For the $Mo^{VI}$ complexation with ligands IDAPr(3,4-HP)$_2$ and EDTAPr(3,4-HP)$_2$, "batch synthesis" procedures were also carried out. $Na_2MoO_4$ (0.0414 M; 8.46 mL, 0.350 mmol) was added to an aqueous solution (100 mL) of IDAPr(3,4-HP)$_2$ (0.170 mmol), and the initial pH was 9.98. This solution was divided into 10 mL samples at different pH values, set with 2 N and 0.2 N HCl solutions. When precipitation of the product occurred at pH < 7, the samples were filtered and the solids isolated. For the EDTAPr(3,4-HP)$_2$ system, a similar procedure was used, namely mixing a 0.0014 M ligand stock solution (50 mL, 0.070 mmol) with a 0.016 M ($NH_4$)$_6$-$Mo_7O_{24}$·4$H_2O$ solution (1.260 mL, 0.138 mmol of $Mo^{VI}$) and pH adjustment up to 9.16 with 2 M KOH solution. Several sample solutions were prepared at different pH values by using a 0.1 M HCl solution. Precipitation started at pH < 3, and the yellow solids were filtered and the corresponding mother solutions were preserved. The solutions were analyzed by ESI-MS whereas some of the solids were characterized by IR spectroscopy and elemental analysis.

**Supporting Information** (see footnote on the first page of this article): Overall stability constants for the species formed in measurable concentrations in the $H^+$–$MoO_4^{2-}$ equilibrium system; UV spectra for solutions containing free IDAPr(3,4-HP)$_2$ and IDAPr(3,4-HP)$_2$, and $Mo^{VI}$; graphical representation of the chemical shifts of the 5-H and 6-H of the hydroxypyridinone ring for the free ligand and for the $Mo^{VI}$–IDAPr(3,4-HP)$_2$ system; potentiometric titration curves of aqueous solutions containing $Mo^{VI}$ and EDDA at different molar ratios; concentration distribution curves for the complexes formed in the $Mo^{VI}$–EDDA system; concentration distribution curves but for the complexes formed in a hypothetical ternary system; UV spectra for solutions containing EDTAPr(3,4-HP)$_2$ free ligand, and in the presence of $Mo^{VI}$ and EDTAPr(3,4-HP)$_2$. $^{17}$O NMR spectra of solutions containing $Mo^{VI}$ and EDTAPr(3,4-HP)$_2$ at the indicated pH values and at ligand-to-metal ratio of 1:1; $^1$H NMR spectra of the aliphatic region for the same

# Rhodium(I) Complexes Containing β-Amino Alcohol and 1,2-Diamine Ligands: Syntheses, Structures, and Catalytic Applications

**Lutz Dahlenburg,*[a] Harald Treffert,[a] Christian Farr,[a] Frank W. Heinemann,[a] and Achim Zahl[a]**

**Keywords:** Rhodium / N,O ligands / N,N ligands / X-ray diffraction / Catalysis

The bridge-opening reaction of $[(\eta^4\text{-}C_8H_{12})_2Rh_2(\mu\text{-}Cl)_2]$ with chiral and achiral β-amino alcohol nucleophiles gave mononuclear complexes $[(\eta^4\text{-}C_8H_{12})RhCl\{HN(R)\cap OH\text{-}\kappa N\}]$ containing the amino alcohol ligands in N-monodentate coordination; HN(R)∩OH = ethanolamine (**4**), 2-amino-2-methyl-1-propanol (**5**), and either enantiomer of (*R*)-, (*S*)-2-amino-3-methyl-1-butanol (D-, L-valinol) [(*R*)-**6**, (*S*)-**6**], (*R*)-, (*S*)-2-pyrrolidinemethanol (D-, L-prolinol) [(*R*)-**7**, (*S*)-**7**], (1*S*,2*R*)-, (1*R*,2*S*)-2-amino-1-phenyl-1-propanol (D-, L-norephedrine) [(1*S*,2*R*)-**8**, (1*R*,2*S*)-**8**], and (1*S*,2*R*)-, (1*R*,2*S*)-*cis*-1-amino-2-indanol [(1*S*,2*R*)-**9**, (1*R*,2*S*)-**9**]. Coordination of the free hydroxy function of the N,O ligands was brought about by both dehydrochlorination, which furnished the neutral valinolato chelate complex $[(\eta^4\text{-}C_8H_{12})Rh\{(S)\text{-}H_2NCH(CHMe_2)CH_2O\text{-}\kappa N,\kappa O\}]$, (*S*)-**10**, and by precipitation of the metal-bound chloride with $TlO_3SCF_3$ to produce ionic chelate complexes $[(\eta^4\text{-}C_8H_{12})Rh\{HN(R)\cap OH\text{-}\kappa N,\kappa O\}]O_3SCF_3$; HN(R)∩OH = 2-amino-2-methyl-1-propanol (**11**), (*S*)-2-amino-3-methyl-1-butanol [(*S*)-**12**], (*S*)-2-pyrrolidinemethanol [(*S*)-**13**], (1*R*,2*S*)-2-amino-1-phenyl-1-propanol [(1*R*,2*S*)-**14**], and (1*R*,2*S*)-*cis*-1-amino-2-indanol [(1*R*,2*S*)-**15**]. Except for only two in situ characterized $[\{(R)\text{-binap}\}Rh(H_2N\cap OH\text{-}\kappa N,\kappa O)]^+$ cations, where H₂N∩OH = L-valinol or L-norephedrine, no compound containing the various N,O ligands in addition to mono- or bidentate phosphanes could be prepared. In contrast, the $P_2/N_2$-coordinated chelate complexes $[\{(R)\text{-binap}\}Rh(H_2N\cap NH_2)]BF_4$ with $H_2N\cap NH_2 = H_2NCMe_2CMe_2NH_2$ [(*R*)-(**16**)], (*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$ [(*R*),(*R*,*R*)-**17**], and (*R*,*R*)-1,2-$(H_2N)_2C_6H_{10}$ [(*R*),(*R*,*R*)-**18**] were easily obtained from $[(\eta^4\text{-}C_8H_{12})Rh\{(R)\text{-binap}\}]BF_4$ and 1,2-diamines. Oxidative addition of HCl to (*R*),(*R*,*R*)-**17** produced *trans*-$[\{(R)\text{-binap}\}Rh(H)(Cl)\{(R,R)\text{-}H_2NCH(Ph)CH(Ph)NH_2\}]BF_4$ [(*R*),(*R*,*R*)-**19**]. If activated by strong base (KOH), (*R*),(*R*,*R*)-**17** and (*R*),(*R*,*R*)-**19** acted as moderately active and enantioselective catalysts for the reduction of acetophenone by both direct and transfer hydrogenation: $ee_{max}$: 71% (*S*). The crystal structures of **4**, (*S*)-**6**, (*R*)-**7**, (1*R*,2*S*)-**8**, (*S*)-**10**, (1*R*,2*S*)-**14**, (1*R*,2*S*)-**15**, (*R*)-**16**, (*R*),(*R*,*R*)-**17**, and two alcohol/alcoholato addition compounds, $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2O\text{-}\kappa N,\kappa O)][(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)][(\eta^4\text{-}C_8H_{12})RhCl_2]$ [**1·2**], and $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2O\text{-}\kappa N,\kappa O)][(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)]Cl$ [**1·3**], were determined.

## Introduction

Our recent activities have focused on the catalytic potential of iridium (and rhodium) complexes bearing various β-aminophosphanes derived from optically active amino alcohols in asymmetric C=O hydrogenation reactions.[1] Following these studies, we have turned our attention to coordination compounds of the two platinum metals containing the very same β-amino alcohols and some akin 1,2-diamines as ligands.

Whereas ruthenium(II) complexes with N,O- and N,N donors − in particular, *N*-methyl-1,2-diphenylethanolamine and 1,2-diphenylethylenediamine − are well known to serve as efficient catalysts for the asymmetric hydrogenation and transfer hydrogenation of ketones and imines,[2] virtually no systematic studies on amino alcohol compounds of rhodium or iridium in their +1 or +3 oxidation states have so far been reported. Noteworthy exceptions are (1) the (amino alcoholato)rhodium(III) chelate $[\{\eta^5\text{-}C_5Me_4\text{-}(1R,2S)\text{-}C_6H_4CH_2NHCH(Me)CH(Ph)O\text{-}\kappa N,\kappa O\}RhCl]$, which contains an *N*-benzyl-(L)-norephedrine component tethered to a tetramethylcyclopentadienyl ligand and has been used as a highly active catalyst for the asymmetric reduction of ketones,[3] and (2) the acetate salt of the $[(\eta^4\text{-}C_8H_{12})Rh\{(S)\text{-}H_2NCH(Ph)CH_2OH\text{-}\kappa N,\kappa O\}]^+$ cation published only recently in this journal.[4]

Furthermore, notwithstanding that cationic $[(\eta^4\text{-}C_8H_{12})M(diamine)]^+$ complexes, where M = Rh or Ir and diamine = ethylenediamine, *o*-phenylenediamine, 1,8-diaminonaphthalene, and the like, are well-documented,[5] we are not aware of any previously described diphosphane(diamine)-coordinated cations $[M(R_2P\cap PR_2)(H_2N\cap NH_2)]^+$ or $[M(X)(Y)(R_2P\cap PR_2)(H_2N\cap NH_2)]^+$ (X, Y = halide, hy-

dride) which, at least from a structural point of view, bear a direct resemblance to the famous $[Ru(X)(Y)(R_2P\cap PR_2)(H_2N\cap NH_2)]$ hydrogenation catalysts. A limited number of examples coming closest to the so far unknown diphosphane(diamine) chelate compounds of the two metals include the dihydrides $[MH_2(PPh_3)_2(H_2NC_2H_4NH_2)]^+$ (M = Rh,[6] Ir[7]) along with only two in situ characterized $Rh^{I}$ species, $[Rh\{(S)\text{-binap}\}(NEt_3)_2]^+$[8] and $[Rh(dppe)(NH_3)_2]^+$,[9] respectively.

Using the chlorido-bridged dimer $[(\eta^4\text{-}C_8H_{12})_2Rh_2(\mu\text{-}Cl)_2]$ as a common starting material, we have obtained a family of (cyclooctadiene)rhodium(I) complexes containing both chiral and achiral amino alcohols in κ*N*-monodentate and κ*N*,κ*O*-bidentate coordination. It is envisaged that such compounds and some related (diphosphane)diamine chelate complexes $[Rh\{(R)\text{-binap}\}(H_2N\cap NH_2)]^+$, both of which are the subject of this communication, can be useful for the construction of stereoselective catalysts,[10] and a first account of their application to homogeneous C=O hydrogenation is given in the following.

## Results and Discussion

### β-Amino Alcohol Complexes

Initial attempts were directed towards the synthesis of amino alcoholato derivatives of $Rh^{I}$ by treating $[(\eta^4\text{-}C_8H_{12})_2Rh_2(\mu\text{-}Cl)_2]$ with solutions of the respective sodium alkoxides $H_2N\cap ONa$ in $H_2N\cap OH$/toluene. Although such experiments did produce amino alcoholato complexes as desired, their results remained inconclusive in that mixtures of the neutral and ionic chelates, $[(\eta^4\text{-}C_8H_{12})Rh(H_2N\cap O\text{-}\kappa N,\kappa O)]$ and $[(\eta^4\text{-}C_8H_{12})Rh(H_2N\cap OH\text{-}\kappa N,\kappa O)]^+$, were formed. Thus, the sodium salt of 2-amino-2-methyl-1-propanol reacted in $H_2NCMe_2CH_2OH$/toluene to give $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2O\text{-}\kappa N,\kappa O)]$ (**1**) as the wanted target complex but also furnished the amino alcohol chelated salts $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)][(\eta^4\text{-}C_8H_{12})RhCl_2]$ (**2**) and $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)]Cl$ (**3**) as unwanted byproducts. Repeated crystallizations of such mixtures and subsequent single-crystal X-ray diffraction studies revealed that **1** and **2** cocrystallized from thf/*n*-pentane as the addition compound **1·2**·thf stabilized by multiple O–H···O, N–H···O, and N–H···Cl hydrogen bonding interactions, whereas **1** and **3** were separated from solution as the likewise hydrogen-bonded adduct **1·3**, if crystallized from toluene/*n*-hexane mixtures.

In the structure of **1·2**·thf, the two rhodium-alcohol(ato) constituents were located on crystallographically independent positions of a triclinic unit cell (space group $P\bar{1}$) and, hence, could be distinguished without difficulty (Figure 1). In contrast, the tetragonal unit cell of **1·3** (crystallizing in the space group $P\bar{4}2c$) was found to contain neutral $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2O\text{-}\kappa N,\kappa O)]$ and cationic $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)]^+$ on symmetry-related sites such that the mixed composition of the compound was only evident from the presence of one chloride anion spread with quarter occupancies over special positions *a* and *b* of the cell (Figure 2). For the two structures, the rhodium–oxygen and rhodium–nitrogen bond lengths fall in the usual range.[11] The molecular parameters of the $[(\eta^4\text{-}C_8H_{12})RhCl_2]^-$ anion also deserve no further comment as they are very similar to those previously measured for the same ion in a number of related $[(\eta^4\text{-}C_8H_{12})RhL_2][(\eta^4\text{-}C_8H_{12})RhCl_2]$ complexes.[11]

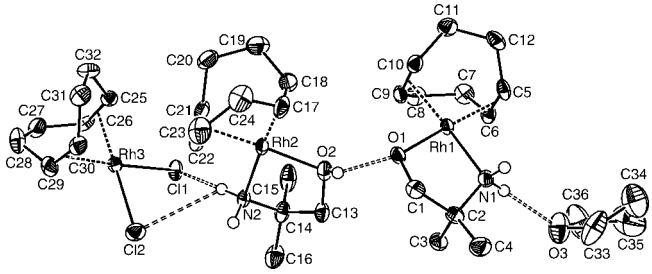

Figure 1. Molecular structure of the addition compound $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2O\text{-}\kappa N,\kappa O)]\cdot[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)][(\eta^4\text{-}C_8H_{12})RhCl_2]\cdot$thf (**1·2**·thf), which shows the multiple O–H···O, N–H···O, and N–H···Cl hydrogen bonding interactions (H atoms of the diolefin ligand are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–O1, 2.053(3); Rh1–N1, 2.093(4); Rh2–O2, 2.065(4); Rh2–N2, 2.098(4); Rh3–Cl1, 2.387(1); Rh3–Cl2, 2.372(2). O1–Rh1–N1, 81.2(1); O2–Rh2–N2, 80.4(1); Cl1–Rh3–Cl2, 89.47(5). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å °]: O2–H···O1, 0.82, 1.79, 2.417(5), 132.5; N1–H···O3, 0.92, 2.15, 3.015(6), 155.4; N2–H···Cl1, 0.92, 2.55, 3.447(4), 165.5; N2–H···Cl2, 0.92, 2.95, 3.422(5), 113.6; N1–H···Cl1_#1, 0.92, 2.40, 3.289(5), 163.3; N2–H···Cl2_#2, 0.92, 2.65, 3.353(4), 133.6. Symmetry transformations used to generate equivalent atoms: #1 = $x$, $y+1$, $z$; #2 = $-x+1$, $-y-1$, $-z$.

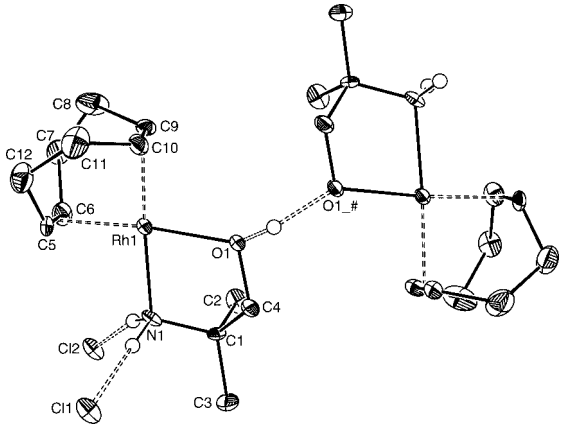

Figure 2. Molecular structure of the hydrogen-bonded amino alcohol/amino alcoholato adduct $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2O\text{-}\kappa N,\kappa O)]\cdot[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)]Cl$ (**1·3**), where the two complex moieties reside on symmetry-related positions and the chloride counterion is distributed with 1/4 occupancies over special sites *a* (0, 0, 3/4) and *b* (0, 1/2, 3/4) of space group $P\bar{4}2c$ (H atoms of the diolefin ligand are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–O1, 2.074(5); Rh1–N1, 2.112(5). O1–Rh1–N1, 81.0(2). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å °]: O1–H···O1_#, 0.85, 1.55, 2.396(9), 171.3; N1–H···Cl1, 0.92, 2.43, 3.339(5), 168.9; N1–H···Cl2, 0.92, 2.51, 3.418(5), 167.9. Symmetry transformation used to generate equivalent atoms: #1 = $-x+1$, $y$, $-z+1$.

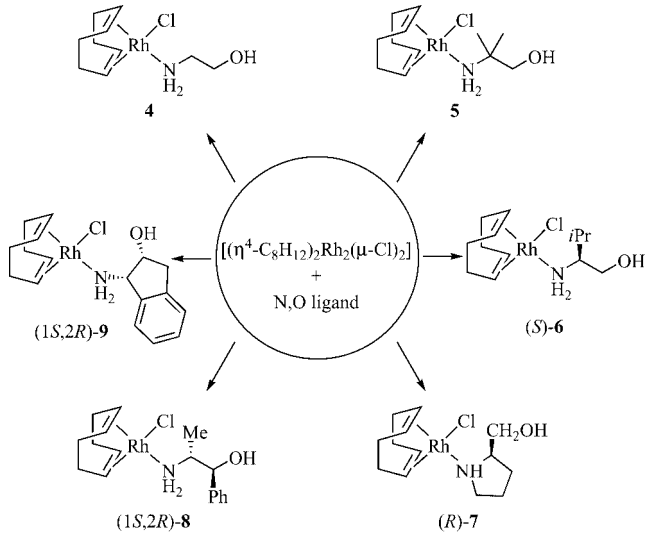
The transformation of $[(\eta^4\text{-}C_8H_{12})_2Rh_2(\mu\text{-}Cl)_2]$ by the $H_2NCMe_2CH_2ONa/H_2NCMe_2CH_2OH$ mixture to give, in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

addition to neutral alcoholato complex **1**, the ionic products $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)][(\eta^4\text{-}C_8H_{12})RhCl_2]$ (**2**) and $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)]Cl$ (**3**) is reminiscent of some bridge-cleaving reactions of the dimer with a number of aliphatic diamines described in earlier work, where either ion-pair complexes $[(\eta^4\text{-}C_8H_{12})Rh(diamine)][(\eta^4\text{-}C_8H_{12})RhCl_2]$ or chloride-containing products $[(\eta^4\text{-}C_8H_{12})Rh(diamine)Cl]$ were obtained. Different from **3**, however, the latter were formulated as neutral pentacoordinate rather than ionic tetracoordinate species.[5e]

From the above results it was inferred that better-defined products could arise from preparations that avoid the presence of alkoxide base in the initial reaction solutions. Hence, further experiments used the $[(\eta^4\text{-}C_8H_{12})_2Rh_2(\mu\text{-}Cl)_2]$ starting compound together with toluene dilutions of the pure amino alcohols. Under these conditions, smooth opening of the chloride bridges by the amine nucleophiles was observed to give high yields of mononuclear products $[(\eta^4\text{-}C_8H_{12})RhCl\{HN(R)\cap OH\text{-}\kappa N\}]$ (R = H, alkyl), **4**–**9**, containing the amino alcohol ligands in monodentate coordination: HN(R)∩OH = ethanolamine (**4**), 2-amino-2-methyl-1-propanol (**5**), as well as either enantiomer of (*R*)-, (*S*)-2-amino-3-methyl-1-butanol (D-, L-valinol) [(*R*)-**6**, (*S*)-**6**], (*R*)-, (*S*)-2-pyrrolidinemethanol (D,- L-prolinol) [(*R*)-**7**, (*S*)-**7**], (1*S*,2*R*)-, (1*R*,2*S*)-2-amino-1-phenyl-1-propanol (D-, L-norephedrine) [(1*S*,2*R*)-**8**, (1*R*,2*S*)-**8**], and (1*S*,2*R*)-, (1*R*,2*S*)-*cis*-1-amino-2-indanol [(1*S*,2*R*)-**9**, (1*R*,2*S*)-**9**], respectively (Scheme 1).



Scheme 1. Synthesis of κ*N*-monodentate amino alcohol complexes **4**–**9**; only one enantiomer of chiral molecules **6**–**9** is drawn.

Complexes **4**–**9** form relatively air-stable yellow crystals which are readily soluble in the more polar solvents, for example methanol, thf, $CHCl_3$, $CH_2Cl_2$, and the like. From such solutions, compounds **4**, (*S*)-**6**, (*R*)-**7**, and (1*R*,2*S*)-**8** (crystallizing as a solvate with the idealized composition $[(\eta^4\text{-}C_8H_{12})RhCl\{(1R,2S)\text{-}H_2NCH(Me)CH(Ph)CH_2OH\}]\cdot 1/4CH_2Cl_2\cdot 1/4thf$) were isolated as single-crystals and subjected to X-ray structure analyses (Figures 3, 4, 5, and 6. Whereas the asymmetric units of **4** and (*S*)-**6** comprised one complex molecule each, two crystallographically independent molecules with partially disordered pyrrolidine and cyclooctadiene rings were found in structures (*R*)-**7** and (1*R*,2*S*)-**8**. In the solid-state packing of the four compounds, the individual complexes are assembled through O–H···Cl and N–H···Cl hydrogen bonds from the dangling hydroxy group and the ligated amino groups to the chlorido ligands of neighboring molecules. Not unexpectedly, neither the Rh–Cl distances (2.381–2.398 Å) nor the Rh–$NH_2$ bond lengths (2.127–2.137 Å) displayed any significant differences.

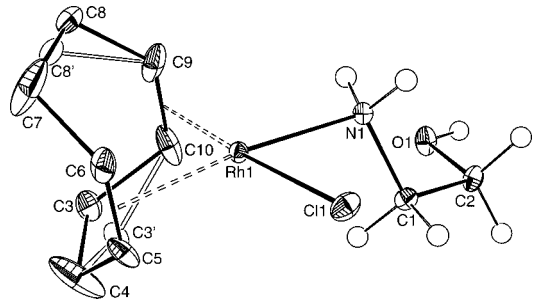


Figure 3. Molecular structure of $[(\eta^4\text{-}C_8H_{12})RhCl\text{-}(H_2NCH_2CH_2OH\text{-}\kappa N)]$ (**4**), which shows the twofold disorder of two methylene C atoms in the $C_8H_{12}$ ring (H atoms of the diolefin ligand are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–Cl1, 2.3930(4); Rh1–N1, 2.128(2). Cl1–Rh1–N1, 88.38(4). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å [°]]: O1–H···Cl1_#1, 0.84, 2.39, 3.128(2), 147.5; N1–H···Cl1_#2, 0.92, 2.73, 3.623(2), 164.5; N1–H···O1_#3, 0.92, 2.19, 3.002(2), 147.3. Symmetry transformations used to generate equivalent atoms: #1 = $-x+2$, $y+1/2$, $-z+1/2$; #2 = $x$, $-y+11/2$, $z-1/2$; #3 = $x$, $-y+11/2$, $z+1/2$.

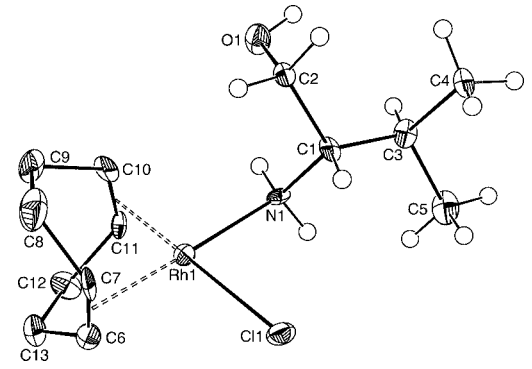

Figure 4. Molecular structure of $[(\eta^4\text{-}C_8H_{12})RhCl\{(S)\text{-}H_2NCH(CHMe_2)CH_2OH\text{-}\kappa N\}]$, (*S*)-**6** (H atoms of the diolefin ligand are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–Cl1, 2.395(3); Rh1–N1, 2.127(8). Cl1–Rh1–N1, 86.5(2). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å [°]]: O1–H···Cl1_#1, 0.84, 2.42, 3.250(8), 171.5; N1–H···Cl1_#2, 0.92, 2.57, 3.301(9), 137.2. Symmetry transformations used to generate equivalent atoms: #1 = $-x+1$, $y+1/2$, $-z$; #2 = $-x$, $y+1/2$, $-z$.

For converting the $[(\eta^4\text{-}C_8H_{12})RhCl\{HN(R)\cap OH\text{-}\kappa N\}]$ complexes into N,O-chelated derivatives, two obvious approaches can be taken into account: (1) removal of both the chlorido ligand and the OH proton by base to give neutral amino alcoholato products $[(\eta^4\text{-}C_8H_{12})Rh\{HN(R)\cap O\text{-}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

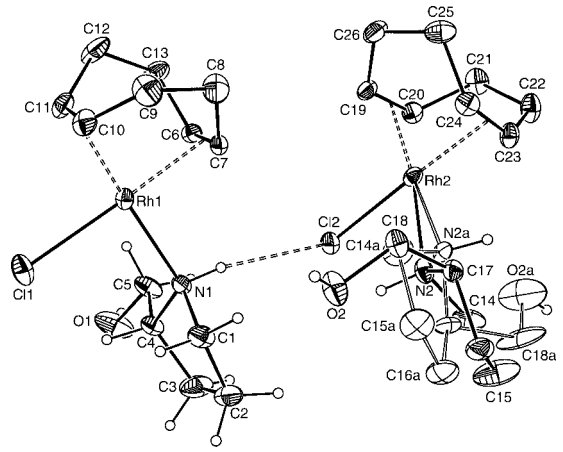

Figure 5. Structure of the two crystallographically independent hydrogen-bonded molecules of $[(\eta^4\text{-}C_8H_{12})RhCl\{(R)\text{-}HN(CH_2CH_2CH_2CH)CH_2OH\text{-}\kappa N\}]$, (*R*)-**7** (H atoms of the diolefins and the disordered D-prolinol ligand are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–Cl1, 2.381(2); Rh1–N1, 2.134(4); Rh2–Cl2, 2.397(2); Rh2–N2, 2.13(1); Rh2–N2A, 2.18(1). Cl1–Rh1–N1, 90.3(1); Cl2–Rh2–N2, 77.4(3); Cl2–Rh2–N2A, 95.4(3). Symmetry transformations used to generate equivalent atoms: #1 = *x*, *y*+1, *z*; #2 = *x*, *y*–1, *z*; #3 = *x*–1, *y*, *z*.

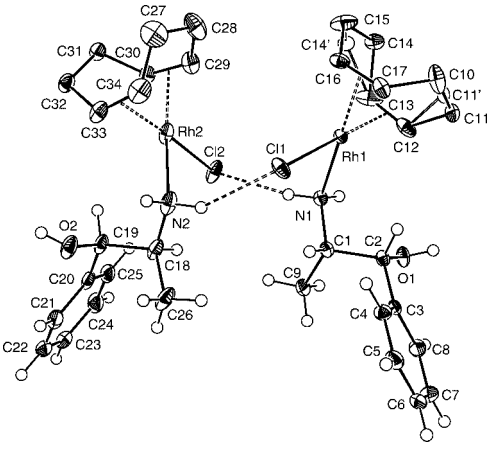

Figure 6. Structure of the two crystallographically independent hydrogen-bonded complex molecules (1*R*,2*S*)-**8** of $[(\eta^4\text{-}C_8H_{12})RhCl\{(1R,2S)\text{-}H_2NCH(Me)CH(Ph)OH\text{-}\kappa N\}]\cdot 1/4CH_2Cl_2\cdot 1/4thf$, which shows the twofold disorder of two methylene C atoms in one of the $C_8H_{12}$ ligands (cyclooctadiene H atoms and solvate molecules are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–Cl1, 2.3912(4); Rh1–N1, 2.134(2); Rh2–Cl2, 2.3982(5); Rh2–N2, 2.137(2). Cl1–Rh1–N1, 88.16(5); Cl2–Rh2–N2, 88.54(5). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å [°]]: N1–H···Cl2, 0.92, 2.38, 3.281(2), 167.7; N2–H···Cl1, 0.92, 2.52, 3.338(2), 148.8; O1–H···Cl2_#1, 0.84, 2.28, 3.109(2), 171.8; O2–H···Cl1_#3, 0.84, 2.28, 3.111(2), 172.6; N1–H···ClCH$_2$Cl_#2, 0.92, 2.88, 3.703(3), 149.5; N2–H···ClH$_2$Cl_#3, 0.92, 2.83, 3.646(5), 148.8; N2–H···OC$_4$H$_8$_#3, 0.92, 2.34, 3.137(4), 144.5. Symmetry transformations used to generate equivalent atoms: #1 = -*x*+1, *y*–1/2, –*z*+1; #2 = –*x*+1, *y*+1/2, –*z*+1; #3 = –*x*+1, *y*+1/2, –*z*+2.

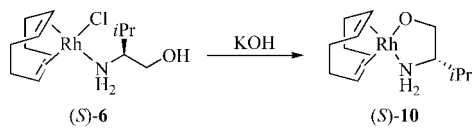
κ*N*,κ*O*}]; (2) precipitation of the metal-bound chloride as, for example, AgCl or TlCl to afford cationic amino alcohol chelates $[(\eta^4\text{-}C_8H_{12})Rh\{HN(R)\cap OH\text{-}\kappa N,\kappa O\}]^+$.

Method (1) was probed by using $[(\eta^4\text{-}C_8H_{12})RhCl\{(S)\text{-}H_2NCH(CHMe_2)CH_2OH\text{-}\kappa N\}]$ [(*S*)-**6**] together with powdered KOH in $CH_2Cl_2$ (Scheme 2). This dehydrochlorination reaction furnished the "valinolato" chelate complex $[(\eta^4\text{-}C_8H_{12})Rh\{(S)\text{-}H_2NCH(CHMe_2)CH_2O\text{-}\kappa N,\kappa O\}]$ [(*S*)-**10**] which crystallized from the reaction solution in the (rare) triclinic space group *P*1 with one molecule of lattice water per formula unit. The water of crystallization served to assemble two molecules of (*S*)-**10**·$H_2O$ in the unit cell by multiple N–H···$OH_2$ and O–H···O hydrogen bonds, as shown in Figure 7. The metal-to-nitrogen und metal-to-oxygen bond lengths as well as the O–Rh–N angles closely resemble those measured for $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2\text{-}CH_2O\text{-}\kappa N,\kappa O)]$ (**1**) in its thf-solvated addition compound with $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)][(\eta^4\text{-}C_8H_{12})RhCl_2]$ (**2**).



Scheme 2. Formation of L-valinolato chelate complex (*S*)-**10** by dehydrochlorination of (*S*)-**6**.

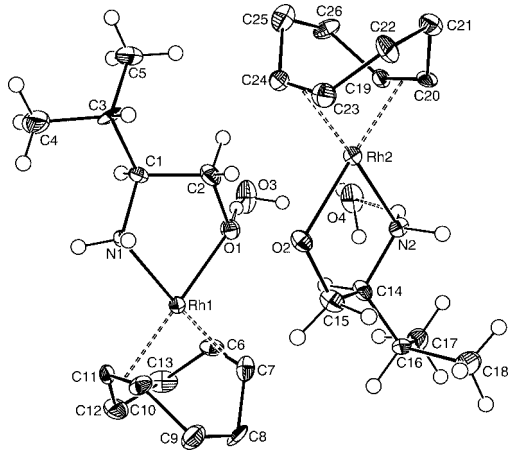


Figure 7. Structure of the two lattice water-containing molecules $[(\eta^4\text{-}C_8H_{12})Rh\{(S)\text{-}H_2NCH(CHMe_2)CH_2O\text{-}\kappa N,\kappa O\}]\cdot H_2O$ [(*S*)-**10**·$H_2O$] which fill the triclinic unit cell of space group *P*1 (cyclooctadiene H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–O1, 2.037(7); Rh1–N1, 2.102(7); Rh2–O2, 2.041(6); Rh2–N2, 2.126(8). O1–Rh1–N1, 82.9(3); O2–Rh2–N2, 81.4(3). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å [°]]: O3–H···O1, 0.85, 2.00, 2.83(1), 167.0; N2–H···O4, 0.92, 1.94, 2.77(1), 148.9; O3–H···O2_#1, 0.85, 1.95, 2.77(1), 162.2; O4–H···O2_#1, 0.85, 1.94, 2.69(1), 146.5; N1–H···O3_#2, 0.92, 2.00, 2.92(1), 171.6. Symmetry transformations used to generate equivalent atoms: #1 = *x*–1, *y*, *z*; #2 = *x*+1, *y*, *z*.

Attempts to induce chelation of the unligated hydroxy groups of complexes **4**–**9** by reaction with soluble silver salts such as $AgBF_4$ or $AgO_3SCF_3$ according to method (2) resulted in the deposition of elemental silver rather than silver chloride with concomitant decomposition of the com-

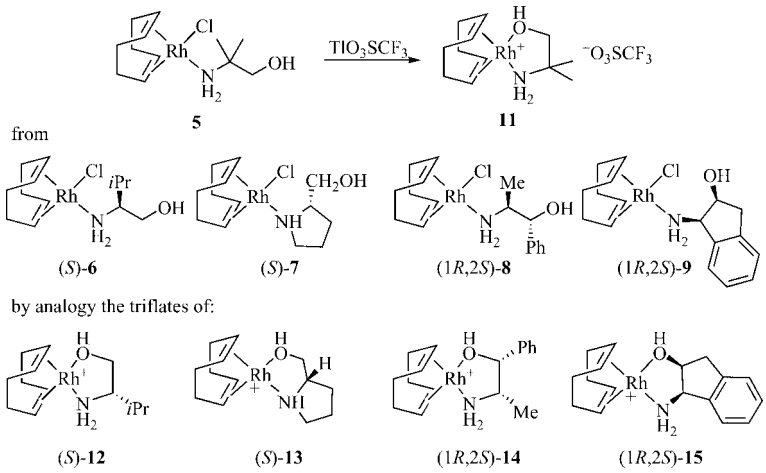

Scheme 3. Synthesis of triflate salts **11**–**15** containing chelated β-amino alcohol ligands.

pounds. Reduction of the $Ag^+$ ion is most likely caused by the free OH functions of the amino alcohols as may be judged from the standard electrode potentials for the equilibria "$Ag^+ + e^- = Ag$" ($E^0 = +0.799$ V) and, as a rough estimate, "$CH_3CHO + 2\ H^+ + 2\ e^- = C_2H_5OH$" ($E^0 = +0.192$ V).[12] Because of the low standard potential of the redox couple $Tl^+/Tl$ ($E^0 = -0.336$ V), thallium(I) trifluoromethanesulfonate proved to be a more suitable chloride-precipitating reagent, which smoothly converted the [($\eta^4$-$C_8H_{12}$)RhCl{HN(R)∩OH-κ*N*}] complexes into the triflate salts [($\eta^4$-$C_8H_{12}$)Rh{HN(R)∩OH-κ*N*,κ*O*}]$O_3SCF_3$, where HN(R)∩OH-κ*N*,κ*O* stands for chelated 2-amino-2-methyl-1-propanol (**11**), (*S*)-2-amino-3-methyl-1-butanol (L-valinol) [(*S*)-**12**], (*S*)-2-pyrrolidinemethanol (L-prolinol), [(*S*)-**13**], (1*R*,2*S*)-2-amino-1-phenyl-1-propanol (L-norephedrine) [(1*R*,2*S*)-**14**], and (1*R*,2*S*)-*cis*-1-amino-2-indanol [(1*R*,2*S*)-**15**] (Scheme 3). As mentioned in the introductory section, the closely related (*S*)-2-amino-2-phenylethanol containing compound [($\eta^4$-$C_8H_{12}$)Rh{(*S*)-$H_2$NCH(Ph)-$CH_2$OH-κ*N*,κ*O*}]$O_2$CMe was only recently isolated from the bridge-cleaving reaction of the amino alcohol with the [($\eta^4$-$C_8H_{12}$)$_2$Rh$_2$(μ-$O_2$CMe)$_2$] dimer.[4]

Complexes (1*R*,2*S*)-**14** and (1*R*,2*S*)-**15** were fully characterized by single-crystal X-ray diffraction (Figures 8 and 9). In both structures, the complex cations and their counterions are linked by hydrogen-bonding interactions from the coordinated amino and hydroxy donors to the triflate anion acceptors. Relative to the metal-to-oxygen bond lengths measured for the two crystallographically independent molecules of alcoholato complex (*S*)-**10**, 2.037(7) and 2.041(6) Å, the Rh–O separations observed for (1*R*,2*S*)-**14**, 2.125(3) Å, and the two cations filling the asymmetric unit of (1*R*,2*S*)-**15**, 2.086(4) and 2.089(4) Å, tend to be slightly elongated, which thereby reflects the weaker bonding capabilities of neutral alcohol than those of anionic alkoxo donor groups.

In the $^1$H NMR spectra of both the monodentate and the chelated amino alcohol complexes [($\eta^4$-$C_8H_{12}$)-RhCl{HN(R)∩OH-κ*N*}] (**4**–**9**) and [($\eta^4$-$C_8H_{12}$)Rh{HN(R)-∩OH-κ*N*,κ*O*}]$O_3SCF_3$ (**11**–**15**) measured at ambient temperature, largely unresolved broad multiplets, each accounting for four protons, are observed for the allylic $CH_2$ ($\delta \approx$ 1.6–1.8 and 2.3–2.5 ppm) and the olefinic CH groups ($\delta \approx$ 4.0–4.2 ppm) of the diene ligand. In the $^{13}$C NMR spectra, the olefinic carbon atoms similarly give rise to very broad signals centered at $\delta \approx$ 77–83 ppm; the resonances of the methylene carbon atoms appear as either one or two singlets ($\delta \approx$ 29–32 ppm), which likewise show line broadening. From these NMR spectroscopic data it is apparent that a dynamic process occurs in solution, which averages the chemical nonequivalency of the CH=CH groups that are bound *trans* to N and Cl in **4**–**9** and *trans* to N and O in **11**–**15**, respectively.

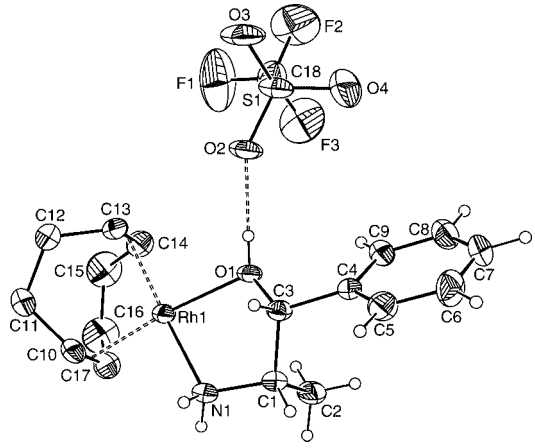

Figure 8. Structure of the ion pair [($\eta^4$-$C_8H_{12}$)Rh{(1*R*,2*S*)-$H_2$NCH(Me)CH(Ph)OH-κ*N*,κ*O*}]$O_3SCF_3$ [(1*R*,2*S*)-**14**] (cyclooctadiene H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–O1, 2.125(3); Rh1–N1, 2.112(4). O1–Rh1–N1, 78.8(1). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å [°]]: O1–H···O2, 0.82, 1.86, 2.672(5), 174.2; N1–H···O2_#1, 0.90, 2.20, 3.074(7), 164.2; N1–H···O3_#2, 0.90, 2.09, 2.968(6), 164.5. Symmetry transformations used to generate equivalent atoms: #1 = $x-1/2, -y+1/2, -z$; #2 = $x-1, y, z$.

This interconversion of the double bonds could not be frozen by lowering the temperature in the case of the monodentate amino alcohol complexes. Thus, the $^{13}$C NMR

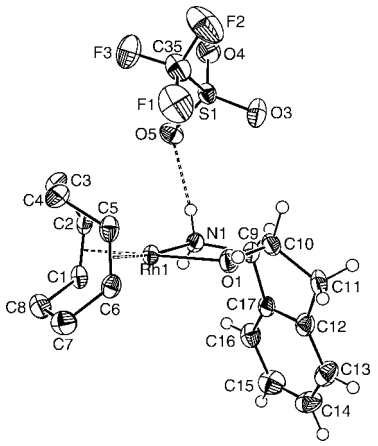

Figure 9. Structure of one of the two crystallographically independent ion pairs of $[(\eta^4\text{-}C_8H_{12})Rh\{(1R,2S)\text{-}H_2NCH[CH(OH)CH_2]\text{-}C_6H_4\text{-}\kappa N,\kappa O\}]O_3SCF_3$ [(1*R*,2*S*)-**15**] (cyclooctadiene H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–O1, 2.089(4); Rh1–N1, 2.109(4). O1–Rh1–N1, 79.6(2). Analogous parameters for ion pair 2: Rh2–O2, 2.086(4); Rh2–N2, 2.124(5). O2–Rh2–N2, 78.6(2). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å [°]]: N1–H···O5, 0.91, 2.09, 2.981(6), 165.7; N1–H···O6_#1, 0.91, 2.26, 3.001(6), 137.9; O1–H···O7_#2, 0.84, 1.82, 2.665(6), 175.4 (both from complex 1 to triflate 2); N2–H···O3_#3, 0.91, 2.27, 3.139(6), 159.0; N2–H···O4_#3, 0.91, 2.65, 3.158(6), 116.3; O2–H···O5_#4, 0.85, 1.81, 2.651(6), 171.6 (all from complex 2 to triflate 1). Symmetry transformations used to generate equivalent atoms: #1 = *x*, *y*, *z* + 1; #2 = –*x*, *y* + 1/2, –*z*; #3 = –*x*, *y* – 1/2, –*z* + 1; #4 = *x*, *y*, *z* – 1.

spectrum of $[(\eta^4\text{-}C_8H_{12})RhCl(H_2NCMe_2CH_2OH\text{-}\kappa N)]$, **5**, which displays two broad signals for the $CH_2$ and CH carbon atoms ($\delta$ = 30.6 and 77.1 ppm) in $[D_6]$DMSO at 30 °C, still showed considerable line-broadening for the cyclooctadiene resonances when recorded in $[D_4]$methanol at –25 °C: $\delta$ = 29.6, 30.7 (both $CH_2$), and 81.7 (CH) ppm. Conversely, it could be demonstrated for the chelated L-norephedrine compound $[(\eta^4\text{-}C_8H_{12})Rh\{(1R,2S)\text{-}H_2NCH(Me)CH(Ph)OH\text{-}\kappa N,\kappa O\}]O_3SCF_3$ [(1*R*,2*S*)-**14**] that a $^{13}C$ NMR spectrum consistent with a rigid $C_1$-symmetric structure of the cation can in fact be observed if a $[D_4]$methanol solution cooled to –35 °C is used. Both the methylene and the olefinic carbon atoms then resolve into four distinct signals, the former protons appear as singlets ($\delta$ = 30.31, 30.90, 32.11, and 32.45 ppm), and the latter protons resonate as $^{103}Rh$-coupled doublets ($\delta$ = 73.41, 73.85, 84.32, and 84.51 ppm; $J_{Rh,C}$ = 11.7–16.9 Hz).

We do not know the mechanism of the olefin site interchange of the coordinated diene in compounds **4**–**9** and **11**–**15** but note that analogous scrambling of two chemically nonequivalent CH=CH bonds was previously described for a number of related four-coordinate rhodium(I) compounds $[(\eta^4\text{-}C_8H_{12})RhCl(R_2P\cap E\text{-}\kappa P)]$ and $[(\eta^4\text{-}C_8H_{12})Rh\{R_2P\cap E\text{-}\kappa P,\kappa E)]^+$ containing different P,N and P,S chelate ligands bonded in a mono- or bidentate fashion.[13] For the chlorido complexes containing "dangling" donor groups similar to the free hydroxy functions of **4**–**9**, the exchange dynamics were accounted for in terms of a fast equilibrium between the square planar form of the molecule and small amounts of a pentacoordinate chelated isomer undergoing rapid pseudorotation.[13a] For the cationic chelate complexes that bear some structural resemblance to **11**–**15**, a mechanism involving breaking of the Rh–N or Rh–S linkage, followed by rotation around the Rh–P bond and rebuilding of the four-coordinate chelate structure was proposed as an alternative.[13b–13d] As a further alternative, the diene dynamics were ascribed to diolefin rotation proceeding by cleavage of one Rh–diene bond, rotation through 180° around the remaining metal–olefin bond, and recoordination of the free CH=CH group either *cis* or *trans* to one of the two different donors of the chelate ligand.[13e]

### 1,2-Diamine Complexes

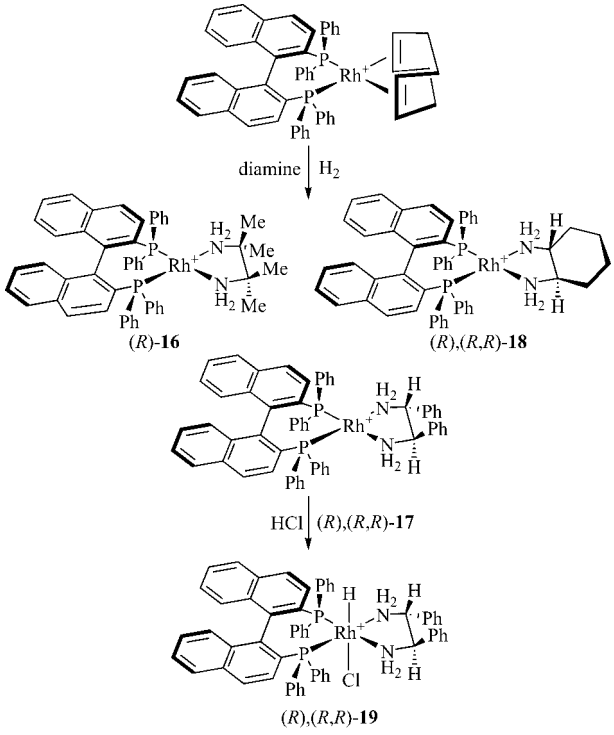
For catalytic applications, it seemed desirable to substitute P donors, in particular chiral diphosphanes, for the cyclooctadiene ligand of the newly prepared complexes bearing the diverse amino alcohols in κ*N*-monodentate or κ*N*,κ*O*-bidentate coordination. Accordingly, numerous attempts were made to obtain phosphane-coordinated products by reaction of the amino alcohol compounds with both chiral and achiral mono- and ditertiary phosphanes or, vice versa, by combining phosphane-containing precursors such as $[(i\text{Pr}_3P)_2Rh_2(\mu\text{-}Cl)_2]$[14] and $[(\eta^4\text{-}C_8H_{12})Rh\{(R)\text{-binap}\}]BF_4$[15] with amino alcohol ligands. So far, all of these experiments failed in that reaction mixtures were produced from which only ill-defined or unwanted compounds could be isolated, some of which were already known. Thus, reactions of the dinuclear bis(triisopropylphosphane) complex with L-valinol or L-norephedrine in thf under a nitrogen atmosphere repeatedly furnished the well-known dinitrogen compound *trans*-$[(i\text{Pr}_3P)_2RhCl(N_2)]$[16] rather than any amino alcohol containing material, whereas both $[(i\text{Pr}_3P)_2Rh_2(\mu\text{-}Cl)_2]$ and $[(\eta^4\text{-}C_8H_{12})Rh\{(R)\text{-binap}\}]BF_4$ afforded mixtures of multifarious unidentified derivatives, if combined with a number of different amino alcohols in $CH_2Cl_2$ or thf under an atmosphere of argon or hydrogen. Largely unidentified products were also formed upon treatment of several $[(\eta^4\text{-}C_8H_{12})RhCl\{HN(R)\cap OH\text{-}\kappa N\}]$ or $[(\eta^4\text{-}C_8H_{12})Rh\{HN(R)\cap OH\text{-}\kappa N,\kappa O\}]O_3SCF_3$ precursors with a number of different mono- or bidentate phosphanes.

For the time being, only L-valinol and L-norephedrine chelate complexes (*S*)-**12** and (1*R*,2*S*)-**14** and the (*R*)-binap ligand reacted to give defined mixtures of products. $^{31}P$ and $^1H$ NMR spectroscopy disclosed the predominant presence (>90%; see Experimental Section) of each an (*R*)-binap-coordinated $C_1$-symmetric species assumed to be $[\{(R)\text{-binap}\}Rh\{(S)\text{-}H_2NCH(CHMe_2)CH_2OH\text{-}\kappa N,\kappa O\}]^+$ and $[\{(R)\text{-binap}\}Rh\{(1R,2S)\text{-}H_2NCH(Me)CH(Ph)OH\text{-}\kappa N,\kappa O\}]^+$, respectively, but all attempts to isolate these cations as pure compounds resulted in their degradation to unidentified materials.

In contrast to the largely unsuccessful reactions of β-amino alcohols with, for example, $[(\eta^4\text{-}C_8H_{12})Rh\{(R)\text{-binap}\}]BF_4$, 1,2-diamines such as 1,1′,2,2′-tetramethylethyl-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

enediamine and (*R*,*R*)-1,2-diphenylethylenediamine, and (*R*,*R*)-1,2-diaminocyclohexane smoothly displaced the $C_8H_{12}$ ligand from the metal giving the chelate complexes [{(*R*)-binap}Rh($H_2N\cap NH_2$)]$BF_4$, if allowed to interact with the diene(diphosphane) complex in thf under a hydrogen atmosphere; $H_2N\cap NH_2$ = $H_2NCMe_2CMe_2NH_2$ [(*R*)-(**16**)], (*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$ [(*R*),(*R*,*R*)-**17**], (*R*,*R*)-1,2-$(H_2N)_2C_6H_{10}$ [(*R*),(*R*,*R*)-**18**]. Further reaction of (*R*),(*R*,*R*)-**17** with hydrogen chloride afforded *trans*-[{(*R*)-binap}Rh(H)(Cl){(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$}]$BF_4$ [(*R*),(*R*,*R*)-**19**], by oxidative addition (Scheme 4). From a structural point of view, the cation of the latter can be regarded as a blueprint of the neutral $Ru^{II}$ complex *trans*-[{(*R*)-binap}Ru(H)(Cl){(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$}], known to be an excellent catalyst precursor for the stereoselective hydrogenation of ketones and imines.[17a]



Scheme 4. Preparation of (*R*)-binap/1,2-diamine complexes (all as $BF_4^-$ salts).

Single-crystals of (*R*)-**16** and (*R*),(*R*,*R*)-**17** containing solvent molecules of crystallization [i.e. (*R*)-**16**·1/2$Me_2CO$·1/4thf and (*R*),(*R*,*R*)-**17**·$CH_2Cl_2$] were obtained upon slow diffusion of diethyl ether into concentrated solutions of the two complexes in acetone/thf and dichloromethane, respectively. As anticipated, the X-ray structure analyses of the two compounds revealed the presence of N–H···F hydrogen-bonded [{(*R*)-binap}Rh($H_2N\cap NH_2$)]$BF_4$ ion pairs with the rhodium atoms in a close to planar coordination geometry (Figures 10 and 11). The metal-to-phosphane and metal-to-amine linkages measure 2.213(2)–2.223(2) Å and 2.147(7)–2.156(7) Å, respectively, which is slightly shorter than, but still comparable to, the Ru–P and Ru–N bond lengths previously reported for the octahedral molecules *trans*-[{(*R*)-binap}Ru(X)(Cl){(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$}] (X = H[17a] or Cl[18]), where *d*(Ru–P) = 2.238–2.282 Å and *d*(Ru–N) = 2.164–2.198 Å.

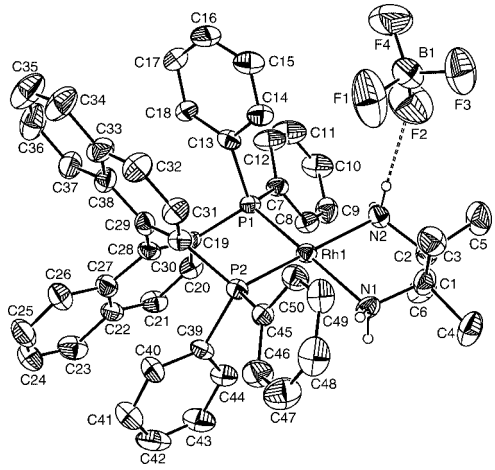


Figure 10. Structure of the ion pair [{(*R*)-binap}Rh($H_2NCMe_2CMe_2NH_2$)]$BF_4$ [(*R*)-**16**] as observed for the solid state of (*R*)-**16**·1/2$Me_2CO$·1/4thf (phenyl and methyl H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–P1, 2.223(2); Rh1–P2, 2.219(2); Rh1–N1, 2.155(6); Rh1–N2, 2.147(7). P1–Rh1–P2, 90.86(8); P1–Rh1–N1, 170.8(2); P1–Rh1–N2, 98.1(2); P2–Rh1–N1, 94.3(2); P2–Rh1–N2, 166.2(2); N1–Rh1–N2, 78.3(3). Hydrogen-bonding interactions as D–H, H···A, D···A, D–H···A [Å [°]]: N2–H···F2, 0.90, 2.26, 3.15(1), 171.1; N2–H···F3_#, 0.90, 2.23, 3.13(1), 176.7. Symmetry transformation used to generate equivalent atom: # = $-x$, $y-1/2$, $-z+1/2$.

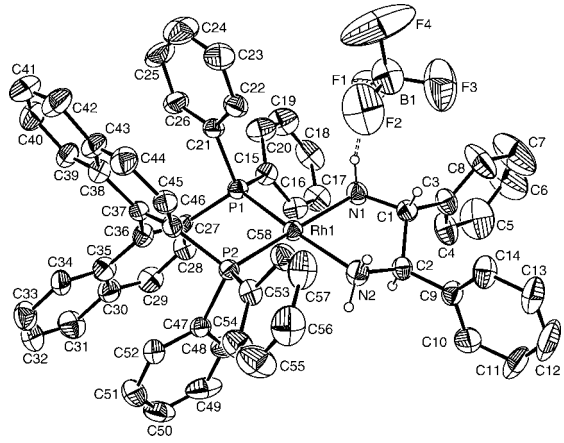

Figure 11. Structure of the ion pair [{(*R*)-binap}Rh{(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$}]$BF_4$ [(*R*),(*R*,*R*)-**17**] as observed for the solid state of (*R*),(*R*,*R*)-**17**·$CH_2Cl_2$ (phenyl H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh1–P1, 2.219(2); Rh1–P2, 2.213(2); Rh1–N1, 2.147(7); Rh1–N2, 2.156(7). P1–Rh1–P2, 91.00(8); P1–Rh1–N1, 94.3(2); P1–Rh1–N2, 170.0(2); P2–Rh1–N1, 173.0(3); P2–Rh1–N2, 97.3(2); N1–Rh1–N2, 78.0(3). Hydrogen-bonding interaction as D–H, H···A, D···A, D–H···A [Å [°]]: N1–H···F1, 0.90, 2.05, 2.92(1), 163.2.

## Catalytic C=O Hydrogenation

The close structural relationship of the ionic $Rh^I$ and $Rh^{III}$ complexes (*R*),(*R*,*R*)-**17** and (*R*),(*R*,*R*)-**19** to the neutral $Ru^{II}$ ketone hydrogenation (pre)catalysts *trans*-[{(*R*)-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

binap}Ru(X)(Cl){(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$}] (X = H,[17a] Cl[18]) prompted us to also inspect the two rhodium compounds for their ability to form C=O hydrogenation catalysts. In these probing experiments, which were run in 2-propanol with acetophenone at a substrate-to-catalyst (*s*:*c*) ratio of 200:1 under the conditions summarized in Table 1, virtually no conversion to 1-phenylethanol was observed on attempted catalysis in the absence of an activating basic additive (Table 1, Entries 1 and 4). Only when combined with strong base (typically, 5 equiv. of KOH) did both complexes behave as relatively sluggish catalysts for the hydrogenation of the ketone functionality − irrespective of whether the reactions were carried out in the absence of hydrogen gas (Table 1, Entries 2 and 5) or under $H_2$ pressure (Table 1, Entries 3 and 6). These observations clearly demonstrate that neither the $d^8$ species [{(*R*)-binap}Rh{(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$)]$BF_4$ nor its HCl adduct *trans*-[{(*R*)-binap}Rh(H)(Cl){(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$)]$BF_4$ as such can act as catalysts for C=O hydrogenation, whereas the two base-modified systems are able to catalyze the transfer of $H^+$ and $H^-$ equivalents both from the solvent and the gas molecule to the carbonyl dipole. Reduction of the substrate is slower in the absence than in the presence of hydrogen gas, which indicates that the two catalytic systems favor the direct hydrogenation by $H_2$ gas over the transfer of hydrogen from solvent molecules. The product alcohol was obtained in higher (albeit still modest) enantiomeric excess for the (*S*) enantiomer by transfer hydrogenation (64 and 71% *ee*) than by direct hydrogenation (30 and 33% *ee*).

Table 1. Hydrogenation of acetophenone in the presence of (*R*),(*R*,*R*)-**17** and (*R*),(*R*,*R*)-**19** as precatalysts.[a]

| No. | Complex/base (equiv. rel. to $C_{Rh}$) | $p(H_2)$ [bar] | *t* [h] | % PhCH(OH)Me | % *ee* (config.) |
|---|---|---|---|---|---|
| 1 | (*R*),(*R*,*R*)-**17**/none | 10 | 20 | | |
| 2 | (*R*),(*R*,*R*)-**17**/KOH (5) | | 5 | 57 | 71 (*S*) |
| 3 | (*R*),(*R*,*R*)-**17**/KOH (5) | 10 | 2.5 | 100 | 33 (*S*) |
| 4 | (*R*),(*R*,*R*)-**19**/none | 10 | 20 | | |
| 5 | (*R*),(*R*,*R*)-**19**/KOH (5) | | 5 | 30 | 64 (*S*) |
| 6 | (*R*),(*R*,*R*)-**19**/KOH (5) | 10 | 2.5 | 75 | 30 (*S*) |

[a] Acetophenone (2.0 mmol) together with (*R*),(*R*,*R*)-**17** or (*R*),(*R*,*R*)-**19** (0.01 mmol), plus added base, in 2-propanol (3 mL) at 50 °C.

Recent results of Rautenstrauch, Morris et al. have shown that the established $Ru^{II}$-based ketone hydrogenation precatalyst *trans*-[{(*S*)-tolbinap}$RuCl_2${(*S*,*S*)-$H_2NCH(Ph)CH(Ph)NH_2$}] (tolbinap = the di-*p*-tolyl analogue of binap) and its (*R*),(*R*,*R*) enantiomer also display catalytic activity for ketone transfer hydrogenation, if modified by strong alkaline base (usually KO*t*Bu) in 2-propanol.[17b] Relative to rhodium precatalysts (*R*),(*R*,*R*)-**17** and (*R*),(*R*,*R*)-**19**, the ruthenium complexes form much more active systems and work very fast at *s*:*c* = $10^5$–$10^6$ under the conditions of direct hydrogenation and with a reduced rate, but still much faster than both (*R*),(*R*,*R*)-**17** and (*R*),(*R*,*R*)-**19**, at *s*:*c* = $10^4$–$10^5$ under transfer hydrogenation conditions. With acetophenone as the substrate ketone, the (*R*),(*R*,*R*) forms of both the ruthenium and the rhodium catalysts favor the formation of the product alcohol as the (*S*) enantiomer. In direct hydrogenation, distinctly higher *ee*'s are achieved with the Ru systems than the Rh systems (≈80% versus ≈30%), although the latter give somewhat better optical yields than the former if allowed to operate on the pathway of transfer hydrogenation (64–71% versus 42–62%).

## Conclusions

This work shows that β-amino alcohols behave as N-monodentate ligands towards the dirhodium complex [($\eta^4$-$C_8H_{12}$)$_2$$Rh_2$(μ-Cl)$_2$] to form [($\eta^4$-$C_8H_{12}$)RhCl{HN(R)∩OH-κ*N*}] by nucleophilic cleavage of the chlorido bridges. Coordination of the free hydroxy function of the N,O ligands can be brought about either by dehydrochlorination to furnish alcoholato chelates [($\eta^4$-$C_8H_{12}$)Rh($H_2$N∩O-κ*N*,κ*O*)] or by precipitation of the metal-bound chloride as TlCl, which converts the neutral [($\eta^4$-$C_8H_{12}$)RhCl{HN(R)∩OH-κ*N*}] compounds into cationic [($\eta^4$-$C_8H_{12}$)Rh{HN(R)∩OH-κ*N*,κ*O*}]$^+$ amino alcohol chelate complexes. Whereas the exploratory studies aimed at the coordination of the amino alcohols to phosphane-containing rhodium compounds remain largely inconclusive, similar complexes could easily be made from [($\eta^4$-$C_8H_{12}$)Rh{(*R*)-binap}]$BF_4$ and 1,2-diamine ligands. If activated by strong base, the resulting products [{(*R*)-binap}Rh($H_2$N∩$NH_2$)]$BF_4$ can act as moderately active and selective catalysts for the reduction of acetophenone by both direct and transfer hydrogenation, as was demonstrated for [{(*R*)-binap}Rh{(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$)]$BF_4$ and its HCl adduct *trans*-[{(*R*)-binap}Rh(H)(Cl){(*R*,*R*)-$H_2NCH(Ph)CH(Ph)NH_2$)]$BF_4$.

## Experimental Section

**General:** All manipulations were performed under a nitrogen or argon atmosphere, except for the preparation of the 1,2-diamine complexes [{(*R*)-binap}Rh($H_2$N∩$NH_2$)]$BF_4$ (**16**–**18**) from [($\eta^4$-$C_8H_{12}$)Rh{(*R*)-binap}]$BF_4$, which were carried out under a hydrogen atmosphere. Solvents were distilled from the appropriate drying agents prior to use. IR spectra were obtained with a Mattson Polaris spectrometer. $^1$H, $^{13}$C, and $^{31}$P NMR were obtained with Bruker DPX 300 or Bruker DRX 400 spectrometers with $SiMe_4$ as the internal standard or with $H_3PO_4$ as the external standard (downfield positive) at ambient temperature, unless stated otherwise ("m" = deceptively simple multiplet). HPLC were obtained with a Thermoquest P 4000 (UV detector) apparatus. The amino alcohols, as well as the diphosphane and diamine ligands (*R*)-2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl, (*R*,*R*)-1,2-diphenylethylenediamine, and (*R*,*R*)-1,2-diaminocyclohexane, were used as obtained commercially. 1,1′,2,2′-Tetramethylethylenediamine,[19] [($\eta^4$-$C_8H_{12}$)$_2$$Rh_2$(μ-Cl)$_2$],[20] [($\eta^2$-$C_8H_{14}$)$_4$$Rh_2$(μ-Cl)$_2$],[21] and [($\eta^4$-$C_8H_{12}$)Rh{(*R*)-binap}]$BF_4$[15] were prepared according to published procedures or slight modifications thereof.

**[(η⁴-$C_8H_{12}$)Rh{(*S*)-$H_2NCH(CHMe_2)CH_2O$-κ*N*,κ*O*}]·$H_2O$, (*S*)-10·$H_2O$:** Powdered potassium hydroxide (300 mg, 5.35 mmol) was added to a solution of [(η⁴-$C_8H_{12}$)RhCl{(*S*)-$H_2NCH(CHMe_2)$-$CH_2OH$-κ*N*}], [(*S*)-**6**; (105 mg, 0.30 mmol] in dichloromethane (5 mL). The mixture was stirred for 16 h at room temperature and excess KOH was removed by filtration. Orange crystals identified as (*S*)-**9**·$H_2O$ by X-ray structure determination (see below) were deposited from the filtrate upon standing for several days at ambient conditions.

**Chelated Amino Alcohol Complexes [(η⁴-$C_8H_{12}$)Rh{HN(R)∩OH-κ*N*,κ*O*}]$O_3SCF_3$ (11–15):** Solid thallium trifluoromethanesulfonate was added in 10–20% excess to stirred solutions of the required monodentate amino alcohol complex [(η⁴-$C_8H_{12}$)RhCl(HN-(R)∩OH-κ*N*)] (0.25–0.40 mmol) in dichloromethane (5–10 mL). After stirring for 30 min at room temperature, the precipitated thallium chloride was filtered off and the products were isolated as yellow powders by removing all volatile material from the filtrates.

**[(η⁴-$C_8H_{12}$)Rh($H_2NCMe_2CH_2OH$-κ*N*,κ*O*)]$O_3SCF_3$ (11):** From **5** (99 mg, 0.29 mmol) and $TlO_3SCF_3$ (125 mg, 0.35 mmol) in $CH_2Cl_2$ (5 mL). **Reaction of $[(\eta^4\text{-}C_8H_{12})_2Rh_2(\mu\text{-}Cl)_2]$ with $H_2NCMe_2CH_2ONa$/$H_2NCMe_2CH_2OH$:** A solution of $[(\eta^4\text{-}C_8H_{12})_2Rh_2(\mu\text{-}Cl)_2]$ (50 mg, 0.10 mmol) in toluene (3 mL) was treated with a solution of $H_2NCMe_2CH_2ONa$ in 2-amino-2-methyl-1-propanol (1.1 M, 0.2 mL), prepared by dissolving the required amount of sodium metal in that amino alcohol. Stirring at room temperature for several minutes produced a yellow precipitate which was collected by filtration. Slow diffusion of *n*-pentane into a saturated thf solution of the solid afforded the addition compound $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2O\text{-}\kappa N,\kappa O)]\cdot[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)][(\eta^4\text{-}C_8H_{12})RhCl_2]\cdot$thf (**1·2·**thf), while recrystallization of the crude product from a toluene/*n*-hexane mixture resulted in the isolation of the adduct $[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2O\text{-}\kappa N,\kappa O)]\cdot[(\eta^4\text{-}C_8H_{12})Rh(H_2NCMe_2CH_2OH\text{-}\kappa N,\kappa O)]Cl$ (**1·3**), as shown by X-ray structure analyses (see below).

**Formation of *trans*-$[(i\text{Pr}_3\text{P})_2RhCl(N_2)]$:** L-Valinol was added in slight excess to the solution formed by mixing $[(\eta^2\text{-}C_8H_{14})_4Rh_2(\mu\text{-}Cl)_2]$ (103 mg, 0.14 mmol) in thf (5 mL)with $Pi\text{Pr}_3$ (0.11 mL, ca. 4 equiv.) under a nitrogen atmosphere at room temperature. Gentle warming of the solution resulted in an immediate change in color from dark red to orange. All volatile materials were then removed, and the remaining orange solid was redissolved in $CH_2Cl_2$. Slow evaporation of the solvent induced the deposition of orange crystals which X-ray crystallography showed to be *trans*-$[(i\text{Pr}_3\text{P})_2RhCl(N_2)]$ (see below). $^{31}$P NMR (121.5 MHz, $CDCl_3$): $\delta$ = 49.52 (d, $^1J_{Rh,P}$ = 120.3 Hz); ref.[15b]: $\delta$ = 41.8 (d, $^1J_{Rh,P}$ = 122.5 Hz) in [D$_8$]toluene. No identifiable products were formed when the reaction was carried out under an atmosphere of argon or hydrogen.

**Reaction of $[(\eta^4\text{-}C_8H_{12})Rh(H_2N\cap OH\text{-}\kappa N,\kappa O\})]O_3SCF_3$ Chelate Complexes (*S*)-12 and (1*R*,2*S*)-14 with (*R*)-binap:** (*a*) A solution of L-valinol complex (*S*)-**12** (55 mg, 0.12 mmol) in thf (5 mL) was treated with an equimolar quantity of (*R*)-binap (74 mg). The color of the mixture changed immediately from yellow to red–orange. After stirring for 3 h at ambient temperature, the solvent was removed to leave an orange powder (109 mg), the $^{31}$P NMR spectrum of which revealed the presence of an (*R*)-binap-coordinated $C_1$-symmetric species, assumed to originate from the $[\{(R)\text{-binap}\}Rh\{(S)\text{-}H_2NCH(CHMe_2)CH_2OH\text{-}\kappa N,\kappa O\}]^+$ cation. $^{31}$P NMR (121.5 MHz, [D$_8$]thf): $\delta$ = 47.58 (dd, $^1J_{Rh,P}$ = 172.7 Hz, $^2J_{P,P}$ = 62.4 Hz), 55.71 (dd, $^1J_{Rh,P}$ = 207.2 Hz); comparative $^{31}$P NMR spectroscopic data ($CD_2Cl_2$) for an in situ generated cationic complex formulated as $[\{(R)\text{-binap}\}Rh\{(S)\text{-nobin}\}]^+$ ($SbF_6^-$ salt; nobin = 2′-amino-1,1′-binaphth-2-ol): $\delta$ = 39.4 (dd, $^1J_{Rh,P}$ = 203.6 Hz, $^2J_{P,P}$ = 89.3 Hz), 40.1 (dd, $^1J_{Rh,P}$ = 201.5 Hz) ppm.[10] The product also contained traces of uncoordinated (*R*)-binap ($\delta$ = –14.19 ppm) in addition to minor quantities (ca. 6%) of oxidized forms of the ligand, that is, (*R*)-binap(O) ($\delta$ = –13.76, 26.84 ppm) and (*R*)-binap(O)$_2$ ($\delta$ = 29.39 ppm); ref.[22] $\delta$ = –14.3, 28.1 ppm for binap(O) and $\delta$ = 29.3 ppm for binap(O)$_2$. Only inferior amounts (ca. 4%) of the $[(\eta^4\text{-}C_8H_{12})Rh\{(R)\text{-binap}\}]^+$ cation resulting from substitution of the amino alcohol rather than the diolefin were detected by $^{31}$P NMR spectroscopic analysis: $\delta$ = 26.71 (d, $^1J_{Rh,P}$ = 147.1 Hz) ppm; comparative data for authentic $[(\eta^4\text{-}C_8H_{12})Rh\{(R)\text{-binap}\}]BF_4$ (121.5 MHz, $CDCl_3$): $\delta$ = 26.65 (d, $^1J_{Rh,P}$ = 144.8 Hz) ppm. The predominant replacement of the diene ligand by the diphosphane was also evident from the $^1$H NMR spectrum (300.1 MHz,

[a] Racemic twin.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[$D_8$]thf) showing free cyclooctadiene ($\delta$ = 2.22 and 5.39 ppm) together with coordinated L-valinol: $\delta$ = 0.54, 0.75 (both d, $J$ = 6.60, 6.78 Hz, 3 H each, both $CH_3$), 1.98 ("dq", $J$ = 6.60, 6.78 Hz, 1 H, C*H*Me$_2$), 2.48 (br. m, 3 H, NCH and $NH_2$ superimposed), 3.38 (m, 1 H, 1 $CH_2O$), 3.76 (dd, $^2J$ = 9.98 Hz, $^3J$ = 3.48 Hz, 1 H, $CH_2O$); comparative data for free L-valinol: $\delta$ = 0.71, 0.72 (both d, $J$ = 6.78 Hz each, 3 H each, both $CH_3$), 1.41 ("dq", $J$ = 6.78 Hz, 1 H C*H*Me$_2$), 2.36 (m, 1 H, NCH), 2.4 (br., 2 H, $NH_2$), 3.11 (m, 1 H, 1 $CH_2O$), 3.42 (dd, $^2J$ = 10.53, $^3J$ = 3.75 Hz, 1 H, $CH_2O$). (*b*) The unwanted formation of the binap(O), binap(O)$_2$, and [($\eta^4$-$C_8H_{12}$)-Rh{(*R*)-binap}]$^+$ byproducts could be suppressed by using a slight deficiency of the diphosphane as shown by the reaction of the L-norephedrine chelate complex (1*R*,2*S*)-**14** (129 mg, 0.25$_2$ mmol) with the (*R*)-binap ligand (156 mg, 0.25$_0$ mmol) in dichloromethane (4 mL). $^{31}$P NMR spectroscopic data (121.5 MHz, $CD_2Cl_2$) attributed to the [{(*R*)-binap}Rh{(1*R*,2*S*)-$H_2$NCH(Me)CH(Ph)OH-κ*N*,κ*O*}]$^+$ cation: $\delta$ = 47.39 (dd, $^1J_{Rh,P}$ = 173.8 Hz, $^2J_{P,P}$ = 60.1 Hz, 55.70 (dd, $^1J_{Rh,P}$ = 204.2 Hz) ppm. So far, all attempts to isolate the suspected (*R*)-binap/amino alcohol complexes as pure compounds resulted in their decomposition to unidentified products.

**General Procedure for Catalytic C=O Hydrogenation:** A 10-mL Schlenk tube equipped with a small magnetic stirring bar was charged with the catalyst complex dissolved in 2-propanol (typically 0.01 mmol in 3.0 mL). The required equivalent of potassium hydroxide (if any; see Table 1) and acetophenone (2.0 mmol) were added, the mixture was stirred for 10 min at ambient conditions, and the tube was inserted into an argon-filled stainless steel autoclave. The autoclave was sealed and, in direct hydrogenation experiments, vented several times with $H_2$ (Messer-Griesheim; 99.999%), subsequently pressurized to 10 bar and kept at 50 °C with stirring. Transfer hydrogenation experiments were carried out under an atmosphere of argon. At the end of the reaction, the pressure was vented, the solvent removed under vacuum, and the residue was diluted with *n*-pentane to precipitate the catalyst as a red oil. The pentane solution was decanted and chromatographed on silica gel (diethyl ether/*n*-pentane, 1:1). Volatile material was distilled off, and the mixture of products was analyzed by $^1$H NMR spectroscopy. Conversions and product compositions were determined on the basis of the integrations of the PhC(O)C*H*$_3$ and PhCH(OH)C*H*$_3$ signals. Enantiomeric excesses were measured by HPLC by using a Daicel Chiralcel OD column.

**X-ray Structure Determinations:** Single-crystals of the addition compounds **1·2**·thf and **1·3** were obtained by crystallizing the precipitates formed upon treatment of [($\eta^4$-$C_8H_{12}$)$_2$Rh$_2$(μ-Cl)$_2$] with $H_2$NCMe$_2$CH$_2$ONa/$H_2$NCMe$_2$CH$_2$OH from thf/*n*-pentane and toluene/*n*-hexane, respectively. Crystals suitable for X-ray work of **4**, (*S*)-**6**, (*R*)-**7**, (1*R*,2*S*)-**14**, and (1*R*,2*S*)-**15** were grown from dichloromethane. Crystal growth of (1*R*,2*S*)-**8** from thf/$CH_2Cl_2$ and (*R*)-**16** from diethyl ether/acetone/thf afforded solvent-containing specimens having the idealized compositions (1*R*,2*S*)-**8**·1/4$CH_2Cl_2$·1/4thf and (*R*)-**16**·1/2Me$_2$CO·1/4thf (see below). Crystals of (*S*)-**10**·$H_2O$ grew from the mother liquor of the reaction between (*S*)-**6** and powdered KOH in $CH_2Cl_2$; those of (*R*),(*R*,*R*)-**17**·$CH_2Cl_2$ were deposited upon slow diffusion of diethyl ether into a concentrated dichloromethane solution of the complex. Diffraction measurements were made with an Enraf–Nonius CAD-4 MACH 3 diffractometer (compounds **1·2**·thf, **1·3**, (*S*)-**6**, (*S*)-**10**·$H_2O$, (1*R*,2*S*)-**15**, (*R*)-**7**, (1*R*,2*S*)-**14**, (*R*)-**16**·1/2Me$_2$CO·1/4thf, and (*R*),(*R*,*R*)-

Table 3. Crystal data and structure refinement for compounds (1*R*,2*S*)-**8**·1/4$CH_2Cl_2$·1/4thf,[a] (*S*)-**10**·$H_2O$, (1*R*,2*S*)-**14**, (1*R*,2*S*)-**15**, and (*R*)-**16**·1/2Me$_2$CO·1/4thf.

[a] Formula idealized for integer number of atoms in unit cell (see text). [b] Empirical formula given for the hydrogen-bonded dimeric unit (see Figure 6) including the solvent of crystallization.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**17**·$CH_2Cl_2$) and a Bruker-Nonius Kappa CCD instrument (compounds **4** and (1*R*,2*S*)-**8**·1/4$CH_2Cl_2$·1/4thf), by using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å); data corrected for absorption either semiempirically from equivalents[23] (**4** and (1*R*,2*S*)-**8**·1/4$CH_2Cl_2$·1/4thf) or by $\psi$-scans.[24]

The structures were solved by direct methods and subsequently refined by full-matrix least-squares procedures on $F^2$ with allowance for anisotropic thermal motion of all non-hydrogen atoms employing both the SHELXTL NT 6.12[25] and the WinGX[26a] packages with some of the relevant programs (SIR-97,[27] SHELXL-97,[28] ORTEP-3[26b]) implemented therein. Crystals of **1·3** showed racemic twinning which was refined to give a twin component ratio close to 1:1. The split occupancies for the disordered cyclooctadiene carbon atoms in structure **4** (Figure 3) refined to 0.55 and 0.45, those of (1*R*,2*S*)-**8**·1/4$CH_2Cl_2$·1/4thf (Figure 6) to 0.74 and 0.26, and those of the atoms belonging to the disordered D-prolinol ligand in structure (*R*)-**7** (Figure 5) to 0.73 and 0.27. The residual electron density remaining after refinement of the structural model resulting for complex (*R*)-**16** was modeled by assuming the presence of solvent of crystallization (acetone and thf) with site occupancies fixed to 0.5 for the acetone and 0.25 for the thf molecule: (*R*)-**16**·1/2$Me_2CO$·1/4thf. Similarly, the final $\Delta F$ maps of the structure analysis of (1*R*,2*S*)-**8** indicated that in the crystal under study two different solvent molecules ($CH_2Cl_2$ and thf) shared a single crystallographic site with occupancies refining to 0.23 for the $CH_2Cl_2$ and 0.27 for the thf of crystallization, that is, close to (1*R*,2*S*)-**8**·1/4$CH_2Cl_2$·1/4thf. Further details of the X-ray structure determinations and results of the structure refinements are provided in Tables 2 3, and 4. For comparison with previously published data,[16b] the results of the structure determination carried out for the already known dinitrogen complex *trans*-[($i$Pr$_3$P)$_2$RhCl($N_2$)] have also been included in Table 4.

Table 4. Crystal data and structure refinement for compounds (*R*),(*R*,*R*)-**17**·$CH_2Cl_2$ and *trans*-[($i$Pr$_3$P)$_2$RhCl($N_2$)].

# Purines Bearing Phenanthroline or Bipyridine Ligands and Their $Ru^{II}$ Complexes in Position 8 as Model Compounds for Electrochemical DNA Labeling – Synthesis, Crystal Structure, Electrochemistry, Quantum Chemical Calculations, Cytostatic and Antiviral Activity

**Milan Vrábel,[a] Michal Hocek,*[a] Luděk Havran,[b] Miroslav Fojta,*[b] Ivan Votruba,[a] Blanka Klepetářová,[a] Radek Pohl,[a] Lubomír Rulíšek,[c] Lucie Zendlová,[c] Pavel Hobza,[c] I-hung Shih,[d] Eric Mabery,[d] and Richard Mackman[d]**

**Keywords:** Purines / Nucleobases / Bipyridines / Phenanthrolines / Ru complexes / Electrochemistry

A series of ethynyl- or (4-boronophenyl)bipyridines and -phenanthrolines were prepared as versatile building blocks for attachment of bidentate N-ligands to other molecules via cross-coupling reactions. Their complexation with $Ru(bpy)_2Cl_2$ gave the corresponding $Ru^{II}$ complexes. 9-Benzyladenine derivatives bearing the bipyridine or phenanthroline complexes in position 8, attached via a conjugate acetylene or phenylene linker were prepared by cross-coupling reactions of the ethynyl- or 4-boronophenylbipyridines and -phenanthrolines with 9-benzyl-8-bromoadenine. Their complexation with $Ru(bpy)_2Cl_2$ afforded the corresponding Ru complexes as model compounds for electrochemical DNA labeling. The same compounds were also prepared directly by cross-coupling of 9-benzyl-8-bromoadenine with Ru complexes of the alkynes and boronic acids. Both approaches are compared in terms of potential applications for labeling of nucleic acids. The crystal structures of two Ru complexes were determined by X-ray diffraction. The electrochemistry of the model purines bearing the phenanthroline or bipyridine ligands and the Ru complexes was studied by means of cyclic or square-wave voltammetry with carbon paste and mercury electrodes. The experimental redox potentials of the title compounds were compared with quantum chemical calculations. A very good agreement between experiment and theory was obtained, with a standard deviation of 0.13 V. It was shown that theoretical calculations can be of a limited predictive power for new $Ru^{II}$ complexes, though it was difficult to reproduce differences smaller than 0.05 V. Several compounds of this series exhibited a considerable cytostatic effect and activity against the hepatitis C virus (HCV).

