm (d, $^4J_{P,P}$ = 11 Hz, $^1J_{P,Pt}$ = 5002 Hz, $P_{Pt}$), 49.9 (d, $^4J_{P,P}$ = 11 Hz, $^3J_{P,Pt}$ = 73 Hz, $P_{Mo}$)], indicating the presence of two nonequivalent phosphane ligands. A singlet for the $-SiMe_3$ groups ($\delta$ = 0.63 ppm) in the $^1H$ NMR spectrum as well as a broad resonance in the $^{11}B\{^1H\}$ NMR spectrum ($\delta$ = 100 ppm) were observed downfield shifted with respect to the signals of the starting material **3**.[11b] The reaction with $[Pt(PCy_3)_2]$ (**13**) proceeds even faster than that with $[Pd(PCy_3)_2]$ (**12**), or the one of **13** with the W-borylene **2**.[10b] Therefore, very fast work-up is required, since the NMR spectroscopic data recorded 1 h after mixing the reactants already indicated a 2:2:1 mixture of the subsequently isolated product $[(Cy_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pt(PCy_3)]$ (**19**), the borylene complex *trans*-$[(Cy_3P)(OC)_4Mo{=}BN(SiMe_3)_2]$ (**11**)[11b] and $[(Cy_3P)Mo(CO)_5]$ (**18**) (Scheme 1). After one week, the ratio has changed to 1:2:2, thus explaining the low yield of 12%.

The molecular constitution of **19** was determined by a single-crystal X-ray diffraction study (see Figure 3). The complex crystallises in the triclinic space group $P\bar{1}$ and



Scheme 1. Survey for the reaction mechanism of the formation of different semi-bridging borylene complexes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

shows similar structural features to the W analogue **20**[10b] or the Mo–Pd compound **16** particularly with respect to the geometries of the CO [Pt–Mo–C1 51.38(14)°; Mo–C1–O1 165.7(4)°] and borylene ligands [Pt–Mo–B 49.34(15)°; Mo–B–N 153.2(4)°]. These data together with the short B=N double bond [1.408(7) Å] and the orthogonal orientation of the aminoborylene group with respect to the M–B–Pt plane [Si2–N–B–Mo 91.2(9)°] demonstrate the presence of semi-bridging borylene and CO ligands, respectively. Comparison of the Mo–B bond lengths in the mono- and diphosphane complexes **16** and **19**, however, reveals distinct differences. In the case of **19**, the Mo–B separation of 2.138(6) Å is significantly smaller than that in **16** [2.235(4) Å] but falls barely below the Mo–B distance in **3** [2.1519(15) Å][11b] despite the higher coordination number of the boron atom in the diphosphane complex **19**. The same effect has already been observed in the corresponding complexes of W (**15** and **20** in comparison with **2**).[10b] Clearly, the presence of the $PCy_3$ group in a *trans* position to the borylene leads to a decreased M–B separation due to the reduced π acceptor abilities of the phosphane when compared with CO, thus inducing a stronger M–B $d_\pi$–$p_\pi$ back donation. A similar observation was made in the case of terminal borylene complexes **1**–**3**, substituted with a phosphane ligand in *trans* position to the boron atom [*trans*-[$(Cy_3P)(OC)_4$M=BN$(SiMe_3)_2$] (M = Cr, **9**; Mo, **11**; W, **10**)].[10b,11b]

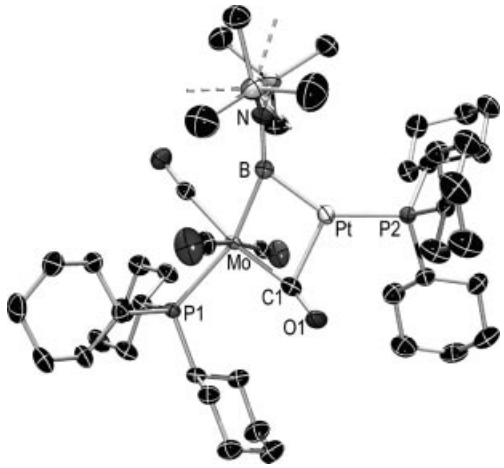


Figure 3. Molecular structure of [$(Cy_3P)(OC)_3$Mo(μ-CO){μ-BN$(SiMe_3)_2$}Pt$(PCy_3)$] (**19**). Thermal ellipsoids are set at the 50% probability level Selected bond lengths [Å] and angles [°]: B–N 1.408(7), Mo–B 2.138(6), Pt–P2 2.2912(13), Mo–P1 2.5587(12), Pt–Mo–C1 51.38(14), Mo–C1–O1 165.7(4), Pt–Mo–B 49.34(15), Mo–B–N 153.2(4), Si2–N–B–Mo 91.2(9).

## Calculations

To gain some deeper insight into the electronic structures of semi-bridging borylene complexes, we performed DFT computations on model systems of the complexes **16**, **17** and **19**.[26] Since no significant difference was observed between the Pd and Pt analogues, only the results for the Pd complexes are presented. To reduce computation time $PMe_3$ was used instead of $PCy_3$ and $N(SiMe_3)_2$ was replaced by $N(SiH_3)_2$.

To our surprise, the optimised geometry of the model compound [$(OC)_4$Mo(μ-CO){μ-BN$(SiH_3)_2$}Pd$(PMe_3)$] (**16a**) displays a Si–N–B–Mo torsion angle of ca. 41°. Reoptimisation with the smaller $NH_2$ group (**16b**$_{Min}$) led to the coplanar system $C_\mu M_2B{=}NH_2$, thus allowing π interaction between the electron lone pair on the nitrogen and the empty p orbital of the boron atom to extend to both metal atoms, thus providing evidence that the mutual orthogonal orientation of the amino-group and the four-membered ring $C_\mu M_2B$ is caused by steric effects. The molecule with an orthogonal disposition of the two respective planes was found to be a transition state (**16b**$_{TS}$) on the PES which is 34.4 kJ mol$^{-1}$ higher in energy than the coplanar minimum structure **16b**$_{Min}$.

As mentioned before, the B–N bond in **16** is only negligibly longer than that in the terminal borylene **3** (137.6 vs. 135.5 pm). The DFT computations for **16b**$_{Min}$ and **16b**$_{TS}$ result in very similar B–N distances (138.5 and 139.9 pm respectively) thus mirroring the short experimental B–N bond despite the orthogonal orientation of the amino-group to the $BM_2$ plane. The arguments against $sp^2$ hybridisation of boron were already raised in the crystal structure discussion and are supported by theory. Even for **16b**$_{TS}$ with its orthogonally orientated amino-group, one can identify an orbital clearly describing the B=N π interaction (HOMO–8), thus backing up the relative high s character of the hybrid orbital at the boron atom (see Figure 4).

We analysed the canonical orbitals of the parent compound **16b**$_{TS}$ with regards to interaction between the Mo borylene moiety [$(OC)_5MoBNH_2$] and the metal base [$Pd(PH_3)$]. For this analysis the transition state geometry **16b**$_{TS}$ rather than the minimum **16b**$_{Min}$ was employed since it displays the same orientation for the amino group as that found experimentally for **16**. Selected orbitals for **16b**$_{TS}$ are depicted in Figure 4.

The HOMO-9 and HOMO-10 are characterised mainly by σ interaction between the lone pair of the formal borylene $BNH_2$ and d orbitals of palladium. The HOMO-7 is primarily composed of a palladium $d_{xz}$ + $d_{yz}$ hybrid (ca. 2:1) orbital with some admixture of the boron $p_z$ orbital and thus describes the Pd→B π backbonding interaction. Inspection of the orbitals revealed, that in spite of similarities between borylenes and carbonyls, there is a difference in their interaction with metal bases. Marder et al. employed the Fragment Orbital Analysis for [($\eta^5$-$C_5H_5$)(OC)Rh(μ-CO)$_2$Cr(CO)($C_6H_6$)] and found that the dominant interaction between the metal-base [($\eta^5$-$C_5H_5$)(OC)Rh] and the metal-carbonyl fragment [$(OC)_3$Cr($\eta^6$-$C_6H_6$)] is that of occupied d orbitals of rhodium with unoccupied π* orbitals on the carbonyl groups. In the case of the borylene, however, the HOMO-3 shows no bonding character between the boron and metal centre because the hybrid orbital on boron is a mixture of $p_y$ and $p_x$ with s orbitals. Mixing of both p functions adjusts the direction of the hybrid towards molybdenum and subtraction of the s function removes a lobe pointing toward palladium and leads to further polari-

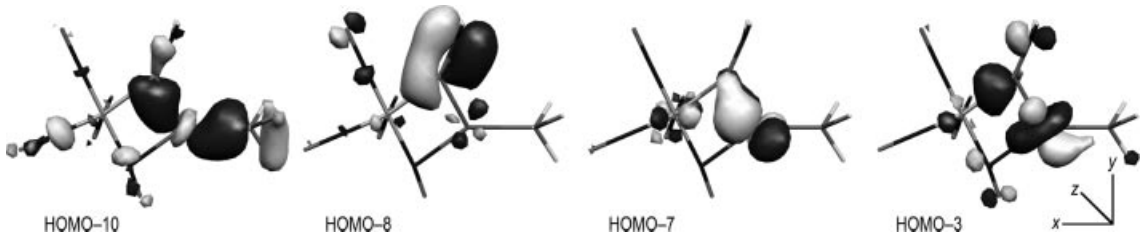

Figure 4. Kohn–Sham orbitals of $[(OC)_4Mo(\mu\text{-}CO)(\mu\text{-}BNH_2)Pd(PH_3)]$ **16b**$_{TS}$.

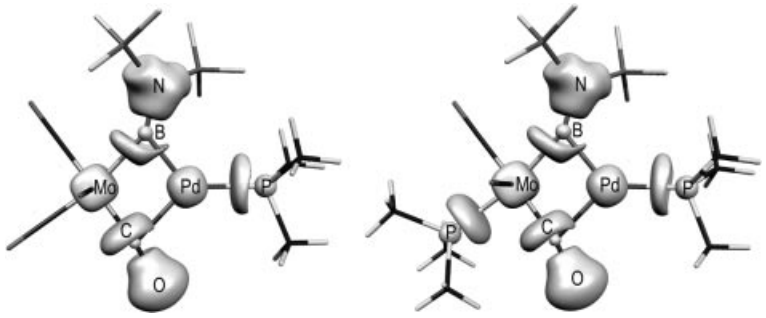

Figure 5. Plot of the ELF (isosurface: 0.70) of $[(OC)_4Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiH_3)_2\}Pd(PMe_3)]$ **16a** and $[(Me_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiH_3)_2\}Pd(PMe_3)]$ **17a**. The ELF surface around the ligands has been omitted for clarity.

sation towards Mo. The interaction of the Pd-fragment with the unoccupied orbital of the carbonyl group plays only a minor role as also indicated by the experimental data, i.e. the Pd–$C_\mu$ distance is significantly greater than the Pd–B separation.

Analysis of the Electron Localisation Function (ELF) can provide insight into the topology of valence electron pairs. Similar to $[(\mu_3\text{-}BMe)\{[(\eta^5\text{-}C_5H_5)Mn(CO)_2][Pd(PMe_3)]_2\}]$,[8c–8d] ELF computations located, in all computed molecules, three-synaptic basins representing (3c,2e)–Mo–B–Pd bonds, with their attractors localised on the boron-metal side. The situation of the bridging carbonyls resembles that of the borylenes. The ELF attractors of the Mo–C–Pd basins are also placed between Mo and the bridging atom (see Figure 5). In all cases the highest atomic contribution to the three-synaptic basins is provided by the central atom (ca. 50%).

The shape of the ELF basins of **16a** is very similar to that of $[(Me_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiH_3)_2\}Pd(PMe_3)]$ (**17a**). There is, however, a distinct discrepancy in the population of the B–N disynaptic basins which illustrates the difference in the *trans* effect of carbonyl vs. the phosphane groups. Formal exchange of CO in **17a** by a phosphane leads to a stronger Mo–B interaction, thus resulting in weaker B=N and B–Pd bonds. This phenomenon is reflected in the values of the Wiberg Bond Index (WBI). The WBI of the B–Mo bonds increases from 0.59 to 0.76 while at the same time it decreases for the B–Pd bonds from 0.61 to 0.53 when compared **16a** with **17a**. It should be mentioned, that despite short interatomic distances, neither ELF attractors nor the WBI indicates a distinct Mo–Pd interaction (see Table 1).

Table 1. Analysis of bonding in $[(OC)_4Mo(\mu\text{-}CO)(\mu\text{-}BNH_2)Pd(PH_3)]$ (**16b**$_{Min}$ and **16b**$_{TS}$) $[(OC)_4Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiH_3)_2\}Pd(PMe_3)]$ (**16a**), and $[(Me_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiH_3)_2\}Pd(PMe_3)]$ (**17a**).

## Conclusions

The first Mo-based semi-bridging borylene complexes $[(OC)_4Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (**16**) and $[(Cy_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pt(PCy_3)]$ (**19**) were ob-

tained from the reaction of $[(OC)_5Mo{=}B{=}N(SiMe_3)_2]$ (**3**) with the late transition metal complexes $[M(PCy_3)_2]$ (M = Pd, **12**; Pt, **13**) and fully characterised in solution and in the crystalline state. As indicated by multinuclear NMR spectroscopy, the formation of these heterodinuclear species is induced by cleavage of $PCy_3$ from the Pd and Pt precursors and subsequent addition of the Lewis-basic metal fragments $[M(PCy_3)]$ to the borylene moiety, thus representing a rare case of reactivity of terminal aminoborylene complexes under thermal (i.e. nonphotolytic) conditions. The generally increased lability of Mo organometallics with respect to their Cr and W counterparts is reflected by the rapid formation of the borylene species reported here and, in particular, by their enhanced reactivity, thus leading to the formation of a variety of side and degradation products. This, above all, is true for the instantaneous generation of the diphosphane complex **19** which is supposedly formed via a monophosphane intermediate $[(OC)_4M(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pt(PCy_3)]$ analogous to **16** and which is known for M = Cr and W but could not be detected here in the case of M = Mo. Besides, this facile substitution of CO by $PCy_3$ provides further evidence of the strong *trans* influence of boron centred ligands.

The particular coordination mode of the aminoborylene ligand in the title compounds was elucidated for the first time by detailed DFT and ELF studies which demonstrated, in agreement with the structural data, that the $(Me_3Si)_2NB$ moiety adopts a semi-bridging position which is well known for related carbonyl complexes but has only very recently started to appear for borylenes. From the computational data it can be concluded that the $(Me_3Si)_2NB$ ligand is characterised by a pronounced B=N double bond and a predominantly sp hybridised boron atom and donates σ electron density from its formal lone pair to both metal centres and receives in return π back donation into a $p_z$ orbital. In addition, structural and computational data indicate that a phosphane group *trans* to the semi-bridging borylene (e.g. **19**) increases the Mo–B bond strength with respect to a *trans* CO ligand, due to the higher π acceptor abilities of the latter.

## Experimental Section

All manipulations were performed either under an atmosphere of dry argon or in vacuo using standard Schlenk line and glove-box techniques. Solvents were dried by standard methods and were distilled and stored over molecular sieves prior to use. Deuterated solvents ($C_6D_6$) were degassed by three freeze-pump-thaw cycles and stored over molecular sieves in the glove-box. The irradiation experiments were carried out using a Heraeus TQ 150 high-pressure Hg lamp. IR spectra were recorded as toluene solutions between NaCl plates on a Bruker Vector 22 FTIR spectrometer. NMR spectra were acquired either on a Bruker AMX 400 or a Bruker Avance 500 NMR spectrometer. Reaction mixtures were monitored on a Bruker Avance 200 NMR spectrometer. $^1H$ and $^{13}C\{^1H\}$ NMR spectra were referenced to external TMS by the residual proton resonances of the solvent ($^1H$) or the solvent itself ($^{13}C$). $^{11}B\{^1H\}$ NMR spectra were referenced to external $BF_3{\cdot}OEt_2$ and $^{31}P\{^1H\}$ NMR spectra to 85% $H_3PO_4$. Microanalyses for C, H and N were performed on a Leco CHNS-932 elemental analyser.

**$[(OC)_4Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (16):** Solid $[(OC)_5Mo{=}B{=}N(SiMe_3)_2]$ (**3**) (0.060 g, 0.147 mmol) was added to a pale yellow solution of $[Pd(PCy_3)_2]$ (**12**) (0.098 g, 0.147 mmol) in $C_6D_6$ (0.5 mL). After 5 min the reaction mixture was layered with hexane (2 mL) and stored at –35 °C. Over night orange crystals of $[(OC)_4Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (**16**) had formed (0.062 g, 53%). $^1H$ NMR (400 MHz, $C_6D_6$, 21 °C): $\delta$ = 1.97–1.14 (m, 33 H, Cy), 0.41 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (101 MHz, $C_6D_6$, 21 °C): $\delta$ = 213.0 (d, $J_{C,P}$ = 2 Hz, CO), 210.8 (d, $J_{C,P}$ = 4 Hz, CO), 34.0 (d, $^1J_{C,P}$ = 13 Hz, $C^1$, Cy), 31.5 (d, $^3J_{C,P}$ = 5 Hz, $C^{3,5}$, Cy), 27.8 (d, $^2J_{C,P}$ = 11 Hz, $C^{2,6}$, Cy), 26.5 (d, $^4J_{C,P}$ = 1 Hz, $C^4$, Cy), 3.8 (s, $SiMe_3$) ppm. $^{11}B\{^1H\}$ NMR (64 MHz, $C_6D_6$, 23 °C): $\delta$ = 99 (br. s, $\omega_{1/2}$ = 810 Hz) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $C_6D_6$, 21 °C): $\delta$ = 35.1 (s) ppm. IR (toluene): $\tilde{\nu}$ = 2043, 1962, 1939, 1876 [ν(C=O)] $cm^{-1}$. $C_{29}H_{51}BMoNO_5PPdSi_2$ (794.03): calcd. C 43.87, H 6.47, N 1.76; found C 43.77, H 6.47, N 1.72.

**$[(Cy_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pt(PCy_3)]$ (19):** Solid $[(OC)_5Mo{=}B{=}N(SiMe_3)_2]$ (**3**) (0.045 g, 0.110 mmol) was added to a pale yellow solution of $[Pt(PCy_3)_2]$ (**13**) (0.084 g, 0.110 mmol) in toluene (0.5 mL). The solution turned brown and then red. After 5 min the reaction mixture was layered with hexane (2 mL) and the solvent was allowed to slowly evaporate in the glovebox. The solid was extracted with $C_6D_6$, the red solution was layered with hexane (1.5 mL) and the solvent was allowed to evaporate. After 4 d pale red-brown crystals formed which were recrystallised from toluene/hexane yielding 15 mg (12%) of $[(Cy_3P)(OC)_3Mo(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pt(PCy_3)]$ (**19**). $^1H$ NMR (500 MHz, $C_6D_6$, 27 °C): $\delta$ = 2.20–2.05 (m, 18 H, Cy), 1.80–1.58 (m, 30 H, Cy), 1.28–1.20 (m, 18 H, Cy), 0.63 (s, 18 H, $SiMe_3$) ppm. $^{13}C\{^1H\}$ NMR (126 MHz, $C_6D_6$, 27 °C): $\delta$ = 220.4 (d, $^2J_{C,P}$ = 2 Hz, CO), 220.3 (d, $^2J_{C,P}$ = 2 Hz, CO), 37.1 (d, $^1J_{C,P}$ = 13 Hz, $C^1$, $Cy^{Mo}$), 36.4 (d, $^1J_{C,P}$ = 22 Hz, $C^1$, $Cy^{Pt}$), 31.1 (d, $^3J_{C,P}$ = 2 Hz, $C^{3,5}$, $Cy^{Pt}$), 30.4 (s, $C^{3,5}$, $Cy^{Mo}$), 28.1 (d, $^2J_{C,P}$ = 10 Hz, $C^{2,6}$, $Cy^{Mo}$), 27.9 (d, $^2J_{C,P}$ = 11 Hz, $C^{2,6}$, $Cy^{Pt}$), 26.8 (s, $C^4$, $Cy^{Mo}$), 26.7 (s, $C^4$, $Cy^{Pt}$), 4.2 (s, $SiMe_3$) ppm. $^{11}B\{^1H\}$ NMR (160 MHz, $C_6D_6$, 27 °C): $\delta$ = 100 (br. s, $\omega_{1/2}$ = 1557 Hz) ppm; $^{31}P\{^1H\}$ NMR (202 MHz, $C_6D_6$, 27 °C): $\delta$ = 70.6 (d, $^4J_{P,P}$ = 11 Hz, $^1J_{P,Pt}$ = 5002 Hz, $P^{Pt}$), 49.9 (d, $^4J_{P,P}$ = 11 Hz, $^3J_{P,Pt}$ = 73 Hz, $P^{Mo}$) ppm. IR (toluene): $\tilde{\nu}$ = 1985, 1889, 1796, 1766 [ν(C=O)] $cm^{-1}$. $C_{46}H_{84}BMoNO_4P_2PtSi_2$ (1135.11): calcd. C 48.67, H 7.46, N 1.23; found C 48.54, H 7.11, N 1.20.

**Crystal Structure Determination:** The crystal data of **16** and **19** were collected on a Bruker X8APEX diffractometer with a CCD area detector and Mo-$K_\alpha$ radiation monochromated by using a multilayer mirror. The structures were solved by direct methods, refined with the Shelx software package (G. Sheldrick, University of Göttingen, 1997) and expanded using Fourier techniques. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were assigned to idealised positions and were included in structure factor calculations.

**Crystal Data for 16:** $C_{29}H_{51}BMoNO_5PPdSi_2$, $M_r$ = 794.01, orange bar, 0.23 × 0.21 × 0.13 mm, orthorhombic space group $Pna2_1$, $a$ = 17.7385(13) Å, $b$ = 9.5613(7) Å, $c$ = 21.3089(15) Å, $V$ = 3614.1(5) $Å^3$, $Z$ = 4, $\rho_{calcd}$ = 1.459 $g\,cm^{-3}$, $\mu$ = 0.990 $mm^{-1}$, $F(000)$ = 1632, $T$ = 173(2) K, $R_1$ = 0.0307, $wR_2$ = 0.0649, 7134 independent reflections [$2\theta \leq 52.24°$] and 370 parameters.

**Crystal Data for 19:** $C_{46}H_{84}BMoNO_4P_2PtSi_2$, $M_r$ = 1135.10, yellow block, 0.19 × 0.10 × 0.07 mm, triclinic space group $P\bar{1}$, $a$ = 12.2522(7) Å, $b$ = 13.4914(8) Å, $c$ = 16.2482(10) Å, $\alpha$ = 96.7280(10)°, $\beta$ = 101.2180(10)°, $\gamma$ = 96.7180(10)°, $V$ = 2589.3(3) $Å^3$, $Z$ = 2, $\rho_{calcd}$ = 1.456 $g\,cm^{-3}$, $\mu$ = 3.088 $mm^{-1}$, $F(000)$ =

# Synthesis and Characterization of New Organosilyl Derivatives of Polyoxometalates ($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$SiRR′$_2$] (R = R′ = Et, $i$Pr, O$t$Bu, Ph; R = $t$Bu and R′ = Me) – X-ray Crystal Structure of ($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$SiPh$_3$]

**Fatma Bannani,[a,b] René Thouvenot,*[b] and Mongi Debbabi*[a]**

**Keywords:** Polyoxometalates / Organic–inorganic hybrid / Multinuclear NMR spectroscopy

Reactions of ($n$Bu$_4$N)$_4$[(NbW$_5$O$_{18}$)$_2$O] with trialkyl/arylsilanols in dichloromethane and/or acetonitrile forms respectively ($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$SiRR′$_2$] [R = R′ = Et (**1**), $i$Pr (**3**), O$t$Bu (**4**), Ph (**5**); R = $t$Bu and R′ = Me (**2**)] in ca. 90–64 % isolated yields. The compounds have been characterized by elemental analysis, IR, Raman, multinuclear NMR in solution ($^1$H, $^{13}$C, $^{29}$Si, $^{183}$W) and in the solid-state by $^{29}$Si CP-MAS NMR spectroscopy. Multinuclear NMR and IR spectroscopic data suggest that the SiRR′$_2^+$ electrophilic fragment binds selectively to the terminal NbO oxygen atom which appears the most reactive site in ($n$Bu$_4$N)$_3$[NbW$_5$O$_{19}$]. This is supported by X-ray crystallographic analysis of ($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$SiPh$_3$] (**5**) which crystallizes in the monoclinic system, space group $P2_1/a$ with lattice parameters $a$ = 19.884(5), $b$ = 16.801(2), $c$ = 20.644(3) Å, $\beta$ = 112.050(12)°, $V$ = 6392(2) Å$^3$, and $Z$ = 4. Hydrolysis of the alkyl/arylsilyloxide derivatives leads to the back formation of the (NbW$_5$O$_{18}$)$_2$O$^{4-}$ dimer by the cleavage of the Si–O bond.

## Introduction

Polyoxometalates (POMs) form a class of inorganic metal-oxygen cluster compounds having a rising popularity in diverse fields ranging from catalysis to pharmacology.[1] These interesting properties have increased studies to modify polyoxometalates and prepare new compounds in order to well understand polyoxometalates reactivities.[2,3] One of the classical methods to obtain derivatized polyoxometalates is the reaction between the nucleophilic oxygen atom in d$^0$ transition metal oxocomplexes and electrophilic species[4–6] such as organic and organometallic groups. With organic groups bearing reactive moieties, these hybrid species may be further functionalized to be ultimately grafted onto surfaces for obtaining photo- or electrochemical materials. While monosubstituted niobotungstates are relatively poorly reactive,[7] dimeric species with connecting Nb–O–Nb bridge(s) are excellent starting materials for the preparation of organic and organometallic derivatized polyoxoanions.[8–11] Herein, we report the preparation and characterization by IR, Raman, and multinuclear NMR spectroscopy of the $n$Bu$_4$N$^+$ (TBA) salts of alkyl/arylsilylated Nb$^V$-monosubstituted Lindqvist POMs and the X-ray structural determination of ($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$SiPh$_3$] (**5**). In addition the reaction of these anions with respect to hydrolysis has been investigated.

## Results and Discussion

### Synthesis and Reactivity

The substitution of Nb$^V$ for W$^{VI}$ in the inert hexatungstate results in the increase of the overall charge of the polyoxometalate and in partial localization of the supplementary charge on the terminal oxygen atoms bound to the Nb atom.[17,18] Moreover, the oxygen–niobium bond in NbW$_5$O$_{19}$ is known to be labile with respect to $^{17}$O exchange.[8,19] Although the terminal ONb oxygen atoms are not the most basic among the oxygen atoms bound to Nb atoms both the lability and steric interaction allow reactions with electrophilic species to occur selectively at this oxygen site.[8] Actually in the case of the substituted Keggin anion PW$_{11}$NbO$_{40}$ the reaction of Me$_3$SiSO$_3$CF$_3$ leads directly to the trimethylsilyl derivatives PW$_{11}$O$_{39}$NbOSiMe$_3$.[20] In our case the reaction of R$_3$SiSO$_3$CF$_3$ (R = Me, Et) and $t$BuMe$_2$SiSO$_3$CF$_3$ with NbW$_5$O$_{19}^{3-}$ leads invariably to complex mixtures. By reacting alcohols and silanols with the dimeric form (Nb$_2$W$_4$O$_{18}$)$_2$O$^{6-}$ instead of the monomer Klemperer described the clean synthesis of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

terminal alkoxide and organosilyl-Lindqvist derivatives.[21] Later Beer[8] applied the same strategy to prepare terminal alkoxide Lindqvist derivatives by reacting the dimeric form of $NbW_5O_{19}^{3-}$ with alcohols. In light of the reactivities of the dimers it was expected that $(NbW_5O_{18})_2O^{4-}$ could also react under controlled conditions with silanols to give $NbW_5O_{19}SiRR'_2{}^{2-}$ according to Equation (1).

$$(NbW_5O_{18})_2O^{4-} + 2SiRR'_2OH \rightarrow 2NbW_5O_{19}SiRR'_2 + H_2O \quad (1)$$

The reaction of $(n\mathrm{Bu}_4\mathrm{N})_4[(NbW_5O_{18})_2O]$ with a stoichiometric amount of $RR'_2SiOH$ at room temperature, under argon, in freshly distilled dichloromethane (R = R′ = Et, *i*Pr; R = *t*Bu, R′ = Me) or in acetonitrile (R = R′ = Ph, O*t*Bu) yields $NbW_5O_{19}SiRR'_2{}^{2-}$ [R = R′ = Et (**1**), *i*Pr (**3**); R = *t*Bu, R′ = Me (**2**)] in satisfactory yields. For R = Ph (**5**) or O*t*Bu (**4**) the low yields (ca. 25%) in $CH_2Cl_2$ were increased by using acetonitrile as the solvent.

As shown by the solution studies the hybrid anions are relatively stable in $CH_2Cl_2$ and $CH_3CN$ but they are progressively hydrolyzed by atmospheric moisture to give $(NbW_5O_{18})_2O^{4-}$ which crystallizes from these solutions.

The formation of the dimer is described by Equation (2); the dimeric anion is in equilibrium with the protonated monomer according to Equation (3).

$$2NbW_5O_{19}SiRR'_2 + H_2O \rightarrow (NbW_5O_{18})_2O^{4-} + 2SiRR'_2OH \quad (2)$$

$$(NbW_5O_{18})_2O^{4-} + H_2O \rightleftarrows 2HNbW_5O_{19}^{2-} \quad (3)$$

This behavior is similar to that observed by Klemperer on $(Nb_2W_4O_{18})_2O^{6-}$ and by Beer on α-$\{PW_{11}O_{39}\}$-$NbOEMe_3^{3-}$[20,21] where (E = C, Si). Beer demonstrated using $^{17}O$ NMR that the primary hydrolysis product of the hybrid species is the dimer $(\alpha\text{-}\{PNbW_{11}O_{39}\})_2O^{6-}$ which hydrolyzes further to the monomer $\alpha\text{-}PNbW_{11}O_{40}^{4-}$.

In our case the reaction stops at the dimer because of its insolubility in dichloromethane and in acetonitrile.

Moreover, in more polar solvents such as DMSO the species are not stable and completely decompose into nonidentified species as shown by both IR and $^{183}W$ NMR spectroscopy.

## Vibrational Spectroscopy

### *IR Characterization*

Infrared spectroscopy analysis gives preliminary structural information in the solid state. Characteristic bands of the parent anion are present at nearly the same positions as in $(n\mathrm{Bu}_4\mathrm{N})_3[NbW_5O_{19}]$ namely at 810 $cm^{-1}$ ($\nu_{as}$ M–$O_b$), 584 $cm^{-1}$ ($\nu_s$ M–$O_b$), 446 $cm^{-1}$ (δ M–$O_b$) indicating that the Lindqvist structure is kept in the organic–inorganic hybrid. Nevertheless the strong band assigned to ($\nu_{as}$ W–$O_t$) shifts from 958 $cm^{-1}$ in $NbW_5O_{19}^{3-}$ to 971 $cm^{-1}$ in $(NbW_5O_{18})_2O^{4-}$ and the organosilyl species. Such a high frequency shift has already been observed for Keggin silyl derivatives[22] as a consequence of the grafting of organosilyl moieties on the POM framework. In the low-wave number region (from 300 to 1000 $cm^{-1}$) characteristic of the metal oxygen framework vibration, all compounds exhibit nearly identical spectra (Figure 1). The absence of the bands at 692 $cm^{-1}$ characteristic of the Nb–O–Nb bridge of the $(NbW_5O_{18})_2O^{4-}$ shows that the hybrid species is built up from the monomeric anion while the lack of the Nb–$O_t$ (915 $cm^{-1}$) in the $NbW_5O_{19}^{3-}$[23] pleads in favor of derivatization at this terminal ONb oxygen atom.

### *Raman Characterization*

Raman spectra of the dimer and of all hybrid derivatives are very similar in the low-wavenumber part ($\tilde{\nu}$ <1050 $cm^{-1}$)

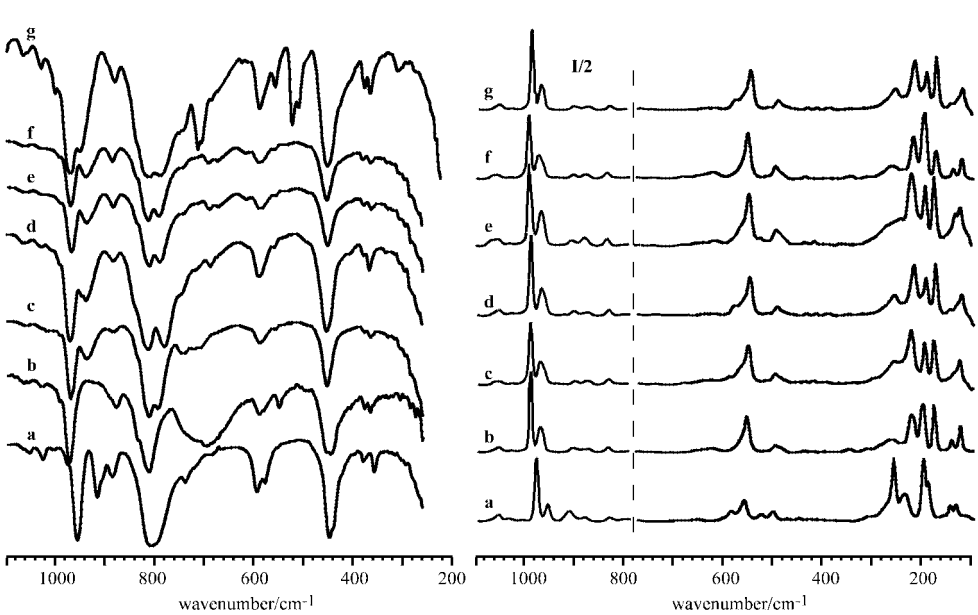

Figure 1. Infrared (left) and Raman (right) spectra of tetrabutylammonium salts of (a) $NbW_5O_{19}^{3-}$, (b) $(NbW_5O_{18})_2O^{4-}$, (c) $NbW_5O_{19}SiEt_3^{2-}$ (**1**), (d) $NbW_5O_{19}Si\mathit{t}BuMe_2^{2-}$ (**2**), (e) $NbW_5O_{19}Si\mathit{i}Pr_3^{2-}$ (**3**), (f) $NbW_5O_{19}Si(O\mathit{t}Bu)_3^{2-}$ (**4**), (g) $NbW_5O_{19}SiPh_3^{2-}$ (**5**). The high frequency part (>800 $cm^{-1}$) of the Raman spectra is scaled by half.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(Figure 1). They differ markedly from the spectrum of $NbW_5O_{19}^{3-}$ in the low frequency region $<300\ cm^{-1}$ and also in the high frequency region (900–1000 $cm^{-1}$); in particular as for IR the $\nu_s(W–O_t)$ and $\nu_{as}(W–O_t)$ are shifted by ca. 13 $cm^{-1}$ to a higher frequency in the dimer and in the hybrid species.

### *Multinuclear NMR Characterization*

The presence of several NMR active nuclei allows the structural characterization of POMs by multinuclear NMR spectroscopy.[24–28] Moreover, the high solubility of the TBA salt of POMs in some polar organic solvent permits us to prepare the concentrated solutions required for $^{183}W$ and $^{29}Si$ NMR spectroscopy. Multinuclear NMR ($^1H$, $^{13}C$, $^{29}Si$, and $^{183}W$) measurements have been performed in dichloromethane and acetonitrile solutions. Because of the presence of the organic moieties, $NbW_5O_{19}SiRR'_2$ hybrids are soluble in the less polar organic solvents such as $CH_2Cl_2$.

The $^1H$ and $^{13}C$ spectra of the hybrid species present the signals characteristic of the organosilyl part along with those of the TBA cations (see experimental part). The relative integration of the signals agrees with two TBA for one $SiRR'_2$ group according to the formula $(n-Bu_4N)_2[NbW_5O_{19}SiRR'_2]$.

Room-temperature solid-state $^{29}Si$ CP-MAS spectra were obtained for compounds **1**, **2**, **3**, and **5** (Table 1). They all present only one isotropic signal; while for **3** the signal is relatively narrow ($\Delta\nu_{1/2}$ ca. 100 Hz, 1.3 ppm), it appears broader for the three other compounds ($\Delta\nu_{1/2}$ 300 to 500 Hz, see Table 1); this differential behavior is likely due to more or less rapid rotation around the Si–O bond, leading to different motional narrowing of the $^{29}Si$ resonances. No significant signal could, however, be obtained for compound **4**, even with a large contact time, likely because of inefficient transfer between the silicium nucleus and the more remote protons. The $^{29}Si$ solution spectra present also a single line; contrary to the $^{29}Si$ spectra of the silyl derivatives of Keggin polyoxometallates,[22,27] no $^{183}W$ satellites could be detected for the $NbW_5$ hybrids; this is again in favor of the $SiRR'_2$ group grafted on $O_t$–Nb. The observed chemical shifts are as expected for the M ($SiOC_3$) group in the case of **1**, **2**, **3**, and **5** and for a Q ($SiO_4$) group for **4** (see Table 1). The close values of the isotropic chemical shifts in solution and in the solid-state indicate that hybrid anions keep their structures in solution; at variance with the solid-state case, the line in the solution spectra are, however, very narrow, which agrees with rapid reorientation of the organosilyl part in solution.

The $^{183}W$ NMR spectra of all compounds exhibit two narrow signals around 28–35 ppm (4 W) and 75–79 ppm (1 W) assigned to four equatorial and one axial tungsten atoms, respectively (Figure 2). Each signal presents a pair of satellites due to homonuclear tungsten–tungsten coupling with a coupling constant value (9 Hz) in the classical range characteristic of an "edge-sharing-junction" in iso- and heteropolyanions.[24,26,28] This is again consistent with an effective $C_{4v}$ symmetry of the hybrid anions in solution, with rapid reorientation of the organosilyl group grafted onto the terminal $O_t$–Nb oxygen atom.

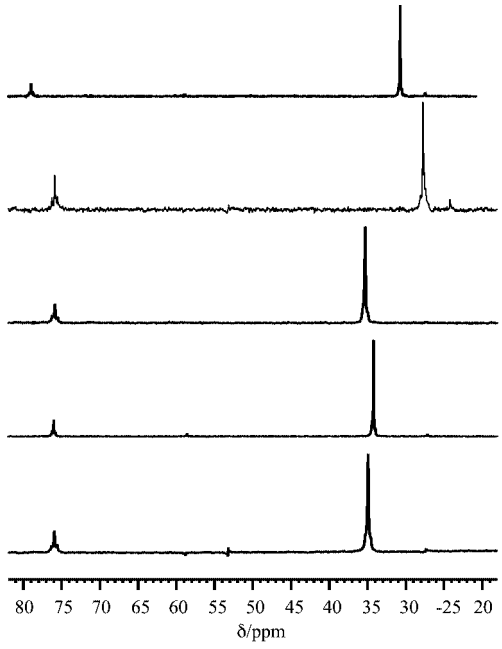

Figure 2. $^{183}W$ NMR solution spectra of the siloxide derivatives: from top to bottom, $NbW_5O_{19}SiPh_3^{2-}$ (**5**), $NbW_5O_{19}Si(O\mathit{t}Bu)_3^{2-}$ (**4**), $NbW_5O_{19}Si\mathit{i}Pr_3^{2-}$ (**3**), $NbW_5O_{19}Si\mathit{t}BuMe_2^{2-}$ (**2**), and $NbW_5O_{19}SiEt_3^{2-}$ (**1**).

The $^{183}W$ chemical shifts are known to be extremely sensitive to subtle structural changes.

In the present case changing the substituent on the Si atom induces chemical shift variations of ca. 7 and 4 ppm

for equatorial and axial W nuclei, respectively. These small variations are nevertheless relatively important if we consider that these W atoms are five- and seven-bond remote from the substituting atom. Moreover, by comparison with the monomeric nonderivatized anion, the signals of the two types of W nuclei exchange their position and shift to the opposite direction in $(NbW_5O_{18})_2O^{4-}$ and in the silicon derivatives, i.e. the equatorial Ws are shielded by ca. 40 ppm in the organosilyl derivatives and by ca. 50 ppm in the dimer while the axial Ws are deshielded by about 45 ppm (Figure 3). This behavior has been already noticed by Finke on niobium derivatives of the Keggin anion: dimerization of $SiNb_3W_9$ by formation of three Nb–O–Nb bridges induces the shielding of the proximal W by ca. 30 ppm.[9]

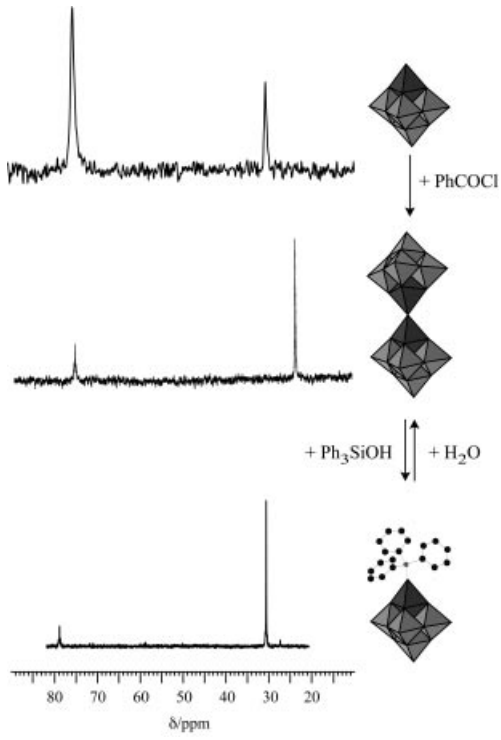

Figure 3. Comparison of the $^{183}W$ NMR spectra of: from top to bottom, $NbW_5O_{19}^{3-}$, $(NbW_5O_{18})_2O^{4-}$, and $NbW_5O_{19}SiPh_3^{2-}$ (left) and schematic representation of the formation and cleavage of $NbW_5O_{19}SiPh_3^{2-}$.

$^{93}Nb$ NMR was registered for two compounds namely **2** and **4**; as was observed by Beer et al. for the dimeric form, the $^{93}Nb$ resonances of the silyl derivatives are very broad compared with that of underivatized monomeric $NbW_5O_{19}$. While the line width for a concentrated viscous solution of $NbW_5O_{19}^{3-}$ in DMSO does not exceed 5 kHz, it amounts to 12 and 25 kHz for **4** and **2** in diluted solution in the low-viscosity solvents acetonitrile and dichloromethane, respectively. This large $^{93}Nb$ line width originates from very rapid quadrupolar relaxation of the $^{93}Nb$ nucleus ($I = 9/2$); such a rapid relaxation ($T_2 < 3$ μs) explains the narrow $^{183}W$ resonance due to an effective self-decoupling of the $^{93}Nb$ nucleus.

### X-ray Diffraction Analysis of $(n-Bu_4N)_2[NbW_5O_{19}SiPh_3]$ (5)

Whatever the nature of the solvents, attempts to grow crystals of hybrids suitable for X-ray crystallographic study were unsuccessful. Actually in all cases the crystals which formed were proved to contain the poorly soluble μ-oxo-bridged dimer $(NbW_5O_{18})_2O^{4-}$ which was formed by hydrolysis of the organosilyl $NbW_5O_{19}SiR_3^{2-}$ compounds (see above). Nevertheless, good quality crystals of $(n-Bu_4N)_2$-$[NbW_5O_{19}SiPh_3]$ were formed slowly at room temperature on the bottom of the firmly taped NMR tube containing the concentrated acetonitrile solution. The molecular structure of the anion **5** is shown in Figure 4. The X-ray single crystal study confirmed the monomeric structure of **5**, in fact the structure of the hybrid anion is built up from the monosubstituted Lindqvist anion $NbW_5O_{19}$ on which is grafted the $\{Si(C_6H_5)_3\}$ fragment through the terminal $O_t$–Nb oxygen atom. The asymmetric unit contains one $NbW_5O_{19}SiPh_3^{2-}$ anion and two TBA cations. The hybrid anion $NbW_5O_{19}SiPh_3^{2-}$ does not possess any crystallographic symmetry element in the solid state. However, in solution, because of rapid reorientation of the organosilyl fragment, the symmetry of the hybrid anion is consistent with $C_{4v}$ as shown by $^{183}W$ NMR spectroscopy. Moreover, the grafting of this fragment to the Lindqvist anion hinders the random orientational disorder of the $NbW_5O_{19}$ unit[12] and allows differentiation of the Nb from the W atoms and access to precise metrical data for these anions (Table 2).

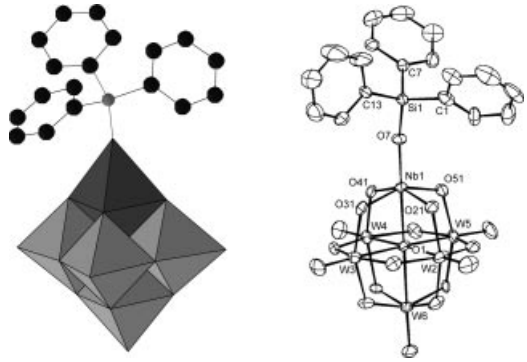

Figure 4. Representations of the molecular structure of $NbW_5O_{19}SiPh_3^{2-}$. Left: combined polyhedral and ball and stick model; right: Cameron representation with ellipsoids drawn at the 30% probability level.

The Nb–O bond length of 1.871(9) Å in the Nb–O–Si bridge compares well with similar bonds in $(n-Bu_4N)_3$-$[Nb_2W_4O_{19}\{Si(Me)_2(CMe_3)\}]$ [1.86(2) Å], while the Nb–O–Si bridge is more open (167°) in **5** than in the $Nb_2W_4O_{19}$ derivative (154°). The mean terminal and bridging W–O (1.70 and 1.92 Å, respectively) are also similar to those observed in $W_6O_{19}^{2-}$ (1.69 and 1.92 Å).[29]

Concerning the metal–central oxygen distances, Nb–$O_1$ (2.262 Å) is significantly shorter than the W–O mean value for the equatorial bonds W–$O_1$ (2.32 Å) and than the axial $W_6$–$O_1$ (2.373 Å); the relatively short Nb–$O_c$ distance is a consequence of the reduced *trans* influence of $O_7$ in the Nb–O–Si bridge. Analogous contractions have been observed in

monofunctionalized Lindqvist-type polyoxometallates such as $\mathrm{Nb_2W_4O_{19}Si(Me)_2(CMe_3)^{3-}}$ where Nb–$O_c$ and $W_{ax}$–$O_c$ amount to 2.27 and 2.37 Å, respectively. The remaining geometrical parameters of the $\mathrm{NbW_5O_{19}}$ core are very similar; for example Nb–O–W bridge angles (between 116.09 and 117.51°) are only slightly smaller than the W–O–W ones (between 117.09 and 118.93°).

The tetrahedral Si atom displays a slight distortion from ideal geometry toward the terminal O–Nb bond with C–Si–C and O–Si–C angles on average 110.0° and 108.3°, respectively. The Si–C distances, which range from 1.823(19) to 1.871(19) Å, are longer than Si–O [1.633(11) Å].

## Conclusions

In this work we report a valuable method for the clean preparation of organosilyl derivatives of monosubstituted hexaniobotungstate in good yields. Equation (1) features this functionalization which consists of a selective coordination of an electrophilic fragment $\{\mathrm{SiRR'}_2\}^+$ [R = R′ = Et (**1**), *i*Pr (**3**), O*t*Bu (**4**), Ph (**5**); R = *t*Bu and R′ = Me (**2**)] to the terminal Nb–$O_t$ oxygen atom which leads to the formation of a terminal organosilyloxide-derivatized monosubstituted niobotungstate. This organic–inorganic hybrid has a good solubility in a variety of polar organic solvents that makes it easily studied and characterized in solution by multinuclear NMR spectroscopy. Spectroscopic studies, along with an X-ray study of $\mathrm{NbW_5O_{19}SiPh_3^{2-}}$ show that derivatization of $\mathrm{NbW_5O_{19}^{3-}}$ occurs selectively at the terminal Nb–$O_t$ rather than the bridging Nb–$O_b$–W oxygen atoms. Grafting of $\mathrm{R_3Si^+}$ permits the resolution of the disorder problem in crystal structure. Hydrolysis of the siloxide derivative occurs at the Si–O bond and leads to the back formation of the starting material $\mathrm{(NbW_5O_{18})_2O^{4-}}$.

## Experimental Section

**Reagents and Methods:** Solvents (analytical grade) and the following reagents were purchased from commercial sources and used without further purification: triphenylsilanol, triethylsilanol, triisopropylsilanol, *tert*-butyldimethylsilanol, tri-*tert*-butoxysilanol, diethyl ether. Acetonitrile and dichloromethane were distilled under argon from $CaH_2$. Syntheses of $(n\mathrm{Bu_4N})_4[(\mathrm{NbW_5O_{18}})_2\mathrm{O}]$ and $(n\mathrm{Bu_4N})_3[\mathrm{NbW_5O_{19}}]$ followed literature procedures described.[8,12] All subsequent reactions were performed under an inert atmosphere of argon in a Schlenk line to avoid the polymerization of the silanols by the air moisture. The $^1$H and $^{13}$C spectra were obtained at 300 K from $CD_2Cl_2$ and $CD_3CN$ solutions in 5-mm o.d. tubes at 300 and 75.5 MHz, respectively, with Bruker AC300 or Bruker AvanceII spectrometers. $^{29}$Si and $^{183}$W spectra were recorded at 300 K from $CH_2Cl_2/CD_2Cl_2$ solution in a 10-mm o.d. tube with the Bruker AC300 (59.6 and 12.5 MHz) and Bruker DRX 500 (99.3 and 20.8 MHz) spectrometers. Chemical shift values for $^1$H, $^{13}$C, and $^{29}$Si were internally referenced to tetramethylsilane (TMS) using the solvent peak as secondary standard and for $^{183}$W are given with respect to an external 2 M $Na_2WO_4$ solution in alkaline $D_2O$, using a saturated solution of dodecatungstosilicic acid ($\mathrm{SiW_{12}O_{40}H_4}$) as a secondary standard ($\delta$ = –103.8 ppm). The solid-state $^{29}$Si NMR CP-MAS spectra were obtained at room temperature with a Bruker Avance 400 spectrometer operating at 79.5 MHz; spinning rates of 5 kHz, contact times of 3 to 10 ms, and a recycling delay of 5 s were used for obtaining spinning-sideband-free spectra in ca. 10 h. Chemical shifts of the isotropic line are reported with respect to TMS. FTIR spectra were recorded from KBr pellets with a Bio-rad FTS 165 IR-FT spectrometer with a resolution of 4 $cm^{-1}$. Raman spectra were collected with a Kaiser Optical Systems HL5R Raman spectrometer equipped with a near-IR laser diode working at 785 nm. The laser power was adjusted to 10–15 mW at the sample position for all spectra. The average resolution is equal to 3 $cm^{-1}$. Elemental analyses were performed by the Laboratoire Central d′Analyses du CNRS (Vernaison, France).

**Crystal-Structure Analysis:** Crystal structure data are summarized in Table 3. A colorless parallelepiped crystal (0.08 × 0.10 × 0.25 mm) of $(n\mathrm{Bu_4N})_2[\mathrm{NbW_5O_{19}Si}P\mathrm{h_3}]$ was glued to a glass fiber, covered with a thin layer of epoxy cement, and examined by X-ray crystallography. Data were collected with a Kappa-CCD Bruker AXS diffractometer at 300 K using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Lattice parameters were obtained by

Table 3. Crystal data and structure refinement for $(n\mathrm{Bu_4N})_2[\mathrm{NbW_5O_{19}SiPh_3}]$ (**5**).[a]

least-squares refinement of the diffraction data of 151 reflections within the range of $4° < 2\theta < 22°$. The index ranges of data collection were $-27 \le h \le 20$, $-23 \le k \le 22$, $-29 \le l \le 29$. Intensity data were collected using 6674 reflections with $I \ge 3\sigma(I)$. The structure was solved by direct methods and refined with full-matrix least-squares technique on $F$ using the SHELXS86[13] and CRYSTALS[14] programs. Hybrid anion atom parameters were refined anisotropically and TBA cations were refined isotropically. The values of the discrepancy indices $R_1$ ($R_{w2}$) for all data were 0.0434 (0.0517). The molecular structure was drawn with Diamond and Cameron programs[15,16] and reported in Figure 4.

CCDC-635634 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$SiEt$_3$] (1):** To a suspension of ($n$Bu$_4$N)$_4$[(NbW$_5$O$_{18}$)$_2$O] (1 g, 0.28 mmol) in 30 mL of dry dichloromethane was added $(C_2H_5)_3SiOH$ (0.086 mL, 0.56 mmol). The resulting solution was stirred vigorously at ambient temperature under a static argon atmosphere for 24 h, then centrifuged at 4000 rpm for 15 min. The supernatant was added with diethyl ether, whilst stirring, precipitation of the hybrid has generally to be initiated by scraping the beaker walls with a glass spatula; the white precipitate was filtered and washed three times with 100 mL of diethyl ether and dried under vacuum to give 788 mg of crude product (73% yield). $C_{38}H_{87}N_2NbO_{19}SiW_5$ (1916.23): calcd. C 23.79, H 4.57, N 1.46, Nb 4.84, W 47.99; found C 23.73, H 4.57, N 1.33, Nb 4.16, W 47.35. IR (1300–400): $\tilde{\nu}$ = 446 (s), 583 (m), 706 (m), 718 (m), 742 (m), 792 (vs), 809 (vs), 884 (w), 938 (m), 971 (vs), 1239 (w) cm$^{-1}$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 3.28 (t, 16 H, N–C$H_2$–CH$_2$–CH$_2$–CH$_3$), 1.71 (q, 16 H, N–CH$_2$–C$H_2$–CH$_2$–CH$_3$), 1.49 (m, 16 H, N–CH$_2$–CH$_2$–C$H_2$–CH$_3$), 1.08 (m, 33 H, N–CH$_2$–CH$_2$–CH$_2$–C$H_3$), 0.75 (q, 6 H, Si–C$H_2$–CH$_3$) ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 59.06 (N–*C*H$_2$–CH$_2$–CH$_2$–CH$_3$), 24.34 (N–CH$_2$–*C*H$_2$–CH$_2$–CH$_3$), 20.09 (N–CH$_2$–CH$_2$–*C*H$_2$–CH$_3$), 13.89 (N–CH$_2$–CH$_2$–CH$_2$–*C*H$_3$), 6.61 (Si–*C*H$_2$–CH$_3$), 7.47 (Si–CH$_2$–*C*H$_3$) ppm. $^{29}$Si NMR (0.06 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = 25.8 ppm. $^{183}$W NMR (0.06 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = 34.9 ($J_{W-W}$ = 8.8 Hz, 4 W, $W_{eq}$), 75.9 ($J_{W-W}$ = 8.8 Hz, 1 W, $W_{ax}$) ppm.

**($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$Si$t$BuMe$_2$] (2):** This compound was prepared by the same procedure as for **1** using $[C(CH_3)_3(CH_3)_2]SiOH$ (0.16 mL, 0.56 mmol) instead of $(C_2H_5)_3SiOH$ (yield of crude product: 977 mg, 91%). $C_{38}H_{87}N_2NbO_{19}SiW_5$ (1916.23): calcd. C 23.79, H 4.57, N 1.46, Nb 4.84, W 47.99; found C 23.62, H 4.53, N 1.33, Nb 4.43, W 47.5. IR (1300–400): $\tilde{\nu}$ = 446 (s), 583 (m), 683 (w), 738 (sh), 777 (vs), 810 (vs), 881 (w), 938 (m), 970 (vs), 1029 (w), 1066 (w), 1108 (w), 1152 (w), 1253 (m) cm$^{-1}$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 3.28 (t, 16 H, N–C$H_2$–CH$_2$–CH$_2$–CH$_3$), 1.72 (q, 16 H, N–CH$_2$–C$H_2$–CH$_2$–CH$_3$), 1.49 (m, 16 H, N–CH$_2$–CH$_2$–C$H_2$–CH$_3$), 1.08 (m, 33 H, N–CH$_2$–CH$_2$–CH$_2$–C$H_3$), 0.24 [s, 6 H, Si(C$H_3$)$_2$C(CH$_3$)$_3$] ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 58.57 (N–*C*H$_2$–CH$_2$–CH$_2$–CH$_3$), 25.31 [Si(CH$_3$)$_2$C(*C*H$_3$)$_3$], 23.98 (N–CH$_2$–*C*H$_2$–CH$_2$–CH$_3$), 19.67 (N–CH$_2$–CH$_2$–*C*H$_2$–CH$_3$), 19 [Si(CH$_3$)$_2$*C*(CH$_3$)$_3$], 13.54 (N–CH$_2$–CH$_2$–CH$_2$–*C*H$_3$), –3.85 [Si(*C*H$_3$)$_2$C(CH$_3$)$_3$] ppm. $^{29}$Si NMR (0.06 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = 25.7 ppm. $^{183}$W NMR (0.06 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = 34.5 ($J_{W-W}$ = 8.8 Hz, 4 W, $W_{eq}$), 76.3 ($J_{W-W}$ = 8.8 Hz, 1 W, $W_{ax}$) ppm.

**($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$Si$i$Pr$_3$] (3):** This compound was prepared by the same procedure as for **1** using $[CH(CH_3)_2]_3SiOH$ (0.11 mL, 0.56 mmol) instead of $(C_2H_5)_3SiOH$ (yield of crude product: 923 mg, 84%). $C_{41}H_{93}N_2NbO_{19}SiW_5$ (1958.27): calcd. C 25.12, H 4.78, N 1.43, Si 1.43, W 46.96; found C 24.87, H 4.74, N 1.23, W 46.12. IR (1300–400): $\tilde{\nu}$ = 445 (vs), 583 (m), 611 (w), 668 (sh), 687 (w), 739 (sh), 788 (vs), 809 (vs), 883 (m), 969 (vs), 1062 (w), 1107 (w), 1152 (w), 1247 (w) cm$^{-1}$. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 58.42 (N–*C*H$_2$–CH$_2$–CH$_2$–CH$_3$), 23.59 (N–CH$_2$–*C*H$_2$–CH$_2$–CH$_3$), 19.46 (N–CH$_2$–CH$_2$–*C*H$_2$–CH$_3$), 17.1 [SiCH(*C*H$_3$)$_2$], 13.06 (N–CH$_2$–CH$_2$–CH$_2$–*C*H$_3$), 0.81 [Si*C*H(CH$_3$)$_2$] ppm. $^{29}$Si NMR (0.06 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = 24.8 ppm. $^{183}$W NMR (0.06 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = 35.3 ($J_{W-W}$ = 9 Hz, 4 W, $W_{eq}$), 75.9 ($J_{W-W}$ = 9 Hz, 1 W, $W_{ax}$) ppm.

**($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$Si(O$t$Bu)$_3$] (4):** To a suspension of ($n$Bu$_4$N)$_4$[(NbW$_5$O$_{18}$)$_2$O] (1 g, 0.28 mmol) in 30 mL of dry acetonitrile was added, under argon, $[OC(CH_3)_3]_3SiOH$ (148 mg, 0.56 mmol). The resulting clear colorless solution was stirred vigorously at room temperature for 24 h. This solution was centrifuged at 4000 rpm for 15 min and then diethyl ether was added to the supernatant from which a white powder was precipitated under vigorous stirring. It was washed twice with diethyl ether and dried under vacuum to give 1013 mg in 88% yield. IR (1400–400): $\tilde{\nu}$ = 447 (s), 511 (w), 540 (w), 584 (m), 651 (m), 705 (m), 741 (m), 791 (vs), 811 (vs), 880 (m), 938 (m), 968 (vs), 996 (m), 1031 (m), 1077 (vs), 1189 (s), 1244 (s), 1367 (s), 1390 (m) cm$^{-1}$. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 59.31 (N–*C*H$_2$–CH$_2$–CH$_2$–CH$_3$), 31.43 [SiOC(*C*H$_3$)$_3$], 24.37 (N–CH$_2$–*C*H$_2$–CH$_2$–CH$_3$), 20.32 (N–CH$_2$–CH$_2$–*C*H$_2$–CH$_3$), 13.89 (N–CH$_2$–CH$_2$–CH$_2$–*C*H$_3$) ppm. $^{29}$Si NMR (0.06 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = –100.7 ppm. $^{183}$W NMR (0.05 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = 27.7 ($J_{W-W}$ = 9 Hz, 4 W, $W_{eq}$), 75.9 ($J_{W-W}$ = 9 Hz, 1 W, $W_{ax}$) ppm.

**($n$Bu$_4$N)$_2$[NbW$_5$O$_{19}$SiPh$_3$] (5):** To a mixture of ($n$Bu$_4$N)$_4$[(NbW$_5$O$_{18}$)$_2$O] (1 g, 0.28 mmol) and $(C_6H_5)_3SiOH$ (0.155 g, 0.56 mmol) was added with stirring 30 mL of dry acetonitrile. The resulting slightly cloudy solution was stirred vigorously at room temperature for 48 h under a static argon atmosphere. This solution was centrifuged for 15 min and then diethyl ether was added to the supernatant from which a white powder was precipitated under vigorous stirring. It was washed twice with diethyl ether and dried under vacuum to give 745 mg of air- and moisture-stable microcrystalline white powder, in 64% yield. $C_{50}H_{87}N_2NbO_{19}SiW_5$ (2060.23): calcd. C 29.12, H 4.25, N 1.36, Si 1.36, Nb 4.5, W 44.64; found C 29.15, H 4.26, N 1.32, Si 1.65, Nb 3.48, W 43.65. IR (1450–400): $\tilde{\nu}$ = 445 (vs), 504 (m), 517 (m), 552 (w), 584 (m), 703 (m), 710 (m), 787 (vs), 810 (vs), 879 (w), 951 (m), 971 (vs), 1002 (sh), 1030 (w), 1066 (w), 1106 (sh), 1117 (s), 1162 (w), 1190 (w), 1262 (w), 1430 (m) cm$^{-1}$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 3.42 (t, 16 H, N–C$H_2$–CH$_2$–CH$_2$–CH$_3$), 1.8 (q, 16 H, N–CH$_2$–C$H_2$–CH$_2$–CH$_3$), 1.45 (m, 16 H, N–CH$_2$–CH$_2$–C$H_2$–CH$_3$), 1 (t, 24 H, N–CH$_2$–CH$_2$–CH$_2$–C$H_3$), 7.46 (m, 6 H, *meta*), 7.5 (dd, 3 H, *para*), 7.75 (dd, 6 H, *ortho*) ppm. $^{13}$C NMR ($CD_2Cl_2$): $\delta$ = 137.5, 142.3, 141.6, 135.2 (Ph), 59.1 (N–*C*H$_2$–CH$_2$–CH$_2$–CH$_3$), 24.24 (N–CH$_2$–*C*H$_2$–CH$_2$–CH$_3$), 20.09 (N–CH$_2$–CH$_2$–*C*H$_2$–CH$_3$), 13.66 (N–CH$_2$–CH$_2$–CH$_2$–*C*H$_3$) ppm. $^{29}$Si NMR (0.06 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = –12.8 ppm. $^{183}$W NMR (0.04 M, $CH_2Cl_2/CD_2Cl_2$): $\delta$ = 30.7 ($J_{W-W}$ = 8.7 Hz, 4 W, $W_{eq}$), 79.0 ($J_{W-W}$ = 9.2 Hz, 1 W, $W_{ax}$) ppm. The product is contaminated by a very small amount of hexatungstate $W_6O_{19}^{2-}$ as shown by $^{183}$W NMR spectroscopy.

## Acknowledgments

This work is supported by the Centre National de Recherche Scientifique (CNRS), France and the Direction Générale de la Recherche Scientifique (DGRST), Tunisia in the frame of a bilateral joint project. We gratefully acknowledge the Comité Mixte pour la Coopération Universitaire (CMCU) (program 05G1211). We are also grateful to Patrick Herson (UPMC) for crystal data collection and for his assistance in structure resolution, and to Jocelyne Maquet for her help in recording the $^{29}$Si solid-state CP-MAS spectra on the Bruker Avance 400 spectrometer (S.I.A.R.E. UPMC).

The $P_2/N_2$-coordinated *cis*-dihydridoiridium(III) chelate complexes (*OC*-6-13)-[$IrH_2(H_2N\cap NH_2)(PR_3)_2$]$BF_4$ [$PR_3$ = $PPh_3$, $H_2N\cap NH_2$ = 1,2-$(H_2N)_2C_6H_4$ (**1a**); (1*R*,2*R*)-$(H_2N)_2C_6H_{10}$ {(*R*,*R*)-dach} (**1b**); (*R*)-2,2′-diamino-1,1′-binaphthyl {(*R*)-dabin} (**1c**); $PR_3$ = P*i*Pr$_3$, $H_2N\cap NH_2$ = (*R*,*R*)-dach (**2a**), (*R*)-dabin (**2b**); $PR_3$ = $PCy_3$, $H_2N\cap NH_2$ = (*R*)-dabin (**3**)] were obtained by treating the respective diamine ligands with labile precursors such as [$IrH_2(OCMe_2)_2(PPh_3)_2$]$BF_4$, [($\eta^4$-1,5-$C_8H_{12}$)Ir($PPh_3$)$_2$]$BF_4$, or [$IrH_5(PR_3)_2$]/$HBF_4$ (R = *i*Pr, Cy). While oxidative addition of HCl to [($\eta^4$-1,5-$C_8H_{12}$)Ir{(*S*,*S*)-bdpcp}]$BF_4$ [(*S*,*S*)-bdpcp = (1*S*,2*S*)-$(Ph_2P)_2C_5H_8$] yields the usual mononuclear adduct [($\eta^4$-1,5-$C_8H_{12}$)Ir(H)(Cl){(*S*,*S*)-bdpcp}]$BF_4$ (**4**), similar treatment of [($\eta^4$-1,5-$C_8H_{12}$)Ir{(*R*)-binap}]$BF_4$ furnishes the triply chlorido-bridged diiridium complex [{(*R*)-binap}$_2$$Ir_2H_2(\mu$-Cl)$_3$]$BF_4$ (**5**). Opening of the μ-Cl bridges of **5** by N,N nucleophiles was used to synthesise the three diamine/(*R*)-binap complexes [Ir(H)(Cl)-($H_2N\cap NH_2$){(*R*)-binap}]$BF_4$ [$H_2N\cap NH_2$ = (1*R*,2*R*)-$H_2NCH(Ph)CH(Ph)NH_2$ {(*R*,*R*)-dpen} (**6a**), (*R*,*R*)-dach (**6b**), and $H_2NCMe_2CMe_2NH_2$ {tmen} (**6c**). Whereas the dihydrides [$IrH_2${(*R*,*R*)-dach}$(PR_3)_2$]$BF_4$ and [$IrH_2${(*R*)-dabin}-$(PR_3)_2$]$BF_4$ (R = *i*Pr, Ph) are only poor (pre)catalysts for the enantioselective hydrogenation of acetophenone, complexes **6a**–**c** catalyze the formation of 1-phenylethanol in good enantiomeric excess [$ee_{max}$ = 82–84 % (*S*)] in the presence of base. The crystal structures of **1a**, **4**, and **5** have been determined. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

We recently[1] described some 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl-coordinated diamine(diphosphane)-rhodium(I) complexes such as [Rh{(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$}{(*R*)-binap}]$BF_4$ and the like, which were made without difficulty by treating [($\eta^4$-1,5-$C_8H_{12}$)Rh{(*R*)-binap}]$BF_4$ with N,N-chelate ligands under hydrogen. Oxidative addition of HCl led to the rhodium(III) derivative (*OC*-6-43)-[Rh(H)(Cl){(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$}{(*R*)-binap}]$BF_4$. From a structural point of view, this latter complex can be regarded as an analog of the neutral ruthenium(II) compound (*OC*-6-43)-[Ru(H)(Cl){(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$}{(*R*)-binap}], which is well known to be an excellent (pre)catalyst for the stereoselective hydrogenation of ketones and imines.[2a]

If activated by a strong base in 2-propanol, the diamine-(diphosphane)rhodium complexes were also found to act as enantioselective catalysts for the reduction of acetophenone, although both their activity and selectivity ($ee_{max.}$ = 71 %)[1] were inferior to those of the established $Ru^{II}$-based systems.[3]

In our search for complexes of the Group 9 transition metals with possibly improved catalytic properties we set out to synthesize and investigate some cationic hydrido compounds of iridium(III) with coordination spheres dominated by (preferentially chiral) diamine and (di)phosphane ligands, namely [$IrH_2(H_2N\cap NH_2)(PR_3)_2$]$BF_4$ (R = Ph, *i*Pr, Cy) and [Ir(H)(X)($H_2N\cap NH_2$)($Ph_2P\cap PPh_2$)]$BF_4$ (X = H or Cl).

## Results and Discussion

### Complexes

Either of the cationic $Ir^I$ or $Ir^{III}$ complexes [($\eta^4$-1,5-$C_8H_{12}$)Ir$(PR_3)_2$]$^+$ and [$IrH_2(OCMe_2)_2(PR_3)_2$]$^+$ (R = Ph),[4] respectively, or the pentahydrides [$IrH_5(PR_3)_2$] (R = *i*Pr, Cy)[5] could be used as starting material for the preparation of the target compounds [$IrH_2(H_2N\cap NH_2)(PR_3)_2$]$^+$. Thus, stoichiometric 1:1 reactions of the solvento complex [Ir-$H_2(OCMe_2)_2(PPh_3)_2$]$BF_4$ with 1,2-phenylenediamine (1,2-phdn) or (1*R*,2*R*)-1,2-diaminocyclohexane [(*R*,*R*)-dach] resulted in smooth replacement of the loosely bound acetone

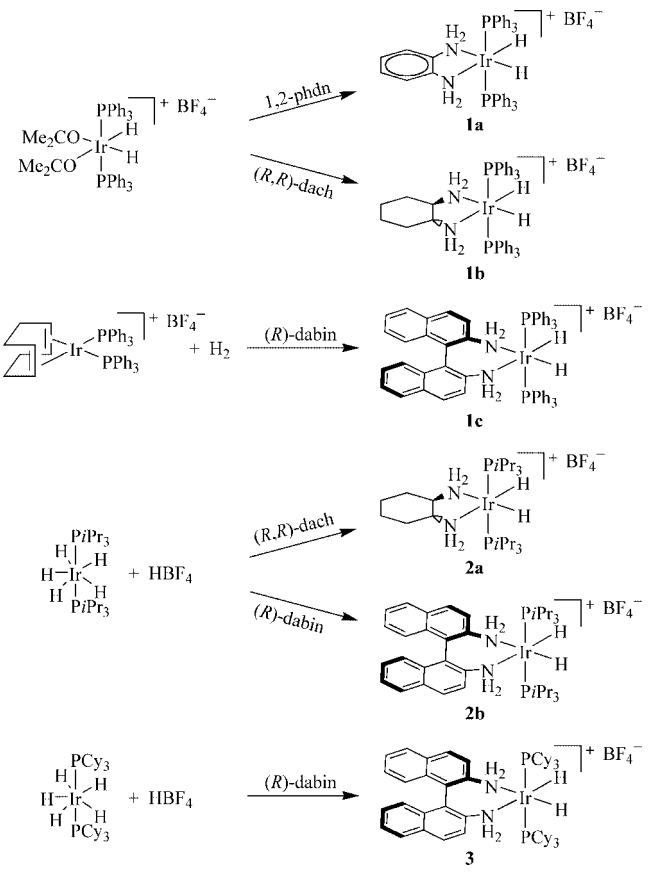
ligands by the two diamines to give $[IrH_2(1,2\text{-phdn})(PPh_3)_2]BF_4$ (**1a**)[6] and $[IrH_2\{(R,R)\text{-dach}\}(PPh_3)_2]BF_4$ (**1b**), as expected (Scheme 1). Since the weakly solvated dihydrides $[IrH_2(solv)_2(PR_3)_2]^+$ are formed in the presence of a coordinating solvent, either by hydrogenation of $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir(PR_3)_2]^+$[4] or by protonation of $[IrH_5(PR_3)_2]$ with a strong acid,[4c,5b] both the dieneiridium(I) complexes and the pentahydrides could be employed as precursors as well. For example, treatment of $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir(PPh_3)_2]BF_4$ with an equimolar amount of (*R*)-2,2′-diamino-1,1′-binaphthyl [(*R*)-dabin] in $CH_2Cl_2$ under hydrogen gave $[IrH_2\{(R)\text{-dabin}\}(PPh_3)_2]BF_4$ (**1c**) as an additional diamine-containing bis(triphenylphosphane) complex, whereas the triisopropyl- and tricyclohexylphosphane analogues $[IrH_2\{(R,R)\text{-dach}\}(PiPr_3)_2]BF_4$ (**2a**), $[IrH_2\{(R)\text{-dabin}\}(PiPr_3)_2]BF_4$ (**2b**), and $[IrH_2\{(R)\text{-dabin}\}(PCy_3)_2]BF_4$ (**3**) were obtained from $[IrH_5(PiPr_3)_2]$ or $[IrH_5(PCy_3)_2]$ by acidolysis with $HBF_4$ (54% in $Et_2O$) and subsequent reaction with the required diamine in a 1:1 molar ratio (Scheme 1).



Scheme 1. Synthesis of complexes **1**–**3**.

The *OC*-6-13 stereochemistry of compounds **1**–**3** (Scheme 1) follows from the observation of their IrH resonances between $\delta$ = –21 and –27 ppm, which is typical for hydridoiridium(III) complexes with hard donor ligands *trans* to H.[4b] Further confirmation of the coordination geometry depicted in Scheme 1 came from the *cis*-$^2J_{P,H}$ coupling constants of 16–18 Hz found in all cases.

Crystals of $[IrH_2(1,2\text{-phdn})(PPh_3)_2]BF_4$ (**1a**) suitable for an X-ray diffraction study were grown from dichloromethane. As anticipated, the structure determination revealed the presence of N–H···F hydrogen-bonded ion-pairs with the iridium atom in the close to octahedral coordination environment inferred from the NMR spectroscopic data above (Figure 1). The hydride ligands could not be located from the final density maps in any of the structures reported in this paper but were placed, with *d*(Ir–H) restrained to 1.6 Å, at the positions calculated by Orpen's HYDEX energy-minimizing procedure.[7,8] The metal-to-phosphane distances of 2.292(1) and 2.302(1) Å are slightly shorter than, but still comparable to, the Ir–P bond lengths previously reported by Crabtree for the structurally related acetone complex $[IrH_2(OCMe_2)_2(PPh_3)_2]BF_4$ [*d*(Ir–P) = 2.313 and 2.321 Å].[4c] A feature of interest is the coordination of the *ortho*-phenylenediamine ligand, with the two Ir–$NH_2$ distances amounting to 2.163(4) and 2.202(5) Å. The Ir–$NH_2$ linkages of **1a** tend to be longer than the iridium–amine bond lengths of, for example, (*OC*-6-12)-$[IrCl_2\{Me_2P(CH_2)_2NH_2\}_2]PF_6$ [*d*(Ir–$NH_2$) *trans* to Ir–N: 2.090 Å),[9a] (*OC*-6-43)-[Ir(H)(Cl)$\{Ph_2P(CH_2)_2NH_2\}_2$]Cl [*d*(Ir–N) *trans* to Ir–P: 2.136 and 2.137 Å),[10a] and (*OC*-6-13)-$[IrCl_2\{Ph_2P(CH_2)_2NH_2\}_2]BF_4$ [*d*(Ir–N) *trans* to Ir–P: 2.142 and 2.152 Å),[9b] which reflects the high *trans*-bond-weakening influence of the two hydrides opposite to the amine donors.

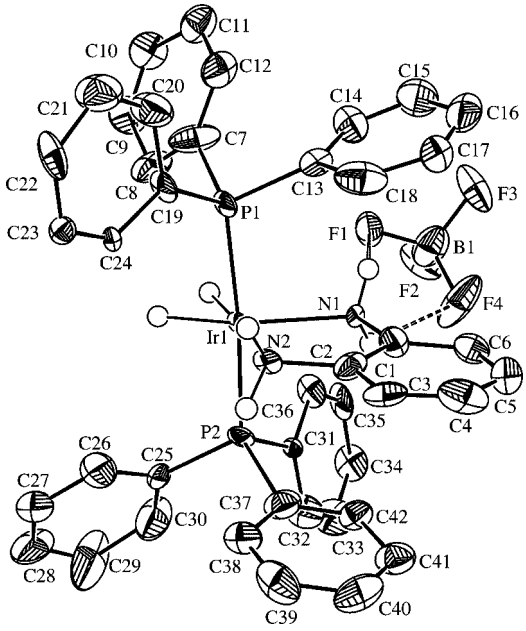


Figure 1. Structure of the ion-pair $[IrH_2(1,2\text{-phdn})(PPh_3)_2]BF_4$ (**1a**); phenyl H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ir1–P1 2.302(1), Ir–P2 2.292(1), Ir–N1 2.163(4), Ir–N2 2.202(5); P1–Ir–P2 174.37(6), P1–Ir–N1 93.5(1), P1–Ir–N2 90.8(1); hydrogen-bonding interactions (D–H, H···A, D···A [Å], D–H···A [°]): N1–H···F1 0.92, 2.27, 2.854(5), 121.1; N1–H···F4 0.92, 2.42, 2.997(6), 120.5; N2–H···F2_#1 0.92, 2.17, 2.863(7), 131.2; N2–H···F3_#1 0.92, 2.37, 3.001(6), 125.3. Symmetry transformation used to generate equivalent atoms: #1 = $x$ + 1/2, $y$ + 1/2, $z$.

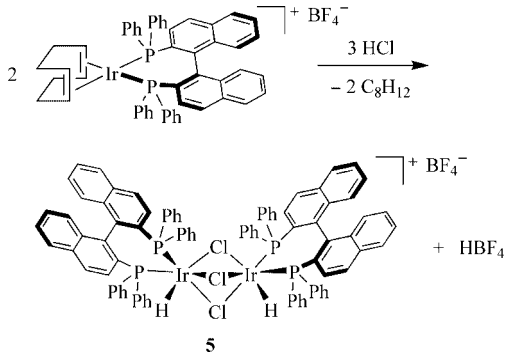
In exploratory studies aimed at synthesizing the $P_2/N_2$-coordinated hydride complexes $[Ir(H)(X)(H_2N\cap NH_2)(Ph_2P\cap PPh_2)]BF_4$ (X = H, Cl), which have one chiral bidentate rather than two achiral monodentate phosphorus ligands, two diene(diphosphane) complexes $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir(Ph_2P\cap PPh_2)]BF_4$ {$Ph_2P\cap PPh_2$ = (*R*)-binap[11] and (1*S*,2*S*)-1,2-bis(diphenylphosphanyl)cyclopentane [(*S*,*S*)-bdpcp]} were selected as potential starting materials. As mentioned by way of introduction, related rhodium chemistry has shown that the bis(chelates) $[Rh(H_2N\cap NH_2)\{(R)\text{-binap}\}]BF_4$ {$H_2N\cap NH_2$ = $H_2NCMe_2CMe_2NH_2$ (tmen), (1*R*,2*R*)-$H_2NCH(Ph)CH(Ph)NH_2$ [(*R*,*R*)-dpen], or (1*R*,2*R*)-1,2-$(H_2N)_2C_6H_{10}$ [(*R*,*R*)-dach]} are smoothly formed when $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Rh\{(R)\text{-binap}\}]BF_4$ is hydrogenated in the presence of the required diamine ligand.[1] In view of the greater stability of the Ir–H bond than the Rh–H bond, we expected that similar treatment of the diene(diphosphane) iridium precursors $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir(Ph_2P\cap PPh_2)]BF_4$ would result in the formation of mixed-ligand complexes $[IrH_2(H_2N\cap NH_2)(Ph_2P\cap PPh_2)]BF_4$ by oxidative addition of dihydrogen to initially formed $[Ir(H_2N\cap NH_2)(Ph_2P\cap PPh_2)]BF_4$ intermediates. However, only mixtures of various hydride-containing complexes were produced, from which none of the hoped-for compounds could be isolated.

Expecting that it might be easier to substitute the hard nitrogen donors for the σ,π-bonded diolefin ligand at the $Ir^{III}$ rather than the $Ir^{I}$ oxidation stage, we prepared the complex $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir(H)(Cl)\{(S,S)\text{-bdpcp}\}]BF_4$ (**4**) by oxidative addition of hydrogen chloride to its $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir\{(S,S)\text{-bdpcp}\}]BF_4$ precursor. Compound **4** was shown by NMR spectroscopy, together with an X-ray structure analysis, to bear *trans*-bonded chlorido and hydrido ligands. The structure consists of discrete $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir(H)(Cl)\{(S,S)\text{-bdpcp}\}]^+$ cations (Figure 2) and $BF_4^-$ anions. The Ir–Cl bond *trans* to the hydride is long at 2.490(4) Å,[12] which is entirely consistent with the strong *trans* influence of hydrido ligands.

In contrast to the "normal" oxidative addition of HCl to $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir\{(S,S)\text{-bdpcp}\}]BF_4$, the reaction of hydrogen chloride with $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir\{(R)\text{-binap}\}]BF_4$ did not lead to a mononuclear $Ir^{III}$ complex but instead gave the triply chlorido-bridged binuclear product $[\{(R)\text{-binap}\}_2Ir_2H_2(\mu\text{-}Cl)_3]BF_4$ (**5**) (Scheme 2). It is well known that $Ir^{III}$ has a pronounced tendency to form cationic[13] confacial-bioctahedral structures held together by three connecting mononegative donors such as halide, hydride, alkoxide, amide, and the like. Reported examples include the (*R*)-binap-coordinated complexes $[\{(R)\text{-binap}\}_2Ir_2H_2(\mu\text{-}OR)_2(\mu\text{-}Cl)]Cl$ (R = H, $CH_3$), which were obtained by oxidative addition of the O–H bonds of water and methanol



Scheme 2. Formation of diiridium complex **5**.

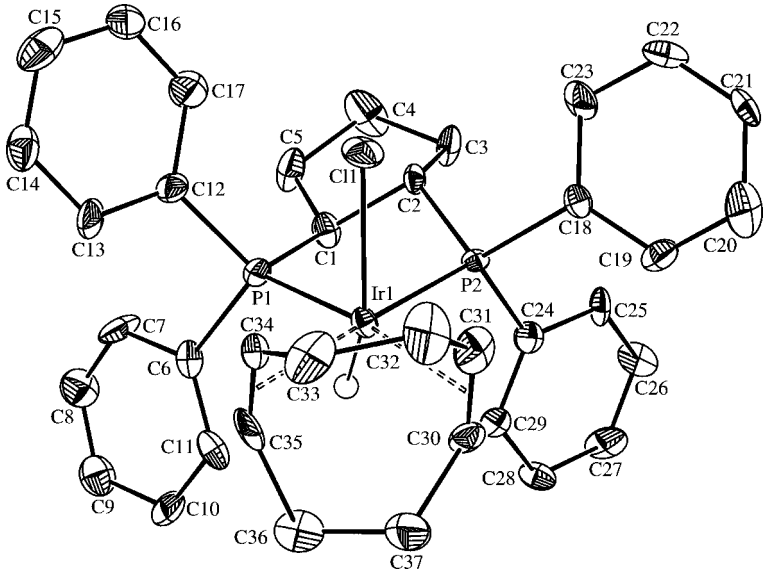


Figure 2. Structure of the cation of $[(\eta^4\text{-}1,5\text{-}C_8H_{12})Ir(H)(Cl)\{(S,S)\text{-bdpcp}\}]BF_4$ (**4**); carbon-bonded H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ir–Cl1 2.490(4), Ir–P1 2.332(4), Ir–P2 2.319(4); Cl1–Ir–P1 88.8(1), Cl1–Ir–P2 84.0(1), P1–Ir–P2 85.5(1).

to [{(*R*)-binap}$_2$Ir$_2$(μ-Cl)$_2$],[13h] as well as the recently described halide salts [{(*S*)-binap}$_2$Ir$_2$H$_2$(μ-X)$_3$]X (X = Cl, Br, I), which were formed by sequential treatment of [(η$^2$-C$_8$H$_{14}$)$_4$Ir$_2$(μ-Cl)$_2$] first with the chelate phosphane and then with aqueous HX.[13p]

We propose that [(η$^4$-1,5-C$_8$H$_{12}$)Ir{(*R*)-binap}]BF$_4$ reacts with hydrogen chloride to initially give an HCl adduct similar to **4**, where the greater bulkiness of the two "Ph$_2$Pnaphthyl" binap building blocks than that of the two "Ph$_2$Palkyl" halves of the chelate ring in the mononuclear complex

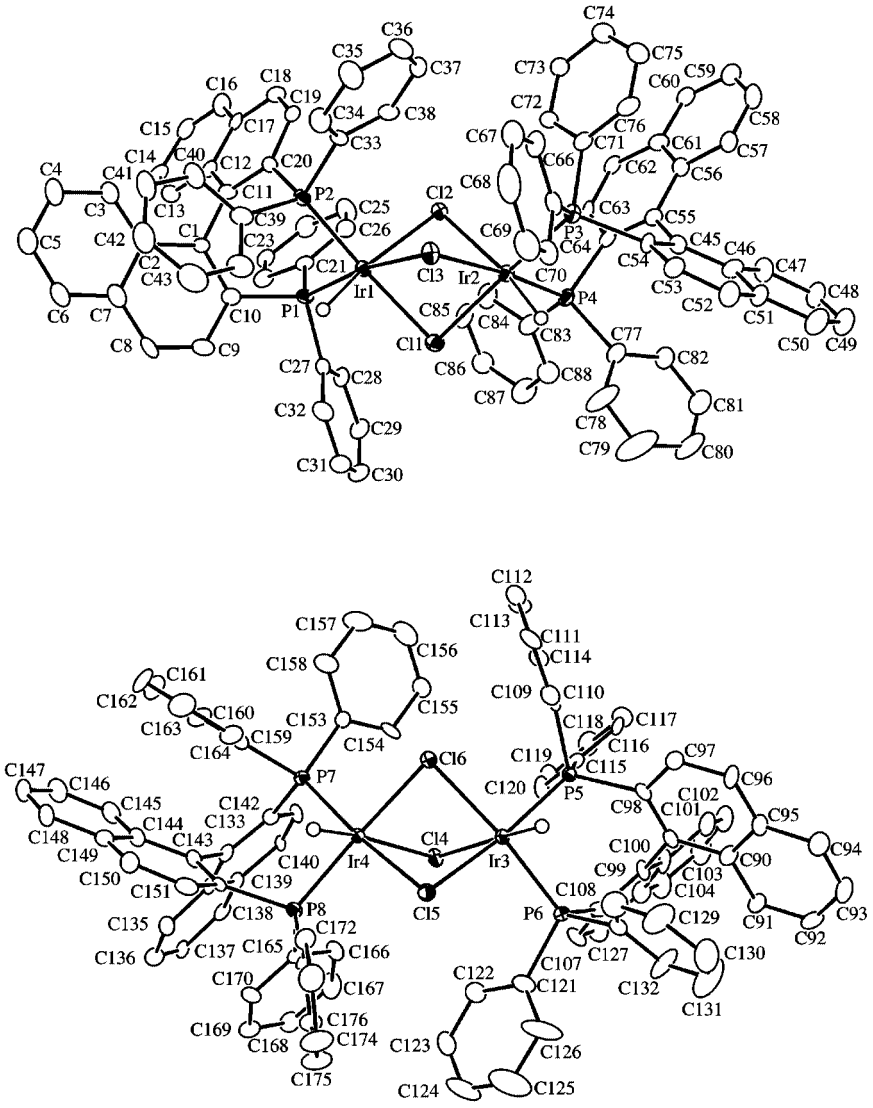

Figure 3. Structures of the two crystallographically independent cations of [{(*R*)-binap}$_2$Ir$_2$H$_2$(μ-Cl)$_3$]BF$_4$ (**5**); aryl H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°] for cation I: Ir1–Cl1 2.470(1), Ir1–Cl2 2.534(1), Ir1–Cl3 2.428(1), Ir1–P1 2.251(1), Ir1–P2 2.257(1), Ir2–Cl1 2.436(1), Ir2–Cl2 2.532(1), Ir2–Cl3 2.458(1), Ir2–P3 2.252(1), Ir2–P4 2.245(1); Cl1–Ir1–Cl2 78.99(4), Cl1–Ir1–Cl3 79.37(5), Cl1–Ir1–P1 94.37(5), Cl1–Ir1–P2 173.17(5), Cl2–Ir1–Cl3 79.27(4), Cl2–Ir1–P1 106.40(5), Cl2–Ir1–P2 100.72(5), Cl3–Ir1–P1 170.74(5), Cl3–Ir1–P2 93.85(5), P1–Ir1–P2 92.26(5), Cl1–Ir2–Cl2 79.65(4), Cl1–Ir2–Cl3 79.45(5), Cl1–Ir2–P3 170.01(5), Cl1–Ir2–P4 94.66(5), Cl2–Ir2–Cl3 78.77(4), Cl2–Ir2–P3 106.54(5), Cl2–Ir2–P4 100.37(5), Cl3–Ir2–P3 93.89(5), Cl3–Ir2–P4 174.11(5), P3–Ir2–P4 91.94(5), Ir1–Cl1–Ir2 86.10(1), Ir1–Cl2–Ir2 82.76(1), Ir1–Cl3–Ir2 86.52(1). Selected dihedral angles, given as (plane)/(plane) [°]: (Ir1,Cl1,Cl2)/(Ir2,Cl1,Cl2) 58.43(4), (Ir1,Cl1,Cl3)/(Ir2,Cl1,Cl3) 54.49(5), (Ir1,Cl2,Cl3)/(Ir2,Cl2,Cl3) 58.44(4), (Ir1,Cl1,Ir2)/(Ir1,Cl2,Ir2) 61.00(1), (Ir1,Cl1,Ir2)/(Ir1,Cl3,Ir2) 57.72(1), (Ir1,Cl2,Ir2)/(Ir1,Cl3,Ir2) 61.28(1), (naphthyl C1–C10)/(naphthyl C11–C20), 76.1(1); (naphthyl C45–C54)/(naphthyl C55–C64), 67.7(1). Corresponding parameters for cation II: Ir3–Cl4 2.530(1), Ir3–Cl5 2.426(1), Ir3–Cl6 2.463(1), Ir3–P5 2.259(1), Ir3–P6 2.250(1), Ir4–Cl4 2.542(1), Ir4–Cl5 2.452(1), Ir4–Cl6 2.440(1), Ir4–P7 2.260(1), Ir4–P8 2.257(1); Cl4–Ir3–Cl5 79.80(4), Cl4–Ir3–Cl6 79.03(4), Cl4–Ir3–P5 107.61(5), Cl4–Ir3–P6 98.80(5), Cl5–Ir3–Cl6 79.83(4), Cl5–Ir3–P5 168.85(5), Cl5–Ir3–P6 93.89(5), Cl6–Ir3–P5 93.21(5), Cl6–Ir3–P6 173.61(5), P5–Ir3–P6 93.18(5), Cl4–Ir4–Cl5 79.10(4), Cl4–Ir4–Cl6 79.23(4), Cl4–Ir4–P7 100.53(5), Cl4–Ir4–P8 105.97(5), Cl5–Ir4–Cl6 79.78(5), Cl5–Ir4–P8 92.68(5), Cl5–Ir4–P7 174.44(5), Cl6–Ir4–P7 94.69(5), Cl6–Ir4–P8 170.00(5), P7–Ir4–P8 92.74(5), Ir3–Cl4–Ir4 82.33(1), Ir3–Cl5–Ir4 86.38(1), Ir3–Cl6–Ir4 85.83(1); (Ir3,Cl4,Cl5)/(Ir4,Cl4,Cl5) 58.37(5), (Ir3,Cl4,Cl6)/(Ir4,Cl4,Cl6) 59.38(5), (Ir3,Cl5,Cl6)/(Ir4,Cl5,Cl6) 54.29(3), (Ir3,Cl4,Ir4)/(Ir3,Cl5,Ir4) 60.85(1), (Ir3,Cl4,Ir4)/(Ir3,Cl6,Ir4) 61.92(1), (Ir3,Cl5,Ir4)/(Ir3,Cl6,Ir4) 57.23(1), (naphthyl C89–C98)/(naphthyl C99–C108), 73.0(1); (naphthyl C133–C142)/(naphthyl C143–C152), 72.0(1).

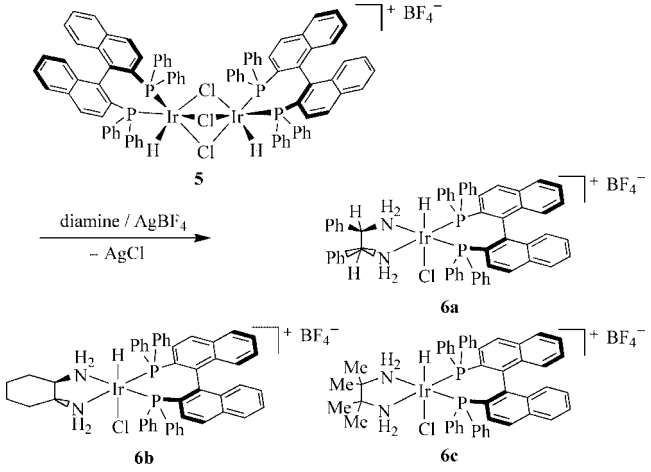
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

facilitates the decoordination of the cyclooctadiene ligand through "steric pressure".[14a,14b] Bridge-closing combination of the remaining "[{(*R*)-binap}Ir(H)(Cl)]$^+$ fragments would then form [{(*R*)-binap}$_2$Ir$_2$H$_2$(μ-Cl)$_2$]$^{2+}$, which stabilizes to **5** by the addition of an extra chloride ion provided by the excess of HCl.[14c]

The bimetallic structure of **5** was confirmed by X-ray analysis. Single crystals grown from an acetone/diethyl ether solvent mixture were found to have the idealized composition [{(*R*)-binap}$_2$Ir$_2$H$_2$(μ-Cl)$_3$]BF$_4$·Me$_2$CO·1/2 H$_2$O·1/4 Et$_2$O and to contain, in addition to the different solvent molecules, two crystallographically independent ion pairs in the asymmetric unit. Perspective views of the molecular models that resulted for the cationic parts are presented in Figure 3. The structures of the two cations are very close to $C_2$-symmetric, with the twofold rotation axes passing through the midpoints of the Ir···Ir vectors and the chlorido ligands Cl2 and Cl4 *trans* to the Ir–H bonds. In solution, this molecular $C_2$ symmetry is mirrored by a deceptively simple AA′BB′ $^{31}$P{$^1$H} NMR pattern arising from the two chiral diphosphane ligands (pairs of "doublets", where only $|^2J_{P,P} + {}^4J_{P,P}|$ = 20.0 Hz is resolved). The pair-wise shared coordination planes spanned by one metal center and two bridging chlorido ligands are inclined to each other at angles between 120.62° and 125.71°, with the interplanar angles of the Ir(μCl)Ir bridges varying from 118.08(1)° to 122.77(1)° (ranges of the supplementary dihedral angles given in the legend to Figure 3: 59.38(5)–54.29(3)° and 61.92(1)–57.23(1)°, respectively). The angles between the normals to the four pairs of naphthyl least squares planes amount to 67.7(1)° and 76.1(1)° in cation I and 72.0(1)° and 73.0(1)° in cation II. Though much less than the dihedral angle of 81.4° displayed by the pairs of naphthalene rings in the related [{(*R*)-binap}$_2$Ir$_2$H$_2$(μ-OCH$_3$)$_2$(μ-Cl)]$^+$ cation,[13h] these values clearly fall within the limits of about 65–77° that have previously been reported for several mono- and binuclear binap compounds of Ru$^{II}$, Rh$^{I}$, Ir$^{I}$, and Ir$^{III}$.[13p,15] As anticipated, the Ir–Cl bonds *trans* to Ir–H [2.530(1)–2.534(1) Å] are significantly longer than those opposite to the Ir–P bonds [2.426(1)–2.470(1) Å] and are amongst the longest Ir$^{III}$–μ–Cl distances reported to date.[16] The Ir–P bond lengths of **7** vary between 2.246(1) and 2.260(1) Å and thus compare favorably with the metal-to-phosphorus distances of 2.248 and 2.262 Å measured for the aforementioned chlorido/methoxido-bridged diiridium(III) complex.[13h] The obtuse P–Ir–P angles of 91.94(5)–93.18(5)° likewise closely resemble those of other structurally characterized iridium complexes bearing (*R*)- or (*S*)-binap ligands.[13h,13p,15g,15h]

Completely unexpectedly, the reaction of [(η$^4$-1,5-C$_8$H$_{12}$)-Ir(H)(Cl){(*S*,*S*)-bdpcp}]BF$_4$ (**4**) with different H$_2$N∩NH$_2$ chelate ligands did not result in diene/diamine exchange. Depending on the reaction conditions, the less basic aromatic or aliphatic amines 2,2′-diamino-1,1′-binaphthyl and 1,2-diphenylethylenediamine either left the compound unchanged or furnished mixtures with the dehydrochlorinated iridium(I) precursor [(η$^4$-1,5-C$_8$H$_{12}$)Ir{(*S*,*S*)-bdpcp}]BF$_4$. Complete removal of hydrogen chloride from the Ir$^{III}$ center was observed in the reaction of the HCl adduct with the stronger basic aliphatic diamine 1,2-(H$_2$N)$_2$C$_6$H$_{10}$. Brønsted base-assisted dehydrohalogenations, as observed between **4** and diamines, are the infrequently encountered reverse reaction of HX oxidative addition; they are comparatively common with Ir$^{III}$.[17] In fact, similar amine-induced eliminations of HCl have recently been reported for some triply chlorido-bridged binuclear hydrides of iridium(III) bearing trimethylene-linked N-heterocyclic carbenes (NHCs) as terminal ligands.[13o] Whereas those [{(NHC)(CH$_2$)$_3$(NHC)}$_2$Ir$_2$H$_2$(μ-Cl)$_3$]PF$_6$ dimers underwent complete degradation in the presence of nitrogen bases, binap-chelated diiridium complex **5** reacts with several diamines to smoothly produce the diamine(diphosphane) target compounds [Ir(H)(Cl)(H$_2$N∩NH$_2$){(*R*)-binap}]BF$_4$ [H$_2$N∩NH$_2$ = (*R*,*R*)-dpen (**6a**), (*R*,*R*)-dach (**6b**), and tmen (**6c**)] by nucleophilic opening of the chlorido bridges. In order to favor the formation of these three cationic species (Scheme 3), the liberated chloride was removed by precipitation with AgBF$_4$, although the addition of Ag$^+$ is not imperative with the completely aliphatic and, hence, more electron-rich diamines tmen and dach. Diiridium complex **5** does not undergo the bridge-opening reaction upon combination with (*R*)-2,2′-diamino-1,1′-binaphthyl, either because of too much steric pressure in the resulting [Ir(H)(Cl){(*R*)-dabin)}{(*R*)-binap}]$^+$ cation or because of a too low nucleophilicity of the aromatic (*R*)-dabin ligand.



Scheme 3. Synthesis of mixed-ligand complexes **6a**–**c**.

Complexes **6a**–**c** proved difficult to crystallize and therefore could only be characterized spectroscopically. Their $^1$H NMR spectra were found to display hydride signals at around $\delta$ = –20 ppm as doublets of doublets. Two $^2J_{P,H}$ coupling constants amounting to around 16 and 18 Hz place these hydrido ligands in a position *cis* to two chemically inequivalent binap P atoms which, accordingly, give rise to two $^{31}$P{$^1$H} doublets ($\delta$ = –13 to –10 and –1 ppm; *cis*-$^2J_{P,P} \approx$ 22 Hz). These data indicate that the stereochemistry of **6a**–**c** is either *OC*-6-43 with the hydride trans to Cl, as proposed for [Rh(H)(Cl){(*R*,*R*)-dpen}{(*R*)-binap}]-BF$_4$,[1] or *OC*-6-23, where the Ir–H bond is opposite to one

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the $NH_2$ functionalities. Although we could not corroborate the actual structure by X-ray analysis, the geometry with the hydride *trans* to chloride shown in Scheme 3 is favored over the *trans*-H–Ir–N alternative by comparison with the IrH NMR spectroscopic data of some [Ir(H)(Cl)(aminophosphane)$_2$]X chelate complexes having crystallographically established *OC*-6-43 stereochemistry, for example [Ir(H)(Cl)($H_2N(CH_2)_2PPh_2)_2$]Cl[10a] and [Ir(H)(Cl){*o*-HN(R)$C_6H_4PPh_2$}$_2$]X (R = Et, $CH_2Ph$; $X^-$ = $Cl^-$, $OH^-$, $MeCO_2^-$).[18] Similar to **6a**–**c**, all of these compounds display $\delta$(IrH) in the range –22 to –20 ppm with *cis*-$^2J$(P,H) ≈ 18 Hz.[19]

## Catalytic Hydrogenation of Acetophenone

Both the chiral chlorido-hydrido complexes [Ir(H)(Cl)($H_2N\cap NH_2$){(*R*)-binap}]$BF_4$ [$H_2N\cap NH_2$ = (*R*,*R*)-dpen (**6a**), (*R*,*R*)-dach (**6b**), or tmen (**6c**)] and the dihydrides [$IrH_2${$H_2N\cap NH_2$}$(PR_3)_2$]$BF_4$ [$H_2N\cap NH_2/PR_3$ = (*R*,*R*)-dach/$PPh_3$ (**1b**), (*R*)-dabin/$PPh_3$ (**1c**), (*R*,*R*)-dach/P*i*$Pr_3$ (**2a**), or (*R*)-dabin/P*i*$Pr_3$ (**2b**)] were investigated for their ability to form stereoselective >C=O hydrogenation catalysts. In fact, all of them catalyzed the asymmetric hydrogenation of acetophenone to (*S*)-1-phenylethanol at substrate-to-catalyst (*s*:*c*) ratios ranging from 200:1 to 5000:1 in the presence of a strong base (typically 50 equiv. of KOH) in alcoholic solution under $H_2$ (20 bar) at 40–60 °C (Table 1). The success of these hydrogenation reactions depends critically on the presence of extra base in the catalytic system and the use of a protic reaction medium. Thus, virtually no catalytic >C=O reduction occurred in alcohols in the absence of base or in an aprotic solvent such as benzene containing a basic additive. Methanol proved to be the solvent of choice, as reactions in ethanol and 2-propanol proceeded slower and resulted in reduced enantioselectivity (Table 1, entries 2–4).

The likelihood of the ketone reduction proceeding by direct metal-assisted transfer of $H^{\delta-}/H^{\delta+}$ equivalents from the $H_2$ molecule to the carbonyl dipole was substantiated by ruling out the alternative pathway involving $H^{\delta-}/H^{\delta+}$ transfer from the solvent. Thus, when a solution of acetophenone in $CH_3OH$ was hydrogenated with $D_2$ (10 bar) employing the combined **6b**/KOH catalyst, α-deuterated $PhCD(OH)CH_3$ was formed as the main alcohol product, which was demonstrated by NMR spectroscopy as described previously.[10b] The observation of minor amounts of $PhCH(OH)CH_3$ as a by-product of the deuteration reaction cannot be attributed to the methanol molecule serving as a hydrogen source because no formation of $PhCH(OH)CH_3$ or $PhCD(OH)CH_3$ was observed when the reaction was carried out in the absence of hydrogen gas in $CH_3OH$ or $CD_3OH$. The formation of the non-deuterated isotopomer rather points to "$D_2 + CH_3OH = CH_3OD + HD$" and "$HD + CH_3OH = CH_3OD + H_2$" exchange processes accompanying the catalysis. We have shown in previous work[10b] that the exchange of isotopes between a protic solvent and the hydrogen atmosphere, which is typical of heterolytic activation of the hydrogen molecule during reaction,[20] is a characteristic feature of iridium-based >C=O hydrogenation catalysts bearing ligands that, like the diamines used in the present study, have acidic primary or secondary amine ends.

Table 1. Enantioselective hydrogenation of acetophenone in the presence of base-modified iridium(III) precatalysts; $p(H_2)$ = 20 bar.

| No. | Precatalyst | *t* [h] | PhCH(OH)Me [%] | *ee* [%] (config.) |
|---|---|---|---|---|
| 1 | **6a**[a] | 1.5 | 100 | 82 (*S*) |

| 13 | **5**/(*R*,*R*)-dach[e] | 2 | 100 | 71 (*S*) |

[a] Acetophenone (5.0 mmol), 0.01 mmol of $Ir^{III}$ complex, KOH (50 equiv.), methanol (3 mL); *T* = 50 °C. [b] In ethanol at *s*:*c* = 500:1; *T* = 40 °C. [c] In 2-propanol at *s*:*c* = 200:1; *T* = 60 °C. [d] 33.0 mmol of acetophenone, $6.6\times10^{-3}$ mmol of $Ir^{III}$ complex, and 0.33 mmol of KOH in methanol (4 mL); *T* = 50 °C. [e] In situ catalysts activated with 25 equiv. of KOH in methanol; *s*:*c* = 250:1, *T* = 50 °C.

As compared to complexes **1b**/**1c** and **2a**/**2b**, where only the diamine ligands can contribute to the (poor) stereoselective outcome of the catalytic runs (Table 1, entries 6–9), compounds **6a**–**c**, which possess an additional (*R*)-binap ligand, form much more enantioselective systems, as expected. Best results of 82–84% *ee* were obtained with the preformed complex [Ir(H)(Cl){(*R*,*R*)-dpen}{(*R*)-binap}]$BF_4$ (**6a**) and its in situ generated equivalent [{(*R*)-binap}$_2Ir_2H_2(\mu\text{-}Cl)_3$]$BF_4$/(*R*,*R*)-dpen [**5**/(*R*,*R*)-dpen; Table 1, entries 1 and 12).[21] With (*R*,*R*)-dach as the diamine co-ligand, the *ee* achieved with both the preformed and the in situ catalysts **6b** and **5**/(*R*,*R*)-dach was seen to drop to 71–75% (Table 1, entries 2 and 13). Further replacement of the (*R*,*R*)-dach chelate by the achiral diamine $H_2NCMe_2CMe_2NH_2$ in precatalyst **6c** left the optical yield of the (*S*) isomer (73%; Table 1, no. 5) essentially unchanged, thus suggesting that it is preferentially the diphosphane which determines the asymmetric induction. Comparison of these results with those obtained with isoelectronic $Ru^{II}$-based catalysts reveals some interesting trends.

At first glance, the combined system [Ir(H)(Cl)(tmen){(*R*)-binap}]$BF_4$/KOH/MeOH appears to be superior in selectivity [73% for (*S*)-PhCH(OH)Me] to the [Ru(H)(Cl)(tmen){(*R*)-binap}]-derived dihydride [Ru(H)$_2$(tmen){(*R*)-binap}], which produced the (*S*) isomer of 1-phenylethanol in only 6–14% yield when used in 2-propanol without added base.[2b,2c] However, the seemingly poor performance of this ruthenium complex results from catalyst deactivation by formation of diastereomeric alkoxides such as [Ru(H){(*S*)-OCH(Me)Ph}(tmen){(*R*)-binap}] and [Ru(H)-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

{(*R*)-OCH(Me)Ph}(tmen){(*R*)-binap}] during the build up of the acidic product alcohol. This unwanted side reaction can be prevented by the addition of base or by lowering the polarity of the solvent. Running the Ru-catalyzed reaction in 2-propanol in the presence of base or in benzene (where Ir complex **6c** remains completely inactive) thus established an inherent enantioselectivity of 51–68% (*R*) for the ruthenium-based (*R*)-binap/tmen system,[2b,2c] which is therefore comparable to **6c** with respect to the *ee* values that can be attained but yields the opposite enantiomer. In the presence of base, the $Ru^{II}$ complex [Ru(H)(Cl){(*R*,*R*)-dach}{(*R*)-binap}] catalyzes the hydrogenation of acetophenone (neat or dissolved in benzene) to afford (*S*)-PhCH(OH)Me in 88% *ee*,[2a,2c] which makes it a somewhat more selective catalyst than [Ir(H)(Cl){(*R*,*R*)-dach}{(*R*)-binap}]$BF_4$ (**6b**), which gives the (*S*) form of the alcohol in only around 75% *ee*. With base-modified [Ru(H)(Cl){(*R*,*R*)-dpen}{(*R*)-binap}], the Morris group has achieved 73% *ee* for the formation of (*S*)-PhCH(OH)Me,[2a] while the catalytic species generated in basic media from the dichlorido precursor [$RuCl_2$\{(*S*,*S*)-dpen\}{(*S*)-tolbinap}] (tolbinap is the di-*p*-tolyl analogue of binap) afforded the (*R*) enantiomer in 78–83% yield, as reported independently by Noyori and coworkers[22] and Rautenstrauch and Morris et al.[2d] Hence, the selectivity of the corresponding iridium-based system [Ir(H)(Cl){(*R*,*R*)-dpen}{(*R*)-binap}]$BF_4$/KOH/MeOH [82% *ee* for the (*S*) isomeric alcohol] compares favorably with that observed for the two established ruthenium catalysts possessing the same ligands. However, the $Ru^{II}$ complexes, which work very fast at substrate-to-catalyst ratios as high as $10^5$–$10^6$, form much more active systems: the most active $Ir^{III}$ catalyst studied in this work is formed from the only moderately selective complex **6b** in the presence of 50 equiv. of KOH. This system furnished 62% of 1-phenylethanol within 3 h at *s*:*c* = 5000, albeit with a reduced selectivity of 66% *ee* for the (*S*) isomer (Table 1, entry 11). Under identical conditions, the most selective precatalyst **6a** maintains an optical yield of 80% *ee* (*S*) but shows poor activity, transforming only 11% of the ketone to the product alcohol (Table 1, entry 10).

## Conclusions

This work has shown that cationic dihydridoiridium(III) complexes with two monodentate phosphanes and one chelating diamine can easily be made by treating different $H_2N\cap NH_2$ ligands with a number of readily accessible substitutionally labile precursors. The preparation of the mixed-ligand bis(chelates) [Ir(H)(Cl)($H_2N\cap NH_2$){(*R*)-binap}]$BF_4$ [$H_2N\cap NH_2$ = (*R*,*R*)-dpen (**6a**), (*R*,*R*)-dach (**6b**), or tmen (**6c**)] is more involved and requires dinuclear [{(*R*)-binap}$_2$$Ir_2H_2(\mu\text{-}Cl)_3$]$BF_4$ as a synthetic intermediate. While *cis*-dihydrides such as [$IrH_2$\{(*R*,*R*)-dach\}$(PR_3)_2$]$BF_4$ and [$IrH_2$\{(*R*)-dabin\}$(PR_3)_2$]$BF_4$ (R = *i*Pr, Ph) are only poor (pre)catalysts for the enantioselective hydrogenation of acetophenone to 1-phenylethanol, the combined systems (**6a**–**c**)/KOH/MeOH catalyze the formation of the product alcohol with a degree of enantioselectivity which, in the most favorable cases, closely matches that of established isoelectronic $Ru^{II}$-based catalysts containing identical phosphorus and nitrogen donor ligands.

## Experimental Section

**General:** All manipulations were performed under nitrogen or argon, unless stated otherwise. Solvents were distilled from the appropriate drying agents prior to use. NMR: Bruker DPX 300 (300.1 MHz for $^1H$, 75.5 MHz for $^{13}C$, and 121.5 MHz for $^{31}P$) with $SiMe_4$ as internal or $H_3PO_4$ as external standard (downfield positive) at ambient temperature ("m" = deceptively simple multiplet). GC: Shimadzu GC-17A (FID). Silver tetrafluoroborate, $HBF_4$ (54% in $Et_2O$), and the diphosphane and diamine ligands (*R*)-2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl [(*R*)-binap], 1,2-phenylenediamine (1,2-phdn), (*R*)-2,2′-diamino-1,1′-binaphthyl [(*R*)-dabin], (1*R*,2*R*)- and (1*S*,2*S*)-1,2-diphenylethylenediamine [(*R*,*R*)-, (*S*,*S*)-dpen], and (1*R*,2*R*)-1,2-diaminocyclohexane [(*R*,*R*)-dach] were used as purchased. 1,1′,2,2′-Tetramethylethylenediamine (tmen),[23] (1*S*,2*S*)-1,2-bis(diphenylphosphanyl)cyclopentane [(*S*,*S*)-bdpcp],[24] [$(\eta^4\text{-}1,5\text{-}C_8H_{12})_2Ir_2(\mu\text{-}Cl)_2$],[25] [$(\eta^4\text{-}1,5\text{-}C_8H_{12})$-$Ir(PPh_3)_2$]$BF_4$,[4d,4e] [$IrH_2(OCMe_2)_2(PPh_3)_2$]$BF_4$,[4d,4e] [$IrH_5$(P-*i*$Pr_3)_2$],[5d] and [$IrH_5(PCy_3)_2$][5e] were prepared according to published procedures or slight modifications thereof. The complex [$(\eta^4$-1,5-$C_8H_{12})$Ir\{(*R*)-binap\}]$BF_4$ was previously made from [$(\eta^4$-1,5-$C_8H_{12})$$Ir(NCMe)_2$]$BF_4$ which, in turn, was synthesized from [$(\eta^4$-1,5-$C_8H_{12})_2Ir_2(\mu\text{-}Cl)_2$] via [$(\eta^4$-1,5-$C_8H_{12})_2Ir$]$BF_4$ as a further intermediate.[11] A more direct route is given here: A 1:2:2 molar mixture of [$(\eta^4$-1,5-$C_8H_{12})_2Ir_2(\mu\text{-}Cl)_2$] (425 mg, 0.63 mmol), (*R*)-binap (785 mg, 1.26 mmol), and $AgBF_4$ (245 mg, 1.26 mmol) in 30 mL of methanol was stirred for 24 h at ambient conditions with the exclusion of light. Precipitated silver chloride was then removed by filtration through diatomaceous earth (Celite® 521), which was washed with small portions of $CH_2Cl_2$ until the residue on the filter was colorless. Evaporation of the filtrate to a final volume of about 2 mL followed by dilution with 30 mL of diethyl ether gave the product as a raspberry-colored solid, which was filtered off, washed with diethyl ether (3 × 5 mL), and dried under vacuum; yield: 950 mg (75%). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 1.84–2.30 (m, 8 H, $CH_2$), 4.15, 4.40 (both m, 2 H each, both CH), 6.39–7.78 (m, 32 H, aryl H) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 16.05 (s) ppm [ref.[11] $\delta$ = 15.1 ppm in $CDCl_3$]. $C_{52}H_{44}BF_4IrP_2$ (1008.9): calcd. C 61.85, H 4.39; found C 62.08, H 4.54.

[$(\eta^4$-1,5-$C_8H_{12})$Ir\{(*S*,*S*)-bdpcp\}]$BF_4$ was isolated in 60% yield from a similar 1:2:2 reaction of [$(\eta^4$-1,5-$C_8H_{12})_2Ir_2(\mu\text{-}Cl)_2$] with $AgBF_4$ and the diphosphane in methanol: $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 1.16, 1.70–2.36 (both m, 2 + 12 H, both $CH_2$), 2.74 (m, 2 H, PCH), 4.00, 4.73 (both m, 2 H each, both diene CH), 7.31–7.89 (m, 20 H, aryl H) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 20.70 (s) ppm. $C_{37}H_{40}BF_4IrP_2$ (825.70): calcd. C 53.82, H 4.88; found C 53.61, H 4.71.

**[$IrH_2$(1,2-phdn)($PPh_3)_2$]$BF_4$ (1a):** A solution of [$IrH_2(OCMe_2)_2$-$(PPh_3)_2$]$BF_4$ (440 mg, 0.49 mmol) in 15 mL of thf was stirred with 1,2-phenylenediamine (55 mg, 0.50 mmol) at room temperature. After a short while the product separated from the reaction mixture as a colorless solid, which was filtered off, washed with diethyl ether (2 × 3 mL), and dried under vacuum. Yield: 198 mg (44%). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = –20.84 (t, $^2J_{P,H}$ = 16.7 Hz, 2 H, $IrH_2$), 4.04 (br., 4 H, $NH_2$), 6.77, 7.03 (AA′BB′-type m, 4 H, phenylene H), 7.30–7.51 (m, 30 H, phenyl H) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 128.58, 129.66 (both s, phenylene C-3,6 and C-4,5), 129.88 (t, $^3J_{P,C}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

= 20.2 Hz, phenyl C-3,5), 131.70 (s, phenyl C-4), 132.26 (t, $^1J_{P,C}$ = 103.9 Hz, phenyl C-1), 133.99 (t, $^2J_{P,C}$ = 24.5 Hz, phenyl C-2,6), 139.81 (phenylene C-1,2) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 24.49 (s) ppm. $C_{42}H_{40}BF_4IrN_2P_2$ (913.71): calcd. C 55.21, H 4.41, N 3.07; found C 54.71, H 4.25, N 2.72.

**$[IrH_2\{(R,R)$-dach$\}(PPh_3)_2]BF_4$ (1b):** This complex was prepared as described for **1a** from $[IrH_2(OCMe_2)_2(PPh_3)_2]BF_4$ (200 mg, 0.22 mmol) and the diamine ligand (25 mg, 0.22 mmol) in 10 mL of thf. Yield: 121 mg (60%) of a colorless solid. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = –21.07 (t, $^2J_{P,H}$ = 17.6 Hz, 2 H, $IrH_2$), 0.33, 0.71, 1.20–1.33, 1.39, 1.75 (all m, 2 + 2 + 4 + 2 + 2 H, $CH_2$ and $NH_2$), 2.79 (m, 2 H, CH), 7.4–7.7 (m, 30 H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 25.13 (s, $C_6H_{10}$ C-4,5), 36.28 (s, $C_6H_{10}$ C-3,6), 60.96 (s, $C_6H_{10}$ C-1,2), 129.96 (t, $^3J_{P,C}$ = 20.2 Hz, phenyl C-3,5), 131.62 (s, phenyl C-4), 133.66 (t, $^1J_{P,C}$ = 104.0 Hz, phenyl C-1), 134.10 (t, $^2J_{P,C}$ = 24.6 Hz, phenyl C-2,6) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 21.92 (s) ppm. $C_{42}H_{46}BF_4IrN_2P_2$ (919.81): calcd. C 54.84, H 5.04, N 3.05; found C 54.45, H 5.49, N 2.91.

**$[IrH_2\{(R)$-dabin$\}(PPh_3)_2]BF_4$ (1c):** A solution of $[(\eta^4$-1,5-$C_8H_{12})$-$Ir(PPh_3)_2]BF_4$ (106 mg, 0.12 mmol) and an equimolar quantity of (*R*)-dabin (34 mg) in 10 mL of $CH_2Cl_2$ was stirred for 20 min under an atmosphere of hydrogen, which caused the mixture to change color from red to pale yellow. The off-white product was isolated by adding diethyl ether (80 mL), then washed with $Et_2O$ and dried under vacuum. Yield: 109 mg (83%). $^1H$ NMR ([D$_6$]acetone): $\delta$ = –23.48 (t, $^2J_{P,H}$ = 18.1 Hz, 2 H, $IrH_2$), 3.62 (br., 4 H, $NH_2$), 5.90, 6.05, 6.44 (all d, $^3J_{H,H}$ = 8.8, 10.4, and 8.2 Hz, 2 H each, all aryl H), 7.17, 7.28, 7.37, 7.91 (all m, 44 H, aryl H) ppm. $^{31}P\{^1H\}$ NMR ([D$_6$]acetone): $\delta$ = 24.33 (s) ppm. Complex **1c** as well as its analogues **2a**, **2b**, and **3** were found to retain varying amounts of residual $CH_2Cl_2$ solvent so that no satisfactory elemental analyses could be obtained: $C_{56}H_{48}BF_4IrN_2P_2$ (1090.0): calcd. C 61.71, H 4.44, N 2.57; found C 59.45, H 4.38, N 2.31; calcd. for $C_{56}H_{48}BF_4IrN_2P_2{\cdot}CH_2Cl_2$ (1162.9): calcd. C 57.84, H 4.33, N 2.41.

**$[IrH_2\{(R,R)$-dach$\}(P\mathit{i}Pr_3)_2]BF_4$ (2a):** Tetrafluoroboric acid (54% in $Et_2O$) was added dropwise to a solution of $[IrH_5(P\mathit{i}Pr_3)_2]$ (525 mg, 1.02 mmol) in 15 mL of benzene until no further evolution of hydrogen was observed. The diamine ligand (116 mg, 1.02 mmol) was then added and the resulting mixture stirred for 1 h at room temperature. The residue remaining after evaporation to dryness was redissolved in 5 mL of $CH_2Cl_2$ and the product was isolated as an off-white solid by adding 50 mL of diethyl ether. Yield: 418 mg (57%). $^1H$ NMR ($C_6D_6$): $\delta$ = –23.28 (t, $^2J_{P,H}$ = 18.0 Hz, 2 H, $IrH_2$), 0.58 (m, 4 H, $CH_2$), 1.19 (dd, $^3J_{H,H}$ = 7.1, $^3J_{P,H}$ = 15.4 Hz, 36 H, $CH_3$), 1.37 (m, 4 H, $CH_2$), 2.17 (m, 6 H, PCH), 2.46, 2.60 (both br., 2 H each, both $NH_2$), 3.88 (m, 2 H, NCH) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 44.02 (s) ppm. $C_{24}H_{58}BF_4IrN_2P_2$ (715.71): calcd. C 40.28, H 8.17, N 3.91; found C 39.13, H 7.90, N 3.78; calcd. for $C_{24}H_{58}BF_4IrN_2P_2{\cdot}CH_2Cl_2$ (800.64): calcd. C 37.50, H 7.55, N 3.50. Compounds **2b** and **3** were obtained analogously:

**$[IrH_2\{(R)$-dabin$\}(P\mathit{i}Pr_3)_2]BF_4$ (2b):** Synthesized from $[IrH_5(P\mathit{i}Pr_3)_2]$ (228 mg, 0.44 mmol), treated with $HBF_4$ as described above, and (*R*)-dabin (125 mg, 0.44 mmol) in 15 mL of benzene in 82% yield (320 mg). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = –26.56 (t, $^2J_{P,H}$ = 18.3 Hz, 2 H, $IrH_2$), 0.86 (dd, $^3J_{H,H}$ = 6.6, $^3J_{P,H}$ = 14.8 Hz, 36 H, $CH_3$), 2.06 (m, 6 H, PCH), 4.98, 5.10 (both br., 2 H each, both $NH_2$), 6.69 (d, $^3J_{H,H}$ = 8.8 Hz, 2 H, aryl 3-H), 7.15 ("t", $\Sigma^3J_{H,H}$ = 15.0 Hz, 2 H, aryl 6-H), 7.35 (m, 4 H, aryl 7,8-H), 7.82 (d, $^3J_{H,H}$ = 8.2 Hz, 2 H, aryl 5-H), 7.98 (d, $^3J_{H,H}$ = 8.8 Hz, 2 H, aryl 4-H) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 44.35 (s) ppm. $C_{38}H_{60}BF_4IrN_2P_2$ (885.87): calcd. C 51.52, H 6.83, N 3.16; found C 49.73, H 6.60, N 3.08; calcd. for $C_{38}H_{60}BF_4IrN_2P_2{\cdot}CH_2Cl_2$ (970.81): calcd. C 48.25, H 6.44, N 2.89.

**$[IrH_2\{(R)$-dabin$\}(PCy_3)_2]BF_4$ (3):** Synthesized from $[IrH_5(PCy_3)_2]$ (115 mg, 0.15 mmol), treated with $HBF_4$ as outlined for **2a**, and the diamine (43 mg, 0.15 mmol) in 10 mL of benzene in 80% yield (135 mg). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = –26.57 (t, $^2J_{P,H}$ = 18.1 Hz, 2 H, $IrH_2$), 1.15–1.87 (m, 66 H, cyclohexyl H), 2.06 (m, 6 H, PCH), 4.99, 5.21 (both br., 2 H each, both $NH_2$), 6.82 (d, $^3J_{H,H}$ = 8.8 Hz, 2 H, aryl 3-H), 7.15 ("t", $\Sigma^3J_{H,H}$ = 15.0 Hz, 2 H, aryl 6-H), 7.42 (m, 4 H, aryl 7,8-H), 7.98 (d, $^3J_{H,H}$ = 8.2 Hz, 2 H, aryl 5-H), 8.10 (d, $^3J_{H,H}$ = 8.8 Hz, 2 H, aryl 4-H) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 20.92 (s) ppm. $C_{56}H_{84}BF_4IrN_2P_2$ (1126.27): calcd. C 59.72, H 7.52, N 2.49; found C 58.66, H 7.14, N 2.32; calcd. for $C_{56}H_{84}BF_4IrN_2P_2{\cdot}CH_2Cl_2$ (1211.2): calcd. C 56.52, H 7.16, N 2.31.

**$[(\eta^4$-1,5-$C_8H_{12})Ir(H)(Cl)\{(S,S)$-bdpcp$\}]BF_4$ (4):** Dropwise addition of a saturated solution of hydrogen chloride in diethyl ether to a suspension of $[(\eta^4$-1,5-$C_8H_{12})Ir\{(S,S)$-bdpcp$\}]BF_4$ (204 mg, 0.25 mmol) in 20 mL of thf gave a clear yellow solution, from which the product separated within 1 h as pale-yellow microcrystals. Yield (after washing three times with 2 mL of $Et_2O$ and drying): 190 mg (89%). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = –14.05 (dd, *cis*-$^2J_{P,H}$ = 7.1 and 11.5 Hz, 1 H, IrH), 0.96, 1.47 (both m, 1 H each, both $CH_2$), 1.85–2.86 (m, 14 H, $CH_2$ and phosphane CH), 3.89, 4.27, 5.32 (all m, 1 + 2 + 1 H, diene CH), 7.21–7.82 (m, 20 H, aryl H) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = 6.03, 15.30 (both d, $J_{P,P}$ = 15.6 Hz) ppm. $C_{37}H_{41}BClF_4IrP_2$ (862.16): calcd. C 51.55, H 4.79; found C 50.98, H 4.66.

**$[\{(R)$-binap$\}_2Ir_2H_2(\mu$-Cl$)_3]BF_4$ (5):** A solution of dry HCl gas in diethyl ether was added dropwise to a stirring solution of $[(\eta^4$-1,5-$C_8H_{12})Ir\{(R)$-binap$\}]BF_4$ (205 mg, 0.20 mmol) in 10 mL of thf under ambient conditions. The red mixture gradually became yellow and the addition of $HCl{\cdot}Et_2O$ was stopped when no further color change was discernible. The product was precipitated after stirring for an additional 10 min and concentration of the solution to about 1 mL by adding 20 mL of diethyl ether. It was then washed twice with 2 mL of $Et_2O$ and dried under vacuum. Yield: 172 mg (94%). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = –22.73 (dd, $^2J_{P,H}$ = 15.6 and 21.5 Hz, 2 H, IrH), 6.30–8.03 (m, 64 H, aryl H) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = –6.54, 1.59 (both AA′BB′-type "d", $|^2J_{P,P} + {}^4J_{P,P}|$ = 20.0 Hz) ppm. $C_{88}H_{66}BCl_3F_4Ir_2P_4$ (1825.0): calcd. C 57.89, H 3.65; found C 57.83, H 3.50.

**$[Ir(H)(Cl)\{(R,R)$-dpen$\}\{(R)$-binap$\}]BF_4$ (6a):** A mixture of (*R*,*R*)-dpen (44 mg, 0.21 mmol) and $AgBF_4$ (20 mg, 0.10 mmol) in 5 mL of thf was added to a solution of **5** (185 mg, 0.10 mmol) in 5 mL of thf. After stirring for 30 min under ambient conditions, the precipitate of AgCl was filtered off and the filtrate was concentrated to about 1 mL. Precipitation with 20 mL of diethyl ether, followed by filtration and washing with $Et_2O$ (2 × 3 mL) gave 108 mg (47%) of the product as a yellowish white solid. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = –19.81 (dd, $^2J_{P,H}$ = 15.9 and 18.0 Hz, 1 H, IrH), 2.91, 3.00, 3.29, 3.89 (all br., 1 H each, $NH_2$), 4.39 (m, 2 H, CH), 6.18–8.12 (m, 42 H, aryl H) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = –9.99, –0.64 (both d, $J_{P,P}$ = 22.3 Hz) ppm. $C_{58}H_{49}BClF_4IrN_2P_2$ (1150.5): calcd. C 60.55, H 4.29, N 2.43; found C 61.15, H 4.53, N 2.38. Similar procedures were used for the preparation of complexes **6b** and **6c**.

**$[Ir(H)(Cl)\{(R,R)$-dach$\}\{(R)$-binap$\}]BF_4$ (6b):** Synthesized from **5** (100 mg, 0.05 mmol) and the diamine (13 mg, 0.11 mmol) in 10 mL of thf. Yield: 84 mg (73%). $^1H$ NMR ($CD_2Cl_2$): $\delta$ = –20.35 (dd, $^2J_{P,H}$ = 15.5 and 18.2 Hz, 1 H, IrH), 1.19–2.09 (m, 8 H, $CH_2$), 2.85 (br., 4 H, $NH_2$), 3.01, 4.81 (both m, 1 H each, both CH), 6.28–8.15 (m, 32 H, aryl H) ppm. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta$ = –10.69, –1.10 (both d, $J_{P,P}$ = 22.3 Hz) ppm. $C_{50}H_{47}BClF_4IrN_2P_2$ (1052.4): calcd. C 57.07, H 4.50, N 2.66; found C 56.96, H 4.32, N 2.43.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**[Ir(H)(Cl)(tmen){(*R*)-binap}]$BF_4$ (6c):** Synthesized from **5** (120 mg, 0.07 mmol) and the diamine ligand (16 mg, 0.14 mmol) in thf (10 mL). Yield: 64 mg (48%). $^1$H NMR ($CD_2Cl_2$): $\delta$ = –20.00 (dd, $^2J_{P,H}$ = 15.6 and 17.4 Hz, 1 H, IrH), 1.02, 1.08, 1.12, 1.20 (all s, 3 H each, all $CH_3$), 2.06, 2.37, 3.96, 4.85 (all br., 1 H each, all $NH_2$), 6.23–8.12 (m, 32 H, aryl H) ppm. $^{31}$P{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = –12.92, –1.10 (both d, $J_{P,P}$ = 22.4 Hz) ppm. $C_{50}H_{49}BClF_4IrN_2P_2$ (1054.4): calcd. C 56.96, H 4.68, N 2.66; found C 56.83, H 4.58, N 2.34.

**General Procedure for Catalytic >C=O Hydrogenation:** A 10-mL Schlenk tube equipped with a small magnetic stirring bar was charged with an alcoholic solution of the catalyst complex (typically 0.01 mmol in 3.0 mL of methanol). The required amounts of potassium hydroxide and acetophenone (see Table 1) were then added, the mixture was stirred for 10 min under ambient conditions, and the tube was inserted into an argon-filled stainless steel autoclave. The autoclave was sealed and vented several times with $H_2$ (Messer–Griesheim; 99.999%), subsequently pressurized to 20 bar, and the contents stirred at 40–60 °C. At the end of the reaction, the pressure was vented, the solvent removed under vacuum, and the residue was diluted with diethyl ether to precipitate the catalyst as a brownish black solid. The solution was decanted and chromatographed on a silica gel column using diethyl ether as the eluent. Volatile material was distilled off and the mixture of products was analyzed by $^1$H NMR spectroscopy. Conversions and product compositions were determined on the basis of the integrations of the PhC(O)C$H_3$ and PhCH(OH)C$H_3$ signals. Enantiomeric excesses were measured by GC using a Chrompack Chirasil-Dex CB column.

**X-ray Structure Determinations:** The crystal used for the structure analysis of **1a** was grown from dichloromethane. Recrystallization of **4** and **5** from acetone/diethyl ether mixtures afforded single crystals of solvent-containing addition compounds identified as [($\eta^4$-1,5-$C_8H_{12}$)Ir(H)(Cl){(*S*,*S*)-bdpcp}]$BF_4$·$Me_2CO$ and [{(*R*)-binap}$_2$-$Ir_2H_2(\mu$-Cl)$_3$]$BF_4$·$Me_2CO$·1/2 $H_2O$·1/4 $Et_2O$ ("**4·Me$_2$CO**" and "**5·solv**" hereafter). Diffraction measurements were made at –173(2) °C with a Bruker-Nonius Kappa CCD instrument for compounds **1a** and **5·solv** and at –160(2) °C with an Enraf–Nonius CAD4 MACH3 diffractometer for **4·Me$_2$CO**, both of which used Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å); diffraction data were corrected for absorption by appropriate numerical[26] (**1a**: $T_{min}$ = 0.277, $T_{max}$ = 0.801), refined[27] (**4·Me$_2$CO**: $T_{min}$ = 0.227, $T_{max}$ = 0.621), or empirical[28] (**5·solv**: $T_{min}$ = 0.738, $T_{max}$ = 1.000) methods. The structures were solved by direct methods and subsequently refined by full-matrix (**1a**, **4·Me$_2$CO**) or, in view of the large dimensions of **5·solv**, by block-matrix least-squares procedures on $F^2$ with allowance for anisotropic thermal motion of all non-hydrogen atoms employing both the SHELXTL NT 6.12[29] and the WinGX[30a] package with some of the relevant programs (SIR-97,[31] SHELXL-97,[32] XHYDEX,[7] ORTEP-3[30b]) implemented therein. The crystal of **1a** under study proved to be a pseudomerohedral twin. The twin law used during the refinement was –1 0 0 0 –1 0 0 0 –1 and resulted in a twin component ratio of approximately 5:1 (BASF 0.2122).

**1a:** 0.40 × 0.40 × 0.06 mm$^3$, $C_{42}H_{40}IrN_2P_2$·$BF_4$ (913.71); monoclinic, $C_2$, $a$ = 9.1624(9), $b$ = 17.197(2), $c$ = 24.204(2) Å, $\beta$ = 99.947(7)°, $V$ = 3756.3(9) Å$^3$, $Z$ = 4, $d_{calcd.}$ = 1.616 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 3.693 mm$^{-1}$; 3.33° ≤ $\Theta$ ≤ 28.01°, 30833 reflections collected (–11 ≤ $h$ ≤ +12, –21 ≤ $k$ ≤ +22, –31 ≤ $l$ ≤ +31), 8279 unique ($R_{int}$ = 0.0643); $wR_2$ = 0.1270 for all data and 475 parameters, $R_1$ = 0.0572 for 6804 intensities $I > 2\sigma(I)$; absolute structure parameter $x$ = –0.02(2).[33]

**4·Me$_2$CO:** 0.38 × 0.30 × 0.13 mm$^3$, $C_{37}H_{41}ClIrP_2$·$BF_4$·$C_3H_6O$ (920.18); orthorhombic, $P2_12_12_1$, $a$ = 10.431(1), $b$ = 19.128(3), $c$ = 19.438(7) Å, $V$ = 3878(2) Å$^3$, $Z$ = 4, $d_{calcd.}$ = 1.576 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 3.644 mm$^{-1}$; 2.10° ≤ $\Theta$ ≤ 25.17°, 4928 reflections collected (–3 ≤ $h$ ≤ +12, –3 ≤ $k$ ≤ +22, –3 ≤ $l$ ≤ +23), 4652 unique ($R_{int}$ = 0.0471); $wR_2$ = 0.1373 for all data and 454 parameters, $R_1$ = 0.0578 for 3712 intensities $I > 2\sigma(I)$; absolute structure parameter $x$ = –0.010(17).[33]

**5·solv:** 0.26 × 0.18 × 0.16 mm$^3$, $C_{88}H_{66}Cl_3Ir_2P_4$·$BF_4$·$C_3H_6O$·$HO_{0.5}$·$CH_{2.5}O_{0.25}$ (1910.5); orthorhombic, $P2_12_12_1$, $a$ = 21.205(2), $b$ = 24.821(4), $c$ = 32.830(3) Å, $V$ = 17279(4) Å$^3$, $Z$ = 8, $d_{calcd.}$ = 1.469 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 3.299 mm$^{-1}$; 2.67° ≤ $\Theta$ ≤ 28.00°, 172715 reflections collected (–20 ≤ $h$ ≤ +28, –32 ≤ $k$ ≤ +32, –42 ≤ $l$ ≤ +43), 39510 unique ($R_{int}$ = 0.0462); $wR_2$ = 0.1264 for all data and 1943 parameters, $R_1$ = 0.0427 for 32060 intensities $I > 2\sigma(I)$; absolute structure parameter $x$ = 0.010(4).[33]

CCDC-640544 (for **1a**), -640546 (for **4·Me$_2$CO**), and -640545 (for **5·solv**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

Support of this work by the Deutsche Forschungsgemeinschaft (SFB 583) is gratefully acknowledged. We are also indebted to Mrs. S. Hoffmann and Mr. P. Bakatselos for their skilful assistance.

# The Tuning Effect of 2-Amino-4,6-dipyridylpyrimidine Isomers on the Structural Dimensionalities and Motifs of Copper(I) Cyanide Complexes

**Ying-Nan Chi,[a,b] Feng-Yun Cui,[a,b] Yan-Qing Xu,[a,b] and Chang-Wen Hu*[a,b]**

**Keywords:** Copper / Chelating ligands / N ligands / Crystal engineering

Four novel copper(I) cyanide complexes of three isomeric oligopyridine ligands, namely 2-amino-4,6-bis(2-pyridyl)pyrimidine ($L^1$), 2-amino-4-(2-pyridyl)-6-(4-pyridyl)pyrimidine ($L^2$), 2-amino-4-(2-pyridyl)-6-(3-pyridyl)pyrimidine ($L^3$) have been hydrothermally synthesized. These complexes have one- and two-dimensional structures, as determined by single-crystal X-ray diffraction. The structural dimensionalities and motifs of complexes **1**–**4** are directed by the coordination modes of the ligands. Thus, $L^1$ acts as a bis-chelating ligand in complex **1** to join the adjacent 1D $\{CuCN\}_n$ chains into a two-dimensional corrugated layer. Complexes **2** and **4** both consist of one-dimensional zigzag chains where the ligands ($L^2$ for complex **2** and $L^3$ for complex **4**) occupy the terminal positions and N···$NH_2$ hydrogen bonds play an important role in the assembly of the supramolecular network. Complex **3** (another product isolated from the $L^3$-Cu-CN reaction system) is a two-dimensional network in which $L^3$ acts as a bridging ligand and the cyanide groups exhibit both $\mu_2$ and $\mu_3$ linking modes. Further investigation shows that the thermal stability of complexes **1**–**4** is in the order **1** > **3** > **2** > **4**. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Considerable attention has recently been paid to the crystal engineering of coordination polymers due to their structural and topological novelty[1] and their potential applications in the fields of catalysis, molecular recognition, separation, and nonlinear optics.[2] Although a wide variety of coordination complexes with interesting structures and properties have been reported, it is still a great challenge to control the motifs and dimensionalities of coordination polymers as the formation of these complexes is influenced by many factors, including the coordination behavior of the organic ligand, the solvent system, the metal-to-ligand ratio, the template, and the counteranion.[3] Amongst these factors, the coordination geometry of the organic ligand is very important as, under suitable conditions, the structural information stored in the organic ligand can be read out by the metal ion.[4] This allows the construction of desired architectures by the judicious choice of metal ion and ligand. In this regard, ligand isomers play an important role and sometimes have a tuning effect on the structural dimensionality and motif.[5] A typical case is the bipyridine system, where 4,4′-bipyridine usually acts as a bridging unit to form extended coordination structures with high dimensionalities[6] while 2,2′-bipyridine generally acts as a terminal ligand to form discrete or 1D complexes.[7]

This paper concerns three isomers of 2-amino-4,6-dipyridylpyrimidine, namely 2-amino-4,6-bis(2-pyridyl)pyrimidine ($L^1$), 2-amino-4-(2-pyridyl)-6-(4-pyridyl)pyrimidine ($L^2$), and 2-amino-4-(2-pyridyl)-6-(3-pyridyl)pyrimidine ($L^3$; Scheme 1), and $Cu^{II}$ and $CN^-$ ions for the construction of coordination polymers. The Cu-CN system was selected based on the following considerations. A great deal of attention has been focused on copper cyanide complexes[8] recently because the coordination flexibility of copper ions and the versatile bridging modes of the cyanide ligand make copper cyanide complexes structurally varied.[9] A successful approach employed to develop new metal cyanides is to incorporate bidentate/multidentate organic ligands such as 2,2′-bipyridine or ethylenediamine into the metal-cyanide framework.[10] The structural motifs and dimensionalities of the resultant coordination polymers are often highly influenced by the incorporated ligand.[11] For example, the steric constraints of the introduced ligands and the spatial distances between imine donor groups of the ligands have been shown to have an obvious effect on the structures of Cu-CN complexes.[11a,11c] To the best of our knowledge, however, there is no report of the influence of isomeric ligands on the structure of copper cyanide complexes. Our aim is to understand how the structural motifs and dimensionalities of the Cu-CN coordination polymers can be manipulated by the ligand isomers.

Ligands $L^1$–$L^3$ are pentadentate, multifunctional ligands. The coordination chemistry of these ligands has not been

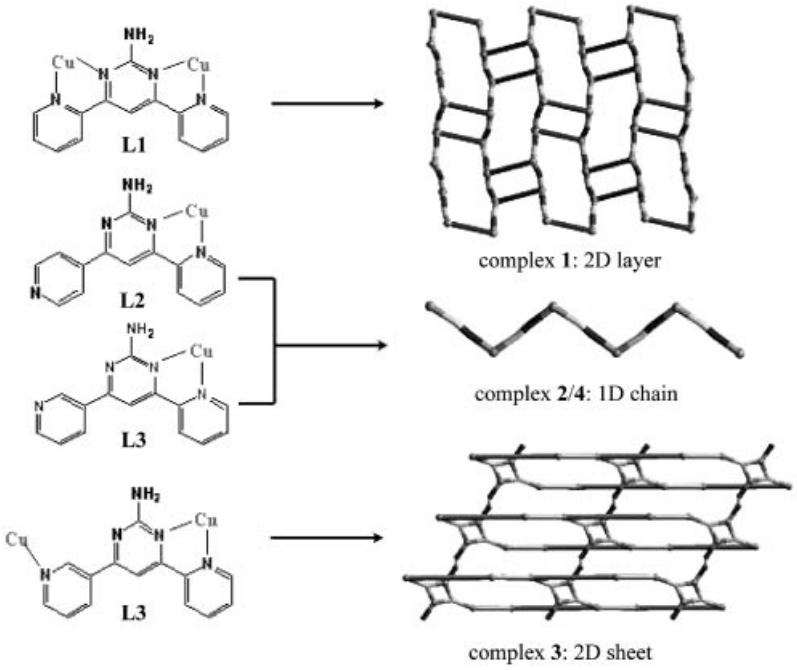

Scheme 1. The coordination modes of the three ligand isomers $L^1$–$L^3$ in complexes **1**–**4** and their resultant structural motifs.

explored widely to date, except for a few silver(I) and copper(I/II) complexes reported by us recently.[12] We found that the structures of these complexes are directed by the counteranions and ligand isomerism. Every isomer has a bidentate binding site that is capable of chelating one metal center, but the different pyridine substituent groups at the 6-position of the pyrimidine ring make them exhibit different coordination modes, which probably have a large influence on the resultant structures. In addition, the three isomers possess hydrogen-bond donor (amino group) and acceptor (aromatic N atoms) groups, which could be available for the formation of an H-bond network.

Herein we report four new copper-cyanide coordination polymers, namely $[Cu_2(CN)_2L^1]_n$ (**1**), $[CuCNL^2]_n$ (**2**), $[Cu_3(CN)_3L^3]_n$ (**3**), and $[CuCNL^3]_n$ (**4**), in all of which $Cu^{II}$ has been reduced to $Cu^{I}$ under the hydrothermal conditions used. The dimensionalities of complexes **1**–**4** vary with the coordination modes of the ligands (Scheme 1) and complexes **2** and **4** have the same molecular formula and different structures. These complexes not only enrich the structural database of copper(I) cyanide complexes but also demonstrate the tuning effect of ligand isomerism upon the dimensionalities and motifs of the resultant crystal structures.

## Results and Discussion

### Synthesis

Solvothermal reactions have recently been demonstrated to be a versatile technique for the construction of coordination polymers, and a large number of cyanide complexes have been synthesized by this method. We chose $K_3[Fe(CN)_6]$ as the source of cyanide anions because cyanide ions are slowly released from this complex under hydrothermal condition. Several kinds of $Cu^{II}$ salts [$CuCl_2{\cdot}2H_2O$, $CuBr_2$, $Cu(NO_3)_2{\cdot}3H_2O$, $Cu(OOCCH_3)_2{\cdot}H_2O$] were investigated but they were found to only act as a copper source and the counteranions are not involved in the crystal structures. Moreover, the $Cu^{II}$ ions are reduced to $Cu^{I}$ in all four complexes. This observation is consistent with the fact that copper(I) cyanide species are more stable than copper(II) complexes at elevated temperatures and pressures.[13] The cyanide groups obtained from the dissociation of $[Fe(CN)_6]^{3-}$ are probably responsible for the reduction process, yielding cyanogen as the oxidation product.

To investigate the influence of the reaction conditions we varied the metal/ligand ratio, reaction time, and temperature. Formation of complexes **1** and **2** is not obviously affected by the metal/ligand ratio ($CuCl_2/K_3[Fe(CN)_6]/L$ = 1:1:1, 1:2:1, 2:1:1, and 2:1:2), reaction time (24, 48, and 72 h), or temperature (120, 140, 160, 180 °C), although the yields did vary somewhat. However, the reaction conditions have a tuning effect on the final product obtained from the reaction between $L^3$, $Cu^{II}$, and $K_3[Fe(CN)_6]$. Thus, when the reaction was run with a molar ratio of 1:2:1 at 160 °C for 72 h the dominant product was complex **4**, whereas complex **3** was isolated in high yield with a 2:1:1 ratio. Similarly, when the same reaction with a 1:1:1 molar ratio was carried out at 160 °C for 24 h **4** was the only product, whereas after 48 or 72 h both complexes **3** and **4** both were obtained with different yields. When reactions with a 1:1:1 molar ratio were performed at 120 °C for 72 h only complex **4** was formed, whereas at 180 °C complex **3** was isolated as a pure phase and at 140 and 160 °C both complexes **3** and **4** were formed. On the basis of the above results we can conclude

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

that increasing the temperature or extending the reaction time is beneficial to the formation of **3**, therefore careful control of the reaction conditions allows us to obtain the desired product.

The coordination modes of ligands $L^1$–$L^3$ and the structural motifs of complexes **1**–**4** are summarized in Scheme 1. The structure of complex **1** consists of a wave-like layer in which CN groups link the $Cu^I$ ions to form a 1D $\{CuCN\}_n$ chain and $L^1$ acts as a bis-chelating ligand to bridge adjacent chains. Complexes **2** and **4** contain a zigzag chain that is unable to propagate to higher dimensionality, probably due to the terminal coordination mode of $L^2$/$L^3$. The structure of complex **3** is a 2D sheet in which the CN groups exhibit both $\mu_2$ and $\mu_3$ bridging modes and $L^3$ binds two metal centers, one through the N atoms in a chelating mode and the other through the N atom on the 3-pyridine ring. We suppose that the different coordination modes adopted by the ligand isomers, in combination with the versatile linking behavior of the cyanide groups, is responsible for the diversity of the structures reported.

## IR Spectroscopy

The IR bands corresponding to the CN stretching vibrations for complexes **1**–**4** appear in the range 2099–2123 $cm^{-1}$, which is typical for bridging cyanide groups and higher than that of terminal cyanide groups (approx. 2050 $cm^{-1}$).[14] The IR spectra of complexes **2** and **4** exhibit one ν(CN) stretching band at 2107 (for **2**) and 2099 (for **4**) $cm^{-1}$, which is in agreement with the presence of only one type of cyanide, while complexes **1** and **3** exhibit two stretching bands, thus indicating the existence of two types of cyanide bridges in the structure. The cyanide groups in the crystal structure of complex **3** exhibit $\mu_2$ and $\mu_3$ bridging modes but for complex **1** there is only one type of $\mu_2$-CN group, therefore the presence of two stretching bands for the latter might originate from the subtle difference of the $Cu^I$–N bond lengths [1.981(4) and 1.952(3) Å]. A similar phenomenon has been observed in other cyanide complexes.[11d,15] The absorption peaks between 3460 and 3280 $cm^{-1}$ are assigned to the asymmetric and symmetric stretching vibrations of the $NH_2$ group, and the absorption peaks below 1700 $cm^{-1}$ are mainly attributed to the vibrations of the aromatic rings.

## X-ray Crystal Structures

### *Complex 1*

The structure of complex **1** can be described as a neutral non-interpenetrating corrugated sheet containing two different types of copper(I) centers (Figure 1), both of which coordinate to two N atoms from $L^1$ and two cyanide groups and exhibit distorted tetrahedron geometries. $L^1$ acts as a bis-chelating ligand bridging two metal centers, as observed previously in silver(I) complexes of $L^1$.[12] The Cu–$N_{aryl}$ bond lengths fall in a narrow range [2.082(3)–2.112(3) Å] and the Cu–$C_{cyanide}$ bond lengths [Cu1–C16 = 1.886(4), Cu2–C15A = 1.885(4) Å] are very similar. The Cu–$N_{cyanide}$ distances [Cu1–N6 = 1.981(4), Cu2–N7A = 1.952(3) Å], however, are different. The acute angles at the chelating sites of $L^1$ [77.20(11)° for N1–Cu1–N4 and 77.23(10)° for N2–Cu2–N5] are responsible for the distorted tetrahedral geometries of the copper centers. In this case, the dihedral angles between the pyrimidine ring and two pyridine rings are 2.0° and 5.2°, respectively, and that between the two pyridine rings is 6.5°. All the dihedral angles in complex **1** are clearly smaller than those observed in $Ag^IL^1$ complexes.[12]

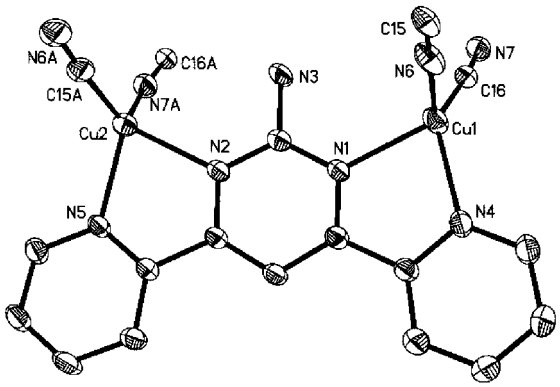

Figure 1. Coordination environments of the Cu ions in complex **1**. All H atoms have been omitted for clarity. Symmetry codes: (A) 5/2 – *x*, –1/2 + *y*, 3/2 – *z*; (B) 2 – *x*, –*y*, 2 – *z*.

As shown in Figure 2, the structure of **1** is constructed from zigzag $\{CuCN\}_n$ chains running along the *c*-axis that are linked together by the $L^1$ ligands to generate a 4.8(2) network (Figure S1 in the Supporting Information). Interestingly, the sheet contains two kinds of rings: a 16-membered $Cu_4(CN)_2(L^1)_2$ ring A and a 26-membered $Cu_8(CN)_6(L^1)_2$ ring B. This means that the structure can also be described as a layer composed of A and B rings. In ring A, the distance between two Cu atoms chelated by the same $L^1$ ligand is 6.154 Å, and two Cu atoms separated by a cyanide group are 4.930 Å apart. In general, 2D networks

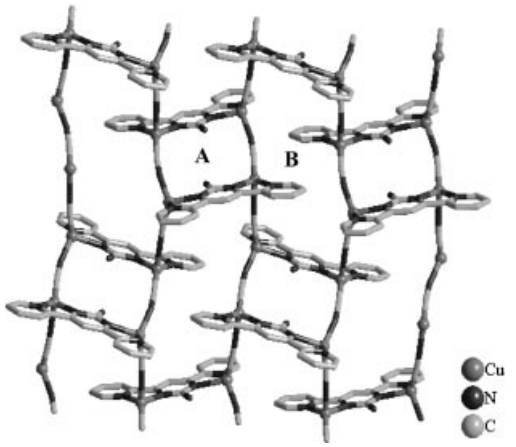

Figure 2. A view of the 2D layer in complex **1**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in the Cu-CN system are generated by the linking of 1D $\{CuCN\}_n$ chains by linear dipodal ligands such as 4,4′-bipyridine, 2,2′-bipyrimidine, pyrazine, etc., and these networks usually only include one kind of ring unit.[7a,10c,11c] The 2D net observed in **1**, however, consists of two types of rings (A and B), and we believe that the non-linear bridging mode of $L^1$ is responsible for this special motif. The 2D sheets are stacked in an ABAB pattern and are assembled into a 3D supramolecular structure by π–π interactions between the $L^1$ ligands, with a plane-to-plane distance of about 3.55 Å (Figure S2).

### *Complex 2*

The cyanide groups in **2** connect the copper(I) anions to form a neutral zigzag chain along the *b*-axis with the $L^2$ ligands hanging from the metal centers (Figure 3). The asymmetric unit in **2** contains one copper center, one cyanide group, and one $L^2$ ligand. The copper ion is coordinated by two cyanide groups and two nitrogen atoms from $L^2$ with a distorted tetrahedral geometry. Ligand $L^2$ does not adopt the bridging mode previously found in $Ag^IL^2$ and $Cu^IL^2$ complexes but acts as a terminal ligand that binds through the chelating N atoms. The N5 atom on the 4-pyr-

idine ring does not participate in coordination and points away from the zigzag chain. The Cu–$N_{py}$ [2.094(4) Å] and Cu–$N_{pym}$ [2.090(3) Å] bond lengths are rather similar and the acute angle at the chelating site of $L^2$ [78.2(3)° for N1–Cu1–N4] accounts for the obviously distorted geometry of the copper ion. The bond lengths involving the cyanide group [Cu1–C6 = 1.874(5), Cu1–N15A = 1.965(4), C15–N6 = 1.148(5) Å] are similar to those found in other copper cyanide complexes.[16] The shortest Cu···Cu distance within the chain is 4.949 Å and the shortest interchain Cu···Cu distance is 6.814 Å. The pyrimidine and 2-pyridine rings are nearly coplanar (dihedral angle of 2.4°) while the 4-pyridine ring lies outside of this plane. The dihedral angle between the 4-pyridine and pyrimidine rings is 23.5° and that between the 4-pyridine and 2-pyridine rings is 24.2°.

Neighboring chains in this structure have different orientations (Figure 4, b) and the $L^2$ ligands from two adjacent chains are stacked in an offset fashion with a plane-to-plane distance of 3.8 Å, thus indicating weak π–π interactions. For clarity, one is referred to as the left-handed chain and the other the right-handed chain. A projected view of the zigzag chain shows that the N atoms of the 4-pyridine and amino groups point in four different directions (Figure 2, a), and every chain forms H-bonds (N···$NH_2$ = 3.041 Å; H–N···N = 150.17°) with four neighboring chains along these four directions. The more interesting observation is that each left-handed chain connects to four adjacent right-handed chains, and vice versa (Figure 4, c and Figure S3, Supporting Information). The isolated zigzag chains are therefore assembled into a 3D supramolecular structure by H-bonds. The H-bond interaction is an important element in the construction of supramolecular structure, but seldom appears in Cu CN complexes.[9c,16] In this case, the successful formation of H-bonds is due to the $L^2$ ligand containing both an H-bond acceptor (N5) and donor ($NH_2$).

### *Complex 3*

The presence of ligand $L^3$ results in a 2D sheet in **3**. As shown in Figure 5 (a), there are three different metal centers (Cu1, Cu2, Cu3) in the asymmetric unit of **3**, all of which are three-coordinate with distorted trigonal geometries. The detailed coordination environments of the three Cu atoms are different. Cu1 is coordinated to three N atoms from two cyanide groups and one $L^3$ ligand with N–Cu–N bond angles varying from 102.6(5)° to 148.2(5)°, Cu2 is ligated to two N atoms from the chelating site of $L^3$ and one cyanide group, with the bond angles around $Cu^I$ ranging from 80.5(3)° to 145.8(4)°, while Cu3 is coordinated by three cyanide groups, with bond angles in the range 107.6(6)°–131.6(7)°. The Cu–$N_{aryl}$ bond lengths range from 2.052(11)

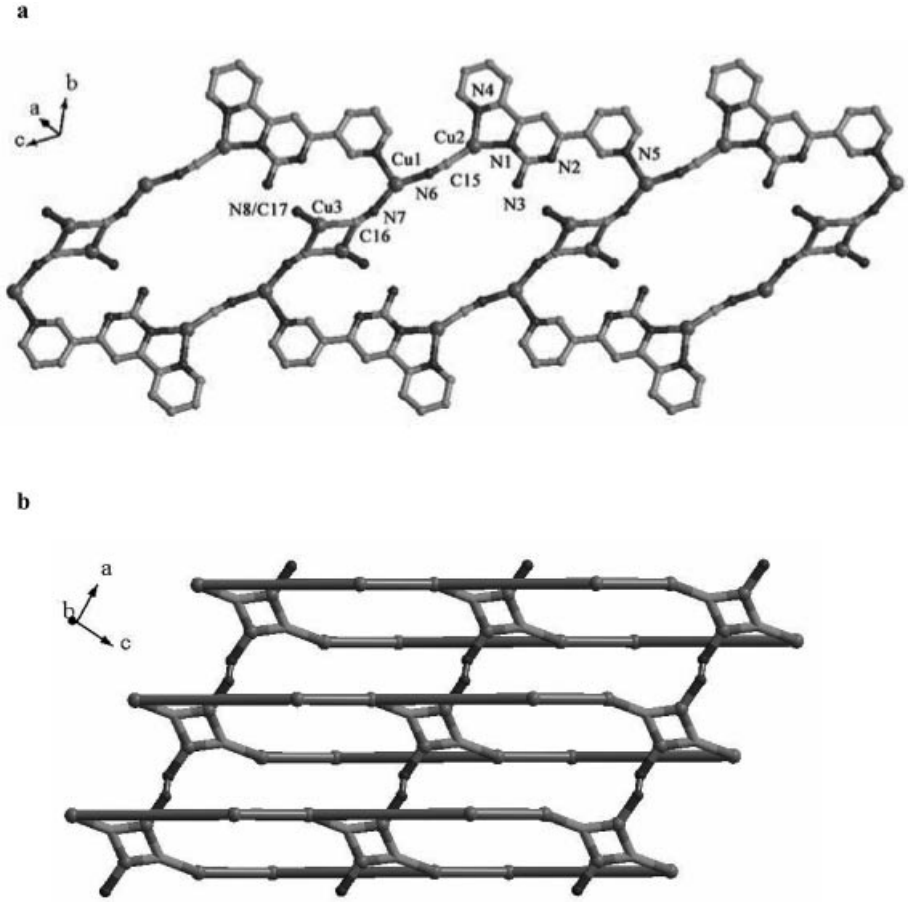

Figure 5. (a) The staggered ladder in complex **3**. All H atoms have been omitted for clarity. (b) A schematic presentation of the 2D sheet of complex **3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to 2.158(12) Å and the Cu–N/$C_{cyano}$ bond lengths are in the range 1.930(13)–2.210(19) Å. $L^3$ acts as a bridging ligand linking two copper centers. The three aromatic rings of $L^3$ are nearly in the same plane, with dihedral angles ranging from 2.3° to 3.6°. All the dihedral angles observed in complex **3** are smaller that those in complexes **1** and **2**.

The cyanide groups in **3** exhibit both $\mu_2$- and $\mu_3$-bridging modes. Two $\mu_3$-cyanide groups bond link two Cu3 centers through their carbon atoms to form a $Cu_2(CN)_2$ unit that includes a $Cu_2C_2$ rhombic ring with a Cu···Cu distance of 2.532 Å. The $Cu_2(CN)_2$ unit is a familiar motif in complexes containing $\mu_3$-cyanide and reported cases almost all have a short $Cu^I$···$Cu^I$ distance of between 2.42 and 2.66 Å.[8c,11c,11d,17] As shown in Figure 5 (a), two $Cu_2(CN)_2$ units, two $\mu_2$-cyanide groups, two $L^3$ ligands, and six copper ions are assembled into a 40-membered ring in which the largest Cu···Cu distance is 22.006 Å, the distance between two Cu atoms chelated by the same $L^3$ ligand is 9.865 Å, and two Cu atoms separated by a $Cu_2(CN)_2$ unit are 9.430 Å apart. Two ligands lie parallel to each other in the macrocycle with the amino groups pointing towards the center of the ring. Adjacent rings are fused along the edges containing the $Cu_2(CN)_2$ unit to form a ribbon. Alternatively, the ribbon may be described as a staggered ladder with $\{CuL^3(CN)\}_n$ chains as the side-rails and $Cu_2(CN)_2$ units as the rungs. For clarity, the staggered ladder can be simplified with the Cu atoms as nodes and $L^3$ ligands and $\mu_2$-cyanide groups as linkers (Figure S4). The rhombic rings of $Cu_2(CN)_2$ units are almost perpendicular to the ladder and the Cu3 atoms point to opposite sides. The disordered $\mu_2$-cyanide groups link the Cu3 centers from adjacent 1D ladders to generate a 2D sheet along the *a*-axis (Figure 5, b). The shortest Cu···Cu distance between adjacent sheets is 3.084 Å.

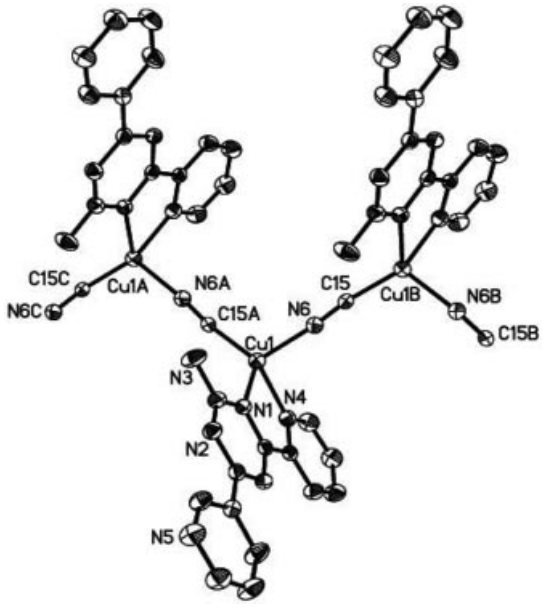

Figure 6. The 1D zigzag chain of complex **4**. All H atoms have been omitted for clarity. Symmetry codes: (A) *x*, 1/2 – *y*, –1/2 + *z*; (B) *x*, 1/2 – *y*, 1/2 + *z*; (C) *x*, *y*, –1 + *z*.

### *Complex 4*

Complex **4** is a 1D zigzag chain extending along the *c*-axis. As shown in Figure 6, there is only one kind of copper center in **4**, which is four-coordinated by two N atoms from $L^3$ and two cyanide groups and adopts a distorted tetrahedron geometry. The bond lengths around $Cu^I$ range from 1.884(3) to 2.099(2) Å and the bond angles are in the range 77.84(9)–119.76(11)°. Ligand $L^3$ does not adopt the bridging mode observed in **3** in this complex but acts as a terminal ligand. The pyrimidine and 2-pyridine rings are almost in the same plane, with a dihedral angle of about 0.8°, and the dihedral angles between pyrimidine and the 2-pyridine and 3-pyridine rings are about 3.1° and 3.9°, respectively. The dihedral angles observed in this crystal are obviously smaller than those in complex **2**. The shortest intrachain Cu···Cu distance is 5.011 Å and the shortest interchain Cu···Cu distance is 5.494 Å.

Complexes **2** and **4** have the same molecular formula and their structures are also very similar. However, a side view

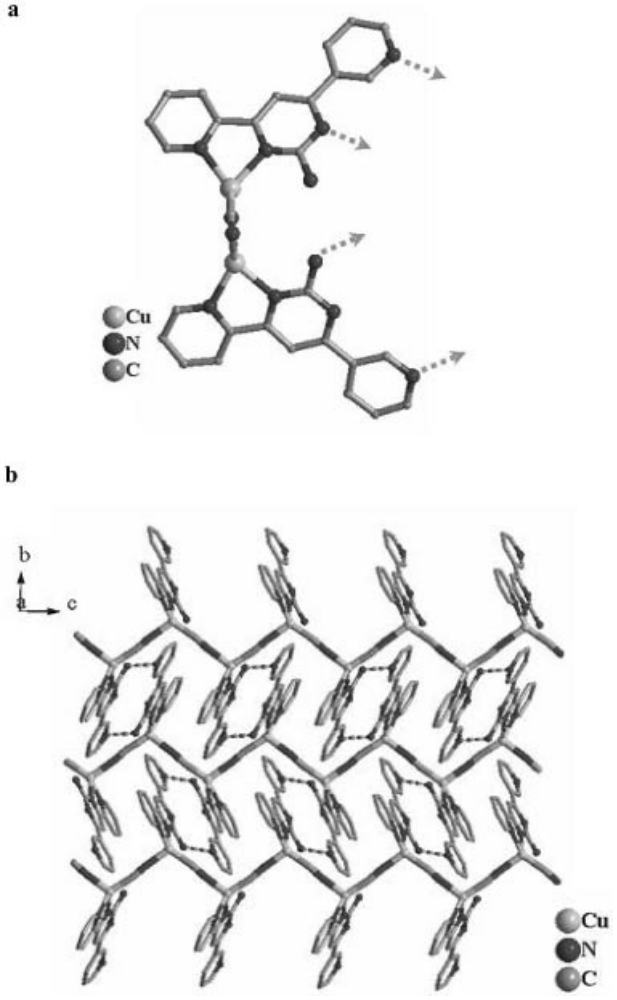

Figure 7. (a) A side view of the zigzag chain in complex **4** projected along the *c*-axis. The dashed arrows represent the directions along which the 1D chain forms H-bonds with two neighboring chains. (b) The 2D supramolecular network in complex **4** assembled by H-bonds. The dashed lines represent the H-bond interactions.

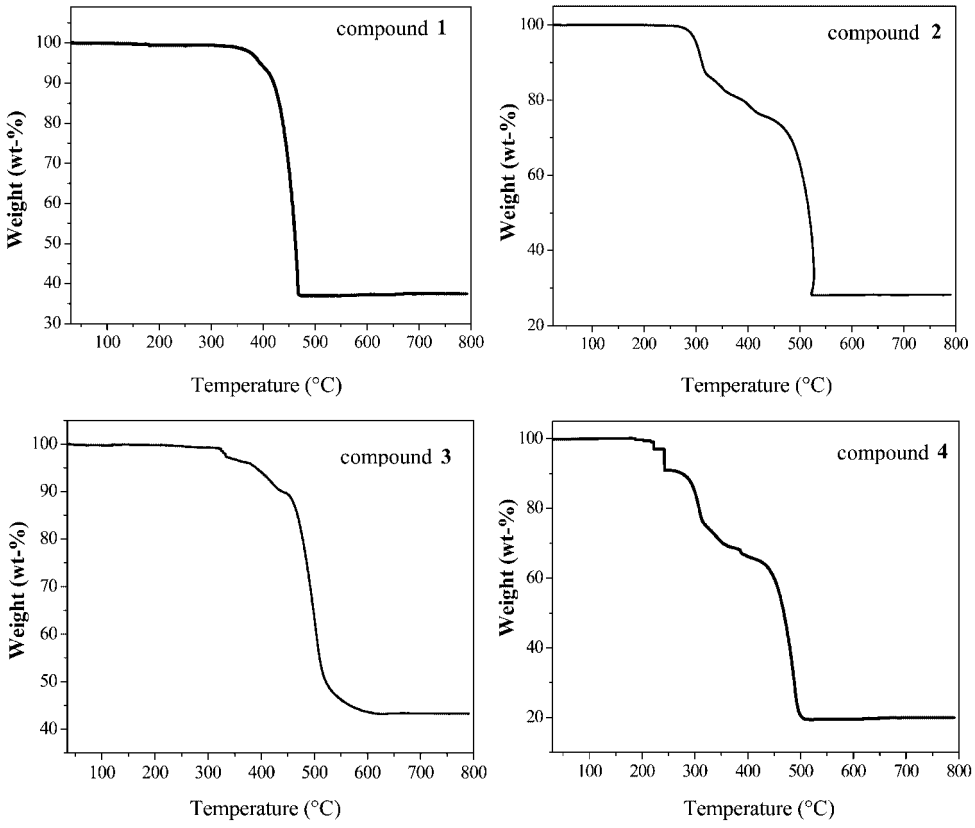

Figure 8. The TG curves of complexes **1**–**4**.

(see parts a in Figures 4 and 7) shows clearly that the orientation of the ligands in the two structures is different. Thus, the $L^2$ ligands are located on the two sides of the chain with the amino groups and the N atoms of the 4-pyridine rings pointing in four different directions in complex **2**, whereas in complex **4** the $L^3$ ligands are nearly oriented on the same side and the amino groups and the uncoordinated N atoms on the 3-pyridine rings point in only two different directions. As in complex **2**, the neighboring chains of **4** have different orientations and are linked together by H-bonds (N···N 2.980 Å; N–H···N 158.53°) between the $NH_2$ and N5 atoms to form a 2D supramolecular network (Figure 7, b). These 2D layers are assembled into a 3D supramolecular framework by π–π interactions between the pyrimidine and 2-pyridine rings (plane-to-plane distance of approx. 3.5 Å).

Interestingly, complexes **3** and **4**, which have distinct structural motifs and dimensionalities, were isolated from the same reaction system. We think that the structural diversity of the Cu/CN/$L^3$ system originates from the flexible and adjustable coordination modes of ligand $L^3$. To the best of our knowledge, this case represents the first example where two Cu-CN coordination polymers are obtained from the same reaction system.

### Thermal Stability

The thermal stability of complexes **1**–**4** was determined by TG analysis (Figure 8). Complex **1** is stable from room temperature up to 350 °C. It then undergoes a total weight loss of 63.02% (calculated value: 64.01%), corresponding to one $L^1$ ligand and one cyanide group, in the range 350–570 °C. Complex **2** shows a two-step weight loss between 275 and 500 °C. The total weight loss of **2** is 72.14% (calculated value: 73.41%), which corresponds to one ligand $L^2$. The weight loss for complex **3** between 320 and 600 °C is 57.99% (calculated value: 56.67%), which corresponds to one $L^3$ ligand and one cyanide group. The total weight loss for complex **4** between 200 and 500 °C is 80.56% (calculated value: 81.12%), which corresponds to one $L^3$ ligand and one cyanide group. The thermal stability of complexes **1**–**4** follows the order **1** (350 °C) > **3** (320 °C) > **2** (275 °C) > **4** (200 °C). These results are consistent with the above structural analysis and confirm that the high-dimensional networks (**1** and **3**) are more stable than the low-dimensional chains (**2** and **4**), and, for the 1D polymers, that the 3D H-bonded supramolecular structure (**2**) is more stable than the 2D supramolecular structure (**4**).

## Conclusions

Four novel copper(I) complexes, **1**–**4**, have been successfully prepared under hydrothermal condition by using three isomeric ligands $L^1$, $L^2$, and $L^3$ in combination with cyanide groups. $L^3$ is a new compound and, to the best of our knowledge, ligands $L^1$, $L^2$, and $L^3$ are employed here in the copper cyanide system for the first time. Ligands $L^2$ and $L^3$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in complexes **2** and **4** act as terminal ligands to form a 1D structure, while the two-dimensional networks of **1** and **3** are constructed from $L^1$ and $L^3$ exhibiting different bridging modes. The above results indicate that the coordination modes adopted by ligand isomers $L^1$, $L^2$, and $L^3$ have a tuning effect on the structural motifs and dimensionalities of the coordination polymers. Further investigation of the role of these three isomeric ligands in other transition metal systems is in progress.

## Experimental Section

**General Remarks:** All copper(II) salts were purchased from commercial sources and used without further purification. Organic solvents with analytical purity were supplied by commercial sources and used as received. Infrared spectra were recorded (as KBr pressed pellets) with a Nicolet 170SXFT/IR spectrometer. $^1$H NMR spectra (for $L^3$) were recorded with a Bruker DPX 500 spectrometer. X-ray powder diffraction (XPRD) patterns were collected with a Japan Rigaku D/max $\gamma$A X-ray diffractometer equipped with graphite-monochromated Cu-$K_\alpha$ radiation ($\lambda$ = 0.154060 nm). Elemental analyses were performed with a Perkin–Elmer 2400 CHN elemental analyzer. TG analyses were carried out in air between 30 and 800 °C at a heating rate of 10 °C min$^{-1}$ with a 2960 SDT simultaneous thermal analyzer.

**Synthesis of $L^1$, $L^2$, and $L^3$:** The ligands $L^1$, $L^2$, and $L^3$ were prepared according to previously reported synthetic procedures.[18] The synthesis of $L^3$ was similar to that of ligands $L^1$[18] and $L^2$.[12a] Data for $L^3$: Yield: 63%; m.p. 182–184 °C. $^1$H NMR ($CDCl_3$, 500 MHz, 25 °C): $\delta$ = 9.35 (s, 1 H, 2-pyridyl), 8.74–8.71 (m, 2 H, pyridyl), 8.43–8.39 (m, 2 H, pyridyl), 8.17 (s, 1 H, pyrimidyl), 7.88–7.86 (m, 1 H, pyridyl), 7.44–7.40 (m, 2 H, pyridyl), 5.24 (s, 2 H, amino group) ppm. IR (KBr): $\tilde{\nu}$ = 3329 (m), 3197 (m), 3055 (w), 2991 (w), 1650 (s), 1575 (s), 1564 (s), 1478 (s), 1433 (w), 1365 (s), 1238 (m), 1133 (w), 1092 (w), 994 (w), 845 (w), 781 (s), 743 (w), 706 (m), 661 (w), 623 (w) cm$^{-1}$.

**Synthesis of $[Cu_2(CN)_2L^1]_n$ (1):** A mixture of $L^1$ (24.9 mg, 0.1 mmol), $CuCl_2{\cdot}2H_2O$ (16.9 mg, 0.1 mmol), $K_3[Fe(CN)_6]$ (32.8 mg, 0.1 mmol), and $H_2O$ (8 mL) was transferred and sealed in a 15-mL Teflon-lined stainless steel autoclave, which was heated to 160 °C for 72 h and then cooled to room temperature. Red-brown cubic crystals were collected for X-ray analysis. Yield: 39.1 mg (91%, based on $L^1$). $C_{16}H_{11}Cu_2N_7$ (428.4): calcd. C 44.86, H 2.59, N 22.89; found C 44.92, H 2.67, N 22.78. IR (KBr): $\tilde{\nu}$ = 3460 (s), 3349 (s), 3096 (w), 3059 (w), 2112 (s), 2101 (s), 1732 (w), 1596 (s), 1583 (s), 1540 (s), 1456 (m), 1421 (m), 1370 (m), 1305 (m), 1240 (s), 1169 (w), 1156 (w), 1055 (w), 1007 (w), 852 (m), 791 (s), 772 (s), 737 (m), 664 (m) cm$^{-1}$.

**Synthesis of $[CuCNL^2]_n$ (2):** Complex **2** was synthesized in a manner similar to that used to obtain complex **1**, but with $L^2$ as ligand. Red-brown stick crystals were collected for X-ray analysis. Yield: 28.8 mg (85%, based on $L^2$). $C_{15}H_{11}CuN_6$ (338.8): calcd. C 53.17, H 3.27, N 24.80; found C 53.11, H 3.36, N 24.89. IR (KBr): $\tilde{\nu}$ = 3422 (m), 3298 (m), 3182 (w), 3066 (w), 2107 (s), 1624 (s), 1583 (s), 1547 (s), 1500 (w), 1470 (m), 1414 (m), 1373 (s), 1257 (w), 1230 (m), 1066 (w), 998 (w), 830 (s), 785 (s), 743 (w), 650 (m), 631 (m) cm$^{-1}$.

**Synthesis of $[Cu_3(CN)_3L^3]_n$ (3):** Complex **3** was synthesized at 180 °C in a manner similar to that used to obtain complex **1**, but with $L^3$ as ligand. Dark red crystals were collected for X-ray analysis. Yield: 19.4 mg (41%, based on $L^3$). $C_{16.5}H_{11}Cu_{2.5}N_{7.5}$ (473.2): calcd. C 41.88, H 2.34, N 22.20; found C 41.94, H 2.42, N 22.29. IR (KBr): $\tilde{\nu}$ = 3615 (w), 3443 (w), 3358 (m), 3059 (w), 2924 (w), 2123 (s), 2101 (s), 1592 (s), 1539 (s), 1478 (s), 1449 (s), 1420 (m), 1367 (s), 1257 (w), 1232 (m), 1200 (w), 1143 (w), 1049 (w), 1028 (w), 1016 (w), 778 (s), 701 (m), 660 (m), 640 (w) cm$^{-1}$.

**Synthesis of $[CuCNL^3]_n$ (4):** A mixture of $L^3$ (24.9 mg, 0.1 mmol), $CuCl_2$ (16.9 mg, 0.1 mmol), $K_3[Fe(CN)_6]$ (65.6 mg, 0.2 mmol), and $H_2O$ (8 mL) was transferred and sealed in a 15-mL Teflon-lined stainless steel autoclave, which was heated to 160 °C for 72 h and then cooled to room temperature. Brown cubic crystals were collected for X-ray analysis. Yield: 30.2 mg (89%, based on $L^3$). $C_{15}H_{11}CuN_6$ (338.8): calcd. C 53.17, H 3.27, N 24.80; found C

**X-ray Crystallographic Analysis:** Suitable single crystals of complexes **1**–**4** were mounted on a Bruker-AXS CCD diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.07103 Å) at 298 K. All absorption corrections were performed with the SADABS program. All the structures were solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in the calculated positions. All calculations were performed using the SHELXTL-97 program.[19] The crystallographic details of complexes **1**–**4** are summarized in Table 1. Selected bond lengths and angles of complexes **1**–**4** are listed in Table 2.

Table 2. Selected bond lengths [Å], angles [°], and other distances for **1**–**4**.[a]

# Charge-Transfer Complexes between the Sulfur Molecules $SO_2$, $S_2O$, $S_3$, SONH, and $SOCl_2$ and the Amine Donors $NH_3$ and $NMe_3$ – A Theoretical Study

**Ralf Steudel*[a] and Yana Steudel[a]**

**Keywords:** Ab initio calculations / Donor–acceptor systems / Thermodynamics / Sulfur / Solvent effects

The formation of adducts between the acceptor molecules $SO_2$, $S_2O$, $S_3$, and $SOCl_2$ and the donor molecules ammonia and trimethylamine has been studied by high-level G3X(MP2) theory, in most cases for the first time. Minimum energy structures with a 1:1 composition and with sulfur–nitrogen bonds have been located for all complexes. The thermodynamic properties, vibrational spectra, and atomic charges of these molecules have been calculated. Of the 10 investigated complexes, only $SO_2{\cdot}NMe_3$ (**2**) and $S_2O{\cdot}NMe_3$ (**4**) are predicted to be thermodynamically stable in the gas phase under standard conditions ($\Delta G°_{298} < 0$). However, all adducts except $S_3{\cdot}NH_3$ (**5**), $SOCl_2{\cdot}NH_3$ (**7**), and $SOCl_2{\cdot}NMe_3$ (**8**) are stable thermodynamically at 77 K. In a polar continuum with a dielectric constant ($\varepsilon$) of 40, complexes **2**, **4**, and $S_3{\cdot}NMe_3$ (**6**) are stable even at 25 °C. However, if the adducts are formed in the polar continuum from the gaseous components, all adducts except $S_3{\cdot}NH_3$ are formed not only exothermally but also exergonically. Complexes **2**, **4**, and **8** are the only species known in the solid state so far. The charge transfer from donor to acceptor in the various complexes in the gas phase ranges from 0.08 to 0.39 electrostatic units and correlates inversely with the S–N bond length, which ranges from 198 to 295 pm. In general, the charge transfer weakens the bonds within the acceptor molecule, which therefore may be considered to become activated. The formation of thionyl imide (SONH) from $SOCl_2$ and $NH_3$ is exergonic in the gas phase and the interaction between SONH and $NH_3$ is very weak. In the case of $SO_2$, the 1:2 complexes $SO_2{\cdot}2NH_3$ (**1a**) and $SO_2{\cdot}2NMe_3$ (**2a**), which contain two S–N bonds, are unstable with respect to their three-component molecules both in the gas phase and in a polar medium at 25 °C, but they are stable in the polar phase with respect to the gaseous components.

## Introduction

Sulfur dioxide forms well-known charge-transfer complexes with both ammonia and trimethylamine and with the two stoichiometries 1:1 and 1:2. The ammonia complexes $SO_2{\cdot}NH_3$ (**1**) and $SO_2{\cdot}2NH_3$ (**1a**) were first discovered by equilibrium vapor pressure measurements on $SO_2/NH_3$ mixtures[1] and were subsequently characterized by matrix infrared spectroscopy[2] and quantum chemical calculations.[3,4] Both molecules have $C_s$ symmetry with sulfur–nitrogen bonds approximately perpendicular to the plane of the $SO_2$ unit.[3] The enthalpies of formation of the two solid compounds **1** and **1a** from the gaseous components were estimated from the above-mentioned vapor pressure measurements as being $-40 \pm 4$ and $-96 \pm 19$ kJ mol$^{-1}$, respectively.[1] On the other hand, ab initio calculations at the MP3/6-31+G(2d,p) level of theory have predicted that the enthalpies of formation from the separated components in the gas phase at 25 °C are only –18.8 for **1** and –31.3 kJ mol$^{-1}$ for **1a**. After correction for the basis set superposition error (BSSE), the (absolute) interaction energy between $SO_2$ and $NH_3$ in **1** was found to be smaller by 6 kJ mol$^{-1}$, at –12.8 kJ mol$^{-1}$.[3] Both **1** and **1a** are unstable at room temperature and ambient pressure.

The related adduct $SO_2{\cdot}NMe_3$ (**2**) is much more stable than **1** and was first prepared in 1943 as a colorless solid.[5] Subsequently, this compound has been extensively studied by X-ray crystallography of single crystals,[6,7] microwave spectroscopy in the vapor phase,[7] UV/Vis spectroscopy in solution,[8] vapor density measurements,[9] and ab initio MO calculations.[3,10–12] The most recent and most sophisticated theoretical study applying the MP2/6-31G* level of theory predicted S–N distances of 235.9 pm for **2** and 270.7 pm for $SO_2{\cdot}2NMe_3$ (**2a**).[3]

The preparation of the adducts $S_2O{\cdot}NMe_3$ (yellow crystals) and $SOCl_2{\cdot}NMe_3$ (colorless crystals) was reported in 1963.[13] Both compounds can be sublimed in a vacuum, probably with complete dissociation in the gas phase. However, neither spectra nor structural determinations or theoretical calculations are known for these complexes. To elucidate the structures, thermodynamics, and bonding of these

interesting adducts and of a number of related species we have carried out extensive quantum chemical calculations at the G3X(MP2) level of theory not only for **1**, **1a**, **2**, and **2a**, but also for the first time for the related complexes $S_2O{\cdot}NH_3$ (**3**), $S_2O{\cdot}NMe_3$ (**4**), $S_3{\cdot}NH_3$ (**5**), $S_3{\cdot}NMe_3$ (**6**), $SOCl_2{\cdot}NH_3$ (**7**), $SOCl_2{\cdot}NMe_3$ (**8**), and $SONH{\cdot}NH_3$ (**9**). The Gibbs energies of formation from the separated components have also been calculated for the species **1**–**8** for the first time, both in the vapor phase and in a polar medium, to predict the thermodynamic stability of these compounds under standard and nonstandard conditions. All relative energies and enthalpies reported in the text for gas-phase species correspond to the G3X(MP2) level, while all reported structural parameters as well as the energies of solvated species correspond to the B3LYP/6-31G(2df,p) level of theory.

## Results and Discussion

### Adducts in the Gas Phase

#### *Adducts of $SO_2$*

The molecular structure of the complex $SO_2{\cdot}NH_3$ (**1**) was confirmed to be of $C_s$ symmetry with a relatively long S–N bond of 266.3 pm. Other bond lengths are given in Figure 1 and bond angles are listed in Table S1 in the Supporting Information. The binding energy of **1** (–18.1 kJ mol$^{-1}$) is approximately one third that of $SO_2{\cdot}NMe_3$ (see below), and the Gibbs energy for the formation reaction of **1** is even positive at 298 K (14.6 kJ mol$^{-1}$; Table 1). In other words, the gaseous complex **1** is not stable under standard conditions with respect to dissociation into the two components. However, at liquid nitrogen temperature (77 K) the Gibbs energy is negative (–10.9 kJ mol$^{-1}$), and even after a BSSE correction of +4.9 kJ mol$^{-1}$ has been applied the Gibbs energy is still –6.0 kJ mol$^{-1}$ (Table 1, last column).

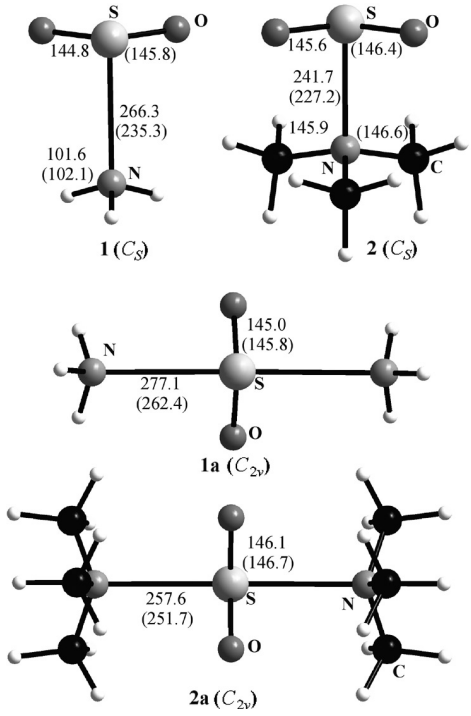

Figure 1. Structures, bond lengths (in pm), and symmetry of the complexes $SO_2{\cdot}NH_3$ (**1**), $SO_2{\cdot}2NH_3$ (**1a**), $SO_2{\cdot}NMe_3$ (**2**), and $SO_2{\cdot}2NMe_3$ (**2a**) in the gas phase. The bond lengths in a polar continuum of dielectric constant $\varepsilon = 40$ are given in parentheses. All data calculated at the B3LYP/6-31G(2df,p) level of theory. See Table S1 (Supporting Information) for bond angles.

The S–O bonds of **1** (144.8 pm) are slightly longer than those calculated for $SO_2$ (144.3 pm). In line with this finding is the fact that the two S–O stretching vibrations are calculated to have somewhat lower wavenumbers (1162 and 1356 cm$^{-1}$) than predicted for free $SO_2$ at the same level of theory (1171 and 1381 cm$^{-1}$). The experimental values for the asymmetric SO stretching vibration of matrix-isolated **1** and of free $SO_2$ are 1338 and 1350 cm$^{-1}$,[2] respectively, in

Table 1. Reaction energies ($\Delta E_o$), enthalpies ($\Delta H°$), and Gibbs energies ($\Delta G°$) [uncorrected G3X(MP2) data in kJ mol$^{-1}$] for the formation of the gaseous donor–acceptor complexes **1**–**8** from their donor and acceptor components, as well as S–N bond lengths ($d_{SN}$) of the adducts along with the dipole moments ($\mu$, in Debye) of the sulfur component (acceptor) and of the complex, calculated at the B3LYP/6-31G(2df,p) level of theory. $\Delta e$ is the charge (in electrostatic units) transferred from the donor(s) to the acceptor on adduct formation, based on the NBO atomic charges. The BSSE correction to the reaction energy [kJ mol$^{-1}$] is given in the last-but-one column and is applied to the Gibbs energy at 77 K in the last column.

[a] Experimental value in the gas phase: 4.800(5) D;[7] estimated experimental value in benzene solution: 4.95 D.[29]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

good agreement with our calculated data. As expected, the calculated O–S–O bond angle of **1** (117.7°) is slightly smaller than that calculated for $SO_2$ (119.2°) as a result of the higher coordination number at the sulfur atom. Our geometrical data are significantly different from the best previous theoretical results obtained at the MP2/6-31G* level.[3] The S–N bond, for example, is shorter (by 5.8 pm), although the overall conformation is identical. Surprisingly, the binding enthalpy calculated here is practically the same as that reported by Wong and Wiberg.[3] The absolute energies and enthalpies of complexes **1**–**9** and their components are given in Table S2.

The structure of the trimethylamine adduct **2** (Figure 1) is in agreement with previous theoretical calculations. The plane defined by the $SO_2$ unit is almost perpendicular to the $C_3$ axis of the donor $NMe_3$ (angle: 83.5°) and the shortest O···H contact is 266.4 pm. The calculated S–O bond length of 145.8 pm agrees very well with the value derived by Kuczkowski et al. from the microwave spectrum of gaseous **2** [144(1) pm] if the uncertainty of the experimental data is taken into account. These authors reported three S–N distances, depending on the type of data analysis with varying simplifications (232.8, 228.5, and 226.0 pm). The larger S–N bond length of 232.8 pm was derived from a least-squares fit of all isotopic data, although the smallest value [226(3) pm] was eventually recommended.[7] Thus, the "estimated uncertainty" of 3 pm reported by Kuczkowski et al. for the S–N distance may be just a lower limit. We obtained an S–N bond length of 239.6 pm by performing DFT calculations at the higher B3LYP/6-31+G(2df,p) level.

The agreement of the gas-phase structure of **2** with the solid-state structure is rather limited and most of the bond lengths differ considerably. In particular, our calculated S–N bond length of 241.7 pm is much larger than the reported solid state value of 204.6(4) pm.[7] This latter value may, however, be affected by packing forces and by the polar environment (see below) due to the large dipole moment (4.34 D) of this complex (Table 1). The charge transfer from the amine to the $SO_2$ unit can be calculated from the NBO atomic charges as being 0.16 electrostatic units. This value is in line with the upper limit of the charge transfer of 0.2–0.3 electrons estimated by Kuczkowski et al.[7] from the experimental dipole moment (4.80 D) and the nitrogen nuclear quadrupole coupling constants. The NBO charges on the sulfur atom (+1.64) and on the nitrogen atom (–0.50) remain practically constant during the formation of this complex, while the oxygen atoms become more negative, changing from –0.82 in $SO_2$ to –0.90 in **2**. In compensation, the nine hydrogen atoms become slightly more positively charged, changing from an average of +0.22 units in $NMe_3$ to +0.24 in **2**. Thus, the electron density moves essentially from the least electronegative atoms (H) to the most electronegative atoms (O) even though these atoms are far apart from each other. The same situation was found for the other adducts discussed below. It can be concluded from the geometry of complexes **1**–**6** that the charge transfer takes place into the π* molecular orbitals of the acceptor molecule. The binding energy is expected to result from charge delocalization as well as from mutual polarization.

The interaction energy between $SO_2$ and $NMe_3$ in the 1:1 complex **2** was first estimated by Grundnes and Christian in 1968 using the concentration- and temperature-dependence of the optical absorption of this charge-transfer complex near 275 nm in the temperature range 39–60 °C.[14] On the assumption that only a 1:1 complex is formed, even with the large excess of $NMe_3$ used in these experiments, the reaction enthalpy in the gas phase was determined as $-40.6 \pm 1.7$ kJ mol$^{-1}$. Our calculations, which include a BSSE correction, gave a $\Delta H°_{298}$ value of –50.9 + 11.8 = –39.1 kJ mol$^{-1}$ for complex **2** and –61.9 kJ mol$^{-1}$ for the formation of the 1:2 complex **2a** from the three components (Table 1). The agreement between experiment and theory is therefore excellent.

In principle, the structures of **1**, **1a**, **2**, and **2a** are models not only for the nucleophilic attack of an amine on an $SO_2$ molecule but also more generally for the solvation of $SO_2$ by Lewis bases in solution and in the solid state. The calculated structures of the 1:2 adducts $SO_2{\cdot}2NH_3$ (**1a**) and $SO_2{\cdot}2NMe_3$ (**2a**) are shown in Figure 1, and bond angles are given in Table S1. These structures are in agreement with previous predictions.[3] No experimental structures of these species are known. The structure of **1a** ($C_{2v}$ symmetry) is characterized by two rather long S–N bonds (277.1 pm). The coordination sphere at the sulfur atom is pseudo-trigonal-bipyramidal, with the oxygen atoms and the assumed lone pair in the equatorial positions. The two axial S–N bonds are bent slightly towards the formal lone pair position with an N–S–N angle of 174.8°. An analogous structure is predicted for the related complex $SO_2{\cdot}2NMe_3$ (**2a**), which is also of $C_{2v}$ symmetry (Figure 1 and Table S1). The thermodynamic data of **1a** and **2a** are given in Table 1. The corrected Gibbs energies of formation of **1a** and **2a** from the components at 298 K are positive (39.6 and 21.5 kJ mol$^{-1}$, respectively), but the corresponding values at 77 K are negative (–9.8 and –43.7 kJ mol$^{-1}$, respectively). Both complexes are therefore predicted to be stable species in the gas phase only at temperatures well below 0 °C or in the presence of a large excess of the amine donor. The dipole moments of these two species are much smaller than those of the corresponding 1:1 complexes (Table 1).

### *Adducts of $S_2O$*

In the gas phase, disulfur monoxide is most conveniently prepared from thionyl chloride and silver sulfide at low pressures [Equation (1)]:[15]

$$SOCl_2 + Ag_2S \rightarrow S{=}S{=}O + 2\,AgCl \quad (1)$$

This molecule was the first example of a compound containing a formal double bond between heavier main group elements to be isolated in a pure form at 20 °C. Gaseous $S_2O$ is stable for a few days at room temperature at pressures of less than 1 mbar.[16] On condensation, even at liquid nitrogen temperatures, immediate exothermic dispro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

portionation and polymerization takes place, with the primary decomposition products being $S_3$ and $SO_2$ [Equation (2)]:[17]

$$2\ S_2O \rightarrow SO_2 + S_3 \quad (2)$$

$\Delta H°_{298} = -49.5\ kJ\,mol^{-1}$, $\Delta G°_{298} = -47.8\ kJ\,mol^{-1}$

We have investigated the structure and properties of the hypothetical adduct $S_2O{\cdot}NH_3$ (**3**), which is predicted to be $C_1$-symmetric with a structure analogous to that of $SO_2{\cdot}NH_3$ (**1**; see Figure 2). Due to the lower positive NBO charge on the central sulfur atom of $S_2O$ (+1.01) compared to $SO_2$ (+1.64), the interaction with Lewis bases is expected to be weaker. Thus, it is not surprising that the S–N bond of **3** is longer (275.5 pm) than that of **1** (266.3 pm). Interestingly, the length of the rather polar S=S bond of free $S_2O$ (190.8 pm) changes only slightly on complex formation with $NH_3$ (by +1.1 pm). The (uncorrected) dissociation enthalpy of **3** is only 11.6 kJ mol$^{-1}$ (Table 1). As a consequence of this weak interaction, the standard Gibbs energy of formation from the two components is positive (21.0 kJ mol$^{-1}$), which means that gaseous **3** is not a stable compound at room temperature.

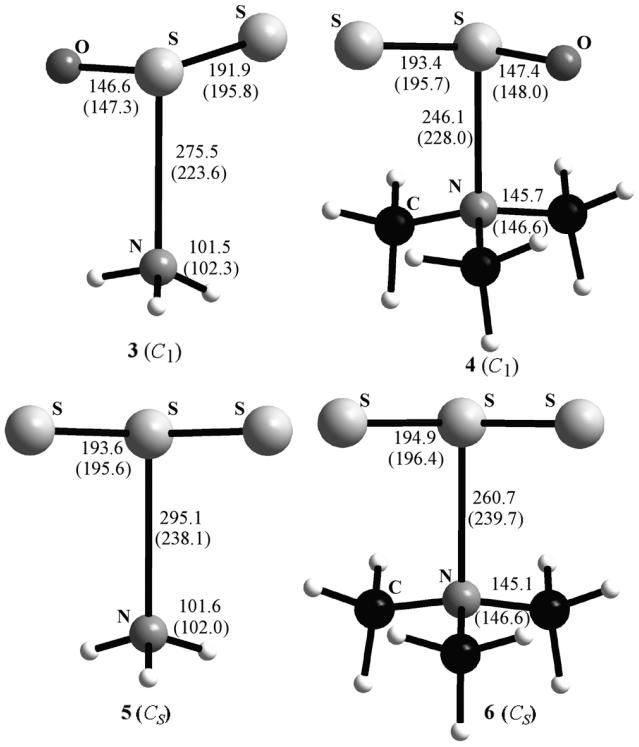

Figure 2. Structures, bond lengths (in pm), and symmetry of the complexes $S_2O{\cdot}NH_3$ (**3**), $S_2O{\cdot}NMe_3$ (**4**), $S_3{\cdot}NH_3$ (**5**), and $S_3{\cdot}NMe_3$ (**6**) in the gas phase. The bond lengths in a polar continuum of dielectric constant $\varepsilon = 40$ are given in parentheses. All data calculated at the B3LYP/6-31G(2df,p) level of theory. See Table S1 (Supporting Information) for bond angles.

The adduct $S_2O{\cdot}NMe_3$ (**4**) was prepared as yellow crystals that are stable only below –30 °C by co-condensation of $S_2O$ and $NMe_3$; its structure is unknown.[15] The calculated structure of **4** is shown in Figure 2 and bond angles are given in Table S1. The S–N bond (246.1 pm) is almost as short as that in $SO_2{\cdot}NMe_3$ (241.7 pm), therefore the interaction is clearly stronger than in the corresponding ammonia complex **3**. As a consequence, the S–S bond length increases by 2.6 pm compared to free $S_2O$ while the S–O bond length increases by only 0.9 pm. Interestingly, the S–N bond dissociation enthalpy of **4** (47.5 kJ mol$^{-1}$) is almost as large as that of the corresponding $SO_2$ adduct **2** (50.9 kJ mol$^{-1}$), whereas the standard Gibbs energy of the dissociation reaction is close to zero (–1.3 kJ mol$^{-1}$) and even becomes positive if a BSSE correction is applied (10.9 kJ mol$^{-1}$). This result explains the reported dissociation of **4** on sublimation in a vacuum. However, the Gibbs energy at 77 K is negative and **4** is expected to be a stable gas-phase species (Table 1).

### *Adducts of $S_3$*

The highly reactive molecule $S_3$ is a component of high-temperature sulfur vapors,[18] although $S_3$ has been isolated in inert matrices at low temperatures and characterized by vibrational and UV/Vis spectroscopy.[19] The structure of $S_3$ has been determined by microwave spectroscopy.[20] As mentioned above, $S_3$ is the primary disproportionation product of $S_2O$. Due to the small positive charge on the central atom of $S_3$ (NBO value: +0.33), adduct formation with $NH_3$ and $NMe_3$ is expected to be relatively weak. However, the structures of the corresponding complexes are analogous to those discussed above. Accordingly, the S–N bond of $S_3{\cdot}NH_3$ (**5**) is much longer (295.1 pm) than in any other adduct investigated in this work (see Table 1 and Figure 2). With the stronger base $NMe_3$, the S–N bond length decreases to 260.7 pm in $S_3{\cdot}NMe_3$ (**6**) (Figure 2). These structural properties are also reflected in the BSSE-corrected S–N bond-dissociation enthalpies, which are only 2.0 kJ mol$^{-1}$ for **5** and 25.6 kJ mol$^{-1}$ for **6** (Table 1). The Gibbs reaction energies for both **5** and **6** are positive at 298 K but negative for **6** at 77 K. In other words, $S_3$ may be stabilized by complex formation with $NMe_3$ at 77 K, in analogy to $S_2O$ (see above). One way to make **6** may be by disproportionation of **4**, in analogy to the reaction shown in Equation (3):

$$2\,S_2O{\cdot}NMe_3\ (\mathbf{4}) \rightarrow SO_2{\cdot}NMe_3\ (\mathbf{2}) + S_3{\cdot}NMe_3\ (\mathbf{6}) \quad (3)$$

This reaction is predicted to be exothermic in the gas-phase by $\Delta H°_{298} = -41.9\ kJ\,mol^{-1}$ ($\Delta G°_{298} = -45.7\ kJ\,mol^{-1}$). It will be shown below that complex **6** is even more stable than in the gas phase at 77 K in a polar continuum.

### *Adducts of $SOCl_2$*

Thionyl chloride vapor reacts violently with gaseous ammonia with elimination of HCl and formation of thionyl imide [OSNH; Equation (4)]:[21]

$$SOCl_2 + 3\,NH_3 \rightarrow O{=}S{=}NH + 2\,NH_4Cl \quad (4)$$

The reaction of $SOCl_2$ with $NH_3$ in solution produces $NH_4Cl$, $S_4N_4$, $NH_4(S_4N_4O)$, and other products.[22] The formation of the adduct $SOCl_2{\cdot}NH_3$ (**7**; Figure 3) may be the first step in these reactions. According to our calcula-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tions, this hypothetical molecule adopts an unusual pseudo-trigonal-bipyramidal structure with the chlorine atoms in axial positions. The S–N bond (198.0 pm) is shorter than in any of the other adducts studied in this work. Most remarkable, however, is the fact that the two chlorine atoms are bent towards the two nearest hydrogen atoms with a non-bonding Cl···H contact of just 254.7 pm and a Cl–S–Cl bond angle of 154.0° compared to 98.0° in free $SOCl_2$. Thus, the elimination of two molecules of HCl and formation of OSNH is already pre-organized in the structure of **7**, which has $C_s$ symmetry. Unexpectedly, the S–O bond of **7** is slightly shorter (143.8 pm) than calculated for free $SOCl_2$ (144.3 pm), and the SO stretching wavenumber of **7** is predicted to be larger (1285 $cm^{-1}$) than calculated for $SOCl_2$ (1271 $cm^{-1}$). The shortest O···H contact is 290.7 pm. Evidently, the considerable positive charge on the sulfur atom of $SOCl_2$ (+1.28) and the large negative charge on the nitrogen atom of $NH_3$ (–1.13) are responsible for the formation of a very short and very polar covalent S–N bond.

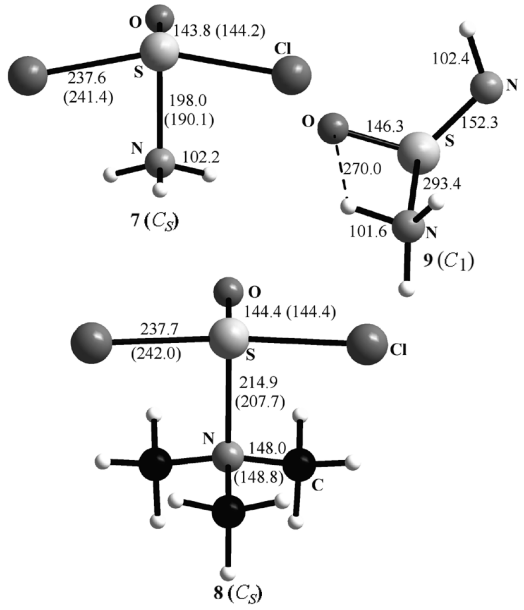

Figure 3. Structures, bond lengths (in pm), and symmetry of the complexes $SOCl_2{\cdot}NH_3$ (**7**), $SOCl_2{\cdot}NMe_3$ (**8**), and $SONH{\cdot}NH_3$ (**9**) in the gas phase. The bond lengths of **7** and **8** in a polar continuum of dielectric constant $\varepsilon = 40$ are given in parentheses. All structures calculated at the B3LYP/6-31G(2df,p) level of theory. See Table S3 (Supporting Information) for bond angles.

However, **7** is not a stable species in the gas phase at 298 K since the binding energy is positive, as is the Gibbs energy of formation from the two components. The energy gained on S–N bond formation is evidently overcompensated by the simultaneous weakening of the two S–Cl bonds, which increase dramatically in length from 212.2 pm in $SOCl_2$ to 237.6 pm in **7**. On the other hand, the NH bond lengths increase by only 0.5 pm. The bond angles of **7** are listed in Table S2.

The formation of gaseous SONH via the hypothetical intermediate Cl–SO–$NH_2$ is exergonic, as shown by the data in Equations (5), (6), and (7):

$$SOCl_2 + NH_3 \rightarrow Cl\text{–}SO\text{–}NH_2 + HCl \quad (5)$$
$$\Delta H°_{298} = -10.2\ kJ\,mol^{-1},\ \Delta G°_{298} = -4.7\ kJ\,mol^{-1}$$

$$Cl\text{–}SO\text{–}NH_2 \rightarrow O{=}S{=}NH + HCl \quad (6)$$
$$\Delta H°_{298} = +20.1\ kJ\,mol^{-1},\ \Delta G°_{298} = -21.2\ kJ\,mol^{-1}$$

$$SOCl_2 + NH_3 \rightarrow O{=}S{=}NH + 2\ HCl \quad (7)$$
$$\Delta H°_{298} = +9.9\ kJ\,mol^{-1},\ \Delta G°_{298} = -25.9\ kJ\,mol^{-1}$$

For comparison, the formation of SONH from $SO_2$ is predicted to be strongly endothermic and endergonic [Equation (8)]:

$$SO_2 + NH_3 \rightarrow O{=}S{=}NH + H_2O \quad (8)$$
$$\Delta H°_{298} = +50.5\ kJ\,mol^{-1},\ \Delta G°_{298} = +51.6\ kJ\,mol^{-1}$$

In contrast to the hypothetical $SOCl_2{\cdot}NH_3$, a compound of composition $SOCl_2{\cdot}NMe_3$ (**8**) has been prepared[15] but its structure is unknown. The predicted structure of gaseous **8** is similar to that of **7** and is also of $C_s$ symmetry (Figure 3; see Table S3 for bond angles). The S–Cl bonds are again quite long (237.7 pm) but the S–N bond (214.9 pm) is considerably longer than in **7** (198.0 pm). The charge difference between N (–0.43) and S (+1.40) is 1.83 units in **8**, which results in a large dipole moment of 6.87 D (Table 1). One can therefore expect this structure to change considerably in a polar environment (see below). All fundamental vibrations of **8** are strongly coupled with other modes. The wavenumber of the S–O stretching mode is predicted to be 1262 $cm^{-1}$, compared to 1271 $cm^{-1}$ calculated for free $SOCl_2$.

Gaseous $SOCl_2{\cdot}NMe_3$ seems to be unstable under standard conditions since the Gibbs energy of the formation reaction is positive. This also holds for a temperature of 77 K if the BSSE correction is taken into account (Table 1). We will show below, however, that the formation of **8** is more favorable in a polar medium.

### *Adduct of SONH*

We have also investigated the structure of a 1:1 adduct of thionyl imide with ammonia, namely $SONH{\cdot}NH_3$ (**9**; see Figure 3). The very long S–N bond (293.4 pm) and the rather small (uncorrected) dissociation enthalpy of 10.4 $kJ\,mol^{-1}$ are surprising since there is an additional O···H bonding interaction between the sulfinyl group and one of the hydrogen atoms of $NH_3$, as can be deduced from the close contact distance of 270.0 pm. This additional interaction can be interpreted as a Coulomb attraction between the positively charged H atom and the π electrons of the almost planar OSNH molecule (O=S=N–H torsion angle: 3.5°) with an H–N–S=O torsion angle of 2.5°. On the other hand, this type of interaction is also known as hyperconjugation between the π electrons of the sulfinyl group and the antibonding σ orbital of the NH bond. The $NH_3$ group is tilted with respect to the S–N single bond as a consequence of this O···H attraction but the N–H bond lengths within the ammonia molecule are all identical (101.6 pm). Because of the small interaction energy of **9** we

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

did not analyze this species any further (see Tables 1 and S2 for more details). Compound **9** may exist as $[NH_4][SON]$ in the solid state.

### *General Considerations*

Analysis of the data in Table 1 reveals that there is an inverse relationship between the formation enthalpies ($\Delta H°_{298}$) of adducts **1**–**8** and the S–N bond lengths, although there is a considerable scattering of the data. No such relationship exists between $\Delta H°_{298}$ and the dipole moments of the acceptors. This is not surprising since the dipole moment vectors of donor and acceptor are almost perpendicular to each other in adducts **1**–**6**. In other words, the dipole–dipole attraction can only be a minor contribution to the interaction energy in these complexes. On the other hand, the charge transfer, $\Delta e$, from donor to acceptor is clearly related to the dissociation enthalpy − a higher $\Delta e$ gives a more negative $\Delta H°_{298}$ (Table 1).

Adduct formation becomes more favorable at low temperatures due to a decrease of the reaction entropy. To study this effect we chose a temperature of 77 K as liquid nitrogen is normally used for cold traps in preparative experiments. The Gibbs energies for the adduct-formation reactions are provided for this temperature in Table 1, assuming all reactants and products still to be gaseous. The data corrected for the BSSE indicate that all adducts except $S_3{\cdot}NH_3$, $SOCl_2{\cdot}NH_3$, and $SOCl_2{\cdot}NMe_3$ are stable at this temperature in the gas phase ($\Delta G°_{77} < 0$).

### Adducts in a Polar Continuum

As outlined above, the transfer of the highly polar adducts **1**–**8** into a polar continuum is expected to result in their stabilization and considerable structural changes, although the polar components are also stabilized in this kind of continuum. Our thermodynamic data calculated at the B3LYP/6-31G(2df,p) level of theory using the polar continuum model (PCM) are summarized in Table 2. The results reveal that all ammonia complexes, with the exception of $SOCl_2{\cdot}NH_3$ (**7**), are expected to be less stable at $\varepsilon = 40$ while all the trimethylamine complexes are predicted to be more stable than in the gas phase. Definitely negative Gibbs energies of formation are predicted at 298 K only for $SO_2{\cdot}NMe_3$ and $S_2O{\cdot}NMe_3$, and these two species do in fact exist as crystalline solids. The reported compound of composition $SOCl_2{\cdot}NMe_3$[15] may therefore have a different structure than assumed in this work. An alternative to the donor–acceptor adduct would be an ionic solid $[Me_3NSOCl]^+Cl^-$ containing a pyramidal coordinated sulfur atom as in $SOCl_2$.

The standard Gibbs energy of formation in the case of $S_3{\cdot}NMe_3$ is close to zero (–0.8 kJ mol$^{-1}$), which means that this adduct may exist at temperatures considerably lower than 25 °C. This prediction is more convincing if one uses the energies of formation of the complexes in the polar continuum but with respect to the *gaseous* components. The corresponding data are presented in Table 3. All complexes except $S_2O{\cdot}NH_3$ and $S_3{\cdot}NH_3$ are thermodynamically stable under standard conditions and with respect to their components, even $SOCl_2{\cdot}NMe_3$. Experimental data are available for the two ammonia complexes of $SO_2$. The reaction enthalpies of the solid adducts from the gaseous components have been determined as $-40 \pm 4$ kJ mol$^{-1}$ for **1** and $-96 \pm 19$ kJ mol$^{-1}$ for **1a** from equilibrium vapor measurements.[1] Our calculations of the reaction enthalpies in the polar continuum but from the gaseous components resulted in enthalpy values of –57.1 and –81.7 kJ mol$^{-1}$, respectively (Table 3), in fair agreement with experiment, especially if the BBSE correction is applied qualitatively.

Table 3. Reaction energies ($\Delta E_o$), enthalpies ($\Delta H°_{298}$), and Gibbs energies ($\Delta G°_{298}$) [G3X(MP2) in kJ mol$^{-1}$] for the formation of the solvated donor–acceptor complexes **1**–**8** in a polar continuum of dielectric constant $\varepsilon = 40$, but from the gaseous components.

[a] Splitting due to coupling with other modes.

The structural changes on transfer of the gaseous complexes into a medium of dielectric constant $\varepsilon = 40$ mainly concern the S–N bonds, which shorten dramatically in adducts **1**–**6** but much less so in the $SOCl_2$ complexes **7** and **8**. Accordingly, the calculated structure of $SO_2{\cdot}NMe_3$ (**2**) at $\varepsilon = 40$ is in much better agreement with the X-ray structure of this complex than the structure predicted for the gas phase. For instance, the calculated S–N bond length decreases from 241.7 pm in the gas phase to 227.2 pm at $\varepsilon = 40$ (a value of 204.6 pm has been derived crystallographically).[7] The O–S–O, O–S–S, and S–S–S bond angles of species **2** all decrease by about 2° in the polar medium (Table S1), and the symmetry of some complexes (e.g., **1**, **1a**, and **8**) is lower in the polar medium ($C_1$) than in the gas phase.

The vibrational spectra also reflect the structural changes of the adducts between the gas phase and the polar continuum. In general, the fundamental modes are strongly coupled due to the low symmetry of the complexes, although a few assignments can be made. The most important vibrations of the acceptor parts of the molecules are given for both phases in Table 4. Thus, while the S–O and S–S stretching vibrations are shifted to lower wavenumbers in the polar continuum, the S–N stretching modes are predicted to appear at higher wavenumbers in the polar phase. For example, the two S–O stretching vibrations of $SO_2$ vary from 1171/1381 $cm^{-1}$ for gaseous $SO_2$, via 1166/1356 $cm^{-1}$ for gaseous $SO_2{\cdot}NH_3$ and 1137/1319 $cm^{-1}$ for gaseous $SO_2{\cdot}NMe_3$, to 1099/1249 $cm^{-1}$ for $SO_2{\cdot}NMe_3$ in the polar continuum. The vibrations of the $NMe_3$ units in complexes **2**, **4**, and **6**, however, are much less affected. For example, the symmetrical stretching mode of the $NC_3$ skeleton always occurs at $818 \pm 1$ $cm^{-1}$ in the gas phase and at $807 \pm 2$ $cm^{-1}$ in the polar continuum, whereas the bending modes of the acceptors do not show any uniform shift on transfer of the gaseous complexes into the polar continuum.

## Conclusions

According to our G3X(MP2) calculations, the structures of the adducts $SO_2{\cdot}NH_3$ (**1**), $SO_2{\cdot}2NH_3$ (**1a**), $SO_2{\cdot}NMe_3$ (**2**), $SO_2{\cdot}2NMe_3$ (**2a**), $S_2O{\cdot}NH_3$ (**3**), $S_2O{\cdot}NMe_3$ (**4**), $S_3{\cdot}NH_3$ (**5**), $S_3{\cdot}NMe_3$ (**6**), $SOCl_2{\cdot}NH_3$ (**7**), $SOCl_2{\cdot}NMe_3$ (**8**), and $SONH{\cdot}NH_3$ (**9**) correspond to energy minima on the corresponding potential hypersurfaces. However, only **2** and **4** are thermodynamically stable in the gas phase under standard conditions with respect to their acceptor and donor components ($\Delta G°_{298} < 0$). The latter two complexes have, in fact, been prepared as solid materials. Species **2**, **4**, and **6** are predicted to be stable in a polar continuum of dielectric constant $\varepsilon = 40$. Thus, the preparation of $S_3{\cdot}NMe_3$ can be expected in the future. All species except **3** and **5** are thermodynamically stable if the equilibrium between the gaseous components and the adduct in the polar continuum is analyzed. The structures of complexes **3**–**9** have been calculated for the first time. The structural changes on complex formation as well as the vibrational spectra indicate a weakening of the bonds in the acceptor molecule, in particular in the polar continuum. On the other hand, the donor–acceptor interaction is stronger in the polar environment than in the gas phase and, as a consequence, the S–N bond lengths are shorter under such circumstances.

## Computational Details

The structures and energies of the various complexes were examined according to G3X(MP2) theory[23] using the GAUSSIAN 03[24] program package. This composite method corresponds effectively to QCISD(T)/G3XL//B3LYP/6-31G(2df,p) energy calculations together with zero-point vibrational and isogyric corrections. The G3X(MP2) theory represents a modification of the G3(MP2)[25] theory with three important changes: (1) B3LYP/6-31G(2df,p) geometry, (2) B3LYP/6-31G(2df,p) zero-point energy, and (3) addition of a *g* polarization function to the G3Large basis set for the second-row atoms at the Hartree–Fock level. All three features are particularly important for the correct description of the sulfur-containing species examined in this work. Harmonic fundamental vibrations were calculated at the B3LYP/6-31G(2df,p) level to characterize stationary points as equilibrium structures, with all frequencies real. A charge density analysis was performed for all investigated species using the natural bond orbital (NBO) approach based on the B3LYP/6-31G(2df,p) wavefunction.[26] NBO atomic charges of small molecules have recently been demonstrated to agree well with experimental values obtained from X-ray diffraction data.[27] As far as gas-phase species are concerned, all relative energies and enthalpies reported in the text correspond to the G3X(MP2) level, while all reported structural parameters correspond to the B3LYP/6-31G(2df,p) level. The correction to the basis set superposition error (BSSE) was calculated at the MP2/GTMP2Large level using the counterpoise method of the GAUSSIAN 03 program. Since this correction is calculated with fixed monomer geometries, taken from the complexes, the obtained data must be considered as upper limits, especially if there is a strong deformation, as is the case for the thionyl chloride complexes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The investigated complexes are characterized by large dipole moments, therefore it is to be expected that the thermodynamics of formation of such species in the solid state and in polar solvents will be quite different from that in the gas phase. Calculations according to Tomasi's polar continuum model (PCM)[28] were carried out at the B3LYP/6-31G(2df,p) level to study the influence of a polar environment. This method of studying the electrostatic solute/solvent interaction has proven to be very successful in reproducing solvent effects as the solvent is represented by a continuous dielectric, characterized by a given dielectric constant ($\varepsilon$), and the solute is assumed to be embedded in a cavity in the medium. The permanent dipole of the solute induces a dipole in the medium, which in turn interacts with the molecular dipole leading to stabilization. A dielectric constant of 40.0 was used for the PCM calculations to represent the polar medium. No such calculations on complexes **1**–**8** have been reported so far.

**Supporting Information** (see footnote on the first page of this article): Absolute energies, bond angles, and atomic coordinates of compounds **1**–**8**.

## Acknowledgments

We appreciate invaluable advice from Prof. Ming Wah Wong (Richard), Singapore, and support from the Norddeutscher Verbund für Hoch- und Höchstleistungsrechnen (HLRN).

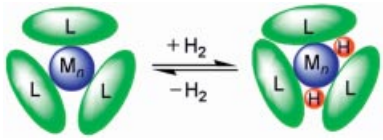
## MICROREVIEW

### Hydrogen on Metal Clusters

**A. S. Weller,* J. S. McIndoe* ... 4411–4423**

Reversible Binding of Dihydrogen in Multimetallic Complexes

**Keywords:** Hydrides / Homogeneous catalysis / Heterogeneous catalysis / Cluster compounds / Hydrogen



The reversible attachment of hydrogen to metal complexes, especially multimetallic systems, constitutes a technologically and academically important area ranging from commodity chemical synthesis (catalysis) through to the storage of hydrogen. In this contribution, the binding of dihydrogen in multimetallic cluster complexes is reviewed.

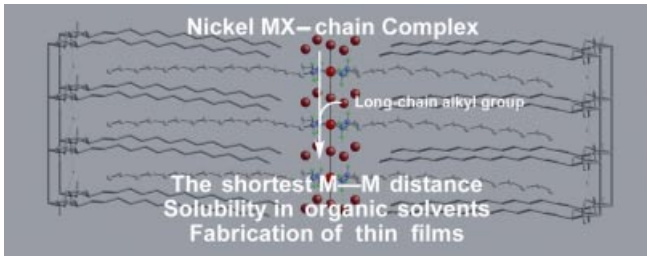
## SHORT COMMUNICATION

### Halogen-Bridged $Ni^{III}$ Nanowires

**H. Ohtsu,* S. Takaishi, K. Imamura, A. Ishii, K. Tanaka, M. Hasegawa, M. Yamashita* ..... 4425–4428**

Remarkable Functions of Long-Chain Alkyl Groups in Halogen-Bridged Nickel(III) Nanowire Complexes

**Keywords:** Nickel / Nanostructures / Long-chain alkyl groups / Average-valent compounds / Thin films



The long-chain alkyl groups of new bidentate ligands make it possible to generate nickel MX–chain complexes exhibiting the shortest $Ni^{III}$–$Ni^{III}$ distance among all MX–chain compounds reported. Dissolution in organic solvents occurs without dissociation of the MX–chain units, and the successful fabrication of thin films is reported.

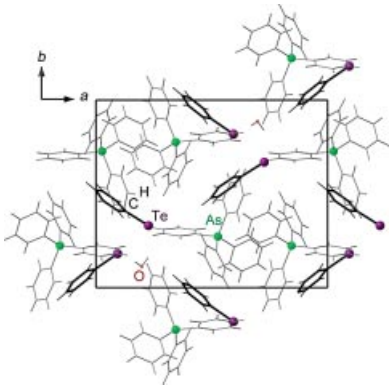
## FULL PAPERS

### Tellurostannates

**E. Ruzin, W. Massa, S. Dehnen* ..... 4429–4433**

Treating $[K_4(H_2O)_{0.5}][SnTe_4]$ with $PPh_4^+$ or $AsPh_4^+$: Formation of a Highly Air-Stable Tellurostannate Salt, a Tellurolate with One-Coordinate Te Atoms, and a Polytelluride Salt with $^{\infty}_{1}[Te_4(H_2O)_2]^{2-}$ Chains

**Keywords:** Arsonium salts / Phosphonium salts / Tellurolate / Tellurostannate / Polytelluride / X-ray diffraction



Beyond a simple cation exchange! By treating orthotellurostannates with $EPh_4Cl$ (E = P, As), one obtains air-stable tellurodistannate **1** by partial replacement of the strongly interacting $K^+$ by the much more weakly interacting $[PPh_4]^+$ cations, or telluropheno late **2** (see figure) with a one-coordinate Te atom upon As–C bond cleavage. Oxidation of the air-sensitive $[Sn_2Te_6]^{4-}$ and $Te^{2-}$ anions in solution produces tetratelluride salt **3** with strands of $H_2O$-bridged $[Te_4]^{2-}$ units.

## Molecular Magnetism

Prediction of the magnetic properties of binuclear $Cu^{II}$ compounds containing asymmetric azide bridges remains a challenge. A combination of correlated ab initio calculations and the analysis of the experimental data shows that the asymmetry of the coordination of the azido bridge is a determining factor in the tuning of the coupling constant value.

## Inorganic Reaction Mechanisms

The kinetics of the process $AuCl_3(am) + Cl^- \rightarrow AuCl_4^- + am$ (am = pyridines with different π systems and $sp^3$ amines) have been studied in methanol at 25 °C. The reactivity of the considered N-donors is different and follows the order $sp^3$ N-donors > "normal" pyridines > "π-extended" pyridines. This result, with the support of ground-state DFT calculations on the $AuCl_3(am)$ derivatives, is explained on the basis of an Au–N bond enforcement due to an increased π-back-donation contribution.

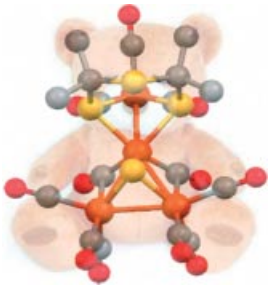
Reactions of 1,2,4-Trithiolanes with Nonacarbonyldiiron: Sulfurdithiolatodiiron and -tetrairon Complexes as Mimics for the Active Site of [Fe-only] Hydrogenase

**Keywords:** Iron / Cluster compounds / S ligands / Hydrogenases / Density functional calculations



The synthesis of novel structural models for the active site of [Fe-only] hydrogenase is described starting from 1,2,4-trithiolane and its derivatives. The products are characterised by spectroscopic methods and X-ray structure analyses. Density functional calculations are reported for a representative example of the unusual tetranuclear iron clusters formed.

## SOD Mimics

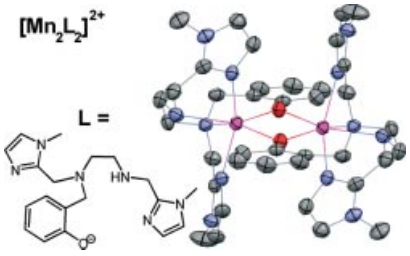
A New Pentadentate Ligand Forms Both a Di- and a Mononuclear $Mn^{II}$ Complex: Electrochemical, Spectroscopic and Superoxide Dismutase Activity Studies

**Keywords:** Manganese(II) / Enzyme models / SOD mimic / N,O ligands / Bioinorganic chemistry



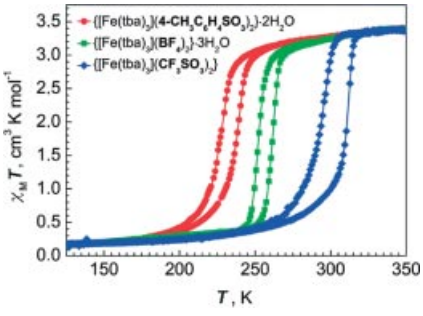
A new 1,2-ethanediamine-centered pentadentate ligand that contains imidazole and phenol moieties is presented and a dinuclear $Mn^{II}-Mn^{II}$ complex of this ligand characterized (X-ray diffraction, electrochemistry, EPR spectroscopy). This complex forms a mononuclear complex, whose SOD-like activity has been evaluated, in aqueous solution.

## Spin-Crossover in $Fe^{II}$ Complexes

**M. Seredyuk, A. B. Gaspar,* M. C. Muñoz, M. Verdaguer, F. Villain, P. Gütlich* ..... 4481–4491**

Cooperative Spin-Crossover Behaviour in Polymeric 1D $Fe^{II}$ Coordination Compounds: $[\{Fe(tba)_3\}X_2]\cdot nH_2O$

**Keywords:** Spin crossover / Bistability / Cooperative effects / Iron(II) complexes / Substituted triazoles



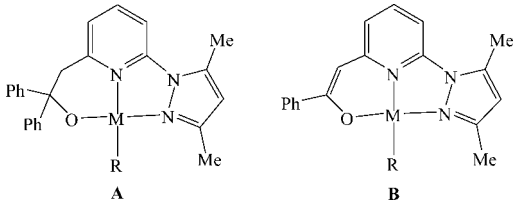
The synthesis and physical characterisation of new 1D cooperative spin-crossover polymers with general formula $[\{Fe(tba)_3\}X_2]\cdot nH_2O$ [tba = *N*-(4*H*-1,2,4-triazol-4-yl)benzamide; X = $CF_3SO_3^-$, $BF_4^-$ and $4\text{-}CH_3C_6H_4SO_3^-$] is reported.

## C–C Coupling

**Z.-X. Wang,* Z.-Y. Chai ..... 4492–4499**

Palladium(II) and Nickel(II) Complexes Bearing N,N,O-Chelate Ligands: Syntheses, Characterization and Catalysis in Heck and Kumada Coupling Reactions

**Keywords:** N,N,O ligands / Palladium / Nickel / Chelates / Homogeneous catalysis / C–C coupling



Novel N,N,O-tridentate ligands and their nickel and palladium complexes **A** and **B** are synthesized and characterized, and the catalytic behavior of these complexes in the Heck and Kumada reactions is evaluated.

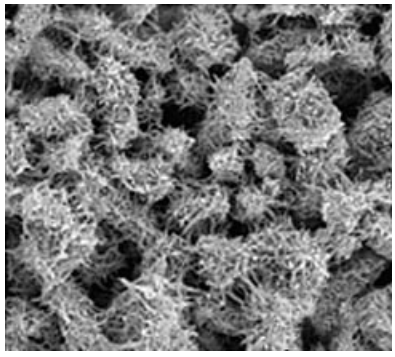
3D Architectures of InOOH: Ultrasonic-Assisted Synthesis, Growth Mechanism, and Optical Properties

**Keywords:** Indium / Mechanism / UV/Vis spectroscopy / Solvothermal synthesis

InOOH with a hierarchical 3D architecture assembled from uniform single-crystalline nanowires was synthesized by an ultrasonic-assisted solvothermal route.

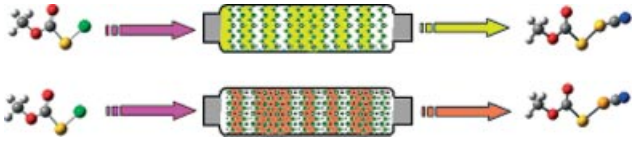


## Dichalcogens

**L. Du, L. Yao, M. Ge* ..... 4514–4519**

Two Novel Species, (Methoxycarbonyl)-sulfenyl Thiocyanate and (Methoxycarbonyl)sulfenyl Selenocyanate: Spectroscopic Characterization by Photoelectron Spectroscopy, and Quantum Chemical Investigation

**Keywords:** Ab initio calculations / Dichalcogens / Electronic structure / Photoelectron spectroscopy



Two novel dichalcogens, $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$, have been generated in a convenient way by gas–solid reactions between $CH_3OC(O)SCl$ and AgSCN or AgSeCN. Photoelectron spectroscopy and theoretical calculations have been performed to investigate their electronic and geometrical structure. Their HOMOs correspond to the electron mainly localized on the S 3p or Se 4p lone pair MOs: $\{38a(n_{S(SCN)})\}^{-1}$ and $\{47a(n_{Se})\}^{-1}$, respectively.

## Metal Phosphonates

**Z.-Y. Du, H.-B. Xu, X.-L. Li, J.-G. Mao* ..... 4520–4529**

A New Approach to Novel Cluster Compounds of Lead(II) Phosphonates

**Keywords:** Lead / Sulfonate-phosphonates / Solvothermal synthesis / Cluster compounds

Five new lead(II) sulfonate-phosphonates, namely $[Pb_3(L)_2(H_2O)_2]\cdot 4H_2O$ (**1**), $[Pb(HL)(phen)]\cdot H_2O$ (**2**), $[Pb_6(L)_4(phen)_8]\cdot 3H_2O$ (**3**), $[Pb_6(L)_4(phen)_{10}]\cdot 2H_2O$ (**4**), and $[Pb_6(L)_4(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (**5**; $H_3L$ = *m*-$HO_3S$-$C_6H_4$-$PO_3H_2$), have been prepared and structurally characterized. They exhibit novel 0D, 2D, or 3D structures. Compounds **3** and **4** are the first cage compounds of $Pb^{II}$ phosphonates.

# Reversible Binding of Dihydrogen in Multimetallic Complexes

**Andrew S. Weller*[a][‡] and J. Scott McIndoe*[b]**

**Keywords:** Hydrides / Homogeneous catalysis / Heterogeneous catalysis / Cluster compounds / Hydrogen

The interaction of hydrogen with metal surfaces is one of the most important and fundamental processes in the chemical industry. Hydrogen is also strongly tipped to play a central role in new challenges that are emerging in terms of climate change and energy supply, and the reversible binding of $H_2$ to suitable materials will play a keystone role in the realisation of the hydrogen economy. The reversible interaction of hydrogen with multimetallic centres is also an important theme in biological processes; the role of hydrogenases in the metabolism of $H_2$ is an example. Thus the reversible interaction of $H_2$ with multimetallic metal complexes is an area that spans considerable breadth. This review is concerned with the reversible interaction of $H_2$ with soluble multimetallic complexes, defined broadly as clusters, in which there are no other ligands lost or gained in the process. The review is organised under the subheadings: equilibrium reversible ($H_2$ is lost upon removal of the $H_2$ atmosphere), thermally reversible or reversible when placed under vacuum, photochemically reversible and electrochemically reversible interactions; a brief outline of reversible $H_2$ binding in systems of biological interest; giant metal clusters that display reversible $H_2$ binding.

## Introduction

The interaction of hydrogen with metal surfaces is one of the most important and fundamental processes in the chemical industry. Catalytic hydrogenations are the largest chemical reactions by volume, as all crude oil is treated with $H_2$ in desulfurisation, while ammonia production from $N_2$ and $H_2$ over an iron oxide catalyst produces ammonia fertiliser on a multimillion tonne scale per year. Both of these processes involve heterogeneous metal catalysts and accordingly the interaction of hydrogen with a metal surface. Hydrogen is also strongly tipped to play a central role in new challenges that are emerging in terms of climate change and energy supply, in that it is a valuable future fuel that when burnt (either in a combustion engine or a fuel cell) releases only water. It is widely accepted that the realisation of the

*Andrew Weller completed his first degree at the University of Warwick and his PhD at the University of Bristol (1994) under the supervision of Dr John Jeffery. After postdoctoral positions with Professor Alan Welch (Heriot-Watt University) and Professor Thomas Fehlner (University of Notre Dame) he returned to the UK and took up a Royal Society University Research Fellowship at the University of Bath in 1999. He was promoted to Reader in 2004. In September 2007 he moved to the Department of Chemistry University of Oxford. His research broadly covers synthetic organometallic chemistry, catalysis and structure and bonding. Major research themes in his group are: (i) the synthesis of high-hydride-content rhodium clusters (and their precursors) and (ii) the transition-metal chemistry of low-coordinate cationic late-transition-metal complexes, especially those incorporating weakly coordinating anions, for use in catalysis and C–H/C–C activation processes.*

*Scott McIndoe was born and educated in New Zealand. He completed his DPhil in synthetic (in)organometallic chemistry at the University of Waikato under the supervision of Professor Brian Nicholson. In 1998, he won a New Zealand Foundation for Research, Science & Technology Postdoctoral Fellowship and joined the group of Professor Brian Johnson FRS at the University of Cambridge (UK). In 2000, he took up a college lectureship, teaching at Trinity and Newnham Colleges, Cambridge, and continued his research in the Department of Chemistry. Three years later he moved to his current position, as assistant professor in the Department of Chemistry at the University of Victoria, where his research group uses mass spectrometry as a rapid discovery tool in organometallic chemistry and catalysis.*

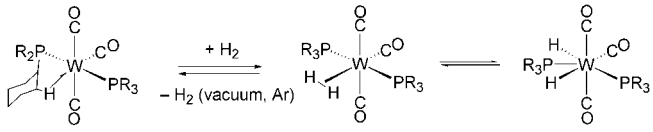
"hydrogen economy"[1] will require breakthroughs in the crucial area of efficient storage of hydrogen accompanied with favourable charge/discharge kinetics and operating temperatures.[2] Although they are not the only possible solution, metal complexes of hydrogen could well make important contributions to the realisation of this goal; even though it is highly unlikely that a practicable solution to store $H_2$ would involve metal complexes from the second or third rows with attached ligands – a consequence of the combined factors of very low %H content and cost. The study of the reversible interaction of hydrogen with metal surfaces and other materials is an area that has been occupying molecular and solid-state chemists, surface scientists and physicists for many years, and the level of interest in this field remains high.

This review is concerned with the reversible interaction of $H_2$ with well-defined multimetallic soluble complexes, defined broadly as clusters. Reversibility in this context suggests that there is no other change in formulation to the cluster material on addition or removal of $H_2$, meaning that there must be no other ligands lost or gained in the process. The consequence of this stipulation is that reversible uptake of $H_2$ in multimetallic systems without ligand displacement must occur on a molecule that has available low lying orbitals to take up the bonding pairs of $H_2$ – in other words the system must be formally electronically (and most likely coordinatively) unsaturated or have access to such a state by ligand or metal-core rearrangement. The review limits itself to well-defined molecular systems, venturing briefly into nearly monodisperse nanoclusters but avoiding larger metal particles, surfaces and bulk metals except for the purpose of comparison.

## Hydrogen–Transition-Metal Bonding

Hydrogen may either chemisorb on a metal surface as atomic hydrogen or physisorb as an intact $H_2$ molecule. Both have parallels in molecular cluster chemistry: metal hydrides and metal dihydrogen complexes, respectively. Detecting hydrogen bound to a metal surface is not straightforward and requires the use of a limited set of high-vacuum techniques, such as electron energy loss spectroscopy (EELS) or scanning tunnelling microscopy (STM).[3] Information obtained from such experiments shows that on a metal(111) surface atomic hydrogen adsorbs to form a monolayer of hydrogen at 37 K, and the H atoms are chemisorbed on threefold face-centred cubic sites, positioned in the hollows between the metal atoms. Binding of intact $H_2$ to nanoclusters and metal surfaces is rare because of the preferential formation of hydrides,[4,5] although there is evidence for dihydrogen bound to a Ni(510) surface.[6] In the molecular realm, the interaction of atomic hydrogen with metal clusters (hydride ligands) is very well documented, and there are literally thousands of examples of metal hydride cluster species.[7] By contrast, the coordination of molecular hydrogen in complexes with multimetallic systems is considerably less common, and to the best of our knowledge only a handful of examples exist in which a relatively reliable indicator such as a short $T_1$ relaxation time associated with the bound dihydrogen has been reported.[8–12]

The exemplar for dihydrogen coordination to soluble metal complexes remains the original Kubas complex $W(PR_3)_2(CO)_3$ (R = Cy, *i*Pr), in which an agostic C–H–M interaction from a bulky cyclohexyl group provides light stabilisation of the metal centre, allowing for an operationally unsaturated 16-electron complex. Addition of $H_2$ displaces this interaction to form the, now classic, complex $W(PR_3)_2(CO)_3(\eta^2\text{-}H_2)$ (R = Cy, *i*Pr) (Scheme 1). Placing this compound under a non-hydrogen atmosphere or vacuum removes the bound $H_2$ and re-establishes the agostic C–H bond.[5,13] These dihydrogen complexes are also in equilibrium in solution with the tautomeric dihydride forms (the dihydrogen complexes are favoured), and the $\Delta G^{\ddagger}$ for this oxidative addition of $H_2$ has been estimated to be 60 kJ mol$^{-1}$. The equilibrium demonstrates an important point in that even though a dihydride is observed as the major (or often the only) species by NMR spectroscopy and X-ray crystallography, a low-energy pathway to a coordinated dihydrogen ligand can allow for the loss of $H_2$. If the resulting complex is stabilised in the absence of $H_2$ by either steric bulk and/or agostic interactions, then the molecule is available to take up $H_2$ again without decomposition. Examples of $H_2$ loss in mononuclear complexes where the resulting molecule is unstable and dimerises to relieve the unsaturation are known, but we do not focus on these here.[10]



Scheme 1. R = Cy.

Although examples of multimetallic complexes where dihydride and dihydrogen complexes are in slow equilibrium with one another are not known, computational and experimental studies indicate that such a transformation is likely to have a comparable barrier to those determined for mononuclear complexes. For example, the rapid H/D exchange in $CpRu(\mu\text{-}H)_4RuCp$ on addition of $D_2$ is calculated as passing through a dihydrogen transition state with a rate-determining barrier of less than 80 kJ mol$^{-1}$.[14] The dihydride complex $Re_2H(\mu\text{-}H)(CO)_9$ irreversibly loses $H_2$ above 253 K and is a highly fluxional molecule, exchanging hydride sites through a low-energy process (Scheme 2).[15] NMR spectroscopic data ($T_1$ measurements) suggest a dihydride structure; however, experimental and theoretical studies are in close agreement and show that the barrier for exchange through a dihydrogen intermediate is only 23 and 27 kJ mol$^{-1}$, respectively. $(\eta^2\text{-}H_2)$(isoPFA)$Ru(\mu\text{-}Cl)_2(\mu\text{-}H)$-$RuH(PPh_3)_2$ undergoes rapid exchange between dihydrogen and bridging dihydride ligands at 20 °C (barrier 53 kJ mol$^{-1}$)[8,16] as do related chelated phosphane complexes[12] and the cluster $[Ru_4(\eta^6\text{-}C_6H_6)_4H_6]^{2+}$,[11] both of which have a mixture of dihydrogen and dihydride ligands

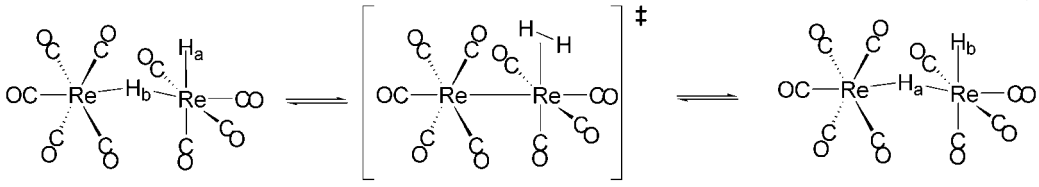

Scheme 2.

as characterised by $T_1$ relaxation time measurements by NMR spectroscopy at low temperature. The iridium dimer $Ir_2(PiPr_3)_2(pz)_2(H)_2(\mu\text{-}H)(\eta^2\text{-}H_2)$ is suggested to have a dihydrogen ligand that undergoes rapid exchange with a terminal hydride, with a barrier of 32 kJ mol$^{-1}$.[17] Mechanisms for hydride/dihydrogen exchange have recently been reviewed in the more general sense of exchange mechanisms in sigma complexes.[18]

In mononuclear complexes hydrogen is found either as a hydride ligand (H) or as dihydrogen ($\eta^2$-$H_2$). The H–H distance defines the difference between a true $H_2$ complex (0.8–1.0 Å) and a dihydride (> 1.6 Å),[5] with intermediate H–H lengths described as elongated $H_2$ complexes or compressed dihydrides.[19] In polynuclear metal clusters, however, hydrogen may occupy a variety of different positions with respect to the metal centres that are not available to mononuclear complexes, including bridging, face-bridging and interstitial locations (Figure 1).

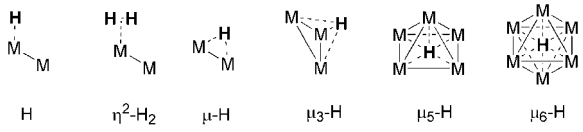

Figure 1. Hydrogen bonding modes observed in cluster complexes; terminal hydride (H), dihydrogen complex ($\eta^2$-$H_2$), bridging hydride (μ-H), face-bridging hydride ($\mu_3$-H) and interstitial hydrides ($\mu_5$- and $\mu_6$-H).

Neutron diffraction studies are the definitive structural answer to the exact mode of hydrogen coordination, and all of the cluster-only ($\mu_n$-) binding modes have been unambiguously characterised by this method; examples include (**μ-H**)$Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-}CCCMe_3)$,[20] (**$\mu_3$-H**)$_4Co_4(\eta^5\text{-}C_5Me_4Et)_4$,[21] [(**$\mu_5$-H**)$_2Rh_{13}(CO)_{24}$]$^{3-}$[22] and [(**$\mu_6$-H**)$Ru_6(CO)_{18}$]$^-$.[23] However, terminal hydride and dihydrogen ligands are sufficiently rare in cluster chemistry, and they remain uncharacterised by neutron diffraction. An unusually well-characterised example of a bimetallic species with a dihydrogen ligand is ($\eta^2$-$H_2$)(isoPFA)Ru(μ-Cl)$_2$(μ-H)RuH($PPh_3$)$_2$ (isoPFA = {$\eta^5$-$C_5H_5$}Fe($\eta^5$-$C_5H_3$($CHMeNMe_2$)-$PiPr_2$}), which was investigated by X-ray crystallography and variable-temperature $^1$H- and $^{31}$P-NMR spectroscopy.[8] The structure (Figure 2) is notable for having three different binding modes of H present in one structure. The NMR spectroscopic data for this compound revealed fast exchange between the $\eta^2$-$H_2$ and the μ-H at 20 °C and a slower exchange of these three hydrogen atoms with the terminal hydride.

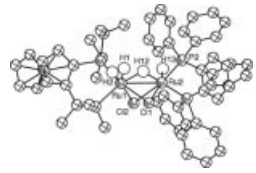

Figure 2. X-ray crystal structure of ($\eta^2$-$H_2$)(isoPFA)Ru(μ-Cl)$_2$(μ-H)RuH($PPh_3$)$_2$.[8]

In almost all instances, addition of hydrogen to a metal cluster is preceded or accompanied by ligand dissociation to generate a coordinatively and electronically unsaturated[24] cluster to which $H_2$ can be added. For example, addition of $H_2$ to $Os_3(CO)_{12-n}(NCMe)_n$ ($n$ = 1,2) occurs by NCMe dissociation and addition of $H_2$ to form $Os_3(CO)_{10}$-(μ-H)$_2$.[25] For unsaturated metal clusters, often decorated with bulky phosphane ligands such as $PtBu_3$, $PCy_3$ and $PiPr_3$, ligand dissociation is not a prerequisite for addition of $H_2$. These ligands provide a steric shield around the metal centre that prevents ligands other than the smallest molecules, such as $H_2$, from easily entering the coordination sphere of the cluster (see Figure 3). Thus these clusters are *kinetically* stabilised with respect to addition of further ligands. As will be shown, these unsaturated complexes often have low-lying unoccupied molecular orbitals that show small HOMO–LUMO gaps and are well set up for uptake of electrons from the $H_2$ bonding pairs.

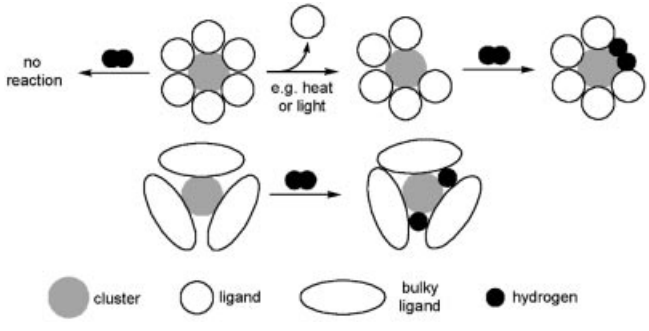

Figure 3. Cartoon showing (top) how most multimetallic compounds require ligand loss prior to hydrogen binding and (bottom) how electronically unsaturated compounds with bulky ligands escape this requirement and can frequently bind hydrogen reversibly without significant structural change.

## Equilibrium Reversible ($H_2$ Is Lost upon Removal of the $H_2$ Atmosphere)

Many unsaturated multimetallic complexes add $H_2$ to give hydride species, but often this is a reversible process, and removal of the $H_2$ atmosphere regenerates the starting material. Given that hydrogen addition and loss are clearly low-energy processes, in these examples it is not surprising to find that many of these complexes also undergo rapid H/D exchange when placed under a $D_2$ atmosphere.

Muetterties, and later Fryzuk, reported that addition of $H_2$ to the unsaturated (28 electrons) dimeric complexes $[L_2Rh_2(\mu\text{-}H)_2]$ (**1a**–**e**) (L = $i$Pr$_2$P(CH$_2$)$_n$P$i$Pr$_2$ $n$ = 2 **1a**; 3 **1b**; 4 **1c**;[26] L = P$i$OPr$_3$ **1d**, L = POMe **1e**[27]) results in the complexes $[L_2Rh_2(\mu\text{-}H)_3H]$ (**2a**–**e**), which are best formulated as having $Rh^{III}/Rh^{I}$ metal centres and have been characterised spectroscopically.[26] For the chelating ligand **2c** with the largest bite angle, the extra hydrides are held quite firmly – even under vacuum – and require an acceptor (1-hexene) to remove $H_2$. For the ligands **2a** and **2b** with smaller bite angles, the hydrogen is lost on removal of the $H_2$ atmosphere. The ligand in **2c** presumably shields the metal centres more effectively and kinetically blocks $H_2$ loss. This reasoning we will return to later, and steric blocking seems important in both the generation and stabilisation of hydrogen-rich complexes. Large ligands block the approach of additional large ligands that would satisfy the metal cluster electronically, resulting in unsaturation at the metal centre, and only the smallest molecule, $H_2$, is allowed access to the metal centre. Accordingly, for the monodentate phosphite species **2d** and **2e** that show less shielding of the metal centres, hydrogen addition is reversible on application of vacuum.[27] Iridium dimers, with stronger M–H bonds, are stable with four hydrides, e.g. $L_2Ir_2(\mu\text{-}H)_3H$ L = $(C_2F_5)_2PCH_2CH_2P(C_2F_5)_2$ ("dfepe") (**3**), but reversibly take up an extra equivalent of $H_2$ to afford $[(dfepe)Ir(H)_2(\mu\text{-}H)]_2$ (**4**), which has two terminal and one bridging hydride ligands per metal centre. The $H_2$ is lost rapidly when the $H_2$ atmosphere is removed to regenerate **3**.[28]

Addition of $H_2$ to 30-electron $Ir_2(t\text{Bu}_2\text{PH})_2(CO)_2(H)(\mu\text{-P}t\text{Bu}_2)$ (**5**) results in the generation of the 32-electron dimetallic complex $Ir_2(t\text{Bu}_2\text{PH})_2(CO)_2(H)_3(\mu\text{-P}t\text{Bu}_2)$ (**6**), in which two hydrides bridge the Ir–Ir connectivity. $T_1$ values from NMR spectroscopy indicated a dihydride, rather than a dihydrogen, structure. This addition is reversible, both in solution and in the solid state, and **6** loses $H_2$ when placed under vacuum or exposed to a $N_2$ purge.[29] The unsaturated, thiol-bridged bimetallic rhodium complex $[Rh(triphos)(\mu\text{-}S)]_2[BPh_4]_2$ (**7**) [triphos = MeC(CH$_2$PPh$_2$)$_3$] reacts with $H_2$ to give $[Rh(triphos)H(\mu\text{-}SH)]_2[BPh_4]_2$ (**8**), in which $H_2$ has undergone heterolytic $H_2$ cleavage[30] to form a Rh-hydride and a {μ-SH} group, presumably via a coordinated dihydrogen intermediate. Removing the $H_2$ under a stream of argon regenerates **7**.[31] Although a dihydrogen intermediate has not been isolated, NMR spectroscopic studies indicate stepwise addition of $H_2$, sequentially at each Rh centre. DFT calculations support this, with a calculated barrier to reversible $H_2$ loss of 35.1 kcal mol$^{-1}$.[32] These complexes also model the reversible, heterolytic cleavage of $H_2$ in hydrogenase enzymes.

Reversible $H_2$ gain and loss is reported for the heterometallic, 58-electron, formally unsaturated cluster, $Os_3Pt(\mu\text{-}H)_2(CO)_{10}(PCy_3)$ (**9**), which adds $H_2$ at high pressure (200 atm) to give the electron-precise, 60-electron cluster $Os_3Pt(\mu\text{-}H)_4(CO)_{10}(PCy_3)$ (**10**). Purging with $N_2$ reforms the starting material.[33]

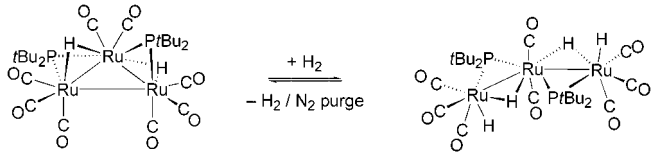
**11** **12** **14**

Duckett, Dyson and Johnson have reported the reversible addition of $H_2$ to a triruthenium cluster $Ru_3(CO)_{10}(PMe_2Ph)_2$ (**11**), which gives a mixture of two exchanging isomers of the product of $H_2$ addition, both of which have a terminal and a bridging hydride (e.g. **12**). On removal of the $H_2$ atmosphere these complexes disappear, suggesting that the $H_2$ binding is reversible. Varying the $H_2$ concentration affords thermochemical data for this process and shows that an equilibrium is established for $H_2$ addition. Interestingly, the mechanism of $H_2$ addition, as well as the exchange of the isomers, invokes a heterolysis of a Ru–Ru bond and an $\eta^2$-$H_2$ ligand bound at a coordinatively unsaturated Ru centre.[34] Reversible addition of $H_2$ to ruthenium carbonyl clusters, $Ru_3H(\mu\text{-}COMe)(CO)_{10}$ (**13**) by displacement of CO to form $Ru_3H_3(\mu\text{-}COMe)(CO)_{10}$ (**14**) has been reported by Keister. Kinetic experiments suggest that the rate-determining step is oxidative addition of $H_2$ at one of the metal centres after CO loss.[35] Reversible addition of $H_2$/CO (at 6.2 bar, 60 °C) to the $Rh^I$ complex *rac*-$[Rh_2(CO)_4(L)][BF_4]_2$, which does not have a Rh–Rh bond, affords the spectroscopically characterised $[Rh^{II}]_2$ dimer *rac*-$[Rh_2H_2(\mu\text{-}CO)_2(CO)_2(L)][BF_4]_2$ [L = $(Et_2PCH_2CH_2)P(Ph)CH_2P(Ph)CH_2CH_2PEt_2$].[36]

Platinum- and palladium-gold clusters such as $[Pt(AuPPh_3)_8][NO_3]_2$ (**15**) have been shown to be excellent catalysts for $H_2/D_2$ equilibration to form HD. The mechanism proposed invokes reversible addition of both $H_2$ and $D_2$ to the metal cluster to afford metal hydride species,[37] which have been observed experimentally to form reversibly on addition of $H_2$.[38] A theoretical analysis suggests that activation occurs at the platinum centre, with dihydrogen and dihydride tautomers being close in energy – consistent with the rapid HD exchange observed experimentally.[39] The unsaturated, 46-electron triosmium dihydride cluster $Os_3(CO)_{10}(\mu\text{-}H)_2$ similarly catalyses $H_2/D_2$ equilibration, but the presumed saturated intermediate $HOs_3(CO)_{10}(\mu\text{-}H)(\eta^2\text{-}H_2)$ has never been isolated or spectroscopically observed.[40] Computational studies have demonstrated that the H/D exchange mechanism in the binuclear polyhydride complex $Cp^*Ru(\mu\text{-}H)_4RuCp^*$[41] on addition of $D_2$ proceeds by an associative mechanism via a number of $\eta^2$-$H_2$, $\eta^2$-HD and $\eta^2$-$D_2$ intermediates that are not experimentally observed.[14]

$H_2$ addition to the *saturated* 48-electron triangular cluster $(\mu\text{-}H)_2Ru_3(CO)_8(\mu\text{-}PtBu_2)_2$ (**16**) results in the opening up of the cluster to form a linear, also electron-precise, $Ru_3$ trimetallic species $(\mu\text{-}H)H_2Ru_3(CO)_8(\mu\text{-}PtBu_2)_2$ (**17**), with no overall loss of CO. Purging a solution with $N_2$ reforms the starting cluster **16**, although in the solid state the cluster is stable to $H_2$ loss.[42] Detailed kinetic studies demonstrated that the mechanism involves CO loss (thus forming an unsaturated cluster) that precedes $H_2$ addition to a single-metal centre with concomitant breaking of a Ru–Ru bond. Addition of CO affords the product that has made a net gain of $H_2$. Interestingly, this reaction does not occur with other bridging phosphido complexes (such a $PPh_2$ or $PCy_2$), and steric arguments are invoked that involve weakening of the Ru–Ru bonding and promotion of CO loss by the bulky $PtBu_2$ groups.[43] Hydrogen addition is suggested to occur at the unsaturated metal centre and not across a metal–metal bond, consistent with orbital symmetry arguments.[44]



**16** **17**

Nocera has reported that the mixed-valence, unsaturated, 32-electron, $Ir_2$ dimer **18** reversibly adds $H_2$ across the Ir–Ir bond to form saturated dihydride **19**.[45] Purging with $N_2$ recovers **18**. The mechanism is suggested to proceed by addition of $H_2$ to one metal centre and then hydride migration rather than the symmetry-forbidden concerted 1,2 addition. Subsequent DFT calculations support this mechanism and show that addition of $H_2$ occurs at one metal centre (to give a dihydrogen complex) and passes through a transition structure with a terminal and bridging hydride, finally to rest at a terminal hydride on each Ir centre.[46] Interestingly, experimentally the reversible hydrogen addition is solvent-dependant. Removal of the $H_2$ atmosphere from a $CH_2Cl_2$ solution of **19** regenerates **18**, but in $CH_3CN$ solutions the solvent has to be evaporated for $H_2$ loss to occur. It is suggested, from crystallographic evidence, that H-bonding interactions with acetonitrile impose a kinetic barrier to $H_2$ loss.

carbonyl groups not shown for clarity

Cowie and Vaartstra reported that addition of $H_2$ to the A-frame iridium dimer, $[Ir_2(dppm)_2H_2(CO)_2I][BF_4]$ (**20**), gives the fluxional tetrahydride, $[Ir_2(dppm)_2H_4(CO)_2I][BF_4]$ (**21**), for which $T_1$ measurements indicate that all the metal-bound hydrogen ligands are hydride-like. Removing the $H_2$ atmosphere regenerates **20** on gentle warming. The neutral, diiodido complex $Ir_2(dppm)_2(CO)_2I_2$ (**22**) also reversibly adds $H_2$ to give a dihydride, $Ir_2H_2(dppm)_2(CO)_2I_2$ (**23**), which loses $H_2$ upon being purged with $N_2$.[47] Although **20** is a 34-electron cluster, and thus would not be expected to add further $H_2$ without rupturing the Ir–Ir bond, the bridging iodine moves to a terminal position in the product **21** (3 $e^-$ to 1 $e^-$), allowing for overall $H_2$ addition. Duckett and co-workers have studied a related compound, $Ir_2(dppm)_2(CO)_2(\mu\text{-}S)_2$ (**24**), by using parahydrogen-induced polarisation NMR spectroscopy, and they also showed that the product of addition of $H_2$, $Ir_2(dppm)_2(CO)_2(H)_2(\mu\text{-}S)_2$ (**25**), also loses $H_2$ upon being purged with $N_2$.[48] In this case, $H_2$ addition transforms a square planar $Ir^I$ centre into an octahedral $Ir^{III}$ centre.

Trigonal bipyramidal, 68-electron $Pt_2Os_3(CO)_{10}(PtBu_3)_2$ (**26**) takes up two molecules of $H_2$ reversibly in a stepwise manner to eventually give $Pt_2Os_3(CO)_{10}(PtBu_3)_2H_4$ (**28**) through the (isolated) intermediate **27**. Purging with $N_2$ removes the bound $H_2$ to reform **26**, although this reaction only gives 28% of the starting material back. The low reverse-conversion is attributed to the open structure of **28** that is more prone to decomposition. On addition of $H_2$, **26** undergoes successive Os–Pt cleavages to give an $Os_3$ triangle with two edge bridging {Pt(CO)P*t*Bu$_3$}groups. This behaviour is in contrast to other, closely related, clusters such as **40** and **41** in which addition of $H_2$ results in no significant core cluster change.[49]

## Thermally Reversible or Reversible When Placed Under Vacuum

Oxidative addition of $H_2$ to the formal triple bond of $[(\eta^5\text{-}C_5H_4i\text{Pr})WCl_2]_2$ (**29**) gives complex **30**, $[(\eta^5\text{-}C_5H_4i\text{Pr})\text{-}W(\mu\text{-}H)Cl_2]_2$, which has bridging dihydrides clearly identified by using NMR spectroscopy by very long $T_1$ times of approximately 1.2 seconds. Gentle heating of **30** results in the reversible (quantitative by NMR spectroscopy) loss of $H_2$ to reform **29**.[50]

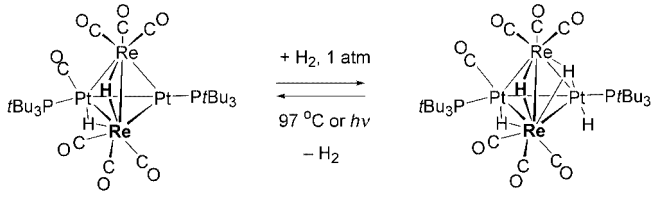
magnetic, 46-electron cluster $(Cp^*Co)_3(\mu_3\text{-}H)(\mu_3\text{-}CMe)$ (**32**). $\Delta G^{\ddagger}$ for this process is calculated as 23.8 kcal mol$^{-1}$.[51] Related chemistry involving reversible addition of $H_2$ to the unsaturated cluster $Cp^*_3Co_3(\mu_3\text{-}CO)_2$ (**33**) yields similar activation parameters.[52] The valence isoelectronic clusters $Cp^*_3Rh_2M(\mu_3\text{-}CO)_2$ (**34**) (M = Co, Ir) also add $H_2$ reversibly to form $Cp_3Rh_2M(\mu_3\text{-}CO)_2(\mu\text{-}H)_2$ (**35**). Warming (to an unspecified temperature, M = Rh) releases the $H_2$ to reform the unsaturated trimetallic cluster.[53]

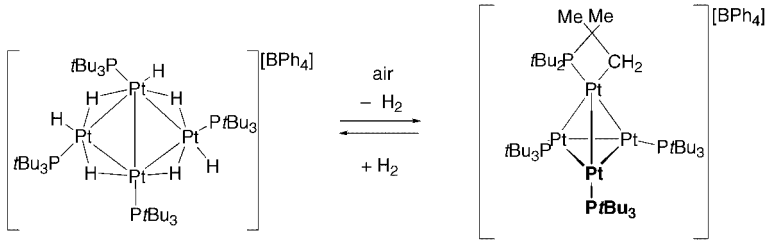
The 56-electron platinum cluster $[Pt_4H_7(PtBu_3)_4][BPh_4]$ (**36**), reported by Spencer in 1984, loses $H_2$ by "atmospheric oxidation" to afford the C–H activated complex $[Pt_4(PtBu_3)_3\{PtBu_2(CMe_2CH_2)\}][BPh_4]$ (**37**), which formally has 50 electrons (this complex was not crystallographically characterised). Cluster **36** can be regenerated by adding $H_2$ (1 atm, 293 K) to **37**.[54] The conversion of **36** to **37** represents a remarkable net loss of 8 hydrogen atoms. Again, the bulky *tert*-butyl groups on the phosphanes no doubt stabilise the cluster towards $H_2$ loss. Although this transformation is described as an oxidation, it might also better be described as initial stepwise loss of $3H_2$, oxidative addition of C–H and loss of $H_2$. Interestingly, the isoelectronic *neutral* cluster $Pt_4H_8(PtBu_3)_4$ is not reported to lose $H_2$,[55] but whether this is a simple consequence of the fact that this complex was never left on the open bench is not clear! Whatever the reason, these unsaturated platinum complexes are fascinating, given the reversible addition of a large amount of $H_2$, and surely warrant further investigation some twenty years after they were reported. A related "oxidative" transformation to **36** → **37** occurs upon addition of $O_2$ to the tetrametallic ruthenium cluster $[Ru_4(\eta^6\text{-}C_6H_6)_4H_6]^{2+}$, **38**,[56] which initially was formulated as a hexahydride but later suggested (on the basis of $T_1$ measurements and DFT calculations) to be a dihydrogen/tetrahydride complex,[11] to form $[Ru_4(\eta^6\text{-}C_6H_6)_4H_4]^{2+}$ (**39**). The tetrahydride cluster adds $H_2$ again (60 atm) to reform **38**.

Adams and co-workers have recently reported a set of unsaturated platinum-rhenium complexes with bulky $tBu_3P$ ligands that allow for electronically unsaturated clusters to be synthesised in a systematic manner. $Pt_2Re_2(CO)_7(PtBu_3)_2\text{-}H_2$ (**40**), an unsaturated 54-electron tetrahedral cluster (tetrahedral $Pt_2M_2$ often have an electron count of 58, especially when decorated with bulky ligands, e.g. $Pt_2Mo_2(\eta^5\text{-}C_5H_4Me)_2(CO)_6(PCy_3)_2$[57]), takes up $H_2$ to form $Pt_2Re_2(CO)_7(PtBu_3)_2H_4$ (**41**), which has 4 hydride ligands. Cluster **41** eliminates $H_2$ nearly quantitatively on heating to 97 °C or on irradiation (UV/Vis). The mechanism for $H_2$ addition (and by the principle of microscopic reversibility, that for $H_2$ loss) has been studied by DFT methods and involves end-on $\eta^1$-attack of $H_2$ on one of the Pt atoms (where the LUMO is centred), moving through an $\eta^2\text{-}H_2$ intermediate, which oxidatively adds to the same Pt atom to give the observed product.[58] Addition of hydrogen results in no gross structural change to the cluster (i.e. metal–metal bond scission or rearrangement of the polyhedral core), consistent with the addition of electron pairs to an unsaturated cluster.

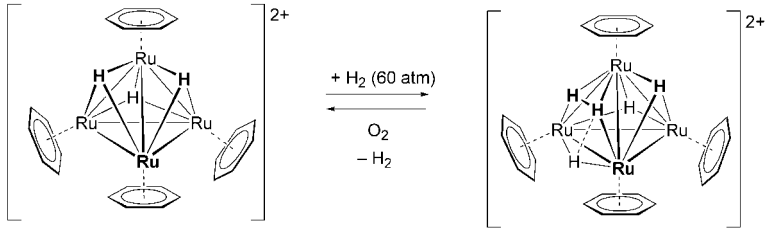
The clusters $[Rh_6(PR_3)_6H_{12}][BAr^F{}_4]_2$ (**42**) (R = *i*Pr **42a**, Cy **42b**) reversibly take up two equivalents of $H_2$ to give the sixteen-hydride clusters $[Rh_6(PR_3)_6H_{16}][BAr^F{}_4]_2$ (**43a**,**b**).[59] This uptake is rapid (less than 5 min). Placing **43a** or **43b**



**40** **41**



**36** **37**



**39** **38**

under vacuum removes the $H_2$ and regenerates **42a**,**b**, both in solution and the solid state. As for **40**, these clusters can be considered as being unsaturated (76-electrons) and DFT calculations show that there are two low-lying empty orbitals available for the take-up of two $H_2$ bonding pairs.[60] Again, it is the bulky alkylphosphane ligands that shield the metal core from decomposition and allow the low electron count to be maintained. DFT calculations also indicate that the sixteen-hydride cluster contains an interstitial hydride and two dihydrogen-like $H_2$ molecules, which have an average binding energy to the cluster of 60 kJ mol$^{-1}$, consistent with that reported for mononuclear dihydrogen complexes (Figure 4).[5] Although these dihydrogen ligands are not observed either by X-ray crystallography or NMR spectroscopy, indirect evidence comes from H/D exchange experiments with $D_2$ and the observation of HD(g). The reversible $H_2$ loss can be modulated by the phosphane. With P*i*Pr$_3$, $H_2$ loss from **43a** when placed under vacuum is relatively quick (12 hours), but for **43b** with $PCy_3$ ligands, $H_2$ loss under vacuum takes 1 week. This difference is accounted for by the tighter interdigitation of the cyclohexyl groups that kinetically stabilise the cluster towards $H_2$ loss.

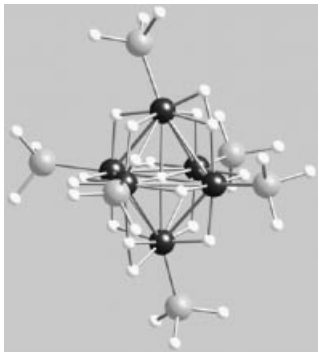

Figure 4. The DFT calculated structure of $[Rh_6(PH_3)_6H_{16}]^{2+}$, showing the two dihydrogen-like ligands.

Reduction of clusters **42** affords $[Rh_6(PR_3)_6H_{12}]^{n+}$ ($n$ = 1 **44**, 0 **45**).[61] Inspection of the frontier molecular orbitals suggests that these clusters should also take up one equivalent of $H_2$. The cluster $[Rh_6(PR_3)_6H_{12}]^+$ (**44**) adds one $H_2$ to give $[Rh_6(PR_3)_6H_{14}]^+$ (**46**), as characterised by ESI-MS. Removing the $H_2$ atmosphere regenerates **44**. By contrast, neutral $[Rh_6(PR_3)_6H_{12}]$ (**45**), which is a paramagnetic species having a triplet ground state ($S$ = 1), takes up $H_2$ to give the diamagnetic cluster $[Rh_6(PR_3)_6H_{14}]$ (**47**) ($S$ = 0, R = *i*Pr only). This reaction is much slower than for the other clusters (16 hours), attributed to "spin blocking" – a significant barrier along the reaction coordinate induced by a spin change that results in a significantly slower reaction when there is a spin-state change.[62] Consistent with microscopic reversibility arguments, **45** does not lose $H_2$ readily.

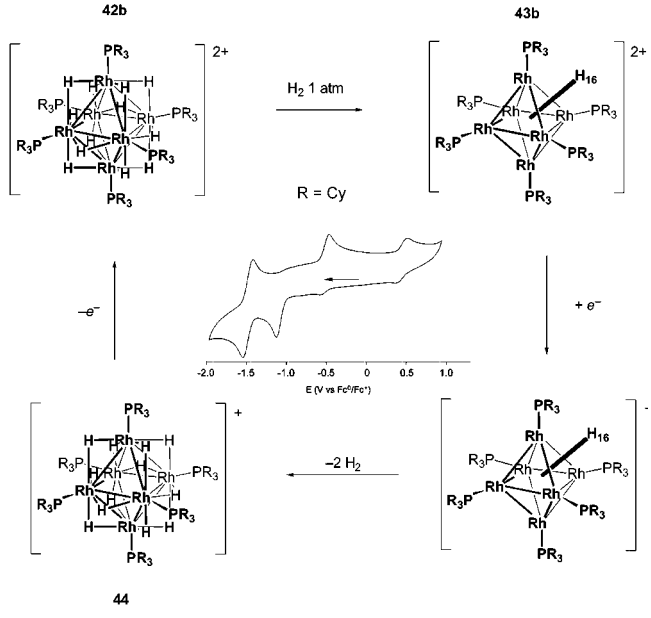
## Electrochemically Reversible

Inspection of the MO diagram for **43a**,**b** suggests that addition of one extra electron would result in the population of a high-lying orbital, and this could destabilise the cluster, resulting in $H_2$ loss to re-establish a large HOMO–LUMO gap. If coupled with a sequential oxidation of the cluster, this potentially could lead to the reversible binding and release of $H_2$, triggered by a single-electron redox event. This prediction was borne out experimentally.[60,61,63] The cyclic voltammogram of **43b** shows an irreversible loss of $H_2$ on reduction, presumably from an unstable, putative species $[Rh_6(PCy_3)_6H_{16}]^+$ (Scheme 3). The formation of $[Rh_6(PCy_3)_6H_{12}]^+$ (**44**) results, which can be oxidised to form $[Rh_6(PCy_3)_6H_{12}]^{2+}$ (**42b**) and subsequently recharged with $H_2$ to reform $[Rh_6(PCy_3)_6H_{16}]^{2+}$ (**43b**), completing a complete hydrogen-store cycle. The loss of $H_2$ is kinetically fast ($t_{1/2}$ as measured electrochemically is 170 ms). The redox cycle can be duplicated by using chemical reductants/oxidants and followed by ESI-MS. This facile, reusable gain and loss of two equivalents of $H_2$ by using a simple one-electron redox switch represents a new method of hydrogen storage. Although the overall storage capacity is very low (0.1% by weight), the attractive conditions of room temperature and pressure, actuation by the addition of a single electron and rapid desorption kinetics makes the concept of interest for future $H_2$ storage applications.



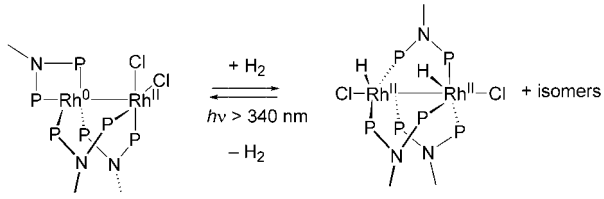
Scheme 3. Insert shows the cyclic voltammogram; the irreversible reductions are attributed to $H_2$ loss at ≈ 1.0 V.

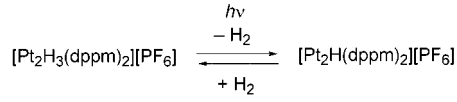
Redox-induced loss of hydrogen or protons is known to occur in mononuclear systems. Irreversible oxidation of the complex $[Co\{P(CH_2CH_2PPh_2)_3\}(H_2)][PF_6]$[64] (originally suggested to be a dihydrogen complex, but later reformulated by Heinekey as a dihydride[65]) results in the loss of a proton, while reduction of vinylidene complex $[Rh(=C=CHPh)\{N(CH_2CH_2PPh_2\}_3][BF_4]$ results in $H_2$ loss, to form an acetylide.[66] Redox-promoted oxidation of $H_2$ to afford protons (or the reverse reaction – electrocatalytic generation of $H_2$) is, of course, also very well documented in the study of hydrogenase chemistry.[67] However, none of these processes involves the reversible binding of $H_2$ as found for **43b**.

## Photochemically Reversible

An early (1983) report of the photolysis of $(\eta^5\text{-}C_5H_5)W(CO)_3H$ suggested that it proceeded by $CO/H_2$ expulsion to afford a putative dimeric species $[(\eta^5\text{-}C_5H_5)W(CO)_2]_2$ (**48**) that reversibly added $H_2$ under photochemical conditions to give $[(\eta^5\text{-}C_5H_5)W(\mu\text{-}H)(CO)_2]_2$, (**49**), which is related to **30**.[68] Aspects of the dimerisation mechanism have been subsequently questioned.[69]

The rhodium analogue of **19**, complex **51**, can be formed by addition of $H_2$ to **50**. Interestingly, complex **51** does not lose $H_2$ readily on standing, nor does it exchange with $D_2$ appreciably after one week. However, $H_2$ loss is fast upon photochemical irradiation to afford **50**.[70] These complexes provide insight into the photocycle for hydrogen production from HX solutions. $[Pt_2H_3(dppm)_2][PF_6]$ (**52**) loses $H_2$ in solution and the solid state on irradiation to give a complex of formula $[Pt_2H(dppm)_2][PF_6]$ (**53**), which reacts back slowly with $H_2$ to give **52**.[71]





The electronically unsaturated, 62-electron trigonal bipyramidal cluster $Pt_3Re_2(PtBu_3)_3(CO)_6$ (**53**) adds three molecules of $H_2$ in a stepwise manner to eventually afford $Pt_3Re_2(PtBu_3)_3(CO)_6H_6$ (**56**). This reaction is reversible under photolytic conditions, and irradiating **56** eliminates dihydrogen, ultimately to afford the dihydride complex $Pt_3Re_2(PtBu_3)_3(CO)_6H_2$ (**54**). The last elimination of $H_2$ is presumably a high-energy process and does not occur under the conditions used.[72] Cluster **53** is unsaturated by 10 electrons for a trigonal bipyramid (albeit platinum clusters often count lower than expected), and the bulky $tBu_3P$ groups no doubt have a role to play in this – stabilising the unsaturated core by providing a steric shield against addition of further, large, metal fragments. Space-filling diagrams nonetheless indicate that there is sufficient room for the approach of a $H_2$ molecule. The molecular orbital structure shows five low-lying unoccupied molecular orbitals,

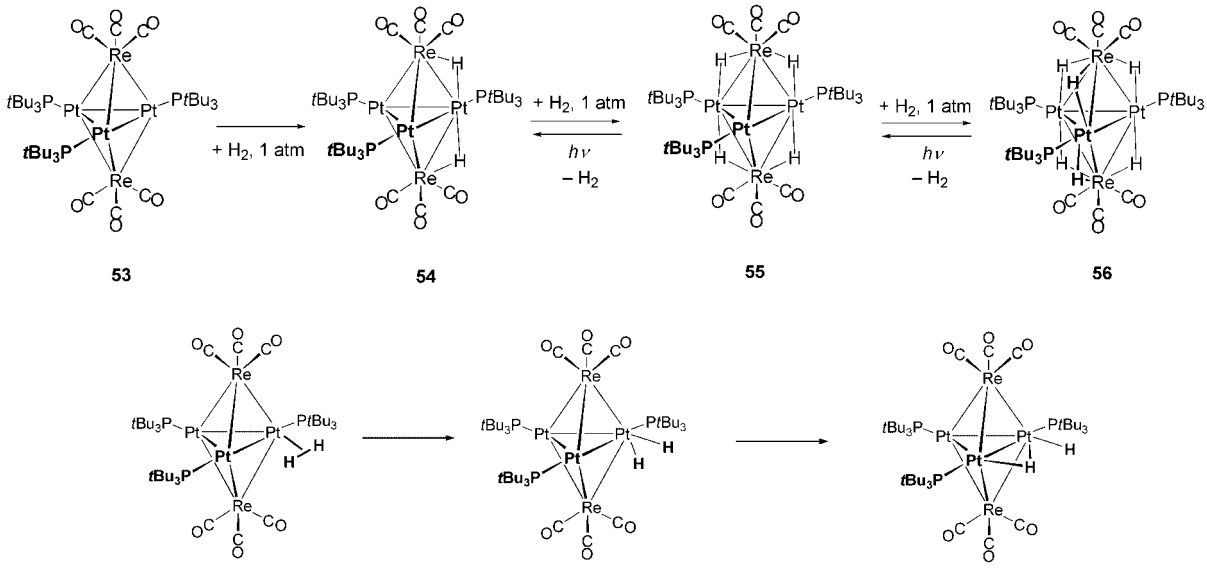
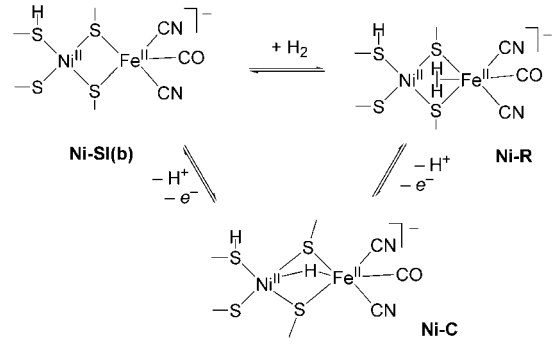


Scheme 4.

three of which are suitably aligned along the Pt–Re bonds to accept electron density from an incoming $H_2$ molecule. Detailed theoretical analysis of the mechanism of $H_2$ addition indicates a possible pathway that starts with hydrogen addition at Pt to give a dihydrogen intermediate, followed by $H_2$ cleavage and the formation of a complex with a terminal hydride and a hydride bridging a Pt–Pt bond. This configuration rearranges to give the observed product with hydrides bridging the Pt–Re bonds (Scheme 4). The related tetranuclear cluster $Pt_2Re_2(CO)_7(tBu_3P)_2H_4$ (**41**) also eliminates one equivalent of $H_2$ on irradiation.[58,73] The addition of $H_2$ to a single metal centre is consistent with qualitative molecular orbital arguments by Hoffman, who showed that intramolecular reductive elimination (and the microscopic reverse: oxidative addition) would be symmetry-forbidden for 1,2-elimination (or 1,2-addition) and have a large barrier for a concerted least-motion pathway.[44]

## Reversible Biological Systems

Hydrogenases regulate the metabolism of hydrogen in microorganisms, and these enzymes have attracted an enormous amount of attention in the hope of developing electrochemically active, bio-inspired catalytic systems employing hydrogen.[74] The active site of one class of these enzymes have been shown crystallographically to contain a dinuclear NiFe cluster with bridging sulfur ligands. The reversible binding of hydrogen at the active site is a key stage in the proposed mechanism of action, and the presence of the biologically unusual, strong-*trans*-influence CO ligand favours this process (by reducing the ability of the metal to back-donate into the σ* orbital of $H_2$). Heterolytic cleavage of $H_2$ follows the binding event, generating a bridging hydride ligand and releasing a proton. The salient part of the enzymatic cycle is shown in Scheme 5.

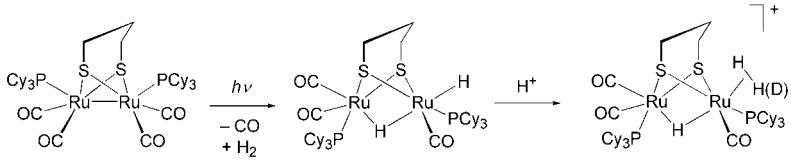


Scheme 5.

**Ni-SI(b)** (the mechanism has its own shorthand) reacts with $H_2$ to generate **Ni-R**, in which the hydrogen is suggested to be present as a dihydrogen ligand bound to $Fe^{II}$. One-electron oxidation of **Ni-R** liberates a proton to generate **Ni-C**, thought to possess a bridging hydride ligand, which, upon further one-electron oxidation, is released as a proton, and **Ni-SI(b)** is regenerated. The involvement of the hydride and dihydrogen intermediates is implicated by the fact that during catalyst turnover under a $D_2$ atmosphere, HD and/or HDO is formed, despite the lack of spectroscopic evidence for the existence of metal–hydride or metal–dihydrogen species. Catalysis of H/D exchange reactions is characteristic of the hydrogenases.[75]

Iron-only hydrogenases also exist, containing a $\{Fe_4S_4\}$ cubane cluster linked to a $\{Fe_2S_3\}$ subsite through a bridging cysteinyl ligand. The fact that both the NiFe and $Fe_2$ units have thiolate, $CN^-$ and CO ligands – all common in coordination chemistry – means that a huge range of dinuclear complexes have been synthesised with the aim of modelling the geometry, connectivity, metals, ligand sets and chemistry displayed by the hydrogenases.[76] This topic has

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



57

been heavily reviewed, so only a few examples with particular relevance to reversible hydrogen binding will be mentioned herein.

Many complexes designed to model the hydrogenases react *irreversibly* with $H_2$, such as the recent example of a water-soluble NiRu complex that takes up $H_2$ under ambient conditions, resulting in heterolytic cleavage of $H_2$ to form $H^+$ and a bridging hydride.[77] Less common are dinuclear complexes that react reversibly with hydrogen; a notable example is from Rauchfuss, who characterised the first dihydrogen complex of a hydrogenase active site model.[78]

$[Ru_2(\mu\text{-}H)(H_2)(\mu\text{-}SCH_2CH_2CH_2S)(PCy_3)_2(CO)_3]^+$ (**57**) was shown to catalyse $H_2/D_2$ equilibration. Related complexes also catalyse H/D scrambling via what is assumed to be an ($\eta^2$-$H_2$)-containing intermediate; examples of compounds displaying this chemistry include $[Fe_2(\mu\text{-}H)(\mu\text{-}SCH_2CH_2CH_2S)(PMe_3)_2(CO)_4]^+$ (**58**)[79] and $[Fe_2(\mu\text{-}H)(\mu\text{-}SCH_2CH_2CH_2S)(CN\textit{t}Bu)_2(CO)_4]^+$ (**59**).[80] A vacant coordination site must first be created, and, consistent with this requirement, the H/D scrambling reaction is often promoted by irradiation with UV light but inhibited by the presence of CO.

## Giant Clusters Displaying Reversible $H_2$ Binding

Palladium metal has an unusually high affinity for hydrogen, absorbing up to 935 times its own volume (an approximate composition of $Pd_4H_3$), and Pd/Ag membranes are used on an industrial scale to produce ultrapure hydrogen.[81] Various models of the hydrogen-rich lattice have been reported, most notably Dahl's cluster $H_{12}Pd_{28}(PtPMe_3)(PtPPh_3)_{12}(CO)_{27}$ (**60**) (Figure 5).[82] The cluster was treated with $D_2$, which resulted in an 80% decrease in the hydride signal by $^1H$ NMR spectroscopy, suggesting that hydrogen is readily exchanged. However, no attempt seems to have been made to add $H_2$ under pressure or to remove it by vacuum, heat or light, so regrettably little is known about the hydrogen storage capabilities of this material.

Giant, ligand-stabilised palladium clusters can be readily synthesised by reduction of palladium acetate with hydrogen gas.[83] With careful control of conditions, the size distribution is nearly monodisperse (see Figure 6) and centred on particular "magic numbers" corresponding to different numbers of concentric shells ($n$) of Pd atoms around a central atom, where each shell contains ($10n^2 + 2$) atoms.[84]

The behaviour of the series $Pd_{55}(phen)_{36}O_{30}$ (2 shells, diameter ≈ 1 nm; phen = phenanthroline), $Pd_{561}(phen)_{36}O_{200}$ (5 shells, diameter ≈ 2.6 nm), $Pd_{1415}(phen)_{60}O_{1100}$ (7 shells, diameter ≈ 3.7 nm) and Pd powder (diameter ≈ 50 μm) towards hydrogen has been investigated in detail by

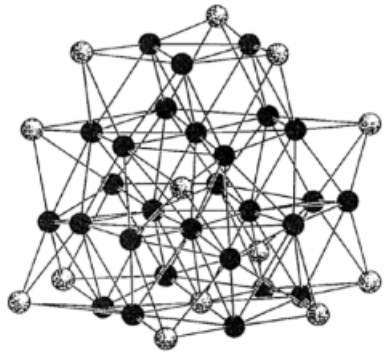


Figure 5. Crystallographically determined metal core (Pd black, Pt grey) structure of $H_{12}Pd_{28}(PtPMe_3)(PtPPh_3)_{12}(CO)_{27}$ (**60**). Hydrogen atoms were not located. Figure reproduced courtesy of the American Chemical Society from ref.[83]

Züttel and co-workers. They found that Pd clusters of all size ranges reversibly absorbed and desorbed hydrogen,[85] but that the reversible hydrogen storage capacity (H/Pd ratio) decreased with decreasing cluster size.[86] This effect was attributed to the fact that the smaller clusters had a greater proportion of surface atoms and that only the interstitial sites in the Pd lattice were available for reversible hydrogen storage. The reasoning here was that the binding energy of the surface hydrides was greater than the interstitial hydrogen, and the surface hydrides could therefore not be easily removed simply by application of vacuum. The cluster samples had dramatically improved discharge kinetics relative to bulk Pd, and X-ray diffraction revealed that the crystallographic structure of the clusters was not altered by absorption and desorption cycles.[87] However, others have shown that 5-nm Pd clusters do undergo structural change

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

upon hydrogen absorption, probably from a cubic lattice to an icosahedral one.[88]

Pd clusters loaded on carbon have been shown to absorb more hydrogen per Pd atom than does bulk Pd,[89] an effect attributed to spillover (a process whereby hydrogen spreads from a metal particle to its support).[90] The absorption was shown to be reversible but a significant fraction of the stored hydrogen required pressures of less than 5 Torr or high temperatures in order to be released.

## Conclusions

Multimetallic compounds that reversibly bind hydrogen without experiencing dramatic structural changes have several features in common:

(i) Bulky ligands (especially phosphanes) are often a feature of the coordination sphere. Such ligands provide kinetically controlled steric blocking of coordination sites, favouring electronic unsaturation. However the smallest of molecules, $H_2$, is often able to penetrate the coordination sphere and binds to the metal to (sometimes only partially) relieve the electronic unsaturation at the metal centre.

(ii) The metals involved are generally late-transition metals, especially Rh, Pd and the surrounding elements, in relatively low oxidation states. Such metals form strong bonds with soft ligands such as the bulky phosphanes that appear to be crucial for successful reversible hydrogen bonding; they also have sufficient d electrons for back-donation to the σ* orbital on H as well as suitable empty acceptor orbitals.

(iii) The hydrogen does not have to be bound side-on as $\eta^2$-$H_2$ in order for reversible binding behaviour to be observed; the rapid exchange between the wide variety of binding modes (including bridging and interstitial) and the low energy differences between them facilitates the ready distribution of H ligands around the cluster core (hence making definitive characterisation of H location often problematic).

Approaches to multimetallic complexes that reversibly bind hydrogen have historically resulted from serendipity as much as from an avowed intention to make compounds with this useful and interesting property (with the notable exception of the efforts to model the hydrogenases). However, a few simple design rules outlined above seem to apply quite generally and it is reasonable to expect that the field will develop by further exploitation of the structural variety and rich redox properties offered by polynuclear metal cores and the kinetic blocking of coordination sites by bulky ligands. Firm establishment of the structure–property relationships inherent to systems that efficiently and reversibly bind hydrogen should allow the application of these concepts to other (cheaper!) metals and materials.

# Remarkable Functions of Long-Chain Alkyl Groups in Halogen-Bridged Nickel(III) Nanowire Complexes

**Hideki Ohtsu,*[a] Shinya Takaishi,[b] Keita Imamura,[b] Ayumi Ishii,[a] Koji Tanaka,[c] Miki Hasegawa,[a] and Masahiro Yamashita*[b]**

**Keywords:** Nickel / Nanostructures / Long-chain alkyl groups / Average-valent compounds / Thin films

The long-chain alkyl groups of new bidentate ligands make it possible to generate nickel MX–chain complexes exhibiting the shortest $Ni^{III}$–$Ni^{III}$ distance among all MX–chain compounds reported. Dissolution in organic solvents occurs without dissociation of the MX–chain units, and the successful fabrication of thin films is reported.

## Introduction

Much attention has been paid to quasi-one-dimensional assembled electronic systems in the fields of chemistry and physics because these compounds exhibit novel phenomena such as the generation of solitons and polarons in π-conjugated polymers,[1,2] metallic-[3] and super-conductivity,[4] and slow magnetic relaxation in several ferromagnetic and ferrimagnetic complexes.[5] Among such one-dimensional compounds, halogen-bridged quasi-one-dimensional transition-metal complexes (MX–chain complexes) have been one of the most important and attractive research objectives, as they exhibit various electronic states and many noticeable physical properties such as intense charge-transfer bands,[6] overtone progressions of the resonance Raman spectra,[7] intense luminescence spectra with large Stokes shifts,[8] photogeneration[9] and long-range migration[10] of solitons and polarons, and gigantic third-order optical nonlinearity,[11] etc.