## Introduction

DNA biosensors and chips[1] are increasingly utilized in current molecular biology, biochemistry, biomedicine and related disciplines. On the basis of DNA hybridization, these devices are used to analyze nucleotide sequences of DNAs or RNAs, searching for mutations, monitoring of gene expression, etc. DNA damage and interaction of DNA with different toxic or biologically active species can also be detected by DNA sensors. In addition to optical methods involved in most of the commercially available systems, electrochemical detection has attracted attention as a less expensive alternative offering comparable sensitivity.

Nucleic acids are electroactive species producing analytically useful oxidation and reduction signals at mercury or solid electrodes.[2,3] In addition to label-free DNA detection, different electroactive (or enzyme) tags tethered to target DNAs or hybridization probes are used to improve sensitivity and/or specificity of the analysis.[3] For example, ferrocene-labeled oligonucleotides (ON) were used as reporter (signaling) probes[4] or as an electrochemical variant of a "molecular beacon."[5] Osmium tetroxide complexes reacting selectively with thymine residues were applied in recently proposed double-surface (biomagnetic) electrochemical DNA hybridization techniques.[3,6] In analogy with the multicolor optical coding, combination of electrochemical tags yielding different signals makes it possible to detect several target DNA sequences in parallel.[7]

Complexes of transition metals, for instance ferrocene,[8] or complexes of bidentate N-ligands[9] (in particular phenanthrolines and bipyridines) with transition metals (Ru, Rh, Ni, Cu, Co, Pt, Pd, Os etc.) possess unique electrochemical and photophysical properties. Some of the phenanthroline complexes, which are also efficient DNA intercallators, have been extensively used as luminescent and electroactive DNA labels.[10] Attachment of probes based on metal complexes directly to a nucleobase via conjugate linkers should increase the efficiency of the charge transfer and thus enhance sensitivity. There are many examples of such probes connected to pyrimidine nucleobases. 5-(Ferrocenylethynyl)pyrimidine nucleosides were synthesized by Sonogashira coupling of 5-iodopyrimidines with ethynylferrocene and incorporated into DNA as electroactive redox markers.[11] Covalently bound conjugates of pyrimidine nucleotides and phenanthroline complexes of Ru and Os have been studied[12] as fluorescence probes for DNA hybridization and charge transfer through DNA. However, there are very few reports of probes conjugated to purines, presumably due to the greater difficulty in preparation and incorporation. Recently, we have reported[13] on the synthesis of model 9-benzyl-8-(ferrocenylethynyl)adenine by cross-coupling of ethynylferrocene with 8-bromoadenine. Preliminary electrochemical and quantum chemical studies showed that even small electronic changes are effectively transferred through the conjugated system and are electrochemically detectable. Moreover, these effects could be reliably calculated and predicted using ab initio calculations. However, the corresponding protected phosphoramidite of 8-(ferrocenylethynyl)-2′-deoxyadenosine was not efficiently incorporated to oligonucleotides[14] presumably due to oxidation of ferrocene followed by nucleophilic displacement. Therefore, our next probes of choice for labeling purines are complexes (Ru and Os) of bipyridine and phenanthroline. Here we describe the synthesis of model adenine derivatives by two different approaches and the study of their electrochemical properties in order to verify applicability of such complexes as probes for labeling nucleic acids. We were also interested in the biological activity of these novel types of adenine derivatives and metal complex conjugates.

## Results and Discussion

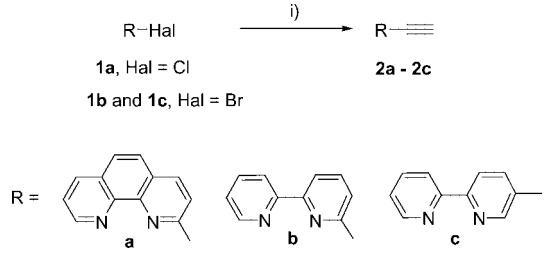
### Synthesis

Two different approaches to the synthesis of target 9-benzyladenines bearing phenanthroline complexes $Ru^{II}$ and $Os^{II}$ in position 8 have been designed and verified in terms of their efficiency, practicability, and compatibility with rather labile nucleic acids. The first one consisted of cross-coupling of 8-bromoadenine with ethynyl- or (4-boronophenyl)-2,2′-bipyridines or -phenanthrolines followed by complexation of the resulting purine-ligand conjugates with a metal. The second approach was based on direct cross-coupling of 8-bromoadenine with preformed Ru complexes of the ligand building blocks. For both approaches we needed the acetylene and boronic acid derivatives of the bidentate N-ligands.

#### *Synthesis of Ligand Building Blocks*

1,10-Phenanthroline (phen), 2,2′-bipyridine (bpy), and 2,2′:6′,2"-terpyridine (tpy) are the most commonly used polypyridine ligands in the chemistry of coordinating compounds[15] and are often used as building blocks for the construction of molecular and supramolecular devices.[16] Cross-coupling reactions are the most versatile tools for construction of molecules containing these ligands connected via conjugate (and thus charge conducting) acetylene or phenylene linkers. However, the chemistry of the corresponding synthetic equivalents for cross-coupling reactions, i.e. boronic acids and acetylene derivatives of oligopyridine ligands, is still underdeveloped and rather difficult. Therefore our first task was to prepare a series of such reagents (some of them were hitherto unknown compounds) not only by application but also by modification and optimization of known methods.

Common starting compounds in the synthesis of the building blocks were halogenated phenanthrolines and bipyridines **1**. 2-Chloro-1,10-phenanthroline (**1a**) was prepared[17] in four steps from the commercially available phenanthroline monohydrate. The Sonogashira cross-coupling reaction of **1a** with (trimethylsilyl)acetylene and subsequent deprotection of the TMS group by treatment with KF in MeOH/THF mixture, led to the desired new 2-ethynyl-1,10-phenanthroline (**2a**) (Scheme 1). Known 6-(ethynyl)-2,2′-bipyridine (**2b**) and 5-(ethynyl)-2,2′-bipyridine (**2c**) were prepared by analogous literature procedures[18] from 6-bromo-2,2′-bipyridine (**1b**) and 5-bromo-2,2′-bipyridine (**1c**), respectively (Scheme 1, Table 1).



Scheme 1. Synthesis of the ligands: i) 1. $[Pd(PPh_3)_2Cl_2]$ (5–10 mol-%), CuI (10 mol-%), TMSA (2.2 equiv.), $Et_3N$ (3.2 equiv.), DMF or THF, 60–70 °C; 2. MeOH/THF KF (2 equiv.).

Table 1. Synthesis of the ethynyl ligands **2**.

| Entry | R-hal | Product | Yield [%] |
|---|---|---|---|
| 1 | **1a** | **2a** | 60 |
| 2 | **1b** | **2b** | 82 |
| 3 | **1c** | **2c** | 83 |

(4-Bromophenyl)bipyridines, -phenanthroline and -terpyridine **3a**–**3d** were the key intermediates for the synthesis of the corresponding boronates **4a**–**4d**. 2-(4-Bromophenyl)-phenanthroline (**3a**) was prepared in 69% yield by a known[19] procedure involving addition of 4-bromophenyllithium to phenanthroline monohydrate followed by oxi-

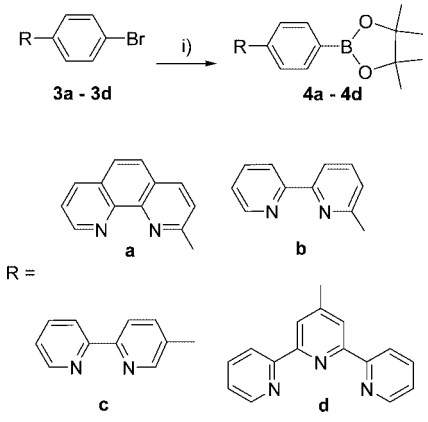
dation with $MnO_2$. The Suzuki cross-coupling reactions of 6-bromo-2,2′-bipyridine or 5-bromo-2,2′-bipyridine with 4-bromophenylboronic acid afforded the *p*-bromophenylene-substituted bipyridines **3b** and **3c** (compound **3c** was reported earlier via heterocyclizations[20]). 4′-(*p*-Bromophenyl)-2,2′:6′,2"-terpyridine **3d** was prepared by a known multistep procedure[21] from 2-acetylpyridine and 4-bromobenzaldehyde. All these bromo derivatives **3a**–**3d** were subjected to cross-coupling reactions with bis(pinacolato)-diboron[22] in the presence of $Pd(dppf)Cl_2$ and KOAc in dioxane at 80 °C to give the series of pinacol boronates **4a**–**4d** in good yields of 60–91% (Scheme 2, Table 2). Compounds **4a** and **4b** were new, while known compounds **4c**[23] and **4d**[21a] were prepared by this method in much higher yields (91 and 81%, respectively) than alternative methods reported in the literature (30 and 42%, respectively).



Scheme 2. Synthesis of the ligands: i) bis(pinacolatodiboron) (1.2 equiv.), [$Pd(dppf)Cl_2$] (5 mol-%), KOAc (1.5 equiv.), dioxane, 80 °C.

Table 2. Synthesis of the phenylene-bridged ligands.

| 2 | **3b** | **4b** | 86 |
| 3 | **3c** | **4c** | 91 |
| 4 | **3d** | **4d** | 81 |

### *Synthesis of Ru Complex-Containing Building Blocks*

Among many transition metals used in coordination chemistry of bipyridine-type ligands, $Ru^{II}$ complexes are one of the most popular due to their chemical stability and favorable redox and photophysical properties.[24] Surprisingly, acetylene or boronic acid building blocks containing the $Ru^{II}$ complexes, ready for a single-step attachment to any aromatic skeleton by cross-coupling reactions, are virtually unknown with the exception of (3- and 4-ethynyl-1,10-phenanthroline)$Ru^{2+}(bipy)_2 \cdot 2PF_6^-$.[25] We have prepared the whole series of $Ru^{II}$ complexes of the ligands **2b**–**2c** and **4a**–**4d**.

Commercially available $Ru(bpy)_2Cl_2 \cdot 2H_2O$ was the compound of choice for the complexation reactions. Its complexation with ligands **2** and **4a**–**4c** under standard conditions,[26] e.g. mixing of the reagents in MeOH or EtOH and refluxing the mixture for several hours under an inert atmosphere, afforded the desired products **5** and **6** in poor yields (12–30%) accompanied by some byproducts. When ethylene glycol was used as the solvent,[27] the yields were improved up to 66% (Scheme 3, Table 3) and the amounts of byproducts significantly decreased. A typical procedure involved a suspension of the starting compounds in ethylene glycol heating the mixture at 150 °C for 2 h, distillation of the solvent and anion exchange precipitation from aqueous solution by treatment with $NH_4PF_6$. The solid was further purified on a silica gel column using a mixture of acetonitrile, water, and saturated $KNO_3$ as the eluent. However, during this separation, partial anion exchange occurred and therefore it was crucial to re-precipitate the final product once again from its aqueous solution by treatment with $NH_4PF_6$. Only after this procedure and final re-crystallization were pure samples of hexafluorophosphate salts **5b**–**5c** and **6a**–**6c** isolated. In the case of terpyridine derivative **4d**, $Ru(tpy)Cl_3$ complex[28] was used as the complexation agent under the same conditions as described above to yield the complex **6d**. It should be mentioned that all the pinacol esters of boronate ligands **4a**–**4d** were cleaved simultaneously during the complexation to afford free boronic acids **6a**–**6d**.

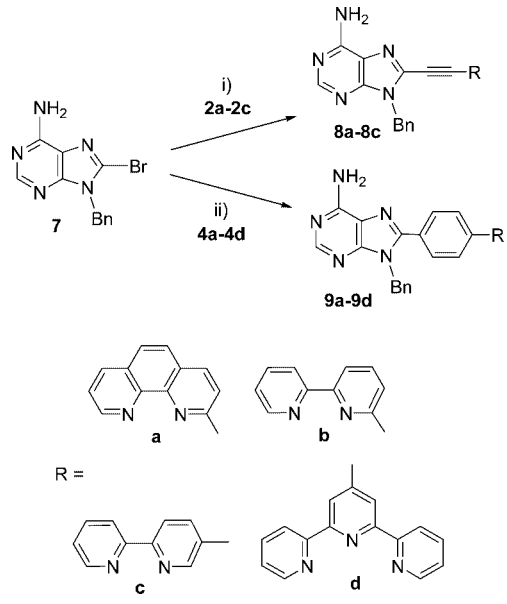
### *Synthesis of Adenine–Ligand Conjugates*

Cross-coupling reactions are often used for introduction of C-substituents to position 8 of purines.[29] The Suzuki–Miyaura reactions with arylboronic acids are usually used[30] for attachment of an aryl group while the Sonogashira reactions with terminal acetylenes are used[13,31] for alkynyl groups. Therefore, these reactions were our methods of choice for the synthesis of the conjugates of adenine with oligopyridine-type ligands connected via acetylene or phenylene bridges.

The Sonogashira cross coupling reactions of 9-benzyl-8-bromoadenine (**7**) with the terminal alkynes **2a**–**2c** in the presence of $[Pd(dppf)Cl_2]$, CuI, and $Et_3N$ in DMF at 90 °C afforded the corresponding acetylene-bridged conjugates **8a**–**8c** in the yields of ca. 55% after crystallization (Scheme 4, Table 4). The Suzuki–Miyaura cross coupling reaction of bromoadenine **7** with pinacol boronates **4a**–**4d** gave the phenylene-linked conjugates **9a**–**9d** (Scheme 4) in ca. 50% yield. All the cross-coupling reactions proceeded very well and quite cleanly. Their moderate isolated yields may have been caused by partial complexation of the Pd-catalysts by the oligopyridine moiety and by some loss during the silica gel chromatography of the quite polar substrates.



Scheme 4. Synthesis of the conjugates: i) $[Pd(dppf)Cl_2]$ (5 mol-%), CuI (5 mol%), $Et_3N$ (8 equiv.), DMF, 90 °C; ii) $[Pd(dppf)Cl_2]$ (5 mol-%), $K_2CO_3$ (4 equiv.), DMF, 90 °C.

Table 4. Synthesis of the conjugates.

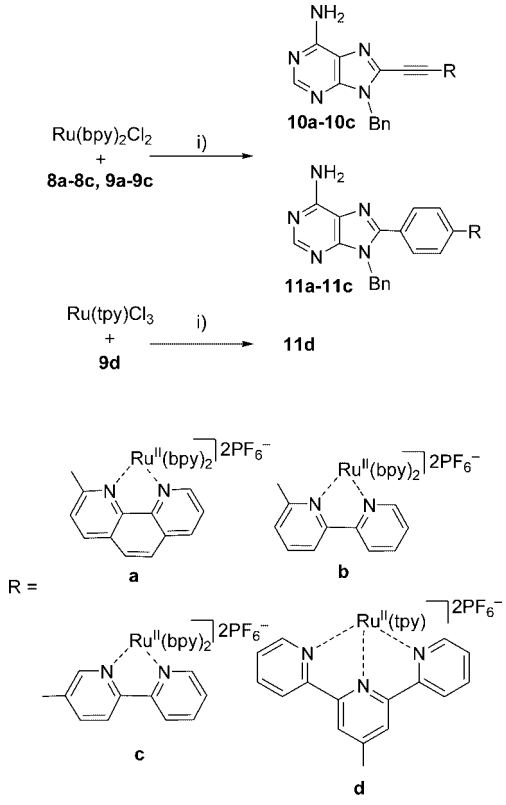
| 6 | **4c** | **9c** | 52 |
| 7 | **4d** | **9d** | 46 |

[a] Yields after crystallization.

### *Synthesis of Adenine–Complex Conjugates by Complexation*

One of the approaches to the desired title model conjugates of adenine and $Ru^{II}$ complexes is the complexation of the adenine-ligand conjugates **8** and **9** (Scheme 5, Table 5). The complexation reactions with either $Ru(bpy)_2Cl_2 \cdot 2H_2O$ or the $Ru(tpy)Cl_3$ complex were performed in ethylene glycol in analogy to the synthesis of the building blocks **5** and **6**. Once again problems were encountered with anion exchange during chromatography and the desired $Ru^{II}$ complexes **10a**–**10c** and **11a**–**11d** could only be isolated in good yields of 65–81% after re-precipitation and recrystallization (Table 5). There was no significant difference in the rate and yield of complexation between the less sterically hindered 5-substituted bipyridines **8c**,**9c** and the more hindered 6-substituted bipyridines **8b**,**9b**.



Scheme 5. Complexations of the conjugates: i) 1. ethylene glycol, 150 °C, 2 h; 2. saturated aqueous solution of $NH_4PF_6$.

In order to compare the chemical and electrochemical properties of the $Ru^{II}$ complexes with the corresponding $Os^{II}$ we have prepared the Os complex **12b** (Scheme 6), using the complexation of **8b** with $Os(bipy)_2Cl_2$[32] under the same conditions as for Ru complexes. In this case the Os complex **12b** was obtained in good yield of 74%.

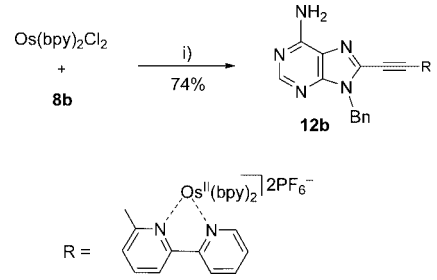
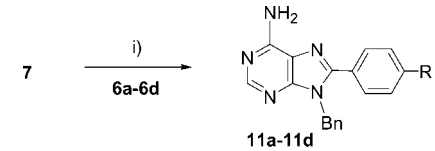


Scheme 6. Synthesis of the $Os^{II}$ complex: i) 1. ethylene glycol, 150 °C, 2 h; 2. saturated aqueous solution of $NH_4PF_6$.

### *Synthesis of Adenine–Complex Conjugates by Direct Cross-Coupling*

The second approach to the title conjugates **10** and **11** was based on direct cross-coupling reactions of **7** with Ru complex containing building blocks **5** and **6**. At first we tried to apply the same cross-coupling conditions utilized in the synthesis of ligand conjugates **8** and **9** (reactions in DMF, $Pd(dppf)Cl_2$ as catalyst and CuI, $Et_3N$ for the terminal alkynes and $K_2CO_3$ for the boronic acids). Unfortunately, none of these reactions proceeded and partial decomposition of the starting materials was observed under prolonged reaction times. Therefore, we tried to apply the aqueous-phase cross-coupling reactions that have been recently successfully used in the attachment of aryl groups[33] including hydrophilic amino acid residues[34] to the 8-position of purine nucleosides. The cross-coupling reactions of **7** with boronic acids **6a**–**6d** using $Pd(OAc)_2$ as the catalyst, water soluble $P(Ph–SO_3Na)_3$ ligand and $Cs_2CO_3$ as a base in a mixture of acetonitrile/water (1:1) proceeded relatively well to give the desired products **11a**–**11d** in moderate yields 24–63% (Scheme 7, Table 6). Application of the aqueous conditions for the Sonogashira cross coupling reactions of **7** with acetylenes **5** was not successful. In conclusion, direct cross-coupling of 8-bromoadenine with Ru complex-containing organometallics is possible with the application of aqueous-phase conditions for attachment of aryl groups by the Suzuki–Miyaura reaction. Presumably, due to the relatively mild conditions and tolerance to unprotected functional groups,[34] this could be the method of choice for direct labeling of nucleotides and oligonucleotides with complexes containing phenylene linkers but not for the attachment of acetylenes.



Scheme 7. Cross coupling reactions with complexes. i) $[Pd(OAc)_2]$ (10 mol-%), $P(Ph-SO_3Na)_3$ (50 mol-%), $Cs_2CO_3$ (3 equiv.), $CH_3CN/H_2O$ (1:1).

Table 6. Cross coupling reactions with Ru complexes.

| Entry | Ru complex | Product | Yield [%] |
|---|---|---|---|
| 1 | **6a** | **11a** | 40 |
| 2 | **6b** | **11b** | 24 |
| 3 | **6c** | **11c** | 53 |
| 4 | **6d** | **11d** | 63 |

### Crystal Structures

Complexes **5b** and **10b** gave monocrystals suitable for X-ray diffraction. However, the crystals of **10b** diffracted rather poorly, which resulted in weak reflections. Consequently, the precision of the structure determination is not excellent, but it still describes reasonably well all the main structural features of this Ru complex. The structures of complexes **5b** and **10b** are depicted in Figure 1.

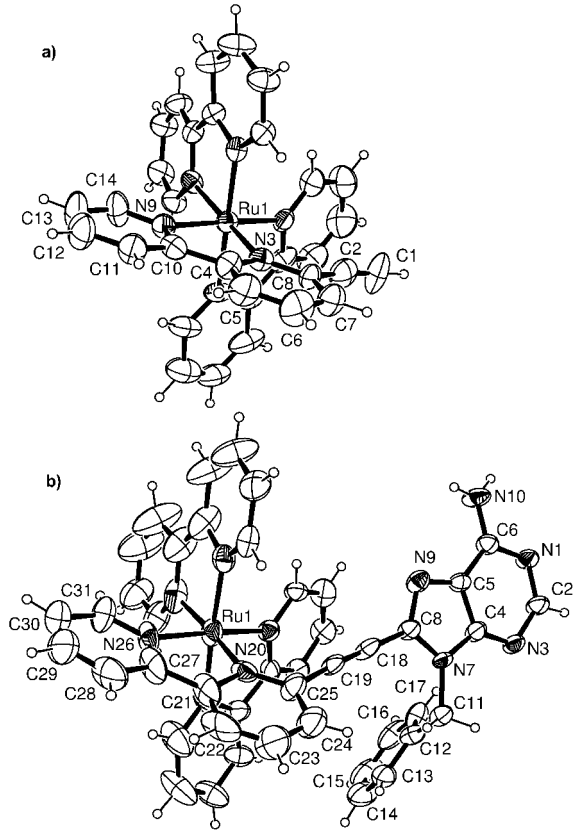


Figure 1. ORTEP diagram of **5b** (a) and **10b** (b) (thermal ellipsoids drawn at the 30% probability level).

The Ru–N bond lengths of **10b** and **5b** are generally comparable to those of the parent ion $[Ru(bpy)_3]^{2+}$ (2.055 Å),[35] with the exception of the shorter bond Ru1–N50 [**10b**,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2.013(9) Å], Ru1–N33 [**5b**, 2.097(10) Å] and especially the significantly elongated bonds Ru1–N20 [**10b**, 2.109(9) Å] and the corresponding bond Ru1–N3 [**5b**, 2.110(6) Å]. This elongation is caused by the steric hindrance of the adjacent 9-benzyl-8-ethynyladenine (**10b**) or acetylene (**5b**) groups and seems to be typical for all structures containing any group attached to the C25 carbon that were found in the Cambridge Structural Database.[36] The structure of the central octahedron in both complexes is more or less the same, but the bipyridine units are slightly shifted due to the presence of substituents (see Figure S1 in the Supporting Information).

## Electrochemistry

The conjugates **10a**–**10c**, **11a**–**11d**, and **12b** involve several electrochemically active centers, including the adenine moiety (potentially reducible at mercury and oxidizable at carbon electrodes[37]), triple bond of the ethynyl bridge (reducible at mercury electrodes[38]) as well as the ruthenium or osmium chelates (expected to undergo reversible one-electron $Ru^{II}/Ru^{III}$ or $Os^{II}/Os^{III}$ oxidation[39]). Using the hanging mercury drop electrode (HMDE), we observed cathodic signals attributable to the adenine (with all conjugates) as well to the triple bond (with **10a**–**10c** and **12b**, see Table 7). Potentials of 9-benzyladenine reduction were influenced by the substituents to some extent. In general, the adenine moiety was reduced more easily in bipyridine conjugates with the phenylene linker than in analogues with the ethynyl linker (**10b** vs. **11b** and **10c** vs. **11c**), in the phenanthroline conjugates (**10a** vs. **11a**), the opposite was true. The potential of the adenine signal in the bipyridine conjugates was also influenced by the position of the bipyridine substitution, being markedly more negative for the 5-substituted (**b**) than for 6-substituted (**c**) bipyridines. The ethynyl linker produced a single reduction peak in conjugates of phenanthroline (**a**) and 6-substituted bipyridine (**b**). In the 5-substituted bipyridine compounds (**a**) involving the acetylene moiety, two cathodic peaks were observed. As expected,[38] reduction of the triple bond was easier in the conjugate **10c** (involving disubstituted acetylene) than in the building block **5c** (monosubstituted acetylene).

With respect to the prospective utilization of the conjugates as DNA labels, our attention was focused mainly on processes related to the metal complexes. Cyclic voltammetry (CV) at a carbon paste electrode (CPE) revealed couples of reversible redox signals for all ruthenium complexes at potentials around +1.2 V (not shown). The CV peaks were, however, relatively poorly developed due to their occurrence at rather positive potentials close to background discharge. We therefore chose square-wave voltammetry (SWV), a technique offering better separation of signals from the background,[40] in further experiments. Peak potentials due to the ruthenium complexes resulting from these measurements are summarized in Table 7. All compounds involving the bipyridine ligand covalently linked to the adenine moiety, regardless of the bridge type or position of the bipyridine substitution, produced net SWV peaks at +1.21 V (compounds **10b**, **10c**, **11b**, and **11c**; in Figure 2 shown for

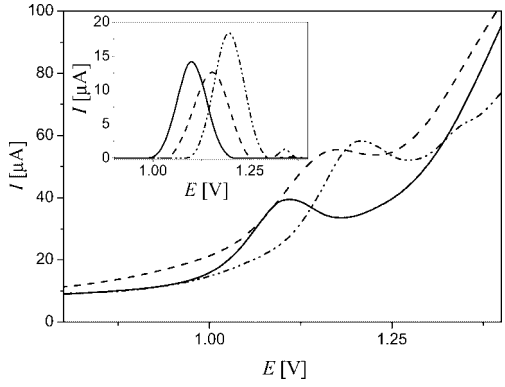

Figure 2. Sections of square-wave voltammograms of unsubstituted complex $[Ru(bipy)_3]^{2+}$ (solid), compound **5b** (dash) and compound **10b** (dash-dot-dot) measured at the CPE. Inset shows the same voltammograms after baseline subtraction.

Table 7. Potentials of electrochemical signals of the synthesized compounds.

| | Oxidation at PGE | | Reduction at HMDE | | |
|---|---|---|---|---|---|
| | $E^{net}$ [a] [V] | $\Delta E^{net}$ [b] [mV] | $E^{ade}$ [c] [V] | $\Delta E^{ade}$ [d] [mV] | $E^{eth}$ [e] [V] |
| $[Ru(bipy)_3]^{2+}$ | 1.095 | 0 | – | – | – |
| 9-benzyladenine | – | – | –1.362 | 0 | – |
| **5c** | 1.175 | 80 | – | – | –1.263; –1.362 |
| **10c** | 1.210 | 115 | –1.355 | 7 | –0.810; –0.886 |
| **10b** | 1.210 | 115 | –1.414 | –52 | –1.062 |
| **6c** | 1.165 | 70 | – | – | – |
| **11c** | 1.210 | 115 | –1.316 | 46 | – |
| **11b** | 1.210 | 115 | –1.378 | –16 | – |
| **10a** | 1.220 | – | –1.372 | –10 | –0.950 |
| **11a** | 1.215 | – | –1.326 | 36 | – |
| **11d** | 1.265 | – | – | – | – |
| **12b** | 0.790 | – | –1.390 | –28 | –1.024 |

[a] $E^{net}$ is the apparent redox potential of the $Ru^{II}/Ru^{III}$ or $Os^{II}/Os^{III}$ couple measured on the net square-wave voltammogram (CPE). [b] $\Delta E^{net}$ is the potential shift relative to unsubstituted $[Ru(bipy)_3]^{2+}$ complex. [c] $E^{ade}$ is the potential of reduction of the 9-benzyladenine moiety in the conjugate measured by linear scan voltammetry (HMDE). [d] $\Delta E^{ade}$ is the potential shift relative to unsubstituted 9-benzyladenine. [e] $E^{eth}$ are potentials of peaks related to reduction of the ethynyl linker triple bond (HMDE). All potentials are measured against a Ag/AgCl/3 M KCl reference electrode.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**10b**). Apparent redox potentials of complexes with covalently coupled phenanthroline ligands **10a**,**11a** were slightly more positive (+1.220 or +1.215 V, respectively) than those of the bipyridine analogues, while the complex **11d** (with ruthenium coordinated by two terpyridines) yielded a peak at +1.265 V. The osmium complex **12b** underwent reversible oxidation at +0.79 V, in agreement with a less positive redox potential of the $Os^{II}/Os^{III}$ couple, compared to $Ru^{II}/Ru^{III}$[39] (not shown).

Compared to unsubstituted $[Ru(bipy)_3]^{2+}$, the apparent redox potentials of compounds **10b–c** and **11b–c** were significantly more positive (see Table 7). This phenomenon can be explained by electron-withdrawing effects of the adenine residue linked via the unsaturated bridges. Reducing electron density at ruthenium results in its more difficult oxidation. Similar effects were recently observed[13] with ferrocenylethyne–adenine conjugates in which the iron oxidation was found to be more difficult, compared to unsubstituted ferrocene or to ferrocene linked to the adenine moiety via a saturated bridge, due to electronic coupling between ferrocene and adenine via the alkyne bridge. Influence of conjugated unsaturated substituents on electrochemical properties of the ruthenium complex is evident from the series $[Ru(bipy)_3]^{2+}$–**5b**–**10b** (Table 7, Figure 2) and series $[Ru(bipy)_3]^{2+}$–**6b**–**11b** (Table 7). The ethynyl (**5b**) or phenylene (**6b**) groups themselves cause shifts in the redox potential of the ruthenium complex by 80 or 70 mV, respectively, towards more positive values. Attachment of the purine moiety offering further electronic conjugation resulted in higher positive potential shifts (about 115 mV relative to the $[Ru(bipy)_3]^{2+}$ for both **10b** and **11b** as well as **10c** and **11c** which involve 5-substituted bipyridine instead of 6-substituted bipyridine present in the series **b**). Similar shifts of the $Ru^{II}/Ru^{III}$ redox potential were observed also with compounds in which the adenine moiety was replaced by another aromatic system (*p*-tolyl, not shown). More details about the electrochemistry of the conjugates and/or the building blocks at carbon or mercury electrodes will be published elsewhere.

### Quantum Chemical Calculations of the Redox Potentials of the Studied Complexes

DFT calculations have been performed in order to verify the potential utilization of these methods for theoretical prediction of redox potentials of the title complexes. Listed in Table 8 are the calculated values of redox potentials for the synthesized compounds, using Equations (1) and (2) (see Experimental Section). It can be seen that the calculated and experimental results are in good agreement (with a standard deviation of 130 mV). The systematic (mean) error of –60 mV can be attributed to several factors: (i) neglect of spin-orbit coupling (SOC) in the nonrelativistic treatment which has been estimated to account for approximately +30 mV on the model $Ru^{2+/3+}$ complex[41] (this effect is by one order of magnitude greater for $Os^{II}$ complexes, viz. Table 8, and has been calculated to account for 200 mV on a small model complex),[41] (ii) the single reference treatment of the triple (quasi)degenerate ground state in $[Ru(bipy)_3]^{3+}$ complexes, (iii) the uncertainty in the absolute potential of SHE, (iv) the difference between the theoretical calculations and the experimental setup (presence of counterions and the adsorption of complexes on the electrode).

Table 8. The calculated redox potentials of the synthesized compounds (vs. Ag/AgCl/3 M KCl reference electrode).

| | Oxidation $Ru^{2+/3+}$ ($Os^{2+/3+}$) | | | Reduction |
|---|---|---|---|---|
| | $E^0_{calc}$ [V][a] | $\Delta E^0_{calc}$ [mV][b] | $\Delta E^0_{exp}$ [mV][c] | $E^0_{calc}$ [V] |
| $[Ru(bipy)_3]^{2+}$ | 1.082a | 0 | 0 | –1.450 |
| **5c** | 1.074 | –8 | 80 | –1.557 |
| **10c** | 1.183 | 101 | 115 | –1.144 |
| **10b** | 1.238 | 156 | 115 | –1.357 |
| **6c** | 1.368 | 286 | 70 | –1.429 |
| **11c** | 0.987 | –95 | 115 | –1.292 |
| **11b** | 1.130 | 48 | 115 | –1.411 |
| **10a** | 1.165 | 83 | (125) | –1.234 |
| **11a** | 1.189 | 107 | (120) | –1.484 |
| **11d** | 0.960 | –122 | (170) | –1.389 |
| **12b** | 1.127 | 45 | (–305) | –1.498 |

[a] $E^0_{calc}$ were calculated using the B3LYP/def2-TZVP//PBE/def2-SVP energies, PBE/def2-SV(P) frequencies, ideal gas approximation for thermodynamic functions, the COSMO solvation model, 4.34 V as the absolute potential of the SHE, and 0.207 V as the potential of the reference electrode used in the electrochemical measurements (Table 7). [b] $\Delta E^0_{calc/exp}(X) = E^0_{calc/exp}(X) - E^0_{calc/exp}([Ru(bipy)_3]^{2+})$. [c] Experimental data taken from Table 7; values in parentheses have not been presented in Table 7 (showing effects of conjugated unsaturated substituents on the $[Ru(bipy)_3]^{2+/3+}$ redox potential) because compounds **10a**, **11a**, **11d** and **12b** involve complexes of different types.

To account for these systematic errors, we further discuss the values of $\Delta E^0$ [$\Delta E^0(X) = E^0(X) - E^0([Ru(bipy)_3]^{2+})$], though it can be noted that an excellent agreement between the calculated and experimental values of $E^0([Ru(bipy)_3]^{2+})$ has been obtained ($E^0_{calc}$ = 1.082 V vs. $E^0_{exp}$ = 1.095 V).

Considering that 100 mV corresponds to ca. 10 kJ mol$^{-1}$, we can see that most of the calculated values are within an error bar of the quantum chemical methods. Specifically, the values of $\Delta E^0$ for four studied complexes (**10c**, **11b**, **10a**, **11a**) are within 42 mV of the experimental values, which can be considered an excellent agreement between theory and experiment. Another two complexes, **5c** and **11b**, deviate by 88 and 67 mV, respectively, which is still a very good agreement. The largest errors are found for **6c** (+216 mV), **11c** (–210 mV), and **11d** (–292 mV). However, an analysis of the spin densities have shown that for the latter two complexes, the unpaired electron is not localized on the Ru atom (Figure 3), but rather resides on the adenine moiety. This finding explains the observed discrepancy between the calculations and experimental data. Whether this is an artifact of the DFT method or an observable phenomenon is a subject of subsequent study.[41] As mentioned above, the discrepancy of +350 mV for **12b** ($Os^{2+/3+}$ complexes) can be mostly attributed to spin-orbit coupling effects, which are not included in the DFT calculations. This is a general effect exercised in octahedral $Os^{2+/3+}$ complexes and may ex-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plain the lower redox potential of the $Os^{2+/3+}$ pair (compared to $Ru^{2+/3+}$).

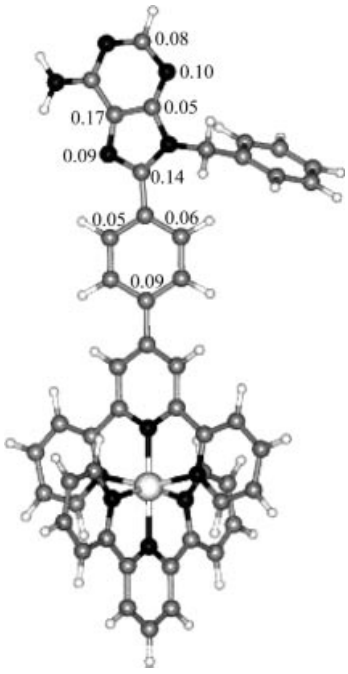

Figure 3. The equilibrium geometry of **11d**. Denoted are the calculated spin densities for the oxidized $Ru^{III}$ complex demonstrating that the unpaired electron is localized on the adenine moiety rather than on the Ru atom.

Structurally, we can observe only very small geometry changes associated with the $Ru^{2+/3+}$ oxidation and $Ru^{2+/1+}$ reduction. The most important parameters, the Ru–N distances, are shortened by ca. 0.004 Å upon the reduction and lengthened by ca. 0.006 Å upon oxidation. All the values of the Ru–N distances are summarized in Table S1 (see supporting information).

Also listed in Table 8 are the values of redox potentials for the reduction of the studied compounds. The interpretation of these values, i.e., the assignment of the formal redox states to subsystems in the studied complexes, is more complicated. In general, the calculated data are in the range of the experimental values: (–1.144, –1.557 V) vs. (–0.810, –1.414 V). The spin densities are strongly delocalized on the ligands, which suggests that these redox potential values do not refer to the reduction of the metal center, in agreement with the experimental data (Table 7).

In summary, it has been demonstrated that the theoretical calculations can satisfactorily reproduce the experimental data and can serve for prediction of redox potentials of new molecules with a reasonable level of fidelity. However, the anticipated differences in redox potential should be higher than ca. 100 mV (which has been shown as an error bar of the method), and care must be taken when interpreting the calculated data, i.e., to formally assign oxidation states and check whether they correspond to the experimentally observed process.

## Biological Activity

HCV chronically infects about 170 million people and the only approved therapy (a combination of interferon-α and ribavirin) is expensive and effective in only 50–60% of patients infected with HCV genotype 1. Development of effective antivirals for combating this pathogen is of great interest within pharmaceutical research. Common nucleoside *anti*-HCV agents are intracellularly phosphorylated to their triphosphates and then inhibit viral RNA synthesis mediated by the HCV RNA-dependent RNA polymerase.[42] Apart from that, there are numerous non-nucleoside inhibitors of this enzyme under current study.[43] Ru complexes of oligopyridine ligands are known to bind to DNA and thus exert antitumor and antiparasitic activity.[44] Some other types of Ru complexes are inhibitors of protein kinases.[45] To the best of our knowledge, neither oligopyridine ligands nor their transition metal complexes have been reported to possess *anti*-HCV activity. Therefore, we have also studied the biological activity (cytostatic effect and *anti*-HCV activity) of the model adenine-ligand and adenine complex conjugates.

Selected compounds and their respective Ru or Os complexes were evaluated in the HCV subgenomic replicon assay and their activity is presented in Table 9.[46] In general, the Ru and Os complex-based inhibitors displayed similar or weaker antiviral activity than their corresponding precursors with the exception of **10c**. However, analog **10c** despite improved antiviral activity compared to its precursor **8c** also showed less than 5-fold selectivity thereby confounding further interpretation of the data. Two of the most potent compounds were the structurally related analogs **9a** and **8a** in which the main structural difference is the bridging group between the purine and metal chelating motif

Table 9. Replicon activity and NS5B 1b enzymatic potency of selected compounds.

| | Replicon $EC_{50}$/μM | Huh-7 $CC_{50}$/μM | NS5B 1b $IC_{50}$/μM | Ru/Os salt complex | Replicon $EC_{50}$/μM | Huh-7 $CC_{50}$/μM |
|---|---|---|---|---|---|---|
| **8a**[a] | 0.73 | 2 | n.d. | **10a** | 17 | 100 |
| **8b** | 5 | >50 | >2 | **10b** | 28 | cytostatic |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(alkynyl or phenyl). Unfortunately, both of these analogs also displayed poor selectivity (less than 3-fold). Analog **9d** was the most potent and selective (at least 200-fold) inhibitor in the series.

Several compounds, including **9d**, were tested for inhibition toward HCV NS5B polymerase 1b (Table 9).[47] None of the noncomplexed analogs demonstrated activity up to 2 μM. Because of poor solubility in the assay buffer, inhibitory activity beyond 2 μM could not be measured. Therefore, determination of whether **9d** inhibits HCV NS5B weakly through an allosteric mechanism, or whether it has other cellular or viral targets will require further study.

The in vitro evaluation of the cell growth inhibition was estimated in mouse lymphocytic leukemia L1210 cells (ATCC CCL 219), CCRF-CEM T lymphoblastoid cells (human acute lymphoblastic leukemia, ATCC CCL 119), human promyelocytic leukemia HL-60 cells (ATCC CCL 240), and human cervix carcinoma HeLa S3 cells (ATCC CCL 2.2). Significant cytostatic activity was found only in compounds **8a** and **9d**. Surprisingly, compound **9a** in contrast to Huh-7 hepatocytes does not exert any cytotoxicity at 10 μmol $L^{-1}$. This discrepancy was rechecked by the analysis of the cell cycle course using flow cytometry. The data revealed that 0.7 μM compound **8a** considerably influences the cell cycle profile, which is characterized by apoptosis inducing activity and reduced proportion of G1 (from 49.4 to 17.5%) and G2/M phases (from 19.7 to 4.9%) compensated by an increase of the S phase (from 30.8 to 77.6%). On the other hand, compound **9a** does not affect the cell cycle pattern even at 2 μM, which represents more than twice the Huh7 $CC_{50}$ value. These results indicate different susceptibilities of various cell lines towards the model adenine ligands (Table 10).

Table 10. Cytostatic activity of selected compounds.

| | $IC_{50}$, μmol $L^{-1}$ | | | |
|---|---|---|---|---|
| | L1210 | HL60 | HeLa S3 | CCRF-CEM |
| **8a** | 0.88 ± 0.06 | 0.57 ± 0.05 | 1.10 ± 0.08 | 1.40 ± 0.10 |
| **9d** | 0.97 ± 0.08 | 1.40 ± 0.08 | > 20 | 1.65 ± 0.11 |

## Conclusions

9-Benzyladenine derivatives bearing Ru complexes in position 8 were prepared as model compounds for electrochemical DNA labeling. Two strategies of synthesis have been explored: (i) synthesis of adenine derivatives of bipyridine ligands followed by complexation with Ru or (ii) cross-coupling of 8-bromoadenine derivatives with boronic acids derived from Ru complexed ligands. None of the two approaches is truly efficient but, due to the relatively harsh conditions, difficult separation, and moderate yields of the complexation in the first approach, the second approach seems to be more suitable for applications in labile nucleosides or oligonucleotides despite its moderate yields. The new Ru-containing acetylene or boronate building blocks **5** and **6** will certainly be useful in labeling of other types of molecules by a direct cross-coupling.

The model compounds have been systematically studied by several methods. Electrochemistry revealed both oxidation and reduction patterns with relatively minor substituent effects. Quantum-chemical calculations were able to predict the values of redox potentials with the precision of ca. 100 mV, which might not always be sufficient for the prediction of differences in redox potentials in DNA. Despite these problems, we will continue our efforts in the synthesis of oligonucleotide probes bearing such transition metal complexes. The most interesting (and rather unexpected) finding was the significant antiviral activity against HCV of the adenine–oligopyridine conjugates, which is unfortunately accompanied by considerable cytotoxicity. Nevertheless, these compounds represent a completely new structural lead in the search for novel antiviral agents.

## Experimental Section

**General Remarks:** All cross-coupling reactions were performed under argon. $Et_3N$ was degassed in vacuo and stored over molecular sieves under argon. Compounds **1a** [ref.[17]], **1b**, **1c**, **2b**, **2c** [ref.[18]], **3a** [ref.[19]], and **3d** [ref.[20]] were prepared according to literature procedures. Other chemicals were purchased from commercial suppliers and used as received. NMR spectra were recorded with Bruker Avance 500 (500 MHz for $^1H$ and 125.8 MHz for $^{13}C$) and Bruker Avance 400 ($^1H$ at 400, $^{13}C$ at 100.6 MHz) spectrometers in $CDCl_3$, [$D_6$]DMSO, or [$D_6$]acetone. Chemical shifts (in ppm, $\delta$ scale) were referenced to TMS (for $^1H$ NMR spectra in $CDCl_3$) and/or to the solvent signal ($CDCl_3$ δ = 7.26 ppm for $^1H$ NMR and δ = 77.0 ppm for $^{13}C$ NMR; [$D_6$]DMSO for $^1H$ NMR ($\delta$ = 2.5 ppm) and for $^{13}C$ NMR ($\delta$ = 39.7 ppm), [$D_6$]acetone for $^1H$ NMR ($\delta$ = 2.05 ppm) and for $^{13}C$ NMR ($\delta$ = 29.8 ppm, $CD_3$ group), coupling constants $J$ are given in Hz. The assignment of proton and carbon signals was based on H,H-COSY, H,C-HSQC, and H,C-HMBC experiments. Melting points were determined on a Kofler block and are uncorrected. Mass spectra were measured on a ZAB-EQ (VG Analytical) spectrometer using FAB (ionization by Xe, accelerating voltage 8 kV, glycerol matrix) or on a LCQ classic spectrometer using electrospray ionization (ESI). X-ray crystallographic analysis of single crystals of **10b** (red, 0.03 × 0.14 × 0.27 mm) and **5b** (red, 0.08 × 0.31 × 0.40 mm) was performed with Xcalibur X-ray diffractometer with Cu-$K_\alpha$ ($\lambda$ = 1.54180 Å), data collected at 150 K (**10b**) and 295 K (**5b**).

**2-Ethynyl-1,10-phenanthroline (2a):** A solution of 2-chloro-1,10-phenanthroline (0.5 g, 2.3 mmol), bis(triphenylphosphane)palladium dichloride (160 mg, 0.23 mmol), CuI (44 mg, 0.23 mmol), $Et_3N$ (1 mL, 7.2 mmol), and (trimethylsilyl)acetylene (0.7 mL, 5.16 mmol) in DMF (5 mL) was stirred at 60 °C under argon for 12 h. The solvent was removed under reduced pressure, the residue was dissolved in $CHCl_3$, and washed with a saturated solution of EDTA. The organic layers were collected and the solvents evaporated to dryness. The crude intermediate was diluted in methanol (5 mL) and $K_2CO_3$ (2.17 mmol, 300 mg) was added. The mixture was stirred for 6 h at room temperature. After evaporation of the solvent under reduced pressure, the crude product was purified by column chromatography (ethyl acetate/hexanes, 1:1) to give 285 mg of **1a** (60%) as brownish crystals with m.p. 52–58 °C. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 3.27 (s, 1 H, HC≡C–), 7.65 (dd, $J_{8,7}$ = 8.1, $J_{8,9}$ = 4.4, 1 H, 8-H), 7.77 (d, $J_{5,6}$ = 8.8, 1 H, 5-H), 7.79 (d, $J_{3,4}$ =

8.2, 1 H, 3-H), 7.81 (d, $J_{6,5}$ = 8.8, 1 H, 6-H), 8.22 (d, $J_{4,3}$ = 8.2, 1 H, 4-H), 8.25 (dd, $J_{7,8}$ = 8.1, $J_{7,9}$ = 1.8, 1 H, 7-H), 9.23 (dd, $J_{9,8}$ = 4.4, $J_{9,7}$ = 1.8, 1 H, 9-H) ppm. $^{13}$C NMR (100.6 MHz, $CDCl_3$): $\delta$ = 78.43 (H*C*≡C–), 83.56 (–*C*≡CH), 123.31 (C-8), 126.04 (C-5), 126.54 (C-3), 127.43 (C-6), 127.91 (C-4a), 128.89 (C-6a), 135.95 (C-7), 136.12 (C-4), 142.56 (C-2), 145.66 (C-10a), 146.28 (C-10b), 150.70 (C-9) ppm. FAB MS: *m*/*z* (%) = 205 (100) [M$^+$ + H]. HRMS (FAB): for $C_{14}H_9N_2$ calcd. 205.0766; found 205.0769. IR ($CHCl_3$): $\tilde{\nu}$ = 3304, 3049, 2968, 2835, 1505, 853 cm$^{-1}$. $C_{14}H_8N_2{\cdot}H_2O$ (222.24): calcd. C 75.66, H 4.54, N 12.6; found C 75.71, H 4.88, N 12.3.

**6-(4-Bromophenyl)-2,2′-bipyridine (3b):** A mixture of 6-bromo-2,2′-bipyridine (1 g, 4.25 mmol), (4-bromophenyl)boronic acid (1.28 g, 5.3 mmol, 1.5 equiv.), $K_2CO_3$ (1.18 g, 8.5 mmol, 2 equiv.), and $Pd(PPh_3)_4$ (245 mg, 0.21 mmol, 5 mol-%) in toluene (5 mL) was stirred under argon for 8 h at 100 °C. After evaporation of the solvent the residue was dissolved in chloroform, washed with saturated solution of EDTA and dried with $MgSO_4$. The product was purified by silica gel column chromatography (ethyl acetate/hexanes, 1:10). The product was obtained as a colorless solid (1.14 g, 86%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 7.33 (ddd, $J_{5',4'}$ = 7.5, $J_{5',6'}$ = 4.8, $J_{5',3'}$ = 1.2, 1 H, 5′-H), 7.63 (m, 2 H, H$^m$ phenylene), 7.74 (dd, $J_{5,4}$ = 7.8, $J_{5,3}$ = 1.0, 1 H, 5-H), 7.85 (ddd, $J_{4',3'}$ = 8.0, $J_{4',5'}$ = 7.5, $J_{4',6'}$ = 1.8, 1 H, 4′-H), 7.89 (t, $J_{4,5}$ = 7.8, $J_{4,3}$ = 7.8, 1 H, 4-H), 8.03 (m, 2 H, H$^o$ phenylene), 8.39 (dd, $J_{3,4}$ = 7.8, $J_{3,5}$ = 1.0, 1 H, 3-H), 8.60 (dt, $J_{3',4'}$ = 8.0, $J_{3',5'}$ = 1.2, $J_{3',6'}$ = 0.9, 1 H, 3′-H), 8.70 (ddd, $J_{6',5'}$ = 4.8, $J_{6',4'}$ = 1.8, $J_{6',3'}$ = 0.9, 1 H, 6′-H) ppm. $^{13}$C NMR (125.8 MHz, $CDCl_3$): $\delta$ = 119.64 (C-3), 120.01 (C-5), 121.25 (C-3′), 123.45 (C$^p$ phenylene), 123.84 (C-5′), 128.49 (C$^o$ phenylene), 131.85 (C$^m$ phenylene), 136.88 (C-4′), 137.84 (C-4), 138.21 (C$^i$ phenylene), 149.11 (C-6′), 155.23 (C-6), 155.88 (C-2), 156.12 (C-2′) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 3011, 2985, 1582, 1562, 1454, 1431, 1009, 817, 637 cm$^{-1}$. FAB MS: *m*/*z* (%) = 311 (100). HRMS (FAB): for $C_{16}H_{12}BrN_2$ calcd. 311.0184; found 311.0179. $C_{16}H_{11}BrN_2$ (311.18): calcd. C 61.76, H 3.56, N 9.00; found C 61.82, H 3.61, N 9.05.

**5-(4-Bromophenyl)-2,2′-bipyridine (3c):** A mixture of 5-bromo-2,2′-bipyridine (1 g, 4.25 mmol), (4-bromophenyl)boronic acid (1.03 g, 5.1 mmol, 1.2 equiv.), $K_2CO_3$ (1.18 g, 8.5 mmol, 2 equiv.), and $Pd(PPh_3)_4$ (245 mg, 0.21 mmol, 5 mol-%) in DMF (5 mL) was stirred under argon for 8 h at 100 °C. After evaporation of the solvent the residue was dissolved in chloroform, washed with saturated solution of EDTA, and dried with $MgSO_4$. The product was purified by silica gel column chromatography (ethyl acetate/hexanes, 1:10). The product was obtained as a colorless solid (780 mg, 59%), which gave analytical data identical to those previously reported.[20]

**General Procedure for Preparation of the Pinacolboronates. Method A:** A bromo derivative (**3a/3d**) (3.5 mmol), bis(pinacolato)diboron (4.2 mmol, 1.2 equiv.), $PdCl_2$ (0.175 mmol, 5 mol-%), dppf (0.175 mmol, 5 mol-%), and KOAc (5.25 mmol, 1.5 equiv.) were combined and stirred under argon in dry dioxane at 80 °C until the TLC showed complete consumption of the starting material. After evaporation of the solvent the residue was dissolved in chloroform, washed with a saturated solution of EDTA and purified by silica gel column chromatography (ethyl acetate/hexanes).

**Pinacol [4-(1,10-Phenanthroline-3-yl)phenyl]boronate (4a):** The product was obtained as brownish crystals in 60% yield (Method A). M.p. 192–193 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.39 (s, 12 H, $CH_3$ dioxaborolane), 7.65 (dd, $J_{8,7}$ = 8.0, $J_{8,9}$ = 4.4, 1 H, 8-H), 7.79 (d, $J_{6,5}$ = 8.8, 1 H, 6-H), 7.83 (d, $J_{5,6}$ = 8.8, 1 H, 5-H), 7.99 (m, 2 H, H$^m$ phenylene), 8.15 (d, $J_{3,4}$ = 8.4, 1 H, 3-H), 8.27 (dd, $J_{7,8}$ = 8.0, $J_{7,9}$ = 1.7, 1 H, 7-H), 8.32 (d, $J_{4,3}$ = 8.4, 1 H, 4-H), 8.36 (m, 2 H, H$^o$ phenylene), 9.26 (dd, $J_{9,8}$ = 4.4, $J_{9,7}$ = 1.7, 1 H, 9-H) ppm. $^{13}$C NMR (100.6 MHz, $CDCl_3$): $\delta$ = 24.92 ($CH_3$ dioxaborolane), 83.88 (C dioxaborolane), 120.86 (C-3), 122.89 (C-8), 126.38 and 126.40 (C-5 and C-6), 127.14 (C$^o$ phenylene), 127.73 (C-4a), 129.08 (C-6a), 135.22 (C$^m$ phenylene), 136.14 (C-7), 136.83 (C-4), 141.94 (C$^i$ phenylene), 146.13 (C-10b), 146.42 (C-10a), 150.45 (C-9), 157.36 (C-2) ppm; C$^p$ phenylene signal not observed. FAB MS: *m*/*z* (%) = 282.1 (70), 382.2 (100) [M$^+$]. HRMS (FAB): for $C_{24}H_{24}BN_2O_2$ calcd. 383.1931; found 383.1924. IR ($CHCl_3$): $\tilde{\nu}$ = 3010, 2981, 1610, 1522, 1360, 1144, 1089, 1017, 858, 842, 662, 650 cm$^{-1}$. $C_{24}H_{23}BN_2O_2{\cdot}1/3H_2O$ (400.28): calcd. C 74.53, H 6.12, N 7.24; found C 74.74, H 6.07, N 6.99.

**Pinacol [4-(2,2′-Bipyridin-6-yl)phenyl]boronate (4b):** The product was obtained as white crystals in 86% yield (Method A). M.p. 121–123 °C. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.38 (s, 12 H, $CH_3$ dioxaborolane), 7.33 (ddd, $J_{5',4'}$ = 7.5, $J_{5',6'}$ = 4.8, $J_{5',3'}$ = 1.2, 1 H, 5′-H), 7.81 (dd, $J_{5,4}$ = 7.8, $J_{5,3}$ = 1.1, 1 H, 5-H), 7.86 (td, $J_{4',3'}$ = 8.0, $J_{4',5'}$ = 7.5, $J_{4',6'}$ = 1.8, 1 H, 4′-H), 7.89 (t, $J_{4,5}$ = 7.8, $J_{4,3}$ = 7.8, 1 H, 4-H), 7.95 (m, 2 H, H$^m$ phenylene), 8.16 (m, 2 H, H$^o$ phenylene), 8.39 (dd, $J_{3,4}$ = 7.8, $J_{3,5}$ = 1.1, 1 H, 3-H), 8.64 (dt, $J_{3',4'}$ = 8.0, $J_{3',5'}$ = 1.2, $J_{3',6'}$ = 1.0, 1 H, 3′-H), 8.70 (ddd, $J_{6',5'}$ = 4.8, $J_{6',4'}$ = 1.8, $J_{6',3'}$ = 1.0, 1 H, 6′-H) ppm. $^{13}$C NMR (125.8 MHz, $CDCl_3$): $\delta$ = 24.89 ($CH_3$ dioxaborolane), 83.88 (C dioxaborolane), 119.57 (C-3), 120.58 (C-5), 121.34 (C-3′), 123.75 (C-5′), 126.13 (C$^o$ phenylene), 135.17 (C$^m$ phenylene), 136.89 (C-4′), 137.67 (C-4), 141.81 (C$^i$ phenylene), 149.04 (C-6′), 155.80 (C-2), 156.23 (C-6), 156.31 (C-2′) ppm; C$^p$ phenylene signal not observed. FAB MS: *m*/*z* (%) = 258.1 (65), 358.2 (100) [M$^+$]. HRMS (FAB): for $C_{22}H_{24}BN_2O_2$ calcd. 359.1931; found 359.1938. IR ($CHCl_3$): $\tilde{\nu}$ = 3010.2998, 2983, 1611, 1566, 1430, 1391, 1361, 1321, 1144, 1088, 1018, 859, 662 cm$^{-1}$. $C_{22}H_{23}BN_2O_2$ (358.24): calcd. C 73.76, H 6.47, N 7.82; found C 73.58, H 6.47, N 7.60.

**Pinacol [4-(2,2′-Bipyridin-5-yl)phenyl]boronate (4c):** The product was obtained as white crystals in 91% yield (Method A) which gave analytical data identical to those previously reported.[23] $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.38 (s, 12 H, $CH_3$ dioxaborolane), 7.33 (ddd, $J_{5',4'}$ = 8.0, $J_{5',6'}$ = 4.8, $J_{5',3'}$ = 1.2, 1 H, 5′-H), 7.67 (m, 2 H, H$^o$ phenylene), 7.84 (td, $J_{4',3'}$ = $J_{4',5'}$ = 8.0, $J_{4',6'}$ = 1.9, 1 H, 4′-H), 7.94 (m, 2 H, H$^m$ phenylene), 8.05 (dd, $J_{4,3}$ = 8.3, $J_{4,6}$ = 2.4, 1 H, 4-H), 8.45 (dt, $J_{3',4'}$ = 8.0, $J_{3',5'}$ = 1.2, $J_{3',6'}$ = 1.0, 1 H, 3′-H), 8.48 (dd, $J_{3,4}$ = 8.3, $J_{3,6}$ = 0.9, 1 H, 3′-H), 8.71 (ddd, $J_{6',5'}$ = 4.8, $J_{6',4'}$ = 1.9, $J_{6',3'}$ = 1.0, 1 H, 6′-H), 8.94 (dd, $J_{6,4}$ = 2.4, $J_{6,3}$ = 0.9, 1 H, 6-H) ppm. $^{13}$C NMR (100.6 MHz, $CDCl_3$): $\delta$ = 24.87 ($CH_3$ dioxaborolane), 83.95 (C dioxaborolane), 120.96 and 121.10 (C-3 and C-3′), 123.72 (C-5′), 126.32 (C$^o$ phenylene), 135.29 (C-4), 135.52 (C$^m$ phenylene), 136.30 (C-5), 136.95 (C-4′), 140.20 (C$^i$ phenylene), 147.72 (C-6), 149.23 (C-6′), 155.14 (C-2), 155.84 (C-2′) ppm; C$^p$ phenylene signal not observed.

**Pinacol [4-(2,2′:6′,2"-Terpyridine-4′-yl)phenyl]boronate (4d):** The product was isolated as white crystals in 81% yield (Method A). M.p. 187–196 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.39 (s, 12 H, $CH_3$ dioxaborolane), 7.36 (ddd, $J_{5',4'}$ = 7.5, $J_{5',6'}$ = 4.8, $J_{5',3'}$ = 1.2, 2 H, 5′-H), 7.88 (td, $J_{4',3'}$ = 8.0, $J_{4',5'}$ = 7.5, $J_{4',6'}$ = 1.8, 2 H, 4′-H), 7.92 (m, 2 H, H$^o$ phenylene), 7.96 (m, 2 H, H$^m$ phenylene), 8.68 (dt, $J_{3',4'}$ = 8.0, $J_{3',5'}$ = 1.2, $J_{3',6'}$ = 0.9, 2 H, 3′-H), 8.74 (ddd, $J_{6',5'}$ = 4.8, $J_{6',4'}$ = 1.8, $J_{6',3'}$ = 0.9, 2 H, 6′-H), 8.76 (s, 2 H, 3-H) ppm. $^{13}$C NMR (100.6 MHz, $CDCl_3$): $\delta$ = 24.93 ($CH_3$ dioxaborolane), 83.98 (C dioxaborolane), 118.94 (C-3), 121.42 (C-3′), 123.85 (C-5′), 126.59 (C$^o$ phenylene), 135.37 (C$^m$ phenylene), 136.90 (C-4′), 140.98 (C$^i$ phenylene), 149.15 (C-6′), 150.15 (C-4), 155.98 (C-2), 156.26 (C-2′) ppm; C$^p$ phenylene signal not observed. **General Procedure for the Complexation Reactions. Method B:** Compounds **2b**–**2c**, **4a**–**4c**, **8a**–**8c** or **9a**–**9c** (1.5 mmol) were combined with commercially available $Ru(bipy)_2Cl_2 \cdot 2H_2O$ (1.65 mmol, 1.1 equiv.) or **4d** or **9d** with $Ru(terpy)Cl_3$ (1.65 mmol, 1.1 equiv.) in ethylene glycol and were then heated for 2 h at 150 °C. The solvent was distilled off under reduced pressure. The residue was dissolved in water and saturated solution of $NH_4PF_6$ was added to the mixture. The precipitate thus formed was collected by filtration. The crude product was purified by silica gel column chromatography using a mixture of $CH_3CN/H_2O$/saturated $KNO_3$ (10:1:0.1) as eluent. The corresponding fractions were combined and the solvent removed in vacuo. The residue was dissolved in a small amount of EtOH and the $KNO_3$ was filtered off. The product was dissolved in water and a saturated solution of $NH_4PF_6$ was added. The product precipitated as hexafluorophosphate salts from the solution. The solid was filtered off. Crystallization from acetone or acetonitrile/*i*PrOH gave pure desired products **5**, **6**, **10** or **11**.

**Complex 5b:** The product was isolated as a red solid in 49% yield (Method B). M.p. 265–274 °C (decomposition). $^1$H NMR (400 MHz, [D$_6$]acetone): $\delta$ = 3.60 (s, 1 H, HC≡C), 7.43 (ddd, $J_{5,4}$ = 7.6, $J_{5,6}$ = 5.7, $J_{5,3}$ = 1.4, 1 H, 5-H bipy), 7.51–7.59 (m, 3 H, 5′-H and 2 × 5-H bipy), 7.63 (ddd, $J_{5,4}$ = 7.6, $J_{5,6}$ = 5.7, $J_{5,3}$ = 1.4, 1 H, 5-H bipy), 7.82 (dd, $J_{5,4}$ = 7.8, $J_{5,3}$ = 1.3, 1 H, 5-H), 7.91–7.97 (m, 4 H, 6′-H and 3 ×6-H bipy), 8.08 (ddd, $J_{4,3}$ = 8.1, $J_{4,5}$ = 7.6, $J_{4,6}$ = 1.5, 1 H, 4-H bipy), 8.18–8.27 (m, 5 H, 4-H, 4′-H and 3 ×4-H bipy), 8.33 (ddd, $J_{6,5}$ = 5.7, $J_{6,4}$ = 1.5, $J_{6,3}$ = 0.8, 1 H, 6-H bipy), 8.71 (ddd, $J_{3,4}$ = 8.1, $J_{3,5}$ = 1.4, $J_{3,6}$ = 0.8, 1 H, 3-H bipy), 8.78–8.84 (m, 4 H, 3′-H and 3 ×3-H bipy), 8.84 (dd, $J_{3,4}$ = 8.2, $J_{3,5}$ = 1.3, 1 H, 3-H) ppm. $^{13}$C NMR (100.6 MHz, [D$_6$]acetone): $\delta$ = 79.31 (*C*≡CH), 88.56 (H*C*≡C), 124.92, 124.98, 125.02, 125.50 and 125.53 (C-3′ and C-3 bipy), 126.04 (C-3), 128.45, 128.50, 128.70, 128.79 and 129.08 (C-5′ and C-5 bipy), 135.16 (C-5), 138.88, 138.97, 139.04, 139.10, 139.14 and 139.33 (C-4, C-4′ and C-4 bipy), 148.19 (C-6), 152.39, 152.44, 152.52, 152.91 and 153.75 (C-6′ and C-6 bipy), 158.03, 158.17, 158.25 and 158.32 (C-2 bipy), 158.79 (C-2′), 159.22 (C-2) ppm. **General Procedure for Cross-Coupling of Complexes 6a–6d with 7 - Method C**

9-Benzyl-8-bromoadenine (20 mg, 0.065 mmol), the corresponding complex (**6a**–**6d**) (0.072 mmol, 1.1 equiv.), and $Cs_2CO_3$ (64 mg, 0.195 mmol, 3 equiv.) were combined and a mixture of degassed $CH_3CN/H_2O$ (1:1, 1 mL) was added. To this mixture was added a solution of Pd(OAc)$_2$ (0.0065 mmol, 10 mol-%) and water soluble P(Ph-*m*$SO_3Na$)$_3$ (0.0325 mmol, 5 equiv. to Pd, 50 mol-%) in $CH_3CN/H_2O$ (1:1, 0.5 mL). The whole mixture was degassed and the flask filled with argon. The mixture was stirred under argon at 95 °C for 7 h. The solvent was than evaporated and the products were purified by silica gel column chromatography using a mixture of $CH_3CN/H_2O$/saturated $KNO_3$ (10:1:0.1) as eluent. The crystallization from acetonitrile or acetone/*i*PrOH, diethylether gave the desired products **11a**–**11d**.

**Complex 11a:** The product was isolated as an orange solid in 72% yield (Method B) and in 40% yield (Method C). **Electrochemistry:** All voltammetric measurements were performed with an Autolab analyzer (Eco Chemie, The Netherlands) in connection with VA-Stand 663 (Metrohm, Switzerland). The three-electrode system was always used. Carbon paste electrodes (CPE) or hanging mercury drop electrodes (HMDE) were used as working electrodes, a Ag/AgCl/3 M KCl electrode as reference and platinum wire as the auxiliary electrode. The CPE was prepared by hand mixing of graphite powder CR-5 (Tesla, Czech Republic) with mineral oil (Sigma) in a weight ratio of 70/30 and filled in a Teflon electrode body. The surface of the CPE was renewed by wiping with wet filtration paper. Square-wave voltammetric measurements at the CPEs were performed with the following settings: frequency 200 Hz, amplitude 25 mV, potential step 5 mV, scan rate: 1 V s$^{-1}$, initial potential: –1.0 V, end potential: +1.6 V. For measurements at the HMDE, linear sweep or cyclic voltammetry was used: scan rate: 1 V s$^{-1}$, potential step 5 mV, initial potential: 0.0 V, end (switching) potential: –1.6 V. All measurements were performed in 0.2 acetate buffer (pH 5.0) at room temperature (22 to 25 °C). Before each measurement at the HMDE, the solution of the background electrolyte was deaerated with argon.

**Computational Details:** All density functional theory (DFT) calculations reported in the study were carried out using the Turbomole 5.8 program.[48] The Perdew–Burke–Ernzerhof (PBE)[49] and hybrid three-parameter Becke's[50] (B3LYP) functionals were used throughout. The calculations were expedited by expanding the Coulomb integrals in an auxiliary basis set, the resolution-of-identity (RI-J) approximation.[51,52] All the geometry optimizations were carried out using the def2-SVP basis set,[53] whereas the single point energies were recomputed in a larger basis set, def2-TZVP (triple-zeta valence with two polarization functions on each atom).[53]

To account for solvation effects, the conductor-like screening model (COSMO) method[54,55] was used with the dielectric constant corresponding to an equimolar mixture of water and acetonitrile ($\varepsilon_r$ = 57). The Gibbs free energy was then calculated as the sum of these contributions [Equation (1)]

$$G = E_{el} + G_{solv} + (E_{ZPE} + nRT - TS) \quad (1)$$

where $E_{el}$ is the in vacuo energy of the system (at the B3LYP/def2-TZVP level and the geometry optimized at the RI-PBE/def2-SVP level), $G_{solv}$ is the solvation free energy (at the RI-PBE/def2-SVP level) and the ($E_{ZPE}$ + $nRT$ – $TS$) term is the zero-point energy, thermal correction to the Gibbs free energy, and entropic term (obtained from a frequency calculation with the same method and software as for the geometry optimizations at the RI-PBE/def2-SV(P) level, 298 K and 1 atm pressure, using an ideal-gas approximation.[56])

The redox potentials were then calculated according to the equation (2)

$$E^0\,[\mathrm{V}] = 27.21(G_{ox}\,[\mathrm{a.u.}] - G_{red}\,[\mathrm{a.u.}]) - 4.34\,\mathrm{V} \quad (2),$$

where $G_{ox/red}$ are free energy values calculated according to Equation (1), and 4.34 V is an absolute redox potential of the standard hydrogen electrode (SHE).[57]

**X-ray Diffraction:** X-ray crystallographic analysis of single crystals of **10b** (red, 0.03 × 0.14 × 0.27 mm) and **5b** (red, 0.08 × 0.31 × 0.40 mm) was performed with the Xcalibur X-ray diffractometer with Cu-$K_\alpha$ ($\lambda$ = 1.54180 Å), data collected at 150 K (**10b**) and 295 K (**5b**). Both structures were solved by direct methods with SIR92[58] and refined by full-matrix least-squares methods based on F with CRYSTALS.[59] Friedel pairs were not merged. Hydrogen atoms were located in a difference map, but those attached to carbon atoms were repositioned geometrically and then refined with riding constraints, all other atoms were refined anisotropically in both cases.

**Crystal Data for 10b:** $C_{44}H_{33}F_{12}N_{11}P_2Ru_1$, monoclinic, space group $P2_1/n$, $a$ = 9.041(4), $b$ = 11.983(4), $c$ = 45.72(2) Å, $\beta$ = 94.34(4)°, $V$ = 4939(3) Å$^3$, $Z$ = 4, $M$ = 1106.81, 73413 reflections measured, 18674 independent reflections. Final $R$ = 0.0866, $wR$ = 0.0701 for 5598 reflections with $I > 1.96\sigma(I)$ and 694 parameters. Several thermal similarity restraints were used in the refinement of the bipyridine units and the hexafluorophosphate anions. The two hexafluorophosphate anions were found to be disordered in three positions with their site occupation factors being 0.75, 0.75, and 0.50.

**Crystal Data for 5b:** $C_{34}H_{24}F_{12}N_6P_2Ru_1$, orthorhombic, space group $Pna2_1$, $a$ = 13.5397(2), $b$ = 25.6956(3), $c$ = 10.0094(2) Å, $V$ = 3482.38(10) Å$^3$, $Z$ = 4, $M$ = 883.58, 56076 reflections measured, 7377 independent reflections. Final $R$ = 0.0331, $wR$ = 0.0380 for 2940 reflections with $I > 1.96\sigma(I)$ and 478 parameters.

CCDC-628693 (for **10b**) and -629224 (for **5b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Biological Activity Screening:** The HCV subgenomic replicon assay was performed according to the published procedure.[46] Inhibition of HCV NS5B polymerase 1b assay was performed according to ref.[47] Cytostatic activity screening was done according to ref.[60] The cell cycle analysis was carried out by the propidium iodide method[61] and evaluated by means of ModFit LT software (Verity Software House, Topsham, ME, USA).

## Acknowledgments

This work is a part of the research project Z4 055 0506. It was supported by EC Specific Targeted Research Project, Control of Assembly and Charge Transport Dynamics of Immobilized DNA (CIDNA) (to M. V. and M. H.), by the Grant Agency of the Czech Republic (a grant No. 203/05/0043 to M. V., M. H., L. H., and M. F. and 203/05/H001 to L. Z.), by the Czech Ministry of Education LC512 and LC06035 (to L. R., L. Z., P. H. and L. H., M. F., respectively) and by Gilead Sciences, Inc. (Foster City, CA, USA).

# Synthesis and Structural Characterization of Novel Ytterbium(III) Complexes with both a μ-Oxo Group and Bridged Indenyl Ligands, and Ytterbium(II) Complexes with Bridged Indenyl Ligands

**Lin Cheng,[a] Yan Feng,[a] Shaowu Wang,*[a,b] Wei Luo,[a] Wei Yao,[a] Zeyan Yu,[a] Xiaobing Xi,[a] and Zixiang Huang[c]**

**Keywords:** Organometallic compounds / Lanthanoids / Synthesis / Ytterbium / X-ray diffraction

The reactivity of the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb(\mu\text{-}Cl)Li(thf)_3$ with different bridged indene compounds in the presence of external donor ligands was studied. Reaction of $[(Me_3Si)_2N]_3Yb(\mu\text{-}Cl)Li(thf)_3$ with the corresponding 1,2-bis-(indenyl)ethane $[(CH_2)_2(C_9H_7)_2]$ or $Me_2Si(C_9H_7)_2$, followed by the addition of excess thf, produced a novel tetranuclear ytterbium complex $[\{\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2\}Yb(\mu\text{-}Cl)(\mu_3\text{-}O)Yb\text{-}(Cl)N(SiMe_3)_2Li(thf)_4]_2$ (**1**) or a novel dinuclear ytterbium complex $[\eta^5\text{:}\eta^5\text{-}(CH_3)_2Si(C_9H_6)_2Yb]_2(\mu\text{-}Cl)(\mu\text{-}O)Li(thf)_2$ (**2**), respectively. Treatment of $[(Me_3Si)_2N]_3Yb(\mu\text{-}Cl)Li(thf)_3$ with $(CH_2)_2(C_9H_6SiMe_3)_2$ (**3**) or $Me_2Si(C_9H_7)_2$ under different conditions produced ytterbium(II) complexes $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2\text{-}(C_9H_5SiMe_3)_2]Yb(thf)_2\cdot(C_6H_{14})_{0.5}$ (**4**) and $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2\text{-}(C_9H_5SiMe_3)_2]Yb\cdot dme$ (**5**) or $[\eta^5\text{:}\eta^5\text{-}(CH_3)_2Si(C_9H_6)_2]Yb\cdot$tmeda (**6**), respectively. Interaction of the ytterbium(III) amide $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]YbN(SiMe_3)_2$ with excess tmeda afforded the ytterbium(II) complex $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]Yb\cdot$tmeda (**7**). All the compounds were fully characterized by spectroscopic methods and elemental analyses. Complexes **1**, **2**, and **4** were additionally characterized by single-crystal X-ray diffraction analyses. The solvents and temperature effects on the reaction are discussed.

## Introduction

Lanthanide complexes have received continuous interest because of their potential applications as catalysts in a wide range of olefin transformations such as olefin polymerization,[1] hydroamination/cyclization,[2] hydrophosphanation,[3] and hydrosilylation of a variety of unsaturated compounds, for example, functionalized alkenes, -alkynes, -allenes, and -dienes.[4] The lanthanide complexes with a Ln–N bond are among the lanthanide complexes that show diverse reactivity toward the Tishchenko reaction,[5] ring-opening polymerization of ε-caprolactone and δ-valerolactone,[6] olefin polymerization,[1,7] hydroamination/cyclization,[2] hydrosilylation,[4a,4b] dimerization of terminal alkyne,[8a] as well as toward the Cannizzaro-type disproportionation of aromatic aldehydes to amides and alcohols.[8b]

It has been documented that lanthanide complexes with pentamethylcyclopentadienyl,[9] Schiff base,[10] dipyrrolide,[11] triamidoamine,[12] carborane,[13] and porphyrinogen[14] ligands can react with thf or oxygen-containing compounds such as epoxides to give the μ-oxo-containing or enolate complexes. It was also reported that the alkyl lanthanide complexes can thermally decompose to give the enolate complexes in the presence of thf/LiCl.[15] However, the synthesis and characterization of lanthanide complexes with either indenyl ligands or the μ-oxo-containing group has been far less studied.

We have reported that the treatment of functionalized indene compounds having internal donor-substituted groups such as the *N*,*N*-dimethylaminoethyl group[16] and the methoxyethyl[17] group with $[(Me_3Si)_2N]_3Ln^{III}(\mu\text{-}Cl)\text{-}Li(thf)_3$ (Ln = Yb, Eu) affords organolanthanide(II) complexes. The treatment of the indenes $C_9H_6$-1-R-3-$CH_2SiMe_2NC_4H_8$ (R = H, $CH_3$) with $[(Me_3Si)_2N]_3Eu^{III}(\mu\text{-}Cl)\text{-}Li(thf)_3$ were also studied, and novel tetranuclear triple-decker and monomeric europium(II) complexes were isolated and characterized.[18a] A novel ytterbium(II) complex in which the indenyl ligand is bonded to the metal through the benzo ring with an $\eta^4$-hapticity was isolated and characterized by treatment of the *N*-piperidinylethyl-functionalized indene compound with the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb(\mu\text{-}Cl)Li(THF)_3$.[18b] The above study indicated that the electronic and steric effects of the ligands have an influence on the homolytic reaction of the Ln–N (Ln = Yb, Eu) bond. In this paper, we report on the reactivity of the ytterbium(III) amide with bridged indene com-

pounds in the presence of external donor ligands such as thf, dme, and tmeda, with the isolation and characterization of a series of novel ytterbium(III) and ytterbium(II) complexes. The effect of the donor ligands and the temperature on the reactivity of the Yb–N bond is also discussed.

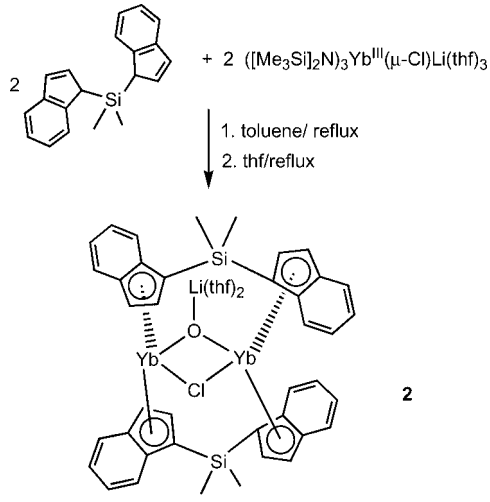
## Results and Discussion

### Synthesis and Characterization of Ytterbium(III) and Ytterbium(II) Complexes

Treatment of 1,2-bis(indenyl)ethane with 1 equiv. $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ in refluxing toluene overnight, followed by the addition of excess thf afforded, after workup, a novel tetranuclear ytterbium(III) complex $[\{\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2\}Yb(\mu\text{-}Cl)(\mu_3\text{-}O)Yb(Cl)N(SiMe_3)_2\text{-}Li(thf)_4]_2$ (**1**) as red crystals (Scheme 1, path A). This result is different from that of our previous studies, which showed that the treatment of indene compounds having internal donor substituents with lanthanide(III) amides $[(Me_3Si)_2N]_3\text{-}Ln^{III}(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu) produce the lanthanide(II) complexes through a tandem silylamine elimination and homolysis of the Ln–N bond.[16–18] This result is also different from that obtained from the direct treatment of 1,2-bis(indenyl)ethane with 1 equiv. $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ in refluxing toluene, the indenyl ytterbium(III) amide complex $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]YbN(SiMe_3)_2$ (Scheme 1, path B).[16a] The color change from yellow to dark blue and the isolation of indenyl ytterbium(III) amide $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]YbN(SiMe_3)_2$ from the dark blue solution suggests that the formation of complex **1** may occur via the indenyl ytterbium(III) amide as intermediate.

X-ray analysis reveals that complex **1** is a centrosymmetric structure and contains a discrete dianion $[\{\eta^5\text{:}\eta^5\text{-}(CH_2)_2\text{-}(C_9H_6)_2\}Yb(\mu\text{-}Cl)(\mu_3\text{-}O)Yb(Cl)N(SiMe_3)_2]_2^{2-}$, with two $\mu_3$-O atoms, and the cations $Li(thf)_4^+$. The presence of the oxygen atoms in **1** likely arises from cleavage of thf, a process that is well documented in lanthanide chemistry.[9–15] In order to extend the scope of the reaction, the reaction of $Me_2Si(C_9H_7)_2$ with $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ was studied.