The electronic structures of MX–chain compounds have been regarded as extended Peierls–Hubbard models,[12] where the electron–phonon interaction ($S$), electron transfer ($T$), and intra- and intersite Coulomb repulsion energies ($U$ and $V$, respectively) compete or cooperate with each other. Pt and Pd compounds indicate charge-density-wave (CDW) states caused by the strong $S$, where the bridging halide ions are displaced from the midpoints between the neighboring two metal ions (···$M^{II}$···$X^-$–$M^{IV}$–$X^-$···$M^{II}$···$X^-$–$M^{IV}$–$X^-$···).[13,14] On the other hand, Ni compounds are Mott–Hubbard-type MX–chain complexes induced by the strong $U$, where the bridging halide ions are located at the midpoints between the neighboring two metal ions (–$M^{III}$–$X^-$–$M^{III}$–$X^-$–$M^{III}$–$X^-$–$M^{III}$–$X^-$–).[13,15]

A number of MX–chain complexes have so far been synthesized and characterized to provide further valuable insight into the characteristic electronic structures and unique physical properties. In particular, the MX–chain complex $[Ni^{III}(chxn)_2Br]Br_2$[16] has been attracting much attention because it shows the largest gigantic third-order optical nonlinearity [$\chi^{(3)}$ = ca. $10^{-4}$ esu].[11] The special feature of this compound, however, appears only in the solid state, as MX–chain units are disrupted in solution. The inherent instability of the complex in solution has precluded further development into useful molecular devices such as thin films.

Reported herein is the synthesis and characterization of nickel MX–chain complexes supported by new bidentate ligands with long-chain alkyl groups (Figure 1) that not only impart solubility to the MX–chain compounds but these groups also cause the shortening of the M–M distances, which can result in increased $\chi^{(3)}$ values.[11] Moreover, we attained the successful fabrication of thin films consisting of the MX–chain complexes, which can be promising candidates for optical switching devices.

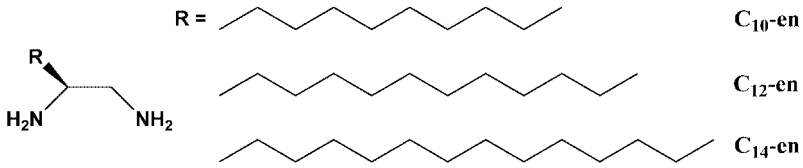

Figure 1. Structures of bidentate ligands having long-chain alkyl groups.

## Results and Discussion

The nickel MX–chain complexes, represented as $[Ni^{III}(C_n\text{-en})_2Br]Br_2$ [$n$ = 10 (**1**), 12 (**2**), and 14 (**3**)], were obtained as black microcrystals by puffing $Br_2$ gas into the corresponding nickel(II) complexes in ethanol, and the compositions of **1**, **2**, and **3** were determined by elemental analysis. The syntheses of these complexes afforded no well-shaped single crystals; however, we successfully obtained accurate powder X-ray diffraction (XRD) data for **1**, **2**, and **3** by synchrotron powder diffraction with a large Debye–Scherrer camera at 100 K and are able to image the XRD data for **3** by the Rietveld method as shown in Figure 2.[17,18]

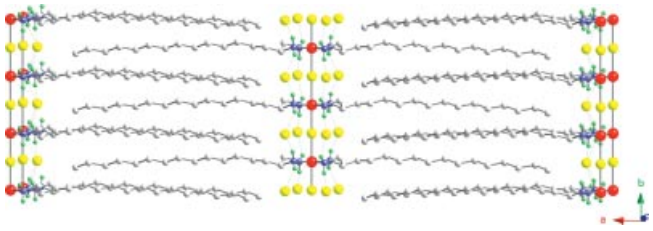

Figure 2. Representation of the molecular structure of **3** on the basis of the results of synchrotron XRD, IR, and EPR measurements (Ni red, Br yellow, C gray, H green, N blue).

$Ni^{III}$ ions and bromide ions are arranged alternately along the *b* axis to form the linear MX–chain structures. The linear chains are connected by hydrogen bonds between the hydrogen atoms of the amino group of the $C_{14}$-en ligand and the counter bromide ions, which is consistent with an IR spectrum exhibiting a signal due to the hydrogen-bonded N–H stretching mode of the ligand at 3005 $cm^{-1}$ (Figure S2).[19] The bridging bromide ions are placed at the midpoints between the neighboring two nickel ions, a fact that indicates the electronic structure of **3** is a Mott–Hubbard state, and the assignment of which is harmonious with the results of IR spectroscopy (Figure S2)[20] and temperature-dependent EPR measurements (Figure S3).[21] In the case of **1** and **2**, these molecular structures and electronic configurations are essentially the same as those of **3** except for the length of the alkyl chain of the bidentate ligands, and the structures are strongly supported by synchrotron XRD, IR, and EPR studies. It should be noted that the $Ni^{III}$–$Ni^{III}$ distance (5.06 Å) in all the complexes is the shortest among all of the MX–chain complexes reported so far {$[Ni^{III}(chxn)_2Br]Br_2$ 5.157(1) Å,[15,16] $[Ni^{III}(bn)_2Br]Br_2$ 5.136(6) Å,[22,23] $[Ni^{III}(pn)_2Br]Br_2$ 5.110(7) Å[22,24]}. Such a drastic shortening in the $Ni^{III}$–$Ni^{III}$ distance may be ascribed to the chemical pressure effect induced by the hydrophobic interaction between the long-chain alkyl groups of the bidentate ligands.

The function of the long-chain alkyl groups *cannot* confine itself to leading the chemical pressure effect. These groups of the ligands enable us to disperse the nickel MX–chain complexes in organic solvents without the decomposition of MX–chain cores and to fabricate thin films containing the MX–chain compounds. Figure 3 displays the absorption spectrum of **3** in chloroform solution and as a thin film together with that in the solid state at 298 K. The intense absorption band centered at 1.33 eV is observed in solution and as a thin film and is quite the same as that in the solid state.[25] This characteristic absorption band can be assigned to the charge-transfer band from the bridging bromide ion to the upper Hubbard band of the nickel $3d_{z^2}$ orbital along the MX–chain direction.[12] In addition, it should be noted that no absorption spectral disturbance caused by light scatterings is observed even in the higher energy region. In fact, the size of **3** (0.1–0.7 μm) as determined by scanning electron microscopy (SEM) is much smaller than the wavelength in the visible light region (Figure S5); the morphology and height distributions of the thin films characterized by using atomic force microscopy (AFM) analysis are quite smooth and $1.54 \pm 0.03$ μm in thickness (Figure S6). The lack of interruption due to light scatterings can thus be the reason why nickel MX–chain complex **3** is dispersed uniformly in solution and as a thin film with the help of the long-chain alkyl groups.[26]

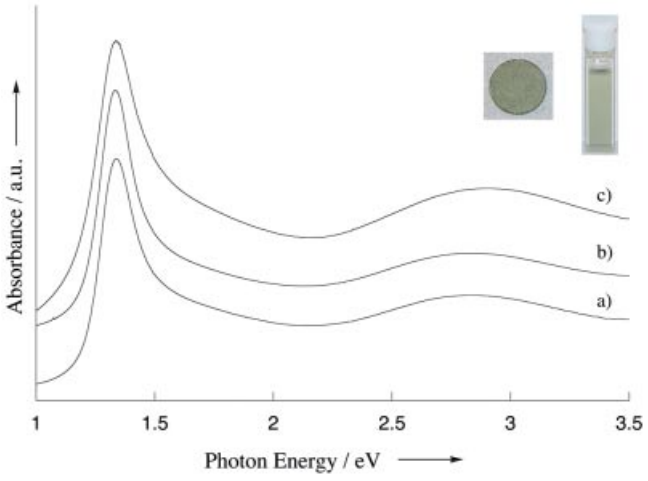

Figure 3. Absorption spectra of **3** in (a) chloroform solution, (b) film state, and (c) solid state at 298 K. Inset: Photographs of **3** (right) in solution and (left) as a thin film.

## Conclusions

We successfully synthesized nickel MX–chain complexes exhibiting not only the shortest $Ni^{III}$–$Ni^{III}$ distance among all MX–chain compounds reported. The solubility of these compounds in organic solvents occurs without dissociation of the MX–chain units bearing new bidentate ligands containing the long-chain alkyl groups. Moreover, the successful fabrication of thin films consisting of the nickel nanowire complex has been accomplished by the spin-coating method. These results provide valuable information for the further development of MX–chain complexes having many interesting physical properties derived from one-dimensional electronic systems and shed light on the applications of functional transition-metal complexes.

## Experimental Section

**Materials:** All chemicals used for the synthesis of the ligands and complexes were commercial products of the highest available purity and were further purified by standard methods.[27] Solvents were also purified by standard methods before use.[27]

**Synthesis:** All ligands and complexes used in this study were prepared according to the following procedures, and the structures of the products were confirmed by analytical data (vide infra).

**(*S*)-Dodecane-1,2-diamine ($C_{10}$-en), (*S*)-Tetradecane-1,2-diamine ($C_{12}$-en), and (*S*)-Hexadecane-1,2-diamine ($C_{14}$-en):** These ligands were synthesized by a literature procedure.[28,29]

**$[Ni^{II}(C_{10}\text{-en})_2Br_2]$:** To a methanol solution of $C_{10}$-en (1.002 g, 5.0 mmol) was added $NiBr_2{\cdot}3H_2O$ (0.681 g, 2.5 mmol) in methanol. Addition of ether to the resulting solution gradually gave pale violet powder that was collected by filtration and recrystallized from ethanol. Yield: 0.628 g (40.5%). $C_{24}H_{56}Br_2N_4Ni$ (619.25): calcd. C 46.55, H 9.11, N 9.04; found C 46.25, H 9.05, N 9.17.

**$[Ni^{II}(C_{12}\text{-en})_2Br_2]$:** This complex was prepared in the same manner as that for the synthesis of $[Ni^{II}(C_{10}\text{-en})_2Br_2]$ by using the $C_{12}$-en ligand instead of $C_{10}$-en. Yield: 1.016 g (60.2%). $C_{28}H_{64}Br_2N_4Ni$ (675.36): calcd. C 49.79, H 9.55, N 8.29; found C 49.34, H 9.02, N 8.28.

**$[Ni^{II}(C_{14}\text{-en})_2Br_2]$:** This complex was prepared in the same manner as that for the synthesis of $[Ni^{II}(C_{10}\text{-en})_2Br_2]$ by using the $C_{14}$-en ligand instead of $C_{10}$-en. Yield: 1.245 g (68.1%). $C_{32}H_{72}Br_2N_4Ni$ (731.47): calcd. C 52.54, H 9.92, N 7.65; found C 52.12, H 9.62, N 7.62.

**$[Ni^{III}(C_{10}\text{-en})_2Br]Br_2$ (1):** $Br_2$ gas was puffed in a ethanol suspension of $[Ni^{II}(C_{10}\text{-en})_2Br_2]$ (0.062 g, 0.1 mmol). Black powder immediately precipitated and was separated by filtration. Yield: 0.056 g (80.7%). $C_{24}H_{57}Br_3N_4NiO_{0.5}$ (708.16): calcd. C 40.70, H 8.11, N 7.91; found C 40.79, H 7.94, N 7.96.

**$[Ni^{III}(C_{12}\text{-en})_2Br]Br_2$ (2):** This complex was prepared in the same manner as that for the synthesis of $[Ni^{III}(C_{10}\text{-en})_2Br]Br_2$ by using $[Ni^{II}(C_{12}\text{-en})_2Br_2]$ instead of $[Ni^{II}(C_{10}\text{-en})_2Br_2]$. Yield: 0.073 g (96.0%). $C_{28}H_{66}Br_3N_4NiO$ (773.28): calcd. C 43.49, H 8.60, N 7.24; found C 43.32, H 8.25, N 7.25.

**$[Ni^{III}(C_{14}\text{-en})_2Br]Br_2$ (3):** This complex was prepared in the same manner as that for the synthesis of $[Ni^{III}(C_{10}\text{-en})_2Br]Br_2$ by using $[Ni^{II}(C_{14}\text{-en})_2Br_2]$ instead of $[Ni^{II}(C_{10}\text{-en})_2Br_2]$. Yield: 0.081 g (99.6%). $C_{24}H_{56}Br_2N_4Ni$ (619.25): calcd. C 46.34, H 8.99, N 6.75; found C 46.00, H 8.55, N 6.75.

**Fabrication of the Thin Films of 3:** Compound **3** (10.0 mg) was dispersed in chloroform (0.5 mL) containing PMMA (36.5 mg) with ultrasonication, and the resulting dispersion was filtered though a 1.0-μm membrane filter. The thin films were prepared from the blend solution by spin-coating on quartz substrates ($\phi$ = 10 mm).

**Measurements:** Synchrotron XRD measurements were carried out with a SPring-8 BL02B2 beam line to obtain XRD data with high angular resolution ($2\theta$ = 1–75°) at 100 K. The sample powders were sufficiently fine and gave a homogeneous intensity distribution in the Debye–Scherrer powder ring. The powder samples were enclosed in silica glass capillaries (0.3 mm internal diameter). The exposure time was 40 min, and reflections were collected on an imaging plate installed on a large Debye–Scherrer camera. The wavelength of the incident X-rays was ≈ 1.0 Å, which was calibrated by using standard $CeO_2$ powder. The structure was solved by the Rietveld technique, and the hydrogen atoms of the $NH_2$ group were located at the calculated positions. Infrared spectra were measured as KBr disks with a JASCO FTIR-620 spectrophotometer. EPR spectra were taken with a JEOL JES-FA200 equipped with an attached VT (Variable Temperature) apparatus and were recorded under nonsaturating microwave power conditions. The magnitude of the modulation was chosen to optimize the resolution and the signal-to-noise ratio of the observed spectra. The *g* values were calibrated with a $Mn^{II}$ marker used as a reference. Electronic absorption spectra were recorded with a Shimadzu UV-3100PC spectrophotometer with the samples prepared as KBr pellets in the case of the solid states. SEM measurements were performed with a JEOL JSM-6390LA operated at an accelerating voltage of 1.5 kV. Samples for SEM studies were prepared by placing a drop of the chloroform dispersion of the nanowire complexes on a piece of Pt plate under ambient conditions; the sample was then dried and stored in vacuo for SEM characterization. AFM imaging was carried out in noncontact mode with a JEOL JSPM-5200. Elemental analyses were carried out at the Research and Analytical Center for Giant Molecules, Graduate School of Science, Tohoku University.

**Supporting Information** (see footnote on the first page of this article): XRD, IR, EPR, absorption spectra, SEM, and AFM data.

## Acknowledgments

The synchrotron radiation X-ray powder diffraction experiments were performed at Spring-8 BL02B2 with the approval of the Japan Synchrotron Radiation Research Institute (JASRI) (proposal no. 2006A1646). We are grateful to Dr. Keiichi Osaka, Dr. Kenichi Kato, and Prof. Masaki Takata for helpful experiments at JASRI and to Dr. Eiji Nishibori, Prof. Masaki Takata, and Prof. Makoto Sakata for permitting the use of their Rietveld program. We also thank JEOL Ltd. for SEM measurements. This work was partly supported by a grant from the Aoyama Gakuin 21st Century COE Program and supported in part by a Grant-in-Aid for Scientific Research on Priority Areas (Chemistry of Coordination Space) from the Ministry of Education, Culture, Sports, Science, and Technology.

# Treating $[K_4(H_2O)_{0.5}][SnTe_4]$ with $PPh_4^+$ or $AsPh_4^+$: Formation of a Highly Air-Stable Tellurostannate Salt, a Tellurolate with One-Coordinate Te Atoms, and a Polytelluride Salt with $^1_\infty[Te_4(H_2O)_2]^{2-}$ Chains

**Eugen Ruzin,[a] Werner Massa,[a] and Stefanie Dehnen*[a]**

*Dedicated to Professor Dieter Fenske on the occasion of his 65th birthday*

**Keywords:** Arsonium salts / Phosphonium salts / Tellurolate / Tellurostannate / Polytelluride / X-ray diffraction

In reactions of potassium orthotellurostannates with $EPh_4Cl$ (E = P, As), different single-crystalline products are obtained. An air-stable dimeric tellurostannate forms by partial replacement of strongly interacting $K^+$ cations by weakly interacting or noninteracting $[PPh_4]^+$ ions. For E = As, an equally air-stable tellurophenolate, in which Te has the rare coordination number 1, results upon As–C bond cleavage at a tetraphenylarsonium cation. Oxidation of the air-sensitive $[Sn_2Te_6]^{4-}$ anion and $Te^{2-}$ by $O_2$ (air) affords a tetratelluride salt with strands of $H_2O$-bridged $[Te_4]^{2-}$ anions.

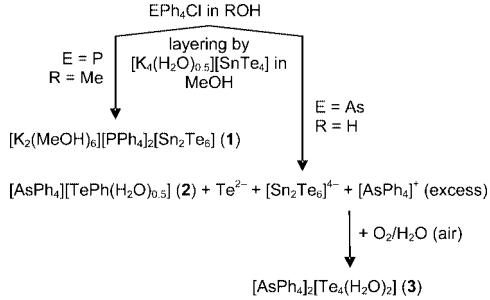
## Introduction

The influence of counterions on both structure and reactivity of complex anions and anionic networks is subtle and therefore actively investigated.[1] Ion-exchange reactions in solution may lead to either crystallization of the anionic structure with another cation or the crystallization of another anionic species than originally used due to a lower solubility of further co-existing components of the equilibrium in solution, or even upon a chemical reaction. Being interested in the effect of bulky cations on the properties of chalcogenostannate anions, we have performed reactions of the highly reactive potassium salt of $[SnTe_4]^{4-}$ with $EPh_4Cl$ (E = P, As). For E = P, the phosphonium salt of dimeric $[Sn_2Te_6]^{4-}$ crystallized – similar to observations that have been made in the presence of $NR_4^+$ cations.[2] However, this salt shows an unexpected air-stability which is unique for tellurostannate compounds. A completely different behavior was observed for E = As, where the only crystalline product evinced to be a tellurolate salt with Te in its rare coordination number 1. If air is allowed to diffuse into the reaction mixture, the tellurolate salt remains unaffected, whereas unreacted telluride species are oxidized to form a novel tetratelluride compound.

## Results and Discussion

$[K_2(MeOH)_6][PPh_4]_2[Sn_2Te_6]$ (**1**), $[AsPh_4][TePh(H_2O)_{0.5}]$ (**2**), and $[AsPh_4]_2[Te_4(H_2O)_2]$ (**3**) were obtained by reactions of $[K_4(H_2O)_{0.5}][SnTe_4]$[3] with $PPh_4Cl$ or $AsPh_4Cl$ (Scheme 1). All compounds have been structurally characterized by means of single-crystal X-ray diffraction.[4,5] Table 1 summarizes the crystallographic data. The anion of compound **1** is the product of a dimerization reaction [Equation (1)] that is based on an aggregation equilibrium [Equation (2)], which is known to occur in protic solutions of $[SnQ_4]^{4-}$ anions (Q = S, Se, Te).[6] However, the reported shift of the respective equilibrium when decreasing the pH value upon addition of acid or dilution of the solution cannot be the reason for the crystallization of the dimeric anion here, since the addition of $PPh_4Cl$ does not affect the pH value. Thus, the observation is rather the result of better crystallization due to better matching sizes of cations and anions when the anionic diameter is increased. Figure 1 shows fragments of the crystal packing in **1**.



Scheme 1. Syntheses of compounds **1**, **2**, and **3**.

The asymmetric unit in **1** comprises half a formula unit, i.e. one half of the hexatellurostannate dimer, "$SnTe_3$", one potassium cation, one tetraphenylphosphonium cation, and

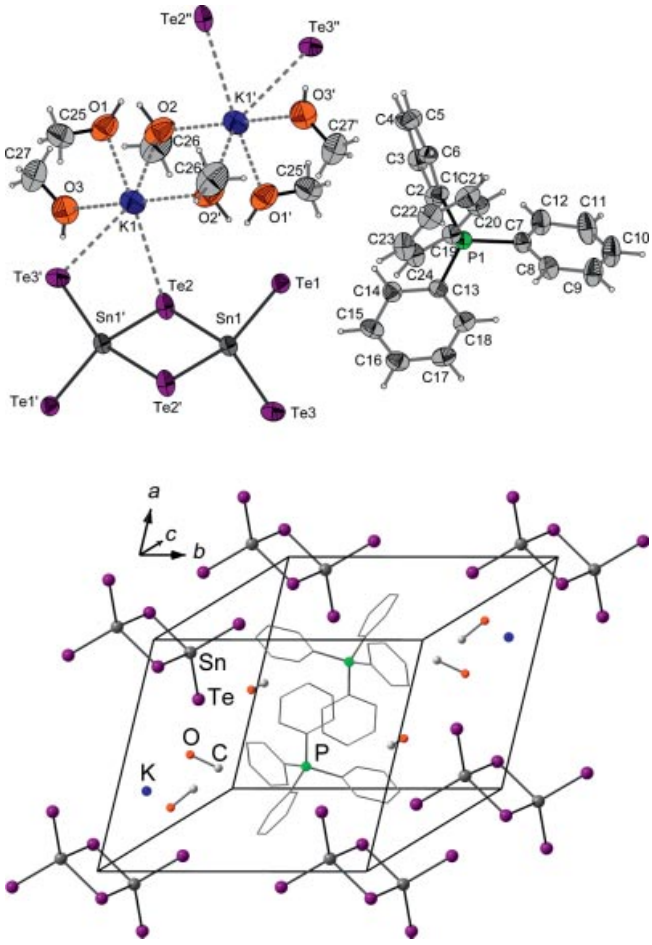

Figure 1. Top: relative orientation of the tetraphenylphosphonium cation, potassium cations within their coordination sphere, and an $[Sn_2Te_6]^{4-}$ anion in **1**. Thermal ellipsoids are drawn to 50% probability. Selected interatomic distances [Å] and angles [°]: Sn–$Te_t$ 2.682(1)–2.806(1), Sn–(μ-Te) 2.794(8)–2.806(1), Sn1···Sn1′ 3.799(1), P–C 1.783(8)–1.793(9), Te···(H–)O 3.481(6)–3.578(10), Te···K 3.383(4)–3.766(4), Te···H(–C) 3.147(5)–3.577(2) K···$O_t$ 2.753(11)–2.789(11), K···(μ-O) 2.670(13)–2.728(11); $Te_t$–Sn–μ-Te 108.41(3)–115.05(3), Te1–Sn–Te3 114.37(3), Te2–Sn–Te2 94.55(3), C–P–C 109.5(3). The subscript "t" denotes terminal atoms. Bottom: fragment of the crystal packing in **1**. H atoms are omitted for clarity.

three MeOH molecules. The latter coordinate to $K^+$ ions to form a coordination aggregate of two edge-sharing octahedra, $[(MeOH)_2Te_2K(\mu\text{-}MeOH)]_2$, the Te donor atoms arising from two adjacent $[Sn_2Te_6]^{4-}$ anions that are linked this way. In addition, all MeOH molecules form hydrogen bonds to terminal tellurium atoms. $PPh_4^+$ cations do not seem to interact significantly with any of the further components. The shortest interatomic distance Te···H–C around the phosphonium group is 3.147(5) Å. Compound **1** is unexpectedly air-stable: although the starting compound, $[K_4(H_2O)_{0.5}][SnTe_4]$, decomposes within seconds upon contact with air, **1** remains unchanged for several days at room temperature. This is in contrast to the air-sensitivity of recently reported $[Mn(en)_3]_2[Sn_2Te_6]{\cdot}nH_2O$[7–9] and $[K_2(2,2,2\text{-crypt-}K)_2][Sn_2Te_6]$.[10] Although all of these salts contain bulky cations, the noninteracting $PPh_4^+$ ion seems to protect the $[Sn_2Te_6]^{4-}$ groups most effectively. This might be due to its own distinct indifference toward air, i.e. its insensitivity toward hydration or oxidation.

The synthesis of compound **2** provides feasible access to the very rare tellurophenolate anion, that could so far only be obtained by using a multistage synthesis in liquid ammonia:[11] free telluride anions, which were obtained according to Equation (2), combine with a phenyl rest of a tetraphenylarsonium cation [Equation (3)]. This observation is in agreement with similar bond strengths of As–C bonds ($E_{Diss}$ = 252 kJ/mol)[12a] and Te–C bonds ($E_{Diss}$ ≈ 250 kJ/mol)[12b,c] in comparison with somewhat stronger P–C bonds ($E_{Diss}$ = 264 kJ/mol)[12d] that are less likely to break.

Compound **2** contains two crystallographically independent cations, two crystallographically independent anions, and one water molecule per asymmetric unit. The latter is situated between two tellurium atoms, forming two hydrogen bonds (Figure 2). Most of the crystal structures of known compounds containing $RTe^-$ exhibit direct Te···A interactions involving the metal counterion $A^+$. For instance, even in the structures of mesitylene analogs with large counterions $[Na(tmeda)_2]^+$ or $[K(18\text{-crown-}6)]^+$, one observes direct Te···A contacts (Te···Na 3.494 Å, Te···K 3.499 Å).[13] Compound **2** is thus one of the very few examples in which Te exhibits the rare coordination number 1. To the best of our knowledge, these are up to now the tellurocyanate $[Ph_3P{=}N{=}PPh_3][TeCN]$,[14] two 2-thienyl analogs, $[PPh_4][C_4H_3STe]$ and its 5-methyl derivative, tetraphenylphosphonium 2-tellurido-5-methylthiophene,[15] and $[Li(THF)_4][(PhMe_2Si)_3C\text{–}Te]$,[16] all four with bulky, weakly interacting cations. However, the low coordination number does not seem to affect the Te–C distances: in **2**, the Te–C distances (2.130 Å on average) range between the extremely short value in the tellurocyanate (2.020 Å) and that in the tris(phenyldimethyl)silyl tellurolate (2.270 Å), all of which do not differ significantly from the Te–C distances of the metal coordinating tellurolates [2.135(5) or 2.150(3) Å].[13]

$$2\,[SnTe_4]^{4-} + 2\,[AsPh_4]^{+} + 0.5H_2O \rightarrow [AsPh_4][TePh(H_2O)_{0.5}]\,(\mathbf{2}) + AsPh_3 + Te^{2-} + [Sn_2Te_6]^{4-} \quad (3)$$

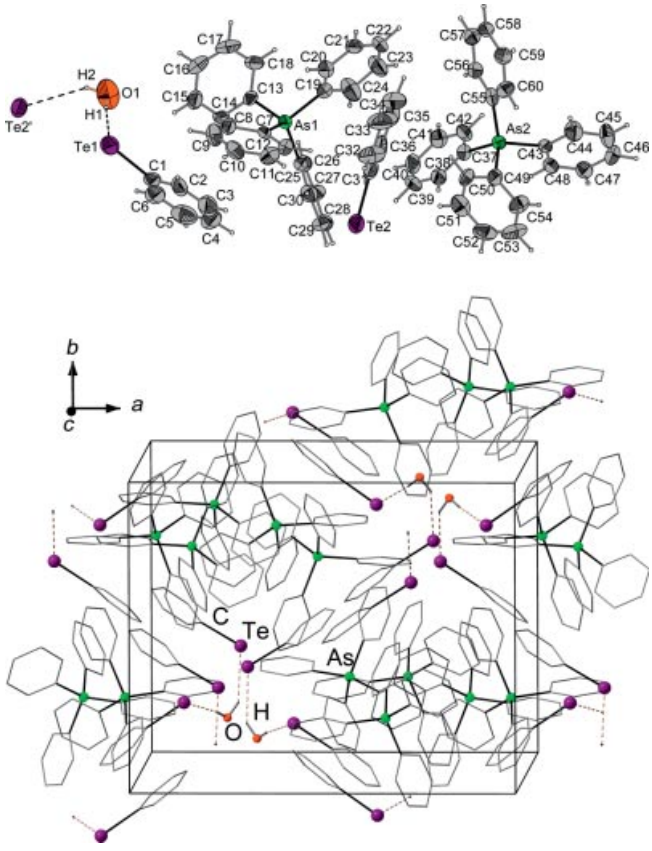

Figure 2. Top: relative orientation of independent cations, anions, and one water molecule in **2**, showing the two independent formula units within one asymmetric unit. Adjacent Te···H distances are indicated by dashed lines. Thermal ellipsoids are drawn to 50% probability. Selected interatomic distances [Å] and angles [°]: As–C 1.899(9)–1.941(8), Te–C 2.123(9)–2.136(10), Te···(H–)O 3.654(9)–3.736(8), Te···H(–C) 3.469(1)–3.553(1); C–As–C 109.3(1). Bottom: fragment of the crystal packing in **2**, viewed down the crystallographic *a* axis. H atoms at C are omitted for clarity.

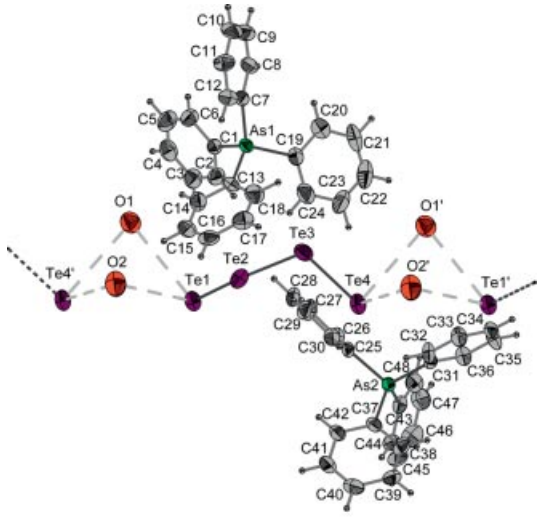
Being interested in the air-stability of **2** within the mother liquor, we allowed air to enter into the reaction mixture for a second. After three months, compound **3** was obtained in addition to unchanged **2**. Upon slow oxidation of the $[Sn_2Te_6]^{4-}$ and $Te^{2-}$ ions [cf. Equation (3)] by air according to Equation (4), the reaction solution turned from red to transparent – an unambiguous hint that oxidation has taken place [Equation (4)].

By the same reaction that led to the synthesis of **1** here [cf. Equation (1)], Haushalter and co-workers obtained a mixture of $[PPh_4]_2[Te_4(MeOH)_2]$ and another, not further specified, tin-containing product.[17] Similar to the process observed here [Equation (4)], intrusion of air caused the formation of the polytelluride. The crystal structure of **3** comprises isolated tetraphenylarsonium cations and water-bridged tetratelluride anions. The relative orientation of the ions are shown as fragments of the crystal packing in **3** (Figure 3). Te1 and Te4 lie one on top of each other in the direction of the crystallographic *a* axis. Thus, the anionic substructure resembles the arrangement of the infinite chains $^1_\infty Te_n$ in elemental α-tellurium,[18] which have been formally cleaved by addition of two extra electrons after every fourth atom, thereby enlarging the Te–Te–Te angles [109.24(1)° and 109.01(1)° in **3**, 103.2° in α-Te]. The dihedral angle Te1–Te2–Te3–Te4 [103.94(1)°] is slightly larger than those in other tetratellurides, such as $[PPh_4]_2[Te_4(MeOH)_2]$ [99.85(12)°] or $[Sr(15\text{-crown-}5)_2][Te_4(H_2O)]$ [102.47(1)°].[19] A significant structural difference between **3**



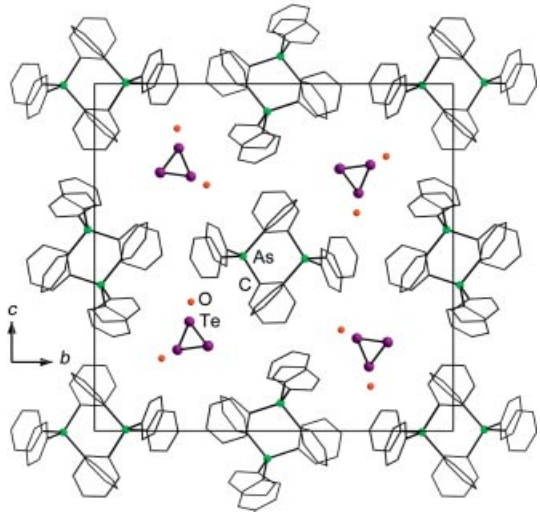


Figure 3. Top: relative orientation of the two independent cations, one tetratelluride anion and bridging water molecules in **3**. Adjacent Te···(H–)O distances are indicated by dashed lines. Thermal ellipsoids are drawn to 50% probability. Selected interatomic distances [Å] and angles [°]: As–C 1.882(10)–1.930(4), Te···(H–)O 3.628(47)–3.703(14), Te1–Te2 2.690(34), Te2–Te3 2.731(36), Te3–Te4 2.718(5), Te1···Te4′ 4.749(1), Te···H(–C) 3.103(1)–3.406(11); C–As–C 109.7(7), Te1–Te2–Te3 109.24(1), Te2–Te3–Te4 109.01(1). Bottom: fragment of the crystal packing in **3**. H atoms are omitted for clarity.

$$[Sn_2Te_6]^{4-} + 2\ Te^{2-} + 3\ O_2 + 8\ H_2O + 4\ [AsPh_4]^+ \rightarrow 2\ [AsPh_4]_2[Te_4(H_2O)_2]\ (\mathbf{3}) + 2\ [Sn(OH)_6]^{2-} \quad (4)$$

and known $[Te_4]^{2-}$ compounds is the coordination sphere around the polytelluride anion: while two methanol molecules each form one hydrogen bond to the terminal tellurium atoms of one polytelluride anion in $[PPh_4]_2[Te_4(MeOH)_2]$,[17] two bridging water molecules lead to the formation of a one-dimensional coordination polymer $^1_\infty[Te_4(H_2O)_2]^{2-}$ in **3**. In other known hydrates of alkali(ne earth) metal polytellurides, $H_2O$ molecules either coordinate to the metal counterion, like in $\{[BaCl(18\text{-crown-}6)(dmf)_2]_2[BaCl(18\text{-crown-}6)(dmf)(H_2O)]_2[Te_4]_2\}$,[16] or one molecule is connected to both ends of one $Te_4^{2-}$ unit through hydrogen bonds, like in $[Sr(15\text{-crown-}5)_2][Te_4(H_2O)]$. Te···(H–)O hydrogen bonds to water {e.g. in **2**, **3**, and $[Sr(15\text{-crown-}5)_2][Te_4(H_2O)]$} are by 11.1 pm longer on average than Te···(H–)O contacts to methanol molecules {e.g. in **1** or $(PPh_4)_2[Te_4(MeOH)_2]$}. Beside the supramolecular arrangement, the structural parameters [see Figure 3 (bottom)] are very similar to those in the cited tetratellurides and show the same characteristic distribution of bond lengths along the polytelluride chain as reported for all structurally characterized polychalcogenides.[20]

## Conclusions

An uncommon synthesis route into a single-crystalline, surprisingly air-stable tellurostannate salt (**1**), a tellurolate salt (**2**), and a tetratelluride salt (**3**) provided high-yield access to these homologues of silicate, thiophenolate, or polysulfide compounds. The presented crystal structures extend the yet limited number of structural reports of $[Sn_2Te_6]^{4-}$, $[TePh]^-$, and $[Te_n]^{2-}$ salts. The synthesis of compound **2** represents a remarkably simple alternative to known syntheses of chalcogenophenolate compounds under drastic conditions. The investigations showed that the nature of cations (and solvent molecules) significantly affect the nature of the stabilized anion and the resulting crystal packing.

## Experimental Section

**General:** All synthesis steps were performed under exclusion of air and external moisture (Ar atmosphere at a high-vacuum, double-manifold Schlenk line or $N_2$ atmosphere in a glove box), unless otherwise noted. MeOH was dried and freshly distilled prior to use; water was degassed by applying dynamic vacuum ($10^{-3}$ Torr) for 1 h.

**$[K_2(MeOH)_6][PPh_4]_2[Sn_2Te_6]$ (1):** $PPh_4Cl$ (375 mg, 1 mmol) was drained in MeOH (5 mL). The solution was layered by a solution of $[K_4(H_2O)_{0.5}][SnTe_4]$ (159 mg, 0.2 mmol) in MeOH (5 mL). Dark red blocks of **1** crystallized after two days. Yield: 275 mg [0.161 mmol, 80.5% according to Equation (1)]. $C_{54}H_{58}K_2O_6P_2Sn_2Te_6$ (1946.20): calcd. C 33.33, H 3.00; found C 33.62, H 2.98.

**$[AsPh_4][TePh(H_2O)_{0.5}]$ (2):** $AsPh_4Cl$ (419 mg, 1 mmol) was drained in $H_2O$ (5 mL). The solution was layered by a solution of $[K_4(H_2O)_{0.5}][SnTe_4]$ (159 mg, 0.2 mmol) in MeOH (5 mL). Large orange parallelepipeds of **2** crystallized after one hour. Yield: 49 mg [0.084 mmol, 83.3% according to Equation (3)]. $C_{30}H_{26}AsO_{0.5}Te$ (597.03): calcd. C 60.35, H 4.39; found C 59.99, H 4.42.

**$[AsPh_4]_2[Te_4(H_2O)_2]$ (3):** Big black blocks of **3** crystallized after three months from the same solution as **2** upon opening the Schlenk tube for one second. Yield: 171 mg [0.130 mmol, 80.7% according to Equation (4)]. $C_{48}H_{44}As_2O_2Te_4$ (1313.07): calcd. C 43.91, H 3.38; found C 44.19, H 3.29.

**Optical Absorption Spectrum of 1:** For the investigation of the optical absorption behavior of compound **1**, a UV/vis spectrum of the single crystalline material was recorded. As expected and in accordance with the visible color of the crystals, the onset of absorption – i.e. the lowest electronic excitation energy $E_g$ – of compound **1** (1.4 eV) is small. It is even smaller than that in $[Mn(en)_3]_2[Sn_2Te_6]\cdot 4H_2O$ (1.6 eV).[5]

**NMR Spectroscopy of 1:** The $^{125}$Te-NMR and $^{119}$Sn-NMR spectra of **1** served to prove the purity of this compound in $D_2O$ solution, according to the known value for $[SnTe_4]^{4-}$.[3] $^{125}$Te: two strong signals at $\delta$ = –199.9 ppm (terminal) and 553.0 ppm (bridged) and a very weak signal at –372.7 ppm arising from the $[SnTe_4]^{4-}$ monomer. $^{119}$Sn: $\delta$ = –1680.5 ppm; slight shift in comparison to the signal of the monomer at –1670.2 ppm, which was not observed here.

**Crystal Structure Analyses:** All X-ray diffraction measurements were performed with Stoe Imaging Plate Systems (IPDS). The crystal data and experimental conditions are summarized in Table 1. For the data sets of **1** and **2** a numerical, for that of **3** a semiempirical absorption correction has been applied. The structures were solved by direct methods of SHELXS-97[4] and refined by full-matrix least-squares methods of SHELXL-97[4] with use of anisotropic displacement parameters for all non-hydrogen atoms. The H-atoms were treated as riding on idealized positions with isotropic displacement parameters set 1.2 $U_{eq}$ (1.5 $U_{eq}$ for methyl groups) of their bonding partners. For **1**, only crystals of poor quality could be quarried out of conglomerates. Thus, the precision of the results is reduced. In the structure of **2**, the H atomic positions of the water molecule were calculated for the orientation of possible H bonds toward the neighboring Te1 and Te2 atoms. The subsequent refinement as rigid groups with free rotation and free common isotropic displacement parameters for the H atoms converged well. The refined Flack parameter of 0.008(15) confirms the correct absolute structure. In the structure of **3**, the crystal showed a small contribution of a (001) reflection twinning. The 24 most affected reflections 4*kl* and 5*kl* were therefore eliminated. The hydrogen atoms of the two water molecules could not be localized.

CCDC 652251 (**1**), -652252 (**2**), and -652253 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Shearing-Like Distortion in Binuclear End-to-End $Cu^{II}$ Azido Compounds: An Ab Initio Study of the Magnetic Interactions

**Maria Angels Carvajal,[a] Christophe Aronica,[b] Dominique Luneau,*[b] and Vincent Robert*[a]**

**Keywords:** Magnetic properties / Azido bridge / Ab initio calculations

The direct control of magnetic interactions in $Cu^{II}$ azido-bridged binuclear complexes is investigated by means of explicitly correlated ab initio calculations. It is shown that in the end-to-end series, the shearing-like asymmetry parameter $\delta = d_{long}(Cu–N) – d_{short}(Cu–N)$ should be considered as an important parameter in the control of the coupling constant. A practical route that could be used to enhance the ferromagnetism of the compound is suggested in light of our calculations.

## Introduction

The synthesis and characterization of magnetic systems such as fascinating single-molecule magnets (SMMs)[1] are of continuous interest. This particular activity stems from a simultaneous need for microscopic interpretations and the design of original materials. In particular, the demand for efficient information storage devices has stimulated the use of various metal centre types ranging from 3d to 4f ions.[1e] Meanwhile, the development of an effective magnetic coupler in binuclear systems has grown since the use of acetate groups.[2] In the $Cu^{II}$ series, the magnetic interactions result from the presence of two unpaired electrons that give rise to the triplet (T) and singlet (S) states of energy difference $J = E_T – E_S$, where $J$ is the traditional magnetic exchange coupling constant in a spin-only Heisenberg-type Hamiltonian $\hat{H} = –2J\hat{S}_1\hat{S}_2$. The intimate participation of the bridging moieties in the magnetic properties has been much investigated in the literature; an important manifestation is the so-called "noninnocent" ligands.[3] In this respect, the prediction of the magnetic properties in binuclear $Cu^{II}$ compounds containing azide bridges remains a challenging issue. It is well-established that the azido group can bridge metal ions in two ways: the so-called end-on (EO) and end-to-end (EE) families (Figure 1). Nevertheless, the determination of the structural parameters that may control the magnetic interaction nature of the compounds is still much debated in the literature.[4,5] The general trend is that the EE mode affords antiferromagnetic interactions, whereas the EO mode favours ferromagnetic behaviour. However, the alternation of short and long Cu–N distances (so-called asymmetric coordination mode, see Figure 1) may result in either ferromagnetic or antiferromagnetic interactions whatever the coordination mode.[4] For symmetrically bridged compounds, theoretical investigations have rationalized the unequivocal distinction between the EO and EE families. Interestingly though, antiferromagnetic behaviour has been predicted in the EO series as soon as the Cu–N–Cu valence angle is sufficiently large (>104°),[6] which has also been experimentally confirmed.[7]

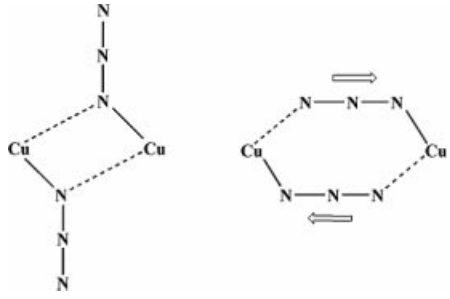

Figure 1. Asymmetric coordination modes of the azide bridge: EO (left) and EE (right). The arrows indicate the shearing distortion which is analyzed in this communication.

Magnetostructural correlations dedicated to EE compounds have pointed out that the symmetry of the coordination sphere measured by the Addison parameter ($\tau$)[8] and the N–Cu···Cu–N torsion angle ($\Delta$) are likely to govern the nature and strength of the magnetic interaction. Regarding the symmetry of the coordination sphere, it was proposed that in the square pyramid (sp) coordination limit ($\tau = 0$) magnetic orbitals are mainly $d_{x^2-y^2}$ and weak ferromagnetic

interactions should result.[4c] Additionally, it was observed that large torsion angles $\Delta$ enhance ferromagnetic behaviour.[4c] Thus, considering the importance of azido-based clusters in the design of magnetic objects, we felt that the role of the coordination mode symmetry should be clarified. With the use of ab initio calculations, the contributions of spin polarization and dynamical correlation effects were analyzed in a series of EE complexes. The present works sheds light on another important structural parameter; the Cu–N bond length alternation. This particular shearing distortion mode acts as an electron-localizing factor in the eight-membered Cu–N rings of EE complexes. To clarify the role of the so-called shearing-mode, we used the crystal structure of a recently reported $Cu^{II}$ azido complex.[9] We carried out the synthesis, structure and magnetic, polarized neutron of an asymmetric EE $Cu^{II}$ azido complex $[Cu(L)(N_3)_2]_2$ [L = 7-(dimethylamino)-1,1,1-trifluoro-4-methyl-5-aza-3-hepten-2-onato] (**1**, Figure 2) that exhibits ferromagnetic interactions ($J$ = 16 $cm^{-1}$) in contrast with most EE systems.[4] The strategy we developed consists of the systematic ab initio evaluation of the exchange coupling constant in a series of fictitious analogues of **1**. Therefore, starting from the experimental geometry for which ferromagnetism has been theoretically elucidated in our previous paper,[9] the Cu–N distances were modified whilst the rest of the complex was kept frozen ($\tau$ = 0.19 and $\Delta$ = 44.3). This particular approach differs from a previous study that focused on the long Cu–N distance;[5] here, we concentrated on the difference between the long and short Cu–N distances. This parameter we shall refer to as $\delta = \delta_{long}$(Cu–N) – $\delta_{short}$(Cu–N) measures the amplitude of this shearing-like distortion away from a perfectly symmetric bridging mode. Let us mention that for $\delta$ = 0 Å, the Cu–N distances all equal 2.155 Å. Along this scheme, the Cu–Cu distance remains unchanged (5.1 Å). We then investigated the sensitivity of $J$ with respect to $\delta$ in EE compounds reported in the literature.

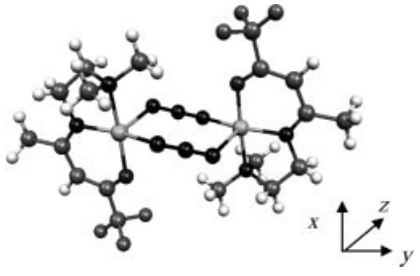

Figure 2. Structure of the EE $[Cu(N_3)L]_2$ compound with L = 7-(dimethylamino)-1,1,1-trifluoro-4-methyl-5-aza-3-hepten-2-onato.[9]

### Theoretical Details

State-of-the-art ab initio, as well as density functional theory (DFT) calculations, proved to reach very satisfactory agreement with experimental measurements in both the EE and EO series. Nevertheless, correlated ab initio calculations were preferred here, as the information extracted from a multiconfigurational wavefunction is very insightful into the mechanism of magnetic interactions. First, complete active space self-consistent field calculations (CASSCF) including two electrons in two orbitals [CAS(2,2)] were performed by using the Molcas5.0 Package[10] to qualitatively incorporate the leading physical configurations. Because the local environments of the $Cu^{2+}$ ions ($d^9$) are roughly $ML_5$, the singly occupied d-type orbitals are perpendicular to the missing ligand direction, which shall be referred to as $z$ (see Figure 2). At this level, the low-lying triplet reads $|gu|$ where $g$ and $u$ are mainly the in-phase and out-of-phase linear combinations of the $d_{x^2-y^2}$ atomic orbitals, respectively (i.e. $g = \frac{a+b}{\sqrt{2}}$, $u = \frac{a-b}{\sqrt{2}}$, where $a$ and $b$ are the $d_{x^2-y^2}$AOs). Along this multiconfigurational scheme, the contributions of the so-called ionic forms $|a\bar{a}|$ and $|b\bar{b}|$in the ground-state singlet $\lambda|g\bar{g}| - \mu|u\bar{u}|$ may be underestimated. Thus, one has to incorporate dynamical correlation effects to fully account for the intimate mechanisms responsible for the singlet-triplet energy gap. By using the triplet molecular orbitals (MOs), dynamic correlation contributions were included with the difference dedicated configuration interaction (DDCI) method[11] implemented in the CASDI code[12] (see the Supporting Information for a detailed description of the computational procedure). This particular framework has provided very accurate results for these types of compounds and solid-state magnetic materials.[9,13]

## Results and Discussion

Detailed analysis of the different contributions to the exchange magnetic coupling constant was given previously.[14] Therefore, we concentrated on: (1) the spin polarization (SP) effects, which are dominated by excitations involving the bridging-ligand orbitals and (2) the dynamical correlation (DC) effects that arise from the instantaneous polarization of the copper ions environments. By allowing specific excitations in the CI treatment, one can grasp selectively those effects and clarify the exchange coupling character. The variations in the $J$, SP and DC contributions as a function of $\delta$ are plotted in Figure 3.

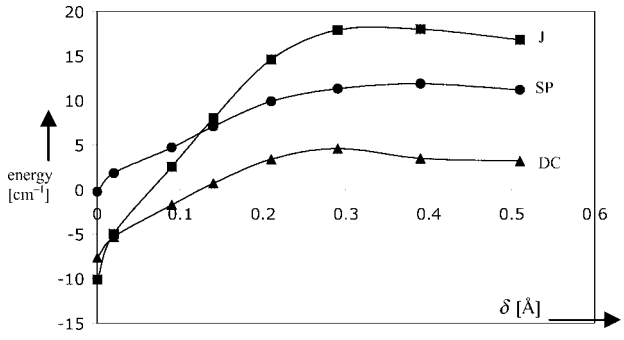

Figure 3. Calculated $J$ (■), SP (●) and DC (▲) energies [$cm^{-1}$] in a series of **1** hypothetical analogues as a function of $\delta$ [Å].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As the asymmetry $\delta$ is increased (i.e. the Cu–N distances become significantly different), our calculated $J$ values steadily increase to finally plateau close to 18 $cm^{-1}$ for $\delta$ ca. 0.3 Å. This is in contrast to the dependence upon the long Cu–N distance for which no monotonic behaviour is observed (Supporting Information, Figure S1).

As previously reported,[14] the SP effects arise mainly from the polarization of the closed shells that are localized on the bridging units. As a result of the exchange operators $\hat{K}_a$ and $\hat{K}_b$, the closed shells $h$ become polarized through $\langle p|K_a|h\rangle$ and $\langle p|K_b|h\rangle$ matrix elements involving virtual MOs $p$. The presence of a reflection plane makes the frontier MOs of the azido part $h$ and $p$ symmetric and antisymmetric, respectively (see Figure 4).

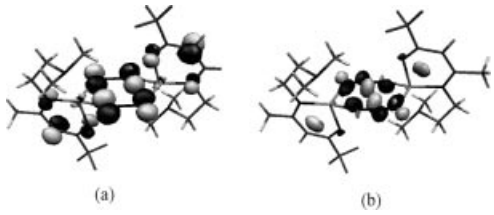

Figure 4. Frontier MOs (a) occupied $h$; (b) virtual $p$.

Thus, one can expect the SP contribution to be negligible, because the matrix elements are vanishingly small in the low-$\delta$ regime. As $\delta$ increases, a competition between the simultaneous shortening and lengthening of the Cu–N bond lengths results. Thus, the different copper–azido overlaps compete to reach a maximum, which fixes the SP contribution, which in turn favours the triplet state. Clearly, given the large Cu–Cu distance in the complex (≈ 5 Å), the contribution of the direct exchange is expected to be negligible.[13] A very similar behaviour for the DC effects is to be noticed. The DC contributions increase regularly with respect to the bridge shearing. The modification of the kinetic exchange only affects the singlet state because the ionic determinants are pure singlet and do not contribute to the triplet wavefunction. A detailed analysis of the wavefunction shows that the weights of these ionic forms is maximum, and still small, in the symmetric complex, i.e. for small $\delta$ values (Supporting Information, Table S1). Therefore, the singlet state is stabilized over the triplet and antiferromagnetic character results. One can intuitively expect the electron delocalization to be less efficient as the Cu–N bond lengths in the eight-membered ring alternate.

To investigate the role of the chemical environment of the copper atoms, we transformed the $CF_3$ electron-withdrawing groups into methyl groups. From our calculations performed at the same level, the magnetic coupling constant is 18 $cm^{-1}$, which is almost identical to the experimental and theoretical values reported for **1**.[9] Thus, one can take advantage of the structuring role of the $CF_3$ groups without greatly affecting the magnetic properties.

From this prospective analysis based on ab initio calculations, we finally examined whether magnetic behaviours could be anticipated in reported EE analogues. Table 1 summarizes the main structural parameters and experimentally determined coupling constants for some EE asymmetric azido-bridged complexes that are available in the literature.

We focused on pentacoordinate Cu compounds with only one exchange pathway. Figure 5 shows the variation of $J$ with respect to both the dihedral angle $\Delta$ and shearing parameter $\delta$. Even though the trend is not monotonous (see Figure 5), complexes with small $\delta$ values exhibit antiferromagnetic character (lower block in Figure 5), whereas ferromagnetic behaviour is exhibited as the shearing deformation increases (upper block in Figure 5). Strikingly though, complex **8** for which $\delta$ is relatively large displays antiferromagnetism. However, this compound presents a very asymmetric structure, with four different Cu–N distances. Moreover, the Cu–Cu distance as well as the $\tau$ value is significantly larger than that in all the other reported

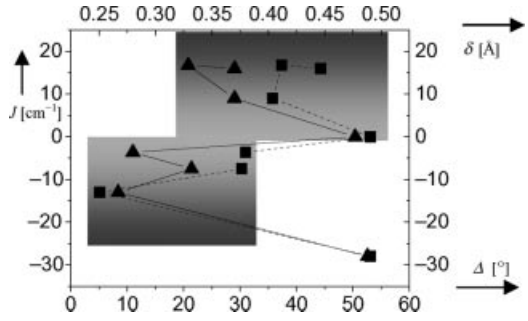

Figure 5. Variations of $J$ with respect to $\Delta$ (■ dashed line) and $\delta$ (▲solid line).

Table 1. Structural and magnetic parameters for asymmetric Cu azido-bridged compounds.

[a] L = 7-(dimethylamino)-1,1,1-trifluoro-4-methyl-5-aza-3-hepten-2-onato, bben = 1,2-bis(benzylamino)ethane, $Et_3dien$ = triethyldiethylenetriamine, bp = 2,2′-bipyridine, $EtMe_4dien$ = 4-ethyl-1,1,7,7-tetramethyldiethylenetriamine, $Me_5dien$ = 1,1,4,7,7- pentamethyldiethylenetriamine, $Et_5dien$ = 1,1,4,7,7-pentaethyldiethylenetriamine, Medpt = methyldipropylenetriamine. [b] Parameters calculated with average angles and bond lengths, as this compound exhibits two nonequivalent dimers.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compounds. Thus, from previous calculations one may expect a simultaneous reduction, though small, of the direct exchange contribution and an enhancement in the superexchange effects. The comparison of **8** with compound **4** is very instructive as the sets of parameters $\Delta$ and $\delta$ are very comparable. Therefore, the unexpected behaviour of **8** is completely attributable to the large $\tau$ value. Clearly, the magnetic behaviour is not strictly governed by a single structural parameter because important variations are observed around $\delta \approx 0.33$ Å (see compounds **4** and **6**).

Finally we looked into the variation of $J$ with respect to $\Delta$ and our shearing parameter $\delta$. Interestingly, these variations are similar (see Figure 5).

Whereas $\Delta$ concentrates on angular distortion, it is rather puzzling that $\delta$, which takes into account the asymmetry of the coordination mode, can describe in a similar way the magnetic behaviour of such a system. This observation clearly deserves further investigation. One may suggest that in synthetic compounds any change in the torsion angle $\Delta$ can be a consequence of a variation of the shear $\delta$ value. From a structural analysis, these parameters cannot be completely independent. Therefore, one may expect a strong correlation between the variations of $\delta$ and $\Delta$. The rationalization we have provided for the influence of this new parameter will call for more magnetostructural data, in particular in the field of single-chain magnets. However, our calculations in which we kept $\Delta$ frozen on purpose indicate that $\delta$ has a direct influence on the $J$ value.

## Conclusions

The $\delta$ parameter, which measures the shearing between the two azido bridges, strongly influences the magnetic behaviour of EE $Cu^{II}$ compounds. The different leading contributions were analyzed by means of explicitly correlated calculations. We believe that magnetostructural correlations should include this particular parameter that turns out to be predictive. This work also suggests that specific magnetic properties can be tuned by varying $\delta$ on copper–azido magnetic prototype compounds. Undoubtedly, the versatility of the azide magnetic coupler arises from its ability to bind paramagnetic centres in various geometries.

**Supporting Information** (see footnote on the first page of this article): The theoretical framework that was used for the ab initio calculations, the xyz files (Angström) of the generated structures and the corresponding variations in the ionic over neutral forms in the singlet wavefunction. Variations in the $J$ values in the reported systems are plotted as a function of the Cu–N long distance as proposed in ref.[5]

# Oriented Attachment Growth of Three-Dimensionally Packed Trigonal Selenium Microspheres into Large-Area Wire Networks

Liangbao Yang,[a] Yuhua Shen,*[a] Anjian Xie,[a] and Jianjun Liang[b]

**Keywords:** Nanostructures / Self-assembly / Selenium

The formation of Se microwire networks by hydrothermal treatment in tungstosilicic acid solution is described. The kinetics of crystallization of the Se assembly is studied as a function of reaction time. During the formation process, single-crystal Se rods can direct the self-aggregation of the amorphous nanoparticles derived from a supersaturation precipitation reaction and promote their crystallization and transformation under mild hydrothermal conditions. In this system, the rod-directed epitaxial aggregation of Se was clearly observed in addition to the traditional Ostwald ripening process.

## Introduction

Solution synthesis has been an important route to nanoparticles with specific shape, size, orientation, etc., which play key roles in tailoring the properties of nanomaterials. Traditional solution-synthetic methods have been widely used for the controlled synthesis of various colloidal nanoparticles.[1] There are different opinions on the mechanisms of morphological synthesis of inorganic nanoparticles. One basic crystal-growth mechanism in solution systems is the well-known "Ostwald ripening process".[2] In the Ostwald ripening process, the formation of tiny crystalline nuclei in a supersaturated medium occurs first. This is followed by crystal growth, in which the larger particles will grow at the cost of the smaller ones, because the smaller ones have a higher solubility on the basis of the Gibbs–Thompson law.[3] Another growth mechanism mainly involving oriented particle aggregation,[4–7] which was conceptually termed "oriented attachment" by Penn and Banfield et al.,[8–12] has emerged recently.[13] In this theory, the bigger particles grow from small primary nanoparticles through an orientated attachment process in which the adjacent nanoparticles self-assemble by sharing a common crystallographic orientation and by docking themselves at a planar interface.[9]

More and more evidence has been observed in several systems for either directed or undirected particle aggregation. A growth mode of this kind can lead to the formation of faceted particles or anisotropic growth if it occurs near equilibrium and if there is sufficient difference in the surface energies of different crystallographic faces.[11] Very recently, Shu-Hong Yu et al. reported evidence for the oriented attachment mechanism in which the nanorods obviously act as epitaxial "substrates" or guide the directional aggregation process for the formation of nanorod-based aggregated structures.[14]

Tungstosilicic acid ($H_4SiW_{12}O_{40}$, TSA) ions form a subset of the polyoxometalates that have Keggin structure. Polyoxometalates with Keggin structure have the general formula $(XM_{12}O_{40})^{(8-n)-}$, where "M" stands for the element W or Mo, "X" stands for heteroatoms such as P, Si, Ge, and $n$ is the valency of X.[15] It is well known that Keggin ions undergo stepwise multielectron redox processes without structural change.[15] They may be reduced electrolytically, photochemically, and chemically (with suitable reducing agents). They are a large category of metal–oxygen cluster anions with well-defined structures and properties, with diverse applications in the fields of analytical chemistry, biochemistry, and solid-state devices, and have been used as antiviral and antitumor reagents. Their redox chemistry is characterized by their ability to accept and release a certain number of electrons, in distinct steps, without decomposition.[16]

Selenium is a material suitable for a self-organization studies, because of the excellent ability of trigonal selenium (t-Se) to grow preferentially along the *c* axis and the possibility of controlling the one-dimensional growth of selenium by diverse approaches.[17–21] If its three-dimensionally packed precursor is obtained, it is possible to transform it to a crossed nanowire array by choosing proper experimental conditions. Due to its photoconductivity with a spectral sensitivity that covers almost the entire visible range, selenium is also important in a wide variety of applications that

range from photocells, photographic exposure meters, and solar cells to semiconductor rectifiers. In this study, we have designed a hydrothermal synthesis for the selenium microcrystal. To the best of our knowledge, a hydrothermal synthesis of a Se single crystal with this novel structure has not been achieved previously in TSA solution.

## Results and Discussion

Figure 1A presents the Raman spectrum of the synthesized sample. The resonance peak at 233 $cm^{-1}$ is a characteristic signature of trigonal selenium, which can be assigned to the vibration of the Se helical chain.[14] A peak around 142 $cm^{-1}$ results from the transverse optical photon mode. For comparison, the characteristic Raman peaks for monoclinic selenium and α-Se are at 256 $cm^{-1}$ and 264 $cm^{-1}$, respectively.[22] The XRD pattern recorded from a drop-coated film of the sample on a glass substrate is shown in Figure 1B, curve a. All of the strong and sharp reflection peaks can be readily indexed to a single phase of trigonal-structured selenium [t-Se, space group $P3_121$ (152)] containing infinite, helical chains of selenium atoms packed parallel to each other along the *c* axis, with cell parameters $a = 0.4367$ nm and $c = 0.4959$ nm. These values are in agreement with the values reported in the literature.[23] For comparison, the XRD spectrum of bulk t-Se is shown in Figure 1B, curve b; it is similar to the spectra recorded by the Xie group.[24,25] These results, obtained from Raman spectroscopy and XRD, indicate that the product is crystalline.

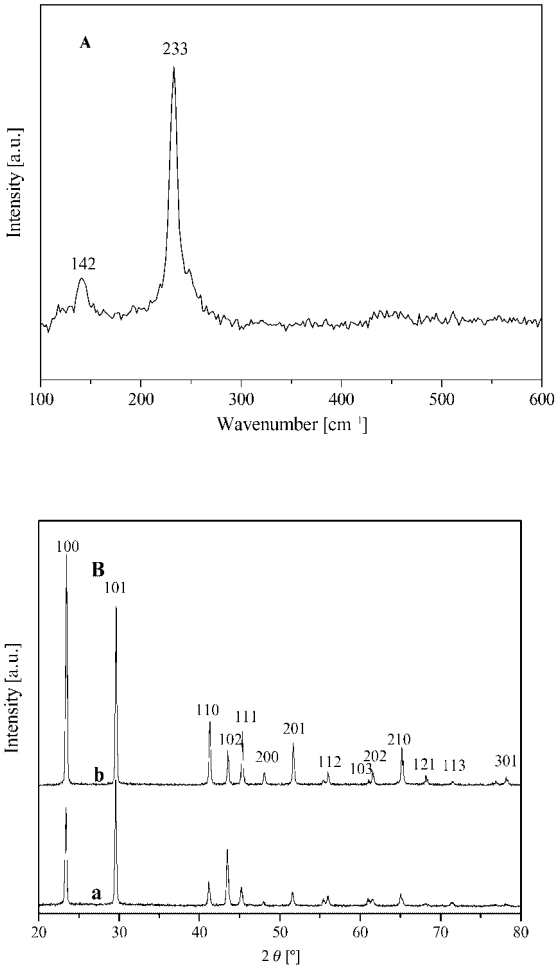

Figure 1. Raman spectrum of the synthesized sample (A) and XRD pattern (B) of a sample of the precipitates obtained as a result of hydrothermal treatment (curve a) and a sample of the bulk t-Se (curve b).

The product was characterized by using scanning electron microscopy (SEM), and a typical image is shown in Figure 2. The image shown in Figure 2A clearly reveals that a large-area microwire network was successfully fabricated. The units for the build-up of the network are uniform microwires with an average diameter of about 1.5 μm and lengths of up to hundreds of micrometers. The aspect ratio of the wire is in the range of several hundreds, which may be a useful feature in some applications. The structure and morphology of the microwires was further characterized by transmission electron microscopy (TEM) and selected-area electron diffraction (SAED). Figure 2B shows a typical TEM image of the microwires, revealing their high aspect ratio, good crystallinity, and uniformity. Figure 2C shows

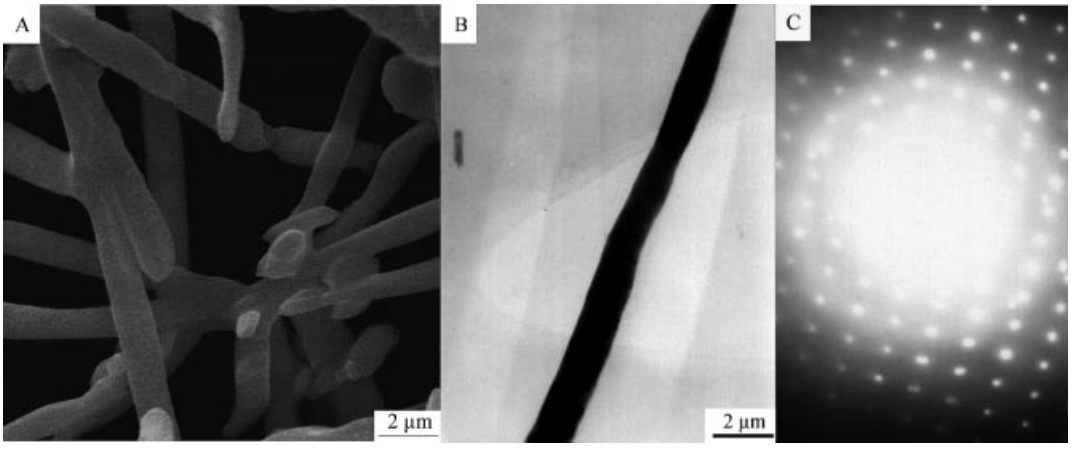

Figure 2. A representative SEM image (A), the TEM image (B), and the associated SAED pattern of the t-Se microcrystal (C).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the associated SEAD pattern recorded by focusing the incident electron beam on an individual microwire and exhibits the single-crystalline nature of the wire. The twofold rotational symmetry associated with this pattern indicates that these t-Se wires have predominately grown along the [001] direction (*c* axis), with the helical *c* chains of the Se atoms parallel to the longitudinal axis.[26] We have also carried out extensive investigations on more individual wires by using electron diffraction (ED), the results of which demonstrate that the as-synthesized sample is single-crystalline.[26]

To ensure that the TSA present in the system has an important effect on the synthesis of the Se particles, a control experiment was performed under the the same conditions, but only without TSA. A lot of irregular microparticles were obtained (see the SEM image in the Supporting Information, FigureS1). On the basis of the above analyses, we conclude that TSA significantly affects the shapes of the particles.

To study the formation mechanism of the network of t-Se microwires, various growth stages of the t-Se microwire network were investigated. Figure 3 shows a set of SEM images corresponding to samples obtained at different growth stages of the microwire. After 1 h of hydrothermal treatment, spherical α-Se was obtained (Figure 3A), and no ED pattern was detected. The image shows highly uniform colloidal particles of predominantly spherical morphology. An analysis of 100 such particles from several SEM micrographs resulted in determination of the average particle size of $64 \pm 14$ nm. When the solution was treated for 3 h, spherical t-Se particles were formed, and some of the spheres were broken (Figure 3B). The size of t-Se spherical particles was about $3.5 \pm 1.4$ μm. In Figure 3C, it is clearly seen that most of the spheres are broken, and an interesting core–shell structure is revealed. The structural characteristics of the crystal were further elucidated by the TEM and ED techniques (inset in Figure 3C). The SAED patterns for the shell and core areas are identical. A further investigation of such a complex growth process is ongoing. The Se rods formed at the initial stage from the seeds of spherical t-Se were observed at a hydrothermal treatment time of 6 h (Figure 3D). It can be seen that some rods and a lot of spheres coexist. The Se microrods grew as the hydrothermal treatment time was prolonged to 12 h. The number of rods increased, the rods became longer, and the spheres tailed off. Most of the spheres grew alongside the rods (Figure 3E). After 24 h of treatment, the t-Se microwires grew into a well-organized, shaped network (Figure 3F), and any longer treatment made no difference in the morphology.

According to the Stranski rule, in crystals that may exhibit various allotropes, the least stable and most soluble phase, which is favored kinetically, usually precipitates first, and then this metastable phase is transformed during the aging process into a more thermodynamically stable phase.[27] In order to understand the growth process of the Se microwires on the basis of the results obtained, a feasible route is presented as shown in Figure 4. First, the unstable spherical α-Se particles are formed (a). Second, α-Se transforms into the more stable t-Se. Under hydrothermal treatment, the Se rods begin to grow on the surface of the spherical t-Se (c–f); then the Se microrods are formed after continuous growth, and at last, the microrods are transformed into the microwire network by the Ostwald ripening process (g). We believe that the aggregated growth along the circumference of the gap in the broken sphere resulting from the hydrothermal treatment leads to the formation of microrods, which is similar to the conclusion reached by Yang et al.[28] It seems that the situation is almost the same in this study. The long-term hydrothermal treatment somehow breaks the selenium sphere and forms a crater on the sphere. The edge of the crater acts as the initiation spot, and further directional growth of the selenium crystal along this crater yields the rod product. The transition of microrods into the microwire network indicates that the wires are thermodynamically stable.

The conventional hydrothermal crystallization or transformation process with amorphous nanoparticles as precursors is a typical Ostwald ripening process, in which a highly supersaturated solution is adopted, and amorphous fine particulates act as the precursors. In this mechanism, the formation of tiny crystalline nuclei in a supersaturated medium occurs at first and is then followed by crystal growth. The larger particles (Figure 3B) will grow at the expense of the small ones (Figure 3A) because of the difference in solubility between large and smaller particles according to the well-known Gibbs–Thomson law. In the early stage, the examination of intermediate products (Figure 3D) shows the coexistence of the short rods and microspherical particles. As the reaction goes on, the microspheres decrease in number, and longer microrods form (Figure 3E), suggesting that the longer rods obviously grow at the expense of the microspheres. On the other hand, we think that the growth mode for rods in our work is similar to the seed-mediated growth mechanism of metals.[29–31] The so-called rod-directed self-aggregation process in our case is the directional aggregation of the tiny spherelike particles on the backbone of the rods. Crystalline microrods with rough surface structures then transform into the microwire network.

We performed an additional experiment to determine whether the growth process was a "ripening" or an "oriented attachment". A fresh mixture of $H_2SeO_3$ and TSA was added to the solutions in the presence of a suitable amount of single-crystal Se wires (0.1 mmol), and the mixture was heated at 160 °C for 3 h. The pure Se wire networks with a typical shape are shown in Figure 5. In general, Se nanospheres transform into networks in 24 h. In this experiment, this process only needed 3 h. The results indicated that all small particles tend to attach onto the backbone of the nanowires and then form micronetworks. It is interesting that no individual dispersed nanoparticles were found in the solution.

A control experiment was performed wherein microspheres were autoclaved for 12 h at 160 °C. At first, the wires and the spheres coexisted (Figure 6A), and then the wire networks were formed (shown in Figure 6B). There is little difference in morphology between Figure 6B and Fig-

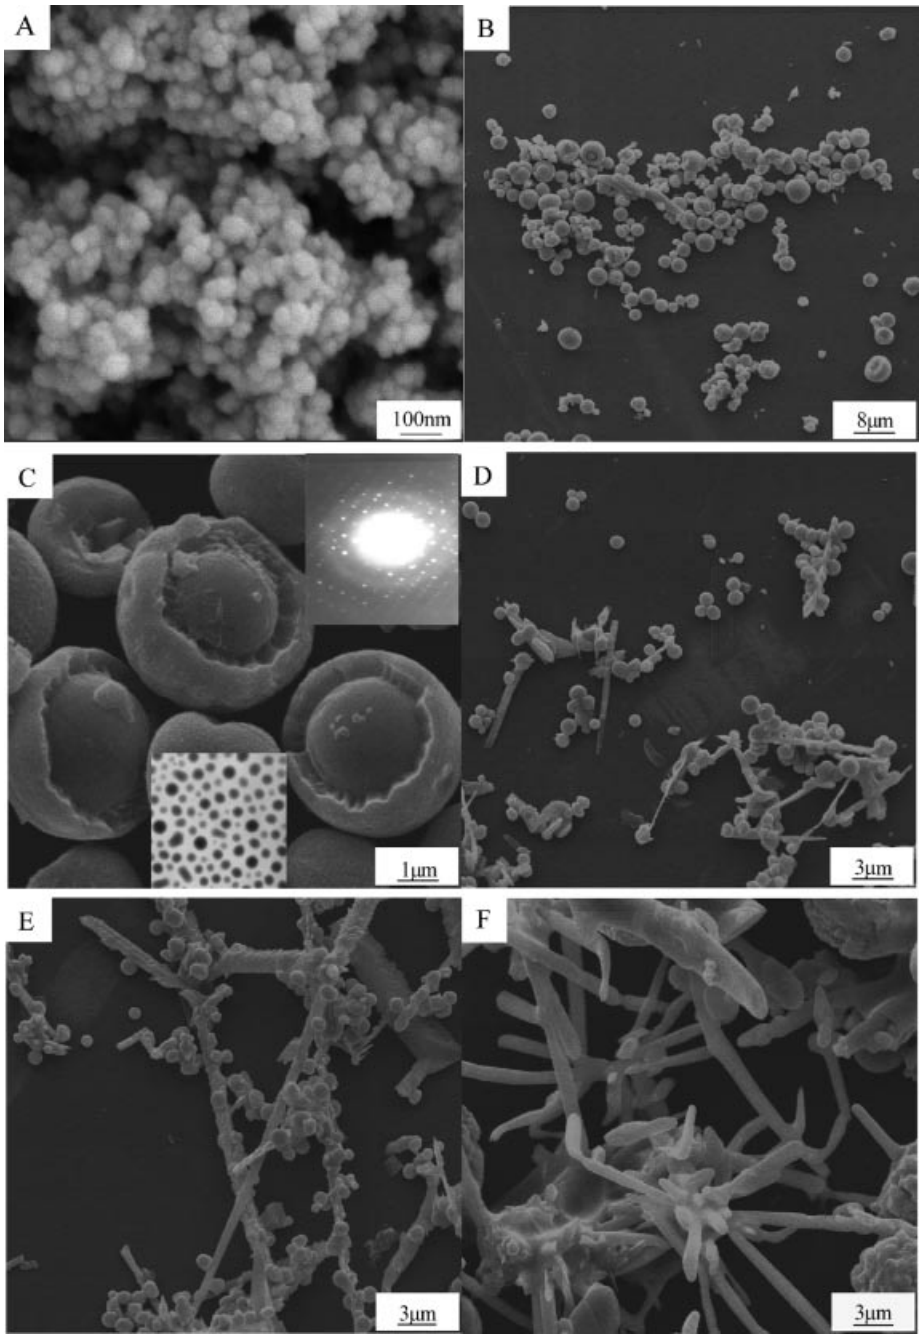

Figure 3. A set of SEM images corresponding to samples at different stages of growth of the microwire network obtained by hydrothermal treatment: after 1 h (A); low (B) and high magnifications of the rough microspheres after 3 h (C), 6 h (D), 12 h (E), and 24 h (F). The insets of (C) are the TEM and ED patterns.

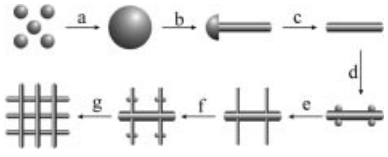

Figure 4. Formation of the wire networks by hydrothermal crystallization. In the early stage, there are a plenty of spheres (a,b); later the short rods and small nanospheres coexist (c–f); at last, the networks of Se form (g).

ure 5. These results indicated that the obvious Se-wire-directed oriented attachment mechanism and its promotion of further crystallization and transformation of the nanoparticulates are undoubtedly the mechanisms involved.

Such spontaneous "landing" of the small spherical particles on the backbone of the rods (Figure 3E) followed by the self-aggregation of these combinations of spheres and rods instead of aggregation among the small particles only could be related with one mechanism: the so-called "contact epitaxy" proposed by Averback et al.[32,33] The driving

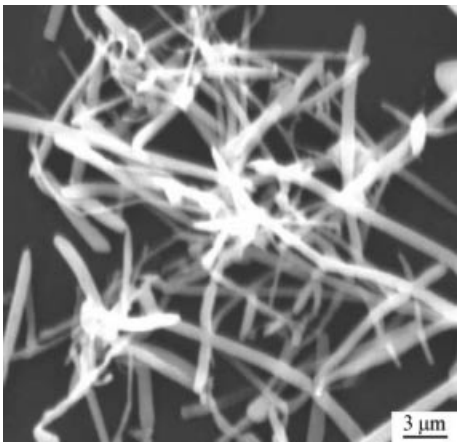

Figure 5. Typical SEM image of the sample which was obtained after adding a fresh mixture of $H_2SeO_3$ and TSA solutions to a 20-mL solution containing 0.1-mmol Se wires and heating the mixture for 3 hours.

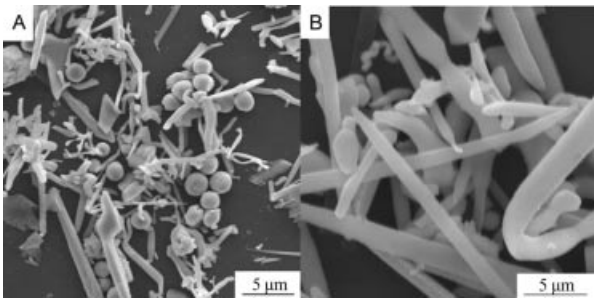

Figure 6. Typical SEM images of the samples which were obtained after heating the microspheres in an autoclave for 2 h (A) and 12 h (B).

force for this spontaneous oriented attachment is that the elimination of the pairs of high energy surfaces will lead to a substantial reduction in the surface free energy from the thermodynamic viewpoint.[10,13] The initial randomly oriented crystals can align epitaxially with the substrate (which are the rods here). This alignment is explained as the rotation of the particles within the aggregates driven by short-range interactions between adjacent surfaces.[32,33]

The surfactants were found to significantly affect the shape of the particles. The shape of the particles obtained in the presence of surfactants was completely different from that observed without surfactants. The surfactant (CTAB or SDB) plays an important role in controlling the mor-

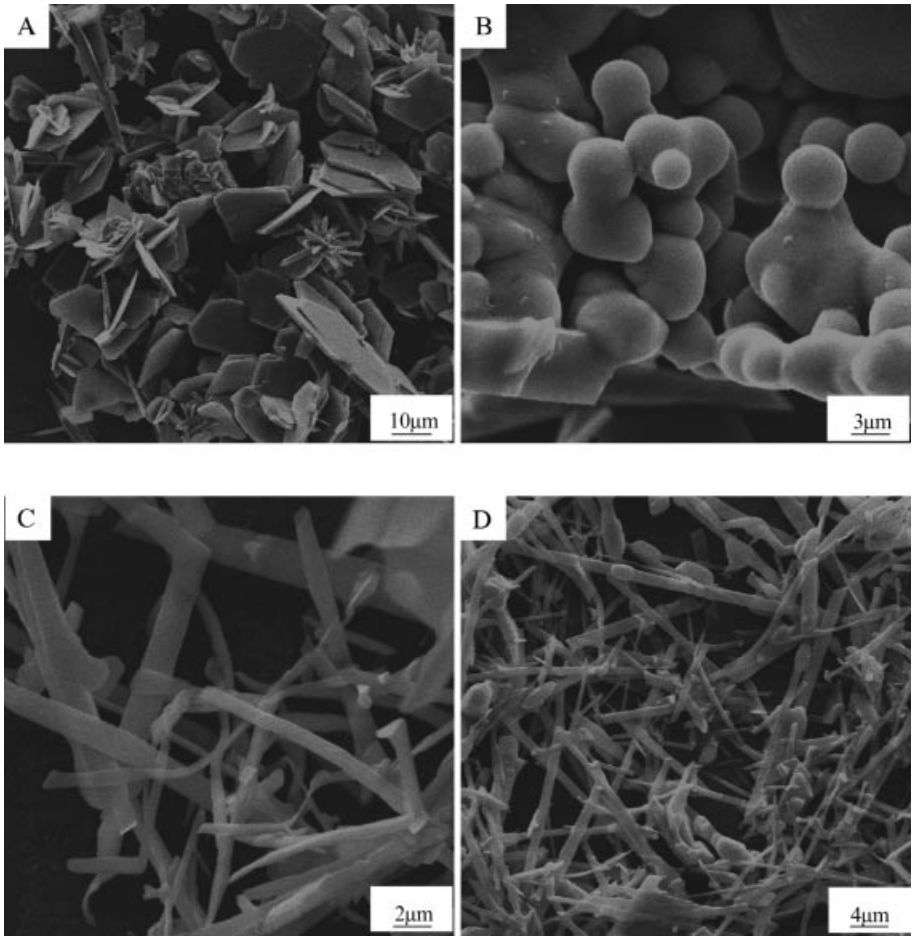

Figure 7. The SEM images of the Se particles synthesized by hydrothermal treatment for 6 h in the presence of CTAB/SDB: CTAB 0.1 M (A); CTAB 0.01 M (B); SDB 0.1 M (C); SDB 0.01 M (D).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phology of Se. When the other conditions are kept the same but CTAB (0.1 M) is added, plenty of flakes are obtained (Figure 7A). When the concentration of CTAB decreases to 0.01 M, there is some effect on the morphology of the Se crystals (Figure 7B). When SDB is added instead of CTAB, a lot of microrods and microbands are obtained at higher concentrations (Figure 7C, 0.1 M) and at lower concentrations (Figure 7D, 0.01 M). This observation can be explained by the fact that CTAB or SDB is adsorbed on specific facets of the Se crystal and changes the surface energy if the amount of CTAB or SDB is appropriate. In contrast, the nonadsorbed facets will grow rapidly. This behavior is similar to that observed in the synthesis of other crystals controlled by a surfactant.[34] When the concentration of CTAB is too low, there will not be enough surfactant adsorbed on all of the facets, and the surfactant loses the ability to control the morphology of the growing crystals (see Figure 7B).

## Conclusion

In summary, on the basis of the structure and surface analysis data, we conclude that the formation of wire networks in our work is based on the Ostwald ripening process and the oriented attachment mechanism. Such spontaneous self-aggregation and crystallization induced by the well-crystallized rods could provide a unique route for improving the properties of an anisotropic material. We believe that this finding could be extended to various oxide systems or even to non-oxide rod systems.

## Experimental Section

**Chemicals:** TSA, selenious acid ($H_2SeO_3$), propan-2-ol [$CH_3CH(OH)CH_3$], cetyltrimethylammonium bromide (CTAB), and sodium dodecyl sulfonate (SDS), were all A.R. grade and obtained from Shanghai Reagent Co. All the reagents in the experiments were used as received. Double-distilled water was used to prepare the solutions.

**Preparation of Se Nanoparticles:** In a typical experiment, an aqueous deaerated solution of TSA (30 mL, 1 mM) was taken in a test tube along with an aqueous deaerated solution of $H_2SeO_3$ (30 mL, 1 mM) and propan-2-ol (2 mL). About 20 mL of the solution was transferred into a 25-mL stainless-steel, Teflon-lined autoclave. The autoclave was sealed, maintained at 160 °C for the corresponding time, and then cooled to room temperature naturally. The precipitates obtained were centrifuged, washed several times with distilled water and absolute ethanol, and dried in vacuo at 60 °C for 6 h. The procedure of the corresponding control experiments with addition of different surfactants to the reaction solution is similar to the above experiments.

**Analysis:** FTIR spectroscopy measurements were carried out with a Nexus 870 FTIR spectrophotometer having a resolution of 4 $cm^{-1}$ (America Nicolet Co.). SEM measurements were performed with a Leica Stereoscan-440 scanning electron microscope. The Raman spectra were recorded with a Jobin Yvon HR800 (Horiba group) instrument by using 514.5 nm as the excitation line. The products were characterized by their X-ray diffraction (XRD) patterns, which were recorded with an MXP 18 AHF X-ray diffractometer (MAC Science Co. Ltd.) with monochromatized Cu-$K_\alpha$ radiation ($\lambda$ = 1.54056 Å). XPS measurements of Se nanoparticles were carried out with a VG ESCALAB MKII instrument at a pressure less than $10^{-6}$ Pa. The general scan and Se core-level spectra were recorded with non-monochromatized Mg-$K_\alpha$ radiation (photon energy = 1253.6 eV). The core-level binding energies (BEs) were aligned with respect to the $C_{1s}$ binding energy (BE) of 285 eV. Samples for TEM analysis were prepared by drop-coating films of the Se solution on carbon-coated copper TEM grids, allowing the grid to stand for 2 min, and then removing the extra solution with blotting paper. The TEM measurements mentioned above were carried out with a JEM model 100SX electron microscope (Japan Electron Co.) operated at an accelerating voltage of 80 kV.

# Synthesis and Reactivity of Alkenyl-Substituted Zirconocene Complexes and Their Application as Olefin Polymerisation Catalysts

**Santiago Gómez-Ruiz,[a] Dorian Polo-Cerón,[a] Sanjiv Prashar,*[a] Mariano Fajardo,[a] Antonio Antiñolo,[b] and Antonio Otero[b]**

**Keywords:** Zirconium / Metallocenes / Polymerisation / Homogeneous catalysis / Cyclopentadienyl ligands

The zirconocene complexes [Zr($\eta^5$-$C_5H_5$){$\eta^5$-$C_5H_4$-($CMe_2CH_2CH_2CH{=}CH_2$)}$Cl_2$] (**4**) and [Zr{$\eta^5$-$C_5H_4$($CMe_2$-$CH_2CH_2CH{=}CH_2$)}$_2Cl_2$] (**5**) were synthesised from the reaction of the lithium derivative [Li{$C_5H_4$($CMe_2CH_2$-$CH_2CH{=}CH_2$)}] (**1**) with [Zr($\eta^5$-$C_5H_5$)$Cl_3$] or $ZrCl_4$, respectively. The *ansa*-zirconocene complex [Zr{$Me_2Si$($\eta^5$-$C_5Me_4$)-($\eta^5$-$C_5H_3${$CMe_2CH_2CH_2CH{=}CH_2$})}$Cl_2$] (**6**) was obtained from the reaction of the lithium precursor [$Li_2${$Me_2Si$($\eta^5$-$C_5Me_4$)($\eta^5$-$C_5H_3${$CMe_2CH_2CH_2CH{=}CH_2$})}] (**3**) with zirconium tetrachloride. Catalytic hydrogenation of **4**–**6** gave the zirconocene complexes [Zr($\eta^5$-$C_5H_5$){$\eta^5$-$C_5H_4$($CMe_2CH_2$-$CH_2CH_2CH_3$)}$Cl_2$] (**7**), [Zr{$\eta^5$-$C_5H_4$($CMe_2CH_2CH_2CH_2$-$CH_3$)}$_2Cl_2$] (**8**) and [Zr{$Me_2Si$($\eta^5$-$C_5Me_4$)($\eta^5$-$C_5H_3${$CMe_2CH_2$-$CH_2CH_2CH_3$})}$Cl_2$] (**9**), respectively. Hydroboration of **4**–**6** with 9-BBN (9-borabicyclo[3.3.1]nonane) yielded [Zr($\eta^5$-$C_5H_5$){$\eta^5$-$C_5H_4$($CMe_2CH_2CH_2CH_2CH_2BC_8H_{14}$)}$Cl_2$] (**10**), [Zr{$\eta^5$-$C_5H_4$($CMe_2CH_2CH_2CH_2CH_2BC_8H_{14}$)}$_2Cl_2$] (**11**) and [Zr{$Me_2Si$($\eta^5$-$C_5Me_4$)($\eta^5$-$C_5H_3${$CMe_2CH_2CH_2CH_2CH_2BC_8$-$H_{14}$})}$Cl_2$] (**12**), respectively, and the catalytic hydrosilylation of **4**–**6** with $SiHMe_2Cl$ gave [Zr($\eta^5$-$C_5H_5$){$\eta^5$-$C_5H_4$($CMe_2$-$CH_2CH_2CH_2CH_2SiMe_2Cl$)}$Cl_2$] (**13**), [Zr{$\eta^5$-$C_5H_4$($CMe_2$-$CH_2CH_2CH_2CH_2SiMe_2Cl$)}$_2Cl_2$] (**14**) and [Zr{$Me_2Si$($\eta^5$-$C_5Me_4$)($\eta^5$-$C_5H_3${$CMe_2CH_2CH_2CH_2CH_2SiMe_2Cl$})}$Cl_2$] (**15**), respectively. The dinuclear complex [$Cl_2$Zr{$Me_2Si$($\eta^5$-$C_5$-$Me_4$)($\eta^5$-$C_5H_3${$CMe_2(CH_2)_4SiMe_2OSiMe_2(CH_2)_4Me_2C$}$\eta^5$-$C_5$-$H_3$)($\eta^5$-$C_5Me_4$)$SiMe_2$}$ZrCl_2$] (**16**) was obtained upon controlled hydrolysis of **15**. The zirconocene compounds were tested as catalysts in the polymerisation of ethylene and propylene. Isotactic polypropylene with [mmmm] pentads of the order of 75 % were obtained with the *ansa*-zirconocene catalysts, whereas the unbridged metallocene catalysts produced atactic polypropylene. The molecular structures of **4** and **5** were determined by single-crystal X-ray diffraction studies.

## Introduction

Metallocene dichloride complexes of group 4 metals have received a large amount of attention in the past few decades because they are excellent catalysts for the polymerisation of α-olefins[1] and for other processes in organic synthesis such as carbometallation, hydrometallation, carbonylation, acylation, isomerisation, hydrogenation, hydroamination, dehydrosilylation and hydrosilylation.[2]

The current goal in the field of olefin polymerisation with metallocene catalysts is moving towards supported catalysts that allow homogeneous single-site selectivity in a heterogeneous medium.[3] A variety of routes have been developed for supporting metallocene complexes on silica, including the direct reaction of silica with a metallocene complex followed by activation with a co-catalyst, such as MAO, reaction of MAO-modified silica with a metallocene complex, or similar approaches where other co-catalysts are supported on silica.[4] Recently, considerable attention has been focused on the anchoring of metallocene complexes on silica through either metallocene synthesis on the support or reaction of a suitably functionalised metallocene complex with silica.[4,5] One of the most common routes for the immobilisation of metallocene complexes is the reactivity of the C=C double bond of an alkenyl substituent on the cyclopentadienido ring or at the *ansa*-bridge atom.[6]

In contrast to their late transition metal analogues,[7] the use and transformation of functional groups at the cyclopentadienido rings of early transition metal compounds has been rather limited.[8] The reactivity of such alkenyl-functionalised metallocene complexes has been mainly studied in olefin metathesis reactions[9,10] and hydrometallation.[10]

As a continuation of our work on the synthesis and catalytic reactivity of group 4 metallocene complexes,[11] we report here the synthesis of new alkenyl-substituted zirconocene and *ansa*-zirconocene complexes and their reactivity in hydrogenation, hydroboration and hydrosilylation processes. We also describe the catalytic behaviour of the zirconocene complexes in the polymerisation of ethylene and propylene.

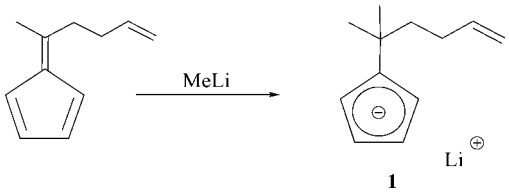
## Results and Discussion

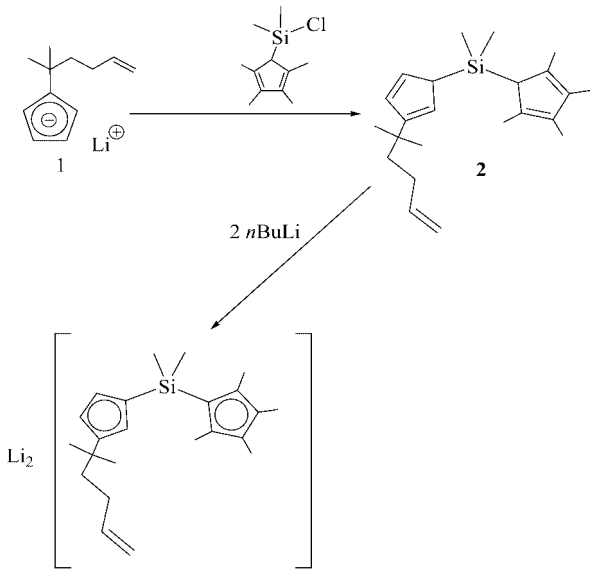
Methyllithium reacts with 6-(4-buten-1-yl)-6-methylfulvene by nucleophilic addition at the exocyclic double bond to give the cyclopentadienidolithium compound [Li{$C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)$}] (**1**) [Equation (1)].



**1** (1)

Complex **1** was characterised by $^1H$ and $^{13}C$ NMR spectroscopy (see Experimental Section). Two multiplets at $\delta$ = 5.46 and 5.48 ppm in the $^1H$ NMR spectrum of **1** can be assigned to the cyclopentadienido ring protons, with a singlet due to the two methyl groups substituting the carbon atom bonded to the cyclopentadienido ring at $\delta$ = 1.19 ppm. The alkenyl fragment exhibits four sets of signals, two corresponding to the $CH_2$ protons (two multiplets at $\delta$ = 1.50 and 1.91 ppm), one corresponding to the proton at C-$\gamma$ (a multiplet at $\delta$ = 5.73 ppm) and two for the terminal olefinic protons (multiplets at $\delta$ = 4.74 and 4.87 ppm). The $^{13}C\{^1H\}$ NMR spectrum of **1** shows the expected signals (one signal at $\delta$ = 46.5 ppm for the carbon atom bonded to the cyclopentadienido ring, one signal at $\delta$ = 35.4 ppm for the two methyl groups, four signals at $\delta$ = 31.0, 31.1, 112.8 and 128.8 ppm for the alkenyl fragment, and three signals at $\delta$ = 100.9, 101.8, and 141.6 ppm for the cyclopentadienido moiety).

The asymmetrically substituted *ansa* ligand precursor $Me_2Si(C_5HMe_4)\{C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)\}$ (**2**) was prepared by treating **1** with $Me_2Si(C_5HMe_4)Cl$ according to previously reported synthetic protocols [Equation (2)].[11a,11b,11f] Compound **2** was isolated as a mixture of the double bond positional isomers, with one isomer being predominant as confirmed by $^1H$ NMR spectroscopy. This compound was also characterised by electron impact mass spectrometry (see Experimental Section). The dilithium derivative, [$Li_2\{Me_2Si(C_5Me_4)(C_5H_3\{CMe_2CH_2CH_2CH{=}CH_2\})\}$] (**3**) was obtained in the traditional manner by treating **2** with *n*-butyllithium. It was isolated as a highly moisture- and oxygen-sensitive white solid and characterised by elemental analysis (carbon and hydrogen; see Experimental Section).



(2)

Treatment of **1** with either [$Zr(\eta^5\text{-}C_5H_5)Cl_3$] or $ZrCl_4$ yielded the corresponding zirconocene(IV) dichloride complexes [$Zr(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)\}Cl_2$] (**4**) and [$Zr\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)\}_2Cl_2$] (**5**), respectively [Equation (3)], which were isolated as crystalline solids and characterised spectroscopically. The $^1H$ NMR spectrum of **4** shows one singlet for the unsubstituted cyclopentadienido ring protons at $\delta$ = 6.48 ppm, two multiplets at $\delta$ = 6.36 and 6.45 ppm for the substituted cyclopentadienido ring protons, and a singlet at $\delta$ = 1.39 ppm corresponding to the two methyl groups. The alkenyl fragment exhibits four sets of signals, two corresponding to the $CH_2$ protons (two multiplets at $\delta$ = 1.56 and 1.75 ppm), one for the proton at C-$\gamma$ (a multiplet at $\delta$ = 5.71 ppm) and two corresponding to the terminal olefinic protons (multiplets at $\delta$ = 4.89 and 4.96 ppm). A similar spectral pattern was also observed for the alkenyl fragment in the $^1H$ NMR spectrum of **5** along with a singlet at $\delta$ = 1.41 ppm (assigned to the two methyl groups) and two multiplets at $\delta$ = 6.32 and 6.41 ppm for the cyclopentadienido protons. The $^{13}C\{^1H\}$ NMR spectrum of **4** shows one signal at $\delta$ = 115.9 ppm assigned to the unsubstituted $C_5$ ring and three signals at $\delta$ = 112.2, 113.0 and 143.3 ppm for the substituted $C_5$ ring. The carbon atom bonded to the cyclopentadienido ring appears in the spectrum as one signal at $\delta$ = 46.1 ppm, and the carbon atoms of the two methyl groups are observed as one signal at $\delta$ = 36.4 ppm. The four signals at $\delta$ = 27.2, 29.0, 114.1 and 138.5 ppm were assigned to the alk-

enyl moiety. The expected signals were observed in the $^{13}C\{^1H\}$ NMR spectrum of **5** (see Experimental Section).

The molecular structures of **4** and **5** were determined by single-crystal X-ray diffraction studies. The molecular structures and atomic numbering schemes are shown in Figures 1 and 2, respectively, and selected bond lengths and angles for **4** and **5** are given in Table 1.

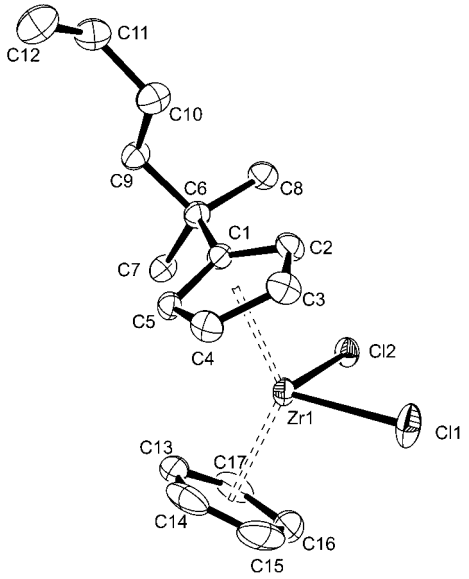

Figure 1. Molecular structure and atom-labelling scheme for $[Zr(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)\}Cl_2]$ (**4**), with thermal ellipsoids at 50% probability.

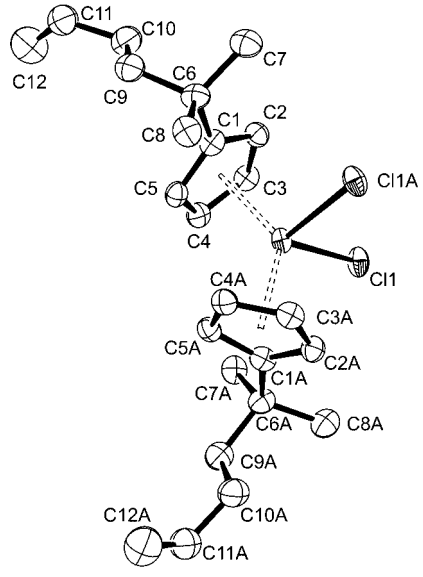

Figure 2. Molecular structure and atom-labelling scheme for $[Zr\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)\}_2Cl_2]$ (**5**), with thermal ellipsoids at 50% probability.

Complex **4** crystallises in the triclinic space group $P\bar{1}$ with four molecules in the unit cell and two in the asymmetric unit that are structurally almost identical. Complex **5**, on the other hand, crystallises in the centrosymmetric monoclinic space group *C*2/*c* with four molecules in the unit cell and only half of the molecule in the asymmetric unit; the other half is generated by symmetry operations. The molecular structures of **4** and **5** reveal that the zirconium atoms have a distorted tetrahedral geometry with both $C_5$ rings bound to the metal atom in an $\eta^5$ mode. The centroids of the cyclopentadienido rings form an angle with the zirconium atom of 129.98° and 130.10° for **4** and 129.22° for **5**, which are typical for zirconocene dichloride complexes. The Zr–Cl distances (approx. 2.45 Å) and Cl–Zr–Cl angle (approx. 95°) for **4** and **5** are in the expected range.[1e] The bond lengths in the butenyl moiety are also normal [C(9)–C(10) 1.541(5) and 1.531(5) Å for **4** and 1.532(5) Å for **5**; C(10)–C(11) 1.496(6) and 1.491(6) Å for **4** and 1.494(5) Å for **5**; C(11)–C(12) 1.294(7) and 1.304(7) Å for **4** and 1.288(6) Å for **5**]. The C(11)–C(12) distances are typical for terminal C–C double bonds[10c,10e] and the C(10)–C(11)–C(12) angle [125.7(4) and 125.4(4)° for **4** and 126.1(4)° for **5**] confirms the $sp^2$ hybridisation of C(12) in both cases. Selected structural data for **4** and **5** are compared with those of similar zirconocene complexes in Table 2.

Table 1. Selected bond lengths [Å] and angles [°] for **4** and **5**.

| | **4** | **4a** | **5** |

| C(9)–C(10)–C(11) | 112.0(3) | 111.8(3) | 112.0(3) |
| C(10)–C(11)–C(12) | 125.7(4) | 125.4(4) | 126.1(4) |

[a] Cent(1) and Cent(2) are the centroids of C(1)–C(5) and C(13)–C(17) for **4** and C(1)–C(5) and C(1A)–C(5A) for **5**, respectively.

Treatment of the dilithium derivative **3** with $ZrCl_4$ gave the corresponding *ansa*-metallocene dichloride complex $[Zr\{Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_3\{CMe_2CH_2CH_2CH{=}CH_2\})\}Cl_2]$ (**6**) [Equation (4)], which was isolated as a crystalline solid and characterised spectroscopically. The $^1H$ NMR spectrum for **6** shows three multiplets for the protons of the alkenyl-substituted $C_5$ ring (between $\delta$ = 5.5 and 7.0 ppm), four singlets for the methyl groups of the tetramethyl-substituted $C_5$ ring (between $\delta$ = 1.9 and 2.1 ppm), and two singlets corresponding to the methyl groups of the $SiMe_2$ bridging unit ($\delta$ = 0.83 and 0.87 ppm).

The signals for the alkenyl fragment have similar chemical shifts and identical spectral patterns to those observed in the zirconocene complexes **4** and **5**. However, the methyl groups substituting the carbon atom bonded to the cyclopentadienido ring are diastereotopic in **6** due to the planar

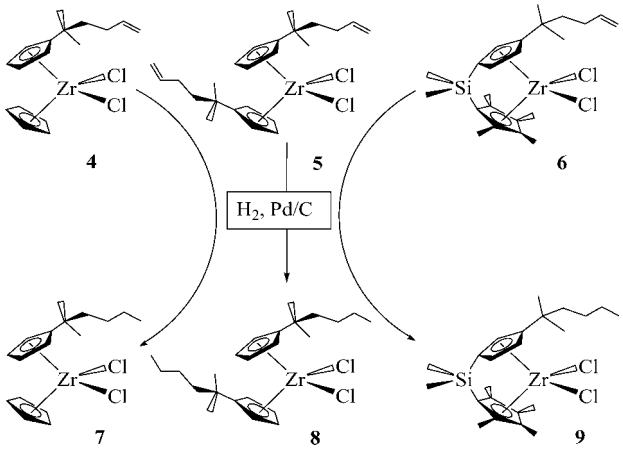
(4)

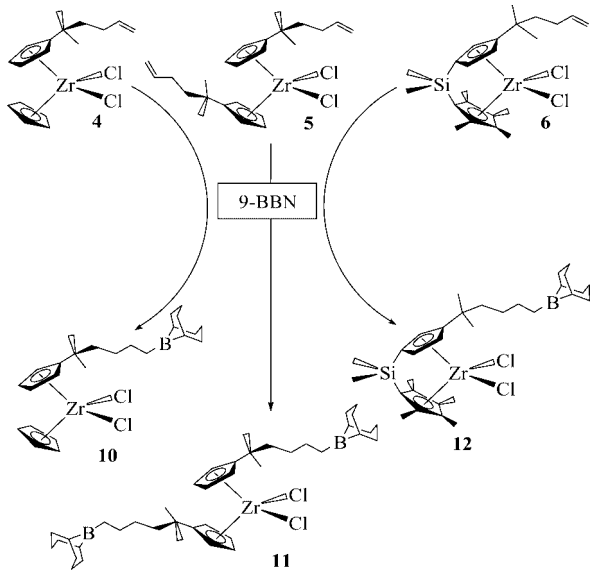
chirality present in the molecule and thus appear as two singlets ($\delta$ = 1.42 and 1.51 ppm) in the $^1$H NMR spectrum.

We next attempted to hydrogenate the C=C double bond of the alkenyl fragment in complexes **4**–**6**. These complexes react with $H_2$ in a Pd/C-catalysed hydrogenation to give the saturated metallocene compounds $[Zr(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH_2CH_3)\}Cl_2]$ (**7**), $[Zr\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH_2CH_3)\}_2Cl_2]$ (**8**) and $[Zr\{Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_3\{CMe_2CH_2CH_2CH_2CH_3\})\}Cl_2]$ (**9**), respectively, as the only products [Equation (5)]. The $^1$H NMR spectra of these complexes show four multiplets about $\delta \approx$ 0.8, 0.9, 1.2 and 1.4 ppm due to the newly formed alkyl moiety, with four signals in the alkyl carbon region between $\delta$ = 23 and 28 ppm in the $^{13}C\{^1H\}$ NMR spectra.



(5)

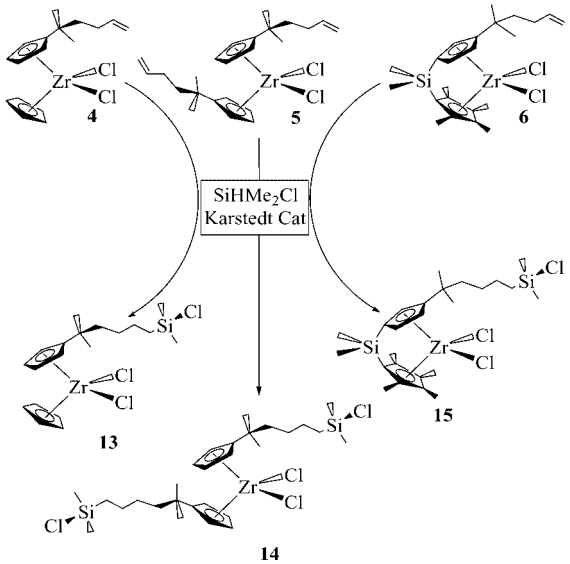
The alkenyl substituent in complexes **4**–**6** should also be suitable for the introduction of borane groups by hydroboration. Since previous studies have shown that a further functionalisation of the alkenyl side-chain and the isolation of the respective product is rather difficult,[10a–10d,11c,12] highly selective 9-borabicyclo[3.3.1]nonane (9-BBN) was chosen as the hydroboration agent. Reaction of complexes **4**–**6** with 9-BBN gave the product resulting from anti-Markovnikoff addition, namely $[Zr(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH_2CH_2BC_8H_{14})\}Cl_2]$ (**10**), $[Zr\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH_2CH_2BC_8H_{14})\}_2Cl_2]$ (**11**) and $[Zr\{Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_3\{CMe_2CH_2CH_2CH_2CH_2BC_8H_{14}\})\}Cl_2]$ (**12**), respectively [Equation (6)]. Complexes **10**–**12** were characterised by standard spectroscopic techniques. The $^1$H NMR spectra of **10**–**12** show four multiplets between $\delta$ = 1.2 and 1.9 ppm for the boranyl moiety, corresponding to the four distinct proton environments (see Experimental Section). In these cases a change in the signals previously attributed to the alkenyl moiety in **4**–**6** to four multiplets at $\delta \approx$ 0.9, 1.0, 1.2 and 1.4 ppm was observed.



(6)

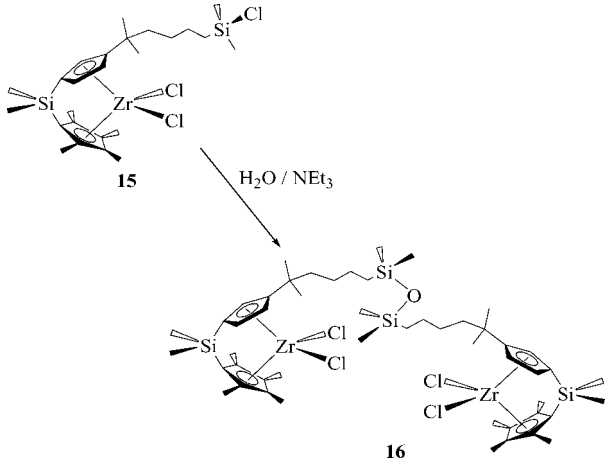
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Catalytic hydrosilylation reactions are an excellent method for constructing different structures containing metallocene complexes.[6,11d,11e,13] With this in mind, we carried out the hydrosilylation reaction of **4**–**6** with an excess of chlorodimethylsilane in the presence of Karstedt's catalyst to give the β-hydrosilylation products [Zr($\eta^5$-$C_5H_5$){$\eta^5$-$C_5H_4$($CMe_2CH_2CH_2CH_2CH_2SiMe_2Cl$)}$Cl_2$] (**13**), [Zr{$\eta^5$-$C_5H_4$($CMe_2CH_2CH_2CH_2CH_2SiMe_2Cl$)}$_2Cl_2$] (**14**) and [Zr{$Me_2Si$($\eta^5$-$C_5Me_4$)($\eta^5$-$C_5H_3${$CMe_2CH_2CH_2CH_2CH_2$-$SiMe_2Cl$})}$Cl_2$] (**15**), respectively [Equation (7)]. Complexes **13**–**15** were characterised by $^1H$, $^{13}C\{^1H\}$, and $^{29}Si\{^1H\}$ NMR and IR spectroscopy and also by mass spectrometry. Completion of the hydrosilylation reaction was monitored by $^1H$ NMR spectroscopy, where the spectra recorded showed the absence of the olefinic proton signals of the alkenyl moiety and the appearance of four multiplets corresponding to the $–CH_2CH_2CH_2CH_2Si–$ fragment in the region $\delta$ = 0.7–1.6 ppm. Additional signals due to the methyl groups attached to the silicon atom are present at $\delta \approx$ 0.4 ppm. The $^{13}C\{^1H\}$, and $^{29}Si\{^1H\}$ NMR spectroscopic data confirmed the proposed structures (see Experimental Section), with a resonance being observed in the $^{29}Si\{^1H\}$ NMR spectra at $\delta \approx$ 30 ppm due to the silicon atom of the new silyl fragment. Mass spectrometric analysis showed the molecular ion peak in all the cases (see Experimental Section).



(7)

The dinuclear, Si–O–Si-bridged complex [$Cl_2Zr${$Me_2Si$-($\eta^5$-$C_5Me_4$)($\eta^5$-$C_5H_3${$CMe_2(CH_2)_4SiMe_2OSiMe_2(CH_2)_4$-$Me_2C$}$\eta^5$-$C_5H_3$)($\eta^5$-$C_5Me_4$)$SiMe_2$}$ZrCl_2$] (**16**) was obtained upon addition of a stoichiometric amount of $H_2O$ to a toluene solution of complex **15** [Equation (8)]. Selective hydrolysis of the Si–Cl bond and formation of an Si–O–Si bridge was confirmed by multinuclear NMR and IR spectroscopy. Complex **15** contains an element of planar chirality, therefore coupling of two such units should lead to the formation of two diastereoisomers (*rac* and *meso*). However, only one set of signals was observed in the NMR spectra of **16**. This is most probably due to the fact that the two chiral metallocene subunits are sufficiently separated in space that the signals corresponding to the respective *rac* and *meso* isomers coincide.



(8)

The signal for the methyl groups attached to the siloxane silicon atoms in the $^1H$ NMR spectrum of **16** is displaced from $\delta$ = 0.39 (in **15**) to 0.00 ppm. The $^{29}Si\{^1H\}$ NMR spectrum shows a new signal at $\delta$ = 7.1 ppm due to the silicon atoms of the Si–O–Si fragment as well as the signal corresponding to the silicon atoms of the *ansa* bridge ($\delta$ = –14.2 ppm). This chemical shift is in agreement with those reported in other studies.[14] It should be noted that similar reactions for early transition metals have been reported recently.[15]

We also examined the polymerisation of ethylene using the zirconocene derivatives described in this paper as catalyst. The polymerisation experiments were conducted with an MAO/metal catalyst ratio of 1000:1 at 20 °C and an olefin pressure of 2 bar during 15 min. Polymerisation was also carried out with the reference compound [Zr($\eta^5$-$C_5H_5$)$_2Cl_2$] under the same experimental conditions. The catalytic activities and polymer molecular weights and molecular weight distributions are given in Table 3.

The symmetrical metallocene systems **5**, **8**, **11** and **14** show lower catalytic activities than the asymmetric or *ansa* complexes. Indeed, **11** is not catalytically active in the polymerisation of ethylene. The asymmetric metallocene catalysts, on the other hand, are active to different degrees, with **13** proving to be the most active catalyst of the series tested, **10** one of the least and **4** giving a value comparable to that of the reference catalyst [Zr($\eta^5$-$C_5H_5$)$_2Cl_2$]. The catalytic activity of the *ansa*-metallocene complexes **6**, **9** and **12** is relatively high, although lower activities were observed for **15** and the dinuclear complex **16**.

In order to explain the zero activity of **11** in polymerisation we prepared the dimethyl/borane derivatives, [$ZrCp'_2Me$][$MeB(C_6F_5)_3$], of **10**–**12** on an NMR scale. According to Horton and co-workers, the chemical shift difference between the *meta*- and *para*-fluorine atoms in the $^{19}F$ NMR spectra provides information about the possible in-

| **15** | 4867 | 224000 | 4.0 |
| **16** | 2800 | 664000 | 7.5 |

[a] At 20 °C, 2 bar monomer pressure, 200 mL of toluene, [Al] = $3\times10^{-2}$ M, [Zr] = $3\times10^{-5}$ M, $t$ = 15 min. [b] In kg polymer (mol Zr h bar)$^{-1}$.

teraction between the anion and the metal centre.[16] A difference of less than 3 ppm indicates the absence of anion coordination to the metal centre, whilst a value between 3 and 6 ppm suggests coordination. We observed that the dimethyl/borane derivatives of **10** and **12** gave values of about 2.1 ppm, thus indicating that anion coordination does not take place and permitting the formation of a vacant site at the metal centre which allows polymerisation. This value is 3.3 ppm for the derivative of the inactive catalyst **11**, and using the above argument one can reason that the anion is coordinated to the metal centre, therefore a vacant site cannot be readily formed at the metal atom for polymerisation.

With the exception of **15** and **16**, the *ansa*-metallocene catalysts gave polyethylene with lower molecular weights (approx. 60000) than that produced with the other catalysts employed in this study. High molecular weight polyethylene was produced with catalysts **4**, **5**, **7** and **10**. The unbridged metallocene complexes **4**, **5**, **7**, **8**, **10** and **13** produced broad polymer molecular weight distributions with polydispersity values between 6 and 10. This phenomenon has previously been explained by considering the rotation of the $C_5$ ring to be slower than the propagation of the polymer chain, which creates different rotamers of the catalyst that act as distinct active centres.[8g,17] One can thus envisage the formation of multi-site catalysts generated by the rotation of the substituted cyclopentadienido ligands. The *ansa*-metallocene catalysts **6**, **9**, **12** and **15** generally gave lower polydispersity values than their analogous unbridged complexes.

The polymerisation of propylene using the zirconocene derivatives **5**, **6**, **8**, **9**, **11**, **12**, **14**, **15** and **16** as catalyst was also examined. The polymerisation experiments were conducted with an MAO/metal catalyst ratio of 3000:1 at 0 °C and an olefin pressure of 2.5 bar during 60 min. Polymerisation was also carried out with the reference compound $[Zr(\eta^5\text{-}C_5H_5)_2Cl_2]$ under the same experimental conditions. The catalytic activities, polymer molecular weights, molecular weight distributions and isotacticities are given in Table 4.

Table 4. Propylene polymerisation results for **5**, **6**, **8**, **9**, **11**, **12**, **14**, **15**, **16** and $[Zr(\eta^5\text{-}C_5H_5)_2Cl_2]$.[a]

| Catalyst | Activity[b] | $M_w$ | $M_w/M_n$ | [mmmm] [%] |
|---|---|---|---|---|
| $[Zr(\eta^5\text{-}C_5H_5)_2Cl_2]$ | 48 | 2000 | 1.8 | 4.0 |
| **5** | 76 | 2300 | 2.0 | 12.1 |
| **6** | 123 | 18100 | 3.0 | 75.2 |
| **8** | 156 | 2200 | 1.9 | 12.3 |
| **9** | 192 | 13700 | 3.1 | 79.0 |
| **11** | 0 | – | – | – |
| **12** | 85 | 13100 | 2.4 | 77.1 |
| **14** | 94 | 2500 | 1.8 | 12.0 |
| **15** | 109 | 2800 | 1.9 | 78.6 |
| **16** | 85 | 2000 | 1.8 | 75.9 |

[a] At 0 °C, 2.5 bar monomer pressure, 200 mL of toluene, [Al] = $2.25\times10^{-1}$ M, [Zr] = $7.5\times10^{-5}$ M, $t$ = 60 min. [b] In kg polymer (mol Zr h bar)$^{-1}$.

All the catalysts tested gave higher activities than the reference catalyst $[Zr(\eta^5\text{-}C_5H_5)_2Cl_2]$, although no polymerisation was observed with **11**. The *ansa*-metallocene catalysts **6**, **9** and **12** produced polypropylene with molecular weights significantly higher than that produced with the other catalysts. The polydispersity values observed were between 1.8 and 3.1 and are typical for single-site catalysts. It appears that rotation of the $C_5$ ring is restricted in the low-temperature polymerisation of propylene, thus preventing the formation of multiple active sites like those proposed in the polymerisation of ethylene.

The isotacticity of the polymers was measured by $^{13}C\{^1H\}$ NMR spectroscopy using the pentad method. The [mmmm] pentad values for the *ansa*-metallocene catalysts **6**, **9**, **12**, **15** and **16** were of the order of 75% and are comparable with those reported previously for similar $C_1$-symmetric complexes.[11b,11f,18] The stereoselectivity exhibited in the polymerisation can be explained by either a Cossee–Arlman site control[11f] or a back-skip mechanism.[11f,18b,19]

The unbridged metallocene catalysts **5**, **8** and **14** produced atactic polypropylene with [mmmm] pentads of 12%. We have previously observed that rotation of the cyclopentadienido ring in similar metallocene systems can be restricted by the introduction of bulky substituents and this translates into the formation of stereoselective active sites and polypropylene with low to medium isotacticity.[11g] However, this is not the case for **5**, **8** and **14**, where one can envisage that the alkenyl or alkyl chain substituents are flexible enough to position themselves so as not to restrict rotation of the cyclopentadienido rings.

## Conclusions

We have reported the synthesis and catalytic activity of new alkenyl-substituted zirconocene complexes along with their structural characterisation. The reactivity of these complexes in hydrogenation, hydroboration and hydrosilylation processes has been studied and opens up not only the possibility of ligand design and modification but also the potential of supporting the catalysts on distinct substrates.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

We have also studied the catalytic activity of the zirconocene and *ansa*-zirconocene complexes in the polymerisation of ethylene and propylene. The polymerisation of propylene using the $C_1$-symmetric *ansa*-metallocene complexes as catalysts gave polymers with relatively high isotacticity.

## Experimental Section

**General Remarks:** All reactions were performed using standard Schlenk tube techniques under dry nitrogen. Solvents were distilled from the appropriate drying agents and degassed before use. $C_5H_2Me_4$, $ZrCl_4$, $HSiMe_2Cl$, $SiMe_3Cl$, *n*BuLi (1.6 M in hexane), MeLi (1.6 M in $Et_2O$), MAO (10 wt.-% in toluene), 9-BBN (0.5 M in thf) and $CH_3COCH_2CH_2CH{=}CH_2$ were purchased from Aldrich and the Karstedt catalyst from ABCR. All commercial reagents were used directly. 6-(4-Buten-1-yl)-6-methylfulvene was prepared according to the methodology described by Little and coworkers.[20] IR spectra were recorded with a Thermo Nicolet Avatar 330 FT-IR spectrophotometer. $^1H$, $^{13}C$ and $^{29}Si$ NMR spectra were recorded with a Varian Mercury FT-400 spectrometer. Microanalyses were carried out with a Perkin–Elmer 2400 or LECO CHNS-932 microanalyzer. Mass spectrometric analyses were performed with a Hewlett–Packard 5988A instrument (*m*/*z* = 50–1000). Polymer molecular weights and distributions were determined by GPC (Waters 150C Plus or Alliance GPC-2000) in 1,2,4-trichlorobenzene at 150 °C. Polymer isotacticity was calculated from the $^{13}C\{^1H\}$ NMR spectra of polymer samples dissolved in 1,2,4-trichlorobenzene/$C_6D_6$ (1:1).

**Preparation of [Li{$C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)$}] (1):** MeLi (12.8 mL, 20.51 mmol) was added dropwise to a solution of 6-(4-buten-1-yl)-6-methylfulvene (3.00 g, 20.51 mmol) in $Et_2O$ (75 mL) at –78 °C. The reaction mixture was warmed to room temperature and stirred for 3 h. The solvent was then removed in vacuo to give a white solid, which was washed with hexane (2 × 50 mL) and dried under vacuum to yield the title complex as a free flowing white solid. Yield: 2.48 g (72%). $^1H$ NMR (400 MHz, [D$_8$]THF, 25 °C): $\delta$ = 1.19 (s, 6 H, C$Me_2$), 1.50 and 1.91 (2 m, each 2 H, C$H_2$C$H_2$), 4.74 (*cis*) and 4.85 (*trans*) (2 dd, $^3J_{cis}$ = 10.0, $^3J_{trans}$ = 16.8 Hz, each 1 H, $CH_2$-CH=C$H_2$), 5.73 (m, 1 H, $CH_2$-C$H$=$CH_2$), 5.46 and 5.48 (2 m, each 2 H, $C_5H_4$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, [D$_8$]THF, 25 °C): $\delta$ = 31.0 and 31.1 (*C*$H_2$*C*$H_2$), 35.4 (C$Me_2$), 46.5 (Cp*C*), 100.9, 101.8 and 141.6 ($C_5H_4$), 112.8 ($CH_2$-CH=*C*$H_2$), 128.8 ($CH_2$*C*H=$CH_2$) ppm. $C_{12}H_{17}Li$ (168.2): calcd. C 85.69, H 10.19; found C 85.33, H 10.17.

**Preparation of $Me_2Si(C_5HMe_4)\{C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)\}$ (2):** $Me_2Si(C_5HMe_4)Cl$ (2.55 g, 11.89 mmol) in thf (50 mL) was added to a solution of **1** (2.00 g, 11.89 mmol) in thf (50 mL) at –78 °C. The reaction mixture was warmed to room temperature and stirred for 6 h. The solvent was then removed in vacuo and hexane (150 mL) was added to the resulting dark orange oil. The mixture was filtered and the solvent removed from the filtrate under reduced pressure to yield the title compound as a dark yellow oil. Yield: 3.96 g (98%). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C; for the predominant isomer): $\delta$ = –0.11 (s, 6 H, Si$Me_2$), 1.19 (s, 6 H, C$Me_2$), 1.59 and 1.83 (2 m, each 2 H, C$H_2$C$H_2$), 1.88 and 2.01 (2 s, each 6 H, $C_5Me_4$), 2.96 and 3.23 (2 m, each 1 H, 2 × *H*$C_5$), 4.90 (*cis*) and 4.97 (*trans*) (2 dd, $^3J_{cis}$ = 10.2, $^3J_{trans}$ = 16.9 Hz, each 1 H, $CH_2$CH=C$H_2$), 5.81 (m, 1 H, $CH_2$C$H$=$CH_2$), 5.92, 6.33 and 6.57 (3 m, each 1 H, $C_5H_3$) ppm. EI MS: *m*/*z* (%) = 340 (28) [M$^+$], 285 (46) [M$^+$ – $CH_2CH_2CH{=}CH_2$], 243 (100) [M$^+$ – $CMe_2CH_2CH_2CH{=}CH_2$]. $C_{23}H_{36}Si$ (340.6): calcd. C 81.10, H 10.65; found C 81.00, H 10.61.

**Preparation of $[Li_2\{Me_2Si(C_5Me_4)(C_5H_3\{CMe_2CH_2CH_2CH{=}CH_2\})\}]$ (3):** *n*BuLi (11.0 mL, 17.62 mmol) was added dropwise to a solution of **4** (3.00 g, 8.81 mmol) in $Et_2O$ (100 mL) at –78 °C. The mixture was warmed to 25 °C and stirred for 15 h. The solvent was then removed in vacuo to give a white solid, which was washed with hexane (2 × 50 mL) and dried under vacuum to yield the title complex as a white solid (2.54 g, 82%). $C_{23}H_{34}Li_2Si$ (352.5): calcd. C 78.37, H 9.72; found C 77.97, H 9.75.

**Preparation of $[Zr(\eta^5\text{-}C_5H_5)\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)\}Cl_2]$ (4):** A solution of **1** (1.00 g, 5.94 mmol) in thf (50 mL) was added dropwise during 15 min to a solution of $[Zr(\eta^5\text{-}C_5H_5)Cl_3]$ (1.56 g, 5.94 mmol) in thf (50 mL) at 0 °C. The reaction mixture was warmed to room temperature and stirred for 2 h. The solvent was then removed in vacuo and hexane (125 mL) added to the resulting solid. The mixture was filtered and the filtrate concentrated (20 mL) and cooled to –30 °C to yield crystals of the title complex. Yield: 1.43 g (62%). IR (ZnSe): $\tilde{\nu}$ = 3100 ($\nu_{CH}$), 1640 ($\nu_{C=C}$) cm$^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.39 (s, 6 H, C$Me_2$), 1.56 and 1.75 (2 m, C$H_2$C$H_2$), 4.89 (*cis*) and 4.96 (*trans*) (2 dd, $^3J_{cis}$ = 10.6, $^3J_{trans}$ = 17.2 Hz, each 1 H, $CH_2$CH=C$H_2$), 5.71 (m, 1 H, $CH_2$C$H$=$CH_2$), 6.36 and 6.45 (2 m, each 2 H, $C_5H_4$), 6.48 (s, 5 H, $C_5H_5$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 27.2 and 29.0 (*C*$H_2$*C*$H_2$), 36.4 (C$Me_2$), 46.1 (Cp*C*), 112.2, 113.0 and 143.3 ($C_5H_4$), 115.9 ($C_5H_5$), 114.1 ($CH_2$-CH=*C*$H_2$), 138.5 ($CH_2$-*C*H=$CH_2$) ppm. EI MS: *m*/*z* (%) = 386 (20) [M$^+$], 331 (36) [M$^+$ – $CH_2CH_2CH{=}CH_2$], 225 (100) [M$^+$ – $C_5H_4(CMe_2CH_2CH_2$-$CH{=}CH_2)$]. $C_{17}H_{22}Cl_2Zr$ (388.5): calcd. C 52.56, H 5.71; found C 52.51, H 5.69.

**Preparation of $[Zr\{\eta^5\text{-}C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)\}_2Cl_2]$ (5):** The synthesis of **5** was carried out in an identical manner to **4** from **1** (1.00 g, 5.94 mmol) and $ZrCl_4$ (0.69 g, 2.97 mmol). Yield: 0.83 g (58%). IR (ZnSe): $\tilde{\nu}$ = 3103 ($\nu_{CH}$), 1637 ($\nu_{C=C}$) cm$^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.41 (s, 12 H, 2 × C$Me_2$), 1.56 (4 H) and 1.77 (4 H) (2 m, each 4 H, 2 × C$H_2$C$H_2$), 4.88 (*cis*) and 4.95 (*trans*) (2 dd, $^3J_{cis}$ = 10.2, $^3J_{trans}$ = 16.9 Hz, each 2 H, 2 × $CH_2$CH=C$H_2$), 5.71 (m, 2 H, 2 × $CH_2$C$H$=$CH_2$), 6.32 and 6.41 (2 m, each 4 H, 2 × $C_5H_4$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 27.1 and 29.0 (*C*$H_2$*C*$H_2$), 36.5 (C$Me_2$), 46.2 (Cp*C*), 112.2, 116.2 and 142.8 ($C_5H_4$), 114.0 ($CH_2$CH=*C*$H_2$), 138.7 ($CH_2$*C*H=$CH_2$) ppm. EI MS: *m*/*z* (%) = 484 (1) [M$^+$], 321 (100) [M$^+$ – $C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)$], 266 (34) [M$^+$ – $C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)$ – $CH_2CH_2CH{=}CH_2$], 231 (41) [M$^+$ – $C_5H_4(CMe_2CH_2CH_2CH{=}CH_2)$ – $CH_2CH_2CH{=}CH_2$ – Cl]. $C_{24}H_{34}Cl_2Zr$ (484.7): calcd. C 59.48, H 7.07; found C 59.39, H 7.02.

**Preparation of $[Zr\{Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^5\text{-}C_5H_3\{CMe_2CH_2CH_2$-$CH{=}CH_2\})\}Cl_2]$ (6):** The synthesis of **6** was carried out in an identical manner to **4** from **5** (1.50 g, 4.25 mmol) and $ZrCl_4$ (0.99 g, 4.25 mmol). Yield: 1.00 g (47%). IR (ZnSe): $\tilde{\nu}$ = 3099 ($\nu_{CH}$), 1632 ($\nu_{C=C}$) cm$^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.83 and 0.87 (2 s, each 3 H, Si$Me_2$), 1.42 and 1.51 (2 s, each 3 H, C$Me_2$), 1.56 and 1.69 (2 m, each 2 H, C$H_2$C$H_2$), 1.92, 2.01, 2.03 and 2.06 (4 s, each 3 H, $C_5Me_4$), 4.88 (*cis*) and 4.95 (*trans*) (2 dd, $^3J_{cis}$ = 10.3, $^3J_{trans}$ = 16.9 Hz, each 1 H, $CH_2$CH=C$H_2$), 5.73 (m, 1 H, $CH_2$C$H$=$CH_2$), 5.57, 5.71 and 6.85 (3 m, each 1 H, $C_5H_3$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = –0.4 and 0.4 (Si$Me_2$), 12.3, 12.5, 15.3 and 15.4 ($C_5Me_4$), 27.4 and 29.0 (*C*$H_2$*C*$H_2$), 36.5 (C$Me_2$), 46.2 (Cp*C*), 97.5 and 104.2 (*C*$^1$-Cp), 113.9 ($CH_2$CH=*C*$H_2$), 138.9 ($CH_2$*C*H=$CH_2$), 111.2, 123.9, 135.0 and 149.9 ($C_5H_3$), 113.5, 126.6, 127.2 and 136.2 ($C_5Me_4$) ppm. $^{29}Si\{^1H\}$

**Polymerisation of Ethylene:** The zirconocene catalyst (6 μmol), MAO (10% in toluene) (6000 μmol) and toluene (200 mL) were mixed together for 15 min in a 1 L glass autoclave. The $N_2$ pressure inside the autoclave was reduced under vacuum, an ethylene pressure of 2 bar was applied and maintained and stirring of the mixture commenced (1000 rpm). Stirring was halted after exactly 15 min and the ethylene pressure released. Excess MAO was then destroyed by cautiously adding a mixture of methanol/HCl (90:10). The polymer was isolated by filtration, washed with ethanol and dried under vacuum at 90 °C for 16 h.

**Polymerisation of Propylene:** The zirconocene catalyst (15 μmol), MAO (10% in toluene) (45000 μmol) and toluene (200 mL) were mixed together for 15 min in a 1 L glass autoclave. The $N_2$ pressure inside the autoclave was reduced under vacuum, a propylene pressure of 2.5 bar was then applied and maintained and stirring of the mixture commenced (1000 rpm). Stirring was halted after exactly 60 min and the propylene pressure released. Excess MAO was then destroyed by cautiously adding a mixture of methanol/HCl (90:10). The solvent was then removed under reduced pressure and a mixture of acetone/methanol (50:50; 200 mL) added. The mixture was stirred for 16 h and then filtered to isolate the polymer, which was washed with ethanol and dried under vacuum at 25 °C for 16 h.

**X-ray Structure Determination of [Zr(η⁵-C₅H₅){η⁵-C₅H₄(CMe₂-CH₂CH₂CH=CH₂)}Cl₂] (4) and [Zr{η⁵-C₅H₄(CMe₂CH₂CH₂-CH=CH₂)}₂Cl₂] (5):** Data for **4** and **5** were collected with a Siemens SMART CCD diffractometer [$\lambda$(Cu-$K_\alpha$) = 1.54178 Å] in the $\omega$- and $\phi$-scans modes. Semiempirical absorption corrections were carried out with SADABS.[21] The structures were solved by direct methods.[22] Structure refinement was carried out with SHELXL-97,[23] which is included in the software package WINGX.[24] All non-hydrogen atoms were refined anisotropically, and the H atoms of the cyclopentadienido rings and the hydrogen atoms of the terminal double bonds were located by difference maps and refined isotropically. Weights were optimised in the final cycles. Crystallographic data are given in Table 5. CCDC-642241 (**4**) and -642240 (**5**) contain the supplementary crystallographic data for this paper.

Table 5. Crystal and structure refinement data for **4** and **5**.[a]

# Displacement of Neutral Nitrogen Donors by Chloride in $AuCl_3$(am) (am = Pyridines and Amines): Kinetics and DFT Calculations Show the Effects of Basicity and π-Acceptor Ability

**Bruno Pitteri*[a] and Marco Bortoluzzi[a]**

**Keywords:** Gold / Kinetics / Nitrogen donors / Reaction mechanisms / DFT

The kinetics of the process $AuCl_3(am) + Cl^- \rightarrow AuCl_4^- + am$ (am = $sp^2$ N-donor isosteric pyridines with different π systems and $sp^3$ amines; they cover a wide range of basicity) have been studied in methanol at 25 °C. The reactions obey the usual two-term rate law observed in substitutions on square-planar complexes. The second-order rate constants, $k_2$, are very sensitive to the nature of the leaving group, and plots of $\log k_2$ against the $pK_a$ of the conjugate acids are linear, with the same slope, –0.68, for both "normal" pyridines and pyridines with a more extended π system, such as 4-cyanopyridine, isonicotinic acid, methyl isonicotinate and 4-acetylpyridine. The reactivity of the considered N-donors is different and follows the order $sp^3$ N-donors > "normal" pyridines > "π-extended" pyridines. This result, with the support of ground-state DFT calculations on the $AuCl_3$(am) derivatives, is explained on the basis of an Au–N bond enforcement due to an increased π-back-donation contribution.

## Introduction

The reactivity of gold(III) derivatives with nitrogen-donor bases has been widely studied, mainly involving pyridine and substituted pyridines (am) as entering nucleophiles or leaving groups.[1–3] Substitution reactions of the type (1) take place with an associative mechanism, whose rate constants, in the forward as well as in the reverse reaction, obey the general relationship $k_{obs} = k_1 + k_2$[nucleophile], which is usual for nucleophilic substitutions at planar four-coordinate $d^8$ metal complexes.[4]

$$AuCl_4^- + am \rightleftarrows AuCl_3(am) + Cl^- \quad (1)$$

The first-order rate constant, $k_1$, and the second-order rate constant, $k_2$, refer to the nucleophilic attack on the substrate by, respectively, the solvent and the nucleophile. The second-order rate constants, $k_2$, are markedly influenced by the nature of am, indicating that the discriminating ability of gold(III) complexes is good. A linear free-energy relationship, $\log k_2 = a pK_a$ + constant, occurs between the rate constant and the basicity of am, measured as the $pK_a$ of its conjugated acid $Ham^+$. Moreover, steric retardation is observed for pyridines containing one or two *ortho* groups.

Recently, we studied the kinetics of the reverse reaction of process (1) using five-membered N-donor heterocycles (thiazoles, oxazoles, imidazoles and their derivatives) as leaving groups[5] and the results were compared with those in a paper[3] where am = pyridines. It was observed that the reactivity depends not only upon the ligand basicity but also upon the nature of the ligand in the order: pyridines > five-membered heterocycles and this behaviour was attributed to different π interactions in the ground state between the metal centre and the N-donor ligands.

In this work we tried to improve the knowledge about the role of π interactions between N-donors and $Au^{III}$ in the kinetics of displacement by chloride of these ligands from $AuCl_3$(am). As for $Pt^{II}$ substrates,[6] on considering the second-order rate constants $k_2$, the displaced nitrogen donors can be divided into three groups: (i) "normal" pyridines, (ii) pyridines having a more extended π system and (iii) $sp^3$ nitrogen-donor bases; and the reactivity towards ligand substitution is in the order: $sp^3$ nitrogen-donor bases > "normal" pyridines > pyridines with a more extended π system. These differences, which were mainly attributed to a ground-state stabilization due to the π-back-donation from the filled orbitals of the metal to the antibonding orbitals of the pyridine ligands, have been correlated in this paper with the calculated Au–N bond lengths of the $AuCl_3$(am) complexes, obtained by performing ground-state DFT B3PW91 calculations. By plotting the $r_{Au-N}$ values of the $AuCl_3$(am) complexes versus the corresponding $pK_a$ values, linear relationships comparable to those derived from the kinetic measurements were obtained. Furthermore, a

systematic shortening of the Au–N bond length was observed for pyridines having an extended π system.

## Result and Discussion

When a methanolic solution of the neutral $AuCl_3$(am) substrate is allowed to react with an appropriate excess of chloride, repetitive scanning of the spectrum in the region 240–360 nm shows that the reaction evolves in a first-order fashion leading to the substitution of the neutral base with a chloride ion. The presence of well-maintained isosbestic points, whose positions depend only upon the spectrum of the starting compound, and the comparison of the final spectrum with that of original samples of the substituted products at the same concentration, clearly indicate a single reaction stage. The addition of $LiClO_4$ indicates that primary salt effects are absent and secondary effects are negligible, thus no further attempt has been made to maintain constant ionic strength. The reactions have been studied in the presence of 0.1 mol dm$^{-3}$ $CH_3SO_3H$. Preliminary experiments have shown that, at constant chloride concentration, the rate of reaction is independent of the concentration of acid over the range 0.02–0.2 mol dm$^{-3}$. The acid simply serves to protonate the released N-donor ligand, thus preventing the reverse reaction and forcing the reaction to completion. Moreover, the presence of acid helps to avoid a slow reduction of the gold(III) derivatives of the most basic amines. The rate constants have been determined in the usual way from the change in absorbance as a function of time at convenient wavelength. All the reactions have been studied in the presence of a sufficient excess of chloride over the substrate to provide pseudo-first-order conditions and the observed rate constants, $k_{obs}$, collected in Table 1, obey the general relationship $k_{obs} = k_1 + k_2[Cl^-]$, which is usual for nucleophilic substitutions on gold(III) complexes.

The $k_1$ terms, referring to the pathway in which the rate-determining step is the nucleophilic attack of the solvent, followed by the rapid entry of chloride into the solvento complex,[7] are quite small and thus this reaction pathway makes a small contribution to the whole process. The $k_2$ terms are the second-order rate constants for the direct at-

Table 1. First-order rate constant, $k_{obs}$, for the reaction $AuCl_3$(am) + $Cl^- \rightarrow AuCl_4^-$ + am in methanol at 25 °C (0.1 mol dm$^{-3}$ $CH_3SO_3H$).

[a] Determined by linear regression of $k_{obs}$ values vs. chloride concentration. [b] p$K_a$ values were taken from ref.[8]

The reacting species can be divided into three groups, as depicted in the plot of $\log k_2$ versus p$K_a$ of $Ham^+$ (Figure 1):

*i*: "normal" pyridines;
*ii*: pyridines with a more extended π system;
*iii*: $sp^3$ nitrogen-donor bases.

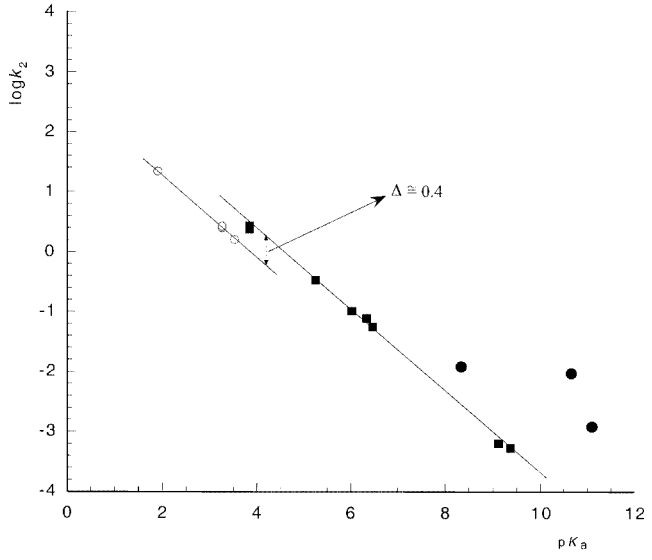

Figure 1. Plots of $\log k_2$ for the reaction $AuCl_3(am) + Cl^- \rightarrow AuCl_4^- + am$ against p$K_a$ of $Ham^+$: (■) pyridine, 4-chloropyridine, 4-methoxypyridine, 4-methylpyridine, 4-bromopyridine, 3,5-dimethylpyridine, 4-aminopyridine, 4-(dimethylamino)pyridine; (○) 4-cyanopyridine, 4-acetylpyridine, methyl isonicotinate, isonicotinic acid; (●) morpholine, cyclohexylamine, piperidine.

The first group includes the complexes with pyridine: 4-bromopyridine, 4-chloropyridine, 4-methylpyridine, 4-methoxypyridine, 4-aminopyridine, 4-(dimethylamino)pyridine and 3,5-dimethylpyridine, while the second group includes the derivatives of 4-cyanopyridine: isonicotinic acid, methyl isonicotinate and 4-acetylpyridine. The lability of pyridines is considerably lower than that of the third group of derivatives, that is, the complexes of the $sp^3$-ligands piperidine, cyclohexylamine and morpholine. Unfortunately, the different steric hindrance around the N atom of these $sp^3$ N-donors avoids a direct relationship between $\log k_2$ and the corresponding p$K_a$ values.

Both "normal" (■ in Figure 1) and "π extended" (○ in Figure 1) pyridines obey the linear relationship $\log k_2 = \alpha pK_a$ + constant, with $\alpha = -0.68$. For the entry of pyridines on $AuCl_4^-$ in the same experimental conditions, a similar free-energy relationship was found,[1] with $\alpha = 0.16$. The parameter $\alpha$ is a measure of the ability of a substrate to discriminate among isosteric nitrogen donors and can be assumed to be a relative measure of its electrophilicity. The asynchronous substitution, characteristic of planar-tetracoordinate gold(III) complexes, offers the opportunity to describe separately the energetic contributions of bond formation and bond rupture to the free energy of activation.[7] The relatively low discrimination among nitrogen donors in the entry reaction ($\alpha = 0.16$), together with the relatively high dependence of reactivity upon the basicity of the leaving nitrogen bases in the reverse processes ($\alpha = -0.68$, this work), strongly suggests a transition state for all these substitutions in which the Au–N bond is only partially formed in the rate-determining transition state, whereas the Au–Cl bond is practically formed to the same extent in the ground and transition states.

The lower lability of pyridine ligands, as compared with the $sp^3$ N-donors, allows the assumption that the Au–N bond in the case of pyridine derivatives may be reinforced by π bonding, that is, by the π-back-donation from the filled orbitals of the metal to the antibonding orbitals of the ligand, leading to a relative stabilization of the corresponding ground state. Moreover, π interactions of this type can also be invoked to explain the small but significant difference between the reactivity of "normal" and "π-extended" pyridines, which is $\Delta\log k_2 \approx 0.4$ (Δ in Figure 1), corresponding to about 2.3 kJ mol$^{-1}$. To support this hypothesis, ground-state DFT calculations on the $AuCl_3(am)$ (am = pyridines) have been performed and the $r_{Au-N}$ bond lengths, collected in Table 3, have been measured.

By plotting the $r_{Au-N}$ values of the $AuCl_3(am)$ complexes versus the corresponding p$K_a$ values, linear relationships comparable to those derived from the kinetic measurements have been obtained, as depicted in Figure 2. "Normal" pyridines (■ in Figure 2) respond to the equation $r_{Au-N} = (-0.0027 \pm 0.0001)pK_a + (2.1119 \pm 0.0005)$, while the equation for "π-extended" pyridines (○ in Figure 2) is $r_{Au-N} = (-0.0027 \pm 0.0001)pK_a + (2.1077 \pm 0.0004)$. The increase of electron density on the N atom, quite well represented by the p$K_a$ values of the free ligands, appears to lead to an enforcement of the Au–N σ bond. The effect of growing

| 4-(Dimethylamino)pyridine | 2.08601 | 9.37 |

[a] More details on the geometries and energies of the optimized systems are available in the electronic supporting information.

$pK_a$ on the metal–pyridine bond shortening was, however, already partly observed in a paper regarding $Pt^{II}$-pyridines derivatives, where it was confirmed on the basis of NMR measurements.[10]

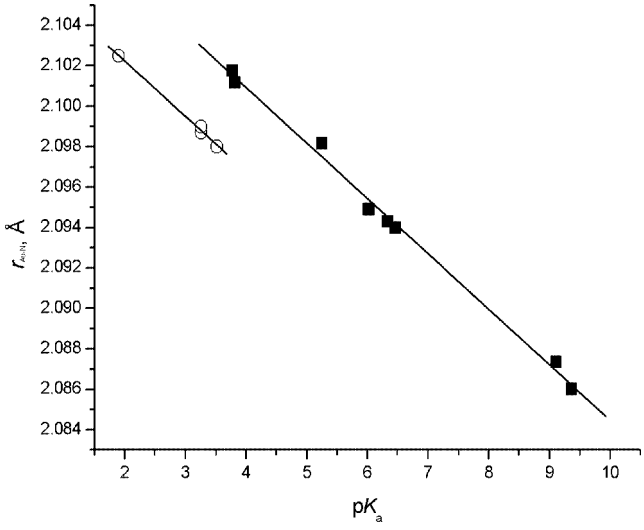

Figure 2. Plots of $r_{Au-N}$ bond lengths against $pK_a$ of $Ham^+$: (■) pyridine, 4-chloropyridine, 4-methoxypyridine, 4-methylpyridine, 4-bromopyridine, 3,5-dimethylpyridine, 4-aminopyridine, 4-(dimethylamino)pyridine; (○) 4-cyanopyridine, 4-acetylpyridine, methyl isonicotinate, isonicotinic acid.

The small difference between the reactivity of the "normal" and "p-extended" groups of pyridines appears to be correlated to a small difference between the corresponding ground-state $r_{Au-N}$ bond lengths, which is about 0.004 Å. As all the considered pyridines are isosteric, it seems reasonable to conclude that this difference could be ascribed to an enforcement of the Au–N bond because of a greater π-back-donation contribution for the second group of ligands, as supposed from the results of the kinetic measurements.

## Conclusion

In summary, the results of kinetic measurements on the process $AuCl_3$(am) + $Cl^- \rightarrow AuCl_4^-$ + am (am = $sp^2$ N-donor isosteric pyridines with different π systems and $sp^3$ amines) reported in this paper highlight the role of π-back-donation from the gold centre to the N-donor ligands in the stabilization of the $AuCl_3$(am) complexes and in the reactivity of these species towards substitution reactions. Besides the great difference between $sp^2$ and $sp^3$ N-donors, the small but significant difference observed between "normal" and "π-extended" pyridines, which has found a nice correlation with the calculated $r_{Au-N}$ bond lengths, should be noted.

## Experimental Section

**Materials:** The compound $KAuCl_4 \cdot 2H_2O$ was prepared from pure gold foil (99.99%). Pure reagent-grade LiCl, $LiClO_4$ and $CH_3SO_3H$ (Aldrich) were used without further purification. Pyridines and amines were recrystallized or distilled before use when necessary. Anhydrous MeOH was obtained by distillation over Mg wires, but traces of water did not appear to have any appreciable effect upon the reactions. Acetone and dimethylformamide were pure reagent-grade products (Aldrich and BDH).

**Instruments:** Electronic spectra and kinetic measurements were obtained on a Perkin–Elmer Lambda 15 spectrophotometer. $^1H$ NMR spectra were taken on Bruker Avance 300 and/or Bruker AC 200 spectrometers at 298 K and are referred to internal tetramethylsilane. The conductivity of $1 \times 10^{-3}$ mol dm$^{-3}$ solutions of the complexes in dimethylformamide at 25 °C was measured with a Radiometer CDM 83 instrument. Elemental analyses were performed by the Microanalytical Laboratory of the Faculty of Pharmaceutical Sciences of the University of Padua.

**Preparation of the Complexes:** Trichloro(pyridine)gold(III) was first characterized by Renz,[9] trichloro(3,5-dimethylpyridine)gold(III) and trichloro(4-methylpyridine)gold(III) by Cattalini and Tobe[3] and trichloro(4-cyanopyridine)gold(III) by Cattalini et al.,[1] but the other derivatives of the type $AuCl_3$(am) are described here for the first time. All the complexes were prepared by the following method: $KAuCl_4 \cdot 2H_2O$ (0.415 g, 1.0 mmol) was dissolved in water (20 mL) and a stoichiometric amount of the nitrogen-donor base, dissolved in a small volume of water (2–3 mL), was added dropwise whilst stirring. The yellow precipitate, formed almost immediately, was filtered off, washed three times with water (10 mL) and dried in vacuo. For the most basic ligands, piperidine, cyclohexylamine, 4-aminopyridine, 4-(dimethylamino)pyridine and morpholine, it was necessary to keep them at 0 °C and in the dark to prevent a possible reduction of gold(III). All the complexes were nonconductive in organic solvents. Yields were in any case nearly quantitative (>95%). Analytical and $^1H$ NMR spectra are collected in Tables 4 and 5, respectively.

**Kinetics:** The reactions were initiated by adding a 0.015 mol dm$^{-3}$ acetone solution (10–20 μL) of the substrate complex, $AuCl_3$(am), to a methanolic solution of chloride ion, previously brought to the reaction temperature (25 °C) in a thermostatted cell in the spectrophotometer. The concentration of the entering group was always large enough to provide pseudo-first-order conditions. After preliminary repetitive scan experiments in the range 240–360 nm to search for isosbestic points and spectral changes, the kinetics were studied by measuring the changing absorbance at suitable wave-

lengths as a function of time. Pseudo-first-order rate constants ($k_{obs}$, $s^{-1}$) were obtained either from the gradient of plots of $\log(D_t - D_\infty)$ versus time or from a nonlinear least-squares fit of experimental data to $D_t = D_\infty + (D_0 - D_\infty)\exp(-k_{obs}t)$ with $D_0$, $D_\infty$ and $k_{obs}$ as the parameters to be optimized ($D_0$ is absorbance after mixing the reactants, $D_\infty$ is absorbance at completion of reaction).

**Computational Details:** The computational geometry optimizations of the $AuCl_3$(am) complexes were performed in vacuo using the hybrid DFT B3PW91 method[11] without symmetry constraints, in combination with the polarized, single-ζ core, triple-ζ valence 6-311G** basis set on the elements of the first rows of the periodic table and the ECP-based SDD basis set on Au.[12] The "restricted" formalism was applied in all calculations, together with tight convergence criteria. All the resultant stationary points were characterized as true minima (i.e., no imaginary frequencies). All calculations were carried out at CINECA (Centro Italiano di Supercalcolo, Bologna, Italy) using IBM p5-575 computers with 64-bit IBM Power5 processors, which operated at 1.9 GHz frequency. The software used was the Gaussian '03.[13] The Natural Bond Orbitals analysis[14] was performed during our studies, using the NBO version 3.1 implemented in Gaussian 03. Unfortunately, the software separated all our complexes into three different fragments, $[AuCl_2]^{x+}$, $[Cl]^{y-}$ and $[pyridine]^{(y-x)+}$, leading to uncorrected results; for example the apparent $d^{10}$ configuration of the gold centres. For this reason, no discussion based on the NBO analysis was helpful for this work.

**Supporting Information** (see also the footnote on the first page of this article): Selected geometry data and energies for the prepared gold(III) complexes.

# Reactions of 1,2,4-Trithiolanes with Nonacarbonyldiiron: Sulfurdithiolatodiiron and -tetrairon Complexes as Mimics for the Active Site of [Fe-only] Hydrogenase

**Jochen Windhager,[a] Helmar Görls,[a] Holm Petzold,[a] Grzegorz Mloston,[b] Gerald Linti,*[c] and Wolfgang Weigand*[a]**

*Dedicated to Prof. Dieter Seebach on the occasion of his 70th birthday*

**Keywords:** Iron / Cluster compounds / S ligands / Hydrogenases / Density functional calculations

The reactions of 1,2,4-trithiolane (**1a**), 3,3,5,5-tetramethyl-1,2,4-trithiolane (**1b**), 3,3,5,5-tetraethyl-1,2,4-trithiolane (**1c**), 3,3,5,5-bis(pentamethylene)-1,2,4-trithiolane (**1d**) and dispiro{tricyclo[3.3.1.1]decane-2,3′′-(1,2,4)-trithiolane-5′,2′-tricyclo[3.3.1.1]decane} (**1e**) with nonacarbonyldiiron (**2**) have been investigated. The sulfurdithiolatodiiron complexes **3a–e**, which can be considered as novel model complexes of the active site of the [Fe-only] hydrogenase, were isolated as the main products of these reactions. X-ray structure analyses were performed on compounds **3b–e**. The carbon dithiolato ($SCR_2S$)-bridged diiron side-products **4a–e** and the tetranuclear clusters **6b–d** were also obtained and characterised by X-ray diffraction analysis (**4b–e** and **6b–d**). In contrast, the reaction of **1e** with **2** affords the trinuclear complex **7**, which contains a side-on bonded adamantanethione, besides **3e** and **4e**. Finally, the reaction of **3a** with two equivalents of $(Et_4N)CN$ gives the monocyanide complex **8** in good yield. Density functional calculations have been performed to evaluate the bonding situation in the di- and tetranuclear clusters.

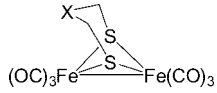
## Introduction

The oxidative addition of platinum(0) complexes to cyclic disulfides has received significant attention during the last few years.[1] We have recently investigated reactions of 1,2,4-trithiolanes with platinum(0) complexes, which lead to the insertion of the platinum(0) complex fragment into the S–S bond,[2] and have also shown that 1,2,4-trithiolane (**1a**) can be added oxidatively to $[Fe_2(CO)_9]$ (**2**) to give the sulfurdithiolatodiiron (SDT) complex $[Fe_2(\mu\text{-}SCH_2SCH_2S\text{-}\mu)(CO)_6]$ (**3a**) as well as $[Fe_2(\mu\text{-}SCH_2S\text{-}\mu)(CO)_6]$ (**4a**).[3,4] Similar reactions involving $[Fe_3(CO)_{12}]$ and **1a**, which lead to complex **3a**, have been reported recently.[3c]

Since publication of the first X-ray structure determination of the [Fe-only] hydrogenase,[6] numerous model compounds for the active site of the enzyme, such as propanedithiolato- (PDT),[7a–7d] azadithiolato- (ADT)[7e–7g] and oxadithiolatodiiron (ODT) derivatives, have been described (Scheme 1).[7f,7i,7l]



Scheme 1. Model complexes for the active site of [Fe-only] hydrogenase with X = $CH_2$, NH, O and S.

In the light of recent results, reactions of iron carbonyls with sulfur-rich heterocycles such as 1,2,4-trithiolanes could offer a new approach to the synthesis of products related to [Fe-only] hydrogenase. To the best of our knowledge, reactions of 1,2,4-trithiolane derivatives with iron carbonyls have seldom been described.[3c,3d]

Here we describe the reactions of tetrasubstituted 1,2,4-trithiolanes **1a–e** (Scheme 2) with $[Fe_2(CO)_9]$ (**2**) as a systematic investigation of the influence of the substituents' size on the molecular structure of the products. Density functional calculations for one complex are also reported.

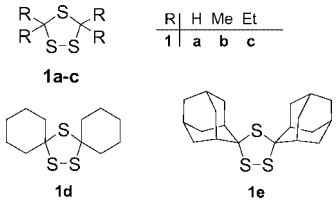
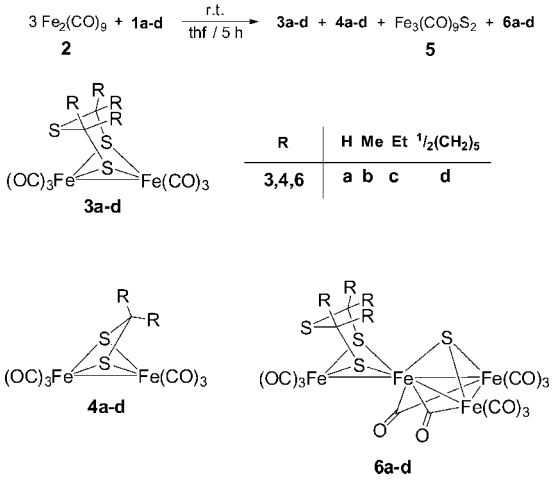


Scheme 2. 1,2,4-Trithiolanes **1a**–**e**.

## Results and Discussion

### Reactions of 1,2,4-Trithiolanes (1a–d) with [$Fe_2(CO)_9$] (2)

Three equivalents of nonacarbonyldiiron (**2**) were treated with one equivalent of the corresponding 1,2,4-trithiolane **1a**–**d** (Scheme 2) for five hours at room temperature in thf to afford a mixture of four compounds of type **3**, **4**, **5** and **6** (Scheme 3), which were isolated by column chromatography. Compounds **3a**,[3] **4a**[4] and **5**[5] have already been described. Complex **6a** was formed at room temperature exclusively but not in the reaction performed at 65 °C.



Scheme 3. Reactions of 1,2,4-trithiolanes **1a**–**d** with [$Fe_2(CO)_9$].

The $^1$H NMR spectra of **3b**,**c** and **4b**,**c** show that the corresponding alkyl groups (R = Me, Et) are chemically equivalent. Furthermore, the $^{13}C\{^1H\}$ NMR spectra display one signal for four methyl groups in **3b** and two signals for four ethyl groups in **3c**. The $^{13}C\{^1H\}$ NMR spectrum of complex **3d** contains three resonance signals at $\delta$ = 22.80, 25.23 and 43.22 ppm, respectively, which were attributed to the pentamethylene moiety. The $^1$H and $^{13}C\{^1H\}$ NMR spectra of **4b**–**d** indicate that the R groups bonded to the bridging carbon atoms ($SCR_2S$) are equivalent. The mass spectra of **3b**–**d** and **4b**–**d** show the molecular peaks (see Experimental Section) and stepwise fragmentation of six CO groups similar to **3a** and **4a**. Finally, X-ray diffraction analysis confirmed the formation of the dithiolatodiiron complexes **3b**–**d** (Figures 1, 2 and 3, respectively) and **4b**–**d** (see Figures S1–S3 in the electronic supporting information).

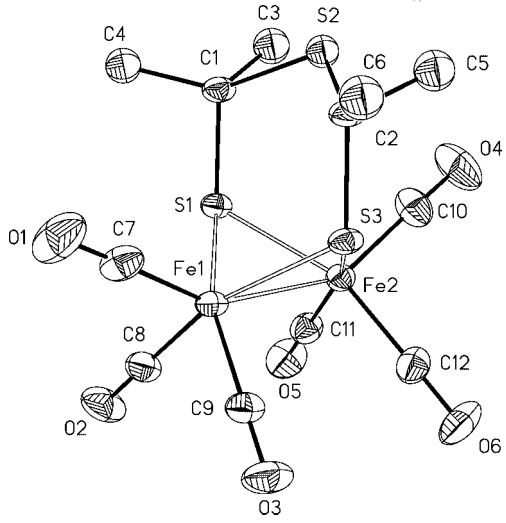


Figure 1. Structure of [$Fe_2\{SC(CH_3)_2SC(CH_3)_2S\}(CO)_6$] (**3b**) showing thermal ellipsoids at the 50% probability level (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°]: Fe(1)–Fe(2) 2.5219(6), Fe(2)–C(7) 1.792(4), Fe(2)–C(8) 1.793(3), Fe(2)–C(9) 1.799(3), Fe(1)–S(1) 2.2495(8), Fe(1)–S(3) 2.2480(9); Fe(1)–S(1)–Fe(2) 68.12(3), Fe(1)–S(3)–Fe(2) 68.18(3).

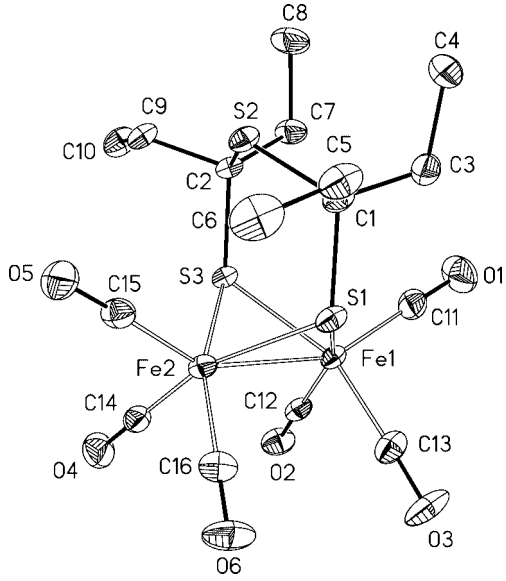

Figure 2. Structure of [$Fe_2\{SC(CH_2CH_3)_2SC(CH_2CH_3)_2S\}(CO)_6$] (**3c**) showing thermal ellipsoids at the 50% probability level (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°]: Fe(1)–Fe(2) 2.5151(4), Fe(1)–C(11) 1.804(2), Fe(1)–C(12) 1.7960(19), Fe(1)–C(13) 1.793(2), Fe(1)–S(1) 2.2648(5), Fe(1)–S(3) 2.2481(5); Fe(1)–S(1)–Fe(2) 67.469(15), Fe(1)–S(3)–Fe(2) 68.055(16).

The iron coordination geometry in **3b**–**d** is rather similar to the sulfurdithiolato (SDT) analogue [$Fe_2(\mu$-$SCH_2SCH_2S$-$\mu)(CO)_6$] (**3a**).[3] The Fe–Fe bond lengths found in **3b**–**d** are between 2.5151 and 2.5288 Å, slightly longer than those in the corresponding PDT [2.5103(11) Å],[7a–7d] ODT [2.5113(13) Å],[7f,7i,7l] ADT [2.4924(7) Å][7e–7g] and SDT analogs [2.5120(5) Å].[3] Simi-

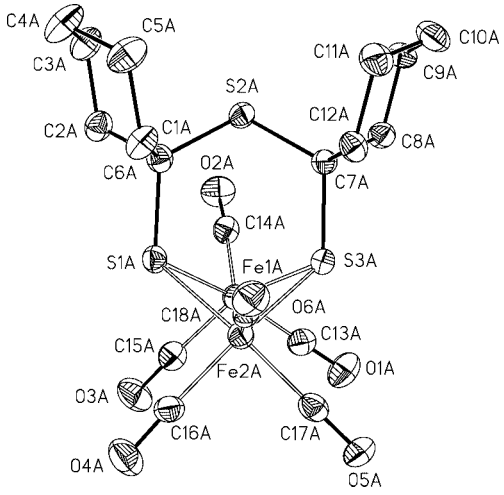

Figure 3. Structure of $[Fe_2\{SC(CH_2)_5SC(CH_2)_5S\}(CO)_6]$ (**3d**) showing thermal ellipsoids at the 50% probability level (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°]: Fe(1A)–Fe(2A) 2.5288(13), Fe(1A)–C(A13) 1.787(8), Fe(A1)–C(A14) 1.819(6), Fe(A1)–C(A15) 1.790(7), Fe(1A)–S(1A) 2.2505(19), Fe(1A)–S(3A) 2.2483(17); Fe(1A)–S(1A)–Fe(2A) 68.31(5), Fe(1A)–S(3A)–Fe(2A) 68.60(5).

larly to the ODT and SDT complexes, the bridgehead sulfur atoms in **3b** and **3d** are disordered (50%).

In contrast to the above-described NMR spectra for complexes **3b**–**d**, the $^1H$ and $^{13}C\{^1H\}$ NMR spectra of **6a**–**d** show that the R groups connected to the bridging carbon atoms ($SCR_2SCR_2S$) are chemically non-equivalent. For example, the $^1H$ NMR spectrum of **6a** contains the splitting pattern of an AA′BB′ system which was assigned to the protons of the two methylene groups, and the IR spectrum displays a characteristic vibration band at 1898 $cm^{-1}$ assigned to the bridging CO ligands. Compound **6b** also shows two singlets attributed to two pairs of non-equivalent methyl groups. Similar observations were made for **6c** and **6d**. The desorption electron ionization (DEI) mass spectra for **6b**, **6c** and **6d** reveal the presence of $[M]^+$ ions at *m*/*z* 744, 800 and 824, respectively, and a stepwise fragmentation of eleven CO groups. Additionally, the IR spectroscopic measurements prove the presence of bridging CO ligands [ν(CO) = 1910 (for **6b**) and 1923, 1901 $cm^{-1}$ (for **6c**)].

Complexes **6b**–**d** were characterised as tetranuclear iron clusters based on the X-ray diffraction analysis (Figure 4 and Figures S5 and S6 in the electronic supporting information). Compounds **6b**–**d** contain an $(OC)_3Fe(\mu\text{-}SCR_2SCR_2S\text{-}\mu)Fe$ fragment [**6b**: R = Me, **6c**: R = Et, **6d**: R = 1/2 $(CH_2)_5$] coordinated to an $Fe_2(CO)_6(\mu\text{-}CO)_2S$ unit which is likely to be formed in the reaction of $Fe_2(CO)_9$ with the sulfur originating from the decomposition of the in situ generated thiosulfinates (see below). The $Fe_2(CO)_6(\mu\text{-}CO)_2S$ moiety acts as a six-electron donor ligand that formally substitutes three CO ligands from the complex of type **3** to finally give an eight-coordinate Fe(2) atom. A similar cluster has been synthesised by the reaction of the sulfur with $Fe_3(CO)_{12}$ in 1-hexene to give $[Fe_4(CO)_{11}(\mu^3\text{-}S)(\mu\text{-}L)]$ (L = 1,2-hexylenedithiolate).[8a,b] In contrast to our results, very unusual triiron clusters with seven coordinated CO ligands were obtained when $[Fe_3(CO)_{12}]$ was treated with 1,2- and 1,3-dithioles in toluene at 70 °C.[8c] The Fe(1) and Fe(2) centres are $\mu^2$-bridged by the alkyl-substituted SDT ligands and the Fe(2), Fe(3), Fe(4) and S(4) atoms form a tetrahedron. The Fe(1)–Fe(2) distances are about 0.04 Å longer than the corresponding bond lengths in **3b**–**d**, and the Fe(2)–Fe(3)/Fe(4) bond lengths in the tetrahedron are remarkably longer than the Fe(1)–Fe(2) distances [e.g. **6b**: 2.6419(9)/2.6365(10) Å].

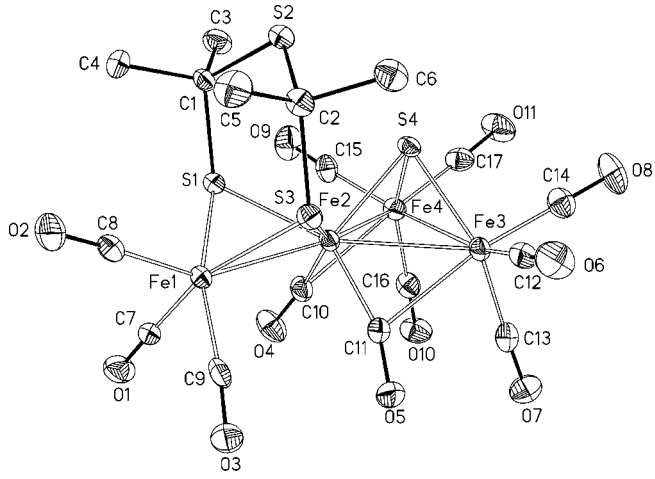

Figure 4. Structure of $[Fe_4(\mu\text{-}SCR_2SCR_2S\text{-}\mu)(CO)_9(\mu\text{-}CO)_2S]$ (**6b**; R = Me) showing thermal ellipsoids at the 50% probability level (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°]: Fe(1)–Fe(2) 2.5672(9), Fe(2)–Fe(3) 2.6419(9), Fe(2)–Fe(4) 2.6365(10), Fe(3)–Fe(4) 2.5855(10), Fe(1)–C(8) 1.804(6), Fe(1)–C(9) 1.806(6), Fe(2)–C(10) 1.813(6), Fe(2)–C(11) 1.827(6), Fe(3)–C(11) 2.381(5), Fe(1)–S(1) 2.2366, Fe(1)–S(3) 2.2329, Fe(2)–S(4) 2.2017(13); Fe(1)–S(1)–Fe(2) 69.65(4), Fe(1)–S(3)–Fe(2) 69.73(4), Fe(3)–Fe(2)–S(4) 52.72(4), Fe(4)–Fe(2)–S(4) 52.39(4), Fe(3)–Fe(2)–Fe(4) 58.66(3), Fe(3)–Fe(4)–Fe(2) 60.78(3).

### Reaction of 1,2,4-Trithiolane 1e with $[Fe_2(CO)_9]$ (2)

The reaction of 1,2,4-trithiolane **1e** with three equivalents of **2** at room temperature in thf gave complexes **3e**, **4e** and **7** (Figures 5 and 6 and Figures S4 in the supporting information) which were separated by column chromatography (Scheme 4). Compound **4e** has already been isolated by Alper et al. from the reaction of adamantanethione with **2** in benzene.[3d] The single-crystal diffraction analysis of **3e** showed that the Fe–Fe distance [2.5525(13) Å] is about 0.045 Å longer than that in **3a** (Figure 5). The Fe–Fe distance in **3e** is very similar to that found in the reduced state diiron subsite of the enzyme structure (2.55 Å).[6a]

Due to the sterically demanding influence of the adamantyl substituents, the average Fe–S–Fe angle of 69.3° is slightly larger than that in **3a** (67.7°). The large C(1)–S(3)–C(11) angle of 111.4(3)° in **3e** differs significantly from that in complex **3a** [102.77(9)°].

Unlike the reactions of **1a**–**d** with **2**, the formation of a tetranuclear iron cluster similar to **6a**–**d** was not observed, although we were able to isolate complex **7**. The DEI mass

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectrum of **7** shows the [M$^+$] ion at *m*/*z* 586 and stepwise fragmentation of nine CO groups. This indicates that three $Fe(CO)_3$ moieties are coordinated to adamantanethione, a result which was also confirmed by X-ray structure analysis (Figure 6).

As a tentative mechanism we propose that the interaction of 1,2,4-trithiolanes **1a**–**e** with an $Fe_2(CO)_6$ complex fragment initially results in its insertion into the S–S bond to form complexes **3a**–**e**. But how can we explain the formation of complexes **4a**–**e**, **6a**–**d** and **7**? The insertion of iron carbonyl into the S–S bond, which results in the formation of **3** (Scheme 5, pathway a), competes with decomposition of the intermediate zwitterion to form **4** (Scheme 5, pathway b), which can be considered as a formal complex of $Fe_2(CO)_6$ with dithiirane, and the corresponding thioketone. In contrast to the enolisable aliphatic and cycloaliphatic thioketones, adamantanethione is a relatively stable compound,[9] which cannot undergo this undesired side reaction and is trapped in situ with the $Fe_3(CO)_9$ fragment to yield **7** (Scheme 5). Less stable aliphatic thioketones or products of their secondary transformations act as sulfur donors in the multistep reaction leading to clusters of type **6**.

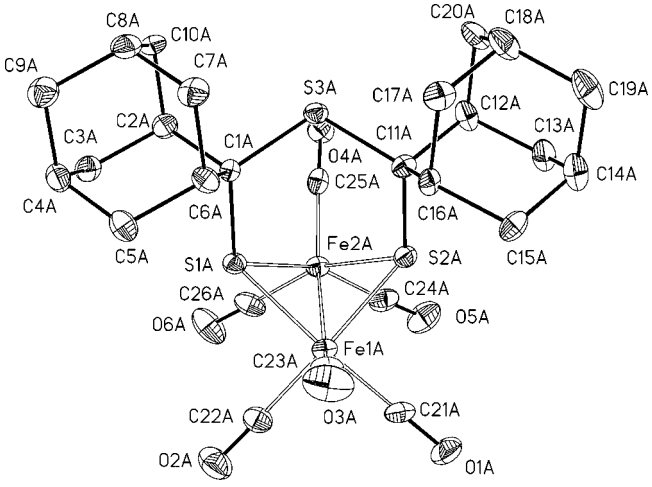

Figure 5. Structure of [$Fe_2${SC(ad)SC(ad)S}$(CO)_6$] (ad = adamantyl) **3e** with thermal ellipsoids set at the 50% probability level (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°]: Fe(1A)–Fe(2A) 2.5525(13), Fe(1A)–C(A21) 1.803(8), Fe(A1)–C(A22) 1.785(8), Fe(A1)–C(A23) 1.807(8), Fe(1A)–S(1A) 2.247(2), Fe(1A)–S(2A) 2.2407(19); Fe(1A)–S(1A)–Fe(2A) 69.18(6), Fe(1A)–S(2A)–Fe(2A) 69.49(6).

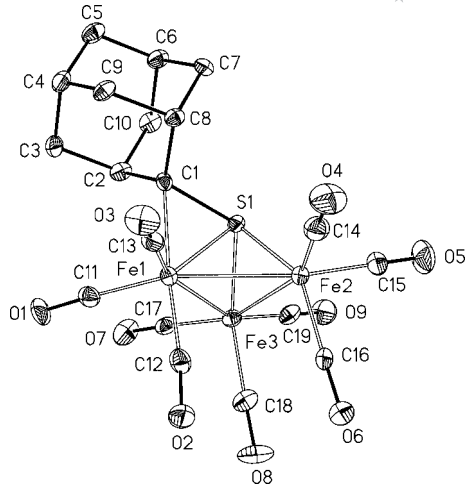

Figure 6. Structure of [$Fe_3$(ad)S$(CO)_9$] (**7**; ad = adamantyl) showing thermal ellipsoids at the 50% probability level (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°]: Fe(1)–Fe(2) 2.6256(11), Fe(2)–Fe(3) 2.6704(12), Fe(3)–Fe(1) 2.6272(12), Fe(1)–C(1) 2.122(6), Fe(1)–S(1) 2.2068(16), S(1)–C(1) 1.781(6); Fe(1)–C(1)–S(1) 68.2(2), Fe(1)–Fe(3)–Fe(2) 59.42(3), Fe(2)–Fe(1)–Fe(3) 61.11(3), Fe(1)–S(1)–Fe(2) 74.34(5), Fe(2)–S(1)–Fe(3) 77.28(6).

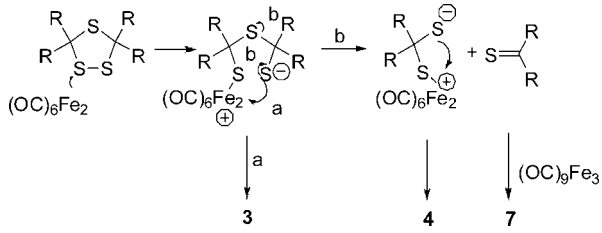
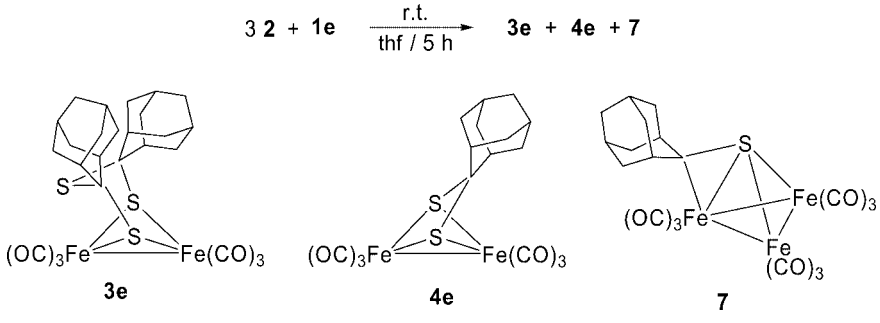


Scheme 5. Proposed mechanism for the formation of **3**, **4** and **7**.

In order to exclude the formation of complexes **4a**–**e** from **3a**–**e** we treated **3b** with an excess of **2** in thf at room temperature for 5 h. Complex **3b** does not react further under these conditions.



Scheme 4. Reaction of 1,2,4-trithiolane **1e** with [$Fe_2(CO)_9$].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Figure 6 shows that the adamantanethione molecule is bonded side-on to a three-iron triangle where Fe(1)–Fe(3) and S(1) form a tetrahedron. The C(1)–S(1) distance [1.781(6) Å] is significantly longer than that in a corresponding organic compound such as thiobenzoephenone due to this side-on coordination.[10]

### Substitution Reaction of 3a with $(Et_4N)CN$

The displacement of one CO ligand with one equivalent of $CN^-$ anion leads to the formation of complex **8**, which was successfully isolated from reaction mixture. This product is formed by the addition of $(Et_4N)CN$ to **3a**. The same reaction has been applied very recently to substitute two CO ligands by $CN^-$ ions to yield $(Et_4N)_2[Fe_2(SDT)(CO)_4(CN)_2]$.[3c]

The $^1H$ NMR spectrum of **8** shows one broad singlet for the $SCH_2S$ groups at $\delta = 2.59$ ppm, which is different to the corresponding resonances in $(Et_4N)_2[Fe_2(SDT)(CO)_4(CN)_2]$ ($\delta = 3.30$ ppm)[3c] and $(Et_4N)[Fe_2(ODT)(CO)_5(CN)]$ ($\delta = 4.09$ ppm).[7] Although both methylene groups in **8** and in $(Et_4N)[Fe_2(ODT)(CO)_5(CN)]$ are diastereotopic, the four protons appear as a broad singlet, which indicates a dynamic process in the complexes. The ESI mass spectrum of **8** reveals the anion at *m*/*z* 401.9 and the cation at *m*/*z* 130.2. All ν(CO) bands in the IR spectra are shifted, as expected, towards lower energies than in **3a** due to the negative charge of the complex. The isotopic pattern for the anion confirmed the postulated monocyanide complex **8** (see Figure S7 in the Supporting Information). The structure of **8** was confirmed by single-crystal X-ray diffraction (Figure 7), which unequivocally confirmed the formation of complex **8**. The Fe–Fe bond length [2.5240(12) Å] is slightly longer than that in **3a** and very similar to that in $(Et_4N)[Fe_2(PDT)(CN)(CO)_5]$ [2.5291(6) Å].[6b] In analogy to $(Et_4N)[Fe_2(PDT)(CN)(CO)_5]$, the five Fe–CO distances (1.77 Å) are shorter than the Fe–CN distance [1.940(6) Å]. In contrast to $(Et_4N)[Fe_2(ODT)(CN)(CO)_5]$, however, where the bridgehead oxygen atom is fixed completely opposite the Fe atom attached to the CN ligand, the bridgehead sulfur atom in complex **8** is orientated towards the Fe atom attached to the cyanide ligand.

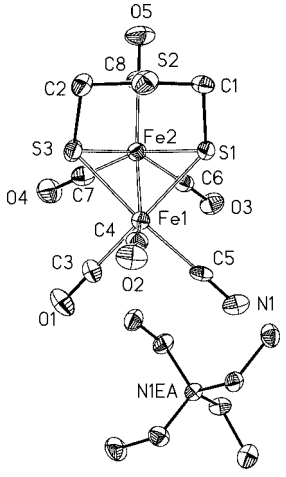


Figure 7. Structure of $(Et_4N)[Fe_2(SDT)(CN)(CO)_5]$ (**8**) showing thermal ellipsoids at the 50% probability level (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°]: Fe(1)–Fe(2) 2.5240(12), Fe(1)–C(3) 1.786(6), Fe(1)–C(4) 1.761(7), Fe(2)–C(5) 1.940(6), Fe(1)–S(1) 2.2488(16), Fe(1)–S(3) 2.2499(17); Fe(1)–S(1)–Fe(2) 67.93(5), Fe(1)–S(3)–Fe(2) 67.92(5).

### Quantum Chemical Calculations

Geometry optimisation was performed at the RI-DFT and DFT levels with BP86 and B3LYP functionals and LANL2DZ, def-SV(P) basis sets using the TURBOMOLE[11–13] and Gaussian 03[14] software packages. The structure calculated for **9** (Figure 8), which differs from **6b** only in the substitution of the methyl groups for hydrogen, has main structural features that are very similar to those of **6b** and are in line with this complex being built up from an $Fe_2(CO)_6S$ (**10**; Figure 9) and an $Fe_2(CO)_5(SCH_2)_2S$ (**12**) unit. Complex **11** is the CO adduct of this latter fragment (Figure 10) and its structural data are similar to those of **3b**.

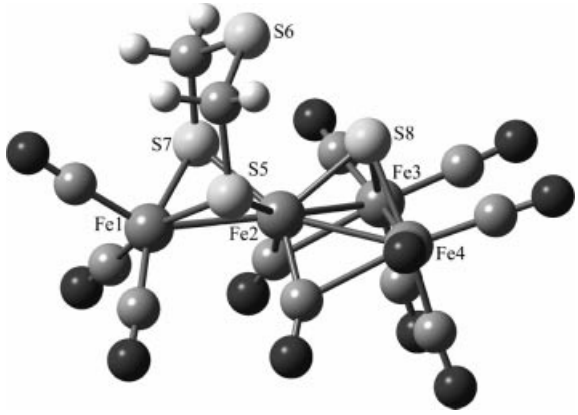

Figure 8. Structure of **9** obtained from the density functional calculations [BP86/def-SV(P)]. Selected distances [Å]: Fe(1)–Fe(2) 2.579, Fe(2)–Fe(3) 2.604, Fe(2)–Fe(4) 2.607, Fe(3)–Fe(4) 2.584, Fe(1)–C 1.775–1.799, Fe(2)–C 1.818, Fe(3)–C 1.785, 2.309, Fe(1)–S(5,7) 2.279, Fe(2)–S(5,7) 2.286, Fe(2)–S(8) 2.208, Fe(3)–S(8) 2.223.

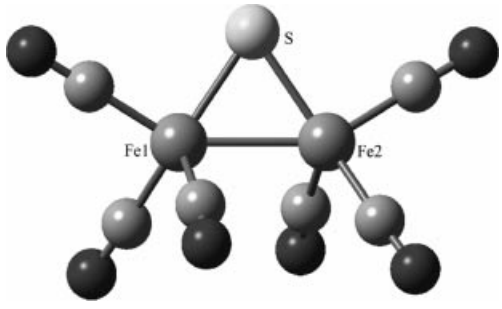

Figure 9. Structure of **10** obtained from the density functional calculations [BP86/def-SV(P)]. Selected distances [Å]: Fe(1)–Fe(2) 2.453, Fe–S 2.159, Fe–C 1.745–1.778.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

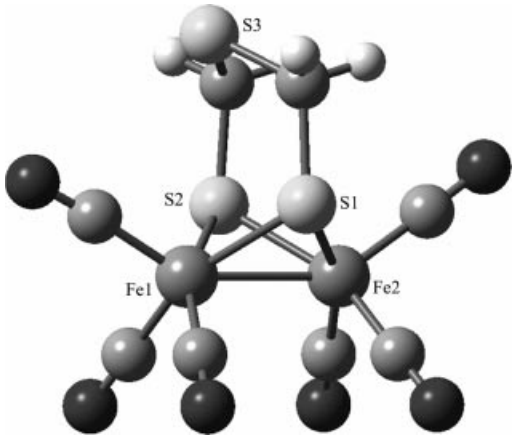

Figure 10. Structure of **11** obtained from the density functional calculations [BP86/def-SV(P)]. Selected distances [Å]: Fe(1)–Fe(2) 2.531, Fe–S 2.295–2.300, Fe–C 1.775–1.783.

Substitution of a CO ligand in **11** for **10** leaves the core of **11** essentially unaffected, whilst **10** is changed more drastically (the Fe–Fe and Fe–S distances are elongated by 0.1 Å). This is also shown by the shared electron numbers (SEN),[15] which indicate shorter Fe–Fe contacts in **10** ($SEN_{Fe–Fe}$ = 1.2) than in **11** ($SEN_{Fe–Fe}$ = 0.88). This is also the case for the Fe–S contacts [$SEN_{Fe–S}$ = 1.47 (**10**), 1.08 (**11**)].

Inspection of the frontier orbitals (Figure 11) shows that the **10** and **11** can be viewed in a first approximation as separate units that are linked mainly by an Fe–S interaction. The pseudo-bridging CO ligands on the Fe(2)–Fe(3,4) edges are only weakly bonded to Fe(3,4).

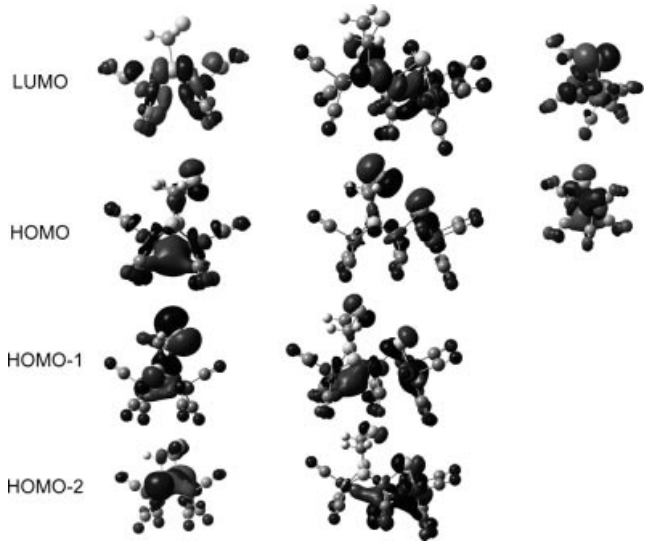

Figure 11. Kohn–Sham frontier orbitals for **9**–**11**.

An alternative description of **9** as a $Fe_3S$ clusters with a $Fe(CO)_3$ ligand attached to two S atoms, as depicted in Scheme 3, might also be possible. Complex **12** would be balanced as a cluster with six skeletal electron pairs, which would fit a Wade-type[16,17] *nido* cluster isolobal with $P_4$. The results of the calculations on **9** and **11**, however, show that this interpretation is less valid.

## Conclusions

We have shown that the 1,2,4-trithiolanes **1a**–**e** react with $[Fe_2(CO)_9]$ (**2**) by insertion into the S–S bond to provide novel mimics (**3a**–**e**) of [Fe-only] hydrogenase. We also succeeded in isolating the carbondithiolato ($SCR_2S$)-bridged diiron products **4a**–**e** and the tetranuclear clusters **6b**–**d** as side products. Interestingly, the reaction of **1e** with **2** yielded the adamantanethione complex **7** as well as **3e** and **4e**; no tetranuclear cluster of type **6** was observed. These reaction pathways can be explained by an interaction of the $Fe_2(CO)_6$ complex fragment with the disulfide moiety in the 1,2,4-trithiolanes **1a**–**e**, which induces ring opening. Reaction of the resulting zwitterionic intermediate competes with its decomposition to **4**, which can be considered as a formal complex of $Fe_2(CO)_6$ with dithiirane, and the corresponding thioketone. In the case of **7**, the eliminated adamantanethione, which is a relatively stable compound,[9] is trapped in situ by an $Fe_3(CO)_9$ fragment (Scheme 5). Less stable aliphatic thioketones or products of their secondary transformations act as sulfur donors in the multistep reaction leading to clusters of type **6**. Density functionl calculations have shown that tetrairon clusters of type **6** are built from two dinuclear subunits linked by iron–sulfur contacts.

## Experimental Section

**General:** The $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker DRX 200 or DRX 400 spectrometer using the solvent as reference. The 2D NMR measurements were done on the DRX 400 spectrometer. The mass spectra were recorded with a FINNIGAN MAT SSQ 710 instrument. The IR spectra were recorded with a Thermoelectron Nicolet AVATAR 30070 DTGS by using KBr pellets, with a Biorad FTF 25 in ATR cuvettetes when measuring neat substance and with a Perkin–Elmer 2000 FT-IR spectrometer when measuring solutions. 1,2,4-Trithiolane (**1a**), 3,3,5,5-tetramethyl-1,2,4-trithiolane (**1b**), 3,3,5,5-tetraethyl-1,2,4-trithiolane (**1c**), 3,3,5,5-bis(pentamethylene)-1,2,4-trithiolane (**1d**) and dispiro{tricyclo[3.3.1.1]decane-2,3′′-(1,2,4)-trithiolane-5′,2′-tricyclo[3.3.1.1]decane} (**1e**) were prepared according to literature protocols.[18–20] Elemental analyses were performed with LECO CHNS-932. Solvents and $[Fe_2(CO)_9]$ (**2**) were purchased from Sigma–Aldrich. Thf was dried with sodium/benzoephenone before use. Reported yields refer to the amount of purified products. Merck Silica gel 60 (0.015–0.040 mm) was used for column chromatography. TLC was performed on Merck TLC aluminium sheets (slica gel 60 $F_{254}$).

**Preparation of Complexes 3a–e, 4a–e, 6a–d and 7. General Procedure:** Nonacarbonyldiiron (**2**; 4.5 mmol) and 1,2,4-trithiolane **1a**–**e** (1.5 mmol) were dissolved in thf (20 mL) and stirred at room temperature for five hours under argon. The light-orange solution turned deep red and a brown solid (mixture of inorganic iron sulfides) precipitated. The solvent was removed under reduced pressure and the crude product was purified by column chromatography using hexane as eluent. A yellow fraction representing the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

side products **4a**–**e**, the orange main fraction containing complexes **3a**–**e**, and the third, red-brown and brown fractions containing **6a** and **6b**–**d** and **7**, respectively, were collected and the solvent removed in vacuo. The products were obtained as red-orange (for **3a**–**e** and **4a**–**e**), dark-red (for **6a**) or brown solids (for **6b**–**d** and **7**).

Crystals suitable for X-ray diffraction analysis were obtained by slow evaporation of hexane into a concentrated pentane solution at 0 °C (for **3a**–**e**). Products **3a**–**e**, **4a**–**e**, **6b**–**d** and **7** were crystallised from a solution of hexane at –25 °C.

**Preparation of the Monocyanide Complex ($Et_4N$)[$Fe_2$(SDT)(CO)$_5$-(CN)] (8):** A solution of **3a** (100 mg, 0.25 mmol) in MeCN (15 mL) at 0 °C was treated with a solution of $Et_4NCN$ (80 mg, 0.50 mmol) in MeCN (15 mL). After warming the reaction mixture to room temperature, it was stirred for an additional 1.5 h. The solvent was then removed in vacuo and the residue washed thoroughly with diethyl ether and hexane. The washed residue was again evaporated to dryness to give a red solid. Single crystals suitable for X-ray diffraction analysis were obtained by diffusion of pentane into its MeCN solution. Yield 120 mg (90%). $^1$H NMR (200 MHz, $CD_3CN$): $\delta$ = 3.18 (br. s, 8 H, $CH_2CH_3$), 2.43 (br. s, 4 H, $SCH_2$), 1.10 (br. s, 12 H, $CH_2CH_3$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CD_3CN$): $\delta$ = 8.0 ($CH_2CH_3$), 27.3 ($SCH_2$), 53.3 ($CH_2CH_3$), 150.7 (*C*N), 219.7 (*C*O) ppm. FT-IR (thf solution): $\tilde{\nu}$ = 2052 [s (νCN)], 2033 (s), 1981 (s), 1953 (m), 1921 [w (νCO, terminal)] cm$^{-1}$. MS (ESI pos., 70 eV): *m*/*z* (%) 130.2 (100) [M⁺, $C_8H_{20}N$]. MS (ESI neg., 70 eV): *m*/*z* (%) 401.9 (100) [M⁻, $C_8H_4Fe_2NO_5S_3$].

**Supporting Information** (see also the footnote on the first page of this article): Figures S1, S3 and S4 display the X-ray structures of compounds **4b**, **4d** and **4e**. The structure of **4c** is available as Figure S2. Figures S5 and S6 present the X-ray structures of **6c** and **6d**, respectively. Figure S7 shows the experimental and theoretical isotopic pattern of **8**⁻ (anion of **8**).

**X-ray Structure Determination of 3b, 3c, 3d, 3e, 4b, 4c, 4d, 4e, 6b, 6c, 6d, 7 and 8:**[21] Intensity data were collected with a Nonius Kappa CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz polarisation, but not for absorption effects.[22,23] Crystallographic data as well as structure solution and refinement details are summarised in Tables 1 and 2.

The structures were solved by direct methods (SHELXS[24]) and refined by full-matrix least-squares techniques against $F_o^2$ (SHELXL-97[25]). The hydrogen atoms were included at calculated

positions with fixed thermal parameters. All non-hydrogen atoms except for the disordered part of molecules were refined anisotropically.[25] The quality of the data of compound **4c** was poor therefore we will only publish the conformation of the molecule and the crystallographic data. The data have no been deposited in the Cambridge Crystallographic Data Centre.

## Acknowledgments

Financial support for this work was provided by the Freistaat Thüringen (Landesgraduiertenstipendium for J. W.). We are grateful to Ulf-Peter Apfel for experimental assistance.

# A New Pentadentate Ligand Forms Both a Di- and a Mononuclear $Mn^{II}$ Complex: Electrochemical, Spectroscopic and Superoxide Dismutase Activity Studies

**Federico Cisnetti,[a,b] Anne-Sophie Lefèvre,[a,b] Régis Guillot,[b,c] François Lambert,[a,b] Guillaume Blain,[b,c] Elodie Anxolabéhère-Mallart,[b,d] and Clotilde Policar*[a,b]**

**Keywords:** Manganese(II) / Enzyme models / SOD mimic / N,O ligands / Bioinorganic chemistry

The X-ray crystal structure of the dinuclear complex [**1**$(PF_6)_2$] derived from a new ligand bearing both imidazole and phenolato moieties, namely *N*-(2-hydroxybenzyl)-*N*,*N*′-bis[2-(*N*-methylimidazolyl)methyl]ethane-1,2-diamine (LH), is described and its properties in organic solvent ($CH_3CN$) investigated (EPR, electrochemistry). [**1**$(PF_6)_2$] is shown to be a mononuclear $Mn^{II}$ species in aqueous solution and displays an efficient SOD-like activity, as measured by the McCord–Fridovich assay performed both in conventional phosphate buffer and in a noncoordinating buffer (PIPES).

## Introduction

Superoxide is known to be a toxic reactive oxygen species (ROS) involved in oxidative stress[1–4] and is considered to be responsible for several pathologic situations. Under normal conditions, its concentration is kept low (8–40 pM)[5,6] by metalloenzymes, known as superoxide dismutases (SODs), that catalyze its dismutation. As the therapeutic use of purified enzymes has major drawbacks,[3] different low molecular weight complexes have been synthesized for this purpose using either copper, iron, manganese, or cobalt ions. As Mn derivatives do not lead to Fenton chemistry, special interest has been devoted to Mn complexes (oxidation states II, III, or IV) as antisuperoxide agents for possible therapeutic use.[2–4] Free $Mn^{II}$[7–9] or Mn coordinated to salen derivatives,[8,10–12] cyclic polyamines,[3,13–19] tri- or dipodal ligands,[20–28] 1,2-ethanediamine-based ligands,[29–32] desferrioxamine derivatives[13,33,34] polyaminocarboxylato[35–37] or polycarboxylato ligands,[38] peptides,[39–41] as well as $Mn^{III}$ porphyrins,[42–47] or dinuclear biliverdin manganese complexes[48] have been reported to react with superoxide either as a true SOD mimetic or as a scavenger.

One of the goals of our research is the synthesis of bioactive complexes of therapeutic interest in the case of oxidative stress.[2–4] In the past few years we have synthesized a series of Mn complexes containing tripodal amines as tetradentate ligands that show an SOD-like activity, according to the results of the indirect McCord–Fridovich assay[24,27,28] and pulsed radiolysis experiments.[26,27] These complexes were designed as bio-inspired functional SOD mimics bearing in mind that the active site of Mn-based SODs has a trigonal-bipyramidal $N_3O_2$ core with three histidines, a monodentate aspartate, and an aqua or hydroxido ligand.[49]

Pentadentate ligands based on a 1,2-ethanediamine moiety are interesting alternatives to the previous tetradentate N-tripod series because they offer a larger number of possible variations.[50–52] We report here the synthesis of a complex with a new pentadentate ligand L [LH = *N*-(2-hydroxybenzyl)-*N*,*N*′-bis[2-(*N*-methylimidazolyl)methyl]ethane-1,2-diamine], which contains a 1,2-ethanediamine backbone bearing one phenol (mimicking the monodentate carboxylate present at the Mn-SOD active site) and two 1-methylimidazole groups (mimicking the histidine side-chains) as coordinating groups (Scheme 1). We describe the structure and solution characterization (EPR and UV/Vis spectroscopy, electrochemistry) of the dinuclear complex [(L)MnMn(L)]$(PF_6)_2$ [**1**$(PF_6)_2$] in organic solution and show that in aqueous solution this complex is in the monometallic form $[(L)Mn]^+$ (EPR, cyclic voltammetry). The SOD-like activity of the $[(L)Mn]^+$ species has been measured in aqueous solution using the conventional McCord–

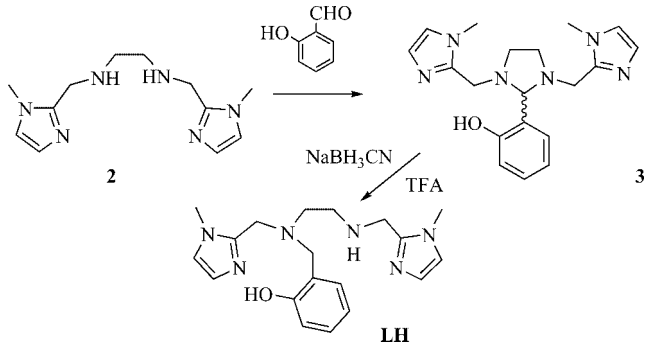
Fridovich test under noncoordinating conditions. The good activity found is consistent with the redox potential of the $[(L)Mn]^+$ species measured by CV.



Scheme 1. Synthetic route to LH.

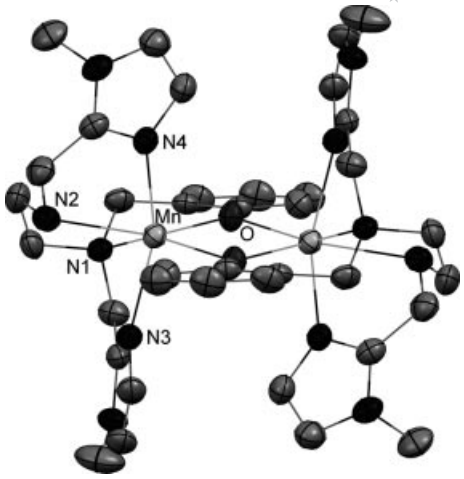


Figure 1. Ellipsoid plot of the centrosymmetric cationic moiety **1**, produced with Mercury 1.4.2.[56] Ellipsoids are drawn at 50% probability level. $PF_6^-$ and H atoms have been omitted for clarity.

## Results and Discussion

The synthesis of LH is straightforward. *N*,*N*′-Bis[2-(*N*-methylimidazolyl)methyl]ethane-1,2-diamine (**2**) was obtained by a conventional two-step reductive amination procedure starting from 1-methyl-2-imidazolecarboxaldehyde[53] and 1,2-ethanediamine, as published elsewhere.[54] The dissymmetric pentadentate ligand containing a phenolic group was then obtained by treating **2** with salicylaldehyde to obtain the aminal **3** (Scheme 1), which was reductively opened with $NaBH_3CN$ in the presence of an acid.[55] The whole synthesis proceeded with high yields. The reaction of crude LH with $MnBr_2$ in warm methanolic solution led to the formation of a $Mn^{II}$ complex. Crystals suitable for X-ray diffraction were grown by cooling this solution to room temperature under argon in the presence of hexafluorophosphate anion.

### Description of the Structure

The X-ray crystal structure of this complex revealed it to be dinuclear with the formula $[(L)MnMn(L)](PF_6)_2$ [**1**$(PF_6)_2$]. A view of cation **1** is presented in Figure 1. This cation is dinuclear and centrosymmetric with a central di-μ-phenolato $Mn_2O_2$ diamond core. Selected bond lengths and angles are reported in Table 1.

Each $Mn^{II}$ ion is hexacoordinate, with four nitrogen atoms of the anionic form $L^-$ of the ligand and two oxygen atoms from the phenolato groups, the first one from the same ligand and the other one from the ligand chelating the second $Mn^{II}$ ion. The Mn environment departs from that of a regular octahedron (see Table 1). The longest coordination bond is that to the secondary amine N2, and the N2–Mn–O angle is much larger than the ideal value for an octahedron. These distances and deformations are similar to those reported for similar $Mn^{II}$ dinuclear compounds,[50,51] in particular to the dinuclear phenolate-bridged dication $[(mL')Mn^{II}Mn^{II}(mL')]^{2+}$ [mL′H = *N*-(2-hydroxybenzyl)-*N*′-methyl-*N*,*N*′-bis(2-pyridylmethyl)-ethane-1,2-diamine].[51] Such a dinuclear structure in which manganese atoms show a distorted octahedral geometry is in line with the fact that $Mn^{II}$ complexes, due to their half-filled $d^5$ shell, have no electronic coordination preference.[57]

### EPR Spectroscopy

The X-band EPR spectrum of a 1.1 mM acetonitrile solution of **1**$(PF_6)_2$ in the presence of 0.1 M tetrabutylammonium perchlorate was recorded at 7 K in both the perpendicular and parallel modes. The spectrum recorded in the perpendicular mode exhibits features extending from 0 to 800 mT (Figure 2), which arise from the superimposition of the signal of the five paramagnetic spin states $S$= 1 to 5 and is characteristic of dinuclear $Mn^{II}$ complexes.[51,52,58–63] The band at around 260 mT (B) shows a nice hyperfine structure with a field separation between two lines of about 41 G (see insert Figure 2), which is typical of dinuclear $Mn^{II}Mn^{II}$ complexes. Increasing the temperature induced only slight modifications in the spectral profile [the band at around 204 mT (A) and the intensity of the signal at 330 mT (C)]. Unlike previous observations with a dinuclear bis-μ-phenolato $Mn^{II}Mn^{II}$ complex with a $J$-value of $-1.5\ cm^{-1}$,[50] the intensities do not reach a maximum but decrease on increasing the temperature from 7 to 30 K (see Figure 2). This thermal behavior is consistent with the very

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

weak *J*-value estimated from the measurement of the magnetic susceptibility as a function of temperature (see Experimental Section).

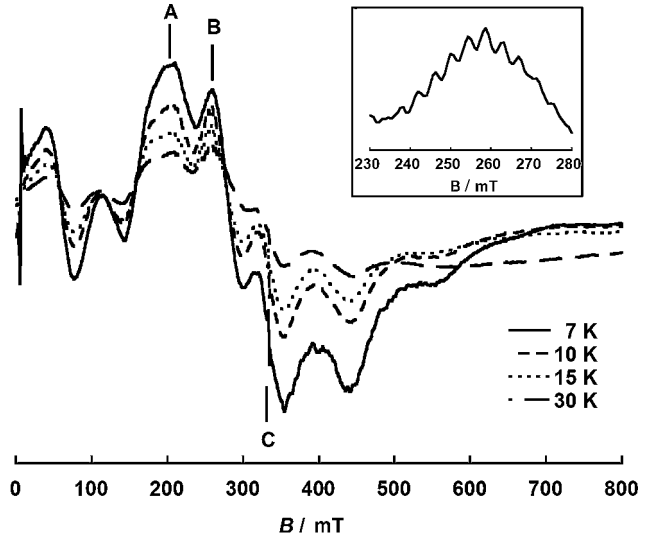

Figure 2. X-band EPR spectrum of $\mathbf{1}(PF_6)_2$ (1.1 mM in $CH_3CN$ containing 0.1 M tetrabutylammonium perchlorate) at 7 K. Microwave frequency: 9.63 GHz; microwave power: 2 mW; modulation amplitude: 0.5 mT; modulation frequency: 100 kHz; gain: 40 dB.

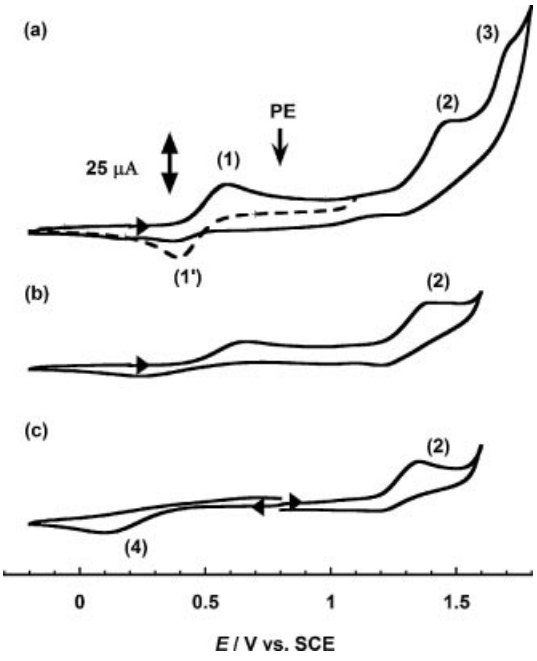

Figure 3. Cyclic voltammograms of $\mathbf{1}(PF_6)_2$ (1.1 mM in $CH_3CN$ with 0.1 M tetrabutylammonium perchlorate) under argon (v = 0.1 $V s^{-1}$; working electrode: glassy carbon; counter electrode: Pt wire; reference electrode: $Ag/AgClO_4$) at 20 (a) –25 (b), and –25 °C after electrolysis at $E$ = +0.8 V vs. SCE (c). PE = potential of the preparative electrolysis.

### Electrochemical Access to $Mn^{III}$

The cyclic voltammogram of a 1.1 mM acetonitrile solution of $\mathbf{1}(PF_6)_2$ is shown in Figure 3. The CV trace shows a well-defined anodic wave (wave 1 in Figure 3a) at $E_p^a$ = 0.58 V vs. SCE and a well-defined cathodic wave on the reverse scan at $E_p^c$ = 0.39 V vs. SCE (wave 1′). The difference between these two values ($\Delta E_p = E_p^a - E_p^c$) of 190 mV is indicative of a slow electron transfer. A similar behavior has previously been reported for related dinuclear $Mn^{II}Mn^{II}$ complexes with pyridine instead of imidazole moieties.[50] Controlled potential coulometry performed at +0.8 V vs. SCE indicated a one electron per Mn process for the first oxidation. Thus, the first anodic wave (1/1′; $E_{1/2}$ = 0.485 V vs. SCE)[64] can be attributed to a two-electron $Mn^{II}Mn^{II} \rightarrow Mn^{III}Mn^{III}$ process. This oxidation occurs at lower potential than that reported for the pyridine-containing ligand mL′[51] as the imidazole group has a higher electron-donating effect than pyridine, which leads to greater stabilization of the $Mn^{III}$ oxidation state.

Two other anodic peaks (labeled 2 and 3 in Figure 3, a) are observed at $E_p^a$ = 1.4 and 1.7 V vs. SCE respectively. These second and third oxidation processes are tentatively attributed to $Mn^{III}$ to $Mn^{IV}$ and phenolato oxidation processes.[50,65]

In an effort to determine the exact nature of the resulting $Mn^{III}$ species, a controlled potential electrolysis was performed at +0.8 V vs. SCE at –25 °C. Aliquots of the electrolyzed solution were collected during the course of the electrolysis and their UV/Vis absorption (Figure 4) and EPR spectra recorded. Figure 3 shows the cyclic voltammograms recorded at –25 °C before (Figure 3, b) and after (Figure 3, c) complete electrolysis at +0.8 V vs. SCE. After electrolysis one anodic process was detected at $E_p^a$ = +1.35 V vs. SCE

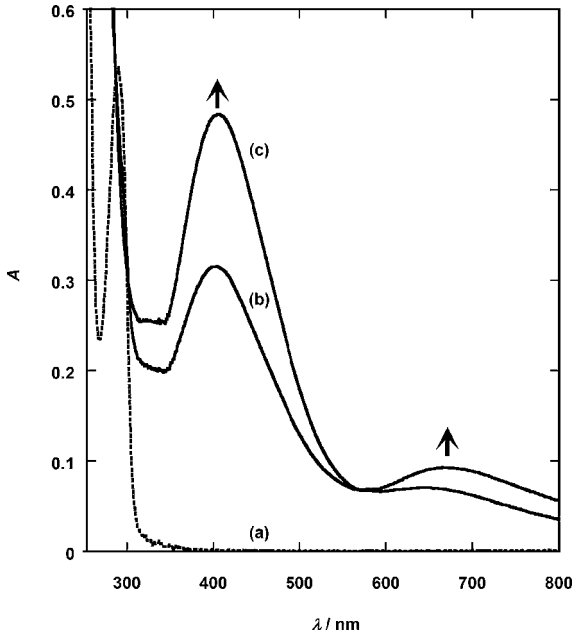

Figure 4. Evolution of the UV/Vis spectrum of $\mathbf{1}(PF_6)_2$ (1.1 mM acetonitrile solution) during bulk electrolysis at $E$ = 0.8 V vs. SCE before electrolysis (a), after 0.5 electron/Mn (b), and after 1 electron/Mn (c) at room temperature. Path length = 0.1 cm.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and one irreversible cathodic process at $E_p^c$ = +0.1 V vs. SCE when scanning towards low potential (labeled 4 in Figure 3, c).

As expected for a $Mn^{II}$ oxidation state, the UV/Vis spectrum of **1** (Figure 4) only shows features in the UV region ($\lambda_1$ = 287 nm, $\varepsilon_1$ = 4909 $M^{-1}cm^{-1}$) associated with π–π* transitions of the ligand. The colorless solution turns pink upon oxidation at 0.8 V and two new absorption bands appear at $\lambda_2$ = 403 and $\lambda_3$ = 672 nm. Based on a complete conversion of the initial $Mn^{II}$ into $Mn^{III}$, the extinction coefficients calculated per Mn ion are $\varepsilon_2$ = 2181 and $\varepsilon_3$ = 432 $M^{-1}cm^{-1}$. Similar bands have been reported in the literature for mononuclear $Mn^{III}$ complexes[66] or dinuclear $Mn^{III}Mn^{III}$ complexes with phenolato/pyridine ligands.[65] The band at 403 nm can therefore be attributed to a phenolato to $Mn^{III}$ LMCT transition. Due to the lower value of its extinction coefficient, and previous reports in the literature, the band at 672 nm can be attributed to a d-d transition.[67,68]

The intensity of the X-band perpendicular mode EPR spectrum of the initial $Mn^{II}Mn^{II}$ complex decreased during the course of the electrolysis. After completion of the electrolysis (1 electron/1 Mn), the pink solution was EPR-silent in the perpendicular mode (data not shown), as expected for a $Mn^{III}$ complex. Unfortunately, no signal was detected when a parallel mode EPR spectrum was recorded for the pink solution.

The above-mentioned experimental data confirm the $Mn^{III}$ oxidation state of the oxidized species, although the exact nature of the $Mn^{III}$ species remains uncertain as a dinuclear bis-μ-phenolato $Mn^{III}Mn^{III}$ complex is likely to be unstable in solution. As reported previously in the literature, the bis-μ-phenolato bridge can easily break and generate two mononuclear $[(L)Mn^{III}(S)]^{2+}$ complexes, where S can either be a water molecule or a solvent molecule.[51] It should be noted that wave 2 disappeared upon addition of 2,6-lutidine[69] and a new anodic wave appeared at 1.02 V vs. SCE. Based on these results (see Figure S1 in the electronic supporting information), wave 2 can be assigned to the $[(L)Mn^{III}(OH_2)]^{2+}/[(L)Mn^{IV}(OH_2)]^{3+}$ oxidation process and the wave at 1.02 V to the $[(L)Mn^{III}(OH)]^{+}/[(L)Mn^{IV}(OH)]^{2+}$ oxidation process as deprotonation of the aqua complex lowers the $Mn^{IV}/Mn^{III}$ redox potential. Wave 4 can tentatively be assigned to reduction of the mononuclear $[(L)Mn^{III}(OH_2)]^{2+}$ species into $[(L)Mn^{II}(OH_2)]^{+}$.

## Nature of the Complex in Water

Cyclic voltammetry and the EPR spectrum recorded in $CH_3CN$ are consistent with a dinuclear $[(L)MnMn(L)]^{2+}$ species (**1**; see above). In order to investigate the behavior of the complex in aqueous solution, electrochemistry and EPR spectra were recorded in a noncoordinating buffer, namely piperazine-*N*,*N*′-bis(2-ethanesulfonic acid) (PIPES; 50 mM, pH 7.5).[38,70]

The EPR spectra of a 1 mM solution in PIPES (Figure 5) displays a large six-line signal at $g$ = 2 ($\Delta B_{av}$ = 96 G) characteristic of a mononuclear $Mn^{II}$ center. The low-intensity signal at $g \approx 3.94$ is typical for distorted $Mn^{II}$ environ-

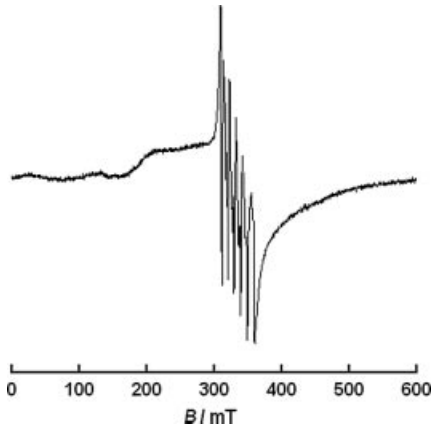

Figure 5. X-band EPR spectra of $\mathbf{1}(PF_6)_2$ ($10^{-3}$ M in 50 mM aqueous PIPES buffer, pH 7.5). Microwave frequency: 9.38 GHz; microwave power: 2.0 mW; modulation amplitude: 0.5 mT; modulation frequency: 100 kHz; gain: 20 dB.

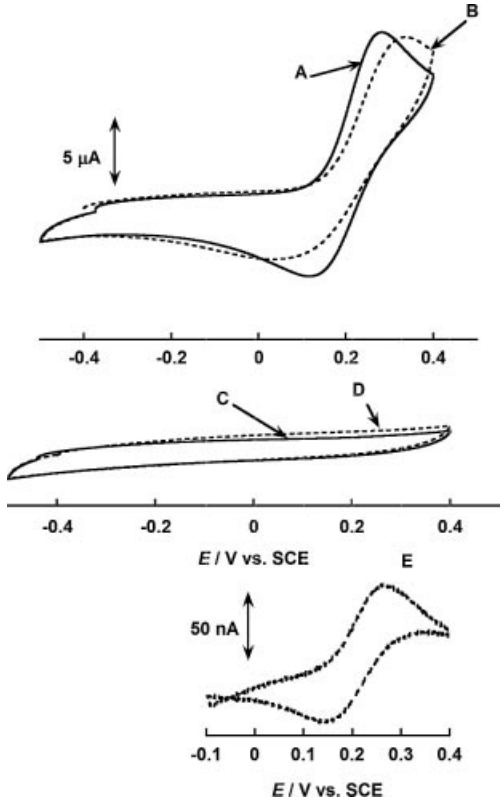

Figure 6. Cyclic voltammograms in aqueous solution: (A) $\mathbf{1}(PF_6)_2$ ($10^{-3}$ M) in aqueous PIPES buffer (pH 7.5, 50 mM) and (B) in aqueous phosphate buffer (pH 7.8, 50 mM); (**C**) $MnCl_2$ ($10^{-3}$ M) in aqueous PIPES buffer (pH 7.5, 50 mM) and (D) in aqueous phosphate buffer (pH 7.8, 50 mM); (E) $\mathbf{1}(PF_6)_2$ ($10^{-5}$ M) in aqueous PIPES buffer (pH 7.5, 50 mM; the signal recorded for pure PIPES buffer has been subtracted). Working electrode: glassy carbon; counter electrode: Pt wire; reference electrode: SCE.

ments.[71–74] This species will be labeled $[(L)Mn]^+$ in the following discussion, although there is probably a water molecule coordinated to the metal center.

Figure 6 shows the cyclic voltammogram of $[\mathbf{1}(PF_6)_2]$ dissolved in PIPES (1 mM; trace A). Trace A displays a well-defined anodic wave at $E_p^a = 0.282$ V vs. SCE and a well-defined cathodic wave on the reverse scan at $E_p^c = 0.116$ V vs. SCE ($E_{1/2} = 0.199$ V vs. *SCE* and $\Delta E_p = 165$ mV). Neither $MnCl_2$ (trace C in Figure 6) nor $Mn(ClO_4)_2$ (not shown) dissolved in PIPES show any wave at these potentials. A similar voltammogram, although less reversible, was recorded for $\mathbf{1}(PF_6)_2$ dissolved in pH 7.8 phosphate buffer (see Figure 6 trace B, $E_{1/2} = 0.184$ V vs. SCE; $E_p^a = 0.334$ V, $E_p^c = 0.037$ V vs. SCE; $\Delta E_p = 331$ mV).

Taken together, the EPR spectra and cyclic voltammograms unambiguously indicate that in aqueous solution the metal-containing species is therefore mononuclear $Mn^{II}$ (EPR) coordinated to L (the CV signature is different from that of uncoordinated $Mn^{2+}$).

The nature of this species was also investigated at $10^{-5}$ M both by CV and EPR spectroscopy. The electrochemical signature of the mononuclear $[(L)Mn]^+$ complex was still observed, with an intensity two orders of magnitude smaller, as expected for a concentration that is two orders of magnitude smaller. This indicates that no de-coordination occurs at this low concentration and is also consistent with the electrospray mass spectrometry analysis of a $10^{-5}$ M aqueous solution of $\mathbf{1}(PF_6)_2$, which shows a peak assigned to the mononuclear $[(L)Mn]^+$ cation (with spacings in the *M* multiplet equal to 1) and no peaks assignable to either **1** (at $M_{dinuclear}/2$, with expected spacings of 1/2) or to monocationic adducts.

## SOD-Like Activity in Aqueous Buffer

The mononuclear $[(L)Mn]^+$ cation was tested for its superoxide dismutase like activity using the McCord–Fridovich assay,[34,75] as published previously,[24,27] with ferricytochrome c as the detector. Two different buffers, namely phosphate buffer (pH 7.8, 50 mM) and the noncoordinating buffer PIPES (pH 7.5, 50 mM), were used, as in a previous study by Fridovich et al.[38] To the best of our knowledge, the PIPES buffer has only been used in the original publication by Fridovich et al.[38] even though these conditions appear to be a good alternative to phosphate buffer conditions.

The complex $[(L)Mn]^+$ displays very similar SOD-like activity under both sets of conditions, as shown by the inhibition of the reduction of ferricytochrome c. As shown in Figure 7, the activity of the complex is different from that of $Mn^{2+}_{aq}$ (see insert in Figure 7 and Table 2), which is consistent with the fact that the complex remains coordinated in dilute aqueous solution, as evidenced by the CV and ES-MS experiments at $10^{-5}$ M (see above).

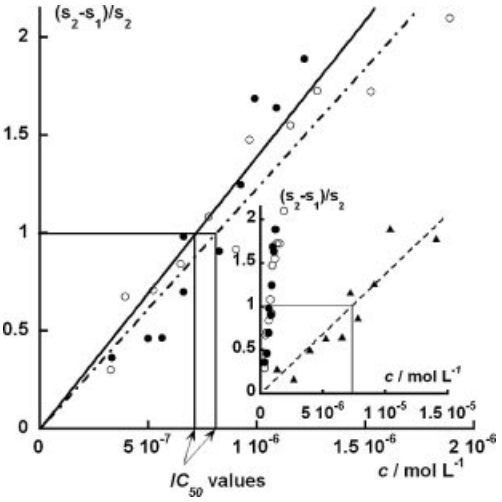

Figure 7. Determination of the $IC_{50}$ value for $[(L)Mn]^+$ in PIPES buffer (50 mM, pH 7.5; exp. points: filled circles; linear curve fit: solid line) and phosphate buffer (50 mM, pH 7.8; exp. points: open circles; linear curve fit: dot-dashed line). Inset: comparison with $MnCl_2$ in 50 mM PIPES (exp. points: triangles; linear fit: dashed line). The assay was performed by recording the reduction of ferricytochrome c at 550 nm as a function of time. The slope of the line $A_{550nm} = f(t)$ before addition of the SOD mimic is $s_1$ and $s_2$ is the slope after addition of the SOD mimic. $(s_1 - s_2)/s_2$ was plotted against the complex concentration to provide a line, and the $IC_{50}$ was then obtained for $(s_1 - s_2)/s_2 = 1$.[79]

Table 2. $IC_{50}$ values.

| | $IC_{50\ buffer}$[a,b] | $k_{McCF}$ [$M^{-1}\,s^{-1}$][c] |
|---|---|---|
| $Mn^{2+}_{aq}$ ($MnCl_2$) | $IC_{50\ PIPES} = (7.3 \pm 0.5) \times 10^{-6}$ M | –[d] |
| $[(L)Mn]^+$ | $IC_{50\ PIPES} = (7.2 \pm 0.4) \times 10^{-7}$ M | – |
| | $IC_{50\ Phosphate} = (8.1 \pm 0.3) \times 10^{-7}$ M | $(7.0 \pm 0.3) \times 10^6$ |

[a] 50% Inhibition concentration. [b] Uncertainties were obtained from the fitting linearization procedure. [c] $k_{McCF}$ values were recalculated from the $IC_{50}$ value. [d] $k_{McCF}$ was not recalculated as free $Mn^{II}$ is known to be catalytically inactive.[2] See ref.[4] for a comparison with similar $N_4O$ complexes.

$IC_{50}$ values are dependent on the concentration of the detector, therefore in order to determine the activity we recalculated the apparent kinetic constant $k_{McCF}$.[27] At the $IC_{50}$ value, the kinetics of the reduction of ferricytochrome c by superoxide is reduced by 50% as 50% of the superoxide is consumed by the ferricytochrome c and 50% by the complex (auto-dismutation being negligible in comparison). The apparent kinetic constant can thus be defined as $k_{McCF} = k_{detector} \times [detector]/IC_{50}$[27,76] and can be derived in the case of the phosphate buffer, for which the kinetic constant $k_{cytC}$ has been measured [$k_{cytC}$ (pH 7.8, 50 mM phosphate, 21 °C) = $2.6 \times 10^5$ $M^{-1}\,s^{-1}$].[77,78] The complex $[(L)Mn]^+$ therefore displays an apparent catalytic rate $k_{McCF}$ of $(7.0 \pm 0.3) \times 10^6$ $M^{-1}\,s^{-1}$.

The activity reported here is one of the best reported for the series of $Mn^{II}$ complexes with a similar coordination sphere (N/O coordination sphere with N from imidazole or pyridine and O from carboxylato or phenolato) reported by us and others,[23–25,27,28,80] which makes sense in light of the redox potential for the mononuclear $[(L)Mn]^+$ species mea-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sured in aqueous buffer. As the catalysis of the dismutation of superoxide is a redox process involving both $Mn^{II}$ and $Mn^{III}$ oxidation states, the potential of the $Mn^{II}/Mn^{III}$ couple is a key parameter.[27] It should lie between the potential of the two couples $O_2/O_2^-$ and $O_2^-/H_2O_2$ with the optimum being the midpoint, that is 0.12 V vs. SCE (at pH 7), which is the case for all SODs.[27,81,82] The mononuclear complex $[(L)Mn]^+$ ($E_{1/2}$ = 0.199 V vs. SCE) fulfills this requirement.

## Conclusions

The dinuclear bis-μ-phenolato complex $[(L)Mn^{II}Mn^{II}(L)](PF_6)_2$ [**1**$(PF_6)_2$], which contains a new amino/imidazole pentadentate $N_4O$ ligand, has been synthesized and its structure resolved by X-ray diffraction. An X-band EPR spectroscopy investigation has confirmed the dinuclear nature of the compound in acetonitrile solution. The cyclic voltammogram of **1** in acetonitrile solution displays a quasi-reversible anodic process at $E_{1/2}$ = 0.485 V vs. SCE assigned to the two-electron oxidation of the $Mn^{II}Mn^{II}$ species into the $Mn^{III}Mn^{III}$ species. The electrochemical formation of a $Mn^{III}$ species has been followed by UV/Vis and EPR spectroscopy. In aqueous solution, the dinuclear complex has been shown to be converted into a cationic mononuclear complex $[(L)Mn]^+$ with a redox potential of +0.199 V vs. SCE. Its superoxide dismutase-like (SOD-like) activity has been evaluated by the means of the McCord–Fridovich assay. The complex has a potent SOD-like activity, with an apparent catalytic rate, $k_{McCF}$, of $(7.0 \pm 0.3) \times 10^6$ $M^{-1}s^{-1}$. The development of manganese complexes based on 1,2-ethanediamine is of interest for the synthesis of efficient SOD mimics.

## Experimental Section

All reagents were bought from Acros Organics and used without further purification. 1-Methyl-imidazole carboxaldehyde was synthesized according to Iberson et al.[53] *N*,*N*′-Bis[2-(*N*-methylimidazolyl)methyl]ethane-1,2-diamine was synthesized according to Laronde et al.[54] NMR spectra were recorded with a Bruker AV360 or DRX300 spectrometer. IR spectra (KBr pellets) were recorded with a Bruker IFS 66 FT-IR spectrometer. Microanalysis was performed by the Service de Microanalyse de l'ICSN (Gif-sur-Yvette, France) for C,H,N, and by the Service Central d'Analyse du CNRS (Vernaison, France) for other elements.

Electrospray-ionization mass spectra were recorded with a Finnigan Mat 95S in the BE configuration at low resolution. X-band EPR spectra were recorded with a Bruker ELEXSYS 500 spectrometer fitted with an Oxford Instrument continuous-flow liquid helium or nitrogen cryostat and a temperature control system. UV/Vis spectra were recorded with a Cary 300 Bio Spectrophotometer with a 0.1-cm optical path quartz cuvette. The McCord–Fridovich assay was performed on the same apparatus at 25 °C and with a 1-cm optical path quartz cuvette. All electrochemical experiments were performed under argon. Cyclic voltammetry and coulometry were performed with a M273 EGG PAR potentiostat. The counter electrode for cyclic voltammetry was a Pt wire and the working electrode a glassy carbon disk, which was carefully polished before each voltammogram with a 1-μm diamond paste, sonicated in an ethanol bath, and then washed carefully with ethanol and dried. The counter electrode for bulk electrolysis was a piece of Pt separated from the rest of the solution with a fritted bridge. The working electrode was a Pt gauze (about 20 $cm^2$). The solvent used was (a) distilled acetonitrile with tetrabutylammonium perchlorate added to obtain a 0.1 M supporting electrolyte or (b) doubly distilled water with either phosphate or PIPES buffer (50 mM). The reference electrode was (a) an $Ag/AgClO_4$ electrode (0.3 V vs. SCE) for experiments in $CH_3CN$ and (b) an SCE electrode for experiments in water. In both cases, the reference electrode was isolated from the rest of the solution with a fritted bridge. Temperature regulation (20 °C) was ensured by a Julabo circulation cryostat.

**2-(2-Hydroxybenzyl)-*N*,*N*′-bis[2-(*N*-methylimidazolyl)methyl]imidazolidine (3):** A solution of compound **2**[54] (0.500 g, 2.01 mmol, 1 equiv.) in absolute ethanol (10 mL) was mixed with salicylaldehyde (0.246 g, 215 μL, 2.01 mmol, 1 equiv.). After stirring the reaction mixture for 24 h at ambient temperature, anhydrous sodium sulfate (0.5 g) was added to eliminate water. After stirring for a further 30 min the reaction mixture was filtered and the solvent evaporated to give the crude product as a yellow oil (0.700 g, quantitative yield). $^1$H NMR (360 MHz, $CDCl_3$, 23 °C): $\delta$ = = 7.22 (t, $J$ = 7.8 Hz, 1 H, $CH_{PhOH}$), 7.06 (d, $J$ = 7.3 Hz, 1 H, $CH_{PhOH}$), 6.8 (m, 4 H, $H_{Ar}$), 6.70 (s, 2 H, $CH_{Im}$), 3.91 (s, 1 H, $CH_{aminal}$), 3.78 (d, $J$ = 13.3 Hz, 2 H, $CH_2$-Im), 3.51 (d, $J$ = 13.3 Hz, 2 H, $CH_2$-Im), 3.35 (s, 6 H, $CH_3$), 3.05 (m, 2 H, $NCH_2CH_2N$), 2.79 (m, 2 H, $NCH_2CH_2N$) ppm. $^{13}$C NMR (90.6 MHz, $CDCl_3$, 23 °C): $\delta$ = 157.8 ($C_{Ar}$-OH), 144.0 ($C_{quatIm}$), 131.2, 130.4, 119.0, and 116.6 ($C_{PhOH}H$), 127.1 and 121.7 ($C_{Im}H$), 120.6 ($C_{quatPhOH}$), 88.1 ($CH_{aminal}$), 49.6 and 48.0 ($CH_2C_{Im}$, N-$CH_2$-$CH_2$-N), 32.4 (Me) ppm. ES-MS: *m*/*z* (%) 353.4 (100) $[M + H]^+$.

***N*-(2-Hydroxybenzyl)-*N*,*N*′-bis[2-(*N*-methylimidazolyl)methyl]ethane-1,2-diamine (LH):** $NaBH_3CN$ (0.107 g, 1.70 mmol, 1 equiv.) and then $CF_3COOH$ (0.390 g, 340 mL, 3.40 mmol, 2 equiv.) were added to a solution of **3** (0.600 g, 1.70 mmol, 1 equiv.) in absolute ethanol (30 mL). After stirring for 2 h, 1 M NaOH (10 mL) was added and the ethanol was evaporated. $CH_2Cl_2$ (20 mL) was then added and the pH adjusted to 9 by addition of 1 M HCl. The organic phase was decanted and the aqueous phase extracted with $3 \times 20$ mL of $CH_2Cl_2$. The combined organic fractions were concentrated to obtain the product as a yellow oil (0.600 g, quantitative yield). $^1$H NMR (300 MHz,$CDCl_3$, 23 °C): $\delta$ = 7.18 (t, $J$ = 7.5 Hz, 1 H, $H_{Ar}$), 6.92 (d, $J$ = 7.5 Hz, 1 H, $H_{Ar}$), 6.8 (m, 6 H, $H_{Ar}$), 3.74 (s, 2 H, N-$CH_2$-$C_{Ar}$), 3.71, (s, 2 H, N-$CH_2$-$C_{Ar}$), 3.70 (s, 2 H, N-$CH_2$-$C_{Ar}$), 3.58 (s, 3 H, N-$CH_3$), 3.40 (s, 3 H, N-$CH_3$), 2.78 (m, 4 H, $CH_2$-$CH_2$) ppm. $^{13}$C NMR (75.5 MHz, $CDCl_3$, 23 °C): $\delta$ = 157.0 ($C_{Ar}$-OH), 145.1 and 144.7 ($C_{quatIm}$), 130.1, 128.6, 126.3, 122.7, 121.0, 120.7, 118.4, and 116.1 ($C_{Ar}$-H), 123.1 ($C_{quatPhOH}$), 56.1, 51.6, 49.3, 45.4, and 43.4 ($CH_2$), 32.8 and 32.3 (N-$CH_3$) ppm. ES-MS: *m*/*z* (%) 355.3 $[M + H]^+$ (100). IR (KBr pellet): $\tilde{\nu}_{max}$ = 757 ($\delta_{imidazol}$), 1282 ($\nu_{C-O}$), 1454 and 1487 $cm^{-1}$ ($\nu_{C=N}$).

**$[Mn_2(L)_2](PF_6)_2$:** $NEt_3$ (16 mg, 21 μL, 0.155 mmol, 0.5 equiv.) was added to a solution of LH (0.110 g, 0.310 mmol, 1 equiv.) in MeOH (40 mL) and argon was bubbled into the solution to remove $O_2$. A deoxygenated solution of $MnBr_2$ (67 mg, 0.310 mmol, 1 equiv.) in MeOH (10 mL) was added to this mixture and the solution heated at 50 °C for 30 min. A deoxygenated solution of $NH_4PF_6$ (101 mg, 0.621 mmol, 2 equiv.) in methanol (1 mL) was then added and the resulting solution allowed to cool overnight. The complex started to crystallize out of solution, and 92 mg (40% yield) of nearly colorless crystals were isolated by filtration. ES-MS [dilute aqueous solution ($5 \times 10^{-5}$ M and $5 \times 10^{-6}$ M)]: *m*/*z* (%) 408.6 $[(L)Mn]^+$ (100), 353.3 $[LH + H]^+$ (23). The peak separation within the 408.6 mul-

tiplet is +1, which indicates a +1 charge and is consistent with the monometallic species $[(L)Mn]^+$. IR (KBr pellet): $\tilde{\nu}_{max}$ = 760 ($\delta_{imidazol}$), 837 ($PF_6$), 1290 ($\nu_{C-O}$), 1447 and 1484 $cm^{-1}$ ($\nu_{C=N}$). $C_{38}H_{50}F_{12}Mn_2N_{12}O_2P_2$ (1106.7): calcd. C 41.24, H 4.55, Mn 9.93, N 15.19, P 5.60; found C 40.99, H 4.61, Mn 9.36, N 14.98, P 5.48.

**Magnetic Measurements and Fitting Procedures:** Magnetization data were collected for ground crystals with a Quantum Design MPMS5 magnetometer in the 2–300 K temperature region (applied field: 10 kG). The data were corrected for the diamagnetism contributions of the sample and of the cell. At 300 K, $\chi T$ = 8.01 $cm^3 K mol^{-1}$. This value remained constant down to about 50 K upon lowering the temperature and then decreased abruptly to a value of 0.65 $cm^3 K mol^{-1}$ at 2 K. This behavior is indicative of an antiferromagnetic coupling between the two $Mn^{II}$ ions. The experimental data were fitted to the expression for a dinuclear $Mn^{II}$ ($S_1$ = 5/2)–$Mn^{II}$ ($S_2$ = 5/2) complex using the Hamiltonian $H = -JS_1S_2$ (Marquardt algorithm from KaleidaGraph). A $g$-value of 1.94 was obtained from the fitting of $\chi T = f(T)$ at high temperatures. A $J$-value of –0.9 $cm^{-1}$ was obtained by fitting $\chi = f(T)$ using $g$ = 1.94. As shown in Figure 8, a good agreement was obtained for $\mathbf{1}(PF_6)_2$ in the whole temperature range for both $\chi T$ and $\chi$.

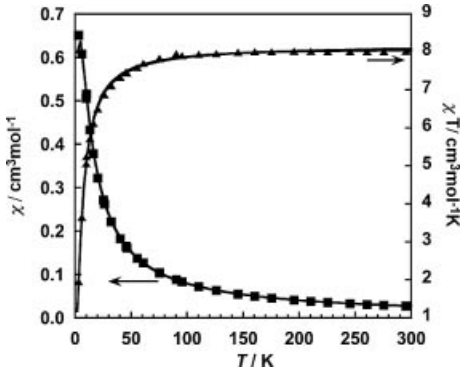

Figure 8. Thermal variation of $\chi T$ (triangles) and $\chi$ (squares) vs. temperature for $\mathbf{1}(PF_6)_2$. For clarity, only 30% of the recorded data are shown. The solid lines correspond to the data calculated with the parameters $g$ = 1.94 and $J$ = –0.9 $cm^{-1}$ with $H = -JS_1S_2$.

**X-ray Crystallography:** X-ray diffraction data for $\mathbf{1}(PF_6)_2$ were collected with a Kappa X8 APPEX II Bruker diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and corrected for Lorentz, polarization, and absorption effects. The structures were solved by direct methods using SHELXS-97[83] and refined against $F^2$ by full-matrix least-squares techniques using SHELXL-97[84] with anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were located on a difference Fourier map and introduced into the calculations as a riding model with isotropic thermal parameters. All calculations were performed with the crystallographic software package WINGX.[85] The crystal data collection and refinement parameters are given in Table 3.

CCDC-622751 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**SOD Activity Measurements:** The assay and controls to ensure reliability were performed as described previously.[24,27] The standard conditions used were: $T$ = 25 °C (potassium phosphate buffer, 50 mM, pH 7.8 or PIPES, 50 mM, pH 7.5),[38] [xanthine] = 200 μM and a quantity of xanthine oxidase ensuring a $\Delta A$ of at least 0.025 $min^{-1}$. The reduction of ferricytochrome c at 550 nm was monitored first in the absence of any putative SOD mimic and then after addition of the mimic. The slope of the line $A_{550nm} = f(t)$ before addition of the SOD mimic is $s_1$ and $s_2$ is the slope after addition of the SOD mimic. $(s_1 - s_2)/s_2$ was plotted against the complex concentration to provide a line and the $IC_{50}$ was then obtained for $(s_1 - s_2)/s_2 = 1$. Experiments were performed in duplicate for each buffer.

[78] It should be noted that the kinetic constant for the reaction between ferricytochrome c in PIPES at pH 7.5 has not been measured, but the fact that the $IC_{50}$ values are very close in PIPES at pH 7.5 and phosphate buffer at pH 7.8 suggests that the $k_{cytC}$ (pH 7.5, PIPES 50 mM, 21 °C) should be very close to that reported in phosphate buffer.

# Cooperative Spin-Crossover Behaviour in Polymeric 1D $Fe^{II}$ Coordination Compounds: $[\{Fe(tba)_3\}X_2]\cdot nH_2O$

**Maksym Seredyuk,[a] Ana B. Gaspar,*[b] M. Carmen Muñoz,[c] Michel Verdaguer,[d] Françoise Villain,[d] and Philipp Gütlich*[a]**

**Keywords:** Spin crossover / Bistability / Cooperative effects / Iron(II) complexes / Substituted triazoles

A new family of 1D cooperative spin-crossover polymers with general formula $[\{Fe(tba)_3\}X_2]\cdot nH_2O$ [tba = *N*-(4*H*-1,2,4-triazol-4-yl)benzamide; X = $CF_3SO_3^-$, *n* = 2 (**1**), *n* = 0 (**4**); $BF_4^-$, *n* = 3 (**2**), *n* = 0 (**5**); 4-$CH_3C_6H_4SO_3^-$, *n* = 3 (**3**), *n* = 0 (**6**)] has been synthesised and characterised using a series of spectroscopic methods, X-ray powder diffraction, magnetic susceptibility measurements and differential scanning calorimetry. The copper analogue of **1**, $[\{Cu(tba)_3\}(CF_3SO_3)_2]\cdot 3H_2O$ (**7**), has also been synthesised and its crystal structure solved at 293 K. Compound **7** crystallises in the $P\bar{1}$ space group. The bidentate *N*-(4*H*-1,2,4-triazol-4-yl)benzamide ligand bridges the copper ions through the 1,2-nitrogen positions leading to a one-dimensional infinite polymer. The EXAFS data collected at 80 K for **1** agree perfectly with a linear chain structure, as observed for **7**, with $[Fe(tba)_3]$ chromophores linked to each other through the adjacent nitrogen atoms of three *N*-(4*H*-1,2,4-triazole-4-yl)benzamide ligands. IR spectroscopic studies confirm the retention of the $C_{2v}$ symmetry for the triazole rings in **2** and **3**, thereby suggesting a similar chainlike arrangement in these compounds. Compound **1** is low spin (LS) at room temperature while **2** and **3** are high spin (HS). The latter two complexes undergo cooperative thermal spin transition at $T_c\downarrow$ = 250 and $T_c\uparrow$ = 258 K in **2** and $T_c\downarrow$ = 226 and $T_c\uparrow$ = 238 K in **3**. The spin transition in **2** and **3** is accompanied by a change of colour from white in the HS state to violet in the LS state. The thermodynamic parameters associated with the spin transition estimated from DSC measurements are $\Delta H$ = 17.8 (**2**) and 14.6 kJ mol$^{-1}$ (**3**), and $\Delta S$ = 67.2 (**2**) and 63.5 J K$^{-1}$ mol$^{-1}$ (**3**). In contrast, the dehydrated compounds **4**, **5** and **6** show very different spin-transition behaviour. Complex **4** exhibits an abrupt spin transition centred at room temperature and is accompanied by a relatively large hysteresis loop with a width of 25 K ($\Delta H$ = 19.7 kJ mol$^{-1}$ and $\Delta S$ = 65.6 J K$^{-1}$ mol$^{-1}$). Like **2** and **3**, **4** shows a dramatic colour change upon the spin transition. Complex **5** shows a continuous and incomplete spin transition, and **6** is HS over the whole temperature range investigated (10–400 K).

## Introduction

Spin crossover (SCO) has turned out to be a particularly appealing phenomenon as it offers one of the best examples of molecular bistability. This reversible change between low-spin (LS) and high-spin (HS) states driven by variation of temperature and/or pressure or also by light irradiation is mainly observed in pseudo-octahedral iron(II) coordination complexes. SCO compounds have distinct magnetic and optical properties, dielectric constant, colour and structure in the HS and LS states. These properties may be altered drastically in a narrow temperature range for cooperative transitions.[1–4] Furthermore, hysteresis accompanies a first-order spin transition (ST) when the structural changes are transmitted cooperatively throughout the whole solid.

SCO materials are potentially useful for rewritable optical, thermal or pressure memories at a nanometric scale due to their switching properties.[5–7] The necessary conditions that an SCO material must fulfil for the construction of devices for thermal displays or recording data include abruptness of spin transition with hysteresis, room-temperature operation, change of colour and chemical stability. Prototypes of thermal displays based on the 1D SCO polymeric systems $[Fe(4\text{-}Rtrz)_3](ClO_4)_2$, $[Fe(4\text{-}R^1trz)_{3-3x}(4\text{-}R^2trz)_{3x}](A)_2\cdot nH_2O$ and $[Fe(4\text{-}Rtrz)_3](A^1{}_{1-x}A^2{}_x)_2\cdot nH_2O$ (4-Rtrz = 4-substituted-1,2,4-triazole), where $x \leq 1$ and $n \geq 0$, have been described.[6,7] These salts, and their closely related

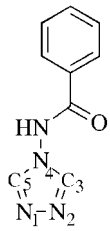
analogs $[Fe(Htrz)_3](A)_2$, have been subjected to intense studies because of their interesting properties.[8] Similarly, 4-substituted triazole ligands like 4-amino-1,2,4-triazole,[9] 4-(2′-hydroxyethyl)-1,2,4-triazole (hyetrz),[10] 4-*n*-alkyl-1,2,4-triazoles[11] and 4-(3′-hydroxypropyl)-1,2,4-triazole (hyptrz)[12] have also afforded interesting 1D SCO polymers. This family of polymeric compounds has recently been reviewed.[13] Several of the polymers belonging to this family undergo cooperative SCO at close to room temperature with large hysteresis loops. Furthermore, these materials display dramatic changes in colour from purple to white upon spin transition LS↔HS, which makes them particularly attractive for memory and sensor devices.[6,7] Other groups linked to the 4-substituted triazole ligands have yielded 1D SCO polymers exhibiting liquid-crystal properties,[14] Langmuir–Blodgett films showing spin transition and SCO gels.[15b,15c] Two more kinds of one-dimensional (1D) $Fe^{II}$ SCO compounds can be distinguished depending on the nature of the N-donating groups involved in the bridges, namely those bearing tetrazole[13,16,17] or pyridine groups.[18–21]

In our search for new SCO systems, and in light of the suitability of triazole-based ligands for achieving cooperative spin transitions, we chose the ligand *N*-(4*H*-1,2,4-triazol-4-yl)benzamide (tba). Herein we present the synthesis and physical characterisation by means of magnetic susceptibility measurements, Mössbauer spectroscopy, differential scanning calorimetry, EXAFS and XRD analysis of a new family of 1D spin crossover polymers with general formula $[\{Fe(tba)_3\}X_2]\cdot nH_2O$ [Scheme 1; X = $CF_3SO_3^-$, $n$ = 2 (**1**), $n$ = 0 (**4**); $BF_4^-$, $n$ = 3 (**2**), $n$ = 0 (**5**); 4-$CH_3C_6H_4SO_3^-$, $n$ = 3 (**3**), $n$ = 0 (**6**)]. The copper analogue $[\{Cu(tba)_3\}(CF_3SO_3)_2]\cdot 3H_2O$ (**7**) has also been synthesised and its crystal structure solved at 293 K.



Scheme 1. Ligand *N*-(4*H*-1,2,4-triazol-4-yl)benzamide (tba).

## Results and Discussion

### Crystal Structure of $[\{Cu(tba)_3\}(CF_3SO_3)_2]\cdot 3H_2O$ (7)

As discussed in the Experimental Section, all attempts to obtain single crystals of the $[\{Fe(tba)_3\}X_2]\cdot nH_2O$ compounds were unsuccessful. However, it proved possible to obtain single crystals of the copper analog $[\{Cu(tba)_3\}(CF_3SO_3)_2]\cdot 3H_2O$ (**7**). X-ray diffraction data were collected at 293 K and the structure was solved by direct methods using SHELXS-97[22] and refined by full-matrix least squares on $F^2$ using SHELXL-97. Due to the medium quality of the single crystals it was not possible to decrease the *R* factor of the structure below 0.1749. The powder diffraction pattern of **7** was collected at 293 K, where it matches exactly that calculated from the single crystal data (Figure S1, Supporting Information). Compound **7** crystallises in the triclinic space group $P\bar{1}$. The crystallographic data are provided in the Experimental Section and a selection of bond lengths and angles is given in Table 1. Figure 1 displays a fragment of the 1D polymer **7** together with the corresponding atom-numbering scheme. The unit cell contains four crystallographically independent copper ions with an occupancy factor of 0.5 for Cu1 and Cu4, nine tba

Table 1. Selected bond length [Å] and angles [°] for **7** at 293 K.

ligands, six $CF_3SO_3^-$ anions and nine water molecules. The bidentate *N*-(4*H*-1,2,4-triazol-4-yl)benzamide ligand bridges the copper ions through the 1- and 2-nitrogen atoms to form a one-dimensional infinite polymer. Each $Cu^{II}$ ion is coordinated to six N atoms belonging to six tba ligands with pseudo-octahedral symmetry, as indicated by the bond lengths and angles (Table 1). The axial bond lengths are notably larger than the equatorial ones due to the Jahn–Teller distortion, which are in the range 2.242(10)–2.351(10) Å for the four $Cu^{II}$ ions. The average $Cu^{II}$–N bond length is 2.134, 2.154, 2.143 and 2.135 Å for Cu1, Cu2, Cu3 and Cu4, respectively. The Cu–Cu distance through the tba bridge is 3.8915(12) Å. These structural parameters are similar to those observed previously for other $Cu^{II}$-triazole systems.[23]

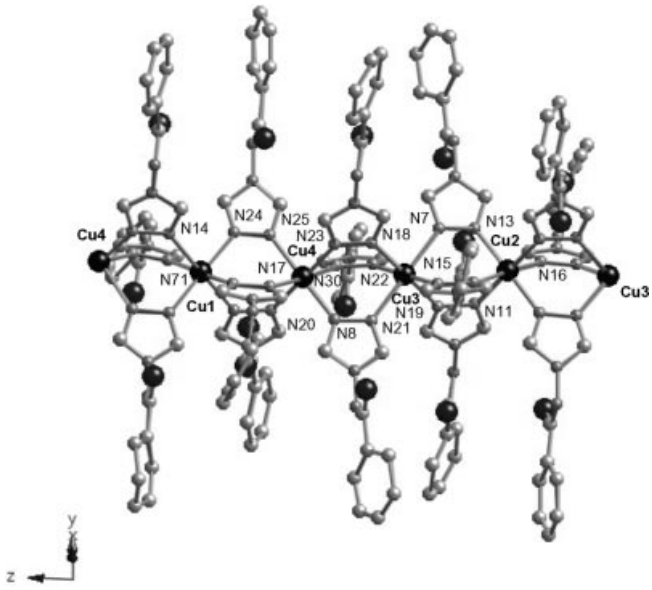

Figure 1. Fragment of the 1D polymer **7** together with the corresponding atom numbering scheme.

Figure 2 illustrates the crystal packing of **7** in the *xy* plane. The molecular crystal packing of **7** can be described as an infinite hexagonal array of $[Cu(tba)_3]^{2+}$ linear chains along the *z* direction, with water molecules and $CF_3SO_3^-$ counterions in the vacancies. The distance between the $Cu^{II}$ linear chains is 17.816(2) Å. There are no intermolecular interactions between the chains through the phenyl group of the tba ligands or between the counterions, the water molecules and the tba ligands. The shortest distance between the carbon atoms of two phenyl groups belonging to adjacent chains is 5.219(2) Å. The water molecules are located around the $Cu^{II}$ linear chain at a distance to the $Cu^{II}$ ion between 4.509(2) and 4.951(2) Å.

## X-ray Powder Diffraction of Compounds 1–3 and 7

X-ray powder patterns of **1**–**3** and **7** were recorded at 293 K (Figure 3). Only two compounds have similar profiles, namely compounds **1** and **7**, where small discrepancies between weak peaks can be interpreted as being due to the hydration numbers of both compounds. The profiles of compounds **2** and **3** are not similar and therefore they are not isostructural with **1**. Only two intense peaks located at about the same values (5–6° and 23–24°) were found to be common to all the patterns. This, together with the fact that similar patterns are only found for the triflate complexes of iron(II) and copper(II), shows that, although a chain structure seems to be present in all of these compounds, the dif-

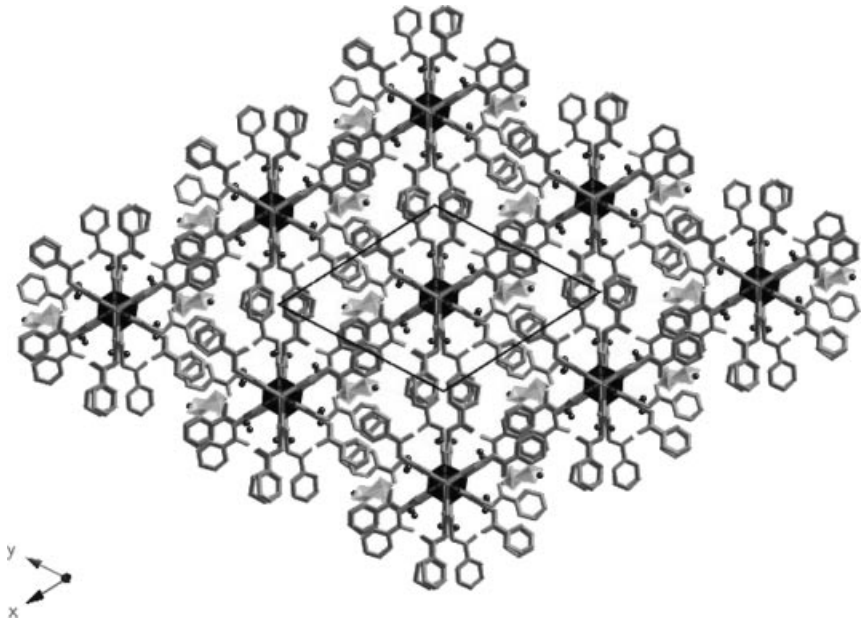

Figure 2. View of the crystal packing of compound **7** in the *xy* plane depicting the packing of the $CF_3SO_3^-$ anions (light grey polyhedra) and water molecules (black spheres) between the cationic linear chains.

ferent packing and lattice arrangements caused by the different nature of the anions yield completely different crystallographic patterns.[24]

### IR Spectroscopic Studies of 1–3 and 7

Information about the coordination modes of tba in complexes **1**–**3** and **7** can be derived directly from the room-temperature IR spectra. The intense peaks located at 627, 625, 625 and 628 $cm^{-1}$ for **1**–**3** and **7**, respectively, correspond to torsion vibrations of the triazole rings coordinated in a bridging fashion through N(1) and N(2) (Scheme 1) to neighbouring $Fe^{II}$ or $Cu^{II}$ ions.[25a] The band at 1207 $cm^{-1}$ assigned to the exocyclic N–N bond stretching in uncoordinated tba ligand should be shifted to higher frequency upon bidentate coordination. Indeed, the value of this band in the linear coordination polymers is typically 15–30 $cm^{-1}$ higher than in the free ligand[25b] (1228, 1222, 1223 and 1227 $cm^{-1}$ for compounds **1**–**3** and **7**, respectively). These findings confirm the one-dimensional polymeric organisation of **1** and **7** and strongly suggest the same for compounds **2** and **3**.

### EXAFS and XANES Characterisation of Compound 1

The normalised XANES spectrum of **1** recorded at 80 K is typical for an octahedral complex of iron(II) (Figure 4a). It includes absorption in the pre-edge region P assigned to the symmetry-forbidden electronic dipolar 1s→3d transition.[26] The first strong absorption (peak A) is located at 7130 eV and can be attributed to a metal 1s→4p dipole-allowed transition.[26] Further intense shoulders B and M with energies of 7142 and 7154 eV, respectively, are caused by multiple electron-scattering processes.[27] Finally, absorp-

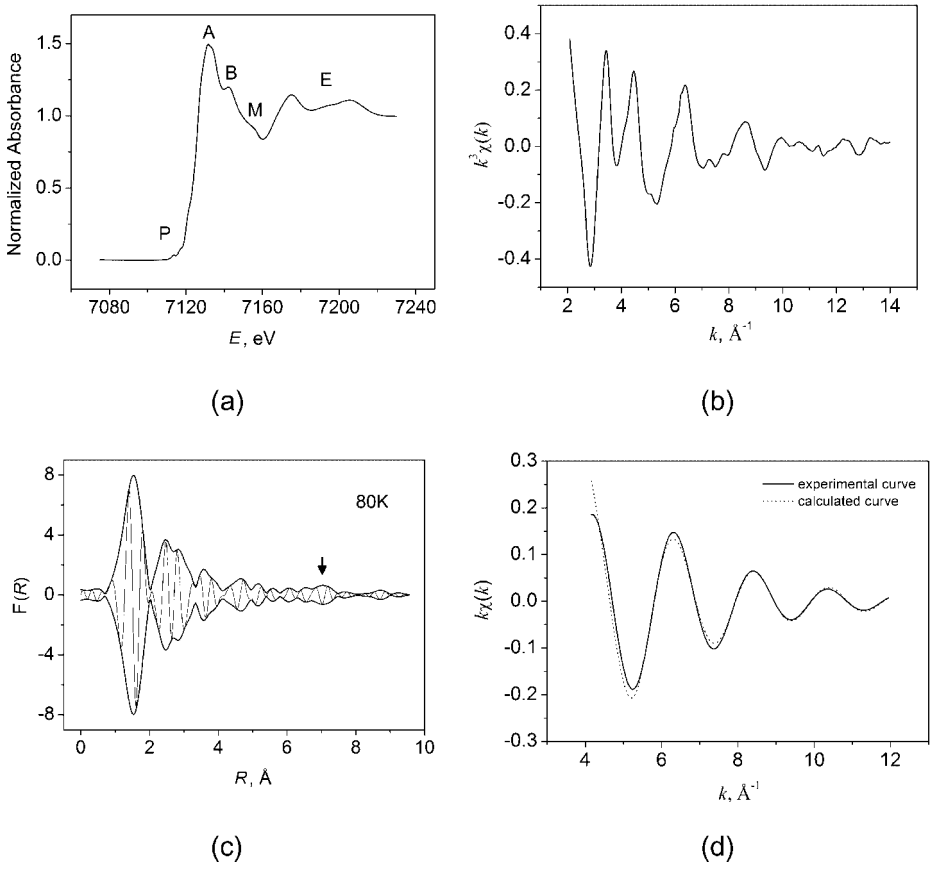

Figure 4. (a) XANES spectrum of complex **1** at 80 K. P: pre-edge; A: top of the edge; B and M: shoulders; E: EXAFS oscillations. (b) $k^3\chi(k)$ spectrum of complex **1**. (c) Fourier transforms of the EXAFS spectrum of complex **1** at 80 K including the modulus and imaginary parts. The arrow indicates the peak at about 7 Å that corresponds to the multiple scattering path Fe–Fe–Fe.  © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

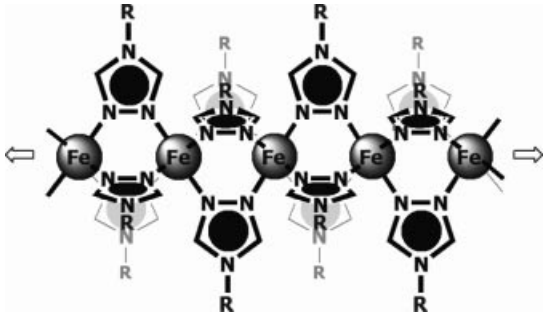
tion E is at the frontier of the XANES and EXAFS regions and, for such molecular systems, is mainly determined by scattering processes inside the first coordination shell. The EXAFS oscillation positioned at relatively high energy (7205 eV) confirms the low-spin character of the iron centre.

The EXAFS spectrum of **1** measured at 80 K is shown in Figure 4b, with its Fourier transform displayed in Figure 4c. The EXAFS signal provides direct information about the radial distribution of the backscattering atoms around the absorbing atom. Similar materials have been investigated by means of EXAFS analysis in previous studies and their linear local structure deduced.[28–30] The complex shown in Scheme 2 is composed of triazole moieties and iron(II) ions arranged in a one-dimensional fashion, with the N–N groups of the triazoles bridging adjacent metal centres. The spectrum at 80 K consists of five main peaks (Figure 4c). The first intense peak at 1.53 Å can be attributed to the first coordination shell $N_6(1)$ of the iron ion. The peak value is located at a short distance, thus clearly indicating the LS state. Several peaks are distinguishable in the region between 2 and 4 Å. These correspond to several kinds of distances such as Fe–N(2), C(5), Fe–N(3), C(4) (Scheme 1), and Fe with its two nearest Fe neighbours.[28] According to a previous study,[29] the peak at about 7.0 Å for the LS triazole-based complexes is ascribed to the Fe–Fe–Fe alignment, the intensity of which is strongly enhanced due to the multiple-scattering focusing effect of the collinearly arranged Fe chains.[28] The presence of this peak provides confirmation of the polymeric structure of **1**.



Scheme 2. Drawing of the linear chain structure of $[Fe(R\text{-}trz)_3]^{2+}{}_\infty$.

A curve-fitting analysis was performed for the first coordination sphere of iron (Figure 4d). The fitting variables were the Fe–N distance $R$, the edge energy shift $\Delta E_0$ and the Debye–Waller factor $\sigma$; the coordination number $N$ was fixed to 6. The obtained values were $R$ = 1.96 Å, $\Delta E_0$ = 1.8 eV, $\sigma$ = 0.068 Å with goodness of fit $\rho$ = 1.2%. The value of the Fe–N contact distance is in good agreement with previously reported data for the same type of compounds.[28,30]

## Magnetic Properties of Compounds 1–6

The magnetic data expressed in the form of $\chi_M T$ vs. $T$ plots, where $\chi_M$ is the molar magnetic susceptibility and $T$ the temperature, are shown in Figure 5 for compounds **1**–**6**. The temperature dependence of the magnetic susceptibility was recorded at a rate of 2 K min$^{-1}$. Compound **1** is in the LS configuration at 290 K, as shown by the low $\chi_M T$ value. Upon heating, $\chi_M T$ increases abruptly, reaching a value of 3.29 cm$^3$ K mol$^{-1}$ at 400 K. TGA experiments have shown that dehydration takes place in the same temperature region where the change of spin state occurs (Figure S2, Supporting Information). The dehydration and change of spin state take place in two distinct steps. A synergy between dehydration and spin-state change, as observed in this material, has been reported in several other cases.[1,6,14]

The $\chi_M T$ value for compound **2** at 330 K is 3.41 cm$^3$ K mol$^{-1}$, which falls into the range of values expected for an $Fe^{II}$ compound in the high-spin configuration. This value decreases abruptly at around 260 K as a conse-

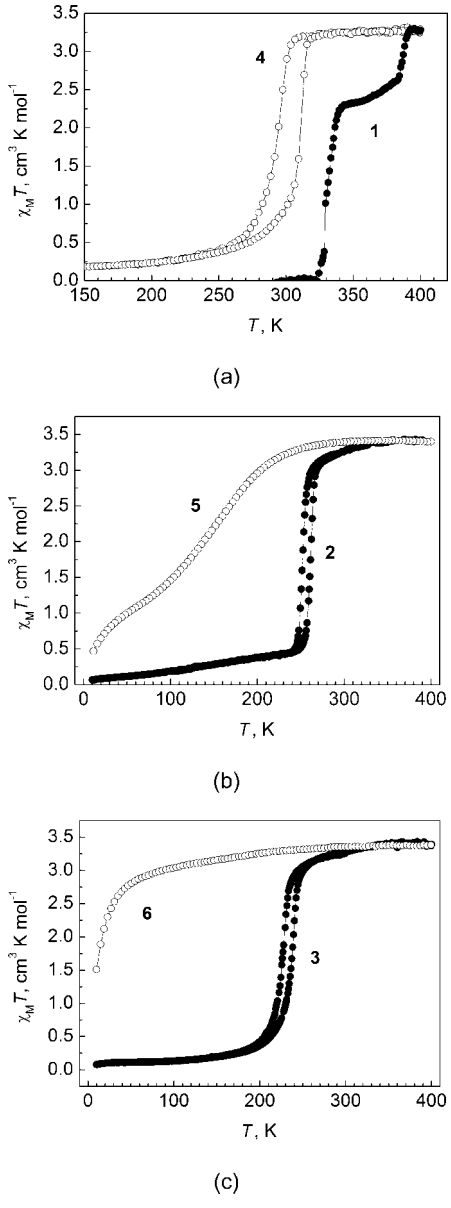


Figure 5. Magnetic properties of compounds **1**–**6** in the form of $\chi_M T$ vs. $T$ plots.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

quence of a spin transition, reaching a value of 0.43 $cm^3 K mol^{-1}$ at 230 K ($T_c\downarrow$ = 250 K). The transition is complete at this temperature as the magnetic susceptibility decreases only very gradually down to 0.07 $cm^3 K mol^{-1}$ at 10 K, thus indicating that almost all the $Fe^{II}$ ions are in the LS state. In the warming mode, the measurement reveals a hysteresis width of 8 K ($T_c\uparrow$ = 258 K).

Like **2**, compound **3** undergoes an abrupt spin transition, although at lower temperatures ($T_c\downarrow$ = 226 and $T_c\uparrow$ = 238 K). The $\chi_M T$ value for **3** at 290 K is 3.30 $cm^3 K mol^{-1}$, which diminishes slightly on lowering the temperature to 250 K (3.07 $cm^3 K mol^{-1}$). $\chi_M T$ falls to 0.65 $cm^3 K mol^{-1}$ upon further cooling as a consequence of a change of spin state of approximately 90% of the $Fe^{II}$ ions. The $\chi_M T$ value at 145 K is 0.19 $cm^3 K mol^{-1}$, which corresponds to about 95% LS $Fe^{II}$.

The magnetic properties of the dehydrated complexes **4**–**6** were also investigated (Figure 5). Dehydration of these complexes is complete at 400 K (Figure S2, Supporting Information). The samples were therefore heated from 300 to 400 K and then kept at this temperature for 15 min in the SQUID magnetometer. Subsequently, the magnetic susceptibility of the dehydrated samples was recorded from 400 K down to 10 K and again up to 400 K. Compound **4** exhibits an abrupt spin transition centred at room temperature. The $\chi_M T$ value at 400 K is 3.28 $cm^3 K mol^{-1}$, which remains practically constant down to the vicinity of $T_c\downarrow$. $\chi_M T$ diminishes suddenly at 300 K, reaching a value of 0.39 $cm^3 K mol^{-1}$ at 250 K and 0.090 $cm^3 K mol^{-1}$ at 10 K. The critical temperatures in the cooling and warming mode ($T_c\downarrow$ and $T_c\uparrow$) are 284 and 309 K, respectively. It is worthwhile mentioning the relatively large hysteresis width of 25 K that accompanies the spin transition in **4**. The reproducibility of the thermal hysteresis loops in **2**–**4** was confirmed, and they are perfectly reproducible after two or three cooling/warming cycles. Moreover, the spin transition in **2**–**4** is accompanied by a change of colour from white (HS state) to violet (LS state).

Compound **5** exhibits a very gradual and incomplete spin transition. The $\chi_M T$ value at around 400 K shows that all molecules are in the HS state (3.41 $cm^3 K mol^{-1}$). This value remains practically constant down to 250 K, where the HS→LS transition sets in. A further decrease of the temperature gives rise to a progressive decrease of the magnetic susceptibility due to a spin transition of approximately 50% of the $Fe^{II}$ ions. This spin transition is kinetically blocked below 70 K, and the decrease of $\chi_M T$ below this temperature is due most probably to zero-field splitting (ZFS) of the 50% of $Fe^{II}$ ions that remain in the HS state ($S$ = 2). The temperature dependence of the magnetic susceptibility of compound **6** shows a high spin behaviour over the whole temperature range under study (10–400 K). The $\chi_M T$ value at 400 K is 3.38 $cm^3 K mol^{-1}$ and remains constant down to 100 K, where it diminishes most probably due to ZFS.

A weak antiferromagnetic coupling between high-spin iron(II) ions for **5** and **6** cannot be excluded from this explanation. This could, in part, also be responsible for the decrease of the susceptibility on lowering the temperature since a similar behaviour has been found in the triazole-based copper analogue **7** (Figure S3, Supporting Information) as well as in another copper-based triazole polymer.[23a]

### Mössbauer Spectroscopy of Compounds 1–4

Table 2 collects the Mössbauer parameter values and percentages of populations in the HS and LS states for compounds **1**–**4** recorded at different temperatures. The Mössbauer spectrum of compound **1** was recorded at 80 K (Figure 6a). This spectrum clearly indicates the presence of only one slightly asymmetrical doublet characterised by an isomer shift and a quadrupole splitting typical of LS iron(II), which matches the data from the magnetic measurements of **1**. The Mössbauer spectrum of **4** recorded at 80 K shows a doublet with parameters typical for HS iron(II) (Table 2), the intensity of which increases dramatically upon heating up to 330 K. The spectrum also reveals the presence of LS $Fe^{II}$ ions, thereby confirming the incomplete character of the spin transition.

Table 2. Mössbauer parameters ($IS$ and $\Delta E_Q$) for **1**–**4** at different temperatures.

| | $T$ [K] | Spin state | $IS$ [mm $s^{-1}$] | $\Delta E_Q$ [mm $s^{-1}$] | $A$ [%] |
|---|---|---|---|---|---|
| **1** | 80 | d, LS | 0.49(0) | 0.23(1) | 100 |
| **2** | 80 | d, LS | 0.51(0) | 0.27(0) | 97 |
| | | d, HS | 1.22(0) | 3.40(0) | 3 |
| | 290 | d, LS | 0.29(0) | 0.15(0) | 3 |
| | | d, HS | 1.04(0) | 2.80(1) | 97 |
| **3** | 145 | d, LS | 0.52(1) | 0.28(1) | 95 |
| | | d, HS | 1.15(1) | 3.35(0) | 5 |
| | 290 | d, LS | 0.40(1) | 0.14(0) | 8 |
| | | d, HS | 1.05(0) | 2.85(1) | 92 |
| **4** | 80 | d, LS | 0.51(0) | 0.25(1) | 95 |
| | | d, HS | 1.17(1) | 3.29(0) | 5 |
| | 330 | d, LS | 0.32(0) | 0.20(0) | 14 |
| | | d, HS | 1.02(0) | 2.71(1) | 86 |

The Mössbauer spectra of **2** were recorded above and below $T_c$ (Figure 7a). The spectrum at 290 K shows mainly a doublet characteristic of the HS state of $Fe^{II}$. The Mössbauer spectrum recorded at 80 K clearly evidences the change of spin state. After cooling, the HS doublet almost disappears and the LS fraction increases significantly. Like the magnetic measurements, the Mössbauer analysis proves that almost 100% of the $Fe^{II}$ ions undergo a spin transition in **2**.

The Mössbauer spectra of **3** were recorded at 290 and 145 K (Figure 7b). Two doublets are observed at 290 K corresponding to the HS and LS states of the $Fe^{II}$ ions. The analysed spectrum at 290 K yields a relative population of 95% HS and 5% LS states. There is a clear inversion of the population distribution at 145 K due to spin transition: practically all the $Fe^{II}$ ions are in the LS state at this temperature (92%). The Mössbauer spectral analyses of **1**–**4** agree well with the above reported magnetic properties.

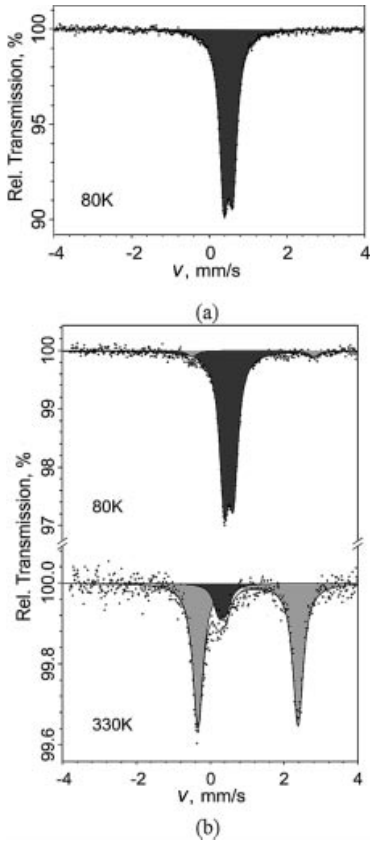

Figure 6. (a) Mössbauer spectrum of **1** at 80 K. (b) Mössbauer spectra of **4** recorded at 80 and 330 K. Dark grey corresponds to the LS doublet; light grey corresponds to the HS doublet.

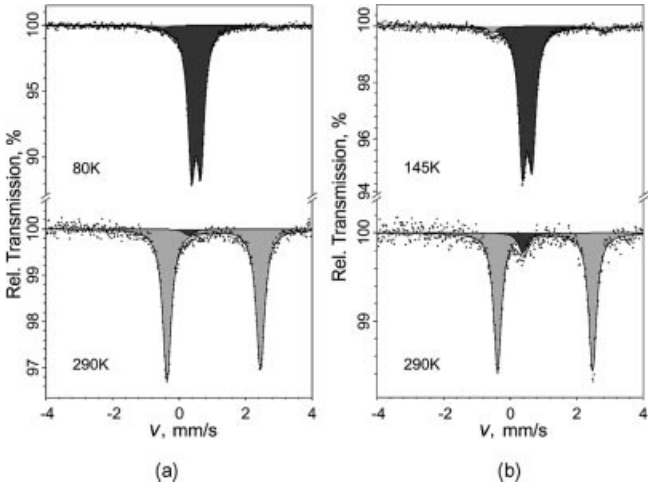

Figure 7. (a) Mössbauer spectra of **2** at 80 and 290 K. (b) Mössbauer spectra of **3** recorded at 145 and 290 K. Dark grey corresponds to the LS doublet; light grey corresponds to the HS doublet.

## Differential Scanning Calorimetry of Compounds 2–4

The differential scanning calorimetric measurements were carried out in the 175–400 K temperature range at a rate of 7 K min$^{-1}$. The temperature dependence of the heat flow in the heating and cooling modes for **2**–**4** is shown in Figure 8. The anomalies in the heat flow for compound **2** appear in the cooling mode at $T_c\downarrow$ = 240 and $T_c\uparrow$ = 252 K in the warming mode, thus indicating the occurrence of a hysteresis with a width of 12 K. These values agree reasonably well with those observed from the $\chi_M T$ vs. $T$ plot. Compounds **3** and **4** exhibit anomalies in the heat flow at $T_c\downarrow$ = 226 and $T_c\uparrow$ = 238 K and $T_c\downarrow$ = 290 and $T_c\uparrow$ = 310 K, respectively, which match reasonably well with the reported magnetic data. The small differences in critical temperatures between the DSC and magnetic data are due to the different heating/cooling rates used in the experiments. Table 3 summarises the derived thermodynamic pa-

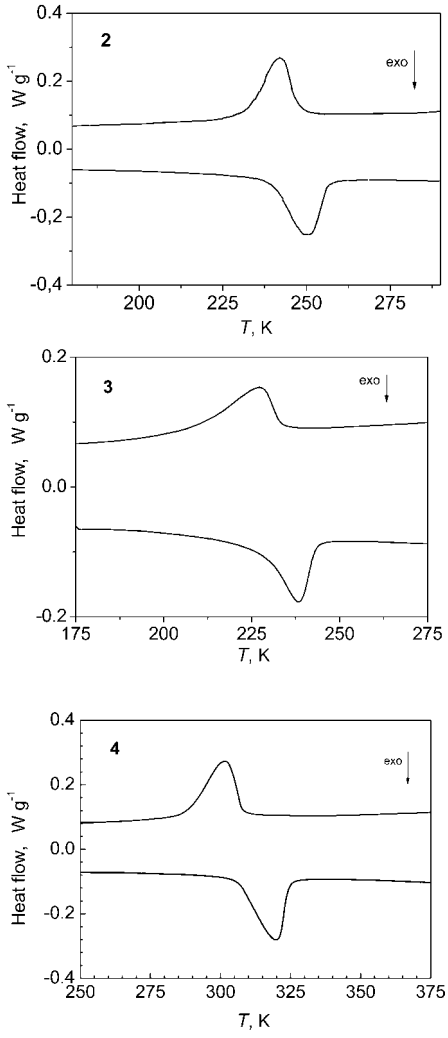

Figure 8. DSC data of complexes **2**–**4** in the warming and cooling modes recorded at a rate of 7 K min$^{-1}$.

Table 3. Thermodynamic parameters ($\Delta H$ and $\Delta S$) for compounds **2**–**4**.

| | $\Delta H$ [kJ mol$^{-1}$] | $\Delta S$ [J K$^{-1}$ mol$^{-1}$] |
|---|---|---|
| **2** | 17.8 | 67.2 |
| **3** | 14.6 | 63.5 |
| **4** | 19.7 | 65.6 |

rameters $\Delta H_{SCO}$ and $\Delta S_{SCO}$ for the compounds **2**–**4**; the values obtained are in the range of values expected for $Fe^{II}$ SCO compounds.[1,31,32]

## Discussion

The linear chain structure of compound **1** has been convincingly derived from EXAFS data, thereby confirming the collinear alignment of the metal ions within the polymeric aggregates formed by alternating triazole bridges. Moreover, the crystal structure of the analog $[\{Cu(tba)_3\}(CF_3SO_3)_2]\cdot 3H_2O$ (**7**) confirms the structural features of **1** due to the almost identical powder XRD profiles of these two complexes. The fact that the powder X-ray patterns of **2** and **3** are not similar to those of **1** and **7** does not rule out a similar structure for these complexes as different packing and lattice arrangements would yield different crystallographic patterns even for similar linear chain structures. The final evidence for the similar structural organisation in **1**–**3** and **7** is provided by IR spectroscopy, namely by the absorption bands assigned to the vibrations of the bridging triazole rings featuring $C_{2v}$ symmetry.

The new family of chainlike 4-substituted-1,2,4-triazole $Fe^{II}$ compounds $[\{Fe(tba)_3\}X_2]\cdot nH_2O$ presents similar SCO characteristics to other complexes reported previously.[6–13] Three main influences have been reported to play a crucial role in the spin transition and its characteristics in these compounds: (i) the water content in the crystal lattice,[4,10] (ii) the chemical nature and size of the 4-R substituents[11] and the counterions,[12] and (iii) the length of the polymeric chains.[24a] Stabilisation of the low-spin state by interaction with lattice water molecules has frequently been observed for $Fe^{II}$ SCO compounds, particularly for polymers based on a triazole bridge.[1,13] This is also the case for compound **1**, which loses its lattice water upon heating and undergoes an abrupt change from the LS to the HS state. When the dehydrated material **4** is cooled, an abrupt HS→LS transition occurs at $T_c\downarrow$ = 284 K ($T_c\uparrow$ = 309 K). Subsequent reheating reveals a hysteresis loop of 25 K width centred at room temperature. The length of the chains has been found to be critical for the observation of cooperative and complete spin transition in such triazole polymers.[6–13] The longer the chains are the lower is the residual HS fraction. The Mössbauer spectrum of compound **4** at 80 K clearly denotes the completeness of the spin transition in this complex, with almost all iron(II) ions in the LS state. For compound **1**, the Mössbauer spectrum recorded at 80 K shows that all iron(II) ions are in the LS state. These facts, together with the observation that all water molecules are removed below 400 K (lattice water), allow us to rule out the possibility of having water coordinated to the outer iron(II) ions of the polymeric chains in **1** and **4**. It is therefore likely that the end groups are monocoordinated tba ligands. Taking into account that the spin-transition properties and thermodynamic parameters of **4** are similar to those observed in $[Fe(Htrz)trz](BF_4)$, one could suggest a similar average chain size for both compounds (around 13 nm).[24a]

Compounds **2** and **3** undergo abrupt spin transitions at 258 and 238 K, respectively, both with a hysteresis width of about 10 K. A similar cooperative spin transition has also been observed for $[Fe(fatrz)_3](X)_2\cdot nH_2O$[24a] and $[Fe(4\text{-}n\text{-alkyl-trz})_3](X)_2\cdot nH_2O$.[11] The estimated average chain size in these compounds is 7 nm.[24] Mössbauer spectra recorded for compounds **2** and **3** at liquid-nitrogen temperature indicate that almost all $Fe^{II}$ ions are in the LS state, with a small residual HS fraction. A very different temperature-dependent magnetic behaviour is observed for the corresponding dehydrated compounds **5** and **6**. Thus, complex **5** presents a continuous and incomplete spin transition at $T_{1/2} \approx 100$ K, while **6** shows a paramagnetic behaviour over the whole temperature range studied (10–400 K). These results demonstrate that the water contained in the lattices of these compounds plays a dominant role in the SCO behaviour.

## Conclusion

The present family of polymeric 4-R-substituted triazole $Fe^{II}$ compounds adds new examples to the richness of spin-transition properties of triazole-based polymers. These materials have been suggested to have possible applications as optical sensors by virtue of their thermochromic properties. Indeed, compound **1** represents a new example of a material with potential applications as a temperature threshold optical indicator. As compound **4** is stable at ambient conditions, however, **1** can only be used as a "single-shot" indicator. On the other hand, compound **4** could be used for thermal displays or recording data as it fulfils the necessary conditions (abruptness, hysteresis, room-temperature operation, change of colour and chemical stability). Compounds **2** and **3** could be useful in another temperature range of operation, namely the freezing-water region.

## Experimental Section

**Synthesis of Materials:** Starting reagents and solvents were obtained commercially from Aldrich and used as received.

**Measurements:** FTIR spectra (KBr pellets) were recorded with a Bruker Tensor 27 spectrometer in the range of 400–4000 $cm^{-1}$. Elemental analyses were performed with a Vario EL Mikro Elementaranalysator. NMR spectroscopic measurements were performed with a Bruker DRX 400 spectrometer.

***N*-(4*H*-1,2,4-Triazol-4-yl)benzamide (tba):** A suspension of 4-amino-4*H*-1,2,4-triazole (4.2 g, 50 mmol) and benzoyl chloride (7.0 g, 50 mmol) in dry pyridine (100 mL) was refluxed for 24 h. The solvents were then removed in vacuo to provide a cream-coloured solid, which was dissolved in hot water (100 mL) and neutralised with sodium hydrogen carbonate until no further effervescence was observed. The white precipitate obtained on cooling was filtered, washed with water and finally recrystallised from ethanol to give 6.48 g of tba (69%). $^1H$ NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 12.1 (br. s, 1 H, N*H*), 8.73 (s, 2 H, CH of trz), 7.89 (dd, $J$ = 1.36, 7.20 Hz, 2 H, ph*H*), 7.61 (tt, $J$ = 1.36, 7.20 Hz, 1 H, ph*H*), 7.52 (t, $J$ = 7.2 Hz, 2 H, ph*H*) ppm. FT-IR (KBr): $\tilde{\nu}$ = 3113 [$\nu$(CH of trz)], 2000–1750 [$\nu$(Ph)], 1674 [$\nu$(C=O)] $cm^{-1}$. $C_9H_8N_4O$ (188.19): calcd.

**General Procedure for the Synthesis of the Iron(II) Salts:** Iron powder was dissolved in an aqueous solution containing a stoichiometric amount of the corresponding acid by heating. The greenish crystalline precipitate that formed upon cooling was filtered off and air-dried to provide the analytically pure salt in quantitative yield.

**$[Fe(CF_3SO_3)_2]·6H_2O$:** FT-IR (KBr): $\tilde{\nu}$ = 3473 [br., ν(O–H)], 1188 [$\nu_a(SO_3^-)$], 1035 [s, ν(C–F)] $cm^{-1}$. $C_2H_{12}F_6FeO_{12}S_2$ (462.06): calcd. C 5.20, H 2.62, S 13.88; found C 5.25, H 2.60, S 13.89.

**$[Fe\{4\text{-}CH_3(C_6H_4)SO_3\}_2]·6H_2O$:** FT-IR (KBr): $\tilde{\nu}$ = 3407 [br., ν(O–H)], 1669 (s), 1496 (s), 813 [s, ν(Ph)], 1190 [s, $\nu_a(SO_3^-)$], 3407 [br., ν(O–H)] $cm^{-1}$. $C_{14}H_{26}FeO_{12}S_2$ (506.32): calcd. C 33.21, H 5.18, S 12.67; found C 33.24, H 4.93, S 13.05.

**General Procedure for the Synthesis of Compounds 1–3 and 7:** A methanolic solution of the $MA_2$ salt (0.53 mmol; M = Cu or Fe; A = 4-$CH_3C_6H_4SO_3^-$, $CF_3SO_3^-$, $BF_4^-$) was added to a hot methanolic solution of *N*-(4*H*-1,2,4-triazol-4-yl)benzamide (0.3 g, 1.6 mmol). The mixture was refluxed for 5 min, then concentrated by concentrating and cooled to room temperature. The resulting precipitate was filtered off and dried in air. The yields of complexes varied in the range 70–85%.

**$[\{Fe(tba)_3\}(CF_3SO_3)_2]·2H_2O$ (1):** FT-IR (KBr): $\tilde{\nu}$ = 3483 [br., ν(O–H)], 2000–1750 [ν(Ph)], 1694 [ν(C=O)], 1269 [$\nu_{as}(SO_3^-)$] $cm^{-1}$. $C_{29}H_{28}F_6FeN_{12}O_{11}S_2$ (954.57): calcd. C 36.49, H 2.96, N 17.61, S 6.72; found C 36.10, H 2.93, N 17.21, S 6.95.

**$[\{Fe(tba)_3\}(BF_4)_2]·3H_2O$ (2):** FT-IR (KBr): $\tilde{\nu}$ = 3491 [br., ν(O–H)], 3127 [$\nu_{as}$(C–H)], 2000–1750 [ν(Ph)], 1688 [ν(C=O)], 1093 [ν(B–F)]. $C_{27}H_{30}B_2F_8FeN_{12}O_6$ (848.06): calcd. C 38.24, H 3.57, N 19.82; found C 38.02, H 3.56, N 19.87.

**$[\{Fe(tba)_3\}(4\text{-}CH_3C_6H_4SO_3)_2]·3H_2O$ (3):** FT-IR (KBr): $\tilde{\nu}$ = 3483 [br., ν(O–H)], 2000–1750 [ν(Ph)], 1694 [ν(C=O)], 1168 [$\nu_{as}(SO_3^-)$] $cm^{-1}$. $C_{41}H_{44}FeN_{12}O_{12}S_2$ (1016.84): calcd. C 48.43, H 4.36, N 16.53, S 6.31; found C 47.61, H 4.50, N 16.20, S 6.65.

**$[Fe(tba)_3](CF_3SO_3)_2$ (4), $[Fe(tba)_3][BF_4]_2$ (5) and $[Fe(tba)_3](4\text{-}CH_3C_6H_4SO_3)_2$ (6):** Compounds **4**–**6** were obtained by heating the hydrated compounds **1**–**3** in an oven at 400 K for 30 min.

**$[\{Cu(tba)_3\}(CF_3SO_3)_2]·3H_2O$ (7):** This complex was recrystallised from hot water by slow cooling in a thermostat overnight to provide blue, needle-like crystals. FT-IR (KBr): $\tilde{\nu}$ = 3480 [br., ν(O–H)], 2000–1750 [ν(Ph)], 1697 [ν(C=O)], 1267 [$\nu_{as}(SO_3^-)$] $cm^{-1}$. $C_{29}H_{32}CuF_6N_{12}O_{13}S_2$ (998.30): calcd. C 34.89, H 3.23, N 16.84, S 6.42; found C 35.03, H 3.11, N 16.55, S 6.24.

**Thermogravimetric Analysis:** TGA measurements were performed with a Mettler Toledo TGA/SDTA 851 in tandem with a mass spectrometer in the 300–680 K temperature range under nitrogen with a heating rate of 10 K $min^{-1}$.

**Differential Scanning Calorimetry:** DSC measurements were performed with a Mettler model DSC 822e calibrated with metallic indium and zinc. The samples were located in sealed sample pans. DSC profiles were recorded at the rate of 7 K $min^{-1}$ and analysed with the Netzsch Proteus software (NETZSCH-Geraetebau GMBH; http://www.e-thermal.com/proteus.htm).

**Magnetic Susceptibility Measurements:** The variable-temperature magnetic susceptibility measurements were performed with a Quantum Design MPMS2 SQUID susceptometer equipped with a 5.5 T magnet at 1 T and 1.8–400 K. Experimental data were corrected for diamagnetism using Pascal's constants.[33]

**Mössbauer Spectroscopy:** Mössbauer spectra were recorded in transmission geometry with a $^{57}Co/Rh$ source kept at room temperature and a conventional spectrometer operating in the constant-acceleration mode. The samples were sealed in a Plexiglass sample holder and mounted in a nitrogen-bath cryostat. The Recoil 1.03a Mössbauer Analysis Software (Dr. E. Lagarec; http://www.isapps.ca/recoil/) was used to fit the experimental spectra.

**X-ray Single-Crystal Crystallographic Study:** Diffraction data for complex **7** were collected with a Nonius Kappa-CCD single crystal diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). A multiscan absorption correction was found to have no significant effect on the refinement results. The structure was solved by direct methods using SHELXS-97 and refined by full-matrix least squares on $F^2$ using SHELXL-97.[22] All non-hydrogen atoms were refined anisotropically. Further details can be found in Table 4. CCDC-636097 contains the supplementary crystallographic data for compound **7**. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 4. Crystal data for **7** at 293 K.

| | |
|---|---|
| Empirical formula | $C_{29}H_{30}CuF_6N_{12}O_{12}S_2$ |
| Formula mass | 980.31 |
| Space group | $P\bar{1}$ |
| *a* [Å] | 17.8020(3) |
| *b* [Å] | 17.8160(4) |
| *c* [Å] | 23.2650(5) |
| *α* [°] | 89.2120(10) |
| *γ* [°] | 60.3130(10) |
| *V* [$Å^3$] | 6371.8(2) |
| *Z* | 6 |
| $D_{calcd.}$ [mg $cm^{-3}$] | 1.533 |
| *F*(000) | 2994 |
| *μ* (Mo-$K_\alpha$) [$mm^{-1}$] | 0.709 |
| Crystal size [mm] | 0.02 × 0.02 × 0.05 |
| Temperature [K] | 293(2) |
| Total reflections | 16963 |
| Reflections [$I > 2\sigma(I)$] | 10839 |
| $R_1$[a] [$I > 2\sigma(I)$] | 0.1749 |
| *wR* | 0.4591 |
| *S* | 1.396 |

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$; $w = 1/[\sigma^2(F_o^2) + (mP)^2 + nP]$ where $P = (F_o^2 + 2F_c^2)/3$, $m$ = 0.2000 and $n$ = 0.0000.