Treatment of $Me_2Si(C_9H_7)_2$ with $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ in toluene, followed by the addition of excess thf and by heating the mixture at reflux for 6 h produced an ytterbium(III) complex $[\eta^5\text{:}\eta^5\text{-}(CH_3)_2Si(C_9H_6)_2Yb]_2(\mu\text{-}Cl)(\mu\text{-}O)Li(thf)_2$ (**2**) (Scheme 2).



**2**

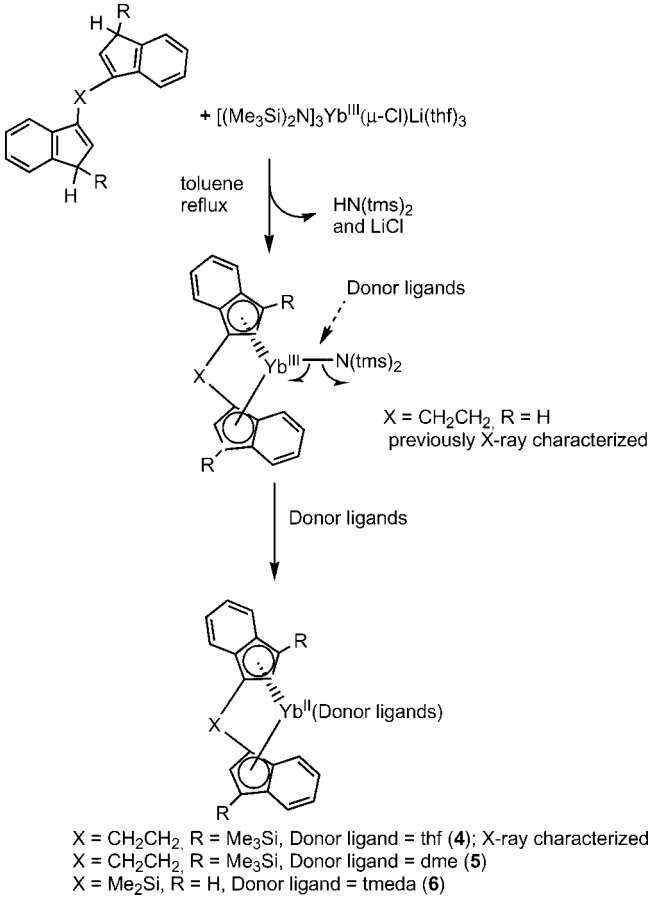
Scheme 2.

Complexes **1** and **2** are soluble in thf and pyridine, but they are insoluble in toluene and hexane. They were fully characterized by spectroscopic methods and elemental analyses, and their structures were determined by single-crystal X-ray analyses. $^1H$ NMR analyses of the complexes gave no information because of the lack of locking signals, which probably results from the strong paramagnetic property of the complexes. This suggests that the oxidation state of the central ytterbium metal atom may be +3, which was confirmed by X-ray structural analyses. The formation of complexes **1** and **2** is somewhat different from the thermal decomposition of alkyl lanthanide complexes to form the enolate complexes in the presence of thf/LiCl.[15]

When $(CH_2)_2(C_9H_6SiMe_3)_2$ (**3**) and 1 equiv. ytterbium(III) amide $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ were treated in refluxing thf and not in toluene, with the addition

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

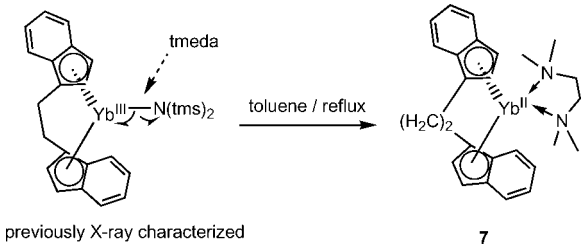
of excess thf, an ytterbium(II) complex $[\eta^5{:}\eta^5\text{-}(CH_2)_2(C_9H_5SiMe_3)_2]Yb(thf)_2{\cdot}(C_6H_{14})_{0.5}$ (**4**) (Scheme 3) was isolated and characterized on the basis of elemental, spectroscopic, and single-crystal X-ray analyses. The solvated *n*-$C_6H_{14}$ and coordinated thf can be evaporated under vacuum, as suggested by the elemental analyses data. The formation of the ytterbium(II) complex **4** suggests that the reaction involves a one-electron reductive elimination process, which is different from process for the formation of complexes **1** and **2** and indicates the temperature or solvent effects on the reaction that result from the difference in the boiling points of the refluxing toluene and thf. The experiments to prove the hypothesis that the formation of complexes **1** and **2** occurs via an ytterbium(II) intermediate, which then reacts with thf to give the μ-oxo complexes that results from the abstraction of the oxygen atom of the thf ring, by heating complex **4** in toluene at reflux were unsuccessful. This is because of the formation of an insoluble solid, which is difficult to purify by recrystallization or other techniques. Formation of complex **4** indicates that interaction of the Yb–N bond with an external donor ligand may provide a new method for the preparation of organolanthanide(II) complexes. Thus, the interactions of the Yb–N bond with other external donor ligands such as dme and tmeda were studied.



Scheme 3.

Reaction of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ with $(CH_2)_2(C_9H_6SiMe_3)_2$ (**3**) in refluxing dme for 24 h produced, after workup, an ytterbium(II) complex $[\eta^5{:}\eta^5\text{-}(CH_2)_2(C_9H_5SiMe_3)_2]Yb{\cdot}dme$ (**5**) (Scheme 3). The reaction of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ and $(CH_2)_2(C_9H_6SiMe_3)_2$ (**3**) in toluene at first, followed by the addition of excess dme also produced complex **5**, on the basis of elemental and spectroscopic analyses. Treatment of $Me_2Si(C_9H_7)_2$ with $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ in refluxing toluene for 6 h, followed by the addition of excess tmeda, produced, after workup, an ytterbium(II) complex $[\eta^5{:}\eta^5\text{-}(CH_3)_2Si(C_9H_6)_2]Yb{\cdot}tmeda$ (**6**) (Scheme 3). The μ-oxo-containing complex has not been isolated in the above reactions. $^1H$ NMR analyses showed that the ratio of the indenyl ligand and the dme or tmeda ligands is 1:1. The diamagnetic property of the complexes suggests that the oxidation state of the central metal is +2. These complexes are extremely air- and moisture sensitive and they are soluble in thf and dme.

The fact that reaction of the ytterbium(III) amide $[\eta^5{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]YbN(SiMe_3)_2$ with tmeda produced the ytterbium(II) complex $[\eta^5{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]Yb{\cdot}tmeda$ (**7**) (Scheme 4) suggests that the formation of **4**–**6** may involve indenyl ytterbium(III) amide as an intermediate. Moreover, homolysis of the Yb–N bond has not been observed either by heating the indenyl ytterbium(III) amide $[\eta^5{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]YbN(SiMe_3)_2$ at reflux in toluene for 3 d, by heating the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ at reflux in toluene, or by sublimation of the amide $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ in vacuo.



Scheme 4.

The above results suggest that a one-electron reductive elimination process occurs after the formation of the indenyl ytterbium(III) amides $[\eta^5{:}\eta^5\text{-}(X)(C_9H_5R)_2]Yb^{III}N(SiMe_3)_2$ (X = bridging group $CH_2CH_2$ or $Me_2Si$; R = H or $Me_3Si$) resulting from the reactions of the indene compounds with the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$. Reactions of external donor ligands such as thf, dme, or tmeda with the resulting indenyl ytterbium(III) amides $[\eta^5{:}\eta^5\text{-}(X)(C_9H_5R)_2]Yb^{III}N(SiMe_3)_2$ produce the ytterbium(II) complexes. The above results also indicate that this method for the preparation of organoytterbium(II) complexes by interaction of the Yb–N bond with external donor ligands at moderately high temperatures can be suitable for different cases.

On the basis of these results, the pathway for the formation of ytterbium(II) complexes **4**–**6** is proposed as follows: the reactions of the bridged indene compounds $(X)(C_9H_6R)_2$ (X = bridging group $CH_2CH_2$ or $Me_2Si$; R = H

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

or $Me_3Si$) with the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ produces the indenyl ytterbium(III) amide $[\eta^5{:}\eta^5\text{-}(X)(C_9H_5R)_2]Yb^{III}N(SiMe_3)_2$, which then reacts with external donor ligands to give the ytterbium(II) complex $[\eta^5{:}\eta^5\text{-}(X)(C_9H_5R)_2]Yb^{II}(D)$ (D = thf, dme, or tmeda) by coordination of the donor ligands to the central metal, leading to the homolysis of the Yb–N bond that resulted in the reduction of ytterbium(III) to ytterbium(II) (Scheme 3). Thus, the method for the preparation of the ytterbium(II) complexes through homolysis of the Yb–N bond by treatment of internally substituted indene compounds with $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ may be extended to the reaction of ytterbium complexes having the Yb–N bond with suitable external donor ligands at moderately high temperatures such that the reduction of ytterbium(III) to ytterbium(II) may proceed relatively easily.[16–18] However, the formation pathway of complexes **1** and **2** remains to be further examined.

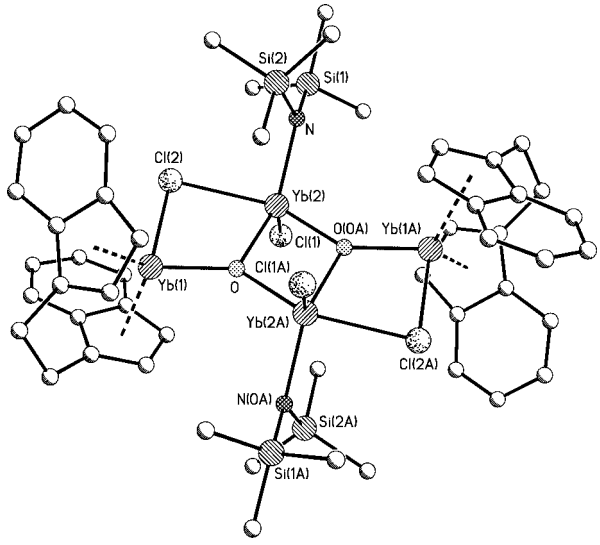


Figure 1. Molecular structure of the dianion $[\{\eta^5{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2\}Yb(\mu\text{-}Cl)(\mu_3\text{-}O)Yb(Cl)N(SiMe_3)_2]_2^{2-}$ in **1**.

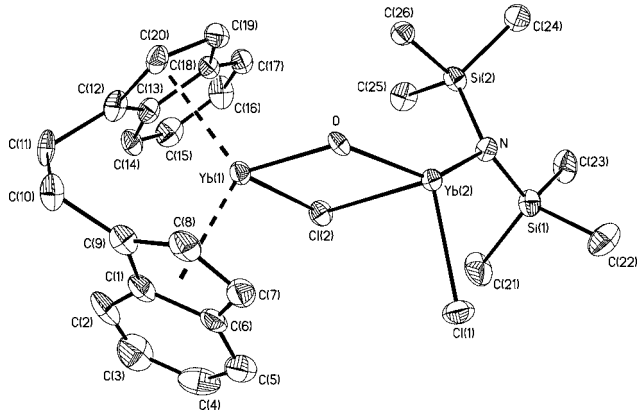

Figure 2. Structure of one symmetrical unit of the dianion in **1**. The atoms are labelled.

## Molecular structure

The structures of complexes **1** (Figures 1 and 2), **2** (Figure 3), and **4** (Figure 4) were determined by single-crystal X-ray analyses, which reveals that both **1** and **2** are oxygen-containing complexes and that the central ytterbium atoms are in the +3 oxidation state.

The key structural feature of complex **1** (Figures 1 and 2) is that the four ytterbium atoms Yb(1), Yb(1A), Yb(2), Yb(2A), the two oxygen atoms O and O(OA), and two chlorine atoms Cl(2), Cl(2A) are coplanar with a mean deviation of 0.0588 Å on the basis of a least-squares calculation. It represents the first example of a tetranuclear ytterbium complex containing both μ-oxo groups and bridged indenyl ligands in the molecular structure.[19] The Yb–O distances of 2.126(8), 2.107(9), and 2.200(9) Å (Table 1) in **1** are also notable – these distances are longer than the Sm–O distance in $[(C_5Me_5)_2Sm]_2(\mu\text{-}O)$[9] {2.094(1) Å} but are comparable to that in $\{[Cy(C_4H_3N)_2]Sm\}_4(\mu\text{-}O)$[11] {2.1844(4) Å}. The Yb–O distances in **1** are shorter than the average Sm–O($\mu_4$-O) distance of 2.346(1) Å in $[\{[\eta^5\text{-}Me_2Si(C_5Me_4)(C_2B_{10}H_{11})]Sm\}_2(\mu_2\text{-}Cl)_3(\mu_3\text{-}Cl)_4Li(OEt_2)_2Li(thf)_2Sm(\mu_4\text{-}O)]_2$[13b] and the average Sm–O distance of 2.211(8) Å found in $[\{\eta^5\text{-}(Me_3Si)_2C_2B_4H_4\}Sm]_3[\{\eta^5\text{-}(Me_3Si)_2C_2B_4H_4\}Li]_3(\mu_3\text{-}OMe)][\mu_3\text{-}Li(thf)]_3(\mu_3\text{-}O)$.[13a] The differences in the bond lengths may arise because of the different ionic radii of the lanthanide metals and the O atom and because of the steric effects in the complex.

The structural feature of the oxygen-containing dinuclear complex **2** (Figure 3) is that the silylene-bridged indenyl ligand adopts a bridging coordination, instead of the normal chelating coordination found in organometallic compounds with ligands that contain a silylene-bridge and two cyclopentadienyl or two tetramethylcyclopentadienyl groups.[20] The bridging coordination phenomenon is similar to those found in lanthanide complexes with silylene-bridged fluorenyl cyclopentadienyl ligands.[21]

The Yb(2)–O–Yb(1) angle of 109.7(2)° (Table 1) in **2** is smaller than the Yb(1)–O–Yb(2) angle of 113.4(4)° and the Yb(2A)–O–Yb(1) angle of 144.6(5)° in **1**, but larger than the Yb(2A)–O–Yb(2) angle of 101.9(3)° in **1**. The Yb(1)–Cl–Yb(2) angle of 80.40(7)° in **2** is also smaller than the Yb(1)–Cl(2)–Yb(2) angle of 84.98(11)° in **1**. Both the Yb(1)–Cl(2)–Yb(2) angle of 84.98(11)° in **1** and the Yb(1)–Cl–Yb(2) angle of 80.40(7)° in **2** is smaller than the Yb(1)–Cl(3)–Yb(1a) angle of 104.54(8)° in the dimeric ytterbium(III) chloride $[\{\eta^5{:}\eta^1{:}\sigma\text{-}Me_2Si(C_9H_5CH_2CH_2NMe_2)(C_2B_{10}H_{10})\}Yb(\mu\text{-}Cl)]_2$.[22] The Yb–O distances of 2.070(5) Å and 2.063(5) Å in **2** are comparable to the Sm–O distance of 2.094(1) Å in $[(C_5Me_5)_2Sm]_2(\mu\text{-}O)$ if the difference in ionic radii is taken into account.[23] The Yb–Cl distances of 2.603(3) Å and 2.632(2) Å in **2** are longer than the Yb(1)–Cl(2) distance of 2.572(4) Å and the Yb(2)–Cl(1) bond length of 2.532(4) Å in **1**, but shorter than the Yb(2)–Cl(2) bond length of 2.778(4) Å in **1**. The average Yb–C distance ($C_5$ ring) of 2.657(10) Å in **2** is shorter than that in **1** [2.691(17) Å]. These differences are probably due to the differences in the ionic radii and due to steric effects.

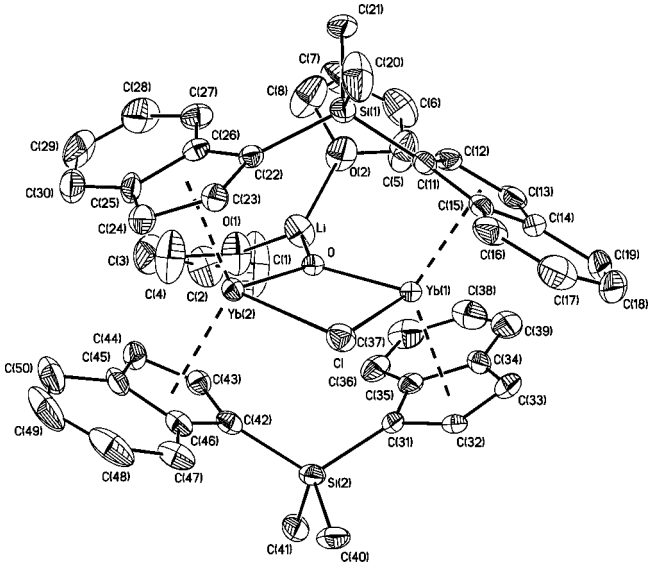

Figure 3. Molecular structure of $[\eta^5{:}\eta^5\text{-}(CH_3)_2Si(C_9H_6)_2Yb]_2(\mu\text{-}Cl)(\mu\text{-}O)Li(thf)_2$ (**2**).

X-ray analyses confirmed that the central ytterbium atom of complex **4** (Figure 4) is in the +2 oxidation state. The central ytterbium atom is coordinated by two indenyl ligands in an $\eta^5$ mode and by two oxygen atoms of the thf molecules in distorted tetrahedral geometry. The Yb–C distances range from 2.714(7) to 2.852(7) Å (Table 1), with an average length of 2.784(9) Å, which is slightly longer than those in $(\eta^5{:}\eta^1\text{-}MeOCH_2CH_2C_9H_5SiMe_3)_2Yb$[17] {2.741(14) Å} and in $(\eta^5{:}\eta^1\text{-}Me_2NCH_2CH_2C_9H_5SiMe_3)_2$-Yb {2.778(14) Å}.[16a] The average Yb–O distance of 2.381(6) Å in **4** is slightly shorter than that in $(\eta^5{:}\eta^1\text{-}MeOCH_2CH_2C_9H_5SiMe_3)_2Yb$[17] {of 2.462(9) Å}, but the O(2)–Yb–O(1) angle of 91.1(2)° in **4** is larger than those in $(\eta^5{:}\eta^1\text{-}MeOCH_2CH_2C_9H_5SiMe_3)_2Yb$[17] {84.5(3)° and 86.3(3)°}, which indicates the influence of steric effects on the coordination geometry of the complex.

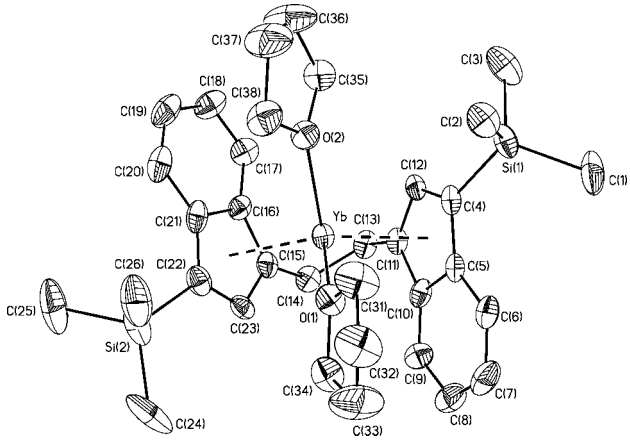

Figure 4. Molecular structure of $[\eta^5{:}\eta^5\text{-}(CH_2)_2(C_9H_5SiMe_3)_2]$ $Yb(thf)_2$ (**4**), solvated *n*-$C_6H_{14}$ is omitted for clarity.

## Conclusions

In summary, the reaction of the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb(\mu\text{-}Cl)Li(thf)_3$ with various bridged indene compounds in the presence of external donor ligands was studied for the first time. In contrast to the result that the indenyl ytterbium(III) amide $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]YbN(SiMe_3)_2$ was isolated by direct treatment of the bridged indene compound $(CH_2)_2(C_9H_7)_2$ with the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb(\mu\text{-}Cl)Li(thf)_3$ in refluxing toluene, the ytterbium(II) complexes were isolated and characterized by direct treatment of indenyl ytterbium(III) amide with external donor ligands such as tmeda or treatment of the bridged indene compounds with the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb(\mu\text{-}Cl)Li(thf)_3$ at moderately high temperatures in the presence of excess external donor ligands such as dme or tmeda. This work also demonstrates that when thf was used as the external donor ligand, the reaction products were complicated depending on the reaction temperatures and the indenyl ligands; when the reaction was carried out in the refluxing toluene in the presence of excess thf, a novel tetranuclear or dinuclear ytterbium(III) complex containing μ-oxo group(s) was isolated, and when the reaction was performed in refluxing thf, and not in toluene with the addition of excess thf, an ytterbium(II) complex was isolated. Thus, this work indicates that reactions of lanthanide(III) complexes having the Ln–N bond with suitable external donor ligands at moderately high temperatures may provide a new method for the preparation of organolanthanide(II) complexes.

## Experimental Section

**General Remarks:** All syntheses and manipulations of air- and moisture-sensitive materials were carried out in flamed Schlenk-type glassware on a Schlenk line. All solvents were refluxed and distilled from either finely divided $LiAlH_4$ or sodium benzophenone ketyl under argon prior to use unless otherwise noted. $CDCl_3$ was dried with activated by 4-Å molecular sieves. $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$,[16a] $(CH_2)_2(C_9H_7)_2$,[24] and $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]YbN(SiMe_3)_2$[16a] were prepared according to the reported procedures. Elemental analyses data were obtained with a Perkin–Elmer 2400 Series II elemental analyzer. IR spectra were recorded with a Perkin–Elmer 983(G) spectrometer (CsI crystal plate, Nujol and Fluorolube mulls. Melting points were determined in sealed capillaries without correction. $^1H$ NMR and $^{13}C$ NMR spectra for analyses of compounds were recorded with a Bruker Avance-300 NMR spectrometer in $[D_5]$pyridine for lanthanide complexes and in $CDCl_3$ for organic compounds, and chemical shifts for $^1H$ and $^{13}C$ NMR spectra were reported with reference to internal solvent resonances.

**$[\{\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2\}Yb(\mu\text{-}Cl)(\mu_3\text{-}O)Yb(Cl)N(SiMe_3)_2Li(thf)_4]_2$ (1)**: To a toluene solution (50.0 mL) of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ (2.208 g, 2.42 mmol) was added $(CH_2)_2(C_9H_7)$ (0.624 g, 2.42 mmol). The reaction mixture was heated at reflux overnight, and the color of the solution changed to dark blue. An ytterbium(III) amide complex with the formula $[\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_6)_2]YbN(SiMe_3)_2$ (determined by X-ray data) was isolated from this solution. To the reaction mixture was added thf (2.0 mL, 24.66 mmol, excess). The reaction mixture was then heated at reflux for 2 d. The color of the mixture gradually changed from dark blue to dark purple. The solvents were pumped off under vacuum. The residue was washed with *n*-hexane (10.0 mL) and was then extracted with thf (2 × 10.0 mL). The extract was combined and concentrated to about 10.0 mL. Dark red crystals were obtained by cooling the concentrated solution at –10 °C for several days (1.49 g, 44%). M.p. 243–245 °C (dec.). NMR analyses were not informative because of the lack of locking signals, which results from the paramagnetic property of the complex. IR (Nujol and Fluorolube mulls): $\tilde{\nu}$ = 2952 (s), 2851 (s), 2725 (s), 1693 (w), 1606 (w), 1461 (s), 1377 (s), 1305 (w), 1260 (m), 1094 (m), 1019 (m), 933 (w), 805 (m), 768 (m), 720 (m), 393 (w) $cm^{-1}$. $C_{84}H_{132}Cl_4Li_2N_2O_{10}Si_4Yb_4$ (2290.12): calcd. C 44.06, H 5.81, N 1.22; found C 44.32, H 5.74, N 1.10.

**$[\eta^5\text{:}\eta^5\text{-}(CH_3)_2Si(C_9H_6)_2Yb]_2(\mu\text{-}Cl)(\mu\text{-}O)Li(thf)_2$ (2):** To a toluene solution (30.0 mL) of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ (1.10 g, 1.20 mmol) was slowly added a toluene solution (10.0 mL) of $(CH_3)_2Si(C_9H_7)_2$ (0.35 g, 1.20 mmol). The reaction mixture was stirred and heated at reflux for 6 h. To the reaction mixture was added thf (1.0 mL, 12.33 mmol, excess). The reaction mixture was heated at reflux for another 24 h. The color of the mixture gradually changed to dark red. The solvent was pumped off under vacuum, leaving a dark red solid. The solid was washed with *n*-hexane (10.0 mL), and the residue was extracted with toluene (2 × 10.0 mL). The extract was combined and concentrated to about 15.0 mL. Dark red crystals were obtained by cooling the solution at 0 °C for several days (0.75 g, 56%). M.p. 180–182 °C. NMR analyses were not informative because of the lack of locking signals, which probably results from the paramagnetic property of the complex. IR (Nujol and Fluorolube mulls): $\tilde{\nu}$ = 2930 (s), 2958 (s), 1461 (m), 1383 (m), 1251 (w), 1143 (w), 1025 (w), 959 (w), 810 (w), 715 (w) $cm^{-1}$. $C_{48}H_{52}ClLiO_3Si_2Yb_2{\cdot}C_7H_8$ (1213.70): calcd. C 54.42, H 4.98; found C 53.91, H 5.25.

**$(CH_2)_2(C_9H_6SiMe_3)_2$ (3):** To a diethyl ether solution of $(CH_2)_2(C_9H_7)_2$ (6.0 g, 23.3 mmol) was slowly added a 1.59 M *n*-hexane solution of *n*BuLi (29.3 mL, 46.6 mmol) at 0 °C. The reaction temperature was gradually raised to room temperature, and the reaction mixture was stirred at room temperature overnight. The reaction mixture was cooled to 0 °C. To the reaction mixture was added $Me_3SiCl$ (15.0 mL, 119.0 mmol, excess) in one portion. The mixture was then stirred at room temperature overnight. The precipitate was filtered off, and the solvent and excess $Me_3SiCl$ was evaporated under reduced pressure to leave a yellow solid, which was then washed with *n*-hexane to give a pale yellow solid (7.4 g, 65%). M.p. 143–145 °C. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.10–7.50 (m, 8 H), 6.36 (m, 2 H), 3.36 (m, 2 H, $C_9H_6$), 2.96 (m, 4 H, $CH_2CH_2$), –0.09 [s, 18 H, $Si(CH_3)_3$] ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 146.0, 144.4, 141.6, 130.1, 124.6, 123.7, 122.9, 119.0, 44.6 ($C_9H_6$), 27.2 ($CH_2CH_2$), –2.3 $[Si(CH_3)_3]$ ppm. IR (Nujol and Fluorolube mulls): $\tilde{\nu}$ = 2923 (s), 2854 (s), 1714 (m), 1604 (m), 1461 (s), 1377 (m), 1345 (m), 1259 (m), 1248 (m), 1034 (m), 937 (w), 877 (m), 763 (m), 737 (w), 699 (w), 615 (w), 368 (w) $cm^{-1}$. $C_{26}H_{34}Si_2$ (402.66): calcd. C 77.54, H 8.51; found C 77.32, H 8.81.

**$[\eta^5\text{:}\eta^5\text{-}(CH_2)_2(C_9H_5SiMe_3)_2]Yb(thf)_2{\cdot}(C_6H_{14})_{0.5}$ (4):** To a thf solution (30.0 mL) of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(thf)_3$ (1.290 g, 1.41 mmol) was added a thf solution (10.0 mL) of $(CH_2)_2(C_9H_6SiMe_3)_2$ (0.570 g, 1.41 mmol). After the reaction mixture was heated at reflux for 24 h, the solvent was evaporated under vacuum, leaving a red solid. The residue was extracted with *n*-hexane (2 × 10.0 mL), and the extract was combined and concentrated to about 10.0 mL. Red crystals were obtained by cooling the concentrated solution at –10 °C for several days (0.46 g, 46%). M.p. 154–

157 °C. $^1$H NMR ([D$_5$]pyridine): $\delta$ = 8.63–8.46 (m, 8 H), 7.16 (s, 2 H, C$_9H_5$), 4.78 (m, 8 H, OC$_4H_8$), 2.73 (m, 8 H, OC$_4H_8$), 2.22 (m, 2 H), 1.88 (m, 2 H, C$H_2$C$H_2$), 1.10 [s, 18 H, Si(C$H_3$)$_3$] ppm. $^{13}$C NMR ([D$_5$]py): $\delta$ = 147.7, 145.8, 142.8, 137.1, 136.5, 125.1, 124.4, 121.1, 68.94, 26.9, 4.2, 3.7, 3.3, –1.2, –1.8 ppm. IR (Nujol and Fluorolube mulls): $\tilde{\nu}$ = 2949 (m), 2600 (m), 1249 (m), 1160 (w), 1031 (m), 931 (w), 878 (m), 839 (s), 763 (m), 722 (m), 617 (w), 239 (w) cm$^{-1}$. $C_{26}H_{32}Si_2Yb$ (**4** – 2thf – 1/2$C_6H_{14}$) (573.69): calcd. C 54.45, H 5.62; found C 54.54, H 6.07.

Heating **4** in toluene at reflux led to an insoluble solid, which could not be purified by recrystallization and other methods.

**[$\eta^5$:$\eta^5$-(CH$_2$)$_2$(C$_9$H$_5$SiMe$_3$)$_2$]Yb·dme (5):** To a dme solution (30.0 mL) of [(Me$_3$Si)$_2$N]$_3$Yb$^{III}$($\mu$-Cl)Li(thf)$_3$ (1.414 g, 1.55 mmol) was added a dme solution (10.0 mL) of (CH$_2$)$_2$(C$_9$H$_6$SiMe$_3$)$_2$ (0.624 g, 1.55 mmol). After the reaction mixture was heated at reflux for 24 h, the solvent was pumped off, leaving a red solid. The solid was washed with *n*-hexane (8.0 mL). The solid was extracted with toluene (2 × 10.0 mL), and the extract was combined and concentrated to about 10.0 mL. The red crystalline solid was obtained by cooling the concentrated solution at –10 °C for several days (0.57 g, 55%). M.p. 165–168 °C. $^1$H NMR ([D$_5$]pyridine): $\delta$ = 7.30–6.43 (m, 10 H, C$_9H_5$), 3.46 (m, 4 H), 3.23 (m, 4 H, CH$_3$OC$H_2$C$H_2$-OCH$_3$), 2.71 (s, 6 H, C$H_3$OCH$_2$CH$_2$OC$H_3$), –0.10 [s, 18 H, Si-(C$H_3$)$_3$] ppm. IR (Nujol and Fluorolube mulls): $\tilde{\nu}$ = 2925 (s), 2855 (s), 1602 (m), 1460 (s), 1377 (m), 1260 (m), 1249 (m), 1104 (m), 1029 (m), 931 (m), 878 (m), 839 (s), 763 (m), 722 (m), 696 (m), 617 (m), 393 (w) cm$^{-1}$. $C_{30}H_{42}O_2Si_2Yb$ (663.83): calcd. C 54.28, H 6.38; found C 54.10, H 6.38.

Heating the reaction mixture of [(Me$_3$Si)$_2$N]$_3$Yb$^{III}$($\mu$-Cl)Li(thf)$_3$ and (CH$_2$)$_2$(C$_9$H$_6$SiMe$_3$)$_2$ in toluene at reflux for 6 h followed by the addition of excess dme also produced complex **5**. The complex was characterized by elemental and spectroscopic analyses.

**[$\eta^5$:$\eta^5$-(CH$_3$)$_2$Si(C$_9$H$_6$)$_2$]Yb·tmeda (6):** To a toluene solution (30.0 mL) of [(Me$_3$Si)$_2$N]$_3$Yb$^{III}$($\mu$-Cl)Li(thf)$_3$ (1.10 g, 1.20 mmol) was slowly added a toluene solution (10.0 mL) of (CH$_3$)$_2$Si-(C$_9$H$_7$)$_2$ (0.35 g, 1.20 mmol). The reaction mixture was stirred at room temperature for 6 h. To the reaction mixture was added tmeda [(CH$_3$)$_2$NCH$_2$CH$_2$N(CH$_3$)$_2$] (1.0 mL, 6.62 mmol, excess). The reaction mixture was then heated at reflux for 24 h. The color of the solution changed to purple. The solvent was pumped off under vacuum, and the solid residue was washed with *n*-hexane (10.0 mL). The solid was extracted with toluene (2 × 10.0 mL), and the extract was combined and concentrated to about 15.0 mL. The purple crystalline solid was obtained by cooling the solution at 0 °C for several days (0.47 g, 68%). M.p. 98–100 °C. $^1$H NMR ([D$_5$]pyridine): $\delta$ = 7.63–7.56 (m, 8 H), 7.26–7.19 (m, 4 H, C$_9H_6$), 2.19 (m, 4 H), 2.13 [s, 12 H, (C$H_3$)$_2$NC$H_2$C$H_2$N(C$H_3$)$_2$], 0.71–1.04 [m, 6 H, Si(C$H_3$)$_2$] ppm. $C_{26}H_{34}N_2SiYb$ (547.66): calcd. C 54.25, H 5.95, N 4.86; found C 54.23, H 6.20, N 4.83.

**[$\eta^5$:$\eta^5$-(CH$_2$)$_2$(C$_9$H$_6$)$_2$]Yb·tmeda (7):** To a toluene solution (15 mL) of [$\eta^5$:$\eta^5$-(CH$_2$)$_2$(C$_9$H$_6$)$_2$]YbN(SiMe$_3$)$_2$ (0.347 g, 0.059 mmol) was added a tmeda (1.20 mL, 7.95 mmol, excess). The mixture was heated at reflux for 24 h. The color of the mixture completely changed from dark blue to red. The solvent was evaporated under vacuum, and the resulting solid was washed with *n*-hexane and extracted with diethyl ether (2 × 10.0 mL). The extract was combined and was then evaporated to dryness to afford **7** as a red solid (0.13 g, 43%). M.p. 183–185 °C. $^1$H NMR ([D$_5$]pyridine): $\delta$ = 7.36–7.21 (m, 8 H), 7.16–7.07 (m, 4 H, C$_9H_6$), 2.24 (m, 2 H), 1.89 (m, 2 H, C$H_2$C$H_2$), 2.20 (m, 4 H), 2.15 [s, 12 H, (C$H_3$)$_2$NC$H_2$-C$H_2$N(C$H_3$)$_2$] ppm. $C_{28}H_{32}N_2Yb$ (569.61): calcd. C 57.27, H 5.87, N 5.13; found C 56.92, H 6.02, N 5.04.

**Crystal Structure Analyses of 1, 2 and 4:** Suitable crystals of complexes **1**, **2** and **4** were mounted in sealed capillaries. Diffraction was performed on a Siemens SMART CCD-area detector diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), temperature 293(2) K, the $\phi$ and $\omega$ scan technique; SADABS effects and empirical absorption were applied to the data for correction. All structures were solved by direct methods (SHELXTL-97),[24] completed by subsequent difference Fourier syntheses, and refined by full-matrix least-square calculations based on $F^2$ (SHELXTL-97). The hydrogen atom coordinates were calculated with SHELXTL by using an appropriate riding model

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** the crystal structures of three diiron complexes with bridging hydrocarbyl ligands of increasing size and complexity: from the bridging aminocarbyne (at the back) through to the bridging vinyliminium (in the middle) to the allylidene complex (in the front). The complexes are the result of subsequent additions of alkynes and acetylides that take place at the bridging unit. For each step, the bridging coordination provides activation and also regio- and stereocontrol of the addition reactions. Thus, the nature and conformation of the growing bridging organic frame can be largely predicted and properly designed. Details are discussed in the article by V. Zanotti et al. on p. 1799 ff.

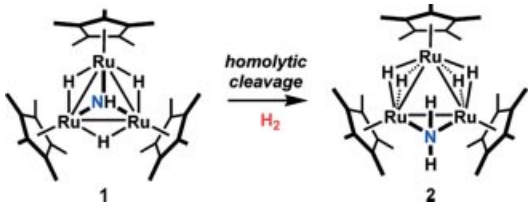
## SHORT COMMUNICATION

### Dihydrogen Activation

**H. Kameo, Y. Nakajima, H. Suzuki* ..... 1793–1798**

Hydrogenation of a Trinuclear $\mu_3$-Imido Complex of Ruthenium: Homolytic or Heterolytic H–H Bond Cleavage?

**Keywords:** Hydrido complexes / Ruthenium / Cleavage reactions / Imido complexes / Trinuclear complexes



To elucidate the mode of hydrogen–hydrogen bond cleavage at transition metal sites, the hydrogenation of $(Cp^*Ru)_3(\mu_3\text{-}NH)(\mu\text{-}H)_3$ ($Cp^* = \eta5\text{-}C_5Me_5$) with deuterium was carried out. The percentage of deuterium content in the amido ligand of $(Cp^*Ru)_3(\mu\text{-}NH_2)(\mu\text{-}H)_4$ proved the mode of cleavage of dihydrogen in the reaction.

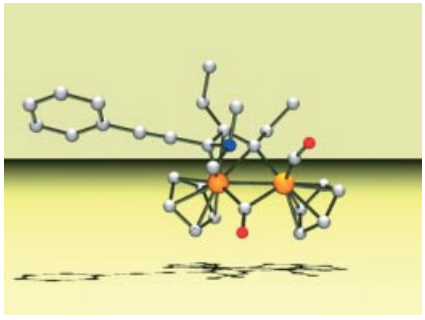
## FULL PAPERS

### Growing Bridging Organic Frames

**L. Busetto, F. Marchetti, S. Zacchini, V. Zanotti* ..... 1799–1807**

Acetylide Addition to Bridging Vinyliminium Ligands in Dinuclear Complexes

**Keywords:** Acetylides / Dinuclear complexes / Bridging ligands / C–C bond formation



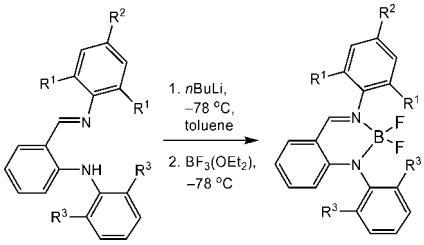
Functionalized organic frameworks are built on diiron complexes by the addition of acetylides to bridging vinyliminium ligands under regio- and stereocontrolled conditions.

### Organoboron Complexes

**Y. Ren, X. Liu, W. Gao, H. Xia, L. Ye, Y. Mu* ..... 1808–1814**

Boron Complexes with Chelating Anilido-Imine Ligands: Synthesis, Structures and Luminescent Properties

**Keywords:** Organoboron compounds / Schiff-base ligands / Luminescence



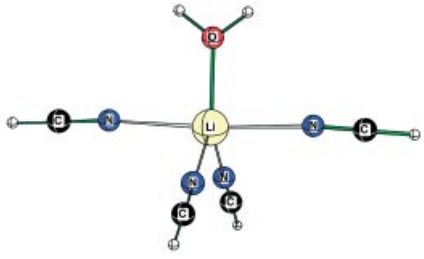
Three new organoboron complexes with anilido-imine ligands were synthesized. All complexes were characterized by $^1H$, $^{11}B$, $^{13}C$ and $^{19}F$ NMR spectroscopy, X-ray crystallography, elemental analyses and mass spectrometry. These complexes show excellent luminescent properties.

### Ligand-Exchange Mechanisms

**E. Pasgreta, R. Puchta, A. Zahl, R. van Eldik* ..... 1815–1822**

Ligand-Exchange Processes on Solvated Lithium Cations: Acetonitrile and Hydrogen Cyanide

**Keywords:** Lithium / Acetonitrile / Hydrogen cyanide / Solvation / Exchange mechanism



Experimental and theoretical studies indicate that $Li^+$ is four coordinate in $CH_3CN$ and in $CH_3CN$/water mixtures. Water coordinates strongly to $Li^+$ such that addition of water immediately leads to the formation of $[Li(H_2O)_4]^+$. Ligand-exchange reactions on $Li^+$ most probably follow an associative mechanism.

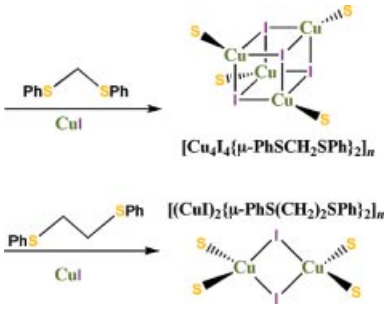
## Luminescent Coordination Polymers

**H. N. Peindy, F. Guyon,* A. Khatyr, M. Knorr,* C. Strohmann ..... 1823–1828**

Construction of 1D and 2D Copper(I) Coordination Polymers Assembled by $PhS(CH_2)_nSPh$ ($n$ = 1, 2) Dithioether Ligands: Surprising Effect of the Spacer Length on the Dimensionality, Cluster Nuclearity and the Fluorescence Properties of the Metal–Organic Framework

**Keywords:** Dithioethers / Copper / Fluorescence / Coordination polymers / Metal–metal interactions

Treatment of CuI with $PhS(CH_2)_nSPh$ ($n$ = 1, 2) affords the strongly luminescent 1D metal–organic coordination polymer, $[Cu_4I_4\{\mu\text{-}PhS_2CH_2SPh\}_2]_n$, and the 2D coordination polymer, $[(CuI)_2\{\mu\text{-}PhS(CH_2)_2SPh\}_2]_n$, respectively, by a self-assembly reaction.

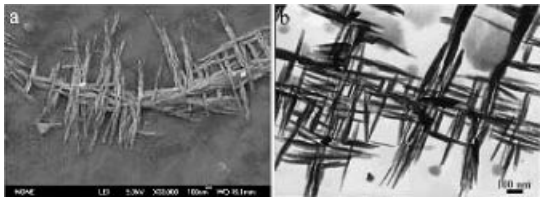


## Nanostructures

**Q.-R. Zhao, X. Zhu, X. Bai, H.-H. Fan, Y. Xie* ..... 1829–1834**

Synthesis and Optical Properties of β-$BaB_2O_4$ Network-Like Nanostructures

**Keywords:** Nonlinear optics / Materials science / Sol–gel processes / Borates



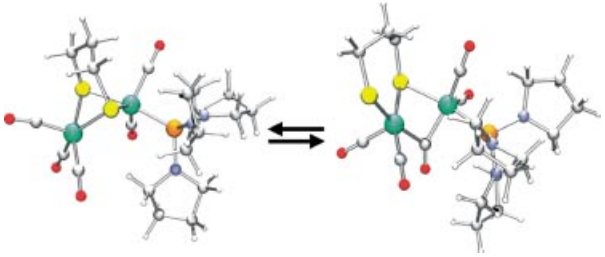
Network-like nanostructures made from the nonlinear optical material beta barium metaborate (β-$BaB_2O_4$, β-BBO) have been successfully synthesized from a BBO gel precursor using a sol–gel method. The morphology of the synthesized β-$BaB_2O_4$ materials exerts a significant influence on the second harmonic generation (SHG) efficiency.

## Biomimetic Dihydrogen Evolution

**C. Greco, M. Bruschi, P. Fantucci, L. De Gioia* ..... 1835–1843**

Influence of a Large σ-Donor Ligand on Structural and Catalytic Properties of Di-Iron Compounds Related to the Active Site of Fe-Hydrogenase – A DFT Investigation

**Keywords:** Hydrogenases / Biomimetic chemistry / Catalytic $H_2$ evolution / Density functional calculations / Iron



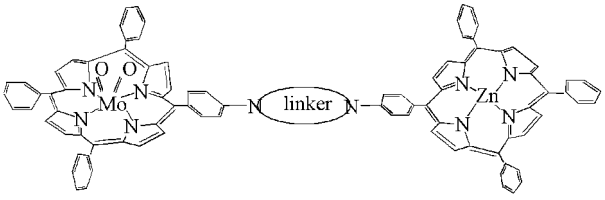
The structural and electronic properties of $(\mu\text{-pdt})[Fe_2(CO)_5P(NC_4H_8)_3]$, a recently synthesized model of the active site of Fe-hydrogenase, have been studied by means of density functional theory. The unprotonated, mono-, and di-protonated forms of this compound were taken into account, in order to disclose the geometric features of the various intermediates involved in the electrocatalytic process of $H_2$ evolution.

## Porphyrinoids

**S.-N. Song, D.-M. Li,* J.-F. Wu, C.-F. Zhuang, H. Ding, W.-B. Song, L.-F. Cui, G.-Z. Cao, G.-F. Liu .... 1844–1853**

Syntheses and Characterization of Molybdenum/Zinc Porphyrin Dimers Bridged by Aromatic Linkers

**Keywords:** Porphyrinoids / Heteronuclear complexes / Bridging ligands / Molybdenum / Zinc / Electrochemistry



Heterobinuclear porphyrin dimers are obtained by two different methods. They are characterized by UV/Vis, IR, XPS, $^1H$ NMR, and luminescence spectroscopy and their TG-DTA and electrochemical properties determined.

# Hydrogenation of a Trinuclear $\mu_3$-Imido Complex of Ruthenium: Homolytic or Heterolytic H–H Bond Cleavage?

**Hajime Kameo,[a] Yumiko Nakajima,[a] and Hiroharu Suzuki*[a]**

**Keywords:** Hydrido complexes / Ruthenium / Cleavage reactions / Imido complexes / Trinuclear complexes

To elucidate the mode of hydrogen–hydrogen bond cleavage at transition metal sites that cooperate with a heteroatom, the hydrogenation of trinuclear $\mu_3$-imido complex $(Cp^*Ru)_3(\mu_3\text{-}NH)(\mu\text{-}H)_3$ ($Cp^* = \eta^5\text{-}C_5Me_5$) (**1**) with deuterium was carried out. The percentage of deuterium content in the amido ligand of $(Cp^*Ru)_3(\mu\text{-}NH_2)(\mu\text{-}H)_4$ (**2**), which was generated as an intermediate in the reaction of **1** with dihydrogen, proved that hydrogenation of **1** to **2** proceeded through homolytic cleavage of dihydrogen.

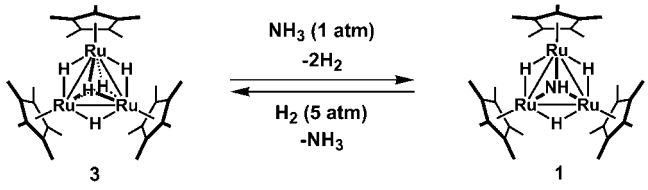
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Activation of dihydrogen at transition metal sites is a critical issue in a wide field ranging from inorganic and organometallic chemistry to enzymology.[1] One focus of interest is the mode of hydrogen–hydrogen bond cleavage. Two possible pathways, namely homolysis and heterolysis, are proposed for the activation of dihydrogen. H–H bond cleavage by oxidative addition of dihydrogen to the metal center to form a dihydridometal species is a typical example of homolysis. In contrast, [FeFe]- and [FeNi]hydrogenase, of which the active site consists of iron and nickel ions bridged by two sulfur atoms and another heteroatom, is recognized to activate dihydrogen in a heterolytic manner to generate hydride and a proton.[2] In connection with the enzymatic reaction, the reaction of dihydrogen with a complex whose metal center cooperates with a heteroatom has engaged the attention of inorganic chemists.[3]

We have reported, thus far, that the reaction of triruthenium pentahydrido complex, $(Cp^*Ru)_3(\mu\text{-}H)_3(\mu_3\text{-}H)_2$ (**3**), with ammonia or hydrazine leads to the formation of the corresponding mono($\mu_3$-imido) complex, $(Cp^*Ru)_3(\mu\text{-}H)_3(\mu_3\text{-}NH)$ (**1**).[4,5] The resulting $\mu_3$-imido complex **1** readily undergoes hydrogenation with 5 atm of dihydrogen to afford **3** and ammonia, quantitatively (Scheme 1).

Complex **1** has a Lewis basic nitrogen atom directly bound to the ruthenium center and it would be of interest to determine whether the hydrogenation reaction proceeds by way of homolytic cleavage of dihydrogen at one of the ruthenium atoms or by heterolytic cleavage with participation of the adjacent nitrogen atom (Figure 1). In the homolysis step with the use of deuterium instead of hydrogen (Figure 1a), the deuterium molecule can access the ruthenium atom from the opposite face of the $\mu_3$-NH ligand with respect to the $Ru_3$ plane as a result of the decreased steric hindrance; therefore, the deuterium molecule can undergo oxidative addition to form a dideuterido species. Alternatively, a deuterium molecule approaching the reaction site from the NH-bridged face might be expected to undergo heterolytic cleavage by interaction with both the nitrogen and ruthenium atoms (Figure 1b). We report herein a mech-



Scheme 1. Activation of N–H bonds of ammonia by trinuclear polyhydrido cluster **3** and hydrogenolysis of $\mu_3$-imido complex **1**.

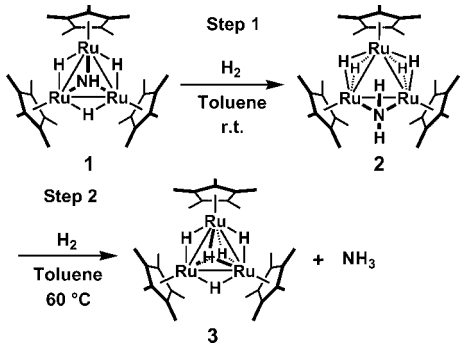
anistic study of the hydrogenation of $\mu_3$-imido complex **1** where deuterium-labeling experiments showed conclusively that the reaction proceeds through oxidative addition of deuterium to the ruthenium atom.

## Results and Discussion

Hydrogenation of $\mu_3$-imido complex **1** proceeds via intermediary μ-amido complex **2**.[5] The reaction of **1** with 1 atm of hydrogen at room temperature was monitored by $^1$H NMR spectroscopy, and the formation of μ-amido complex **2** was revealed; the yields of **2** and pentahydride **3** reached 91 and 6%, respectively, after 170 h. Intermediary μ-amido complex **2** underwent subsequent hydrogenation at 60 °C for 90 h to lead to the quantitative formation of **3** and ammonia (Scheme 2).



Scheme 2. Stepwise hydrogenolysis of $\mu_3$-imido cluster **1** to generate **3** and $NH_3$ via μ-amido cluster **2**.

Compound **2** was isolated by crystallization from a cold (–30 °C) toluene solution of a mixture of **1**, **2**, and **3**. The structure of compound **2** was determined by an X-ray diffraction study with the use of a single crystal that was obtained from the NMR sample solution (Figure 2). The nitrogen atom of the amido ligand is located above the plane defined by the three ruthenium atoms. Notably, one of the hydrogen atoms attached to the nitrogen atom, $H_A$, is located inside the $Ru_3N$ core and the other hydrogen atom, $H_B$, is located outside the $Ru_3N$ core. The broad resonance signals which appeared at $\delta$ = 2.86 and 5.05 ppm in the $^1$H NMR spectrum of **2** recorded at –60 °C were assigned to $H_A$ and $H_B$, respectively, on the basis of shielding/deshielding effects of the aromatic ring current. The resonance signal of the proton located inside the $Ru_3N$ core is shielded by the ring current, and as a result it is shifted upfield. Variable temperature $^1$H NMR spectra exhibited broadening of signals for both $H_A$ and $H_B$ and a reduction in the difference of the chemical shifts between these two μ-amido protons along with the rise in temperature. This showed the site-exchange between $H_A$ and $H_B$, possibly by a pivot motion (Scheme 3), and was confirmed by an SST experiment.[6] This type of dynamic process, namely, in-to-out site-exchange of protons, was reported for several trinuclear transition-metal clusters.[7]

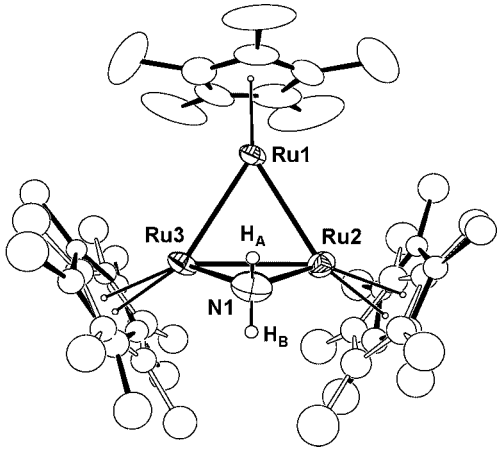


Figure 2. Molecular structure of μ-amido complex **2** with thermal ellipsoids at the 30% probability level.

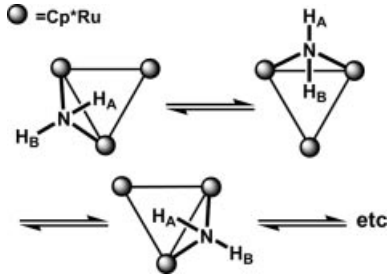


Scheme 3. Exchange of the sites between $H_A$ and $H_B$.

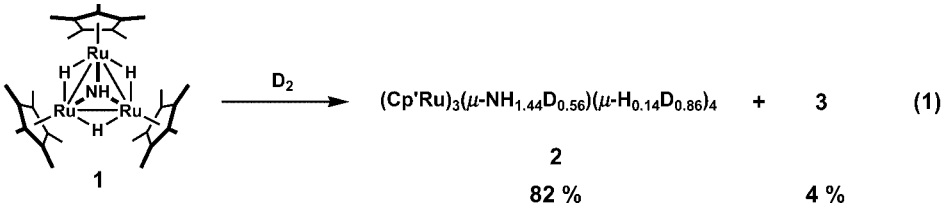
Two sets of hydrido ligands of **2** exchange the coordination site with each other, and their resonance signals coalesce around room temperature. The enthalpy and entropy of activation for this exchange process were estimated at $\Delta H^{\ddagger} = 12.6 \pm 0.6$ kcal mol$^{-1}$ and $\Delta S^{\ddagger} = 3.6 \pm 0.1$ cal mol$^{-1}$ K$^{-1}$, respectively, on the basis of line-shape analysis with the use of a *g*-NMR program package (vide infra). Interestingly, the hydrido ligands and the amido hydrogen of **2** do not undergo coordination site-exchange whereas the hydrido ligands mutually exchange the coordination sites. It should be noted that there is also no site-exchange process between the imido hydrogen and the hydrido ligands in **1**.

As mentioned above, amido complex **2** reacted with 1 atm of hydrogen to afford **3** with an equimolar amount of ammonia. In contrast, complex **2** underwent disproportionation to yield **1** and **3** in the absence of hydrogen, but the conversion of **2** is at most 4% after 120 h at room temperature.

On the basis of the above observations, the reaction of **1** with deuterium was examined to elucidate the mode of hydrogen activation in the hydrogenolysis of the ruthenium–nitrogen bond. The reaction was monitored by $^1$H NMR spectroscopy, and the product and isotopomer ratios were estimated on the basis of the integral intensity of the resonance signals.[8]

The reaction of $\mu_3$-imido complex **1** with 1 atm of deuterium in [$D_8$]toluene was monitored at ambient temperature by $^1$H NMR spectroscopy by using cyclooctane ($\delta$ =

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



1.49 ppm, [$D_8$]toluene, 23 °C) as an internal standard. Conversion of **1** reached 86% after 125 h, and the molar ratio among **1**, μ-amido complex **2**, and pentahydrido complex **3** was 14:82:4 [Equation (1)].

In the hydrido region of the $^1$H NMR spectrum, two singlet peaks assignable to the signal of the hydrido ligands of isotopomers $(Cp^*Ru)_3(\mu\text{-}H)_2(\mu\text{-}D)(\mu_3\text{-}NH)$ (**1**-$d_1$) and $(Cp^*Ru)_3(\mu\text{-}H)(\mu\text{-}D)_2(\mu_3\text{-}NH)$ (**1**-$d_2$) appeared at $\delta$ = –14.51 and –14.73 ppm, respectively. Notably, the hydrido signal of isotopomer **1**-$d_0$ ($\delta$ = –14.30 ppm) disappeared. Although the hydrido signal of isotopomer $(Cp^*Ru)_3(\mu\text{-}D)_3(\mu_3\text{-}NH)$ (**1**-$d_3$) was, of course, not observable, the amount of **1**-$d_3$ formed in the reaction was unambiguously estimated on the basis of the integral intensity ratio between the Cp* proton signal and the hydrido signals. As a result, the isotopomer ratio **1**-$d_0$/**1**-$d_1$/**1**-$d_2$/**1**-$d_3$ was estimated at 0:1:4:9, and the percentage of deuterium content in the hydrido ligand of unconverted **1** was 86%. Here, it should be stressed that the hydrogen of the imido ligand was not replaced by deuterium at all, and this clearly shows the absence of a direct exchange process between the hydrogen at the imido nitrogen and atmospheric deuterium.

Conversely, the integral intensity of the signal for the amido proton of **2** formed in the reaction was 1.44 H, and the percentage of deuteration for the amido proton was estimated to be 28%, whereas that for the hydrido ligand was estimated at 86% (0.56 H). Interestingly, the percentage of deuteration was practically equal for both amido signals at $\delta$ = 2.86 and 5.05 ppm. This strongly supports the presence of a dynamic process, such as a pivot-motion mentioned above, which exchanges the site of the two amido protons, $H_A$ and $H_B$.

We then examined the reaction of **2**, which was isolated in the reaction of **1** with dihydrogen, with deuterium. The reaction of **2** with deuterium (1 atm) was monitored by $^1$H NMR spectroscopy with the use of cyclooctane as an internal standard. The reaction proceeded slowly at ambient temperature, and the conversion yield from **2** to **3** is at most 4% after 280 h. The hydrido ligand of unconverted amido complex **2** was partially deuterated, and the percentage of deuteration of the hydrido ligand was estimated at 74%. In contrast to the hydrido ligand, the integral intensity of the amido proton signal remained almost unchanged despite a long reaction time, and the percentage of deuteration was estimated at less than 5%.

These results show that there is not any direct exchange process between the hydrogen atom of the amido ligand and atmospheric deuterium. According to these observations, we concluded that the deuterium was incorporated into the amido ligand of **2** through hydrogenolysis of the Ru–N bond of **1**, which involves the heterolytic activation of $D_2$ (path **a**) or through reductive coupling between the imido group and the deuterido ligand formed as a result of the homolytic activation, namely, oxidative addition of $D_2$ (path **b**). The two possible reaction paths are shown in Scheme 4.

If hydrogenation of **1** proceeded by path **a**, the percentage of deuteration of the amido ligand should be 50%. This value is far from the observed one, and path **a** should, therefore, be disregarded.

Path **b** involves the formation of $\mu_3$-imido-pentahydrido species **B**. The formation of 48e species **B** is rationalized because the H/D exchange reaction between the hydrido ligand of **1** and $D_2$ likely proceeds through an associative pathway rather than a dissociative path by way of an intermediary $\mu_3$-imido-monohydrido species (44e). In the first stage, deuterium would oxidatively add to $\mu_3$-imido complex **1** via an intermediary $\sigma$-$D_2$ complex to generate isotopomer **B**-$d_2$ (48e), in which the coordination sites were exchanged between the deuterides and the hydrides. As a result, the deuterium atom would scramble around the coordination sites for the hydrido ligand. Rapid scrambling of the deuterido ligand is proved by the fact that the $^1$H NMR spectroscopic signals for the three $C_5Me_5$ groups are observed to be equivalent at any percentage of deuterium content in **1**-$d_n$. Isotopomer **B**-$d_2$ would then undergo reductive coupling between the imido nitrogen and the hydrido ligand to yield μ-amido complex **2**-$d_2$. The percentage of deuterium content in the amido ligand should, therefore, be 20% (0.4 D/2 H). In contrast, the liberation of hydrogen ($H_{1.2}D_{0.8}$) from **B**-$d_2$ affords $\mu_3$-imido complex **1**-$d_{1.2}$. Isotopomer **1**-$d_{1.2}$ would react again with deuterium to generate **2**-$d_{3.2}$, which should contain 0.64 D (32% deuterium content) at the amido nitrogen atom. The observed value of 28% for the percentage of deuterium content in the amido ligand in **2** is approximately consistent with that anticipated for the reaction paths involving homolytic activation, namely, oxidative addition of deuterium. This is strongly supported by the time-course of the yield of **2** and the percentage of deuterium content in the amido ligand (Figure 3). The percentage of deuterium content is about 20% in the early stage of the reaction, and grows gradually along with the progress of the reaction. The deuterium content finally reached 28% after 125 h. Path **b** rationally accounts for these results.

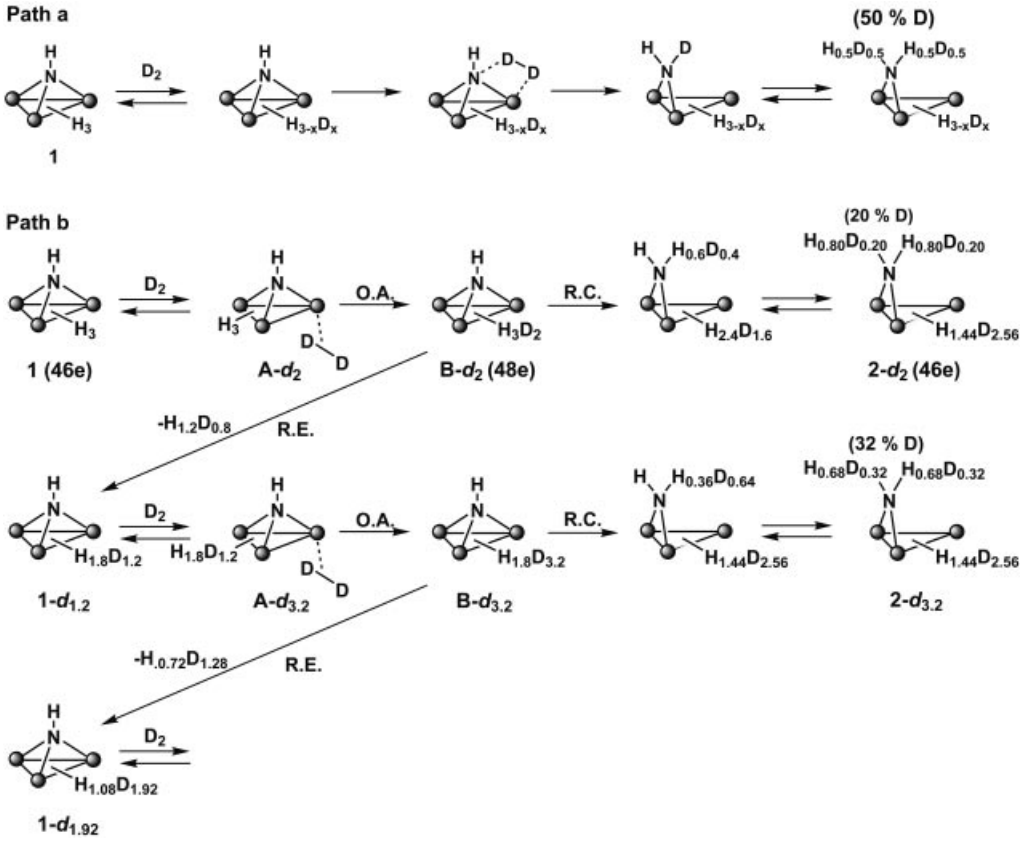

Scheme 4. Plausible mechanism for the reaction of **1** with $D_2$.

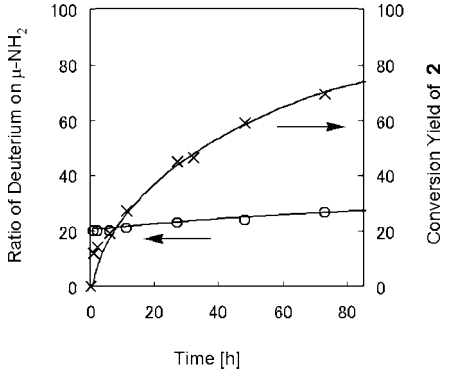

Figure 3. Time conversion regarding the reaction of **1** with $D_2$ (×: conversion yield of **2**, ○: the percentage of deuteration for the amido proton).

## Conclusion

We have experimentally elucidated that hydrogenation of triruthenium $\mu_3$-imido complex **1** to yield μ-amido complex **2** (Step 1, Scheme 2) proceeds through homolytic cleavage of dihydrogen. However, the reaction path for the hydrogenation of **2** to form **3** and ammonia (Step 2, Scheme 2) still remains unclear. Theoretical study is now in progress by using $[(C_5H_5)Ru]_3(\mu\text{-}H)_3(\mu_3\text{-}NH)$ as a model compound.

## Experimental Section

**General Procedure:** The compounds described below were handled under an argon atmosphere with rigorous exclusion of air and water by using Schlenk techniques. Dihydrogen and deuterium were obtained from Fujii Co. Ltd., and no further purification was performed. $(Cp^*Ru)_3(\mu\text{-}H)_3(\mu_3\text{-}NH)$ (**1**), $(Cp^*Ru)_3(\mu\text{-}H)_4(\mu\text{-}NH)$ (**2**), and $(Cp^*Ru)_3(\mu\text{-}H)_3(\mu_3\text{-}H)_2$ (**3**) were prepared as described previously.[4,5] $[D_8]$toluene was dried with sodium benzophenone ketyl and distilled under an argon atmosphere. $^1H$ and $^{13}C$ NMR spectra were recorded with a Varian INOVA 400 Fourier transform spectrometer with tetramethylsilane as an internal standard.

**Reaction of $(Cp^*Ru)_3(\mu_3\text{-}NH)(\mu\text{-}H)_3$ (1) with $H_2$. Formation of μ-Amido Complex 2:** An NMR sample tube equipped with a Teflon stopcock was charged with **1** (6.1 mg, 0.0084 mmol), $[D_8]$toluene (0.4 mL), and cyclooctane (1 μL) as an internal standard. The sample tube was evacuated at –196 °C, and atmospheric pressure of dihydrogen (2.6 mL, 0.12 mmol) was introduced. The reaction was performed at room temperature and monitored by $^1H$ NMR spectroscopy. After 170 h, $(Cp^*Ru)_3(\mu\text{-}NH_2)(\mu\text{-}H)_4$ (**2**) and $(Cp^*Ru)_3(\mu_3\text{-}H)_2(\mu\text{-}H)_3$ (**3**) were formed in 91 and 6% yield, respectively. The reaction was further carried out at 60 °C for 90 h to generate **3** quantitatively. Data for **2**: $^1H$ NMR (400 MHz, $[D_8]$toluene, –80 °C, TMS): $\delta$ = –17.71 (s, 2 H, Ru-*H*), –5.48 (s, 2 H, Ru-*H*), 1.81 (s, 30 H, Cp*-*Me*), 2.06 (s, 15 H, Cp*-*Me*), 2.88 (br. s, 1 H, $w_{1/2}$ = 10.5 Hz, N-*H*), 5.09 (br. s, 1 H, $w_{1/2}$ = 10.4 Hz, N-*H*) ppm. $^1H$ NMR (400 MHz, $[D_8]$toluene, 80 °C, TMS): $\delta$ = –11.83 (br. s, 4 H, $w_{1/2}$ = 45.2 Hz, Ru-*H*), 1.76 (s, 30 H, $C_5Me_5$), 1.96 (s, 15 H, $C_5Me_5$), 2.78 (br. s, 1 H, $w_{1/2}$ = 20.5 Hz, N-*H*), 4.85 (br. s, 1 H,

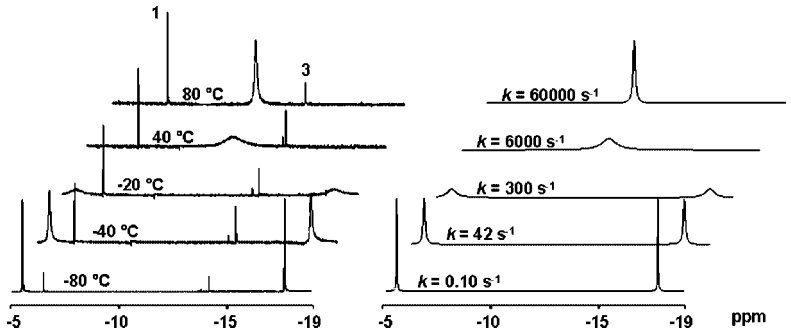

Figure 4. Experimental (left) and simulated (right) variable-temperature $^1$H NMR spectra of **2**, which shows the region of the hydride protons.

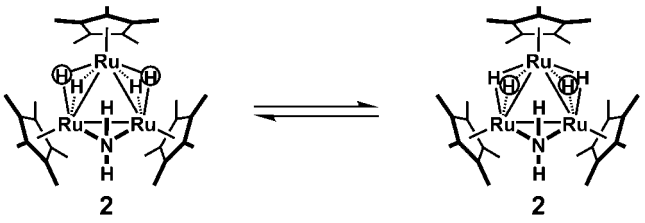
$w_{1/2}$ = 20.3 Hz, N-*H*) ppm. $^{13}$C NMR (100 MHz, [D$_8$]toluene, 23 °C, TMS): $\delta$ = 12.4 (q, $J_{CH}$ = 125.6 Hz, Cp*-*Me*), 13.2 (q, $J_{CH}$ = 125.4 Hz, Cp*-*Me*), 84.1 (s, Cp*-ring), 85.1 (s, Cp*-ring) ppm. $C_{30}H_{51}N_1Ru_3$ (728.9): calcd. C 49.57, H 6.79, N 1.92; found C 49.22, H 6.81, N 2.03.

**X-ray Diffraction Studies:** A single crystal of **2** for X-ray analysis was obtained directly from the preparations described above and mounted on glass fibers. The diffraction experiment was performed with a Rigaku R-AXIS RAPID imaging plate diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71069 Å) at 173 K within 3.28° < $\theta$ < 27.48°. Cell refinement and data reduction were performed with the PROCESS-AUTO program.[9] Intensity data were corrected for Lorentz-polarization effects and for empirical absorption. The structure of **2** was solved by the Patterson method by using the SHELX-97 program package.[10] All non-hydrogen atoms were found by the difference Fourier synthesis and were refined anisotropically except for the disordered atoms described below. The refinement was carried out by least-squares methods based on $F^2$ with all measured reflections. For **2**, disorder at Cp* ligands bonded at Ru(2) and Ru(3) were refined in the ratio of 40:60. Crystal data for **2**: monoclinic, space group $P2_1/n$ (No. 14), $a$ = 11.9713(10), $b$ = 11.7390(10), $c$ = 22.540(2) Å, $\beta$ = 102.602(8)°, $V$ = 3091.3(5) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 1.566 Mg m$^{-3}$, $\mu$(Mo$_{Ka}$) = 1.464 mm$^{-1}$, of the 24614 reflections that were collected, 7410 were unique ($R_{int}$ = 0.0981), $R_1$ = 0.1089 [$I > 2\sigma(I)$], $wR_2$ = 0.3149 [$I > 2\sigma(I)$], GOF = 1.250, $\Delta\rho_{min/max}$ = +4.030/–1.855 e Å$^{-3}$. CCDC-630784 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Measurement of 2 by Variable-Temperature $^1$H NMR Spectroscopy:** An NMR sample tube equipped with a Teflon stopcock was charged with **2** (10.2 mg, 0.0014 mmol), [D$_8$]toluene (0.5 mL), and cyclooctane (1 μL) as an internal standard. Figure 4 shows the $^1$H NMR spectra (hydride region) of **2** at variable temperatures. The signals on the left-hand side are the experimental set, and the right-hand side shows the signals simulated. The activation parameters were estimated by line-shape analysis using the g-NMR program. Temperature dependence of the rate constants gave activation parameters $\Delta H^\ddagger$ = 12.6 ± 0.6 kcal mol$^{-1}$, $\Delta S^\ddagger$ = 3.6 ± 0.1 cal mol$^{-1}$ K$^{-1}$, and $\Delta G^\ddagger$ = 13.2 ± 0.6 kcal mol$^{-1}$. This exchange process is shown in Scheme 5.

**Thermolysis of 2:** An NMR sample tube equipped with a Teflon stopcock was charged with **2** (8.1 mg, 0.011 mmol), [D$_8$]toluene (0.4 mL), and cyclooctane (1 μL) as an internal standard. The reaction was performed at room temperature and monitored by $^1$H NMR spectroscopy. After 120 h, the $^1$H NMR spectrum showed



Scheme 5. Coordination site exchange between the two sets of hydrido ligands of **2**.

that **2** underwent disproportionation to afford **1** and **3**, both in 2% yield.

**Reaction of Complex 1 with Molecular Deuterium:** An NMR sample tube equipped with a Teflon stopcock was charged with **1** (8.3 mg, 0.011 mmol), [D$_8$]toluene (0.4 mL), and cyclooctane (1 μL) as an internal standard. The sample tube was evacuated at –196 °C, and atmospheric pressure of molecular deuterium (2.6 mL, 0.12 mmol) was introduced. The reaction was performed at room temperature and monitored by $^1$H NMR spectroscopy. After 125 h, the $^1$H NMR spectrum showed the formation of **1**, **2**, and **3** in 14, 82, and 4% yield, respectively. The percentages of deuteration of unconverted **1** for the imido proton and the hydrido ligand were estimated at 0 and 86%, respectively. The percentages of deuteration of **2** for the amido proton and the hydrido ligand were estimated at 28 and 86%, respectively.

**Reaction of Complex 2 with Molecular Deuterium:** An NMR sample tube equipped with a Teflon stopcock was charged with **2** (7.5 mg, 0.010 mmol), [D$_8$]toluene (0.4 mL), and cyclooctane (1 μL) as an internal standard. The sample tube was evacuated at –196 °C, and atmospheric pressure of molecular deuterium (2.6 mL, 0.12 mmol) was introduced. The reaction was performed at room temperature and monitored by $^1$H NMR spectroscopy. After 280 h, the $^1$H NMR spectrum showed the formation of **2** and **3** in 96 and 4% yield, respectively. The percentage of deuteration of **2** for the hydrido ligand was estimated at 74%, and that for the amido proton was estimated at less than 5%.

## Acknowledgments

The present research is supported by the Ministry of Education, Culture, Sports, Science, and Technology, Japan by grant No. 18064007 (Priority Area "Synergy of Elements") and from Japan Society of the Promotion of Science by grant No.18105002 [Scientific Research (S)]. [6] The spin saturation transfer experiment was carried out at 80 °C with complex **2**. It was observed that irradiation of the amido peak at $\delta$ = 2.78 ppm led to an approximately 80% decrease in intensity of another N–H signal at $\delta$ = 4.85 ppm in the $^1$H NMR spectrum. This observation can be interpreted to result from an in-to-out exchange process of the protons.

# Acetylide Addition to Bridging Vinyliminium Ligands in Dinuclear Complexes

**Luigi Busetto,[a] Fabio Marchetti,[b][‡] Stefano Zacchini,[a] and Valerio Zanotti*[a]**

**Keywords:** Acetylides / Dinuclear complexes / Bridging ligands / C–C bond formation

The (vinyliminium)diiron complexes $[Fe_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C_\gamma(R')=C_\beta(R')C_\alpha{=}N(Me)(R)\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$ [R = Xyl, R′ = Me (**1a**); R = Xyl, R′ = Et (**1b**); R = R′ = Me (**1c**); R = Me, R′ = Et (**1d**); R = $CH_2Ph$, R′ = Me (**1e**); Xyl = 2,6-$Me_2C_6H_3$] undergo regio- and stereoselective addition by lithium acetylides. Addition of LiC≡CR′′ (R′′ = Tol, Ph, $SiMe_3$; Tol = 4-$MeC_6H_4$) to *trans*-**1a** occurs at the $C_\beta$ atom of the vinyliminium ligand and results in the formation of the bis(alkylidene) complexes *cis*-$[Fe_2\{\mu\text{-}\eta^1{:}\eta^2\text{-}C(Me)C(Me)(C{\equiv}CR'')CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2]$ [R′′ = Tol (**2a**), Ph (**2b**), $SiMe_3$ (**2c**)]. The molecular structure of **2a** has been determined by X-ray diffraction. Similarly, the diruthenium complex $[Ru_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C(Me)=C(Me)C=N(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$ (**3**) reacts with LiC≡CTol to give the bis(alkylidene) compound $[Ru_2\{\mu\text{-}\eta^1{:}\eta^2\text{-}C(Me)C(Me)(C{\equiv}CTol)CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2]$ (**4**). Conversely, **1c** and **1d** undergo acetylide attack at the $C_\alpha$ atom of the vinyliminium ligand to yield the allylidene complexes $[Fe_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C(R')C(R')C(C{\equiv}CR'')N(Me)_2\}(\mu\text{-}CO)(CO)(Cp)_2]$ [R′ = Me, R′′ = Tol (**5a**); R′ = Me, R′′ = Ph (**5b**); R′ = Me, R′′ = $SiMe_3$ (**5c**); R′ = Me, R′′ = *n*Bu (**5d**); R′ = Me, R′′ = $C(Me)=CH_2$ (**5e**); R′ = Me, R′′ = H (**5f**); R′ = Et, R′′ = Tol (**5g**); R′ = Et, R′′ = Ph (**5h**); R′ = Et, R′′ = $SiMe_3$ (**5i**); R′ = Et, R′′ = $C(Me)=CH_2$ (**5j**)]. Analogously, the reaction of **1e** with LiC≡CPh affords $[Fe_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C(Me)C(Me)C(C{\equiv}CPh)N(Me)(CH_2Ph)\}(\mu\text{-}CO)(CO)(Cp)_2]$ (**6**). The molecular structure of **5h** has been determined by X-ray diffraction. Finally, **1b**, in both its *cis* and *trans* forms, undergoes acetylide attack at the $C_\alpha$ atom of the vinyliminium ligand to give the complexes $[Fe_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C(Et)C(Et)C(C{\equiv}CR'')N(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2]$ [R′′ = $SiMe_3$ (**7a**), H (**7b**)].

## Introduction

Dinuclear complexes are expected to provide new reactivity patterns that are distinct from those of similar monometallic complexes and open novel perspectives in the field of homogeneous catalysis and metal-assisted organic synthesis.[1] Our interest in this area has been focused on the chemistry of the vinyliminium-bridged diiron complexes **I** and **II** (Figure 1), which are obtained by the insertion of primary and secondary alkynes, respectively, into the metal–carbyne bond of $[Fe_2\{CN(Me)(R)\}(\mu\text{-}CO)(CO)(NCMe)(Cp)_2][SO_3CF_3]$.[2]

The carbon skeleton of the bridging framework in **I** and **II** should be able to be expanded by addition of appropriate carbon nucleophiles by taking advantage of the electrophilic character of the vinyliminium ligand. Thus, it has been found that the addition of $CN^-$ can be selectively directed to the iminium carbon atom ($C_\alpha$) or to the adjacent $C_\beta$ atom to afford $\mu\text{-}\eta^1{:}\eta^3$-vinylalkylidene and $\mu\text{-}\eta^1{:}\eta^2$-bis(alkylidene) ligands, respectively,[3] in a similar way to that reported for hydride addition.[4] However, the acidity of the

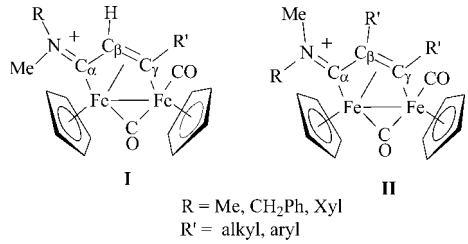

Figure 1. μ-Vinyliminium complexes.

$C_\beta$-H proton in complexes of type **I** represents a serious limitation to the addition of carbon nucleophiles. Indeed, reactions with organolithium reagents result in $C_\beta$-H proton removal rather than nucleophilic addition.[5] To overcome this limitation, further studies have been restricted to vinyliminium complexes of type **II**, which do not contain $C_\beta$-H protons. Nevertheless, organolithium reagents (LiMe, LiPh) have been found to attack the $C_5H_5$ ring instead of the bridging ligand. This initial attack is followed by hydride migration from the $C_5H_5R$ ring to the iminium carbon atom ($C_\alpha$).[6]

Moreover, we have recently communicated that the reaction of *cis*-$[Fe_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C(Me)=C(Me)C=N(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$ with acetylides occurs at the carbonyl group with cleavage of the carbon–oxygen bond.[7] The three-carbon-atom chain of the bridging frame grows

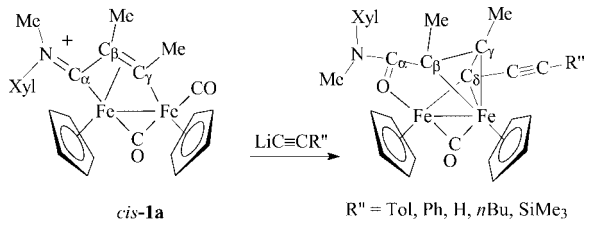
by several units due to the inclusion of both the alkynyl (C≡CR′′) and the $C_\delta$ atom, which originates from the CO ligand (Scheme 1).

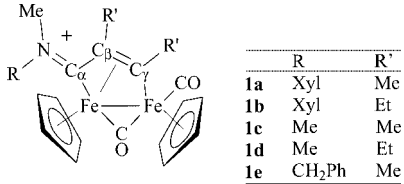


Scheme 1.

Herein we report on an extension of these studies, the aim of which was to establish whether the reaction reported above has a general character or if other reaction paths are available. A number of μ-vinyliminium complexes containing different substituents on the bridging ligand and displaying *cis* or *trans* geometry were examined in order to determine possible steric and electronic effects.

## Results and Discussion

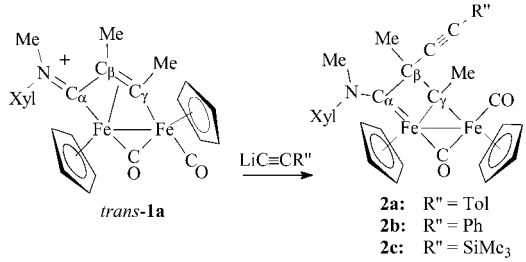
The vinyliminium complexes investigated in this work are shown in Figure 2. They were obtained by insertion of the appropriate disubstituted alkyne into the Fe–aminocarbyne bond of the complexes $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)(NCMe)(Cp)_2][SO_3CF_3]$ and $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)(Cl)(Cp)_2]$ according to published methods.[2] It should be remembered that compounds **1a** and **1b** assume a *trans* geometry when they are obtained from the aminocarbyne complexes $[Fe_2\{\mu\text{-}CN(Me)(R)\}(\mu\text{-}CO)(CO)(Cl)(Cp)_2]$ by chloride abstraction in the presence of the appropriate alkyne, and that they can be converted into the corresponding *cis* isomers by heating in refluxing thf. Conversely, complexes **1c**–**e** are only isolated as their *cis* isomers.[2b]



| | R | R′ |
|---|---|---|
| **1a** | Xyl | Me |
| **1b** | Xyl | Et |
| **1c** | Me | Me |
| **1d** | Me | Et |
| **1e** | $CH_2Ph$ | Me |

Figure 2. Vinyliminium complexes examined in this work.

Complex *trans*-**1a** reacts with LiC≡CR′′ (R′′ = Tol, Ph, $SiMe_3$; Tol = 4-$MeC_6H_4$) in thf solution to afford the corresponding acetylene-functionalised bis(alkylidene) complexes $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^2\text{-}C(Me)C(Me)(C{\equiv}CR'')CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2]$ (**2a**–**c**) as a consequence of nucleophilic addition at the $C_\beta$ atom of the vinyliminium ligand (Scheme 2).



Scheme 2.

Thus, the reaction of *trans*-**1a** has a completely different outcome to that of the corresponding *cis* isomer (Scheme 1). Compounds **2a**–**c** were obtained in good yields (ca. 70%) after purification by column chromatography on alumina and were characterised by IR and NMR spectroscopy.

The structure of **2a** was determined by X-ray diffraction: the ORTEP molecular diagram is shown in Figure 3 and relevant bond lengths and angles are listed in Table 1.

The bridging ligand is coordinated to the Fe atoms through a bridging alkylidene carbon atom ($C_\gamma$) and an aminocarbene moiety. The main bond lengths and angles are similar to those of the analogous bis(alkylidene) complex $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^2\text{-}C(CO_2Me)CH_2CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2]$, which was obtained by hydride addition to $C_\beta$ of the vinyliminium ligand in *cis*-$[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^3\text{-}C(CO_2Me){=}C(H)C{=}N(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$.[4a] In particular, both the N(1)–C(15) [1.321(7) Å] and the Fe(1)–C(15) [1.899(6) Å] interactions show some double-bond character, which is typical for a terminal aminocarbene ligand.[8] In agreement with this, both C(15) and N(1) adopt a nearly perfect $sp^2$ hybridisation [sum of angles: 360.1(8)° and 360.0(8)°, respectively]. Moreover, the iron atoms are bound through nearly pure σ-interactions to the $C_\gamma$ atom [Fe(1)–C(13) 1.970(6), Fe(2)–C(13) 1.992(5) Å], as expected for a bridging alkylidene. Finally, the C(13)–C(14) [1.562(8) Å] and C(14)–C(15) [1.510(7) Å] interactions are typical for pure C–C single bonds, in agreement with the $sp^3$ hybridisation assumed by C(14); conversely, the C(17)–C(18) interaction [1.189(8) Å] exhibits a triple-bond character and the C(14)–C(17)–C(18)–C(19) unit is almost perfectly linear, as expected for an alkynyl group [C(14)–C(17)–C(18) 172.6(6), C(17)–C(18)–C(19) 179.6(7)°].

The spectroscopic data for **2a**–**c** are consistent with the structure of **2a**. The IR spectra (in $CH_2Cl_2$ solution) exhibit absorptions for a terminal and a bridging carbonyl group (1919 and 1749 $cm^{-1}$ for **2a**), and a band attributable to the $C_\alpha$–N interaction at about 1510 $cm^{-1}$. The $^{13}C$ NMR spectra contain a low-field resonance due to the aminocarbene carbon atom $C_\alpha$ ($\delta$ = 268.8 ppm for **2a**) and the $C_\gamma$ resonance ($\delta$ = 181.5 ppm for **2a**), in the range typical for alkylidene carbon atoms. Moreover, NOE experiments indicate that **2a**–**c** adopt the same geometry in solution as in the solid, with the Cp ligands mutually *cis* and a (*Z*) configuration for the Me and Xyl groups. Therefore, the acetylide addition is accompanied by *trans*/*cis* isomerisation.[9] The

NMR spectra of **2a**–**c** also show that only one isomer is present in solution, thereby indicating that the acetylide addition, which generates a stereogenic centre at $C_\beta$, is stereospecific. Thus, we assume that the acetylene fragment is exclusively placed on the opposite side to the sterically demanding Cp ligands, as shown by the structure of **2a** in the solid.

Interestingly, the observed nucleophilic addition at the $C_\beta$ position of the bridging ligand does not correspond to the reactivity expected for a non-coordinated vinyliminium functionality, which should react at the iminium carbon atom ($C_\alpha$) or at the conjugated $C_\gamma$ position. This unusual reactivity shown by the bridging $C_3$ frame presumably originates from the stability of the bis(alkylidene) coordination mode, which is assumed to be a consequence of the nucleophilic addition and C–C bond formation at $C_\beta$.

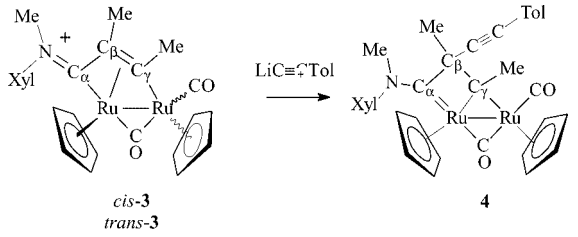
The most relevant feature of the reactions described above is the completely different outcome of the acetylide addition for *cis*-**1a** and *trans*-**1a**. The mutual arrangement of ancillary ligands in dinuclear complexes rarely exerts any relevant influence on the reactivity of adjacent ligands,[10] although the results reported above are not entirely unexpected. In a very similar and previously reported reaction, the *cis* and *trans* isomers of **1b** were found to react with $NaBH_4$ in different ways: the *cis* isomer was found to undergo hydride addition at $C_\alpha$, whereas the *trans* isomer reacts at $C_\beta$.[4b] This seems to indicate that the *trans* arrangement of the Cp ligands is more favourable than the *cis* one for addition at the $C_\beta$ position.

A second point to be noted is that neither *cis*-**1a** nor *trans*-**1a** undergo acetylide attack at the iminium carbon atom ($C_\alpha$), in spite of its strongly electrophilic character. This can be explained in terms of restricted access to the $C_\alpha$ position due to the presence of the sterically demanding Xyl group.

Since (μ-vinyliminium)diruthenium complexes analogous to **1a**–**e** are known, and their chemistry generally parallels that of their diiron counterparts,[11] we extended the investigation to the diruthenium species in order to detect possible effects due to the nature of the metal atom. Thus, we studied the reactions of the *trans* and *cis* isomers of the diruthenium complex $[Ru_2\{\mu\text{-}\eta^1\text{:}\eta^3\text{-}C(Me){=}C(Me)C{=}N(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$ (**3**), which is an ana-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

logue of **1a**, with lithium acetylides. Surprisingly, both *trans* and *cis* isomers react in the same way to give the acetylene-functionalised bis(alkylidene) compound $[Ru_2\{\mu\text{-}\eta^1{:}\eta^2\text{-}C(Me)C(Me)(C{\equiv}CTol)CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2]$ (**4**; Scheme 3).



Scheme 3.

Complex **4**, which is an analogue of the diiron compound **2a**, was characterised by spectroscopy and elemental analysis. In particular, its NMR spectroscopic data well parallel those of **2a** (see Experimental Section), thereby suggesting that the two compounds adopt identical geometries.

Further investigations concerned the complexes $[Fe_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C(R')=C(R')C=N(Me)_2\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$ [R′ = Me (**1c**), Et (**1d**)], which exist only as *cis* isomers. Compounds **1c** and **1d** differ from **1a** in that they contain a methyl group instead of a Xyl group in the iminium moiety. Therefore, in the absence of steric protection due to the Xyl group, the iminium carbon atom is expected to be the preferential site of addition. Accordingly, the reactions of **1c** and **1d** with a series of lithium acetylides LiC≡CR′′ [R′′ = H, Ph, Tol, $SiMe_3$, $C(Me)=CH_2$] resulted in the formation of the novel bridging acetylene-functionalised allylidene complexes **5a**–**j**, as reported in Scheme 4.

Compounds **5a**–**j** were obtained in good yields after purification by column chromatography on alumina and were characterised by IR and NMR spectroscopy. The structure of **5h** was determined by X-ray diffraction; the ORTEP molecular diagram is shown in Figure 4 and selected bond lengths and angles are listed in Table 2.

The $C_3$-bridged coordination framework exhibits some changes as a consequence of acetylide addition, although it remains σ-bound to Fe(2) [Fe(2)–C(13) 1.987(3) Å] and $\eta^3$-coordinated to Fe(1) [Fe(1)–C(13) 2.010(3), Fe(1)–C(14) 2.040(3), Fe(1)–C(15) 2.098(3) Å]. The usual description for this bonding mode is a mix of vinylalkylidene and allylidene

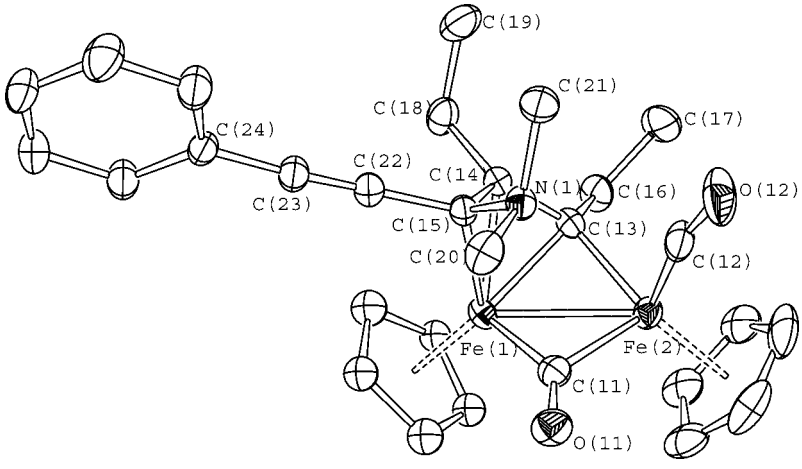

Figure 4. ORTEP drawing of $[Fe_2\{\mu\text{-}\eta^1{:}\eta^3\text{-}C(Et)C(Et)C(C{\equiv}CPh)N(Me)_2\}(\mu\text{-}CO)(CO)(Cp)_2]$ (**5h**). All H atoms have been omitted for clarity. Thermal ellipsoids are at the 30% probability level.

contributions (Figure 5, **A** and **B**, respectively).[12] The structure of **5h** can be compared to that of the related complexes $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^3\text{-}C_\gamma(Tol)C_\beta(H)C_\alpha(H)N(Me)_2\}(\mu\text{-}CO)(CO)(Cp)_2]$ (**III**),[4a] $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^3\text{-}C_\gamma(SiMe_3)C_\beta(H)C_\alpha(CN)N(Me)_2\}(\mu\text{-}CO)(CO)(Cp)_2]$ (**IV**),[3] and $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^3\text{-}C_\gamma(Me)C_\beta(Me)C_\alpha(CN)N(Me)_2\}(\mu\text{-}CO)(CO)(Cp)_2]$ (**V**),[3] which were obtained by hydride or cyanide addition.[3] Compound **III** has a $C_\alpha$–$C_\beta$ bond length [1.408(9) Å] shorter than that of $C_\beta$–$C_\gamma$ [1.441(8) Å], and has been described as containing a bridging vinylalkylidene. Conversely, **5h** shows the opposite trend, namely the $C_\beta$-$C_\gamma$ bond length [1.435(4) Å] is shorter than that of $C_\alpha$–$C_\beta$ [1.463(4) Å], and because of this closely resembles **IV** and **V** [$C_\beta$–$C_\gamma$ 1.414(3) and 1.419(3), $C_\alpha$–$C_\beta$ 1.447(3) and 1.449(3) Å, respectively], which were more appropriately described as allylidene complexes (Figure 5, **B**). This observation, together with the fact that the C(15)–N(1) ($C_\alpha$–N) [1.455(4) Å] and Fe(1)–C(15) interactions [2.098(3) Å] are almost a single bond and both C(15) and N(1) deviate appreciably from $sp^2$ hybridisation [sum of angles: 348.5(3) and 334.6(4)°, respectively], suggests that the ligand can also be described in terms of a $\eta^1$:$\eta^2$-vinyl contribution (Figure 5, **C**), although the most representative description is as an allylidene (**B**).

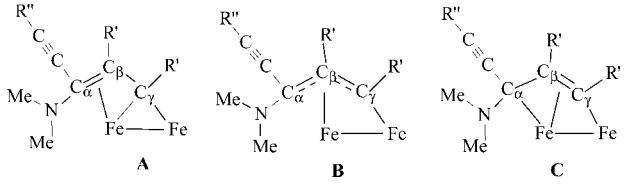

Figure 5. Description of the bridging ligand in complexes of type **5**.

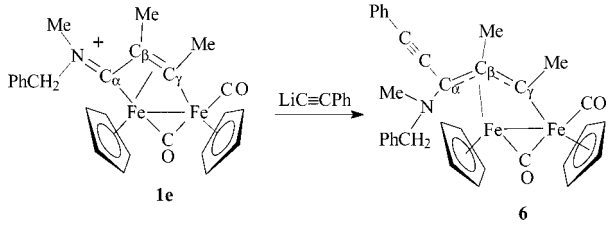
A further difference between **5h** and the complexes derived by hydride addition to $C_\alpha$ (**III**) consists in the orientation of the $NMe_2$ group. Thus, in the acetylene-functionalised compound **5h** it lies *trans* to the R substituent of $C_\beta$ whereas it is *cis* in complex **III**.[4a] In this respect **5h** more closely resembles the products obtained by cyanide addition (**IV** and **V**), which display an analogous *trans* orientation.[3]

The spectroscopic data of **5a**–**j** are fully consistent with the proposed formulation. The IR spectra (in $CH_2Cl_2$ solution) exhibit the usual ν(CO) band pattern and a weak absorption at 2120–2180 $cm^{-1}$ for the C≡C bond. The $^1H$ NMR spectra suggest a single isomer in solution, which indicates that the reaction is regio- and stereoselective. In particular, NOE investigations carried out on **5b** show that irradiation of the $C_\beta$-*Me* resonance ($\delta$ = 2.18 ppm) results in a significant enhancement of the *N*-methyl resonance at $\delta$ = 1.64 ppm, whereas no NOE is detected between $C_\beta$-*Me* and the other N–*Me* ($\delta$ = 2.31 ppm) or between the *N*-bound methyl groups and the Cp ligands. Indeed, looking at the structure of **5h**, the $NMe_2$ group is placed on the side opposite to the Cp ligand and one *N*-methyl group lies much closer to the $C_\beta$ substituent than the other.

The major features of the $^{13}C$ NMR spectra concern the $C_\alpha$ and $C_\gamma$ resonances: the latter is found downfield ($\delta$ = 203.4 ppm for **5h**), whereas the former is shifted upfield ($\delta$ = 72.8 ppm for **5h**), with respect to the vinyliminium precursors. These data are consistent with the alkyl nature of $C_\alpha$ and the vinyl character of $C_\gamma$. Finally, two signals in the range $\delta$ = 89–107 ppm can be assigned to the sp carbon atoms ($\delta$ = 92.4 and 91.1 ppm for **5h**).

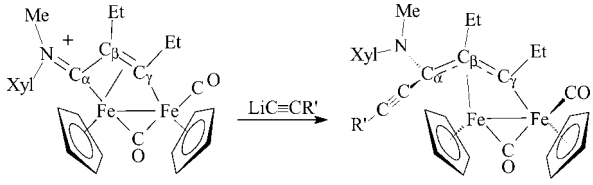
The reaction of $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^3\text{-}C(Me)=C(Me)C=N(Me)(CH_2Ph)\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$ (**1e**) with LiC≡CPh was also investigated. Compared to **1a** and **1c**, compound **1e** has one benzyl group as an *N*-substituent. The aim of this study was to determine to what extent substituents with a steric hindrance intermediate between Me and Xyl can exert steric protection on the iminium carbon atom ($C_\alpha$). The addition occurs selectively at $C_\alpha$ and results in the formation of complex **6** (Scheme 5).



Scheme 5.

The spectroscopic data of **6** are similar to those of **5a**–**j**. However, by contrast with **5a**–**j**, complex **6** contains minor amounts of a second isomeric form in solution (isomer ratio about 12:1). These isomers are presumably due to the different orientations that the methyl and benzyl substituents can adopt as a consequence of hindered rotation around the $C_\alpha$–N bond. NOE experiments on the major isomer suggest that the most favourable geometry is that with the bulkier benzyl group pointing toward the bridging and terminal CO.

Finally, the reactions of compound **1b** with LiC≡CR′ (R′ = $SiMe_3$, H) resulted in the formation of complexes $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^3\text{-}C(Et)C(Et)C(C{\equiv}CR')N(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2]$ (R′ = $SiMe_3$ **7a**, H **7b**) in low yields (20–30%; Scheme 6).



| | R′ | |
|---|---|---|
| **1b** | $SiMe_3$ | **7a** |
| **1b** | H | **7b** |

Scheme 6.

It is noteworthy that both *cis*- and *trans*-**1b** react in the same way. Unexpectedly, the addition occurs selectively at the iminium carbon atom rather than producing CO cleavage, in spite of the presence of the Xyl group and a *cis* arrangement of the Cp ligands.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Compounds **7a** and **7b** are unstable and decompose in $CH_2Cl_2$ solution at room temperature after 12 h. Nonetheless, they could be purified by chromatography on alumina and characterised by IR and NMR spectroscopy. Their NMR spectroscopic data, and in particular the $C_\alpha$, $C_\beta$ and $C_\gamma$ resonances (see Experimental Section), are consistent with their acetylene-functionalised allylidene nature. NOE studies were carried out on complex **7b**. Thus, irradiation of the Cp resonance at $\delta$ = 3.68 ppm resulted in significant enhancement of the resonances at $\delta$ = 4.67 (Cp), 2.62 (N-*Me*) and 1.29 ppm (Xyl-*Me*). This indicates that the Cp ligands adopt a *cis* geometry and the N(Me)(Xyl) is close to one Cp ring. Thus, the geometry of the substituents at the $C_\alpha$ atom seems to be different from that found in **5h**, since the alkynyl moiety in **7b** points toward the CO ligands.

## Conclusions

Complexes containing bridging vinyliminium ligands are very reactive toward acetylides: they undergo nucleophilic addition with C–C bond formation at the $C_3$ bridging ligand. Several reaction paths have been evidenced, in addition to the nucleophilic attack to CO and its cleavage, previously communicated. The results evidence that, although several sites of addition are available, the reactions are selective and do not produce mixtures of isomers. The site of addition is largely determined by steric arguments, related to the nature of the substituents on the vinyliminium ligand. Thus, the iminium carbon atom ($C_\alpha$) appears as the most reactive site, but it is made hardly accessible by the presence of the sterically demanding Xyl substituent. Likewise, nucleophilic addition at the $C_\beta$ position is hampered when the Cp ligands are mutually *cis*, or in the presence of $C_\beta$ substituents more sterically demanding than a methyl group. When all these factors operate, the acetylide attack is directed to the CO and is soon followed by an intramolecular rearrangement involving the vinyliminium ligand. Thus, the reactions lack a general character and, in some cases, are difficult to predict. On the other hand, the bridging $C_3$ moiety displays a variety of possible ways in which it can add an alkynyl group to generate new bridging hydrocarbyl ligands with more complex architectures.

## Experimental Section

**General:** All reactions were routinely carried out under nitrogen using standard Schlenk techniques. Solvents were distilled immediately before use under nitrogen from appropriate drying agents. Chromatographic separations were performed on columns of deactivated alumina (4% w/w water). Glassware was oven-dried before use. IR spectra were recorded with a Perkin–Elmer Spectrum 2000 FT-IR spectrophotometer and elemental analyses were performed with a ThermoQuest Flash 1112 Series EA Instrument. All NMR measurements were performed with Varian Gemini 300 and Mercury Plus 400 instruments. The chemical shifts for $^1H$ and $^{13}C$ were referenced to internal TMS. The spectra were fully assigned by DEPT experiments and $^1H$,$^{13}C$ correlation through gs-HSQC and gs-HMBC experiments.[13] All NMR spectra were recorded at 298 K; NMR signals due to a second isomeric form (where it was possible to detect and/or resolve them) are *italicized*. NOE measurements were recorded using the DPFGSE-NOE sequence.[14] All reagents were commercial products (Aldrich) of the highest purity available and were used as received. $[Fe_2(CO)_4(Cp)_2]$ was purchased from Strem and used as received. Complexes $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^3\text{-}C(R')=C(R')C=N(Me)(R)\}(\mu\text{-}CO)(CO)(Cp)_2][SO_3CF_3]$ (**1a**–**e**)[2] and $[Ru_2\{\mu\text{-}C(Me)=C(Me)C=N(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2][CF_3SO_3]$ (**3**)[11] were prepared as described in the literature.

**Synthesis of $[Fe_2\{\mu\text{-}\eta^1\text{:}\eta^2\text{-}C(Me)C(Me)(C{\equiv}CR'')CN(Me)(Xyl)\}(\mu\text{-}CO)(CO)(Cp)_2]$ [R'' = Tol (2a), Ph (2b), $SiMe_3$ (2c)]:** A solution of *trans*-**1a** (201 mg, 0.311 mmol), in thf (8 mL), was treated at room temperature with a thf solution of LiC≡CTol (1.2 mL, 0.620 mmol) freshly prepared from *n*BuLi and HC≡CTol. The mixture was stirred for 30 min, then it was concentrated under reduced pressure. Chromatography of the residue on alumina, using diethyl ether as eluent, afforded a red band corresponding to **2a**. Yield: 137 mg (72%). Crystals suitable for X-ray diffraction were obtained by layering a diethyl ether solution of **2a** with petroleum ether (b.p. 40–60 °C) at –20 °C. $C_{35}H_{35}Fe_2NO_2$ (613.35): calcd. Complex **7b** was obtained according to the same procedure described for the synthesis of **7a** by treating *cis*-**1b** (180 mg) with LiC≡CH. **7b:** Yield: 37 mg (25%). Colour: brownish green. $C_{30}H_{33}Fe_2NO_2$ (551.28): calcd. C 65.36, H 6.03; found C 65.42, H 6.00. IR ($CH_2Cl_2$): ν(CO) 1945 (vs), 1762 (s) cm$^{-1}$. $^1$H NMR ($CDCl_3$): δ = 7.19–6.96 (m, 3 H, $Me_2C_6H_3$), 4.67, 3.68 (s, 10 H, Cp), 3.76 (m, 2 H, $C_\gamma CH_2$), 2.62 (s, 3 H, NMe), 2.18 (s, 1 H, C≡CH), 2.02, 1.68 (m, 2 H, $C_\beta CH_2$), 1.29, 1.26 (s, 6 H, $Me_2C_6H_3$), 1.22 (t, $^3J_{H,H}$ = 7 Hz, 3 H, $C_\gamma CH_2CH_3$), 0.43 (t, $^3J_{H,H}$ = 7 Hz, 3 H, $C_\beta CH_2CH_3$) ppm.

**X-ray Crystallography**: The X-ray intensity data for **2a** and **5h** were collected at room temperature with a Bruker AXS SMART 2000 CCD diffractometer using Mo-$K_\alpha$ radiation. Intensity data were measured over full diffraction spheres using 0.3°-wide ω-scans and a crystal-to-detector distance of 5.2 cm. Cell dimensions and orientation matrixes were initially determined from least-squares refinements on reflections measured in three sets of 20 exposures collected in three different ω-regions and eventually refined against all reflections. The software SMART[15] was used for collecting frames of data, indexing reflections and determining the lattice parameters. The collected frames were then processed for integration by the software SAINT and empirical absorption corrections were applied with SADABS.[16] The structure was solved by direct methods and refined by full-matrix least squares based on all data using $F^2$.[17] Crystal data are listed in Table 3. Non-H atoms were refined anisotropically, unless otherwise stated; H atoms were placed in calculated positions and treated isotropically using the 1.2-fold $U_{iso}$ value of the parent atoms, except methyl protons, which were assigned the 1.5-fold $U_{iso}$ value of the parent C atoms. One Cp ligand in both **2a** and **5h** is disordered. Disordered atomic positions were split and refined isotropically using similar distance and similar *U* restraints and one occupancy parameter per disordered group. CCDC-626314 (**2a**) and -626315 (**5h**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 3. Crystal data and experimental details for **2a** and **5h**.

| Complex | **2a** | **5h** |
|---|---|---|
| Empirical formula | $C_{35}H_{35}Fe_2NO_2$ | $C_{29}H_{31}Fe_2NO_2$ |
| Formula mass | 613.34 | 537.25 |
| λ [Å] | 0.71073 | 0.71073 |
| Crystal system | monoclinic | triclinic |
| Space group | $P2_1/c$ | $P\bar{1}$ |
| *a* [Å] | 14.2068(6) | 9.2783(19) |
| *b* [Å] | 9.1543(4) | 11.275(2) |
| *c* [Å] | 22.3490(10) | 12.226(2) |
| α [°] | 90 | 95.73(3) |
| β [°] | 94.0690(10) | 100.61(3) |
| γ [°] | 90 | 92.50(3) |
| *V* [Å$^3$] | 2899.2(2) | 1248.3(4) |
| *Z* | 4 | 2 |
| $D_c$ [g cm$^{-3}$] | 1.405 | 1.429 |
| μ [mm$^{-1}$] | 1.033 | 1.188 |
| *F*(000) | 1280 | 560 |
| Crystal size [mm] | 0.21 × 0.18 × 0.12 | 0.24 × 0.21 × 0.13 |
| θ limits [°] | 1.44–24.11 | 1.70–26.37 |
| Reflections collected | 22967 | 12447 |
| Independent reflections | 4629 ($R_{int}$ = 0.1321) | 5099 ($R_{int}$ = 0.0319) |
| Data/restraints/parameters | 4629/26/363 | 5099/27/309 |
| Goodness on fit on $F^2$ | 1.061 | 1.013 |
| $R_1$ [$I > 2\sigma(I)$] | 0.0696 | 0.0435 |
| $wR_2$ (all data) | 0.1865 | 0.1232 |
| Largest diff. peak/hole [e Å$^{-3}$] | 0.550/–1.053 | 0.526/–0.334 |

# Boron Complexes with Chelating Anilido-Imine Ligands: Synthesis, Structures and Luminescent Properties

Yi Ren,[a] Xiaoming Liu,[a] Wei Gao,[a] Hong Xia,[a] Ling Ye,[a] and Ying Mu*[a]

**Keywords:** Organoboron compounds / Schiff-base ligands / Luminescence

Three new boron complexes with anilido-imine ligands, *ortho*-$C_6H_4(NAr^1)(CH{=}NAr^2)BF_2$ [$Ar^1$ = 2,6-$Et_2C_6H_3$, $Ar^2$ = *p*-$MeC_6H_4$ (**3a**); $Ar^1$ = 2,6-*i*$Pr_2C_6H_3$, $Ar^2$ = *p*-$MeC_6H_4$ (**3b**); $Ar^1$ = 2,6-*i*$Pr_2C_6H_3$, $Ar^2$ = 2,6-$Me_2C_6H_3$ (**3c**)] were synthesized by the reaction of $BF_3(OEt_2)$ with the lithium salt of the corresponding ligands. All complexes were characterized by $^1H$, $^{11}B$, $^{13}C$ and $^{19}F$ NMR spectroscopy, elemental analyses and mass spectrometry. The molecular structures of complexes **3a**–**3c** were determined by X-ray crystallography. DSC analysis of **3a**–**3c** demonstrates their good thermal stability. Luminescent properties of the ligands and the complexes **3a**–**3c** in solution and the solid state were studied.

## Introduction

Luminescent tricoordinate and tetracoordinate boron complexes, due to their high thermal stability, adequate electron transport and excellent luminescent properties, have recently attracted a great deal of attention in the field of organic light-emitting devices (OLEDs) application.[1] Marder et al.[2] and Cornu et al.[3] focus their works on the three-coordinate organoboron compounds and π-conjugated systems incorporating closo-dodecaborate clusters, respectively, and study their optical properties. Wang and co-workers have explored some devices made from $BR_2q$ [R = Et, Ph, 2-naphthyl, q = 8-hydroxyquinolato][4] and boron complexes with modified 8-hydroxyquinoline ligands,[5] which not only are promising emitters, but also were found to possess excellent electron transport properties. Y. Wang's group has reported some boron complexes with phenol-pyridyl ligands and investigated their applications in OLEDs.[6] Meanwhile, many boron complexes with N,N-chelate ligands were reported.[7] Some of these complexes provide excellent luminescent properties, and cover almost the entire visible region when changing substituents on the ligands.[7a–7f] Recently, some luminescent complexes with Schiff-base ligands were synthesized and showed potential applications in organic optoelectronics.[8] However, luminescent boron complexes with Schiff-base ligands are rather rare. We recently reported a new class of aluminum complexes with Schiff base type chelating anilido-imine ligands showing good luminescent properties.[9] However, the aluminum complexes are usually vulnerable, to some extent, to air and moisture.[10] In contrast, the boron complexes are generally chemically and thermally stable, and thus more promising for practical applications.[7b,11] We have therefore synthesized a number of new boron complexes with anilido-imine ligands: *ortho*-$C_6H_4(NAr^1)(CH{=}NAr^2)BF_2$ [$Ar^1$ = 2,6-$Et_2C_6H_3$, $Ar^2$ = *p*-$MeC_6H_4$ (**3a**); $Ar^1$ = 2,6-*i*$Pr_2C_6H_3$, $Ar^2$ = *p*-$MeC_6H_4$ (**3b**); $Ar^1$ = 2,6-*i*$Pr_2C_6H_3$, $Ar^2$ = 2,6-$Me_2C_6H_3$ (**3c**)]. Herein, we report the syntheses, characterizations, and fluorescent properties of these complexes.

## Results and Discussion

### Synthesis of Ligands

Anilido-imine ligands *ortho*-$C_6H_4(NHAr^1)(CH{=}NAr^2)$ [$Ar^1$ = 2,6-$Et_2C_6H_3$, $Ar^2$ = *p*-$MeC_6H_4$ (**2a**); $Ar^1$ = 2,6-*i*$Pr_2C_6H_3$, $Ar^2$ = *p*-$MeC_6H_4$ (**2b**); $Ar^1$ = 2,6-*i*$Pr_2C_6H_3$, $Ar^2$ = 2,6-$Me_2C_6H_3$ (**2c**)] were synthesized in good yields by the reaction of *ortho*-$C_6H_4F(CH{=}NAr^2)$ (**1**) with corresponding $LiN(H)Ar^1$ (Scheme 1) according to the literature procedure.[9,12] Among the ligands, **2a** and **2b** are new compounds while **2c** has been reported previously.[9] The reaction was carried out in THF and the crude products were purified by crystallization from methanol. Compounds **2a** and **2b** were characterized by $^1H$ and $^{13}C$ NMR spectroscopy along with elemental analyses. The $^1H$ NMR spectra of both compounds exhibit resonances around $\delta$ 8.59 ppm for the CH protons in –CH=N– group, with the corresponding $^{13}C$ NMR resonances occurring about $\delta$ = 162.4 ppm. The NH resonances appear at characteristically low field ($\delta$ = 10.65, 10.60 ppm). The infrared absorption bands of the imine C=N stretching occur at 1615 and 1624 $cm^{-1}$. These data are similar to the corresponding values of **2c**.[9]

## Synthesis of Complexes

The boron difluoride complexes **3a**–**3c** were synthesized in reasonable yields (71–78%) by the reaction of $BF_3(OEt_2)$ with the lithium salt of corresponding ligand that was generated in situ by treating the free ligand with *n*BuLi in toluene at –78 °C (Scheme 2). These complexes are well soluble in dichloromethane, diethyl ether, toluene and THF, but less soluble in saturated hydrocarbons. All complexes **3a**–**3c** were characterized by elemental analyses, $^1$H, $^{13}$C, $^{19}$F and $^{11}$B NMR spectroscopy, and satisfactory analytic results were obtained. In the $^1$H NMR spectra of **3a**–**3c**, the resonances for the imino CH protons are at $\delta$ = 8.37, 8.37 and 8.12 ppm, respectively. While the resonances ($\delta$ = 159.9–163.9 ppm) for the imino C-atoms in the $^{13}$C NMR spectra shift to high field in comparison with the corresponding signals of the free ligands and the dichloride aluminum complexes.[13] The N–H signals of the free ligands disappear in the $^1$H NMR spectra of the complexes **3a**–**3c**, which is indicative of the formation of B–N bond in these complexes. The two methyl groups of the isopropyl units in complexes **3b** and **3c** are inequivalent, since the coordination of the anilido-imine ligands to the boron center causes rotation about the N–aryl bond to become slow on the NMR time scale.[14] In addition, in the $^1$H and $^{13}$C NMR spectra of these complexes **3a**–**3c**, the resonances for 2,6-substituents of the aromatic ring at the amido nitrogen are equal, which indicates these complexes all have Cs-symmetric structures in solution. In $^{11}$B NMR spectra, complexes **3a**–**3c** exhibit triplet at $\delta$ 4.534, 4.527 and 4.335 ppm respectively, due to coupling with two equivalent fluorine atoms. These resonances of complexes **3a**–**3c** are in lower field compared to those of 2,4-diethyl-4,4-difluoro-1,3,5,7,8-pentamethyl-4-bora-3a,4a-diaza-*s*-indacene ($\delta_B$ = 3.8)[15a] and *p*-Tol$_2$nacnacBF$_2$ ($\delta_B$ 2.0),[15b] while in substantially higher field in comparison with that of tricoordinate boron complex [(Tolylnacnac)BMe]$^+$[MeB(C$_6$F$_5$)$_3$]$^-$ ($\delta_B$ = 37.1).[15b] The narrow linewidth of $^{11}$B NMR spectra for all complexes is consistent with tetrahedral boron. Complexes **3a**–**3c** are air- and moisture-stable in solution and solid state. Differential scanning calorimetry (DSC) analysis of complexes **3a**–**3c** shows that complexes **3a**–**3c** melt at 159.8, 176.8 and 221.5 °C, respectively. These data are close to the melting points of similar tetra-coordinated boron complexes, 2-(4′-methylquinolinyl)-2-phenolato)BPh$_2$ (210 °C),[16a] and 1,6-bis(2-hydroxyphenyl)pyridylboron–2-methoxybenzene (227 °C).[16b] DSC analysis of **3a**–**3c** also exhibits their high thermal stability since they can be heated to 250 °C without decomposition. They also have good thermal stability in solution and can be heated in boiling toluene or ethanol for several hours without obvious decomposition.

## Crystal Structures

Molecular structures of the complexes **3a**–**3c** were determined by X-ray crystallographic analysis. The crystals of complexes **3a**–**3c** suitable for crystal structure analysis were obtained from *n*-hexane at 5 °C. The ORTEP drawings of molecular structures of **3a**, **3b** and **3c** are shown in Fig-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ures 1, 2, and 3, respectively. Selected bond lengths and angles for these complexes are given in Table 1. The X-ray analysis reveals that complexes **3a**–**3c** are four-coordinate and adopt a distorted tetrahedral geometry at the boron center. Complex **3a** belongs to the monoclinic space group $P2_1/n$, **3b**,**3c** to the triclinic space group $P\bar{1}$. In these complexes, the anilido-imine ligands chelate to the boron center to form the six-membered chelating rings that are nearly planar with the boron atom lying 0.0594 Å, 0.3127 Å, and 0.3020 Å out of the plane, respectively. The imino C=N bonds in these complexes retain their double bond character, being 1.307(2) Å, 1.302(2) Å, and 1.306(3) Å for **3a**, **3b**, and **3c**, respectively. The B–N (amido) distances (1.510(3) Å for **3a**, 1.521(3) Å for **3b**, 1.531(3) Å for **3c**) are shorter than the B–N (imine) distances (1.564(3) Å for **3a**, 1.580(2) Å for **3b**, 1.581(3) Å for **3c**) which is consistent with the fact that the B–N (amido) bond is a covalent bond while the B–N (imine) bond is a coordination bond. The B–N (imine) distances are larger than those values (1.550(3) Å and 1.553(3) Å] previously reported for *p*-Tol$_2$nacnacBF$_2$,[15b] while the B–N (amido) distances are shorter than the values (1.740(4) Å] of 2,6-(NMe$_2$)$_2$C$_6$H$_3$BCl(Ph).[15c] The average B–F bond lengths of 1.382(9) Å in those boron complexes are close to those values of 2,2-difluoro-1,3,4,6-tetramethyl-3-aza-1-azonia-2-bora-4,6-cyclohexadiene (1.403(2) Å][17a] and 4,4-difluoro-1,3,5,7,9-pentamethyl-3a,4a-diaza-4-bora-*s*-indacene (1.394(3) Å].[17b,17c] The F–B–F bond angles (107.5(2)° for **3a**, 108.86(18)° for **3b**, 108.5(2)° for **3c**) of those complexes are similar, which are slightly larger than 107.1(2)° for 2,2-difluoro-1,3,4,6-tetramethyl-3-aza-1-azonia-2-bora-4,6-cyclohexadiene,[17a] but smaller than the ideal tetrahedral angles (109.49°). The dihedral angles between the six-membered chelating ring and the aromatic ring at the amido nitrogen are 87.00° for **3a**, 83.65° for **3b**, and 82.00° for **3c**, while the dihedral angles between the six-membered chelating ring and the aromatic ring at the imine nitrogen are 51.40°, 55.17° and 80.60° for **3a**, **3b** and **3c**, respectively.

### UV/Vis and Fluorescent Properties

Table 2 summarizes the UV/Vis and fluorescent properties of compounds **2a**–**2c** and **3a**–**3c** determined in both solution and the solid state. The free ligands **2a**–**2c** all display weak blue fluorescence with emission maxima of 448, 446 and 420 nm, respectively. UV/Vis absorptions of complexes **3a**–**3c** are displayed in Figure 4. The maximal absorptions of **3a**–**3c** ($\lambda_{abs}$ = 440, 440 and 429 nm) are close to those of their aluminum analogues ($\lambda_{abs}$ = 437, 436, 436, 447 nm).[13] The fluorescent spectra of complexes **3a**–**3c** are shown in Figure 5. Complexes **3a**–**3c** in solution all give a broad emission band (bandwidth at half-height: 64, 61, 69 nm) with $\lambda_{max}$ = 511, 512 and 491 nm, respectively. The quantum yields of these complexes are relatively high in solution. The emission energies of these complexes are significantly red-shifted in comparison with their free ligands. As previous reported,[9,13] the observed luminescence of these complexes could be attributed to π*–π transition of their conjugated chelating anilido-imine ligands. The role of the coordination of the ligand to the boron atom in the luminescence of **3a**–**3c** should be twofold as pointed out in literatures for coordination complexes.[18] The formation of the B–N bond via the donation of lone-pair of the N atom to the B atom lowers the energy gap between π* and π of the ligand, and the chelating ring makes the ligand more rigid, which can reduce the loss of energy via vibrational motions and increase the emission efficiency. The emission maxima of complexes **3a** and **3b** are close to each other, while the emission maximum of **3c** is blue-shifted for about 20 nm compared to the ones of **3a** and **3b**. Such a result might be attributed to the differences in the number and size of the *ortho*-substituents on the rotatable aryl rings of their ligands that could affect the dihedral angles between the six-membered chelating ring and the aromatic ring at the imine nitrogen and thus the conjugated extent of these complexes.[5,19a,19b] In addition, the lower basicity and electron density of the anilido may also be responsible for the emission red shift in **3a** and **3b**.[19c] Compared to its aluminum analogue, [*ortho*-$C_6H_4N(C_6H_3i Pr_2$-2,6)-(CH=$NC_6H_3Me_2$-2,6)$AlCl_2$] ($\lambda_{max}$ = 510),[13] the emission maximum of complex **3c** is blue-shifted by 19 nm in hexane. The emission energies of complexes **3a**–**3c** in solution are close to or slightly higher than those of related boron compounds, 4,4-difluoro-8-(4-hydroxyphenyl)-4-bora-3a,4a-diaza-*s*-indacene ($\lambda_{abs}$ = 518 nm)[20a] and 2,4-diethyl-4-fluoro-1,3,5,7,8-pentamethyl-4-phenyl-4-bora-3a,4a-diaza-*s*-indacene ($\lambda_{abs}$ = 536 nm).[20b] All complexes **3a**–**3c** exhibit bright

fluorescence in the solid state when irradiated with an adequate excitation wavelength. The emission spectra of these complexes in the solid state are shown in Figure 6. Complexes **3a**, **3b**, and **3c** each has a relatively narrow emission band (bandwidth at half-height: 55, 75, 74 nm) with $\lambda_{max}$ = 527, 518 and 519 nm, respectively. The emission maxima of these complexes in the solid state are red-shifted compared to their corresponding emission maxima in solution. Red shifting of emission maximum can be normally observed for most fluorescent compounds in the solid state due probably to π-π staking of aromatic rings in the molecules.

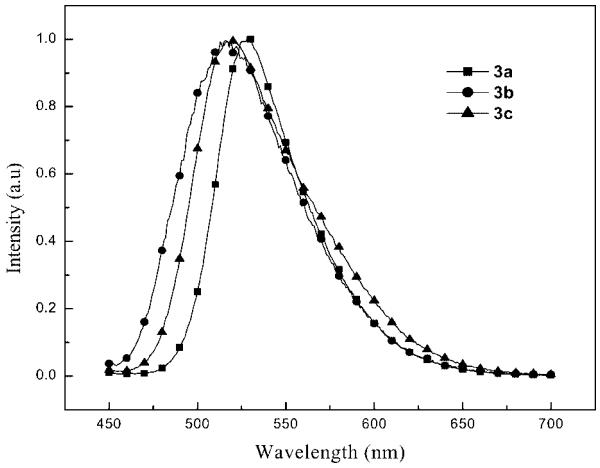

Figure 6. Emission spectra of complexes **3a**–**3c** in the solid state.

## Experimental Section

**General:** All reactions were performed using standard Schlenk techniques in an atmosphere of high-purity nitrogen or glove-box techniques. Toluene, hexane, THF, and diethyl ether were dried by reflux over sodium and benzophenone and distilled under nitrogen prior to use. $C_6D_6$ was dried with activated 4-Å molecular sieves and vacuum-transferred to a sodium-mirrored air-free flask. $CDCl_3$ was dried with $CaH_2$ for 48 h and vacuum-transferred to an air-free flask. $BF_3(OEt_2)$ and *n*BuLi were purchased from Aldrich and used as received. The pre-ligands and the ligands were synthesized according to literature procedures.[9,12] $^1H$ and $^{13}C$ NMR spectra were measured using a Bruker AVANCE-500 NMR spectrometer. $^{11}B$ NMR spectra were measured using a Bruker AVANCE-500 NMR spectrometer at 160 MHz with $BF_3(OEt_2)$ as external reference (positive values downfield).$^{19}F$ NMR spectra were measured using a Bruker AVANCE-500 NMR spectrometer at 376.27 MHz with $CFCl_3$ as external reference (positive values downfield). The elemental analysis was performed with a Perkin–Elmer 2400 microanalyzer. UV/Vis absorption spectra were recorded on a PE UV-lambdazo spectrophotometer. Fluorescence measurements were carried out on a Shimadzu RF-5301PC. The melting points were determined on a Fisher–Johns melting point apparatus. Differential scanning calorimetric measurements were performed on a NETZSCH DSC204 instrument.

***ortho*-$C_6H_4NH(C_6H_3Et_2$-2,6)(CH=$NC_6H_4$Me-*p*) (2a):** A solution of *n*BuLi (25.29 mL, 30.35 mmol) in hexanes was added to a solution of 2,6-diethylaniline (5.0 mL, 30.35 mmol) in THF (20 mL) at –78 °C. The reaction mixture was warmed to room temperature and stirred overnight. The resulting solution of LiNHAr was transferred into a solution of *ortho*-$C_6H_4F(CH{=}NC_6H_4Me$-*p*) (6.47 g, 30.35 mmol) in THF (20 mL) at 25 °C. After stirring for 24 h, the reaction was quenched with $H_2O$ (20 mL), the mixture was extracted with *n*-hexane, and the organic phase evaporated to dryness in vacuo to give the crude product as yellow solid. Pure product (7.79 g, 75%) was obtained as yellow crystals by recrystallization from ethanol at –20 °C. $C_{24}H_{26}N_2$ (342.48): calcd. C 84.17, H 7.65, N 8.18; found C 84.12, H 7.67, N 8.21%. $^1H$ NMR (500 MHz, $CDCl_3$, 293 K): $\delta$ = 1.09 (t, 6 H, $CH_2CH_3$), 2.30 (s, 3 H, $CH_3$), 2.47 (q, 2 H, $CH_2CH_3$), 2.57 (q, 2 H, $CH_2CH_3$), 6.18 (d, 1 H, Ph-*H*), 6.62 (t, 1 H, Ph-*H*), 7.03–7.34 (m, 9 H, Ph-*H*), 8.59 (s, 1 H, C*H*=NAr) 10.65 (s, 1 H, N*H*) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 293 K): $\delta$ = 15.1 ($CH_3$), 21.0 ($CH_2CH_3$), 25.1 ($CH_2CH_3$), 76.8, 77.1, 77.3, 111.9, 115.5, 117.1, 120.9, 126.8, 127.0, 127.6, 129.9, 132.0, 134.6, 142.9, 149.0, 149.1, 162.4 (*C*H=NAr) ppm.

***ortho*-$C_6H_4NH(C_6H_3iPr_2$-2,6)(CH=$NC_6H_3C_6H_4$Me-*p*) (2b):** A solution of *n*BuLi (22.1 mL, 26.5 mmol) in hexanes was added to a solution of 2,6-diisopropylaniline (5.0 mL, 26.5 mmol) in THF (20 mL) at –78 °C. The reaction mixture was warmed to room temperature and stirred overnight. The resulting solution of LiNHAr was transferred into a solution of *ortho*-$C_6H_4F(CH{=}NC_6H_4Me$-*p*) (5.7 g, 26.5 mmol) in THF (20 mL) at 25 °C. After stirred for 24 h, the reaction was quenched with $H_2O$ (20 mL), the mixture was extracted with *n*-hexane and the organic phase evaporated to dryness in vacuo to give the crude product as yellow solid. Pure product (7.7 g, 78%) was obtained as yellow crystals by recrystallization from ethanol at –20 °C. $C_{26}H_{30}N_2$ (370.53): calcd.C 84.28, H 8.16, N 7.56; found C 84.31, H 8.11, N 7.58%. $^1H$ NMR (500 MHz, $CDCl_3$, 293 K): $\delta$ = 1.07 (d, 6 H, $CH(CH_3)_2$), 1.10 (d, 6 H, $CH(CH_3)_2$), 2.29 (s, 3 H, $CH_3$), 3.09 (sept, 2 H, $CH(CH_3)_2$), 6.18 (d, 1 H, Ph-*H*), 6.61 (t, 1 H, Ph-*H*), 7.02–7.33 (m, 9 H, Ph-*H*), 8.59 (s, 1 H, C*H*=NAr), 10.60 (s, 1 H, N*H*). $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 293 K): $\delta$ = 21.1 ($CH_3$), 22.9 ($CH(CH_3)_2$), 25.0 ($CH(CH_3)_2$), 28.6 ($CH(CH_3)_2$), 76.8, 77.1, 77.3, 112.1, 115.4, 116.9, 120.9, 123.8, 127.4, 129.8, 132.0, 134.5, 135.0, 135.5, 147.6, 149.0, 149.8, 162.4 (*C*H=NAr).

***ortho*-$C_6H_4N(C_6H_3Et_2$-2,6)(CH=$NC_6H_4$Me-*p*)$BF_2$ (3a):** 0.49 mL of an *n*BuLi solution (0.58 mmol) was added to the solution of the ligand **2a** *ortho*-$C_6H_4NH(C_6H_3Et_2$-2,6)(CH=$NC_6H_4$Me-*p*) (0.2 g, 0.58 mmol) in toluene with stirring at –78 °C. The mixture was warmed to room temperature and stirred overnight. The resulting mixture was added dropwise to a toluene suspension of $BF_3(OEt_2)$ (0.71 mL, 0.58 mmol) at –78 °C with stirring. The mixture was warmed to room temperature, then stirred overnight at 80 °C. The solvent was removed in vacuo. The 9 mL of hexane was added to the yellow solid residue. Insoluble material was removed by filtration through Celite. Yellow crystals (0.18 g, 78%) were obtained from *n*-hexane solution at 5 °C. $C_{24}H_{25}BF_2N_2$ (390.28): calcd. MS, *m*/*z*: 413.1 [(M – F)$^+$].

**PL Quantum Yield Measurements:** Room-temperature luminescence quantum yields were measured at a single excitation wavelength (360 nm) referenced to quinine sulfate in sulfuric acid aqueous solution ($\Phi$ = 0.546). The quantum yields were calculated using known procedures.[21] The excitation wavelength was 440, 440, and 429 nm for complexes **3a**, **3b** and **3c**, respectively.

**X-ray Structure Determinations of 3a, 3b and 3c:** Single crystals of **3a**, **3b** and **3c** suitable for X-ray structural analysis were obtained from *n*-hexane. Diffraction data were collected at 293 K with a Rigaku R-AXIS RAPID IP diffractometer equipped with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) for **3a**, **3b** and **3c**. Details of the crystal data, data collections, and structure refinements are summarized in Table 2 and Table 3. The structures were solved by direct methods[22] and refined by full-matrix least-squares on $F^2$. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in idealized position. All calculations were performed using the SHELXTL[23] crystallographic software packages.

CCCD-619766 (for **3a**), -619767 (for **3b**), and -619768 (for **3c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 3. Crystal data and structural refinements details for **3a**, **3b** and **3c**.

# Ligand-Exchange Processes on Solvated Lithium Cations: Acetonitrile and Hydrogen Cyanide[‡]

Ewa Pasgreta,[a] Ralph Puchta,[a,b] Achim Zahl,[a] and Rudi van Eldik*[a]

**Keywords:** Lithium / Acetonitrile / Hydrogen cyanide / Solvation / Exchange mechanism

Solutions of $LiClO_4$ in solvent mixtures of acetonitrile and water, or acetonitrile and nitromethane, were studied by $^7Li$ NMR spectroscopy. Measured chemical shifts indicate that the $Li^+$ cation is coordinated by four acetonitrile molecules. In the binary water/acetonitrile mixture, water coordinates more strongly to $Li^+$ than acetonitrile such that addition of water immediately leads to the formation of $[Li(H_2O)_4]^+$. The solvent-exchange mechanism for $[Li(L)_4]^+$ (L = $CH_3CN$ and HCN) was studied by using DFT calculations (RB3LYP/6-311+G**). This process was found to follow a limiting associative mechanism involving the formation of relatively stable five-coordinate intermediates. The suggested mechanisms are discussed with reference to available experimental and theoretical data.

## Introduction

The ongoing discussion on sustainability in chemistry[1] is partly focused on the role of solvents and especially on alternatives for common organic solvents. Such alternatives could be, for example, ionic liquids[2–5] or supercritical carbon dioxide.[6–10] A detailed knowledge of the properties and structural motifs, as well as of elementary reactions such as solvent-exchange processes in different solvents, is an important prerequisite for selecting, optimizing and tailoring the ideal solvent.

Acetonitrile is a common solvent in chemical laboratories, for example it is used in reactions[11,12] or in the investigation of complexation phenomena and complex-formation constants.[13–18] Use of its hydrogen derivative HCN is mostly prevented by its high toxicity and its boiling point of 25 °C. Experimental studies dating back to the middle of the 20th century show that HCN is a water-like solvent that is well suited for dissolving organic and inorganic compounds. Salts such as LiCl, LiBr or $LiClO_4$ are highly soluble in Hydrogen cyanide, most likely because of its high dielectric constant of 123 (at 15.6 °C).[19–23] However, HCN serves as an excellent simplified model of $CH_3CN$ and thus can be used instead in quantum chemical studies of $CH_3CN$.

The behaviour of pure acetonitrile and acetonitrile mixtures was studied experimentally[24,25] and computationally.[24,26] Since an ion in solution strongly disturbs the local solvent structure,[27] a detailed knowledge of the environment is an essential prerequisite for understanding reactions in the neighbourhood of the ion. Several studies investigated solvated $Li^+$ ions in acetonitrile both experimentally with various spectroscopic techniques[28–31] and computationally with different classical molecular dynamics (MD) methods[32–35] and Monte Carlo simulations of solvated alkali and halide ions in $CH_3CN$.[36] Over the past decade, DFT and ab initio calculations on $[Li(CH_3CN)_n]^+$ and related clusters were also performed by different groups.[30,37–40]

There has been a special interest in the properties of Li salts, such as conductivity,[41–44] transport abililty,[45–47] viscosity,[48] and osmotic behaviour[49], in solvents and solvent mixtures because of the use of $Li^+$ ions in batteries of high energy density.[50] Such studies are not restricted to liquid systems. $Li^+$ mobility in potential solid electrolytes was also investigated intensively both experimentally and theoretically.[51–53]

To the best of our knowledge, however, investigations of solvent-exchange reactions in acetonitrile and acetonitrile/water mixtures or in HCN and HCN/water mixtures have not been performed. Whereas experimental investigations study reactions under real conditions in a whole ensemble of molecules,[54,55] quantum chemical calculations focus on one molecule and a small number of solvent molecules, for example, the first solvent shell.[56–60] This approach enables a more detailed mechanistic insight.

In this contribution, we extend our combined quantum chemical and experimental investigations on ligand coordination and ligand exchange on $Li^+$ in acetonitrile and

HCN, as well as in $CH_3CN/H_2O$ and $HCN/H_2O$ mixtures. The calculations mainly focus on HCN for two reasons: (1) to gain a deeper insight into this solvent, which is not used often, and (2) HCN is a good working model for $CH_3$–CN as its use prevents well known problems associated with rotating $CH_3$ groups and to facilitate studies with solvent models.

## Results and Discussion

### Coordination Number of $Li^+$

The structures of $Li^+$–acetonitrile solvates are in general less well known than the structures of $Li^+$–water solvates. The $Li^+$ ion was found to be four coordinate by NMR spectroscopic studies in which acetonitrile was gradually replaced by water when water was added to an acetonitrile solution of $LiClO_4$ (1.6 M),[61] and on the basis of IR spectroscopic intensities measured for the acetonitrile CN stretching vibrations.[62,63] Even compounds with mixed coordination of a counterion and acetonitrile were reported to be four coordinate, namely $[Li(CH_3CN)_3Br]$ formed from 0.58 M LiBr in $CH_3CN$.[64] Extensive concentration-dependent ion-pairing was also found for weak coordinating counterions, such as in $LiBF_4$[30] and $LiClO_4$,[62] by studying the CN vibration.[65] These findings for the coordination number are in good agreement with published X-ray structures.[66–68]

However, Sajeevkumar and Singh found the average coordination number to be 4.7,[69] whereas Megyes et al. found up to six acetonitrile molecules surrounding the $Li^+$ ion in the gas phase by means of mass spectrometry.[70] Therefore, we reinvestigated the maximum coordination number of $[Li(CH_3CN)_n]^+$ both experimentally and computationally, and purely quantum chemically for $[Li(NCH)_n]^+$.

In order to determine the coordination number of $Li^+$ by using NMR techniques, the concentration of $LiClO_4$ was kept constant and the $CH_3CN$ concentration was varied over a wide range. To use this method, the cation must be dissolved in solvent mixtures consisting of one coordinating and one non-coordinating component. The measured chemical shifts are then plotted against the mol ratio of cation to coordinating solvent. When such a plot shows a marked discontinuity, the appropriate solvent/cation ratio can be taken as the coordination number of the cation. There are, however, a few conditions that must be obeyed. An inert non-coordinating solvent must be available that will dissolve all solution components, a measurable parameter must exist that is a function of the solvent composition, and the formation constant of the solvate must be sufficiently large so that a limiting value of the parameter can be reached. In this case, the selected parameter was the $Li^+$ NMR signal; its position in the NMR spectrum depends on the composition of the coordination sphere of the studied ion. Typical alkali metal salts are not appreciably soluble in truly inert solvents. Therefore, it is necessary to select a solvent that minimally interacts with $CH_3CN$ and the alkali metal ion.[71]

Nitromethane (Gutmann donor number $DN$ = 2.7)[72] represents a good compromise for the various requirements. It appreciably dissolves alkali metal salts and its interaction with $Li^+$ is much weaker than that between $CH_3CN$ (Gutmann donor number $DN$ = 14.1) and a metal cation. The mol ratio data obtained confirms the "inertness" of this solvent and indicates that it is in fact sufficiently unreactive for the purpose of this study.

Figure 1 and Figure 2 illustrate the results obtained from the $^7Li$ NMR spectroscopic study. Figure 2 shows a plot of the chemical shift as a function of the mol ratio of the $CH_3CN/LiClO_4$ system; the $LiClO_4$ concentration was kept at 0.05 M in nitromethane. A clear break can be observed at a $[CH_3CN]/[Li^+]$ ratio of 4:1, which indicates that $Li^+$ is coordinated by 4 acetonitrile molecules under these conditions. It appears, therefore, that NMR studies of alkali metal ion coordination can be carried out even in solvents that are not totally inert toward the reacting metal ion provided that the interaction between the metal ion and the stronger donor solvent dominates.

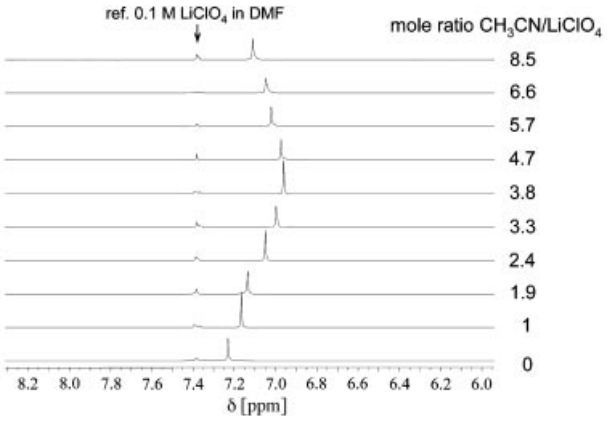

Figure 1. $^7Li$ NMR spectra recorded as a function of $CH_3CN/LiClO_4$ mol ratio (0.05 M $LiClO_4$ in the $CH_3CN$/nitromethane mixture) at 25 °C.

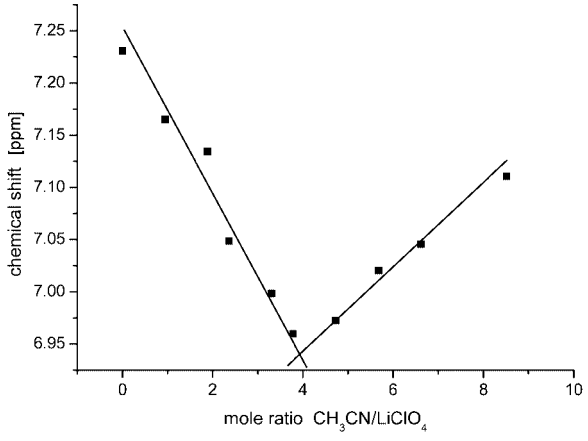

Figure 2. $^7Li$ NMR shift measured for 0.05 M $LiClO_4$ in $CH_3CN$/nitromethane solvent mixtures.

### Selective Coordination of $Li^+$

Selective coordination occurs when the solvate prefers one of the solvent components over the other. The exchange of ions between different environments is usually rapid with respect to the NMR time scale, and this results in only one resonance signal at an average frequency determined by the magnetic shielding and lifetime of the nucleus in each of the sites. Variation of parameters such as concentration, counterions and solvent produces changes in the relative proportion and type of environment, which may be reflected by the NMR spectra in terms of chemical shift, line shape and/or line width of the observed resonance.[73]

We performed the measurements by keeping the concentration of $LiClO_4$ constant (0.1 M) and by changing the composition of the $H_2O/CH_3CN$ mixtures. The concentration of $H_2O$ (molar ratio) was increased from 0 to 100%. For each sample, the $^7Li$ NMR spectrum was recorded. The chemical shift changed as the amount of water in the sample was varied.

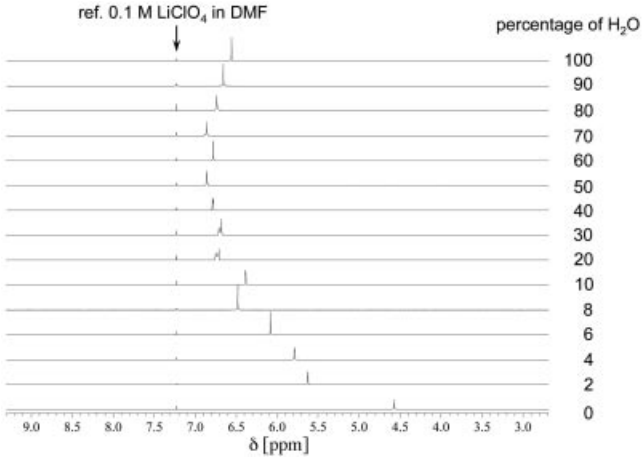

Figure 3. $^7Li$ NMR spectra of 0.1 M $LiClO_4$ in $H_2O/CH_3CN$ mixtures.

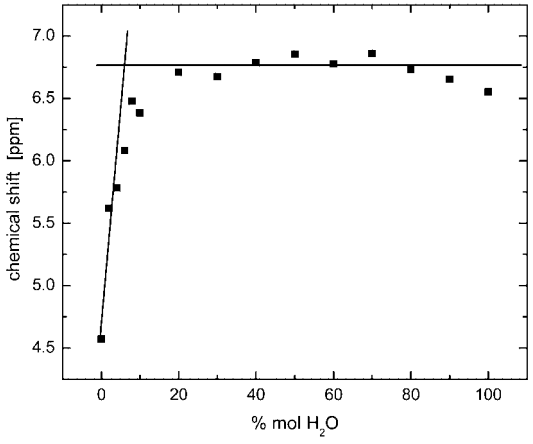

Figure 4. $^7Li$ NMR shift for 0.1 M $LiClO_4$ as a function of the $H_2O/CH_3CN$ composition.

It was observed that the position of the NMR signal moved significantly (from 4.5 to 6.4 ppm) even when the amount of added water was very small (only 10% $H_2O$). The chemical shift value then increased slightly and remained almost constant when the amount of water was changed from 10 to 100% (see Figure 3 and Figure 4). This observation confirms that water coordinates much more strongly to the $Li^+$ ion than acetonitrile. Thus, addition of water immediately leads to the formation of the aquated cation.

### Ligand Exchange on Solvated $Li^+$

It was not possible to follow the exchange process for $CH_3CN$ on $Li^+$ experimentally. As reported before, the rate constant of water exchange on $Li^+$ is extremely fast (approximately $10^9$ $s^{-1}$ at 25 °C) although water is a relatively strong donor (*DN* = 33.0). As $CH_3CN$ coordinates much more weakly (*DN* = 14.1), its exchange on $Li^+$ is even faster, which makes it impossible to study experimentally. Therefore, theoretical calculations are essential and may be very useful in such investigations.

### Quantum Chemical Calculations

We studied the ligand exchange process in more detail and provide computational evidence for a limiting associative exchange mechanism on the HCN- and $CH_3CN$-solvated lithium cation. As mentioned before, HCN was employed as a simplified working model to perform quantum chemical calculations on $CH_3CN$. Our calculations corroborated the results of the experimental study in solution (vide supra)[29] and in the solid state,[68] which showed that the first coordination sphere around $Li^+$ consists of four tightly bound $CH_3CN$ and HCN molecules. The five-coordinate intermediates are 3.7 kcal/mol and 4.6 kcal/mol [3.2 kcal/mol B3LYP(IPCM: acetonitrile)/6-311+G**//B3LYP/6-311+G**] higher in energy for acetonitrile and HCN, respectively. The computed Li–N distance for $Li(NCH)_4$ and $Li(NCCH_3)_4$ are 2.06 and 2.05 Å, respectively. Additional solvent molecules do not coordinate to $Li^+$, but instead form a second coordination sphere, mainly through electrostatic interactions. The gas-phase binding energy for the fifth acetonitrile molecule in $[Li(NCCH_3)_4(NCCH_3)]^+$ is 6.1 kcal/mol, with a Li–N distance of 6.65 Å. The fifth molecule is stabilized only by a weak $H_{CH_3}$–NC–$CH_3$ interaction of 2.32 Å. The fifth HCN molecule is bound through a weak hydrogen bond (2.04 Å) in the second coordination sphere. This bond stabilizes the system by 8.9 kcal/mol (see Figure 5).

The HCN exchange itself proceeds through a trigonal-bipyramidal intermediate $[Li(NCH)_5]^+$ that is reached via a late transition state. The entering HCN molecule approaches the lithium cation directly and pushes three coordinated solvent molecules away toward the equatorial positions. In line with the experimental observation of a very fast exchange process (vide supra), the computed activation

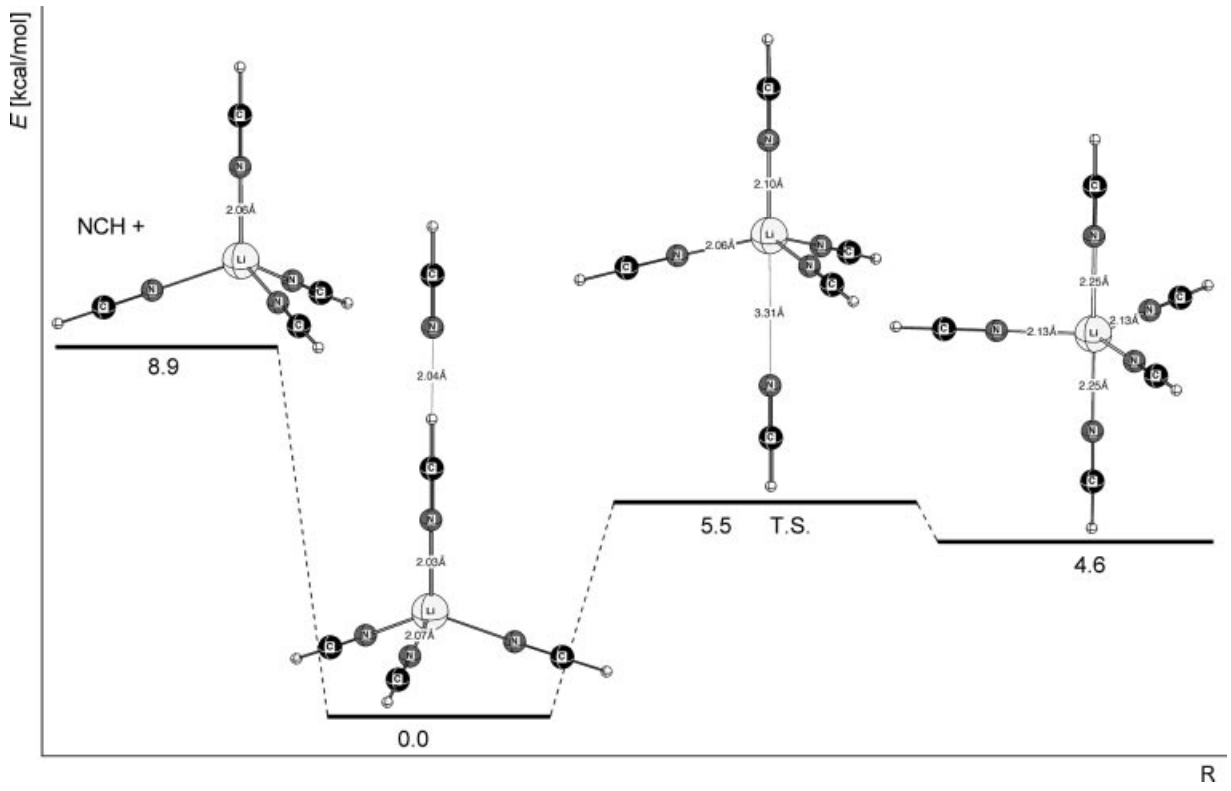

Figure 5. Energy profile (RB3LYP/6-311+G**) for the exchange of HCN on $[Li(NCH)_4]^+$.

barrier is only 5.5 kcal/mol, while the five-coordinate intermediate is 4.6 kcal/mol less stable than the precursor complex. The very low barrier toward dissociation of only 0.9 kcal/mol means that the five-coordinate intermediate is very short-lived. The evaluation of the energy at the MP2(full)/6-311+G**//B3LYP/6-311+G** and B3LYP/6-311+G**//B3LYP/6-311+G** levels shows only minor differences in the computed energies, except in those for the intermediate ($[Li(L)_4(L)]^+$) (see Table 1). We attribute this to an incorrectly balanced description of the metal–ligand and hydrogen-bond strengths by DFT methods as observed earlier by Rotzinger and others in studies on water exchange reactions.[74,75] Inclusion of solvent effects at the B3LYP(CPCM)/6-311+G**//B3LYP/6-311+G** and B3LYP(IPCM)/6-311+G**//B3LYP/6-311+G** level clearly favours a four-coordinate structure with NCH in the second coordination sphere or uncoordinated. Therefore, the transition state is also stabilized since the entering NCH molecule can best be addressed as uncoordinated (see Table 1 and Figure 5). Unfortunately, the transition state is modelled as being too stable in the B3LYP(IPCM)/6-311+G**//B3LYP/6-311+G** approximation, irrespective of whether acetonitrile or water is used in the modelling by the IPCM formalism.

In trigonal-bipyramidal $[Li(NCH)_5]^+$, the axial Li–N distances are 0.11 Å longer than the equatorial distances, which may be taken as a clear indication that one of the axial ligands will be expelled. The energy profile for the exchange of acetonitrile on $[Li(NCCH_3)_4]^+$ shows the same topology, only the energy differences are somewhat smaller.

Table 1. Calculated relative energies (in kcal/mol) for the exchange of L at $[Li(L)_4]^+$ (L = HCN, $CH_3CN$).[a]

| L = HCN | $[Li(L)_4]^+ + L$ | $[Li(L)_4\cdots(L)]^+$ | TS | $[Li(L)_4(L)]^+$ |
|---|---|---|---|---|
| B3LYP | 8.9 | 0.0 | 5.5 | 4.6 |
| MP2(full) | 9.5 | 0.0 | 3.2 | 0.5 |
| IPCM | –2.8 | 0.0 | –2.6 | 3.2 |
| CPCM | –0.4 | 0.0 | 1.8 | 1.4 |
| L = $H_3CCN$ | | | | |
| B3LYP | 6.1 | 0.0 | 4.1 | 3.7 |

[a] B3LYP: B3LYP/6-311+G**//B3LYP/6-311+G**; MP2(full): MP2(full)/6-311+G**//B3LYP/6-311+G**; IPCM: B3LYP/(IPCM: acetonitrile)/6-311+G**//B3LYP/6-311+G**; CPCM: B3LYP/(CPCM: water)/6-311+G**//B3LYP/6-311+G**.

We attribute this difference to stabilization effects caused by the methyl group and to the absence of hydrogen bonding. A detailed investigation was prevented since a local minimum was not reached with $[Li(NCCH_3)_4(NCCH_3)]^+$ because of the rotation of the methyl groups, and the IPCM calculations show the well-documented problems in reaching an energy convergence.[4,76]

These findings fully corroborate the results expected for small ions coordinated by small ligands. The dissociation of a molecule of HCN from $[Li(NCH)_4]^+$ results in the intermediate $[Li(NCH)_3]^+$ with a $D_{3h}$ symmetry, which is 14.3 kcal/mol higher in energy and less favourable. In addition, there is no visible steric crowding, which is necessary for a dissociative mechanism. Interchange mechanisms are known for $Li^+$, e.g. in the case of ammonia exchange on

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2. Calculated energies for the subsequent reactions of $[Li(NCH)_4]^+$ with water.

| B3LYP(IPCM)/6-311+G**//B3LYP/6-311+G** [kcal/mol] | Gas phase | IPCM: acetonitrile | IPCM: water |
|---|---|---|---|
| $[Li(NCH)_4]^+ + H_2O \rightarrow [Li(H_2O)(NCH)_3]^+ + NCH$ | –0.5 | +1.7 | +1.6 |
| $[Li(H_2O)(NCH)_3]^+ + H_2O \rightarrow [Li(H_2O)_2(NCH)_2]^+ + NCH$ | –0.5 | –1.4 | –1.6 |
| $[Li(H_2O)_2(NCH)_2]^+ + H_2O \rightarrow [Li(H_2O)_3(NCH)]^+ + NCH$ | –0.3 | –3.6 | –3.9 |
| $[Li(H_2O)_3(NCH)]^+ + H_2O \rightarrow [Li(H_2O)_4]^+ + NCH$ | +0.1 | –0.9 | –1.2 |
| $\Sigma$ | –1.3 | –4.2 | –5.1 |

$Li^+$,[77] but requires a five-coordinate transition state that would contradict the five-coordinate intermediate in our mechanism. Analogous arguments can also be applied for the second reaction under investigation.

Under actual experimental conditions water can never be excluded. Therefore, and because of the importance of solvent mixtures in technical and laboratory applications, we modelled the HCN/$H_2O$ exchange process exemplarily for $[Li(NCH)_4]^+$ to $[Li(NCH)_3(H_2O)]^+$ (Table 2). In this case, NCH can again be considered as a model for acetonitrile.

From experiments (vide supra) and from the Gutmann donor number for acetonitrile, which is only 50% of that for water, it is known that addition of water to solutions of lithium ions in acetonitrile leads to the formation of a water-coordinated $Li^+$ complex. This can be reproduced for HCN as a model by quantum chemical calculations (RB3LYP/6-311+G**).

By including solvent effects at the B3LYP(IPCM)/6-311+G**//B3LYP/6-311+G** level, the reaction energies are significantly increased, regardless of whether water or acetonitrile is selected as solvent.

We investigated the mechanism of the first reaction step in detail (see Figure 6). As shown before,[29,68] the first coordination sphere around $Li^+$ consists of four tightly bound acetonitrile molecules, here NCH molecules. An additional solvent molecule does not coordinate to the $Li^+$ ion; a second coordination sphere is formed in which water is bound by one linear hydrogen bond (1.88 Å). The gas-phase hydrogen-bond energy for the $H_2O$ molecule in $[Li(NCH)_4\cdots(OH_2)]^+$ is 9.5 kcal/mol. Again, the entering solvent, here water, approaches the $Li^+$ ion directly through a face of the $[Li(NCH)_4]^+$ tetrahedron and pushes three coordinated HCN molecules away. According to the movement of the water molecule in the transition state (7.1 kcal/mol higher in energy), one would expect an intermediate with three HCN molecules in equatorial positions and the fourth together with the $H_2O$ molecule in the axial positions. During the optimization steps, the structure rearranges to form an intermediate 3.7 kcal/mol lower in energy, with two HCN molecules in the axial positions and the $H_2O$ molecule together with the two remaining HCN molecules in the equatorial positions. The bonds for the axial molecules are

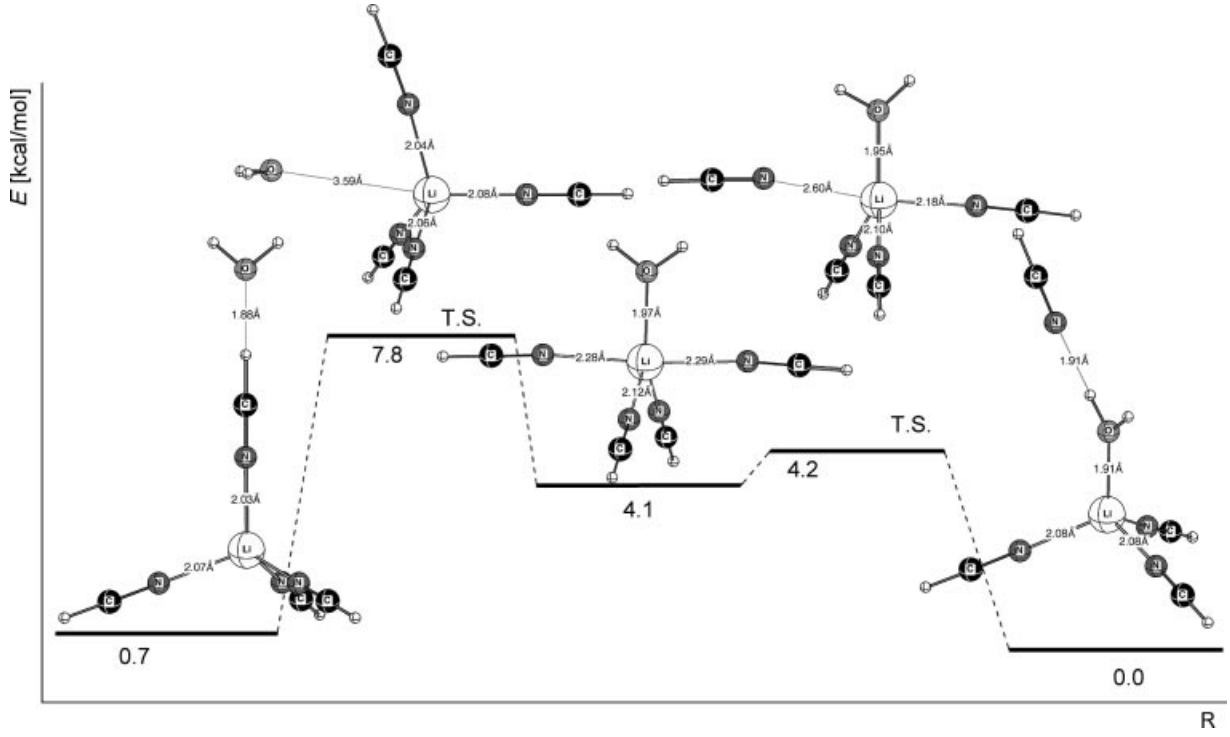

Figure 6. Energy profile (RB3LYP/6-311+G**) for the HCN/water exchange on $[Li(NCH)_4]^+$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.16 Å longer than those for the equatorial HCN ligands – it can be concluded that one axial ligand will be expelled to reach a four-coordinate product. The activation barrier for the release of an axial HCN molecule is rather low (0.1 kcal/mol), which means that the five-coordinate intermediate will be very short-lived. On the assumption that the expelled HCN molecule will form a hydrogen bond with the nearest hydrogen atom, one would expect the product $[Li(NCH)_3(H_2O)\cdots(NCH)]^+$ to form at an energy that is 4.2 kcal/mol lower than that of the second transition state. The energy required to destroy this hydrogen bond is 9.7 kcal/mol (Table 3).