**X-ray Powder Diffraction:** X-ray measurements were obtained with a STOE STADI 2 diffractometer equipped with a linear position-sensitive detector (STOE mini PSD). Monochromatic Cu-$K_\alpha$ radiation was obtained by using a curved germanium detector (111 plane).

**X-ray Absorption Data Recording and Processing:** The Fe K-edge XANES (X-ray absorption near-edge structures) and EXAFS (extended X-ray absorption fine structures) data were taken in the conventional transmission mode on beamline A1 at the German Electron Synchrotron (DESY), Hamburg. The spectrum was recorded from 6970 to 7997 eV. The energy scale at the iron K-edge

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was calibrated with reference to the strong absorption peak of elemental iron at 7111.2 eV. A water-cooled Si(111) channel-cut crystal was employed as a monochromator. The intensities of the incident and transmitted X-rays were recorded using ionisation chambers. The mass of the sample was calculated to obtain a product $a \times d$ of about 2.5 for energies just above the absorption K-edge of iron ($a$ is the linear absorption coefficient and $d$ is the thickness of the pellet). The calculated amount of sample was ground, then mixed with crystalline cellulose and pressed into a pellet of 13 mm diameter and about 1 mm thickness. The temperature of the experiment was 80 K, which was maintained with a closed-cycle He cryostat. The temperature was measured with an Si diode placed close to the sample. The acquisition time for each data point was 1 s. EXAFS data analysis was performed with the program EXAFS98.[34] This standard analysis includes linear pre-edge background removal, a smoothing spline atomic absorption energy-dependent procedure, called Lengeler–Eisenberg EXAFS spectrum normalisation, and reduction from the absorption data $\mu(E)$ to the EXAFS spectrum $\chi(k)$ with

$$k = \sqrt{\frac{2m_e}{(\hbar)^2}(E - E_0)}$$

where $E_0$ is the energy threshold taken at the absorption maximum ($7130 \pm 1$ eV). The radial distribution function $F(R)$ was calculated by Fourier transformation of $k^3 w(k)\chi(k)$ in the 2–14 Å$^{-1}$ range; $w(k)$ is a Kaiser–Bessel apodisation window with smoothness coefficient $\tau = 3$. After Fourier filtering, the first single-shell Fe–$N_6$ was fitted in the 4–12 Å$^{-1}$ range to the standard EXAFS formula, without multiple scattering:

$$k_\chi(k) = -S_0^2 \sum_{i=1,5} \left[ \frac{N_i}{R_i^2} \cdot (F\pi, k) \,|\, e^{-2\sigma^2 k^2} e^{-\frac{2R_i}{\lambda(k)}} \sin(2kR_i + 2\partial_1(k) + \Psi(k)) \right]$$

where $S_0^2$ is the inelastic reduction factor, $N$ is the number of nitrogen atoms at a distance $R$ from the iron centre, $\lambda$ is the mean free path of the photoelectron, $\sigma$ is the Debye–Waller coefficient, characteristic of the width of the Fe–N distance distribution, $\partial_1(k)$ is the central atom phase shift, and $|(F\pi,k)|$ and $\psi(k)$ the amplitude and phase of the nitrogen back-scattering factor, respectively. The curve-fitting analysis for the first coordination sphere of the iron atom was performed with the Round Midnight[35] code after Fourier filtering in the 0.7–2.0 Å range of the EXAFS spectrum with spherical-wave theoretical amplitudes and phase shifts calculated by the McKale[36] code. Since theoretical phase shifts were used, it was necessary to fit the energy threshold $E_0$ by adding an extra fitting parameter, $\Delta E_0$. The goodness of fit was given by:

$$\rho(\%) = \frac{\Sigma[k\chi_{exp}(k) - k\chi_{th}(k)]^2}{\Sigma[k\chi_{exp}(k)]^2}$$

**Supporting Information** (see footnote on the first page of this article): XRD diffraction patterns of **7**, both experimental and calculated from the single crystal data (Figure S1), TGA plots of compounds **1**–**3** (Figure S2), and magnetic properties of compound **7** in the form of a $\chi_M T$ vs. $T$ plot (Figure S3).

## Acknowledgments

We acknowledge financial help from the Deutsche Forschungsgemeinschaft (Priority Program 1137 "Molecular Magnetism"), the Fonds der Chemischen Industrie and the Materialwissenschaftliches Forschungszentrum der Universität Mainz. A. B. G. thanks the Spanish MEC for a Ramón y Cajal research contract and the Alexander von Humboldt Foundation for a fellowship. A. B. G. and M. C. M. thank the Spanish MEC (project CTQ2004-03456-BQU) and the Generalitat Valenciana (ACOMP07/110). We thank Dr. V. Ksenofontov for helpful discussions. We also acknowledge the support of Dr. E. Welter from HASYLab, Dr. H. Ehrenberg and Dominic Stürmer from TU Darmstadt for the EXAFS measurements at beamline A1, the technicians E. Muth and P. Räder from MPI Polymerforschung Mainz for DSC and TGA measurements and A. Michalowicz for providing us with his XAS analysis package.[35]

# Palladium(II) and Nickel(II) Complexes Bearing N,N,O-Chelate Ligands: Syntheses, Characterization and Catalysis in Heck and Kumada Coupling Reactions

**Zhong-Xia Wang*[a] and Zuo-Yun Chai[a]**

**Keywords:** N,N,O ligands / Palladium / Nickel / Chelates / Homogeneous catalysis / C–C coupling

Two new anionic ligands, namely [2-{$OC(Ph)_2CH_2$}-6-(3,5-$Me_2C_3HN_2$)$C_5H_3N$]$^-$ ($L1^-$) and [2-{OC(Ph)=CH}-6-(3,5-$Me_2C_3HN_2$)$C_5H_3N$]$^-$ ($L2^-$), and their palladium and nickel complexes, were synthesized and characterized. 6-(3,5-Dimethyl-1*H*-pyrazol-1-yl)-2-methylpyridine was lithiated with *n*BuLi and the lithiated product treated with benzophenone to give Li(L1) (**2**), whereas treatment of 2-[6-(3,5-dimethyl-1*H*-pyrazol-1-yl)pyridin-2-yl]-1-phenylethanone with NaH afforded Na(L2) (**6**). The palladium and nickel complexes [(L1)PdCl] (**3**), [(L1)NiAr] [Ar = *o*-$MeC_6H_4$ (**4a**), 1-$C_{10}H_7$ (**4b**)], [(L2)PdCl] (**7**) and [(L2)NiAr] [Ar = *o*-$MeC_6H_4$ (**8a**), 1-$C_{10}H_7$ (**8b**)] were obtained by ligand-transfer reactions between Li(L1) or Na(L2) and [$PdCl_2$(PhCN)$_2$] or [$(Ph_3P)_2$Ni(Ar)Cl] (Ar = *o*-$MeC_6H_4$ and 1-$C_{10}H_7$, respectively). These complexes are diamagnetic and were characterized by NMR spectroscopy and elemental analyses. The structures of complexes **4b** and **8a** were determined by single-crystal X-ray diffraction techniques. The catalytic activity of the nickel and palladium complexes in the Heck and Kumada cross-coupling reactions were investigated.

## Introduction

Group 10 metal catalyzed C–C coupling has been recognized as one of the most useful methods for C–C bond formation in organic synthesis and has been well developed over the past decades.[1] The most frequently used cross-coupling reactions include the reactions of alkyl halides or pseudohalides with olefins (Heck reaction) and with nucleophilic organometallic reagents such as Grignard reagents (Kumada reaction), organozinc reagents (Negishi reaction), and organotin (Stille reaction), organoboron (Suzuki reaction), and organosilicon (Hiyama reaction) derivatives.[1] The Heck reaction, which is mainly catalyzed by palladium complexes, is one of the simplest ways to obtain variously substituted olefins, dienes, and other unsaturated compounds.[2] Other transition metals can also catalyze this reaction but they normally exhibit lower catalytic activity. The Kumada reaction, which was the first reported cross-coupling (early 1970s),[3] is still attracting attention over 30 years later. Current investigation focuses mainly on the development of new catalyst systems and extension of this reaction to substrates such as organic chlorides.[4] Complexes of Ni, Pd, Fe, Co, and other transition metals have been used to catalyze this reaction,[1,4,5] although nickel and palladium complexes are the most attractive and intensively studied.

The choice of supporting ligands on the central metal atoms is crucial to the catalytic behavior of the complexes. The most often used ligands, which have achieved great success in catalysts for the Heck and Kumada reactions, are tertiary phosphanes. However, phosphane ligands are often expensive, poisonous, air-sensitive, and prone to degrade at elevated temperatures;[6] therefore the development of phosphane-free ligands is a topic of current interest in this area. A number of phosphane-free ligands have been examined for palladium- and nickel-catalyzed Heck and Kumada couplings, some of which have exhibited excellent behavior.[7] Herein we report the syntheses and characterization of new N,N,O-chelate ligands and their nickel and palladium complexes as well as the catalytic behavior of these complexes in the Heck and Kumada coupling reactions.

## Results and Discussion

### Syntheses and Characterization of Compounds 2–8b

The syntheses of the compounds discussed in this paper are shown in Scheme 1. 2-(3,5-Dimethyl-1*H*-pyrazol-1-yl)-6-methylpyridine (**1**) was prepared by treatment of 2-hydrazino-6-methylpyridine with pentane-2,4-dione in acetic acid according to our previously reported method.[8] Compound **1** was readily lithiated by treatment with LDA and the lithiated product treated with benzophenone to afford [Li{2-[$OC(Ph)_2CH_2$]-6-(3,5-$Me_2C_3HN_2$)$C_5H_3N$}] (**2**) in good yield. Complex **2** proved to be a good ligand-transfer reagent in reactions with [$PdCl_2$(PhCN)$_2$] and [$(Ph_3P)_2$Ni-

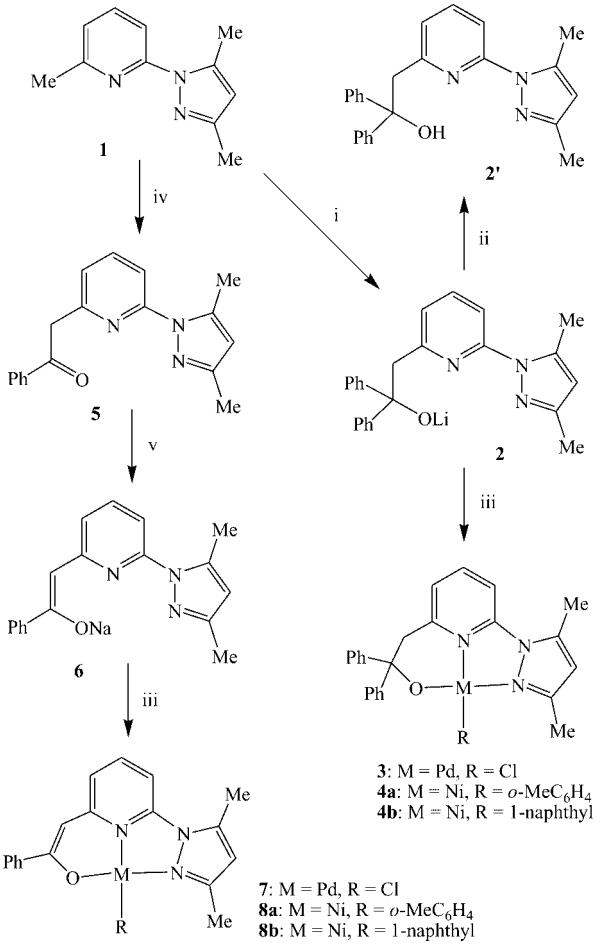
(Ar)Cl] (Ar = *o*-$MeC_6H_4$, 1-$C_{10}H_7$), yielding the corresponding complexes **3**, **4a** and **4b**, respectively. Lithiated **1** was treated with PhCN and subsequently dilute $H_2SO_4$ to afford 2-[6-(3,5-dimethyl-1*H*-pyrazol-1-yl)pyridin-2-yl]-1-phenylethanone (**5**). Treatment of **5** with *n*BuLi or LDA gave a mixture of the lithiated product and unreacted **5**. However, the reaction with NaH in thf formed [Na{2-[OC(Ph)=CH]-6-(3,5-$Me_2C_3HN_2$)$C_5H_3N$}] (**6**) cleanly.



Scheme 1. Ligand and complex syntheses. Reagents and conditions: (i) LDA, thf, –60 to –20 °C, 20 min, then $Ph_2CO$, –80 °C to room temp., 12 h; (ii) 2 M aqueous solution of HCl, room temp., 1 h; (iii) [$PdCl_2(PhCN)_2$] or [$(Ph_3P)_2Ni(Ar)Br$] (Ar = *o*-$MeC_6H_4$ or 1-$C_{10}H_7$), thf, –80 °C to room temp., 10–30 h; (iv) LDA, thf, –60 to –20 °C, 20 min, then PhCN, –80 to –20 °C, 30 min, room temp., 10 h, then 2 M aqueous $H_2SO_4$, 0 °C to room temp., 10 h; (v) NaH, thf, refluxing, 12 h.

Treatment of **6** with [$PdCl_2(PhCN)_2$] afforded the palladium complex [PdCl{2-[OC(Ph)=CH]-6-(3,5-$Me_2C_3HN_2$)-$C_5H_3N$}] (**7**), while treatment of **6** with [$(Ph_3P)_2Ni(Ar)Cl$] (Ar = *o*-$MeC_6H_4$, 1-$C_{10}H_7$) afforded complexes **8a** and **8b**, respectively. Attempts to synthesize [Ni(X){2-[OC(Ph)$_2$-$CH_2$]-6-(3,5-$Me_2C_3HN_2$)$C_5H_3N$}] and [Ni(X){2-[OC(Ph)=CH]-6-(3,5-$Me_2C_3HN_2$)$C_5H_3N$}] (X = Cl, Br) by treating **2** and **6**, respectively, with various nickel compounds such as [(dme)$NiCl_2$], [$(R_3P)NiCl_2$] (R = Ph, Et), [$(Ph_3P)NiBr_2$], and $NiBr_2$ were unsuccessful. Each reaction produced an unidentified white precipitate. The neutral compound **5** is a pale-yellow solid and was characterized by $^1H$ and $^{13}C$ NMR spectroscopy and elemental analysis. Complexes **2** and **6** are air-sensitive colorless (**2**) or pale-yellow (**6**) crystals. The palladium and nickel complexes are pale-yellow (**3**), brown (**8a**), or red (**4a**, **4b**, **7** and **8b**) crystals and are air-stable in the solid state. The nickel complexes are soluble in $CHCl_3$, $CH_2Cl_2$, and thf, but only slightly soluble in toluene. The palladium complexes are soluble in $CH_2Cl_2$, partly soluble in thf, and almost insoluble in toluene and $Et_2O$. Each of the complexes was characterized by NMR spectroscopy and elemental analyses and the data were found to be consistent with their respective structures. In addition, the diamagnetism of the four-coordinate palladium and nickel complexes revealed that these complexes have a square-planar geometry at the respective central metal atom, which means that the ligand coordinates to the central metal atom as an N,N,O-tridentate chelate. This was confirmed by single-crystal X-ray diffraction analyses of complexes **4b** and **8a**.

An ORTEP drawing of complex **4b** is presented in Figure 1 along with selected bond lengths and bond angles. This complex shows a distorted square-planar geometry around the nickel atom. The fact that the N1–Ni1–O1 bond angle [95.73(10)°] is wider than N1–Ni1–N3 [82.54(11)°] is consistent with the corresponding chelate ring size. Similarly, the Ni1–N1–C15 angle [126.3(2)°] is also wider than Ni1–N1–C19 [113.6(2)°]. The Ni1–N3 distance of 1.893(2) Å is shorter than that of Ni1–N1 [1.959(2) Å] and is also much shorter than the distances between the pyrazolyl nitrogen atoms and the nickel atom in [$NiCl_2${$NCH_2CH_2(N_2C_3HMe_2$-3,5)}]·$H_2O$ [2.0334(19) and 2.069(2) Å, respectively],[9] but similar to the Ni–N dis-

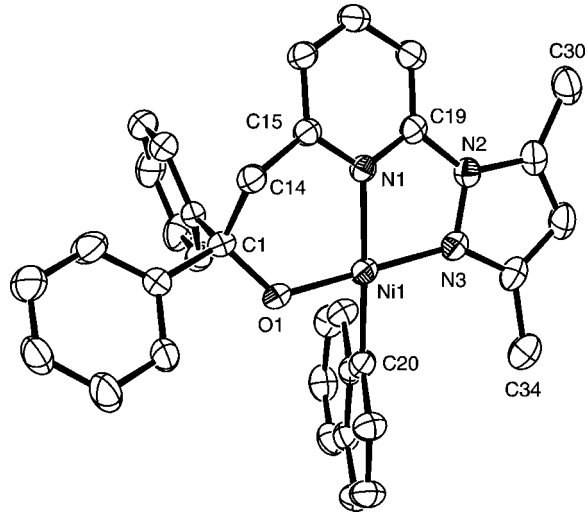


Figure 1. ORTEP drawing of complex **4b** with thermal ellipsoids drawn at the 30% probability level. Selected bond lengths [Å] and angles [°]: Ni1–O1 1.840(2), Ni1–N1 1.959(2), Ni1–N3 1.893(3), Ni1–C20 1.900(3), C1–O1 1.397(3), C1–C14 1.553(4), C14–C15 1.486(4), N2–N3 1.395(3), N2–C19 1.406(4), N1–Ni1–O1 95.73(10), N3–Ni1–O1 175.05(10), C20–Ni1–O1 86.30(11), N1–Ni1–N3 82.54(11), N1–Ni1–C20 172.68(12), N3–Ni1–C20 95.98(12), Ni1–N1–C19 113.6(2), Ni1–N3–N2 112.69(18), Ni1–O1–C1 122.03(18), Ni1–N1–C15 126.3(2).

tances in $[Ni_2\{(NSiMe_3)_2CPh\}_2]$ [1.868(5)–1.876(5) Å][10] and $[Ni\{(2,6\text{-}Me_2C_6H_3)NC(Me)C(H)C(Ph)O\}_2]$ [Ni1–N2 = 1.901(3) Å].[11] The Ni–O and Ni–C distances are within the normal range.

An ORTEP drawing of complex **8a** is presented in Figure 2 along with selected bond lengths and angles. Complex **8a** also shows a distorted square-planar geometry at the nickel atom and its structural skeleton is similar to that of complex **4b**, although with some differences in the bond lengths and angles. For example, the Ni1–N1, Ni1–N3, and Ni1–C19 distances in **8a** are shorter than the corresponding ones in **4b**, while the N1–Ni1–C19 and N3–Ni1–O2 angles in **8a** are wider than the corresponding ones in **4a**. The C6–C7 distance of 1.370(8) Å in **8a** is typical of a C–C double bond. The C5, C6, C7, and O2 atoms are almost coplanar, with a torsion angle of 0.5°.

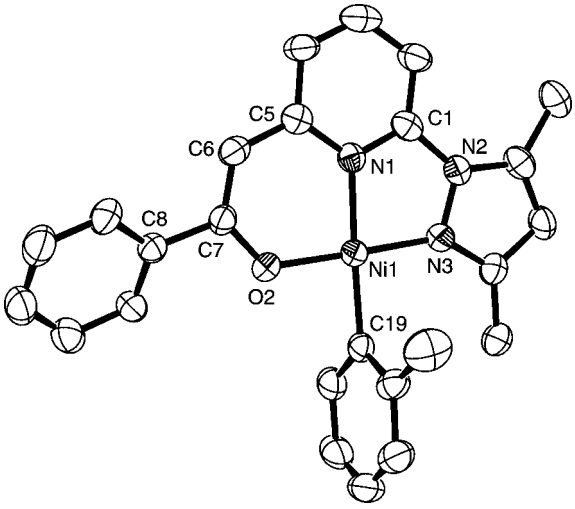

Figure 2. ORTEP drawing of complex **8a** with thermal ellipsoids drawn at the 30% probability level. Selected bond lengths [Å] and angles [°]: Ni1–O2 1.840(4), Ni1–N1 1.908(5), Ni1–N3 1.888(5), Ni1–C19 1.886(6), C5–C6 1.423(8), C6–C7 1.370(8), C7–O2 1.300(6), N2–C1 1.410(7), N2–N3 1.408(6), O2–Ni1–C19 85.1(2), O2–Ni1–N3 177.2(2), C19–Ni1–N3 96.0(2), O2–Ni1–N1 95.88(18), C19–Ni1–N1 174.9(2), N1–Ni1–N3 83.2(2).

### Catalytic Activity of Complexes 3, 4, 7, and 8 in the Heck and Kumada Reactions

We first examined the catalytic activity of complexes **3**, **4**, **7**, and **8** in the Heck reaction. The palladium complexes **3** and **7** catalyze the coupling of aryl iodides and bromides with butyl acrylate in the presence of a base, whereas under similar reaction conditions the nickel complexes only catalyze the reactions of aryl iodides with butyl acrylate. Complex **3** exhibits a higher catalytic activity than complex **7** in most cases, especially for substrates *p*-$MeC(O)C_6H_4Br$ and *p*-$MeOC_6H_4Br$. For example, 0.1 mol-% of **3** catalyzes the coupling of *p*-$MeOC_6H_4Br$ with butyl acrylate at 120 °C in NMP in the presence of $K_2CO_3$ to give the coupling product *trans*-*p*-$MeOC_6H_4CH{=}CHCOO$*n*Bu in 86% yield (Table 1, Entry 7), while the reaction of the same substrates catalyzed by 0.1 mol-% of **7** under the same conditions afforded the coupling product in only 15% yield (Table 1, Entry 22). The iodides were found to be more reactive than the bromides, and aryl chlorides were completely inert. The electronic effects of the substituents on the aryl ring of the halides obviously affect the coupling reactions catalyzed by **7** as both electron-withdrawing and electron-donating groups lead to a large decrease of the reactivity of the aryl bromides (Table 1, Entries 15, 18, 22, 36, 38, and 40). However, the electronic effects of the substituents on the aryl ring of the halides is much smaller in the reactions catalyzed by **3** than in the same reactions catalyzed by **7** (Table 1, Entries 2, 4, 7, 29, 31, and 33). The type of base used also affects the reaction. Thus, $K_2CO_3$ gave excellent results in the catalyst systems tested, while $Et_3N$ led to relatively poor results in most cases.

Complexes **4a**, **4b**, **8a**, and **8b** showed similar catalytic activity, with 0.5 mol-% of catalyst being sufficient to drive the reaction between PhI and butyl acrylate to completion with a quantitative yield of coupling product.

The couplings of aryl iodides or bromides with $PhCH{=}CH_2$ were also investigated. The nickel complexes were found to be almost inactive to the coupling reactions, although the palladium complexes **3** and **7** exhibited catalytic activity. These reactions showed a similar trend with respect to the reactions between aryl halides and butyl acrylate. Between 0.5 and 2 mol-% of the catalysts was required to drive these reactions to completion, depending on the aryl bromides employed. In addition, each coupling reaction gave only the *trans* product (by $^1H$ NMR spectroscopy); no *cis* isomer was observed.

de Vries and other researchers have recently reported that most of the palladium catalysts used for the Heck reaction decompose to form soluble palladium(0) colloids or nanoparticles at high temperature (higher than 120 °C), and that this colloidal palladium reacts further with aryl halides to form anionic intermediates.[12] The reaction temperature is as high as 120 °C in our reaction system, and thus it seems that the palladium complexes might have decomposed during reaction. However, we did observe different catalytic activity between complexes **3** and **7**. For comparison, we also tested the Heck reaction catalyzed by $PdCl_2$ and $PdCl_2$ together with neutral ligand **2′** using the same substrates and reaction conditions as those for **3**. The results showed that $PdCl_2$ alone exhibits very low catalytic activity (Table 1, Entries 42 and 44), while $PdCl_2$+**2′** shows good catalytic activity (Table 1, Entries 43 and 45), although a little lower than that of **3**. This could be because the ligand stabilizes the colloids and prevents their aggregation, as suggested by de Vries.[12a] The ligand probably also stabilizes the anionic palladium species formed by reaction of colloidal palladium with aryl bromides.

The catalytic behavior of complexes **3**, **4**, **7**, and **8** in the Kumada cross-coupling reaction was also evaluated. Palladium complexes **3** and **7** were found to catalyze the coupling of both aryl iodides and aryl bromides with *p*-$MeC_6H_4MgBr$ to give the cross-coupling products (Table 2). Complex **7** exhibits a slightly better catalytic ac-

tivity than complex **3**. For example, 1 mol-% of **7** gave a 99% yield of the coupling product of PhBr and *p*-$MeC_6H_4MgBr$, while 1 mol-% of **3** under the same conditions gave only 93% of the coupling product. The nickel complexes also catalyze the coupling of aryl iodides with *p*-$MeC_6H_4MgBr$ efficiently. However, the coupling of aryl bromides gave very low product yields. Complexes **4a**, **4b**, **8a**, and **8b** show very similar catalytic activity in the reactions tested, and 2 mol-% of catalyst was sufficient to drive the reactions to completion. These nickel complexes also proved to be good catalysts for deactivated aryl iodides. For example, 2 mol-% of **4b** or **8b** can catalyze the coupling of *p*-$MeOC_6H_4I$ with *p*-$MeC_6H_4MgBr$ to give the cross-coupling product in excellent yield (Table 2, Entries 10 and 19). We also found that increased steric hindrance of the reaction substrates led to a decrease of the product yields. For

[a] Reactions were carried out in a 1:1 mixture of thf/toluene unless otherwise indicated. [b] Bath temperature. [c] Yields of isolated products. [d] Reaction was carried out in thf.

example, the reactions of 2,4,6-$Me_3C_6H_2MgBr$ with 2,4,6-$Me_3C_6H_2Br$ or *o*-$MeC_6H_4Br$ catalyzed by either **3** or **7** gave relatively low yields of coupling products (Table 2, Entries 4, 5, 14 and 15). The reaction between *o*-$MeC_6H_4MgBr$ and *o*-$MeC_6H_4I$ catalyzed by the nickel catalysts **4a** or **8a** also gave lower yields of coupling product than the reaction between *p*-$MeC_6H_4MgBr$ and $C_6H_5I$ (Table 2, Entries 8 and 17), whereas the reaction of *o*-$MeC_6H_4MgBr$ and *o*-$MeC_6H_4Br$ catalyzed by **3** or **7** seems to be unaffected (Table 2, Entries 3 and 13).

## Conclusion

We have synthesized and characterized nickel and palladium complexes of the novel ligands [2-{$OC(Ph)_2CH_2$}-6-(3,5-$Me_2C_3HN_2$)$C_5H_3N$]$^-$ and [2-{OC(Ph)=CH}-6-(3,5-$Me_2C_3HN_2$)$C_5H_3N$]$^-$. These complexes have square-planar coordination geometries around the metal centers, as shown by their diamagnetism and single-crystal X-ray diffraction results (for complexes **4b** and **8a**). The palladium complexes exhibit good catalytic activity in the Heck and Kumada reactions. The nickel complexes also catalyze the coupling reaction between aryl iodides and butyl acrylate or *p*-$MeC_6H_4MgBr$.

## Experimental Section

**General Procedure:** All experiments were performed under nitrogen using standard Schlenk and vacuum-line techniques. Solvents were distilled under nitrogen from sodium (toluene), sodium/benzophenone (thf, $Et_2O$ and *n*-hexane), or $CaH_2$ ($CH_2Cl_2$) and degassed prior to use; dmf and dmp were dried with activated molecular sieves, distilled under nitrogen, and degassed prior to use. $CDCl_3$, $C_5D_5N$, and $C_6D_6$ (Acros Organics) were degassed and stored over either activated molecular sieves ($CDCl_3$ and $C_5D_5N$) or Na/K alloy ($C_6D_6$). 2-Hydrazino-6-methylpyridine,[13] [$(Ph_3P)_2Ni(Ar)Br$],[14] and [$PdCl_2(PhCN)_2$][15] were prepared according to literature methods. Diisopropylamine was dried with NaOH, distilled under nitrogen, and degassed prior to use. The aryl bromides used for preparation of Grignard reagents, including *p*-$MeC_6H_4Br$, *o*-$MeC_6H_4Br$, and α-bromonaphthalene, were distilled and degassed prior to use. All other chemicals were obtained commercially and used as received. NMR spectra were recorded with a Bruker av300 spectrometer at ambient temperature. $^1H$ and $^{13}C$ NMR chemical shifts are referenced to TMS or internal solvent resonances. Elemental analyses were performed by the Analytical Center of the University of Science and Technology of China.

### Preparations

**2-(3,5-Dimethyl-1*H*-pyrazol-1-yl)-6-methylpyridine (1):**[8] Pentane-2,4-dione (0.48 g, 48 mmol) was added dropwise to a stirred solution of 2-hydrazino-6-methylpyridine (0.50 g, 40.6 mmol) in acetic acid (10 mL) at room temperature and the resultant mixture refluxed for 12 h. The acetic acid was then removed under reduced pressure and the residue dissolved in $CH_2Cl_2$ (20 mL). This $CH_2Cl_2$ solution was washed twice with 10% $Na_2CO_3$ solution and then dried with $Na_2SO_4$. The $Na_2SO_4$ was removed by filtration and the solvent removed from the filtrate by rotary evaporation. The residue was distilled under reduced pressure to give a colorless oil (0.71 g, 93%), b.p. 78–80 °C/0.1 Torr. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.24 (s, 3 H, Me), 2.46 (s, 3 H, Me), 2.55 (s, 3 H, Me), 5.90 (s, 1 H, pyrazolyl), 6.93 (dd, $J$ = 0.9, 7.4 Hz, 1 H, Py), 7.52–7.61 (m, 2 H, Py) ppm.

**[Li{2-[OC(Ph)$_2$CH$_2$]-6-(3,5-Me$_2$C$_3$HN$_2$)C$_5$H$_3$N}] (2):** A solution of 2-(3,5-dimethyl-1*H*-pyrazol-1-yl)-6-methylpyridine (0.48 g, 2.57 mmol) in thf (10 mL) was cooled to about –60 °C and a solution of LDA in $Et_2O$ [prepared from diisopropylamine (0.29 g, 2.8 mmol) and *n*BuLi (1.2 mL of a 2.5 M solution in hexane, 3 mmol) in $Et_2O$] was added with stirring. After stirring at –20 °C for 20 min, the mixture was added dropwise to a solution of benzophenone (0.50 g, 2.75 mmol) in thf (5 mL) at about –80 °C. The resultant mixture was warmed to room temperature and stirred for 12 h. The solvent was then removed under vacuum and the residue dissolved in toluene (10 mL). The solution was filtered and the filtrate was concentrated to about 2 mL. Diethyl ether (2 mL) was added to the solution to give compound **2** (0.54 g, 56%) as colorless crystals, m.p. 227–228 °C. $^1$H NMR ($C_6D_6$): $\delta$ = 1.79 (s, 3 H, Me), 2.20 (s, 3 H, Me), 3.86 (s, 2 H, $CH_2$), 5.41 (s, 1 H, pyrazolyl), 6.12 (d, $J$ = 8.1 Hz, 1 H, Py), 6.23 (d, $J$ = 7.5 Hz, 1 H, Py) 6.68 (t, $J$ = 7.8 Hz, 1 H, Py), 6.84–6.87 (m, 2 H, Ph), 6.98 (br., 4 H, Ph), 7.65 (d, $J$ = 7.2 Hz, 4 H, Ph) ppm. $^{13}$C NMR ($C_6D_6$): $\delta$ = 13.03, 14.01, 53.27, 81.62, 109.45, 122.48, 124.31, 126.84, 137.06, 138.04, 148.64, 151.04, 162.25 ppm. $C_{24}H_{22}LiN_3O$ (375.39): calcd. C 76.79, H 5.91, N 11.19; found C 76.90, H 5.90, N 11.11.

**2-[OC(Ph)$_2$CH$_2$]-6-(3,5-Me$_2$C$_3$HN$_2$)C$_5$H$_3$N (2′):** Hydrochloric acid (2 M, 20 mL) was added to a solution of **2** [prepared from **1** (0.72 g, 3.85 mmol), LDA, and $Ph_2CO$ according to the above procedure] in thf (15 mL). The mixture was stirred for 1 h and then neutralized with 2 M NaOH. The aqueous layer was extracted twice with $CH_2Cl_2$ (20 mL each time), and the combined organic layers were dried with $MgSO_4$. After concentration in vacuo, the product was recrystallized from $CH_2Cl_2$/$Et_2O$ to give a white solid (1.0 g, 70.4% based on the amount of **1**), m.p. 156–157 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 2.28 (s, 3 H, Me), 2.43 (s, 3 H, Me), 3.74 (s, 2 H, $CH_2$), 5.98 (s, 1 H, pyrazolyl), 6.91 (dd, $J$ = 2.4, 6 Hz, 1 H, Py), 7.12–7.27 (m, 7 H, Ph), 7.41–7.44 7.12–7.27 (m, 3 H, Ph), 7.50–7.66 (m, 2 H, Py) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 13.70, 14.22, 47.50, 78.36, 109.33, 114.74, 122.11, 126.32, 126.78, 128.13, 139.28, 141.11, 146.89, 150.26, 152.30, 157.22 ppm. $C_{24}H_{23}N_3O$ (369.46): calcd. C 78.02, H 6.27, N 11.37; found C 77.79, H 6.24, N 11.22.

**[Pd(Cl){2-[OC(Ph)$_2$CH$_2$]-6-(3,5-Me$_2$C$_3$HN$_2$)C$_5$H$_3$N}] (3):** A solution of **2** (0.11 g, 0.29 mmol) in thf (5 mL) was added to a stirred solution of [$PdCl_2(PhCN)_2$] (0.105 g, 0.27 mmol) in thf (10 mL) at about –80 °C. The mixture was warmed to room temperature and stirred for 10 h, then the solvent was removed under vacuum. The residue was dissolved in $CH_2Cl_2$ and then filtered. Concentration of the filtrate afforded pale-yellow crystals (0.11 g, 80%), m.p. 293–295 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 2.54 (s, 3 H, Me), 2.59 (s, 3 H, Me), 3.97 (s, 2 H, $CH_2$), 6.01 (s, 1 H, pyrazolyl), 7.03 (d, $J$ = 7.8 Hz, 1 H, Py), 7.12–7.25 (m, 7 H, Ph+Py), 7.62 (d, $J$ = 8.1 Hz, 4 H, Ph), 7.80 (t, $J$ = 8.4 Hz, 1 H, Py) ppm. $C_{24}H_{22}ClN_3OPd$ (510.32): calcd. C 56.49, H 4.35, N 8.23; found C 56.89, H 4.23, N 8.28.

**[Ni(*o*-MeC$_6$H$_4$){2-{OC(Ph)$_2$CH$_2$}-6-(3,5-Me$_2$C$_3$HN$_2$)C$_5$H$_3$N}] (4a):** A solution of **2** (0.22 g, 0.59 mmol) in thf (5 mL) was added to a stirred solution of [$(Ph_3P)_2$Ni(*o*-$MeC_6H_4$)Br] (0.44 g, 0.58 mmol) in thf (10 mL) at about –80 °C. The resultant solution was warmed to room temperature and stirred for 30 h, then the solvent was removed under vacuum and the residue was extracted with $CH_2Cl_2$. The solvent was removed from the extract under reduced pressure and the residual solid was recrystallized from thf to give red crystals (0.28 g, 92%), m.p. 203–204 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 1.16 (s, 3 H, Me), 2.39 (s, 3 H, Me), 2.78 (s, 3 H, Me), 3.49 (d, $J$ = 14.4 Hz, 1 H, CH), 3.68 (d, $J$ = 14.4 Hz, 1 H, CH), 5.74 (s, 1 H, pyrazolyl), 6.68–7.10 (m, 11 H, Ar), 7.37 (d, $J$ = 6.3 Hz, 2 H, Ar), 7.61–7.70 (m, 4 H, Ar) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 13.50, 21.32, 24.97, 49.05, 77.27, 113.98, 122.05, 122.38, 124.83, 125.14, 125.36, 126.40, 126.59, 126.87, 127.08, 128.08, 128.27, 128.88, 136.72, 137.72, 147.52, 155.62, 159.87 ppm. $C_{31}H_{29}N_3NiO$ (518.28): calcd. C 71.84, H 5.64, N 8.11; found C 71.76, H 5.51, N 8.19. Single crystals of complex **4a** suitable for an X-ray diffraction analysis were obtained by recrystallization of the sample from a mixture of thf and toluene.

**[Ni(1-C$_{10}$H$_7$){2-{OC(Ph)$_2$CH$_2$}-6-(3,5-Me$_2$C$_3$HN$_2$)C$_5$H$_3$N}] (4b):** A solution of **2** (0.08 g, 0.21 mmol) in thf (5 mL) was added to a stirred solution of [$(Ph_3P)_2$Ni(naphthyl)Br] (0.17 g, 0.22 mmol) in thf (10 mL) at about –80 °C. The mixture was warmed to room temperature and stirred for 30 h, then the solvent was removed under vacuum and the residue extracted with $CH_2Cl_2$. The extract was filtered and then concentrated to dryness to give a red solid, which was recrystallized from a mixture of $CH_2Cl_2$/hexane (1:1) to afford red crystals (0.11 g, 83%), m.p. 171–173 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 0.72 (s, 3 H, Me), 2.32 (s, *Me*$C_6H_5$), 2.38 (s, 3 H, Me), 3.54 (d, $J$ = 15.3 Hz, 1 H, CH), 3.81 (d, $J$ = 15.3 Hz, 1 H, CH), 5.63 (s, 1 H, pyrazolyl), 6.90–6.98 (m, 4 H, Ar), 7.06–7.15 (m, 6 H, Ar), 7.20–7.31 (m, 5 H, Ar), 7.37 (d, $J$ = 7.2 Hz, 3 H, Ar), 7.60 (d, $J$ = 7.2 Hz, 3 H, Ar), 7.70 (t, $J$ = 8.1 Hz, 1 H, Ar), 8.00 (d, $J$ = 6.9 Hz, 1 H, Ar), 9.29–9.32 (m, 1 H, Ar) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 13.86, 21.58, 49.32, 77.27, 107.16, 114.41, 122.19, 122.74, 123.70, 123.79, 123.92, 125.08, 125.24, 125.43, 125.96, 126.72, 127.42, 127.61, 128.02, 128.36, 129.17, 132.75, 133.54, 133.89, 138.02, 139.14, 140.23, 141.68, 151.77, 151.82, 156.11, 156.97, 160.38 ppm. $C_{34}H_{29}N_3NiO{\cdot}0.8C_7H_8$ (628.02): calcd. C 75.73, H 5.68, N 6.69; found C 75.75, H 5.75, N 6.67.

**2-[6-(3,5-Dimethyl-1*H*-pyrazol-1-yl)pyridin-2-yl]-1-phenylethanone (5):** A solution of 2-(3,5-dimethyl-1*H*-pyrazol-1-yl)-6-methylpyridine (0.48 g, 2.57 mmol) in thf (10 mL) was cooled to about –60 °C and a solution of LDA in $Et_2O$ [prepared from diisopropylamine (0.29 g, 2.8 mmol) and *n*BuLi (1.2 mL of a 2.5 M solution in hexane, 3 mmol) in $Et_2O$] was added with stirring. The mixture was stirred at –20 °C for 20 min and was then added dropwise to PhCN (0.30 g, 2.91 mmol) at about –80 °C. The resultant solution was stirred at –20 °C for 30 min and at room temperature for 10 h. A 2 M aqueous solution of $H_2SO_4$ (10 mL) was then added at 0 °C. The mixture was stirred at room temperature for 10 h and then neutralized with NaOH solution. The organic layer was separated and the aqueous layer was extracted twice with diethyl ether (20 mL each time). The combined ether solutions were dried with $Na_2SO_4$, then the $Na_2SO_4$ was removed by filtration and the filtrate was concentrated to give pale-yellow crystals (0.49 g, 66%), m.p. 80–81 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 2.19 (s, 3 H, Me), 2.41 (s, 3 H, Me), 4.37 (s, 2 H, $CH_2$), 5.86 (s, 1 H, pyrazolyl), 7.07 (t, $J$ = 4.2 Hz, 1 H, Ar), 7.32–7.50 (m, 3 H, Ar), 7.65 (d, $J$ = 4.2 Hz, 2 H, Ar), 7.94–7.97 (m, 2 H, Ar) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 13.67, 14.64, 47.89, 109.05, 113.66, 120.71, 125.44, 128.43, 128.66, 128.85, 133.31, 136.59, 138.90, 141.68, 149.81, 153.28, 153.68, 196.73 ppm. $C_{18}H_{17}N_3O$ (291.35): calcd. C 74.20, H 5.88, N 14.42; found C 74.28, H 5.58, N 14.26.

**[Ni(1-C$_{10}$H$_7$){2-[OC(Ph)=CH]-6-(3,5-Me$_2$C$_3$HN$_2$)C$_5$H$_3$N}] (8b):** A solution of **5** (0.17 g, 0.54 mmol) in thf (5 mL) was added to a stirred solution of $[(PPh_3)_2Ni(naphthyl)Br]$ (0.40 g, 0.51 mmol) in thf (10 mL) at about –80 °C. The resultant solution was warmed to room temperature and stirred for 30 h, then the solvent was removed under vacuum and the residue dissolved in $CH_2Cl_2$. The mixture was filtered and the filtrate was concentrated to give red crystals of **8b** (0.17 g, 71%), m.p. 239–240 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 0.84 (s, 3 H, Me), 2.48 (s, 3 H, Me), 5.76 (s, 1 H, pyrazolyl), 6.08 (s, 1 H, CH), 6.75 (d, $J$ = 7.8 Hz, 1 H, Py), 6.84 (d, $J$ = 8.1 Hz, 1 H, Py), 7.01–7.15 (m, 5 H, Ar), 7.27–7.43 (m, 5 H, Ar), 7.53 (t, $J$ = 8.1 Hz, 1 H, Py), 7.58–7.62 (m, 1 H, Ar), 7.89 (d, $J$ = 6.6 Hz, 1 H, Ar), 9.66 (d, $J$ = 7.8 Hz, 1 H, Ar) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 14.39, 15.27, 93.11, 99.56, 113.89, 119.66, 122.72, 123.56, 123.77, 124.23, 126.59, 127.82, 127.86, 128.38, 128.70, 129.19, 132.86, 133.16, 133.88, 136.17, 139.77, 140.18, 141.97, 146.45, 153.84, 155.16, 155.32, 170.23 ppm. $C_{28}H_{23}N_3NiO$ (476.20): calcd. C 70.62, H 4.87, N 8.82; found C 70.46, H 4.81, N 9.07.

**Crystal Structure Determination:** Single crystals were mounted in Lindemann capillaries under nitrogen. Diffraction data were collected with a Siemens CCD area detector with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structure was solved by direct methods using SHELXS-97[16] and refined against $F^2$ by full-matrix least squares using SHELXL-97.[17] Hydrogen atoms were placed in calculated positions. Crystal data and experimental details of the structure determinations are listed in Table 3. CCDC-641763 and -641764 (for **4b**·$C_7H_8$ and **8a**·0.5$C_6H_6$, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 3. Summary of crystal data for complexes **4b** and **8a**.

| | **4b**·$C_7H_8$ | **8a**·0.5$C_6H_6$ |
|---|---|---|
| Empirical formula | $C_{41}H_{37}N_3NiO$ | $C_{28}H_{26}N_3NiO$ |
| Formula mass | 646.45 | 479.23 |
| Crystal system | monoclinic | monoclinic |
| Space group | $P2_1/n$ | $C2/c$ |

**General Procedure for the Heck Reactions:** A Schlenk tube was charged with aryl halide (2 mmol), butyl acrylate or styrene (3 mmol), a base (3 mmol), the pre-catalyst, and solvent (6 mL) and the mixture was stirred at the appropriate temperature for the specified period of time. The mixture was then cooled to room temperature and quenched with a 1 M aqueous solution of hydrochloric acid (3 mL). The aqueous phase was extracted with $CH_2Cl_2$ ($3 \times 5$ mL), then the combined organic layers were washed with water (10 mL) and dried with $Na_2SO_4$. The $NaSO_4$ was removed by filtration and the filtrate was concentrated. The residue was purified by column chromatography.

**General Procedure for the Kumada Reactions:** A Schlenk tube was charged with aryl halide (2 mmol), pre-catalyst, solvent (4 mL), and a magnetic stir bar, then a thf solution of *p*-$MeC_6H_4MgBr$ (prepared from 2.4 mmol of *p*-$MeC_6H_4Br$ and 3 mmol of Mg in thf) was added dropwise at room temperature with stirring. The reaction mixture was stirred at the appropriate temperature for the specified period of time. After the mixture had been cooled to room temperature, the reaction was quenched with water. The aqueous phase was extracted with $CH_2Cl_2$ ($3 \times 5$ mL) and the combined organic layers were dried with $MgSO_4$. The $MgSO_4$ was removed by filtration and the filtrate was concentrated. The residue was purified by column chromatography.

# Oxidation of $N^{III}$ and $N^{-I}$ by an $\{Mn_4O_6\}^{4+}$ Core in Aqueous Media: Proton-Coupled Electron Transfer

**Suranjana Das[a] and Subrata Mukhopadhyay*[a]**

**Keywords:** Kinetics / Mechanisms / Manganese / Oxidation / Nitrogen

$[Mn_4(\mu\text{-}O)_6(bipy)_6]^{4+}$ ($\mathbf{1}^{4+}$; bipy = 2,2′-bipyridine) and its conjugate acid $[Mn_4(\mu\text{-}O)_5(\mu\text{-}OH)(bipy)_6]^{5+}$ ($\mathbf{1}H^{5+}$) quantitatively oxidise $N^{III}$ ($HNO_2$ and $NO_2^-$) and $N^{-I}$ ($NH_3OH^+$ and $NH_2OH$) to $N^V$ (nitrate) and $N^I$ (nitrous oxide), respectively, in aqueous solution (pH 2.0–6.0), with $\mathbf{1}H^{5+}$ reacting much faster than $\mathbf{1}^{4+}$. An uncommon feature of these reactions is the kinetic superiority of $HNO_2$ over its conjugate base $NO_2^-$. $NH_2OH$, however, behaves normally – the conjugate acid $NH_3OH^+$ is less reactive than $NH_2OH$. These reactions show remarkable kinetic isotope effects: the observed rate of $N^{III}$ oxidation increases in $D_2O$ media whereas the $N^{-I}$ oxidation rate slows down in media enriched with $D_2O$. A search of the available data on the redox kinetics of multinuclear oxidants suggests that the title $\{Mn_4O_6\}^{4+}$ reduction by $N^{III}$, the rate of which is accelerated in $D_2O$, is the only one established so far. A hydrogen atom transfer (HAT) mechanism (1e, $1H^+$; electroprotic) is proposed.

## Introduction

The oxygen-evolving complex (OEC)[1–5] oxidises water to molecular dioxygen in photosystem II (PS II) at the redox catalytic centre on the lumenal side of PS II, which includes four manganese ions, a calcium ion and a chloride ion.[6,7] The OEC cycles over five redox states $S_0$–$S_4$, where the index refers to the number of oxidising equivalents stored;[8,9] dioxygen is evolved in the $S_4 \rightarrow S_0$ transition.

Successive changes in the redox states of the Mn atoms in the OEC during this cycle are associated with protonation/deprotonation of the oxo bridges[10] and of the nearby amino acid residues as well as the simultaneous movements of proton and electrons within the OEC.[11]

The acid/base chemistry resulting from oxo-bridge protonations in synthetic multinuclear Mn complexes has been studied mostly in non-aqueous media.[12] It has also been demonstrated that oxo-bridge protonation sometimes increases the reactivity of a binuclear Mn oxidant[12d,12e] and completely quenches the catalase activity of an $Mn^{IV}$ dimer.[12c] How such protonations affect the chemical behaviour of higher-valent synthetic Mn complexes is not known, despite the relevance of such knowledge to PS II. This is particularly true in water, the medium where PS II acts.

The title complex $[Mn_4(\mu\text{-}O)_6(bipy)_6]^{4+}$ ($\mathbf{1}^{4+}$; Figure 1) formally corresponds to the fully oxidised $S_3$ or $S_4$ state of OEC[2] [although involvement of an even higher state ($Mn^V$) is feasible in the water oxidation process],[13] which is stable in aqueous solution over a wide acidity range (pH 2.0–6.0). Its one-electron-reduced, mixed-valent $Mn^{IV}{}_3Mn^{III}$ form is an EPR spectroscopic model for the $S_2$ state,[14] which means that the electron-transfer reactivity of the title Mn tetramer will thus be instructive.

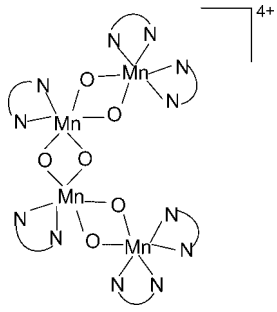

Figure 1. Schematic drawing of $[Mn_4(\mu\text{-}O)_6(bipy)_6]^{4+}$. N-N = 2,2′-bipyridine.

We demonstrated recently that $\mathbf{1}^{4+}$ oxidises glyoxylic and pyruvic acid through an electroprotic mechanism and that the oxo-bridged protonated species $\mathbf{1}H^{5+}$ is a kinetically superior oxidant to $\mathbf{1}^{4+}$.[15] It therefore seemed worthwhile to investigate whether the relative acidities of the reducing agents influence the proton-coupled electron transfer mechanism as well as the reactivity of the oxo-bridged protonated oxidant. The present investigation was thus planned with two selected reducing agents, namely $HNO_2$ and $NH_3OH^+$ (and their conjugate bases), which have a sufficient separation in their $pK_a$ values.[16,17] We further note that hydroxylamine[18] reduces the Mn ions in PS II whereas nitrite does not.[19]

## Results and Discussion

### Equilibrium Measurements

The measured p$K_a$ values of these reducing acids in a 95% $D_2O$ medium are $3.80 \pm 0.10$[20,21] and $6.40 \pm 0.10$ for nitrous acid and hydroxylammonium cation respectively. The reported p$K_a$ values used in this investigation for $HNO_2$ and $NH_3OH^+$ in an $H_2O$ medium are 3.00[16] and 6.00,[17] respectively. All the p$K_a$ values are at 25.0 °C, $I$ = 1.0 M ($NaNO_3$). The pH-metric titration of the title tetranuclear Mn oxidant, however, did not result in any ionisation constant in the pH interval 2.0–7.0.

### Stoichiometric Analyses

Nitrate ($NO_3^-$) was detected as the oxidation product of nitrite whereas no red colouration was observed when the product solutions of the redox reaction of hydroxylamine were tested for nitrite or nitrate. The results of several stoichiometric experiments, under both kinetic ($T_R > 4[Mn^{IV}_4]$) and non-kinetic conditions ($T_R < 4[Mn^{IV}_4]$), are summarised in Table 1, which establishes a 1:4 stoichiometry (oxidant:reductant) for both the redox reactions, where $T_R$ is the analytical concentration of the reducing agent defined as $T_R = [HNO_2] + [NO_2^-]$ for $[N^{III}]_T$ and $T_R = [NH_3OH^+] + [NH_2OH]$ for $[N^{-I}]_T$. The title Mn tetramer is not a powerful oxidant (see below) and it is clear from the ratio $\Delta[Mn^{IV}_4]/\Delta[T_R]$ (Table 1) that $N_2O$ is the sole oxidation product of hydroxylamine − no further oxidation of $N_2O$ to nitrite or nitrate was observed. The results of EDTA titrations of the product solutions revealed quantitative formation of $Mn^{II}$ as the sole reduction product of $Mn^{IV}$. The likely $Mn^{II}$ species under these reaction conditions is an $Mn^{II}$-bipy complex.[22] Optical spectra for the product solutions were superimposable on those of mixtures of $Mn(NO_3)_2$ and 2,2′-bipyridine under similar experimental conditions. Equations (1) and (2) are thus closest to our above observations.

$$[Mn_4O_6(bipy)_6]^{4+} + 4\,NO_2^- + 4\,H^+ \longrightarrow 4\,Mn^{2+} + 4\,NO_3^- + 6\,bipy + 2\,H_2O \quad (1)$$

$$[Mn_4O_6(bipy)_6]^{4+} + 4\,NH_2OH + 4\,H^+ \longrightarrow 4\,Mn^{2+} + 2\,N_2O + 6\,bipy + 8\,H_2O \quad (2)$$

### Kinetics

The decay in absorbance vs. time plots could be fitted with standard first-order decay curves at least up to three half-lives. The observed first-order rate constants ($k_0$) do not depend on the wavelength chosen for the measurements (380–500 nm) where only the oxidant absorbs sufficiently, the presence or absence of dissolved oxygen in the reaction medium or on the concentration of the Mn oxidant (0.05–0.30 mM). Averages of $k_0$ values from at least three measurements were taken and the average coefficients of variation (CV)[23] for these measurements were within 3%. The observed proton-dependences of $k_0$ in these two redox reactions is interesting (Table 2). For nitrite oxidation, $k_0$ values increase with an increase in acidity of the reaction medium whereas they decrease with increasing acidity for hydroxylamine oxidation until the very low pH region, where $k_0$ increases with a decrease in pH. We can suppose a superior kinetic reactivity of $HNO_2$ over $NO_2^-$ from these trends whereas $NH_2OH$ is superior to $NH_3OH^+$. However, the title complex ($\mathbf{1}^{4+}$) may suffer protonation at very low pH, as was evident from its reaction with α-keto acids.[15] The species formed ($\mathbf{1}H^{5+}$) may act as an additional oxidant in the low pH region despite being present in only a low concentration. Protonated oxidants always react quicker than their conjugate bases[24] within a system, and thus $\mathbf{1}H^{5+}$ is expected to react faster than $\mathbf{1}^{4+}$. We measured several $k_0$ values in the presence of varying amounts of added bipy over the entire pH range for both the redox reactions. The lack of influence of added bipy on the observed rate of either reaction at any acidity rules out the possibility of bipy dissociation from the parent Mn complex in solution. We observed a linear variation of $k_0$ with $T_R$ in the entire pH range studied and found no indication of rate saturation even at the highest $T_R$ studied. Table 2 collects some representative $k_0$ values.

A strong pre-equilibrium ($K$) binding of the reducing species with the title oxidant followed by reaction of the intermediate thus formed with a second reducing species would lead to the observed kinetics (linear dependence of $k_0$ on $T_R$) provided that $KT_R$ is much greater than 1, which requires a $K$ value as high as $10^4$ (lowest $T_R = 5.0 \times 10^{-3}$ M). However, the tetranuclear Mn oxidant is coordinatively saturated at each Mn centre and an inner-sphere attachment of reducing species seems unlikely. Moreover, $d^3$ $Mn^{IV}$ is substitution inert and the oxidant retains its bipy ligands in aqueous solution in the entire pH range studied (see above), which means there is no scope for the formation of the aqua species that could lead to an inner-sphere mechanism in solution. We thus disregard this kind of pathway in the kinetics of the title redox reaction. The observed proton-

dependence of $k_0$ on [$H^+$] could not be fitted to any type of reaction scheme with only one protic equilibrium, which means that Equations (3) and (4) need to be considered simultaneously, as shown in Scheme 1 for both the reactions under investigation.

Scheme 1 leads to the rate law in Equation (9), assuming that $K_1$[$H^+$] is much less than 1. This scheme does not take into account any protonation equilibrium of $HNO_2$[25] to generate $NO^+$ [Equation (10)] or a disproportionation equilibrium of $HNO_2$[26] to generate NO and $NO_2$ [Equation (11)]. A reaction path involving NO would require an $[HNO_2]^2$ term in the rate law and $NO^+$ requires a third-order term $[Mn^{IV}_4][HNO_2][H^+]$. The equilibrium constants of these reactions are small, which might be the main reason for not obtaining the reactivities, if any, of these species. We therefore used $[N^{III}]_T = [HNO_2] + [NO_2^-]$. Except for $NH_2OH$ and $NH_3OH^+$, no other pH-dependent $N^{-I}$ species are known.

$$1^{4+} + H^+ \overset{K_1}{\rightleftharpoons} 1H^{5+} \quad (3)$$

$$RH \overset{K_a}{\rightleftharpoons} R^- + H^+ \quad (4)$$

$$1H^{5+} + RH \xrightarrow{k_1} \text{products} \quad (5)$$

$$1H^{5+} + R^- \xrightarrow{k_2} \text{products} \quad (6)$$

$$1^{4+} + RH \xrightarrow{k_3} \text{products} \quad (7)$$

$$1^{4+} + R^- \xrightarrow{k_4} \text{products} \quad (8)$$

Scheme 1. (RH = $HNO_2$ or $NH_3OH^+$).

$$k_0(K_a + [H^+])/T_R = k_1K_1[H^+]^2 + (k_2K_1K_a + k_3)[H^+] + k_4K_a \quad (9)$$

$$HNO_2 + H^+ \rightleftharpoons NO^+ + H_2O \qquad K = 3.0 \times 10^{-7} \quad (10)$$

$$2\,HNO_2 \rightleftharpoons NO + NO_2 + H_2O \qquad K = 6.0 \times 10^{-6} \quad (11)$$

Plots of the left-hand side of Equation (9) resulted in a good polynomial fit of [$H^+$] for both redox reactions (Figure 2, $r > 0.98$), from which we obtain $k_1K_1$, $(k_2K_1K_a + k_3)$

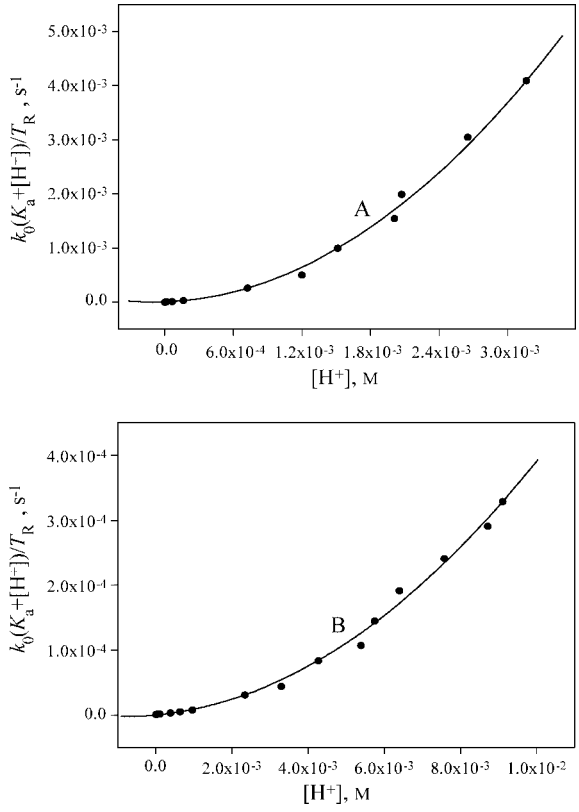

Figure 2. Plot of the left-hand side of Equation (9) vs. [$H^+$]. [complex] = 0.10 mM, $T$ = 25.0 °C, $I$ = 1.0 M. A: $N^{III}$, $C_{bipy}$ = 3.0 mM; B: $N^{-I}$, $C_{bipy}$ = 5.0 mM.

| 95% $D_2O$ medium $N^{-I}$ | $0.65 \pm 0.04$ | $(1.9 \pm 0.1) \times 10^{-4}$ | $(5.5 \pm 0.3) \times 10^{-2}$ |

and $k_4$ (see Table 3). The non-existence of the $k_4$ path for the nitrite redox reaction, as determined by the above second-order polynomial, was further confirmed by plotting $k_0(K_a + [H^+])/(T_R[H^+])$ against $[H^+]$ (see electronic supporting information), which resulted in a good straight line ($r > 0.98$) with slope $k_1K_1$ and intercept ($k_2K_1K_a + k_3$), in close agreement (within 5%) with the values reported in Table 3. On the other hand, the $k_4$ path was found to be significant for hydroxylamine redox above a pH of about 4, and a plot of $T_R/k_0$ against $[H^+]$ yielded a good straight line with slope $1/k_4$ and intercept $1/(k_4K_a)$ at pH $\geq$ 5.3 (see electronic supporting information). The value of $k_4$ determined in this way matches well with the values reported in Table 3.

It cannot be concluded, however, that, as $\mathbf{1}^{4+}$ does not react with $NO_2^-$ (the $k_4$ path does not contribute to the overall rate), $\mathbf{1}H^{5+}$ would not oxidise $NO_2^-$. Protonated metal complexes are superior oxidants than their deprotonated analogues[20,24] and a finite contribution of $k_2$ path may therefore be anticipated, although kinetic resolution of the proton-ambiguous $k_2$ and $k_3$ paths is not possible. We also note that the $k_1$ path starts contributing towards the observed rate at pH $\leq$ 5.0 for the $N^{III}$ redox reaction whereas for the $N^{-I}$ redox reaction a more acidic environment is needed to ensure a finite contribution of the $k_1$ path (pH $\leq$ 4.0), as judged by the values of $k_1K_1[H^+]^2$ and $(k_2K_1K_a + k_3)[H^+]$ for both redox reactions at these pHs. Below pH 3.0, hydroxylamine is almost quantitatively present as cationic $NH_3OH^+$, whose oxidation by $\mathbf{1}H^{5+}$ is electrostatically more unfavourable than the oxidation of $NH_2OH$. Oxidation of cationic $NH_3OH^+$ requires higher concentrations of $\mathbf{1}H^{5+}$, which are produced at much lower pH than that required for the oxidation of neutral $HNO_2$ purely on charge grounds.

It should be noted here that a scheme comprising only $HNO_2$ as the active reducing species reacting with $\mathbf{1}H^{5+}$ ($k_1$) and $\mathbf{1}^{4+}$ ($k_1'$) is an alternative to Scheme 1 and results in $k_1K_1$ and $k_1'$ values identical to those reported in Table 3 ($k_1'$ is similar to $k_3$ in Scheme 1, assuming the $k_2$ path is absent). However, this alternative cannot confirm the absence of the $k_2$ path in the nitrite redox reaction. The rate constants measured in presence of varying amounts of added $NaNO_3$ might be instructive here. At pH 4.7 (where $[NO_2^-] >> [HNO_2]$), $k_0$ increases substantially with a decrease in ionic strength of the reaction medium (Table 2), which indicates a reaction between opposite charges, therefore a finite contribution of the $k_2$ path may thus be anticipated ($\mathbf{1}H^{5+}$ is a stronger oxidant than $\mathbf{1}^{4+}$ and the $k_4$ path is absent in $N^{III}$ oxidation), while at pH 5–6 the value of $k_0$ remains unaltered in the range $I$ = 1.0–0.1 M ($NaNO_3$) for the $N^{-I}$ redox reaction (Table 2), in line with the maximum contribution of the uncharged $NH_2OH$ path ($k_4$) towards the overall rate at the highest pH extreme. Around pH 2.5, where $[HNO_2]$ is much greater than $[NO_2^-]$, the rate of the nitrite redox reaction was found to be independent of any variation in the ionic strength of the medium (Table 2), whereas at pH 2.1 or 3.6, where $[NH_3OH^+]$ is much greater than $[NH_2OH]$, the rate of hydroxylamine oxidation decreases significantly with decreasing ionic strength of the medium (Table 2). These observations qualitatively support the involvement of neutral $HNO_2$ and cationic $NH_3OH^+$ as reactive species with cationic $\mathbf{1}^{4+}$ or $\mathbf{1}H^{5+}$.

We can estimate $K_1$ to be between $10^{-9}$ and 10 from the fact that $K_1[H^+]$ is much less than 1 and the $k_1K_1$ values listed in Table 3. The fact that $K_1[H^+]$ is much less than 1 sets an upper limit for the pre-equilibrium binding of nearly 10 as the maximum $[H^+]$ used in this study is $10^{-2}$ M. Assuming the diffusion-controlled limit is $10^{11}$ $M^{-1}s^{-1}$, the lower limit of $K_1$ derived from the $k_1K_1$ values in Table 3 is around $10^{-9}$. For comparison, we note that the reported p$K_a$ of the analogous complex $[Mn^{IV}_4(\mu\text{-}O)_5(\mu\text{-}OH)(bpea)_4]^{5+}$ [bpea = *N*,*N*′-bis(2-pyridylmethyl)ethylamine] is –6,[12h] which shows that the bridging oxo group is much less basic. The strong acidity of the protonated oxo-bridge may thus be inferred. The Mn tetramer used here does not undergo any spectral change in the pH range 2.0–6.0 therefore spectral evaluation of its basicity was not possible.

It appears from Table 3 that the maximum value of $k_3$ is $4.4 \times 10^{-3}$ $M^{-1}s^{-1}$ for $N^{-I}$ oxidation while it is $8.2 \times 10^{-2}$ $M^{-1}s^{-1}$ for $N^{III}$ oxidation. The reactivity of $NH_2OH$ is higher than $NH_3OH^+$ as the rate increases with pH while it decreases with an increase in pH for the $N^{III}$ redox reaction. The maximum value of $k_2K_1$ for this latter reaction is 82 (much lower than $k_1K_1$), which clearly indicates that $HNO_2$ reacts much quicker with $\mathbf{1}H^{5+}$ or $\mathbf{1}^{4+}$ than $NO_2^-$. The overwhelming dominance of the reactivity of $\mathbf{1}H^{5+}$ is clear in both redox reactions.

## Mechanism

The electrochemistry of $[Mn_4(\mu\text{-}O)_6(bipy)_6]^{4+}$ has been extensively studied by Dunand-Sauthier et al.[27] The cyclic voltammogram of $[Mn_4(\mu\text{-}O)_6(bipy)_6]^{4+}$ in bipy/Hbipy$^+$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

buffer shows only an irreversible reduction peak near 0.40 V (vs. Ag/AgCl) which leads to the formation of $[Mn(bipy)_3]^{2+}$ species.[27] Attempts at electrolytic reduction resulted in decomposition of the tetranuclear complex into four $Mn^{II}$ ions. Standard chemical reduction in solution also failed to achieve the monoreduced form $[Mn^{IV}{}_3Mn^{III}(\mu\text{-}O)_6(bipy)_6]^{3+}$.[14] Exhaustive reduction of $[Mn_4(\mu\text{-}O)_6(bipy)_6]^{4+}$ at 0.20 V (vs. Ag/AgCl) consumes almost eight equivalent of electrons per mole of the tetranuclear oxidant and leads to $Mn^{II}$.[27a] These authors have also shown an intermediate generation of the mixed-valent $[Mn^{III,IV}(\mu\text{-}O)_2(bipy)_4]^{3+}$ species during the conversion to $Mn^{II}$. This mixed-valent species could not, however, be generated selectively and quantitatively as the reduction of the tetranuclear and the mixed-valent species occurs at a very similar potential (approx. 0.4 V vs. Ag/AgCl).[27] We did not observe formation of any such spectrally characterisable binuclear intermediate during the chemical reduction of the title oxidant when reducing agents were used in either excess, deficit or stoichiometric amounts, see Equations (1) and (2).

We can conclude from the known electrochemical behaviour of the title tetranuclear Mn comlex that this species is not a powerful oxidant. The one-electron oxidation of $NO_2^-$ or $HNO_2$ and $NH_2OH$ or $NH_3OH^+$ is, however, highly endothermic. The one-electron oxidation potentials for $NO_2^-/NO_2$, $HNO_2/NO_2$, $H^+$, $NH_2OH/NH_2OH^+$ and $NH_3OH^+/NH_2OH^+$, $H^+$ couples are –1.04,[26] –1.22,[28] –0.91[29] and –1.30 V respectively.[28] An initial one-electron exchange between $[Mn_4(\mu\text{-}O)_6(bipy)_6]^{4+}$ and these reducing species is thus energetically unfavourable although we observe that these reducing agents smoothly reduce the $Mn^{IV}$ oxidant to $Mn^{II}$. An inner-sphere attachment of the reducing species to the $Mn^{IV}$ centres that could provide an alternative pathway is not likely as the $d^3$ $Mn^{IV}$ atoms in the coordinatively saturated oxidant are substitution inert. However, it can be concluded from the known electrochemical behaviour of the tetranuclear Mn oxidant that the intermediate mixed-valent forms are too reactive. In fact, the very high reactivity of the most likely one-electron reduced species produced by cryogenic radiolytic reduction of $\mathbf{1}^{4+}$, namely $[Mn^{IV}{}_3Mn^{III}(\mu\text{-}O)_6(bipy)_6]^{3+}$, has been documented.[30] This species is very unstable even at low temperature (190 K).[30]

In order to further explore the electron-transfer mechanism we measured $k_0$ values in media enriched with $D_2O$ and computed the second-order rate constants or their composites (Table 3) in the same way as in pure $H_2O$ media; they showed kinetic isotope effects. Interestingly, we also note that the $k_1K_1$ path in $N^{III}$ oxidation increases substantially in $D_2O$ media whereas all the other rate constants or their composites decrease. A lowering of the rate in $D_2O$ media is clearly indicative of an electroprotic mechanism.[31] Notably, we also found that the rate enhancement and rate decrease in $H_2O/D_2O$ mixtures for $N^{III}$ and $N^{-I}$ oxidations, respectively, are linearly related ($r > 0.98$) to the $D_2O$ content (Figure 3), which suggests transfer of a single proton in the slow steps.[32]

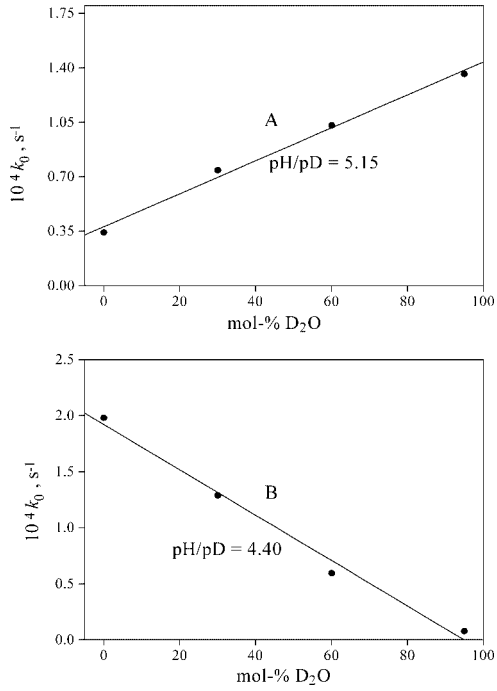

Figure 3. Effect of the amount of $D_2O$ (mol-%) on $k_0$. [complex] = 0.10 mM, $T$ = 25.0 °C, $I$ = 1.0 M. A: $N^{III}$, $[N^{III}]_T$ = 0.05 M, $C_{bipy}$ = 3.0 mM; B: $N^{-I}$, $[N^{-I}]_T$ = 0.01 M, $C_{bipy}$ = 5.0 mM.

An initial one-electron transfer rate-limiting step in the overall eight electron transactions [Equations (5)–(8)] is proposed to result in the intermediate mixed-valent Mn species $Mn^{IV}{}_3Mn^{III}$, which is likely to be reduced quickly in the following steps by the excess reducing agents or the radicals generated at the rate-determining step. We did not observe any polymerisation in either redox reaction when the reactions were carried out in 6% v/v acrylonitrile, although this does not rule out the production of radicals as they may react faster with the one-electron reduced mixed-valent Mn species, which is itself very reactive.[30] The one-electron reduced species of $\mathbf{1}^{4+}$ or $\mathbf{1}H^{5+}$ would have much more basic oxo bridges that immediately accept a proton from the reaction medium, which could remove thermodynamic or kinetics barriers to further reduction.[33] A large increase in the basicity of oxo bridges after one-electron reduction of the bridge carrying higher valent Mn atoms in di- or polynuclear Mn complexes is well documented[34] and is a key feature in the redox steps of the Kok cycle in PS II.[1c,35] Radicals produced from one-electron oxidation of nitrite and hydroxylamine, namely $NO_2$ and $NH_2OH^+$, are well-documented in the literature and pathways leading to the formation of nitrate[16b,36] and nitrous oxide[37] are well-established facets of nitrogen chemistry.

It has been known for a long time that rate increases significantly with $D_2O$ content in an $H_2O/D_2O$ mixture if acid/base pre-equilibrium steps are involved prior to the rate-determining step.[38a–38c] $D_2O$ has a smaller autoprotolysis constant than $H_2O$ by a factor of about 5 and thus it is less basic than water,[38a] which means that the oxo bridges in the title oxidant will be able to compete with the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solvent for the deuteron in $D_2O$ more effectively than for the proton in $H_2O$. An increase in the $K_1$ value in $D_2O$ is thus expected. In general, weak acids in $H_2O$ become much weaker in $D_2O$,[38] and we found that reducing acids like glyoxylic, pyruvic, nitrous and hydroxylammonium cation have considerably higher p$K_a$'s in $D_2O$.[15,20,21] We can thus reasonably expect a higher concentration of $\mathbf{1}H^{5+}$ in $D_2O$ and the observed reversal in the rate constants $k_1K_1$ in the two redox reactions might be a result of competitive increase in the $K_1$ value and a decrease in the $k_1$ value (electroprotic mechanism).

It has been shown recently[39] that an inverse deuterium isotope effect ($k_H < k_D$) is observed during charge recombination between the fully reduced $FADH^-$ anion (FAD = flavin adenine dinucleotide) and the neutral (deprotonated) radical of the solvent-exposed tryptophan W306. This can be interpreted by a model of fast protonation equilibrium for the W306 radical that involves an increase in the p$K_a$ of the radical in $D_2O$, which is 0.56-times that in $H_2O$ buffer. The authors were able to kinetically separate the rate constants, and the rate constant for recombination via deprotonated radical was found to be higher in $H_2O$ than in $D_2O$ (1.4 times).

It seems likely that the second-order rate constants decrease to such a great extent that this overcompensates the effect of an increase in the $K_1$ value in $D_2O$ for the $N^{-I}$ redox reaction whereas it is unable to slow down the $N^{III}$ redox reaction. The rate retardations in $D_2O$ for the oxidation of glyoxylic and pyruvic acid by the title Mn oxidant are much smaller[15] than those observed in the oxidation of $N^{-I}$, which might indicate that the effect of an increase in $K_1$ is almost cancelled out by the decrease in rate constants in $D_2O$ for the oxidations of these α-keto acids. A substantial decrease of $K_a$ in $D_2O$ (compared to that in $H_2O$) also contributes significantly to a remarkable decrease of the composite ($k_2K_1K_a + k_3$) for the $N^{III}$ redox reaction in $D_2O$.

The contribution of reaction (8) in Scheme 1 (for $R^- = NO_2^-$) towards the overall rate is statistically insignificant (Table 3). Moreover, $(k_2K_1)_{max}$ is much lower than $k_1K_1$ for $N^{III}$ oxidation, therefore we may reasonably expect that the $k_3$ path contributes significantly to the measured rate of $N^{III}$ oxidation. The superior reactivity of $HNO_2$ over $NO_2^-$ in reducing $\mathbf{1}^{4+}$ or $\mathbf{1}H^{5+}$ is thus clearly established. Both $NH_2OH$ and $NH_3OH^+$, on the other hand, react with the tetrameric Mn oxidant. It appears that the presence of an H-atom in both these reducing agents is responsible for the observed reactivity and thus a hydrogen atom transfer (HAT) from the reducing acids may be mechanistically conceived to produce the radicals $NO_2^{\cdot}$ or $NHOH^{\cdot}$ along with the protonated oxo bridge in the mixed-valent $Mn^{IV}_3Mn^{III}$ species. The kinetic superiority of $\mathbf{1}H^{5+}$ may be due, at least in part, to its more oxidising nature than $\mathbf{1}^{4+}$ as well as a more facile movement of hydrogen or hydrogen ion through the H-bonding framework formed from the oxo bridges of $\mathbf{1}H^{5+}$ and the oxygen and hydrogens of the reducing species. The molecular mechanics computed structure of the OEC reveals a network of organised hydrogen-bonded species around the OEC[13a,13b,40] cluster, thereby providing an insight into the movement of protons and water in the site.

## Experimental Section

**Materials:** The complex salt hydrate $[Mn_4(\mu\text{-}O)_6(bipy)_6][ClO_4]_4 \cdot 2H_2O$ was synthesised following the literature procedure.[14] One of its water molecules is easily lost[14] therefore the elemental analyses of the material closely resemble the values expected for the monohydrate. The tetramer used here thus appears to be the monohydrate. $C_{60}H_{50}Cl_4Mn_4N_{12}O_{23}$: calcd. C 43.16, H 2.99, N 10.07; found C 43.39, H 3.03, N 10.00.

The preparation, standardisation and storage of sodium nitrite, hydroxylamine nitrate and sodium nitrate have been described previously.[20,41] 2,2′-Bipyridine was used as received from Sigma. $D_2O$ (99.9 atom-% D) and $DNO_3$ (99+ atom-% D) were also purchased from Sigma. All other chemicals were of reagent grade and used as received. Doubly distilled, deionised and then freshly boiled water was used throughout.

**Equilibrium Measurements:** The acid dissociation constants of the reducing acids $HNO_2$ and $NH_3OH^+$ cation in 95% $D_2O$ medium were determined by pH-metric titration using a Metrohm (736 GP Titrino) autotitrator at 25.0(±0.1) °C, $I$ = 1.0 M ($NaNO_3$), as described previously.[20,41,42] To avoid nitrous acid decomposition in acidic media, solutions of $NaNO_2$ were titrated with $DNO_3$ while aliquots of hydroxylamine solutions (initially at pH 2 made by adding $HNO_3$) were titrated with carbonate-free NaOH. The reported values[16,17] of these ionisation constants in $H_2O$ media were used. A similar pH-metric titration of $[Mn_4(\mu\text{-}O)_6(bipy)_6]^{4+}$ was performed in the pH range 2.0–7.0 to examine the basicity of its oxo bridges.

**Stoichiometry Measurements:** The stoichiometries of the reactions were measured with both an excess and a deficit of reducing agent. Reaction mixtures containing 6–15-times $N^{III}$ over the Mn oxidant (0.05–1.50 mM) were allowed to react until the solutions became colourless (absorbance of less than 0.01 at 420 nm). Unreacted $N^{III}$ in these product mixtures was determined colourimetrically. After appropriate dilution, the product solutions were treated with α-naphthylamine and sulfanilic acid. The red dye thus formed was estimated at 520 nm ($\varepsilon = 4.0 \times 10^4$ $M^{-1}cm^{-1}$).[43] We verified that bipyridine, $Mn^{II}$ and $ClO_4^-$ do not interfere in this coupling reaction. $NO_3^-$ as the $N^{III}$ oxidation product was qualitatively detected by the above-mentioned coupling reaction after adding Zn dust. For this purpose reaction mixtures were prepared with complex:$N^{III}$ ratios of between 1:2 and 1:4. The Mn tetramer did not interfere in this colour reaction. Unreacted hydroxylamine was determined by titrating with standard $KBrO_3$ in the usual manner[44] when $Mn^{IV}_4$ (0.5–1.50 mM) was treated with (5–10 mM) $N^{-I}$. Formation of $NO_2^-$ or $NO_3^-$ as the $N^{-I}$ oxidation product was also tested by the coupling reaction described above. Under non-kinetic conditions, 0.10–0.50 mM of the $Mn^{IV}_4$ complex was treated with a less than stoichiometric amount of the reducing agents. Unreacted $Mn^{IV}_4$ complex was measured at 420 nm ($\varepsilon = 7.5 \times 10^3$ $M^{-1}cm^{-1}$) when the reactions reached equilibrium. $Mn^{II}$ in the product solutions was estimated by EDTA titrations using EBT as indicator.[45] For this purpose, excess reducing agent was treated with the Mn oxidant until the absorbance at 420 nm became less than 0.01 and then $Mn^{II}$ was estimated. We verified that $NO_2^-$, $NO_3^-$, $NH_2OH$ or bipy do not interfere in this complexometric titration.

**Physical Measurements and Kinetics:** Absorbance and electronic spectra were recorded with a Shimadzu (1601 PC) spectrophotome-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ter using 1.00-cm quartz cells. The kinetics was monitored in situ with the instrument in "kinetic mode" at 420 nm in an electrically controlled thermostatted 25.0(±0.1) °C cell housing (CPS-240A). Reactions with $t_{1/2}$ less than 30 seconds were monitored using a Biologic SFM-03/QS stopped-flow spectrophotometer with DT-2801 data transmission system. The ionic strength was normally maintained at 1.0 M with $NaNO_3$. The excess 2,2′-bipyridine concentration, $C_{bipy}$ = [(Hbipy$^+$) + (bipy)] was in the range 1–80 mM and acted as a good buffer in the pH range studied (2.0–6.0), which was measured with an Orion-Ross Combined electrode system (Model 81–02) before and after the reaction. Excess bipyridine present in the reaction medium buffers the reaction within 0.05 pH units in the entire pH range studied for nitrite oxidation while for hydroxylamine oxidation a maximum pH increase of 0.15 units was seen when working at a pH below 3.0 but above pH 3.0 the pH drift was around 0.05 pH units. It is possible that $HNO_2$ in the low pH range and both bipyridine and hydroxylamine in the higher pH range act as good buffers.

The electrode calibration was described earlier to read $-\log_{10}[H^+]$ directly from a calibration curve constructed by plotting the pH-meter reading against $-\log_{10}[H^+]$.[46] For reactions in $D_2O$, pD was calculated as $pH_{measured} + 0.40$.[47] An excess of reducing agent was maintained in all the kinetic runs. The $\log_{10}$(absorbance) vs. time plots were found to be good straight lines for up to at least 90% completion of reactions and the observed rate constants ($k_0$) were calculated in the usual way.

**Supporting Information** (see also the footnote on the first page of this article): Linearisation of Equation (9) for the $N^{III}$ redox reaction and evaluation of $k_4$ for the $N^{-I}$ redox reaction from a linear plot at pH ≥ 5.3.

## Acknowledgments

The award of a Senior Research Fellowship (SRF) to Suranjana Das by the Council of Scientific and Industrial Research, New Delhi, India is gratefully acknowledged. We also thank Professor Soumen Basak, Head, Chemical Sciences Division, Saha Institute of Nuclear Physics (SINP), Salt Lake, Calcutta 700 064 and Dr. Kalyan Giri of SINP for permitting us to use the stopped-flow spectrophotometer at SINP and providing kind help.

# 3D Architectures of InOOH: Ultrasonic-Assisted Synthesis, Growth Mechanism, and Optical Properties

Liyong Chen,[a] Xuchu Ma,[a] Yankuan Liu,[a] Yan'ge Zhang,[a] Weizhi Wang,[a] Yi Liang,[a] and Zude Zhang*[a]

**Keywords:** Indium / Mechanism / UV/Vis spectroscopy / Solvothermal synthesis

An ultrasonic-assisted solvothermal route based on the hydrolysis of $In^{3+}$ was utilized to synthesize InOOH with a hierarchic three-dimensional (3D) architecture, which was assembled by single-crystalline nanowires with diameters of about 10 nm and lengths up to several hundred nanometers. X-ray powder diffraction (XRD), field emission scanning electron microscopy (FE-SEM), transmission electron microscopy (TEM), and FTIR spectra were used to characterize the obtained products. Alkaline media and solvent play crucial roles in influencing the phase and the morphology of the products. A possible mechanism was proposed to explain the formation process of the InOOH 3D nanostructure. The optical properties of InOOH was also investigated by ultraviolet and visible (UV/Vis) spectroscopy, which indicated that InOOH is a wide band-gap semiconductor.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

In the past few years the synthesis of materials has essentially focused on size and shape and dimensionality control.[1] To date, challenges in the synthesis of nanomaterials include the control of morphology and the assemblage of ensembles of nanostructures. Because hierarchical structures may provide new forms with extremely high surface-to-volume ratios with potential applications as new catalysts or as a scaffolding support, nanoscale units used to build complex and hierarchical nanoarchitectures have attracted significant interest in material synthesis and device fabrication; some of these architectures include hierarchical three-dimensional (3D) MnS[2] and $TiO_2$,[3] flower-like iron oxide[4] and AlOOH,[5] dandelion-like CuO[6] and ZnO,[7] and urchin-like NiS[8] and $WO_3$.[9] Previously, several synthetic strategies were developed to fabricate 3D architectures assembled from nanowires, where polymers or solid templates were required to control the highly oriented growth of the nanowires.[10] However, the use of additives (i.e. polymers, templates) would increase the production cost and also introduce heterogeneous impurities. Thus, it is still a significant project to develop facile, additive-free, and easily controlled synthetic methods for the construction of 3D architectures of anisotropic materials.

Nanometer-scale indium oxyhydroxide (InOOH) and indium sesquioxide ($In_2O_3$) have found applications in the fields of semiconductors and optical materials.[11] InOOH, the hydrate of $In_2O_3$,[12] can be directly formed by the dehydration of $In(OH)_3$. Further calcination of InOOH at ambient pressure will produce metastable corundrum-type $In_2O_3$, an important n-type semiconductor with a direct bandgap of ca. 3.6 eV.[11b,13] To the best of our knowledge, many efforts have been made to synthesize micro- and/or nanostructured InOOH with different morphologies, such as nanofibers,[13a] nanotubes,[13b] and hollow spheres.[11c] However, hierarchical InOOH architectures consisting of nanoscale units have seldom been reported. Recently, sonochemical methods were proposed to synthesize nanomaterials with various structures,[14] because ultrasonic sound waves can provide energy by radiating through a solution and causing alternative high and low pressures in the liquid medium. The energy released from sonication can lead to enhanced chemical reactivity and accelerated reaction rates. Herein, we address our recent work on the synthesis of hierarchically 3D InOOH architectures composed of uniform nanowires, which involves an additives-free ultrasonic-assisted solvothermal route. This method uses the reaction among ethylenediamine (En), water, and $In^{3+}$. On the basis of investigations on the effect of En, we find that it might server as the structure-directing agent in the formation of InOOH nanowires, similar to the role of En as a structure-directing coordination template in previous studies.[15] Moreover, the UV/Vis spectrum showed that InOOH with a hierarchical 3D architecture is a typical wide band-gap semiconductor with $E_g$ of ca. 4.44 eV, which suggests that InOOH has the potential to be used in optical devices.

## Results and Discussion

Figure 1 shows the XRD pattern of the products prepared at 210 °C for 24 h. All the diffraction peaks can be indexed to orthorhombic InOOH with cell parameters $a$ = 5.23 Å, $b$ = 4.55 Å, and $c$ = 3.26 Å, which are in good agreement with values from the standard card (JCPDS No. 71-2277). The XRD pattern confirms a highly crystalline nature of InOOH. Note that the diffraction peaks become broad, indicating that the size of the domain may be small.

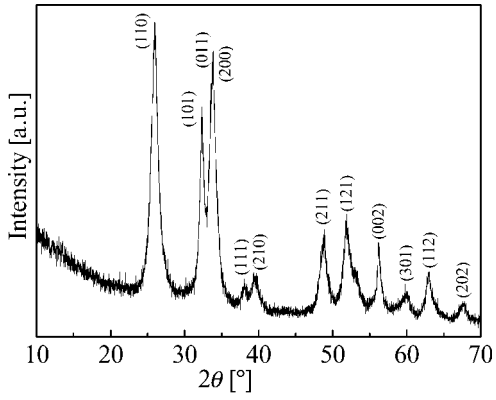

Figure 1. XRD pattern of InOOH prepared at 210 °C for 24 h.

The morphology and structure of the products obtained at 210 °C for 24 h were determined by FE-SEM and TEM. Figure 2a shows a panoramic FE-SEM image that shows that the samples have hierarchical 3D architectures with sizes in the range of several hundred nanometers to 1 μm. Figure 2b is a high-magnification FE-SEM image and Figures 2c–e are TEM images. Through careful observation (Figure 2b, d), we find that the architectures consist of nanowires with uniform diameters of ca. 10 nm and lengths up to several hundred nanometers. The nanowires were also investigated by the selected area electron diffraction (SAED) pattern and high-resolution transmission electron microscopy (HR-TEM). In the SAED pattern (Figure 2e, inset), the first diffraction ring corresponds to the (110) plane reflection of the orthorhombic InOOH structure. Owing to the fact that the atomic plane spacings of (101), (011), and (200) are very close, and that these three reflection rings look like one, the second diffraction ring cannot be distinguished well. Figure 2f is a HRTEM image, taken from a randomly chosen nanowire, where the average value of the plane spacing along the vertical direction is ca. 0.265 nm, and the value of the plane spacing along the inclined direction is about 0.279 nm. These two series of interplanar spacings correspond to the d spacing of the (101) and (200) planes of orthorhombic InOOH, respectively. These results further confirm the single-crystal nature of the samples.

In this strategy, we explored the influencing factors and optimized the reaction conditions; we coupled this with the appropriate choice of alkaline media and solvent to control the phase and the morphology of the obtained products. Sonication was extensively used for the generation of zero-

Figure 2. dimensional (0D) and one-dimensional (1D) nanostructures, as sonication is generally used as the driving force for nucleation. Here, we utilized the energy from the sonication process to induce the formation of uniform seeds,[14c] which favored the formation of nanowires with uniform diameters under solvothermal conditions. The TEM image (Figure 3a) reveals that the morphology of the products prepared without presonication have 3D structures composed of nonuniform nanowires. Figure 3b presents a high-magnification TEM image taken from their edge, which further testifies to the fact that the diameter of these nanowires are not uniform.

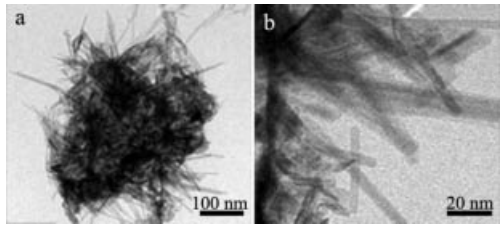

Figure 3. (a) Low-magnification TEM image of 3D InOOH architectures; (b) high-magnification TEM image recorded at the edge of the InOOH 3D architectures that shows nanowires with nonuniform diameters. These InOOH products were prepared without sonication.

As far as the alkaline media was concerned, En was found to be important in determining the phase and the morphology of the products. En acts as a structure-direct-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing coordination agent to obtain InOOH nanowires as a result of it being a good ligand. En also provides the basicity for the system and facilitates the hydrolysis reaction of $In^{3+}$ and the formation of the orthorhomic InOOH phase. To better understand the role of En in this synthetic process, different organic amines such as hexamethylene diamine or diethylamine were used as a substitute for En in controlled experiments. Figures 4a, b show TEM images of the products prepared in both parallel experiments; both products are solid quasispherical structures composed of nanoparticles. Their phases are characterized by XRD patterns (Figure 4c), where all diffraction peaks can be indexed to cubic $In_2O_3$ (JCPDS No. 76-0152). Obviously, En may play a crucial factor in determining the phase and morphology of InOOH. To further explore the function of En, the intermediate products prepared in the initial 1, 2, 6, and 24 h were studied by FTIR as shown in Figure 4d, Curves 1–4, respectively. Figure 4d, Curve 1 clearly displays peaks at 3220 and 3097 $cm^{-1}$ for the –NH stretching vibration; it is shifted to lower wavenumbers than that of free En, whereas peaks at 2936 and 2890 $cm^{-1}$ for the $–CH_2$ stretching vibration and the peak at 1580 $cm^{-1}$ for the –NH bending vibration are shifted to higher wavenumbers relative to free En.[15c,16] These data confirm that the coordinative effect of En mostly exists in our experiments. Curves 3 and 4 (Figure 4d) exhibit two peaks at 3425 and 1980 $cm^{-1}$ together with a broad band at 2700 $cm^{-1}$ for the –OH vibration of InOOH and another peak at 445 $cm^{-1}$ for the In–O vibration absorption,[11c,17] which reveals that InOOH has already formed after the initial 6 h. On the contrary, the intensity of the characteristic absorption peaks of En gradually decreases, whereas those of InOOH gradually increase with prolonged reaction times. These experimental results reveal that En is the optimum alkaline medium and has a great influence on the growth of InOOH with 3D architectures.

To further investigate the mechanism of formation of InOOH with a hierarchical 3D architecture, time-dependent experiments involved in growth processes were conducted. The products prepared at various stages were followed by TEM imaging. Figure 5 shows TEM images of the intermediate samples obtained at 1, 2, 6, 8, 12, and 36 h. At the initial stage there are many nanoparticles formed with small sizes (Figure 5a, b). With prolonged reaction times, some short nanorods are developed at the expense of these small nanoparticles (Figure 5c). After longer reaction times, the nanoparticles gradually disappear and nanorods slowly grow into long nanowires (Figure 5d, e). These images clearly show the transformation process of the products from nanoparticles to nanorods and then to nanowires. However, the obtained sample has a 3D architecture composed of nonuniform nanowires (Figure 5f) when the reaction time is prolonged to 36 h, which reveals that an increase in the reaction time to greater than 24 h is unfavorable for the formation of uniform nanowires. The evolution of the products was also tracked by XRD (Figure 6a–f). As shown in Figure 6a, the product formed in the initial first hour is amorphous. From Figure 6b, it is found that there

is a diffraction peak at 22.4°, which corresponds to the diffraction of (200) lattice plane of cubic $In(OH)_3$ (JCPDS No. 85-1338) and indicates that the products already exist as cubic $In(OH)_3$ phases in the initial 2 h. By increasing the reaction time to 6 h and then 8 h, the diffraction peak of the (200) lattice plane increases firstly (Figure 6c), but then gradually decreases (Figure 6d). When the reaction time reaches 12 h, the diffraction peak completely disappears (Figure 6e). The orthorhombic InOOH diffraction peaks are also observed in the initial 2 h, and they progressively become sharper and stronger with longer reaction times. When the reaction time is increased to 36 h, a highly crystalline InOOH phase is obtained (Figure 6f). On the basis of these XRD patterns there is evidence to support a "dissolution–recrystallization" process. The $In(OH)_3$, nanoparticles are first formed and then slowly dissolved together with the gradual formation of InOOH nanocrystals owing to the fact that the solubility of $In(OH)_3$ is larger than that of InOOH. Hence, the phase transformation from $In(OH)_3$ to InOOH exists in this strategy, and the reactions can be simply expressed in Equations (1) and (2).

$$In^{3+} + 3H_2O \rightarrow In(OH)_3 + 3H^+ \quad (1)$$

$$In(OH)_3 \rightarrow InOOH + H_2O \quad (2)$$

Additionally, it is found that the morphology and the phase of the products also depend on the solvents used in the synthesis process. A mixture of dimethyl formamide (DMF) and water as the solvent results in the growth of uniform InOOH nanowires rather than 3D structures. If dimethyl acetamide (DMA) is used as the solvent instead of DMF while all other conditions are kept unchanged, only aggregated InOOH nanorods are obtained (Figure 7a), which indicates that InOOH nanowires could not form in DMA medium. The experimental result reveals that DMF is favorable for the exhibition of the coordination template effect from En. Also, when varying the volume of deionized water, the formation of the products prepared is seriously affected. Figure 7b shows the TEM image of a sample obtained in the presence of 1 mL of deionized water; it indicates that the increase in water facilitates the formation of aggregated InOOH short nanorods. Moreover, if the amount of water is less than 0.25 mL or more than 5 mL, we cannot obtain pure InOOH, which denotes that the amount of water is a crucial factor in controlling the phase of the orthorhombic InOOH. This is possibly due to small amounts of water inhibiting the hydrolysis of $In^{3+}$ and the abundant amount of water restraining dehydration of $In(OH)_3$ [Equations (1) and (2)]. These control experiments revealed that 3D InOOH architectures consisting of nanowires can be obtained when using a mixture of DMF (15 mL) and water with a volume between 0.25 and 0.4 mL.

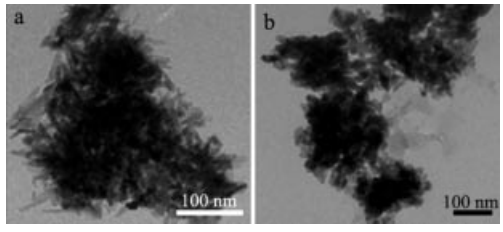

Figure 7. TEM images of samples: (a) when dimethyl acetamide was used as the solvent; (b) in the presence of deionized water (1 mL).

Combined with the above-mentioned discussion, a structure-directing coordination template mechanism under the ultrasonic-assisted conditions is proposed. The growth process of InOOH with hierarchical 3D architecture undergoes four distinctive stages: (1) Sonication induces the nucleation from the reaction of water, En, and $In^{3+}$. (2) Subsequently, many nanoparticles with small sizes are formed under the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solvothermal conditions and aggregate loosely due to the presence of the amido groups on the surface of the nanoparticles. Here, the phase of products formed in the stage is cubic $In(OH)_3$, which results from the hydrolysis of amorphous precursors. (3) Owing to the difference in solubilities of $In(OH)_3$ and InOOH, $In(OH)_3$ progressively dehydrolyzes to form InOOH. Simultaneously, InOOH nanorods are gradually obtained in the "dissolution–recrystallization" process of the particles of the precipitate as a result of the anisotropic crystal structure and the structure-directing coordination template effect from En, because En selectively adsorbs onto the lateral surfaces of the InOOH nanorods and restrains the lateral growth of the nanorods.[18] (4) With longer reaction times, all of the $In(OH)_3$ is eventually transformed into InOOH. Moreover, the nanorods would develop continuously into long nanowires and these nanowires could assemble into a 3D architecture because of the presence of hydrogen bonding between the hydroxy[5] and amido groups on the surface of the nanowires.

Finally, a UV/Vis spectrum was recorded with ethanol used as a reference to investigate the optical properties of the synthesized InOOH with a hierarchical 3D architecture. Figure 8 shows a typical UV/Vis spectrum; there is a broad absorption peak located at 279 nm (ca. 4.44 eV). Relative to the literature data of 3.5 eV,[11c] an obvious blueshift is observed, which can be attributed to the smaller diameters and larger aspect ratios of the nanowires.[19] The result from the UV/Vis spectrum indicates that InOOH is a wide band-gap semiconductor.

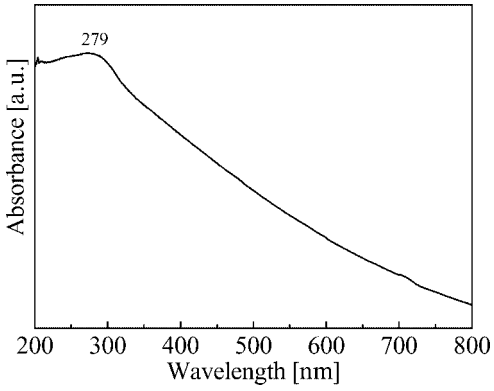

Figure 8. UV/Vis absorbance spectrum of InOOH with 3D architectures.

## Conclusions

InOOH with a hierarchical 3D architecture was synthesized by a facile solvothermal route under the assistance of ultrasonic conditions. The phase and the morphology of the products were controlled by the choice of alkaline media and also the solvent. Sonication can help to form nucleation of uniform nanowires that assemble into 3D nanostructures. A possible structure-directing coordination template mechanism is proposed to explain the formation of InOOH with 3D hierarchical architectures. On the basis of a UV/Vis spectrum, InOOH is an important wide band-gap semiconductor. The present method is simple, and it can be extended to the preparation of other 3D nanostructured materials.

## Experimental Section

**Preparation of InOOH with a Hierarchical 3D Architecture:** All reagents were of analytical grade, purchased from Shanghai Chemical Company, and used without further purification. In a typical procedure, $InCl_3{\cdot}4H_2O$ (0.5 mmol) and deionized water (0.25–0.40 mL) were mixed in a conical flask. After $InCl_3$ dissolution, dimethylformamide (15 mL) and ethylenediamine (5 mL) were added into the flask, and then the mixture was sonicated for about 1 h. The resulting solution was transferred to a 22-mL Teflon-lined autoclave, which was sealed and maintained between 210–220 °C for 24 h in a digital-temperature-controlled oven. The autoclave was cooled to room temperature naturally, and a white precipitate was collected by centrifugation and washed with distilled water and absolute ethanol several times, and dried in vacuo at 50 °C for 4 h.

**Sample Characterization:** The XRD patterns of the sample were recorded with a Philips X′pert X-ray diffractometer with Cu-$k_\alpha$ radiation ($\lambda$ = 1.54187 Å). The morphology of the sample was observed with a JOEL JSM-6700 field emission scanning electron microscopy (FE-SEM). The nanostructures of the sample were analyzed with a JEOL-2010 transmission electron microscopy (TEM) at an acceleration voltage of 200 kV. The FTIR spectra were obtained with a PerkinElmer FTIR spectrometer. The ultraviolet and visible (UV/Vis) spectrum was recorded with a Shimadzu DUV-3700 spectrophotometer.

# Two Novel Species, (Methoxycarbonyl)sulfenyl Thiocyanate and (Methoxycarbonyl)sulfenyl Selenocyanate: Spectroscopic Characterization by Photoelectron Spectroscopy and Quantum Chemical Investigation

**Lin Du,[a,b] Li Yao,[a,b] and Maofa Ge*[a]**

**Keywords:** Ab initio calculations / Dichalcogens / Electronic structure / Photoelectron spectroscopy

Two novel dichalcogens, (methoxycarbonyl)sulfenyl thiocyanate, $CH_3OC(O)SSCN$, and (methoxycarbonyl)sulfenyl selenocyanate, $CH_3OC(O)SSeCN$ have been generated in a convenient way by gas-solid reactions between $CH_3OC(O)SCl$ and AgSCN or AgSeCN. Photoelectron spectroscopy and theoretical calculations have been performed to investigate their electronic and geometrical structures. Both compounds are theoretically predicted to prefer *gauche* structure as the most stable conformation. In $CH_3OC(O)SSCN$, the S–S bond length and the dihedral angle around the S–S bond for the most stable conformer are 2.075 Å and 80.5°, respectively. And the S–Se bond length and the dihedral angle around the S–Se bond in $CH_3OC(O)SSeCN$ are predicted to be 2.210 Å and 80.4°, respectively. The first vertical ionization energies of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ are determined to be 10.19 and 9.84 eV, respectively. The HOMOs correspond to the electron mainly localized on the S 3p or Se 4p lone pair MOs: $\{38a(n_{S(SCN)})\}^{-1}$ and $\{47a(n_{Se})\}^{-1}$, respectively.

## 1. Introduction

In recent years, it has been found that chalcogen–chalcogen interactions play a crucial role in the structure and reactivity of a great variety of chalcogen-containing compounds.[1,2] The chalcogen–chalcogen bonds in bivalent compounds (REE′R′, E, E′ = O, S, Se) are known to prefer *gauche* conformations, which is usually attributed to lone-pair interactions.[3] These interactions favor a dihedral angle of about 90°, and steric interactions between the substituents (R, R′) tend to increase this angle. There are many experimental studies about the structural and conformational properties of homonuclear dichalcogens ROOR′,[4,5] RSSR′,[6,7] and RSeSeR′.[8,9]

In 1977, Snyder et al.[10] discussed the lone pair interactions in RSSR vs. RSOR by means of semiempirical MO calculations. Particular attention was paid to the α-lone pair interactions, and the study concluded that the two species were predicted to exhibit comparable equilibrium geometries. Because of the instability of thioperoxides RSOR′, until recently, only a few experimental studies were performed to investigate their structural and conformational properties.[11–13] Very recently, the parent compound of thioperoxides, HSOH was studied by microwave spectroscopy and high-level ab initio calculations [CCSD(T)/cc-pCVQZ],[14] which demonstrated its structure in detail. As for the experimental studies of the electronic structure of thioperoxides, dimethoxysulfane $[(CH_3O)_2S]$ and dimethoxydisulfane $[(CH_3O)_2S_2]$ were discussed according to their photoelectron spectra.[15] In 2006, Zeng et al.[16] investigated bis(trifluoroaceto) disulfide, $CF_3C(O)OSSOC(O)CF_3$, by Raman, photoelectron spectroscopy (PES), and theoretical calculations.

The electronegativity of selenium is close to that of sulfur. Therefore, similar structural and spectroscopic characteristics are expected in the selenium and sulfur derivatives.[17] As for the studies of sulfenoselenates with the general formula RSSeR′, there were some theoretical investigations about HSSeH,[18–20] and the crystal structure of NCSSeSCN[21] was also reported. In 2003, Sanz et al.[22] investigated the gas-phase acidity of 1,8-chalcogen-bridged naphthalenes, which also possess the S–Se bond, by means of high-level density functional theory computations.

However, there is no experimental work reported of RSSeR′, and no electronic structure information is currently available. They are quite unstable and difficult to obtain for experimental detection. In the present work, a simple dichalcogen hydride, (methoxycarbonyl)sulfenyl selenocyanate $[CH_3OC(O)SSeCN]$, was generated and characterized by photoelectron spectroscopy. With the help of quantum chemical calculations, its geometric structure was theoretically predicted and its electronic structure was discussed. The first vertical ionization energy of $CH_3OC(O)$-

SSeCN was determined for the first time by means of PES. In addition, a novel disulfide, (methoxycarbonyl)sulfenyl thiocyanate [$CH_3OC(O)SSCN$], which has a similar structure to $CH_3OC(O)SSeCN$, was generated and characterized with the same method for comparison.

## 2. Results and Discussion

### 2.1 Molecular Structure

For both compounds, stable conformers with synperiplanar (sp) or antiperiplanar (ap) orientation of the C=O bond with respect to the S–S or S–Se bond are expected. Preliminary structure optimizations at the B3LYP/6-31G* level resulted in *gauche* structures around the S–S or S–Se bond. The potential functions for internal rotation around the S–S bond in $CH_3OC(O)SSCN$ were derived by structure optimizations at fixed dihedral angles between 30° and 330° using the HF and B3LYP method with the basis set of 6-31G* (Figure 1). There is no other minimum except the expected minima for the *gauche* structures with the dihedral angle around 80° (HF/6-31G*) or 90° (B3LYP/6-31G*). And the energy barrier for the S–S rotation is calculated to be 4.42 (HF/6-31G*) and 3.84 (B3LYP/6-31G*) kcal/mol, respectively. This is caused by the S–S lone pair repulsion and steric interactions between $CH_3OC(O)$ and CN moieties. Because of the structural similarity between the title compounds, the situation for $CH_3OC(O)SSeCN$ is probably the same, that is to say, conformers with *gauche* structure around the S–Se bond should be stable. Furthermore, according to the relative orientation of the $CH_3O$ moiety with respect to the C=O bond, which also can be synperiplanar (sp) or antiperiplanar (ap), four possible conformers exist for each of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$. After structural optimization and vibrational analysis, three conformers of each compound are found to be stable, except the conformers with the C=O bond *anti* to the S–S or S–Se bond and $CH_3O$ *anti* to the C=O bond. The three stable conformers of $CH_3OC(O)SSeCN$ are presented in Figure 2.

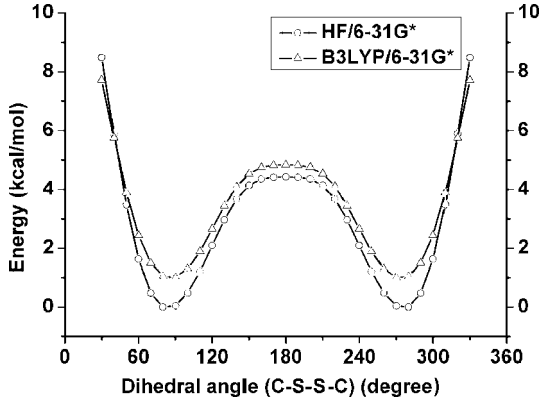

Figure 1. Calculated potential curves for internal rotation around the S–S bond in $CH_3OC(O)SSCN$. The curve of B3LYP/6-31G* is shifted by 1 kcal/mol.

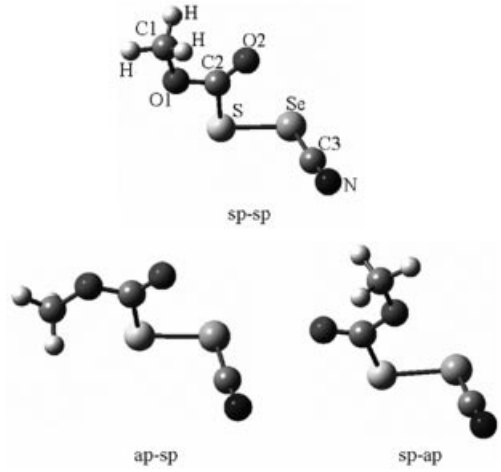

Figure 2. Schematic representation of the three stable conformers of $CH_3OC(O)SSeCN$.

Relative Gibbs free energies ($\Delta G$) calculated at 298 K for all the stable conformers of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ are summarized in Table 1. According to these relative Gibbs free energies, the *gauche* (sp-sp) and the *gauche* (sp-ap) conformers are expected to be more stable. All the calculations predict the lowest energy for the *gauche* (sp-sp) conformer. Similar to their parent compound, $CH_3OC(O)SCl$, the structures of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ can be rationalized by the aromaticity and the anomeric effect.[23] The stabilization of the *gauche* (sp-sp) conformers are accounted for by the attractive π nonbonded interactions in those conformations. Moreover, the instability of the *anti* conformers in these two molecules can be understood on the basis of the aromaticity. Besides, if one of the central atoms in an A–B–C–D chain, e.g., B, possesses one or more lone pairs, the generalized anomeric effect may have a large influence on the conformational properties.[24] This effect contributes to the preference for the *syn* form for the conformation of –C(O)-S–containing compounds.[25] Our discussion of the geometrical and electronic structures of these two compounds will mainly focus on the theoretically most stable conformers.

Table 1. Calculated relative Gibbs free energies ($\Delta G$, kcal/mol, $T$ = 298 K) for different conformers of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$.

| | HF/6-31+G* | B3PW91/6-31+G* | B3LYP/6-311G* |
|---|---|---|---|
| $CH_3OC(O)SSCN$ | | | |
| *gauche* (sp-sp)[a] | 0 | 0 | 0 |
| *gauche* (ap-sp) | 8.93 | 6.32 | 6.93 |
| *gauche* (sp-ap) | 1.09 | 0.62 | 0.81 |
| $CH_3OC(O)SSeCN$ | | | |
| *gauche* (sp-sp) | 0 | 0 | 0 |
| *gauche* (ap-sp) | 8.42 | 5.91 | 6.94 |
| *gauche* (sp-ap) | 0.60 | 0.19 | 0.77 |

[a] *gauche* refers to the configuration around the S–S or S–Se bond. The first orientation (sp or ap) refers to $CH_3O$ with respect to the C=O bond, and the second orientation (sp or ap) refers to the C=O bond with respect to the S–S or S–Se bond.

[a] Distances in Å, angles in degrees. All the calculations were performed with the basis set of 6-311++G(d,p). As for the atom numbering of $CH_3OC(O)SSeCN$, see Figure 2. [b] For $CH_3OC(O)SSCN$, Se atoms should be replaced by the corresponding S atoms.

The electronegativity of selenium and sulfur are close to each other. Therefore, the structures of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ are similar (Table 2). It is well known that the B3LYP method doesn't do well in modeling relatively weak polar bonds. The MP2 method is believed to be more accurate to obtain the geometry. When optimized with the three methods (Table 2), polarization and diffusion functions were added to assure the calculations were more accurate. The optimized structures with B3LYP and B3PW91 methods, both of which are DFT methods, are nearly identical. Our discussion of the geometry is based on the structures optimized with the MP2 method.

A study on the structural and conformational properties of disulfanes has been reported recently.[7] The conformation of dichalcogens (REE′R′) is mainly determined by the geometry of the EE′ moiety. According to theoretical calculations, the S–S or S–Se bond lengths of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ are 2.075 Å and 2.210 Å [MP2/6-311++G(d,p)], respectively. The S–S bond length in $CH_3OC(O)SSCN$ is slightly larger than that of its parent compound, HSSH [2.0610(3) Å].[26] However, there is no experimental work reported about HSSeH. The S–Se bond length in HSSeH was predicted to be 2.269 Å according to ab initio calculations.[19] As determined by X-ray diffraction, the S–Se bond length in NCSSeSCN is 2.214 Å,[21] which is quite close to the predicted value of $CH_3OC(O)SSeCN$.

Besides the E–E′ bond length, another important structural parameter for dichalcogens is the torsional angle $\delta_{REE'R'}$, which greatly influenced the whole structure of the molecules. Gas-phase structures of noncyclic dichalcogens are characterized by the dihedral angle $\delta_{REE'R'}$ close to 90°: for example, HOOH (112°),[27] HSSH [90.76(6)°],[26] and $CH_3SeSeCH_3$ (87.5°).[8] The torsional angle in HSOH was 91.3°, as determined by high-level ab initio calculations [CCSD(T)/cc-pCVQZ].[14] In $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$, the dihedral angles around the S–S or S–Se bond are 80.5° and 80.4° [MP2/6-311++G(d,p)], respectively. The interpretation of the population analysis[28] is consistent with two qualitative arguments about the preference of about 90° of the RSSR′ dihedral angle. A plausible interpretation of the population analysis is related to the resulting barrier formed by the repulsion of 3pπ AO lone pairs. The repulsion is minimized, if these AOs are oriented orthogonal to each other. The second argument[29] is based on a hyperconjugative mechanism, whereby the π-character of the S–S bond is enhanced when, for example in HSSH, the S–H bonds are aligned for maximum transfer of electron density through the 3pπ AOs to the H atom. This feature is consistent with the anomeric effect, that is, the electron donation from the sulfur lone pair into the empty σ* orbitals of the opposite S–H bonds.[24] In other dichalcogens, a similar feature may also exist.

### 2.2 Photoelectron Spectroscopy

Photoelectron spectroscopy with a HeI resonance source (58.4 nm) is an effective method to investigate electronic structures of unstable compounds and free radicals in combination with ab initio calculations.[30,31] The valence shell structure of molecular vapors can be readily obtained by HeI photoelectron energy analysis, especially for studying similar molecules.[32] The HeI photoelectron spectra of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ are shown in Figure 3 and Figure 4, respectively. Before assigning the spec-

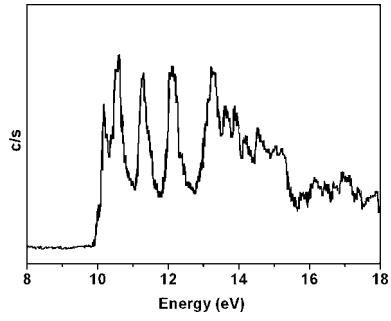

Figure 3. HeI photoelectron spectrum of $CH_3OC(O)SSCN$.

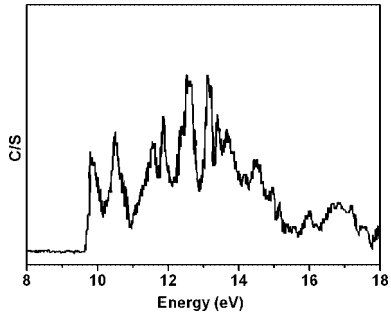

Figure 4. HeI photoelectron spectrum of $CH_3OC(O)SSeCN$.

tra, ROVGF[33] calculations were carried out to obtain the ionization energies for $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$. No noticeable difference can be found between the orbital energies of the two stable conformers of *gauche* (sp-sp) and *gauche* (sp-ap), therefore our discussion is reduced to the analysis of the slightly more stable conformer *gauche* (sp-sp). The experimental vertical ionization potentials, theoretical vertical ionization energies, molecular orbitals, and corresponding characters of outer valence shells for the *gauche* (sp-sp) conformers of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ are listed in Table 3. The ROVGF results are in general in agreement with the experimental data. Drawings of nine MOs for $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ are given in the supporting information.

Table 3. Experimental vertical ionization energies (IP in eV), computed vertical ionization energies [ROVGF/6-311++G(d,p), $E_v$ in eV], and molecular orbital characters for $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$.

| Molecule | Exp. IP | Calcd. $E_v$ | MO | Character |
|---|---|---|---|---|
| $CH_3OC(O)SSCN$ | | | | |
| | 10.19 | 10.27 | 38 | $n_{S(SCN)}$ |

| | | 13.70 | 39 | $\pi_{SeCN}$ |

As pointed out by Baker et al.,[34] for disulfides, peroxides, and diselenides, the first two bands in the photoelectron spectra correspond to the symmetric and antisymmetric linear combinations of the outermost *p*-atomic orbitals. The first two peaks in the photoelectron spectrum of $CH_3OC(O)SSCN$ are centered at 10.19 and 10.60 eV. The main characters for the first two outmost orbitals are $\{38a(n_{S(SCN)})\}^{-1}$ and $\{37a(n_{S(COS)})\}^{-1}$, and the theoretically predicted first two vertical ionization energies are 10.27 and 10.64 eV, respectively, in good agreement with the experimentally observed values. The energy difference $\Delta E$ between the first two bands in $CH_3OC(O)SSCN$ ($\delta_{CSSC}$ = 80.5°) is 0.41 eV, which is bigger than that of $FC(O)SSCH_3$ [$\Delta E$ = 0.3 eV, $\delta_{CSSC}$ = 83.5(15)°].[35] This difference is originated by the interaction of the two lone pairs at the adjacent S atoms showing a clear dependence on the dihedral angle. Generally, it is to be expected that as the dihedral angle $\delta$ deviates from 90°, the energy difference $\Delta E$ will increase, i.e., the 3p orbitals in parallel configuration ($\delta$ = 0°, 180°) interact more strongly than in an orthogonal configuration ($\delta$ = 90°).[28]

The most peculiar aspects of the photoelectron spectra of the dichalcogens (REE′R′) concern the pattern of the n ionization energies, whose ordering and splitting have been rationalized in terms of the popular concepts of mediated interplay of through-bond and through-space interactions between semilocalized orbitals.[20] In general, the pattern of the splitting is predicted to be $\Delta(OO) > \Delta(SS) \approx \Delta(SeSe)$ for the homonuclear systems and $\Delta(SO) > \Delta(SeS)$ for the heteronuclear; the differences in heteronuclear systems are much larger than those in homonuclear systems.[20] The successive replacement of O by S and Se causes only a progressively minor perturbation of the electronic structure, as is expected from the electronegativity sequence of the chalcogens, O (3.5 on Pauling's scale), S (2.5), and Se (2.4).[20] For sulfenoselenates with the general formula RSSeR′, the splitting of the bands also exists in the photoelectron spectra. The first two peaks in the photoelectron spectrum of $CH_3OC(O)SSeCN$ is centered at 9.84 and 10.56 eV, respectively, which are lower than the corresponding ionization energies of $CH_3OC(O)SSCN$. The energy difference $\Delta E$ in $CH_3OC(O)SSeCN$ is 0.72 eV. This difference is larger than that of $CH_3OC(O)SSCN$, but close to its parent compound HSSeH (0.66 eV),[20] as clearly seen from Figure 5.

The third band (11.32 eV) in the photoelectron spectrum of $CH_3OC(O)SSCN$ can be attributed to the $n_O$ electron of the C=O bond, which is similar to the corresponding orbital of the third band (11.54 eV) in that of $CH_3OC(O)SSeCN$. In comparison to the first band of $CH_3OC(O)H$[32] at 10.99 eV $\{13a'(n_{O(C=O)})\}^{-1}$, the inductive effect of the SSCN or SSeCN moiety has raised the ionization energy of the carbonyl oxygen lone pair orbital $n_O$ by 0.33 and 0.55 eV, respectively. The third band in the photoelectron spectrum of $FC(O)SSCH_3$ (11.3 eV),[35] also caused by the ionization of the $n_O$ lone pair, is nearly equal to the corresponding ionization energy of $CH_3OC(O)SSCN$. The ionization from the orbital mainly localized at the $\sigma$ bond of the SS or SSe moiety and the $\pi$ orbital on the C≡N moiety causes the energies of 12.08 and 11.84 eV in $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$, respectively. Both are smaller than the ionization energies from $\sigma_{EE'}$ orbitals of their corresponding parent compounds (Figure 5). The differences are caused by the effect of the different substituents on the E–E′ bonds.

The vertical ionization energies from the ionization process of $\{4a''(n_{O(CH3O)}, n_{O(C=O)})\}^{-1}$ in $CH_3OC(O)Cl$ and $CH_3OC(O)CN$ are 12.21 and 12.01 eV, respectively.[32] While in $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$, the corresponding ionization energies are 12.08 and 12.50 eV, respectively. The ionization energies from 13.26 eV to 14.17 eV in $CH_3OC(O)SSCN$ correspond to different orbitals on the SCN moiety. The situation in $CH_3OC(O)SSeCN$ is similar. The electronic structure of the SeCN moiety can be explained in two ways.[17] We can assume a single Se–C bond and a triple C≡N bond, so two bands from the C≡N $\pi$ bond are expected in the low-energy region of the spectrum. Another interpretation is when the SeCN unit is con-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

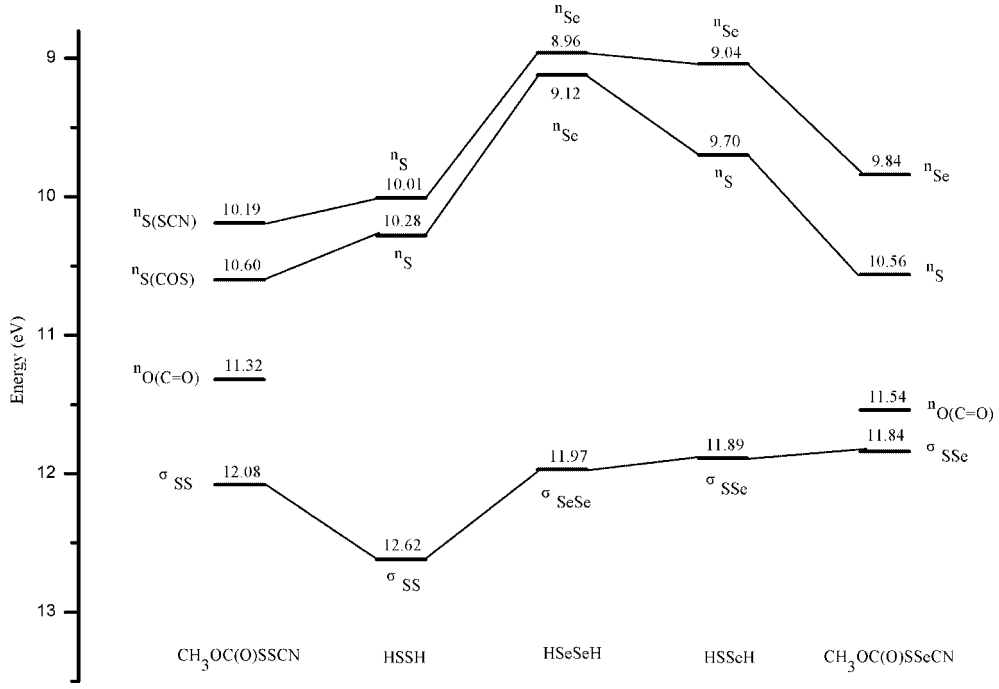

Figure 5. Correlation between selected dichalcogens (REE′R′). The ionization energies of HSSH are taken from ref.,[36] and those of HSeSeH and HSSeH are taken from ref.[20]

sidered as two perpendicular four-electron three-center π systems, which suggests four new bands in the spectrum (the high-energy $\pi_1$ and $\pi_{1\perp}$ and the low-energy $\pi_2$ and $\pi_{2\perp}$). If the molecular skeleton is linear, the perpendicular MO pairs are degenerate. In the case of the *gauche* $CH_3OC(O)SSeCN$, all four bands are expected theoretically. However, the Se lone pair in the SeCN moiety is part of a π system and the $\sigma_{SSe}$ orbital is also part of the perpendicular π system. In a word, only two additional bands from the π orbitals of the SeCN moiety are expected in the low-energy region. The assignments for the bands of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ agree with this explanation, as summarized in Table 3. The remaining bands in the high-ionization region (>14.5 eV) arising from inner molecular orbitals can not be assigned with certainty.

## 3. Conclusion

(Methoxycarbonyl)sulfenyl thiocyanate, $CH_3OC(O)SSCN$, and (methoxycarbonyl)sulfenyl selenocyanate, $CH_3OC(O)SSeCN$ are generated and characterized by photoelectron spectroscopy. With the help of quantum chemical calculations, the geometry of the two molecules are investigated and the electronic structure analyzed. Both compounds prefer a *gauche* conformation as predicted by structural optimization and vibrational analysis. The first vertical ionization energies of $CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ are determined to be 10.19 and 9.84 eV, respectively. The HOMOs are mainly localized at the lone pair of the S and Se atom, respectively.

## Experimental Section

$CH_3OC(O)SSCN$ and $CH_3OC(O)SSeCN$ were heterogeneously generated at a room temperature of 20 °C by passing $CH_3OC(O)SCl$ vapor over finely powdered AgSCN or AgSeCN, respectively, and the photoelectron spectrum was recorded subsequently after generation. Simultaneously, the product was checked by photoionization mass spectrometry. In the mass spectrum of $CH_3OC(O)SSCN$, there is no signal of the parent ion of the precursor [$CH_3OC(O)SCl^{+}$, $m/z$ = 126], which indicates that $CH_3OC(O)SCl$ reacts with AgSCN completely. However, there are characteristic signals of the product $CH_3OC(O)SSCN$: $CH_3OC(O)SSCN^{+}$ ($m/z$ = 149), $NCSSC(O)^{+}$ ($m/z$ = 118), and $NCSS^{+}$ ($m/z$ = 90). Similarly, in the mass spectrum of $CH_3OC(O)SSeCN$, there are analogously characteristic signals, $CH_3OC(O)SSeCN^{+}$ ($m/z$ = 197), $NCSeSC(O)^{+}$ ($m/z$ = 166), and $NCSeS^{+}$ ($m/z$ = 138), which can confirm the generation of $CH_3OC(O)SSeCN$. The reaction route is illustrated below:

$$CH_3OC(O)SCl\,(g) + AgSCN\,(s) \rightarrow CH_3OC(O)SSCN\,(g) + AgCl\,(s)$$
$$CH_3OC(O)SCl\,(g) + AgSeCN\,(s) \rightarrow CH_3OC(O)SSeCN\,(g) + AgCl\,(s)$$

The precursor $CH_3OC(O)SCl$ was purchased from Alfa Aesar, and used without further purification after confirmation of its identity by obtaining its photoionization mass spectrum. AgSCN was purchased from Alfa Aesar. AgSeCN was prepared according to the previous report[37] by adding a solution of KSeCN to a solution of $AgNO_3$ in stoichiometric amounts. The precipitate formed was collected by filtration, washed with water, and dried in a desiccator under dynamic vacuum. Care should be taken to avoid exposure to light. Before reaction, both silver salts were dried in vacuo ($1 \times 10^{-4}$ Torr) for 2 h.

The photoelectron spectrum was recorded on a double-chamber UPS-II instrument,[16,30] which was specially designed for detecting unstable species. The spectral resolution of the HeI spectrum is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

about 30 meV, when measured as the full width at half-maximum (FWHM) of the $3p^{-1}\ ^2P_{2/3}\ Ar^+ \leftarrow Ar\ (^1S_0)$ line. During the experiments, small amounts of Ar gas and $CH_3I$ were added to the sample flow, which were used to calibrate the experimental vertical ionization potentials.

Quantum chemical calculations were performed for the investigated molecules by the Gaussian 03 program package.[38] The structures of all the stable conformers were optimized with ab initio and DFT methods. Higher levels of theory were used to optimize the theoretically most-stable conformers. To interpret the photoelectron spectra, ROVGF[33] calculations with the basis set of 6-311++G(d,p) were performed to obtain the theoretical vertical ionization energies.

# A New Approach to Novel Cluster Compounds of Lead(II) Phosphonates

Zi-Yi Du,[a] Hai-Bing Xu,[a] Xiu-Ling Li,[a] and Jiang-Gao Mao*[a]

**Keywords:** Lead / Sulfonate-phosphonates / Solvothermal synthesis / Cluster compounds

Five new lead(II) sulfonate-phosphonates, namely $[Pb_3(L)_2(H_2O)_2]\cdot 4H_2O$ (**1**), $[Pb(HL)(phen)]\cdot H_2O$ (**2**), $[Pb_6(L)_4(phen)_8]\cdot 3H_2O$ (**3**), $[Pb_6(L)_4(phen)_{10}]\cdot 2H_2O$ (**4**), and $[Pb_6(L)_4(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (**5**; $H_3L$ = *m*-$HO_3S$-$C_6H_4$-$PO_3H_2$, phen = 1,10-phenanthroline, 4,4′-bipy = 4,4′-bipyridine) have been prepared and structurally characterized. Compound **1** features a novel 3D framework in which 1D chains of $Pb_3O_4$ cluster units are further bridged by sulfonate-phosphonate ligands, whereas compound **2** features a layer structure in which 1D chains of $Pb_2O_4$ clusters are further bridged by sulfonate-phosphonate ligands. Compounds **3** and **4** represent the first zero-dimensional lead(II) phosphonates and feature novel isolated hexanuclear lead(II) clusters in which six $Pb^{II}$ ions are bridged by two tetradentate and two pentadentate phosphonate groups. Compound **5** features a 3D framework that is similar to that in compound **1** despite the different coordination modes for some sulfonate groups of the ligands. The main difference is that an aqua ligand in compound **1** is replaced by a nitrogen atom of the 4,4′-bipy ligand, which results in the splitting of the large cavities in compound **1** into two small apertures in compound **5**. Compounds **1** and **5** exhibit strong broad blue fluorescent emission bands at 398 and 420 nm, respectively.

## Introduction

The chemistry of metal phosphonates has been expanding rapidly in recent years, mainly due to their potential application in the areas of catalysis, ion exchange, proton conductivity, intercalation chemistry, photochemistry, and material chemistry.[1] Similarly, the surface modification of inorganic surfaces with phosphonic acids is of growing importance since it opens the way to a large variety of novel functional materials.[1c,1d] Most investigations have been concentrated on the divalent transition and trivalent lanthanide elements.[2–6] Lead(II), however, has a lone pair of electrons and could therefore lead to interesting topological arrangements or to materials with redox as well as catalytic properties.[7–11] A wide variety of lead(II) phosphonates have been reported to date.[7–11] The strategy of using bisfunctional or multifunctional anionic units, such as diphosphonates, aminophosphonates, or phosphonocarboxylates, has led to a number of new lead phosphonates with microporous or open-framework structures.[7–10] Another useful way of building new types of phosphonate hybrids is by introducing a second metal linker, and we have used an acidic metal linker such as carboxylic acid or carboxylic-sulfonic acid to prepare a series of lead phosphonate hybrids with different architectures.[11] The carboxylic or carboxylic-sulfonic acid acts either as a multidentate bridging ligand or pendant group on the lead(II) phosphonate layer or intercalates between two layers.[11] These materials mostly exhibit layered structures, although 3D networks with micropores and 1D chains have also been reported.[7–11] Surprisingly, no discrete lead phosphonates have been reported thus far.

Three zinc(II) phosphonates based on tetranuclear or hexanuclear cluster units and four lanthanide(III) phosphonates based on tetranuclear cluster units have been isolated by our group by using *m*-sulfophenylphosphonic acid and a basic second metal linker such as 4,4′-bipy or phen.[12] The weak coordination ability of the sulfonate group and the bidentate chelating nature of the second ligand such as phen facilitate the formation of cage compounds with discrete cluster units. We therefore hoped that such an approach might be extended to the field of $Pb^{II}$ phosphonates, where the isolation of cluster compounds is very difficult. The combination of $Pb^{II}$ and *m*-sulfophenylphosphonic acid with a basic second metal linker led to five novel, discrete, 2D or 3D lead(II) sulfonate-phosphonates based on cluster units, namely $[Pb_3(L)_2(H_2O_2)]\cdot 4H_2O$ (**1**), $[Pb(HL)(phen)]\cdot H_2O$ (**2**), $[Pb_6(L)_4(phen)_8]\cdot 3H_2O$ (**3**), $[Pb_6(L)_4(phen)_{10}]\cdot 2H_2O$ (**4**), and $[Pb_6(L)_4(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (**5**). Herein we report their syntheses, crystal structures, and characterization.

## Results and Discussion

Compounds **1**–**5** represent the first series of lead(II) compounds based on sulfonate-phosphonate ligands. Com-

pounds **3** and **4** also represent the first discrete $Pb^{II}$ polynuclear clusters based on phosphonate ligands. They exhibit novel, discrete, hexanuclear, 2D or 3D structures.

## Synthesis

Compounds **1**–**5** were obtained during our systematic investigation of the Pb/L/phen (or bipy) systems with different Pb/L/phen ratios and pH values. We successfully prepared single-phase products for all five compounds except compound **4**. The preparations of compounds **1**–**5** rely on well-established hydrothermal methods. In general, a mixture of $Pb(OAc)_2$ and $H_3L$, with or without a second ligand such as phen or 4,4′-bipy, was treated hydrothermally for four days at 150 °C to produce crystalline products. The type of second ligand used has a strong influence on the final structure of these lead(II) sulfonate-phosphonates as compounds **2**–**5** were obtained instead of compound **1** when phen or 4,4′-bipy was employed as the second ligand. The molar ratio of reactants as well as the reaction pH also play important roles. Thus, compounds **2**–**4** were obtained from the $Pb(OAc)_2/H_3L$/phen system when the amount of phen and the reaction pH increased. We still do not fully understand why these compounds form under different reaction conditions, but it seems likely that the nature and amount of the second ligand play an important role by changing the coordination environment around the metal ions and the connectivities between the metal ions. Furthermore, the reaction medium becomes less acidic when more phen is used, and this can affect the coordination mode that the phosphonate ligand adopts.

## Structure of $[Pb_3(L)_2(H_2O)_2]\cdot 4H_2O$ (1)

The structure of compound **1** features a novel porous 3D network with three unique lead(II) ions in the asymmetric unit (Figure 1). Pb(1) is six-coordinate with four phosphonate oxygen atoms from four $L^{3-}$ anions as well as two sulfonate oxygen atoms from another two $L^{3-}$ anions. Its coordination geometry can be described as a severely distorted $PbO_6$ octahedron. Pb(2) ion is five-coordinate with three phosphonate oxygen atoms from three $L^{3-}$ anions and one sulfonate oxygen atom from another $L^{3-}$ anion as well as an aqua ligand. The coordination geometry around Pb(2) can be described as a severely distorted ψ-$PbO_5$ octahedron with one site occupied by the lone pair of the $Pb^{II}$ ion. The coordination environment of Pb(3) ion is similar to that of Pb(2) ion. The Pb–O distances [2.311(5)–2.833(7) Å] are similar to those reported for other lead(II) phosphonates and sulfonates.[7–11]

There are two unique $L^{3-}$ ligands in compound **1**. The first, containing atoms P(1) and S(1), is hexadentate and bridges six lead(II) ions through its three phosphonate oxygen atoms and one sulfonate oxygen atom. Two phosphonate oxygen atoms [O(1) and O(3)] act as a $\mu^2$-bridging ligand. The second sulfonate-phosphonate containing P(2) and S(2) is octadentate, with all three phosphonate oxygen atoms and three sulfonate oxygen atoms involved in metal coordination. Two phosphonate oxygen atoms [O(7) and O(8)] act as a $\mu^2$-bridging ligand (Scheme 1).

The interconnection of the $Pb^{II}$ ions via the bridging phosphonate groups leads to a 1D lead(II) phosphonate chain based on "$Pb_3O_4$" cluster units. Each pair of $Pb^{II}$ ions within a $Pb_3O_4$ cluster unit is bridged by a pair of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phosphonate oxygen atoms, and neighboring cluster units are further interconnected by bridging phosphonate and sulfonate groups into a 1D hybrid chain (Figure 2, a). These 1D chains are further cross-linked by the bridging $L^{3-}$ ligands into a 3D network with long, narrow apertures along *a*-axis (Figure 3). The total solvent accessible space is about 24.3% of the cell volume according to our calculations.[13] The lattice water molecules are located in the above apertures and there are a number of hydrogen bonds between sulfonate oxygen atom O(11), the aqua ligands, and lattice water molecules (Table 1), with O···O contacts ranging from 2.71(1) to 3.03(1) Å. It is interesting to note that the hydrogen bonds between water molecules lead to the formation of a 1D water chain along the *a*-axis (Figure 2, b).

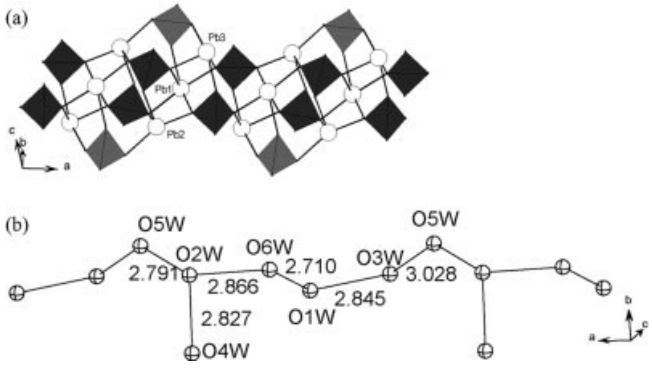

Figure 2. A 1D lead sulfonate-phosphonate chain based on $Pb_3O_4$ cluster units (a) and a 1D hydrogen-bonded water chain (b) in compound **1**. The $CPO_3$ and $CSO_3$ groups are shaded in dark and medium gray, respectively. Pb, O, and C atoms are drawn as white, crossed and black circles, respectively.

The open framework of compound **1** remains intact after heating at 180 °C for 3 h based on X-ray powder diffraction studies (see Supporting Information).

### Structure of $[Pb(HL)(phen)]\cdot H_2O$ (2)

The structure of compound **2** features a layered architecture. The Pb(1) ion is six-coordinate with three phosphonate oxygen atoms from three $HL^{2-}$ anions, one sulfonate oxygen atom from another $HL^{2-}$ anion, and one bidentate chelating phen ligand (Figure 4). The coordination geometry around Pb(1) can be described as a severely distorted $PbO_4N_2$ octahedron, with Pb–O [2.531(5)–2.820(5) Å] and Pb–N [2.446(6)–2.499(5) Å] distances similar to those reported for other lead(II) phosphonates and sulfonates.[7–11]

There is one unique $HL^{2-}$ ligand in compound **2**. The phosphonate group of this ligand is singly protonated, as indicated by the much longer P(1)–O(3) bond [1.579(5) Å] than those of the other two P–O bonds [P(1)–O(2) 1.496(5), P(1)–O(1) 1.512(5) Å]. The $HL^{2-}$ ligand is tetradentate and bridges four lead(II) ions via its two phosphonate oxygen atoms and one sulfonate oxygen atom (Scheme 1). O(1) acts as a $\mu^2$-metal linker. Each pair of $Pb^{II}$ ions is bridged by a pair of phosphonate oxygen atoms into a $Pb_2O_2$ dimer. These $Pb_2O_2$ dimeric units are further interconnected by bridging phosphonate groups into a 1D chain along the *a* axis, and these chains are further connected by the bridging $HL^{2-}$ ligands into a layered structure (Figure 5). Strong hydrogen bonds are formed between noncoordinated phosphonate and sulfonate oxygen atoms [O(3)···O(4) 2.650(8) Å; symmetry code: $-x$, $3-y$, $2-z$) within the 2D layer. The 2D layers in compound **2** are assembled into a three dimensional structure through van der Waals forces (Figure 6). The lattice water molecules are located at the cavities of the structure and are involved in hydrogen bonding with coordinated phosphonate oxygen atom O(2) (Table 1).

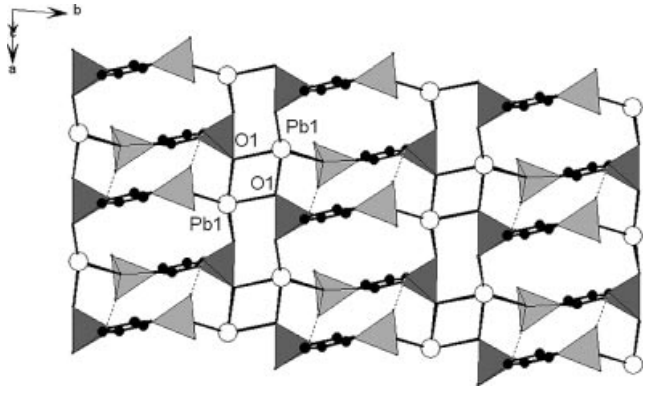

Figure 5. A lead(II) sulfonate-phosphonate layer in compound **2**. The $CPO_3$ and $CSO_3$ groups are shaded in medium and light grey, respectively. The phen ligands have been omitted for clarity. Hydrogen bonds are drawn as dashed lines.

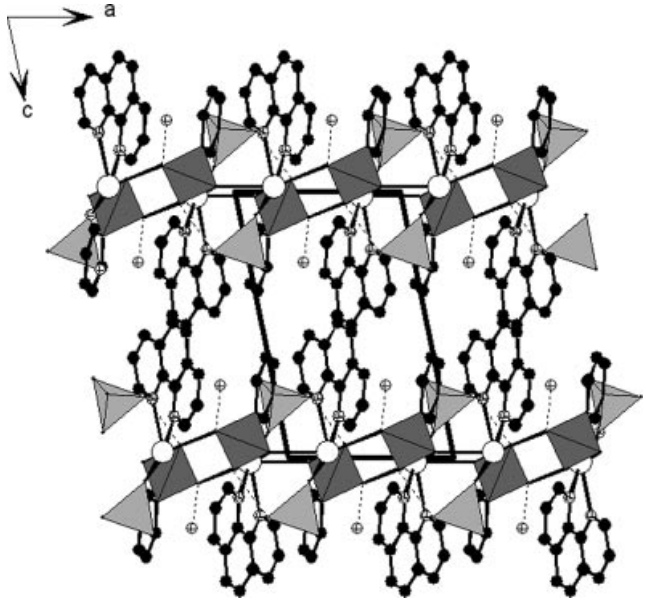

Figure 6. View of the structure of compound **2** down the *a*-axis. The $CPO_3$ and $CSO_3$ groups are shaded in medium and light gray, respectively. Pb, O, N and C atoms are drawn as open, crossed, octanded, and black circles, respectively. Hydrogen bonds are drawn as dashed lines.

### Structure of $[Pb_6(L)_4(phen)_8]\cdot 3H_2O$ (3)

The structure of compound **3** features an isolated hexanuclear lead(II) cluster unit. There are three crystallographically independent lead(II) ions in the structure (Figure 7). The Pb(1) ion is four-coordinate with two phosphonate oxygen atoms from two $L^{3-}$ anions as well as one bidentate chelating phen ligand. The coordination geometry around Pb(1) can best be described as a slightly distorted ψ-$PbO_4$ square-pyramid. The Pb(2) ion is six-coordinate with four phosphonate oxygen atoms from four $L^{3-}$ anions as well as one bidentate chelating phen ligand. The coordination geometry around Pb(2) can be described as a slightly distorted ψ-$PbO_4N_2$ pentagonal pyramid with the lone pair occupying the open site of the pyramid. Pb(3) is seven-coordinate with three phosphonate oxygen atoms from two $L^{3-}$ anions as well as two bidentate chelating phen ligands. The coordination geometry around Pb(3) can best be described as an irregular $PbO_4N_2$ polyhedron. The Pb–O [2.291(5)–2.697(5) Å] and Pb–N [2.544(7)–3.00(1) Å] distances are similar to those reported for other lead(II) phosphonates and sulfonates.[7–11]

There are two unique $L^{3-}$ anions in compound **3**. The first, which contains P(1) and S(1), is pentadentate and bridges four $Pb^{II}$ ions by using its three phosphonate oxygen atoms, whereas the other $L^{3-}$ anion, which contains P(2) and S(2), is tetradentate and bridges four $Pb^{II}$ ions through its three phosphonate oxygen atoms. O(1), O(3), and O(7) act as a $\mu^2$-bridging ligand (Figure 7, Scheme 1). The interconnection of six $Pb^{II}$ ions by the above two types of $L^{3-}$ anions results in a novel hexanuclear cluster unit (Figure 8, a) which can be viewed as a double-cage structure. This "double-cage" hexanuclear cluster unit is different from our previously reported "chair-like" hexanuclear cluster units in zinc(II) sulfonate-phosphonates[8] owing to the different coordination modes of the sulfonate-phosphonate ligands. Thus, the two independent $L^{3-}$ ligands in $[Zn_6L_4(phen)_8]\cdot 11H_2O$ connect three and four $Zn^{II}$ ions, respectively, whereas each $L^{3-}$ ligand in $[Zn_6L_4(bipy)_6(H_2O)_4]\cdot 18H_2O$ bridges three $Zn^{II}$ ions.

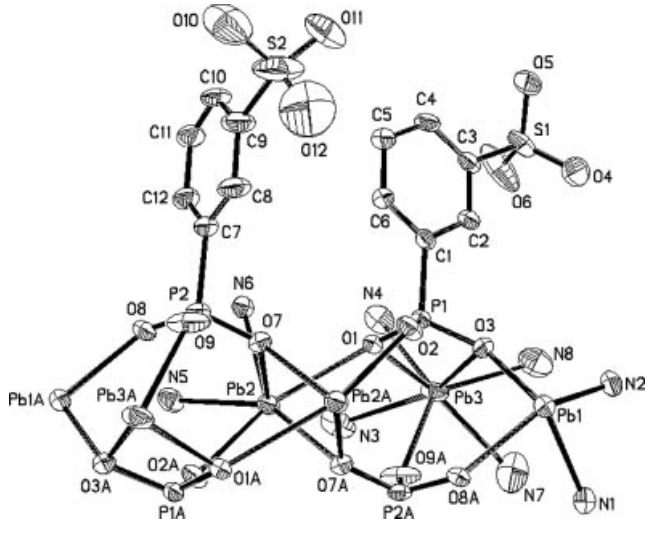

Figure 7. ORTEP representation of the selected unit of **3**. The thermal ellipsoids are drawn at 30% probability. Lattice water molecules and the carbon atoms of the phen ligands have been omitted for clarity. Only one orientation is shown for the disordered Pb(3) atom for the sake of clarity. Symmetry codes for the generated atoms: A) $1-x$, $1-y$, $1-z$.

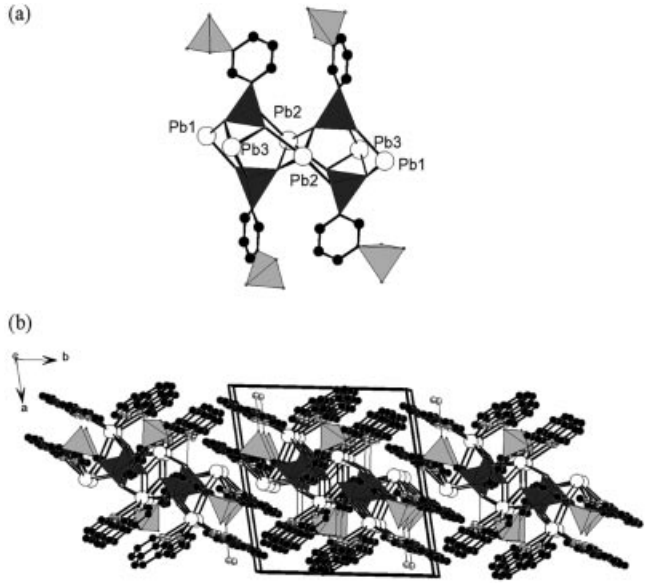

Figure 8. A $\{Pb_6L_4\}$ cluster unit in compound **3** (a) and a view of the structure of compound **3** down the *c*-axis (b). The $CPO_3$ and $CSO_3$ groups are shaded in dark and light gray, respectively. Pb, O, N and C atoms are drawn as open, crossed, octanded, and black circles, respectively. Hydrogen bonds are drawn as dashed lines.

The discrete clusters in compound **3** are assembled into a three dimensional structure through van der Waals forces (Figure 8, b). The lattice water molecules are located in the cavities of the structure, and O(2w) forms a hydrogen bond with the noncoordinating sulfonate oxygen atom O(6) (Table 1).

### Structure of $[Pb_6(L)_4(phen)_{10}]\cdot 2H_2O$ (4)

Compound **4** contains two more phen ligands than compound **3**. Its structure also features an isolated hexanuclear $Pb^{II}$ cluster similar to that in compound **3**. There are three crystallographically independent lead(II) ions in the asymmetric unit (Figure 9). Pb(1) is six-coordinate with two phosphonate oxygen atoms from two $L^{3-}$ anions as well as two bidentate chelating phen ligands. The coordination geometry around Pb(1) can be described as a distorted ψ-$PbO_2N_4$ pentagonal pyramid. Pb(2) is six-coordinate with four phosphonate oxygen atoms from four $L^{3-}$ anions as well as a bidentate chelating phen ligand. Pb(3) is seven-coordinate with three phosphonate oxygen atoms from two $L^{3-}$ anions as well as two bidentate chelating phen ligands. The coordination environments around Pb(2) and Pb(3) are same as those in compound **3**. The Pb–O [2.286(6)–2.750(5) Å] and Pb–N [2.502(8)–2.95(1) Å] distances are similar to those reported for other lead(II) phosphonates and sulfonates.[7–11]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

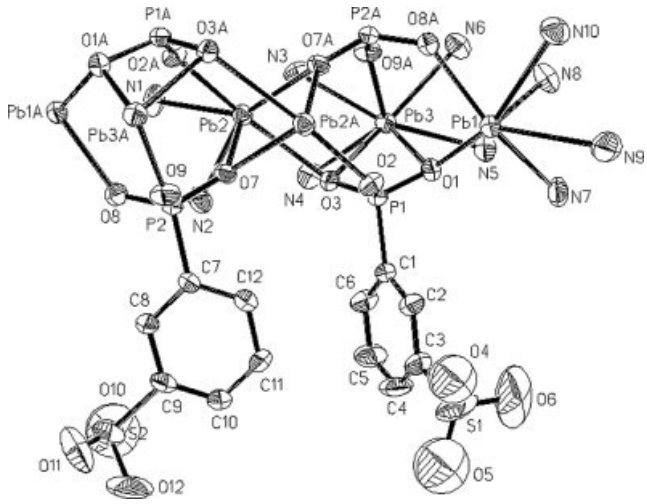

Figure 9. ORTEP representation of the selected unit of **4**. The thermal ellipsoids are drawn at 30% probability. Lattice water molecules and carbon atoms of the phen ligands have been omitted for clarity. Only one orientation is shown for the disordered O(11) atom for the sake of clarity. Symmetry codes for the generated atoms: A) $1 - x, -y, 1 - z$.

The coordination modes of the two unique $L^{3-}$ anions in compound **4** are the same as those in compound **3** which means that the cluster unit of compound **4** is similar to that of compound **3**, the only difference being that Pb(1) in compound **4** has a higher coordination number due to the coordination of an additional phen ligand.

The discrete clusters in compound **4** are also assembled into a three-dimensional structure through van der Waals forces as well as a π···π packing interaction between the phen ligands (Figure 10). The lattice water molecules [O(1w)] are located in the cavities and form weak hydrogen bonds with the noncoordinating sulfonate oxygen atoms O(12) (Table 1).

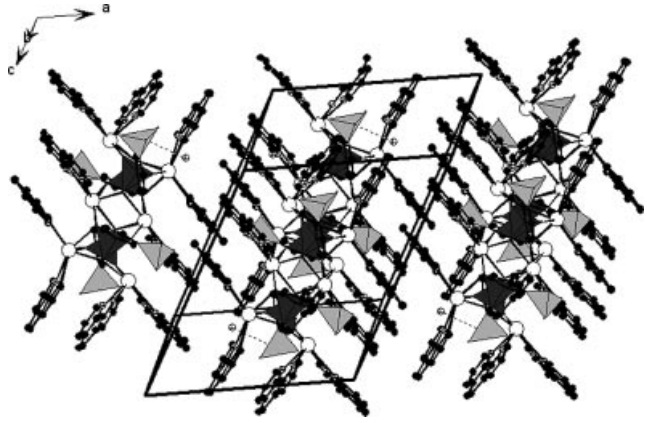

Figure 10. View of the structure of compound **4** down the *b*-axis. The $CPO_3$ and $CSO_3$ groups are shaded in dark and light gray, respectively. Pb, O, N, and C atoms are drawn as open, crossed, octanded, and black circles, respectively. Hydrogen bonds are drawn as dashed lines.

### Structure of $[Pb_6(L)_4(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (5)

The structure of compound **5** features a complex 3D network. There are three unique $Pb^{II}$ ions in the asymmetric unit of compound **5** (Figure 11). Pb(1) is five-coordinate with four phosphonate oxygen atoms from four $L^{3-}$ anions and one sulfonate oxygen atom from another $L^{3-}$ anion. The coordination geometry around Pb(1) can be described as a distorted ψ-$PbO_5$ octahedron with one axial site occupied by the lone pair of the $Pb^{II}$ ion. Pb(2) is five-coordinate with three phosphonate oxygen atoms from three $L^{3-}$ anions, one sulfonate oxygen atom from another $L^{3-}$ anion, and a nitrogen atom from a 4,4′-bipy ligand. The coordination geometry around Pb(2) can be described as a severely distorted ψ-$PbO_4N$ octahedron with one site occupied by the lone pair of the $Pb^{II}$ ion. Pb(3) is four-coordinate with three phosphonate oxygen atoms from three $L^{3-}$ anions and one aqua ligand. The coordination geometry around Pb(3) can be described as a distorted ψ-$PbO_4$ trigonal bipyramid with one pyramidal site occupied by the lone pair of the $Pb^{II}$ ion. The Pb–O [2.270(6)–2.882(9) Å] and Pb–N [2.631(9) Å] distances are similar to those reported for other lead(II) phosphonates and sulfonates.[7–11]

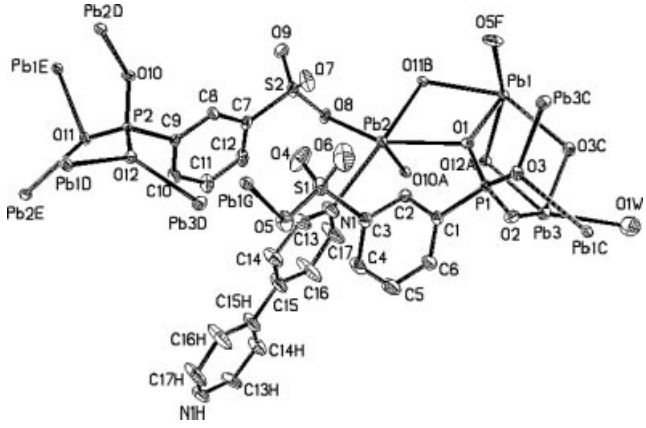

Figure 11. ORTEP representation of the selected unit of **5**. The thermal ellipsoids are drawn at 30% probability. Lattice water molecules have been omitted for clarity. Symmetry codes for the generated atoms: A) $-1/2 + x, -1/2 - y, -1/2 + z$; B) $-3/2 - x, -1/2 + y, 1/2 - z$; C) $-3 - x, -1 - y, -z$; D) $1/2 + x, -1/2 - y, 1/2 + z$; E) $-3/2 - x, 1/2 + y, 1/2 - z$; F) $-5/2 - x, -1/2 + y, 1/2 - z$; G) $-5/2 - x, 1/2 + y, 1/2 - z$; H) $-2 - x, -y, -z$.

There are two unique $L^{3-}$ ligands in compound **5**, both of which are hexadentate and bridge six lead(II) ions through three phosphonate oxygen atoms and one sulfonate oxygen atom. Four phosphonate oxygen atoms [O(1), O(3), O(11), and O(12)] act as a $\mu^2$-bridging ligand. A similar type of coordination mode has also been observed in compound **1**. Interconnection of the $Pb^{II}$ ions through the bridging phosphonate groups leads to a 1D chain based on $Pb_3O_4$ cluster units (Figure 12, a). In contrast to the 1D chain in compound **1**, neighboring $Pb_3O_4$ cluster units within the chain are interconnected solely by the bridging phosphonate groups. These 1D chains are further cross-linked by the bridging $L^{3-}$ and 4,4′-bipy ligands into a 3D network with small apertures along the *a*-axis (Figure 12,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

b). Although fewer sulfonate oxygen atoms are involved in metal coordination in compound **5** than in compound **1**, the framework of compound **5** is still somewhat similar to that in compound **1**. The replacement of one aqua ligand in compound **1** by a nitrogen atom from a 4,4′-bipy ligand in compound **5** results in the splitting of the large cavities in compound **1** into two smaller parts (Figure 12). Due to the occupation of the cavities by the 4,4′-bipy ligands, compound **5** contains only a few lattice water molecules. A number of hydrogen bonds are formed among non-coordinating sulfonate oxygen atoms [O(7), O(9)], aqua ligands, and lattice water molecules (Table 1), with O···O contacts ranging from 2.84(2) to 2.93(1) Å.

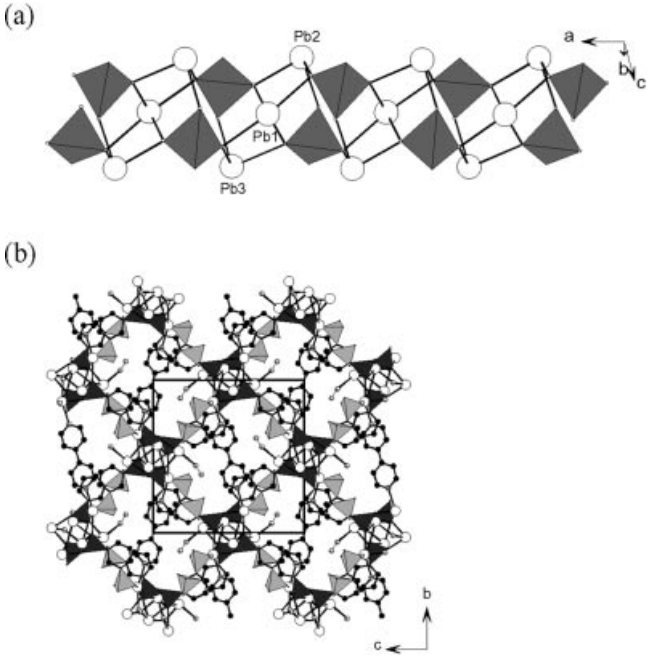

Figure 12. A 1D lead(II) phosphonate chain based on $Pb_3O_4$ units (a) and a view of the structure of compound **5** along the *a*-axis (b). The $CPO_3$ and $CSO_3$ groups are shaded in dark and medium grey, respectively. Pb, O, N, and C atoms are drawn as white, crossed, octanded, and black circles, respectively.

## Luminescent Properties

The solid-state luminescent properties of compounds **1**, **2**, **3**, and **5** as well as the free phosphonate ligand were investigated at room temperature. The free ligand exhibits only a fluorescent emission band at $\lambda_{max}$ = 370 nm upon excitation at 308 nm. The phen ligand displays a fluorescent emission band at $\lambda_{max}$ = 381 nm with a shoulder at 364 nm upon excitation at 339 nm. Compound **1** displays a strong fluorescent emission band at $\lambda_{max}$ = 398 nm ($\lambda_{ex}$ = 330 nm; Figure 13) upon complexion of the $L^{3-}$ ligands with the $Pb^{II}$ ions, whereas compounds **2** and **3** display a weak broad emission band in the range 350–600 nm upon complexion of both sulfonate-phosphonate and phen ligands with the lead(II) ions. The bipy ligand displays a broad fluorescent emission band at $\lambda_{max}$ = 423 nm ($\lambda_{ex}$ = 345 nm), and upon complexion of both $L^{3-}$ and bipy ligands with the $Pb^{II}$ ions compound **5** displays a fluorescent emission band at $\lambda_{max}$ = 420 nm ($\lambda_{ex}$ = 330 nm; Figure 13). These emission bands are neither metal-to-ligand charge transfer (MLCT) nor ligand-to-metal charge transfer (LMCT) in nature, but rather can be attributed to an intraligand emission state.

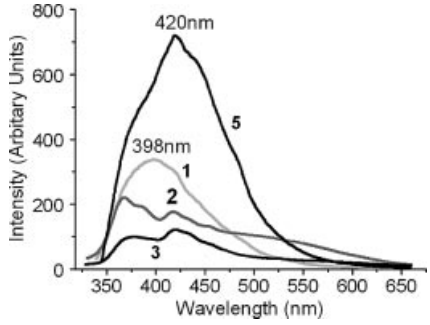

Figure 13. Solid-state emission spectra of compounds **1**, **2**, **3**, and **5**.

## TGA Studies

The TGA curves of compounds **1**, **2**, **3**, and **5** all exhibit three main weight loss steps (Figure 14). The onset and final temperatures of these three steps as well as the weight

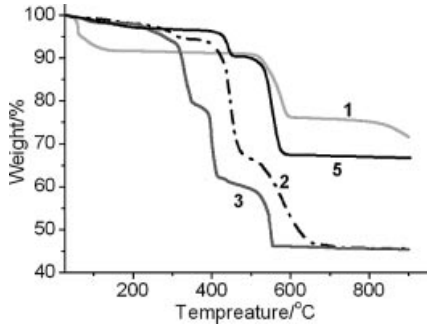

Figure 14. TGA curves for compounds **1**, **2**, **3**, and **5**.

Table 2. TGA data of compounds **1**, **2**, **3**, and **5**.

| | First step | | Second step | Third step | Total weight loss |
|---|---|---|---|---|---|
| | Temperature (onset/end) [°C] | Weight loss of $H_2O$ (exp./calcd.) [%] | Temperature (onset/end) [°C] | Temperature (onset/end) [°C] | [%] |
| **1** | 40/180 | 8.6/9.0 | 492/605 | 780/>900 | 28.4 |
| **2** | 45/205 | 2.5/2.8 | 240/336 | 370/735 | 54.1 |

losses are given in Table 2, where it can be seen that the observed weight losses of water molecules are close to the calculated values. The final residues were not characterized. The thermal stability of compound **4** was not studied due to our failure to obtain it as a single-phase product.

## Conclusions

In summary, we have reported the hydrothermal synthesis, crystal structures, and characterization of five new lead(II) sulfonate-phosphonates, namely $[Pb_3(L)_2(H_2O)_2]\cdot 4H_2O$ (**1**), $[Pb(HL)(phen)]\cdot H_2O$ (**2**), $[Pb_6(L)_4(phen)_8]\cdot 3H_2O$ (**3**), $[Pb_6(L)_4(phen)_{10}]\cdot 2H_2O$ (**4**), and $[Pb_6(L)_4(4,4'\text{-bipy})(H_2O)_2]\cdot 2H_2O$ (**5**; $H_3L$ = *m*-$HO_3S$-$C_6H_4$-$PO_3H_2$). The diverse structural frameworks of these five compounds depend on the flexible coordination ability of $Pb^{II}$ as well as the mediation of an auxiliary ligand such as phen or 4,4′-bipy. *m*-Sulfophenylphosphonic acid is a versatile ligand that can adopt various coordination modes. In the absence of the second ligand or with 4,4′-bipy, which usually binds in a bidentate bridging mode, two types of 3D networks (compounds **1** and **5**) are obtained. The dimensionality of the structure is reduced when the bidentate chelating ligand phen is added as the second metal linker. Compound **2**, which has a layered structure, is obtained with a Pb/phen ratio close to 1:1. Further increase of the amount of phen and the pH leads to two types of discrete clusters (compounds **3** and **4**) which have the same skeleton but differ in the coordination numbers of the lead(II) ions. The results of our study indicate that by using *m*-sulfophenylphosphonic acid with phen as the auxiliary ligand we should be able to synthesize cluster compounds of not only d-block and f-block metals but also main group metals. Future research effects will be devoted to the designing of new types of cluster compounds containing other metal phosphonates.

## Experimental Section

**Materials and Methods:** *m*-Sulfophenylphosphonic acid (*m*-$HO_3S$-$C_6H_4$-$PO_3H_2$, $H_3L$) was synthesized according to the procedures previously described by Montoneri.[14] All other chemicals were obtained from commercial sources and used without further purification. Elemental analyses were performed with an Elementary Vario EL III instrument. The FT-IR spectra were recorded with a Nicolet Magna 750 FT-IR spectrometer using KBr pellets in the range of 4000–400 $cm^{-1}$. Photoluminescence analyses were performed with a Perkin–Elmer LS55 fluorescence spectrometer. Thermogravimetric analyses were carried out with a NETZSCH STA 449C unit at a heating rate of 10 °C $min^{-1}$ under an oxygen atmosphere. X-ray powder diffraction (XRD) patterns (Cu-$K_\alpha$) were collected with a XPERT-MPD θ–2θ diffractometer.

**Synthesis of $[Pb_3(L)_2(H_2O)_2]\cdot 4H_2O$ (1):** The pH of a mixture of $Pb(OAc)_2$ (0.32 mmol) and $H_3L$ (0.3 mmol) in 10 mL of distilled water was adjusted to about 4.8 with 1 M NaOH solution and the mixture was then sealed into a Parr Teflon-lined autoclave (23 mL) and heated at 150 °C for 4 d. The final pH was 4.6. Colorless brick-shaped crystals of **1** were collected in approx. 62% yield (0.079 g) based on Pb. The purity of this compound was confirmed by powder XRD (see Supporting Information). $C_{12}H_{20}O_{18}P_2S_2Pb_3$ (1199.9): calcd. C 12.01, H 1.68; found C 11.95, H 1.57. IR (KBr): $\tilde{\nu}$ = 3436 (s), 3059 (m), 2924 (m), 2852 (w), 1631 (m), 1402 (m), 1102 (s), 1022 (vs), 995 (vs), 962 (s), 800 (m), 669 (m), 618 (m), 557 (s) $cm^{-1}$.

**Synthesis of $[Pb(HL)(phen)]\cdot H_2O$ (2):** A mixture of $Pb(OAc)_2$ (0.3 mmol), $H_3L$ (0.3 mmol), and phen (0.32 mmol) in 10 mL of distilled water, with an initial pH of 3.6, was sealed into a Parr Teflon-lined autoclave (23 mL) and heated at 150 °C for 4 d. The final pH remained unchanged. Colorless pillar-shaped crystals of **2** were collected in approx. 85% yield (0.16 g) based on Pb. The purity of this compound was confirmed by powder XRD (see Supporting Information). $C_{18}H_{15}N_2O_7PPbS$ (641.54): calcd. C 33.70, H 2.36, N 4.37; found C 33.75, H 2.68, N 4.29. IR (KBr): $\tilde{\nu}$ = 3582 (m), 3423 (m), 3062 (m), 2833 (m), 1624 (m), 1593 (m), 1520 (m), 1495 (m), 1428 (m), 1400 (m), 1188 (s), 1147 (s), 1106 (vs), 1025 (vs), 915 (s), 850 (s), 803 (m), 792 (m), 727 (m), 694 (m), 681 (m), 617 (m), 555 (s), 528 (m) $cm^{-1}$.

**Synthesis of $[Pb_6(L)_4(phen)_8]\cdot 3H_2O$ (3):** A mixture of $Pb(OAc)_2$ (0.36 mmol), $H_3L$ (0.3 mmol), and phen (0.48 mmol) in 10 mL of distilled water, with its pH adjusted to about 4.0 with 1 M NaOH solution, was sealed into a Parr Teflon-lined autoclave (23 mL) and heated at 150 °C for 4 d. The final pH was 3.9. Colorless brick-shaped crystals of **3** were collected in approx. 77% yield (0.17 g) based on Pb. The purity of this compound was confirmed by powder XRD (see Supporting Information). $C_{120}H_{86}N_{16}O_{27}P_4Pb_6S_4$ (3679.3): calcd. C 39.17, H 2.36, N 6.09; found C 39.01, H 2.49, N 5.91. IR data (KBr): $\tilde{\nu}$ = 3435 (s), 3055 (m), 2923 (m), 2852 (m), 1621 (m), 1588 (m), 1512 (m), 1424 (m), 1343 (m), 1189 (s), 1097 (vs), 1029 (vs), 996 (s), 956 (m), 845 (m), 795 (m), 728 (m), 700 (m), 686 (m), 617 (m), 549 (m) $cm^{-1}$.

**Synthesis of $[Pb_6(L)_4(Phen)_{10}]\cdot 2H_2O$ (4):** A mixture of $Pb(OAc)_2$ (0.3 mmol), $H_3L$ (0.27 mmol), and phen (0.5 mmol) in 10 mL of distilled water, with its pH adjusted to about 6.0 with 1 M NaOH solution, was sealed into a Parr Teflon™-lined autoclave (23 mL) and heated at 150 °C for 4 d. The final pH was 5.8. Colorless crystals of compound **4** were collected with some unidentified impurities. Although many experiments were performed under different reaction conditions, compound **4** could not be obtained as a single phase.

**Synthesis of $[Pb_6(L)_4(4,4'\text{-Bipy})(H_2O)_2]\cdot 2H_2O$ (5):** A mixture of $Pb(OAc)_2$ (0.36 mmol), $H_3L$ (0.3 mmol), and 4,4′-bipy (0.25 mmol) in 10 mL of distilled water, with its pH adjusted to about 4.6 with 1 M NaOH solution, was sealed into a Parr Teflon-lined autoclave (23 mL) and heated at 150 °C for 4 d. The final pH was 4.7. Colorless brick-shaped crystals of **5** were collected in apprx. 64% yield (0.093 g) based on Pb. The purity of this compound was confirmed by powder XRD (see Supporting Information). $C_{34}H_{32}N_2O_{28}P_4Pb_6S_4$ (2411.9): calcd. C 16.93, H 1.34, N 1.16; found C 16.62, H 1.47, N 1.10. IR (KBr): 3435 (s), 3053 (m), 2924 (m), 2846 (w), 1604 (m), 1400 (m), 1220 (s), 1165 (s), 1101 (vs), 1059 (s), 1019 (vs), 995 (vs), 967 (vs), 796 (m), 686 (m), 623 (m), 552 (s) $cm^{-1}$.

**Single-Crystal Structure Determination:** Data collection for compounds **1**, **2**, and **5** was performed with a Siemens Smart CCD diffractometer, data collection for compound **3** was performed with a Mercury CCD diffractometer, and that for compound **4** with a Saturn 70 CCD diffractometer. All diffractometers were equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å). Intensity data for all compounds were collected by the narrow frame method at 293 K. The data sets were corrected for Lorentz and polarization factors as well as for absorption with SADABS or by the multi-scan method.[15a,15b] All structures were

solved by direct methods and refined by full-matrix least-squares fitting on $F^2$ with SHELX-97.[15c] All non-hydrogen atoms, except O(2w) in compound **3**, were refined with anisotropic thermal parameters. All hydrogen atoms were generated geometrically and refined isotropically. The hydrogen atoms for the water molecules are not included in the refinements. Pb(3) in compound **3** is severely disordered and displays two orientations with 50% occupancy for each site. One sulfonate group in compound **2** is also severely disordered with O(11) exhibiting two orientations with 50% occupancy each. The occupancy factor of O(2w) in compound **3** was reduced to 50% due to its large thermal parameter. Important bond lengths are listed in Table 1. Crystallographic data and structural refinements for compounds **1**–**5** are summarized in Table 3.

CCDC-632076–632080 (for **1**–**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Figure S1. Simulated and experimental XRD powder patterns for compounds **1**, **2**, **3**, and **5** (Figure S1).

# Synthesis and Characterization of a New Guanidine–Borane Complex and a Dinuclear Boron(II) Hydride with Bridging Guanidinate Ligands

**Oxana Ciobanu,[a] Pascal Roquette,[a] Simone Leingang,[a] Hubert Wadepohl,[a] Jürgen Mautz,[a] and Hans-Jörg Himmel*[a]**

**Keywords:** Hydrides / Boron / Low oxidation states / Hydrogen elimination

We report the synthesis and structural characterization of the new monomeric borane complex $H_3B$·hppH (hppH = 1,3,4,6,7,8-hexahydro-2*H*-pyrimido[1,2-*a*]pyrimidine), which represents the first example of a structurally characterized 1:1 complex between hppH and a group 13 element hydride. Significant intramolecular and, in the crystalline phase, intermolecular H···H contacts are established in this complex. It is shown that the complex can be used as a precursor to new dinuclear boron(II) compounds featuring a B–B single bond. Thus $H_2$ elimination followed by dimerization of $H_3B$·hppH leads to $[(hpp)BH]_2$ with two bridging hpp units. The structural details derived from X-ray diffraction measurements are reported.

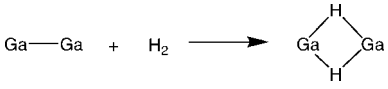
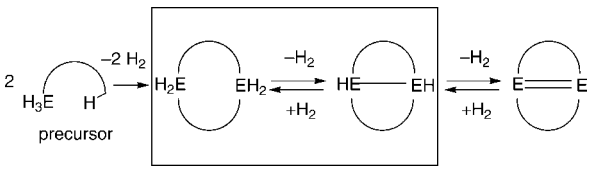
## Introduction

In Linus Pauling's concept of electronegativity, the dissociation energy of a compound A–B is comparable to half of the sum of the dissociation energies of $A_2$ and $B_2$, if A and B have similar electronegativities. This implies that reactions of the type E–E + $H_2 \rightarrow$ 2EH (where E represents any element in the periodic table) should be associated with a small reaction enthalpy at standard conditions if the electronegativity of E is close to that of H. If the reaction barrier can be controlled to remain low, the chances of reversibility of such a reaction under mild conditions are increased, and E–E might be regarded as a molecular hydrogen storage material. An inspection of the periodic table shows that the (Pauling) electronegativities of main-group elements E such as B (2.0), P (2.1), As (2.0), Sb (1.9), Bi (1.9) and Te (2.1) are close to that of H (2.1). Of these elements, boron stands out as by far the lightest and therefore most interesting element with regard to applications in the field of hydrogen storage.[1] That group 13 element compounds are in principle interesting in this context has been shown by our group with a very simple example, namely the diatomic $Ga_2$ (Ga being the heavier "sister" of B). The $Ga_2$ dimer, which can be stabilized with the help of the matrix isolation technique, readily takes up dihydrogen to form a cyclic $Ga(\mu\text{-}H)_2Ga$ molecule [see Equation (1)].[2] The reaction barrier, estimated on the basis of the IR spectra recorded in experiments with mixtures of $H_2$ and $D_2$, amounts to ca. 40 kJ mol$^{-1}$, a value which is in good agreement with the results of quantum chemical calculations.[3]



(1)

These experiments therefore demonstrated that low reaction barriers are indeed possible. However, $Ga_2$ is not stable under normal conditions and therefore not directly relevant for application purposes. It would also be more interesting to find B compounds, which are lighter than their Ga counterparts. Therefore we searched for suitable dinuclear B compounds in low oxidation states in which the two B atoms can establish a direct B–B bond. In general, this can be achieved by bridging the two B atoms with one or more suitable ligands. If the two bridging ligands coordinate, the general reaction sequence (2) describes the possible uptake or release of $H_2$ for these molecular compounds (E being preferably B).



(2)

In the hpp ligand, which is obtained after H abstraction from hppH (1,3,4,6,7,8-hexahydro-2*H*-pyrimido[1,2-*a*]pyrimidine), we have now found a first example of a ligand where this concept might work. This ligand has been used extensively to bring together two transition-metal atoms in dinuclear compounds and engage them in direct and sometimes multiple metal–metal bonding. Examples of this in-

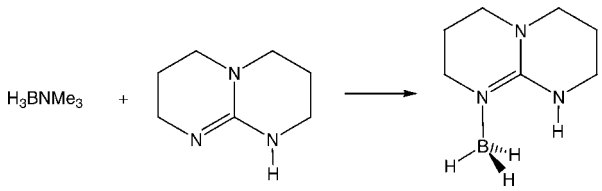
clude the complexes $Nb_2(hpp)_4$[4] and $M_2(hpp)_4Cl_2$ (where, for example, M = Ru,[5] W, Os and Pt[6]). Reaction sequence (2) then describes the conversion of a mononuclear $E^{III}$ compound into a dinuclear $E^{III}$ compound, which then eliminates dihydrogen to form a dinuclear $E^{II}$ and finally a dinuclear $E^{I}$ compound, the latter two featuring direct E–E bonding. It has also been shown recently that activation of hydrogen by subvalent compounds featuring direct E–E bonds is possible for the dinuclear compound Ar′GeGeAr′ [Ar′ = $C_6H_3$-2,6($C_6H_3$-2,6-*i*$Pr_2$)$_2$], which can add one, two or three equivalents of $H_2$ to give first Ar′(H)GeGe(H)Ar′, then Ar′$H_2$GeGe$H_2$Ar′ and finally Ar′$GeH_3$.[7] It should also be noted that catalytic $H_2$ elimination from amine–borane adducts such as $H_3BNMe_2H$ has been extensively studied recently.[8]

## Results and Discussion

First we prepared the monomeric compound $H_3B$·hppH [see Equation (3)]. It is the first example of a structurally characterized 1:1 adduct of hppH to a group 13 element hydride, and it can be used as a precursor to the desired dinuclear hydrides. $H_3B$·hppH was synthesized by heating a solution containing equimolar quantities of $H_3B$·$NMe_3$ and hppH for a period of 18 h at 60 °C. The analogous reaction between $H_3Ga$·$NMe_3$ and hppH resulted in the direct formation of the dinuclear compound $[H_2Ga(hpp)]_2$,[9] even at 0 °C, and it proved impossible to isolate this adduct. In the crystal structure of $H_3B$·hppH illustrated in Figure 1[10] are featured two intramolecular as well as two intermolecular H···H contacts that are established between positively and negatively polarized H atoms.



(3)

These contacts are important, since they lower the barrier for $H_2$ elimination (vide infra). The intramolecular H···H contacts between two of the H atoms attached to the B atom and the H atom attached to the N atom of the same molecule are 223 and 224 pm (217 and 218 pm when normalized E–H distances are used[11]), respectively, and the corresponding intermolecular contacts measure 228 and 236 pm (220 and 228 pm). The B–N bond length is 157.5 pm. This value is shorter than the B–N bonds of borane–amine adducts. To name two recently reported examples, the B–N bond distances in the $BH_3$ adducts of $PhCH_2N(CH_3)_2$[12] and $HC(CH_2CH_2)_3N$[13] have been determined to be 162.0(2) and 160.8(5) pm, respectively. The distance is also shorter than that reported for imine adducts such as the *N*-benzyl (Bn) imine adduct $Ph_2C{=}N(Bn)$·$B(C_6F_5)_3$ featuring a B–N bond length of 164.2(8) pm.[14] The B–H bond lengths measure 110(2) (no H···H contacts),

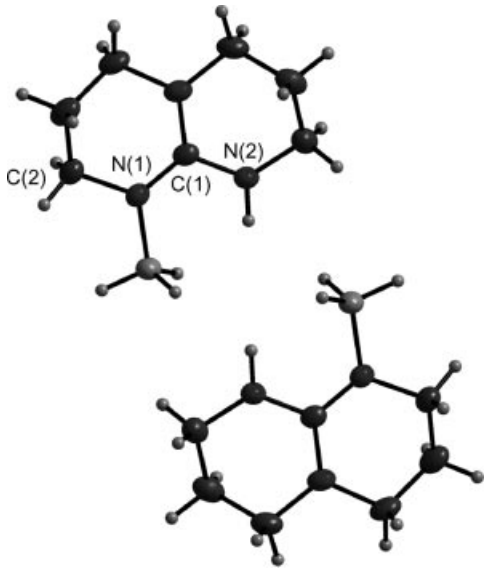


Figure 1. Molecular structure of $H_3B$·hppH in the crystalline phase showing the arrangement of two symmetrically equivalent molecules. The thermal ellipsoids are drawn at the 50% probability level. Selected bond parameters (distances in pm, bond angles in degrees): B–H 110(2), 112(1), 112(2); B–N(1) 157.5(2); N(2)/N(1)–C(1) 134.8(2)/132.1(2); N(2)–H 89(2); B–N(1)–C(1) 122.3(1); B–N(1)–C(2) 117.8(1); N(1)–C(1)–N(2) 118.0(1).

112(1) and 112(2) pm, and the N–H bond is 89(2) pm long. Calculations were carried out to determine whether the inter- or intramolecular H···H contacts are responsible for the conformation of the $BH_3$ group. Calculations for an isolated molecule returned a conformation very close to that observed, and thus the intramolecular H···H contacts determine the geometry. This is also in line with the smaller observed values for the intramolecular H···H distances. In Figure 2 the relative energy is plotted as a function of the dihedral angle between the C–N–B and the N–B–H planes as calculated by using MP2/SVP.[15] It can be seen that the barrier for rotation around the B–N axis is no more than 4.5 kJ mol$^{-1}$.

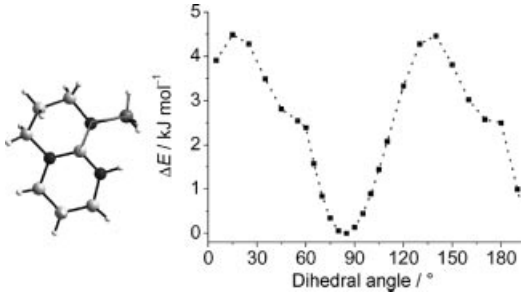

Figure 2. Relative energy as a function of the dihedral angle C–N–B–H as calculated with MP2/SVP.

Hydrogen is eliminated if a solution of the precursor $H_3B$·hppH is heated in toluene to 110 °C for 20 h. Interestingly, we did not obtain $[H_2B(hpp)]_2$ as the product of this reaction, as in the reaction of the corresponding Ga homologue,[9] but rather $[HB(hpp)]_2$ was produced directly [see

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Equation (4)]. The barrier for $H_2$ elimination from $[H_2B(hpp)]_2$ is so small that this process occurs at temperatures below 110 °C. $[HB(hpp)]_2$ is the product of a redox reaction and features two B atoms in the formal oxidation state +2. In the case of $[H_2Ga(hpp)]_2$, we observed $H_2$ elimination even at 25 °C, and all signs indicated that $[HGa(hpp)]_2$ was the product.[9] However, we have so far been unable to structurally characterize this species. In the case of the boron compound, we have obtained good-quality crystals from toluene solutions, and Figure 3 illustrates the crystal structure derived from our X-ray diffraction data.[10] $[HB(hpp)]_2$ features a B–B single bond measuring 177.2(3) pm and a *cis*-bent arrangement of the H–B–B–H fragment [with B–H distances of 115(3) and 106(4) pm]. The value of the B–B bond length is in a range typical for B–B single bonds. For example, gas-phase electron diffraction measurements of $B_2(NMe_2)_4$ and $B_2(OMe)_4$ indicated B–B bond lengths of 176.2(1.1) and 172.0(6) pm.[16] The four B–N bond lengths are almost equal: 158.2(3), 156.3(3), 157.2(3) and 157.1(3) pm. The two five-membered BBNCN rings are almost planar, and the dihedral angle between them is 67.80(8)°. The IR spectrum contains absorptions in a region typical for terminal B–H stretches (2398–2230 $cm^{-1}$).

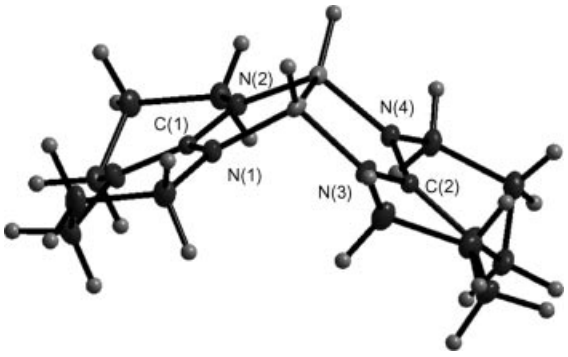

Figure 3. Molecular structure of $[HB(hpp)]_2$ in the crystalline phase. The thermal ellipsoids are drawn at the 50% probability level. Selected bond parameters (distances in pm, bond angles in degrees): B–H 115(3), 106(4); B–B 177.2(3); B–N 157.1(2), 157.2(3), 156.3(3), 158.2(3); N(1)/N(2)–C(1) 133.1(2), 134.3(2); N(3)/N(4)–C(2) 133.8(2), 133.4(2); N(1)–C(1)–N(2) 115.6(2); N(3)–C(2)–N(4) 115.3(2); N(1)/N(2)–B–N(3)/N(4) 111.0(2), 110.8(2).

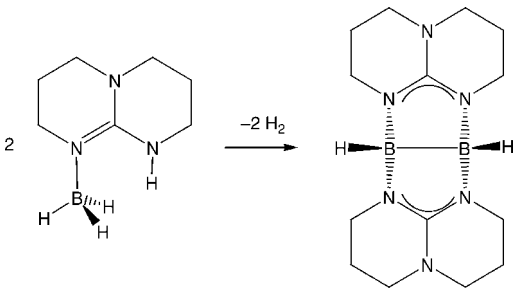
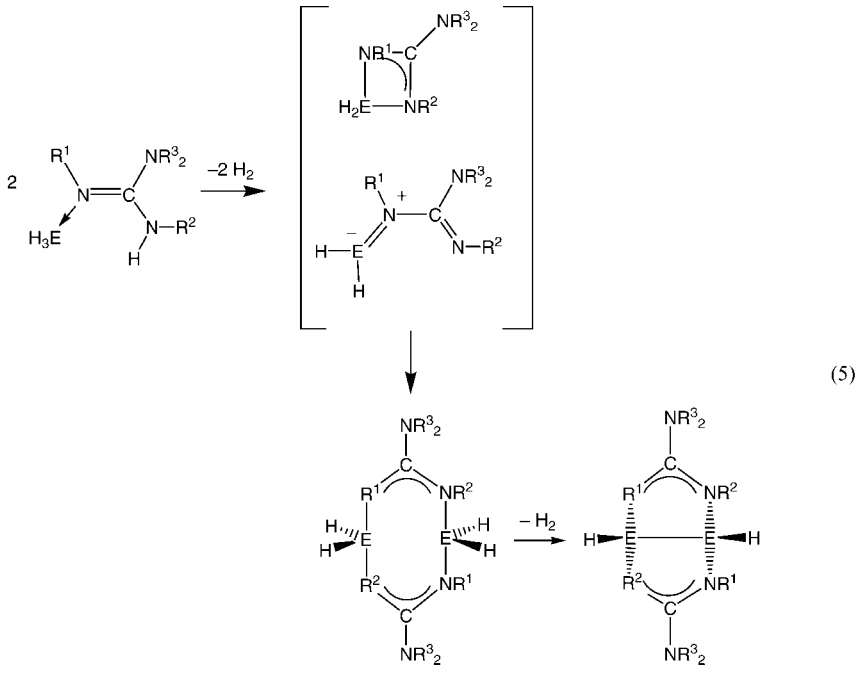


(4)

The reaction pathway proposed on the basis of quantum chemical calculations leading from $H_3B{\cdot}hppH$ to $[HB(hpp)]_2$ is illustrated in reaction sequence (5) (generalized to guanidine derivatives). Intramolecular $H_2$ elimination from $H_3B{\cdot}hppH$ is facilitated by intramolecular H···H contacts and leads to a diene-type intermediate. The reaction energy and the standard Gibbs free energy for this first step are +74 (+46 with zero-point vibrational energy corrections) and +17 kJ $mol^{-1}$, respectively.[14] This diene-type intermediate is in equilibrium with a four-membered ring structure



(5)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in which the guanidinate ligand adopts a chelating binding mode. The standard Gibbs free energy change between the diene and the four-membered ring is calculated to be no more than 3 kJ mol$^{-1}$ (in favour of the four-membered ring). The diene subsequently undergoes a [4+4] cycloaddition to give $[H_2B(hpp)]_2$. This second step is associated with an energy change of –109 (–118 including zero-point vibrational energy corrections) kJ mol$^{-1}$ and a standard Gibbs free energy change of –87 kJ mol$^{-1}$. Finally, and most importantly, the reaction energy and standard Gibbs free energy for the formation of $[HB(hpp)]_2$ by $H_2$ elimination from $[H_2B(hpp)]_2$ come out to be +32 (+1 including zero-point vibrational energy corrections) and –30 kJ mol$^{-1}$, respectively. Solvation effects for this particular reaction were estimated by using the COSMO method[17] with $\varepsilon_r$ = 2.38 for toluene. As expected, the effects are very small ($\Delta E$ decreases to +30 kJ mol$^{-1}$, and $\Delta G^0$ increases slightly to –27 kJ mol$^{-1}$). Figure 4 shows $\Delta G$ for the decomposition reaction of $[H_2B(hpp)]_2$ to give $[HB(hpp)]_2$ and $H_2$ as a function of temperature at a pressure of 1 bar. Experiments will be undertaken to analyze whether the $H_2$ elimination can be accomplished reversibly. We are also extending our work to related compounds featuring two B atoms connected by one or two bridging guanidinate or amidinate ligands.

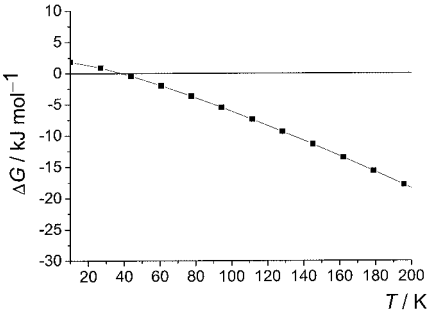


Figure 4. $\Delta G$ for the reaction $[H_2B(hpp)]_2 \rightarrow [HB(hpp)]_2 + H_2$ as a function of temperature at a constant pressure of 1 bar.

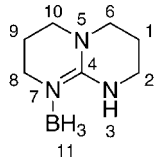
## Conclusion

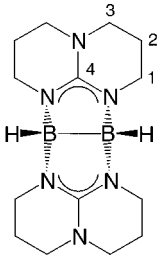
The base exchange reaction between $H_3B{\cdot}NMe_3$ and the guanidine derivative hppH affords the new borane adduct $H_3B{\cdot}$hppH . Intramolecular BH···HN contacts are established therein, facilitating $H_2$ elimination, which was observed around 110 °C. Dimerization and repeated $H_2$ elimination leads directly to the new diborane (4) derivative $[HB(hpp)]_2$. X-ray diffraction measurements reveal the presence of a trigonal prismatic central $B_2N_4$ unit in this hydride. Quantum chemical calculations were carried out to analyse the reaction pathway. These calculations suggest the formation of a diene-type intermediate upon intramolecular $H_2$ elimination followed by cycloaddition and elimination of a second $H_2$ molecule to give the observed product. Future experiments concentrate on the synthesis of other derivatives of this class of compounds, which might also be interesting for $H_2$ activation, and on the synthesis of the intermediate $[HB(hpp)]_2$ by catalytic dehydrocoupling reactions.

## Experimental Section

All reactions were carried out under a dry argon atmosphere by using standard Schlenk techniques. All solvents were dried by using standard methods followed by distillation. $H_3B{\cdot}NMe_3$ and hppH were purchased from Aldrich and used as received.



**$H_3B{\cdot}$hppH:** A solution of $H_3B{\cdot}NMe_3$ (0.524 g, 7.18 mmol) in toluene (20 mL) was added to a solution of hppH (1.00 g, 7.18 mmol) in toluene (20 mL) by syringe, and the reaction mixture was stirred for 18 h at 60 °C. The colourless solution was concentrated, and *n*-pentane (ca. 10 mL) was added to obtain a white precipitate in 70% yield (0.70 g, 5.03 mmol). Crystals suitable for X-ray diffraction were grown from a hexane/toluene (2:1) mixture at –20 °C. $C_7H_{16}BN_3$ (153.03): calcd. C 54.94, H 10.54, N 27.46; found C 54.36, H 10.38, N 26.91. $^1$H NMR (400 MHz, $C_6D_6$): $\delta$ = 6.29 (s, 1 H, NH), 3.34 (t, $^3J$ = 5.9 Hz, 2 H, 8-H), 2.83 (br. q, $^1J$ = 93 Hz, 3 H, $BH_3$), 2.27 (t, $^3J$ = 5.9 Hz, 2 H, 6-H), 2.13 (t, $^3J$ = 6.0 Hz, 2 H, 10-H), 2.03 (t, $^3J$ = 6.0 Hz, 2 H, 2-H), 1.17 (quint, $^3J$ = 6.0 Hz, 2 H, 9-H), 0.91 (quint, $^3J$ = 6.0 Hz, 2 H, 1-H) ppm. $^{13}$C{$^1$H} NMR (100.55 MHz, $C_6D_6$): $\delta$ = 150.69 (C-4), 47.47 (C-8), 47.27 (C-10), 46.82 (C-2), 38.38 (C-6), 21.80 (C-9), 21.57 (C-1) ppm. $^{11}$B NMR (128.30 MHz, $C_6D_6$): $\delta$ = –19.15 (q, $^1J$ = 93 Hz, $BH_3$) ppm. HRMS (EI+): *m*/*z* (%) = 152.14 (100.0) $[M - H]^+$, 138.10 (28.2) $[hpp]^+$, 122.09 (5.6) $[M - CH_3NH_2]^+$, 113.00 (5.1) $[M - CH_3NB]^+$, 95.07 (2.8) $[M - C_2H_9NB]^+$. IR (solid CsI): $\tilde{\nu}$ = 3352 (s) (N–H val), 2960 (m) (C–H val), 2872 (m) (C–H val), 2363 (m) (B–H), 2301 (m) (B–H), 2253 (m) (B–H), 1625 (s) (C=N val.), 1570 (s) (N–H def.), 1447 (w) (C–H def.), 1322 (m), 1174 (m) (B–N), 1148 (m) cm$^{-1}$.



**$[HB(hpp)]_2$:** A solution of $H_3B{\cdot}NMe_3$ (0.21 g, 2.9 mmol) in toluene (15 mL) was slowly added to a solution of hppH (0.4 g, 2.9 mmol) in toluene (15 mL). The reaction mixture was heated under reflux for 20 h at 110 °C. The solution was concentrated, and colourless crystals of the toluene solvate were obtained from these solutions after storage for several days at –20 °C. $^1$H NMR (600 MHz, [D$_8$]toluene): $\delta$ = 3.23 (t, $^3J$ = 5.8 Hz, 2 H, 1-H), 2.57 (t, $^3J$ = 6.6 Hz, 2 H, 3-H), 1.56 (quint, 2 H, 2-H) ppm. $^{13}$C{$^1$H} NMR (150.9 MHz, [D$_8$]toluene): $\delta$ = 47.96 (C-3), 47.19 (C-1), 24.21 (C-2) ppm. $^{11}$B{$^1$H} NMR (192.5 MHz, [D$_8$]toluene): $\delta$ = –2.39 (BH) ppm. MS (EI+): *m*/*z* = 299.4 $[C_{14}H_{26}B_2N_6]^+$, 138.2 $[hpp]^+$. IR (solid CsI): $\tilde{\nu}$

# Synthesis and Crystal Structure of New Early-Lanthanide Organometallic Clusters

Eyal Barnea,[a] Claudia Averbuj,[a] Moshe Kapon,[a] Mark Botoshansky,[a] and Moris S. Eisen*[a]

**Keywords:** Organolanthanide halide clusters / Lithium / Bridging ligands

Reaction of $Cp^*_2NdCl{\cdot}LiCl{\cdot}2thf$ (**1**) with excess catecholborane affords the hexameric cluster $(Cp^*NdCl_2)_6(LiCl)_3(thf)_3$ (**2**) bearing three types of bridging chloride ions. Heating the reaction mixture affords the tetrameric cluster $[(Cp^*NdCl_2)_4(\mu_4\text{-}Cl)]_2[LiO_2][LiO_2{}^*Li_2O^*O_2]$ (**3**), which has the first crystal structure with the $LiO_2^+$ motif. Reaction of complex **1** or the analogous Sm complex, **4**, with pinacolborane affords clusters **5a** (Nd) or **5b** (Sm), respectively, a second type of hexameric cluster built from two $CpNd_3Cl_5(thf)$ units bonded by two $\mu_2$-Cl atoms.

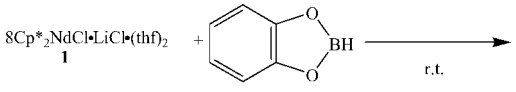
## Introduction

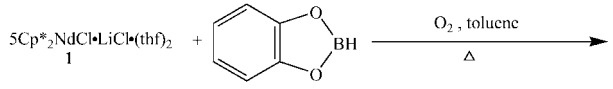
Organometallic rare-earth complexes bearing one Cp* ligand and a heteroatom have received considerable attention in recent years due to their potential use in homogeneous catalysis, especially in the polymerization of olefins.[1] However, the synthesis of mono(Cp) complexes of lanthanides is still a challenging task, because of the relative ease of the synthesis of bis(Cp) complexes and/or their rearrangement into the more thermodynamically stable homoleptic tris(Cp) derivatives.[2] In addition, these metals are also known to form organometallic heteroatom clusters.[3] Recently, Visseaux et al.[4] reported the synthesis and crystal structure of new monocyclopentadienyl lanthanide clusters bearing chlorido or borohydride bridges and up to six Nd or Sm atoms in the metallic backbone. Higher-order lanthanide–halide clusters bearing up to 12 metal atoms in the backbone were reported by Kretschmer et al.[5] In this contribution, we present the crystal structures of four new organolanthanide chlorido clusters as well as the unique counterion $LiO_2^+$.

## Results and Discussion

We recently reported the synthesis of inclusion complexes of organic ligands with f-elements in which the metal is encapsulated by trianionic triborate–tribenzo crown ethers.[6a] When we attempted to prepare such a macrocyclic complex bearing Nd as the metal center by the reaction of catecholborane (HBcat) with complex **1**, $Cp^*_2NdCl{\cdot}LiCl{\cdot}2thf$ [Equation (1a)], we found that the presence of HBcat (neat, no solvent) induced a selective clustering reaction, yielding cubelike blue crystals of cluster **2**, which were analyzed by X-ray crystallography. Cluster **2** crystallizes in the cubic space group $I\bar{4}3d$ (see Table 1 for complete crystallographic data and Figure 1 for selective bond lengths and angles). The X-ray diffraction analysis (Figure 1) revealed a hexameric cluster structure bearing six Nd atoms bridged by 14 chloride ions. In addition, three groups of four chloride ions are bridged by a Li–thf moiety. Each Nd atom is also bonded to one Cp* ligand outside the cluster. The six Nd atoms describe a trigonal prism, which has a central isolated chloride ion (Cl7). The bonds between the Nd atoms and the central Cl atom are considerably longer (3.388 Å) than other Nd–Cl bonds in the cluster (2.92 Å in average, similar to those observed in the literature[4,5]). Each Nd atom has nine coordination sites. Interestingly, the presence of a $\mu^6$-heteroatom in the center of a cluster has been already observed for oxygen,[7] halogen,[8] and selenium.[9]



$$\underset{\mathbf{2}}{Cp^*_6Nd_6Cl_{15}Li_3(thf)_3} + 4Cp^*Li + 2NdCp^*_3 + LiCl + 13thf \qquad (1a)$$



$$\underset{\mathbf{3}}{Cp^*_4Nd_4Cl_9LiO_2} + 3Cp^*Li + NdCp^*_3 + LiCl + 10thf \qquad (1b)$$

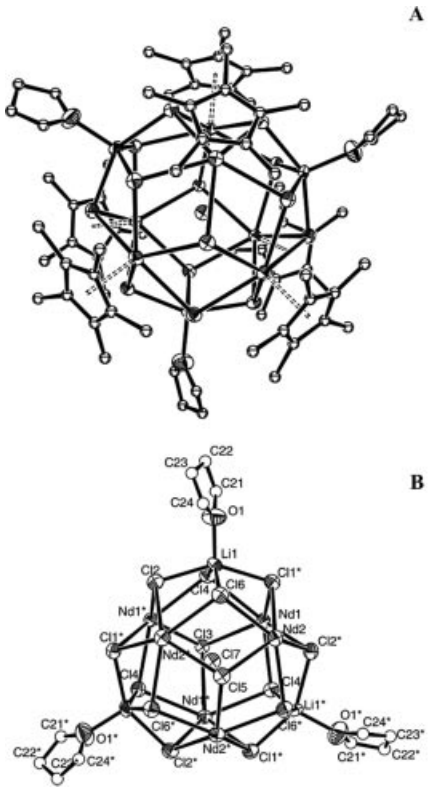

Figure 1. ORTEP representation (50% probability) of the molecular structure of complex **2**. (A) Full structure and (B) with removal of hydrogen atoms and Cp* ligands for clarity. Selected bond lengths [Å] and angles [°]: Nd1–Cl1* 2.898(3), Nd–Cp*(CNT) 2.341(10), Nd1–Cl2 2.882(3), Nd1–Cl5 2.972(4), Nd1–Cl7 3.388(5), Cl–Li 2.488(5), Li1–O1 1.931(6), Nd1–Nd2 4.427(10); Nd1–Cl7–Nd2 80.08(9), Nd1–Cl7–Nd1* 82.63(9), Nd1–Cl1*–Nd2 98.26(9).

The formation of **2** is accompanied by the formation of LiCp*, NdCp*$_3$,[10] and LiCl, as presented in Equation (1a); in contrast, a very small amount of product forms when the reaction is carried out in only a slight excess of the borane. It is important to point out that our attempts to perform the same reaction in the absence of the borane or by adding a strong Lewis acid ($Me_3Al$) resulted in decomposition products only.

When the same reaction was performed at higher temperatures (in the expectation of lowering the clustering effect) a different cluster was formed [Equation (1b)]. The crystal structure of cluster **3** (Figure 2 and Figure 3) revealed a tetrameric cluster with four Cp*Nd units bridged by eight $\mu_2$-Cl ions. In addition, in the center of the square described by the four Nd atoms lies an isolated $\mu_4$-Cl ion.[11] The unit cell contains two clusters, each with a –1 charge. These charges are counterbalanced by two microstructures of $LiO_2^+$ ion outside the cluster. In the first structure, the $Li^+$ ion is bonded to $O_2$ in a triangular fashion to form the ordered $[LiO_2]^+$. To the best of our knowledge, this is the first solid-state characterization of this motif. The O–Li–O angle is 46.5 °, which is the same as the calculated angle of the $LiO_2$ radical of 46.5 °.[12] However, the Li–O bond length (1.922 Å) differs significantly from the calculated length (1.76 Å),[12] which is reasonable if it is taken into account that the calculations were done for the $LiO_2$ radical and not the cationic $[LiO_2]^+$. We believe that the oxygen comes from contamination of the reaction mixture with traces of molecular oxygen in the glove box, where there is

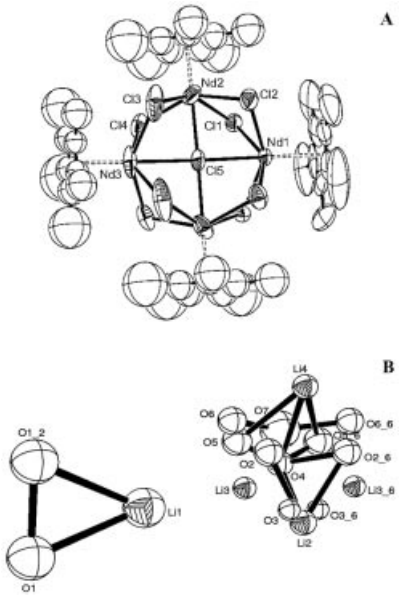

Figure 2. ORTEP representation (30% probability) of the molecular structure of compound **3**. (A) Side view of the anionic cluster; hydrogen atoms were removed for clarity. (B) Top view of both cationic microstructures: the ordered $LiO_2^+$ (left) and the disordered $LiO_2^+/Li_2O/O_2$ cluster fragment. Selected bond lengths [Å] and angles [°]: Nd1–Cl1 2.877, Nd–Cp*(CNT) 2.414, Nd1–Cl2 2.825, Nd1–Cl5 2.875, O1–Li1 1.943, Nd1–Nd2 4.090, O1–O1_2 1.534; Nd1–Cl5–Nd2 90.75, Nd2–Cl5–Nd3 89.17, Nd1–Cl1–Nd2 91.03, Nd1–Cl2–Nd2 92.32, O1–Li1–O1_2 46.87.

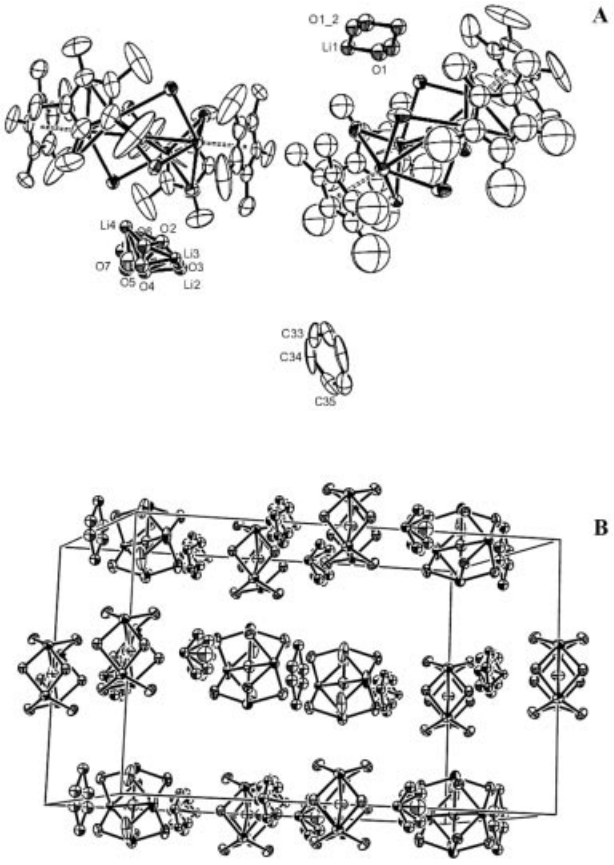

Figure 3. ORTEP representation (30% probability) of (A) the two different cluster units of complex **3**, along with the solvent molecule and the two microstructures of $LiO_2^+$ and (B) the unit cell of complex **3**. Cp* methyl groups and hydrogen atoms were removed for clarity.

no humidity and hence no hydrolysis products were observed. The presence of molecular oxygen can also be inferred from the second cationic microstructure, which shows a highly disordered $Li_3O_5^+$ fragment. This results from the combination of the following motifs: $LiO_2^+$, $Li_2O$, and $O_2$. The formulation of these fragments is postulated according to the occupancies of the different atoms, bond length, angles, and total charge of the unit cell.[13]

Addition of dry oxygen to the reaction mixture allowed us to synthesize complex **3**, although the yield was not predictable. It seems that the most important factor is the concentration of the oxygen dissolved in the solution and not its total amount in the Schlenk tube.

As we have reported,[6] the reaction of the analogous complex **4**, $Cp^*_2SmCl{\cdot}MgCl_2{\cdot}2thf$ with HBcat yields a macrocyclic inclusion complex. To exclude the option of macrocycle formation, we turned our attention to pinacolborane (HBpin), which was found to be inactive in the macrocycle formation reaction.[6a] The reaction of complexes **1** or **4** with excess HBpin at room temperature afforded crystals of the isostructural clusters **5a** (Ln = Nd) or **5b** (Ln = Sm), respectively [Equations (2a) and (2b)], which were characterized by X-ray crystallography. Both clusters crystallize in the monoclinic space group *C*2/*c* with almost

identical unit cells (see Table 2 for complete crystallographic data and Figure 4 for selective bond lengths and angles). As depicted in Figure 4, compound **5** is a hexameric cluster built from two symmetric units, which are bonded by two $\mu_2$-Cl ions (Cl6 and Cl6*). Each unit is built from three Ln atoms, two of which are bonded to the two $\mu_2$-Cl ligands, while the third Ln atom has a coordinated thf ligand, maintaining the stereoelectronic saturation of the cluster. In each $(Cp^*Ln)_3Cl_5$ unit, there are two $\mu_3$ (Cl1 and Cl4) and three $\mu_2$ (Cl2, Cl3, and Cl5) bridging chlorido ligands. The structure of the fragment can be regarded as a hexagonal plane of alternating Ln and Cl atoms and two apical Cl ligands bonded to the metal. In the overall structure of the cluster, the six Ln centers adopt a chairlike geometry with Cp*Ln(thf) ends, similar to that of the mixed chlorido/borohydride clusters presented by Visseaux et al.[4] As can be expected from the smaller ionic radii of Sm relative to Nd, the bond lengths in **5b** are slightly shorter than those in **5a**.[14] Regarding the role of borane in the formation of the clusters, we suggest that the thf ligands of complexes **1** and **4** are removed by the borane in order to coordinate

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the boron atom instead of the Li or Mg salt. Attempts to determine the fate of the Cp* ligation were unsuccessful. The removal of LiCl/$MgCl_2$ and solvent from the starting complex by the strong Lewis acidic borane induces the coordinative unsaturation of the resulting complex. In addition, we propose that the borane fragment has a role in trapping one of the Cp* ligands of the starting complex. These two factors increase the tendency of the remaining Cp*LnCl fragments to form clusters. Attempts to perform the reaction without a borane did not lead to products but rather resulted in decomposition.

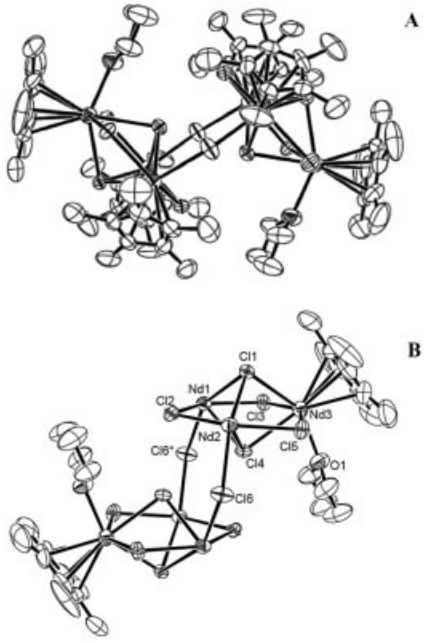

Figure 4. ORTEP representation (50% probability) of the molecular structure of complex **5a**: (A) full structure and (B) with removal of hydrogen atoms and Cp* ligands (bonded to Nd1 and Nd2) for clarity. Selected bond lengths [Å] and angles [°]: Nd–Cl1 2.932, Nd–Cp*(CNT) 2.414(9), Nd–Cl4 2.898(2), Nd1–Cl2 2.795(2), Nd1–Cl3 2.834(2), Nd1–Cl6* 2.758(2), Nd2–Cl6 2.772(2), Nd3–Cl3 2.784(2), Nd3–O1 2.458(6), Nd–Nd 4.122(5); Nd1–Cl1–Nd2 88.58(12), Nd1–Cl4–Nd2 91.59(6), Nd1–Cl2–Nd2 95.81(6), Nd2–Cl6–Nd1* 136.60(9). Complex **5b** shows an isostructural cluster. Selected bond lengths [Å] and angles [°] for complex **5b**: Sm–Cl1 2.884, Sm–Cp*(CNT) 2.361(15), Sm–Cl4 2.912(4), Sm1–Cl2 2.789(3), Sm1–Cl3 2.825(4), Sm1–Cl6* 2.743(3), Sm2–Cl6 2.769(4), Sm3–Cl3 2.771(4), Sm3–O1 2.435(10), Sm–Sm 4.101(7); Sm1–Cl1–Sm2 88.66(9), Sm1–Cl4–Sm2 91.63(9), Sm1–Cl2–Sm2 95.63(9), Sm3–Cl6–Sm1* 137.05(14).

## Conclusion

In conclusion, we have presented four new mono-Cp* lanthanide clusters, composed of tetramers or hexamers with chloride ions as the bridging units of the cluster. These complexes are formed by the reaction of a borane with the complexes containing chlorido ligands. In addition, the crystal structure of the unique and unusual $LiO_2^+$ counterion was presented.

## Experimental Section

**Instruments and Methods:** All manipulations of air-sensitive materials were performed with the rigorous exclusion of oxygen and moisture in flamed Schlenk-type glassware on a dual-manifold Schlenk line, in a Schlenk line interfaced with a high-vacuum ($10^{-5}$ Torr) line, or in a nitrogen-filled Vacuum Atmospheres glovebox with a medium-capacity recirculator (1–2 ppm $O_2$). Argon and nitrogen were purified by passage through a MnO oxygen removal column and a Davison 4 Å molecular sieves column. NMR spectra were recorded with Avance 300 and Avance 500 spectrometers. Chemical shifts for $^1$H NMR and $^{13}$C NMR are referenced to internal solvent resonances and are reported relative to tetramethylsilane. The NMR experiments were conducted in Teflon valve-sealed tubes (J. Young) after vacuum transfer of the liquids in a high vacuum line.

**Reagents and Standards:** Hydrocarbon solvents [$D_8$]thf, [$D_6$]benzene, and [$D_8$]toluene (Aldrich) were distilled under nitrogen from over a Na/K alloy. All solvents for vacuum line manipulations were stored in vacuo over Na/K alloy in resealable bulbs. $NdCl_3$ (Aldrich) was degassed and stored under argon. Catecholborane (HBcat) and pinacolborane (Hbcat) (Aldrich) were used without purification. Cp*$_2$NdCl·LiCl·2thf[15] and Cp*$_2$SmCl·$MgCl_2$·2thf[6c] were prepared according to published procedures.

**Crystal Structure Determination – General Procedure:** Single crystals immersed in Parathone-N oil were quickly removed with a glass rod and mounted on a KappaCCD diffractometer under a cold stream of nitrogen at 230 K. Data collection was carried out with monochromatized Mo-$K_\alpha$ radiation by using omega and phi scans to cover the Ewald sphere.[16] Accurate cell parameters were obtained with complete collections of intensities and these were corrected in the usual way.[17,18] The structures were solved by direct methods and completed by using successive Fourier difference maps.[19] Refinements were performed anisotropically with respect to the non-hydrogen atoms.[20] Hydrogen atoms were placed at calculated positions and refined by using the riding model until convergence was reached. Figures were prepared with ORTEP.[21]

**Syntheses**

**Cp*$_6$Nd$_6$Cl$_{15}$Li$_3$(thf)$_3$ (2):** A Schlenk tube was charged in the glovebox with Cp*$_2$NdCl·LiCl·2thf (35 mg, 0.056 mmol) and HBcat (80 mg, 0.67 mmol). After 24 h at room temperature, the large, cubelike, blue crystalline precipitate was isolated (15 mg, 86%) and characterized by single-crystal X-ray diffraction. $^1$H NMR (500 MHz, [$D_8$]thf, 298 K): $\delta$ = 8.23 (s, 15 H, $C_5Me_5$) ppm. $^{13}$C NMR (125 MHz, [$D_8$]thf, 298 K): $\delta$ = 243.6 (s, $C_5$Me$_5$), –14.7 (s, $C_5Me_5$) ppm. $C_{72}H_{114}Cl_{15}Li_3Nd_6O_4$ (2483.5): calcd. C 34.79, H 4.59, Cl 21.44; found C 35.02, H 4.12, Cl 21.21.

**[Cp*$_4$Nd$_4$Cl$_9$]$_2$[$LiO_2$]$_2$·$Li_2O$·$O_2$·3$C_6H_6$ (3):** A Schlenk tube was charged in the glovebox with Cp*$_2$NdCl·LiCl·2thf (35 mg, 0.056 mmol), HBcat (80 mg, 0.67 mmol), and toluene (1 mL) and then heated to 110 °C for a few days. After the heating period, the white precipitate was removed by filtration to leave behind a clear blue solution. The solvent was removed by vacuum, and benzene was added to the tube by vacuum transfer. The tube was allowed to stand at high temperature for 24 h, affording a few pale blue crystals, which were isolated (10 mg, 44%) and characterized by single-crystal X-ray diffraction. $^1$H NMR (500 MHz, [$D_8$]thf, 298 K): $\delta$ = 8.55 (s, 15 H, $C_5Me_5$) ppm. Attempts to introduce measured amounts of dry oxygen resulted in the same product but in lower yields. When a measured amount or regular-moisture air was introduced into the reaction mixture, no product was observed.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$C_{98}H_{138}Cl_{18}Li_4Nd_8O_7$ (3245.6): calcd. C 36.24, H 4.25, Cl 19.68; found C 35.02, H 4.09, Cl 20.67.

**[Cp*$_3$Nd$_3$Cl$_5$(thf)]$_2$(μ$_2$-Cl)$_2$ (5a):** A Schlenk tube was charged in the glovebox with Cp*$_2$NdCl·LiCl·2thf (35 mg, 0.056 mmol) and HBpin (80 mg, 0.62 mmol). After 72 h at room temperature, the blue crystalline precipitate was isolated (18 mg, 86%) and characterized by single-crystal X-ray diffraction. $^1$H NMR (500 MHz, [D$_8$]thf, 298 K): $\delta$ = 7.89 (s, 15 H, C$_5$*Me*$_5$) ppm. $^{13}$C NMR (125 MHz, [D$_8$]thf, 298 K): $\delta$ = 240.5 (s, *C*$_5$Me$_5$), –13.2 (s, C$_5$*Me*$_5$) ppm. $C_{68}H_{106}Cl_{12}Nd_6O_2$ (2246.37): calcd. C 36.32, H 4.71, Cl 18.96; found C 35.94, H 4.47, Cl 19.11.

**[Cp*$_3$Sm$_3$Cl$_5$(thf)]$_2$(μ$_2$-Cl)$_2$ (5b):** A Schlenk tube was charged in the glovebox with Cp*$_2$SmCl·MgCl$_2$·2thf (35 mg, 0.054 mmol) and HBpin (80 mg, 0.62 mmol). After 72 h, the colorless crystalline precipitate was isolated (18 mg, 87.8%) and characterized by single-crystal X-ray diffraction. $^1$H NMR (500 MHz, [D$_8$]thf, 298 K): $\delta$ = 2.45 (s, 15 H, C$_5$*Me*$_5$) ppm. $^{13}$C NMR (125 MHz, [D$_8$]thf, 298 K): $\delta$ = 113.8 (s, *C*$_5$Me$_5$), 16.3 (s, C$_5$*Me*$_5$) ppm. $C_{68}H_{106}Cl_{12}O_2Sm_6$ (2283.09): calcd. C 35.74, H 4.64, Cl 18.65; found C 36.01, H 4.35, Cl 18.11.

**Crystal Structure Analysis of Complex 3:** A single pale blue crystal was removed from Parathone oil and mounted on the KappaCCD diffractometer under a cold stream of nitrogen at 230 K. Unit cell parameters were determined with 9306 reflections by using Mo-$K_\alpha$ radiation. The complete set of 15080 reflections were collected and processed in the usual way. The structure was solved by direct methods with the program package 'maXus'. After the correct space group *C*2/*m* was established, Fourier maps revealed the positions of the heavy atoms as follows: Nd1, Nd3, and Cl5 on the mirror plane at $y$ = 0 site *i*, Cl6 and Cl7 on the mirror plane at $y$ = 0.5 site *i*, Cl9 on site 2/*m* (*b*) and Nd2, Nd4, Cl1, Cl2, Cl3, Cl4, and Cl8 in general positions. The positions of these heavy atoms were refined anisotropically by using the SHELXL97 program package. The carbon atoms of the Cp* groups found from Fourier difference maps were refined anisotropically, whereas the positions of the methyl hydrogen atoms were calculated and shifted by using the riding model.

At this stage it was clear that the unit cell contains six cluster units of $Nd_4Cl_9Cp^*_4$ bearing a charge of –1 by assuming a valence of +3 for the Nd cation. One cluster unit defined by Nd1–Nd3 is located on a mirror plane at $y$ = 0, whereas a second cluster defined by Nd4 occupies a 2/*m* site (*b*), and the overall number of clusters is (½ + ¼)·8 = 6. Careful examination of the difference maps revealed numerous small peaks which could not be assigned easily as $Li^+$ counterions. Three peaks with occupancies of ½ were identified as half benzene rings located on the mirror plane at $y$ = 0. The remaining peaks were found to be grouped into two regions, and they were analyzed by considering the interaction of disordered $Li^+$ ions with oxygen molecules and charged oxygen species. After tedious attempts, the following occupancies were given to the Li and oxygen atoms by constraining the total charge, keeping reasonable geometries for the Li–O species, and meaningful $U_{iso}$ values for the various atomic positions (Table 3).

This model fulfils the following formula per unit cell: $6LiO_2{\cdot}Li_2O{\cdot}O_2$ or $LiO_2{\cdot}Li_2O{\cdot}O_2$ per cluster unit. The $LiO_2$ unit grouped separately is located on a mirror plane and is attributed to the interaction of $Li^+$ with neutral $O_2$. The second region of grouped peaks contains $Li_2O$ composed of $Li^+$ and $O^{-2}$. There is also $O_2$ as a neutral species. In this model only one $Li^+$ neutralizes the charge of one cluster unit.

CCDC-643835, 643836, 643843, 643844 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via http://www.ccdc.cam.ac.uk/data_request/cif.

Table 3. List of atoms and occupancies in one of the counterions for complex **3**.

| Atom | Occupancy | $U_{iso}$ | Number of atoms in the unit cell |
|---|---|---|---|
| Li1 | 0.25 | 0.072 | 2 |
| Li2 | 0.25 | 0.056 | 2 |
| Li3 | 0.25 | 0.044 | 2 |
| Li4 | 0.25 | 0.055 | 2 |
| O1 | 0.50 | 0.087 | 4 |
| O2 | 0.50 | 0.069 | 4 |

## COVER PICTURE

**The cover picture shows** unique examples of homo- and heterochiral, dimeric metal capsules resulting from the self-assembly of two helical, bowl-shaped tetranuclear copper(II) complexes that encapsulate different anions in the solid state, like pearls in an oyster (shown as the background). This kind of self-assembled, coordination-bonded motifs are a major topic in metallosupramolecular chemistry because of their binding capabilities and associated host–guest chemistry. However, their magnetic properties are largely unexplored, and here we provide one of the rare magnetic studies on these host–guest systems. For more details on the combined structural and magnetic investigations of this class of synthetic "oyster" molecules, see the article by F. Lloret, Y. Journaux et al. on p. 4569ff.

## 1D Water Cluster

$\{[Co(tart)(phen)]\cdot 6H_2O\}_n$ (**1**) (tart, tartrate dianion; phen, 1,10-phenanthroline) forms a 3D supramolecular network through π-π and H-bonding interactions. A variable-temperature magnetic study **1** has been carried out and the interpretation of the already reported $\{[Co(tart)(bpy)]\cdot 5H_2O\}_n$ (**2**) has been re-visited: both **1** and **2** show weak antiferromagnetic interaction.

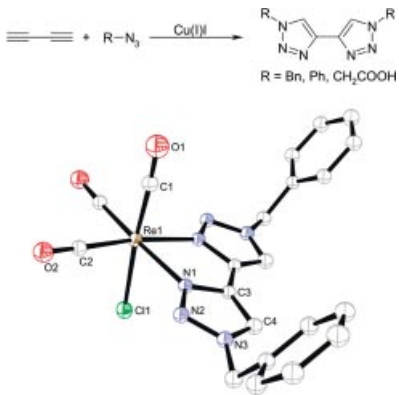
## FULL PAPERS

### Bi-1,2,3-triazole Ligand Properties

**U. Monkowius,* S. Ritter, B. König,* M. Zabel, H. Yersin ..... 4597–4606**

Synthesis, Characterisation and Ligand Properties of Novel Bi-1,2,3-triazole Ligands

**Keywords:** N ligands / Ligand design / Nitrogen heterocycles / Click reaction / 1,2,3-Triazole



Three bi-1,2,3-triazoles (R-bta; R = Bn, Ph, $CH_2COOH$) were synthesised by a $Cu^I$-catalysed "click" reaction to act as potential bidentate, nitrogen-based ligands. The ligand properties were probed by the preparation of $Ru^{II}$, $Cu^I$, and $Re^I$ complexes. X-ray crystallographic data are presented for the ligands and complexes as well as the results of electronic absorption spectroscopy.

### Tetrahedral Cobalt Complexes

**M. C. Aragoni, M. Arca, M. B. Carrea, A. Garau, F. A. Devillanova, F. Isaia,* V. Lippolis, G. L. Abbati, F. Demartin, C. Silvestru, S. Demeshko, F. Meyer ..... 4607–4614**

Tetrahedral $Co^{II}$ Complexes with $CoI_2O_2$ and $CoO_2S_2$ Cores – Crystal Structures of $[Co\{HN(OPPh_2)(SPPh_2)\text{-}O\}_2I_2]$ and $[Co\{N(OPPh_2)(SPPh_2)\text{-}O,S\}_2]$

**Keywords:** Cobalt / O,S ligands / Phosphanes / Sulfides / Density functional calculations / Magnetic properties

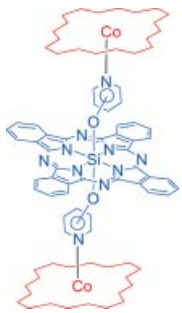
Two $Co^{II}$ complexes were synthesised with the ligand $HN(OPPh_2)(SPPh_2)$, which contains mixed hard (O) and soft (S) donor atoms. The X-ray crystal structures of these compounds show the presence of a $CoI_2O_2$ and a $CoO_2S_2$ core. The mutual conversion of the complexes is driven by the protonation/deprotonation of the imido nitrogen atoms.

### Phthalocyanine–Porphyrin Arrays

**X. Leng, D. K. P. Ng* ..... 4615–4620**

Axial Coordination of Porphyrinatocobalt(II) Complexes with Bis(pyridinolato)-silicon(IV) Phthalocyanines

**Keywords:** Phthalocyanines / Porphyrins / Axial coordination / UV/Vis spectroscopy



Bis(pyridinolato)silicon(IV) phthalocyanins axially bind to porphyrinatocobalt(II) complexes forming the novel hetero phthalocyanine–porphyrin dyads and triads. The binary complexes are stable and can thus be isolated and spectroscopically characterized.

### Water–Chloride Clusters

# Template-Controlled Reactivity in the Organic Solid State by Principles of Coordination-Driven Self-Assembly

**Dejan-Krešimir Bučar,[a] Giannis S. Papaefstathiou,[b] Tamara D. Hamilton,[a] Qianli L. Chu,[a] Ivan G. Georgiev,[a] and Leonard R. MacGillivray*[a]**

**Keywords:** Self-assembly / Dimerization / Solid-state reactivity / Hydrogen bonds

In this microreview, we show how principles of coordination-driven self-assembly can be used to direct chemical reactivity in the organic solid state. We also show how products obtained from the templated solid-state reactions can be used as organic building units of metal–organic frameworks and coordination capsules. Self-assembled structures based on dinuclear $Zn^{II}$ and $Ag^{I}$ complexes are used to direct stereocontrolled [2+2] photodimerizations of vinylpyridines in the solid state in up to quantitative yield. The products are used as bi- and polytopic ligands of self-assembled coordination capsules and metal–organic frameworks. We also describe emerging metal-based approaches to conduct mechanochemical reactions in organic solids. In addition to the field of supramolecular coordination chemistry, these observations impact the field of green chemistry.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Reactions that occur in the organic solid state bear widespread relevance to organic synthesis and materials science. The homogeneous, confined and surprisingly flexible nature[1] of a molecular lattice means that molecules can react in solids with perfect control of stereochemistry and in a quantitative yield. That such reactions can occur in the absence of solvent also means that reactions in the organic solid state bear relevance to the field of green chemistry.[2] Green chemistry has emerged owing to the accepted need to reduce and prevent pollution from the use and production of hazardous chemicals in synthetic chemistry. Thus, the development of strategies that employ reduced amounts of solvent, as well as other chemical auxiliaries, in chemical synthesis is a central goal of green chemistry.[2]

Photoinduced reactions in the organic solid state were first discovered near the beginning of the last century. In the early 1900s, Riiber discovered that cynnamylidineacetic acid and cynnamylidinemalonic acid could photoreact in the solid state to give cyclobutanes.[3] Two decades later, Stobbe and de Jong discovered that the α- and β-forms of *trans*-cinnamic acid undergo solid-state [2+2] photodimerizations to give α-truxillic and β-truxinic acid, respectively. It was proposed that the reactions were a consequence of the packing of the monomer units;[4] however, the mechanistic details of the reactions were not well understood. This was largely a result of a lack of efficient methods to characterize the structures of organic solids. Consequently, it was difficult, at the time, to foresee practical uses of reactions in organic solids. This contrasts reactivity in the liquid phase, which was being systematically studied and becoming reasonably well understood.

On the basis of X-ray crystal structure analyses of a wide range of cinnamic acids, Schmidt and coworkers identified, during the 1960s, structural requirements for two C=C bonds to undergo a [2+2] photodimerization in the solid state.[5] The requirements, collectively known as the topochemical[6] postulate, state that a [2+2] photodimerization can be expected to occur if the C=C bonds lie parallel to each other and with a centre-to-centre distance <4.2 Å. Thus, of the three known polymorphs of *o*-ethoxy-*trans*-cinnamic acid, namely α-, β- and γ-, the α- and β-forms are photoactive (Figure 1).[7] In all three solids, the alkenes

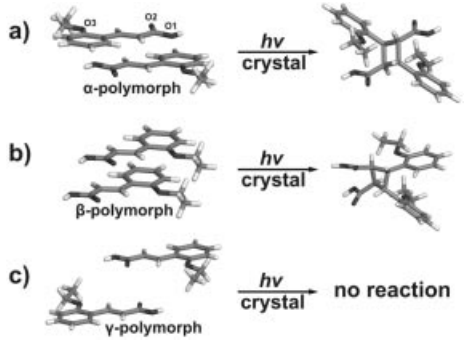

Figure 1. Solid-state reactivity of *o*-ethoxy-*trans*-cinnamic acid: (a) α-, (b) β- and (c) γ-polymorphs.

pack parallel in one-dimensional (1D) slipped stacks. In the cases of the α- and β-forms, C=C bonds of neighbouring monomers lie parallel to each other and are separated by approximately 4 Å. Adjacent monomers of the α-polymorph adopt an antiparallel orientation, and they are related by a crystallographic centre of inversion. This geometry leads to the formation of the "head-to-tail" α-truxillic acid dimer upon photoreaction. Adjacent monomers of the

*Dejan-Krešimir Bučar was born in Zagreb, Croatia in 1975. He obtained a BSc in chemistry from the University of Zagreb in 2004. In 2005 he joined the research group of Professor Leonard R. MacGillivray at the University of Iowa as a graduate student. His principal research interests concern various aspects of organic solid-state chemistry with particular focus on template-directed solid-state synthesis and pharmaceutical cocrystals. He is also interested in synthetic organic chemistry, single-crystal X-ray crystallography and coordination-driven self-assembly.*

*Giannis S. Papaefstathiou obtained his BA in 1998 and his PhD in 2002 from the University of Patras, Greece, while working with Professor Spyros P. Perlepes. He moved to the University of Iowa in 2002 to work with Professor Leonard R. MacGillivray as a postdoctoral fellow for two years. He then moved back to Greece to work as a temporary Lecturer at the University of Patras and as an Associate Instructional Personnel at the Hellenic Open University. He joined the faculty at the Department of Chemistry of the National and Kapodistrian University of Athens in 2006 as a Lecturer. His current research interests are in aspects of coordination chemistry and supramolecular chemistry.*

*Tamara D. Hamilton was born in Nova Scotia, Canada in 1979. In 2001, she graduated from Acadia University with a BSc (Honours). In 2005, she obtained her PhD from the University of Iowa for studies on the coordination chemistry of products from template-directed synthesis in the solid state with Professor Leonard R. MacGillivray. Currently, she is a Natural Sciences and Engineering Research Council of Canada (NSERC) postdoctoral researcher in the group of Professor James D. Wuest at l'Université de Montréal. Her research involves engineering crystals built from molecular tectons with pyrogallol functionalities.*

*Qianli Chu was born in 1975. He performed his undergraduate studies in organic chemistry at Shanghai University, P. R. China (1993–1997). He then spent four years at the Shanghai Institute of Organic Chemistry (SIOC) as a Research Assistant with Professor Shizheng Zhu. He joined the research group of Professor Leonard R. MacGillivray at the University of Iowa where he obtained his PhD in supramolecular chemistry in 2005. He is currently working as a postdoctoral fellow under the guidance of Professor Dennis P. Curran at the University of Pittsburgh with research efforts that mainly focus on fluorous organocatalysis and molecular recognition. His research interests are concentrated at the interface of organic chemistry and supramolecular chemistry.*

*Ivan G. Georgiev was born in Bulgaria in 1973. He received his BA in chemistry from Missouri State University in 2002 and then graduated with a MA degree from the same university conducting research under the supervision of Professor Eric Bosch on the design and synthesis of supramolecular complexes. He is currently a fourth year graduate student at the University of Iowa and working in the laboratory of Professor Leonard R. MacGillivray. His research interest lies in the areas of supramolecular chemistry and organic solid-state reactivity.*

*Len MacGillivray was born in Nova Scotia, Canada, where he received a BSc in chemistry (honours) from Saint Mary's University in 1994. After receiving a PhD from the University of Missouri-Columbia in 1998 while working in the lab of Professor Jerry L. Atwood, he joined the Functional Materials Program at the Steacie Institute of Molecular Science, National Research Council of Canada, Ottawa, where he was a Research Associate and Adjunct Research Professor with the Carleton-Ottawa Chemistry Institute from 1998 to 2000. In 2000, he joined the Department of Chemistry at the University of Iowa as an Assistant Professor and was promoted to his current rank of Associate Professor in 2005. His research focuses upon the field of supramolecular chemistry, particularly as it relates to the design and construction of organic solids.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

β-polymorph adopt a parallel orientation, and they are related by a translation axis. Photodimerization of the β-polymorph produces a "head-to-head" β-truxinic acid. The γ-polymorph is photostable, and the C=C bonds are too far apart to react.

In recent years, we introduced a method to direct [2+2] photodimerizations in the solid state by using principles of molecular recognition and self-assembly.[8] The method exploits the strength and directionality of hydrogen bonds to construct target molecules such as cyclophanes[9] and ladderanes[10] by using small molecules in the form of templates. In this microreview, we will outline how the template approach can be expanded to the principles of coordination-driven self-assembly.[11] We will also demonstrate how molecules constructed with the use of the template method can be used as building blocks of finite and infinite coordination assemblies.[12] We will then discuss how the area of mechanochemistry[13] can be applied to eliminate solvents associated with reactions mediated by metal ions in organic solids.

## Template-Controlled Photodimerizations by Using Organic Molecules

In 2000, we introduced a method to control chemical reactivity in the organic solid state by using small organic molecules that function as linear templates.[8] The templates assemble olefins for [2+2] photodimerizations within multi-component supramolecular assemblies. In particular, we demonstrated that resorcinol (res) can be used as a linear template to assemble and juxtapose *trans*-1,2-bis(4-pyridyl)-ethylene (4,4′-bpe) for photoreaction. Cocrystallization of res with 4,4′-bpe produced the four-component assembly 2(res)·2(4,4′-bpe) held together by four O–H···N hydrogen bonds. The two olefins were oriented by res in a parallel fashion and at a distance of 3.65 Å (Figure 2). This placed the C=C bonds of 4,4′-bpe in a geometry that conformed to the topochemical postulate of Schmidt for the reaction. UV irradiation of crystalline 2(res)·2(4,4′-bpe) produced the corresponding photodimer, *rctt*-tetrakis(4-pyridyl)cyclobutane (4,4′-tpcb), regiospecifically and in 100% yield.[14]

In addition to 4,4′-tpcb, we showed that the method can be used to construct relatively complex molecules such as a [2.2]paracyclophane and [*n*]ladderanes (where: $n$ = 3 or 5).[9,10] Templates based on res were used to organize di- and triolefins, similar to 2(res)·2(4,4′-bpe), within four-component hydrogen-bonded assemblies. UV irradiation of the solids produced the targeted cyclophane and ladderanes regiospecifically and in quantitative yield (Figure 3).

## Template-Controlled Photodimerizations by Using Metal Ions

Inspired by work in the field of coordination-driven self-assembly,[15] we recently addressed whether transition-metal-ion complexes can be used as linear templates to di-

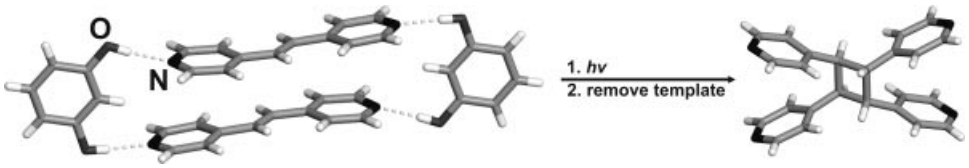

Figure 2. Solid-state synthesis of 4,4′-tpcb by using resorcinol as a template.

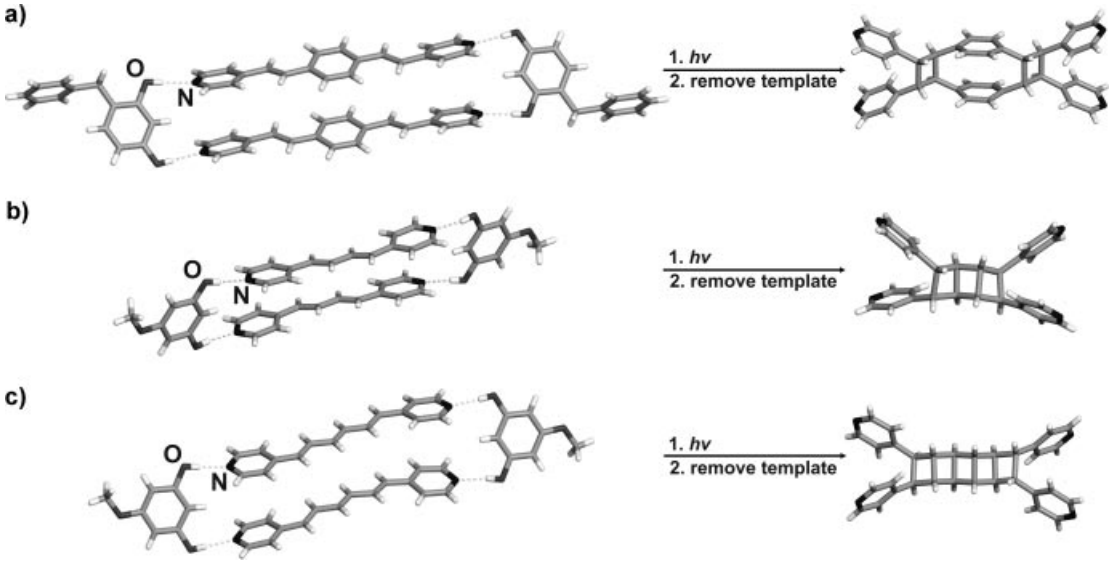

Figure 3. Solid-state synthesis of: (a) [2.2]paracyclophane, (b) [3]ladderane and (c) [5]ladderane.

rect [2+2] photodimerizations in the solid state. The field of coordination-driven self-assembly, which has experienced tremendous growth during the last decade,[15,16] involves reactions of metal ions with bi- and polytopic ligands. The metal and organic components are used to form finite (e.g. metallomacrocycle) and/or infinite [e.g. metal–organic framework (MOF)] self-assembled frameworks. The frameworks are designed to exhibit properties (e.g. host–guest, magnetic) typically not encountered in the individual components. We wondered whether coordination bonds could be used to effectively replace the hydrogen bonds of a resorcinol-based template. In such a design, a dinuclear metal complex would assemble and preorganize two olefins to react in a solid. The ensuing solid-state reaction could also be used to affect bulk physical properties[11a] conferred by the metals in a solid.

Prior to our work, there were two examples in which a metal-ion complex facilitated a [2+2] photodimerization in the solid state (Figure 4).[17–19] In particular, Praetorius and Korn reported the ability of a mononuclear complex of uranyl chloride and *trans,trans*-dibenzylideneacetone (dba) to undergo a stereospecific photodimerization to give the truxillic-type dimer *rctt*-1,3-bis(3-phenylprop-2-enoloxo)-2,4-bis(phenyl)cyclobutane (Figure 4a).[17] X-ray crystal structures of both the unsolvated and solvated forms, $[(UO_2)Cl_2(dba)_2]$ and $[(UO_2)Cl_2(dba)_2]\cdot 2CH_3CO_2H$, showed that the metal ions adopted an octahedral geometry surrounded by two chlorine atoms, two oxygen atoms of the uranyl group and two keto-oxygen atoms of the dba ligand (Figure 4a).[18] The complexes assembled in the solid such that the distances between the alkenes of adjacent dba ligands were 4.09 and 3.51 Å in the unsolvated and solvated forms, respectively. The reactivity was, thus, largely the result of the packing of the complexes. Later, Lewis and coworkers demonstrated [2+2] photoreactivity in a series of crystalline cinnamic esters mediated by Lewis acids (e.g. $SnCl_4$).[19] The cinnamic esters formed 1:1 complexes with $BF_3$ and 2:1 complexes with $SnCl_4$. UV irradiation of the solids produced truxillic-type dimers (Figure 4b). A structure analysis of the ethyl cinnamate–$SnCl_4$ complex revealed an octahedral coordination environment around the $Sn^{IV}$ ion (Figure 4b). The photoreaction occurred between neighbouring cinnamate ligands. Adjacent ligands were stacked in a head-to-tail fashion and were separated by 4.12 Å.

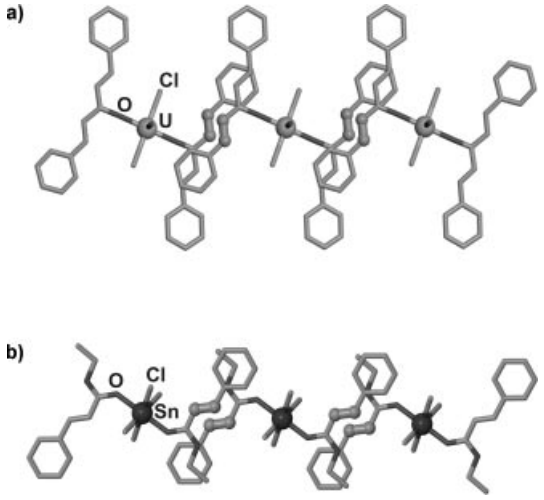

Figure 4. Crystal structures of the photoactive: (a) dba–$UO_2Cl_2$ complex and (b) ethyl cinnamate–$SnCl_4$ complex. Reactive alkene groups highlighted.

Our first study pertaining to a dinuclear complex involved the Schiff base complex $[Zn_2\mathbf{L}(OH)]^{2+}$ {where: **L** = 2,6-bis[*N*-(2-pyridylethyl)formimidoyl]-4-methylphenol} as a template (Figure 5).[11a] The Schiff base ligand was originally introduced by Robson and Okawa as a model of enzymatic processes (Figure 5a.).[20] An analysis of the Cam-

bridge Structural Database revealed that the metal atoms of such complexes are separated on the order of 3.10 to 3.15 Å. This range was well within the distance criterion of Schmidt for photodimerization in a solid. We showed that reaction of $[Zn_2\mathbf{L}(OH)](ClO_4)_2$ with 4,4′-bpe produces the tetranuclear assembly $[Zn_4\mathbf{L}(OH)_2(4,4'\text{-bpe})_2](ClO_4)_2$ (Figure 5b). The metal atoms of the assembly adopted a square-pyramidal coordination environment and the two stacked pyridine moieties were located in the apical positions. The C=C bonds of the olefins were arranged parallel and separated by 3.64 Å. UV irradiation of the solid produced 4,4′-tpcb in quantitative yield. We later showed that stacked molecules of 4,4′-bpe could be achieved within the 1D MOF $\{[Zn_2\mathbf{L}(OH)(4,4'\text{-bpe})_2](ClO_4)_2\}_\infty$.[11b] In this case, each metal ion adopted an octahedral coordination environment. The solid reacted to give 4,4′-tpcb in 95% yield (Figure 5c).[21]

During the course of our studies involving tetranuclear $[Zn_4\mathbf{L}(OH)_2(4,4'\text{-bpe})_2](ClO_4)_2$, we determined that the photoreaction proceeded by a rare single-crystal-to-single-crystal (SCSC) transformation (Figure 6).[22] We also discovered that the single crystals displayed different fluorescence emissions before and after the photoreaction.[11a] Specifically, excitation of the crystals with 290 nm light prior to the photoreaction produced a blue emission at 464 nm, whereas the fully reacted solid produced a green emission at 520 nm. That the change in emission was a consequence of the solid-state reaction was supported by laser-scanning confocal fluorescence microscopy, which revealed a difference in the fluorescence between the unreacted and reacted solid. To the best of our knowledge, the tetranuclear assembly represented the first example of a SCSC reaction that exhibited photocontrolled fluorescence. The reaction involving the 1D framework $[Zn_2\mathbf{L}(OH)(4,4'\text{-bpe})_2](ClO_4)_2$ did not occur through a SCSC transformation.

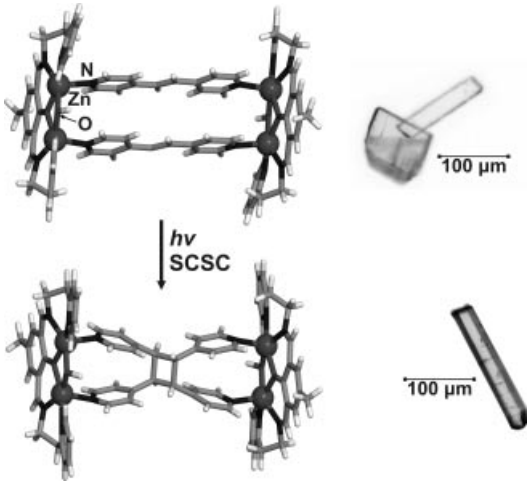

Figure 6. Photocontrolled fluorescence in single-crystalline $[Zn_4L_2(OH)_2(4,4'\text{-tpcb})](ClO_4)_4{\cdot}4H_2O$.

To expand the template method to an additional dinuclear unit, we turned to the $Ag^I$ ion.[11c] It is well established that $Ag^I$ exhibits linear coordination while also participating in $Ag^I\cdots Ag^I$ or argentophilic forces.[23] $Ag^I$ ions engaged in argentophilic forces are separated on the order of 3.40 Å, which falls within the distance criterion of Schmidt. These observations encouraged us to investigate the ability of $Ag^I$ ions, in a T-shaped geometry, to steer *trans*-coordinated olefins towards a [2+2] photodimerization. In this design, the argentophilic forces would stack two pairs of olefins for reaction in a solid. We determined the ability of the $Ag^I$ ions to assemble *trans*-1-(4-pyridyl)-2-(phenyl)ethylene (4-stilbz) in crystalline $[Ag_2(4\text{-stilbz})_4][CO_2CF_3]_2$ for a regiocontrolled head-to-head photodimerization to give *rctt*-1,2-bis(4-pyridyl)-3,4-bis(phenyl)cyclobutane (4-pyr-ph-cb) in quantitative yield (Figure 7). The metal ions were separated by 3.41 Å, whereas the C=C bonds of the stacked olefins exhibited a disordered criss-cross arrangement with a separation of 3.82 Å. That the photoreaction was able to proceed, despite the C=C bonds being crossed, was attributed to the olefins undergoing a pedal-like rotation.[11c] Similar to $[Zn_4\mathbf{L}(OH)_2(4,4'\text{-bpe})_2](ClO_4)_2$, the photoreaction proceeded through a SCSC transformation.[22]

Figure 7. Alignment of 4-stilbz molecules within the dinuclear complex $[Ag_2(4\text{-stilbz})_4]^{2+}$.

The photoreaction involving $[Ag_2(4\text{-stilbz})_4][CO_2CF_3]_2$ also converted the dinuclear complex into a 1D coordination network (Figure 8). In particular, the generation of the photoproduct involved major movements of the metal and organic components. The $Ag^I$ ions moved away from each other by approximately 1.16 Å ($Ag^I\cdots Ag^I$ distance 5.73 Å), which broke the argentophilic forces. This movement was accompanied by an approximate 90° rotation of the carboxylate ions. As a result of these movements, $Ag^I\cdots C$(phenyl) forces ($Ag^I\cdots C$ distance 2.63 Å) formed between each repositioned $Ag^I$ ion and the *para* carbon atom of the phenyl group of a neighbouring assembly. These new forces served,

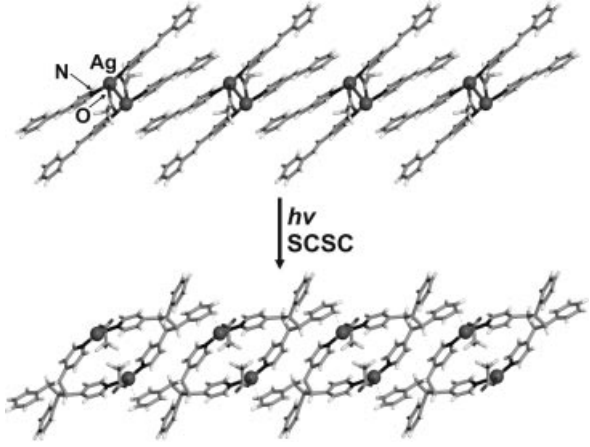

Figure 8. SCSC conversion of $[Ag_2(4\text{-stilbz})_4]^{2+}$ into 1D $[Ag_2(4\text{-py-ph-cb})_2]^{2+}_\infty$.

in effect, to link adjacent complexes to produce a linear coordination network. The photoconversion of $[Ag_2(4\text{-stilbz})_4]^{2+}$ into $[Ag_2(4\text{-py-ph-cb})_2]^{2+}$ was, to the best of our knowledge, the first case in which a metal complex was transformed into an infinite coordination network by a photoreaction. In related and earlier work, Foxman had revealed the ability of the $Ni^{II}$ complex $[NiBr_2(PCH_2CH_2CN)_3]$ to undergo a highly stereocontrolled thermal polymerization in a solid that involved the formation of Ni–N coordination bonds.[24]

## Applications of the Products

The products of the [2+2] photodimerizations that we conducted in the solid state are functionalized with, in a minimal case, two pyridyl groups. The products also typically form in quantitative yield, gram amounts and in the absence of byproducts.[8] For us, these features made the products attractive for studies in coordination-driven self-assembly. We hypothesized that the products, once removed from the template, could serve as bi- and polytopic linkers of MOFs and related materials.[12,25–28] A cyclobutane ring could serve as a hub[29] providing both acute and obtuse angles to propagate the coordination geometry of a metal in an assembly process. Importantly, whereas molecules synthesized in the liquid phase routinely encounter practical applications in areas ranging from pharmaceutical chemistry to materials science, the products of molecules synthesized in the solid state had experienced virtually none.[30] This can be attributed to difficulties in engineering solid-state structures such that the molecules can undergo reactions "at will" to synthesize molecules by design.[31]

### 1D MOF

In 2002, we set out to determine whether the products obtained from linear templates in the solid state could be used as ligands to form MOFs. The major driving force behind the synthesis of MOFs is a promise to generate materials with tailorable electronic,[32] magnetic,[33] optical[34] and/or host–guest properties.[35] Thus, MOFs with cavities and pores are expected to exhibit properties akin to zeolites and mesoporous materials and, thereby, have applications in areas such separations,[36] gas storage[37] and catalysis.[38]

One of our first reactions involved 2,2′-tpcb with $CuSO_4{\cdot}5H_2O$. We generated 2,2′-tpcb by using a hydrogen-bond-mediated synthesis.[39] In particular, we showed that the components assembled in the solid state to give a 1D MOF in which 2,2′-tpcb served as a bis-chelating ligand in $[Cu_2(\mu\text{-}2\text{-}SO_4)_2(\mu\text{-}2,2'\text{-tpcb})(H_2O)_2]_\infty$ (Figure 9).[25] Each $Cu^{II}$ ion exhibited a square-pyramidal coordination environment with two N atoms of two 2-pyridyl groups, one O atom of a sulfate ion and one O atom of a water molecule in the basal plane. The apical site was occupied by an O atom of a second sulfate ion. The 1D polymer assembled in parallel and offset strands, with interstices occupied by solvent water molecules. In the same report, we showed that the self-assembly process was sensitive to changes to the counterion.

Specifically, reaction of 2,2′-tpcb with $Cu(NO_3)_2{\cdot}2.5H_2O$ produced the dinuclear complex $[Cu_2(NO_3)_4(\mu\text{-}2,2'\text{-tpcb})]$. Similar to the 1D framework, 2,2′-tpcb served as a bis-chelating ligand. Two chelating nitrate ions completed a distorted octahedral coordination sphere.

### 2D MOFs

That same year, we determined that 4,4′-tpcb could be used as a 4-connected node of a porous 2D MOF. Specifically, reaction of 4,4′-tpcb with the copper paddle-wheel complex $[Cu_2(O_2CCH_3)_4(H_2O)_2]$ produced the 2D MOF $[Cu_4(O_2CCH_3)_8(4,4'\text{-tpcb})]_\infty$ (Figure 10).[12a] The cyclobutane and dicopper complex produced a 2D grid with identical rhombic cavities of approximate dimensions 17.2 Å × 17.2 Å and corner angles 75° and 104° (Figure 10a). The 2D grids stacked to form a 3D framework with isolated 1D channels of approximate dimensions 10 Å × 12 Å (Figure 10b). The channels were occupied by benzene solvent molecules, which assembled in an edge-to-face manner. We showed that the solvent molecules could be removed from the framework by a SCSC transformation.[22] We also revealed that the methyl groups of the paddle-wheel complex were directed into the cavities. In doing so, the methyl groups segregated the space of the cavities into smaller compartments. These observations suggested that further functionalization of the cavities could be achieved by modifying the R group of the paddle-wheel complex. We termed the framework an inverted MOF (IMOF), as the metal complex acted as a linear bridge and

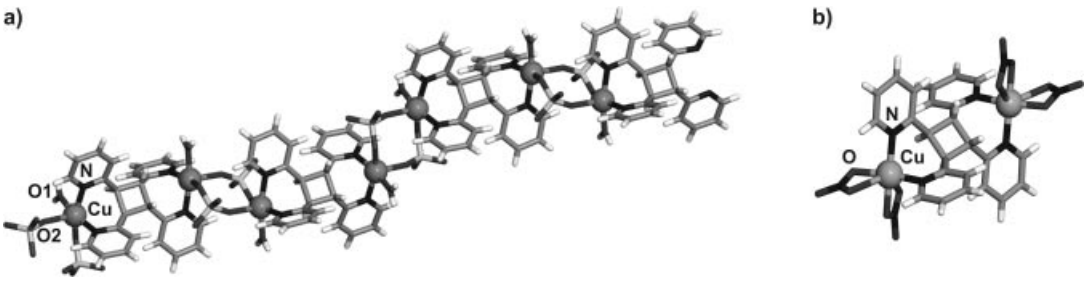

Figure 9. View of: (a) 1D polymer $[Cu_2(\mu\text{-}2\text{-}SO_4)_2(\mu\text{-}2,2'\text{-tpcb})(H_2O)_2]_\infty$ and (b) dinuclear complex $[Cu_2(NO_3)_4(\mu\text{-}2,2'\text{-tpcb})]$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the organic spacer served as a node; thus, the roles of the metal and organic components, relative to a more conventional MOF,[15,16] were inverted or reversed. Moreover, that the metal component served as a linear bridge meant that the terminal carboxylates were available to decorate the cavities of the framework.

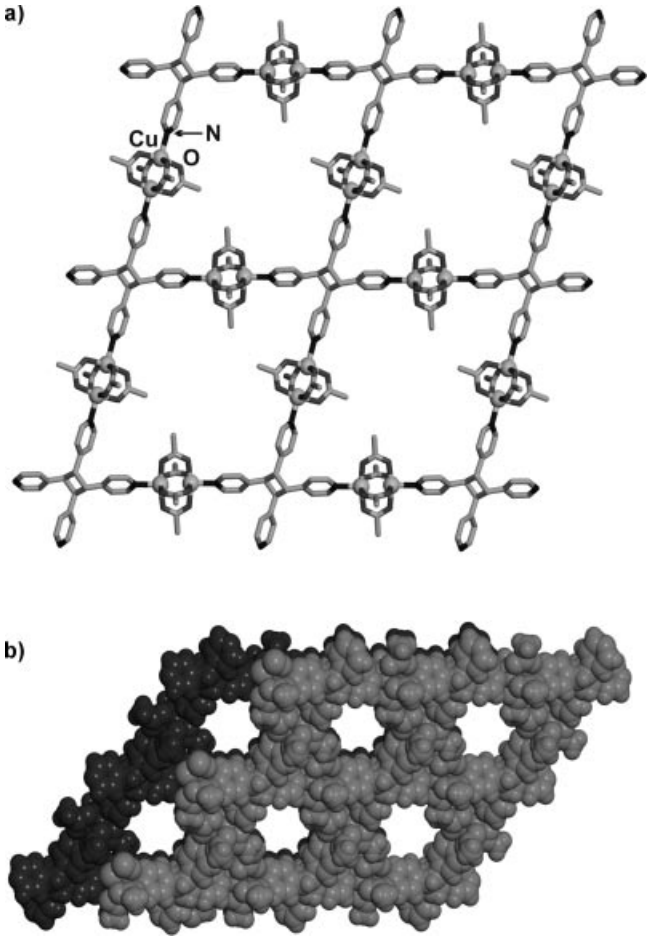

Figure 10. Perspective views of $[Cu_4(O_2CCH_3)_8(4,4'\text{-tpcb})]_\infty$: (a) ball-and-stick model and (b) space-filling model of the stacking of two layers.

In a later report, we described a 2D MOF based on 4,4′-tpcb that involved metal and cyclobutane components that served as 4-connected nodes.[40] In particular, reaction of 4,4′-tpcb with $[Co(O_2CCH_3)_2(H_2O)_4]$ produced the 2D MOF $[Co(O_2CCH_3)_2(4,4'\text{-tpcb})]_\infty$. The framework, similar to $[Cu_4(O_2CCH_3)_8(4,4'\text{-tpcb})]_\infty$, possessed rhombic cavities with edge lengths of 7.3 Å. In contrast to $[Cu_4(O_2CCH_3)_8(4,4'\text{-tpcb})]_\infty$, however, the framework was made up of two different rhombic cavities (Figure 11). That the framework possessed two different cavities was a result of the stereochemistry of the cyclobutane ring, which provided two different angles (75 and 104°) for cavities within the network. The cavities stacked in an ABAB manner producing small interstices occupied by solvent methanol molecules. We also demonstrated that the crystallinity of the solid was maintained upon removing the guests by heating.

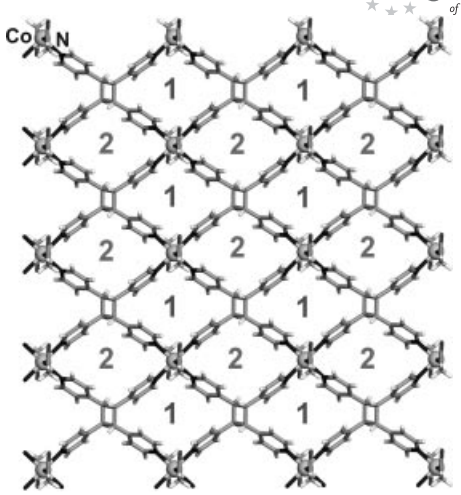

Figure 11. Perspective view of $[Co(O_2CCH_3)_2(4,4'\text{-tpcb})]_\infty$ that illustrates the different cavities of the 2D MOF.

More recently, we demonstrated that a product of a template-directed solid-state synthesis forms a 2D MOF with a topology that conforms to a nonregular net (Figure 12). Most 2D MOFs exhibit topologies of regular (i.e. tiling of regular polygons with identical nodes) or semiregular (i.e. tiling of different regular polygons with identical vertices) nets. In the minimal case, a MOF with a topology of a nonregular net will possess two different polygonal cavities and two nodes of different connectivity. It was recently argued that the self-assembly process that produces a MOF is predisposed to generate high-symmetry frameworks

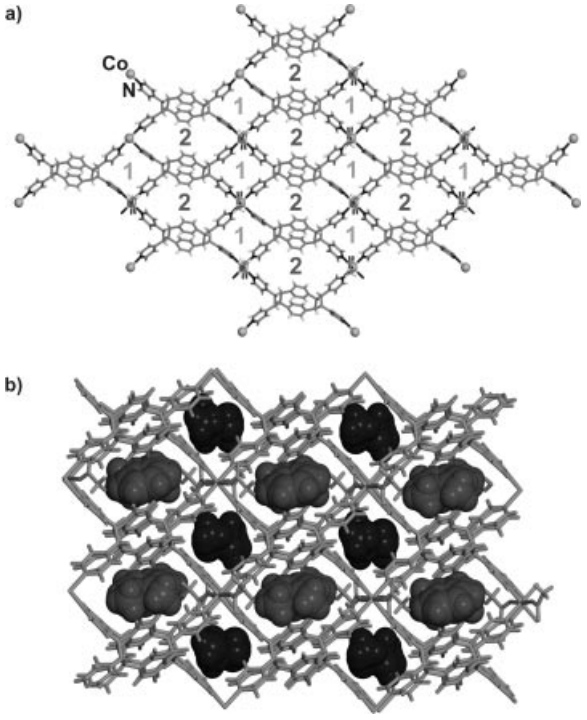

Figure 12. Perspective view of $[Co(O_2CCH_3)_2(4,4'\text{-tppcp})]_\infty$: (a) different cavities of the 2D framework and (b) space-filling model of the included solvent molecules.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

based on identical nodes (i.e. regular and semiregular nets).[41] To design a MOF that conforms to a nonregular net, we treated the [2.2]paracyclophane 4,4′-tppcp with $Co(O_2CCH_3)_2{\cdot}4H_2O$, which afforded the 2D MOF $[Co(O_2CCH_3)_2(4,4'\text{-tppcp})]_\infty$ (Figure 12a).[28] The components self-assembled to give a 2D MOF with both square and hexagonal cavities in which 4,4′-tppcp and the $Co^{II}$ ion served as 3- and 4-connected nodes, respectively. The paracyclophane effectively served as two covalently fused 3-connected nodes in which the stacked rings of the cyclophane provided the covalent connection. Moreover, that the cyclophane acted as two fused 3-connected nodes meant that the formation of higher-symmetry MOFs with structures solely based on linkages between 3- and 4-connected nodes (i.e. with no linkages between two 3-connected nodes) was prohibited. The two different cavities hosted two different solvent molecules as guests. Specifically, a methanol molecule filled hydrophilic square cavities, whereas toluene molecules filled hydrophobic hexagon cavities (Figure 12b).

## Metal–Organic Polyhedra and Polygons

In addition to MOFs, we discovered that products of linear templates in the solid state can generate metal–organic polyhedra and polygons.[12b,26,27] The internal cavities of such self-assembled frameworks have, in recent years, gained much attention as materials with applications in areas such as logical gates,[42] reaction vessels[43] and catalysis.[44]

Our first report described the self-assembly of the unsymmetrical tetrapyridine 2,4′-tpcb (Figure 13) with $Cu^{II}$ ions to form a polyhedron. Reaction of 2,4′-tpcb with $Cu(ClO_4)_2{\cdot}6H_2O$ produced a hexanuclear polyhedron in $[Cu_6(2,4\text{-tpcb})_6(H_2O)_6][ClO_4]_{12}$ with a structure that conformed to a trigonal antiprism (Figure 13).[12b] Each metal ion adopted a square-pyramidal coordination environment and occupied a vertex of the polyhedron. The coordination environment consisted of two chelating 2-pyridyl groups and two monodentate 4-pyridyl groups that formed the base and a water molecule that formed the apex. Thus, the 4-pyridyl groups corresponded to the edges of the polyhedron whereas the 2-pyridyl groups corresponded to the corners. The coordination behaviour of the 2- and 4-pyridyl groups was consistent with the MOFs involving 4,4′- and 2,2′-tpcb.[12] The assembly process produced a central cavity that hosted two $ClO_4^-$ anions as guests.

Very recently, we showed that an unsymmetrical isomer of the 2,4′-tpcb ligand, namely 2,3′-tpcb, assembles with $Cu^{II}$ ions to form a polyhedron with a structure that conforms to a tetrahedron (Figure 14).[26] We anticipated that changing the 4-pyridyl group to a 3-pyridyl group would result in a smaller polyhedron owing to a decrease in the angle of the coordination vector (Figure 15). We employed a hydrogen-bond-directed synthesis to generate 2,3′-tpcb. As expected, 2,3′-tpcb assembled with the metal ions to form a smaller polyhedron. To our surprise, the polyhedron $[Cu_4(2,3'\text{-tpcb})_4(H_2O)_4]^{8+}$ adopted a topology of a tetrahedron and exhibited a chiral $D_2$ topology. The structure was a rare example of a chiral self-assembled polyhedron composed of achiral components. The chirality of the tetrahedral capsule was attributed to a geometric fit of the metal and organic components, which prohibited the formation of mirror planes in the structure. As in the case of the trigonal antiprism, the $Cu^{II}$ ions occupied the corners of the tetrahedron and exhibited a square-pyramidal coordination environment. The tetrahedron also possessed a central cavity that hosted a $NO_3^-$ ion as a guest.

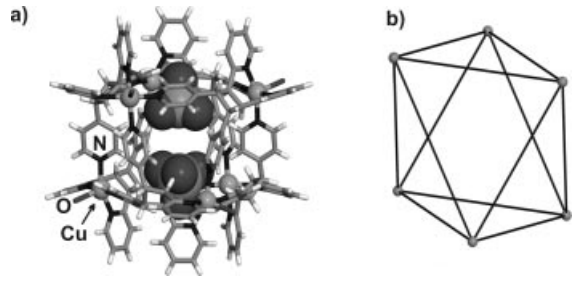

Figure 13. Perspective view of $[Cu_6(2,4\text{-tpcb})_6(H_2O)_6]^{12+}$: (a) space-filling model of two encapsulated $ClO_4^-$ ions and (b) the trigonal antiprism formed by the $Cu^{II}$ ions.

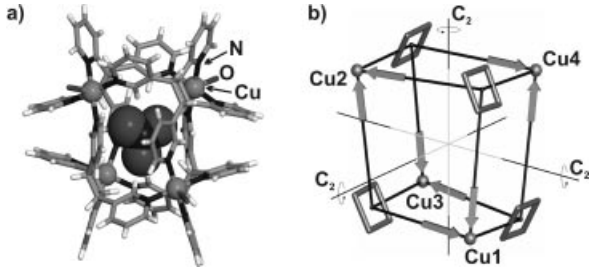

Figure 14. Perspective view of $[Cu_4(2,3'\text{-tpcb})_4(H_2O)_4]^{8+}$: (a) space-filling model of the encapsulated $NO_3^-$ ion and (b) the tetrahedron topology.

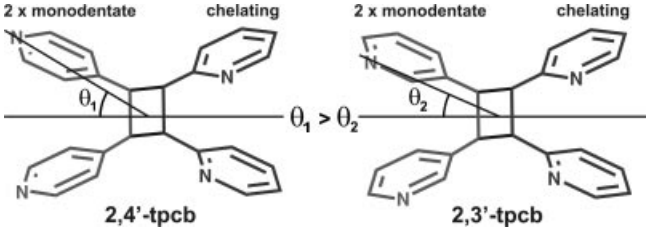

Figure 15. Polydentate 2,3′-tpcb and 2,4′-tpcb ligands (θ – angle of the coordination vector).

In addition to a polyhedron, we demonstrated that 2,4′-tpcb can form a polygon.[27] By changing from a noncoordinating (i.e. $ClO_4^-$) to chelating counter anion, in the form of the hexafluoroacetylacetonate anion (hfacac), we described the formation of the tetranuclear metal–organic rhomboid $[Cu_4(2,4\text{-tpcb})_2(hfacac)_8]$ (Figure 16a). In particular, two molecules of 2,4′-tpcb assembled with the $Cu^{II}$ ions to give a dinuclear cavity of approximate dimensions 4.0 Å × 4.2 Å and corner angles of 79 and 101°. Mono-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

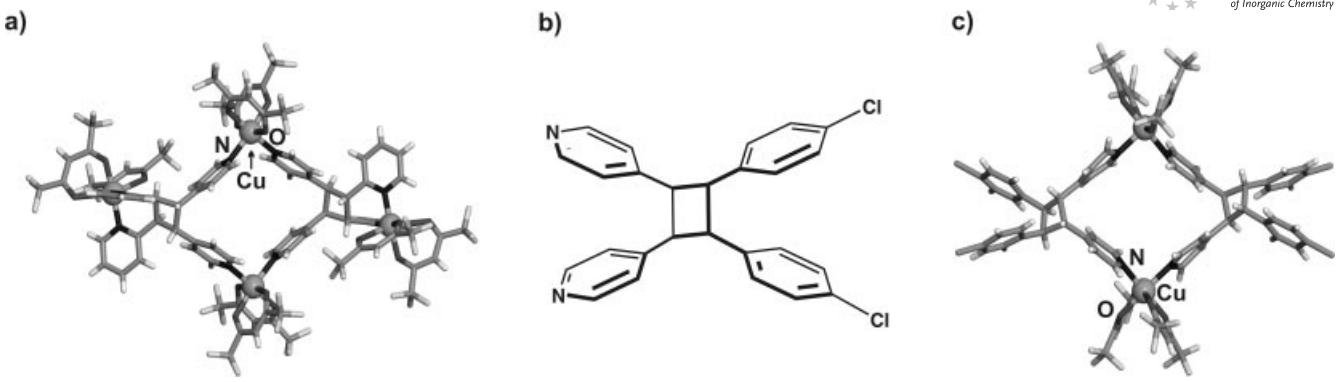

Figure 16. Perspective views of: (a) $[Cu_4(2,4\text{-tpcb})_2(hfacac)_8]$, (b) schematic representation of 4-py-4-Cl-p-cb and (c) $[Cu_2(4\text{-py-4-Cl-p-cb})_2(hfacac)_4]$.

dentate 4-pyridyl groups defined the edges of the polygon. Each $Cu^{II}$ ion exhibited octahedral coordination with two 4-pyridyl units and two hfacac anions in a *cis* arrangement. Chelating 2-pyridyl groups were located along the periphery of the assembly and were being coordinated to two $Cu^{II}$ ions. We also showed that the bifunctional cyclobutane *rctt*-1,2-bis(4-pyridyl)-3,4-bis(chlorophenyl)cyclobutane (4-py-4-Cl-p-cb; Figure 16b) supports the formation of a dinuclear polygon by, similar to $[Cu_4(2,4\text{-tpcb})_2(hfacac)_8]$, the 4-pyridyl groups (Figure 16c).[27]

## Emergence of Mechanochemical Preparation of Coordination Materials

The coordination solids described above were prepared by using crystallizations that involve an organic solvent. To increase the relevance of the template approach to the field of green chemistry,[2] it would be desirable to further reduce the organic solvents employed in the syntheses. In recent years, the field of coordination chemistry has witnessed a rapid surge of interest in the development of solvent-free, or mechanochemical, methods[45] to synthesize self-assembled coordination materials. The approach relies on simple grinding of metal and organic components to induce the formation of metal complexes and self-assembled materials.

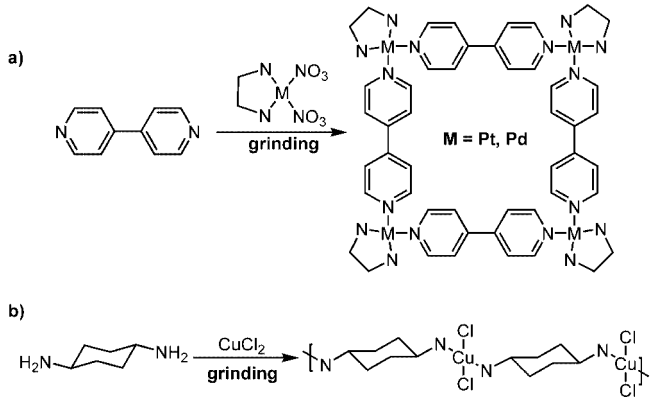

Figure 17. Coordination solids based on both (a) finite and (b) infinite self-assembled architectures constructed by mechanochemical methods.

Coordination solids based on both finite and infinite self-assembled architectures have been constructed by this approach (Figure 17).[46,47] We are now addressing whether mechanochemical methods can be applied to construct reactive, self-assembled solids, as well as the applications of the molecules synthesized in the solid state.

## Summary and Outlook

Linear templates allow chemists to organize reactive molecules within finite supramolecular assemblies constructed by coordination-driven self-assembly. In such assemblies, olefins are preorganized to conform to Schmidt's topochemical postulates for a [2+2] photodimerization in a solid. The strategy has been, thus far, used to synthesize mono- and polyfunctional pyridyls in solids. Here, we have also presented the diversity of products obtained in studies that apply the ligands in metallosupramolecular chemistry. We have revealed that the template method provides access to molecules that can be used as organic building units of self-assembled polygons and polyhedra, as well as MOFs. We are now moving to develop this approach for the application in more mainstream synthetic chemistry and with an increasing relevance to green chemistry.

# Solid-State Anion–Guest Encapsulation by Metallosupramolecular Capsules Made from Two Tetranuclear Copper(II) Complexes

**Emilio Pardo,[a] Kevin Bernot,[a] Francesc Lloret,*[a] Miguel Julve,[a] Rafael Ruiz-García,[b,c] Jorge Pasán,[d] Catalina Ruiz-Pérez,[d] Danielle Cangussu,[e] Valeria Costa,[e] Rodrigue Lescouëzec,[e] and Yves Journaux*[e]**

**Keywords:** Copper / Host–guest systems / Magnetic properties / Polynuclear complexes / Structure elucidation

A new cationic tetranuclear copper(II) complex self-assembles from one 1,3-phenylenebis(oxamato) (mpba) bridging ligand and four $Cu^{II}$ ions partially blocked with *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmen) terminal ligands. In the solid state, two of these tetracopper(II) oxamato complexes of bowl-like shape and helical conformation then serve as a building block for the generation of either hetero- (*MP*) or homochiral (*MM*/*PP*) dimeric capsules depending on the nature of the encapsulated anion guest, perchlorate or hexafluorophosphate. The overall magnetic behaviour of these metallosupramolecular capsules does not depend on the nature of the encapsulated anion guest, but it is consistent with the dimer-of-dimer structure of the tetracopper(II) cation host, where the interdimer magnetic coupling through the *meta*-phenylenediamidate bridge is negligibly small relative to the reasonably strong intradimer one across the oxamato bridge.

## Introduction

Coordination chemistry offers many possibilities for the construction of a seemingly limitless range of metallosupramolecular species based on metal–ligand coordinative interactions.[1] These include a great variety of metal cages formed by the self-assembly of rigid organic ligands and transition metal ions.[2–10] Some of them are formed with the use of templates and counterions, either cations[3] or anions,[4–7] that are hosted within the confined space of the charged metal cage and held through ionic interactions and/or weak coordination bonds. Others are even able to reversibly bind or stabilise neutral guest molecules through hydrophobic interactions and/or hydrogen bonds.[8] In contrast to their purely organic analogues prepared from covalent synthesis[9] and/or hydrogen-bond-directed self-assembly,[10] these metallosupramolecular capsules may possess other interesting properties ligated to the presence of the transition metal ions. Thus, the combination of the encapsulation ability with other metal-based electronic properties (redox, optical or magnetic) would render these assemblies suitable for applications as molecular sensors or switches.

In the search for self-assembling metallosupramolecular complexes with aromatic dioxamato ligands,[11a] we recently prepared double- and triple-stranded binuclear copper(II) complexes of the metallacyclophane- and metallacryptand-type from the self-assembly of two $Cu^{II}$ ions and either two or three 1,3-phenylenebis(oxamato) (mpba) ligands, respectively, which then served as building blocks for discrete hexa- and octanuclear copper(II) complexes.[11b–11d] In this communication, we report the syntheses, X-ray crystal structures and magnetic properties of two new tetranuclear oxamato copper(II) complexes of formula $[Cu_4(mpba)(tmen)_4(H_2O)_4](ClO_4)_4{\cdot}3H_2O$ (**1a**) and $[Cu_4(mpba)(tmen)_4(H_2O)_4](PF_6)_4{\cdot}2H_2O$ (**1b**) (tmen = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine), which constitute unique examples of anion guest encapsulation in the solid state.

## Results and Discussion

Complexes **1a** and **1b** were synthesised in one step by a stoichiometric reaction (1:4) in water of the diethyl ester derivative of 1,3-phenylenebis(oxamic acid)-($H_2Et_2mpba$),[11a] previously treated with 4 equiv. of NaOH

that serve to deprotonate and hydrolyse the amide and ester groups, respectively, and the perchlorate or nitrate salts of the cationic mononuclear copper(II) complex $[Cu(tmen)]^{2+}$, which were prepared in situ from a mixture of either $Cu(ClO_4)_2 \cdot 6H_2O$ or $Cu(NO_3)_2 \cdot 3H_2O$ and tmen in a 1:1 relation. They were isolated as either the perchlorate (**1a**) or the hexafluorophosphate (**1b**) salts by addition of $KPF_6$ at the end of the reaction in the latter case.

The structures of **1a** and **1b** consist of tetranuclear copper(II) cations, $[Cu_4(mpba)(tmen)_4(H_2O)_4]^{4+}$ (Figure 1), crystallisation water molecules and either perchlorate or hexafluorophosphate anions, respectively. The tetracopper(II) cations are formed by four $[Cu(tmen)(H_2O)]^{2+}$ subunits connected by the tetrakis(bidentate) mpba ligand, which adopts a helical conformation with the two oxamato bridging groups tilted up and down with respect to the plane of the *m*-phenylene spacer. The values of the torsion angle around the N(amide)–C(phenylene) bonds ($\phi$) are 91.0(3) and 108.8(4)° for **1a** and 90.7(5) and 112.7(6)° for **1b**, values which are greater than that of $H_2Et_2$mpba [$\phi$ = 32.6(5)°].[11a] This gives rise to chiral bisbinuclear entities of pseudo-twofold symmetry, either *M* or *P* helical conformers, which are made up of two oxamato-bridged $Cu^{II}_2$ units connected through a *meta*-phenylenediamidate bridge between one of the two copper atoms of each binuclear unit (Figure 1, left). The intramolecular distances between the copper atoms through the oxamato bridge average 5.190(2) (**1a**) and 5.224(2) Å (**1b**), whereas those through the *meta*-phenylenediamidate bridge are 7.762(2) (**1a**) and 7.571(2) Å (**1b**).

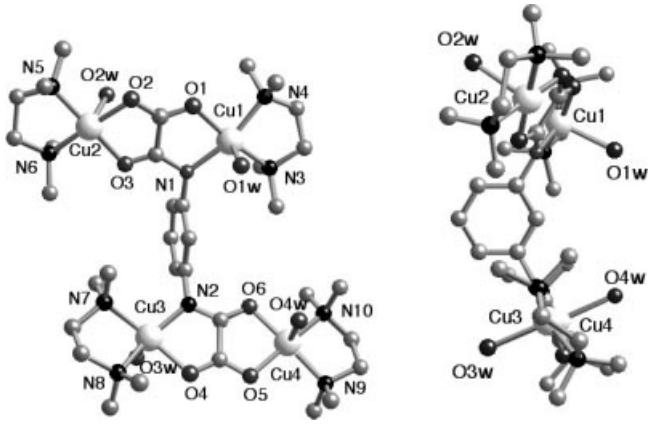

Figure 1. Front and side views of the cationic tetracopper unit of **1a** with the atom numbering scheme for the metal coordination environments (hydrogen atoms are omitted for clarity). Selected intermetallic distances [Å] with standard deviations in parentheses: Cu1–Cu2 5.199(2), Cu1–Cu3 7.762(2), Cu1–Cu4 7.989(2), Cu2–Cu3 7.796(2), Cu2–Cu4 10.844(2) and Cu3–Cu4 5.180(2) for **1a**; Cu1–Cu2 5.229(2), Cu1–Cu3 7.571(2), Cu1–Cu4 8.122(2), Cu2–Cu3 7.654(2), Cu2–Cu4 10.934(2) and Cu3–Cu4 5.218(2) for **1b**.

The four crystallographically independent copper atoms of **1a** and **1b** exhibit five-coordinate square pyramidal geometries, $CuN_3O_2$ for Cu1 and Cu3 and $CuN_2O_3$ for Cu2 and Cu4, with axially coordinated water molecules [Cu–Ow 2.283(8)–2.521(9) for **1a** and 2.365(7)–2.460(6) Å for **1b**], which are arranged in a *trans* position within each binuclear unit (Figure 1, right). The values of the geometric $\tau$ parameter are in the range 0.02–0.20 (for **1a**) and 0.01–0.12 (for **1b**) ($\tau$ = 0 and 1 for ideal square pyramidal and trigonal bipyramidal geometries, respectively).[11d] The two oxamato groups of the mpba ligand coordinate through the amidate nitrogen and carboxylate oxygen atoms to the Cu1 and Cu3 atoms [Cu–N 1.997(6)–2.012(7) (**1a**) and 2.002(6)–2.004(6) Å (**1b**); Cu–O 1.979(5)–2.004(7) (**1a**) and 1.984(5)–2.003(6) Å (**1b**)] and through the carbonyl oxygen atoms to the Cu2 and Cu4 atoms [Cu–O 1.948(5)–1.965(9) (**1a**) and 1.951(5)–1.996(5)(**1b**)], whereas the remaining positions of the equatorial plane are occupied by two amine nitrogen atoms from the tmen ligands [Cu–N 1.994(7)–2.048(7) (**1a**) and 2.000(7)–2.036(8) Å (**1b**)]. The copper basal planes and the oxamato plane of each binuclear unit are quite coplanar [dihedral angles in the range 3.8(2)–17.7(2) (**1a**) and 6.7(2)–11.2(2)° (**1b**)], whereas they are almost perpendicular to the phenylene plane [dihedral angles in the range 70.4(3)–89.3(2) (**1a**) and 75.4(2)–84.1(2)° (**1b**)]. Because of the *meta* topology of the ligand spacer, the two mean planes of the two oxamato bridging groups form a dihedral "bite" angle of 54.5(2) (**1a**) and 53.9(1)° (**1b**), which thus confers a global bowl-like shape to the tetracopper(II) cations (Figure 1, right).

Interestingly, two symmetry-related, bowl-shaped tetranuclear copper(II) cations of opposite (**1a**) or identical (**1b**) chirality encapsulate two perchlorate and three hexafluorophosphate anions, respectively, to yield either a centrosymmetric heterochiral (*MP* mesomer) or a racemic mixture of twofold homochiral (*MM* and *PP* enantiomers) dimeric capsules (Figure 2a and Figure 2b, respectively). The diastereoisomer differentiation that occurs in these 2:2 and 2:3 host–guest complexes, $\{2(ClO_4)\grave{I}meso\text{-}(MP)\text{-}[Cu_4(mpba)(tmen)_4(H_2O)_4]_2\}^{6+}$ and $\{3(PF_6)\grave{I}rac\text{-}(MM/PP)\text{-}[Cu_4(mpba)(tmen)_4(H_2O)_4]_2\}^{5+}$, respectively, would be likely related to the different size and geometry of the tetrahedral perchlorate and octahedral hexafluorophosphate anions. The intermolecular distances between the equivalent copper atoms from each tetranuclear cation are in the range 9.988(2)–14.626(2) (**1a**) and 7.031(2)–14.135(2) Å (**1b**), values which can be taken as the approximate dimensions of these nanometre-sized metallosupramolecular capsules.

The encapsulated $ClO_4^-$ and $PF_6^-$ anions establish weak dative interactions with the coordinatively unsaturated copper atoms [Cu–O 2.894(2) Å (**1a**) and Cu–F 3.044(8)–3.221(8) Å (**1b**)], together with hydrogen bonds with the axially coordinated water molecules pointing toward the inner side of the capsule [Ow–O 2.977(9) Å (**1a**) and Ow–F 2.858(8)–2.933(8) Å (**1b**)]. These coordinative and hydrogen-bonding interactions between the cationic hosts and the anionic guests contribute to stabilise the resulting noncovalent capsules, together with the host–guest Coulombic attractions. The two encapsulated $ClO_4^-$ anions in **1a** occupy equivalent positions within the confined space of the capsule [Cl3–Cl3$^{I}$ 5.247(4) Å] (Figure 2a), whereas the three encapsulated $PF_6^-$ anions in **1b** are disposed in a triangular

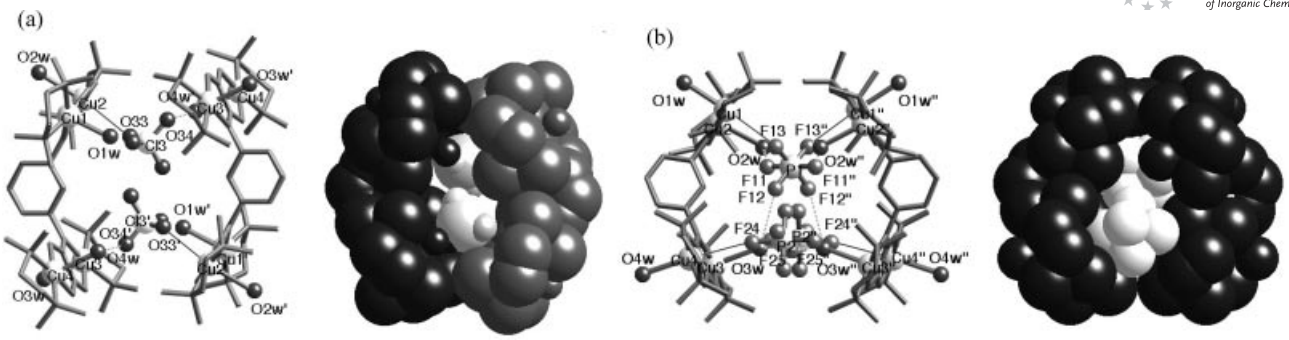

Figure 2. Perspective views of the dimeric capsule of **1a** (a) and **1b** (b) with two and three encapsulated perchlorate and hexafluorophosphate anions, respectively (hydrogen atoms are omitted for clarity). Coordinative and hydrogen bonds with the encapsulated anions are drawn as solid and dashed lines, respectively, in the ball-and-stick model (left). Atoms from each tetracopper helical unit are represented by black (*M* conformer) and grey (*P* conformer) spheres, whereas those of the encapsulated perchlorate and hexafluorophosphate anions are white in the space-filling model (right). Selected intermetallic distances [Å] with standard deviations in parentheses: Cu1–Cu1$^{I}$ 9.988(2), Cu2–Cu2$^{I}$ 14.626(2), Cu3–Cu3$^{I}$ 10.718(2) and Cu4–Cu4$^{I}$ 11.674(2) for **1a**; Cu1–Cu1$^{II}$ 7.031(2), Cu2–Cu2$^{II}$ 10.094(2), Cu3–Cu3$^{II}$ 7.485(2) and Cu4–Cu4$^{II}$ 14.135(2) for **1b** (I = –*x*, – *y*, – *z*; II = –*x*, *y*, 1/2 – *z*).

arrangement [P1–P2 5.632(6) Å and P2–P2$^{II}$ 8.898(7) Å] (Figure 2b).

In the crystal lattice, some of the unencapsulated $ClO_4^-$ and $PF_6^-$ anions also establish weak coordinative bonds with the copper atoms [Cu–O 2.874(8) Å (**1a**) and Cu–F 3.411(8) Å (**1b**)] and hydrogen bonds with the axially coordinated water molecules pointing toward the outer side of the capsule [Ow–O 2.563(8)–2.918(8) Å (**1a**) and Ow–F 2.951(8)–2.959(8) Å (**1b**)]. This situation gives rise to a rather close packing of the spherical-shaped capsules for **1a** and **1b** (Figure 3a and Figure 3b, respectively). Certainly, these intermolecular interactions can play a nonnegligible role in the different metallosupramolecular structural motifs of **1a** and **1b**.

The magnetic properties of **1a** and **1b** in the form of both $\chi_M$ and $\chi_M T$ versus $T$ plots ($\chi_M$ being the magnetic susceptibility per $Cu_4$ unit and $T$ the temperature) indicate an overall antiferromagnetic interaction with a singlet spin ($S$ = 0) ground state (Figure 4). At 315 K, $\chi_M T$ is 0.82 (**1a**) and 0.88 $cm^3 K mol^{-1}$ (**1b**), values which are well below that expected for four magnetically isolated Cu$^{II}$ ions ($\chi_M T$ = 1.65 $cm^3 mol^{-1} K$ with $g$ = 2.1). Upon cooling, $\chi_M T$ decreases continuously and vanishes around 60 (**1a**) and 50 K (**1b**), whereas $\chi_M$ shows a rounded maximum at 310 (**1a**) and 295 K (**1b**).