Table 3. Calculated relative energies for the exchange of $H_2O$/NCH at $[Li(NCH)_4]^+$ (L = HCN; W = $H_2O$).[a]

| | $[Li(L)_4\cdots W]^+$ | TS | $[Li(L)_2\{W(L)_2\}]^+$ | TS | $[Li(L)_3(W)\cdots L]^+$ |
|---|---|---|---|---|---|
| B3LYP | 0.7 | 7.8 | 4.1 | 4.2 | 0.0 |
| MP2(full) | 0.9 | 6.1 | 0.6 | 1.2 | 0.0 |
| IPCM | 0.1 | 2.8 | 1.3 | 1.8 | 0.0 |
| CPCM | 0.1 | 5.6 | 1.0 | 1.5 | 0.0 |

[a] B3LYP: B3LYP/6-311+G**//B3LYP/6-311+G**; MP2(full): MP2(full)/6-311+G**//B3LYP/6-311+G**; IPCM: B3LYP/(IPCM: acetonitrile)/6-311+G**//B3LYP/6-311+G**; CPCM: B3LYP/(CPCM: water)/6-311+G**//B3LYP/6-311+G**.

Whereas MP2(full)/6-311+G**//B3LYP/6-311+G** calculations show typical discrepancies, the application of the IPCM- and CPCM-solvent models dramatically lowers the energy for the intermediate and the transition states. The barriers of 2.8 and 1.8 kcal/mol corroborate the experimental findings for an efficient formation of a water-coordinated $Li^+$ complex.

## Conclusions

It was confirmed both experimentally and theoretically that $Li^+$ is coordinated by four acetonitrile molecules. In the binary mixture of water and acetonitrile, water is coordinated more strongly to the $Li^+$ ion than acetonitrile. Thus, addition of water immediately leads to the formation of the aquated cation. Ligand exchange reactions on $Li^+$ most probably follow an associative mechanism as indicated by the formation of stable five-coordinate intermediates.

## Experimental Section

**General Procedures:** All transformations were carried out under a Ar or $N_2$ atmosphere by using standard Schlenk techniques, under Ar atmosphere in a glove box, or under vacuum. $LiClO_4$ (Aldrich, battery grade) was vacuum dried at 120 °C for 48 h and was then stored under dry nitrogen. Acetonitrile (Acros, extra dry, water < 10 ppm) was used as received. Nitromethane (Roth) was purified and dried by a previously reported method.[78] Solutions of $LiClO_4$ were prepared under dry nitrogen. For $^7$Li NMR spectroscopic studies, these solutions were sealed under a Ar atmosphere in 5-mm NMR tubes.

**$^7$Li NMR Spectroscopy:** Fourier transform $^7$Li NMR spectra were recorded at a frequency of 155 MHz on a Bruker Avance DRX 400WB spectrometer equipped with a superconducting BC-94/89 magnet system. Spinning 5-mm tubes were used with a 1-mm o.d. melting point capillary inserted coaxially in the spinning tube and filled with an external reference solution (usually 1 M $LiClO_4$ in DMF). The experiments were conducted at room temperature and at ambient pressure. For a typical kinetic run, 0.8 mL of solution was transferred under Ar to a Wilmad screw cap NMR tube equipped with a poly(tetrafluoroethylene) septum. All samples were prepared in the same way.

**Quantum Chemical Calculations:** All structures were fully optimized at the B3LYP/6-311+G**[79–82] level of theory and characterized as minima or transition-state structures by computation of vibrational frequencies (for minima, all frequencies are positive, NIMAG = 0; for transition-state structures, exactly one imaginary frequency is present, NIMAG = 1). Single-point energy calculations were performed at the MP2(full)/6-311+G**//B3LYP/6-311+G** level;[83] the influence of the bulk solvent was probed by using the IPCM[84] and CPCM[85,86] formalism and water or acetonitrile as solvent, i.e. B3LYP(IPCM)/6-311+G**//B3LYP/6-311+G** and B3LYP(CPCM)/6-311+G**//B3LYP/6-311+G**.[87] The Gaussian 03 suite of programs was used throughout.[88]

## Acknowledgments

This work was supported by the EC TMR network HPRN-CT-2000-19 ("Solvation Dynamics and Ionic Mobility in Conventional and Polymer Solvents") and the Deutsche Forschungsgemeinschaft (SFB 583 on Redox-active Metal Complexes). We would like to thank Michael Galle for preliminary calculations, Dr. Nico van Eikema Hommes for fruitful discussions, Prof. Tim Clark for hosting this work in the CCC, and the Regionales Rechenzentrum Erlangen (RRZE) for a generous allotment of computer time.

# Construction of 1D and 2D Copper(I) Coordination Polymers Assembled by $PhS(CH_2)_nSPh$ ($n$ = 1, 2) Dithioether Ligands: Surprising Effect of the Spacer Length on the Dimensionality, Cluster Nuclearity and the Fluorescence Properties of the Metal–Organic Framework

**Harmel N. Peindy,[a] Fabrice Guyon,*[a] Abderrahim Khatyr,[a] Michael Knorr,*[a] and Carsten Strohmann[b]**

*Dedicated to the memory of Prof. Liliane G. Hubert-Pfalzgraf*

**Keywords:** Dithioethers / Copper / Fluorescence / Coordination polymers / Metal–metal interactions

Treatment of CuI with $PhSCH_2SPh$ in MeCN solution affords, by a self-assembly reaction, the monodimensional metal–organic coordination polymer $[Cu_4I_4\{\mu\text{-}PhS_2CH_2SPh\}_2]_n$ (**1**), in which $Cu_4(\mu^3\text{-}I)_4$ cluster units are linked by the dithioether ligand in a 1D necklace structure. In contrast, the reaction of $PhSCH_2CH_2SPh$ with CuI results in the formation of the metallopolymer $[(CuI)_2\{\mu\text{-}PhS(CH_2)_2SPh\}_2]_n$ (**2**). The 2D network of **2** is built from dimeric $Cu_2I_2$ units which are connected by 1,2-bis(phenylthio)ethane bridging ligands. The solid-state luminescence spectrum of **1** exhibits a strong emission around 532 nm, whereas a weak emission centred at 413 nm is observed in the case of **2**.

## Introduction

It is well established that interaction of various nucleophiles (L) such as phosphanes, aniline and pyridyl type ligands with copper(I) halides often affords tetranuclear cubane-like $Cu_4X_4L_4$ clusters by a self-assembly process.[1] The interest in these polymetallic systems, in particular those incorporating the $Cu_4I_4$ unit, stems from their remarkable photophysical properties,.[2] Therefore these compounds have also been the object of theoretical studies.[3] Less common is the incorporation of the tetranuclear $Cu_4I_4$ core in a metal–organic network. The known examples of 1D to 3D coordination polymers including $Cu_4I_4$ cores were assembled by using an alkanedinitrile ligand,[4] difunctional pyridyl ligands,[5] dimethylsufide and diethylsulfide,[6a,6b] a functionalized dithioether ligand,[6c] polydentate thioether macrocycles,[7] and a triselenoether macrocycle.[8] The topology of extended networks based on flexible bidentate thioether ligands has been shown in the case of silver(I) to be very dependent on the spacer between the coordinated functions.[9] Our interest in the coordination chemistry of bi- and polydentate thioether ligands[10] has led us to investigate the reactivity of the flexible dithioether ligands $PhS–(CH_2)_n–SPh$ ($n$ = 1–2) towards CuI in order to evaluate the influence of the spacer on the resulting framework.

## Results and Discussion

The reaction of CuI with an equimolar amount of bis(phenylthio)methane in acetonitrile gave colourless crystals of the general formula $[Cu_4I_4\{\mu\text{-}PhSCH_2SPh\}_2]_n$ (**1**) (Scheme 1). Modification of the molar ratio, for example from 1:1 to 1:2, had no influence on the composition of the resulting material, and only compound **1** was formed. This observation is in contrast to the results reported by Sheldrick et al., who used an alkanedinitrile ligand (L) to obtain the 1:1 and 2:1 coordination polymers, $[(CuI)_2L_2]$ and $[(CuI)_4L_2]$, respectively, from the appropriate molar ratio of reactants.[4]

The crystal structure of **1**, viewed along the $c$ axis in Figure 1, consists of cubane-like $Cu_4I_4$ clusters linked by bridging dithioether ligands to form an infinite chain with Cu–S distances of 2.292(2) and 2.301(2) Å. The Cu–I bond lengths range from 2.6077(11) to 2.7704(11) Å. The Cu···Cu distances [2.6173(18)–2.7864(14) Å], comparable to the sum of the van der Waals radii (2.8 Å), lie in the range of distances reported for this interaction in other structurally

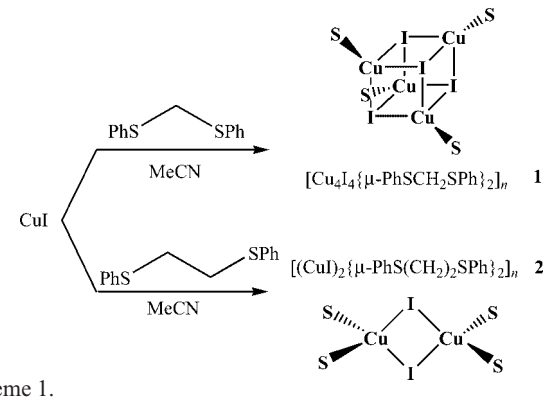

Scheme 1.

characterized $Cu_4I_4$ units. Two adjacent $Cu_4I_4$ cores are linked by two flexible dithioether ligands leading thus to the formation of a 1D necklace structure. Note also that the phenyl substituents adopt a parallel orientation with a short $C_{ipso}$–$C_{ipso}$ distance of 3.502 Å.

Despite the fact that the phenyl groups of neighbouring ribbons are somewhat interpenetrated, there are no close inter-ribbon interactions between the 1D chains of coordination polymer **1**, the separation between the midpoints of two adjacent $Cu_4I_4$ units being 11.64 Å (Figure 2).

The colourless crystals obtained from the reaction between equimolar amounts of CuI and 1,2 bis(phenylthio)-ethane in acetonitrile were identified by an X-ray study as the coordination polymer $[(CuI)_2\{\mu\text{-}PhS(CH_2)_2SPh\}_2]_n$ (**2**). This framework consists of centrosymmetric $Cu_2(\mu^2\text{-}I)_2$ rhomboid dimers, each connected to an adjacent unit via one $\mu^2$-bridging dithioether ligand (Figure 3). Each Cu atom is in a distorted tetrahedral environment, coordinated to the bridging iodido ligand and thioether group of two different ligands.

The 2D network resulting from this coordination mode includes centrosymmetric 24-membered metallomacrocycles constituted from four dithioether ligands, six Cu atoms and two iodido ligands (Figure 4). The average length of the two Cu–S bonds [2.3000(11) and 2.3855(10) Å] is somewhat greater than that in **1**. The Cu···Cu separation of 2.8058(11) Å is much greater than those observed in the above-mentioned $Cu_4I_4$ unit of **1**. A survey of the literature indicates that Cu···Cu separations vary in $[Cu(\mu^2\text{-}I)_2Cu]$ compounds. A dithioether-functionalized tetrathiafulvalene Cu complex was reported to have a relatively small Cu···Cu separation of 2.65 Å.[11a] Distances close to the value in **2** have been reported for $[Cu_2I_2[16]aneS_4]_n$ ([16]aneS$_4$ = 1,5,9,13-tetrathiacyclohexadecane) [2.8079(12) Å][7] and $[\{MeSi(CH_2SMe)_3\}CuI]_2$ [2.862(2) Å].[11b] A far longer

Cu···Cu interaction of 3.18 Å has been found in the two-dimensional sheet structure of polymeric $[Cu_2I_2(dtpcp)_2]$·thf (dtpcp = 2,11-dithia[3.3]paracyclophane).[11c–11d] Our discovery that a subtle steric modification of the dithioether has a major impact on the cluster nuclearity suggests that a small energetic difference exists between the centrosymmetric rhomboid $Cu_2I_2$ motif and the cubane-like $Cu_4I_4$ cluster. Note that treatment of $[Cu(MeCN)_4][BF_4]$ with 1,2-bis(phenylthio)ethane affords the mononuclear chelate complex $[Cu\{PhS(CH_2)_2SPh\}_2][BF_4]$, which has been reported to undergo facile ligand dissociation in solution.[12]

The solid-state emission spectra of **1** and **2** are shown in Figure 5. Upon excitation at 360 nm, a strong emission band was observed for the tetranuclear adduct, **1**, with a maximum at 532 nm. Emissions in a similar spectral range have been observed for nitrogen-substituted $Cu_4I_4L_4$ clusters and were attributed to an emission from a triplet cluster centred excited state ($^3$CC).[3b,13] In fact, this broad CC excited state emission is mixed in character with equal contributions of iodine to copper charge transfer (XMCT) and copper orbital centred (d→s) transitions.[3b] In contrast, the emission spectrum recorded for polymeric **2** containing the

dinuclear $Cu_2I_2$ unit exhibits, under similar experimental conditions, only a very weak emission centred at 413 nm with a shoulder at 438 nm. Although less studied than the tetranuclear systems, photophysical properties of some dinuclear $Cu_2X_2$ compounds have been reported in the literature, but are currently limited to those of *N*-heterocyclic ligands.[3c,14] The observation of a shoulder suggests a mixed emission with different contributions from the XMCT and Cu (d→s) transitions. To confirm this hypothesis, advanced photophysical studies and ab initio calculations are in progress. Solution measurements carried out in acetonitrile at room temperature show no luminescence for either **1** or **2**. This is probably due to a disassembly of the cluster units by this strongly coordinating solvent.

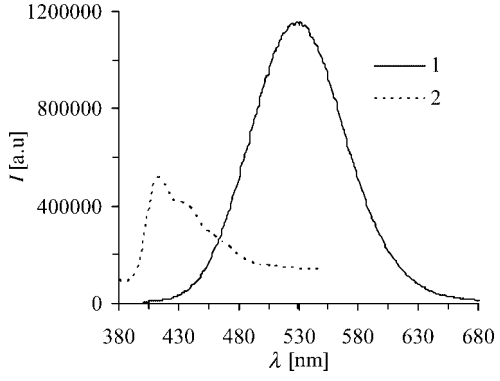

Figure 5. Corrected solid-state luminescence spectra recorded at room temperature for compounds **1** (solid) and **2** (dotted).[15]

## Conclusions

In summary, this work has shown that the dithioether ligand spacer length has a significant impact on the dimensionality of the resulting coordination polymer and the cluster nuclearity. It therefore determines, indirectly, the luminescence properties of the resulting metal–organic framework. We are currently varying the spacer length and nature of the copper salt systematically in order to establish a correlation between $PhS(CH_2)_nSPh$ and the motif of the framework. In addition, detailed photophysical studies and theoretical computations on these coordination polymers are underway.

## Experimental Section

$PhSCH_2SPh$ and $PhS(CH_2)_2SPh$ were prepared according to ref.[16] and ref.,[17] respectively. The solid-state emission spectra were recorded at room temperature with a Jobin–Yvon Fluorolog-3 spectrometer using a cylindrical 0.5 cm diameter quartz capillary with a scan speed of 1 nm/s. Intensity scales are presented in arbitrary units.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Preparation of 1 and 2**: To a suspension of CuI (191 mg, 1.0 mmol) in acetonitrile (10 mL) was added $PhSCH_2SPh$ (232 mg, 1.0 mmol). The mixture was heated at reflux for 15 min, then the solution was allowed to reach room temperature. After one day, colourless crystals of **1** formed. Yield 0.22 g, 72%. $C_{13}H_{12}Cu_2I_2S_2$ (613.23): calcd. C 25.46, H 1.97; found C 25.89, H 2.05. The reaction of CuI with $PhS(CH_2)_2SPh$ under similar conditions afforded compound **2**. Yield 0.33 g, 75%. $C_{14}H_{14}CuIS_2$ (436.81): calcd. C 38.49, H 3.23; found C 38.77, H 3.30.

**X-ray Crystallography:** Crystal data and experimental details are given in Table 1. Data were collected with a Stoe IPDS diffractometer at 173(2) K. The intensities were determined and corrected with the program INTEGRATE in IPDS.[18] An empirical absorption correction was employed using the FACEIT program in IPDS.[19] All structures were solved by applying direct and Fourier methods. For each structure, the non-hydrogen atoms were refined anisotropically. All hydrogen atoms were placed in geometrically calculated positions, and each was assigned a fixed isotropic displacement parameter based on a riding model. Refinement of the structures was carried out by full-matrix least-squares methods based on $F_o^2$. All calculations were performed with the WinGX crystallographic software package, using the programs SHELXS-90[20] and SHELXL-97.[21] CCDC-623106 and -623107 contain the supplementary data for **1** and **2**, respectively. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Optical Properties of β-$BaB_2O_4$ Network-Like Nanostructures

Qingrui Zhao,[a] Xi Zhu,[a] Xue Bai,[a] Haihua Fan,[b] and Yi Xie*[a]

**Keywords:** Nonlinear optics / Materials science / Sol–gel processes / Borates

Network-like nanostructures made from the nonlinear optical material beta barium metaborate (β-$BaB_2O_4$, β-BBO) have been successfully synthesized from a BBO gel precursor by a sol–gel method. The homogeneous BBO gel precursor is prepared by the hydrolysis and condensation of barium acetate, sorbitol, and boric acid in a mixture of polyethylene glycol (PEG200) and water. We have also demonstrated that the morphology of the synthesized β-$BaB_2O_4$ materials exerts a significant influence on the second harmonic generation (SHG) efficiency. Importantly, the preparation and second-order nonlinear optical studies with different shapes will offer great opportunities to explore the dependence of a material's second-order nonlinear optical properties on its morphology and is essential for the manufacture of potential nanoscale optoelectronic and nonlinear optical devices.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Much attention has been focused on nonlinear optical (NLO) materials during the past decades owing to their promising future applications in a number of fields such as laser medicine, optical communication, and signal processing.[1–5] Among the nonlinear optical bulk crystals, beta barium metaborate (β-$BaB_2O_4$, β-BBO) has shown good promise due to its large second harmonic generation (SHG) coefficients. SHG is a well-documented nonlinear optical effect that occurs when laser radiation strikes the surface of a material and a fraction of the incident light is frequency-doubled.[6,7] Generally, β-$BaB_2O_4$ single crystals are prepared by high temperature solution growth, such as the Czochralski technique[8] and Flux method.[9] Recent developments in the fast evolving field of nanoscience and nanotechnology, where size and shape are crucial for the optoelectronic properties of materials, especially the preparation of various β-BBO nanostructures such as nanowires, nanorods, and nanotubes and studies on their SHG performance on the nanoscale, are worthy of note.[10,11] Most recently, Hong et al. have reported that β-BBO nanoparticles with a diameter of 40 nm,[12] which show promising applications in the photoelectronic industry, can be prepared by coprecipitation followed by annealing at 700 °C. Despite this excellent progress in our ability to prepare β-BBO nanoparticles, no reports concerning the synthesis of one-dimensional (1D) nanostructures are available as yet, which therefore limits the shape-and-size dependent nonlinear optical responses of this functional material.

1D Nanostructures are an ideal system not only for understanding the functional phenomena in low-dimensional systems but also for developing new generation nanodevices with high performance. Furthermore, it is generally accepted that 1D nanostructures provide a good system to investigate the relationship between size and properties.[11] However, as far as NLO materials are concerned, including $KNbO_3$, $KH_2PO_4$ (KDP), α-$LiIO_3$, and β-BBO etc., there are few reports on the synthesis of 1D nanostructures. Only recently, for example, have Magrez et al. reported the growth of $KNbO_3$ nanowires by a hydrothermal route.[13] Similarly, Pribošič et al. have recently prepared $KNbO_3$ perovskite in the form of nanoneedles and nanoplatelets by crystallization of the amorphous gel.[14] Further research efforts are therefore needed to develop the fabrication of 1D NLO nanostructures from only $KNbO_3$ to other NLO materials such as β-BBO.

Inspired by these ideas, in this paper we report a simple, inexpensive, and efficient sol–gel approach as the first example of a morphology-controlled synthesis of β-$BaB_2O_4$ nanostructures with novel and interesting 1D morphologies. Interestingly, we show that the prepared β-$BaB_2O_4$ nanorods self-organize to form network-like structures. β-BBO nanoparticles can also be fabricated by varying the experimental parameters. In addition, the second-harmonic generation (SHG) efficiency of β-BBO network-like nanostructures and nanoparticles are described. The experimental results indicate that the β-BBO network-like nanostructures and nanoparticles have obvious differences in their SHG efficiency, which suggests that SHG is sensitive to the electronic properties of nanostructures of varying shape, size,

composition, and spatial organization.[15–18] Thus, the preparation and properties of β-BBO nanostructures provide a fine example of the dependence of a material's second-order nonlinear optical properties on its morphology and will find many interesting applications in the field of NLO devices.

## Results and Discussion

The crystal structure and phase composition of the as-prepared product were characterized by X-ray powder diffraction (XRD). Figure 1 (a) shows a typical XRD pattern of the as-prepared product. All the peaks can be readily indexed to the hexagonal phase of β-BBO (JCPDS file, no. 80-1489), with lattice constants of $a$ = 12.53 and $c$ = 12.72 Å (Figure 1, b). No characteristic peaks were observed for any impurities.

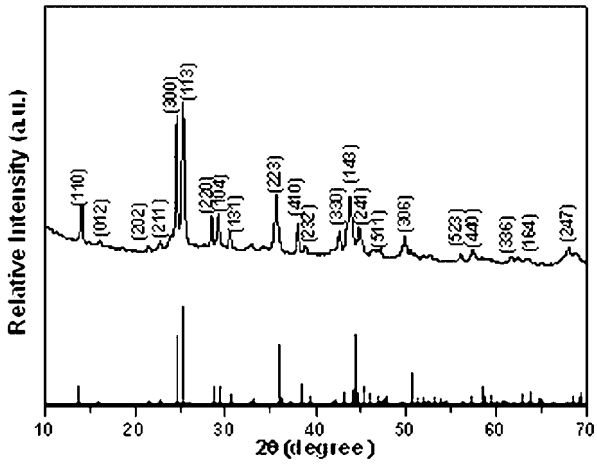

Figure 1. XRD pattern of network-like β-$BaB_2O_4$ nanostructures.

X-ray photoelectron spectra were also recorded to further characterize the product; the results are shown in Figure 2. High resolution spectra were recorded in the Ba 3d (Figure 2, a), B 1s (Figure 2, b), and O 1s (Figure 2, c) regions. The peak at 781.7 eV can be attributed to Ba $3d_{5/2}$, and the peak at 193.5 eV corresponds to B 1s of β-$BaB_2O_4$. The O 1s binding energy of 532.8 eV (Figure 2, c) indicates that the oxygen atoms are present as $O^{2-}$ species in the compounds. These results are in good agreement with the values for crystalline β-$BaB_2O_4$ found in the literature.[19]

Further evidence for the composition of the sample was obtained from the Raman and IR spectra. The β-BBO crystal belongs to the $C_{3v}^6$ space group and group theory analysis predicts the zone–center optical modes $A_1$ and E, both of which are Raman and IR active. Figure 3 (a) shows the Raman spectra of a typical sample. The peaks centered at 1539, 784, 632, and 597 $cm^{-1}$ can be assigned to $A_1$ [transversal-optical (TO) photon mode], and the peaks at 971, 661, 480, 384, and 703 $cm^{-1}$ can be assigned to E [longitudinal-optical (LO) photon mode].[20] We also measured the IR spectra of the sample (Figure 3b). The full-range IR spectra between 800 and 3000 $cm^{-1}$ shows broad absorptions in the range 900–1500 $cm^{-1}$ for the characteristic absorption of β-BBO. The absorption peaks at 1078 and 1243 $cm^{-1}$ are due to the B–O stretching modes in the $BO_3^{3-}$

unit, which is a component of the $(B_3O_6)^{3-}$ ring.[21] The bands observed at 962 and 1415 $cm^{-1}$ are B–O extra-ring stretching modes,[22] which is further evidence that high quality β-BBO nanocrystals have been obtained.

Figure 4 presents typical FESEM, TEM, and HRTEM images of the β-BBO network-like nanostructures obtained at different magnifications. The low magnification FESEM image in Figure 4 (a) shows the panoramic morphology of the products and the three-dimensional features and regularity of the network. Part b of Figure 4 is a TEM image, which reveals that the building blocks of the network-like nanostructures are uniform nanorods. These nanorods interlink in an orderly fashion that resembles a nanoweb. The average diameter of the nanorods is about 30 nm and their lengths range from 300 to 400 nm. Some building blocks of the network-like nanostructures are bundles of nanorods. For HRTEM imaging the samples were dispersed in ethanol and deposited on carbon-coated copper grids. The HRTEM image shown in parts c and d of Figure 4 show the high crystallinity of the product; defects such as twin structures, stacking faults, or dislocations are not seen in this image. This typical HRTEM image indicates that β-BBO nanostructures are single crystals that grow preferentially along the *a* [113] direction.

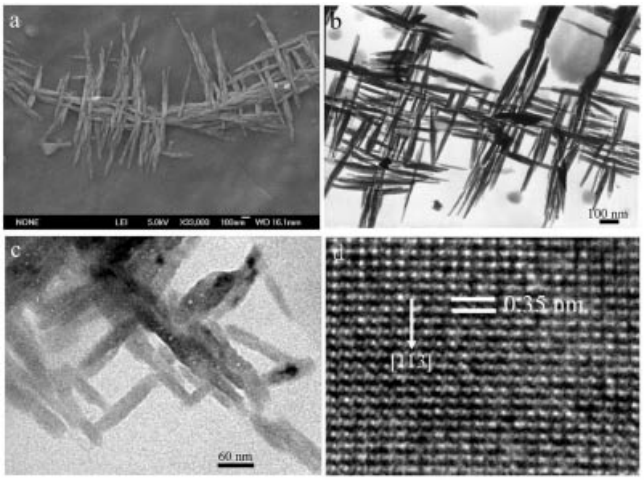

Figure 4. Electron microscopy images of the β-$BaB_2O_4$ network-like nanostructures: a) FESEM image; b) TEM image; c) high-magnification TEM image; d) HRTEM image along the [113] axis.

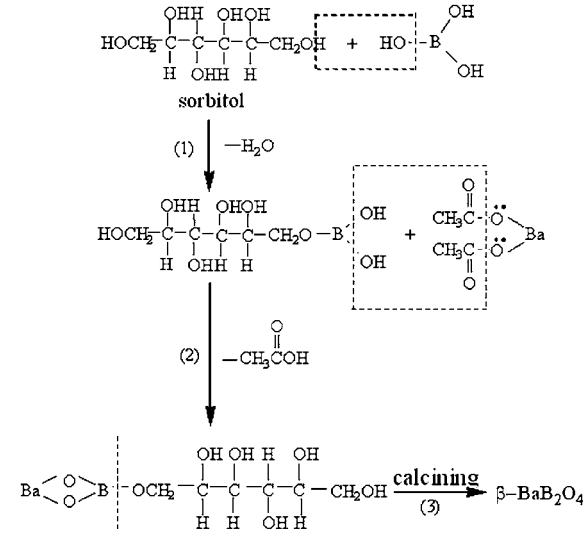
The sol–gel technique has been widely adopted to fabricate various nanostructures.[23] In our process, sorbitol coordinates to boric acid to form complexes by dehydration, which could prevent boric acid from volatilizing.[24] This complex solution then reacts with barium acetate, which loses its acetate to form the precursor.[25] When this mixture is heated continually it forms a homogeneous sol that then undergoes polycondensation and crosslinking to produce a gel. When calcined, this gel decomposes to form β-BBO nanostructures. The whole process is summarized in Scheme 1.

These β-BBO nanostructures are synthesized from a BBO gel precursor in a mixture of polyethylene glycol (PEG200) and water. The representative IR absorption



Scheme 1. The formation of β-$BaB_2O_4$.

spectra of the sol and gel shown in parts a and b of Figure 5 provide a direct way of investigating the sol–gel process. The bands at 2875, 1455, and 1351 $cm^{-1}$ in part a of Figure 5 are assigned to the vibration of the C–H bond of PEG,[21] whereas the absorption peaks at 831, 888, and 944 $cm^{-1}$ are due to the B–O stretching modes, which is a component of the $(B_3O_6)^{3-}$ ring.[21] The bands at 1100 and 1249 $cm^{-1}$ are due to the vibration of the C–O bond,[26] and the intense bands at 1657 $cm^{-1}$ are due to the presence of a carbonyl group.[27] Bands at around 1574, 1408, and 1069 $cm^{-1}$ are clearly observed in Figure 5 (b). The strong absorption band from the carbonyl group at 1657 $cm^{-1}$ has disappeared, which implies that acetic acid is released during the sol–gel process. The characteristic bands of PEG at 2875, 1455, and 1351 $cm^{-1}$ have also disappeared, which indicates that the PEG has been removed completely. The appearance of a band at 1574 $cm^{-1}$ indicates the presence of Ba–O. The absorption peak at 1069 $cm^{-1}$ is due to the B–O stretching modes in the $BO_3^{3-}$ unit and the band observed at 1408 $cm^{-1}$ can be attributed to B–O extra-ring stretching modes.[21] The characteristic peaks of B–O at 1408 and 1069 $cm^{-1}$ gradually shift to lower frequency and decrease in intensity, which suggests that polycondensation reactions of the $H_3BO_3$ precursor have occurred.

The cross-linking reagent PEG200 plays an important role in the formation of a gel precursor with high homogeneity, and hence a low degree of aggregation of the resulting nanostructures,[28] in this system, as can be seen from the IR spectra in Figure 5. The hydrolysis and polycondensation velocity of the precursor is lowered in the presence of PEG200, which minimizes the aggregation of the nanostructures during calcination. In addition, the short chain polymer PEG200 also acts as a structure-directing agent in the formation of 1D β-BBO nanostructures. PEG200 is easily adsorbed on the surface of the colloid due to its uniform and ordered chain structure, as reported previously.[29] From a kinetic point of view, if the polymer adsorbs on the surface of the growing colloid, thereby

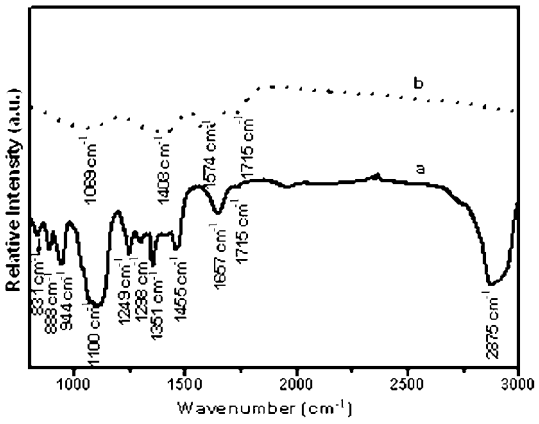

Figure 5. IR spectra of the samples in the sol–gel process: a) the precursor sol [$Ba(OAc)_2$ + $H_3BO_3$ + sorbitol + PEG); b) the precursor gel.

blocking this region, the growth of the colloid in one direction will be restricted. Therefore, the addition of PEG200 to the solution will modify the growth kinetics of the colloid, which finally leads to anisotropic growth of the samples. Previous research has provided many excellent samples where a polymer helps the growth of 1D nanostructures.[30] In the present work, PEG200 can efficiently adsorb to the surfaces of the precursor colloids, which leads to the growth of β-BBO along a certain direction.

We also performed a series of experiments to investigate the effect of the reaction conditions on the formation of β-BBO network-like nanostructures. We found that the use of PEG200 and the appropriate proportion of PEG200 and $H_2O$ had a decisive effect on the formation of network-like β-BBO nanostructures. Our experiment showed that only β-BBO nanoparticles with an average diameter of 80 nm, as shown in Figure 6 (a), are formed in water with no PEG200, which confirms its important role as a structure-directing agent. When the experiment was carried out in the absence of water the reaction did not initiate and therefore no β-BBO was obtained. This result suggests that the addition of water increases the solubility of barium acetate, sorbitol, and boric acid and facilitates the formation of the homogeneous sol and the gel. The appropriate proportion of PEG200 is also critical for the formation of 1D β-BBO nanostructures. When the experiment was done with a PEG200 and $H_2O$ ration 2:1 under otherwise identical conditions β-BBO shuttle-like nanostructures (Figure 6, b) were obtained. When the volume ratio of PEG200 and $H_2O$ was changed to 1:1, however, β-BBO network-like nanostructures were obtained. This phenomenon might occur because the different amount of PEG200 results in a different rate of hydrolysis and condensation of the precursors.[31] The addition of an appropriate amount of PEG200 could control the rate of hydrolysis and condensation of the precursors and prevent the early precipitation of the metal ions from solution, thus allowing the formation of a homogeneous gel.

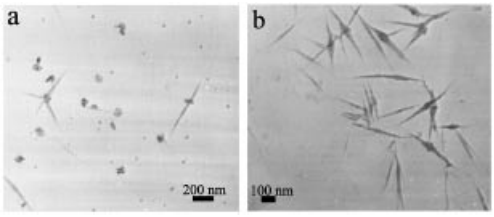

Figure 6. TEM images of as-prepared β-$BaB_2O_4$ samples formed in the presence of different amounts of PEG and $H_2O$: a) nanoparticles (without PEG); b) nanoshuttles (volume ratio of PEG and $H_2O$ of 2:1).

It is known that β-BBO crystals have a high transmissivity from 190 to 3500 nm. Figure 7 (a) shows the UV/Vis/NIR absorption data of the as-obtained products. It can be seen that β-BBO is transparent up to 200 nm (6.22 eV). The absorption spectra are relatively featureless, and the broad and overall constant low absorbance from 200 to 1600 nm is consistent with the reported values for single crystals,[31] thus demonstrating that it is transparent from ultraviolet to the mid-infrared regions. The room temperature PL spectrum of the β-BBO network-like nanostructures (Figure 7, b) was recorded at an excitation wavelength of 245 nm. It can be seen that the spectrum features a strong emission band at 377 nm (approx. 3.3 eV). Earlier reports have indicated that β-BBO exhibits a dominant peak near 355 nm (3.5 eV).[32] The luminescence of these β-BBO network-like nanostructures at 3.3 eV is an intrinsic property of β-BBO due to radiative annihilation of the self-trapped exciton.[32]

Generally, NLO materials lacking an inversion symmetry and containing a π-electron conjugated system should exhibit an efficient SHG. Furthermore, SHG is sensitive to the electronic properties of nanostructures of varying shape, size, composition, and spatial organization. The structure of β-BBO (Scheme 2) is made up of slightly distorted $(B_3O_6)^{3-}$ anionic hexagonal groupings with a threefold axis. These plane-like $(B_3O_6)^{3-}$ units are stacked along the *c* axis.[33] The boroxyl ring $(B_3O_6)^{3-}$ is the unit that contributes most to the material's non-linearity.

Powder SHG measurements of the β-BBO network-like nanostructures (Figure 8) were performed to determine its second-order nonlinear optical behavior and hopefully allow us to determine the relationship between their properties and morphologies. The β-BBO nanostructures were irradiated with the fundamental laser wavelength of 1064 nm and light transmitted through the β-BBO nanostructures was found to have a wavelength of 531–533 nm, thus proving the generation of frequency doubling. The results in Figure 8 reveal that the SHG efficiency of the β-BBO network-like nanostructures is 78% relative to that of the reference sample (urea). At the same time, the contrast experiment found that the SHG efficiency of β-BBO nanostructures is nearly 10 times that of the β-BBO nanoparticles with a diameter of about 80 nm prepared without PEG200. These results indicate that the morphology of the materials has an important effect on their nonlinear optical properties and that the SHG is sensitive to the electronic properties of nanostructures of varying shape, size, composition,

and spatial organization. For example, the measured second-order susceptibilities of ZnO nanowires are different from those of ZnO nanoribbons, which may be due to subtle changes in their structural or electronic properties.[34] This suggests that an in-depth investigation of the relationship between the structures and their second-order nonlinear optical susceptibilities is needed. Meanwhile, it is reasonable to suggest that some more complicated or special morphologies of β-BBO nanostructures with higher SHG intensity and wider transmissions might exist. This lays the groundwork for possible practical applications of nonlinear optical nanomaterials by replacing their single crystalline counterparts, and this kind of work on nonlinear optical nanomaterials provides new physical insights, which will be helpful to researchers in applied physics. Thus, there is still a long way to go in synthesizing nonlinear optical nanomaterials and studying their optical properties in the future.

## Conclusions

In summary, a sol–gel method using the polymer PEG200 as structure-directing agent has been successfully used to synthesize β-BBO network-like nanostructures on a large scale. PEG200 plays an important role in the formation of β-BBO network-like nanostructures. This method has a lot of merits, such as not requiring complicated procedures and a short processing time. Investigations into the optical properties of β-BBO network-like nanostructures reveal that they have a wide transparency range from 200 to 1600 nm and a strong PL emission. The SHG efficiency of β-BBO nanostructures is close to that of urea and larger than that of β-BBO nanoparticles. Consequently, the fabrication and study of different β-$BaB_2O_4$ nanostructures has revealed the existence of a profound shape/property relationship and the potential promise for their application in the photoelectronics industry and as nonlinear optical devices.

## Experimental Section

In a typical experiment, 6 mL of an aqueous solution containing barium acetate (0.25 g, 1 mmol), sorbitol (0.18 g, 1 mmol), and bo-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ric acid (0.13 g, 2 mmol) was put in a conical flask and stirred with a magnetic stirrer until a transparent solution had formed. This solution was then mixed with 6 mL of polyethylene glycol (PEG200, $M_w$ = 200), in which the volume ratio of PEG200 and water was 1:1, and transferred into a 15-mL Teflon-lined stainless-steel autoclave. The mixed solution was kept at 180 °C for 12 h to homogenize the precursor sol. After the reaction was complete, the solution was heated to 330 °C for 5 h to form a homogeneous gel and then to 800 °C for 2 h under oxygen. The resultant white products were collected and rinsed several times with distilled water and absolute ethanol, and then dried under vacuum at 40 °C for 4 h.

The samples were characterized by X-ray powder diffraction (XRD) with a Japan Rigaku D/max rA X-ray diffractometer equipped with graphite-monochromated high-intensity Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å) in the $2\theta$ range from 10° to 70°. The transmission electron microscopy (TEM) images were recorded with a Hitachi Model H-800 instruments with a tungsten filament, using an accelerating voltage of 200 kV. The high-resolution transmission electron microscopy (HRTEM) images were recorded with a JEOL-2010 TEM at an acceleration voltage of 200 kV. The field emission scanning electron microscopy (FE-SEM) images were recorded with a JEOL JSM-6700F SEM. X-ray photoelectron spectroscopy (XPS) was performed with an ESCALAB MKII with Mg-$K_\alpha$ radiation ($hv$ = 1253.6 eV) as the excitation source. The binding energies obtained in the XPS spectral analysis were corrected for specimen charging by referencing the C 1s peak to 284.6 eV. FT-IR absorption spectra were recorded with a Nicolet FT-IR-170SX spectrometer in the range 800–3000 $cm^{-1}$ at room temperature, in transmission mode in a KBr pellet. Absorption spectra were recorded with a Shimadzu UV-365 UV/Vis-NIR Recording Spectrophotometer. The room-temperature photoluminescence (PL) spectra were recorded with a Jobin Yvon–Labram Steady-State/Lifetime Spectrofluorometer with an HeCd laser. The second-order nonlinear optical intensities were estimated for powder samples with a diameter of 76–154 μm in the form of a pellet. The thickness of each pellet was about 0.8 mm. The experimental arrangement for the nonlinear optical properties utilizes an OPG pumped by a PC2143 series laser at a repetition rate of 10 Hz. The selected wavelength is 1064 nm. After the selection of the wavelength, the laser beam is split into two parts, one of which is used to generate the second harmonic signal in the reference (urea pellet).

# Influence of a Large σ-Donor Ligand on Structural and Catalytic Properties of Di-Iron Compounds Related to the Active Site of Fe-Hydrogenase – A DFT Investigation

**Claudio Greco,[a] Maurizio Bruschi,[b] Piercarlo Fantucci,[a] and Luca De Gioia*[a]**

**Keywords:** Hydrogenases / Biomimetic chemistry / Catalytic $H_2$ evolution / Density functional calculations / Iron

The complex $(S_2C_3H_6)[Fe_2(CO)_5P(NC_4H_8)_3]$ (**A**), a recently synthesized functional model of the active site of Fe-hydrogenases, is able to electrocatalyze proton reduction, leading to molecular hydrogen evolution. Experimental results suggested that the presence of the electron donor $P(NC_4H_8)_3$ ligand in **A** could favor the formation of a μ-CO species similar to that observed in the enzymatic cluster. However, insight into the structural features of key catalytic intermediates deriving from reduction and protonation of **A** was still lacking. Here we present results obtained using density functional theory to evaluate structures, relative stabilities, and spectroscopic properties of several species relevant for the electrocatalytic $H_2$ evolving process. The results enabled us to unravel the structure of the μ-CO complex experimentally detected after monoelectronic reduction of **A**. Moreover, we show that the introduction of the large electron-donor ligand $P(NC_4H_8)_3$ in the biomimetic complex does not favour the stabilization of terminal-hydrido adducts, which are expected to be very reactive in terms of $H_2$ production. The comparison of our findings with previous theoretical and experimental results obtained on similar model complexes suggests that the introduction of an electron donor ligand as good as $P(NC_4H_8)_3$, but less sterically demanding, could represent a better choice to facilitate the formation of μ-CO complexes more closely resembling the structure of the enzymatic cluster.

## Introduction

The possibility of producing molecular hydrogen through eco-compatible, hydrocarbon-independent processes has been stimulating chemists towards the synthesis of inexpensive catalytic materials that could replace the currently used platinum-containing electrocatalysts.[1] The search for cheaper, but still efficient catalysts could take advantage from the study of hydrogenases,[2] which are metallo-enzymes that are able to catalyze the evolution of molecular hydrogen at high rates starting from protons and electrons.

Three classes of hydrogenases have been characterized so far: Ni–Fe hydrogenases, which include both iron and nickel atoms as metal centers of functional importance, and two classes of iron-dependent enzymes, i.e. the "iron-sulfur-cluster-free" hydrogenases,[3] and another group of proteins containing $Fe_xS_x$ clusters, commonly referred to as "Iron-only" or Fe-hydrogenases. X-ray crystallographic studies on Fe-hydrogenases from *C. pasteurianum*[4] and *D. desulfuricans*[5] have shown that the active site of these enzymes includes an $Fe_2S_2$ sub-site bearing CO and $CN^-$ ligands. The iron atoms of the sub-site are bridged by two sulfur atoms of a 1,3-propanedithiolato (pdt) or a related bis(thiomethyl)amino unit. One of the iron atoms shares a cysteinyl sulfur ligand with a classical $Fe_4S_4$ cluster; the resulting iron–sulfur complex is usually referred to as the H-cluster. Experimental results[6] indicate that the unprotonated, $Fe^{I}$-$Fe^{II}$ form of the H-cluster di-iron subsite should correspond to a catalytically active state characterized by the presence of a carbonyl ligand bridging the two iron centers. As shown in Scheme 1, the coordination site *trans* to the bridging CO remains vacant, and this observation suggests that protons and dihydrogen could occupy such a position during the catalytic process. Upon monoelectronic reduction of the H-cluster, the bridging CO moves to a terminal position, but it still remains localized in the region of space between the iron ions (see Scheme 1).[6]

The above-mentioned studies have stimulated experimental chemists towards the synthesis of organometallic models that could reproduce the main structural and functional features of the H-cluster.[7] Unfortunately, the biomimetic clusters obtained so far fail to reproduce the precise orientation of ligands found in the H-cluster, a fact that is expected to be at the basis of the reduced catalytic efficiency of synthetic assemblies. For example, in the complex (μ-

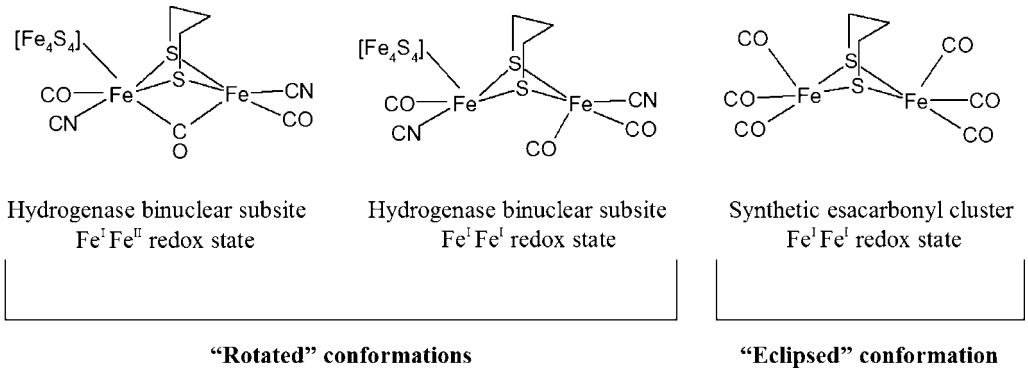


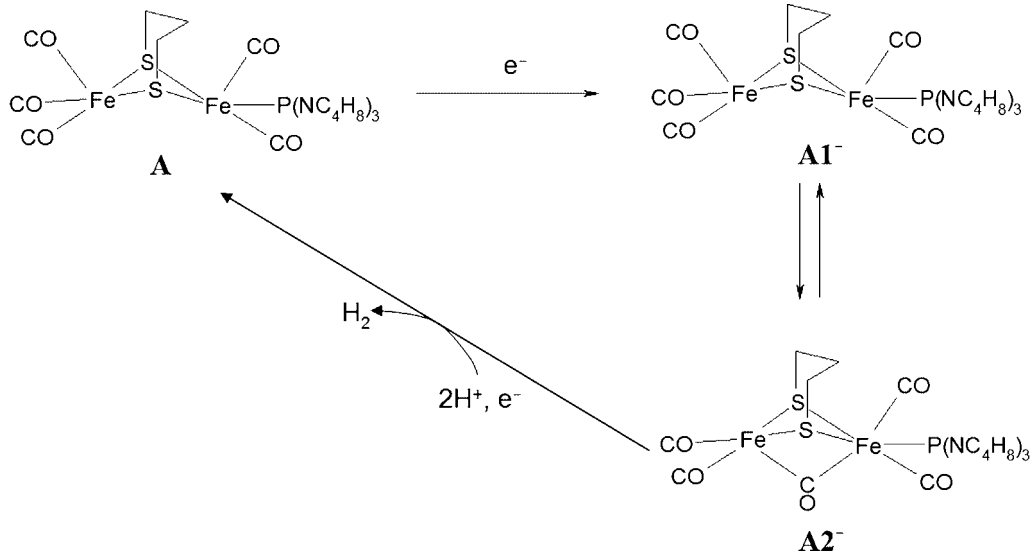
Scheme 1. Structures of the Fe-hydrogenase binuclear subsite in two different redox states, and geometry of the synthetic complex (μ-pdt)[Fe(CO)$_3$]$_2$.

pdt)[Fe(CO)$_3$]$_2$, the simplest functional model of the active site of Fe-hydrogenases, all the carbonyl groups are in the terminal position.[7h] Such an arrangement of ligands will be referred to as the "eclipsed conformation," as opposed to the "rotated conformation" that can be observed in Fe-hydrogenases (Scheme 1).

Theoretical studies have been carried out to understand the causes of the structural difference between synthetic models and the enzyme active site.[8,9] It turned out that the presence of good electron donor ligands bound to the metal centers can help in stabilizing the rotated conformation of di-iron clusters. Such observations have been recently taken into account by Hou and collaborators, who probed the effects of the introduction of tris(*N*-pyrrolidinyl)phosphane, a very good donor ligand, on the structural and functional properties of the synthetic species (μ-pdt)[Fe$_2$(CO)$_5$P(NC$_4$H$_8$)$_3$] (**A**).[10] It turned out that **A** (Scheme 2) is characterized by eclipsed conformation, while monoelectronic reduction leads to the formation of a μ-CO species that was tentatively assigned, on the basis of IR data, to a rotated conformer closely resembling the unprotonated form of the H-cluster (species **A2**$^-$, Scheme 2). Nothing is known about the regiochemistry of protonation of this synthetic cluster, an issue that is expected to be relevant to rationalize the electrocatalytic properties shown by (μ-pdt)[Fe$_2$(CO)$_5$P(NC$_4$H$_8$)$_3$] (for details on the mechanism proposed by Hou and collaborators for hydrogen evolution mediated by the di-iron assembly, see Scheme 2). In order to shed light on the structure-function relationships in **A**, we carried out a DFT investigation of structures, spectroscopic properties, and relative stabilities of several plausible isomers of this biomimetic compound, both in its protonated and unprotonated forms. Results allowed us to obtain a detailed structural characterization of key intermediate species, and a better understanding of the electrocatalytic cycle. DFT results are expected to be helpful also for the design of better bioinspired electrocatalytic compounds.

## Methods

DFT calculations have been carried out using the pure functional BP86[11] in conjunction with a valence triple-ζ basis set with polarization on all atoms (TZVP).[12]



Scheme 2. The electrocatalytic mechanism of $H_2$ evolution mediated by (μ-pdt)[Fe$_2$(CO)$_5$P(NC$_4$H$_8$)$_3$], as proposed in ref.[10]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Calculations have been carried out with the TURBOMOLE 5.7 suite[13] applying the resolution-of-the-identity technique.[14]

Stationary points of the energy hypersurface have been located by means of energy gradient techniques and full vibrational analysis has been carried out to further characterize each stationary point. In order to characterize isomeric forms, DFT optimizations were repeated several times, starting from different initial geometries.

Free energy ($G$) values have been obtained from the electronic SCF energy considering three contributions to the total partition function ($Q$), namely $q_{translational}$, $q_{rotational}$, $q_{vibrational}$, under the assumption that $Q$ may be written as the product of such terms.[15] In order to evaluate enthalpy and entropy contributions, the value for the temperature, pressure, and scaling factor for the SCF wavenumbers have been set to 298.15 K, 1 bar, and 0.9914, respectively. Rotations have been treated classically and vibrational modes described according to the harmonic approximation.

The optimized structures of the complexes reported in the present study always correspond to low spin states; high spin states are characterized by higher energies (not shown), as expected considering the characteristics of the ligands forming the coordination environment of the metal atoms.

The relative energies discussed in the present work are Gibbs free energies where the contributions described above are taken into account. The effect of the solvent (acetonitrile, $\varepsilon$ = 36.64) has been evaluated according to the COSMO approach.[16]

## Results and Discussion

For the sake of clarity, hereafter experimental complexes will be designated with capital bold letters, while computational models will be referred to using lower case bold letters. As for the nomenclature of the iron atoms, the metal center bound to the phosphane ligand will be referred to as the "proximal iron" ($Fe_p$), while the other iron ion will be named "distal" ($Fe_d$).

In order to validate the computational approach adopted in this paper (BP86/TZVP, see Methods), we initially opti-

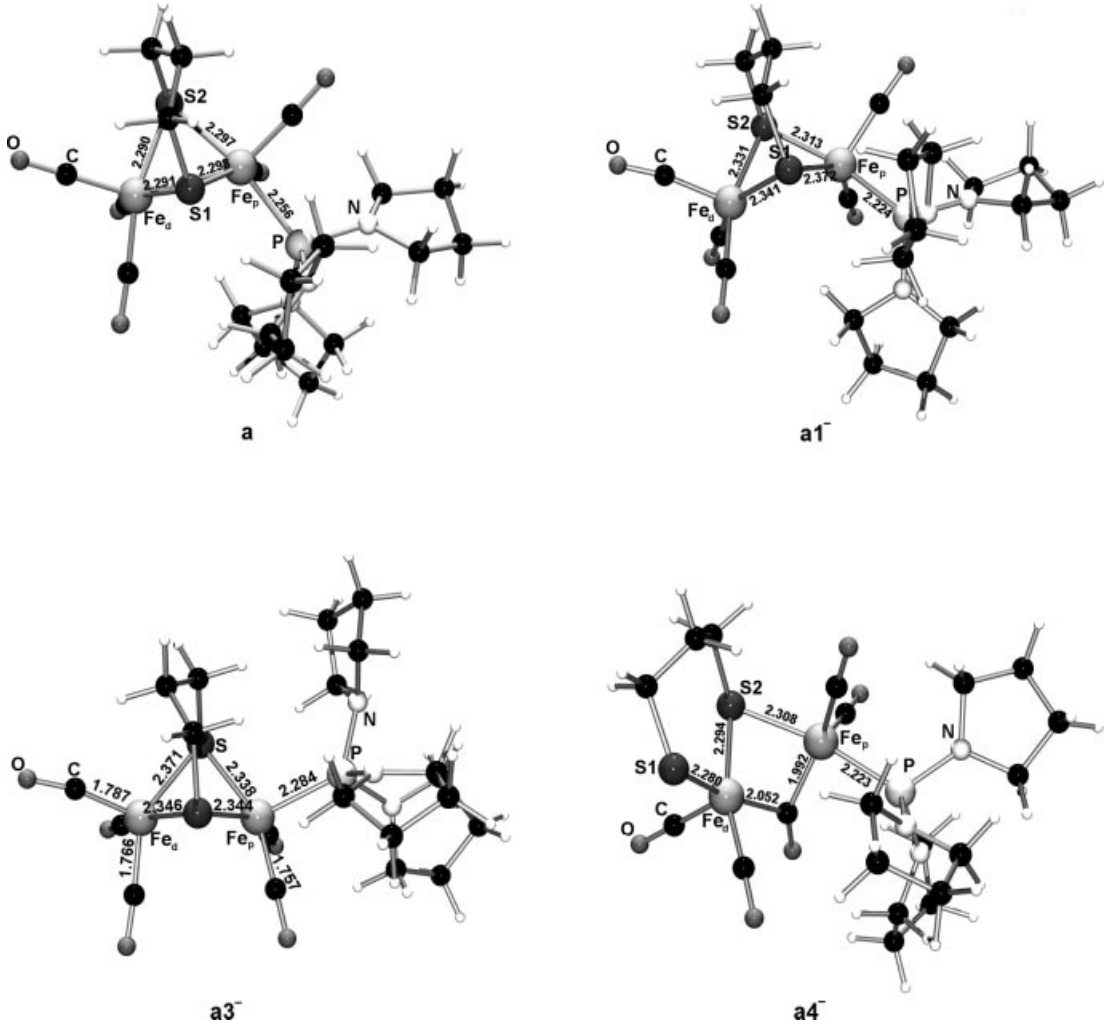


Figure 1. Optimized geometries of complexes **a**, **a1**$^-$, **a3**$^-$ and **a4**$^-$; $S$ = 0 and 1/2 for neutral and monoanionic complexes, respectively. Selected distances are given in Å.

mized the geometry of complex **a**, and compared the resulting structure (see Figure 1) with its experimental counterpart. As shown in Table 1, the differences in bond lengths between **a** and **A** never exceed 0.059 Å. Similarly good results are obtained when bond angles are considered: in fact, the maximum difference between calculated and experimental values is very low (4.7 deg; for the $Fe_p$–$Fe_d$–C angle, the latter atom belonging to the carbonyl group *trans* to the S2 atom of pdt. See Figure 1).

Table 1. Comparison between experimental and computed bond lengths for complex **A**. Distances in Å.

| Bond | Experimental bond lengths (**A**) | Calculated bond lengths (**a**) | Difference |
|---|---|---|---|
| $Fe_d$–$Fe_p$ | 2.5527 | 2.611 | 0.0583 |
| $Fe_p$–S | 2.2418; 2.2675 | 2.279; 2.300 | 0.0372; 0.0325 |
| $Fe_d$–S | 2.2542; 2.2615 | 2.286; 2.297 | 0.0318; 0.0355 |
| $Fe_p$–P | 2.2563 | 2.286 | 0.0297 |
| P–N | 1.662; 1.670; 1.682 | 1.711; 1.721; 1.731 | 0.049; 0.051; 0.049 |

An excellent correlation between computed and experimental CO stretching frequencies was also found, confirming that the BP86/TZVP level of theory is well suited to describe this class of compounds.[17] In fact, linear regression analysis gives rise to a $R^2$ value as large as 0.997 (Figure 2).

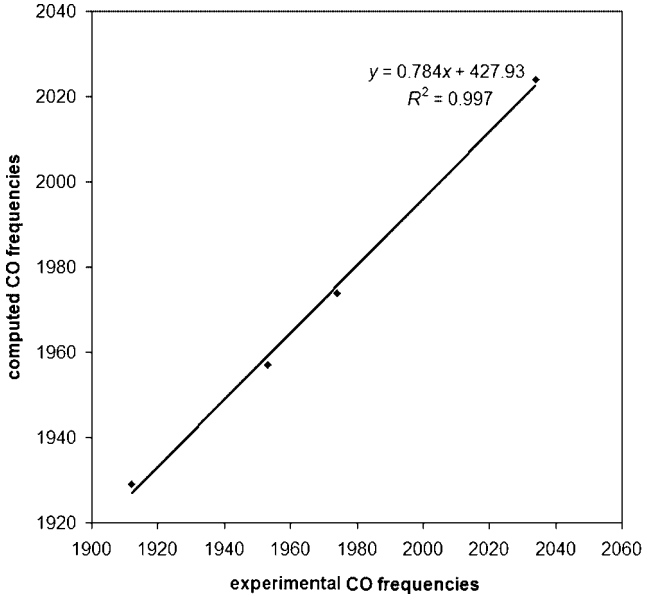

Figure 2. Linear fitting of calculated and experimental CO stretching frequencies for species **A**.

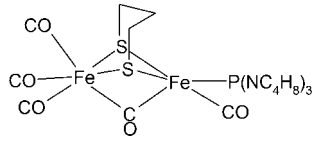
## Structural Characterization of the Experimentally Observed Monoanionic Derivatives

The first optimized monoanionic isomer considered as a plausible product of the monoelectron reduction of **a** is **a1**$^-$, which shares a high degree of structural similarity with the parent complex **a**, the main differences being restricted to a limited decrease of the $Fe_p$–P bond length, while all the other bonds are slightly elongated in **a1**$^-$ (see Figure 1).

Hou et al.[10] proposed that **A1**$^-$ could undergo a conformational rearrangement leading to a μ-CO species structurally related to the enzymatic $Fe_2S_2$ subsite (complex **A2**$^-$, see Scheme 2). Prompted by these considerations, we carried out the geometry optimization of $(CO)_2Fe_d(\mu\text{-pdt})(\mu\text{-CO})Fe_p(CO)_2[P(NC_4H_8)_3]$ (**a2**$^-$), a species in which one of the terminal carbonyls bound to $Fe_d$ in **a1**$^-$ has moved to a bridging position. However, it turned out that **a2**$^-$ (structure not shown) corresponds to a third-order saddle point on the potential energy surface (imaginary frequencies: 47.95i, 29.72i, 14.91i $cm^{-1}$). Moreover, **a2**$^-$ is 12.5 kcal $mol^{-1}$ less stable than **a1**$^-$. DFT optimizations started from slightly different initial geometries converged on **a1**$^-$ or **a2**$^-$. Taken as a whole, these results indicate that **a2**$^-$ cannot correspond to the μ-CO species experimentally observed (**A2**$^-$).

In principle, another isomer closely resembling the structure of the unprotonated enzymatic cofactor could be present in solution: in fact, a terminal CO bound to $Fe_p$ could move to a bridging position, thus giving place to $(CO)_3Fe_d(\mu\text{-pdt})(\mu\text{-CO})Fe_p(CO)[P(NC_4H_8)_3]$, see Scheme 3. However, all the attempts to obtain such a geometry as a result of DFT optimization failed: several calculations were carried out starting from slightly different guess structures, but all of them fell back towards the **a1**$^-$ conformation. This indicates that a minimum corresponding to such a μ-CO geometry does not exist on the PES of $(\mu\text{-pdt})[Fe_2(CO)_5P(NC_4H_8)_3]$. The instability of this structure can be ascribed to the presence of a μ-CO group *trans* to another π-acid carbonyl ligand, and to a vacant coordination site.

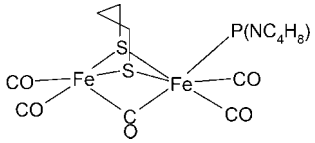


Scheme 3. Schematic structure of a hypothetical adduct showing rotated conformation.

Previous computational studies[18,19] have shown that the stabilization of rotated conformations in di-iron biomimetic complexes can be achieved positioning a good σ-donating group *trans* to the incipient μ-CO. In view of this observation, we have evaluated (i) if the sterically impeded ligand $P(NC_4H_8)_3$ can move to assume an apical position on $Fe_p$ in an eclipsed conformer, and (ii) if such a disposition of ligands on $Fe_p$ can favor the rotation of ligands around $Fe_d$. In fact, an eclipsed geometry showing an apical $P(NC_4H_8)_3$ ligand corresponds to an energy minimum structure (adduct **a3**$^-$, Figure 1). **a3**$^-$ is 4.1 kcal $mol^{-1}$ less stable than **a1**$^-$ due to the unfavorable interactions between the pyrrolidine rings of the phosphane ligand and the alkyl chain of pdt. These repulsive interactions played a relevant role in the optimization of the corresponding rotated species **a3-rotated**$^-$, see Scheme 4. In fact, the distortion of pdt geometry led one of its sulfur atoms to detach from the proximal

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

iron ion, a rearrangement accompanied by bridging-to-terminal movement of the μ-CO group, resulting in a four-coordinate $Fe_p$ atom (structure not shown).



Scheme 4. Starting structure used for geometry optimization of **a3-rotated**$^-$.

The instability of μ-CO anionic complexes leaves unanswered the question of the nature of the spectroscopically characterized μ-CO species. Indeed, it was recently shown that hexacarbonyl di-iron complexes including a pdt ligand can assume a structure in which a sulfur atom of pdt has moved from a bridging to a terminal position;[20] such a rearrangement may allow one of the terminal CO ligands to become a μ-CO. Analysis of **a1**$^-$ suggests that this species might undergo a similar rearrangement: in fact, one of the Fe–S bonds ($Fe_p$–S1, 2.372 Å, see Figure 1) is significantly elongated with respect to the other three Fe–S bonds (2.313, 2.331, 2.341 Å). The weakening of the bonding interaction between $Fe_p$ and S1 could favor isomerization, giving place to the DFT-optimized species **a4**$^-$ (see Figure 1). Notably, this isomer is only slightly less stable (2.9 and 5.0 kcal mol$^{-1}$ when considering SCF energy differences and $\Delta G$ values, respectively) than **a1**$^-$; thus, these two adducts could be present simultaneously in solution, with **a1**$^-$ representing the main product of the monoelectronic reduction of **a**.

The co-existence of **a4**$^-$ and **a1**$^-$ is also supported by the comparison between the computed CO stretching frequencies of these two species and the experimental IR bands: in fact, the IR spectrum collected after electrochemical reduction of **a** is characterized by six distinct bands – five intense bands in the region between 1845 and 2015 cm$^{-1}$, and a weak absorption at lower wavenumbers (1778 cm$^{-1}$). In light of our computational results, we propose that the spectrum region above 1850 cm$^{-1}$ is dominated by the stretching modes of the five terminal carbonyls included in the main reduction product **a1**$^-$; the less stable **a4**$^-$ species is detectable thanks to its bridging CO group, whose predicted IR stretching frequency (1742 cm$^{-1}$) is located largely below 1845 cm$^{-1}$. All the other computed CO peaks from **a4**$^-$ fall in a narrow region between 1872 and 1953 cm$^{-1}$, where the most populated **a1**$^-$ isomer gives place to intense absorption bands. As a further support to this hypothesis, a very good correlation between the selected six computed IR frequencies and the corresponding experimental bands could be evidenced after linear regression fitting analysis ($R^2$ = 0.990, see Figure 3).

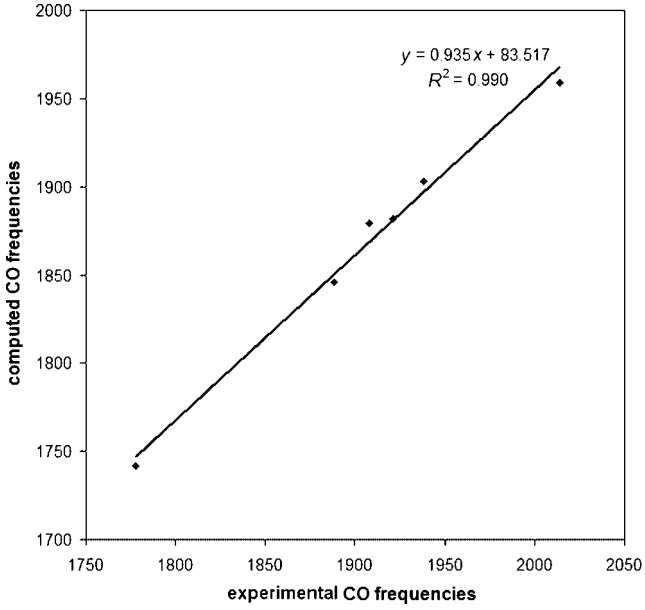


Figure 3. Linear fitting of the calculated and experimental CO frequencies for the anionic adducts coming from monoelectronic reduction of **A**.

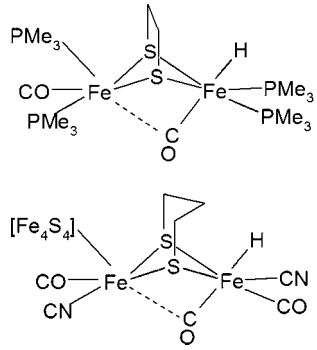
## Protonation of Monoanionic Derivatives

In the electrocatalytic cycle, monoelectronic reduction of **A** should be followed by protonation of the resulting monoanionic complex. The regiochemistry of protonation can influence the efficiency of hydrogen evolution, as shown recently for the biomimetic di-iron compound $[Fe_2(S_2C_2H_4)(\mu\text{-CO})(H)(CO)(PMe_3)_4]^+$, which revealed that a hydrido ligand terminally bound to one of the iron ions is much more reactive than a μ-H group.[21] This result supports the hypothesis that the formation of a terminal hydrido *trans* to a μ-CO or a semi-bridging carbonyl is crucial to explain the very high efficiency of Fe-hydrogenases (Scheme 5). However, in the case of simple Fe-hydrogenase functional models such as (μ-pdt)$[Fe(CO)_3]_2$, formation of μ-H derivatives (as opposed to terminal-hydrido adducts) is highly favored.[20a,22]



Scheme 5. Schematic structure of the synthetic complex obtained by Rauchfuss et al.,[21] and hypothetical structural features of the corresponding state of the active site of Fe-hydrogenase.

In view of these observations, we have studied the effects of the introduction of the donor ligand $P(NC_4H_8)_3$ on the relative stabilities of monoprotonated pentacarbonyl diiron complexes. To this end, we carried out geometry optimization of several different isomers, whose optimized structures are collected in Figure 4.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

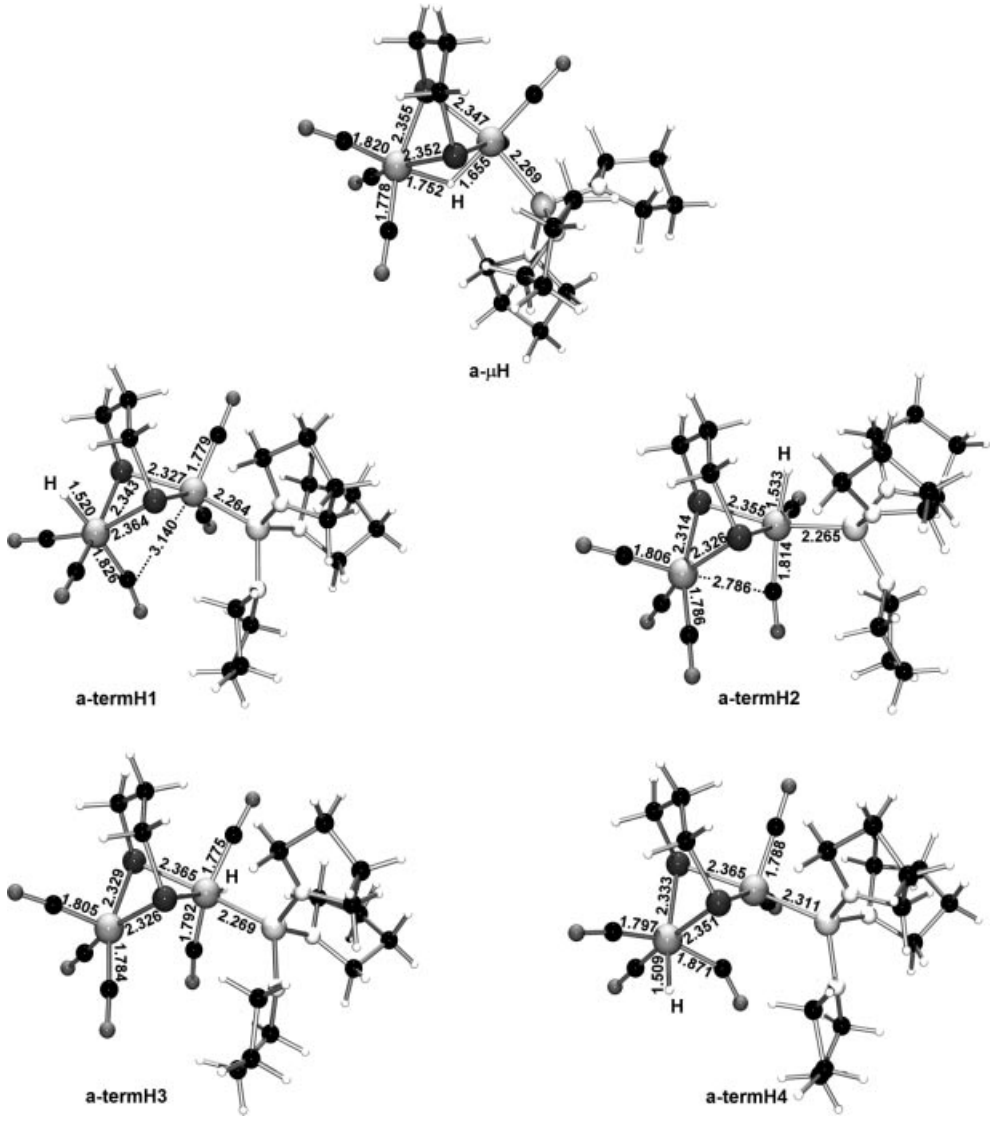


Figure 4. Optimized geometries of complexes **a-μH**, **a-termH1**, **a-termH2**, **a-termH3**, and **a-termH4**; for all these species $S = 1/2$. Selected distances are given in Å. The hydrido group has been labelled for the sake of clarity.

In line with previous observations regarding the protonated form of (μ-pdt)[Fe(CO)$_3$]$_2$,[20] the μ-H species **a-μH** is more stable than all the terminal-hydrido adducts considered in the present study (see Table 2 for a summary of the calculated $\Delta G$ values). Particularly relevant in the context of relative stabilities analysis are the cases of **a-termH1** and **a-termH2**: these complexes feature a terminal hydrido ligand *trans* to a carbonyl ligand, and can thus be considered the isomers with greater similarity to the most plausible protonated form of the enzymatic di-iron subsite (Figure 4). However, the free energy difference between **a-termH1** and **a-μH** is large ($\Delta G_{\mathbf{a\text{-}termH1-a\text{-}\mu H}}$ = 11.3 kcal mol$^{-1}$) and, more importantly, it is even larger than the energy difference between the corresponding monoprotonated hexacarbonyl complexes (**b-μH** and **b-termH**, see Figure 5; $\Delta G_{\mathbf{b\text{-}termH1-b\text{-}\mu H}}$ = 8.2 kcal mol$^{-1}$). The increase in the energy gap observed going from the hexacarbonyl to the pentacarbonyl species is due to steric repulsion between the carbonyl *trans* to the terminal hydrido in **a-termH1** and the phosphane ligand bound to Fe$_p$. In fact, this CO group can be considered a terminal carbonyl in the pentacarbonyl complex, since the Fe$_p$–C distance is as long as 3.140 Å, while the corresponding interatomic distance in (μ-pdt)[Fe(H)(CO)$_3$]$_2$ is significantly shorter (2.856 Å).

Table 2. Free energy difference between the μ-H adduct **a-μH** and the various terminal-hydrido isomers considered in this paper.

| Adduct | Free energy difference relative to **a-μH** [kcal mol$^{-1}$] |
|---|---|
| **a-termH1** | 11.3 |
| **a-termH2** | 10.3 |
| **a-termH3** | 11.2 |
| **a-termH4** | 18.0 |

When **a-termH2** is considered, a large energy difference relative to **a-μH** is also observed ($\Delta G_{\mathbf{a\text{-}termH1-a\text{-}\mu H}}$ = 10.3 kcal mol$^{-1}$). In this case, however, the CO *trans* to the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

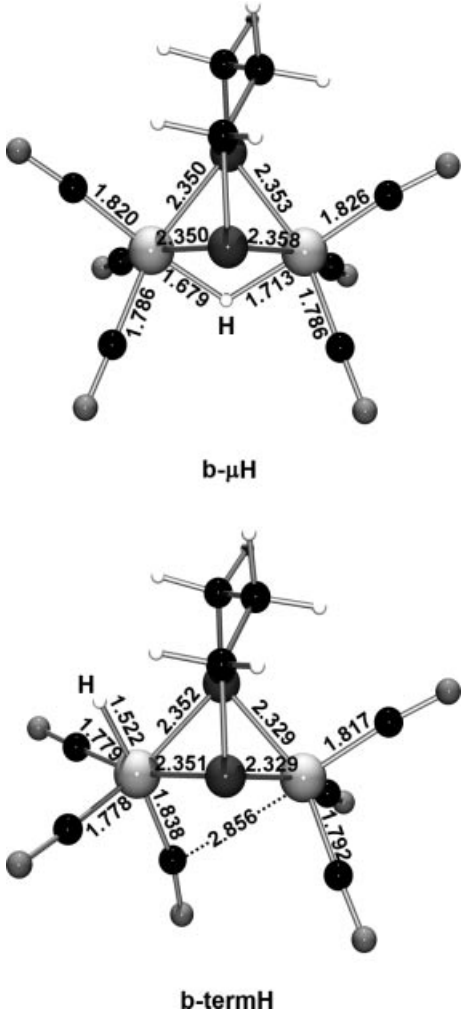

Figure 5. Optimized geometries of complexes **b-μH** and **b-termH**; for these two species $S = 1/2$. Selected distances are given in Å. The hydrido group has been labelled for the sake of clarity.

terminal hydrido on $Fe_p$ remains closer to the second iron center ($Fe_d$–C bond length: 2.786 Å, see Figure 4), a behavior that is again correlated with the repulsive interactions between the carbonyl ligand and the pyrrolidine rings included in $P(NC_4H_8)_3$.

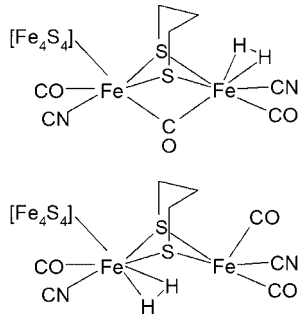
To complete the characterization of the monoprotonated species, we optimized also the structures of two adducts bearing a hydrido *trans* to the sulfur atoms of pdt (**a-termH3** and **a-termH4**, see Figure 4); both of them show free energy gaps larger than 11 kcal mol$^{-1}$, when compared to **a-μH**.

In summary, our computational results demonstrate that the formation of terminal-hydrido ligands should have small, if any, importance in the electrocatalytic cycle mediated by (μ-pdt)[$Fe_2(CO)_5P(NC_4H_8)_3$]. Moreover, the comparison between theoretical data obtained for (μ-pdt)[$Fe(CO)_3]_2$ and (μ-pdt)[$Fe_2(CO)_5P(NC_4H_8)_3$] indicates that the introduction of the electron donor ligand $P(NC_4H_8)_3$ does not lead to stabilization of terminal-hydrido complexes.

### Diprotonated Neutral Complexes

Experimental data show that (μ-pdt)[$Fe_2(CO)_5P(NC_4H_8)_3$] undergoes two reduction and two protonation steps to allow $H_2$ evolution and closure of the catalytic cycle. Formation of diprotonated neutral species could thus have a role in electrocatalysis. In view of this, we studied neutral species derived from reduction and protonation of neutral, monoprotonated model complexes. In particular, we investigated the possible outcome of monoelectronic reduction and protonation of both a μ-H adduct (**a-μH**), and a terminal-hydrido compound (**a-termH1**).

It is important to note that the catalytic cycle of Fe-hydrogenases has been proposed to involve diprotonated intermediates in which a $H_2$ molecule is terminally bound to one of the iron centers in the binuclear subsite[23] (see Scheme 6). However, reduction and protonation of both **a-μH** and **a-termH1** does not lead to $H_2$-bound complexes: the addition of one electron and one proton to **a-μH** led to **a-$H_2$** (Figure 6), in which both hydrogen atoms, which are separated by 1.78 Å, occupy terminal positions on the two iron centers.



Scheme 6. The two possible versions of the $H_2$ bound H-cluster, as reported in ref.[23]

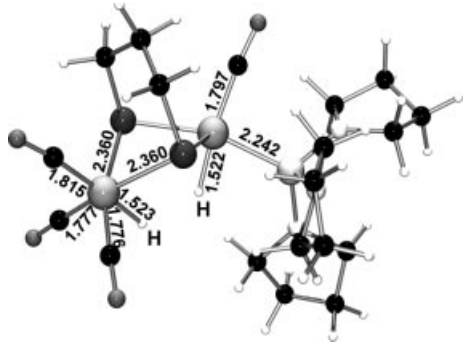


Figure 6. Optimized geometry of complex **a-$H_2$**, a diprotonated neutral complex in the singlet state ($S = 0$). Selected distances are given in Å. Labels are added only to metal-bound hydrogen atoms.

Interestingly, during the optimization of a species obtained by mono-electron reduction and protonation of **a-termH1**, the release of $H_2$ from the complex was observed. This result corroborates the hypothesis that the formation of **a-termH1** during electrocatalysis would give rise to a very efficient $H_2$ evolving route. Therefore, efforts aiming at the stabilization of pentacarbonyl diiron adducts bearing a ter-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

minal hydrido ligand could assume great relevance for the development of better electrocatalytic materials.

## Conclusions

In the first part of this work, we investigated the structural properties of several plausible isomers obtained by monoelectron reduction of the biomimetic complex (μ-pdt)[$Fe_2(CO)_5P(NC_4H_8)_3$]. Our computational study allowed us to show that complexes **a1**$^-$ and **a4**$^-$ should coexist in solution. The former adduct corresponds to a "classical" eclipsed conformation, while the second one is a μ-CO species structurally not related to the Fe-hydrogenases binuclear subsite. Therefore, the possibility that a rotated conformer closely resembling the H-cluster geometry can be formed during electrocatalysis is excluded. The ineffectiveness of $P(NC_4H_8)_3$ in stabilizing the rotated form of the synthetic assembly can be rationalized in light of recent theoretical results regarding monosubstituted derivatives of (μ-pdt)[$Fe(CO)_3$]$_2$ (i.e., adducts in which only one carbonyl has been replaced by a good σ-donor).[18,19] In fact, it has been shown that a good electron-donating ligand (L) is able to stabilize the rotated conformation of (μ-pdt)[$Fe(CO)_3$-$Fe(CO)_2(L)$]$^-$ complexes, when L is *trans* to the incipient bridging CO group.[18,19] Nevertheless, if L corresponds to $P(NC_4H_8)_3$, it is not possible to place the σ-donor *trans* to the incipient μ-CO, since in such a configuration the alkyl chain of pdt would cause steric clashes with the pyrrolidine rings included in $P(NC_4H_8)_3$. These observations suggest that the introduction of an electron donor ligand as good as $P(NC_4H_8)_3$, but less sterically demanding, could represent a better choice to facilitate the formation of more stable rotated adducts.

In the second part of the study, we have shown that the most stable protonated, uncharged form of (μ-pdt)-[$Fe_2(CO)_5P(NC_4H_8)_3$] corresponds to a μ-H adduct (**a-μH**), and that terminal-hydrido complexes – which turned out to be highly reactive according to DFT results – are not involved in the electrocatalytic cycle. In fact, all the terminal-hydrido species here investigated are less stable than the hydrido-bridged isomer **a-μH** by at least 10 kcal mol$^{-1}$. The steric repulsion between the $P(NC_4H_8)_3$ ligand and the carbonyl ligands plays a relevant role in determining such large energy gaps.

In conclusion, DFT results allowed us to rationalize why the synthetic complex (μ-pdt)[$Fe_2(CO)_5P(NC_4H_8)_3$] is significantly less efficient then the enzyme in $H_2$ production,[10,24] and might contribute to the design and synthesis of novel functional models of the active site of Fe-hydrogenase.

[19] It is interesting to note that a similar stabilizing effect exerted by the ligand *trans* to the μ-CO could be operative also in the enzyme active site. In fact, the $Fe_4S_4$ subcluster included in the H-cluster proved to be a good electron-donating group (see ref.[7e]) and it has been demonstrated that good donors localized at the position occupied by the Fe–S cubane can favor the rotation of ligands bound to the distal iron center (see ref.[8]).

# Syntheses and Characterization of Molybdenum/Zinc Porphyrin Dimers Bridged by Aromatic Linkers

Sai-Nan Song,[a] Dong-Mei Li,*[a,b] Jun-Feng Wu,[a] Chang-Fu Zhuang,[a] Hong Ding,[a] Wen-Bo Song,[a] Li-Feng Cui,[a] Geng-Zhen Cao,[a] and Guo-Fa Liu[a]

**Keywords:** Porphyrinoids / Heteronuclear complexes / Bridging ligands / Molybdenum / Zinc / Electrochemistry

Two new heterobinuclear porphyrin dimers, namely [{$Mo^{VI}O_2$}-DBPA-Zn] (**1**; $H_4$DBPA = *N*,*N*′-dibenzylidenebis-[4-(10,15,20-triphenyl-21*H*,23*H*-porphin-5-yl)phenylamine]) and [{$Mo^{VI}O_2$}-PBDA-Zn] (**2**; $H_4$PBDA = *N*,*N*′-bis[4-(10,15,20-triphenyl-21*H*,23*H*-porphin-5-yl)phenyl]-1,3-benzenedicarboxamide), have been synthesized. These bis-(porphyrin)s were obtained by treating 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrinatomolybdenum and -zinc with benzene-1,4-dicarboxaldehyde or benzene-1,3-dicarboxylic acid. They have been characterized by UV/Vis, IR, X-ray photoelectron, luminescence, and $^1$H NMR spectroscopy, and their TG-DTA behavior and molar conductances have also been determined. Th *cis*-dioxomolybdenum(VI) unit in these complexes is contained in one of the porphyrin moieties and zinc(II) ion is tetracoordinated in the other. Their electrochemical properties have also been investigated in detail.

## Introduction

Large π-conjugated macrocyclic systems like porphyrins are fascinating functional materials with high chemical and thermal stability whose photophysical and photochemical properties can be finely tuned by structural modifications involving the substitution of functional groups or different metal coordination.[1–3] Among the many porphyrins and metalloporphyrin complexes, dimeric and oligomeric porphyrins with extensive electronic delocalization have attracted increasing interest due to their potential applications in molecular electronics and photonics, which range from light-emitting diodes,[4] nonlinear optical (NLO) materials,[5] information storage materials,[6] photovoltaic cells,[7–9] chemical sensors,[10] biomimetic systems,[11,12] photosensitizers in photodynamic therapy,[13,14] and so forth. Optional linkages connecting monomeric porphyrin rings would allow the spatial configuration of porphyrins to be adjusted, thereby altering the sizes and shapes of the porphyrinato cavities. Generally speaking, three kinds of linkages are observed in porphyrin dimers and oligomers: (1) a flexible spacer such as a variable-length hydrocarbon or one containing mixed atoms;[15] (2) a rigid spacer such as diphenylanthracene, diphenylene, or *o*-phenylene;[16] (3) a direct *meso*-linked dimer or oligomer.[17,18]

Bis(porphyrin) complexes containing different metal ions, for example Mo/Os, W/Ru, Sn/Mo, and Gd/Co,[19–22] afford heterometallic dimers with extremely interesting magnetic or bifunctional catalytic properties compared with homometallic bis(porphyrin)s (Co/Co, Pd/Pd).[23,24] Molybdenum exhibits oxidation states from +2 to +6 in its porphyrin complexes[25–27] and several studies have demonstrated that high-valent molybdenum porphyrin complexes with *trans*-diperoxo, *cis*-dioxo, and *cis*-oxo-peroxo groups exhibit good oxygen transport activity in vivo and high catalytic activity toward oxygenation reactions.[28–31] We are currently focussing on heterometallic bis(porphyrin)s containing molybdenum in a high oxidation state (+6), and in this paper we report the syntheses, spectral characterization, and electrochemical properties of two new molybdenum–zinc porphyrin dimers, namely [{$Mo^{VI}O_2$}-DBPA-Zn] (**1**; $H_4$DBPA = *N*,*N*′-dibenzylidene-bis[4-(10,15,20-triphenyl-21*H*,23*H*-porphin-5-yl)phenylamine]) and [{$Mo^{VI}O_2$}-PBDA-Zn] (**2**; $H_4$PBDA = *N*,*N*′-bis[4-(10,15,20-triphenyl-21*H*,23*H*-porphin-5-yl)phenyl]-1,3-benzenedicarboxamide) that contain a *p*-bis(Schiff base)phenyl or a *meta*-diimidophenyl as a linking spacer.

## Results and Discussions

### Synthesis of the Complexes

Bis(porphyrin)s can be obtained by self-assembly of monomeric porphyrins through van der Waals or π–π interactions.[32–34] Herein, two kinds of linkers have been chosen, one of which is formed by simple acylation of a diacid and 5-(*p*-aminophenyl)-10,15,20-triphenylporphyrin [5-(*p*-$NH_2$)-TPP] whilst the other is obtained by direct reaction of a dialdehyde and 5-(*p*-$NH_2$)TPP. Two strategies to insert dif-

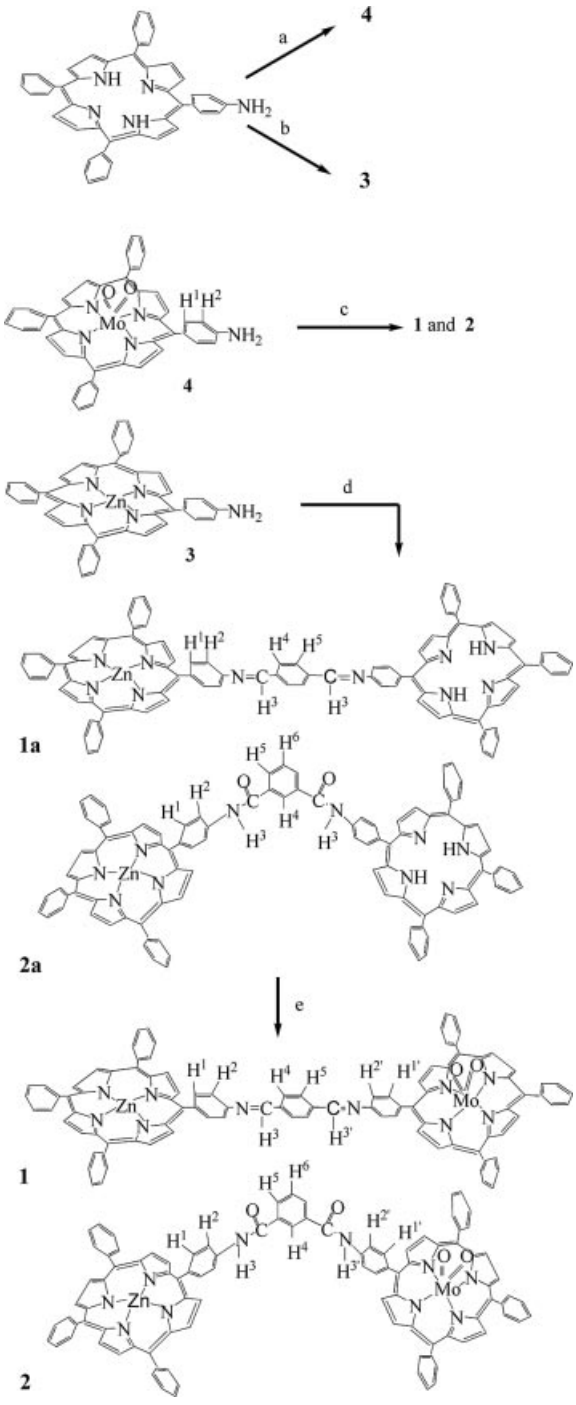
ferent metal ions into the bis(porphyrin) cavities have also been followed, both of which gave satisfactory results. One approach involves the reaction of one molar equivalent of the mononuclear porphyrin complexes [{5-(*p*-$NH_2$)TPP}-Zn] (**3**) and [{5-(*p*-$NH_2$)TPP}$Mo^{VI}O_2$] (**4**) with the bridge-linking reagents (see Scheme 1).



Scheme 1. a: $Mo(CO)_6$, 1,2,4-trichlorobenzene; b: $Zn(OAc)_2{\cdot}2H_2O$, dmf; c: **3** and benzene-1,4-dicarbaldehyde in dmf (to yield **1**) or benzene-1,3-dicarboxylic acid in dmf (to yield **2**); d: 5-(*p*-$NH_2$)TPP and benzene-1,4-dicarbaldehyde (to yield **1a**) or benzene-1,3-dicarboxylic acid in dmf (to yield **2a**); e: $Mo(CO)_6$, 1,2,4-trichlorobenzene.

The progress of the reaction was monitored by recording the UV/Vis absorption spectra. Completion of the reaction was indicated by a change in the relative intensities of the bands centered at about 555 and 595 nm and the appearance of a new band at around 450 nm. However, this reaction also produces several by-products and therefore requires further purification steps. Follow-up experiments revealed that adjusting the molar ratio (1:1) and the charging sequence of the starting materials improves the yield.

The second synthetic strategy consists of two steps: preparation of the mono-zinc bis(porphyrin) complexes **1a** and **2a**, and subsequent treatment of **1a**, **2a** with $Mo(CO)_6$ to give the Mo/Zn compounds.[35] This method produces fewer by-products, although the yield of compound **2** is low, presumably due to the cleavage of the imido linkage at higher temperatures.

### Composition of the Complexes

The heterobimetallic porphyrin complexes **1** and **2** were isolated as stable, purple, microcrystalline solids, although recrystallization from different organic solvents failed to give crystals suitable for an X-ray diffraction study. This lack of crystals led us to seek alternative ways to deduce the possible coordination modes of the central metals. The formulations [{$Mo^{VI}O_2$}-DBPA-Zn] (**1**) and [{$Mo^{VI}O_2$}-PBDA-Zn] (**2**) are proposed based on the elemental analyses, mass spectra, molar conductance, and XPS (as well as spectral and electrochemical characteristics, see below). First, the elemental analyses of **1**, **2**, and **4** are consistent with their respective compositions, thus implying that the *cis*-dioxomolybdenum unit has been successfully inserted into the porphyrinato rings. Second, the mass spectrum of [{5-(*p*-$NH_2$)TPP}$Mo^{VI}O_2$] (**4**) shows the molecular ion peak at *m*/*z* 757 $[M + 2]^+$ and the base peak at *m*/*z* 741 $[M + 2 - O]^+$. The MALDI-TOF spectrum of **1** matches the calculated abundance, thereby confirming its elemental composition and the dimeric structure (peaks at *m*/*z* 736.0 and 692.1 attributable to [{5-(*p*-$NH_2$)TPP}$Mo^{VI}O$] and [{5-(*p*-$NH_2$)TPP}Zn], respectively). This evidence suggests that four nitrogen atoms from the porphyrin β-pyrroles are chelated to the molybdenum atom with the two oxo ligands adopting a *cis* configuration on the same side of the porphyrin ring. Third, the molar conductance values in $1.0 \times 10^{-3}$ M chloroform solution at 25 °C are 0.028, 0.039, 0.022, 0.030, 0.030, and 0.033 $\Omega^{-1}\,cm^2\,mol^{-1}$ for dimers **1**, **2**, **1a**, and **2a** and monomers **3** and **4**, respectively, thus indicating that all these porphyrin complexes exhibit nonelectrolytic behavior.[36] Finally, X-ray photoelectron spectroscopy (XPS) was employed to determine the oxidation state of the molybdenum atoms in the Mo/Zn dimers. Mo $3d_{5/2}$ binding energies of 232.3 eV for compound **1** and 232.6 eV for compound **2** were observed, which suggests that the valence state of molybdenum atom in the two compounds is +6.[37,38] Thus, on the basis of the data available, it is assumed that the zinc(II) ion in these Mo/Zn dimers is tetracoordinate to the four pyrrole nitrogens from one

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

porphyrin ring while the molybdenum(VI) atom is hexacoordinate to the other porphyrin ring with the two oxygen atoms located in a *cis* position, as illustrated in Scheme 1.

No axial ligand is present in the porphyrinatozinc subunits of **1** and **2** as two important effects of axial ligands are not observed.[39–41] Thus, the absorption spectrum of [{5-(*p*-$NH_2$)TPP}Zn] (**3**) was obtained in chloroform, a poorly coordinating solvent, which means that no solvent molecule is ligated to the zinc ion. The other complexes **1a**, **2a**, **1**, and **2** did not show a red shift of their Soret bands relative to **3**. Similarly, no change in the relative intensities of the bands at around 550 and 590 nm is observed (see UV/vis section below).[39] This kind of coordination mode for two metal centers is different from the known anthracene-bridged Mo/Zn porphyrin dimer with an oxomolybdenum(V) unit[42] and other zinc porphyrin complexes with different axial ligands.[43] In fact, some mixed-metal Zn/M bis(porphyrin) complexes (M = Pd, Zn, $H_2$) possess a similar coordination mode, mainly due to the different synthetic methodologies.[15,44,45]

### Infrared Spectra

The mono-zinc and heterometallic Mo/Zn bis(porphyrin) complexes give complicated IR spectra. However, they display characteristic IR absorptions that are helpful for identifying the functional groups. For example, the mono-zinc bis(porphyrin) **1a** shows strong stretching bands at 1659 and 1628 $cm^{-1}$ for the C=N bond of the Schiff base, while the mono-zinc bis(porphyrin) **2a** exhibits intense bands at 1652 and 1635 $cm^{-1}$ due to the symmetric C=O stretching vibrations of the imido groups. Upon coordination of the mono-zinc bis(porphyrin)s to the molybdenum atom these bands shift to higher wavenumbers (1697 and 1651 $cm^{-1}$ for **1** and 1652 $cm^{-1}$ for **2**). This shift is primarily associated with the increasing asymmetry of the molecule as a whole. Furthermore, additional bands at 910 and 951 $cm^{-1}$ are observed in **1** and **2**, respectively, due to the Mo=O stretching vibrations. Similar bands have also been found in other molybdenum porphyrin complexes such as [O=Mo(TPP)OH] and [O=Mo(TPP)X] [X = OMe, OEt, O*i*Pr, O*t*Bu].[43]

### UV/Vis Spectra

The bis(porphyrin)s with different bridges exhibit typical UV/Vis spectra in chloroform in the visible and near-ultraviolet regions. Their maximum absorption wavelengths are listed in Table 1 along with the corresponding monoporphyrin compounds.

As can be seen in Figure 1 (a) and Table 1, Mo/Zn bis(porphyrin) complexes **1** and **2** show very similar absorptions and the mono-zinc bis(porphyrin) complexes **1a** and **2a** also give quite similar absorptions. Apparently, the two different linkers do not significantly influence the UV/Vis absorptions of the bis(porphyrin)s. The Mo/Zn dimers give two Soret absorptions at around 340 and 424 nm, which suggest that both $Mo^{VI}$ and Zn ions can be introduced into the porphyrin rings since the absorptions in the ranges 330–340 nm and 420–425 nm are much closer to those found in the monomeric complexes **4** and **3**, respectively. Figure 1 (b) shows the UV/Vis spectra of **3** and **4** as well as their superposition. It is to be expected, and is indeed observed, that the overlapping peaks of **3** and **4** should be similar to those of **1** and **2** (there is no obvious shift in the Soret bands). This result strongly suggests that no axial ligand (e.g., ethanol) is coordinated to the $Zn^{2+}$ ion.

### $^1$H NMR Spectra

Further confirmation of the identity of **1** and **2** was provided by their $^1$H NMR spectra. We collected the $^1$H NMR spectroscopic data of mono-zinc bis(porphyrin)s **1a** and **2a** and Mo/Zn porphyrin dimers **1** and **2** in $CDCl_3$. A weak signal at $\delta$ = –2.75 ppm was observed for **1a** and **2a** due to the pyrrolic nitrogen protons. This signal disappears after the four pyrrolic nitrogens become coordinated to the molybdenum atom. On the other hand, the broad singlet at $\delta$ = 4.11 ppm due to the amino protons in **4** disappears after

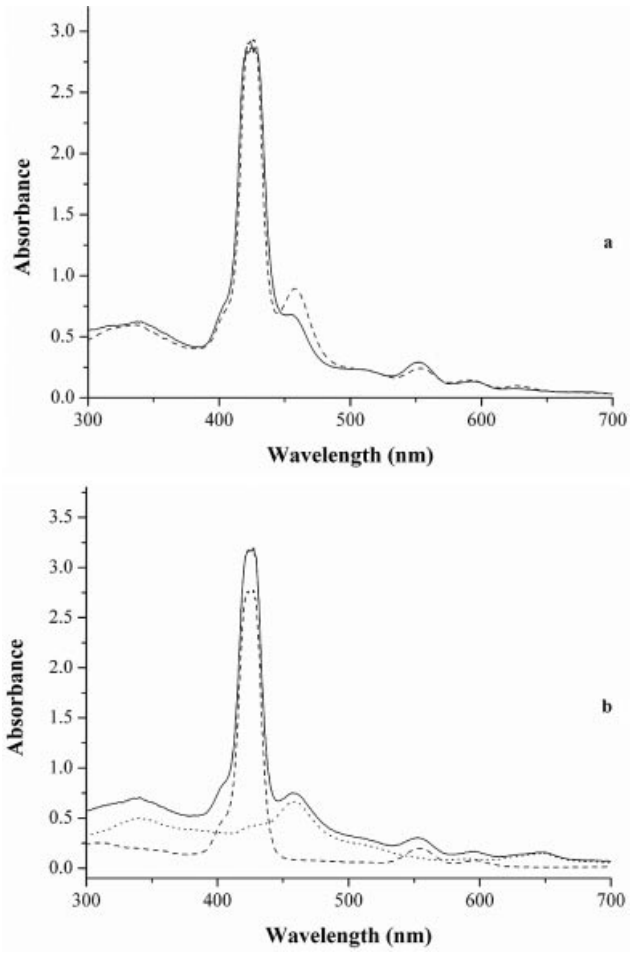

Figure 1. UV/Vis spectra of a series of porphyrin complexes in chloroform at room temperature: (a) Mo/Zn bis(porphyrin) complexes **1** (solid line) and **2** (dashed line); (b) [{5-(*p*-$NH_2$)TPP}Zn] (dashed line), [{5-(*p*-$NH_2$)TPP}$Mo^{VI}O_2$] (dotted line), and their difference spectrum (solid line).

reaction with the linkers. New broad singlets at around $\delta$ = 10.15 ppm due to the protons of the Schiff base [C(*H*)=N] are observed in **1a** and **1**, whereas a new resonance at around $\delta$ = 10.30 ppm is found for the amide proton [C(O)-N*H*] in **2a** and **2**. Mono-substitution on the phenyl rings impose an effective $C_s$ symmetry on the metalloporphyrin moiety, which leads to a splitting of the pyrrole resonances. This tendency is also observed here, where the pyrroles adjacent to the 5-*meso* position bear non-equivalent pairs of protons (see Experimental Section). Besides, **1a** shows a singlet at $\delta$ = 8.23 ppm due to the *ortho* protons, two doublets at $\delta$ = 7.89 and 7.77 ppm due to the *para* and *meta* protons of the *meso*-substituted phenyls, respectively, and two doublets at $\delta$ = 8.08 and 7.63 ppm due to the 5-*meso*-substituted phenyl. For the corresponding Mo/Zn complex **1**, these signals are observed at $\delta$ = 8.24, 7.86, 7.76, 8.07, and 7.69 ppm, respectively. Obviously, these values are too similar to allow any distinctive differences between the two compounds to be determined. Similar phenomena are observed for **2a** and **2**. As regards the Schiff base linker, **1a** shows two doublets at $\delta$ = 7.57 and 7.53 ppm attributable to the phenyl protons, and these resonances are observed at $\delta$ = 7.53 and 7.50 ppm for **1**. For the imido linkage, **2a** shows signals at $\delta$ = 8.01 and 7.95 ppm due to the phenyl protons while signals at $\delta$ = 7.99, 7.88, and 7.46 ppm are observed for **2**. Therefore, the ring current originating from the neighboring porphyrin macrocycle does not cause a significant upfield shift of the phenyl protons *para* or *meta* to the bis(porphyrin)s.[45]

## Thermal Studies

Thermogravimetric analyses of monoporphyrins **3** and **4** and bis(porphyrin)s **1a**, **1**, **2a**, and **2** were carried out. These six compounds were found to be thermally stable up to 150 °C, as indicated by a horizontal plateau in their TG curves. However, the mono- and bis(porphyrin)s show slightly different thermal processes. Monomers **3** and **4**, for example, exhibit similar TG curves with three obvious weight-loss processes. For **4**, the first stage, which involves the loss of a small amount of adsorbent water, four *meso*-phenyl groups, and one terminal oxygen atom, starts at 150 °C and is complete at 301.5 °C. The observed weight loss is 54.56%, in good agreement with the calculated weight loss of 54.90%. This is a continuous exothermic process. The second stage, which corresponds to the collapse of the porphyrinato skeleton, involves a strong exotherm at 373.5 °C; the process is complete at 457.8 °C. This stage leads to the stable product $MoO_3$ with a total weight loss of 26.16%, in agreement with the theoretical value of 26.03%. Following the second step, a medium exothermic process occurs with a further weight loss of 4.85%, thus indicating that $MoO_3$ is not the final product in compound **4**. According to the literature, a possible explanation for this may be the occurrence of self-heating or autocatalysis to yield a nonstoichiometric molybdenum oxide with the formula $MoO_{2.56}$.[46] In contrast to the monomers, the bis(porphyrin)s exhibit continuous decomposition processes. Figure 2 shows the TG and DTA curves for compound **2**. The decomposition of **2** starts at 150 °C and the process ends at

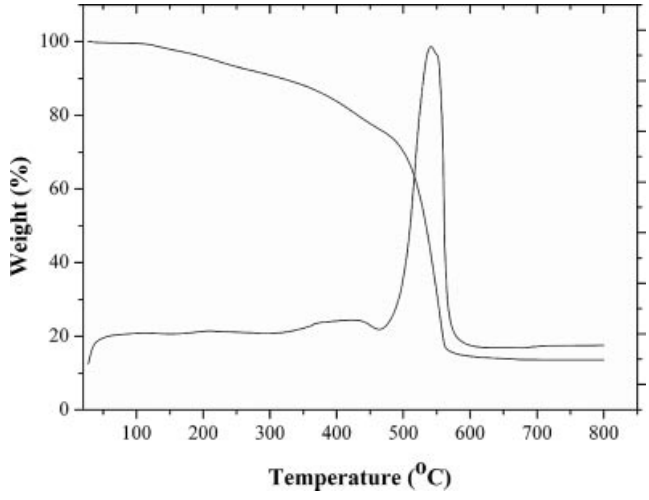

Figure 2. TG and DTA curves of compound **2**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

600 °C, as revealed by the weight loss curve. The experimental weight loss for the process is 85.57%, in good agreement with the expected value of 85.72%. This step involves the loss of a small amount of adsorbed water and the collapse of the whole porphyrin framework; the final products are expected to be $MoO_3$ and ZnO. Therefore, one possible reason why the yield of **2** is so low could be that Mo/Zn bis(porphyrin)s with an imidophenyl linkage are not very stable at high temperature.

### Luminescence Studies

Excited-state processes in porphyrins are extremely important for their applications in molecular devices. Two fluorescence bands [S2 (B band) and S1 (Q band)] are observed in the porphyrin complexes. These are attributable to the transitions from the second excited singlet state (S2) to the ground state (S0; S2→S0) and from the lowest excited singlet state (S1) to S0 (S1→S0), respectively. The room-temperature fluorescence spectra of monomers **3** and **4** and bis(porphyrin)s **1a**, **1**, **2a**, and **2** in chloroform ($1 \times 10^{-5}$ M) were recorded. The excitation spectra are approximately mirror images of the absorption spectra in the Q-band region. The emission spectra obtained at an excitation wavelength of 420 nm are shown in Figure 3.[47]

The Q(0–0) fluorescence bands of these metalloporphyrin complexes are observed in the region 601–608 nm, with the Q(0–1) fluorescence bands in the region 651–655 nm, although they differ with respect to their relative intensities and fluorescent yields. It should be noted that the Q(1–0) absorption bands around 560 nm observed in the zinc tetraarylporphyrin complexes do not appear in the emission spectra of our monomer or dimers. This is probably because this band is too weak to be observed.[47] Several interesting results can be extracted from Table 3: first, the monozinc bis(porphyrin) complex **1a** has weaker Q(0–0) and more intense Q(0–1) bands than **2a**, probably due to a radiationless deactivation process. Second, the Mo/Zn porphyrin dimers **1** and **2** give almost identical fluorescence spectra, thus suggesting that the two *meso* linkages have no significant influence on the fluorescence spectra of these dimers. Third, the emission spectra of monomers **3** and **4** are obviously different, for example an intense Q(0–0) band is observed in **3** while an intense Q(0–1) band is found in **4**. The different coordination modes of the central metals are likely to be responsible for this difference − the molybdenum unit is six-coordinate while the zinc ion is only four-coordinate. Thus, the extent of spin-orbit coupling is strongly dependent on the axial ligands of the porphyrins, such as O, Cl, Br, and I. Fourth, the fluorescent yields of all six porphyrin compounds are less than 0.2, which is in accordance with those reported previously, thereby implying that the excited state S1 is primarily deactivated by radiation-less decay in porphyrins.[47] Monomers **3** and **4** give three- to five-times higher fluorescent yields than ZnTPP due to the effect of the *para*-$NH_2$ group on the rate of nonradiative quenching of S1 (as shown in Table 2). Furthermore, the fluorescence

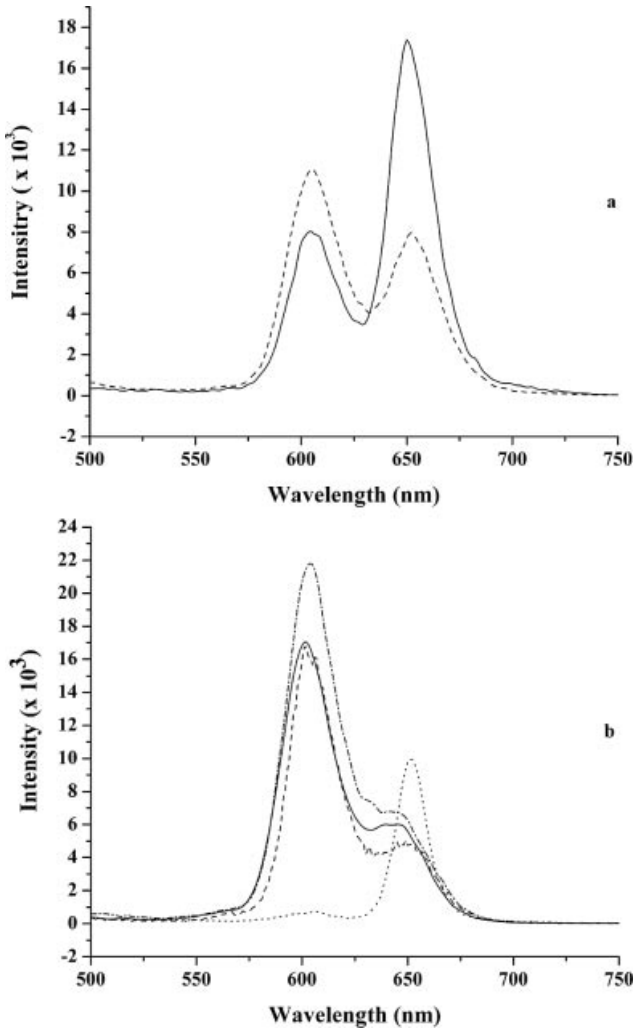

Figure 3. Emission spectra of (a) monozinc bis(porphyrin) **1a** (solid line) and **2a** (dashed line); (b) Mo-Zn porphyrin dimers **1** (solid line) and **2** (dashed line) and monomeric porphyrin complexes **3** (dash dotted line) and **4** (dotted line).

is also dependent on the coplanarity of the compounds. The coplanarity of **3** is better than that of **4**, which leads to its relatively high fluorescence yield. The fluorescent yields of bis(porphyrin)s **1a**, **2a**, **1**, and **2** are quite close to that of ZnTPP, which is due to the lack of interaction between two porphine π systems or a larger dihedral angle between the

Table 2. Emission spectra data and quantum yields ($\Phi_f$) of the monomers and dimers.

| Compounds | Q(0–0) | Q(0–1) | $\Phi_f$ |
|---|---|---|---|
| 5-(*p*-$NH_2$)TPP | | 651 | 0.032 |

two planes, which means that the two porphine π systems in the dimers exhibit independent fluorescence properties.

### Electrochemistry

The electrochemical behavior of **1a**, **1**, **2a**, and **2** was investigated by cyclic voltammetry in dmf containing 0.1 M TEAP. The redox properties of three precursor monoporphyrinates, namely 5-(*p*-$NH_2$)TPP, **3**, and **4** were also studied under the same experimental conditions for comparison. The potentials were scanned positively at either +1.0 $V s^{-1}$ for 5-(*p*-$NH_2$)TPP, **1a**, **2**, **3**, and **4**, or at +1.25 $V s^{-1}$ for **1** and **2a**. All potentials are quoted relative to an $Ag^+/Ag$ electrode.

As shown in Figure 4 (c), complex **4** gives a complicated cyclic voltammogram. It undergoes four reduction steps at $E_{1/2}$ = –1.86, –1.46, –1.16, and –0.43 V (vs. $Ag^+/Ag$; labeled as peaks I–IV). An irreversible oxidation process is also ob-

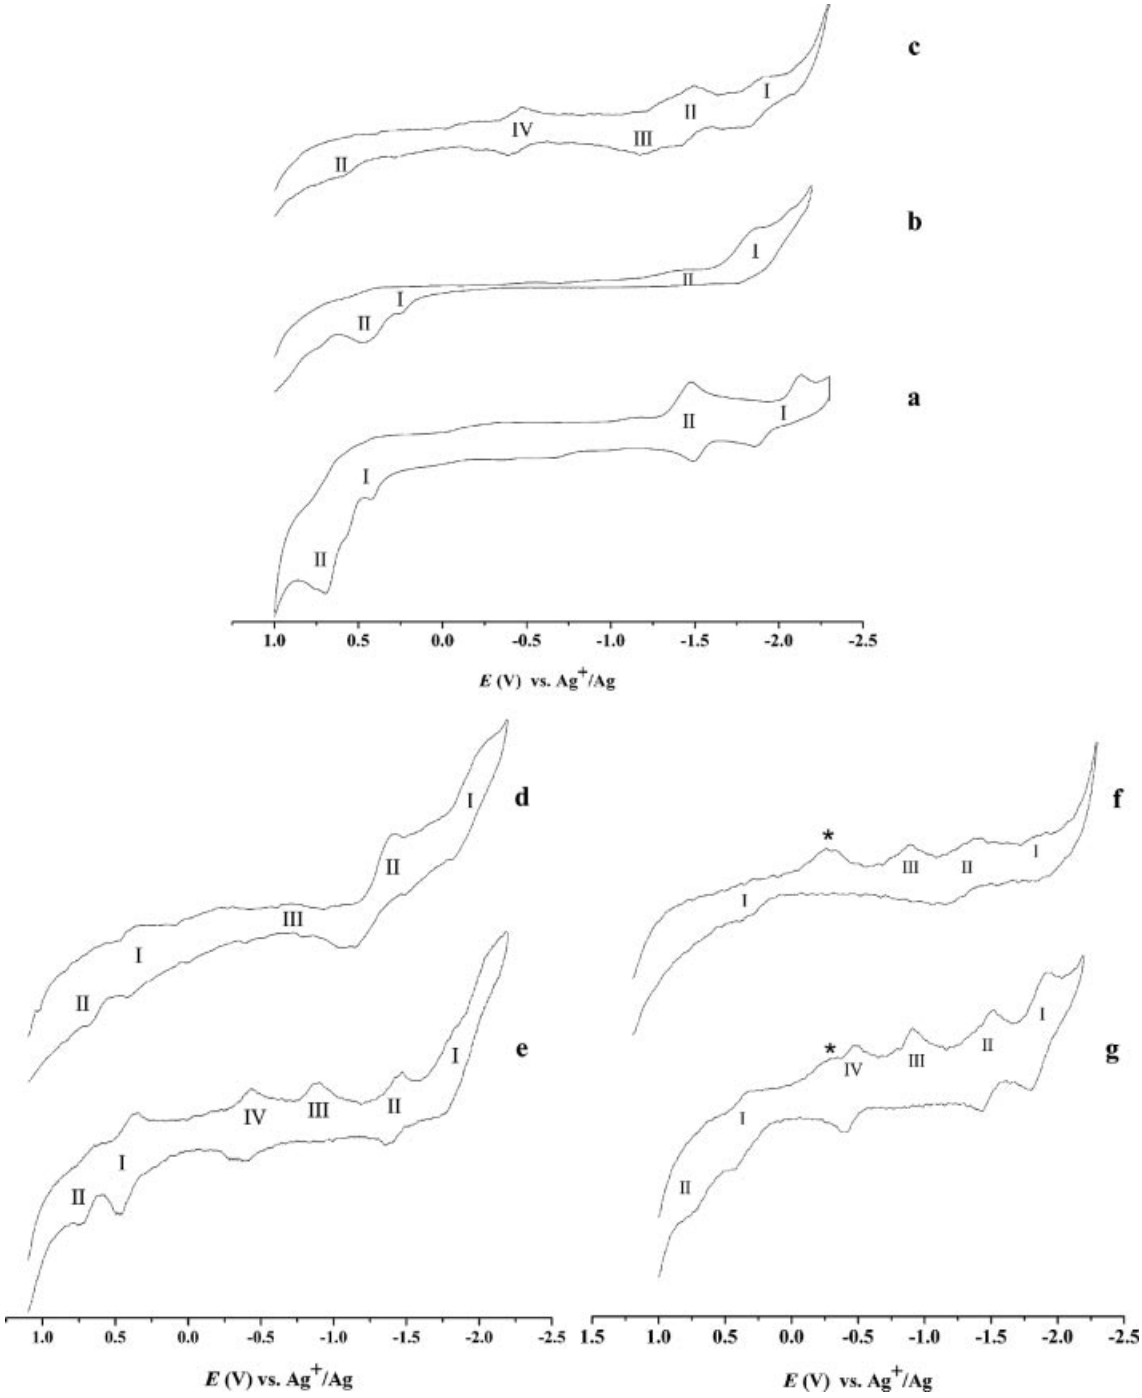

Figure 4. Cyclic voltammograms of 5-(*p*-$NH_2$)TPP (a), [{5-(*p*-$NH_2$)TPP}Zn] (**3**; b), [{5-(*p*-$NH_2$)TPP}$Mo^{VI}O_2$] (**4**; c), [($H_2$DBPA)Zn] (**1a**; d), [{$Mo^{VI}O_2$}-DBPA-Zn] (**1**; e), [{$H_2$PBDA}Zn] (**2a**; f), and [{$Mo^{VI}O_2$}-PBDA-Zn] (**2**; g) in dmf + 0.1 M TEAP. The cathodic peaks marked with asterisks (*) at around –0.3 V in **2a** and **2** are due to impurities.

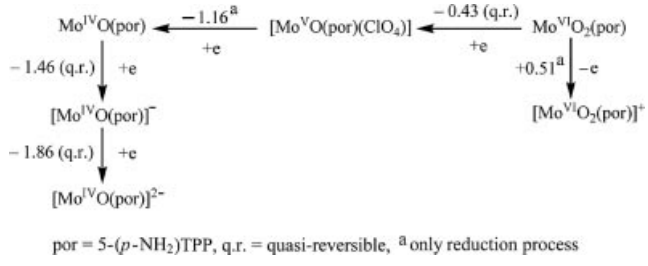
served at $E_p$ = 0.51 V (vs. $Ag^+/Ag$). Each of these processes is a one-electron reduction or oxidation. The first two quasi-reversible reduction steps were assigned to the reductions of the central Mo (waves IV and III), namely $Mo^{VI}$ to $Mo^{V}$ and $Mo^{V}$ to $Mo^{IV}$, while the reduction reactions occurring at the porphyrin ring (waves I and II) yield the dianion and anion radical. These reactions are shown in Scheme 2.[48] Kadish et al. have systematically investigated the electrochemistry of monomeric molybdenum porphyrins such as $[Mo^{VI}O_2(TPP)]$, $[Mo^{VI}O(TMP)(O_2)]$ (TMP = 5,10,15,20-tetramesitylporphyrinato dianion), $[Mo^{V}O(TPP)(X)]$ (X = $MeO^-$, $OAc^-$, $Cl^-$), $[Mo^{IV}O(TPP)]$ in dichloromethane.[30,49–54] A comparison with these molybdenum porphyrin compounds indicates that the two oxidation potentials at around 1.22 and 1.49 V (vs. SCE) in $[Mo^{VI}O_2(TPP)]$ are not observed in compound **4**, although a weak oxidation peak at 0.51 V, which is assumed to be due to the formation of the porphyrin cation radical $[Mo^{VI}O_2(por)]^{\cdot+}$, is found.[49] Furthermore, the electroreductions on the porphyrin rings of **4** in dmf are more negative than those for $[Mo^{VI}O_2(TPP)]$ in dichloromethane or 1,2-dichloroethane (–1.13 and –1.48 V vs. SCE).[54] The use of a different solvent (dmf or dichloromethane) may be the cause of this. This was further confirmed by the electrochemical behavior of the free porphyrin 5-(*p*-$NH_2$)TPP and the corresponding zinc complex (see parts a and b in Figure 4). [{5-(*p*-$NH_2$)TPP}Zn] (**3**) gives two reduction potentials at –1.81 and –1.45 V for $por^-/por^{2-}$ and $por/por^-$ and two oxidation potentials at 0.26 and 0.48 V for $por^{\cdot+}/por$ and $por^{\cdot2+}/por^+$, respectively. It should be noted that all three potentials related to the reductions of the porphyrin ring of **3** and **4** are shifted slightly to more positive potentials upon metalation relative the free-base porphyrin ($E_{1/2}$ = –2.00, –1.49 V). The presence of amine groups has been reported to bring about a multi-electron oxidation, particularly the potentials at 0.5–0.6 V vs. SCE that occur in $H_2T$(*p*-$NH_2$)PP in dichloromethane, although this kind of oxidation could not be distinguished in these three compounds.[54]



Scheme 2. The electrochemical oxidation and reduction of **4**. Values are quoted in volts.

The four bis(porphyrin) complexes **1a**, **1**, **2a**, and **2** (d–g, respectively, in Figure 4) exhibit systematic redox processes. The Mo/Zn dimers **1** and **2** exhibit similar cyclic voltammograms while the monozinc bis(porphyrin)s **1a** and **2a** also have similar properties, thus indicating that the introduction of Schiff-base or imido linkers at the periphery of porphyrins has a similar influence on their redox potential values. As seen in Table 3, the two oxidation waves at around 0.40 and 0.70 V and the two reduction waves in the ranges –1.30 to –1.45 V and –1.86 to –1.91 V correspond to the reduction of the porphyrin units in these four cases. The new totally irreversible cathodic potential at around –0.90 V that appears in the bis(porphyrin)s was assigned to the reduction of the porphyrin ligands. It is thus supposed that the increased asymmetry of bis(porphyrin)s **1a**, **2a**, **1**, and **2** may result in multiple redox processes at the porphyrin rings. Only one quasi-reversible reduction at the central metal ($Mo^{VI}/Mo^{V}$) is observed in **1** and **2** ($E_{1/2}$ = –0.44 V), thus indicating that further reduction from $Mo^{V}$ to $Mo^{IV}$ is difficult when **4** is connected to another zinc porphyrin subunit by the bridging linker.

Table 3. Half-wave potentials (V vs. $Ag^+/Ag$) for some porphyrin complexes in dmf containing 0.1 M TEAP as supporting electrolyte.

| Ligand/complex | Reduction waves | | | | Oxidation waves | |
|---|---|---|---|---|---|---|
| | I | II | III | IV | I | II |
| 5-(*p*-$NH_2$)TPP | –2.00 | –1.49 | | | 0.43[a] | 0.70[a] |
| **3** | –1.81 | –1.45[b] | | | 0.26[a] | 0.48[a] |

[a] Only reduction process. [b] Only oxidation process.

The abstraction of an electron from $Mo^{VI}$, $Zn^{II}$, or the oxo ligand of the four bis(porphyrin) complexes is impossible, therefore the only reasonable site for oxidation is the porphyrin system; this yields the radical cations. Figure 4 (parts d–g) shows the almost identical oxidation reactions that occur at around 0.40 and 0.70 V at the porphyrin moiety, similar to those of monomeric **3** and **4**. However, these peaks are weak in comparison with those found in dichloromethane. It is noteworthy that a large decrease of the HOMO–LUMO gap, as expressed by the half-wave potential difference $E_{1/2}$(1st ox) – $E_{1/2}$(1st red), is observed for **1** and **2** (approx. 0.85 V), in comparison with the corresponding monoporphyrin complexes (approx. 1.80 V), monozinc bis(porphyrin) complexes (approx. 1.10 V), and anthracene-bridged Mo/Zn porphyrin dimer (1.27 V).[42,55] Detailed investigations of this phenomenon are currently underway.

## Conclusions

We have reported the synthesis of two kinds of Mo/Zn bis(porphyrin) complexes by treating 5-(4-aminophenyl)-10,15,20-triphenylporphyrinatomolybdenum/zinc complexes with benzene-1,4-dicarbaldehyde or benzene-1,3-dicarboxylic acid. Unfortunately, we have not been able to obtain good quality single crystals for an X-ray diffraction analysis. However, we have thoroughly investigated them by

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

recording their electronic absorption spectra, thermal stability, luminescent spectra, and electrochemical properties. Taking into consideration previously reported Mo and Mo/Zn porphyrin complexes, we suggest that the dioxomolybdenum(VI) unit is inserted into the porphyrin ring with the two oxo groups in a *cis* configuration.

## Experimental Section

**Materials:** Unless otherwise stated, all reagents, such as $Zn(OAc)_2 \cdot 2H_2O$, $Mo(CO)_6$, benzene-1,4-dicarbaldehyde and benzene-1,3-dicarboxylic acid, were obtained commercially and used without further purification. *N*,*N*-Dimethylformamide (dmf) for electrochemical measurement was distilled from 4 Å molecular sieves under reduced pressure before use. 5-(*p*-Aminophenyl)-10,15,20-triphenylporphyrin [5-(*p*-$NH_2$)TPP] and its zinc complex [{5-(*p*-$NH_2$)TPP}Zn] (**3**) were prepared following a literature procedure.[56–58] TEAP (tetraethylammonium perchlorate) was also obtained by the literature method.[59]

**Physical and Chemical Measurements:** UV/Vis spectra were recorded with a Shimadzu UV2155 spectrometer. IR spectra were measured with a Tensor 27 Fourier Transform spectrometer in the region 4000–400 $cm^{-1}$ using KBr pellets. Elemental analyses (C,H,N) were determined with a Perkin–Elmer 2400 LSII elemental analyzer. Excitation and emission spectra were recorded with a Shimadzu PTI-600 fluorescence spectrometer at room temperature in the range from 300 to 800 nm; the quantum yields were calculated using [Zn(TPP)] as standard ($\Phi_f$ = 0.033). Molar conductances of a $1 \times 10^{-3}$ M solution in chloroform at 25 °C were measured with a DDX-111A conductometer. $^1$H NMR spectra were recorded with a Varian-Unity 500 NMR spectrometer for solutions in $CDCl_3$ with tetramethylsilane (TMS) as an internal standard. The MALDI-TOF mass spectrum for **1** was recorded with a Bruker BIFLEX III spectrometer. The ESI MS spectrum for **4** was measured with a Finnigan MATLCQ electrospray ionization-ion trap mass spectrometer. Thermogravimetric analyses (TGA) and differential thermal analyses (DTA) were performed with a thermoanalyzer (TA SDT 2960) in air at a heating rate of 10 °C $min^{-1}$. The redox behaviors of the complexes (ca. $1 \times 10^{-3}$ M) were determined at a scan rate of 100 mV $s^{-1}$ with an EG&G Princeton Applied Research Model 263A potentiostat/galvanostat at room temperature. An ohmic drop compensation was applied during the CV acquisition. A conventional three-electrode system was used in all electrochemical measurements, consisting of a platinum plate electrode as working electrode, a platinum-wire electrode as counter electrode, and a standard $Ag^+/Ag$ (0.1 M $AgNO_3$ in dmf containing 0.1 M TEAP) reference electrode. The solutions were thoroughly degassed with nitrogen for at least 15 min prior to measurements.

**Method 1. Preparation of [{5-(*p*-$NH_2$)TPP}$Mo^{VI}O_2$] (4):** 5-(*p*-$NH_2$)TPP (200 mg, 0.32 mmol) and $Mo(CO)_6$ (200 mg, 0.76 mmol) were added to 15 mL of 1,2,4-trichlorobenzene under $N_2$ and the mixture was heated at 190 °C for 2 h while stirring. The progress of the reaction was monitored by UV/Vis spectroscopy. After cooling to room temperature, the solution was passed through a silica gel column (2 × 20 cm). The first band eluted with $CHCl_3$ was the free-base porphyrin. The second green band eluted with 2% $C_2H_5OH/CHCl_3$ (v:v) was collected, and the solvents evaporated to dryness to give the desired product as a brown-green powder (80.44 mg, 35%). $C_{44}H_{29}N_5MoO_2$ (755.67): calcd. C 69.93, H 3.87, N 9.27; found C 68.87, H 4.04, N 8.89. ESI-MS: *m*/*z* 757 [M + 2H]$^{2+}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon$) = 341 nm [50.7 ($\times 10^3$ $M^{-1}cm^{-1}$)], 459 (66.5), 647 (14.9). IR (KBr): $\tilde{\nu}$ = 3418 br s, ($\nu_{N-H}$), 2953 w, 2923 m, 2853 m ($\nu_{C-H}$), 1625 s ($\nu_{C-N}$), 1125 w ($\nu_{C-O}$), 946 m, 910 w ($\nu_{Mo-O}$) $cm^{-1}$. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 8.95 (br. s, 2 H, β-pyrrole), 8.23 (br. s, 6 H, β-pyrrole), 7.97 (br. s, 6 H, *ortho* ArH), 7.81 (br. s, 2 H$^1$, ArH *meta* to amido), 7.71 (dd, *J* = 4, 7 Hz, 3 H, *para* ArH), 7.54 (d, *J* = 2 Hz, 3 H, *meta* ArH), 7.05 (s, 2 H$^2$, ArH *meta* to amido), 4.11 (br. s, 2 H, NH) ppm.

**Preparation of [{$Mo^{VI}O_2$}-DBPA-Zn] (1):** [{5-(*p*-$NH_2$)TPP}Zn] (**3**; 37 mg, 0.053 mmol) and benzene-1,4-dicarbaldehyde (10 mg, 0.075 mmol) were dissolved in 20 mL of dmf. The solution was refluxed for 30 min while being stirred under $N_2$. [{5-(*p*-$NH_2$)-TPP}$Mo^{VI}O_2$] (50 mg, 0.053 mmol) was added to the above mixture and refluxing was continued for another 3 h. After the mixture had cooled to room temperature, the suspension was mixed with $CHC1_3$ and extracted several times with distilled water. The chloroform layer was collected and dried with anhydrous $Na_2SO_4$. After removal of the solvent, the residue was purified by chromatography on a neutral alumina column (2 × 10 cm) using 2% $C_2H_5OH/CHCl_3$ (v:v) as eluent to give the desired product. Recrystallization from $CHCl_3$ gave [{$Mo^{VI}O_2$}-DBPA-Zn], which was dried under vacuum to give a purple powder (46 mg, 57%). $C_{96}H_{60}MoN_{10}O_2Zn$ (1546.9): calcd. C 74.55, H 3.91, N 9.06; found C 73.18, H 3.60, N 8.68. MALDI-TOF MS: *m*/*z* 1526.0, 736.0, 692.1. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon$) = 337 nm [62.4 ($\times 10^3$ $M^{-1}cm^{-1}$)], 425 (285.6), 454 (68.1), 552 (29.0), 593 (13.4), 625 (7.6). IR (KBr): $\tilde{\nu}$ = 3434 m, 1697 s, 1651 s, 1523 m, 910 m, 844 w $cm^{-1}$. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 10.14 (s, 1 H, C*H*$^3$=N), 10.00 (s, 1 H, C*H*$^{3'}$=N), 9.05 (d, *J* = 4 Hz, 2H$_\beta$, β-pyrrole), 8.96 (d, *J* = 5 Hz, 12 H$_\beta$, β-pyrrole), 8.90 (br. s, 2 H, β-pyrrole), 8.24 (br. s, 12 H, *ortho* ArH), 8.07 (d, *J* = 8 Hz, 2 H$^1$ and 2 H$^{1'}$, ArH *meta* to Schiff base), 7.86 (d, *J* = 8 Hz, 6 H, *para* ArH), 7.76 (s, 12 H, *meta* ArH), 7.69 (br. s, 2 H$^2$ and 2 H$^{2'}$, ArH *para* to Schiff base), 7.53 (br., 2 H$^4$, bridge-phenyl), 7.50 (d, *J* = 8 Hz, 2 H$^5$, bridge-phenyl) ppm.

**Preparation of [{$Mo^{VI}O_2$}-PBDA-Zn] (2):** [{5-(*p*-$NH_2$)TPP}Zn] (30 mg, 0.043 mmol) and benzene-1,3-dicarboxylic acid (12 mg, 0.072 mmol) were dissolved in 20 mL of dmf and the solution was refluxed for 30 min under $N_2$. [{5-(*p*-$NH_2$)TPP}$MoO_2$] (**4**; 28 mg, 0.039 mmol) was then added to the reaction solution and reflux was continued for another 3 h. After the mixture had cooled to room temperature the suspension was poured into 70 mL of $CHC1_3$ and extracted three times with distilled water. The chloroform layer was collected and dried with anhydrous $Na_2SO_4$. After the removal of the solvent, the residue was purified by chromatography on a neutral alumina column (2 × 10 cm) using 2% $C_2H_5OH/CHCl_3$ (v:v) as eluent to afford the desired product, which was dried under vacuum to give a purple powder (44 mg, 59%). $C_{96}H_{60}MoN_{10}O_4Zn$ (1578.9): calcd. C 73.04, H 3.80, N 8.88; found C 72.38, H 4.15, N 8.11. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon$) = 340 nm [59.8 ($\times 10^3$ $M^{-1}cm^{-1}$)], 424 (293.8), 458 (89.5), 553 (24.1), 590 (14.5), 626 (9.7). IR (KBr): $\tilde{\nu}$ = 3434 s, 1652 m, 1620 br. s, 1520 s, 951 br m, 875 br w, $cm^{-1}$. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 10.30 (br. s, 2 H, O=C–N*H*$^3$–), 8.95 (m, 12 H$_\beta$, β-pyrrole), 8.84 (br. s, 4 H$_\beta$, β-pyrrole), 8.231 (d, *J* = 6 Hz, 12 H, *ortho* ArH), 7.99 (s, 1 H$^4$, bridge-phenyl), 7.94 (br., 2 H$^1$, ArH *meta* to imido), 7.88 (d, *J* = 5 Hz, 2 H$^5$, bridge-phenyl), 7.75 (br. s, 8 H, *meta* ArH), 7.62 (m, 4 H, *meta* ArH), 7.53 (t, *J* = 6 Hz, 6 H, *para* ArH), 7.46 (t, *J* = 8 Hz, 1 H$^6$, bridge-phenyl), 7.18 (m, 2 H$^{1'}$, ArH *meta* to imido), 6.91 (d, *J* = 3 Hz, 2 H$^2$, ArH *ortho* to imido), 6.64 (br., 2 H$^{2'}$, ArH *ortho* to imido) ppm.

**Method 2. Preparation of [($H_2$DBPA)Zn] (1a):** 5-(*p*-$NH_2$)TPP (200 mg, 0.32 mmol) and benzene-1,4-dicarbaldehyde (50 mg, 0.37 mmol) were added to 30 mL of dmf and the mixture was re-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fluxed for 30 min under $N_2$. [{5-(*p*-$NH_2$)TPP}Zn] (220 mg, 0.32 mmol) was then added and the reflux was maintained for another 3 h, during which time the process was monitored by UV/Vis spectroscopy every 10 min. After cooling to room temperature, 70 mL of $CHC1_3$ was poured into the solution and this mixture extracted several times with distilled water. The $CHCl_3$ layer was collected, dried with anhydrous $Na_2SO_4$, filtered to remove the drying agent, and finally evaporated to a small volume. The crude product was purified by chromatography on a neutral alumina column (3.0 × 10 cm). The first band, which eluted with $CHCl_3$, was unreacted [{5-(*p*-$NH_2$)TPP}Zn]. The main purple band, which eluted with 2% $C_2H_5OH/CHCl_3$ (v:v), was collected and condensed to dryness on a rotary evaporator to afford the desired product (108 mg, 24%). $C_{96}H_{62}N_{10}Zn$ (1421.0): calcd. C 81.14, H 4.40, N 9.86; found C 79.98, H 4.55, N 8.97. UV/Vis ($CHCl_3$), $\lambda_{max}$ ($\varepsilon$): 429 nm [269.3 ($10^3$ м$^{-1}$ cm$^{-1}$)], 517 (18.3), 554 (27.3), 595 (12.5), 648 (4.9). IR (KBr): $\tilde{\nu}$ = 3430 s, 1659 m, 1628 s, 1550 m, 963 m cm$^{-1}$. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 10.16 (s, 2 H, C*H*$^3$=N–), 9.02 (br., 2 $H_\beta$, β-pyrrole), 8.95 (d, *J* = 9 Hz, 4 $H_\beta$, β-pyrrole), 8.85 (d, J = 5 Hz, 4 $H_\beta$, β-pyrrole), 8.64–8.58 (br., 6 $H_\beta$, β-pyrrole), 8.23 (br. s, 12 H, o*rtho* ArH), 8.08 (d, *J* = 9 Hz, 4 H$^1$, ArH, *meta* to Schiff base), 7.89 (d, *J* = 8 Hz, 6 H, *para* ArH), 7.77 (d, *J* = 7 Hz, 12 H, *meta* ArH), 7.63 (d, *J* = 6 Hz, 4 H$^2$, ArH, *para* to Schiff base), 7.57 (d, *J* = 7 Hz, 2 H$^4$, bridge-phenyl), 7.53 (d, *J* = 9 Hz, 2 H$^5$, bridge-phenyl), –2.75 (s, 2 H, N–H) ppm.

**Preparation of [($H_2$PBDA)Zn] (2a):** 5-(*p*-$NH_2$)TPP (200 mg, 0.32 mmol) and benzene-1,3-dicarboxylic acid (60 mg, 0.36 mmol) were added to 30 mL of dmf and the mixture was refluxed for 30 min under $N_2$. [{5-(*p*-$NH_2$)TPP}Zn] (**3**; 220 mg, 0.32 mmol) was then added and the mixture was refluxed for another 3 h, during which the process was monitored by UV/Vis spectroscopy every 10 min. After cooling to room temperature, 70 mL of $CHC1_3$ was poured into the solution and the mixture extracted several times with distilled water. The $CHCl_3$ layer was collected, dried with anhydrous $Na_2SO_4$, filtered to remove the drying agent, and finally evaporated to a small volume. The crude product was purified by chromatography on a neutral alumina column (2× 10 cm). The first band, which eluted with $CHCl_3$, was unreacted [{5-(*p*-$NH_2$)-TPP}Zn]. The main purple band, which eluted with 2% $C_2H_5OH/CHCl_3$ (v:v), was collected and the solvents evaporated to dryness to obtain the desired product (164 mg, 35%). $C_{96}H_{62}N_{10}O_2Zn$ (1453.0): calcd. C 79.35, H 4.30, N 9.64; found C 77.97, H 3.98, N 9.17. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon$) = 428 nm [277.1 ($10^3$ м$^{-1}$ cm$^{-1}$)], 519 (17.2), 554 (26.0), 594 (11.8), 650 (4.9). IR (KBr): $\tilde{\nu}$ = 3380 m, 1652 s, 1635 s, 1532 m, 966 w cm$^{-1}$. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 10.27 (br. s, 2 H, O=C–N*H*$^3$–), 8.87–8.83 (br., 12 H, β-pyrrole), 8.81–8.80 (br., 4 $H_\beta$, β-pyrrole), 8.21 (d, *J* = 6 Hz, 12 H, *ortho* ArH), 8.01 (s, 2 H$^4$, bridge-phenyl), 7.95 (d, *J* = 7 Hz, 2 H$^5$, bridge-phenyl), 7.93 (br. s, 4 H$^1$, *meta* ArH), 7.74 (t, *J* = 6 Hz, 12 H, *meta* ArH), 7.53 (t, *J* = 6 Hz, 6 H, *para* ArH), 6.91 (br., 4 H$^2$, ArH *ortho* to imido), –2.75 (s, 2 H, N–H) ppm.

**Preparation of [{$Mo^{VI}O_2$}-DBPA-Zn] (1):** [($H_2$DBPA)Zn] (**1a**; 50 mg, 0.035 mmol) and $Mo(CO)_6$ (50 mg, 0.190 mmol) were added to 10 mL of 1,2,4-trichlorobenzene and the mixture was refluxed while stirring for 4 h under $N_2$. The progress of the reaction was monitored by UV/Vis spectroscopy. After cooling to room temperature, the solution was transferred directly onto a neutral alumina column (2 × 10 cm). The first red band, which eluted with $CHCl_3$, was unreacted [($H_2$DBPA)Zn]. The second purple-red band, which eluted with 2% $C_2H_5OH/CHCl_3$ (v:v), was collected and the solvents evaporated to dryness to give the desired product (23 mg, 42%).

**Preparation of [{$Mo^{VI}O_2$}-PBDA-Zn] (2):** [($H_2$PBDA)Zn] (50 mg, 0.035 mmol) and $Mo(CO)_6$ (50 mg, 0.190 mmol) were added to 10 mL of 1,2,4-trichlorobenzene and the mixture was refluxed while stirring for 4 h under $N_2$. The progress of the reaction was monitored by UV/Vis spectroscopy. After cooling to room temperature, the solution was transferred directly onto a neutral alumina column (2 × 10 cm). The first red band, which eluted with $CHCl_3$, was unreacted [($H_2$PBDA)Zn]. The second purple-red band, which eluted with 2% $C_2H_5OH/CHCl_3$ (v:v), was collected and the solvents evaporated to dryness to give the desired product (10 mg, 5.5%).

# Synthesis, Crystal Structures, and Photoluminescence of a Series of Coordination Polymers with Two Homologous Functional Flexible Ligands

Hong-Ping Zhou,*[a] Peng Wang,[a] Zhang-Jun Hu,[a] Lin Li,[a] Jing-Jin Chen,[a] Yang Cui,[a] Yu-Peng Tian,*[a–c] Jie-Ying Wu,[a] Jia-Xiang Yang,[a] Xu-Tang Tao,[b] and Min-Hua Jiang[b]

**Keywords:** Coordination polymers / Flexible ligands / Supramolecular chemistry / Luminescence

Two functional, flexible ligands, namely 3,6-dipyrazolyl-9-ethylcarbazole (**L¹**) and 3,6-diimidazolyl-9-ethylcarbazole (**L²**) have been synthesized and characterized and their coordination to various $Ag^{I}$, $Cd^{II}$, and $Co^{II}$ salts investigated. Six new complexes, **1**–**6**, have been obtained and fully characterized by IR spectroscopy, elemental analysis, and single-crystal X-ray diffraction. The 2D double helix framework of the complex $[CdL^{1}I_2]_n$ (**1**) is formed by C–H···I hydrogen bonds, whereas the same 2D double helix framework of compound $[\{AgL^{1}SO_3PhCH_3\}_2(CH_3OH)(H_2O)]_n$ (**2**) is formed by S–O···H and C–H···O hydrogen bonds and weak π–π interactions. The coordination modes of $Cd^{II}$ and $Co^{II}$ in $[CdL^{2}_2(NCS)_2]_n$(**3**),$[CoL^{2}_2(NCS)_2(CHCl_3)_2]_n$(**4**),$[CdL^{2}_2(NO_3)_2(CH_3OH)_2]_n$ (**5**), and $[CoL^{2}_2(NO_3)_2(CH_3OH)_2]_n$ (**6**) are the same, but in the packing diagram interlayers form a 3D network through C–H···S interactions and π–π interactions in **3**, interlayers form a 3D network through S···S interactions and π–π interactions in **4**, novel 3D structures are formed by interchain O···H–C hydrogen bonding and interlayer O···H–C hydrogen-bonding and π–π interactions in **5** and **6**. The structural differences between these complexes show the influence of the orientation of the coordinating group of the ligand. These results also show that the metal ion, anion, and nonbonding and π–π interactions are significant factors in controlling the structural topology of these metal-organic supramolecular architectures. In addition, the luminescence properties of **L¹**, **1**, **L²**, and **3** are investigated in the solid state at room temperature.

## Introduction

Much recent work has been devoted to the design, synthesis, and structural characterization of novel multidimensional metal-organic frameworks (MOFs),[1–3] with the increasing volume of research being reflected in the exponential growth of the number of structures reported over the past few years. These structures are assembled by very strong and highly directional coordinative interactions, nonbonding weak interactions, and π–π interactions and display properties related to both the pure organic and inorganic compounds. The motivation behind such research lies in the large variety of peculiar architectures, together with the various potential applications of these compounds as functional materials (e.g., porosity allied with guest exchange, catalysis, gas storage, photoluminescence, nonlinear optical properties, chirality, clathration abilities, and magnetic properties).[4,5]

Biimidazole and bipyrazole have been widely used as biomimetic ligands in bioinorganic chemistry,[6] bridging ligands in organometallic chemistry for catalysis,[7] antitumor drugs,[8] and as building blocks of multidimensional MOFs due to their ability to coordinate to several metal centers in various modes.[9] However, it is difficult to model the structural and functional aspects of these complexes. It is well known that organic ligands with special functionality for use in supramolecular architectures have rarely been reported to date due to the synthetic difficulties involved. We expected to be able to combine such functionality by coordination using the ligands 9-ethyl-3,6-dipyrazolylcarbazole (**L¹**) and 9-ethyl-3,6-diimidazolylcarbazole (**L²**; Scheme 1). As imidazole[10] and pyrazole are electron-rich aromatic compounds, we introduced imidazolyl or pyrazolyl groups at the carbazole ring, in high yield, by a two-step Ullmann reaction. This functionalization of the organic molecule (addition of donor atoms such as N or O) allows its incorporation into inorganic coordination complexes, which have the advantage of higher thermal stability and solvent resistance than organic materials. Compared with our previous reports concerning 9-ethyl-3,6-bis[2-(2-pyridyl)ethenyl]carbazole and 9-ethyl-3,6-bis[2-(4-pyridyl)ethenyl]carbazole,[11]

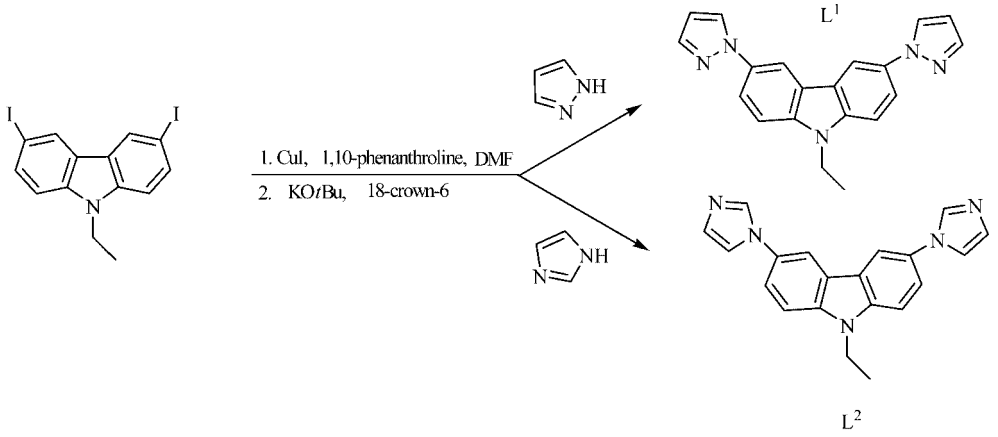
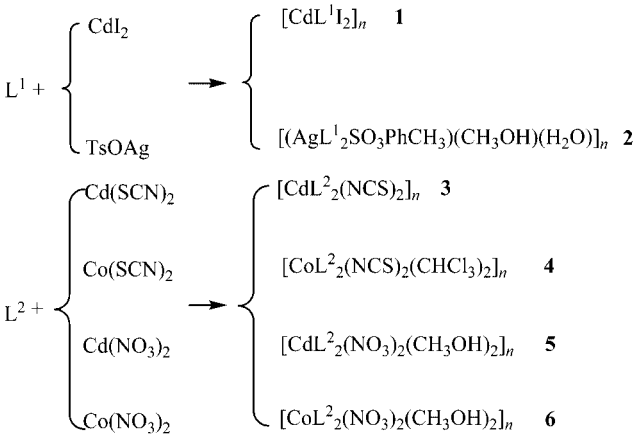


Scheme 1. Synthesis of ligands **L¹**, and **L²**.

replacement of the two pyridylethene groups with two imidazolyl or pyrazolyl groups enhances the flexibility of the ligand greatly. These ligands have a greater number of possible coordination modes than their more rigid analogs due to their flexibility and low symmetry since they can adopt different orientations according to the geometric needs of different metal ions. As a result of a systematic study of these ligands, this paper will describe a series of novel 2D and 3D coordination polymers with intermolecular weak non-bonding and π–π interactions and their photoluminescence properties. All the compounds have been characterized by IR spectroscopy, elemental analysis, and X-ray crystallography. In addition, the luminescence properties of the ligands and complexes **1** and **3** in the solid state are investigated.



Scheme 2. Summary of the reactions between ligands and transition-metal salts.

## Results and Discussion

We synthesized the ligands 9-ethyl-3,6-dipyrazolylcarbazole and 9-ethyl-3,6-diimidazolylcarbazole in good yield by a ligand-accelerated catalytic Ullmann reaction. The Ullmann reaction of aryl halides with amines or heterocycles is traditionally carried out by heating the reagent with copper powder in the presence of a base such as sodium carbonate or hydroxide.[12] However, we found that the Ullmann reaction of 9-ethyl-3,6-diiodocarbazole and imidazole or pyrazole could not be carried out under these conditions. Fortunately, addition of 1,10-phenanthroline and 18-crown-6 allowed **L¹** and **L²** to be synthesized in 84% and 79% yield, respectively.

### Crystal Structures

The ligands react readily with a variety of $Cd^{II}$, $Co^{II}$, and $Ag^{I}$ salts to form complexes **1**–**6**, which were fully characterized by IR spectroscopy, elemental analysis, and single-crystal X-ray diffraction. The general reaction is shown in Scheme 2. The coordination of $Cd^{II}$ and $Ag^{I}$ salts to **L¹** produced 2D polymer chains **1** and **2**, while the coordination of $Cd^{II}$ and $Co^{II}$ salts to **L²** produced the 3D polymers **3**–**6**.

#### *Crystal Structure of $[CdL^1I_2]_n$ (1)*

Single-crystal X-ray diffraction analysis revealed that the structure of the complex presents unusual double helices, as depicted in Figure 2 below. Further crystallographic details are given in the Experimental Section, and selected bond lengths and angles are listed in Table 1. It can clearly be seen from Figure 1 that the cadmium(II) ion displays a distorted tetrahedral geometry with two nitrogens from two $L^1$ ligands and two iodines in the coordination sphere. The bond angles around Cd(1) are in the range 99.73(16)–119.22(3)°, and the bond lengths between the $Cd^{II}$ center and nitrogen range from 2.288(6) to 2.309(6) Å. The two pyrazolyl rings of each $L^1$ ligand have opposite orientations in complex **1**, and the pyrazolyl rings of the two independent $L^1$ ligands are twisted to meet the requirements of steric hindrance, with the dihedral angles between the pyrazolyl rings and the corresponding carbazolyl rings linked to them being 44.5° and 53.3°. Furthermore, the dihedral angle between the pyrazolyl rings in $L^1$ is 64.1°.

The helical polymer is composed of $[CdL^1I_2]$ monomers. A loose, single-stranded helical chain is formed by self-assembly of $[CdL^1I_2]$ by coordination of the metal-bound peripheral pyrazole-N of this unit to the neighboring $Cd^{II}$

center running along the *a* direction with a long pitch of about 3.819 Å (distance between two Cd centers with the same phase). At the widest point the diameter of the helix is 8.990 Å. The adjacent helical chains in $[CdL^1I_2]_n$, one of which is left-handed and the other right-handed, are not entangled but interact through C–H···I interactions (H···I 3.207 Å, ∠C–H···I 156.2°) between two helical chains to generate a very loose double-stranded helical chain [Figure 2(b)]. To illustrate this more clearly, the left- and right-handed helical chains are represented in Figures 2(a) and (c), respectively. These double-stranded helical chains are further extended into a two-dimensional architecture by C–H···I (H···I 3.207 Å, ∠C–H···I 156.2°; H···I 3.135 Å, ∠C–H···I 175.2°) interactions along the *b* axis (Figure 3). Taking the van der Waals radii of H and I to be 1.20 and 2.15 Å, respectively, any H···I contact of less than 3.35 Å and C–H···I angle greater than 130° can therefore be considered as being significant.[13–15] Because left- and right-handed helical chains coexist in the crystal structure, the whole crystal is mesomeric and does not exhibit chirality.

### *Crystal Structure of $[\{AgL^1SO_3PhCH_3\}_2(CH_3OH)(H_2O)]_n$ (2)*

The structure of complex **2** consists of a novel two-dimensional double helical chain. As depicted in Figure 4, the structure of **2** reveals that the asymmetric unit contains two crystallographically and conformationally inequivalent molecules (a) and (b). Each silver(I) center is three-coordinate to two nitrogen donors of two independent $L^1$ ligands [Ag(1)–N(3) 2.19(2) Å, Ag(1)–N(5A) 2.056(16), Ag(2)–N(8)

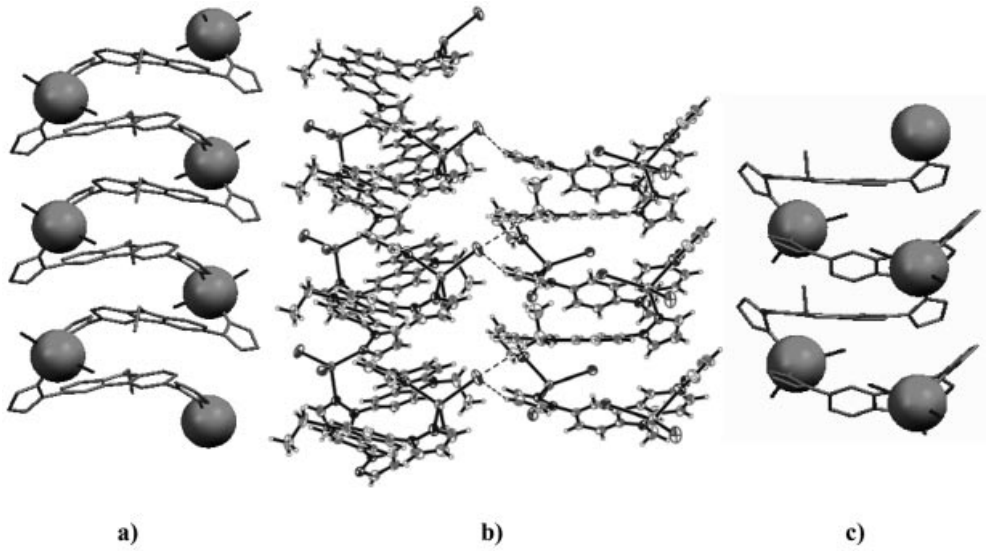

Figure 2. Ball-and-stick model of **1**. Cd atoms are given as balls and H atoms have been omitted for clarity. (a) Left-handed chain and (b) ball-and-stick plot of the double helix bridged by C–H···I interactions (dotted lines) in complex **1**; (c) right-handed chain.

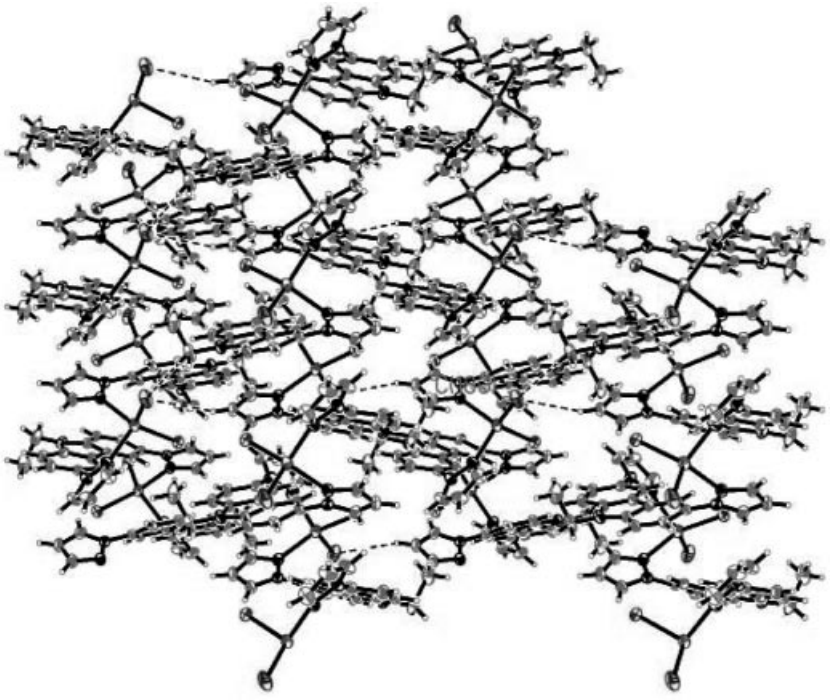

Figure 3. 2D network viewed along the *ab* plane in complex **1** showing C–H···I interactions as dotted lines.

2.17(2), Ag(1)–N(10A) 2.274(16) Å] and one oxygen atom of one *p*-toluenesulfonate anion [Ag(1)–O(1) 2.467(14), Ag(1)–O(4) 2.539(15) Å] to form a distorted trigonal geometry. The two pyrazolyl rings of $L^1$ also exhibit opposite orientations in complex **2**. These components connect to form an infinite polymeric chain structure similar to complex **1**. The dihedral angle between the two pyrazolyl rings of $L^1$ is about 71.4° or 108.6° and the dihedral angles between pyrazolyl rings and the corresponding carbazolyl rings linked to them are 57.6° and 43.0° in the Ag(1) chain. The dihedral angle between the two pyrazolyl rings of $L^1$ is about 73.9° or 106.1° and the dihedral angles between the pyrazolyl rings and the corresponding carbazolyl rings linked to them are 42.3° and 63.0° in the Ag(2) chain. Two loose single-stranded helical chains are formed by self-assembly of $[AgL^1{}_2SO_3PhCH_3]$ through coordination of the *meta*-bound peripheral pyrazole-N of this unit to the neighboring $Ag^I$ center running along the crystallographic $2_1$ axis in the *b* direction with a long pitch of about 5.3385 Å; at the widest point the diameter of the helix is 8.7711 Å.

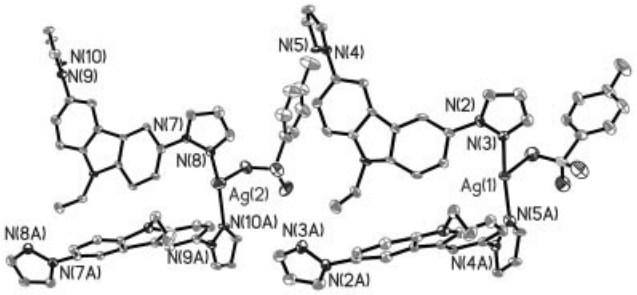

Figure 4. ORTEP diagram showing the structure of compound **2** with thermal ellipsoids at the 50% probability level. H atoms and water and methanol molecules have been omitted for clarity.

In addition, like complex **1**, the adjacent helical chains in compound **2**, one of which is left-handed and the other right-handed, are not entangled together but interact through an S–O···H interaction (H···O 2.469 Å, ∠ S–O···H 136.5°), which alternates between the two helical chains to generate a loose, double-stranded helical chain. Taking the van der Waals radii of H and O to be 1.20 and 1.40 Å, respectively, any H···O contact less than 2.60 Å and S–O···H angle above 130° can be considered to be significant. To illustrate this clearly, the left- and right-handed helical chains are represented in Figure 5. Like complex **1**, these double-stranded helical chains are further extended into a two-dimensional architecture by O···H–C hydrogen-bond interactions between the ligands and oxygen atoms of adjacent chains (O···H 2.455 Å, ∠ O···H–C 152.1°) and a very weak π–π stacking interaction (the shortest distance between carbazolyl rings is 4.3477 Å) along the *a* axis in compound **2** (Figure 6). The whole crystal is mesomeric and does not exhibit chirality, just like compound **1**.

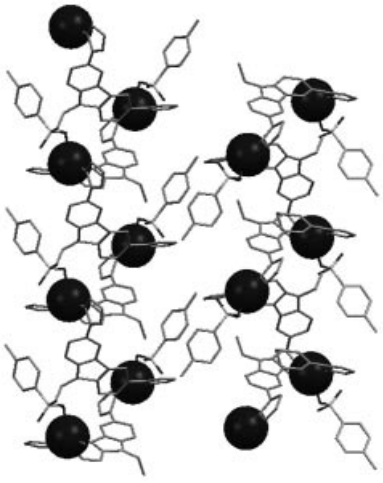

Figure 5. A ball-and-stick model of complex **2** showing the helicity. Ag atoms are given as balls and H atoms and water and methanol molecules have been omitted for clarity.