The temperature dependence of the magnetic susceptibility data of **1a** and **1b** were fitted according to the spin Hamiltonian for a "dimer-of-dimers" model, $\mathbf{H} = -J(\mathbf{S}_1 \cdot \mathbf{S}_2 + \mathbf{S}_3 \cdot \mathbf{S}_4) - J'(\mathbf{S}_1 \cdot \mathbf{S}_3) + g\beta(\mathbf{S}_1 + \mathbf{S}_2 + \mathbf{S}_3 + \mathbf{S}_4) \cdot B$ [Equation (1), with $S_1 = S_2 = S_3 = S_4 = S_{Cu} = 1/2$], where $J$ ($J = J_{12} = J_{34}$) and $J'$ ($J' = J_{13}$) are the intra- and interdimer coupling constants, respectively, and $g$ is the Zeeman factor of the Cu$^{II}$ ions.[12] In this model, the interdimer interactions given by $J''$ ($J'' = J_{14} = J_{23}$) and $J'''$ ($J''' = J_{24}$) were ignored because they involve longer exchange pathways. The quality of the fit according to this model does not depend on the sign and magnitude of the $J'$ value, which can be varied from zero to a few tens of $cm^{-1}$, either positive or negative, with a relatively small variation in the $J$ value.[13]

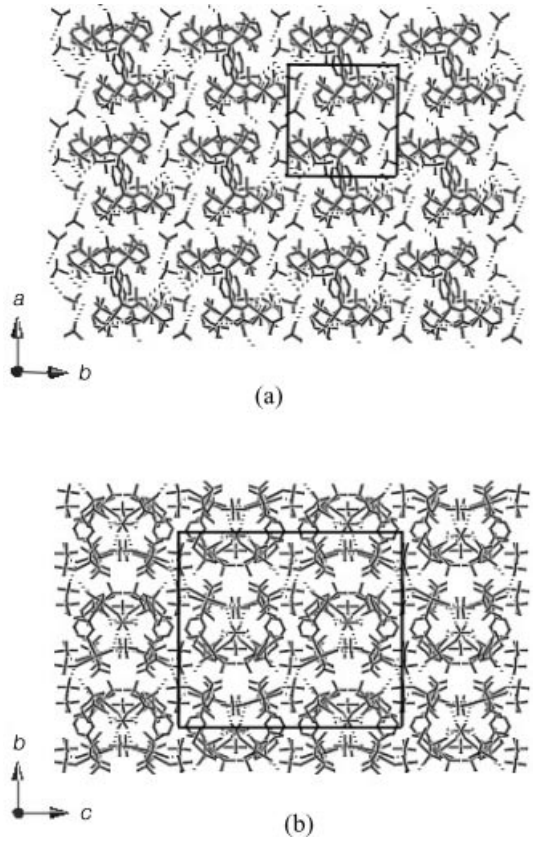

Figure 3. View of the crystal packing of the dimeric capsules of **1a** (a) and **1b** (b) with both encapsulated and unencapsulated perchlorate and hexafluorophosphate anions, respectively, and crystallisation water molecules (hydrogen atoms are omitted for clarity). Coordinative and hydrogen bonds with the anions are drawn as solid and dashed lines, respectively.

This fact suggests that the interdimer magnetic coupling through the *meta*-phenylenediamidate bridge is negligible relative to the intradimer one across the oxamato bridge. Least-squares fit of the experimental data through the Bleaney–Bowers equation for a dimer model ($J'$ = 0) gave

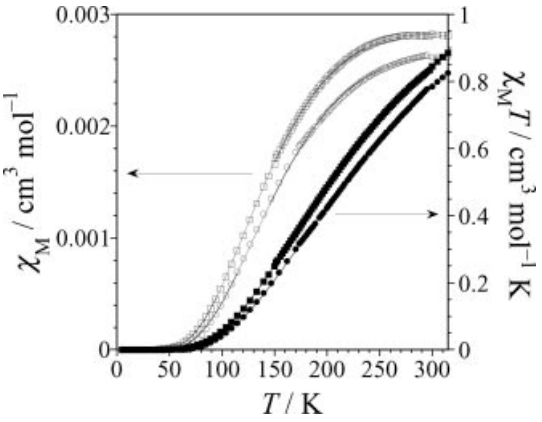

Figure 4. Temperature dependence of $\chi_M$ and $\chi_M T$ for **1a** (○,●) and **1b** (□,■). The solid lines are the best fit curves (see text).

$J = -350$ cm$^{-1}$, $g = 2.09$ and $R = 3.4 \times 10^{-8}$ for **1a**, and $J = -330$ cm$^{-1}$, $g = 2.10$ and $R = 3.0 \times 10^{-8}$ for **1b** {$R$ is the agreement factor defined as $R = \Sigma[(\chi_M T)_{exp} - (\chi_M T)_{calcd}]^2 / \Sigma[(\chi_M T)_{exp}]^2$}. The theoretical curves reproduce very well the experimental data over the whole temperature range (solid lines in Figure 4). The calculated $-J$ values for **1a** and **1b** agree with those reported for related strong antiferromagnetically coupled oxamato-bridged dicopper(II) complexes ($-J$ = 366–425 cm$^{-1}$).[14]

## Conclusions

Discrete cationic tetranuclear copper(II) complexes possessing a helical conformation and a bowl-like shape were self-assembled through metal–ligand coordinative interactions from a *m*-phenylenedioxamato acting as a tetrakis(bidentate) bridging ligand toward four $Cu^{II}$ ions with a diamine as a blocking ligand. Importantly, two of these tetracopper(II) cations further self-assemble in the solid state through noncovalent host–guest interactions (Coulombic attractions, weak coordination and hydrogen bonds) with anions of different size and geometry to yield unusual examples of homo- and heterochiral metallosupramolecular capsules. Current efforts are devoted to analyse the influence of the nature of the ligand spacer (size, rigidity and substitution pattern) of related tetranuclear copper(II) oxamato complexes on their anion encapsulation ability in the solid state.

## Experimental Section

**Preparation of the Complexes:** A solution of $H_2Et_2$mpba (0.077 g, 0.25 mmol) in water (10 mL) and NaOH (0.040 g, 1.0 mmol) was added dropwise to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.37 g, 1.0 mmol) and tmen (0.150 mL, 1.0 mmol) in water (10 mL). The obtained deep-green solution was filtered and allowed to evaporate in air at room temperature. X-ray quality green prisms of **1a** were obtained after several days on standing. Yield: 0.36 g (75%). IR (KBr): $\tilde{\nu}$ = 3419 (OH), 2986 and 2909 (CH), 1636 (CO), 1144, 1113, and 1089 (ClO) cm$^{-1}$. $C_{34}H_{82}Cl_4Cu_4N_{10}O_{29}$ (1491.06): calcd. C 27.36, H 5.50, N 9.39; found C 27.06, H 5.45, N 9.45.

Complex **1b** was prepared in a similar way as described for **1a**, but with the use of $Cu(NO_3)_2 \cdot 3H_2O$ (0.24 g, 1.0 mmol), and solid $KPF_6$ (0.19 g, 1.0 mmol) was added at the end of the reaction. X-ray quality green prisms of **1b** were obtained by slow evaporation at room temperature of the deep-green filtered solution after 1 d. Yield: 0.31 g (80%). IR (KBr): $\tilde{\nu}$ = 3428 (OH), 2991 and 2930 (CH), 1633 (CO), 841 (PF) cm$^{-1}$. $C_{34}H_{80}Cu_4F_{24}N_{10}O_{12}P_4$ (1655.12): calcd. C 24.65, H 4.83, N 8.46; found C 24.34, H 4.72, N, 8.68.

**X-ray Crystallographic Data:** $C_{34}H_{82}Cl_4Cu_4N_{10}O_{29}$ (**1a**), $M$ = 1491.06, triclinic, space group $P\bar{1}$, $a$ = 14.3494(9) Å, $b$ = 14.8957(15) Å, $c$ = 15.1787(19) Å, $\alpha$ = 70.862(8)°, $\beta$ = 86.966(6)°, $\gamma$ = 88.797(6)°, $V$ = 3060.7(5) Å$^3$, $T$ = 100(2) K, $Z$ = 2, $\rho_{calcd.}$ = 1.618 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 1.634 mm$^{-1}$. $C_{34}H_{80}Cu_4F_{24}N_{10}O_{12}P_4$ (**1b**), $M$ = 1655.12, monoclinic, space group $C2/c$, $a$ = 16.045(2) Å, $b$ = 26.659(2) Å, $c$ = 30.758(3) Å, $\beta$ = 96.187(10)°, $V$ = 13080(3) Å$^3$, $T$ = 293(2) K, $Z$ = 8, $\rho_{calcd.}$ = 1.681 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 1.506 mm$^{-1}$. 13164 (**1a**) and 14223 (**1b**) unique reflections, and 11057 (**1a**) and 6115 (**1b**) observed with $I > 2\sigma(I)$. All the measured independent reflections were used in the analysis. The structures were solved by direct methods and refined with full-matrix least-squares technique on $F^2$ by using the SHELXS-97 and SHELXL-97 programs. The hydrogen atoms from the organic ligands were calculated and refined with isotropic thermal parameters, whereas those from the water molecules were neither found nor calculated. Refinement of 730 (**1a**) and 790 (**1b**) variables with anisotropic thermal parameters for all non-hydrogen atoms gave $R$ = 0.0743 (**1a**) and 0.0854 (**1b**), and $R_w$ = 0.1920 (**1a**) and 0.1379 (**1b**), with $S$ = 1.058 (**1a**) and 1.013 (**1b**) (observed data).

CCDC-650175 (**1a**) and -650176 (**1b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Magnetic Measurements:** Variable-temperature (2.0–315 K) magnetic susceptibility measurements were carried out on powdered samples of **1a** and **1b** with a Quantum Design SQUID magnetometer. The magnetic data were corrected for diamagnetism of the sample holder and the constituent atoms and for the temperature-independent paramagnetism of the copper atoms ($60 \times 10^{-6}$ cm$^3$ per $Cu^{II}$ ion) as well.

# [(Pyridylcarbonyl)pyridyl]triazolopyridines, Useful Ligands for the Construction of Polynuclear Coordination Compounds – Synthesis, Crystal Structure and Magnetic Properties of a Novel Tetranuclear Copper(II) Cubane

**Belén Abarca,*[a] Rafael Ballesteros,[a] Mimoun Chadlaoui,[a] Carmen Ramirez de Arellano,[a] and José A. Real*[b]**

*Dedicated to Professor Ramón Mestres on the occasion of his retirement*

**Keywords:** Polydentate ligands / Triazolopyridine ligands / Copper(II) complexes / Tetranuclear complexes / Molecular magnetism

A new tetranuclear cubane $Cu_4O_4$ complex has been synthesised from assembly of $Cu^{II}$ ions and the polydentate ligand (pyridin-2-yl){6-([1,2,3]triazolo[1,5-*a*]pyridin-3-yl)pyridin-2-yl}methanone. Crystallographic analysis indicates that the $Cu_4O_4$ unit has an $S_4$ symmetry. The magnetic properties have been analysed using the $H = -2\sum_{i,j} J_{ij} S_i S_j$ spin Hamiltonian. Two distinct coupling constants, $2J_{1,3} = -37.4$ cm$^{-1}$ and $2J_{1,2} = -2.6$ cm$^{-1}$, obtained from the fitting of the experimental data have been rationalised on the basis of a density functional study of magnetostructural correlations in cubane complexes containing the $Cu_4O_4$ core.

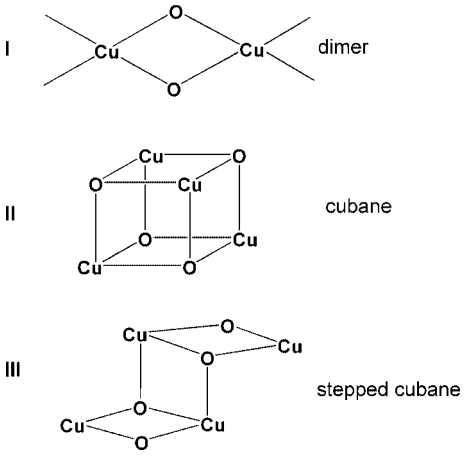
## Introduction

High-nuclearity transition-metal complexes are of importance as new magnetic materials,[1] single molecular magnets (SMM),[2–5] in the emerging science of nanomaterials,[6] and as models for the multimetal active sites of metal storage proteins.[7]

Despite the interest in the properties of such systems, synthetic methods have to reach the level of efficiency attained with mononuclear complexes, and the term "serendipity" is frequently used to explain why one polynuclear complex is obtained rather than another.

Copper(II) complexes are particularly popular since the ion is paramagnetic and polynuclear clusters are easily accessible. Copper(II) forms many dinuclear complexes in which it shows a basically square-planar coordination with two bridging ligands, very frequently hydroxide or alkoxide groups, linking the two metals (Scheme 1, **I**). Copper(II) readily accepts a fifth ligand above the plane, and this offers a means of association of two dimeric units to give either the so-called cubane unit (Scheme 1, **II**) or the stepped cubane (Scheme 1, **III**).[8]



Scheme 1. Di- and tetranuclear copper(II) species.

During our research on the chemistry of [1,2,3]triazolo[1,5-*a*]pyridines, we had synthesized (pyridin-2-yl)([1,2,3]triazolo[1,5-*a*]pyridin-7-yl)methanones of type **1**,[9,10] as starting materials to prepare poly(pyridylcarbonyl)pyridines of type **2**, polydentate ligands able to make high-nuclearity clusters (Scheme 2).[11] In this context we had found an interesting structural feature for the precursor **3A** (**1**, R =

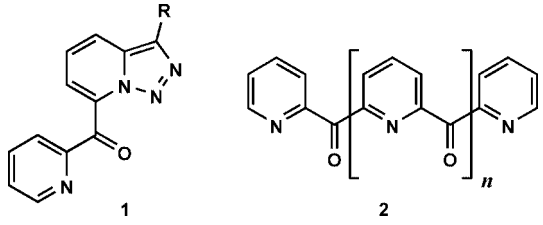
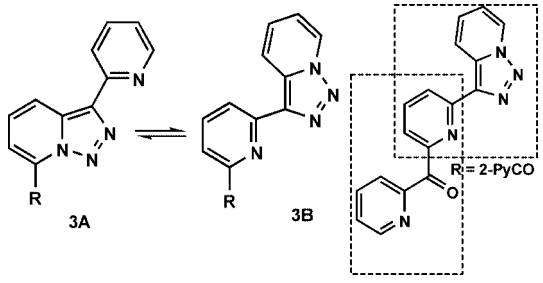
pyridin-2-yl) (Scheme 3). The $^1$H NMR spectrum demonstrates that this compound exists almost entirely as its isomer **3B** (R = 2-PyCO).[10] To account for this structure we assumed that, in solution, the first formed compound **3A** (R = 2-PyCO) {3-(pyridin-2-yl)[1,2,3]triazolo[1,5-*a*]pyridin-7-yl derivative} is in equilibrium with the diazo form, an intermediate which may undergo a new ring-chain isomerisation,[12,13] giving **3B** {6-{[1,2,3]triazolo[1,5-*a*]pyridin-3-yl}pyridin-2-yl derivative} (see Scheme 3). By a $^1$H NMR study and DFT/B3LYP/6-31G* calculations of a series of 7-substituted 3-(pyridin-2-yl)triazolopyridines, we had proved that the **A/B** ratio depends on the electronic properties of the substituent R. Electron-donating substituents [$SiMe_3$, $B(OR)_2$] favour the **A** form, electron-withdrawing substituents [COMe, Br, Cl, I, *p*-MeOPh] favour the **B** form, and only in the case R = Me, both forms are present (75% of **A**, 25% of **B**).[14]



Scheme 2.



Scheme 3.

The structure **3B** (R = 2-PyCO) has two interesting features as a potential ligand to form high-nuclearity transition-metal complexes (Scheme 3). On one hand, a part of the structure is analogue to that of the 3-(pyridin-2-yl)-triazolopyridines, which coordinates through the N2 and N11 atoms, i. e. to $Cu^{II}$, and $Fe^{II}$ ions.[15,16] In particular, the $Fe^{II}$ derivatives with $NCS^-$ and $NCSe^-$ coordinating anions undergo spin crossover behaviour. On the other hand, the 2,2′-dipyridyl ketone moiety is also present. This moiety can undergo metal-assisted nucleophilic attack by solvent molecules on its carbonyl function, thus yielding its *gem*-diol or hemiacetal form, depending on the solvent. Subsequent deprotonations of the hydroxyl groups can yield the mono- or dianion (in the case of the *gem*-diol form), which can adopt a large number of coordination modes, bridging up to five metal ions. The latter coordinating motive has been extensively studied by Perlepes et al.[17–20] and have important magnetic properties.

In this context, we have been investigating **3B** as a suitable candidate to have similar solvolysis, deprotonation, and coordination properties. Here we report the synthesis, crystal structure and magnetic behaviour of the tetranuclear cubane compound $[Cu(\mathbf{3B^*})]_4(NO_3)_4{\cdot}8H_2O$ where the ligand **3B*** is the hemiacetal of the (pyridin-2-yl){6-([1,2,3]triazolo[1,5-*a*]pyridin-3-yl)pyridin-2-yl}methanone.

## Results and Discussion

The molecular structure of a representative fragment of the cationic unit $[Cu(\mathbf{3B^*})]_4^{4+}$ is shown in Figure 1. The cubane shows an $S_4$ symmetry with the $Cu^{II}$ ion in the middle of a strongly distorted $[CuO_3N_3]$ octahedron. Two nitrogen atoms belong to the [N(2) and N(11)] atoms of one ligand **3B*** while the remaining nitrogen atom belongs to the isolate pyridine group [$N(21)^i$] of a second **3B***. The three oxygen atoms correspond to the O(1) site, one belongs to the same ligand that the two nitrogen (N2 and N11) while the other two corresponds to two adjacent ligands. There are four short distances Cu–N(11) 2.0243(23), Cu–N(21) 1.9923(23), Cu–O(1) 1.9519(18), and Cu–$O(1)^{ii}$ = 1.9984(18) Å and two elongated distances Cu–N(2)

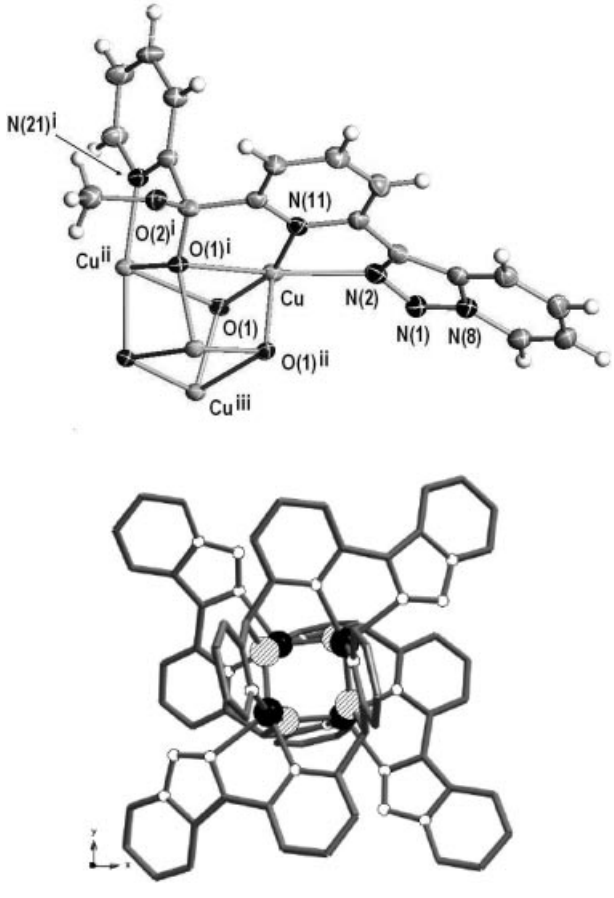


Figure 1. Ellipsoid plot of a representative fragment of the $[Cu(\mathbf{3B^*})]_4^{4+}$ cation with the representative atom numbering (left). Thermal ellipsoids are represented at 50% probability level. View of a complete $[Cu(\mathbf{3B^*})]_4^{4+}$ cation seen along 001 direction [copper (black spheres), oxygen (striped spheres), nitrogen (white spheres)].

2.250(2), and Cu–O(1)$^{i}$ = 2.5775(19) Å [i: $-x + 2$, $-y + 1/2$, $+z$; ii: $-y + 5/4$, $+x - 3/4$, $-z + 5/4$].

The O(1) atom connects three $Cu^{II}$ ions which in addition are coordinated to three O(1) atoms in an approximately orthogonal fashion defining a distorted cube in which the oxygen and copper atoms are arranged in an alternate way. The angles defined by these atoms in the distorted cube are Cu–O(1)–Cu$^{i}$ 89.20(7), Cu$^{i}$–O(1)–Cu$^{iii}$ 89.15(7), Cu–O(1)–Cu$^{iii}$ 110.10(9)° and O(1)–Cu–O(1)$^{i}$ 87.83(7), O(1)–Cu–O(1)$^{ii}$ 88.16(7) and O(1)$^{i}$–Cu–O(1)$^{ii}$ 72.58(7)°. The N(11)-pyridine ring forms dihedral angles of 22.00(7)° and 87.02(10)° with the triazolopyridine and the N(21)-pyridine rings, respectively. The $NO_3^-$ anions and the $H_2O$ molecules interact via hydrogen bonding defining a 3D supramolecular framework with large dodecagon-like section channels where the cationic cubane $[Cu(\mathbf{3B^*})]_4^{4+}$ complexes are intalled (see Figures 2 and 3).

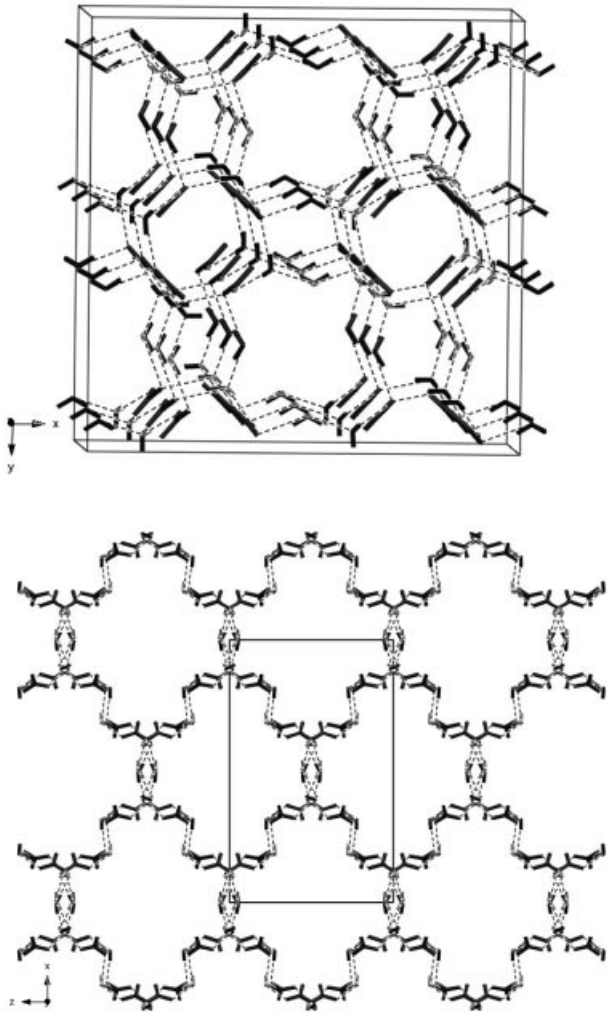

Figure 2. Supramolecular 3D framework defined by hydrogen bond interactions between $NO_3^-$ and $H_2O$. View of the unit cell along $z$ direction (left) and perspective view along $y$ direction (right). The tetranuclear cations, which fill the dodecagonal motives, have been eliminated for simplicity. Doted lines represent the hydrogen bonds.

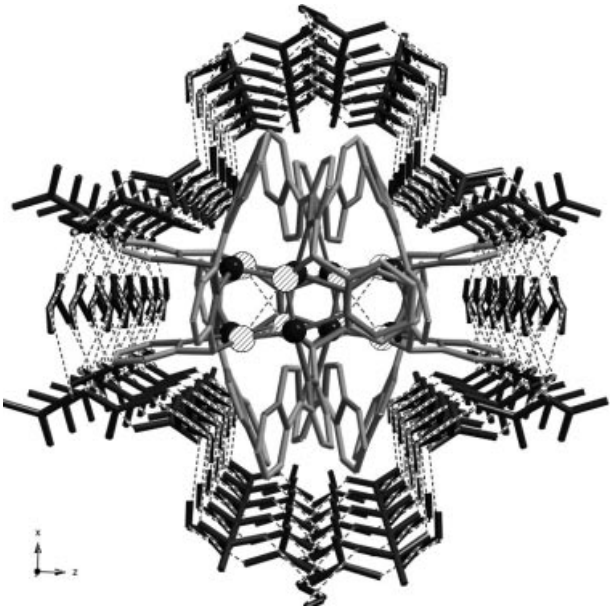

Figure 3. View of a dodecagonal channel loaded with two adjacent $[Cu(\mathbf{3B^*})]_4^{4+}$ cations. Dotted lines represent the hydrogen bonds. Hatched and black spheres correspond to the oxygen atoms of the cubane and the copper ions, respectively.

The hydrogen bond lengths [Å] and angles [°] are: $H_2O(21)\cdots O(11)NO_2$: H(1A)···O(11) 2.10(3), O(21)···O(11) 2.950(4), O(21)–H(1A)···O(11) 159(5); $H_2O(21)$–H(1B)··· O(22)$^{iv}$: H(1B)···O(22)$^{iv}$ 1.85(2), O(21)···O(22)$^{iv}$ 2.740(5), O(21)–H(1B)···O(22)$^{iv}$ 166(6); $H_2O(22)\cdots O(13)^{v}NO_2$: H(2A)···O(13)$^{v}$ 2.12(3), O(22)···O(13)$^{v}$ 2.893(4), O(22)–H(2A)···O(13)$^{v}$ 152(4); $H_2O(22)\cdots O(11)NO_2$: H(2B)···O(11) 2.03(2), O(22)···O(11) 2.853(4), O(22)–H(2B)···O(11) 165(4); $H_2O(22)\cdots O(12)^{v}NO_2$: H(2A)···O(12) 2.58(3), O(22)··· O(12) 3.351(4), O(22)–H(2A)···O(12) 152(4) and $H_2O(22)\cdots O(12)^{v}NO_2$: H(1A)···O(12)$^{v}$ 2.59(5), O(22)···O(12)$^{v}$ 3.262(5), O(22)–H(1A)···O(12)$^{v}$ 132(5) [iv: $-x + 3/2$, $-y + 3/2$, $-z + 3/2$ and v: $-y + 5/4$, $x - 1/4$, $z - 1/4$].

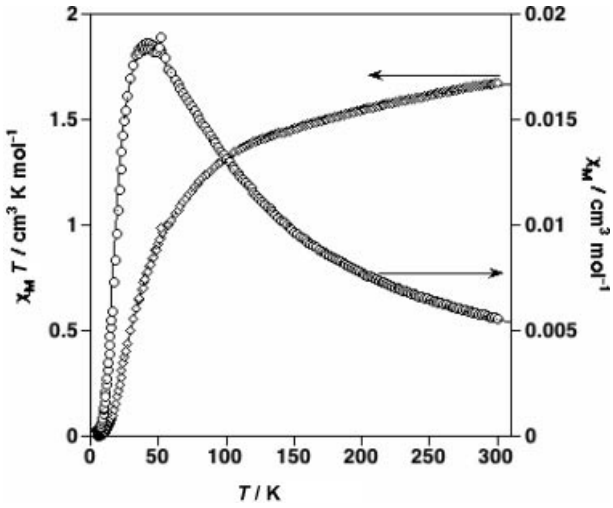

Figure 4. $\chi_M$ and $\chi_M T$ product vs. $T$ plots of $[Cu(\mathbf{3B^*})]_4(NO_3)_4 \cdot 8H_2O$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The magnetic properties of the title compound are displayed in Figure 4 in the form of $\chi_M$ and $\chi_M T$ vs. $T$, where $\chi_M$ represents the magnetic susceptibility per mol of compound and $T$ the temperature. The $\chi_M T$ product is equal to 1.67 $cm^3 K mol^{-1}$, which corresponds quite well to the expected value for four weakly or uncoupled S = ½ centres. This value decreases continuously up to reach a value close to cero below 10 K. In contrast the $\chi_M$ value increases continuously from $5.50 \times 10^{-3}$ $cm^3 mol^{-1}$ at 300 K until $1.86 \times 10^{-2}$ $cm^3 mol^{-1}$ at ca 43 K where the $\chi_M$ vs. $T$ curve passes through a maximum and then decreases to reach values close to cero below 10 K. This behaviour corresponds to intramolecular antiferromagnetic coupling. This magnetic behaviour can be explained in terms of the isotropic Heisenberg–Dirac–van Vleck Hamiltonian (1).

$$H = -2\sum_{i,j} J_{ij} S_i S_j \quad (1)$$

which in the case of a tetranuclear $Cu_4O_4$ core with $S_4$ symmetry becomes Equation (2) (see also Figure 5, a).

$$H = -2J_{1,2}(S_1S_2 + S_3S_4) - -2J_{1,3}(S_1S_3 + S_2S_3 + S_2S_4 + S_1S_4) \quad (2)$$

The analytical of $\chi_M$ vs. $T$ curve deduced from Equation (2) can be expressed as follows in Equation (3).

$$\chi_M = \frac{2N\beta^2 g^2}{kT} \cdot \frac{A}{B} + N\alpha \quad (3)$$

where

$$A = 2\exp(2J_{1,2}/kT) + \exp[(4J_{1,2} - 2J_{1,3})7kT] + 5\exp[(4J_{1,2} + 2J_{1,3})/kT]$$

$$B = 1 + 6\exp[(2J_{1,2})7kT] + \exp[(4J_{1,2} - 4J_{1,3})7kT] + 3\exp[(4J_{1,2} - 2J_{1,3})7kT] + 5\exp[(4J_{1,2} + 2J_{1,3})/kT]$$

The relevant parameters have been obtained by least-squares fitting of Equation (3) to the experimental data. The parameter $N\alpha$ has been fixed at $240 \times 10^{-6}$ $cm^3 mol^{-1}$. The best fit for calculated and experimental $\chi_M$ values has been found for $2J_{13}$ = –37.4 $cm^{-1}$, $2J_{12}$ = –2.6 $cm^{-1}$, $g$ = 2.16 and $R = 1 \times 10^{-4}$. $R$ is the agreement factor defined as $\Sigma_i\{(\chi_M)_i^{exp} - [(\chi_M)_i^{calc}]^2/[(\chi_M)_i^{exp}]^2\}$. The solid line in Figure 4 corresponds to the calculated curve showing that an excellent agreement between the experimental and theoretical $\chi_M$ data is achieved. The magnitude and sign of $J_{12}$ and $J_{13}$ is determined by the angle Cu–O–Cu, Cu–O distances ($d_1$, $d_2$) and the orientation of the orbitals bearing the unpaired electrons (ie $d_{x^2-y^2}$) (see Figure 5, b–d). The exchange pathway determining the $J_{1,2}$ value involves two short and two long Cu–O distances (Figure 5, d), consequently direct overlap between the $d_{x^2-y^2} - d_{z^2}$ orbitals instead of the $d_{x^2-y^2} - d_{x^2-y^2}$ orbitals is observed. Hence, $J_{1,2}$ is expected to be very small and in general positive (ferromagnetic) due to the small participation of the $d_{z^2}$ orbital in the ground state of the $Cu^{II}$ [$\alpha$(Cu–O–Cu) = 89.15°, $d_2$ = 2.578 Å]. Although the exchange pathway $J_{1,3}$ is not appropriate for strong magnetic coupling it is expected to be significantly stronger than $J_{1,2}$ and antiferromagnetic in nature, given that the occurrence of a short Cu–O distance ($d_1$ = 1.998 Å) and a $\beta$(Cu–O–Cu) angle equal to 110.10° facilitates partial overlap between the $d_{x^2-y^2}$ orbitals.

Álvarez and co-workers have recently performed magnetostructural correlations in polynuclear complexes containing $Cu_4O_4$ cubane structure employing theoretical calculations based on DFT.[21] For $S_4$, also referred 4+2, cubanes their theoretical calculations predict that $J_{1,2}$ is small in magnitude, ferromagnetic and little dependent on the geometrical parameters. On the contrary, $J_{1,3}$ displays larger influence of the geometry and changes from ferro- to antiferromagnetic in nature for $\beta$ angles larger than 104°. These predictions clearly justify the results obtained for the title compound. The negative sign of $J_{12}$ may be a consequence of its very small magnitude together with some correlation in the evaluation of the $J_{13}$ parameter.

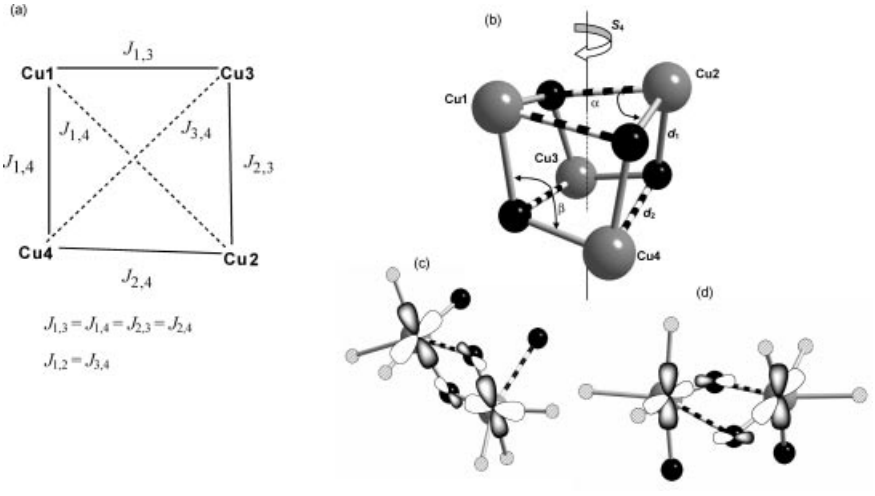

Figure 5. Scheme of the spin-coupling model used for the analysis of the magnetic data (a). Arrangement of the copper atoms in the cubane (b). Magnetic exchange pathways (c) and (d), see text.

## Conclusions

In summary we have demonstrated the capability of the polydentate ligand (pyridin-2-yl){6-([1,2,3]triazolo[1,5-*a*]-pyridin-3-yl)pyridin-2-yl}methanone to afford tetranuclear $Cu^{II}$ complexes. A next step in this research will require the synthesis of novel tetranuclear complexes with other divalent and trivalent first row transition metal ions.

## Experimental Section

**Synthesis:** To a solution of (pyridin-2-yl){6-([1,2,3]triazolo[1,5-*a*]-pyridin-3-yl)pyridin-2-yl}methanone (**3B**) (48 mg, 0.15 mmol) in ethanol (30 mL), a solution of $Cu(NO_3)_2{\cdot}3H_2O$ (40 mg, 0.16 mmol) in water (10 mL) was added. A green solution was formed. It was leaved covered at room temperature till the formation of green crystals, which were filtered and recrystallized from methanol (31.48 mg, 40% yield). $C_{72}H_{72}Cu_4N_{24}O_{28}$ (1975.7): calcd. C 43.76, H 3.65, N 17.02; found C 43.41, H 3.72, N 16.75.

**Magnetic Susceptibility Measurements:** The variable-temperature magnetic susceptibility measurements were performed on small single crystals by using a Quantum Design MPMS2 SQUID susceptometer equipped with a 5.5 T magnet and operating at 1 T and 1.8–375 K. Experimental data were corrected for diamagnetism using Pascal's constants.

**Crystal Data:** Green needle, $0.42 \times 0.12 \times 0.10$ mm size, tetragonal, $I4_1/a$, $a = 23.089(3)$, $c = 14.463(3)$ Å, $V = 7710(2)$ Å$^3$, $Z = 4$, $\rho_{calcd.} = 1.702$ g cm$^{-3}$, $\theta_{max} = 28.29$, Mo-$K_\alpha$, $\lambda = 0.71073$ Å, ω-scan, diffractometer Nonius Kappa CCD, $T = 120(2)$ K, 27774 reflections collected of which 4765 were independent ($R_{int} = 0.077$), direct primary solution and refinement on $F^2$ (SHELXS-97 and SHELXL-97, G. M. Sheldrick, University of Göttingen, 1997), 304 refined parameters, $OH_2$ hydrogen atoms were located in a difference Fourier synthesis, other hydrogen atoms were included using a riding model or as rigid methyl groups, $R_1[I > 2\sigma(I)] = 0.0441$, $wR_2$(all data) = 0.1132.

CCDC-641246 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Charaterisation of Chromium Oxyselenide ($Cr_2Se_{0.7}O_{2.3}$) Formed from Chemical Vapour Synthesis: A New Antiferromagnet

**Nicolas D. Boscher,[a] Claire J. Carmalt,[a] A. Garcia Prieto,[b] Quentin A. Pankhurst,[b] Robert G. Palgrave,[a] and Ivan P. Parkin*[a]**

**Keywords:** Chemical vapour synthesis / Chromium oxyselenide / Antiferromagnet

Chromium oxyselenide $Cr_2Se_{0.71}O_{2.30}$ was synthesised by chemical vapor synthesis of chromium oxychloride and diethyl selenide. The material adopts the $Cr_2Se_3$ structure type with $a$ = 6.26(3) Å and $c$ = 17.45(3) Å. The Raman spectrum shows bands at 225 and 550 $cm^{-1}$. X-ray photoelectron spectroscopy and wavelength dispersive analysis by X-rays confirmed the material was homogeneous and of uniform composition $Cr_2Se_{0.71}O_{2.30}$. The material is an antiferromagnet with a Neel temperature of 43 K. This is the first solid-state chromium oxyselenide reported and shows that the hard oxygen and soft selenium can co-exist in the same lattice if formed under the kinetic product conditions of a rapid gas-phase reaction.

## Introduction

Chromium mixed chalcogenides have been thoroughly investigated by various workers over many years because of their interesting magnetic properties. The synthesis and magnetic properties of chromium sulfoselenide,[1] chromium sulfotelluride[2–4] and chromium selenotelluride[5,6] have been widely reported for a range of different compositions.[7,8] In contrast, only one paper reports the existence of a chromium oxysulfide, $Cr_2S_2O$,[9] neither chromium oxyselenide or oxytelluride phases are known. Indeed this is often a common pattern in solid-state transition metal chemistry where in polarisability terms the "hard" oxygen and "soft" selenium find it difficult to coexist in a solid solution without phase segregation or formation of layered materials in which the oxide and selenide blocks are separated. This is not to say that metal oxide-selenide solid solutions cannot exist, rather that by the conventional synthesis they invariably produce the thermodynamic product. A large number of phases have been reported in the chromium-selenium system and include $Cr_5Se_8$,[10] $CrSe_2$,[11,12] $CrSe_3$[13] and a series of compounds CrSe,[14,15] $Cr_7Se_8$,[16] $Cr_5Se_6$,[17] $Cr_3Se_4$,[18] and $Cr_2Se_3$ with the NiAs-type crystal structure, in which chromium vacancies are ordered. $Cr_2Se_3$ has a rhombohedral-type superstructure, which leads to complex antiferromagnetic arrangements below the Néel temperature $T_N$ = 43 K.[19] An order-order magnetic transition is also known to occur at $T_t$ = 38 K. The chromium-oxygen system is simpler than the chromium-selenium one, the most common phase being $Cr_2O_3$.[20] This phase is also an antiferromagnet with $T_N$ = 307 K. Chromium(III) selenide has found applications such as protective films, black matrix films in liquid crystal displays, solar thermal energy collectors, in catalysis and in tunnel junction barriers.[21,22] Here we present the first report of the existence of a chromium oxyselenide phase formed from a rapid gas phase synthesis route, we hypothesise that the reason we can obtain an oxyselenide in this case is that the reaction is a fast and that we effectively "trap-out" the kinetic product.

## Results and Discussion

Chromium oxyselenide was prepared from the atmospheric pressure chemical vapour deposition (APCVD) reaction of chromyl chloride and diethylselenide. Synthesis was accomplished under a dinitrogen atmosphere (99.99%) in a horizontal-bed cold-wall APCVD reactor heated to 600 °C. $Et_2Se$ and $CrO_2Cl_2$ were preheated to 70 °C and 75 °C in their respective bubblers before being introduced into gas stream of hot $N_2$. They were then passed through a mixing chamber heated to 200 °C and were introduced into the reactor chamber. Chromyl chloride reacts in the gas phase with diethyl selenide to form a black fine powder that collects on the glass substrate. This can be readily removed by brushing with a fine hair-brush. Notably the same reaction at lower substrate temperatures of 400–550 °C forms a green adherent crystalline chromium oxide film and not the black chromium oxy-selenide powder.

Scanning electron microscopy (SEM) images show a single morphological type of spherical nanoparticles with a mean size of 100 nm (Figure 1). Energy and wavelength-dispersive X-ray analysis (EDX/WDX) show that the powder contains chromium, oxygen and selenium. The elemental stoichiometry of the particles was determined to be $Cr_2Se_{0.71}O_{2.30}$ and the chlorine and carbon levels within the powder were found to be below the detection limit of the instrument (less than 0.5 atom-%). The sample was homogeneous by spot EDX analysis.

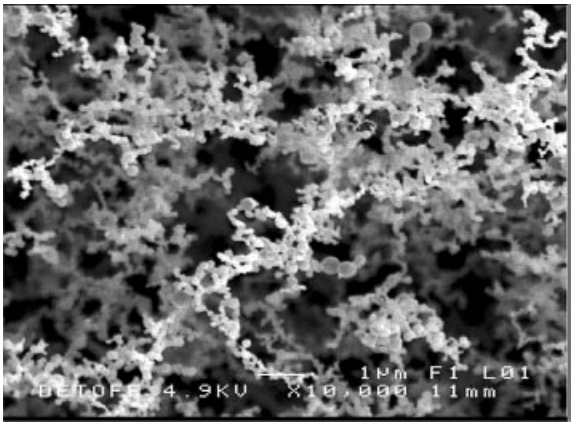

Figure 1. Scanning electron micrograph of the powder produced from the gas phase reaction of $CrO_2Cl_2$ and $Et_2Se$ at 600 °C.

Powder X-ray diffraction (Figure 2) confirmed that the product from the gas-phase reaction is single-phase, crystalline and matches the reported pattern for rhombohedral $Cr_2Se_3$ (JCPDS File No. 040-1403).[19] The lattice parameters were calculated as $a$ = 6.26(3) Å and $c$ = 17.45(3) Å. Notably no chromium oxide was detected by powder diffraction. It has been shown previously that APCVD of chromyl chloride produces crystalline chromium oxide films at the same temperature of deposition (ca. 600 °C).[22–24]

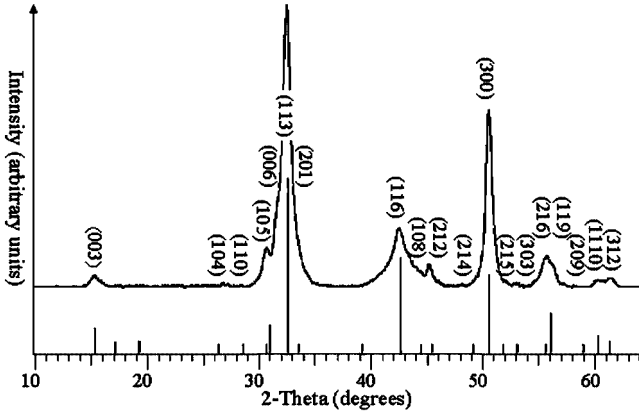

Figure 2. XRD pattern obtained for the powder formed from the APCVD reaction of $CrO_2Cl_2$ and $Et_2Se$ at 600 °C. Literature stick pattern for rh-$Cr_2Se_3$ powder (JCPDS file No. 040-1403) is shown.

X-ray photoelectron spectroscopy of the as-prepared powder (Figure 3) shows the presence of three elements – chromium, oxygen and selenium in the same ratio as found from EDX analysis ($Cr_2Se_{0.7}O_{2.3}$). A single environment can be seen for each element; Cr $2p_{1/2}$ = 583.3 eV, Cr $2p_{3/2}$ = 576.2 eV; O 1s = 531.5 eV; Se $3d_{3/2}$ = 55.1 eV and Se 3d = 54.0 eV. The chromium environment for the $2p_{3/2}$ peak is intermediate between that of $Cr_2O_3$ at 576.6 eV and $Cr_2Se_3$ at 574.6 eV and indicative of $Cr^{III}$.[25,26] The oxygen 1s environment shows a narrow full width half maximum peak at 1.7 eV – indicative of a single environment with a binding energy shift consistent with an oxide and 0.7 eV close to that in chromium oxide 530.8 eV.[27] The selenium $3d_{3/2}$ peak matches that found in $Cr_2Se_3$ at 54.0 eV.[25]

Raman analysis of the powder (Figure 4) reveals broad bands at 225 $cm^{-1}$ and 550 $cm^{-1}$. The absence of the distinctive (relatively intense) $Cr_2O_3$ Raman bands at 307, 350, 524, 551 and 610 $cm^{-1}$ or $CrO_2$ bands at 458, 570 and

682 $cm^{-1}$ (or indeed $CrO_3$) confirms that no chromium oxide was formed and co-doped during the gas-phase reaction of $CrO_2Cl_2$ and $Et_2Se$.[28,29]

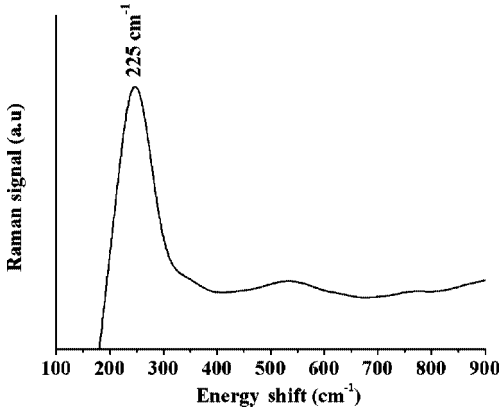

Figure 4. Raman pattern obtained for the powder formed from the gas phase reaction of $CrO_2Cl_2$ and $Et_2Se$ at 600 °C.

The thermogravimetric analysis of $Cr_2Se_{0.7}O_{2.3}$ in air shows a gradual increase in weight of +24% between 60 °C and 420 °C. This is attributed to the oxidation of the selenium in the material to a selenate. A weight loss of –8% is observed from 420 °C to 550 °C corresponding to the decomposition of the selenate to form $Cr_2O_3$ and $SeO_2$ by loss of $O_2$. The second weight loss corresponding to –36% is seen from 600–800 °C and corresponds to the sublimation of all selenium in the form of $SeO_2$.[30]

The dc magnetic susceptibility ($\chi$) as a function of temperature (Figure 5) shows a peak at 11 K. The large particle size (100 nm) precludes the possibility of this being due to a superparamagnetic blocking transition, and the substitution of oxygen with selenium is unlikely to generate any frustrated magnetic states. We therefore attribute the peak to an antiferromagnetic ordering transition. The Néel temperature at $T_N$ = 11 K in $Cr_2Se_{0.7}O_{2.3}$ is less than that of $Cr_2Se_3$ ($T_N$ = 43 K),[19] and much less that that of $Cr_2O_3$ ($T_N$ = 307 K),[31] implying that the new material has somewhat different magnetic properties compared to its parent compounds.

The characterization data are all consistent with the formation of a hitherto unknown solid solution of $Cr_2Se_{0.7}O_{2.3}$ rather than the formation of two intimately mixed phases of $Cr_2O_3$ and $Cr_2Se_3$. SEM analysis shows a single type of particle morphology – spherical and agglomerated together – consistent with a gas-phase reaction, rather than two types of crystallite. WDX and EDX analysis show that the material is homogeneous to spot analysis with the same elemental formulation across the surface. The X-ray diffraction pattern shows a single-phase material of the $Cr_2Se_3$ structural type but with a larger unit cell. Previously we have shown that $Cr_2O_3$ is crystalline when prepared by CVD at 400 °C and adopts an adhesive film with angular crystallites.[22–24] Furthermore, we showed in this work at deposition temperatures from 450–600 °C a green chromium oxide film formed from reaction of $Et_2Se$ and $CrO_2Cl_2$. It was only at 600 °C and above that a chromium

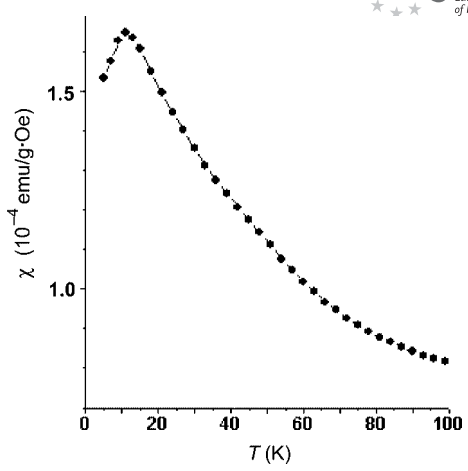

Figure 5. DC magnetic susceptibility (in a measurement field of 10 Oe) as a function of temperature for $Cr_2Se_{0.7}O_{2.3}$.

oxyselenide phase formed, by gas-phase nucleation that "snowed" onto the surface to form a poorly adherent film that could be readily collected. The XPS analysis for the chromium oxyselenide showed only a single chromium environment rather than two well separated peaks for the oxide and selenide, furthermore the quantification of the element abundances matched the WDX analysis. The thermal gravimetric analysis results also correlate well with the elemental formula. The Raman pattern does not show any chromium oxide (corundum) in the powder but is consistent with a layered metal-selenide type structure. Furthermore the magnetic properties of the new material are unlike either – $Cr_2Se_3$ or $Cr_2O_3$ – which although both are antiferromagnets and have Néel temperatures of 43 and 307 K respectively. Hence there is strong evidence for the formation of a new chromium oxyselenide phase. We have yet to account for why the Néel temperature is depressed for the new oxyselenide phase compared to the end members of the series – however the magnetic structure of $Cr_2Se_3$ is extraordinarily complicated.[19] We are hopeful that by varying the reaction conditions it will be possible to make other compositions within the solid solution series $CrO_xSe_y$ ($x + y = 3$). This work has shown that the "hard" oxygen and "soft" selenium can marry in the same chromium solid-state material without phase segregation. It also indicates that a fast gas-phase kinetic route could be the way forward for making a range of hitherto unknown oxyselenide phases.

## Experimental Section

Synthesis of the chromium oxyselenide nanoparticles was carried out under a dinitrogen atmosphere (99.99%) on glass substrates using a conventional horizontal bed cold-wall atmospheric pressure CVD reactor. The glass substrate was $SiO_2$ coated standard float glass (Pilkington, UK). The substrate was heated to 600 °C by a graphite block and the nitrogen carrier gas was preheated to 150 °C by being passed along 2 m lengths of coiled stainless steel tubing inside a tube furnace. The gases in the reaction were made to pass over the heated substrate and confined in position by a top plate that was ca. 4 mm above the substrate. After passage through the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

reaction chamber the gas stream was treated with bleach to destroy the possible presence of $H_2Se$ and vented inside a fume cupboard.

Chromyl chloride was obtained form Strem and diethyl selenide was supplied by Aldrich. They were both used without further purification. The chromyl chloride and diethyl selenide were placed into two different stainless steel bubblers, which were respectively heated to 75 °C and 70 °C by an external jacket. They were both introduced into gas streams by passing hot $N_2$ through the bubblers. Flow rates of nitrogen through the $CrO_2Cl_2$ bubbler and $Et_2Se$ were respectively 0.2 L min$^{-1}$ (3 mmol min$^{-1}$) and 2.0 L min$^{-1}$ (30 mmol min$^{-1}$) and the flow rate through the mixing chamber was kept constant to 3.0 L min$^{-1}$. Deposition time for the experiment was one minute. At the end of the deposition, the bubbler line was closed and the substrate was cooled under nitrogen in the reactor. Then the samples were collected on the substrate and handled briefly in air before storage in a dry oxygen-free nitrogen atmosphere in a glove box. It was subsequently found that the samples were air and water stable, so this procedure was not necessary.

X-ray diffraction patterns were measured on a Bruker AX5 B8 instrument using monochromated Cu-$K_{\alpha 1}$ radiation ($K_{\alpha 1}$ = 1.5406 Å). The diffractometer used glancing incident radiation (5°). The samples were indexed using Unit cell and compared to database standards. Wavelength dispersive X-ray and Energy dispersive X-ray analysis were obtained on a Philips XL30ESEM instrument and SEM was obtained on a JEOL 6301 instrument. Raman spectra were acquired on a Renishaw Raman System 1000 using a helium–neon laser of wavelength 632.8 nm. The Raman system was calibrated against the emission lines of neon. X-ray photoelectron spectroscopy was undertaken using a VG ESCALAB 220I XL instrument with focused (300 mm spot) monochromatic Al-$K_\alpha$ radiation at a pass energy of 20 eV. Scans were acquired with steps of 50 meV. A flood gun was used to control charging. Binding energies were referenced to an adventitious C 1s peak at 284.6 eV (this peak is due to residual pump oil used in the XPS high vacuum system, but is removed on the first argon ion etching). Argon sputtering was used for approximately 1 min in a rastering mode in order to remove surface contamination. Thermal gravimetric analysis (TGA) was performed with a heating rate of 10 °C min$^{-1}$ and on a Netzsch STA 449C instrument. Direct-current magnetic susceptibility measurements were performed using a commercial SQUID magnetometer (Quantum Design MPMS-XL) in a magnetic field of 10 Oe.

# f-Block-Element–f-Block-Element NMR Spin–Spin Coupling

**Anna M. Dietel,[a] Oleg Tok,[a] and Rhett Kempe*[a]**

*Dedicated to Professor Bernd Wrackmeyer on the occasion of his 60th birthday*

**Keywords:** Amido ligands / Bimetallic complexes / Dynamic N ligands / NMR spectroscopy / Ytterbium

This is a report on the synthesis and structure of novel dinuclear $Yb^{II}$ complexes. In one of the described compounds, the two $Yb^{II}$ centres are in close proximity and chemically different. Thus, an f-block-element–f-block-element coupling pattern was observed. The low-field $^{171}Yb$ signal consists of a central singlet and two satellites with integral intensities of about 7 % each. This 14 % approximately corresponds to the natural abundance of the $^{171}Yb$ isotope and was assigned as a doublet arising from $^{1}J(^{171}Yb, ^{171}Yb)$ spin–spin coupling with a magnitude of 76.1 Hz. Furthermore, the relevance of such studies in understanding dimer equilibria and the rearrangement chemistry of rather bulky structural ensembles is discussed.

## Introduction

The last decade has seen a dramatic increase in the importance of the organometallic chemistry of lanthanide elements. Solution-state NMR, one of the organometallic chemist's most informative tools, has been applied infrequently to the direct observation of compounds of f-block elements. This omission is probably because the majority of the complexes (except those of $La^{III}$, $Yb^{II}$ and $Lu^{III}$) are paramagnetic, and many of the NMR-active f-block nuclei have large quadrupole moments. $^{171}Yb$ is a spin-1/2 nucleus, with a natural abundance of 14.31 % and a moderately sized, positive gyromagnetic ratio ($4.735 \times 10^7$ rad $T^{-1}$ $s^{-1}$); these features combine to give a receptivity about 4.5 times greater than that of $^{13}C$.[1] The first direct high-resolution NMR observation of an f-block element was reported by Lawless, Lappert, et al.[2] In principle, $^{171}Yb$–$^{171}Yb$ coupling should be observable as well. Dinuclear and polynuclear Yb complexes are a well-documented class of compounds. The metal centres in many of these complexes are close enough (3.5 Å was used as the upper limit)[3] to observe f-block-element–f-block-element spin–spin coupling. Complexes that meet this requirement can consist of $Yb^{III}$,[4] exhibit mixed oxidation states (II/III)[5] or might be diamagnetic due to the presence of $Yb^{II}$[6,7] ions only. Nonsymmetrical polynuclear $Yb^{II}$ complexes are rare,[6] and metal centres in different chemical environments are a prerequisite to observe $^{1}J(^{171}Yb,^{171}Yb)$ coupling. Furthermore, in systems undergoing dynamic processes such as bridge–terminal exchange or monomer–dimer equilibria, coupling constants will be time-averaged and thus may be unobservable.[1] On the other hand, $^{1}J(^{171}Yb,^{171}Yb)$ coupling patterns, if observed, could be a highly sensitive probe on the dynamic aspect of f-block-element–f-block-element interactions in solution, an area of chemistry difficult to access by other methods. We started recently a research program in which we used very bulky aminopyridinato ligands[8] in order to avoid ligand redistribution in low-valent and organolanthanide chemistry.[9] We report here on the synthesis and structure of a novel dinuclear $Yb^{II}$ complex in which the two $Yb^{II}$ centres are in close proximity and chemically different within the NMR time scale, as well as the $^{171}Yb$ NMR spectroscopy of this species.

## Results and Discussion

Bimetallic $Yb^{II}$ complexes should be accessible by the introduction of a sterically encumbered extension at an aminopyridinato ligand, which leads to bipyridylamide ligands, and the nonsymmetrical bulk could lead to homobimetallic complexes having $Yb^{II}$ in different chemical environments. The "simple" bipyridylamide ligand was already used successfully by Müller-Buschbaum to stabilise, for instance, multinuclear $Yb^{III}$ complexes.[10] The sterically demanding dipyridylamide ligand precursor **1** was synthesised by Pd-catalysed aryl amination (Scheme 1) in good yield.

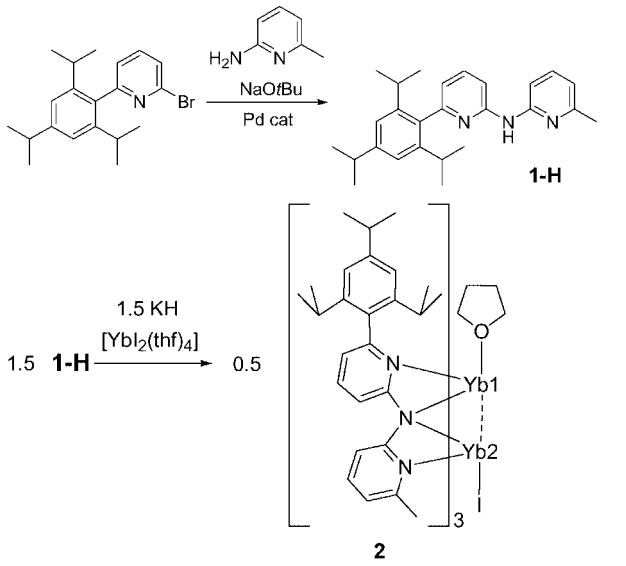

Scheme 1. Synthesis of **1** and **2**.

The reaction of **1-H** with KH and subsequent treatment with $[YbI_2(thf)_4]$[11] leads to the bimetallic complex **2** with a residual iodido ligand to guarantee asymmetry. The molecular structure of complex **2** (Figure 1) was investigated by X-ray crystal structure analysis[12] and NMR spectroscopy.

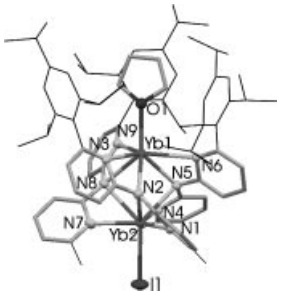

Figure 1. Molecular structure of **2** (ORTEP plot for all non-C,H-atoms). Substituents at the pyridine rings are plotted in wire frame style for clarity. Selected bond lengths [Å] and angles [°]: Yb1–Yb2 3.4200(3), N1–Yb2 2.469(3), N2–Yb1 2.538(3), N2–Yb2 2.640(3), N3–Yb1 2.611(3), N4–Yb2 2.476(3), N5–Yb1 2.568(3), N5–Yb2 2.578(3), N6–Yb1 2.681(3), N7–Yb2 2.451(4), N8–Yb1 2.604(3), N8–Yb2 2.622(3), N9–Yb1 2.613(3), O1–Yb1 2.431(3), I1–Yb2 3.0714(4); N5–Yb1–N6 52.19(10), N2–Yb1–N3 53.32(10), N8–Yb1–N9 52.55(10), N4–Yb2–N5 53.61(10), N7–Yb2–N8 53.58(10), N1–Yb2–N2 53.28(10).

The two $Yb^{II}$ ions in complex **2** are triply bridged by the amido N atoms of **1**, which results in a short metal–metal distance [3.4200(3) Å]. Shorter $Yb^{II}$–$Yb^{II}$ distances have been observed for carbon- and oxygen-bridged dimers.[5,6] The Yb–$N_{amido}$ bond lengths are indicative of two symmetric bridges (N5 and N8) and one nonsymmetrical (via N2) bridge. N2 seems to provide the anionic function of the amido ligand dominantly to Yb1, which is perfectly in accordance with the facts that the additional neutral ligand (thf) coordinates Yb1 and the anionic iodido ligand binds Yb2.

The bimetallic nature of complex **2** in solution was confirmed by $^{171}Yb$ NMR spectroscopy. In $C_6D_6$ there are two signals at 585.6 (broad, $\nu_{1/2}$ = 92.0 Hz) and 646.6 (sharp, $\nu_{1/2}$ = 8.5 Hz) ppm. The broad signal belongs to the Yb atom bonded directly to iodine, and the broadening arises from unresolved $^{171}Yb$–$^{127}I$ scalar coupling. The low-field signal consists of a central singlet and two satellites with an integral intensity of about 7% each. This 14% approximately corresponds to the natural abundance of the $^{171}Yb$ isotope and was assigned as a doublet arising from $^1J(^{171}Yb, ^{171}Yb)$ spin–spin coupling with a magnitude of 76.1 Hz. The chemical shift for $Yb^{II}$ amides ranges from $\delta(^{171}Yb)$ = 614 ppm to $\delta(^{171}Yb)$ = 1228 ppm, and the line width associated with $^{171}Yb$ resonances of these compounds ranges from $\Delta\nu_{1/2}$ = 70 Hz to $\Delta\nu_{1/2}$ = 550 Hz.[2] $^nJ(^{171}Yb,X)$ couplings have been observed for a variety of nuclei. Coupling constants usually cover a large range, for instance from 8627–9479 Hz (X = $^{119}Sn$) and 8254–9058 Hz (X = $^{117}Sn$),[13] 758 Hz (X = $^{125}Te$),[14] 233–265 Hz (X = $^{13}C$; resulting from alkyl carbon atoms)[15] up to 73 Hz (X = $^{31}P$).[16] Well-resolved $^3J(^{171}Yb,^{19}F)$ and $^4J(^{171}Yb,^{19}F)$ couplings have been recorded for perfluorophenyl ytterbium complexes. Coupling constants range from 13 to 48 Hz.[17]

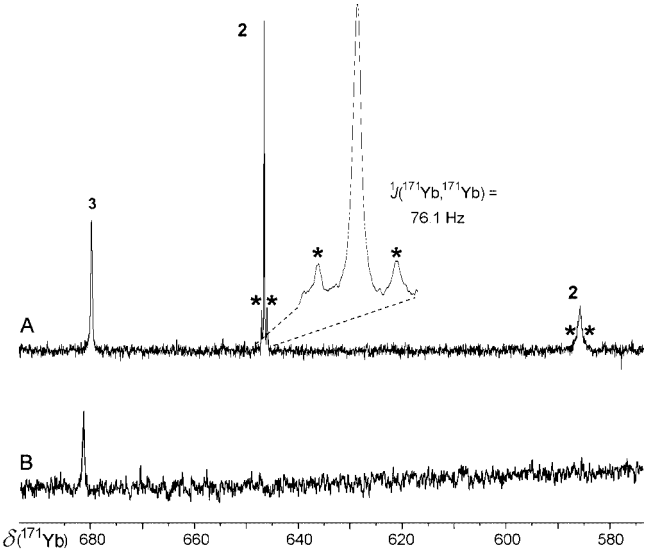

Figure 2. $^{171}Yb\{^1H\}$ NMR spectra (69.96 MHz, $[D_8]$thf) of complex **2** (A) and complex **3** (B).

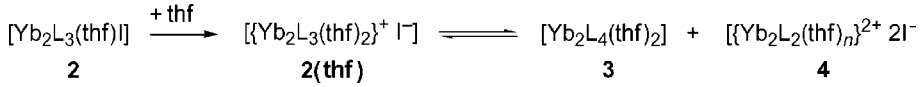
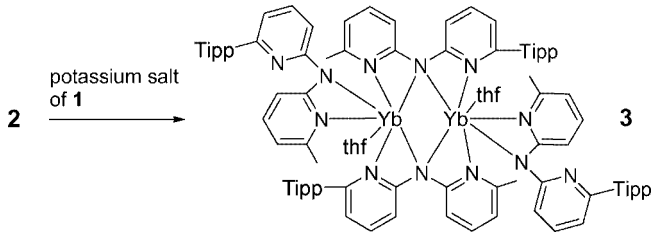


Scheme 2. Observed rearrangement reactions of **2** in thf (L = **1**).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Although complex **2** is stable in $C_6D_6$ for days, the $^{171}$Yb NMR spectrum in [$D_8$]thf solution consists of two already noted resonances ($\delta$ = 585.6 and 646.6 ppm) together with a third signal at $\delta$ = 679.8 ppm ($\nu_{1/2}$ = 25.5 Hz). In the $^1$H NMR spectrum at room temperature there is an additional set of broad signals. At low temperature (from 0 °C and lower), the signal set which belongs to the monoiodido complex **2** did not change, but the broad lines were more narrow and gave two sets (in a ratio of ca. 1:3) where the chemical shifts of the major set were completely identical to the $^1$H NMR spectrum of binuclear complex **3** (Scheme 2). In the $^{171}$Yb NMR spectrum of **3** in [$D_8$]thf, the signal at $\delta$ = 681.9 ppm was observed (Figure 2B). This value is very close to the chemical shift of the third signal in the spectrum presented in Figure 2A. Both $^1$H and $^{171}$Yb NMR spectroscopic data suggest that in thf solution complex **2** can dissociate to give cationic compound **2**(thf), where one coordination position is occupied by thf instead of iodine (Scheme 2). Complex **2**(thf) seems not to be stable and rearranges with the formation of neutral compound **3** and (most likely) dicationic **4**. The signal for complex **4** was not observed because of the low solubility of the complex (precipitation was observed).

In order to confirm the identity of complex **3**, it was independently synthesised by the reaction of **2** with the potassium salt of **1-H**, generated by treatment of **1-H** with KH (Scheme 3).



Scheme 3. Synthesis of **3** [Tipp = tri(isopropyl)phenyl].

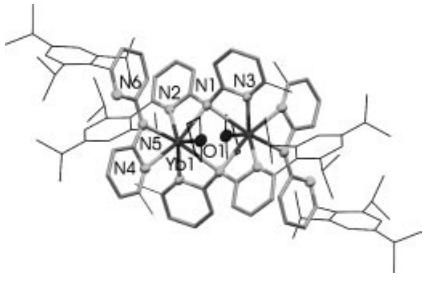


Figure 3. Molecular structure of **3** (ORTEP plot for all non-C,H-atoms). Substituents at the pyridine rings are plotted in wire frame style for clarity. Selected bond lengths [Å] and angles [°]: Yb1–O1 2.457(6); Yb1–N3 2.462(7), Yb1–N5 2.488(7), Yb1–N1 2.517(8), Yb1–N4 2.586(8), Yb1–N2 2.607(8), Yb1–N1′ 2.681(7), Yb1–Yb1′ 3.8685(11); N1–Yb1–N2 53.6(2), N3–Yb1–N1 53.0(2), N5–Yb1–N4 52.7(2).

The X-ray crystal structure analysis of **3** revealed[11] it to be a bimetallic complex in which two deprotonated bipyridylamide ligands act as tridentate bridging ligands and two of them as terminal bidentate aminopyridinates (Figure 3).

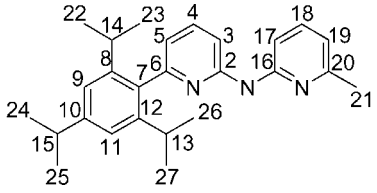
## Conclusion

We observed the first f-block-element–f-block-element coupling pattern in solution and have shown the relevance of such investigations in understanding dimer equilibria and rearrangement chemistry of rather bulky structural ensembles. Chemical transformations of low-valent lanthanide species has hitherto been difficult to follow.

## Experimental Section

**NMR Investigations:** The $^{171}$Yb NMR spectra were recorded by using a single-pulse sequence with pulse: approx. 30°, relaxation delay: 1 s, digital FID resolution: 0.3–0.5 Hz before zero filling and with proton decoupling during acquisition. The suitable signal-to-noise ratio was reached after 2–4 h. The chemical shifts are given relative to 0.171 M [Yb($\eta^5$-$C_5Me_5$)(thf)$_2$] in thf [$\delta$ ($^{171}$Yb) = 0 ppm for $\Xi$ ($^{171}$Yb) = 17.499306 MHz].

**Synthesis of Complex 2:**



In a glove box, [$YbI_2(thf)_4$][18] (2.13 g, 2.98 mmol) and 1.90 g (3.82 mmol) of **1-K** were combined in a flask and thf (100 mL) was added at 0 °C. The resulting dark red reaction mixture was stirred at room temperature for 16 h. After separation of the solution from the precipitated potassium iodide by filtration, the solvent was removed under reduced pressure. The resulting solid was dissolved in toluene (100 mL) and filtered. The filtrate was reduced to dryness, and a dark red-black product was obtained. Crystals of **2** were grown from a concentrated toluene solution. Yield 2.06 g (72%). M.p. 190 °C. $C_{82}H_{104}IN_9OYb_2{\cdot}3C_4H_8O$ (1921.06): calcd. C 58.77, H 6.72, N 6.56; found C 58.77, H 6.67, N 6.93. $^1$H NMR (250 MHz, $C_6D_6$, 323 K): $\delta$ = 0.67–1.24 (m, $^3J$ = 6.7 Hz, 54 H, 22-H, 23-H, 24-H, 25-H, 26-H, 27-H), 1.43 (br., 4 H, β-C$H_2$, thf), 2.38 (sept, $^3J$ = 6.9 Hz, 3 H, 15-H), 2.60 (sept, $^3J$ = 7.0 Hz, 3 H, 14-H), 2.66 (s, 9 H, 21-H), 2.78 (sept, $^3J$ = 6.7 Hz, 3 H, 13-H), 3.53 (br., 4 H, α-C$H_2$, thf), 6.00 (d, $^3J$ = 6.7 Hz, 3 H, 19-H), 6.16 (d, $^3J$ = 6.6 Hz, 3 H, H$^5$), 6.83–7.16 (m, 18 H, 3-H, 4-H, 9-H, 11-H, 17-H, 18-H) ppm. $^{13}$C NMR (62.9 MHz, $C_6D_6$, 298 K): $\delta$ = 24.0 (s, C-22, C-23, C-26, C-27), 24.1 (s, C-22, C-23, C-26, C-27), 24.2 (s, C-22, C-23, C-26, C-27), 24.3 (s, C-22, C-23, C-26, C-27), 26.1 (s, β-*C*H$_2$, thf), 26.8 (s, C-24, C-25), 27.1 (s, C-24, C-25), 29.8 (s, C-13, C-14), 30.0 (s, C-13, C-14), 34.6 (s, C-15), 67.7 (s, α-*C*H$_2$, thf), 109.5 (s, C-19), 113.4 (s, C-17), 114.5 (s, C-5), 116.2 (s, C-3), 121.0 (s, C-9, C-11), 135.8 (s, C-4), 137.5 (s, C-7, C-18), 137.6 (s, C-7, C-18), 146.9 (s, C-8, C-12), 147.1 (s, C-8, C-12), 148.5 (s, C-10), 156.8 (s, C-2, C-16), 157.4 (s, C-2, C-16), 164.2 (s, C-20), 169.1 (s, C-6) ppm. $^{171}$Yb NMR (70 MHz, $C_4H_8O$, 298 K): $\delta$ = 646.6 [s, $^1J$($^{171}$Yb, $^{171}$Yb) = 76.1 Hz, *Yb*-thf], 585.6 (br., *Yb*-I) ppm.

# Chiral Calix[4]arene-Based Diphosphites as Ligands in the Asymmetric Hydrogenation of Prochiral Olefins

**Angelica Marson,[a] Zoraida Freixa,[b] Paul C. J. Kamer,*[c] and Piet W. N. M. van Leeuwen*[a]**

**Keywords:** Homogeneous catalysis / Stereoselective catalysis / Asymmetric hydrogenation / Calixarenes / Diphosphites

Chiral calixarene-based diphosphite ligands **3a**–**d** have been obtained via lower-rim functionalisation of the *p*-*tert*-butylcalix[4]arene core. High enantiomeric excesses (up to 94 %) and good activities were obtained in the rhodium-catalyzed asymmetric hydrogenation of prochiral olefins with TADDOL-containing diphosphites **3c**,**d**. This is the first example of chiral calix[4]arene-modified ligands that induce high enantioselectivity in metal-catalysed asymmetric reactions.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Asymmetric reactions catalysed by transition metals are among the most efficient methods for preparing a wide range of enantiomerically pure compounds.[1] The tremendous achievements in organometallic chemistry have resulted in fundamental understanding of elementary steps and consequently in many examples of rational ligand design.[2] Still, the rates and selectivity of enzymatic catalysis are seldom equalled by transition metal catalysis. Chemical transformations catalyzed by enzymes often operate via complicated mechanisms and require large and sophisticated protein structures that have been obtained after millions of years of evolution. Although nowadays enzymes are applied successfully in many chemical conversions, their substrate specificity can be too high in certain cases and the biological reaction conditions might be not wanted. This is why the majority of industrial processes is based on man-made catalysts. Many attempts are being made to obtain efficient catalysts that can compete with enzymes in substrate-selectivity and activity, such as incorporation of transition metal complexes in proteins and antibodies.[3] To bridge the gap between enzyme and transition metal catalysts it is important to develop new catalyst systems that, mimicking enzymes, impose steric confinement on metal and substrates in addition to the well-explored ligand effects.

Calixarenes form a suitable scaffold for the development of new bulky and structurally well-defined ligands.[4] The combination of calixarene cavities with catalytic centres might lead to shape-selective catalysts, adding this successfully exploited feature of biological systems to transition metal catalysis. Although the number of successful applications of the shape selectivity of calixarene-based catalysts is growing,[5] high selectivities in asymmetric catalysis have not been achieved so far.[6]

From the different functionalities that one can consider, phosphite ligands proved their adequacy in many transition metal-catalysed reactions such as hydrogenation, hydroformylation, hydrocyanation and allylic alkylation.[2]

## Results and Discussion

Here we report on the asymmetric hydrogenation of prochiral olefins, as model reaction, using enantiopure calix[4],BINOL- and calix[4],TADDOL-containing diphosphites. The effective formation of a shape defined active site is achieved by directly attaching three of the hydroxy groups of the calix[4]arene through $\mu_3$-bridging phosphorus atom. In this way, these new C1-symmetric bidentate ligands, which combine the intrinsic steric bulk of the calix[4]arene scaffold with a stereocentre located on a phosphite pendent arm linked to the lower rim of the calix[4]-cavity, represent the first class of chiral calix[4]arene-modified ligands to be reported in literature and successfully applied in metal-catalysed asymmetric reactions. In order to gain information about the potential of such type of ligands, we carried out some preliminary investigations on two different types of

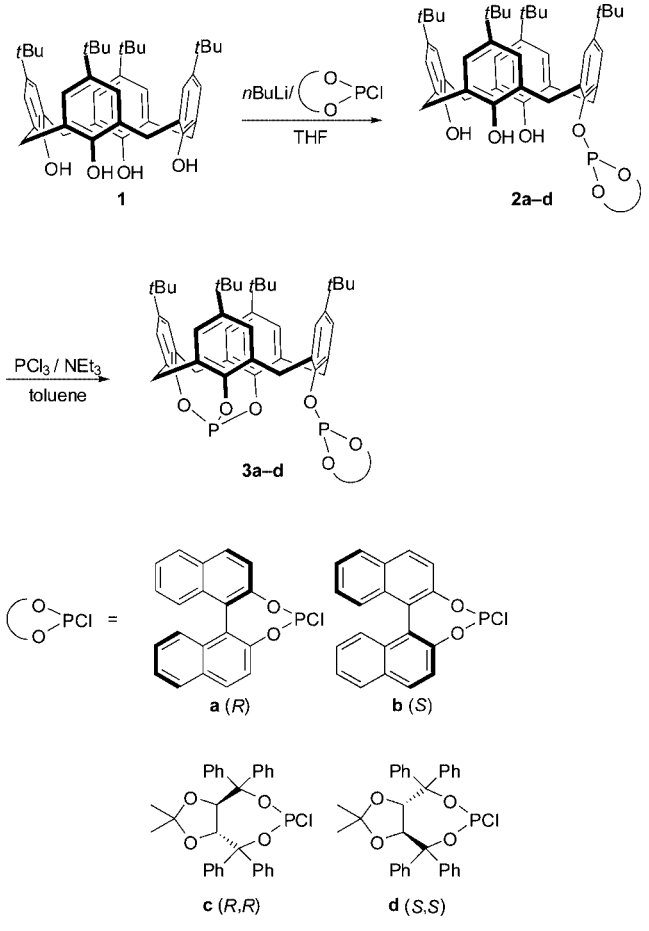
chiral moieties and by comparing the role of the stereocentre, we evaluated the efficacy of the ligand systems and their catalytic performances.

Chiral diphosphite ligands **3a**–**d** were prepared through a two-step synthesis according to reported calixarenes-phosphorylation procedures (Scheme 1).[5g] Since the sequence in which the two steps are followed is crucial in order to obtain diphosphites in the appropriate *cone* conformation,[5d,7] *p*-*tert*-butylcalix[4]arene **1** was firstly treated with one equivalent of *n*BuLi in THF at room temperature and then reacted with one equivalent of chiral phosphorochloridites (**a**–**d**),[8,9] affording the monofunctionalised calix[4]arene intermediates **2a**–**d**. In the present study, we focused our attention on chiral units derived from commercially available diols such as (*R*)- and (*S*)-BINOL [(*R*)-, (*S*)-2,2′-dihydroxy-1,1′-binaphthyl] and (*R*,*R*)- and (*S*,*S*)-TADDOL [(*R*,*R*)-, (*S*,*S*)-2,2-dimethyl-α,α,α′,α′-tetraphenyldioxolane-4,5-dimethanol] which allow an economically attractive preparative method of bidentate ligands and a fast and efficient preliminary investigation of the catalytic performances of the corresponding metal complexes.



Scheme 1. Synthesis of chiral calix[4]arene-based diphosphites **3a**–**d**.

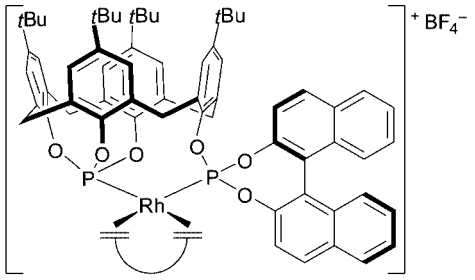
The first reaction step is not very selective towards monofunctionalisation and gives rise to the formation of by-products, like 1,3-disubstituted calix[4]arenes. We observed that the steric bulk of the phosphorochloridites strongly affects the product distribution. As expected, the more sterically hindered fragments (i.e. TADDOL-PCl **c**,**d**) afford mainly monofunctionalised products, while with the bare BINOL derivatives **a**,**b** the two fractions are obtained in a 1:1 ratio. Nevertheless, no further purification was carried out on the isolated crude products, which were treated in the second step with an excess of $PCl_3/NEt_3$ to give, after chromatographic separation, the pure chiral diphosphite products **3a**–**d**. Thus, the resulting calix[4],BINOL- (**3a**,**b**) and calix[4],TADDOL-based diphosphites **3c**,**d** are characterised by the presence of one phosphorus atom, acting as a triple $\mu_3$-*O*,*O*,*O* bridge, at the lower rim of the calix[4]-cavity and a second phosphorus atom on a pendent chiral unit.

The $^{31}P$ NMR spectra show in all cases two distinctive singlets for the two non-equivalent phosphite moieties of each ligand: one at $\delta$ = 104 ppm for the $\mu_3$-bridging phosphorus atom and one for the chiral fragment-containing phosphite ($\delta$ = 147 ppm for BINOL derivatives **3a**,**b**; $\delta$ = 140 ppm for TADDOL derivatives **3c**,**d** respectively). Both chemical shifts fall into the expected ranges for calix[4]-based $\mu_3$-bridging phosphites,[5d,5g] and for TADDOL- or BINOL-based phosphite ligands.[10] Also in the corresponding $^1H$ NMR spectra, ligands **3a**–**d** show similar spectroscopic features. The four *tert*-butyl signals and the four AB patterns for the bridging methylene units (Ar$CH_2$Ar), with AB separations larger than 1 ppm, clearly prove the $C_1$ symmetry of these structures and the overall *cone* conformation of the calix[4]arene backbone This geometry was further confirmed by the $^{13}C$ NMR spectra in which some of the signals for the Ar$CH_2$Ar fall into the expected range for *syn*-oriented phenolic neighbours (ca. 35–36 ppm), while others fall in an intermediate range of values (ca. 36–37 ppm).[5g,11] It should be recalled that, due to the strain imposed by the very short $\mu_3$-bridging phosphite unit, the observation of signals with an intermediate chemical shift might be interpreted in terms of partial flattening of the calixarene core.

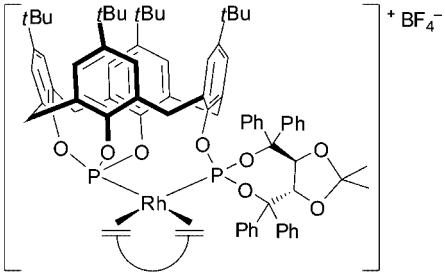
Investigations have been carried out to define the coordination chemistry of diphosphites **3a**,**d** and assess their chelating abilities towards square planar $Rh^I$ precursors. The complexation reaction of ligands **3a**,**c** with one equivalent of $[Rh(nbd)_2BF_4]$ (nbd = 2,5-norbornadiene) in dichloromethane solution proceeds rapidly. Displacement of one molecule of 2,5-norbornadiene occurs after 30 minutes at room temperature whilst stirring, affording complexes $[Rh(nbd)(P^1 \cap P^2)][BF_4]$ (**4a**,**c**). The corresponding $^{31}P$ NMR spectra showed two distinctive double doublets as a result of phosphorus–rhodium and phosphorus–phosphorus couplings [$^1J(Rh,P^1)$ = 274 Hz, $^1J(Rh,P^2)$ = 265 Hz and $^2J(P^1,P^2)$ = 83 Hz (**4a**); $^1J(Rh,P^1)$ = 265 Hz, $^1J(Rh,P^2)$ = 249 Hz and $^2J(P^1,P^2)$ = 81 (**4c**)].

The observed rhodium–phosphorus coupling constants are very similar to those reported for $[Rh(diolefin)(P^1 \cap P^2)]^+$ rhodium complexes with coordinated diphosphite ligands, while the coupling constants between the two non-equivalent phosphorus atoms are larger than expected.[12] Coupling constants between 27 and 50 Hz are generally observed

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



**4a**



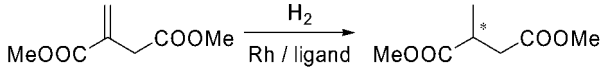
**4c**

between the two non-equivalent phosphorus atoms in relative *cis* positions. Lowering the temperature to 193 K did not result in any additional splitting of the $^{31}P$ NMR signals, which indicates that, for both rhodium complexes **4a**,**c**, only one isomer is present in solution. Clearly, this might represent an advantage in terms of enantioselectivity when these complexes are employed as catalysts in asymmetric transformations.

Chiral diphosphites **3a**–**d** were tested as ligands in the asymmetric rhodium-catalysed hydrogenation and of prochiral olefins using $[Rh(nbd)_2BF_4]$ as metal precursor. Catalytic experiments were run in a parallel manner using an autoclave equipped with 5, 8, or 15 mini-reactors (see Supporting Information for details). The catalyst precursors were formed in situ by mixing metal complexes with ligands **3a**–**d** under inert atmosphere. The autoclave was purged four times with hydrogen and then charged with the appropriate gas pressure.

The rhodium-catalysed hydrogenation, carried out under mild conditions (25 °C, 5 bar $H_2$), was examined as model reaction employing dimethyl itaconate (**A**) and α-(acylamino)acrylate (**B**) as representative substrates. Parallel experiments were run employing a standard substrate/rhodium ratio of 100 and using catalyst precursors formed in situ by mixing ligands **3a**,**c** with $[Rh(nbd)_2BF_4]$. The formation of the active species $[Rh(P^1 \cap P^2)(solvent)_2][BF_4]$, generated by removal of the diolefin, is generally faster when it involves the hydrogenation of the more reactive norbornadiene rather than that of cyclooctadiene.[13] Different outcomes have been observed, regarding both the activity and the selectivity of the catalytic process, depending on the nature of the substrate and of the diphosphite used.

The hydrogenation of dimethyl itaconate providing dimethyl methylsuccinate [**A**; Equation (1)], in dichloromethane, was chosen as the test reaction and the activity and the enantioselectivity of the catalyst precursors evaluated at different reaction conditions (Table 1). Initially the ligand to rhodium ratio was kept constant at 1.5 (entries 1 and 6), then the reaction time and the substrate/rhodium ratios were changed from 20 h to 4 h (entries 2 and 7) and from 100 to 1000 (entries 3 and 8), respectively.



**A** (1)

Table 1. Asymmetric hydrogenation of prochiral olefins with $[Rh(nbd)_2BF_4]$ and ligands **3a**–**d**.[a]

| Entry | Ligand | Substrate | % Conv. (*t* [h])[b] | % *ee* (config.)[c] |
|---|---|---|---|---|
| 1 | **3a** | **A** | 100 (20) | 74 (*R*) |
| 2 | **3a** | **A** | 100 (4) | 74 (*R*) |
| 3[d] | **3a** | **A** | 100 (4) | 76 (*R*) |
| 4[e] | **3a** | **A** | 60 (20) | 20 (*S*) |
| 5 | **3a** | **B** | 100 (20) | 32 (*R*) |
| 6 | **3c** | **A** | 100 (20) | 92 (*R*) |
| 7 | **3c** | **A** | 100 (4) | 92 (*R*) |
| 8[d] | **3c** | **A** | 100 (4) | 94 (*R*) |
| 9[f] | **3c** | **A** | 100 (20) | 92 (*R*) |
| 10 | **3c** | **B** | 100 (20) | 94 (*R*) |
| 11 | **3b** | **A** | 100 (20) | 75 (*S*) |
| 12 | **3d** | **A** | 100 (20) | 92 (*S*) |

[a] Standard conditions: [Rh] = 1 mM; [ligand]/[Rh] = 1.5; [substrate]/[Rh] = 100; solvent = $CH_2Cl_2$ (2.0 mL); $p$ = 5 bar; $T$ = 25 °C; catalyst precursors prepared in situ. [b] Percent conversion measured by GC. [c] Percent enantiomeric excess measured by chiral GC. [d] [substrate]/[Rh] = 1000. [e] Solvent: $CH_2Cl_2$/toluene, 1:3. [f] [ligand]/[Rh] = 5.

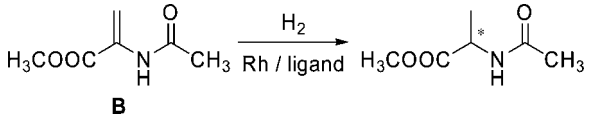
The results summarised in Table 1 show that the catalytic systems obtained with diphosphites **3a**,**c** are very active in the hydrogenation of dimethyl itaconate (**A**) and, although a standard reaction time of 20 h was chosen, complete conversion was already reached after 4 h. The increase of the ligand to rhodium ratio or the substrate to rhodium ratio does not have a negative effect on the activity of the reported catalytic systems, which still afford high enantioselectivities (*ee* up to 94%) and full conversions after 4 h reaction time. In one case (entry 4) the solvent of the reaction was changed to a mixture of dichloromethane/toluene (1:3) showing that the efficiency of the process depends strongly on the nature of solvent employed, and that the catalyst performance, both in terms of activity and enantioselectivity, was best when pure dichloromethane was used. Interestingly, opposite stereoinduction was observed in this case. It should be noted that rhodium-catalysed asymmetric hydrogenation reactions are commonly performed in methanol, but since phosphite ligands are known to decompose in protic solvents,[14] further hydrogenation reactions were studied using dichloromethane.

Ligand **3c**, which contains the bulky TADDOL moiety, affords the best catalyst, reaching enantioselectivities around 92% in all experiments. The results obtained with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ligand **3a** follow the same trend as observed for ligand **3c**, but the enantioselectivities are somewhat lower. As it would be expected by less bulky ligands, the asymmetric inductions with precursors containing ligand **3a** are lower than those with ligand **3c**. Besides ligands **3a**,**c**, which were used extensively in these catalytic investigations, their enantiomers, namely ligands **3b**,**d**, were also employed in analogous hydrogenation experiments showing, as expected, identical results but with opposite stereoinduction (entries 11,12).

We also studied the hydrogenation of α-(acylamino)acrylates [Equation (2)] under standard reaction conditions. Hydrogenation of methyl α-acetamidoacrylate [**B**; Equation (2)] giving the alanine derivative afforded high enantioselectivity (*ee* = 94%) with ligand **3c**, while a low value of 32% was obtained with ligand **3a**. In both cases complete conversion was reached after 20 h reaction time (entries 5,10).



(2)

In general, the catalytic systems obtained with calix[4]-arene-based diphosphites **3a**–**d** were found to be comparable, in terms of performances, to the diphosphites previously reported in literature by Reetz et al. and by Claver et al., leading to excellent activities and high enantioselectivities in the hydrogenation of dimethyl itaconate and methyl α-acetamidoacrylate.[10a,12,15]

## Conclusions

We have synthesized novel chiral diphosphite ligands built up on calix[4]arene backbones and characterised by a $C_1$ symmetry. We employed these ligands in the rhodium-catalysed hydrogenation of prochiral olefins, reaching excellent activities and enantioselectivities in the hydrogenation of dimethyl itaconate and methyl α-acetamidoacrylate. The best enantioselectivities have been obtained for both substrates with the same, most bulky, ligand. These preliminary investigations demonstrated for the first time that calix[4]-arene-based $C_1$-symmetric diphosphites can be successfully applied in metal-catalysed asymmetric transformations. Due to their ease of preparation, different classes of chiral bidentates can be generated, for example, by systematic variation of the steric and electronic properties of the stereocentre linked to the lower rim of the calix[4]-cavity. Thus, the results reported herein have to be considered as an important starting point and further study of this promising type of ligands in homogeneous catalysis is in progress.

## Experimental Section

Experimental details for all compounds and procedures are given in the Supporting Information.

# Self-Assembled 1D Water Cluster in a Supramolecular Architecture of $Co^{II}$(Tartrate)(Phenanthroline/Bipyridine): An Assessment of Magnetic Property

**Subal Chandra Manna,[a] Ennio Zangrando,[b] Joan Ribas,*[c] and Nirmalendu Ray Chaudhuri*[a]**

**Keywords:** Cobalt(II) / Tartrate / Magnetic properties / Water cluster

The coordination polymer, $\{[Co(tart)(phen)]\cdot 6H_2O\}_n$ (**1**) (tart, tartrate dianion; phen, 1,10-phenanthroline) has been synthesized and characterized by single-crystal X-ray structure determination, magnetic measurement and thermal analysis. The structural analyses reveal two adjacent parallel 1D –[Co(phen)-tart-Co(phen)]– coordination polymers zipped through π-π interactions. The lattice water molecules, forming a 1D water cluster, function as glue to form a 3D supramolecular network through an extended hydrogen bonding. A comparison highlighting the structural differences with the corresponding 2,2′-bipyridine (bpy) derivative, $\{[Co(tart)(bpy)]\cdot 5H_2O\}_n$ (**2**) containing a less amount of lattice water molecules is discussed. The variable-temperature magnetic study of **1** has been carried out and interpretation of the already reported complex **2** has been re-visited: both polymers **1** and **2** show weak antiferromagnetic interaction.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

For the unusual properties and fundamental importance manifested in many biological and physico-chemical processes, water and hydrogen bonds have received considerable attention in current research.[1] The environment designed by the crystal host stabilizes various topologies of water clusters and plays an important role in the formation of different water morphology.[2] The structural study sometimes supported by theoretical and experimental research on such "discrete" water clusters is of great importance for the understanding of the behavior of bulk water or ice.[3] Recently, a number of papers describing the cooperative association of water molecules to form a variety of oligomers and clusters,[4,5] sometimes connected to form one dimensional,[6] layered aggregates,[7] and 3D "ice-like" open frameworks,[8] have been published. However, the study of larger water aggregates, which represent the bridge between cluster and bulk water, is still a challenging scientific endeavor.[9]

Here we report on the synthesis, X-ray crystal structure, and thermal study of a 3D supramolecular architecture, $\{[Co(tart)(phen)]\cdot 6H_2O\}_n$ (**1**) (tart, tartrate dianion; phen, 1,10-phenanthroline). The structural data are compared with analogous 2,2′-bipyridine (bpy) derivative, $\{[Co(tart)(bpy)]\cdot 5H_2O\}_n$ (**2**).[10] The magnetic behavior of **1** is also reported which questions the reliability of the corresponding data of **2**, demanding the re-magnetic measurement of **2**.

## Results and Discussion

X-ray crystal structure analysis reveals that complex **1** consists of 1D polymeric chains, elongated along axis *a*, having Co(phen) units doubly chelated by tartrate dianion. The dianion acts as $\eta^4\mu$-tetradentate ligand through hydroxyl and carboxyl oxygen atoms and assumes a conformation as indicated by the torsion angle in the carbon atom skeleton of –151.13(18)°. The octahedral cobalt ligand arrangement is severely distorted with bond angles considerably deviating from ideal values (Table 1). The Co–N bond lengths average to 2.124(2) Å, and the Co–O(carboxylate) bond lengths, located in *trans* position to nitrogen atoms [2.058(2) and 2.047(2) Å], are slightly shorter than the others involving hydroxyl groups, of 2.163(2) and 2.172(2) Å. The polymers are arranged in pairs zipped by π-π interactions between phen aromatic rings with distances between ring centroids of 3.623(2) and 3.547(2) Å (Figure 1). The complex **1** is isomorphous and isostructural with the $Mn^{II}$ and $Cu^{II}$ derivatives.[11,12]

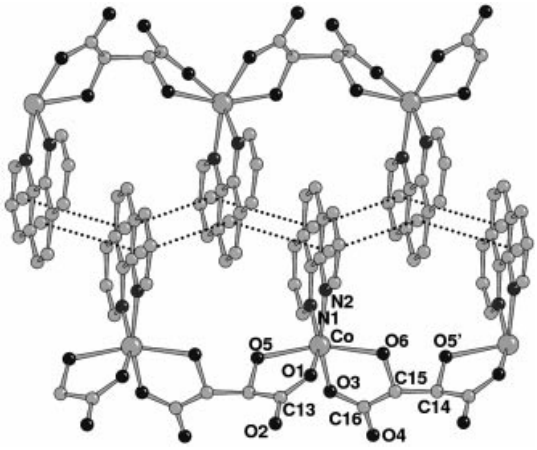

Figure 1. Coordination polymeric chains zipped by π-π interactions in **1**.

The complex {[Co(tart)(bpy)]·5H$_2$O}$_n$ (**2**), containing a smaller amount of guest water molecules, is isostructural to **1** and has been reported recently.[10] However, subtle differences are apparent between the two structures. The intrachain Co–Co distances in **1** and **2** are comparable within 2–3σ [6.617(3) vs. 6.629(1) Å, respectively], but the shortest metal–metal separation between coupled chains in **1** is 8.870 Å, significantly larger than the value of 7.507 Å measured in the bpy analogue (**2**).[10] This feature is ascribed due to the less bulky bpy which lacks the ethylene bridge and allows a better interdigitation between adjacent 1D chains.

The six crystallographically independent lattice water molecules, held together by hydrogen bonds with an ordered proton arrangement form a cluster sitting between the pairs of 1D coordination chains (Figure 2).

The water network consists of tetramers [O(3w–6w)] connected through the O(6w)–H···O(3w) hydrogen bond. In addition, two water molecules [O(2w) and O(1w)] are appended in sequence to the rhomboid structural motif at O(6w). The ΔFourier map allows to detect all the water hydrogen atoms and O(2w), O(3w), and O(6w) show a tetrahedral environment, as these behave as double donors and acceptors. This feature is evident for O(6w) from Figure 2, while the tetrahedral geometry about molecules O(2w) and O(3w) is completed, respectively, through the donor properties towards O(1), O(3), and O(2) of the tartrate dianion (Table 1S). The dicarboxylate provides potential hydrogen bonding intermolecular interactions, beside its coordination ability towards metal ions.

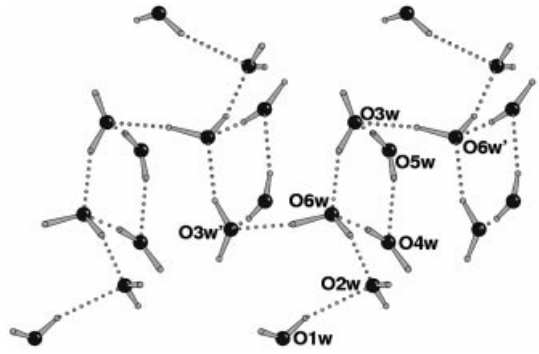

Figure 2. View of the hydrogen-bonding motif of the water molecules in **1**.

The H-bonds between the water cluster and the tartrate oxygen atoms build up a supramolecular 3D network. The O···O distances of hydrogen bonds engaging water molecules as H donor average to 2.79 Å, while those involving the hydroxyl tartrate oxygen (mean 2.62 Å) indicate slightly stronger interactions.

On the other hand, it is worth to note that the water molecules in {[Co(tart)(bpy)]·5H$_2$O}$_n$ (**2**) form a totally different 1D sequence containing cyclic pentamers sharing a side with an appended dimer.[10] Thus, in complex **1** the water molecules are structured by the cobalt polymers and the crystal structure may simulate the interactions occurring between the polymer and the water in a ca. 9 M frozen concentrated solution. Interestingly, among the numerous water networks reported in the literature,[4–8] complex **1** as well as **2**,[10] Mn$^{II}$ and Cu$^{II}$ derivatives[11–12] represent examples where the structured water molecules are not involved in any weak or strong direct interaction with the metal ion.

Thermal analysis reveals that complexes start dehydration at about 35 °C and lose all the lattice water molecules in a number of steps overlapping to each other. The deaquated species collapses immediately upon deaquation at about 150 °C.

The temperature-dependent magnetic susceptibility measurement[13] for **1** has been carried out on a polycrystalline sample in the temperature range 2–300 K. The $\chi_M T$ vs. $T$ plot for **1** ($\chi_M$ is the molar magnetic susceptibility for one Co$^{II}$ ion) is shown in Figure 3. $\chi_M T$ value at 300 K is 3.6 cm$^3$ mol$^{-1}$ K which progressively decreases up to 2.05 cm$^3$ mol$^{-1}$ K at 2 K.

Based on the reasoning already reported by us[14] relating to the calculation of an estimated $J$ value, we have used the two-exponential Rueff expression,[15,16] $\chi_M T = A \exp(-E_1/kT) + B \exp(-E_2/kT)$ {$A + B$ equals the Curie constant [about 2.8–3.4 cm$^3$ mol$^{-1}$ K for octahedral cobalt(II) ions], and $E_1$, $E_2$ represent the "activation energies" corresponding to the spin-orbit coupling and the antiferromagnetic exchange interaction}, which is suitable for any temperature greater than the possible $T_c$. The best-fit values obtained

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

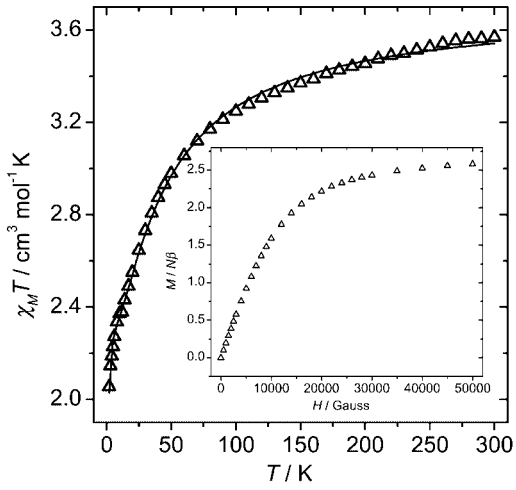

Figure 3. Top: $\chi_M T$ vs. $T$ plot for complex **1** (solid line represents the best fit). Inset: plot of the reduced magnetization ($M/N\beta$) vs. $H$ at 2 K for **1**.

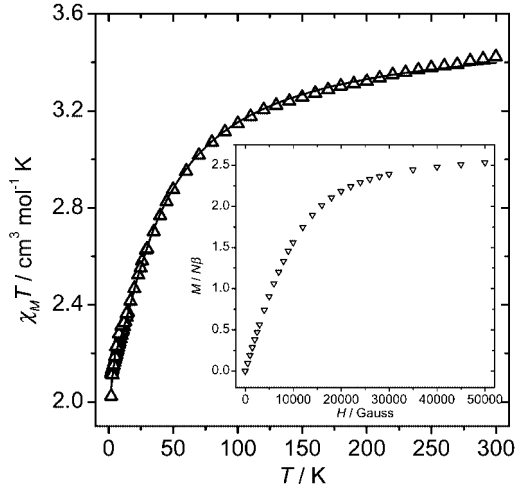

Figure 4. $\chi_M T$ vs. $T$ plot for complex **2** (solid line represents the best fit). Inset: plot of the reduced magnetization ($M/N\beta$) vs. $H$ at 2 K for **2**.

with this procedure are: $A + B = 3.41$ cm$^3$ mol$^{-1}$ K, in perfect agreement with those given in the literature for the Curie constant ($C \approx 2.8$–$3.4$ cm$^3$ mol$^{-1}$ K),[15,16] $E_1/k = 42.32$ K which is of the same magnitude to those reported by Rueff *et al* for several one- and two-dimensional cobalt(II) complexes.[16] As far as the antiferromagnetic exchange interaction, the value found is very weak ($E_2/k = 0.35$ K), corresponding to $J = -0.70$ K ($= -0.50$ cm$^{-1}$), according to the Ising chain approximation, $\chi_M T \propto \exp(J/2kT)$. The small $J$ value is compatible with the two possible exchange pathways between Co atoms. One is across the saturated dicarboxylate {with the long bridging spacer [O(6)–O(5) distance of 2.76 Å, O(6)–C(15)–C(14)–O(5′) torsion angle of –38.8°]} which should be a very weak exchange interaction. The other exchange pathway is through the π-π stacking of the phenanthroline ring, which is very weak in this system. The small $J$ value agrees with those reported by Coronado et al. for a series of Co$^{II}$ (as well as Mn$^{II}$, Fe$^{II}$, and Ni$^{II}$) complexes with tartrate as ligand.[17] The reduced magnetization curve, $M/N\beta$, at 2 K tends to $2.5N\beta$ at 5 T (Figure 3, inset) in perfect agreement with the values reported for isolated or quasi-isolated cobalt(II) ions.[15] Interestingly, Lu et al. reported a ferromagnetic interaction for the bpy derivative **2**.[10]

After going through the magnetic result we have identified a wrong interpretation in fitting the magnetic data of **2** (assuming that there is no spin-orbit coupling). Thereby we have repeated the synthesis and structural characterization of complex **2**. The structural results match those already reported,[10] but the magnetic results (Figure 4) follow those of complex **1**. Corresponding fitting parameters are $A + B = 3.43$, $E_1/k = 36.97$ K, $E_2/k = 0.21$ K, $J = -0.42$ K ($= -0.30$ cm$^{-1}$). The $J$ value for **1** and **2** are almost equal based on the accuracy of the fitting method. Thus the $J$ value is weak and equally antiferromagnetic for the two complexes as expected.

## Conclusions

We have presented here the synthesis, crystal structure, magnetic behavior and thermal study of Co$^{II}$(tart)(phen/bpy) complexes having a well resolved water chain, which acts as glue in stabilizing the host chains and gives origin to a 3D supramolecular architecture. In phen derivative the water chain consists of cyclic tetramers with appended water dimers whereas in bpy derivative there is totally different 1D sequence containing cyclic pentamer sharing a side with an appended dimer. Thus, the study provides an example of a differently structured water cluster realized by modulating the size of the metal-organic framework. Both complexes show similar weak antiferromagnetic interaction, in agreement with structures.

## Experimental Section

**Complex 1:** Single crystals of **1** were obtained by diffusing an aqueous solution (5 mL) of cobalt nitrate hexahydrate (0.291 g, 1 mmol) on a water/methanol (1:2) layer (15 mL) of disodium tartrate (0.150 g, 1 mmol) and phen (0.198 g, 1 mmol) mixture in a corked tube. The red colored single crystals were deposited at the junction of the two solutions after a few weeks, yield 74%, 0.366 g. $C_{16}H_{24}CoN_2O_{12}$ (495.30): calcd. C 38.76, H 4.84, N 5.65; found C 39.23, H 4.51, N 5.92. IR: $\tilde{\nu}$ = 3480–3030 (vs), 2868 (s), 2720 (s), 1618 (vs), 1518 (s), 1426 (s), 1361 (vs), 1294 (s), 1224 (w), 1126 (s), 1069 (w), 997 (vw), 924 (vw), 850 (s), 820 (s), 726 (vs), 642 (vw), 526 (vw) cm$^{-1}$.

**Complex 2:** Preparation by adopting the same procedure as described for **1**; bpy (0.156 g, 1 mmol) instead of phen, yield 70%, 0.317 g. $C_{14}H_{22}CoN_2O_{11}$ (453.27): calcd. C 37.06, H 4.85, N 6.18; found C 37.62, H 4.66, N 6.34. IR: $\tilde{\nu}$ = 3470–3050 (vs), 1640 (vs), 1605 (vs), 1474 (s), 1447 (s), 1363 (vs), 1313 (s), 1232 (w), 1176 (w), 1129 (s), 1057 (s), 1025 (w), 885 (w), 825 (w), 775 (w), 729 (w), 648 (vw) 532 (vs) cm$^{-1}$.

**X-ray Diffraction Studies:** Diffraction data of **1** were collected at room temperature on a Nonius DIP-1030H system, equipped with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) graphite-monochromatized. Cell refinement, indexing and scaling of the data set were carried out using programs Denzo[18] and Scalepack[18] The structure was solved by Patterson and Fourier analyses[19] and refined by the full-matrix least-squares method based on $F_2$ with all observed reflections.[19] The H atoms of water molecules were located on the ΔFourier map, others at geometrically calculated positions. All the calculations were carried out using program WinGX system, Ver 1.70.01.[20]

CCDC-632709 contains the supplementary crystallographic data for **1**. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystal Data for 1:** $C_{16}H_{24}CoN_2O_{12}$, $M$ = 495.30, orthorhombic, space group $P2_12_12_1$, $a$ = 6.617(3), $b$ = 15.313(3), $c$ = 20.110(4) Å, $V$ = 2037.7(11) Å$^3$, $Z$ = 4, $D_c$ = 1.615 g/cm$^3$, $\mu$(Mo-$K_\alpha$) = 0.910 mm$^{-1}$, $F$(000) = 1028, $\theta$ range = 2.66–29.65°. Final $R1$ = 0.0344, $wR2$ = 0.0871, $S$ = 0.970 for 323 parameters and 22937 collected reflections, 5526 unique [$R$(int.) = 0.0400], of which 4614 with $I > 2\sigma(I)$, absolute structure parameter = 0.002(14), max. positive and negative peaks in the $\Delta F$ map: 0.299 and –0.326 e Å$^{-3}$.

Three 1,1′-disubstituted 4,4′-bi-1*H*-1,2,3-triazols [R-bta; R = Bn (**1**), Ph (**2**), $CH_2COOH$ (**3**)] have been synthesised as bidentate, nitrogen-based ligands by a $Cu^I$-catalysed "click" reaction between 1,3-butadiyne and organic azides. Their ligand properties were investigated by preparation of the complexes $[Ru^{II}(R\text{-bta})_3]Cl_2$ [R = Bn (**4**), Ph (**5**), $CH_2COOH$ (**6**)], $[(Bn\text{-bta})Cu^I(DPEPhos)]$ (**7**) [DPEPhos = bis{2-(diphenylphosphanyl)phenyl} ether] and $[(Bn\text{-bta})Re^I(CO)_3Cl]$ (**8**) following standard reaction procedures. All compounds were analysed by elemental analysis, mass spectrometry and NMR, IR, UV/Vis and luminescence spectroscopy. In addition, the molecular structures of **1**–**4**, **7**, and **8** have been determined by X-ray crystallography. In all complexes the Bn-bta acts as a bidentate ligand with structural features comparable to the analogous 2,2′-bipyridine complexes. In their electronic absorption spectra the $Ru^{II}$ and $Re^I$ complexes exhibit a lowest energy band at around 300 nm, which is substantially higher in energy than in analogous complexes with bpy ligands. All R-bta ligands yield complexes that are not luminescent in solution or in the solid state, which makes these ligands particularly suited for use as spectator ligands.

## Introduction

A large number of transition metal complexes based on the 2,2′-bipyridine (bpy) ligand and its derivatives have been investigated in different fields of chemistry due to their high stability and remarkable (electro)chemical and photophysical properties. More than 4200 entries were found in the Cambridge Structural Database when searching for complexes with byp (February 2007). There have been many reports about the application of these metal complexes in opto-electronic devices, as redox- and photo-catalysts, as building blocks of supramolecular structures and for medical and analytical purposes.[1–4] Prominent examples are $[Ru(bpy)_3]^{2+}$ and related octahedral $d^6$ transition metal complexes, which are frequently employed in studies that take advantage of the properties of their excited state, such as in photochemistry, chemoluminescence, electro-chemoluminescence and electron-transfer chemistry.[5–8]

New chromophoric ligands that are capable of generating emissions in the blue region of the spectrum are in demand due to the rapid development of OLED (organic light emitting device) technology. It has been shown that the emission energy increases with decreasing size of the chromophoric π-system, and this strategy has been successfully applied by Thompson et al. in the case of cyclometallated $Ir^{III}$ complexes, where replacement of the pyridine moiety by the five-membered ring of a pyrazolyl group led to a hypsochromic shift of the emission wavelength.[9] Chelating ligands with high energy electronic states are also useful as auxiliary, ancillary, spectator or innocent ligands in light-emitting complexes.[10] De Cola et al. recently reported a blue light emitting heteroleptic $Ir^{III}$ complex ($\lambda_{max}$ = 461 nm), where the anionic 1,2,4-triazolyl ligand (Figure 1) does not participate directly in the electronic transition.[11–13]

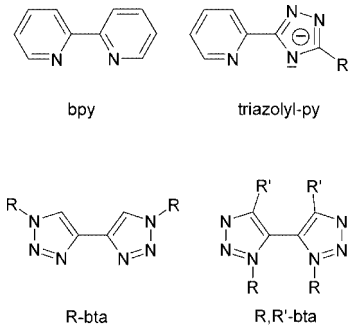

Figure 1. Bpy and triazolyl-py, R-bta and R,R′-bta ligands.

1,1′-$R_2$-4,4′-Bi(1,2,3-triazole) ligands (R-bta, R = organic group) seem to be promising alternatives to bipyr-

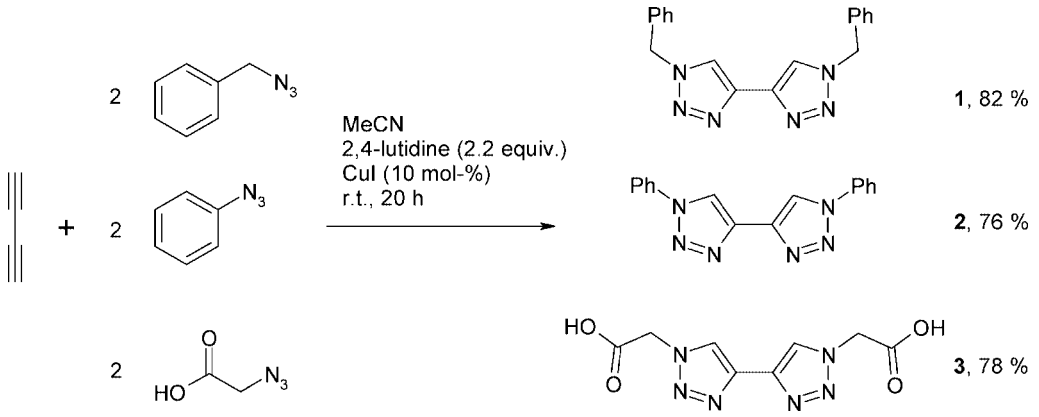

Scheme 1. Synthesis of the bitriazoles **1**–**3**.

idine ligands in transition metal complexes (Figure 1). In addition, functionalisation with a wide range of different substituents is possible using the "click chemistry" approach for the preparation of novel R-bta ligands.[14] Compared to bpy, where substitution with certain organic groups is usually cumbersome,[4,15] this may facilitate ligand preparation significantly. CuAAC (copper-catalysed azide-alkyne cycloaddition) has been used recently to synthesise 1,4-disubstituted 1,2,3-triazole ligands,[16] and the oxidative coupling products R,R′-bta (Figure 1) have been observed as major products under basic conditions in the CuAAC.[17]

Complexes of $Ru^{II}$, $Re^{I}$ and $Cu^{I}$ have been synthesised to evaluate the ligand properties of R-bta and the spectroscopic behaviour of these ligands and complexes investigated by UV/Vis and luminescence spectroscopy.

## Results and Discussion

### Synthesis of Triazole Ligands

The desired R-bta ligands **1**–**3** were synthesised by a $Cu^{I}$-catalysed cycloaddition between 1,3-butadiyne and the organic azides (benzyl azide, phenyl azide[14] and β-azidoacetic acid). The 1,3-butadiyne was freshly prepared from 1,4-dichlorobutyne[18] and treated immediately with the azide compound in basic acetonitrile solution in the presence of a catalytic amount of copper iodide (Scheme 1). Workup with aqueous $H_2O_2$ (3%) and saturated aqueous EDTA was necessary to remove the $Cu^{I}$ salt as it could form a complex with the synthesised R-bta ligands. Compounds **1**–**3** were obtained in acceptable yields as colourless powders after purification. All compounds are sparingly soluble in most organic solvents and insoluble in water.

### Spectroscopic Characterisation

The spectroscopic properties of compounds **1**–**3** were investigated by UV/Vis and luminescence spectroscopy. The compounds absorb in the UV region between 220 and 260 nm (Figure 11, Figures S3 and S4 in the Supporting Information). Compound **3** shows a very weak emission signal at 414 nm ($\lambda_{ex}$ = 267 nm) in the luminescence spectrum.

### Structural Studies

All free ligands were structurally characterised by single-crystal X-ray experiments. Ligand **1** crystallises in two different modifications, namely prisms (monoclinic space group $P2_1/c$, with two molecules in the unit cell) and needles (monoclinic space group *Cc*, with four molecules in the unit cell). Whereas the prisms crystallise as the more stable form from most organic solvents used (e.g. $CH_2Cl_2$, $CHCl_3$, MeCN), needles are obtained as the major fraction only by slow crystallisation from methanol. Because each of the equivalent molecules in crystals of the first modification of **1** has an inversion centre, the asymmetric unit contains only one half of the formula unit (Figure 2). The individual molecules in the latter modification show no crystallographically imposed symmetry, but they approach closely the symmetry of the molecules in the prismatic crystal (Figure 3).

per asymmetric unit. This means that there are two independent molecules present, one of which is centrosymmetric and the other roughly $C_2$-symmetric (Figure 4). Crystals of compound **3** are monoclinic (space group $P2_1/c$ with two molecules in the unit cell). Again, the molecules in crystals of compound **3** are centrosymmetric and the asymmetric unit consists of one half of the formula unit (Figure 5). The carboxylate proton exhibits an intermolecular hydrogen bond with the N3 atom of a neighbouring molecule to form helices [*d*(O1–H) 0.80(6), *d*(H–N3) 1.88(6), *d*(O1–N3) 2.670(4) Å; ∠(O1–H–N3) 171(4)°; Figure 6]. Each discrete helical subunit is connected to two others by the second carboxylate group of the molecule to yield a layered structure of interconnected helices (Figure S1).

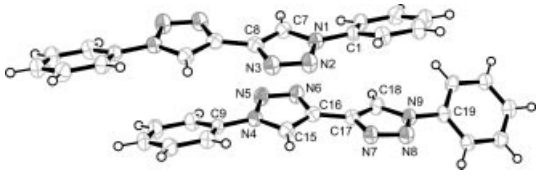

Figure 4. Structure of the two independent molecules in crystals of compound **2**. Selected bond lengths [Å], angles [°] and torsion angles [°]: C8–C8′ 1.452(2), N1–N2 1.357(3), N2–N3 1.310(3), N3–C8 1.365(4), C7–C8 1.372(4), N4–N5 1.358(3), N5–N6 1.312(3), N6–C16 1.368(4), C15–C16 1.372(4), C16–C17 1.449(4), C17–C18 1.374(4), C17–N7 1.368(4), N7–N8 1.310(3), N8–N9 1.362(3); N2–N1–C7 110.5(2), N1–N2–N3 107.4(2), N2–N3–C8 108.7(2), N1–C7–C8 105.1(2), N3–C8–C7 108.3(2), C7–C8–C8′ 129.6(2), N5–N4–C15 110.6(2), N4–N5–N6 107.3(2), N5–N6–C16 108.9(2), N4–C15–C16 105.0(2), N6–C16–C15 108.3(2), N8–N7–C17 108.9(2), N7–N8–N9 107.3(2), N8–N9–C18 110.4(2), N7–C17–C18 108.1(2), C15–C16–C17 130.5(2), C16–C17–C18 129.7(2), C17–C18–N9 105.3(2); N3–C8–C8′–N3′ 180.0(2), N6–C16–C17–N7 173.3(2).

The bitriazole units of molecules **1**–**3** are planar with an (*E*)-configuration of the 3,3′-N atoms. This configuration is also found in all solid-state structures of the free ligand 2,2′-bipyridine.[19] All bond lengths and angles of the triazole moiety lie in a very narrow range and are comparable to those of previously published structures of 1,2,3-triazole compounds.[20] The C–C bonds between the triazole groups have lengths of between 1.449 and 1.466 Å and are therefore shorter than the analogous bond in 2,2′-bipyridine [1.4881(13) Å] (Table 1).[19]

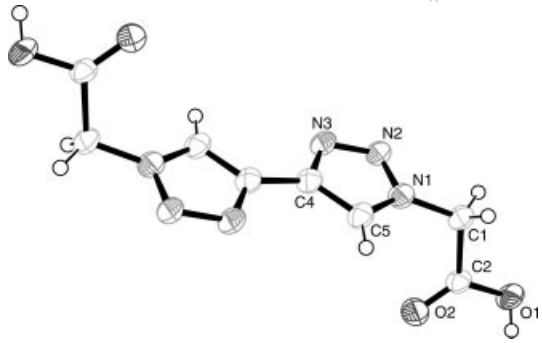

Figure 5. Molecular structure of compound **3**. Selected bond lengths [Å], angles [°] and torsion angles [°]: N1–N2 1.339(4), N2–N3 1.328(5), N3–C4 1.359(5), N1–C5 1.345(5), C4–C4′ 1.446(5), C4–C5 1.377(5); N1–N2–N3 106.1(3), N2–N3–C4 109.5(3), N3–C4–C5 107.9(3), C4–C5–N1 104.6(3), N2–N1–C5 112.0(3), C4′–C4–C5 130.0(3); N3–C4–C4′–N3′ 180.0(4).

## Synthesis of Complexes

The synthesis of homoleptic $Ru^{II}$ complexes of ligands **1**–**3** was carried out with $RuCl_3 \cdot 4H_2O$ in boiling ethylene glycol solution. Precipitation of complexes **4**–**6** was provoked by addition of ethanol or diethyl ether (Scheme 2).

The synthesis of a heteroleptic $Cu^{I}$ complex (**7**) was performed with ligand **1**, bis[2-(diphenylphosphanyl)phenyl] ether (DPEPhos) and $[Cu^{I}(NCMe)_4]PF_6$ (Scheme 3). The DPEPhos ligand was chosen as related heteroleptic $Cu^{I}$ complexes with a 1,10-phenanthroline (phen) ligand show high quantum yields.[21] The colourless crystals of this complex are only modestly soluble in polar organic solvents. Complex **7** is perfectly stable in solution and the solid state in air at room temperature; no oxidation to $Cu^{II}$ occurs.

The heteroleptic carbonylrhenium(I) complex **8** was obtained from ligand **1** and $[Re^{I}(CO)_5]Cl$, after reaction in toluene and recrystallisation from $MeCN/Et_2O$, as colourless crystals in almost quantitative yield (Scheme 4). This complex is modestly soluble in hot MeCN and, as is the case for its bpy and phen analogs, it is stable in solution and the solid state in air.

## Structural Studies

Recrystallisation from ethylene glycol/ethanol or MeCN/$Et_2O$ yielded complexes **4**–**6** as light yellow crystals, although only the crystals of complex **4** were of sufficient, though still low, quality for an X-ray structure refinement (Figure 7). The quality of the structural data is less accurate because crystals of **4** contain an unspecified number and type of solvent molecules (Figure S2 in the Supporting Information). Complex **4** crystallises in the monoclinic space group $P2_1/a$ with four molecules in the unit cell. The $Ru^{II}$ atom shows a distorted octahedral coordination geometry with both the Λ and Δ enantiomers present in the unit cell. The benzyl substituents have a random orientation and do not approach a symmetrical pattern. The average Ru–N distances of the cations in **4** [*d*(Ru–N) 2.05(3) Å] and $[Ru(bpy)_3]^{2+}$ [*d*(Ru–N) 2.056(2) Å] are roughly the same within experimental error. The average bite angles of the bpy ligand in $[Ru(bpy)_3]^{2+}$ are 79° compared to 77.7(12)° and 77.9(11)° (N7–Ru1–N10 and N13–Ru1–N16, respectively) for the bta ligand in complex **4**.[22] A further discussion of the structural data and a comparison with the free ligand **1** is not meaningful due to the inaccuracy of the experimental data.

The crystals of **7** obtained upon cooling of a dichloromethane solution to –35 °C are triclinic (space group $P\bar{1}$ with four molecules in the unit cell). The asymmetric unit contains two independent complexes with both copper atoms coordinated by **1** and DPEPhos in a distorted tetrahedral environment (Figures 8 and 9). There are no sub van der Waals contacts between the oxygen of the phosphane ligands and the copper centres. Both cations differ in their geometrical parameters, with one benzyl group being disordered over two positions in the cation containing Cu2 (occupation 55:45). Furthermore, the bta ligand deviates significantly from planarity in the case of the cation containing Cu1 [Cu1: ∠(N3–C45–C46–N4) 14.9(8)°; Cu2: ∠(N10–C106–C107–N9) 3.0(6)°]. There is a high degree of asymmetry in the bitriazole coordination [Cu1–N3 2.118(4), Cu1–N4 2.201(5), Cu2–N9 2.233(5), Cu2–N10 2.075(6) Å], as was also found, although less pronounced, for bpy in the crystal structure of the complex $[(bpy)Cu(PPh_3)_2]ClO_4$.[23] The bite angle of bpy in the latter complex and of the bi-triazoles in **7** are comparable [78.53(18)/78.7(2)° vs. 79.6(4)°].[23] The asymmetric coordination of the copper atoms in the crystal structure of **7** arises due to the steric restraints of the bta and DPEPhos ligand, and the differences between the two cations are caused by the disordered benzyl group and packing forces.

Crystals of **8** were obtained from MeCN/$Et_2O$. The compound crystallises in the orthorhombic space group *Pnma* with four molecules in the unit cell. The complexes in the crystals possess a mirror plane including Re1, Cl1 and C1, thus the asymmetric unit contains only one half of the formula unit. The $Re^{I}$ atom exists in a distorted octahedral

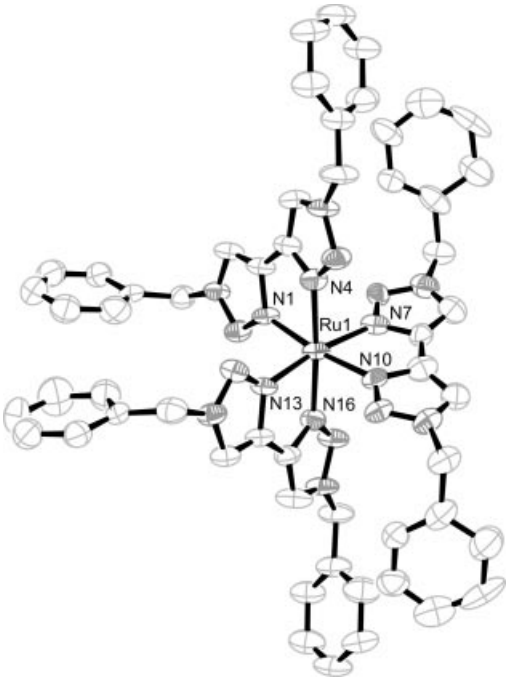

Figure 7. Crystal structure of the homoleptic $Ru^{II}$ complex cation of **4** (H atoms, chloride anions and solvent molecules have been omitted for clarity). Because of the low quality of the structure no atom distances or torsion angles are discussed (see text and Supporting Information). Bond angles [°]: N1–Ru1–N4 74.9(12), N7–Ru1–N10 77.7(12), N13–Ru1–N16 77.9(11), N4–Ru1–N10 100.7(11), N7–Ru1–N16 98.7(12), N1–Ru1–N10 167.5(10), N4–Ru1–N16 172.5(12), N7–Ru1–N13 172.1(11).

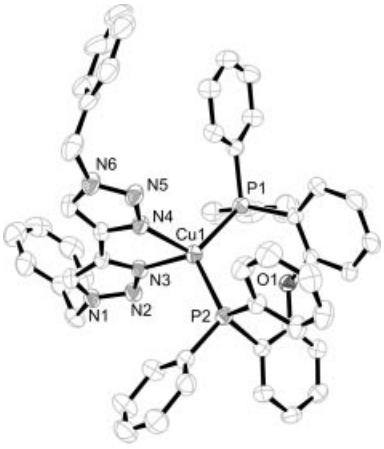

Figure 8. ORTEP drawing (30% probability ellipsoids) of the structure of the cation containing Cu1 in the crystals of **7**. Selected bond lengths [Å], angles [°] and torsion angles [°]: Cu1–P1 2.2631(17), Cu1–P2 2.3016(19), Cu1–N3 2.118(4), Cu1–N4 2.201(5); P1–Cu1–P2 115.44(7), P1–Cu1–N3 119.68(15), P2–Cu1–N4 113.05(13), N3–Cu1–N4 78.53(18); N3–C45–C46–N4 14.9(8).

environment defined by a *fac* arrangement of the three carbonyl groups, the chloride atom and the two nitrogen atoms of the bta ligand (Figure 10). The distortion from octahedral symmetry essentially arises from the steric demands of the chelating bta ligand. Again, the bite angle of the bitriazole [∠(N1–Re–N1′) 73.4(2)°] is very similar to the bite

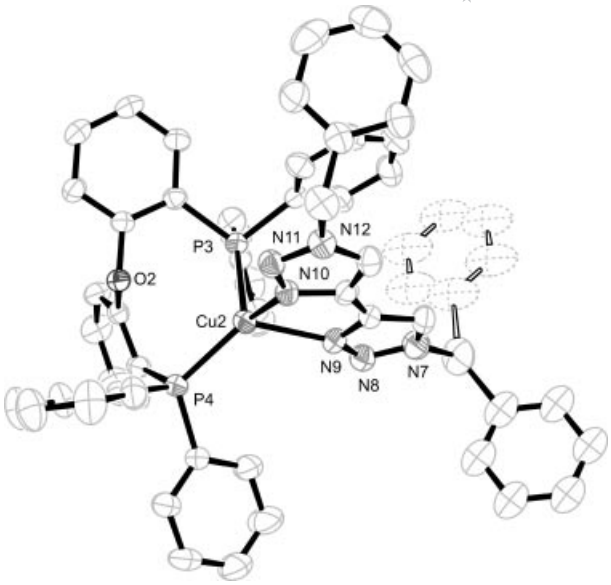

Figure 9. ORTEP drawing (30% probability ellipsoids) of the structure of the cation containing Cu2 in the crystals of **7**. Selected bond lengths [Å], angles [°] and torsion angles [°]: Cu2–P3 2.3079(18), Cu2–P4 2.2292(16), Cu2–N9 2.233(5), Cu2–N10 2.075(6); P3–Cu2–P4 114.39(7), P3–Cu2–N9 97.32(14), P4–Cu2–N10 130.61(14), N9–Cu2–N10 78.7(2); N10–C105–C106–N9 3.0(6). As indicated in the text, one benzyl group is disordered.

angles of several complexes of the type [(s-bpy)$Re^{I}(CO)_3X$] (X = anionic or neutral ligand) containing a substituted bpy ligand [∠(N1–Re–N1′) ca. 74°].[24] The bitriazole ligand is perfectly planar as a result of the mirror symmetry. The characteristic bond lengths and angles are normal and are similar to previously reported values in analogous bpy complexes.[24]

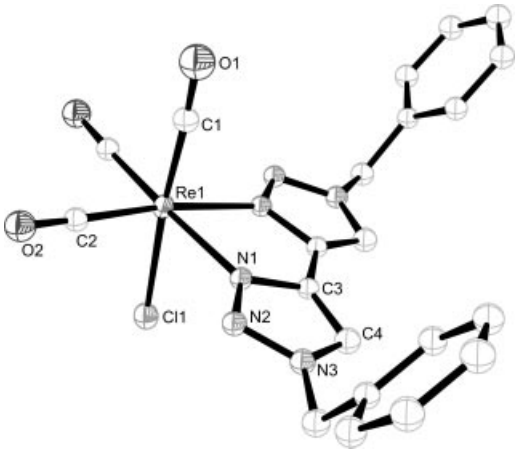

Figure 10. Crystal structure of **8** (H atoms have been omitted for clarity). Selected bond lengths [Å], angles [°] and torsion angles [°]: Re1–N1 2.176(6), Re1–Cl1 2.494(2), Re1–C1 1.890(12), Re1–C2 1.907(8), C1–O1 1.175(15), C2–O2 1.161(10); N1–Re1–N1 73.4(2), Cl1–Re1–N1 81.26(18), Cl1–Re1–C1 175.3(4), N1–Re1–C1 95.0(3), N1–Re1–C2 99.1(3), C1–Re1–C2 88.1(4), Re1–C2–O2 177.7(6), Re1–C1–O1 176.9(11); N1–C3–C3′–N1′ 0.0(9).

The present crystal structures display the strong similarities of the ligand properties of 2,2′-bipyridines and bi-1,2,3-triazoles in terms of steric features.

### Spectroscopic Characterisation

All compounds were analysed by NMR, IR and UV/Vis spectroscopy (see Experimental Section). No $^{13}C$ NMR spectra could be recorded for complexes **4**, **7** or **8** due to their low solubility. The proton and carbon signals in the NMR spectra are in the usual regions, and the IR spectrum of **8** shows three intense signals at $\tilde{\nu}$ = 2018, 1906 and 1866 $cm^{-1}$, as expected for the vibrations of carbonyl groups in a facial conformation.[25]

The electronic absorption spectra of ligand **1** and its complexes with $Ru^{II}$, $Re^{I}$ and $Cu^{I}$ are depicted in Figure 11. Each complex exhibits a low-energy band at $\lambda_{max}$ = 302 (**4**, log $\varepsilon$ = 4.549), 272 (**7**, log $\varepsilon$ = 3.883) and 302 (**8**, log $\varepsilon$ = 3.918), and complexes **4** and **7** also exhibit a transition near the band of the free ligand absorption. The lowest energy band of complexes **5** and **6** appears at $\lambda$ = 307 (log $\varepsilon$ = 4.517) and 299 nm (log $\varepsilon$ = 4.169), respectively (see Figures S3 and S4 in the Supporting Information). The complexes show absorption peaks between 270 and 370 nm, a region where no corresponding ligand absorption is found. We therefore tentatively assign these absorptions to MLCT bands. It is noteworthy that the maxima of the lowest absorptions in $[(bpy)Re^{I}(CO)_3Cl]$ ($\lambda_{max}$ = 386 nm)[26] and $[(bpy)_3Ru]^{2+}$ ($\lambda_{max}$ = 451 nm)[27] are substantially lower in energy than in the complexes of ligands **1**–**3**. Poor solubility in non-polar solvents precludes a more detailed study. None of the complexes is an emitter in solution or the solid state.

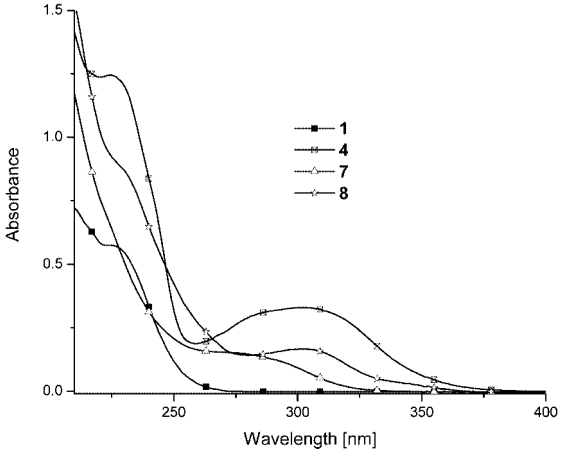

Figure 11. Electronic absorption spectra of compounds **1**, **4**, **7**, and **8** in acetonitrile ($c$ = 20 μM).

### Summary

New 1,1′-disubstituted 4,4′-bi-1,2,3-triazole compounds have been synthesised by a $Cu^{I}$-catalysed cycloaddition between 1,4-butadiyne and various alkyl and aryl azides. These compounds have been employed as ligands for transition metal complexes. Three homoleptic $Ru^{II}$ complexes of the obtained ligands as well as one $Cu^{I}$ and $Re^{I}$ complex with one of the ligands have been synthesised. All of them are readily accessible by standard reactions and are perfectly stable. The steric properties of the ligands are similar to those of 2,2′-bipyridine, although the photophysical properties are not. The complexes show no luminescence. Application of these new compounds as bidentate and easy-to-modify "innocent" ligands may be envisaged. The ligand properties may be varied using established synthetic routes. For example, monosubstituted 4,4′-bitriazoles could be obtained from 1,4-butadiyne and a mixture of alkyl azide and trimethylsilyl azide.[28] This would allow the formation of a triazolyl anion after deprotonation of the unsubstituted triazole and asymmetric functionalisation. The use of 2,6-diethynylpyridine instead of 1,4-butadiyne would give access to terpyridine analogues, and substitution of the triazole-CH would allow introduction of further functionality at the ring carbon atom.[29]

## Experimental Section

**General Information:** All reactions were performed under an inert atmosphere of $N_2$ using standard Schlenk techniques, unless otherwise stated. Melting points were determined on a Tottoli micro melting point apparatus and are uncorrected. TLC analyses were performed on silica gel 60 F-254 with a 0.2-mm layer thickness. Detection was by UV light at 254/366 nm or by discolouration with ninhydrin in EtOH. Merck Geduran SI 60 silica gel was used for preparative column chromatography. Commercially available solvents of standard quality were used. Unless otherwise stated, purification and drying was done according to accepted general procedures.[30] Elemental analyses were carried out by the Centre for Chemical Analysis of the Faculty of Natural Sciences of the University of Regensburg.

**Safety Note:** *Sodium azide is toxic and can generate the extremely hazardous hydrazoic acid (volatile, toxic, explosive) if it comes into contact with acids. Organic azides with a saturated carbon:azide ratio of less than 6 may be heat- and shock-sensitive and should be handled with care.*

Absorption spectra were recorded with a Varian Cary BIO 50 UV/Vis/NIR Spectrometer with a 1-cm quartz cell (Hellma) and Uvasol solvents (Merck or Baker). NMR spectra were recorded with a Bruker Avance 300 spectrometer ($^1H$: 300.1 MHz; $^{13}C$: 75.5 MHz; $T$ = 300 K). The chemical shifts are reported in ppm relative to external standards (solvent residual peak) and coupling constants are given in Hertz. The spectra were analysed as being first order. Assignment of signals in the $^{13}C$ NMR spectra was performed with the DEPT technique (pulse angle: 135°) and given as (+) for $CH_3$ or CH, (–) for $CH_2$ and ($C_{quat}$) for quaternary C. Error of reported values: chemical shift: 0.01 ppm for $^1H$ NMR, 0.1 ppm for $^{13}C$ NMR and 0.1 Hz for coupling constants. The solvent used is reported for each spectrum. Mass spectra were recorded with a Varian CH-5 (EI), Finnigan MAT 95 (CI, FAB and FD) or Finnigan MAT TSQ 7000 (ESI) spectrometer with xenon as the ionisation gas for FAB. IR spectra were recorded with a Bio-Rad FTS 2000 MX FT-IR or Bio-Rad FT-IR FTS 155 spectrometer.

**Synthesis of Triazole Ligands and Complexes. General Procedures:**

**GP 1: Twofold "Click Reaction" with 1,3-Butadiyne:** The freshly prepared butadiyne was condensed into 5 mL of acetonitrile at –40 °C and a solution of the azide (2.0 equiv.), 2,4-lutidine (2.2 equiv.) and CuI (10 mol-%) in 10 mL of acetonitrile was cooled to –40 °C and added. The reaction mixture was then warmed to room temperature. The reaction vessel was stored in a closed autoclave to prevent evaporation of the butadiyne. After stirring for

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

20 h, the mixture was poured into 50 mL of an aqueous solution of $H_2O_2$ (3%). The mixture was stirred until the generation of gas ceased, then 50 mL of a saturated aqueous solution of EDTA was added and the mixture was stirred for 30 min. Further purification was different for each compound.

**GP 2: Synthesis of Homoleptic $Ru^{II}$ Complexes:** The bitriazole ligand (3 equiv.) and $RuCl_3·4H_2O$ were suspended in ethylene glycol (10 mL) in a round-bottomed flask (25 mL). The mixture was heated (oil bath temperature: 200 °C) to yield a dark-red solution, which slowly turned to brownish orange over 20 h. The solution was concentrated in vacuo with heating to 3 mL, then boiling ethanol was added to the solution at 80 °C until a white precipitate appeared. The mixture was stored at –20 °C overnight to complete precipitation, then the solid was separated by centrifugation and dried in vacuo.

**1,1′-Dibenzyl-4,4′-bi-1*H*-1,2,3-triazolyl (1):** Synthesised following GP 1 from butadiyne (563 mg, 11.3 mmol), benzyl azide (3.00 g, 22.5 mmol, 2 equiv.), 2,4-lutidine (2.65 g, 2.86 mL, 24.8 mmol, 2.2 equiv.) and CuI (214 mg, 1.13 mmol, 10 mol-%). After workup, the aqueous solution was extracted with $CHCl_3$ (3 × 100 mL) and the organic phase was dried with $Na_2SO_4$, filtered and concentrated at reduced pressure. The crude product was purified by column chromatography with a dichloromethane/MeOH gradient from 99:1 to 96:4. This yielded 2.93 g of **4** as colourless crystals (82%). M.p. 228 °C. $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 5.67 (s, 4 H, $CH_2$), 7.31–7.40 (m, 10 H, CH), 8.58 (s, 2 H, triazole) ppm. $^{13}$C NMR (75.5 MHz, [D$_6$]DMSO): $\delta$ = 52.8 (–, 2 C), 121.7 (+, 2 C, triazole), 127.9 (+, 4 C), 128.1 (+, 2 C), 128.7 (+, 4 C), 139.2 (1 C, $C_{quat}$), 142.2 (1 C, $C_{quat}$) ppm. MS (ESI, DCM/MeOH): *m*/*z* (%) 317.1 (100) [$MH^+$]. $C_{18}H_{16}N_6$ (316.37): calcd. C 68.34, H 5.10, N 26.56; found C 68.21, H 5.21, N 26.42. UV/Vis (MeCN): $\lambda$ (log $\varepsilon$) = 225 nm (4.458). IR (KBr): $\tilde{\nu}$ = 3133, 3101, 3031, 2984, 2946, 2858, 1673, 1494, 1439, 1410, 1364, 1293, 1231, 1076, 1058, 949, 836, 722 cm$^{-1}$.

**1,1′-Diphenyl-4,4′-bi-1*H*-1,2,3-triazolyl (2):** Synthesised following GP 1 from butadiyne (335 mg, 6.7 mmol), phenyl azide (1.60 g, 13.4 mmol, 2 equiv.), 2,4-lutidine (1.58 g, 1.70 mL, 14.8 mmol, 2.2 equiv.) and CuI (127 mg, 0.67 mmol, 10 mol-%). After workup, the aqueous solution was heated to 40 °C and extracted with warm $CHCl_3$ (40 °C, 8 × 80 mL). The organic phase was dried with $Na_2SO_4$, filtered, concentrated at reduced pressure and dried in vacuo. The residue was dissolved in boiling $CHCl_3$, filtered through charcoal and Celite and concentrated again. The crude product was purified by recrystallisation from $CHCl_3$/petroleum ether. This yielded 1.47 g of **2** as colourless crystals (76%). M.p. 236 °C. $^1$H NMR (300 MHz, $CHCl_3$): $\delta$ = 7.49 (t, $^3J$ = 7.7 Hz, 2 H, CH), 7.53–7.59 (m, 4 H, CH), 7.82 (d, $^3J$ = 7.6 Hz, 4 H, CH), 8.59 (s, 2 H, triazole) ppm. $^{13}$C NMR (75.5 MHz, $CHCl_3$): $\delta$ = 118.9 (+, 2 C, triazole), 120.6 (+, 4 C), 129.0 (+, 2 C), 129.9 (+, 4 C), 136.9 (1 C, $C_{quat}$), 140.5 (1 C, $C_{quat}$) ppm. MS (ESI, DCM/MeOH): *m*/*z* (%) 289.1 (100) [$MH^+$]. $C_{16}H_{12}N_6$ (288.31): calcd. C 66.66, H 4.20, N 29.15; found C 66.57, H 4.31, N 29.01. UV/Vis ($CH_3CN$): $\lambda$ (log $\varepsilon$) = 232 (4.480), 257 nm (4.366). IR (KBr): $\tilde{\nu}$ = 3132, 3093, 3065, 1654, 1597, 1504, 1464, 1396, 1257, 1234, 1034, 825, 756 cm$^{-1}$.

**1,1′-Bis(carboxymethyl)-4,4′-bi-1*H*-1,2,3-triazolyl (3):** Synthesised following GP 1 from butadiyne (541 mg, 10.8 mmol), β-azidoacetic acid (2.18 g, 21.6 mmol, 2 equiv.), 2,4-lutidine (2.55 g, 2.75 mL, 23.8 mmol, 2.2 equiv.) and CuI (206 mg, 1.08 mmol, 10 mol-%). After workup, the aqueous solution was acidified to pH 2 with 6 N aqueous HCl. The precipitate was filtered, washed with water and suspended in 10 mL of water. A 0.1 N aqueous solution of NaOH was then added dropwise until the solid dissolved completely. The solution was lyophilized to yield the sodium salt of **3** (2.50 g, 8.4 mmol, 78%). NMR, mass and UV spectra were recorded for this salt. The solid was dissolved in water (20 mL), the solution was heated to reflux and 0.5 N aqueous HCl was added dropwise until a precipitate appeared. After cooling to room temperature, 2 N aqueous HCl was added until no further product precipitated. The solid was filtered, washed with water and dried in vacuo. This yielded 2.12 g of **3** as colourless crystals (78%). M.p. > 215 °C (decomp.). $^1$H NMR (300 MHz, $D_2O$): $\delta$ = 5.05 (s, 4 H, $CH_2$), 8.20 (s, 2 H, triazole) ppm. $^{13}$C NMR (75.5 MHz, $D_2O$): $\delta$ = 53.3 (–, 2 C), 123.9 (+, 2 C, triazole), 138.6 (2 C, $C_{quat}$), 173.1 (2 C, $C_{quat}$) ppm. MS (ESI, $H_2O$/MeCN): *m*/*z* (%) 253.1 (100) [$MH^+$]. $C_8H_8N_6O_4$ (252.16): calcd. C 38.10, H 3.20, N 33.32; found C 37.97, H 3.32, N 33.17. UV/Vis ($H_2O$): $\lambda$ (log $\varepsilon$) = 225 nm (4.092). IR (KBr): $\tilde{\nu}$ = 3435, 3151, 3117, 3013, 2947, 2792, 2708, 2594, 2511, 1930, 1794, 1724, 1496, 1420, 1347, 1295, 1257, 1223, 1151, 1109, 1064, 1011, 976, 896, 795 cm$^{-1}$.