### *Crystal Structure of $[CdL^2_2(NCS)_2]_n$ (3)*

The coordination environment of the $Cd^{II}$ ion in complex **3** is shown in Figure 7. Each $Cd^{II}$ center, which is located at an inversion center, is in an octahedral environment com-

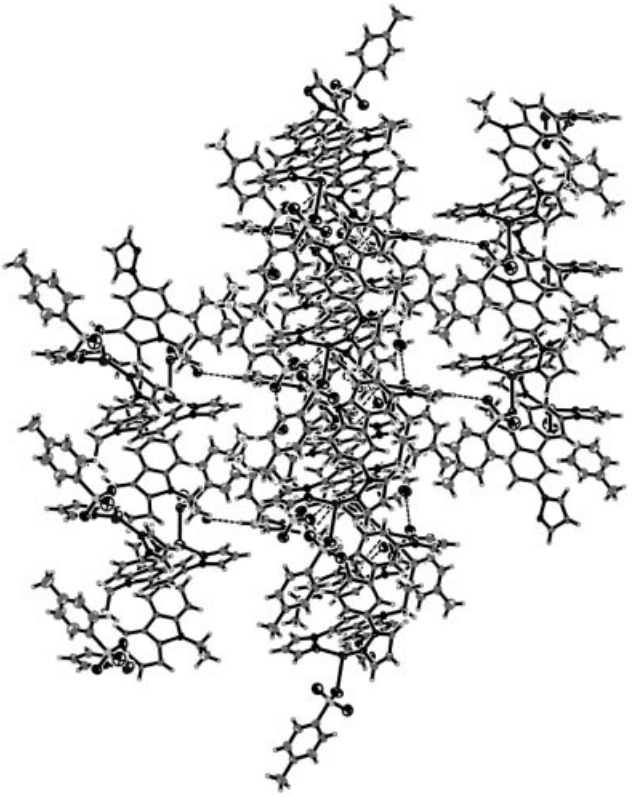

Figure 6. 2D network viewed along the *ab* plane in compound **2** showing the π–π stacking interactions and S–O···H and C–H···O interactions (dotted lines); the shortest H···O interaction is 2.455 Å.

posed of two nitrogen atoms from two $NCS^-$ groups in the axial positions and four imidazolyl nitrogen atoms from four $L^2$ molecules in the equatorial plane. The Cd–$N_{NCS}$ [2.347(3) Å] bond length is longer than Cd–$N_{im}$ [Cd–N(1) 2.345(2), Cd–N(5) 2.323(3) Å], and N–Cd–N bond angles with the same orientational fall in the range 88.59(12)–91.04(11)°. The two terminal $NCS^-$ groups are bent, with a

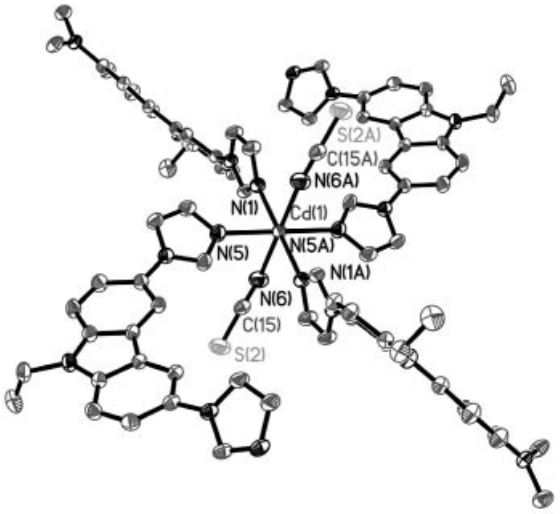

Figure 7. Octahedral coordination geometry around the cadmium center in **3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Cd(1)–N(6)–C(15) bond angle of 140.4(3)°, and are coordinated axially in opposite directions. The two imidazolyl rings within each ligand deviate from coplanarity, the dihedral angles between each terminal imidazolyl ring and the central carbazole unit being 139.8° and 31.4°.

The two imidazolyl rings of $L^2$ in complex **3** adopt the same orientation, the dihedral angle between two imidazolyl rings being 54.3°, and each one bridges two $Cd^{II}$ centers to form a 2D sheet containing $[Cd_4L^2_4]$ macrocycles as subunits. The $Cd^{II}$ atoms lie at the nodes of a rhombic grid in the undulating $[CdL^2_2(NCS)_2]_n$ layer, with ligand-bridging Cd···Cd distances of 23.744 and 12.769 Å (Figure 8). Each layer contains π–π interactions (the shortest distance between parallel carbazole rings is 3.89 Å), and these layers are stacked by C–H···S (H···S 2.913 Å) interactions along the *c* axis (Figure 9) to form a 3D network. Taking the van der Waals radii of H and S to be 1.00 and 2.05 Å, respectively, any H···S contact less than 3.05 Å can be considered significant. The H···S distance of 2.913 Å indicates the formation of C–H···S hydrogen bonds. C–H···S hydrogen-bonding interactions are very important in several novel supramolecular structures.[16]

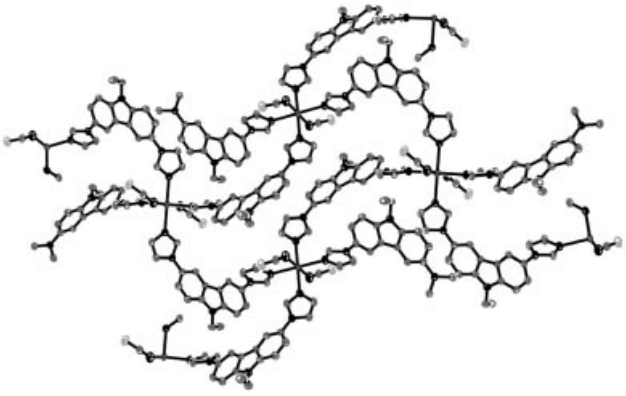

Figure 8. Two-dimensional grid structure of **3**.

### *Crystal Structure of $[CoL^2_2(NCS)_2(CHCl_3)_2]_n$ (4)*

The coordination environment of the $Co^{II}$ ion in **4** is shown in Figure 10. Each metal center is six-coordinate to two NCS groups and four $L^2$ ligands. The Co–N bond involving the NCS group [Co–$N_{NCS}$ 2.128(3) Å] is shorter than the other Co–N bonds [2.144(3) and 2.161(3) Å]. It is clear that each $Co^{II}$ center lies in the same octahedral coordination environment as complex **3**, and N–Co–N angles with the same orientation lie in the range 87.92(11)–92.08(11)°, similar to that for $Cd^{II}$. The oppositely oriented N–Co–N bond angles for $NCS^-$ and the $L^2$ ligands are 180°. The NCS ligands are coordinated axially in a terminal mode with angles of 180°. The two imidazolyl rings within each $L^2$ deviate by 50.2° and 140.7°, respectively, from the carbazole plane. The two imidazolyl rings of $L^2$ in complex **4** also adopt the same orientation and their dihedral angle is 65.0°. Selected bond lengths and angles for **4** are listed in Table 1.

Figure 11 shows the lamellar network of **4** in which the adjacent $Co^{II}$ centers are linked by a bridging $L^2$ ligand in two different directions to form large and nearly square repeating grids (the ligand-bridging Co···Co distances are 12.492 and 20.845 Å) in a 2D sheet. Each sheet contains weak π–π interactions[17] (the shortest distance between parallel carbazole rings is 4.225 Å), and these sheets are stacked by π–π (the shortest distance between parallel carbazole rings is 3.753 Å) and S···S (S···S 3.589 Å) interactions along the *a* axis (Figure 12) to form a 3D network. Taking the van der Waals radii of S to be 2.05 Å, any S···S contact less than 4.10 Å and C–S···S angle greater than 130° may therefore potentially be considered significant. The S···S distance of 3.589 Å and C–S···S angle of 153.2° in complex **4** indicate such an S···S interaction. In general, weak S···S interatomic interactions are often observed in multi-sulfur systems,[18] and these S···S weak interactions in complex **4** construct a novel supramolecular network structure. The shortest intersheet Co···Co distance is 13.139 Å. The coordination environment of the metal ions is similar

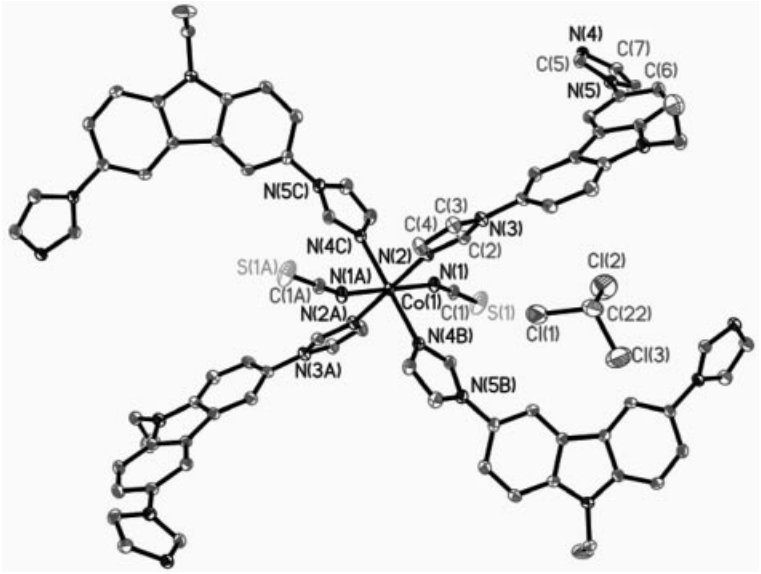

Figure 10. Octahedral coordination geometry around the cobalt center in **4**.

to that in complex **3**, but they adopt a different stacking arrangement due to the presence of different metal ions.

### *Crystal Structure of $[CdL^2_2(NO_3)_2(CH_3OH)_2]_n$ (5)*

The crystallographic analysis of complex **5** revealed that its structure is a 1D polymeric chain structure which is constituted by $[CdL^2_2(NO_3)_2]$ units. As shown in Figure 13, the $Cd^{II}$ atoms reside on crystallographic inversion centers and each has a slightly distorted octahedral $[CdN_4O_2]$ coordination geometry with the equatorial sites occupied by imidazolyl nitrogen donors from $L^2$; the axial positions are occupied by two monodentate nitrate counterions. The Cd–N and Cd–O bonds fall in the range of 2.307(7)–2.328(6) Å and 2.258(10) Å, respectively, which are very close to the corresponding bond lengths found in $[Cd(NO_3)_2(L)_2]$ [L = 2,5-bis(3-pyridyl)-3,4-diaza-2,4-hexadiene].[7] Two imidazolyl rings of $L^2$ also adopt the same orientation with a dihedral angle of 67.9°.

Compound **5** adopts a chain motif in the solid state with the $Cd^{II}$ centers linked by four crystallographically equiva-

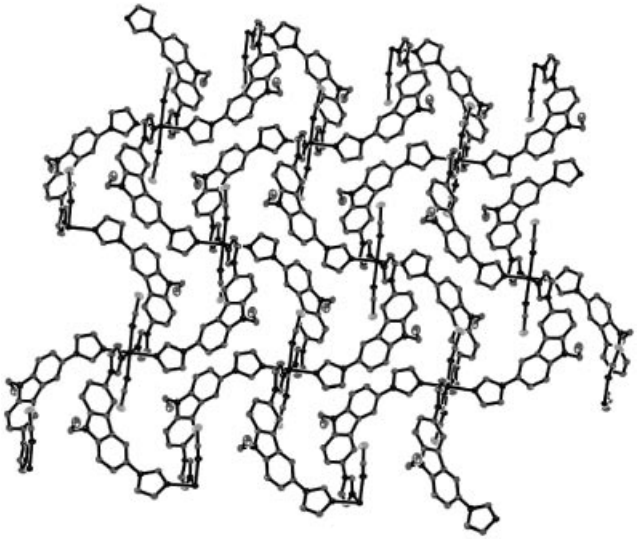

Figure 11. Two-dimensional grid structure of **4**.

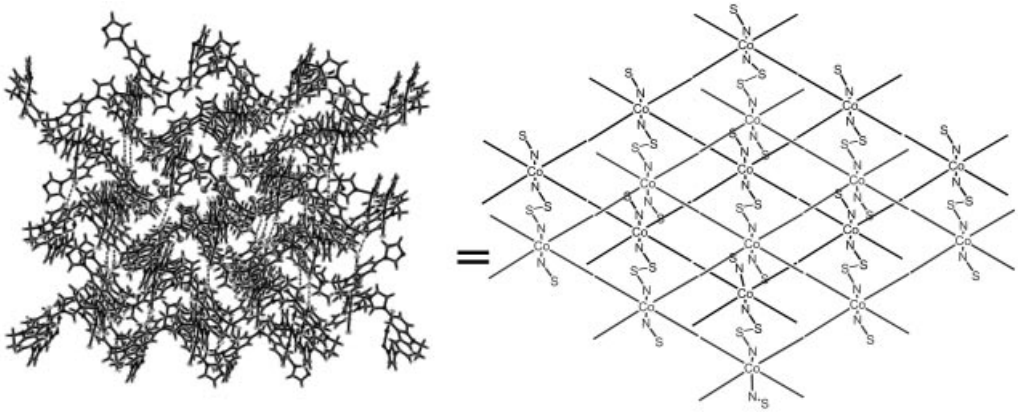

Figure 12. Molecular packing viewed along the *c* axis showing the intermolecular S···S and π–π interactions (dotted lines).

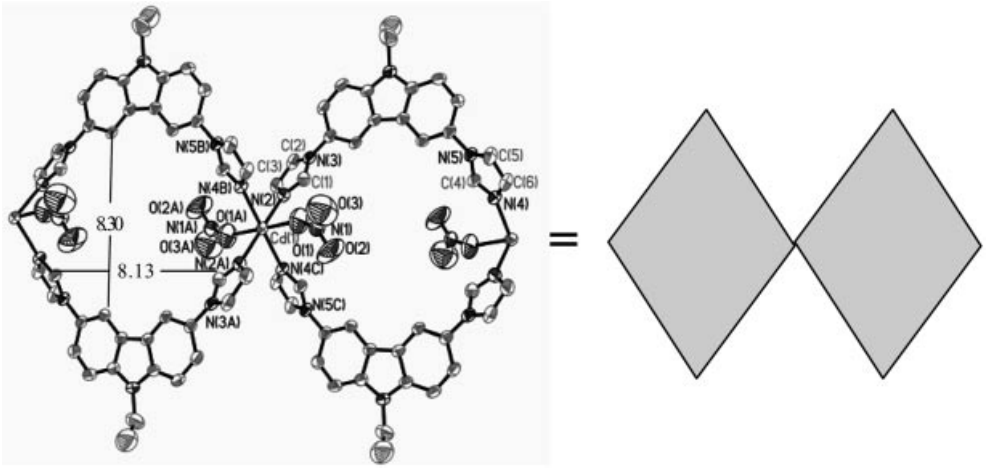

Figure 13. View of the basic box unit in the polymer chains of **5** (methanol molecules have been omitted for clarity).

lent $L^2$ ligands into an undulating one-dimensional chain running along the *b* axis (Figure 14). As shown in Figure 13, the individual "links" in the chain consist of $M_2L_2$ units, which a form 26-membered ring. The approximate (crystallographic) dimensions of the rings are $8.13 \times 8.30$ Å$^2$ (Figure 13). The intra- and interchain Cd···Cd distances are both 11.861 Å. Two crystallographically equivalent monodentate $NO_3^-$ ions are located above and below the $M_2L_2$ ring planes. In addition, hydrogen-bonding interactions between the chains, involving one uncoordinated O of the monodentate nitrate ion and H on the methyl and ethyl group of a ligand in an adjacent chain, are present in **5** (Figure 15). The O···H contacts are 2.498 and 2.534 Å. The existence and structural importance of weak C–H···O hydrogen-bonding interactions are now well established and they are present in many molecular and polymeric compounds.[19–22] O···H–C hydrogen bonds, although they are weak and are accompanied by π–π interactions (the shortest distance between parallel carbazolyl rings is 3.685 Å), contribute significantly to the structural organization of **5** in the crystalline phase, giving rise to a two-dimensional arrangement in which one-dimensional chains align together in a shoulder-to-shoulder fashion to generate a 2D sheet along the *a* axis. It is very interesting that these sheets are stacked to form a 3D structure along the *c* axis by intersheet hydrogen-bonding interactions and π–π interactions (the shortest distance between parallel carbazolyl rings is 3.4791 Å). Figure 16 shows that these sheets are overlapped vertically by the other uncoordinated O of the monodentate nitrate ion and two H atoms of the phenyl group of a ligand in the other sheet (the O···H contacts are 2.460 and 2.475 Å, respectively).

The metal ion in this complex is the same as in complex **3** but the anion is different, which indicates that the nature of the anion is a significant factor in controlling the structural topology of these metal-organic supramolecular architectures and offers the opportunity to control the coordination networks by changing the anion.

### *Crystal Structure of $[CoL^2{}_2(NO_3)_2(CH_3OH)_2]_n$ (6)*

In general, all the $Co^{II}$ centers in the coordination polymers generated from cobalt nitrate and *N*,*N*′-bidentate ligands adopt a $\{CoN_3O_4\}$ coordination environment.[22] zur Loye[19] reported the first $\{CoN_4O_2\}$ coordination sphere in coordination polymers. Compound **6** reported here also has a $\{CoN_4O_2\}$ coordination sphere and is similar to compound **5**. One of the Co–N bond lengths is 2.117(5) Å, which is significantly shorter than the corresponding Co–N bond lengths [2.210(2)–2.261(2) Å] in the $\{CoN_4N'_2\}$ coordination spheres but is consistent with the Co–N bond lengths in a $\{CoN_3O_4\}$ coordination sphere.[23] The two imidazolyl rings of the ligand also adopt the same orientation, with a dihedral angle of 69.4°.

Compound **6** is isostructural with **5** except that the $Cd^{II}$ centers are replaced by $Co^{II}$ atoms. The intra- and interchain Co···Co distances are both 11.72 Å. The same interchain hydrogen-bonding system is present in **6** (O···H 2.27, O···C 2.939 Å; O···H–C 125.9°) and π–π interactions

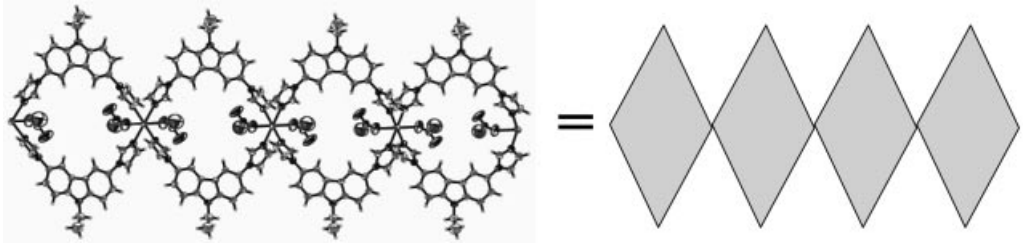

Figure 14. 1D chain in **5**.

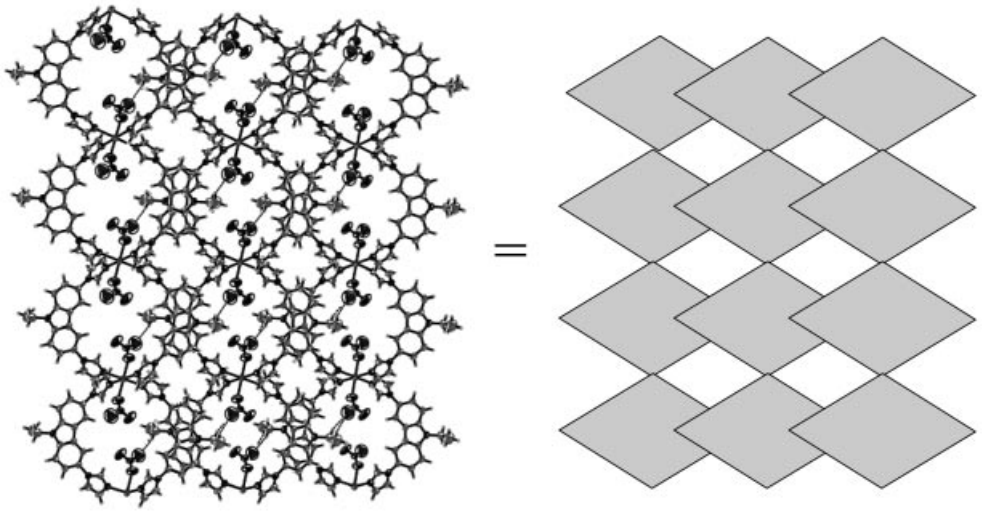

Figure 15. A view of the 2D networks formed by adjacent 1D chains in **5** showing the C–H···O hydrogen-bonding system and π–π interactions (dotted lines).

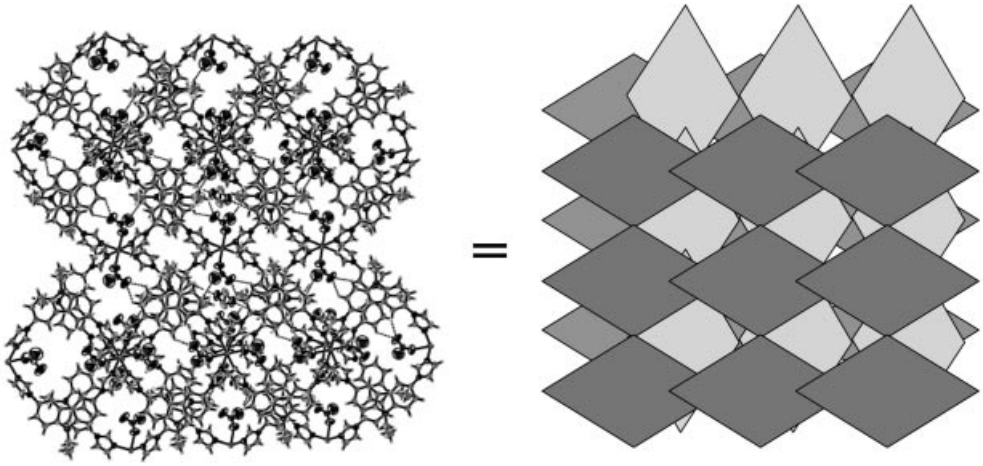

Figure 16. A view of the 3D network formed by interlayer C–H···O hydrogen bonding and π–π interactions (dotted lines).

(the shortest distance between parallel carbazolyl rings is 3.743 Å). The same intersheet hydrogen-bonding system is also present in **6** (O···H 2.56 and 2.514 Å; O···C 3.153 and 3.12 Å; O···H–C 122.0° and 123°) and π–π interactions (the shortest distance between parallel carbazolyl rings is 3.8135 Å). When compared with complex **4**, this complex again shows that the nature of the anion is a significant factor in controlling the structural topology of these metal-organic supramolecular architectures.

When the ligands of complexes **1**–**6** are compared, it can be seen that the two pyrazolyl rings of $L^1$ keep the same opposite orientation with a different dihedral angle during the complex formation (the dihedral angles of the two pyrazole rings are 64.1° for **1** and 71.4°, 73.9° for **2**) and the two imidazolyl rings of $L^2$ keep the same orientation with a different dihedral angle during the complex formation (the dihedral angles of the two imidazole rings are 54.3°, 65.0°, 67.9°, and 69.4° for **3**, **4**, **5**, and **6**, respectively). The opposite orientation and corresponding angle allow $L^1$ to coordinate the metal ion as a bidentate ligand using the nitrogen atom and form 1D helical chains, whereas the same orientation and corresponding angle allow $L^2$ to coordinate the metal ion as a bidentate ligand using the nitrogen atom and form a 2D grid or a 1D double chain. Finally, the intermolecular nonbonding weak interactions link low-dimensional entities into high-dimensional supramolecular frameworks.

In summary, two novel functional ligands and six coordination complexes (**1**–**6**) have been prepared and structurally characterized; the latter display metal-organic supramolecular architectures. As flexible bridging ligands can easily produce unique frameworks with useful properties due to their flexibility and orientational freedom,[24] we designed and synthesized conveniently two novel functional flexible ligands, namely 9-ethyl-3,6-dipyrazolylcarbazole and 9-ethyl-3,6-diimidazolylcarbazole, that are capable of coordinating to metal centers through their respective imidazolyl or pyrazolyl nitrogen atoms form novel 2D or 3D polymers. The results indicate that the metal ion, anion, and non-

bonding and π–π interactions are significant factors in controlling the structural topology of these metal-organic supramolecular architectures.

## Experimental Section

All chemicals and solvents were dried and purified by usual methods. Elemental analyses were performed with an Elmentar Vario EL-III analyzer. IR spectra were recorded with a Nicolet FT-IR Nexus 870 instrument in the range 4000–400 cm$^{-1}$ by using KBr pellets. $^1$H NMR spectra were recorded with a Bruker 600 MHz Ultrashield spectrometer and are reported in parts per million (ppm) from TMS ($\delta$). Melting points were recorded with a Perkin–Elmer Pris-1 DMDA-V1 analyzer under $N_2$ at a heating rate of 5 °C min$^{-1}$. The luminescent spectra were recorded for single crystals at room temperature using a Fluorolog-3-TAU steady-state/lifetime spectrofluorometer. The excitation slit and the emission slit were 2.5 nm.

**X-ray Crystallography:** Single-crystal X-ray diffraction measurements were performed with a Bruker Smart 1000 CCD diffractometer equipped with a graphite crystal monochromator situated in the incident beam for data collection at room temperature. Unit cell parameters and data collections were performed with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Unit cell dimensions were obtained with least-squares refinements, and all structures were solved by direct methods using SHELXL-97.[26] The other non-hydrogen atoms were located in successive difference Fourier syntheses. The final refinement was performed by full-matrix least-squares methods with anisotropic thermal parameters for non-hydrogen atoms on $F^2$. The hydrogen atoms were added theoretically as riding on their parent atoms. Crystallographic crystal data and processing parameters for complexes **1**–**6** are given in Table 2. Selected bond lengths and bond angles are listed in Table 1.

CCDC-611826 (for **1**), -611825 (for **2**), -274291 (for **3**), -278330 (for **4**), -278332 (for **5**) and -278331 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Preparation of 9-Ethyl-3,6-dipyrazolylcarbazole ($L^1$):** CuI (0.27 g, 1.35 mmol), 1,10-phenanthroline (0.60 g, 3.02 mmol), and 3 mL of dmf were added to a three-necked flask equipped with a magnetic stirrer and a reflux condenser. This mixture was refluxed for 5 min in an oil bath at 120 °C, cooled to room temperature, and then pyrazole (3.65 g, 53.61 mmol), KO*t*Bu (6.05 g, 54.00 mmol), 9-ethyl-3,6-diiodocarbazole (3.00 g, 6.72 mmol),[11] and 18-crown-6 (little) were added and the mixture heated to 130 °C for 36 h. It was then cooled to room temperature and the residue was extracted with 150 mL of dichloromethane, washed three times with distilled water, and dried with anhydrous magnesium sulfate. It was then filtered and concentrated. Recrystallization from ethyl acetate produced light yellow crystals. Yield: 1.82 g (84%). M.p. 202–202.4 °C. $^1$H NMR (600 MHz, [D$_6$]DMSO): $\delta$ = 1.35 (t, $J$ = 7.20 Hz, 3 H, $CH_3$), 4.51 (q, $J$ = 7.20 Hz, 2 H, $CH_2$), 6.57 (s, 2 H, phenyl), 7.75 (d, $J$ = 8.40 Hz, 4 H, phenyl), 7.98 (d, $J$ = 7.2 Hz, 2 H, pyrazolyl), 8.53 (d, $J$ = 1.8 Hz, 2 H, pyrazolyl), 8.71 (d, $J$ = 0.6 Hz, 2 H, pyrazolyl) ppm. $C_{20}H_{17}N_5$ (327.39): calcd. C 73.37, H 5.23, N 21.39; found C 73.67, H 5.40, N 21.16. IR (KBr): $\tilde{\nu}$ = 3141 (w), 2973 (m), 2937 (w), 1636 (m), 1618 (m), 1584 (w), 1509 (vs), 1483 (vs), 1392 (m), 1316 (s), 1223 (m), 1195 (m), 1153 (m), 1085 (w), 1046 (m), 936 (m), 881 (m), 835 (w), 799 (m), 750 (s), 664 (m), 615 (m) cm$^{-1}$.

**Preparation of 9-Ethyl-3,6-diimidazolylcarbazole ($L^2$): $L^2$** was obtained by a similar method to **$L^1$**. Yield: 1.72 g (79%). M.p. 221–221.6 °C. $^1$H NMR (500 MHz, [D$_6$]DMSO): $\delta$ = 1.34 (t, $J$ = 7.04 Hz, 3 H, $CH_3$), 4.54 (q, $J$ = 6.98 Hz, 2 H, $CH_2$), 7.15 (s, 2 H, imidazolyl), 7.79 (d, $J$ = 8.72 Hz, 2 H, phenyl), 7.75 (t, $J$ = 5.12 Hz, 4 H, phenyl), 8.22 (s, 2 H, imidazolyl), 8.50 (d, $J$ = 1.36 Hz, 2 H, imidazolyl) ppm. $C_{20}H_{17}N_5$ (327.39): calcd. C 73.37, H 5.23, N 21.39; found C 73.30, H 5.19, N 21.07. IR (KBr): $\tilde{\nu}$ = 3104 (m), 2969 (w), 2863 (w), 1637 (m), 1620 (m), 1581 (m), 1506 (vs), 1380 (m), 1320 (m), 1260 (m), 1228 (m), 1105 (m), 1063 (m), 904 (m), 804 (m), 663 (m) cm$^{-1}$.

**Preparation of $[CdL^1I_2]_n$ (1):** 9-Ethyl-3,6-dipyrazolylcarbazole (**$L^1$**; 32.74 mg, 0.1 mmol) and $CdI_2$ (36.62 mg, 0.1 mmol) were dissolved in MeOH (10 mL). The mixture was refluxed for 2 h at 70 °C and then cooled to room temperature to give a clear colorless solution. Pale colorless crystals suitable for X-ray diffraction were obtained after two weeks by slow evaporation of the methanol solution at room temperature. Yield: 61.73 mg (89%). IR (KBr): $\tilde{\nu}$ = 3117 (m), 2971 (w), 2925 (w), 1632 (m), 1613 (m), 1519 (s), 1487 (s), 1403 (m), 1383 (m), 1230 (s), 1192 (m), 1149 (w), 1067 (m), 1038 (m),

958 (w), 894 (m), 874 (m), 805 (m), 746 (vs), 670 (w) $cm^{-1}$. $C_{20}H_{17}CdI_2N_5$ (693.59): calcd. C 34.63, H 2.47, N 10.10; found C 35.01, H 2.50, N 10.15.

**Preparation of $\{[AgL^1SO_3PhCH_3]_2(CH_3OH)(H_2O)\}_n$ (2):** Complex **2** was prepared by a procedure similar to that of **1** except that AgOTs (27.79 mg, 0.1 mmol) was dissolved in MeOH (10 mL) and $H_2O$ (0.5 mL). Colorless transparent cube-shaped crystals of **2** suitable for X-ray structure determination were obtained in 81% yield. $C_{55}H_{54}Ag_2N_{10}O_8S_2$ (1263.0): calcd. C 52.31, H 4.31, N 11.09; found C 52.74, H 4.08, N 11.30. IR (KBr): $\tilde{\nu}$ = 3131 (w), 2978 (w), 2920 (w), 1629 (m), 1581 (m), 1516 (s), 1487 (s), 1404 (m), 1382 (m), 1351 (w), 1317 (m), 1188 (s), 1119 (m), 1064 (m), 1034 (m), 1007 (m), 814 (m), 763 (m), 677 (s), 615 (m), 565 (s) $cm^{-1}$.

**Preparation of $[CdL^2_2(NCS)_2]_n$ (3):** A solution of $L^2$ (65.48 mg, 0.20 mmol) in 5 mL of $CHCl_3$ solution was layered onto a solution of $Cd(SCN)_2$ (22.86 mg, 0.10 mmol) in MeOH (10 mL) and allowed to stand for ten days to give pale-yellow single crystals. Yield: 85% (75.08 mg). $C_{42}H_{34}CdN_{12}S_2$ (883.33): calcd. C 57.11, H 3.88, N 19.03; found C 56.89, H 3.68, N 18.67. IR (KBr): $\tilde{\nu}$ = 3130 (m), 2976 (w), 2933 (w), 2088 (vs), 2034 (s), 1621 (m), 1587 (m), 1508 (vs), 1388 (m), 1332 (m), 1303 (m), 1269 (m), 1228 (s), 1122 (m), 1065 (s), 924 (m), 873 (m), 808 (s), 736 (s), 659 (s) $cm^{-1}$.

**Preparation of $[CoL^2_2(NCS)_2(CHCl_3)_2]_n$ (4):** Complex **4** was prepared by a procedure similar to that for **3** but with $Co(SCN)_2$ (17.48 mg, 0.1 mmol) in place of $Cd(SCN)_2$. Yield: 89% (95.11 mg). $C_{44}H_{36}Cl_6CoN_{12}S_2$ (1068.6): calcd. C 49.45, H 3.40, N 15.73; found C 49.87, H 3.60, N 15.36. IR (KBr): $\tilde{\nu}$ = 3131 (m), 2977 (w), 2930 (w), 2076 (vs), 2033 (s), 1614 (w), 1585 (m), 1508 (vs), 1380 (m), 1330 (m), 1268 (m), 1229 (m), 1152 (w), 1123 (w), 1090 (w), 1064 (s), 935 (m), 833 (m), 809 (m), 744 (s), 661 (s) $cm^{-1}$.

**Preparation of $[CdL^2_2(NO_3)_2(CH_3OH)_2]_n$ (5):** Complex **5** was prepared by a procedure similar to that for **3** but with $Cd(NO_3)_2$ (34.60 mg, 0.1 mmol) instead of $Cd(SCN)_2$. Yield: 80% (76.42 mg). $C_{42}H_{42}CdN_{12}O_8$ (955.28): calcd. C 52.81, H 4.43, N 17.60; found C 52.98, H 4.05, N 17.38. IR (KBr): $\tilde{\nu}$ = 3134 (m), 2977 (w), 2928 (w), 1640 (w), 1615 (m), 1585 (w), 1515 (vs), 1405 (m), 1385 (vs), 1317 (s), 1272 (m), 1230 (m), 1143 (w), 1115 (m), 1066 (s), 931 (m), 873 (w), 809 (m), 742 (m), 659 (m), 663 (s) $cm^{-1}$.

**Preparation of $[CoL^2_2(NO_3)_2(CH_3OH)_2]_n$ (6):** Complex **6** was prepared by a procedure similar to that for **3** but with $Co(NO_3)_2$ (33.10 mg, 0.1 mmol) instead of $Cd(SCN)_2$. Yield: 85% (76.65 mg). $C_{42}H_{42}CoN_{12}O_8$ (901.81): calcd. C 55.94, H 4.69, N 18.64; found C 56.31, H 4.26, N 18.79.. IR (KBr): $\tilde{\nu}$ = 3142 (w), 2977 (w), 2929 (w), 1633 (w), 1581 (w), 1510 (vs), 1385 (vs), 1334 (m), 1309 (m), 1260 (m), 1231 (s), 1148 (w), 1117 (m), 1086 (m), 1063 (s), 965 (w), 937 (m), 866 (m), 811 (s), 742 (m), 660 (s) $cm^{-1}$.

**Thermogravimetric Analysis:** Complexes **2**, **4**, **5**, and **6** are unstable in air. Complexes **1** and **3** are stable under ambient conditions, and thermogravimetric experiments were performed on single-crystalline samples. The TG-DSC measurements of complexes **1** and **3** were determined in the range 20–800 °C under nitrogen. TG data show that **1** is stable up to 223 °C and then loses weight from 223 to 298 °C, corresponding to decomposition of ligand $L^1$. The final weight loss occurs at 543 °C. The TG data of **2** show that it is also stable up to 245 °C and then keeps losing weight from 245 °C to 301 °C, corresponding to decomposition of ligand $L^2$. The final weight loss occurs at 568 °C.

**Luminescent Properties:** Metal complexes are promising luminescent materials with potential applications as light-emitting materials (LEDs) owing to their ability to enhance, shift, and quench luminescent emission of organic ligands by metal coordination. The solid-state emission spectra of $L^1$, **1**, $L^2$, and **3** are shown in Figure 17(a) and (b). The nanosecond range of the lifetime in the solid state at 298 K reveals that the emission is fluorescent in nature. A comparison of the fluorescence spectra of $L^1$, **1**, $L^2$, and **3** suggests their emission origin. The solid-state fluorescent analyses show that the complexes exhibit different properties. Free $L^1$ exhibits an emission maximum at 414 nm with a shoulder peak at about 435 nm, which is completely invariant upon excitation in the range 270–369 nm; complex **1** presents a broad strong emission band with a maximum at 470 nm upon excitation in the range 275–383 nm, which can be tentatively assigned to a MLCT based on a significant red shift from $L^1$ to **1** and literature studies.[25] Free $L^2$ exhibits an emission maximum at 396 nm with a shoulder peak at about 412 nm, which is completely invariant upon excitation in the range 260–312 nm; complex **3** presents a sharp strong emission band with a maximum at 400 nm upon excitation in the range 268–362 nm, which is largely characteristic of an intraligand fluorescent emission. It is obvious that insoluble **1** and **3** possess strong fluorescent intensity, which suggests they may have potential applications in solvent-resistant fluorescent materials.

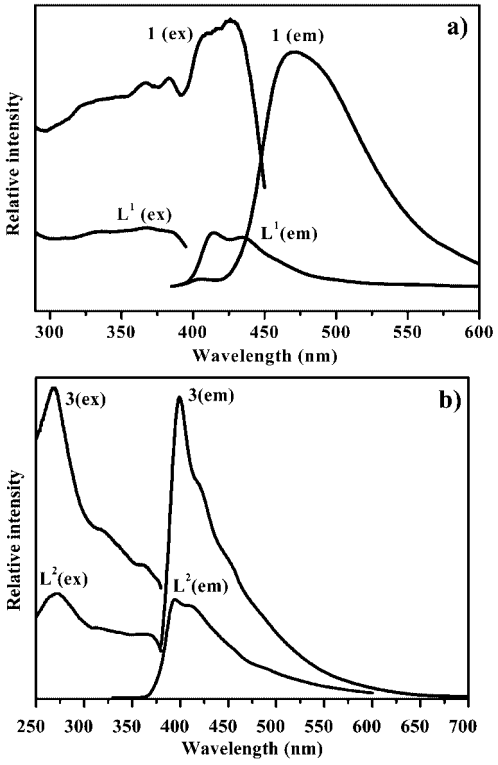

Figure 17. Fluorescent spectra of $L^1$ and complex **1** (a) and $L^2$ and complex **3** (b) in the solid state at room temperature.

# New Ternary Complexes of Copper(II) with 2,2′-Bipyridine (Bpy) and Phosphocholine ($PCh^-$) or the Quaternary 1-(2-Phosphonomethoxy)ethyl Derivative of 2,4-Diaminopyrimidine ($PMEDAPy^-$)

**Alfonso Fernández-Botello,[a] Albert Escuer,[a] Xavier Solans,[b] Mercè Font-Bardía,[b] Antonin Holý,[c] Helmut Sigel,[d] and Virtudes Moreno*[a]**

**Keywords:** Ternary complexes / Oxido bridges / Phosphonate bridges / Copper(II) / Magnetic properties

The polynuclear $Cu^{II}$ complexes $[Cu_4Cl_2(bpy)_4(PCh^-)_2](ClO_4)_4 \cdot H_2O$ (**1**) and $[Cu_6(bpy)_6(PMEAPy^-)_4](ClO_4)_8 \cdot 2H_2O$ (**2**), where bpy = 2,2′-bipyridine, $PCh^-$ = phosphocholine {[2-(phosphonooxy)ethyl]trimethylammonium} and $PMEDAPy^-$ = 1-[2-(phosphonomethoxy)ethyl]-2,4-diaminopyrimidine, have been synthesized and characterized by X-ray single-crystal analysis. Compound **1** crystallizes in the triclinic system (*P*-1 space group) and consists of tetranuclear $Cu^{II}$ units, which are threefoldly bridged by $\mu_3$-*O*,*O*′,*O*′′-phosphate groups in a square arrangement around the copper atoms. Complex **2** crystallizes in the monoclinic system ($P2_1/c$ space group) and consists of hexanuclear $Cu^{II}$ units containing the same kind of $\mu_3$-phosph(on)ate bridges like **1** and in addition $\mu_4$-*O*,*O*′,*O*′′,*O*′′-phosphonate bridges. The topology of compound **2** can be envisaged as two triangular subunits linked by means of a double Cu–O–Cu bridge provided by the $\mu_4$-phosphonate unit. Magnetic susceptibility measurements of the two complexes in the temperature range of 2–300 K show weak antiferromagnetic couplings mediated by the phosph(on)ate bridges.

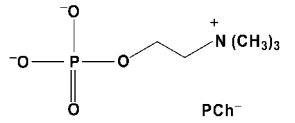
## Introduction

Solid metal phosphates and phosphonates are receiving much attention[1,2] because of their interesting magnetic and electronic properties.[3] They also have promising potential for applications in different areas: supports for catalysts,[4] as sensors[5], and in nonlinear optics.[6] This diversity in applications is a reflection of their diversity in structure and composition which is characteristic for these compounds.

Moreover, the two phosph(on)ate ligands considered in this study are also of biological relevance: phosphocholine ($PCh^-$), also known as 2-(trimethylammonio)ethyl phosphate and [2-(phosphonooxy)ethyl]trimethylammonium (Figure 1), is a fundamental cell metabolite.[7] The quaternary 1-[2-(phosphonomethoxy)ethyl] derivative of 2,4-diaminopyrimidine (Figure 1) is also named 1-[2-(phosphonomethoxy)ethyl]-2,4-diaminopyrimidine ($PMEDAPy^-$)[8] to indicate its structural relationship to several other acyclic nucleotide analogues which show antiviral properties.[9–11] Metal ion complexes of both phosph(on)ate ligands (Figure 1), or at least close relatives, have already been studied in aqueous solution and their corresponding isomeric equilibria were quantified.[8,11,12] Indeed, for the ternary complexes of $PMEDAPy^-$ with $Cu^{2+}$ and 2,2′-bipyridine (bpy) or 1,10-phenanthroline (phen) intramolecular stacking interactions in solution could be established.[8] Knowledge of such weak interactions is important in order to understand biological interactions better, e.g. in structures of proteins, active-site cavities and in many low-molecular-weight



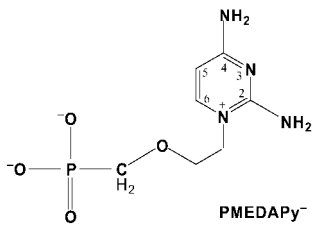


Figure 1. Chemical structures of the anions of phosphocholine ($PCh^-$) and 2,4-diamino-1-[2-(phosphonomethoxy)ethyl]pyrimidine ($PMEDAPy^-$; see also the second paragraph of the Introduction).

mixed-ligand complexes,[13] also their relevance for the stability of DNA, which depends much on the stacking interactions of the nucleobases.[14]

Of course, the biological role of copper is nowadays well established: copper-containing enzymes and proteins are widely distributed in plants and animals,[15] the metal ion being present in the form of ternary or polynuclear complexes.[15,16] For example, exchange-coupled polynuclear $Cu^{II}$ complexes are of relevance in biological processes involving laccase, a metalloprotein which belongs to the family of multicopper oxidases. Laccase contains four copper ions which are coupled to four one-electron substrate oxidations, i.e. the reduction of dioxygen to water.[17,18]

For the various reasons indicated above, we studied ternary $Cu^{II}$ complexes of the phosph(on)ate ligands (Figure 1) in the solid state by employing 2,2′-bipyridine as the second ligand. The syntheses, X-ray crystal structure analyses and magnetic properties of two polynuclear $Cu^{II}$ complexes, $[Cu_4Cl_2(bpy)_4(PCh^-)_2](ClO_4)_4{\cdot}H_2O$ (**1**) and $[Cu_6(bpy)_6(PMEDAPy^-)_4](ClO_4)_8{\cdot}2H_2O$ (**2**), are now presented. In **1** $PCh^-$ acts as tridentate $\mu_3$-*O*,*O*′,*O*′′-bridging ligand, whereas in **2** one half of the $PMEDAPy^-$ ligands acts in a similar way, but the other half forms a tetradentate $\mu_4$-*O*,*O*′,*O*′′,*O*′′-phosphonate bridge. It needs to be emphasized that these coordination modes are quite unusual for phosph(on)ate bridges.

Complexes with large M–O–X–O–M bridges formed by tetrahedral anions like sulfate or phosphate show typically weak magnetic interactions[19] and indeed, compounds **1** and **2**, containing exclusively M–O–P–O–M phosph(on)ato bridges, show a moderately weak antiferromagnetic coupling. In the last few years there is a growing interest in this kind of structural units because of their ability to generate high nuclearity cages with a variety of first row transition cations. Phosph(on)ato ligands can bind up to six metallic centers and, combined with other bridges (mainly hydroxo or alkoxo derivatives), they are able to give high nuclearity systems containing, e.g. $Co_{13}$, $Mn_{12}$, $Fe_9$, $Co_8$ or $Mn_6$.[20] Interesting magnetic properties such as the single molecule magnet (SMM) response have been characterized for some of them.

## Results and Discussion

The reaction of $[Cu(ClO_4)_2]{\cdot}6H_2O$ with 2,2′-bipyridine (bpy) and phosphocholine ($PCh^-$) or 1-[2-(phosphonomethoxy)ethyl]-2,4-diaminopyrimidine ($PMEDAPy^-$) in water with addition of HCl afforded crystals of the complexes $[Cu_4Cl_2(bpy)_4(PCh^-)_2](ClO_4)_4{\cdot}H_2O$ (**1**) and $[Cu_6(bpy)_6(PMEDAPy^-)_4](ClO_4)_8{\cdot}2H_2O$ (**2**) after two or four weeks of evaporation at room temperature, respectively. The crystals were suitable to be studied by X-ray diffraction.

### Crystal Structures

#### *$[Cu_4Cl_2(bpy)_4(PCh^-)_2](ClO_4)_4{\cdot}H_2O$ (1)*

A labeled ORTEP plot of the structure is shown in Figure 2. Selected bond lengths and angles are reported in Table 1 and Table 2, respectively. The structure of the compound consists of a tetranuclear centrosymmetric ternary $Cu^{II}$ complex with bpy and $PCh^-$ as ligands. There are two nonequivalent complexes with the same structure and similar bond parameters in the asymmetric unit of **1**; the following description corresponds to one of them. The Cu1 atoms are pentacoordinated, with a polyhedral arrangement close to a square-pyramidal geometry, where the equatorial plane is defined by two nitrogen (bpy) atoms and two oxygen (phosphate) atoms; one chloride is in the apical position. For Cu2 the main plane is defined by two nitrogen (bpy), one chloride and one oxygen (phosphate) with a water molecule in the axial position. In both cases, the metal ion is above the equatorial plane (see Table 2 for bond angles). The equatorial bond lengths to the *O*-phosphate atoms lie within the short range between 1.899(5) and 1.960(4) Å.

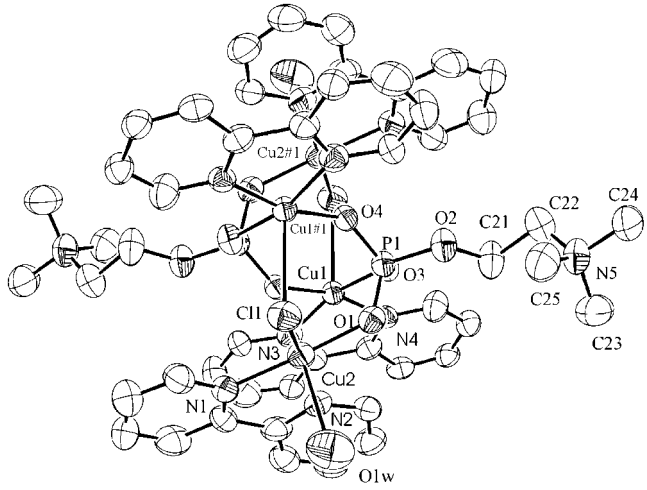

Figure 2. Labeled ORTEP plot (ellipsoid probability 30%) for one of the two nonequivalent units of $[Cu_4Cl_2(bpy)_4(PCh^-)_2](ClO_4)_4{\cdot}H_2O$ (**1**).

[a] Symmetry transformations used to generate equivalent atoms: * $-x+1, -y, -z+1$; ** $-x+2, -y+1, -z$.

The four $Cu^{II}$ ions of the tetranuclear unit define a ring (Figure 3) which is held together by threefold bridged $\mu_3$-*O*,*O*′,*O*′′-phosphate groups. The Cu1···Cu1#1 distance is 4.9967(15) Å, whereas the side-ring distances are 3.8573(15) and 3.5830(13) Å, and thus smaller than the Cu···Cu distances in related dinuclear complexes.[21,22]

[a] Symmetry transformations used to generate equivalent atoms: * $-x + 1, -y, -z + 1$ ** $-x + 2, -y + 1, -z$.

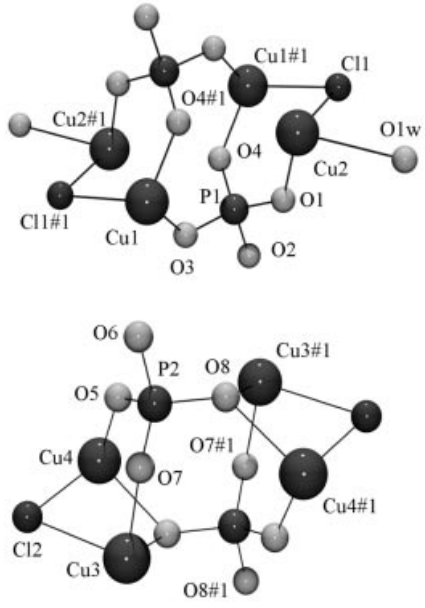

Figure 3. Plot of the $Cu_4$ arrangement for the core of the two nonequivalent units of **1**.

The distances between the two planes defined by the bipyridine ligands are in the range of 4.499(5) to 5.085(4) Å; this is longer than the distances for stacking interactions, which are usually between 3.3 and 3.8 Å.[23] Thus, the existence of a stacking interaction must be ruled out in this case. In Figure 3 a schematic representation of the four-copper atom core is shown for the two nonequivalent units.

### *$[Cu_6(bpy)_6(PMEDAPy^-)_4](ClO_4)_8 \cdot 2H_2O$ (2)*

A labeled ORTEP plot of the structure is shown in Figure 4. Selected bond lengths and angles are reported in Table 3 and Table 4, respectively. The structure of the compound consists of a hexanuclear $Cu^{II}$ ternary complex with bpy and $PMEDAPy^-$ as ligands. Two of the copper atoms are pentacoordinated, with a polyhedral arrangement close to a square-pyramidal geometry, where the equatorial positions are occupied by two nitrogen (bpy) and two oxygen (phosphonate) atoms, and the apical position by one oxygen (phosphonate) atom or one water molecule. The bond lengths for the equatorial position are in the range of 1.887(2)–1.993(2) Å (typical bond lengths), and the bond lengths for the apical position are 2.220(2) Å for Cu3–O8 and 2.486(4) Å for Cu2–O1w. In both cases, the copper

[a] Symmetry transformations used to generate equivalent atoms: * $-x, -y, -z$.

The compound can be envisaged as two trinuclear subunits linked by means of a double oxido bridge. The Cu3···Cu3* distance is 3.1218(6) Å, whereas the distance between the metal ions Cu2 and Cu3 (see Figure 5) is 3.3268(6) Å; it means that this distance is shorter than the Cu···Cu distances in dinuclear complexes.[21,22] A schematic representation of the core environment for the six copper atoms of **2**, including the bridging phosphonate groups, is shown in Figure 5.

This compound exhibits both intra and intermolecular π–π interactions. Intramolecular stacking can be observed for the heteroaromatic rings including N11 and N13, where the distance between the centroids is 3.57 Å (see Figure 4); this distance is in the expected order.[13,24] Intermolecular interactions are found between the pyridine ring including

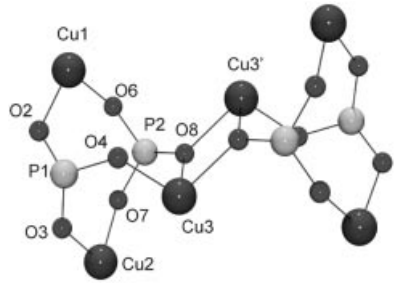

Figure 5. Plot of the core environment for the $Cu_6$ unit of compound **2**.

N6 and the diaminopyrimidine ring including N7/N8 of the neighboring hexanuclear unit with the distance between the centroids of 3.51 Å. These interactions give a supramolecular 1D arrangement of the $Cu_6$ molecules along the [010] direction (Figure 6). Hence, these observations in the solid state confirm the results obtained in aqueous solution for the ternary Cu(bpy)(PMEDAPy)$^+$ and Cu(phen)(PMEDAPy)$^+$ complexes; the formation degree of the intramolecular stacks amounts in these species in solution to about 69 and 77%, respectively.[8] It is not surprising that in the solid state stacking between bpy and the pyrimidine ring occurs in an inter- and not in an intramolecular fashion; crystal packing affects such weak interactions.[24] Indeed, similar differences between the stacking properties in solution and in the solid state have been observed before.[13,24]

## Magnetic Behavior

Experimental susceptibility data indicate that the $\chi_M \cdot T$ product for both compounds exhibits a quasi constant value between room temperature and 100 K. Below this temperature it decreases, approaching zero at very low temperatures, which indicates a weak antiferromagnetic coupling. For compound **1** the $\chi_M \cdot T$ value at room temperature is 1.73 $cm^3 \cdot K \cdot mol^{-1}$ and in good agreement with four isolated $Cu^{II}$ ions (the expected value for $g$ = 2.00 is

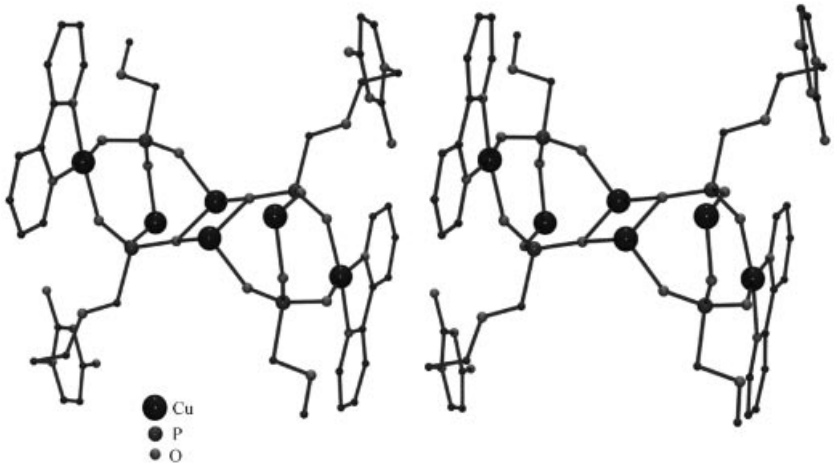

Figure 6. Plot of two $Cu_6$ units showing the π–π stacking between one of the bpy and one of the diaminopyrimidine rings. For clarity, the noninteracting aromatic rings are not plotted.

1.5 $cm^3 \cdot K \cdot mol^{-1}$). The $\chi_M$ vs. $T$ plot shows a maximum of susceptibility around 4 K (see Figure 7). The $\chi_M \cdot T$ value of 2.67 $cm^3 \cdot K \cdot mol^{-1}$ at room temperature for compound **2** is slightly greater than the spin only value of 2.25 $cm^3 \cdot K \cdot mol^{-1}$ expected for six $Cu^{II}$ ions (see Figure 8).

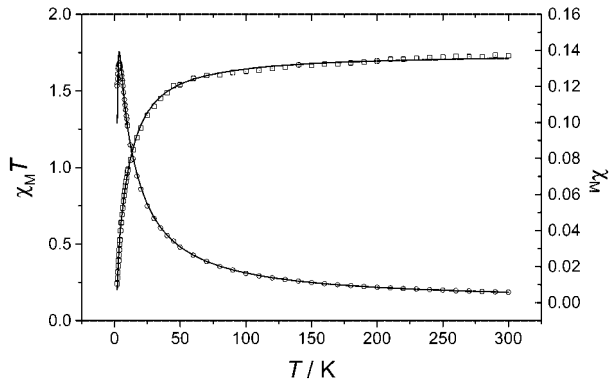

Figure 7. Plot of $\chi_M \cdot T$ vs. $T$ (open squares) and $\chi_M$ vs. $T$ (open circles) for compound $[Cu_4Cl_2(bpy)_4(PCh^-)_2](ClO_4)_4 \cdot H_2O$ (**1**). Solid lines show the best fit of the experimental data.

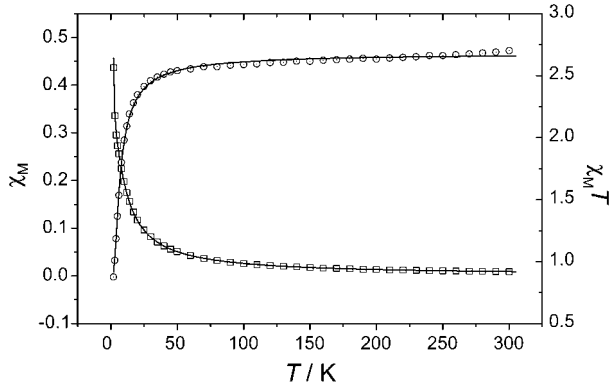

Figure 8. Plot of $\chi_M \cdot T$ vs. $T$ (open circles) and $\chi_M$ vs. $T$ (open squares) for compound $[Cu_6(bpy)_6(PMEDAPy^-)_4]$ $(ClO_4)_8 \cdot 2H_2O$ (**2**). Solid lines show the best fit obtained (see text).

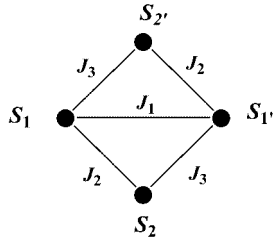
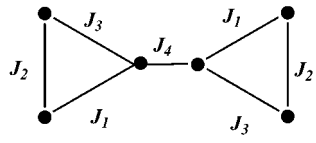
A fit of the experimental susceptibility data for **1** was performed on the basis of the three coupling constants seen in the interaction Scheme 1.



Scheme 1.

$J_1$ corresponds to the double OPO bridge with medium torsion angles, $J_2$ to the single bridge with low torsion angles, and $J_3$ to the single bridge with large torsion. The same Scheme is common for the two nonequivalent molecules present in the structure, which show only a minor difference in the torsion related to $J_2$. The best fit obtained by means of the CLUMAG program, based in the irreducible tensor operator formalism (ITO) on the Hamiltonian $H = -J_1(S_1 \cdot S_{1'}) - J_2(S_1S_2 + S_{1'} \cdot S_{2'}) - J_3(S_{1'} \cdot S_{2'} + S_{1'} \cdot S_2)$, gives the values $J_1 = -9.7$ $cm^{-1}$, $J_2 = -4.2$ $cm^{-1}$, $J_3 = -7.5$ $cm^{-1}$, and $g = 2.157$. A second fit performed assuming $J_2 = J_3$ gives a similar $J_1$ value ($J_1 = -8.7$ $cm^{-1}$) and an average value for $J_2 = J_3$ of 6.3 $cm^{-1}$.

The interaction Scheme for compound **2** consists of seven different interactions (Scheme 2). A negligible or very weak interaction can be expected for the superexchange pathway $J_4$ which relates the $Cu^{II}$ centers by means of an axial–equatorial double oxido bridge. Also, intermolecular interactions mediated by the π–π stacking should be negligible, because the rings involved in this interaction are placed far from the copper atoms.



Scheme 2.

The three remaining interactions correspond to doubly Cu–$(OPO)_2$–Cu bridged fragments, which display large differences within the bond parameters, specially for the Cu–O–O–Cu torsion angles. Trying to fit a weakly coupled system (without susceptibility maximum) with four coupling constants does not make mathematical sense, because many local minima can be found in the least-squares process. Therefore, to avoid overparametrization the experimental data for this compound were fitted assuming an average $J$ value and neglecting the axial–equatorial interaction between the triangular units. The best fit under these conditions, performed by applying the Hamiltonian $H = -J(S_1S_2 + S_2S_3 + S_1S_3)$, gives the values $J = -4.1$ $cm^{-1}$ and $g = 2.180$. Fits including the interaction between the two triangular units gave negligible values for this constant, which is closer to the $\chi_M \cdot T$ value at low $T$ of two independent $Cu^{II}$ ions rather than an S = 0 ground state.

These results are in good agreement with related compounds containing the phosphonato ligand in its $\eta_3$-$O,O',O''$ coordination mode, for which superexchange interactions are typically in the range of –5 to –10 $cm^{-1}$.[25]

## Experimental Section

***Caution!*** *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only a small amount of the material should be prepared and it should be handled with extreme care.*

**$[Cu_4Cl_2(bpy)_4(PCh^-)_2](ClO_4)_4 \cdot H_2O$ (1):** $[Cu(ClO_4)_2] \cdot 6H_2O$ (1 mmol), 2,2′-bipyridine (1 mmol) and [2-(phosphonooxy)ethyl]-trimethylammonium chloride (= phosphocholine; $PCh^-$) (0.5 mmol), obtained from Fluka (Buchs, Switzerland), were mixed in distilled water (20 mL) and stirred for 48 h at room temperature. A few drops of 1 M HCl were then added to the solution. Single dark-blue crystals of **1** suitable for X-ray crystallography were formed by evaporation at room temperature after two weeks.

A few drops of 1 M HCl were then added to the solution. Single blue crystals of **2** suitable for X-ray crystallography were formed by evaporation at room temperature after four weeks. (Yield: 73%). Calculated for $C_{88}H_{100}Cl_8Cu_6N_{28}O_{52}P_4$: C 33.31, N 12.36, H 3.15; found C, 33.82, N 12.47, H 3.06%.

**Magnetic Measurements:** Magnetic susceptibility measurements were carried out for **1** and **2** on microcrystalline samples with a Quantum Design SQUID MPMS5 magnetometer working in the range of 2–300 K under magnetic fields of 7000 G. Application of Pascal's constant was used for diamagnetic corrections. The magnetic measurements were carried out by the Magnetochemistry Services of the University of Barcelona.

**Crystal-Structure Determination:** The X-ray single-crystal data for **1** and **2** were collected on a MAR345 diffractometer with an image plate detector. Crystal size: $0.1 \times 0.1 \times 0.2$ mm. The crystallographic data, conditions used for the intensity data collection, and some features of the structure refinement are listed in Table 5. Unit-cell parameters were determined from 8505 reflections ($3 < \theta < 30°$) in the case of complex **1** and 42513 reflections ($3 < \theta < 31°$) for complex **2**. Both cases were refined by the least-squares method. Intensities were collected with graphite-monochromatized Mo-$K_\alpha$ radiation. 15246 reflections were measured in the range $1.64 \leq \theta \leq 31.65$ and 52896 reflections were measured in the range $1.73 \leq \theta \leq 31.57$ for complex **1** and **2**, respectively. 9819 (complex **1**) and 17121 (complex **2**) reflections were nonequivalent by symmetry [$R$(int) (on $I$) = 0.037 and 0.025 for complex **1** and **2**, respectively]. For complex **1** 5385 reflections were assumed as observed applying the condition $I > 2\sigma(I)$. In the case of complex **2**, 13652 reflections were assumed as observed applying to the condition $I > 2\sigma(I)$. The Lorentz polarization was corrected but no absorption corrections were made in both cases.

The structures were solved by direct methods with the SHELXS computer program[27] and refined by the full-matrix least-squares method (SHELX97 program[27]) using 9819 reflections for complex **1** and 17121 reflections for complex **2** (very negative intensities were not assumed). The minimized function was $\Sigma w||F^o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.1582P)^2]^{-1}$, and $P = (|F_o|^2 + 2|F_c|^2)/3$ in the case of complex **1**. For complex **2** $w = [\sigma^2(I) + (0.1630P)^2 + 1.6389P]^{-1}$, and $P = (|F_o|^2 + 2|F_c|^2)/3$. In both cases, $f$, $f'$, and $f''$ were taken from ref.[28].

All H atoms were computed and refined by a riding model, with an isotropic thermal parameter equal to 1.2 times the equivalent thermal parameter of the C linked to H. The final $R$ (on $F$) factor was 0.070 and 0.054, $wR$ (on $|F|^2$) = 0.210 and 0.168 and goodness of fit was 1.017 and 1.073 for complexes **1** and **2**, respectively, for all observed reflections. For complex **1**, the number of refined parameters was 846. As the ratio number of observed reflections/number of refined parameters was low, oxygen atoms of perchlorate ions were only refined isotropically with bond lengths and angles constrained to have the same value. Max. shift/esd. = 0.00, mean shift/esd. = 0.00. Max. and min. peaks in the final difference synthesis was 0.633 and –0.554 e·Å$^{-3}$, respectively. For complex **2**, the number of refined parameters was 839. Max. shift/esd. = 0.00, mean shift/esd = 0.00. Max. and min. peaks in the final difference synthesis was 0.794 and –0.744 e·Å$^{-3}$, respectively.

CCDC-624676 and -624677 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data@request/cif.

# Receptor versus Counterion: Capability of *N*,*N*′-Bis(2-aminobenzyl)-diazacrowns for Giving Endo- and/or Exocyclic Coordination of $Zn^{II}$

**Lea Vaiana,[a] Carlos Platas-Iglesias,[a] David Esteban-Gómez,[a] Fernando Avecilla,[a] Andrés de Blas,*[a] and Teresa Rodríguez-Blas*[a]**

**Keywords:** Zinc / Macrocyclic ligands / Crown compounds / Coordination modes / Density functional calculations

The structure of $Zn^{II}$ complexes with receptors $L^1$ and $L^2$ [$L^1$ = *N*,*N*′-bis(2-aminobenzyl)-1,10-diaza-15-crown-5 and $L^2$ = *N*,*N*′-bis(2-aminobenzyl)-4,13-diaza-18-crown-6] was studied both in the solid state and in acetonitrile solution. Both receptors form mononuclear $Zn^{II}$ complexes in this solvent, while no evidence for the formation of dinuclear complexes was obtained. This is in contrast with previous investigations that demonstrated the formation of dinuclear complexes of $L^2$ with first-row transition metals such as $Ni^{II}$, $Co^{II}$ and $Cu^{II}$. Compounds of formula $[Zn(L^1)](ClO_4)_2$ (**1**), $[Zn(L^1)](NO_3)_2{\cdot}2CH_3CN$ (**2**), $[Zn(L^2)](ClO_4)_2$ (**3**) and $[Zn(L^2)(NO_3)_2]$ (**4**) were isolated and structurally characterised by X-ray diffraction analyses. $L^1$ forms seven-coordinate $Zn^{II}$ complexes in the presence of both nitrate and perchlorate anions, as a consequence of the good fit between the macrocyclic cavity and the ionic radius of the metal ion. The $Zn^{II}$ ion is deeply buried into the receptor cavity and the anions are forced to remain out of the metal coordination sphere. The cation $[Zn(L^1)]^{2+}$ present in **1** and **2** is one of the very few examples of seven-coordinate Zn complexes. Receptor $L^2$ provides a very rare example of a macrocyclic receptor allowing endocyclic and exocyclic coordination on the same guest cation, depending on the nature of the anion present. Thus, in **3** the $Zn^{II}$ ion is endocyclically coordinated, placed inside the crown hole coordinated to four donor atoms of the ligand in a distorted tetrahedral environment, whereas in **4**, the presence of a strongly coordinating anion such as nitrate results in an exocyclic coordination of $Zn^{II}$, which is directly bound only to the two primarily amine groups of $L^2$ and two nitrate ligands. Spectrophotometric titrations of $[Zn(L^2)]^{2+}$ with tetrabutylammonium nitrate in acetonitrile solution demonstrate the stepwise formation of 1:1 and 1:2 adducts with this anion in acetonitrile solution. The $[Zn(L^1)]^{2+}$, $[Zn(L^2)]^{2+}$ and $[Zn(L^2)(NO_3)_2]$ systems were characterised by means of DFT calculations (B3LYP model). The calculated geometries show an excellent agreement with the experimental structures obtained from X-ray diffraction analyses. Calculated binding energies of the macrocyclic ligands to $Zn^{II}$ are also consistent with the experimental data.

## Introduction

Since Pedersen reported the synthesis and cation complexing characteristics of the crown ethers, there has been increasing interest in these compounds as complexing agents. In particular, the cyclic framework of crown ethers affords an interesting platform for the complexation of metal ions, and the ability of crown ethers to selectively coordinate metal salts has made them attractive building blocks in supramolecular chemistry and material science.[1–6] Likewise, the relative ease with which crown ethers can be functionalised with pendant arm(s) containing additional donor atom(s) allows modification of the cation-binding ability and, in some cases, the selectivity of the parent crown ether.[7] Pendant-armed crowns, also known as lariat ethers, may be regarded as having a structural character intermediate to that of a flexible macrocyclic polyether and a relatively rigid macrobicyclic cage, and the presence of additional donor atoms in the side arms can be used to enhance their coordination potential and/or to build polynuclear structures.[8] Although the coordination chemistry of crowns and armed-crown receptors has been extensively studied over the last decades,[1–4] their coordination capability is not entirely predictable.

The lariat ethers $L^1$ and $L^2$ (Scheme 1) have been revealed as versatile receptors towards different metal ions. In some cases they impose their coordinative preferences whereas in others they adapt to steric and/or electronic requirements of the guest metal ion. In particular, we have found that whereas $L^1$ only forms mononuclear complexes with first-row transition-metal ions such as $Co^{II}$, $Ni^{II}$ and $Cu^{II}$,[9,10] imposing a pentagonal bipyramidal geometry and so dominating over the coordinative preferences of the particular ion guest, $L^2$ only forms dinuclear complexes with these cations and easily adapts to the coordinative preferences of these metal ions.[10,11] In this paper we report the

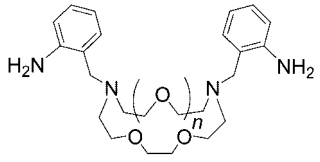
coordinative properties of these two lariat ethers toward $Zn^{II}$. It is well known that coordination properties of transition-metal complexes are mainly related to the partly filled d orbitals of the metal ion and have common types of structures with specific coordination numbers, however, non-transition-metal complexes are able to take various coordination numbers and may show diverse structures because of the fact that d atomic orbitals of the metal centre are fully occupied. In particular, the geometries of $Zn^{II}$ complexes can vary from tetrahedral to octahedral through trigonal-bipyramidal and square-pyramidal, all of them frequently distorted. Likewise, although rare, coordination numbers higher than six may be reached by using high denticity polydentate ligands.



$L^1$: $n$ = 1
$L^2$: $n$ = 2

Scheme 1.

The study presented in this paper provides a very rare example of a macrocyclic receptor allowing endocyclic and exocyclic coordination on the same guest cation depending on the nature of the counterion present.

## Results and Discussion

### Synthesis and Solid-State Structure

The reaction of stoichiometric amounts of *N*,*N*′-bis(2-aminobenzyl)-1-10-diaza-15-crown-5 ($L^1$) or *N*,*N*′-bis(2-aminobenzyl)-4-13-diaza-18-crown-6 ($L^2$) with $Zn^{II}$ salts (perchlorates or nitrates) in ethanol or acetonitrile solution gives compounds of formula $[Zn(L^1)](ClO_4)_2$ (**1**), $[Zn(L^1)](NO_3)_2{\cdot}2CH_3CN$ (**2**), $[Zn(L^2)](ClO_4)_2$ (**3**) and $[Zn(L^2)(NO_3)_2]$ (**4**). The FAB-mass spectrum of each complex displays very intense peaks corresponding to the $[Zn(L\text{-}H)]^+$ and $[Zn(L)(X)]^+$ fragments (L = $L^1$ or $L^2$, X = $ClO_4^-$ or $NO_3^-$), thereby confirming the formation of the complexes. The IR spectra (KBr discs) of the perchlorate complexes **1** and **3** show bands corresponding to the $\nu_{as}$(Cl–O) stretching and $\delta_{as}$(O–Cl–O) bending modes of the perchlorate groups at about 1090 and 620 $cm^{-1}$. The absorption at about 620 $cm^{-1}$ clearly shows up without splitting, as befits an uncoordinated anion.[12] The spectrum of the nitrate complex **2** exhibits an intense band at 1384 $cm^{-1}$, as expected for the presence of ionic nitrate.[12]

The solid-state structures of the four compounds were determined by single-crystal X-ray diffraction analysis. Crystals of **1** and **2** contain the cation $[Zn(L^1)]^{2+}$ and two anions, perchlorate (**1**) or nitrate (**2**), involved in hydrogen-bonding interactions with the $-NH_2$ groups [compound **1**: N(4)···H(4B) 0.868(19) Å, H(4B)···O(9) 2.76(4) Å, N(4)···O(9) 3.209(6) Å, N(4)–H(4B)–O(9) 114(4)°; H(4B)···O(12) 2.18(2) Å, N(4)···O(12) 3.013(5) Å, N(4)–H(4B)–O(12) 162(4)°; N(3)···H(3A) 0.878(18) Å, H(3A)···O(6) 2.23(2) Å, N(3)···O(6) 3.112(7) Å, N(3)–H(3A)–O(6) 178(4)°. Compound **2**: N(2)···H(2N) 0.86(5) Å, H(2N)···O(3) 2.20(5) Å, N(2)···O(3) 2.965(5) Å, N(2)–H(2N)–O(3) 148(4)°; N(2)···H(1N) 0.79(5) Å, H(1N)···O(3) 2.56(5) Å, N(2)–H(1N)–O(3) 157(4)°]. Crystals of **2** also contain two acetonitrile molecules in the asymmetric unit. The structures of the cations present in **1** and **2** are shown in Figure 1, while selected bond lengths and angles are given in Table 1. The structures of both complex cations are very similar, although the one found in **2** is more symmetric and, in fact, the asymmetric unit of **2** only contains half a molecule of $[Zn(L^1)]^{2+}$. In both cases, the cation $[Zn(L^1)]^{2+}$ contains a $ZnN_4O_3$ core with the seven heteroatoms of $L^1$ coordinated to the $Zn^{II}$ ion. The metal ion resides in the macrocyclic cavity bound by the three ether oxygen atoms and the two pivotal nitrogen atoms of the azacrown moiety, while the donor atoms of the pendant arms coordinate apically. The Zn-crown ether oxygen bonds in compounds **1** and **2** are in line with those observed for a seven-coordinate $Zn^{II}$ complex of 15-crown-5, at an average of 2.30 Å.[13] The distances between the $Zn^{II}$ ion and the nitrogen atoms of the aniline groups are about 0.08 Å shorter than those observed for a six-coordinate $Zn^{II}$ complex derived from a triazamacrocycle containing three aniline pendants.[14] However, these distances are about 0.1 Å longer than those observed in the analogous $d^9$ complex $[Cu(L^1)]^{2+}$.[10] The N(3)–Zn–N(4) angle in **1** is 170.7(2)°, while the N(2)–Zn–N(2A) angle in **2** amounts to 175.8(2)°. Angles O(1)–Zn(1)–O(2), N(2)–Zn(1)–O(2), O(3)–Zn(1)–N(2), O(3)–Zn(1)–N(1) and N(1)–Zn(1)–O(1) in **1**, and angles O(1)–Zn(1)–N(1), O(2)–Zn(1)–N(1) and O(2)–Zn(1)–O(2A) in **2** take values close to 72° (Table 1). Thus, the coordination sphere of the zinc ion can be described as a distorted pentagonal bipyramid with an axial compression, as the apical distances between the zinc and the donor atoms of the pendant arms are significantly shorter than the equatorial bonds. The mean deviation from planarity of the plane containing the five equatorial donor atoms and the metal ion is relatively small, and amounts to 0.1668 Å in **1** and 0.1273 Å in **2**. In both compounds the arms of the bibracchial lariat ether $L^1$ are arranged on opposite sides with respect to the crown moiety, resulting in an *anti* conformation.

Both compounds **3** and **4** contain the larger receptor $L^2$, and unlike the analogous compounds containing $L^1$, the presence of different counterions (perchlorate or nitrate) results in dramatically different coordination environments around the $Zn^{II}$ ion. Crystals of **3** contain the $[Zn(L^2)]^{2+}$ cation and two perchlorate anions involved in hydrogen-bonding interactions with the $-NH_2$ groups [N(4)···H(2N) 0.846(19) Å, H(2N)···O(5) 2.27(4) Å, N(4)···O(5) 2.991(5) Å, N(4)–H(2N)–O(5) 171(4)°; N(3)···H(4N) 0.837(19) Å, H(4N)···O(10) 2.13(3) Å, N(3)···O(10) 2.897(6) Å, N(3)–H(4N)–O(10) 151(4)°], whereas the asymmetric unit of **4** contains a half $[Zn(L^2)(NO_3)_2]$ molecule. The structures of $[Zn(L^2)]^{2+}$ and $[Zn(L^2)(NO_3)_2]$ present in

**3** and **4**, respectively, are shown in Figure 2, while Table 2 summarises selected bond lengths and angles of the metal coordination environments. In $[Zn(L^2)]^{2+}$, the $Zn^{II}$ ion is endocyclically coordinated but only four of the eight available donor atoms of $L^2$ form part of the coordination sphere. Thus, the metal ion is directly bound to both aniline pendant arms [N(3) and N(4)], one of the pivotal nitrogen atoms, N(1), and an oxygen atom of the crown, O(2), while the remaining distances between the metal ion and the other heteroatoms of the crown are too long to be considered as bond lengths [Zn–O(1) 2.498 Å; Zn–O(3) 2.596 Å; Zn–O(4) 3.464 Å; Zn–N(2) 3.720 Å]. Receptor $L^2$ adopts an *anti* conformation and the coordination polyhedron around the zinc ion can be described as a distorted tetrahedron. Moreover, the $-NH_2$ group containing N(4) is involved in a hydrogen-bonding interaction with O(4) and N(2) [N(4)···H(1N) 0.80(4) Å, H(1N)···N(2) 2.27(4) Å, N(4)···N(2) 2.904(5) Å, N(4)–H(1N)–N(2) 137(3)°; N(4)···H(1N) 0.80(4) Å, H(1N)···O(4) 2.38(4) Å, N(4)···O(4) 3.063(4) Å, N(4)–H(1N)–O(4) 144(3)°].

[a] Symmetry transformations used to generate equivalent atoms. A: $-x + 1$, $y$, $-z + 3/2$.

In the complex $[Zn(L^2)(NO_3)_2]$ present in **4**, the $Zn^{II}$ ion is exocyclically coordinated with the metal ion only directly bound to the two aniline groups of $L^2$, [N(2)] and [N(2)#1]. The $-NH_2$ groups are also involved in an intramolecular hydrogen-bonding interaction with the pivotal nitrogen atoms and an oxygen atom of the crown moiety [N(2)···H(2A) 0.90 Å, H(2A)···O(1) 2.16 Å, N(2)···O(1) 2.993(4) Å, N(2)–H(2A)–O(1) 153.9°; N(2)···H(2B) 0.90 Å, H(2B)···N(1) 2.04 Å, N(2)···N(1) 2.825(4) Å, N(2)–H(2B)–N(1) 144.7°]. As a consequence, $L^2$ adopts a *syn* arrangement with both aniline pendant arms disposed on the same side of the crown. Coordination number six is completed by two nitrate ligands in a bidentate fashion, as often observed for $Zn^{II}$ complexes with nitrate ligands.[15,16] The structure presents a disorder on one oxygen atom of a coordinated nitrate group and, as a result, the bidentate nitrate ion is coordinated in a nearly symmetrical fashion [Zn(1)–O(1SA) 2.336(13) Å, Zn(1)–O(3S) 2.371(5) Å] or in a clearly asymmetrical one [Zn(1)–O(1SB) 1.929(7) Å, Zn(1)–O(3S)

2.371(5) Å], depending on the occupation of sites O(1SA) or O(1SB).

A comparison of the bond lengths of the metal coordination environment in $[Zn(L^1)]^{2+}$ present in compounds **1** and **2** with those observed for $[Zn(L^2)]^{2+}$ present in **3** clearly shows a shortening of the bond lengths as the coordination number of the metal ion decreases. Likewise, the distances between the $Zn^{II}$ ion and the nitrogen atoms of the aniline groups in compounds **3** and **4** are close to those observed in four-coordinate $Zn^{II}$ complexes containing aniline groups.[17,18]

### Solution Behaviour

The behaviour in [$D_3$]acetonitrile solution of compounds **1**–**4** was investigated by $^1H$ NMR spectroscopy. Significant changes in the chemical shifts, the structures of the signals and even the number of signals are observed in the $^1H$ NMR spectra upon coordination of the receptors to $Zn^{II}$. The most complicated region of the spectra is that where the ethylene and methylene proton signals are observed. The coordination to the metal ion increases the rigidity of the receptor, limiting conformational exchange processes, so that the geminal $CH_2$ protons are no longer equivalent. The aromatic region usually appears more clearly resolved in all complexes except for the nitrate complex **4** because of the presence of a conformational equilibrium between the different species present in solution (see Figure 3).