**Ru Complex 4:** Ligand **1** (100 mg, 0.32 mmol) and $RuCl_3·3H_2O$ (28 mg, 0.11 mmol) were suspended in 20 mL of ethylene glycol in a round-bottomed flask fitted with a reflux condenser and the mixture was heated (oil bath temperature: 200 °C). This yielded a dark-red solution which slowly turned to brownish orange over 20 h. The solvent was removed in vacuo by heating. The remaining solid was dissolved in boiling MeCN and filtered. $Et_2O$ was then added to the solution to precipitate the product. This yielded a light yellow powder, which was recrystallised from MeCN/$Et_2O$ to give 84 mg of **7** as yellowish crystals (0.07 mmol, 68%). M.p. > 210 °C (decomp.). $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 5.55 (s, 12 H, $CH_2$), 7.12–7.18 (m, 12 H, CH), 7.28–7.36 (m, 18 H, CH), 8.54 (s, 6 H, triazole) ppm. MS (ESI, $H_2O$/MeCN): *m*/*z* (%) 525.4 (100) [$(L_3Ru^{2+})^{2+}$], 1185.5 (1) [$(L_3Ru^{2+} + Cl^-)^+$]. $C_{54}H_{48}Cl_2N_{18}Ru·4H_2O$ (1193.1): calcd. C 54.36, H 4.73, N 21.13; found C 54.46, H 4.62, N 20.47. UV/Vis ($H_2O$): $\lambda$ (log $\varepsilon$) = 302 (4.549), 222 nm (5.143). IR (ATR): $\tilde{\nu}$ = 3116, 3032, 1446, 1456, 1426, 1356, 1340, 1276, 1112, 1078, 1042, 720, 694, 654 cm$^{-1}$.

**Ru Complex 5:** Synthesised following GP 2 from **2** (250 mg, 0.87 mmol) and $RuCl_3·4H_2O$ (78 mg, 0.29 mmol). This yielded 665 mg of **5** as colourless crystals (74%). M.p. > 210 °C (decomp.); $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 7.54–7.66 (m, 18 H, CH), 7.89 (d, $^3J$ = 7.1 Hz, 12 H, CH), 9.76 (s, 6 H, triazole) ppm. $^{13}$C NMR (75.5 MHz, [D$_6$]DMSO): $\delta$ = 120.1 (+, 2 C, triazole), 120.5 (+, 4 C), 129.9 (+, 2 C), 130.0 (+, 4 C), 135.6 (1 C, $C_{quat}$), 140.9 (1 C, $C_{quat}$) ppm. MS (ESI, $H_2O$/MeCN): *m*/*z* (%) 483.2 (100) [$(L_3Ru^{2+})^{2+}$], 1115.4 (5) [$(L_3Ru^{2+} + TfO^-)^+$]. UV/Vis ($H_2O$): $\lambda$ (log $\varepsilon$) = 307 (4.517), 239 nm (5.012). IR (KBr): $\tilde{\nu}$ = 3102, 3062, 1595, 1499, 1464, 1422, 1313, 1271, 1065, 999, 760 cm$^{-1}$.

**Ru Complex 6:** Synthesised following GP 2 from **3** (250 mg, 0.99 mmol) and $RuCl_3·4H_2O$ (90 mg, 0.33 mmol). This yielded 634 mg of **6** as colourless crystals (69%). M.p. > 205 °C (decomp.). $^1$H NMR (300 MHz, $D_2O$): $\delta$ = 5.22 (s, 12 H, $CH_2$), 8.50 (s, 6 H, triazole) ppm. $^{13}$C NMR (75.5 MHz, $D_2O$): $\delta$ = 51.5 (–, 6 C), 122.0 (+, 6 C, triazole), 138.2 (6 C, $C_{quat}$), 171.0 (6 C, $C_{quat}$) ppm. MS (ESI, $H_2O$/MeCN): *m*/*z* (%) 478.2 (100), 507.2 (100), 521.3 (100), 955.3 (65). UV/Vis ($H_2O$): $\lambda$ (log $\varepsilon$) = 299 (4.169), 225 nm (4.721). IR (KBr): $\tilde{\nu}$ = 3429. 3136, 2925, 1746, 1629, 1454, 1377, 1288, 1221, 1021 cm$^{-1}$.

**$Cu^I$ Complex 7:** Ligand **1** (50 mg, 0.16 mmol), $[Cu^I(NCMe)_4]PF_6$ (59 mg, 0.16 mmol) and bis[2-(diphenylphosphanyl)phenyl] ether (85 mg, 0.16 mmol) were dissolved in degassed dichloromethane and heated to reflux for 3 h. The solution was concentrated and diethyl ether was added to precipitate the product. The suspension was filtered and the filtrate cooled to – 35 °C. This gave colourless

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

crystals of **7** suitable for X-ray crystallography. Complex **7** was obtained in an overall yield of 73% (123 mg). $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 5.59 (s, 4 H, $CH_2$), 6.66–6.75 (m, 2 H, CH), 6.90–7.02 (m, 4 H, CH), 7.25–7.47 (m, 32 H, CH), 8.12 (s, 2 H, triazole) ppm. $^{31}$P NMR (162 MHz, $CDCl_3$): $\delta$ = –13.38 ppm. MS (ESI): *m*/*z* (%) 317.1 (8) [**1**$^+$], 601.2 (28) [(DPEPhos)Cu$^+$], 642.2 (100) [{(DPEPhos)Cu + MeCN}$^+$], 917.4 (51) [(DPEPhos)(**1**)Cu$^+$]. $C_{54}H_{44}CuN_6OP_2{\cdot}PF_6$ (1063.4): calcd. [a] Crystals of **4** contain an unspecified number of solvents, which are highly disordered, thus no formula and no reliable values for the parameters or formula can be given.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

found C 60.54, H 4.23, N 7.74; UV/Vis (MeCN): $\lambda$ (log $\varepsilon$) = 272 nm (3.883). IR (ATR): $\tilde{\nu}$ = 3138, 2944, 2884, 2364, 2328, 2210, 2162, 2048, 1976, 1498, 1458, 1288, 1260, 1046, 814, 716 cm$^{-1}$.

**Re$^{I}$ Complex 8:** Ligand **1** (50 mg, 0.16 mmol) and [Re$^{I}$(CO)$_5$]Cl (57 mg, 0.16 mmol) were dissolved in degassed toluene and heated to reflux for 12 h. After cooling to room temperature, the colourless precipitate was filtered and dried in vacuo. Recrystallisation from MeCN/Et$_2$O yielded **8** as colourless crystals (94 mg, 96%). $^1$H NMR (300 MHz, CD$_3$CN): $\delta$ = 5.72 (s, 4 H, CH$_2$), 7.39–7.46 (m, 10 H, CH), 8.28 (s, 2 H, triazole) ppm. MS (ESI): *m/z* (%) 91.1 (100) [Bn$^+$], 503.0 (10) [(**1**)Re$^+$], 538.0 (1) [(M – 3CO + H)$^+$], 566.0 (2) [(M – 2CO + H)$^+$], 593.3 (2) [M – CO$^+$], 621.9 (1) [M$^+$]. IR (ATR): $\tilde{\nu}$ = 3136, 2944, 2886, 2018, 1906, 1866, 1494, 1448, 1422, 1292, 1266, 1178, 1158, 1108, 1082, 1050, 818, 744, 698, 660 cm$^{-1}$. UV/Vis (MeCN): $\lambda$ (log $\varepsilon$) = 350 (sh), 302 (3.918), 228 nm (sh). $C_{21}H_{16}ClN_6O_3Re$ (622.05): calcd. C 40.55, H 2.59, N 13.51; found C 40.47, H 2.59, N 13.55.

**Crystal Structure Determination:** Diffraction data for crystals of compound **1** (needles and prisms) and complex **7** were collected with a STOE-IPDS diffractometer[31] with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), whereas data for crystals of **2**, **3**, **4** and **8** were collected with an Oxford Diffraction Gemini Ultra CCD diffractometer[32] with multilayer optics and Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å). Further crystallographic and refinement data can be found in Tables 1 and 2. The structures were solved by direct methods (SIR-97)[33] and refined by full-matrix least-squares on $F^2$ (SHELXL-97).[34] The H atoms were calculated geometrically and a riding model was applied during the refinement process. The structure solution of **4** and **8** was handicapped by poor crystal quality. For **4**, the obviously present solvent molecules could not be identified and were included in the refinement steps as C atoms (C100–C112) or as Cl atoms. For **8** only the heavy atoms could be refined with anisotropic displacement factors.

CCDC-645040–645046 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Tetrahedral $Co^{II}$ Complexes with $CoI_2O_2$ and $CoO_2S_2$ Cores – Crystal Structures of $[Co\{HN(OPPh_2)(SPPh_2)\text{-}O\}_2I_2]$ and $[Co\{N(OPPh_2)(SPPh_2)\text{-}O,S\}_2]$

**M. Carla Aragoni,[a] Massimiliano Arca,[a] M. Bonaria Carrea,[a] Alessandra Garau,[a] Francesco A. Devillanova,[a] Francesco Isaia,*[a] Vito Lippolis,[a] Gian Luca Abbati,[b] Francesco Demartin,[c] Cristian Silvestru,[d] Serhiy Demeshko,[e] and Franc Meyer[e]**

**Keywords:** Cobalt / O,S ligands / Phosphanes / Sulfides / Density functional calculations / Magnetic properties

The compound $[Co^{II}\{HN(OPPh_2)(SPPh_2)\text{-}O\}_2I_2]$ (**1**) was synthesised by the reaction of cobalt in powder with the iodine adduct of tetraphenylthiooxoimidodiphosphinic acid, $HN(OPPh_2)(SPPh_2)$, in $Et_2O$; treatment of compound **1** with NaOH resulted in deprotonation of the ligands bound to the metal ion and a separation of $[Co^{II}\{N(OPPh_2)(SPPh_2)\text{-}O,S\}_2]$ (**2**). Molecular structures of complexes **1** and **2** were elucidated by X-ray diffraction analysis, which revealed a $CoI_2O_2$ tetrahedral core for compound **1** in which two neutral ligands bind through the oxygen atoms the $Co^{II}$ ion, and a tetrahedral $CoO_2S_2$ core for compound **2** with the oxygen and sulfur atoms of each anionic ligand chelating a $Co^{II}$ centre. Variable-temperature magnetic susceptibility measurements are consistent with tetrahedral high-spin ($S = 3/2$) $Co^{II}$ that possesses a $^4A_2$ ground state with best fit parameters $g = 2.25$, $|D| = 12.0\ cm^{-1}$ and $g = 2.37$, $|D| = 11.9\ cm^{-1}$ for complexes **1** and **2**, respectively. The compounds were further characterised by UV/Vis and IR spectroscopy. DFT calculations were performed on model complexes $[Co^{II}\{N(OPH_2)(SPH_2)\text{-}O,S\}_2]$ (**3**) and $[Co^{II}\{N(SPH_2)_2\text{-}S,S'\}_2]$ (**4**) to compare the electronic properties of the $CoO_2S_2$ and $CoS_4$ cores.

## Introduction

The use of iodine or interhalogen charge-transfer adducts of chalcogen donor molecules as oxidising/complexing agents towards zero-valent metals has been attracting some interest in recent years because of their applications both in the recovery of precious metals from waste industrial materials and in the recovery of toxic metals for the environment.[1] Because a great number of iodine adducts with ligands containing sulfur donor atoms have been synthesised, a wide choice of "reagents" is to be considered potentially available for the oxidation/complexation of metals.[2] However, only a few of them have really proved successful to date. Previous studies led us to consider that the overall oxidation/complexation reaction was composed of two distinct processes in which the adduct was accountable for the oxidation of the metal and the ligand/donor for the complexation of the formed metal ion.[3] On the basis of these considerations, the formation of the $I_2$ adduct of tetraphenyldithioimidodiphosphinic acid, $HN(SPPh_2)_2$, $HL_{(SS)}$, represents a successful attempt to join together the donor ability of the phosphane sulfide group and $I_2$. The result is a "robust" adduct, and the intrinsic ability of $HL_{(SS)}$ and its deprotonated form $[N(SPPh_2)_2]^-$, $L_{(SS)}$, to adapt well to the preferred coordination geometries of the metal ion results in a variety of coordination patterns mainly involving S,S′ sulfur chelation. In this respect, the reaction in diethyl ether of the $HL_{(SS)}\cdot I_2$ adduct with a variety of metal powders − Au, Co, Cu, In, Pd and Sb − and liquid Hg allowed their oxidation and the formation of complexes of the resulting metal ions with the ligand in its anionic form.[1c–1e,4] In the reaction with Hg and Cu, it was also possible to separate solid compounds whose crystal structures showed the unusual presence of $HL_{(SS)}$ in a S,S′-isobidentate coordinated fashion, i.e. complexes $[Hg\{HL_{(SS)}\}I_2]$ and $[Cu\{HL_{(SS)}\}_2]I_3$.[1d,5]

As a natural development of this synthetic route, we selected the adduct $HN(OPPh_2)(SPPh_2)\cdot I_2$, $HL_{(OS)}\cdot I_2$, as the oxidising agent on the basis of the ligand containing mixed

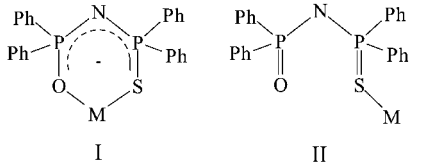
hard (O) and soft (S) donor atoms for better ion-complexing adaptability. The chemistry of this ligand has been studied far less than that of $HL_{(SS)}$; according to the complexes reported in the literature, chelation as an O,S-bidentate anionic ligand [$L_{(OS)}$; Scheme 1, structure I] is dominant, but not exclusive, with the S-monodentate coordination mode (Scheme 1, structure II) being adopted in a variety of complexes.[6] To date, no complexes of $HL_{(OS)}$ have been characterised by X-ray crystallographic analysis.



Scheme 1.

This manuscript reports the reactivity of $HL_{(OS)}$ with cobalt powder by using $I_2$ as the activating agent; the structures of complexes $[Co^{II}\{HN(OPPh_2)(SPPh_2)\text{-}O\}_2I_2]$ (**1**) and $[Co^{II}\{N(OPPh_2)(SPPh_2)\text{-}O,S\}_2]$ (**2**), the latter obtained by imido deprotonation of the ligands in **1**, were determined by single-crystal X-ray diffraction analysis. Magnetic parameters were also determined for both complexes. The reactivity of complex **1** towards a few soft metal ions was studied in an attempt to synthesise heterobinuclear complexes; moreover, the protonation reaction of **2** by aqueous hydroiodic acid is reported. In addition, the electronic nature of the $CoO_2S_2$ and $CoS_4$ cores was investigated by DFT calculations on model compounds $[Co^{II}\{N(OPH_2)(SPH_2)\text{-}O,S\}_2]$ and $[Co^{II}\{N(SPH_2)_2\text{-}S,S'\}_2]$.

## Results and Discussion

### Synthesis and Crystal Structure Determination of $[Co^{II}\{HN(OPPh_2)(SPPh_2)\text{-}O\}_2I_2]$ (1)

The reaction between equimolar amounts of the adduct $HL_{(OS)}\cdot I_2$ and Co powder was carried out under a nitrogen atmosphere in anhydrous diethyl ether. After three days of stirring, $^{31}P$ NMR spectroscopic resonances of the $HL_{(OS)}\cdot I_2$ species were not detectable any longer in the mixture. In the course of the reaction, the initial dark-red colour of the solution, typical of the charge-transfer adduct $HL_{(OS)}\cdot I_2$ bearing the S–I–I group, turned to light emerald green, and gradually, a light greenish powder separated from the solution. Elemental analyses of the separated powder agrees with the formed complex having stoichiometry $[Co^{II}\{HL_{(OS)}\}_2I_2]$ (**1**), and both ligand molecules are coordinated, unprecedentedly, in their neutral form, in accordance with the overall reaction in Equation (1).

$$\underset{HL_{(OS)}}{2\ HN(OPPh_2)(SPPh_2)} + I_2 + Co \xrightarrow{Et_2O} \underset{\mathbf{1}}{[CoI_2\{HN(OPPh_2)(SPPh_2)\}_2]} \quad (1)$$

Because of the different bonding modes that are inherently possible for $HL_{(OS)}$, and the unusual formulation of complex **1**, X-ray diffraction analysis was undertaken to firmly establish the coordination pattern at the cobalt centre.

The molecular structure of **1** is reported in Figure 1; selected bond lengths and angles are given in Table 1. The complex contains a tetrahedral $Co^{2+}$ ion surrounded by two iodide anions and by two $HL_{(OS)}$ monodentate ligands coordinated to the metal atom through the oxygen atom. The tetrahedral $CoO_2I_2$ core is slightly distorted with a Co(1)–I(1)–I(1)/Co(1)–O(1)–O(2) dihedral angle of 84.21(7)°; the X–Co–Y (X, Y = I, O) angles are in the range 100.94(11)–

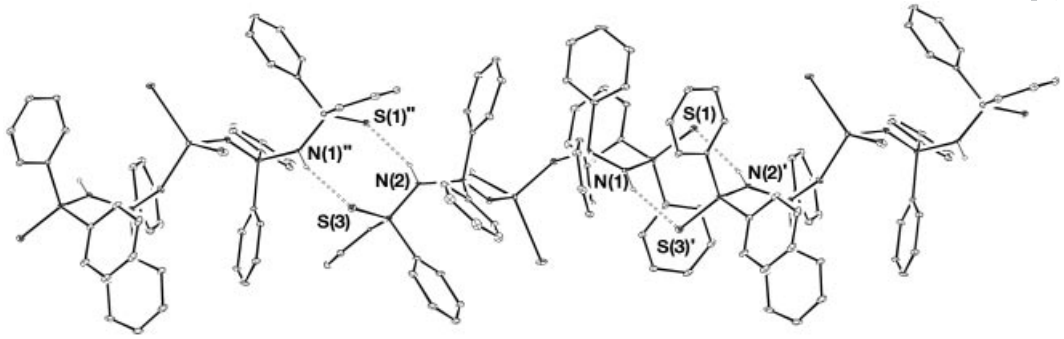

Figure 2. View of the hydrogen bonding pattern for the molecules of compound **1**.

118.93(3)°, and the Co–I and Co–O average distances are 2.5712(8) and 1.966(4) Å, respectively, (Table 1), which are very close to those reported for several monomeric $Co^{II}$ complexes displaying tetracoordination.[7] The O and S atoms of each $HL_{(OS)}$ ligand are on opposite sides with respect to the P–N–P plane and are arranged so that the sulfur atoms are involved in S···H–N hydrogen bonding with adjacent complex molecules to form a polymeric array as shown in Figure 2; the S(1)···N(2)′ (′ = *x*, 3/2 – *y*, 1/2 + *z*) interaction is 3.365(5) Å and the N(1)···S(3)′ is 3.306(4) Å; the S1···H′–N(2)′ and N(1)–H–S(3)′ angles are 161.7 and 155.8°, respectively.

### Reactivity of Complex 1 and Crystal Structure of $[Co^{II}\{N(OPPh_2)(SPPh_2)\text{-}O,S\}_2]$ (2)

The X-ray crystal structure of **1** highlights two interesting features not yet reported: (1) the neutral $HL_{(OS)}$ ligands form units within the complex and (2) the O-monodentate coordination mode at the $Co^{II}$ centre, which leaves the $-PPh_2(S)$ groups in a dangling position. These aspects make compound **1** attractive, as further coordination towards the soft metal centre through the S donor atoms to form heterobinuclear complexes is, in principle, feasible. Moreover, the mono- or dideprotonation of the coordinated ligands in **1** may increase the nucleophilicity of the sulfur donor atoms as a consequence of the delocalisation of the negative charge(s) over the complex. First, the reactivity of **1** was tested towards a soft acceptor species such as molecular iodine, as the formation/separation of 1:1 or 1:2 neutral adducts between **1** and $I_2$ molecules would provide useful information for the bonding ability of the sulfur atoms. The reaction of **1** with increasing amounts of molecular iodine was carried out in MeCN and in the less polar solvent $CH_2Cl_2$. In both cases, the formation of red oils, which failed to crystallise on long standing, was observed. The FT-Raman spectra recorded in the ν(I–I) region at **1**/$I_2$ molar ratios of 1:1 and 1:2 showed an intense peak at 113 $cm^{-1}$ in MeCN and at 110 $cm^{-1}$ in $CH_2Cl_2$ solution, which are indicative of the formation/presence of the $I_3^-$ species. A further addition of $I_2$, according to Raman peaks at 113, 146 and 169 $cm^{-1}$ (MeCN) and 113, 146 and 169 $cm^{-1}$ ($CH_2Cl_2$), led to the formation of complex mixtures.[8]

The reaction of **1** with an equimolar amount of mercury(II) perchlorate or lead(II) nitrate, carried out in MeCN at room temperature, quickly led to the decolouration of the solution with the formation of a mixture of white and brown sticky powders. Conversely, in the reaction with palladium(II) chloride the colour change was not observed, and complex **1** was recovered unreacted when the solution was slowly concentrated in air. Interestingly, when the above reactions were carried out in the presence of aqueous NaOH to obtain a **1**/M/NaOH [M = $Hg^{II}$, $Pb^{II}$ and $Pd^{II}$ ions] reaction molar ratio of 1:1:2, sticky oils including a thin blue powder were observed in all cases. The addition of aqueous NaOH to a solution of complex **1** (**1**/NaOH, 1:2) in $CH_3CN$ readily afforded a deep-blue solution along with a very thin brown powder.[9] From the concentration of the solution a blue powder was obtained, and subsequent crystallisation from $CH_3CN$/hexane yielded well-shaped blue crystals with elemental analyses corresponding to the formulation $[Co\{L_{(OS)}\}_2]$ (**2**).

Solid complexes **1** and **2** and their MeCN solutions are easily recognisable because of their green and blue colour, respectively. Visible absorption spectra of these complexes in the range 500–800 nm are reported in Figure 3; in both compounds, the molar intensities of the d–d electronic transition bands [compound **1**: UV/Vis ($CH_3CN$): $\lambda_{max}$ (ε, $dm^3\,mol^{-1}\,cm^{-1}$) = 661 (172), 696 (346), 734 (432) nm; com-

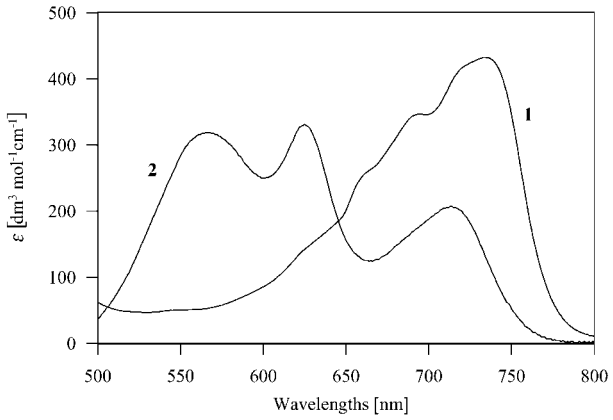

Figure 3. Visible absorption spectra in MeCN of complexes **1** [$\lambda_{max}$ = 734, 696, 661 (sh) nm] and **2** ($\lambda_{max}$ = 715, 625, 566 nm).

pound **2**: UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$, $dm^3 mol^{-1} cm^{-1}$) 566 (319), 625 (331), 715 (205) nm] are consistent with $Co^{II}$ bound in a tetrahedral or distorted tetrahedral coordination geometry.[10] The absorption spectra in the visible region, taken after the addition of increasing amounts of aqueous NaOH to a solution of **1** in MeCN are reported in Figure 4; from the analysis of the bands at 734 and 566 nm, related to complexes **1** and **2**, respectively, it results that only a partial conversion of **1** into **2** occurs because of the observed concomitant formation of a thin brown powder.[9] The inset to Figure 4 gives evidence of this fact and shows that a near sixfold excess of NaOH over the amount of **1** is necessary to obtain a 55% yield of **2**.

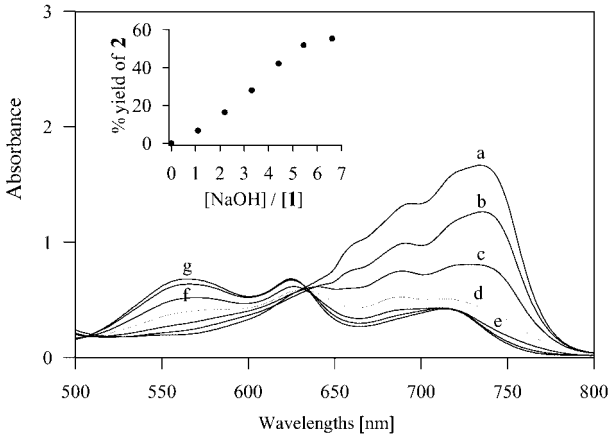

Figure 4. Base-induced conversion of complex **1** into **2**, as monitored by Visible absorption spectroscopy. (a) [Co{$HL_{(OS)}$}$_2I_2$] (**1**), $3.85 \times 10^{-3}$ M in MeCN, 21 °C; and after the addition of NaOH (1.0 M in water) to realise a NaOH/[**1**] molar ratio of (b) 1.1; (c) 2.2; (d) 3.3; (e) 4.4; (f) 5.5 and (g) 6.6. Inset: percent yield of complex **2**, which results from analysis of the bands at 566 and 734 nm, plotted vs. [NaOH]/[**1**] molar ratios.

The molecular structure of **2** (Figure 5 and Table 1) features a $Co^{II}$ ion in a tetrahedral coordination geometry linked through oxygen and sulfur atoms to two bidentate anionic ligands [$N(OPPh_2)(SPPh_2)$]$^-$. As a result, the metal ion is surrounded by a spirobicyclic {$NP_2(S)O$}Co{$O(S)P_2N$} system, with endocyclic S···O bites of 3.439(4)/3.553(5) Å (see Table 1). The tetrahedral $CoO_2S_2$ core is slightly distorted and shows X–Co–Y (X, Y = S, O) angles in the range 105.86(17)–115.03(14)°, Co–O/Co–S average distances of 1.980(6)/2.331(3) Å (Table 1) and a Co(1)–S(1)–O(1)/Co(1)–S(2)–O(2) dihedral angle of 86.28(10)°. The Co–X (X = S, O) bond lengths are very close to those reported for various monomeric $Co^{II}$ complexes with tetra- or octahedral coordination geometry,[11] such as [Co{$N(SPPh_2)_2$}$_2$][4b] [av. Co–S 2.335(2) Å], [$Co(OAc)_2$(etu)$_2$],[12a] [Co–S 2.328(3) Å, av. Co–O 1.957(7) Å; etu = ethylenthiourea] and [$Co(acac)_2(py)_2$][12b] [Co–O 2.034(3) Å; acac = acethylacetonate]. As similarly observed in complexes [Mn{$N(OPPh_2)(SPPh_2)$}$_2$][13a] and [Ni{$N(OPR_2)(SPPh_2)$}$_2$] (R = Ph, Me),[13b] no static disorder effects[13c] in the metal-bonded donor-atom sites are present. Close inspection of the structure shows that the two chemically equivalent, nonplanar $CoO(S)P_2N$ rings exhibit different geometries. The Co(1)–S(2)–P(3)–N(2)–P(4)–O(2) ring in fact, is arranged in a pseudochair conformation with P(4) and S(2) in the apices and dihedral angles between the nearly planar Co(1)–P(3)–N(2)–O(2) array [max. dev. from mean plane ±0.040(2) Å] and Co(1)–S(2)–P(3) and O(2)–P(4)–N(2) planes of 42.08(9) and 13.0(3)°, respectively. Co(1)–S(1)–P(1)–N(1)–P(2)–O(1) indeed shows a highly distorted pseudoboat geometry where S(1) and P(2) act as "bow" and "stern" in comparison to the slightly twisted Co(1)–P(1)–N(1)–P(2) plane [max. dev. ±0.119(2) Å], with P(1)–S(1)–Co(1)–N(1)–P(1)–Co(1)–O(1) and N(1)–P(2)–O(1)–N(1)–P(1)–Co(1)–O(1) dihedral angles of 30.92(15) and 17.7(4)°, respectively. As already observed in the related complex [Co{$N(SPPh_2)$}$_2$], some degree of π-electron delocalisation is present on the $CoO(S)P_2N$ rings, as shown by the P–X (X = S, O) average bond lengths, which increase with respect to [$HN(OPPh_2)(SPPh_2)$][14] by 0.071 Å (P–O) and 0.083 Å (P–S), whereas the average N–P distances decrease by 0.104 Å.

## Reactivity of Complex 2

In previous papers it was demonstrated that in complexes of the formula M{$L_{(SS)}$}$_2$ (M = Pd, Cu)[4c,5] it was possible to protonate the metal-bound ligands to form the corresponding cationic complexes in which the S,S′ chelation of the ligands was preserved. As a result of the different set of donor atoms in complex **2**, the protonation of the metal-bound ligands may induce different coordination modes at the metal centre: complexes with $CoO_2X_2$ or $CoS_2X_2$ cores and with X being a cobalt-coordinating anion. The formation of the cationic complex [Co{$HL_{(OS)}$}$_2$]$^{2+}$ in which the $CoO_2S_2$ core is preserved cannot be excluded either. In this study the reactivity of **2** was only tested towards HI to verify the feasibility of this synthetic procedure and the nature of the formed complex. The reaction of **2** in MeCN with increasing amounts of hydroiodic acid (55 wt.-% in water) to reach a **2**/HI molar ratio of 1:4 results in the complete disappearance of the visible band at 566 nm, which is characteristic of complex **2**, and the formation of the pattern of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bands related to the formation of complex **1**. The diagram reporting the conversion of **2** into complex **1** vs. the molar ratios of HI/**2** shows that such a conversion is almost stoichiometric (ca. 92%) when starting with a HI/**2** molar ratio of 2 (Figure 6).

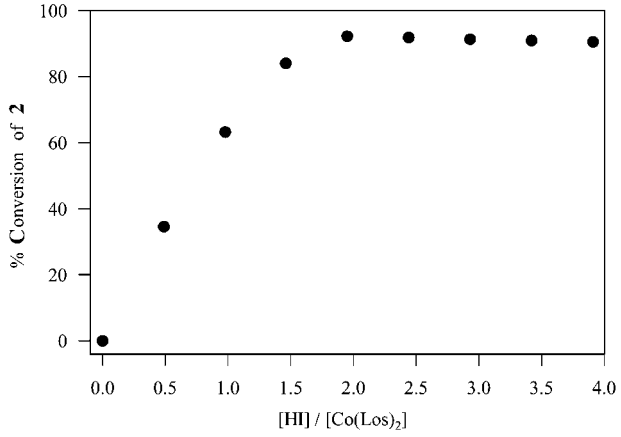

Figure 6. Percent conversion of compound **2** into **1** vs. [HI]/[**2**] molar ratios, which results from analysis of the bands at 566 and 734 nm. $[Co\{L_{(OS)}\}_2]$ (**2**), $7.25 \times 10^{-4}$ M in MeCN, HI (55% in water), 21 °C. HI/[**2**] molar ratios: 0.00, 0.48, 0.97, 1.46, 1.95, 2.44, 2.93, 3.42, 3.91.

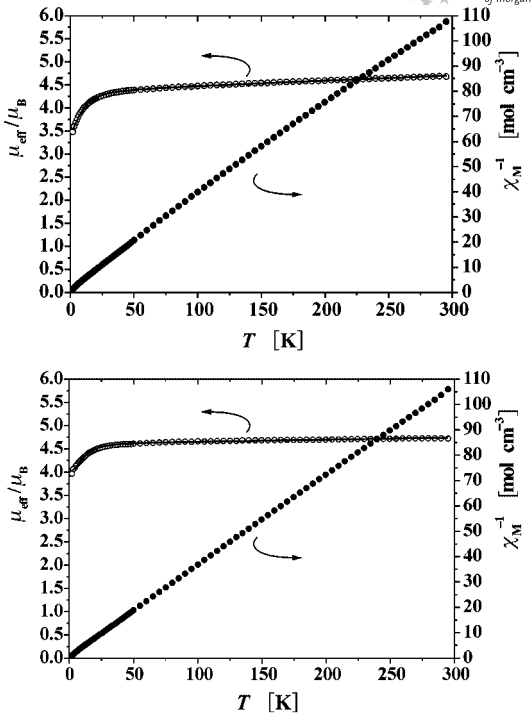

Figure 7. Plots of $\mu_{eff}$ (○) and $\chi_M^{-1}$(●) vs. temperature for **1** (top) and **2** (bottom) at 5000 G; the solid lines represent the fitted calculated curve (see text).

## Magnetic Studies and Theoretical Calculations

Electronic structures of the new complexes were probed by SQUID measurements and DFT calculations. Magnetic susceptibility measurements were carried out for both complexes at two different magnetic fields in a temperature range from 2.0 to 295 K. No significant field dependence was observed for either of the complexes. The temperature dependence of $\chi_M^{-1}$ and the effective magnetic moment $\mu_{eff}$ are shown in Figure 7. The value of $\mu_{eff}$ is around 4.70 or 4.75 $\mu_B$ for **1** or **2**, respectively, at room temperature, which is in the range expected for high-spin ($S$ = 3/2) $Co^{II}$ ions that reside in a tetrahedral environment.[15] The value of $\mu_{eff}$ remains almost constant over a large temperature range but drops to around 3.5 $\mu_B$ at very low temperatures. This may be attributed to zero-field splitting (ZFS) of the $^4A_2$ ground state, which can be quite large for tetrahedral $Co^{II}$ (although smaller than for five- or six-coordinate $Co^{II}$ ions).[15–18] Magnetic parameters were determined by using a fitting procedure to the spin Hamiltonian for axial ZFS and Zeeman interaction as shown in Equation (2).[19]

$$H = D[S_z^2 - 1/3\,S(S+1)] + g\mu_B \vec{S}\cdot\vec{B} \quad (2)$$

Temperature-independent paramagnetism (*TIP*) was included according to $\chi_{calcd.} = \chi + TIP$. For both complexes slightly better agreement with experimental data was obtained when intermolecular interactions were considered in a mean field approach by using a Weiss temperature $\Theta$.[20,21] Best simulation parameters are $g$ = 2.25, $|D|$ = 12.0 $cm^{-1}$, $TIP = 1310 \times 10^{-6}$ $cm^3 mol^{-1}$ and $\Theta$ = 0.11 K for **1** and $g$ = 2.37, $|D|$ = 11.9 $cm^{-1}$, $TIP = 541 \times 10^{-6}$ $cm^3 mol^{-1}$ and $\Theta$ = 0.66 K for **2**. The $|D|$ parameters for **1** and **2** are almost identical and lie in the upper range of typical values for many tetrahedral $Co^{II}$ compounds (7–12 $cm^{-1}$).[15,17] ZFS values around –9.5 $cm^{-1}$ were recently found for two other compounds with a tetrahedral $[CoI_2O_2]$ core, whereas larger values $D$ = –12.4 $cm^{-1}$ and $D$ = –16.7 $cm^{-1}$ were reported for $[CoCl_2(PPh_3)_2]$ and $[CoBr_2(PPh_3)_2]$, respectively.[21] The Weiss temperature $\Theta$ relates to intermolecular interactions $zJ$ of 0.03 $cm^{-1}$ for **1** and 0.18 $cm^{-1}$ for **2**, where $J$ is the interaction parameter between two nearest neighbour magnetic centres and $z$ is the number of nearest neighbours.[22] Intermolecular interactions are apparently very weak if not negligible for both complexes, and they appear to be even smaller for **1** than for **2**. This confirms that no significant coupling occurs through the H-bonding linkages that constitutes the 1D polymeric array in **1**.

DFT calculations (see Experimental Section) were performed on the anionic model ligands $[N(OPH_2)(SPH_2)]^-$, $L'_{(OS)}$, and $[N(SPH_2)_2]^-$, $L'_{(SS)}$, and on the corresponding neutral $Co^{II}$ complexes $[Co\{N(OPH_2)(SPH_2)\text{-}O,S\}_2]$ (**3**) and $[Co\{N(SPH_2)_2\text{-}S,S'\}_2]$ (**4**). The geometry optimisation of these complexes in their quartet electron configuration with the use of the UB3LYP hybrid functional yields bond lengths and angles very close to the structural ones (Tables S1 and S2, Supporting Information). As regards $L'_{(SS)}$, the optimised bond lengths and angles are reproduced well relative to those previously reported with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Gaussian 94 at the same level of theory.[4b] In Figure 8, the HOMO and LUMO computed for $L'_{(OS)}$ and $L'_{(SS)}$ are depicted. In both compounds, the HOMO is mainly built of the in-plane p atomic orbitals of the sulfur donor atoms, which are negatively charged; the calculated Mulliken charge for $L'_{(OS)}$ are $Q_S$ = –0.582 e, $Q_O$ = –0.578 e and for $L'_{(SS)}$ the calculated charge $Q_S$ = –0.561 e. It is noteworthy that the calculated $Q_S$ charges show similar values, which suggests a similar bonding ability for the P–S groups in the related anionic ligands; the acidity constant values determined experimentally for the $HL_{(OS)}$ and $HL_{(SS)}$ ligands ($pK_a$ = 5.42 and 5.61, respectively) further support this view. The Mulliken charge calculated on the metal centre at the fully relaxed geometry (Figure 9) shows a marked difference in the $Co^{II}O_2S_2$ and $Co^{II}S_4$ cores ($Q_{Co}$ = 0.436 and 0.023 e in **3** and **4**, respectively), which might be the basis for the different reactivities of the two complexes. This is reflected in a different charge distribution on the S–P–N–P–O and S–P–N–P–S elements that constitute the backbones of complexes **3** and **4**, which show markedly different values, mostly related to the P=O and P=S groups.

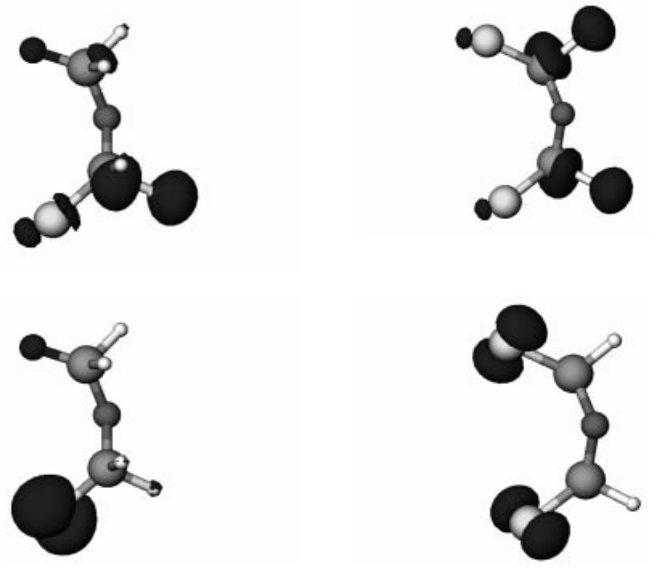

Figure 8. HOMO (bottom row) and LUMO (top row) drawings in $L'_{(OS)}$ (left) and $L'_{(SS)}$ (right). Optimised selected bond lengths and angles: $L'_{(OS)}$: P–S 1.984, P–O 1.504, N–P(O) 1.621, N–P(S) 1.619 Å; P–N–P 128.14°;·$L'_{(SS)}$: P–S 1.980, P–N 1.623 Å; P–N–P 128.20°.

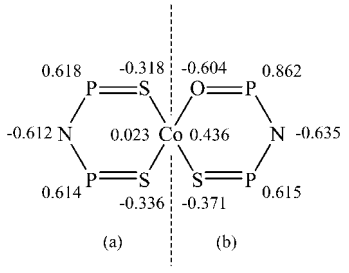

Figure 9. Mulliken charge distribution (e) in model complexes **4** (a) and **3** (b). Hydrogen atoms are omitted for clarity.

## Conclusions

The $Co^{II}$ complex $[Co\{[HN(OPPh_2)(SPPh_2)\text{-}O]_2\}I_2]$ (**1**) was synthesised in a single step from the oxidation of cobalt powder by the adduct $HL_{(OS)}{\cdot}I_2$ in $Et_2O$ prepared in situ. The X-ray crystal structure of this complex shows a $Co^{II}$ ion in a tetrahedral coordination environment with the ligands in a neutral form, which has not been previously observed, and the metal ion is bound through the oxygen atoms and two iodide ions, which completes the $CoI_2O_2$ core. This mode of ligation leaves the $–PPh_2(S)$ groups in a dangling position, which we were unsuccessful in involving in further coordination activity towards "soft" centres. The treatment of **1**, dissolved in MeCN, with NaOH caused the deprotonation of the imido group in the ligands and the formation of $[Co\{[N(OPPh_2)(SPPh_2)\text{-}O,S]_2\}]$ (**2**), in which the $Co^{II}$ ion is found to occupy a tetrahedral coordination environment with a $CoO_2S_2$ core. The magnetic behaviour of **1** and **2** is consistent with tetrahedral high-spin ($S$ = 3/2) $Co^{II}$ possessing a $^4A_2$ ground state with appreciable ZFS ($|D| \approx 12\ cm^{-1}$). When complex **2** is treated with hydroiodic acid, complex **1** is almost quantitatively reobtained. Comparison of the Mulliken charges at the $Co^{II}$ centres in the $CoO_2S_2$ and $CoS_4$ cores reveals that the metal in the latter core is markedly less electropositive (0.437 and 0.023 e, respectively) than the former, which instills different intrinsic reactivity towards nucleophilic agents.

## Experimental Section

**Materials and instrumentation:** Reagents were used as purchased from Aldrich. Diethyl ether was distilled from $LiAlH_4$ shortly before use. IR spectra were measured as KBr (4000–400 $cm^{-1}$) pellets with a Bruker Equinox 55 FTIR spectrometer. FT-Raman spectra were recorded with a Bruker FRS 100/S Fourier transform Raman spectrometer operating with a diode-pumped Nd:YAG exciting laser emitting at 1064 nm. $^{31}P$ NMR spectra were recorded with a Varian Unity 300 MHz spectrometer. The $pK_a$ values of the $HL_{(OS)}$ and $HL_{(SS)}$ ligands were determined by NMR spectroscopic measurements according to the guidelines reported in the IUPAC Technical Report.[23] The $^{31}P$ NMR spectra of 19 different solutions in MeCN/$H_2O$, 4:1 ($5.12 \times 10^{-3}$ M) and 0.1 M $[(Bu)_4N(NO_3)]$, as supporting electrolyte, at (25.0 ± 0.2) °C were recorded in the pH range 2.5–12.0. The pH values were adjusted by the addition of HCl or NaOH (0.1 or 0.5 M). Peak positions are reported relative to $H_3PO_4$ (85%) at $\delta$ = 0.00 ppm used as external reference in a sealed coaxial tube. pH values were measured with a glass electrode. The experimental data were fitted by a sigmoidal equation with the SigmaPlot software (see Supporting Information, section S3). Visible absorption spectra were measured with a Nicolet Evolution 300 spectrophotometer. Susceptibility measurements were carried out with a Quantum-Design MPMS-5S SQUID magnetometer equipped with a 5 T magnet in the range from 295 to 2 K. The powdered samples were contained in a gel bucket and fixed in a nonmagnetic sample holder. Each raw data file for the measured magnetic moment was corrected for the diamagnetic contribution of the sample holder and the gel bucket. Experimental data were corrected for the underlying diamagnetism by using tabulated Pascal constants (incremental method). Simulations of the experimental magnetic data were performed with full-matrix diagonalisation of zero-field splitting

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and Zeeman interaction according to the appropriate Hamiltonian (see text) and including temperature-independent paramagnetism (*TIP*).[24] The ligand $HN(OPPh_2)(SPPh_2)$, $HL_{(OS)}$, was prepared according to ref.[25] Quantum chemical calculations were carried out at the density functional theory (DFT) level by using the NWChem. 4.7 program[26,27] and ECCE 3.2.5.[28] DFT calculations were attempted on $[Co\{[HN(OPh_2)(SPh_2)\text{-}O]_2\}I_2]$, $[Co\{[HN(SPh_2)(OPh_2)\text{-}S]_2\}I_2]$, $[Co\{N(OPh_2)(SPh_2)\text{-}O,S\}_2]$ (**3**) and $[Co\{N(SPh_2)_2\text{-}S,S'\}_2]$ (**4**) by adopting different functionals and basis sets. Unfortunately, notwithstanding the numerous attempts and different types of SCF convergence methods, a combination of functional and basis set capable to allow SCF convergence for all compounds was not found. We report here the results obtained for **3** and **4** by using Schafer, Horn and Ahlrichs all-electron double-ζ basis sets with polarisation function[29] for the ligand atoms, the LanL2DZ basis set along with effective core potentials[30] for Co,[31] with the three-parameter[32] hybrid B3LYP functional (based on the gradient corrected Becke exchange functional[33] along with the Lee, Yang and Parr correlation functional[34]). All calculations were performed on a Pentium 4 workstation running on a Linux Mandriva One 2006 operating system.

**$[Co\{HN(OPPh_2)(SPPh_2)\text{-}O\}_2I_2]$ (1).** A mixture of $HL_{(OS)}$ (0.100 g, 0.230 mmol) and $I_2$ (0.058 g, 0.230 mmol) in diethyl ether (200 mL) was stirred at 25 °C under an atmosphere of $N_2$ until the reagents were completely dissolved. Cobalt metal powder (< 2 μ; 0.014 g, 0.237 mmol) was added while stirring. This was continued at room temperature for ca. 4 d. The resulting emerald green solid was collected by suction filtration, washed with a mixture of $CH_2Cl_2$/*n*-hexane (1:5) and dried in vacuo. Yield: 0.074 g (26.4%). M.p. > 250 °C. IR (KBr): $\tilde{\nu}$ = 2632 (w), 1436 (vs), 1328 (m), 1312 (s), 1172 (s), 1151 (s), 1129 (s), 1099 (s), 1026 (w), 998 (w), 998 (s), 944 (s), 789 (s), 747 (s), 728 (s), 688 (s), 646 (s), 614 (w), 569 (m), 523 (m), 487 (m) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$, $dm^3\,mol^{-1}\,cm^{-1}$) = 661 (172), 696 (346), 734 (432) nm. $C_{48}H_{42}CoI_2N_2O_2P_4S_2$ (1179.57): calcd. C 48.87, H 3.59, N 2.37, S 5.44; found C 49.1, H 3.7, N 2.4, S 5.2.

**$[Co\{N(OPPh_2)(SPPh_2)\text{-}O,S\}_2]$ (2)**. To a stirred solution of compound **1** (0,100 g, 0.084 mmol) dissolved in $CH_3CN$ (25 mL) was slowly added NaOH (1 M, 180 μL, 0.180 mmol). The deep-blue solution was concentrated to separate well-shaped blue crystals that were washed with $CH_2Cl_2$/*n*-hexane (1:5) and dried in vacuo. Yield: 0.064 g (83%). M.p. 176 °C. IR (KBr): $\tilde{\nu}$ = 3054 (w), 1636 (m), 1482 (w), 1436 (s), 1236 (vs), 1233 (vs), 1178 (s), 1121 (s), 1045 (vs), 1025 (s), 998 (m), 799 (w), 745 (s), 725 (vs), 692 (vs), 618 (w), 575 (vs), 548 (vs), 419 (s), 506 (s) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$, $dm^3\,mol^{-1}\,cm^{-1}$) = 566 (319), 625 (331), 715 (205) nm. $C_{48}H_{40}CoN_2O_2P_4S_2$ (923.75): calcd. C 62.41, H 4.36, N 3.03, S 6.94; found C 63.0, H 4.4, N 3.0, S 7.1.

**X-ray Crystallography:** Intensities were corrected for Lorentz-polarisation effects and absorption effects by employing multiscan SADABS for compound **1**,[35] and $\psi$-scan[36a] for compound **2**. Both structures were solved by direct methods (SIR-97)[36b] and refined on $F_o^2$ with the SHELXL-97[36c] program (WINGX suite[36d]). All non-hydrogen atoms were refined with anisotropic displacement parameters. All H atoms, seen on the $\Delta F$ maps, were introduced in the structure model. For compound **1** they were allowed to ride on the corresponding C atoms, whereas for compound **2** they were refined with isotropic displacement parameters. Alternative element type assignments to the donor atoms of the chelating ligands were carefully tested, but led to unphysical variation of displacement parameters across the ligand and discarded. The maximum and minimum residual electron density on the final $\Delta F$ map are 1.344 and –1.050 e $Å^{-3}$, respectively for compound **1** and 0.527 and –0.447 e $Å^{-3}$ for compound **2**.

CCDC-641240 and -641241 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystal data for 1:** $C_{48}H_{42}CoI_2N_2O_2P_4S_2$, $M$ = 1179.57, orthorhombic, $a$ = 21.892(2) Å, $b$ = 18.590(2) Å, $c$ = 24.046(2) Å, $U$ = 9786.1(16) $Å^3$, $T$ = 294(2) K, space group *P*bca (no. 61), $Z$ = 8, $\mu$ = (Mo-$K_\alpha$) 1.868 $mm^{-1}$. 85740 reflections (9660 unique) were collected at room temperature in the range $3.22 \le 2\theta \le 52.20°$ by employing a 0.10 × 0.10 × 0.05 mm crystal mounted on a Siemens SMART CCD diffractometer. 5768 reflections ($R_{int}$ = 0.0807), final $R_1$ [$wR_2$] values of 0.0506 [0.1306] on $I > 2\sigma(I)$ [all data], with GoF = 0.954 for 550 parameters.

**Crystal data for 2:** $C_{48}H_{40}CoN_2O_2P_4S_2$, $M$ = 923.75, monoclinic, $a$ = 12.511(2) Å, $b$ = 18.272(5) Å, $c$ = 19.599(3) Å, $\beta$ = 100.495(10)°, $U$ = 4405.3(16) $Å^3$, $T$ = 298(2) K, space group $P2_1/c$ (no. 14), $Z$ = 4, $\mu$ = (Mo-$K_\alpha$) 0.671 $mm^{-1}$. 7551 reflections (6064 unique) were collected at room temperature in the range $4.22 \le 2\theta \le 46.00°$ by employing a 0.26 × 0.22 × 0.08 mm crystal mounted on a P4RA Siemens automatic diffractometer. 7548 reflections ($R_{int}$ = 0.0563), final $R_1$ [$wR_2$] values of 0.0606 [0.1471] on $I > 2\sigma(I)$ [all data], with GoF = 1.020 for 692 parameters and 4 restraints.

**Supporting Information** (see footnote on the first page of this article): Optimised geometries of complexes **3** and **4** in Cartesian orthogonal coordinate format, as derived from DFT calculations, and $pK_a$ determination of $HN(OPPh_2)(SPPh_2)$ and $HN(SPPh_2)(SPPh_2)$.

## Acknowledgments

Thanks are expressed to Prof. Antonio C. Fabretti (Dipartimento di Chimica, Università di Modena) for helpful discussions and to the "Centro Interdipartimentale Grandi Strumenti (C.I.G.S.)" of the University of Reggio Emilia for providing P4-RA Siemens X-ray equipment. Financial support from the National University Research Council (CNCSIS, Romania; Research project No. A-1456/2007) is greatly appreciated.

# Axial Coordination of Porphyrinatocobalt(II) Complexes with Bis(pyridinolato)silicon(IV) Phthalocyanines

**Xuebing Leng[a] and Dennis K. P. Ng*[a]**

**Keywords:** Phthalocyanines / Porphyrins / Axial coordination / UV/Vis spectroscopy

Treatment of dichlorosilicon(IV) phthalocyanine with 3- or 4-hydroxypyridine in the presence of pyridine in toluene gave the corresponding bis(pyridinolato)silicon(IV) phthalocyanine complexes SiPc(3-OPy)$_2$ (**1**) or SiPc(4-OPy)$_2$ (**2**), respectively, which were spectroscopically and structurally characterized. As shown by electronic absorption spectroscopy, these compounds axially bind to *meso*-tetraphenylporphyrinatocobalt(II) [Co(TPP) (**3**)] and *meso*-tetrakis(3,5-di-*tert*-butylphenyl)porphyrinatocobalt(II) [Co(TBPP) (**4**)] with the two pyridyl ligands forming the corresponding mixed phthalocyanine–porphyrin triads. The binding constants $K_1$ between the 4-pyridyl phthalocyanine **2** and the porphyrinatocobalt(II) complexes ($1.1–1.2 \times 10^4$ M$^{-1}$) are about threefold higher than those for the 3-pyridyl counterpart **1**. The heterodyads **2**·**3** and **2**·**4** were isolated by column chromatography and characterized by mass and absorption spectroscopy.

## Introduction

Phthalocyanines and porphyrins are two important classes of functional dyes. Owing to their unique and intriguing properties, these macrocycles have found widespread applications in various disciplines ranging from materials science, catalysis, nanotechnology to medicine.[1] Despite their structural similarities, these two classes of π systems exhibit very different optical and electronic properties making them useful in different areas. A hybrid system containing both of these macrocycles may combine their advantageous properties and improve the overall performance. One obvious example is the complementary major absorptions of phthalocyanines (650–700 nm) and porphyrins (400–450 nm) in the visible region. Mixed phthalocyanine–porphyrin assemblies can absorb strongly over a large part of the solar spectrum, which can facilitate various light-induced processes. This property is important in applications such as light harvesting, photovoltaics, and molecular photonics.[2] A substantial number of mixed phthalocyanine–porphyrin arrays have been reported.[3] Apart from a covalent linkage the two types of macrocycles can also be linked by a metal center in the form of sandwich-type complexes,[4] by a bridging nitrido, oxo, chloro, or hydroxo ligand to form cofacial complexes[5] or by electrostatic interactions to form face-to-face aggregates.[3,6] The use of host-guest interactions to assemble these macrocycles has also been reported recently.[7] Although axial coordination has been widely used to construct various multiporphyrin systems,[8] the use of this strategy to build mixed phthalocyanine–porphyrin scaffolds remains little studied.[9] We have recently prepared the bis(4-pyridinolato)silicon(IV) phthalocyanine (**2**), which can axially bind to various tetrapyrrolatozinc(II) derivatives forming the corresponding 1:2 or 1:1 molecular assemblies.[9b] We describe herein an extension of this work using **2** as well as the 3-pyridyl analogue **1** as the cores to complex with porphyrinatocobalt(II) complexes. The relatively strong cobalt–pyridine binding interactions allow the isolation of the heterodyads.

## Results and Discussion

The preparation of bis(3-pyridinolato)silicon(IV) phthalocyanine complex **1** was similar to that of the 4-pyridyl analogue **2** (Figure 1).[9b] It involved a ligand-substitution reaction of dichlorosilicon(IV) phthalocyanine with 3-hydroxypyridine in the presence of pyridine in toluene. Both **1** and **2** were soluble in common organic solvents and could be purified readily by column chromatography giving a comparable yield (75% and 72%, respectively). The porphyrinatocobalt(II) complexes Co(TPP) (**3**) and Co(TBPP) (**4**) (Figure 1) were prepared by cobaltation of the corresponding metal-free porphyrins.[10]

Both compounds **1** and **2** were fully characterized by using various spectroscopic methods and X-ray diffraction analyses. Single crystals of **1** were grown by slow diffusion of nitrobenzene into a $CHCl_3$ solution of **1**. The compound cocrystallized with two molecules of nitrobenzene in the triclinic system. As shown in part a of Figure 2, the structure contains an inversion center at the silicon center relating

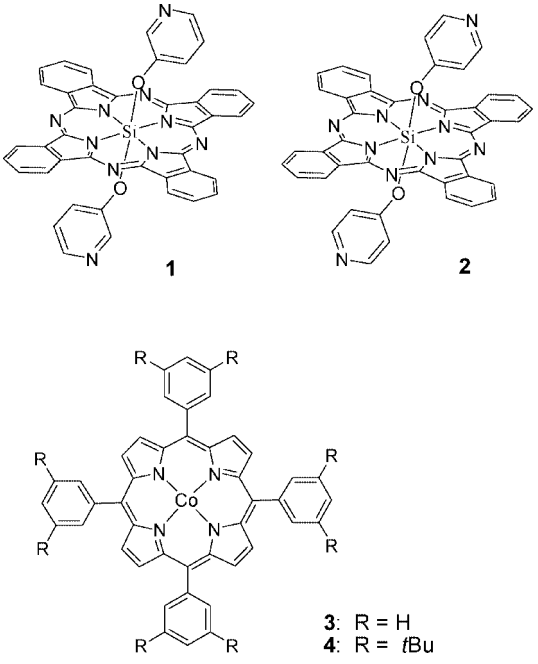

Figure 1. Structures of the bis(pyridyl) phthalocyanines **1** and **2**, and the porphyrinatocobalt(II) complexes **3** and **4**.

the two halves of the molecule. The silicon center is hexacoordinate with four isoindole nitrogen atoms of the phthalocyanine ring and two oxygen atoms of the pyridinolato ligands. The Si–O [1.740(2) Å] and average Si–N [1.912(4) Å] bond lengths as well as the other structural parameters are unexceptional.

Single crystals of **2** were grown by slow diffusion of MeOH into a $CHCl_3$ solution of **2**. The compound crystallized in the monoclinic system. The molecular structure of **2** (Figure 2, b) also contains an inversion center. The Si–O [1.715(2) Å] and average Si–N [1.910(4) Å] bond lengths are comparable with those of **1**. The phthalocyanine rings of **1** and **2** are essentially planar with a dihedral angle of 42.5° and 57.5°, respectively, between the phthalocyanine N(isoindole)$_4$ plane and the pyridyl ring. In both structures, particularly for **2**, the pyridyl-nitrogen atoms point outward favoring the complexation process.

The complexation of SiPc(4-OPy)$_2$ (**2**) and Co(TPP) (**3**) was first studied by electronic absorption spectroscopy. Figure 3 shows the UV/Vis spectra of mixtures of these two compounds in different ratios in $CHCl_3$, where the total concentration was fixed at 5.0 μM. It can be seen that as the mole fraction of SiPc(4-OPy)$_2$ (**2**) increases, the phthalocyanine B band at 354 nm, Q band at 684 nm, and vibronic band at 614 nm all increase in intensity. The porphyrin Soret band at 410 nm becomes attenuated and a new band at

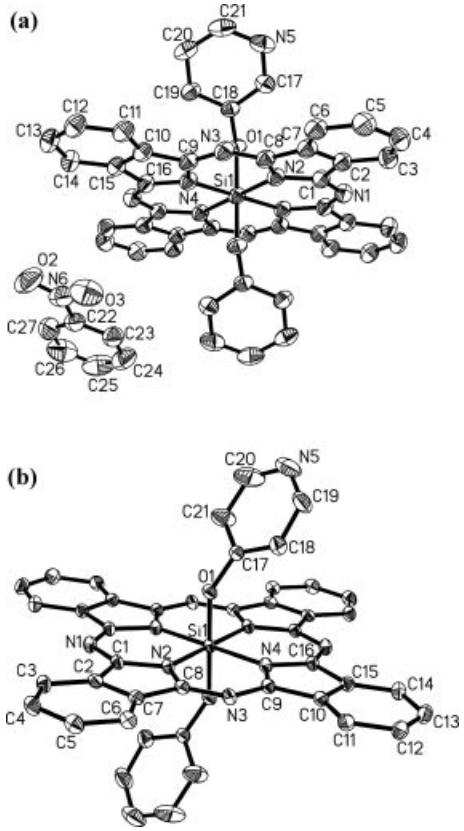

Figure 2. Molecular structures of (a) SiPc(3-OPy)$_2$ (**1**) and (b) SiPc(4-OPy)$_2$ (**2**) showing the 30% probability thermal ellipsoids for all non-hydrogen atoms.

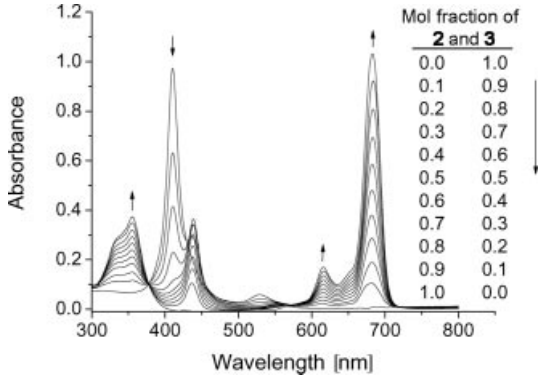

Figure 3. Absorption spectra of mixtures of SiPc(4-OPy)$_2$ (**2**) and Co(TPP) (**3**) in $CHCl_3$. The total concentration of the two compounds was fixed at 5.0 μM.

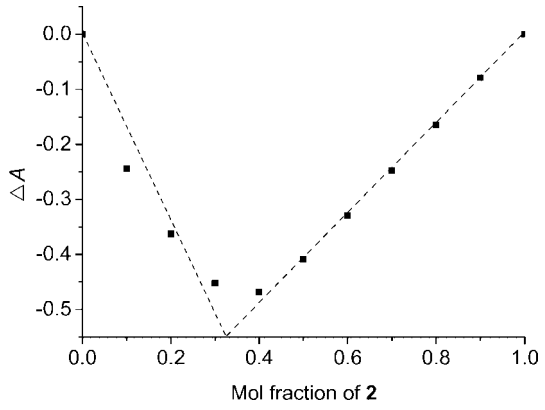

Figure 4. Job's plot for the complexation of SiPc(4-OPy)$_2$ (**2**) and Co(TPP) (**3**) in $CHCl_3$ obtained by monitoring the band at 410 nm.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

435 nm appears, which can be attributed to the axially bound species. The corresponding Job's plot[11] (Figure 4), obtained by monitoring the band at 410 nm, shows a minimum when the mole fraction of **2** is about 0.34. This suggests a 1:2 stoichiometry for **2** and **3**, and the formation of the heterotriad **2**·(**3**)$_2$.

Figure 5 shows the changes of the Soret band of Co(TPP) (**3**), fixed at a concentration of 4.5 μM, upon titration with SiPc(4-OPy)$_2$ (**2**) (from 75 to 260 μM) in $CHCl_3$. The corresponding solution of **2** with the same concentration was used as the reference in recording the spectra. Under these conditions the phthalocyanine SiPc(4-OPy)$_2$ (**2**) was in great excess. Therefore, the 1:1 complex was predominantly formed and the Benesi–Hildebrand equation [Equation (1)] could be applied to determine the binding constant $K_1$.[12]

$$\frac{b}{\Delta A} = \frac{1}{S_t K_1 \Delta\varepsilon[L]} + \frac{1}{S_t \Delta\varepsilon} \quad (1)$$

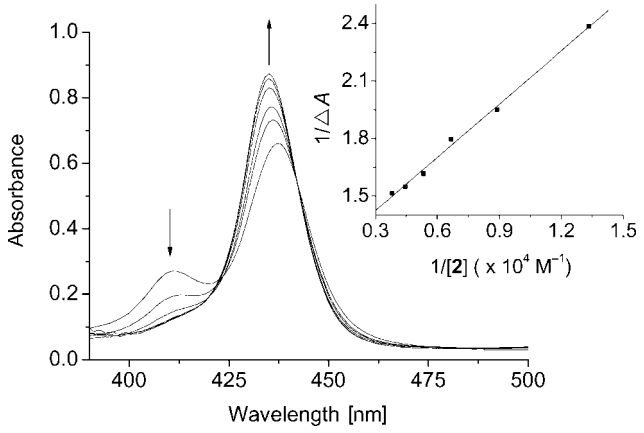

Figure 5. Changes in the UV/Vis spectrum of Co(TPP) (**3**) (4.5 μM) upon titration with SiPc(4-OPy)$_2$ (**2**) (from 75 to 260 μM) in $CHCl_3$. The inset shows the corresponding Benesi–Hildebrand plot obtained by monitoring the change in absorbance at 435 nm.

where $b$ is the optical path length (1 cm); $\Delta A$ is the change in absorbance at 435 nm, where the largest change was observed; $S_t$ is the total concentration of substrate (i.e. **3**); [L] is the concentration of ligand [i.e. **2**, which can be approximated as $L_t$ (the total concentration of ligand) where $L_t >> S_t$]; and $\Delta\varepsilon = \varepsilon_{11} - \varepsilon_S - \varepsilon_L$, where $\varepsilon_{11}$, $\varepsilon_S$, and $\varepsilon_L$ are the molar absorptivities of the 1:1 complex, **3**, and **2** at 435 nm, respectively. A plot of $1/\Delta A$ vs. 1/[**2**] (inset of Figure 5) gave a straight line from which the value of $K_1$ was determined to be $(1.2 \pm 0.1) \times 10^4$ M$^{-1}$. Similarly, a linear relationship was also found in the Scott or Scatchard plot giving virtually the same $K_1$ value.[12]

The complexation of other systems including SiPc(4-OPy)$_2$ (**2**) with Co(TBPP) (**4**), as well as the 3-pyridyl analogue **1** with these two porphyrinatocobalt(II) complexes, was investigated by the same approach. All the systems gave very similar spectral changes except the complexation of SiPc(3-OPy)$_2$ (**1**) with Co(TBPP) (**4**), for which the band ascribed to the axially bound species appeared as a shoulder at ca. 440 nm instead of a distinct signal (see Figure S1 in the Supporting Information). The results showed that both phthalocyanines **1** and **2** bind to porphyrinatocobalt(II) complexes **3** and **4** in a 1:2 manner proceeding in a stepwise fashion as shown in Figure 6.

Table 1 summarizes the binding constants ($K_1$) for these systems determined by absorption spectroscopy. The corresponding data for the complexation of 3- and 4-hydroxypyridine (3-OHPy and 4-OHPy) with Co(TPP) (**3**) were also determined by the same method and are included for comparison. It can be seen that the values for the 4-pyridinolato complex **2** are about three times larger than those of the 3-pyridinolato counterpart **1**. The addition of *tert*-butyl groups on the *meso*-phenyl substituents of porphyrin does not have a significant influence on the binding constants. The stronger binding for **2** compared with that of **1** can be attributed to the fact that the 4-pyridinolato ligand is a better σ donor than the 3-pyridinlolato analogue (because of the presence of the resonance form A as shown in Figure S2 in the Supporting Information). In addition, the 4-pyridin-

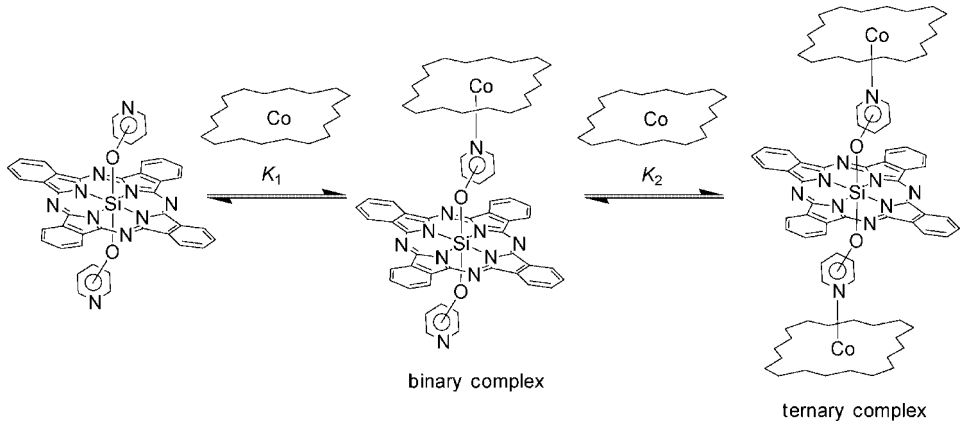

Figure 6. A schematic diagram showing the axial coordination porphyrinatocobalt(II) complexes **3** and **4** with bis(pyridyl) phthalocyanines **1** and **2**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

olato ligand can readily complex with the cobalt center, but for the 3-pyridinolato analogue complexation can only occur when the nitrogen atom is pointing away from the phthalocyanine plane (conformation B rather than C as shown in Figure S3 in the supporting information). However, since the $K_1$ value for 4-OHPy is also almost three times larger than that for 3-OHPy it seems that the electronic factor plays a dominant role. The binding constants determined for these systems are comparable with those reported for other porphyrinatocobalt(II) complexes and pyridine-type donor ligands.[13]

Table 1. Comparison of the binding constants.[a]

| Ligand | Porphyrin | $K_1$ [M$^{-1}$] |
|---|---|---|
| SiPc(3-OPy)$_2$ (**1**) | Co(TPP) (**3**) | $(3.9 \pm 1.2) \times 10^3$ |
| SiPc(3-OPy)$_2$ (**1**) | Co(TBPP) (**4**) | $(4.3 \pm 0.3) \times 10^3$ |
| SiPc(4-OPy)$_2$ (**2**) | Co(TPP) (**3**) | $(1.2 \pm 0.1) \times 10^4$ |

[a] Determined by absorption spectroscopy in $CHCl_3$.

Because of the relatively large binding constants attempts were made to isolate the complexed species. By stirring a 1:2 (in mole) mixture of SiPc(4-OPy)$_2$ (**2**) and Co(TPP) (**3**) or Co(TBPP) (**4**) in $CHCl_3$ a new TLC spot with an $R_f$ value of ca. 0.3 in $CHCl_3$/MeOH (v/v, 5:1) appeared. The new products could be isolated as a blue solid by silica-gel column chromatography using $CHCl_3$/MeOH (v/v, 9:1) as eluent. Mass and UV/Vis spectroscopic methods showed that they were the binary complexes **2·3** and **2·4**. The corresponding ternary complexes **2·(3)**$_2$ and **2·(4)**$_2$ could not be isolated, which is probably because of their small quantity (the binary complexes could only be isolated in ca. 5% yield). The MALDI-TOF mass spectra of the dyads showed an envelope peaking at $m/z$ = 1399.0 or 1847.7, assignable to the corresponding molecular ion. For both signals, the isotopic pattern was in good agreement with the simulated spectrum. The identity of these complexes was further confirmed by accurate mass measurements (using ESI mass spectrometry).

Figure 7 compares the UV/Vis spectrum of the dyad **2·3** in $CHCl_3$ and the sum of the spectra of **2** and **3**, all at the same concentration. It can be seen that the porphyrin Soret band is redshifted from 410 nm to 435 nm upon complexation, while the absorptions of the phthalocyanine component are essentially unchanged. Similar results were obtained for the binary complex **2·4** (see Figure S4 in the Supporting Information). These observations supported the findings that the binary complexes were stable enough to be isolated, which is in contrast to the porphyrinatozinc(II) counterparts.[9b] Under the same conditions, the binary complexes of the 3-pyridyl analogue **1** and the porphyrinatocobalt(II) complexes **3** and **4** could not be isolated, which is in accord with their weaker binding interactions.

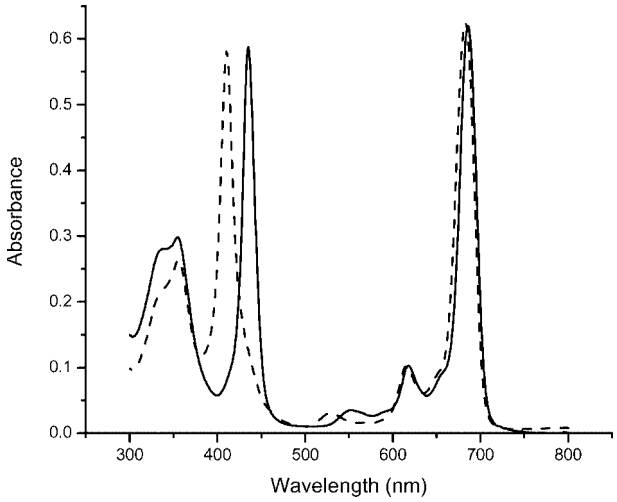

Figure 7. UV/Vis spectrum of the binary complex **2·3** (———) and the addition spectrum of **2** and **3** (-----) in $CHCl_3$. The concentrations of all the species were fixed at 3.2 μM.

## Conclusions

In summary, the bis(pyridyl) phthalocyanines **1** and **2** serve as good building blocks for hetero phthalocyanine–porphyrin arrays. As shown by absorption spectroscopy, they formed 1:2 complexes with porphyrinatocobalt(II) **3** and **4** with binding constants $K_1$ in the range of $3.9 \times 10^3$ to $1.2 \times 10^4$ M$^{-1}$. The heterodyads **2·3** and **2·4** could also be isolated and spectroscopically characterized. It is envisaged that this axial coordination approach can be extended to construct larger mixed phthalocyanine–porphyrin arrays. This work is in progress.

## Experimental Section

**General:** Reactions were performed under nitrogen. Toluene was distilled from sodium prior to use. *N*,*N*-Dimethylformamide (DMF) was predried with barium oxide and distilled under reduced pressure. The chloroform used in the UV/Vis studies was freshly distilled from $CaH_2$ under nitrogen. All other solvents and reagents were used as received. Chromatographic purifications were performed with silica gel (Macherey–Nagel, 70–230 mesh) columns with the indicated eluents. Compounds **2**,[9b] **3**,[10a] and the metal-free *meso*-tetrakis(3,5-di-*tert*-butylphenyl)porphyrin [$H_2$(TBPP)][10b] were prepared by previously described methods. $^1$H and $^{13}$C{$^1$H} NMR spectra were recorded with a Bruker DPX 300 spectrometer ($^1$H NMR, 300; $^{13}$C NMR, 75.4 MHz) in $CDCl_3$. Spectra were referenced internally using the residual solvent ($^1$H NMR: $\delta$ = 7.26 ppm) or solvent ($^{13}$C NMR: $\delta$ = 77.0 ppm) resonances relative to $SiMe_4$. MALDI-TOF mass spectra were recorded with a Bruker bench TOF mass spectrometer equipped with a standard UV-laser desorption source, using α-cyano-4-hydroxycinnamic acid as the matrix. FAB and ESI mass spectra were measured with a Thermo Finnigan MAT 95 XL mass spectrometer. UV/Vis spectra were recorded with a Cary 5G spectrophotometer. Elemental analyses were performed by the Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, China.

**SiPc(3-OPy)$_2$ (1):** A mixture of dichlorosilicon(IV) phthalocyanine (1.0 g, 1.64 mmol), 3-hydroxypyridine (0.32 g, 3.36 mmol), and pyr-

idine (2 mL) in toluene (50 mL) was heated at reflux overnight. The volatiles were then removed under reduced pressure and the residue was chromatographed on a silica gel column using $CHCl_3$/MeOH (v/v, 9:1) as eluent to give the product as a blue solid (0.89 g, 75%). $^1$H NMR: $\delta$ = 9.64–9.67 (m, 8 H, Pc-$H_\alpha$), 8.40–8.43 (m, 8 H, Pc-$H_\beta$), 6.98 (dd, $J$ = 1.6, 4.8 Hz, 2 H, Py-*H*), 5.63 (dd, $J$ = 4.8, 8.4 Hz, 2 H, Py-*H*), 3.92 (d, $J$ = 1.6 Hz, 2 H, Py-*H*), 2.87 (d, $J$ = 8.4 Hz, 2 H, Py-*H*) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 149.7, 146.2, 139.2, 138.5, 135.2, 131.7, 125.6, 124.1, 122.0 ppm. UV/Vis ($CHCl_3$) [$\lambda_{max}$ (log $\varepsilon$)]: 354 (4.89), 614 (4.59), 654 (4.53), 684 (5.36) nm. HRMS (FAB): calcd. for $C_{42}H_{25}N_{10}O_2Si$ [$MH^+$] 729.1931; found 729.1928. $C_{42}H_{24}N_{10}O_2Si$·MeOH (760.85): calcd. C 67.88, H 3.71, N 18.41; found C 67.81, H 4.01, N 18.54.

**Co(TBPP) (4):** A mixture of $H_2$(TBPP) (100 mg, 0.09 mmol) and anhydrous cobalt(II) chloride (20 mg, 0.15 mmol) in DMF (10 mL) was stirred at 120 °C for 8 h. The cooled dark red solution was then poured into MeOH (100 mL), and the precipitate was filtered off and washed with MeOH. The crude product was purified by column chromatography using $CHCl_3$ as eluent (92 mg, 87%). UV/Vis ($CHCl_3$) [$\lambda_{max}$ (log $\varepsilon$)]: 411 (5.18), 528 (4.11) nm. HRMS (FAB): calcd. for $C_{76}H_{92}CoN_4$ [$M^+$] 1119.6653; found 1119.6638.

**Heterodyad 2·3:** A mixture of SiPc(4-OPy)$_2$ (**2**) (20 mg, 0.03 mmol) and Co(TPP) (**3**) (37 mg, 0.06 mmol) in $CHCl_3$ (50 mL) was stirred at room temp. overnight. After removing the solvent in vacuo the residue was chromatographed with $CHCl_3$/MeOH (v/v, 9:1) as eluent. The third blue band was collected and evaporated to give the product (2 mg, 5%). UV/Vis ($CHCl_3$) [$\lambda_{max}$ (log $\varepsilon$)]: 355 (4.96), 435 (5.26), 553 (4.04), 618 (4.51), 686 (5.29) nm. MS (MALDI-TOF): an isotopic cluster peaking at $m/z$ = 1399.0 [$M^+$]. HRMS (ESI): calcd. for $C_{86}H_{53}CoN_{14}O_2Si$ [$MH^+$] 1400.3577; found 1400.3574.

**Heterodyad 2·4:** According to the above procedure, SiPc(4-OPy)$_2$ (**2**) (20 mg, 0.03 mmol) complexed with Co(TBPP) (**4**) (66 mg, 0.06 mmol) in $CHCl_3$ (50 mL) to give the dyad **2·4** (3 mg, 6%). UV/Vis ($CHCl_3$) [$\lambda_{max}$ (log $\varepsilon$)]: 351 (4.95), 437 (5.33), 551 (4.13), 619 (4.52), 688 (5.28) nm. MS (MALDI-TOF): an isotopic cluster peaking at $m/z$ = 1847.7 [$M^+$]. HRMS (ESI): calcd. for $C_{118}H_{117}CoN_{14}O_2Si$ [$MH^+$] 1848.8584; found 1848.8052.

**X-ray Crystallographic Analysis of 1 and 2:** Crystal data and details of data collection and structure refinement are given in Table 2. For **1**, data were collected at 293 K with an MSC/Rigaku RAXIS IIc imaging-plate system using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) from a Rigaku RU-200 rotating-anode generator operating at 50 kV and 90 mA ($2\theta_{min}$ = 3°, $2\theta_{max}$ = 55°, 2–5° oscillation frames in the range 0–180°, exposure 12 min per frame).[14] A self-consistent semi-empirical absorption correction based on a Fourier coefficient fitting of symmetry-equivalent reflections was applied by using the ABSCOR program.[15] Crystallographic data of **2** were collected with a Bruker SMART CCD diffractometer with a Mo-$K_\alpha$ sealed tube ($\lambda$ = 0.71073 Å) at 293 K, using a $\omega$ scan mode with an increment of 0.3°. Preliminary unit-cell parameters were obtained from 45 frames. Final unit-cell parameters were obtained by global refinements of reflections obtained from integration of all the frame data. The collected frames were integrated using the preliminary cell-orientation matrix. The SMART software was used for collecting frames of data, indexing reflections, and determination of lattice constants; SAINT-PLUS for the integration of the intensity of reflections and scaling;[16] SADABS for absorption corrections;[17] and SHELXL for space group and structure determination, refinements, graphics, and structure reporting.[18]

CCDC-644806 and CCDC-644807 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Absorption spectra of mixtures of SiPc(3-OPy)$_2$ (**1**) and Co(TBPP) (**4**) in $CHCl_3$; different resonance structures of the 3- and 4-pyridinolato ligands; schematic diagrams showing the complexation of SiPc(3-OPy)$_2$ (**1**) with porphyrinatocobalt(II) complexes. UV/Vis spectrum of the binary complex **2·4** and the addition spectrum of **2** and **4** in $CHCl_3$.

# Identification of Hexameric Water and Hybrid Water–Chloride Clusters Intercalated in the Crystal Hosts of (Imidoylamidine)nickel(II) Complexes

**Maximilian N. Kopylovich,*[a] Ekaterina A. Tronova,[a,b] Matti Haukka,[c] Alexander M. Kirillov,[a] Vadim Yu. Kukushkin,*[b] João J. R. Fraústo da Silva,[a] and Armando J. L. Pombeiro*[a]**

**Keywords:** Crystal engineering / Hydrogen bonds / Imidoylamidine complexes / Water clusters / X-ray diffraction

Two structurally related bis(imidoylamidine or 1,3,5-triazapentadiene)nickel(II) compounds {Ni[HN=C(3-py)NC(3-py)=NH]$_2$}·$H_2O$·MeOH (**1**) and [Ni{HN=C(3-py)N(H)C(3-py)=NH}$_2$]$Cl_2$ (**2**) with symmetrical 3-pyridyl (3-py) substituents have been prepared by direct 2-butanone oxime mediated transformation of 3-cyanopyridine in the presence of Ni(MeCO$_2$)$_2$·$4H_2O$ or $NiCl_2$·$2H_2O$, respectively. Compounds **1** and **2** have been characterized by elemental analyses, IR, $^1$H and $^{13}$C{$^1$H} NMR spectroscopy, and FAB$^+$ mass spectrometry, while their slow recrystallization in air from organic solvents revealed a high affinity for water and resulted in the formation of the derived compounds [Ni{HN=C(3-py)NC(3-py)=NH}$_2$]·$6H_2O$ (**1′**) and [Ni{HN=C(3-py)N(H)$_{0.5}$C(3-py)=NH}$_2$]Cl·$2H_2O$ (**2′**). Single-crystal X-ray diffraction analyses allowed the identification of discrete hexameric water or hybrid water–chloride clusters hosted by the crystal matrixes of **1′** and **2′**, respectively. Both the $(H_2O)_6$ and $[(H_2O)_4(Cl)_2]^{2-}$ clusters possess similar geometries and consist of cyclic planar tetranuclear $(H_2O)_4$ or $[(H_2O)_2(Cl)_2]^{2-}$ cores with two dangling water molecules. These water associates occupy voids in the crystal cells and display extensive H-bonding interactions with monomeric nickel–organic units, thus playing a key role in the formation of 3D hydrogen-bonded supramolecular assemblies.

## Introduction

The identification, characterization, and classification of various water assemblies in different crystalline materials has recently become a popular research field, namely towards understanding the properties of bulk water in its liquid and solid phases as well as interpretation of water–water interactions in various environments including, for example, inorganic materials, supramolecular systems, and biomolecules.[1–3] In contrast, the investigation of hybrid $H_2O$ clusters composed of hydrogen-bonded water associates with other solvents, counterions, or small molecules has received less attention.[1b,4] In particular, there are only a few reports focused on the experimental identification and analysis of discrete water–chloride clusters[5a,5g] or H-bonded networks between water of crystallization and chloride counterions[1b,5b–5f,5h] in crystalline materials, in spite of the substantial theoretical studies[6] on such objects, and the importance of the latter in, for example, natural environments, biochemistry, materials chemistry, drug design, catalysis, and atmospheric research.[5,6]

Within our ongoing studies on the self-assembly synthesis of various transition-metal complexes,[7] we have recently reported the new Cu/Na[3a] and Ni[3b] coordination compounds and shown that their metal–organic matrixes host different types of decameric water clusters with unusual geometries. Thus, in pursuit of these and other studies, namely focusing on the new synthetic methods for phthalocyanines[8a] and analogous imidoylamidine (imam) compounds,[8b,8c] we report herein the preparation and full characterization of two structurally related bis(imidoylamidine)nickel(II) complexes **1** and **2**, which upon recrystallization lead to the derived compounds **1′** and **2′** that act in the solid state as crystal hosts for water-containing clusters. We also show how a slight modification of the synthetic and crystallization procedures may result in the incorporation of geometrically related, but in their composition distinctly different, hexameric $(H_2O)_6$ or $[(H_2O)_4(Cl)_2]^{2-}$ clusters.

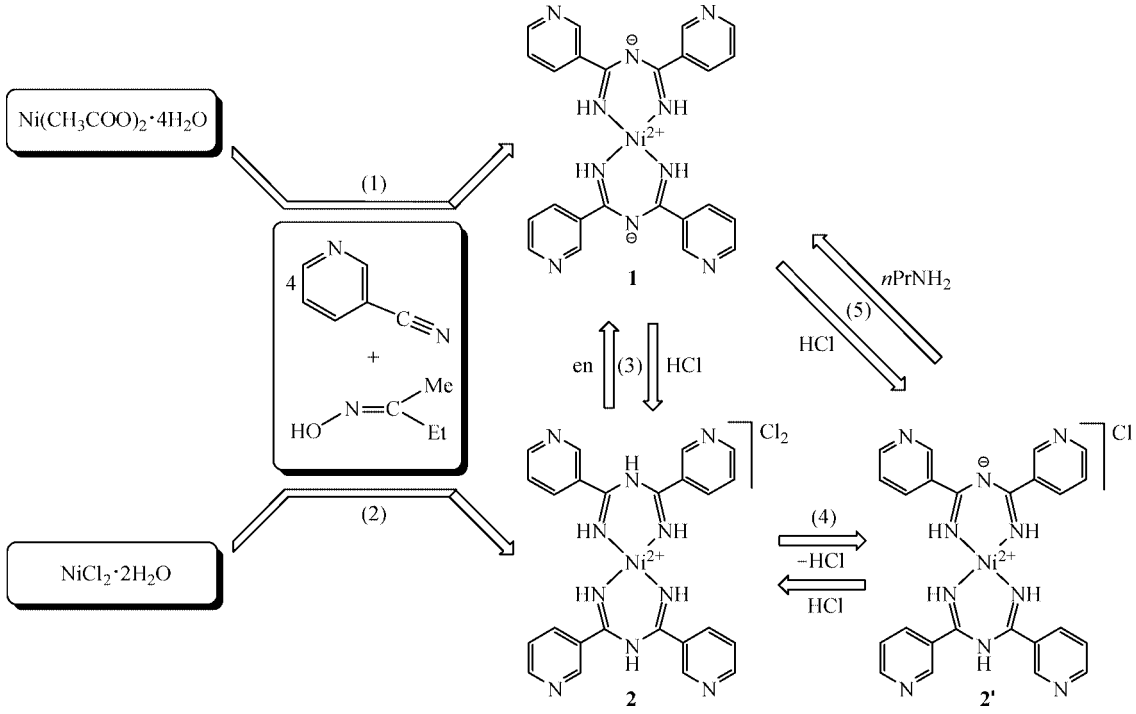
## Results and Discussion

### Synthesis and Spectroscopic Characterization

The bis(imidoylamidine or 1,3,5-triazapentadiene) compounds [Ni{HN=C(3-py)NC(3-py)=NH}$_2$]·$H_2O$·MeOH (**1**)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. Synthesis of bis(imidoylamidine)nickel(II) complexes (solvent molecules of crystallization are omitted for the sake of clarity); en = $H_2NCH_2CH_2NH_2$.

and [Ni{HN=C(3-py)N(H)C(3-py)=NH}$_2$]$Cl_2$ (**2**) with symmetrical 3-pyridyl (3-py) substituents were easily synthesized by modifying our previously reported[8c] (ketoxime)nickel(II)-mediated procedure for a variety of related bis(imidoylamidine) complexes. Hence, treatment of nickel(II) acetate tetrahydrate with 4 equiv. of 3-cyanopyridine in solution of 2-butanone oxime at 70 °C resulted in a single-pot formation of the neutral $Ni(imam)_2$ complex **1** [Scheme 1, reaction (1)]. It was isolated as a bright yellow crystalline solid in the form of a methanol/water solvate upon recrystallization from hot methanol in the presence of ethylenediamine.

However, the repetition of this synthetic procedure using nickel(II) chloride dihydrate as the nickel salt led to the formation of the cationic (+2) complex **2** isolated as a yellow powder from the reaction mixture [Scheme 1, reaction (2)]. The interconversion of compounds **1** and **2** can be achieved by treatment with HCl (**1**→**2**) or ethylenediamine (**2**→**1**) [Scheme 1, reactions (3)]. It should be mentioned that related bis(imidoylamidine)nickel(II) and -copper(II) complexes with various aromatic substituents have been previously reported,[9] but their synthetic procedures are different and more complicated than those now reported for compounds **1** and **2**, usually involving several reaction steps or rather harsh reaction conditions (e.g. solvothermal synthesis).

The presence of 2-butanone oxime (another oxime can also be applied) is essential for the synthesis of **1** and **2**, since the respective reactions between the nickel(II) salts and 3-cyanopyridine do not proceed in the absence of the oxime. In fact, this reagent, namely upon nucleophilic addition to the nitrile (NCR), can promote its hydrolytic conversion into ammonia and amidine $RC(=NH)NH_2$ (the latter upon coupling of $NH_3$ to NCR) which, on further nucleophilic addition to a ligated nitrile, leads to the imidoylamidine products. The reaction can proceed via an intermediate complex derived from double addition of the oxime to the nitrile ligand, as proposed for the oxime-mediated conversion of phthalonitriles into phthalocyanines and for related (ketoxime)nickel(II)-promoted processes.[8] The compounds **1** and **2** have been characterized by IR, $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy, $FAB^+$ mass spectrometry, elemental and single-crystal X-ray diffraction (for products **1′** and **2′** derived upon recrystallization) analysis.

The IR spectra of **1** and **2** show typical bands for bis(imidoylamidine)nickel(II) complexes[8b,8c] due to ν(NH), ν(C=N), and δ(NH) vibrations with absorbance maxima in the ranges of 3292–3169, 1655–1642, and 1548–1547 $cm^{-1}$, respectively. The overall identical $[M + H]^+$ (for **1**) and $[M - H]^+$ (for **2**) ions are observed at *m*/*z* = 507, with the expected isotopic distribution patterns, in the $FAB^+$ mass spectra. The $^1H$ and $^{13}C\{^1H\}$ NMR spectra reveal the expected resonances at typical chemical shifts for the corresponding imam ligands[8b,8c,9b–9d,10] (and solvents of crystallization in the case of **1**), while the elemental analyses are consistent with the proposed formulations. Complexes **1** and **2** are insoluble in water, but during the crystal growth experiments in organic medium, they appear to show a high affinity for water, absorbing its traces from organic solvents and/or air, and resulting in the formation of the derived compounds [Ni{HN=C(3-py)NC(3-py)=NH}$_2$]·$6H_2O$ (**1′**) and [Ni{HN=C(3-py)N(H)$_{0.5}$C(3-py)=NH}$_2$]Cl·$2H_2O$ (**2′**),

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

whose crystal cells according to the X-ray analyses contain 6 or 2 strongly associated water molecules of crystallization, respectively, as discussed below. Compound **2′** resulted from deprotonation of **2** upon recrystallization in air from a methanol/chloroform solution, and regenerated **2** on reaction with HCl [Scheme 1, reactions (4)]. It is also obtained by single protonation (by HCl) of **1** and conversely yielded the latter upon reaction with *n*$PrNH_2$ [Scheme 1, reactions (5)].

### X-ray Crystal Structure of [Ni{HN=C(3-py)NC-(3-py)=$NH\}_2$]·$6H_2O$ (1′)

Compound **1′** crystallizes in the triclinic space group $P\bar{1}$, and consists of the neutral bis(imidoylamidine) [Ni{H*N*=C(3-py)NC(3-py)=*N*H}$_2$] unit (Figure 1a) and six water molecules of crystallization. The nearly square-planar coordination environment around the centrosymmetric tetracoordinate Ni(1) center is filled by two imam ligands. They act as *N*,*N*-chelators through equivalent Ni(1)–N(1) [1.847(1) Å] and Ni(1)–N(3) [1.848(1) Å] bonds, forming the six-membered Ni(1)–N(1)–C(1)–N(2)–C(14)–N(3) rings with N(1)–Ni(1)–N(3) bite angles of 89.48(6)° (Figure 1a). Within the Ni(imam)$_2$ core the N(1)–C(1) [1.310(2) Å] and N(3)–C(14) [1.315(2) Å] bonds are only slightly shorter (by ca. 0.03 Å) than N(2)–C(1) [1.357(2) Å] and N(2)–C(14) [1.353(2) Å], thus potentially indicating a delocalized character of Ni–imam rings, as reported previously for related compounds.[9b] Although the Ni(imam)$_2$ core is almost planar, the 3-pyridyl substituents are significantly bent out of its plane. Most of the bonding parameters in **1′** are comparable to those reported previously for related bis(imidoylamidine)nickel complexes.[8b,8c,9b–9d,10]

The most interesting feature of the solid-state structure of **1′** is the hydrogen-bonding interactions of all six water molecules of crystallization (Table 1), providing the formation of finite hexameric water clusters intercalated in the crystal host of the (imidoylamidine)nickel complex (Figure 2a). Hence, two symmetry-generated water trimers [O(1)···O(2)···O(3)] are doubly interconnected through the O(2)–H(2OA)···O(3)$^{ii}$ [2.901(2) Å] hydrogen bonds generating the $(H_2O)_6$ clusters composed of a cyclic tetrameric core [O(2)···O(3)···O(2)···O(3)] and two pendent water molecules O(1). According to the systematization introduced by Infantes et al.,[1a,1b] such $(H_2O)_6$ clusters can be classified within the *R*4 type. The $(H_2O)_4$ core possesses a planar geometry with the O(2)···O(3)···O(2) and O(3)···O(2)···O(3) angles of ca. 76.89 and 103.11°, respectively (Figure 2a). Within the hexameric water associate the average O···O contact of ca. 2.82 Å (Table 1) is comparable to one found in liquid water (i.e. 2.85 Å)[1d] and in other discrete $(H_2O)_6$ clusters,[1a–1c,2] which are trapped by various metal–organic matrixes and composed of (i) a cyclic hexameric core of diverse conformations,[2a,2b,2d] (ii) a hexameric chain,[3b] or (iii) a cyclic tetrameric core with two pendent water molecules.[2c]

The $(H_2O)_6$ clusters occupy voids in the crystal cell of **1′** (Figure 3a) and extensively interact through multiple O–H···O or N–H···O hydrogen bonds [avg. 2.902(2) Å] with the host metal–organic matrix (Table 1). Hence, each dangling O(1) water molecule interacts with three imam nitrogen atoms [N(1), N(2), and N(5)] and each O(3) water contacts with one N(4) nitrogen atom (Figure 2a, Table 1), leading to the simultaneous multidimensional binding of every $(H_2O)_6$ cluster to eight different Ni(imam)$_2$ units in total. These multiple interactions play a key role in the

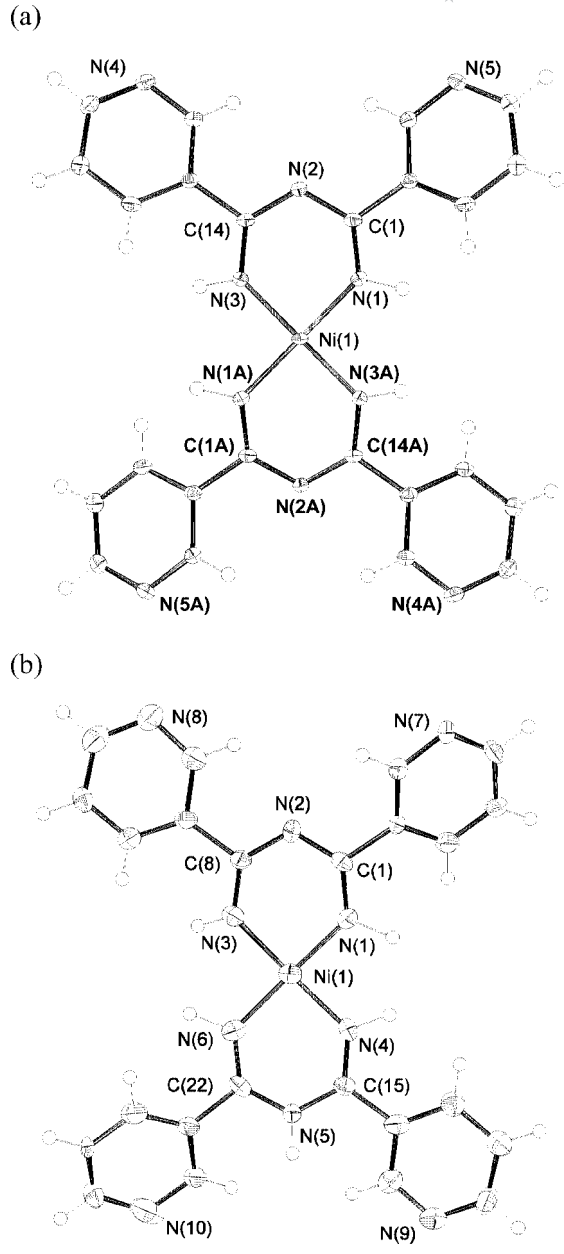


Figure 1. Thermal ellipsoid views of **1′** (a) and **2′** (b) with partial atomic numbering scheme. Thermal ellipsoids are drawn at 50% probability. Water molecules of crystallization and counterions are omitted for clarity. Symmetry transformations used to generate the equivalent atoms in **1′**: (A) $-x + 1, -y, -z + 1$. Figure 2. Perspective representations along the *a* crystallographic axis of discrete hexameric water (a) and water–chloride (b) clusters found in the crystal cells of **1′** (a) and **2′** (b). H-bonds are shown as dotted lines; water oxygen atoms and chloride atoms forming clusters are represented as spheres. Hydrogen-bond geometry parameters are those of Tables 1 and 2. Selected angles [°] within water-containing clusters: **1′**: O(1)···O(2)···O(3) 124.24 and 82.76, O(2)···O(3)···O(2) 76.89, O(3)···O(2)···O(3) 103.11; **2′**: O(99)···O(98)··· Cl(1) 137.73 and 85.80, O(98)···Cl(1)···O(98) 70.20, Cl(1)···O(98)··· Cl(1) 109.80.

structure stabilization and formation of an extended 3D hydrogen-bonded supramolecular assembly (Figure 3a). The separations between neighboring horizontal and vertical $(H_2O)_6$ clusters depicted in Figure 3a are within 8.7894(3) and 12.1448(6) Å, respectively, being equivalent to the *b* and *c* unit-cell dimensions.

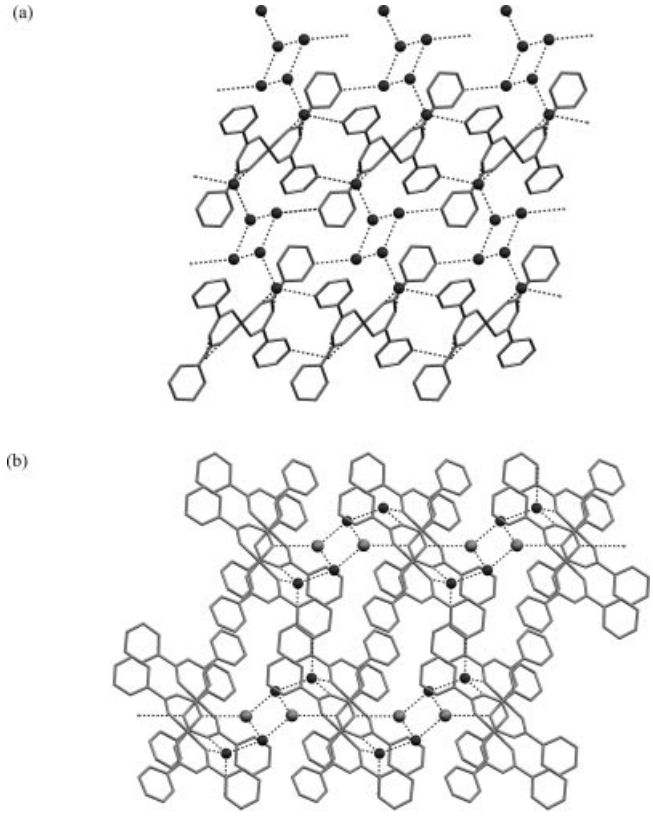

Figure 3. Fragments of the crystal packing diagrams along the *a* crystallographic axis of **1′** (a) and **2′** (b) with extensive hydrogen-bonded networks showing the interactions within the $(H_2O)_6$ and $[(H_2O)_4(Cl)_2]^{2-}$ clusters and between these clusters and the metal–organic matrixes; hydrogen atoms are omitted for clarity. Water oxygen atoms and chloride atoms forming clusters are shown as spheres.

### X-ray Crystal Structure of $[Ni\{HN{=}C(3\text{-py})N(H)_{0.5}C(3\text{-py}){=}NH\}_2]Cl{\cdot}2H_2O$ (2′)

The molecular structure of **2′** is composed of the cationic bis(imidoylamidine) $[Ni\{HN{=}C(3\text{-py})NC(3\text{-py}){=}NH\}\{HN{=}C(3\text{-py})N(H)C(3\text{-py}){=}NH\}]^+$ unit (Figure 1b), represented by $[Ni\{HN{=}C(3\text{-py})N(H)_{0.5}C(3\text{-py}){=}NH\}_2]^+$, with two water molecules of crystallization and one chloride counterion equalizing the positive charge. The latter is caused by protonation of the middle nitrogen atom in one of the two imidoylamidine ligands which, nevertheless, possess almost identical geometry and bonding parameters, both being also similar to those found in **1′** (Figure 1a). Thus, the basic structure of **2′** is not discussed in detail.

As in the case of **1′**, the analysis of hydrogen-bonding interactions in **2′** (Table 2) reveals the formation of hexameric water-containing clusters. Besides, they possess a geometry that is similar to that of **1′** and consists of a cyclic planar tetranuclear core and two dangling water molecules (Figure 2). The main difference arises from the substitution

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of two water molecules in the $(H_2O)_4$ core of **1′** for two chloride atoms, thus leading to the formation of the $[(H_2O)_2(Cl)_2]^{2-}$ core and resulting in a hexanuclear hybrid $[(H_2O)_4(Cl)_2]^{2-}$ cluster in **2′** (Figure 2b). Hence, two symmetry-equivalent water molecules of crystallization O(98) and chloride ions Cl(1) from neighboring units are doubly hydrogen-bonded [O(98)–H(98B)···Cl(1)$^{i}$ 3.172(7) Å] generating the tetranuclear core, which is further connected through the O(99)–H(99A)···O(98) [2.706(9) Å] interactions to give the hexanuclear associate. Within this cluster the O···O and O···Cl separations as well as the corresponding angles (Figure 2b) lie in the range found in other previously identified water–chloride assemblies, which include, for example, discrete cyclic $[(H_2O)_4(Cl)]^-$[5g] and $[(H_2O)_6(Cl)_2]^{2-}$[5a] clusters, as well as various 1D or 2D hydrogen-bonded networks with $\{[(H_2O)_4(Cl_2)]^{2-}\}_n$,[5h] $\{[(H_2O)_6(Cl)_2]^{2-}\}_n$,[5h] $[(H_2O)_7(HCl)_2]_n$,[5f] $\{[(H_2O)_{11}(Cl)_7]^{7-}\}_n$,[5b] $\{[(H_2O)_{14}(Cl)_2]^{2-}\}_n$,[5d] $\{[(H_2O)_{14}(Cl)_4]^{4-}\}_n$,[5e] and $\{[(H_2O)_{14}(Cl)_5]^{5-}\}_n$[5c] compositions.

Table 2. Hydrogen bonds [Å] in **2′**.[a]

| D–H···A | *d*(D···A) |
|---|---|
| Within hexameric water–chloride cluster | |
| O(99)–H(99A)···O(98) | 2.706(9) |
| O(98)–H(98B)···Cl(1)$^{i}$ | 3.172(7) |
| Between water–chloride cluster and metal–organic matrix | |
| O(99)–H(99B)···N(7)$^{ii}$ | 2.808(8) |
| N(5)–H(05)···O(99) | 2.765(8) |
| N(1)–H(01)···O(99)$^{i}$ | 3.115(8) |
| N(4)–H(04)···Cl(1) | 3.277(7) |

[a] Symmetry transformations used to generate equivalent atoms: (i) $-x + 1, -y, -z$; (ii) $x, y - 1, z - 1$.

The $[(H_2O)_4(Cl)_2]^{2-}$ clusters are held in cavities between the monomeric metal–organic units in the crystal cell of **2′** (Figure 3b) by means of extensive H-bonding contacts. Three types have been identified and include the O–H···N, N–H···O, and N–H···Cl interactions ranging from 2.808(8) to 3.277(7) Å (Table 2). As in the case of the $(H_2O)_6$ cluster in **1′**, the pendent water molecules O(99) in **2′** act as both hydrogen-bond donors or acceptors, bridging concurrently between three imidoylamidine nitrogen atoms (Figure 2b), thus leading, along with the N(4)–H(04)···Cl(1) interactions, to the multidimensional linkage of eight different Ni(imam)$_2$ units and resulting in the 3D hydrogen-bonded supramolecular pattern (Figure 3b). The separations between neighboring horizontal and vertical $[(H_2O)_4(Cl)_2]^{2-}$ clusters shown in Figure 3b are also equivalent to the *b* and *c* unit-cell dimensions, respectively (Table 3).

## Conclusion

In the present work we have shown that the previously reported (ketoxime)nickel(II)-mediated transformations of various organonitriles[8] can be applied to 3-cyanopyridine, resulting in the direct synthesis of Ni(imam)$_2$ complexes **1** and **2** with symmetrical 3-pyridyl substituents. We have also demonstrated that the modification of a starting nickel salt [i.e. $Ni(MeCO_2)_2{\cdot}4H_2O$ vs. $NiCl_2{\cdot}2H_2O$] leads to either neutral (**1**) or cationic (**2**) (imidoylamidine)nickel(II) compounds. In spite of being insoluble in water, upon recrystallization **1** and **2** exhibit a high affinity for water, absorbing its traces from organic solvents and/or air, and giving the derivatives **1′** and **2′** with a higher content of water of crystallization.

The single-crystal X-ray diffraction analysis of **1′** and **2′** reveals the formation of hexameric water or hybrid water–chloride clusters, respectively, which are geometrically related, but distinctly different, in composition. They are shown to play the principal role in the formation of 3D supramolecular networks in the solid state through multiple hydrogen-bonding interactions. Hence, the current work provides well-identified examples of such cases and expands the constantly growing family of water[1–3] and, to a lesser extent, water–chloride[5] clusters trapped by various crystalline materials, as well as showing that imidoylamidine compounds can act as suitable matrixes to host different types of water-containing assemblies.

Further developments of this study towards widening of the family of imidoylamidine complexes and the search for their potential applications in various areas (e.g. as coloring materials and/or analogues of phthalocyanines), as well as the identification of new types of hybrid water clusters in diverse crystalline environments, are currently in progress.

## Experimental Section

**General Materials and Procedures:** All synthetic work was performed in air. The reagents and solvents were obtained from commercial sources and used as received, i.e. without further purification or drying. $NiCl_2{\cdot}2H_2O$ was prepared according to an earlier described procedure.[8c] C, H, and N elemental analyses were carried out by the Microanalytical Service of the Instituto Superior Técnico. Melting points were determined with a Leica Gallen III instrument. Positive-ion FAB mass spectra were obtained with a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (*m*NBA) matrices of the samples with 8 keV (ca. 1.18 $10^{15}$ J) Xe atoms. Mass calibration for data system acquisition was achieved using CsI. Infrared spectra (4000–400 $cm^{-1}$) were recorded on KBr pellets with a BIO-RAD FTS 3000MX or Jasco FT/IR-430 instrument. $^1H$ and $^{13}C\{^1H\}$ NMR spectra were measured with a Varian UNITY 300 or Bruker 300 UltraShield™ spectrometer at ambient temperature.

**[Ni{HN=C(3-py)NC(3-py)=NH}$_2$]·H$_2$O·MeOH (1):** $Ni(MeCO_2)_2{\cdot}4H_2O$ (248 mg, 1.00 mmol; Aldrich) was stirred in 2-butanone oxime (5 mL; Aldrich) at 70 °C for 30 min, giving a homogeneous light green solution (solution **a**). 3-Cyanopyridine (416 mg, 4.00 mmol; Aldrich) was stirred separately in 2-butanone oxime (5 mL; Aldrich) at 70 °C for 30 min and then added to the above-mentioned solution **a**. The resulting reaction mixture was heated at 70 °C for 12 h, which resulted in the transformation of the clear green solution to a brownish-orange suspension. This was left to cool to room temperature yielding a dark orange product that was separated by filtration, washed with ethanol (15 mL), diethyl ether (10 mL), and then dried in air at room temperature. Recrystallization of the product from hot methanol with addition of

1.00 mmol of ethylenediamine gave a bright yellow crystalline precipitate of [Ni{HN=C(3-py)NC(3-py)=NH}$_2$]·H$_2$O·MeOH (**1**). Yield: 58%, based on nickel acetate. The compound does not have a characteristic melting point and upon heating decomposes at >300 °C. $C_{25}H_{26}N_{10}NiO_2$ (557.2): calcd. C 53.89, H 4.70, N 25.14; found C 53.67, H 5.06, N 24.55. FAB-MS(+) (*m*NBA): *m*/*z* = 507 [M + H]$^+$ (M = molecular ion of the complex part of the compound). IR (KBr): $\tilde{\nu}$ = 3397 [(s br.) $\nu$(H$_2$O+OH)], 3292 (s br.) [$\nu$(NH)], 1655 [(m-w) $\nu$(C=N)], 1548 [(s) $\delta$(NH)] cm$^{-1}$. $^1$H NMR (300 MHz, [D$_6$]acetone, Me$_4$Si): $\delta$ = 9.22 [s, 4 H, 2-C*H*(3-py)], 8.67 [d, *J* = 6.3 Hz, 4 H, 4-C*H*(3-py)], 8.37 [d, *J* = 7.8 Hz, 4 H, 6-C*H*-(3-py)], 7.46 [dd, *J* = 7.8 and 7.5 Hz, 4 H, 5-C*H*(3-py)], 6.93 (br. s, 4 H, N*H*), 4.11 (s, 1 H, MeO*H*), 3.49 (s, 3 H, C*H*$_3$OH), 3.31 (s, 2 H, *H*$_2$O) ppm. No reliable $^{13}$C{$^1$H} NMR spectrum could be accumulated due to the poor solubility of **1** in common deuterated solvents. The X-ray quality crystals of {Ni[HN=C(3-py)NC-(3-py)=NH]$_2$}·6H$_2$O (**1′**) were grown by slow concentration in air at ca. 25 °C of an acetone/toluene (1:10, v/v) solution of **1**.

**[Ni{HN=C(3-py)N(H)C(3-py)=NH}$_2$]Cl$_2$ (2):** NiCl$_2$·2H$_2$O (166 mg, 1.00 mmol) was stirred in 2-butanone oxime (5 mL; Aldrich) for 5 min, whereupon 3-cyanopyridine (416 mg, 4.00 mmol; Aldrich) was added and the reaction mixture heated at 70 °C for 1 d. Upon addition of 3-cyanopyridine, the homogenization of the reaction mixture was observed for 10 min, giving a greenish-brown solution. The color of the reaction mixture changed with time (ca. 1 h) from greenish-brown to dark brown, and a yellow powder began to form after ca. 3 h, which after 24 h was separated by filtration, washed with three 15-mL portions of acetone and dried in vacuo at room temperature to give **2**. Yield: 55% based on nickel chloride. Compound **2** does not have a characteristic melting point and upon heating decomposes at >300 °C. $C_{24}H_{22}Cl_2N_{10}Ni$ (580.1): calcd. C 49.69, H 3.82, N 24.15; found C 49.30, H 4.02, N 24.19. FAB-MS (+) (*m*NBA): *m*/*z* = 507 [M – H]$^+$. IR (KBr): $\tilde{\nu}$ = 3169 [(s br.) $\nu$(NH)], 1642 [(s) $\nu$(C=N)], 1547 [(s) $\delta$(NH)] cm$^{-1}$. $^1$H NMR [300 MHz, CDCl$_3$ (90%) + CD$_3$OD (10%), Me$_4$Si]: $\delta$ = 8.98 [s, 4 H, 2-C*H*(3-py)], 8.53 [d, *J* = 4.4 Hz, 4 H, 4-C*H*(3-py)], 8.26 [d, *J* = 7.9 Hz, 4 H, 6-C*H*(3-py)], 7.34 [dd, *J* = 7.9 and 7.8 Hz, 4 H, 5-C*H*(3-py)] ppm; NH signals were not observed due to proton exchange with the solvent. $^{13}$C{$^1$H} NMR (75.4 MHz, CDCl$_3$ (90%) + CD$_3$OD (10%), Me$_4$Si): $\delta$ = 123.5 [5-*C*H(3-py)], 134.4 [*1*-*C*H-(3-py)], 135.6 [*6*-*C*H(3-py)], 147.7 [*2*-*C*H(3-py)], 149.9 [*4*-*C*H(3-py)], 162.7 [*C*=N(–N)] ppm. Slow concentration in air at ca. 25 °C of a methanol/chloroform (1:1, v/v) solution of **2** resulted in its dehydrochlorination, giving X-ray quality crystals of [Ni{HN=C(3-py)-N(H)$_{0.5}$C(3-py)=NH}$_2$]Cl·2H$_2$O (**2′**).

**X-ray Crystal Structure Determinations:** X-ray quality single crystals of **1′** and **2′** were mounted in inert oil within the cold gas stream of the diffractometer. The X-ray diffraction data were collected with a Nonius Kappa CCD diffractometer at 120 (**1′**) or 100 (**2′**) K. Since the crystals of **2′** were poorly diffracting leading to a lower data quality, the data were collected at lower temperature in order to obtain a satisfactory structure. The Denzo-Scalepack[11] program package was used for cell refinements and data reduction. Structures were solved by direct methods using the SIR-2004 (**1′**) or SHELXS-97 (**2′**) programs.[12,13] A multiscan absorption correction based on equivalent reflections (XPREP in SHELXTL)[14] was applied to all data. The structures were refined with SHELXL-97[15] and the WinGX graphical user interface.[16] Only NH (in **1′** and **2′**) and H$_2$O (in **1′**) hydrogen atoms were located from the difference Fourier map, but not refined. Other hydrogen atoms were placed in idealized positions and constrained to ride on their parent atoms. The hydrogen-bond geometry parameters as well as the crystallographic data for **1′** and **2′** are summarized in Tables 1–3. The molecular structures of **1′** and **2′** are depicted in Figure 1, the perspective representations of hexameric water-containing clusters found in these compounds are drawn in Figure 2, while the crystal packing diagrams exhibiting the formation of extended hydrogen-bonded polymeric patterns are shown in Figure 3. All symmetry codes in the discussion are those of Tables 1 and 2. CCDC-644970 (**1′**) and -644971 (**2′**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Preparation of Thiocarboxylate, Thiocarbamate and Xanthate Complexes of Pentacoordinate Nickel(II): Insertion of Heterocumulenes Into Nickel(II) Hydroxido Complexes

**M. Dolores Santana,*[a] Magalí Sáez-Ayala,[a] Luís García,[b] José Pérez,[b] and Gabriel García[a]**

**Keywords:** Nickel / Macrocyclic ligands / S ligands / Insertion / NMR spectroscopy / X-ray diffraction

The hydroxido complexes $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ [$N_3$-mc = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene ($N_3$-mc1) or 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene ($N_3$-mc2)] react in the presence of alcohols with $CS_2$ or PhNCS to yield xanthate $[(N_3\text{-mc})Ni\{S_2C(OR')\}][PF_6]$ or *O*-alkyl *N*-phenylthiocarbamate $[(N_3\text{-mc})Ni\{PhNC(OR')S\}][PF_6]$ complexes; these compounds represent the first examples of N,S-chelating thiocarbamates bound to nickel(II). The reactions of $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ with thiocarboxylic acids yield the corresponding thiocarboxylate derivatives $[(N_3\text{-mc})Ni\{SC(O)R'\}][PF_6]$. These paramagnetic nickel(II) complexes were characterized by both one- and two-dimensional (COSY) $^1H$ NMR spectroscopic techniques. The crystal structures of $[(N_3\text{-mc2})Ni(S_2COCH_3)][PF_6]$ (**2**), $[(N_3\text{mc2})Ni\{PhNC(OCH_2CH_3)S\}][PF_6]$ (**8**), $[(N_3\text{-mc2})Ni\{SC(O)CH_3\}][PF_6]$ (**10**) and $[(N_3\text{-mc1})Ni\{SC(O)Ph\}][PF_6]$ (**11**) were determined.

## Introduction

Dimeric hydroxido complexes $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ [$N_3$-mc = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene ($N_3$-mc1) or 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene ($N_3$-mc2)] have been shown to be good precursors in the synthesis of new coordination compounds. The acid–base reaction of these hydroxido complexes with protic acids leads to the formation of mono-[1–3] or dinuclear[4–6] complexes depending on the nature of the deprotonated ligand.

Dithioacid ligands have rich coordination and organometallic chemistry.[7] These ligands and their metal complexes deserve continuous attention due to their interesting structural and chemical properties, as well as their wide range of applications, for example, industrially as pesticides, vulcanization accelerators, lubricants but also as potent biological pesticides.[8] Those metal complexes were generally prepared by metathesis reactions of transition halides with the alkali metal salt of the corresponding thioacid.[8]

In the past decade, growing interest has been directed towards nickel as a biological and spectroscopically relevant metal. The nickel-containing enzyme urease degrades urea to ammonia and carbamate (and finally $CO_2$). The widely accepted mechanism for urease activity suggests that urea is activated by coordination to one nickel(II) ion in conjunction with extensive hydrogen bonding within the active-site pocket of the protein, and it is subsequently attacked by nucleophilic hydroxide ion bound to the opposite nickel(II) centre; the resulting carbamate species then decomposes further to yield carbonic acid and another molecule of ammonia.[9] Bioinorganic synthetic complexes are particularly relevant to the study of the active site of metalloenzymes, because they provide spectroscopic information against which theoretical results can be compared, and they can also be used to carry out hydrolytic transformations at dinuclear nickel(II) cores that mimic the urease active site.[10]

In previous studies we described the preparation of binuclear carbonate complexes $[\{Ni(N_3\text{-mc})\}_2(\mu\text{-}CO_3)][PF_6]_2$ when $CO_2$ was bubbled (or taken up directly from the atmosphere) through a solution of $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ in acetone [or if $(NH_4)HCO_3$ was added].[11] Following our systematic study of the reactivity of hydroxido complexes of nickel, we next investigated the reactivity of nonorganometallic hydroxido nickel complexes such as $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ with related heterocumulenes; carbon disulfide, $CS_2$, or phenylisothiocyanate, PhCNS, in the presence of alcohols R′OH, to form *O*-alkyl dithiocarbonate (xanthate) or *O*-alkyl *N*-phenylthiocarbamate pentacoordinate nickel(II) complexes, respectively. We report herein the first crystal structure of a N,S-chelating *N*-phenylthiocarbamate nickel complex (3D Search using the Cambridge Structural Database, CSD version 5.27, Aug. 2006 release). Thiocarboxylate complexes were also prepared by the acid–base re-

action of the hydroxido complexes and the corresponding thioacid. These paramagnetic nickel(II) complexes were characterized by both one- and two-dimensional (COSY) $^1$H NMR spectroscopic techniques; these techniques can provide a wealth of unique information on the electronic, magnetic and molecular properties of the metal-binding sites; however, relatively few two-dimensional $^1$H NMR spectroscopic studies involving $Ni^{II}$ ions in either model complexes or biological systems have been reported.[12]

## Results and Discussion

### Xanthate and Thiocarbamate Complexes

The hydroxido complexes $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ ($N_3$-mc = $N_3$-mc1, $N_3$-mc2) react with $CS_2$ in R′OH solution to yield the nickel xanthate complexes $[(N_3\text{-mc})Ni\{S_2C(OR')\}][PF_6]$ (**1**–**4**) shown in Scheme 1. The reaction of the nickel hydroxido complexes with PhNCS and alcohols proceeds likewise to yield the *O*-alkyl *N*-phenylthiocarbamate complexes $[(N_3\text{-mc})Ni\{PhNC(OR')S\}][PF_6]$ (**5**–**8**; Scheme 1). The complexes are air-stable, both in solid state and in solution. The new complexes were characterized by partial elemental analyses, $FAB^+$ mass spectrometry and spectroscopic methods (IR, UV/Vis and $^1$H NMR). In acetone solution, these complexes behave as 1:1 electrolytes.[13] The nucleophilicity of the Ni–OH unit in $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ was used here for the attack on cumulated double bond systems. In these reactions, supposedly, the first step consists of the addition of OH across one double bond, and the second step is an esterification of the coordinated acid $[Ni(N_3\text{-mc})(S\text{–}CS\text{–}OH)]^+$ by the alcohol solvent leading to complexes **1**–**8**.

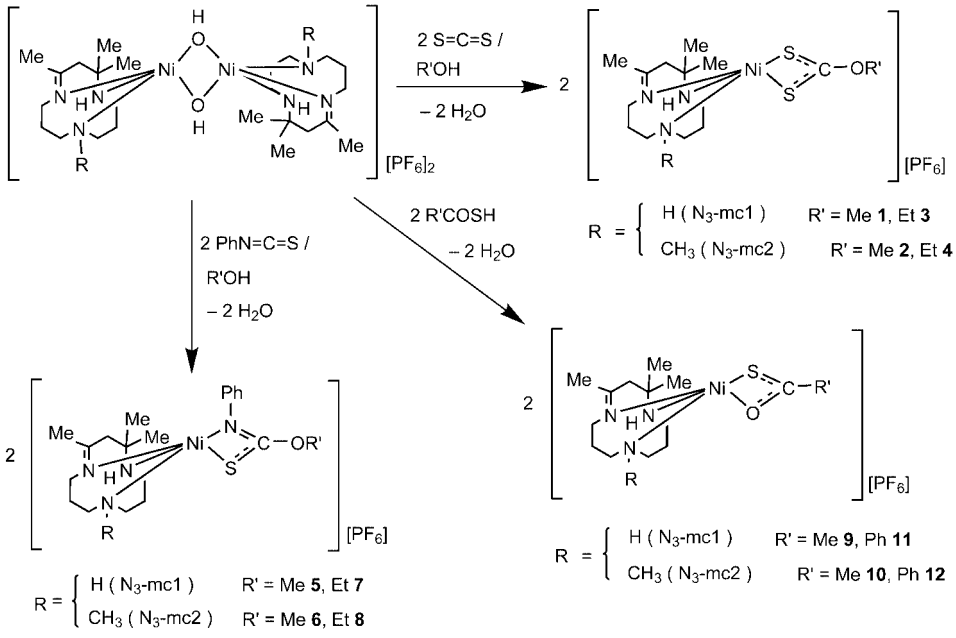
As observed before for related systems,[14] $CS_2$ was inserted in the presence of one equivalent of methanol to yield xanthogenate complexes. The insertion of *p*-nitrophenyl isothiocyanate in ethanol-stabilized chloroform produced iminothiocarbonate complexes.[15]

Moreover, the reactions of $[NBu_4]_2[\{(C_6F_5)_2Ni(\mu\text{-OH})\}_2]$ with alcohols or amines in the presence of carbon disulfide to afford the corresponding xanthate or dithiocarbamate complexes were previously reported.[16]

Xanthate complexes **1**–**4** exhibit three IR bands in the 1240–1030 cm$^{-1}$ region that are related to the vibrations of the $S_2COR'$ group.[17–20] The 1240 cm$^{-1}$ band has a substantial contribution from C–O–C stretching, the band around 1170 cm$^{-1}$ is mainly a contribution of the ν(C–O) mode and the absorption around 1040 cm$^{-1}$ is entirely ν(C=S).[21]

The presence of the thiocarbamate ligand in **5**–**8** is supported by the IR spectra, which show a band at 1537 or 1524 cm$^{-1}$ assignable to ν(C=N). These values are comparable to those reported for thiocarbamate palladium complexes where the thiocarbamate is coordinated to the metal in a N,S-chelating mode.[22] The IR spectra of complexes **1**–**8** also show the characteristic absorptions of the macrocyclic ligands $N_3$-mc1 and $N_3$-mc2 at 3290–3230 cm$^{-1}$ ν(N–H) and ca. 1660 cm$^{-1}$ ν(C=N) and two strong bands as a result of the presence of the $PF_6^-$ ion at 840 and 560 cm$^{-1}$.[4]

The electronic spectra of **1**–**8** are quite similar and show two d–d transitions in acetone solution with $\lambda_{max}$ between 602 and 639 nm (100–70 M$^{-1}$cm$^{-1}$) and between 360 and 380 nm (ca. 300 M$^{-1}$cm$^{-1}$), which could be assigned to the $^3B_1(F) \rightarrow {}^3E(F)$ and $^3B_1(F) \rightarrow {}^3A_2, {}^3E(P)$ transitions, respectively. Both $\lambda_{max}$ values and molar absorptivities are consistent with a pentacoordinate environment around nickel(II).[23]



Scheme 1.

X-ray diffraction studies were carried out on [($N_3$-mc2)-Ni($S_2COCH_3$)][$PF_6$]·1/2 $(CH_3)_2CO$ (**2**). A thermal ellipsoid drawing of the cation of **2** with a partial labelling scheme is shown in Figure 1. Selected geometric data are given in Table 1. The $Ni^{II}$ ion in **2** adopts a distorted square-pyramidal geometry, and the parameter $\tau$[24] shows a value of 0.16. The three nitrogen atoms of the macrocyclic ligand constitute a trigonal face of the pyramid. The two sulfur atoms from the xanthate and the two nitrogen atoms of the macrocycle form the basal plane (rmsd 0.0591). The nickel ion lies above this plane and is displaced 0.3976 Å toward the N3 nitrogen, which constitutes the axial donor. The plane of the chelate moiety defined by S1, S2, C14 and O1 (rms 0.0015) is inclined by 17.19(6)° to the basal plane. The Ni–N distances lie within the range reported in complexes containing the {Ni($N_3$-mc)} moiety.[11] The Ni–S bond lengths are slightly different [2.3930(9) and 2.5119(9) Å]; thus the xanthate ligand is bonded in an asymmetric chelating mode. These bond lengths are longer than those reported for other crystallographically characterized nickel–xanthate complexes with iminophosphanes in a distorted square-planar geometry.[25] Octahedral nickel–xanthate complexes containing phenanthroline[26] or pyrazine,[27] as well as pentacoordinate nickel–xanthate complexes containing triphosphanes,[28]have shorter Ni–S bond lengths. The bite angle of the chelating xanthate anion shows values of 73.46(3)°. The distortion from square-pyramidal geometry is also reflected in the bond angles between the *trans* ligands. The N1–Ni–S2 and N2–Ni–S1 bond angles are 162.05(9) and 152.61(8)°, respectively. The deviation of these angles from the idealized square-pyramidal geometry is also due to the four-membered chelating ring of the xanthate ligand.

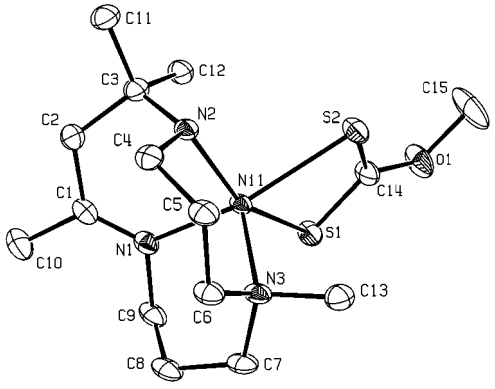

Figure 1. ORTEP drawing of the cation of complex **2** (ellipsoids at 50% probability level) with atom-labelling scheme. For clarity hydrogen atoms are omitted.

Structural studies were also carried out for the complex [($N_3$-mc2)Ni{PhNC($OCH_2CH_3$)S}][$PF_6$] (**8**). As shown in Figure 2 (selected bond lengths and angles in Table 2) the Ni atom has a distorted square-pyramidal geometry with a value of 0.14 for $\tau$. Distortions from the idealized square pyramidal geometry are almost localized in the equatorial plane where the bidentate ligand subtends an angle of 68.17(6)° to the metal. The Ni atom lies above of the basal plane (rmsd 0.0330) by 0.3642 Å. The plane of the chelate moiety defined by the S1, N4, C14 and O1 (rmsd 0.0066) atoms is inclined by 9.49(9)° to the basal plane, and the attached phenyl ring is somewhat rotated [65.33(7)°] about the N4–C17 axis. The C14–O1–C15 angle of 119.26(19)° suggests that the oxygen atom can be considered to be in the $sp^2$-hybridized state, and the C–O bond lengths agree with the values expected for a C($sp^2$)–O–C($sp^3$) system.[29] The C14–S1 bond length of 1.722(2) Å is indicative of a C($sp^2$)–S single bond,[30] whereas double bond character is well-defined in the N4–C14 bond of 1.301(3) Å. Thus, the negative charge within the bidentate ligand seems to be mainly localized on the sulfur atom.[31]

Table 1. Selected bond lengths and angles for complex **2**.[a]

| Bond lengths [Å] | | | |
|---|---|---|---|
| Ni1–N2 | 2.038(3) | Ni1–S1 | 2.3930(9) |

The $^1$H NMR spectra of complexes **1**–**8** exhibit sharp isotropically shifted signals from 375 to –40 ppm, in acetone solution. The spectra show the resonance line pattern observed for the $N_3$-mc ligands that was assigned on the basis of previous studies of nickel macrocyclic complexes.[1–6] A representative $^1$H NMR spectrum for complex **1** is shown in Figure 3. The eight resonance signals due to the α-CH protons were shifted downfield, whereas the six resonance signals for the β-CH protons were shifted upfield relative to the diamagnetic position because of a dominant spin polarization mechanism.[32] Moreover, the equatorial protons were expected to experience larger contact shifts than the axial protons because of the angular dependence of the hyperfine coupling constant,[33] and therefore, the most downfield resonances are due to the α-$CH_{eq}$ protons and the most upfield ones to the β-$CH_{eq}$ protons. The isotropically shifted $^1$H NMR signals observed for the methyl groups [2-Me, 4-Me(a, b) and 9-Me-N] and the alkyl groups of the xanthates and thiocarbamates can be initially assigned by inspection of their peak areas. Therefore, on the basis of X-ray structures of **2** and **8**, the larger distortions in the square-pyramid for **8** as a result of the small bite of the N,S-chelating thiocarbamate moiety (68.17°) results in a larger magnetic anisotropy that in turn induces a larger dipolar shift[34] for the *O*-alkyl substituents. The complete assignment of these isotropically shifted signals required the use of two-dimensional $^1$H NMR spectroscopic techniques. A magnitude COSY spectrum of **6** (Figure 4), recorded at 25 °C, clearly shows cross signals between the resonances at $\delta$ = 27.2 and 17.8 ppm and also between resonances at 17.8, –0.9 and –4.8 ppm. These signals can be assigned to the $CH_3O$- and *N*-phenyl *m*-H (17.8), *o*-H (–0.9) and *p*-H (–4.8) protons, respectively, of the *O*-alkyl *N*-phenylthiocarbamate ligand. The shift direction alternation of the *N*-phenyl protons is characteristic if the π-contact shift is dominant. The net spin density in the $d_\pi$ orbitals could be polarized by the unpaired electrons in the $d_{x^2-y^2}$ and $d_{z^2}$ orbitals through spin-orbit coupling. A similar behaviour was observed elsewhere.[35]

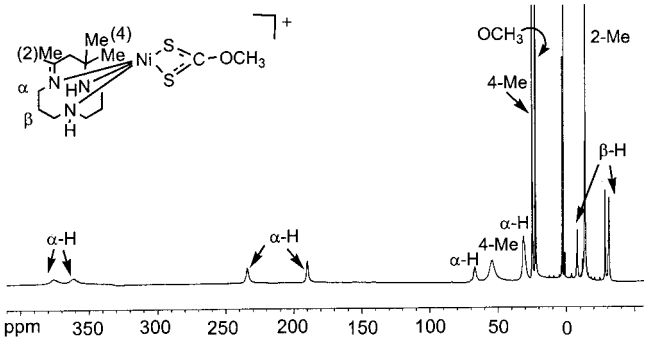

Figure 3. $^1$H NMR spectra [in $(CD_3)_2CO$ solution at room temperature] of complex **1**.

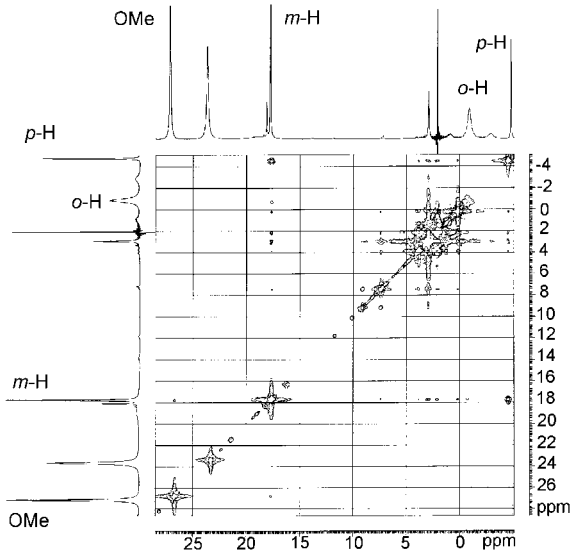

Figure 4. Portion of the $^1$H COSY spectrum of complex **6** [in $(CD_3)_2CO$ solution at 25 °C]. Only the relevant region to assign the *O*-alkyl *N*-phenylthiocarbamate resonances is shown in the top trace.

## Thiocarboxylate Complexes

When $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ was treated with thioacids $HSC(O)CH_3$ or HSC(O)Ph in acetone, complexes **9**–**12** were obtained in moderate-to-high yields (Scheme 1). The acid–base reaction occurred at room temperature in acetone with the concomitant liberation of water for complexes **9**–**12**. The thiocarboxylates anions, $RC(O)S^-$, constitute an interesting class of ligand having a soft sulfur donor site and a hard oxygen donor site.[36] Furthermore, the chemistry of these ligands was relatively unexplored relative to thiolate or thiocarbamate ligands.[37,38] The IR spectra of complexes **9**–**12** show characteristic absorptions for the $N_3$-mc ligands at 3294–3264 $cm^{-1}$ ν(N–H) and ca. 1660 $cm^{-1}$ ν(C=N), and two strong bands due to the presence of the $PF_6^-$ ion at 840 and 560 $cm^{-1}$ are also observed. The thiocarboxylate ligand in compounds **9**–**12** exhibits a $\kappa^2$-coordination mode to the nickel atom, which is suggested by the IR spectra. The spectra show strong absorption bands at ca. 1500 and ca. 980 $cm^{-1}$, which can be assigned to ν(CO) and ν(CS), respectively, and they are consistent with a symmetrical bidentate coordination.[39] This coordination mode was authenticated by X-ray crystal structure determination on **10** and **11** (vide infra). The crystal structures of cations $[(N_3\text{-mc2})Ni\{SC(O)CH_3\}][PF_6]$ (**10**) and $[(N_3\text{-mc1})Ni\{SC(O)Ph\}][PF_6]$ (**11**) are shown in Figures 5 and 6. Selected distances and angles for these complexes are given in Tables 3 and 4. In each crystallized cation, the nickel atom is five-coordinate, with a square-pyramid arrangement of the chelating atoms. The structure of complex **10** shows the presence of two independent molecules. In each one, the Ni atom shows $\tau$ values of 0.26 and 0.27 for **10** and 0.35 for **11**. The three nitrogen atoms of the $N_3$-macrocycle hold the apical position and two adjacent basal ones, whereas the other two basal positions correspond to the *S*,*O*-thiocarboxylate group. The basal plane is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

formed by N1, N2, O1 and S1, with a rms deviation of fitted atoms of 0.1076, by N4, N5, O2 and S2, rmsd 0.1132, for **10** and by N1, N2, O1 and S1, rmsd 0.1448, for complex **11**. The Ni atoms are 0.3850(17) and 0.3888(18) Å above of the corresponding basal plane towards the apical N3 or N6 atom in complex **10** and 0.3346(8) Å in **11**. The Ni–O bond lengths in **10** are 2.119(3) and 2.121(3) Å; in complex **11** the Ni–O bond length is 2.1000(15) Å. These bond lengths are comparable to those reported for other crystallographically characterized homoleptic nickel–thiobenzoate complexes with distorted octahedral[38] geometries. The bite angle of the carboxylate anion shows values of 68.73(10) and 68.42(10)° for complex **10** and 69.05(4)° for **11**. The plane of the chelate moiety defined by S1, O1, C14 and C15 (rmsd 0.0066) is inclined 13.93(15)° with respect to the basal plane N1, N2, O1 and S1; and the plane S2, O2, C29 and C30 (rmsd 0.0020) is inclined by 18.96(16)° to the basal N4, N5, O2 and S2 in complex **10**. In complex **11**, the plane of the chelate moiety defined by S1, O1, C13 and C14 (rmsd 0.0041) is inclined by 18.51(8)° to the basal plane N1, N2, O1 and S1, and the angle between the phenyl ring and the nickel-bounded thiocarboxylate group is 16.29(10)°.

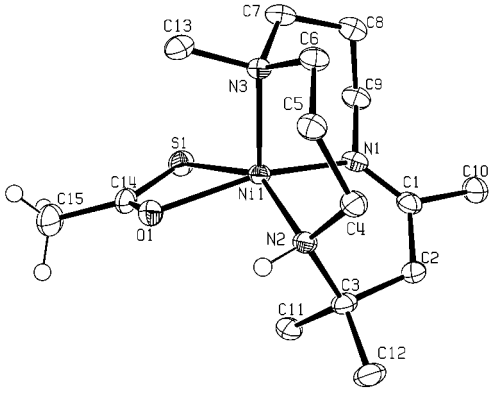

Figure 5. ORTEP drawing of the cation of complex **10** (ellipsoids at 50% probability level) with atom-labelling scheme. For clarity hydrogen atoms are omitted.

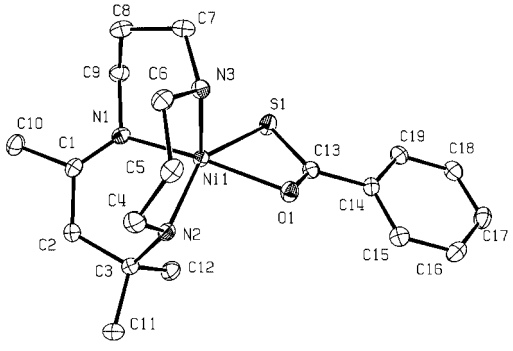

Figure 6. ORTEP drawing of the cation of complex **11** (ellipsoids at 50% probability level) with atom-labelling scheme. For clarity hydrogen atoms are omitted.

Complexes **9**–**12** exhibit relatively sharp hyperfine-shifted $^1$H NMR signals in acetone solution spanning from 390 to –35 ppm. The spectra were assigned on the basis of our previous studies of paramagnetic nickel(II) macrocyclic complexes. The spectra show the expected resonance line pattern because of a dominant spin-polarization mechanism.[32] The spectra of thiocarboxylate derivatives **9**–**12** are similar to those of corresponding complexes **1**–**8** in signals and magnitudes of contact shifts. The mean difference is the large isotropic shift for the $-CH_3$ and –Ph protons, which are consistent with the close proximity of theses groups to the paramagnetic nickel(II) centre. The spectrum of complex **12** is shown in Figure 7, and from its inspection it can be seen that all the resonances of the phenyl rings

are shifted downfield relative to TMS in accordance with a dominant σ-delocalization pattern of spin density that is consistent with the ground state of nickel(II) although the unpaired electrons could polarize the net spin density in the $d_\pi$ orbitals.[6]

## Conclusions

Because many questions still remain about the mechanism of action of the urease metalloenzyme, such as the nature of the hydrolytic attack[40] and the feasibility of carbamate as the first intermediate formed in the reaction,[41] this study investigated the possibility of attack on cumulated double bond systems. In these reactions the proposed first step is the addition of OH across one double bond followed by esterification; however, the external attack by $R'O^-$ of the coordinated heterocumulene cannot be ruled out. Moreover, the proton resonances of the synthetic mononuclear pentacoordinate nickel(II) complexes of relevance to urease were completely assigned by using 1D and 2D $^1H$ NMR spectroscopic methods.

## Experimental Section

**Materials:** Chemicals were purchased from Aldrich and were used without further purification. Solvents were dried and distilled by general methods before use. The complexes $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ [$N_3$-mc = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene ($N_3$-mc1) or 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene ($N_3$-mc2)] were prepared by previously described procedures.[42,43]

**Physical Measurements:** C, H, N and S analyses were carried out with a microanalyzer Carlo Erba model EA 1108. Fast atom bombardment (FAB) mass spectra were obtained with a Fisons VG Autospec spectrometer operating in the positive mode. Infrared spectra were recorded with a Perkin–Elmer 16F PC FTIR spectrophotometer by using Nujol mulls between polyethylene sheets. UV/Vis spectra (in acetone) were recorded with a UNICAM 520 spectrophotometer equipped with matched quartz cells in the 300–800 nm range. $^1H$ NMR spectra were recorded with a Bruker model AV 200E or AV 300 spectrometer. Chemical shifts (in ppm) are reported with respect to the residual solvent signal. The $^1H$ COSY spectrum was obtained at 25 °C for **6** with 512 data points in the $F^1$ dimension and 4096 data points in the $F^2$ dimension with a delay time of 150 ms. An unshifted sine-bell-squared weighting function was applied prior to Fourier transformation followed by baseline correction in both dimensions and symmetrization. Molar conductivities were measured in acetone solutions (ca. $10^{-3}$ mol L$^{-1}$) with a Crison 525 conductimeter.

**$[(N_3\text{-mc})Ni(S_2COCH_3)][PF_6]$:** To a suspension of $[Ni(N_3\text{-mc})(\mu\text{-OH})]_2[PF_6]_2$ (0.15 mmol) in methanol (60 mL) was added $CS_2$ (0.30 mmol). The mixture was stirred at room temperature for 24 h, and the solvent was partially evaporated under reduced pressure to ca. 15 mL. The mixture was filtered and the addition of diethyl ether caused the precipitation of a green solid, which was collected by filtration, washed with diethyl ether and air-dried.

MS (FAB+): *m/z* (%) = 463 (100) $[M]^+$. Green crystals suitable for X-ray diffraction studies were obtained by slow evaporation of the reaction mixture. $C_{22}H_{37}F_6N_4NiOPS$ (609.28): calcd. C 43.37, H 6.12, N 9.20, S 5.26; found C 43.29, H 5.96, N 9.02, S 5.47.

**[($N_3$-mc)Ni(A)][$PF_6$] [$N_3$-mc = $N_3$-mc1, A = SC(O)$CH_3$ (9), SC(O)Ph (11); $N_3$-mc = $N_3$-mc2, A = SC(O)$CH_3$ (10), SC(O)Ph (12)]:** These complexes were prepared by reaction of [Ni($N_3$-mc)(μ-OH)]$_2$-[$PF_6$]$_2$ (0.12 mmol) with the corresponding thiocarboxylic acid [HSC(O)$CH_3$ or HSC(O)Ph, 0.24 mmol] in acetone (25 mL). After stirring for 1 h, the solution was filtered and concentrated under reduced pressure to ca. 8 mL. The addition of diethyl ether caused the precipitation of green solids, which were collected by filtration, washed with diethyl ether and air-dried.

**[($N_3$-mc1)Ni{SC(O)$CH_3$}][$PF_6$] (9):** Yield: 90 mg (79%). $\Lambda_M$ = 140 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR [300 MHz, $(CD_3)_2CO$, TMS]: $\delta$ = 370.1 (α-H), 357.9 (α-H), 235.5 (α-H), 213.6 (α-H), 87.0 (α-H), 81.9 ($CH_3$-, 3 H), 72.7 (α-H), 54.9 (4-Me, 3 H), 36.7 (α-H), 31.2 (α-H), 21.8 (4-Me, 3 H), –8.5 (2 β-H), –12.9 (β-H), –13.7 (2-Me, 3 H), –27.2 (β-H), –29.0 (β-H), –30.5 (β-H) ppm.