The $^1H$ NMR spectra of compounds **1** and **2** are identical, indicating that the presence of different counterions (perchlorate or nitrate) does not affect the structure of the $[Zn(L^1)]^{2+}$ cation in solution. The signals corresponding to the protons of the aromatic units are shifted downfield by about 0.4–0.6 ppm upon coordination to the metal ion, thereby confirming the coordination of the ligand to the metal ion in this solvent (Figures S1 and S2, Supporting Information). Conductivity measurements carried out in acetonitrile solution (281 $\Omega^{-1}cm^2mol^{-1}$ for **1** and 194 $\Omega^{-1}cm^2mol^{-1}$ for **2**) show that **1** and **2** behave as 2:1 electrolytes in this solvent,[19] confirming that the nature of

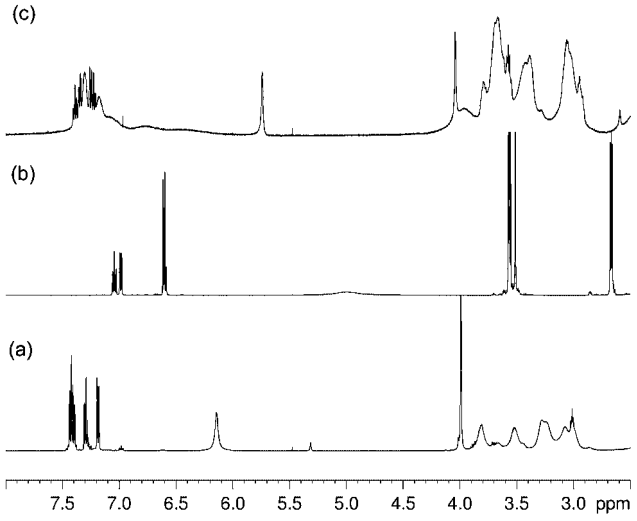

Figure 3. $^1$H NMR spectra recorded at 298 K on $10^{-3}$ M solutions of **3** (spectrum a), $L^2$ (spectrum b) and **4** (spectrum c).

the counterion has no influence in the coordination sphere of the metal ion, in agreement with their solid-state structures. The situation is quite different for compounds **3** and **4**. The molar conductivity measured for **3** in acetonitrile solution (287 $\Omega^{-1}$ cm$^2$ mol$^{-1}$) indicates that this compound behaves as a 2:1 electrolyte in this solvent, while the molar conductivity determined for a solution of **4** (prepared in situ by mixing stoichiometric amounts of $L^2$ and $Zn^{II}$ nitrate) is clearly lower (134 $\Omega^{-1}$ cm$^2$ mol$^{-1}$). These results are in agreement with the coordination of the $NO_3^-$ ligands to the metal ion. The interaction of $[Zn(L^2)]^{2+}$ is, however, relatively weak (vide infra), and therefore the conductivity measured experimentally is an average of the conductivity values of the different species in equilibrium. The $^1$H NMR spectra of **3** and **4** show that the signals of protons of the aromatic and amine groups are shifted downfield with respect to their position in the spectrum of the free receptor, indicating the coordination of the receptor to the metal ion in both compounds. However, while these signals are well resolved in the case of compound **3**, the spectrum of **4** shows broad resonances between 6.5 and 7.5 ppm (Figure 3). This is probably due to the presence in solution of exchange processes involving $[Zn(L^2)(NO_3)_2]$, $[Zn(L^2)(NO_3)]^+$ and $[Zn(L^2)]^{2+}$ complex species (vide infra). The spectra of **3** and **4** are very different (Figure 3), indicating a different structure of the complexes in solution, as also observed in the solid state. This is confirmed by a $^1$H NMR titration experiment, where tetrabutylammonium nitrate was added to a solution of compound **3** (Figure S3, Supporting Information). During the titration the aromatic proton signals gradually shifted upfield, giving rise to an identical spectral pattern to that observed for compound **4**. Upon addition of increasing amounts of $NO_3^-$, the intensity of the sharp signals due to the $[Zn(L^2)]^{2+}$ species gradually decrease as a new set of broad signals appear, in agreement with the formation of the $[Zn(L^2)(NO_3)_2]$ complex.

The UV/Vis spectra of $L^1$ and $L^2$ show two absorption bands at 240 and 290 nm, resulting from the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions on the aromatic subunits of the ligand. Upon addition of $Zn^{II}$ perchlorate both absorption bands show a blueshift while their intensity decreases. Figure 4 shows the spectral changes observed during the formation of the $Zn^{II}$ complexes of $L^1$ and $L^2$. The data display a single inflection point when the M/ligand molar ratio is close to 1, indicating a 1:1 reaction stoichiometry. The steep curvature of the titration profiles corresponds to an especially high equilibrium constant ($\log K > 7$). In particular, the *p* parameter (*p* = [concentration of complex]/[maximum possible concentration of complex]) was found to be higher than 0.8 in both cases, a condition that does not permit the determination of a reliable equilibrium constant.[20] A similar situation was observed for the $Mn^{II}$, $Co^{II}$ and $Ni^{II}$ complexes of $L^1$.[9] It is interesting to note that while $L^2$ is able to form dinuclear complexes with metal ions such as $Co^{II}$, $Ni^{II}$[11] and $Cu^{II}$[10] no evidence has been obtained in

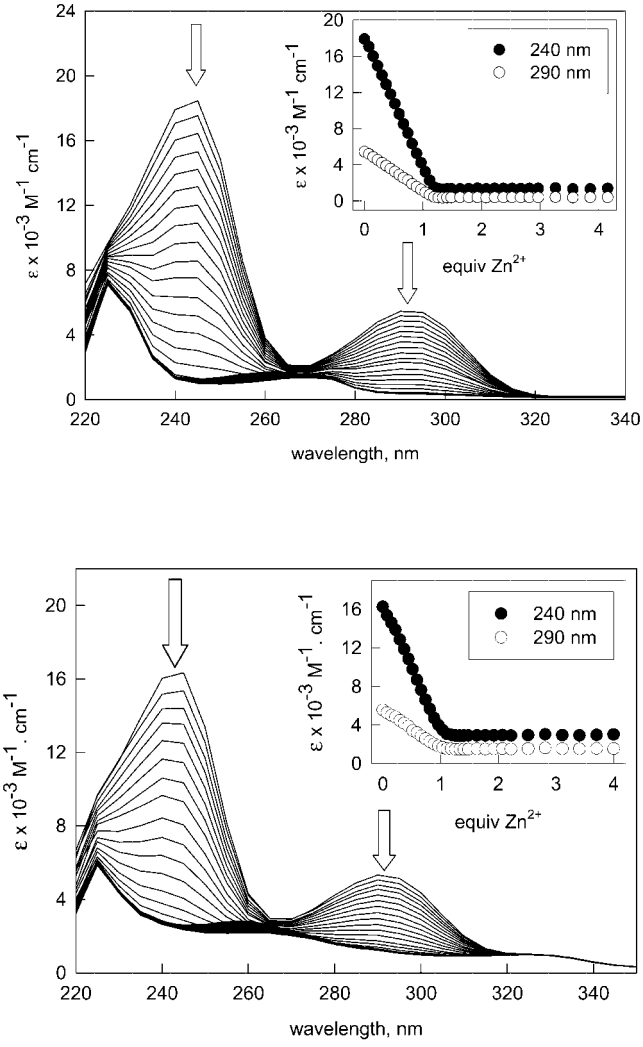

Figure 4. UV/Vis spectrum of $L^1$ (top) and $L^2$ (bottom) in acetonitrile solution and spectral changes upon addition of aliquots of a solution of $Zn(ClO_4)_2 \cdot 6H_2O$ in the same solvent.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

this work for the formation of analogous dinuclear $Zn^{II}$ complexes at room temperature. The UV/Vis spectrum of **$L^2$** recorded in the presence of a 10 fold excess of $Zn^{II}$ does not change when the solution is heated to reflux for 24 h, indicating that no dinuclear species are formed even under these conditions.

The addition of tetrabutylammonium nitrate to a solution of $[Zn(L^2)]^{2+}$ provokes a substantial variation of the UV/Vis spectrum (Figure 5). Upon addition of $NO_3^-$ the intensity of the band that the complex shows at 290 nm increases. This is in agreement with the formation of the exocyclic complex because of the coordination of $NO_3^-$ to the metal ion. Indeed, the X-ray structure of **4** shows that the $Zn^{II}$ ion is not coordinated to the pivotal nitrogen atoms of the macrocycle, while at least one of the pivotal nitrogen atoms is involved in the coordination to $Zn^{II}$ in **3**. Thus, the decoordination of the pivotal nitrogen atoms appears to provoke an increase of the intensity of the band at 290 nm, in line with the spectral variations observed during the formation of complexes $[Zn(L^1)]^{2+}$ and $[Zn(L^2)]^{2+}$. The titration profile shown in the inset of Figure 5 indicates the formation of at least two complex species in solution.

$$[Zn(L^2)]^{2+} + NO_3^- \leftrightarrows [Zn(L^2)(NO_3)]^+ \quad \beta_{11}$$

$$[Zn(L^2)]^{2+} + 2\,NO_3^- \leftrightarrows [Zn(L^2)(NO_3)_2] \quad \beta_{12}$$

The best fit of the experimental data gives $\log\beta_{11}$ = 3.57(2) and $\log\beta_{12}$ = 8.5(1). These results indicate the stepwise formation of 1:1 and 1:2 adducts during the course of the titration. Figure 5 shows how the concentration of the species at the equilibrium, calculated from $\beta_{11}$ and $\beta_{12}$ values, varies upon nitrate addition. It can be seen that, because of the especially high value of $\beta_{12}$, the neutral complex $[Zn(L^1)(NO_3)_2]$ is formed in the early stages of titration. Notice also that under the conditions of the UV/Vis titration experiment the highest concentration of $[Zn(L^1)(NO_3)]^+$ is about 9%, reached after the addition of 1.6 equiv. of $NO_3^-$.

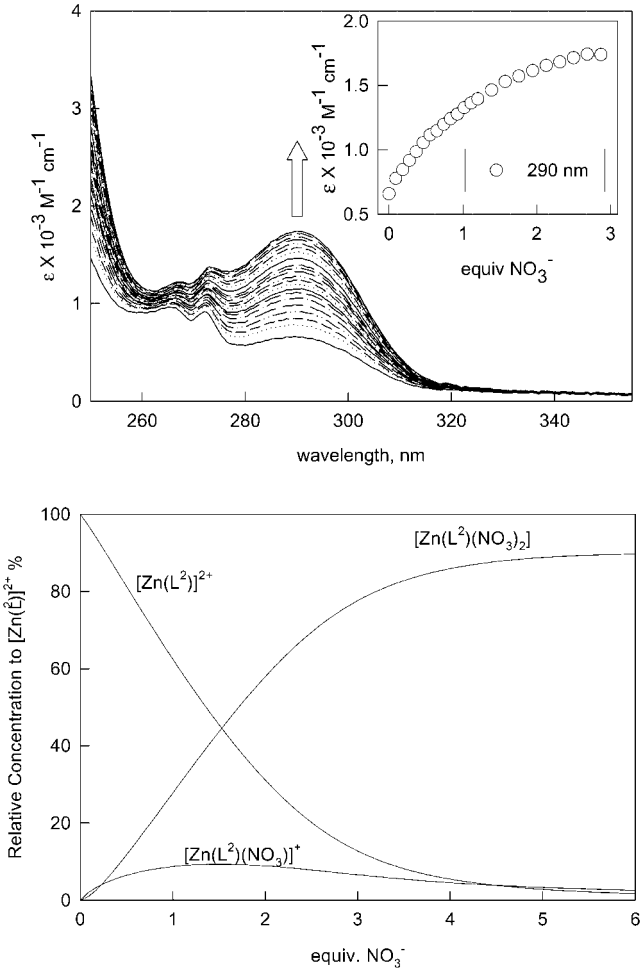

Figure 5. Top: UV/Vis spectrum of $[Zn(L^2)]^{2+}$ in acetonitrile solution and spectral changes upon addition of aliquots of a solution of tetrabutylammonium nitrate in the same solvent. Bottom: Species distribution diagram obtained from the best fit of the experimental data (see text).

## DFT Studies

Density functional theory (DFT) has emerged as the computational method of choice for the solution of many chemical problems. This is because DFT methods have relatively low computational cost, include a significant amount of the dynamic electron correlation and are applicable to a wide range of molecular types, including $Zn^{II}$ complexes.[21] In a recent paper we reported a theoretical study of the $[M(L^1)]^{2+}$ systems (M = Mn, Co or Ni) at the DFT (B3LYP) computational level.[9] The calculated geometries obtained from geometry optimisations for those systems show an excellent agreement with the experimental structures obtained by X-ray diffraction analyses. Moreover, a molecular orbital analysis on the calculated structures allowed us to gain insight into the electronic structure of this family of complexes. Aiming to understand if analogous calculations can reproduce the experimental structures reported in this paper, we have performed DFT calculations on the complexes reported in this work by using the B3LYP model. Full geometry optimisations of the $[Zn(L^1)]^{2+}$, $[Zn(L^2)]^{2+}$ and $[Zn(L^2)(NO_3)_2]$ systems were performed in vacuo by using the standard 6-31G(d) basis on the ligand atoms and Ahlrichs' valence triple-ζ (VTC) on Zn.[22] The latter basis has been shown to provide accurate molecular structures for several first-row transition-metal complexes.[23]

The most relevant geometrical parameters calculated for $[Zn(L^1)]^{2+}$, $[Zn(L^2)]^{2+}$ and $[Zn(L^2)(NO_3)_2]$ systems are given in Table S1 (Supporting Information). The calculated bond lengths for $[Zn(L^1)]^{2+}$ are in excellent agreement with those observed experimentally for compound **2**, as evidenced by the excellent agreement factor obtained (Table 3, $AF_i$ = $[\Sigma(\text{exp} - \text{calcd})^2/\Sigma(\text{exp})^2]^{1/2}$, where exp and calcd denote experimental and calculated values, respectively).[24,25] Calculated bond lengths of the metal coordination environment deviate from the experimental distances determined for **2**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

by less than 0.07 Å, while calculated bond angles of the $Zn^{II}$ coordination environment deviate by less than 4.0° from the experimental values. Although no geometrical constraints were used during the geometry optimisation, the calculated structure of $[Zn(L^1)]^{2+}$ corresponds to a nearly undistorted $C_2$ symmetry that shows a slightly better agreement with the X-ray structure of **2** than with that of compound **1** (Table 3). The agreement factors between calculated and experimental geometrical parameters obtained for $[Zn(L^2)]^{2+}$ indicate that the experimental geometry is well reproduced at the B3LYP/6-31G(d) level, calculated bond lengths deviating from experimental values by less than 0.04 Å. For $[Zn(L^2)(NO_3)_2]$ our calculations provide a poorer agreement with experimental data than for $[Zn(L^1)]^{2+}$ and $[Zn(L^2)]^{2+}$ (Table 3). However, this is not surprising because the X-ray crystal structure of compound **4** shows that the coordinated nitrate anions are disordered, which suggests a rather shallow potential-energy surface for the variation of the Zn–O bond lengths. In the calculated structure the nitrate anions are coordinated in a nearly symmetrical fashion [Zn(1)–O(1S) 2.178 Å, Zn(1)–O(3S) 2.107 Å].

Table 3. Agreement factors ($AF_i$)[a] between exp./calcd. bond lengths and angles of the metal coordination environment for $[Zn(L^1)]^{2+}$, $[Zn(L^2)]^{2+}$ and $[Zn(L^2)(NO_3)_2]$, binding energies of the macrocyclic ligands [kcal mol$^{-1}$] and basis-set superposition error corrections [kcal mol$^{-1}$].

| Binding energy[f] | 412.5 | 405.9 | 50.5 |
| BSSE[f] | 7.8 | 7.3 | 20.6 |

[a] $AF_i = [\sum(\text{exp.} - \text{calcd.})^2/\sum(\text{exp.})^2]^{1/2}$. [b] Experimental data from the X-ray structure of **1**. [c] Experimental data from the X-ray structure of **2**. [d] Calculated by using O(1SA). [e] Calculated by using O(1SB). [f] Binding energies include corrections for basis-set superposition error (BSSE).

The metal cation–ligand binding energies are summarised in Table 3. In these calculations the basis-set superposition error (BSSE) was taken into account by the counterpoise method.[26] BSSE corrections are of similar magnitude for the three systems and do not change the calculated order of binding energies. The results predict a stronger interaction of the macrocyclic ligand with $Zn^{II}$ for $L^1$ than for $L^2$, in agreement with the results from the spectrophotometric titrations. This stronger interaction can be attributed to a better fit of the cation in the macrocyclic cavity of $L^1$ than in that of $L^2$. The lower coordination number of the metal ion in $[Zn(L^2)(NO_3)_2]$, where $Zn^{II}$ is exocyclically coordinated and only bound to the two nitrogen atoms of the aniline groups of the receptor $L^2$, results in a very low binding energy for this one (50.5 kcal mol$^{-1}$), while the binding energy of the two nitrate ligands is much higher (396.2 kcal mol$^{-1}$). These results indicate a strong interaction of the nitrate anions with $Zn^{II}$, while the interaction of the metal ion with the macrocyclic ligand appears to be very weak.

## Conclusions

$Zn^{II}$ binding by the lariat crown ethers $L^1$ and $L^2$ [$L^1$ = *N*,*N*′-bis(2-aminobenzyl)-1,10-diaza-15-crown-5 and $L^2$ = *N*,*N*′-bis(2-aminobenzyl)-4,13-diaza-18-crown-6] was analysed by spectrophotometric measurements in acetonitrile solution. Both receptors form stable mononuclear $Zn^{II}$ complexes in this solvent, while no evidence for the formation of dinuclear complexes was obtained. $L^1$ forms seven-coordinate $Zn^{II}$ complexes in the presence of both nitrate and perchlorate anions, as a consequence of the good fit between the macrocyclic cavity and the ionic radius of the metal ion. The $Zn^{II}$ ion is deeply buried in the receptor cavity and the anions are forced to remain out of the metal coordination sphere. The cation $[Zn(L^1)]^{2+}$ is one of the very few examples of seven-coordinate Zn complexes. In fact, a recent estimate based on the number of transition-metal σ-bonded complexes found in the Cambridge Structural Database reveals that seven-coordinate complexes represent 1.8% of the total number of structures reported and, even more, the distribution of seven-coordination throughout the first metal transition series is also quite irregular and it appears to be more common for manganese, iron and cobalt, than for zinc.

On the other hand, the cavity of $L^2$ is rather large for $Zn^{II}$, so that different coordination environments are observed for the metal cation depending on the coordinative properties of the counterion. The X-ray structure of the perchlorate salt **3** shows the metal ion placed inside the crown hole coordinated to four donor atoms of the ligand in a distorted tetrahedral environment, whereas the presence of a strongly coordinating anion such as nitrate results in an exocyclic coordination of $Zn^{II}$, which is directly bound only to the two primary amine groups of $L^2$. Spectrophotometric titrations of $[Zn(L^2)]^{2+}$ with $NO_3^-$ also indicate an exocyclic coordination of the metal ion in acetonitrile solution. DFT calculations performed at the B3LYP level reproduce the experimental structures of the $[Zn(L^1)]^{2+}$, $[Zn(L^2)]^{2+}$ and $[Zn(L^2)(NO_3)_2]$ systems obtained by X-ray diffraction analysis fairly well. They also predict a stronger binding of $L^1$ to $Zn^{II}$ compared to $L^2$.

The ability of a macrocyclic receptor to give endocyclic and exocyclic coordination on the same guest cation depending on the nature of the anion present in the medium is very rare. Although some examples with S-containing macrocycles and soft metals such as $Pd^{II}$ have been reported,[27] to the best of our knowledge compounds **3** and **4** reported here represent the first example of this with a pendant-armed crown and $Zn^{II}$.

## Experimental Section

**Materials and Synthesis:** *N*,*N*′-Bis(2-aminobenzyl)-1,10-diaza-15-crown-5 ($L^1$)[28] and *N*,*N*′-bis(2-aminobenzyl)-4,13-diaza-18-crown-6 ($L^2$)[10] were prepared as previously reported by us. All other chemicals were purchased from commercial sources and used without further purification. Solvents were of reagent grade purified by the usual methods.

***CAUTION!*** *Perchlorate salts combined with organic ligands are potentially explosive and should be handled in small quantities and with the necessary precautions.*[29]

**$[Zn(L^1)](ClO_4)_2$ (1):** A mixture of $L^1$ (0.100 g, 0.233 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (0.087 g, 0.233 mmol) in ethanol (23 mL) was stirred and heated to reflux over a period of 8 h. The white precipitate formed was isolated by filtration and air-dried (0.152 g, 94%). $C_{24}H_{36}Cl_2N_4O_{11}Zn$ (692.86): calcd. C 41.6, H 5.2, N 8.1; found C 41.3, H 5.1, N 8.0. FAB-MS: *m/z* (%BPI) = 591 (41) $[Zn(L^1)(ClO_4)]^+$, 491 (100) $[Zn(L^1 - H)]^+$. FTIR (KBr): $\tilde{\nu}$ = 3340 [$\nu_{as}(NH_2)$], 3250 [$\nu_s(NH_2)$], 1617 [$\delta(NH_2)$], 1586 [$\nu$(C=C)], 1078 [$\nu_{as}$(Cl–O)], 620 [$\delta_{as}$(Cl–O)] $cm^{-1}$. $\Lambda_M$ (acetonitrile, $cm^2\,\Omega^{-1}\,mol^{-1}$): 281 (2:1 electrolyte). Slow diffusion of diethyl ether into a solution of **1** in acetonitrile gave single crystals suitable for X-ray crystallography.

**$[Zn(L^1)](NO_3)_2{\cdot}2CH_3CN$ (2):** A mixture of $L^1$ (0.104 g, 0.243 mmol) and $Zn(NO_3)_2{\cdot}6H_2O$ (0.075 g, 0.253 mmol) in acetonitrile (20 mL) was stirred and heated to reflux over a period of 6 h. Slow diffusion of diethyl ether into the former solution at room temperature produced colourless crystals that were collected by filtration and air-dried (0.097 g, 57%). $C_{28}H_{42}N_8O_9Zn$ (700.07): calcd. C 48.0, H 6.1, N 15.6; found C 47.1, H 6.1, N 16.0. FAB-MS: *m/z* (%BPI) = 491 (28) $[Zn(L^1 - H)]^+$. FTIR (KBr): $\tilde{\nu}$ = 3268, 3225 [$\nu_{as}(NH_2)$], 3123, 3090 [$\nu_s(NH_2)$], 1618 [$\delta(NH_2)$], 1591 [$\nu$(C=C)], 1384 [$\nu(NO_3)$] $cm^{-1}$. $\Lambda_M$ (acetonitrile, $cm^2\,\Omega^{-1}\,mol^{-1}$): 194 (2:1 electrolyte). Slow diffusion of diethyl ether into a solution of **2** in acetonitrile gave single crystals suitable for X-ray crystallography.

**$[Zn(L^2)](ClO_4)_2$ (3):** The preparation of the white complex followed the same procedure as for **1** by using $L^2$ (0.107 g, 0.226 mmol) and $Zn(ClO_4)_2{\cdot}6H_2O$ (0.085 g, 0.228 mmol) in ethanol (23 mL) (0.125 g, 75%). $C_{26}H_{40}Cl_2N_4O_{12}Zn$ (736.91): calcd. C 42.4, H 5.5, N 7.6; found C 42.0, H 5.5, N 7.5. FAB-MS: *m/z* (%BPI) = 635 (28) $[Zn(L^2)(ClO_4)]^+$, 535 (58) $[Zn(L^2 - H)]^+$, 473 (100) $[L^2 + H]^+$. FTIR (KBr): $\tilde{\nu}$ = 3225 [$\nu(NH_2)$], 1614 [$\delta(NH_2)$], 1589 [$\nu$(C=C)], 1092 [$\nu_{as}$(Cl–O)], 622 [$\delta_{as}$(Cl–O)] $cm^{-1}$. $\Lambda_M$ (acetonitrile, $cm^2\,\Omega^{-1}\,mol^{-1}$): 287 (2:1 electrolyte). Slow diffusion of diethyl ether into a solution of **3** in acetonitrile gave single crystals suitable for X-ray crystallography.

**$[Zn(L^2)(NO_3)_2]$ (4):** Slow diffusion of diethyl ether into a solution of $Zn(NO_3)_2{\cdot}6H_2O$ (0.067 g, 0.225 mmol) and $L^2$ (0.105 g, 0.222 mmol) in acetonitrile (7 mL) gave some single crystals suitable for X-ray crystallography. Attempts to isolate more compound **4** were unsuccessful because it formed an intractable oily product when separated from the solvent.

**Physical Measurements:** Elemental analyses were carried out on a Carlo–Erba 1180 elemental analyser. FAB mass spectra were recorded with a Fisons Quatro mass spectrometer with a Cs ion gun using 3-nitrobenzyl alcohol as matrix. IR spectra were recorded, as KBr discs, using a Bruker Vector 22 spectrophotometer. Conductivity measurements were carried out at 20 °C with a Crison Micro CM 2201 conductimeter using $10^{-3}$ M solutions of the complexes in acetonitrile. $^1H$ NMR spectra were run on a Bruker AC 200 F or a Bruker WM-500 spectrometer. Proton NMR titration was performed on $5 \times 10^{-3}$ M solution of **3** and in [$D_3$]acetonitrile. Typically, aliquots of a fresh tetrabutylammonium nitrate solution (0.5 M) were added, and the $^1H$ NMR spectra of the samples were recorded.

**Spectrophotometric Titrations:** UV/Vis spectra were recorded with Hewlett–Packard 8452A or Perkin–Elmer Lambda 900 spectrophotometers, with a quartz cell (path length: 10 cm). The cell holder was thermostatted at 25.0 °C through circulating water. Spectrophotometric titrations were performed at 25 °C on $5.0 \times 10^{-5}$ M solutions of $L^1$ or $L^2$ in MeCN (polarographic grade). Typically, aliquots of a fresh $Zn(ClO_4)_2{\cdot}6H_2O$ standard solution were added and the UV/Vis spectra of the samples were recorded. The spectrophotometric titration of $[Zn(L^2)]^{2+}$ with tetrabutylammonium nitrate was performed on a $1 \times 10^{-5}$ M solution of the complex, which was titrated with a $1 \times 10^{-2}$ M solution of the tetrabutylammonium salt. All spectrophotometric titration curves were fitted with the HYPERQUAD program.[30]

**X-ray Crystallography:** Crystal data and details on data collection and refinement are summarised in Table 4. Three-dimensional X-

Table 4. Crystal data and structure refinement for compounds **1**–**4**.

ray data for compounds **1**–**4** were collected on a Bruker SMART 1000 CCD diffractometer by the $\phi$-$\omega$ scan method. Reflections were measured from a hemisphere of data collected on frames each covering 0.3° in $\omega$. Data were corrected for Lorentz and polarisation effects and for absorption by semi-empirical methods.[31] Complex scattering factors were taken from the program package SHELXTL[32] as implemented on a Pentium® computer. The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$. The hydrogen atoms were included in calculated positions and refined in riding mode, except for H(3A), H(3B), H(4A) and H(4B) in **1**, H(1N) and H(2N) in **2**, and H(1N), H(2N), H(3N) and H(4N) in **3**, which were first located in a Fourier difference density map and left to freely refine. Minimum and maximum final electron density of –0.370 and 0.474 Å$^{-3}$ for **1**, –0.310 and 0.526 Å$^{-3}$ for **2**, –0.508 and 0.343 Å$^{-3}$ for **3**, and –0.545 and 0.668 Å$^{-3}$ for **4** were found. The structure of **4** presents a disorder on an oxygen atom of the nitrate groups. The disorder has been resolved and two atomic sites have been observed and refined with isotropic atomic displacement parameters. The site occupancy factor was 0.546 for O(1SA).

CCDC-614190 to -614193 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via http://www.ccdc.cam.ac.uk/data_request/cif.

**DFT Studies:** All calculations were performed using the Gaussian 03 (Revision C.01)[33] program package with the B3LYP[34,35] three-parameter hybrid density functional, unless otherwise stated. In vacuo geometry optimisations of the $[Zn(L^1)]^{2+}$, $[Zn(L^2)]^{2+}$ and $[Zn(L^2)(NO_3)_2]$ systems were performed without constraints by using the Ahlrichs' valence triple-ζ (VTC)[22] basis set on Zn and the standard 6-31G(d) basis set on C, H, N and O atoms. The X-ray crystal structures of compounds **1**, **3** and **4** were used as input for geometry optimisations. The stationary points found on the potential energy surfaces as a result of the geometry optimisations have been tested to represent energy minima rather than saddle points by frequency analysis. Binding energies of the macrocyclic ligands were calculated as $E_{bind} = E_{metal\ complex} - (E_{cation} + E_{free\ ligand})$, with the free ligand at the geometry found within the complex. Therefore, calculated binding energies are static and do not include energy contributions because of changes in ligand geometry. The binding energy (of the macrocyclic ligand) in $[Zn(L^2)(NO_3)_2]$ was calculated as $E_{bind} = E_{metal\ complex} - (E_{Zn(NO_3)_2} + E_{free\ ligand})$. Basis Set Superposition Errors (BSSEs) were calculated using the Counterpoise method.[26] BSSE is an undesirable consequence of using finite basis sets that leads to an overestimation of the binding energy.

**Supporting Information** (see also the footnote on the first page of this article): In vacuo optimised Cartesian Coordinates [Å], Table S1 listing experimental and calculated angles of the metal coordination environment for the $[Zn(L^1)]^{2+}$, $[Zn(L^2)]^{2+}$ and $[Zn(L^2)(NO_3)_2]$ systems, and Figures S1, S2 and S3.

# Hydrothermal Synthesis of Single Crystalline (K,Na)$NbO_3$ Powders

Ce Sun,[a] Xianran Xing,*[a,b] Jun Chen,[a] Jinxia Deng,[a] Lu Li,[a] Ranbo Yu,[a] Lijie Qiao,[c] and Guirong Liu[a]

**Keywords:** Hydrothermal synthesis / Crystal growth / Crystal morphology / Niobates

$(K_{1-x}Na_x)NbO_3$ (x = 0.01, 0.24, 0.89, 0.91, 0.99) single crystalline powders with perovskite structure were synthesized by a hydrothermal method with $Nb_2O_5$ in a mixed solution of KOH and NaOH at 220 °C for 24 h. XRD investigations showed that the structure of the synthesized $(K_{1-x}Na_x)NbO_3$ ceramics changed from a $KNbO_3$-type orthorhombic phase (space group *Bmm*2) to a $NaNbO_3$-type monoclinic phase (space group *Pm*) with the increase of Na content. The present results confirmed that $(K_{1-x}Na_x)NbO_3$ exhibited a morphotropic phase boundary (MPB) at around 50 %K separating the orthorhombic phase and monoclinic phase. FE-SEM images showed that the morphological structures of niobates were cubes and nanofingers. The TEM image and the selected area electron diffraction pattern of $(K_{0.01}Na_{0.99})NbO_3$ showed the as-synthesized powder was single crystalline and indexed to be monoclinic. The phase evolution of the products in the hydrothermal route revealed that the hydrothermal synthesis of $(K_{1-x}Na_x)NbO_3$ underwent two steps, where an intermediate product $(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}nH_2O$ was found in the early stage and then pure $(K_{1-x}Na_x)NbO_3$ was obtained after another 30 min of hydrothermal treatment.

## Introduction

Alkaline niobates have captured considerable interest in the scientific community because of their excellent ferroelectric, piezoelectric, electromechanical, nonlinear optical, electricoptic, and ionic conductivity properties.[1–6] The alkaline niobate-based perovskite compounds without toxic elements show a high Curie temperature and low anisotropy. Among them, $(K_{0.5}Na_{0.5})NbO_3$ was considered a good candidate for lead-free piezoelectric ceramics because of its strong piezoelectricity and ferroelectricity.[2,7,8] $(K_{1-x}Na_x)NbO_3$ is a combination of ferroelectrics $KNbO_3$ and antiferroelectrics $NaNbO_3$, and forms a morphotropic phase boundary (MPB) at around 50%K separating two orthorhombic phases[7,9] or orthorhombic and tetragonal phases with the composition modification of Li and Sb.[10] The piezoelectric properties of $(K_{1-x}Na_x)NbO_3$ single crystals were first reported by Egerton et al.[7] and Cross.[11] The hot pressed $(K_{0.5}Na_{0.5})NbO_3$ ceramics have been reported to possess high phase transition temperature ($T_c \approx$ 420 °C), high remanent polarization ($P_r \approx 33\ \mu C/cm^2$), large piezoelectric longitudinal response ($d_{33} \approx 160$ pC/N), and planar coupling coefficients ($k_p \approx 45\%$).[12,13]

To date, several studies have been devoted to the fabricating processes and properties of $(K_{1-x}Na_x)NbO_3$. $(K_{1-x}Na_x)NbO_3$ powders are commonly synthesized by a solid-state method. Saito et al.[2] reported that a high $d_{33}$ (about 416 pC/N) constant was obtained in the textured $(K_{1-x}Na_x)NbO_3$-based ceramics close to a morphotropic phase boundary. Pithan et al.[14] and Zhang et al.[15] prepared $(K_{1-x}Na_x)NbO_3$ by microemulsion mediated and spark plasma sintering methods, respectively. Shiratori et al.[16] synthesized the monoclinic $(K_{0.5}Na_{0.5})NbO_3$ by a microemulsion mediated route. The hydrothermal synthesis method has been used to prepare perovskite-type $NaNbO_3$, $KNbO_3$, $KNb_3O_8$, and $K_4Nb_6O_{17}$ powders over the past decade.[1,17–20] However, synthesis of the complex of $(K_{1-x}Na_x)NbO_3$ has not involved a hydrothermal route.

In the present study, we synthesized single crystalline powders of $(K_{1-x}Na_x)NbO_3$ by a hydrothermal method under moderate conditions. The structural evolution during the reaction between $Nb_2O_5$ and concentrated aqueous NaOH and KOH mixed solution was investigated. The crystal structures of the obtained powders were identified by XRD. The morphology of the samples was studied by field-emission scanning electron microscopy (FE-SEM) and TEM, and elemental analyses for Nb, K, and Na were conducted by inductively coupled plasma (ICP) spectrometry.

## Results and Discussion

The influence of the processing parameters of K/Na molar ratio in the aqueous mixed solution on the formation of $(K_{1-x}Na_x)NbO_3$ is summarized in Table 1. The elemental analysis for Na, K, and Nb was conducted by ICP spectrometry. Because the values of Na and Nb were more accurate than that of K, the stoichiometries of all products were calculated based on the measurements of Na and Nb. KOH/NaOH plays the role of $K^+/Na^+$ source and the alkalinity in the aqueous medium, which affects the nucleation and crystallization of the products. The K/Na molar ratio in the as-synthesized samples increased with the ratio in the mixed solution. However, there was a big jump from KNN2 (Na/K = 24:76) to KNN3 (Na/K = 89:11). This might be attributed to the larger ionic radii of $K^+$ compared to that of $Na^+$, leading to a sharp rise of the reaction activity of $Na^+$ in the solution.

Table 1. K/Na/Nb ratio and the possible formula of the sodium-potassium niobates.

| Sample No. | Concentration [mol/L] KOH | NaOH | K/Na/Nb ratio[a] | Formula |
|---|---|---|---|---|
| KNN1 | 9.0 | 1.0 | 96.2:1.3:100 | $K_{0.99}Na_{0.01}NbO_3$ |
| KNN2 | 8.0 | 2.0 | 76.9:24.4:100 | $K_{0.76}Na_{0.24}NbO_3$ |
| KNN3 | 7.0 | 3.0 | 7.6:88.7:100 | $K_{0.11}Na_{0.89}NbO_3$ |
| KNN4 | 6.0 | 4.0 | 7.8:91.3:100 | $K_{0.09}Na_{0.91}NbO_3$ |
| KNN5 | 5.0 | 5.0 | 3.5:99.4:100 | $K_{0.01}Na_{0.99}NbO_3$ |

[a] Measured by ICP.

The XRD patterns (Figure 1) showed that pure phase $(K_{1-x}Na_x)NbO_3$ powders were obtained in the 10 mol/L KOH and NaOH solution. This indicated that well-crystallized $(K_{1-x}Na_x)NbO_3$ powders were synthesized in the concentrated alkaline solution under mild conditions. $(K_{0.99}Na_{0.01})NbO_3$ and $(K_{0.76}Na_{0.24})NbO_3$ were indexed in orthorhombic symmetry (space group *Bmm*2), but $(K_{0.11}Na_{0.89})NbO_3$, $(K_{0.09}Na_{0.91})NbO_3$, and $(K_{0.01}Na_{0.99})NbO_3$ were indexed in monoclinic symmetry (space group *Pm*), the lattice parameters are labeled in Table 2. The increasing of Na content in (K,Na)$NbO_3$ resulted in the phase transition from a $KNbO_3$-type orthorhombic phase to a $NaNbO_3$-type monoclinic phase.[21] This further confirmed a morphotropic phase boundary at around 50%K separating orthorhombic and monoclinic phases, but not two orthorhombic phases[7,9] or orthorhombic and tetragonal phases with composition modification of Li and Sb[10] as reported before.

Table 2. The crystal system and lattice parameters of the alkaline niobates.

| Sample | Syngony | Lattice parameters[a] *a* [Å] | *b* [Å] | *c* [Å] | *β* [°] |
|---|---|---|---|---|---|
| $K_{0.99}Na_{0.01}NbO_3$ | orthorhombic | 3.976(9) | 5.686(0) | 5.698(0) | – |
| $K_{0.76}Na_{0.24}NbO_3$ | orthorhombic | 3.970(6) | 5.675(5) | 5.687(1) | – |
| $K_{0.11}Na_{0.89}NbO_3$ | monoclinic | 7.773(8) | 7.838(2) | 7.849(8) | 89.901 |
| $K_{0.09}Na_{0.91}NbO_3$ | monoclinic | 7.781(0) | 7.825(6) | 7.867(6) | 89.624 |
| $K_{0.01}Na_{0.99}NbO_3$ | monoclinic | 7.789(3) | 7.819(9) | 7.866(3) | 89.717 |

[a] Lattice parameters were calculated by Powder X and TREOR software.

FE-SEM images of $(K_{0.99}Na_{0.01})NbO_3$ prepared by the hydrothermal treatment (220 °C, 24 h) are shown in Figure 2. Large-scale and well-crystallized $(K_{0.99}Na_{0.01})NbO_3$ cubes in microns were obtained (Figure 2, a), and a few nanofingers were also observed (Figure 2, b), which was confirmed by the previous work.[22] The aspect ratios (approximately length-to-width ratio) of the nanofingers are as high as 10 and their average width is about 60–75 nm.

The TEM images and the selected area electron diffraction (SAED) patterns of $(K_{0.01}Na_{0.99})NbO_3$ are displayed in Figure 3. The TEM image (see Figure 3, a) showed a club-shaped morphology for the $(K_{0.01}Na_{0.99})NbO_3$ single crystal. The SAED pattern (see Figure 3, b) revealed that $(K_{0.01}Na_{0.99})NbO_3$ was single crystalline and was indexed as monoclinic in structure, which was consistent with the present XRD investigation.

The phase evolution of $(K_{0.76}Na_{0.24})NbO_3$ (KNN2) via a hydrothermal synthesizing processing route was studied by XRD (see Figure 4). A series of XRD patterns of KNN2 were obtained at 220 °C and labeled KNN2-*n*, where *n* denoted the hydrothermal treatment time (in min). The raw material of $Nb_2O_5$ was mostly α-$Nb_2O_5$ with a few β-$Nb_2O_5$ as shown in Figure 4 (a). During the first 60 min $Nb_2O_5$ gradually reacted with the alkaline solution, and a new phase emerged as shown in Figure 4 (b,c). The XRD peaks of the new phase were isolated as $K_4Na_4Nb_6O_{19}{\cdot}9H_2O$.[23] However, the molar concentrations of $K^+$ and $Na^+$ were not equal in the final product KNN2 (see ICP result in Table 1), which suggested that the new phase would be $(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}nH_2O$ but not $K_4Na_4Nb_6O_{19}{\cdot}9H_2O$. The dominant phases in KNN2–*90* were $(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}nH_2O$ and $(K_{1-x}Na_x)NbO_3$ with minor $Nb_2O_5$ as shown in Figure 4 (d). After 120 min only one phase of KNN2 was observed (see Figure 4, e). This implied that the

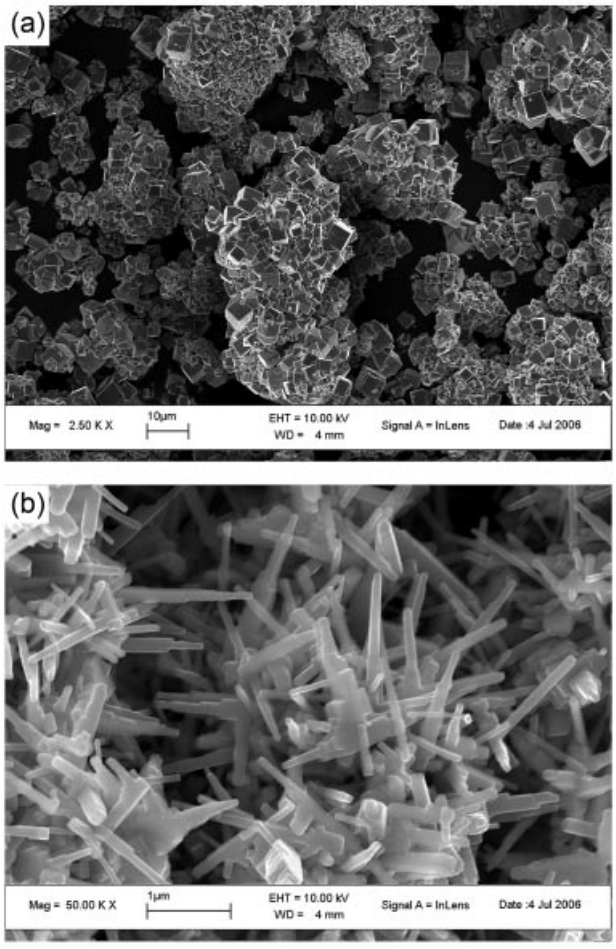

Figure 2. FE-SEM images of $(K_{0.99}Na_{0.01})NbO_3$ synthesized at 220 °C for 24 h: (a) cubes, (b) nanofingers.

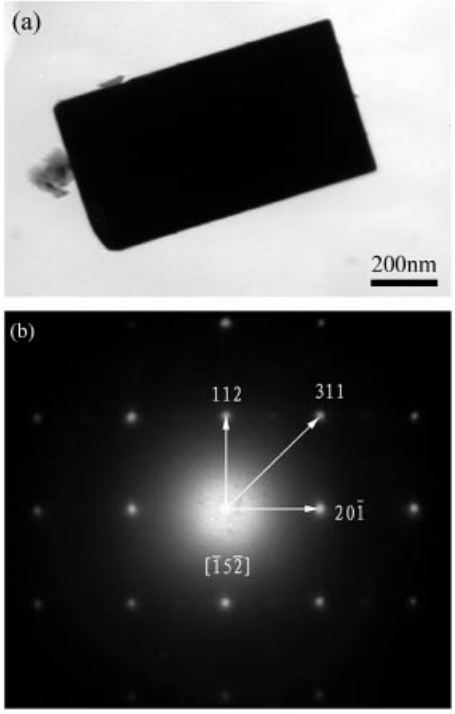

Figure 3. TEM images (a) and selected area electron diffraction (b) of the $(K_{0.01}Na_{0.99})NbO_3$ sample.

intermediate phase $(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}nH_2O$ further reacted with $Nb_2O_5$ to form KNN2 powders. The KNN2–*150* sample was a well-crystallized phase of KNN2 (see part f in Figure 4). The same phase evolution was also observed for $(K_{0.09}Na_{0.91})NbO_3$ (KNN4) as shown in Figure 5, the intermediate product $(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}nH_2O$ was found in the early stage and then pure $(K_{0.09}Na_{0.91})NbO_3$ was obtained after further hydrothermal treatment (see parts d,e in Figure 5).

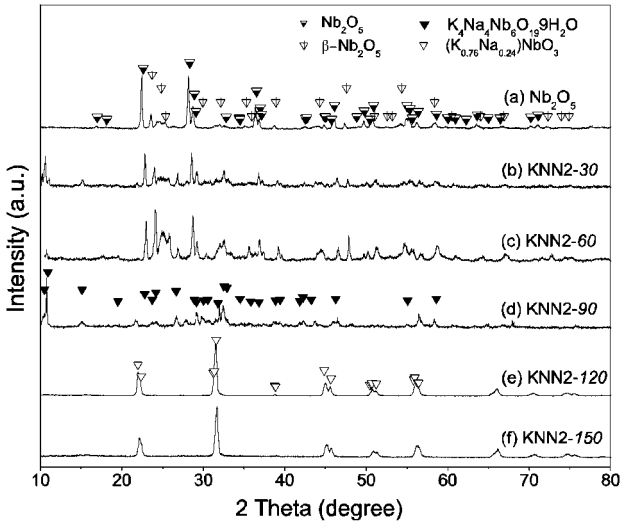

Figure 4. The XRD patterns of $(K_{0.76}Na_{0.24})NbO_3$ (KNN2) samples after various reaction periods (which were indicated in the figure) at 220 °C.

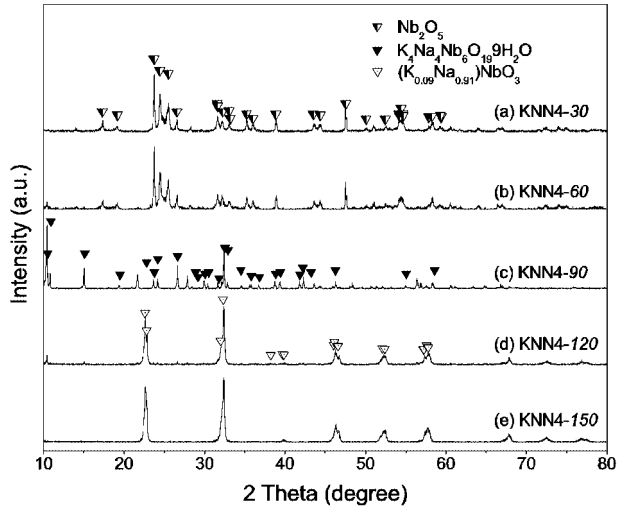

Figure 5. The XRD patterns of $(K_{0.09}Na_{0.91})NbO_3$ (KNN4) samples after various reaction periods (which were indicated in the figure) at 220 °C.

Hence, it was concluded that the formation of $(K_{1-x}Na_x)NbO_3$ occurred in two steps. The first step was that $Nb_2O_5$ reacted with MOH (M = Na, K) to form $(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}nH_2O$ [Equation (1)].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

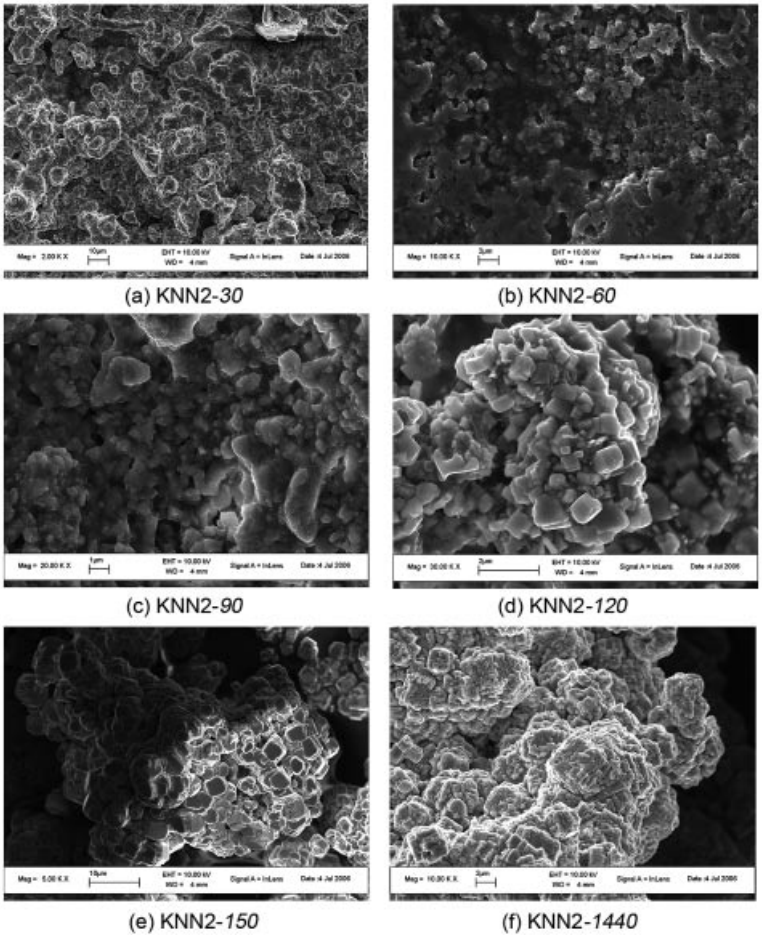

Figure 6. The morphological evolution of the $(K_{0.76}Na_{0.24})NbO_3$ (KNN2) samples during the reaction course by FE-SEM images: (a) KNN2–*30*, (b) KNN2–*60*, (c) KNN2–*90*, (d) KNN2–*120*, (e) KNN2–*150*, (f) KNN2–*1440*.

$$(8-8x)\ KOH + 8x\ NaOH + 3\ Nb_2O_5 + (n-4)\,H_2O = (K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}n\,H_2O \quad (1)$$

The second step was that $(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}n\,H_2O$ reacted with $Nb_2O_5$ [Equation (2)].

$$(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}n\,H_2O + Nb_2O_5 = 8\ (K_{1-x}Na_x)NbO_3 + n\,H_2O \quad (2)$$

The morphological evolution of $(K_{0.76}Na_{0.24})NbO_3$ was investigated by FE-SEM (see Figure 6). The reactants nearly kept the morphology of $Nb_2O_5$ in the first 30 min as shown in Figure 6 (a). But $Nb_2O_5$ gradually fluxed and reacted with the alkaline solution as shown in Figure 6 (b,c). After 120 min a small-scale cubic phase was formed. The KNN2–*150* sample was very pure potassium sodium niobate with a club-shaped morphology as shown in Figure 6 (e). The FE-SEM image and XRD pattern of KNN2–*1440* (KNN2 in Table 1) were similar to KNN2–*150*, and the XRD and ICP investigations demonstrated that it was $(K_{0.76}Na_{0.24})NbO_3$ crystal powder.

## Conclusions

$(K_{1-x}Na_x)NbO_3$ ($x$ = 0.01, 0.24, 0.89, 0.91, 0.99) single crystalline powders with perovskite structure were synthesized by a hydrothermal method with $Nb_2O_5$ in a mixed solution of KOH and NaOH at 220 °C for 24 h. The as-synthesized $(K_{1-x}Na_x)NbO_3$ powders showed that with the increase of Na content the crystal structure changed from a $KNbO_3$-type orthorhombic phase (space group *Bmm*2) to a $NaNbO_3$-type monoclinic phase (space group *Pm*). It further confirmed that $(K_{1-x}Na_x)NbO_3$ exhibited a morphotropic phase boundary at around 50%K separating the orthorhombic and monoclinic phases. The morphological structures of the niobates were cubes and nanofingers. The SAED pattern showed that $(K_{0.01}Na_{0.99})NbO_3$ was single crystalline and indexed as monoclinic in structure, which was consistent with the XRD investigation. We concluded that the hydrothermal synthesis of $(K_{1-x}Na_x)NbO_3$ underwent two steps, and had an intermediate phase as $(K_{8-8x}Na_{8x})Nb_6O_{19}{\cdot}n\,H_2O$. The first step was that $Nb_2O_5$ reacted with MOH (M = Na, K) to form $(K_{8-8x}Na_{8x})$-$Nb_6O_{19}{\cdot}n\,H_2O$. The second step was where $(K_{8-8x}Na_{8x})$-$Nb_6O_{19}{\cdot}n\,H_2O$ reacted with $Nb_2O_5$, and finally formed $(K_{1-x}Na_x)NbO_3$ single crystal powders.

## Experimental Section

**Synthetic Procedures:** KOH, NaOH, and $Nb_2O_5$ (all are analytic reagent grade) were used in the synthesis. In a typical synthesis

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

process, $Nb_2O_5$ (0.5 g) was added to a mixed solution of NaOH and KOH (30 mL), and stirred for half an hour. Then the white slurry was introduced into a Teflon-lined stainless steel autoclave and heated in a furnace at 220 °C for 24 h. After gradually cooling down to room temperature, the precipitates were filtered and washed with distilled water and ethanol, then dried at 80 °C.

**Measurements:** The morphologies of the samples were studied by field-emission scanning electron microscopy (FE-SEM, LEO1530) and transmission electron microscopy (TEM, JEM-100CXII). Elemental analysis for Nb, K, and Na was conducted by inductively coupled plasma (ICP, INC Profile) spectrometry.

**X-ray Structure:** The crystal structures of the obtained powders were identified by powder X-ray diffractometry, performed with a M21XVHF22 diffractometer (Japan) at room temperature. Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å) and a fixed power source (40 kV and 200 mA) were used. The samples were scanned at a rate of 8°/min over a range of 10–90°. The major diffraction peaks of the samples were indexed by Powder X and TREOR software.

# Protonolysis Reactions of $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(thf)_3$ with *t*BuSH or EtSH: Isolation, Structures and Catalytic Properties of Dinuclear Complexes $[\{(Me_3Si)_2N\}_2Ln(\mu\text{-}StBu)]_2$ and Tetranuclear Complexes $[Li(thf)_4][\{(Me_3Si)_2N\}_4Ln_4(\mu_4\text{-}SEt)(\mu\text{-}SEt)_8]$ (Ln = Pr, Sm)

**Mei-Ling Cheng,[a] Hong-Xi Li,[a] Wen-Hua Zhang,[a] Zhi-Gang Ren,[a] Yong Zhang,[a] and Jian-Ping Lang*[a,b]**

**Keywords:** Amidolanthanides / Alkylthiolates / Synthesis / Crystal structure / Ring-opening polymerization

Reactions of $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(thf)_3$ (**1**: Ln = Pr; **2**: Ln = Sm) with an equimolar amount of *t*BuSH or EtSH gave rise to four amidolanthanide alkylthiolate complexes $[\{(Me_3Si)_2N\}_2Ln(\mu\text{-}StBu)]_2$ (**3**: Ln = Pr; **4**: Ln = Sm) and $[Li(thf)_4][\{(Me_3Si)_2N\}_4Ln_4(\mu_4\text{-}SEt)(\mu\text{-}SEt)_8]$ (**5**: Ln = Pr; **6**: Ln = Sm). Compounds **3**–**6** were characterized by elemental analysis, IR and $^1H$ NMR spectroscopy and single-crystal X-ray diffraction, and their catalytic properties were also investigated. Compounds **3** and **4** are thiolate-bridged dimers in which each Ln atom adopts a distorted tetrahedral coordination. Compounds **5** and **6** contain a $Ln_4$ square plane, which is capped by a $\mu_4$-$SEt^-$ ligand. The edges of the square are bridged by four pairs of $SEt^-$ ligands on both sides of the $Ln_4$ plane. Each Ln atom has a distorted octahedral geometry.

## Introduction

In the past decades, synthesis of lanthanide chalcogenolates has attracted much attention due to their interesting structures[1] and their potential applications in advanced materials and catalytic processes.[2] Among these complexes, only a dozen of lanthanide alkylthiolate complexes[3] have been structurally characterized, though some lanthanide alkylthiolate complexes (e.g. $[Gd\{N(SiMe_3)_2\}(\mu\text{-}StBu)]_2$[4] and $[Cp_2Lu(\mu\text{-}StBu)_2Li(thf)_2]$[5]) were reported in 1985. These alkylthiolate complexes can be mainly classified into two types: mononuclear structures {e.g. $[Li(tmeda)]_3[Yb(StBu)_6]$; tmeda = $Me_2NCH_2CH_2NMe_2$},[3c] and dinuclear structures {e.g. $[Yb(StBu)_2(\mu\text{-}StBu)(bipy)]_2$}.[3a] Most of these compounds were prepared by metathesis of lanthanide halides or (substituted) cyclopentadienyl lanthanide complexes with alkali metal thiolates,[3b,3c,3g,4] by insertion reactions of $S_8$ into the Ln–carbon bond[3h] or by protonolysis reactions of (substituted) cyclopentadienyl lanthanide complexes with alkylthiols.[3a,3d–3f,5] It is noted that reactions of amidolanthanide complexes with alkylthiols appear to be less explored. Aspinall et al. reported the first amidolanthanide *tert*-butylthiolate complexes $[Ln\{N(SiMe_3)_2\}(\mu\text{-}StBu)]_2$ (Ln = Gd, Eu), which were prepared from protonolysis reactions of $[(Me_3Si)_2N]_3Ln$ with an equimolar amount of *t*BuSH in toluene/thf at –23 °C. However, these compounds readily decomposed into insoluble polymeric materials at ambient temperature.[4]

We are interested in the preparation of amidolanthanide benzenethiolate complexes from protonolysis reactions of bis(trimethylsilyl)amidolanthanide(III) chloride complexes, $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(thf)_3$, with benzenethiol.[6] For example, reactions of $[(Me_3Si)_2N]_3Nd(\mu\text{-}Cl)Li(thf)_3$ with an equimolar amount of benzenethiol gave rise to cationic tetranuclear complex $Li[\{(Me_3Si)_2N\}_4(\mu_4\text{-}Cl)Nd_4(\mu\text{-}SPh)_8]$. The facile formation of this complex and other previously reported related complexes could be attributed to the incorporation of lithium and chloride ions into their frameworks.[6a] In addition, these complexes exhibited good catalytic activity in the ring-opening polymerization (ROP) of ε-caprolactone. Therefore, if the benzenethiol that was used in the above reactions were to be replaced with different alkylthiols, would reactions between $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(thf)_3$ and the alkylthiols afford amidolanthanide thiolate complexes with different structural frameworks? Moreover, would the resulting complexes show better catalytic activity in the ROP of ε-caprolactone? With these questions in mind, we carried out reactions of $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(thf)_3$ (**1**: Ln = Pr; **2**: Ln = Sm)[7] with two common alkylthiols, *t*BuSH and EtSH, and two neutral binuclear complexes $[\{(Me_3Si)_2N\}_2Ln(\mu\text{-}StBu)]_2$ (**3**: Ln = Pr; **4**: Ln = Sm) and two cationic tetranuclear complexes $[Li(thf)_4][\{(Me_3Si)_2N\}_4Ln_4(\mu_4\text{-}SEt)(\mu\text{-}SEt)_8]$ (**5**: Ln = Pr; **6**: Ln =

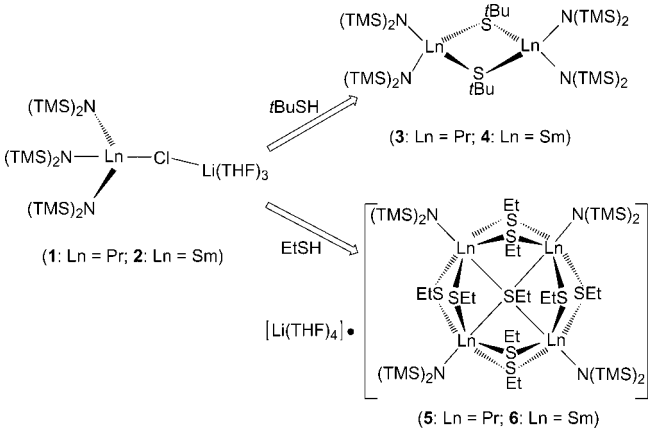
Sm) were isolated therefrom. Compounds **3**–**6** did exhibit better catalytic activity in the ROP of ε-caprolactone than their benzenethiolate analogues. Herein, we report the synthesis, crystal structures and catalytic properties of **3**–**6**.

## Results and Discussion

Treatment of a thf solution of **1** with an equimolar amount of *t*BuSH in thf at ambient temperature led to a yellow solution. After removal of all the volatile species in vacuo, the residue was extracted with toluene and *n*-hexane, and the insoluble LiCl precipitate was filtered off. The filtrate was allowed to stand at 2 °C for three days, which resulted in the formation of yellow crystals of **3**·2(thf)$_{0.5}$ in 43% yield. Analogous reactions of **2** with an equimolar amount of *t*BuSH in thf gave rise to **4** in 40% yield (Scheme 1). Reactions of a thf solution of **1** or **2** in thf with an equimolar amount of EtSH at room temperature followed by a standard workup afforded **5**·0.5$C_7H_8$ in 21% yield or **6**·$C_6H_6$ in 17% yield, respectively (Scheme 1). The preparation of **5** and **6** was reproducible, though their yields were relatively low, which may be due to the formation of a large amount of insoluble material during the preparation. The yield of the two corresponding reactions decreased when **1** or **2** was treated with 2–3 equiv. of EtSH. Even at –20 °C, the formation of **5** or **6** was not observed, but a large amount of insoluble material was always isolated.



Scheme 1.

The protonolysis reactions of **1** and **2** with PhSH, *t*BuSH or EtSH deserve comments. Treatment of **1** or **2** with an equimolar amount of PhSH gave rise to a polymeric complex [{$(Me_3Si)_2N$}$_2$(μ-SPh)Pr(μ-SPh)Li(thf)$_2$]$_\infty$ and a tetranuclear wine-cup-shaped complex [{$(Me_3Si)_2N$}$_4$($\mu_4$-Cl)-$Sm_4$(μ-SPh)$_4$($\mu_3$-Cl)$_4$Li(thf)], respectively, whereas the reaction of **1** with *t*BuSH or EtSH produced binuclear complexes **3** and **4** or tetranuclear cationic complexes **5** and **6**. The remarkable difference in the outcome of these reactions may be related to the steric effects of the R organic group (*t*Bu > Ph > Et) bound to the S atom in the resulting structures. It is assumed that in the case of thiols that bear larger R groups (e.g. *t*Bu), the formation of a structure similar to that of the tetranuclear lanthanide thiolate complexes (e.g. **5** and **6**), described later in this paper, may cause the *t*Bu groups around the $Ln_4$ ring to become more crowded. Therefore, reactions of **1** or **2** with *t*BuSH seem to prefer the formation of smaller complexes **3** and **4**. Another reason for the formation of complexes with larger Ln nuclearity may be ascribed to the incorporation of $Li^+$ and/or $Cl^-$ ions into their structures.[6a] In the cases of **5** and **6**, the larger $[Li(thf)_4]^+$ cation that is incorporated into their structures may to some extent stabilize the larger [{$(Me_3Si)_2N$}$_4$-$Ln_4$($\mu_4$-SEt)(μ-SEt)$_8$]$^-$ anion by ionic interactions.

Compounds **3**–**6** are extremely air- and moisture-sensitive, and they are readily soluble in dme, thf and toluene; they are also slightly soluble in *n*-hexane. Elemental analyses of **3**–**6** are consistent with the proposed formulas. The $^1$H NMR spectra in $C_6D_6$ at room temperature shows the correct $(Me_3Si)_2N^-$/S*t*Bu$^-$ proton ratios for **3** and **4** and the correct $(Me_3Si)_2N^-$/SEt$^-$/thf proton ratio for **5**, though the proton signals of the $(Me_3Si)_2N^-$ and SEt$^-$ or S*t*Bu$^-$ ligands are shifted significantly upfield owing to the paramagnetism of these complexes. The $^1$H NMR spectrum of **6** contains broad uninterpretable signals that give no useful information about the solution behaviour of this paramagnetic complex. The identities of **3**–**6** were finally confirmed by X-ray crystallography.

Compound **3**·2(thf)$_{0.5}$ crystallizes in the triclinic space group $P\bar{1}$ and the asymmetric unit contains half of the [{$(Me_3Si)_2N$}$_2$Pr(μ-S*t*Bu)]$_2$ molecule and two halves of solvated thf molecules, whereas **4** crystallizes in the monoclinic space group $P2_1/c$ and the asymmetric unit contains half of the [{$(Me_3Si)_2N$}$_2$Sm(μ-S*t*Bu)]$_2$ molecule. As the molecular structures of **3** and **4** are very similar, only that of **3** is showed in Figure 1. Their selected bond lengths and angles are compared in Table 1.

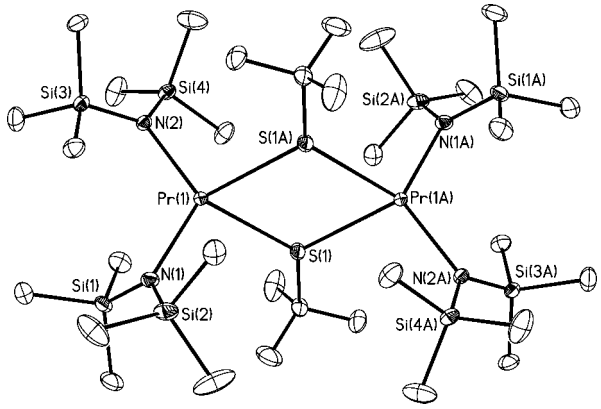


Figure 1. Perspective view of **3** with labelling scheme and 50% thermal ellipsoids. All hydrogen atoms are omitted for charity.

Compounds **3** or **4** consists of two {[$(Me_3Si)_2N$]$_2$Ln} moieties interconnected by a pair of μ-S*t*Bu anions to form a dimeric structure with a crystallographic centre of symmetry at the midpoint of the Ln(1) and Ln(1A) atoms. Although the $Pr_2S_2$ core structure in **3** is uncommon in Pr$^{III}$ thiolate complexes, the analogous $Sm_2S_2$ core structure in

| Ln(1)–S(1)–Ln(1A) | 110.39(5) | 108.46(9) |

[a] Symmetry code: A: $-x+2, -y+2, -z+1$ for **3**; $-x, -y, -z+1$ for **4**.

**4** is found in some known dinuclear $Sm^{III}$ complexes such as $[(thf)_3I_2Sm(\mu\text{-}SC_6H_4(Me_2N)\text{-}4)]_2$,[8] $[(C_8H_8)Sm(\mu\text{-}SPh)(thf)_2]_2$,[9] $[Sm(C_8H_8)(thf)(\mu\text{-}SC_6H_2iPr_3\text{-}2,4,6)]_2$,[9] $[Sm(SC_6H_2iPr_3\text{-}2,4,6)(thf)_3(\mu\text{-}SC_6H_2iPr_3\text{-}2,4,6)]_2$[10] and $[Sm(SC_6F_5)_2(thf)(\mu\text{-}SC_6F_5)]_2$.[11] The Ln(1)···Ln(1A) separation within the dimer in **3** or **4** is 4.703 or 4.568 Å, respectively, which is too long to include any metal–metal interaction. Each Ln centre in **3** or **4** is coordinated by two S atoms from two μ-S*t*Bu$^-$ anions and two N atoms from two $[N(SiMe_3)_2]^-$ anions to form a distorted tetrahedral geometry.

In the $Pr_2S_2$ rhomb of **3**, the two Pr–S bond lengths are unsymmetrical with Pr(1)–S(1) of 2.870(17) Å and Pr(1)–S(1A) of 2.858(13) Å. The mean Pr–S bond length of 2.864(15) Å is comparable to that in $[\{(Me_3Si)_2N\}_2(\mu\text{-}SPh)Pr(\mu\text{-}SPh)Li(thf)_2]_n$ [2.831(5) Å].[6a] The mean Pr–N bond length [2.298(3) Å] is close to that in $[\{(Me_3Si)_2N\}_2(\mu\text{-}SPh)Pr(\mu\text{-}SPh)Li(thf)_2]_n$ [2.312(5) Å],[6a] but slightly shorter than those found in $[(Me_3Si)_2N]_3Pr(\mu\text{-}Cl)Li(thf)_3$ [2.359(3) Å][7b] and $[Pr\{N(SiMe_3)_2\}_4][K(thf)_6]$ [2.428(5) Å].[12]

In the $Sm_2S_2$ ring of **4**, the two Sm–S distances are also not equal [2.786(3) Å and 2.844(3) Å]. The average distance [2.815(3) Å] is close to those found in $[Li(tmeda)_2][Cp^*_2Sm(SC{\equiv}CPh)_2]$ [2.794(4) Å][5] and $\{(Cp_2Sm)_2Mo(\mu\text{-}S)_4\}(PPh_4)$ [2.785(3) Å],[13] but slightly shorter than that in $[Sm(C_8H_8)(thf)(\mu\text{-}SC_6H_2iPr_3\text{-}2,4,6)]_2$ [2.881(5) Å].[9] The mean Sm–N bond length [2.252(8) Å] is somewhat shorter than those in four-coordinate $Sm^{III}$ complexes $SmL[N(SiMe_3)_2]_2$ {2.350(3) Å, L = *N*-*tert*-butyl-*N*-[2-(*tert*-butylamino)ethyl]imidazolylidene}[14] and $Sm[N(SiMe_3)_2]_2(thf)_2$ [2.432(2) Å].[15]

Having a common chemical formula $[Li(thf)_4][\{(Me_3Si)_2N\}_4Ln_4(\mu_4\text{-}SEt)(\mu\text{-}SEt)_8]$, **5**·0.5$C_7H_8$ and **6**·$C_6H_6$ crystallize in the monoclinic space group $P2_1/c$ with half of one toluene solvated molecule (**5**), and one benzene solvated molecule (**6**). As the structures of the $[\{(Me_3Si)_2N\}_4Ln_4(\mu_4\text{-}SEt)(\mu\text{-}SEt)_8]^-$ anions in **5** and **6** are essentially identical, we only show the perspective view of the anion of **5** in Figure 2. The pertinent bond lengths and angles for **5** and **6** are compared in Table 2.

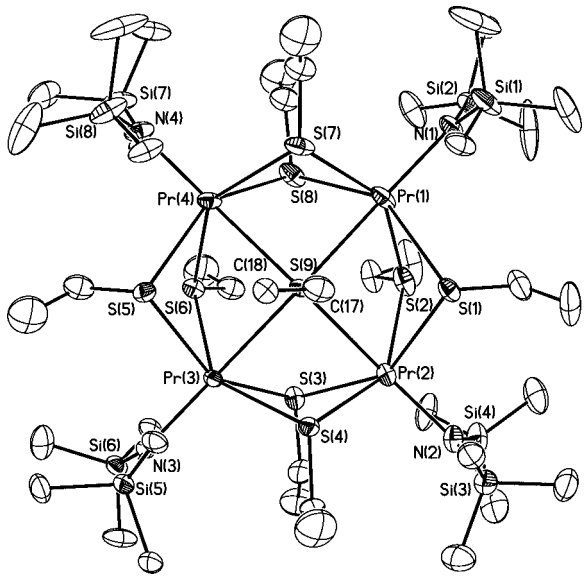

Figure 2. Perspective view of the anion of **5**, where only the disordered C(19)–C(20) atoms with a site occupancy factor of 0.45 are shown. The thermal ellipsoids are drawn at the 50% probability level and all hydrogen atoms are omitted for clarity.

The structures of the anions of **5** and **6** have a square-like $Ln_4$ array that is linked by four pairs of $SEt^-$ ligands and is capped by a $\mu_4$-$SEt^-$ ligand above the $Ln_4$ plane (0.919 Å for **5** and 0.953 Å for **6**). This structure resembles that of $[(thf)_6Yb_4(\mu_4\text{-}S)(\mu\text{-}\eta^2\text{:}\eta^2\text{-}S_2)_4(SC_6F_5)_2]$,[16a] $[(thf)_6Yb_4(\mu_4\text{-}S)(\mu\text{-}\eta^2\text{:}\eta^2\text{-}S_2)_4I_2]$[16b] and $Li[\{(Me_3Si)_2N\}_4Nd_4(\mu_4\text{-}Cl)(\mu\text{-}SPh)_8]\cdot C_6H_6$,[6a] which comprises a square array of $Ln^{III}$ ions connected by four $\mu\text{-}\eta^2\text{:}\eta^2\text{-}S_2$ ligands or four pairs of $SPh^-$ ligands and capped by a $\mu_4$-$S^{2-}$ or $\mu_4$-$Cl^-$ ion above the $Ln_4$ plane. It is noted that the symmetries of the structures of these compounds with the $Ln_4$ core are quite different owing to the different periphery bridging ligands and capping ligands. The structure of the anion of $Li[\{(Me_3Si)_2N\}_4Nd_4(\mu_4\text{-}Cl)(\mu\text{-}SPh)_8]\cdot C_6H_6$ shows an approximate $S_4$ symmetry whereas those of $[(thf)_6Yb_4(\mu_4\text{-}S)(\mu\text{-}\eta^2\text{:}\eta^2\text{-}S_2)_4(SC_6F_5)_2]$ and $[(thf)_6Yb_4(\mu_4\text{-}S)(\mu\text{-}\eta^2\text{:}\eta^2\text{-}S_2)_4I_2]$ have an approximate $C_{2v}$ symmetry. However, the symmetry of the anions of **5** and **6** is $C_2$ because of a $\mu_4$-$SEt^-$ ligand capping onto the $Ln_4$ core. Although thiolates serving as a quadruply bridging ligand are found in several transition- or main group metal–thiolate clusters such as $[\{Ag_8(\mu_4\text{-}SC_2H_4\text{-}NH_3)_6Cl_6\}Cl_2]_n$,[17a] $[Cu_7\{\mu_4\text{-}SCH_2CH_2NH(CH_3)_2\}_6(\mu_3\text{-}Cl)_2(\mu\text{-}Cl)_{13}Cl_2]_n$,[17b] $[Cu_4(\mu\text{-}dppm)_4(\mu\text{-}NS_2)(\mu_4\text{-}NS_2)]\cdot CH_2Cl_2$[17c] and $[\{Tl_7(\mu_4\text{-}Sthff)_6\}_2(PF_6)_2]_n$ (HSthff = tetrahydrofurfuryl-thiol),[17d] the existence of a $\mu_4$-$SEt^-$ ligand in **5** and **6** is unprecedented in the chemistry of lanthanide chalcogenolate complexes.

Each Ln centre in **5** and **6** is coordinated by one N atom from the $[N(SiMe_3)_2]^-$ anion and one $\mu_4$-S atom and four μ-S atoms from the $EtS^-$ ligands to form a distorted octahedral coordination geometry. The mean Ln–$\mu_4$-S bond length, 3.089(3) Å for **5** and 3.029(3) Å for **6**, is much longer than the corresponding Ln–μ-S bonds, which correlates with the number of bonding interactions at the Ln centres.

The average Pr–μ-S bond length [2.877(3) Å] in **5** is the same as that in $Pr[S_2P(C_6H_{11})_2]_3$ [$S_2P(C_6H_{11})_2$ = dicyclohexyldithiophosphinate, 2.877(4) Å].[18] The mean Sm–μ-S bond length [2.822(4) Å] in **6** is comparable to those found in $[\{(Me_3Si)_2N\}_4(\mu_4\text{-Cl})Sm_4(\mu\text{-SPh})_4(\mu_3\text{-Cl})_4Li(thf)]$ [2.822(4) Å],[6a] $[(thf)Sm(SPh)_3]_{4n}$ [2.854(3) Å][19] and $[Sm\{O{=}P(NMe_2)_3\}(SPh)_3]$ [2.830(2) Å].[20] The mean Pr–N bond length [2.312(10) Å] in **5** is smaller than that reported in $Pr[Et_2NCH_2CH_2NC(Me)CHC(Me)NCH_2CH_2NEt_2]Cl_2$ [2.5702(3) Å],[21] whereas the length of the Sm–N bonds [2.279(12) Å] in **6** is between those of $[\{(Me_3Si)_2N\}_4(\mu_4\text{-Cl})Sm_4(\mu\text{-SPh})_4(\mu_3\text{-Cl})_4Li(thf)]$ [2.211(3) Å][6] and $[\{(Me_3Si)_2NSm(\mu\text{-Cl})_2Li(thf)_2\}(\mu\text{-Cl})]_2$ [2.284(4) Å].[22]

Weak coordination of a soft-base sulfur atom to a hard-acid Ln centre in lanthanide thiolate complexes is known to be the cause for their catalytic behaviour in the ROP of ε-caprolactone.[2j,6] Therefore, compounds **3**–**6** (Table 3) were employed to initiate the ROP of ε-caprolactone at ambient temperature. When the polymerization was performed in thf/toluene, a highly viscous product was observed to form in less than 10 min. After the resulting polymers were quenched by the addition of 1 M HCl in EtOH, the poly(ε-caprolactone)s were isolated as white solids and characterized by gel permeation chromatography. Compounds **3**–**6** were found to initiate the ROP of ε-caprolactone at room temperature to give relatively high molecular weight polymers ($M_n > 13400$) with narrow molecular weight distributions ($M_w/M_n$ = 1.17–1.56) in good yields within a few minutes. For comparison, Table 3 lists the results for the ROP of ε-caprolactone initiated by **1**–**6** along with two known $Pr^{III}$ and $Sm^{III}$ benzenethiolate complexes, $[\{(Me_3Si)_2N\}_4(\mu_4\text{-Cl})Sm_4(\mu\text{-SPh})_4(\mu_3\text{-Cl})_4Li(thf)]$ (**7**) and $[\{(Me_3Si)_2N\}_2$-

[a] Temperature: 298 K; solvent: thf/toluene (1:4); $V_{\varepsilon\text{-caprolactone}}:V_{solvent}$ = 1:5. [b] Yield: weight of polymer obtained/weight of monomer used. [c] Determined by GPC analysis in thf, calibrated to a polystyrene standard.

$(\mu\text{-SPh})Pr(\mu\text{-SPh})Li(thf)_2]_n$ (**8**).[6a] Complexes **3**–**6** showed better catalytic activity than their precursors, **1** and **2**, which may be ascribed to the weak Ln–S bonds in **3**–**6**.[2g,2i,6] In addition, complexes **5** and **6** showed even better catalytic activity than complexes **3** and **4** under the same reaction conditions, which might be due to the fact that **3** and **4** have a less open coordination environment around the Ln metal (coordination number four) than **5** and **6**. Complex **3** and its $Pr^{III}$/benzenethiolate complex **8** had similar catalytic activity for the ROP of ε-caprolactone. In the case of [monomer]/[cat.] = 600, **6** initiated the polymerization of ε-caprolactone at a faster rate than its benzenethiolate analogue **7**. The former reaction was complete in 9 min with a 100% yield whereas the latter was complete in 15 min with a 75% yield. Therefore, we tentatively ascribed this difference to the fact that the $SEt^-$ anions may be more easily dissociated from the $Ln^{III}$ centres in **6** than the $SPh^-$ and $Cl^-$ anions in **7**.

## Conclusions

In summary, the protonolysis reaction of **1** or **2** with an equimolar amount of *t*BuSH or EtSH was studied and amidolanthanide alkylthiolate complexes **3**–**6** were isolated in reasonable yields. Compounds **3**–**6** were characterized by elemental analysis, IR spectroscopy and X-ray analysis. Compounds **3** and **4** contain a $Ln_2S_2$ core structure whereas **5** and **6** consist of a square $Ln_4$ array with one $SEt^-$ ligand capping above the mean $Ln_4$ plane. Occurrence of a $\mu_4$-$SEt^-$ ligand in the structures of **5** and **6** is rare in the chemistry of lanthanide chalcogenolate complexes. Compounds **3**–**6** showed better catalytic activity in the ROP of ε-caprolactone than their precursors **1** and **2** and their benzenethiolate analogues. It is anticipated that **1** or **2** could react with other thiols such as 1,2-diethanedithiol or cationic thiol $TabHPF_6$ [TabH = 4-(trimethylammonio)benzenethiol] to afford other lanthanide thiolate complexes with more interesting structural frameworks and better catalytic activities in the ROP of ε-caprolactone. Studies on these respects are underway in this laboratory.

## Experimental Section

All manipulations were carried out under an atmosphere of argon by using standard Schlenk techniques. All solvents were heated at reflux and distilled from sodium benzophenone ketyl under an atmosphere of argon prior to use. $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(thf)_3$ (**1**: Ln = Pr; **2**: Ln = Sm),[7] $LnCl_3$[23] and $LiN(SiMe_3)_2$[24] were prepared according to literature methods. *t*BuSH and EtSH were obtained from commercial sources and used as received. ε-Caprolactone, purchased from ACROS Com, was dried by stirring with $CaH_2$ for 8 d and then distilled under reduced pressure. $^1H$ NMR spectra were recorded at ambient temperature with a Varian UNITYplus-400 spectrometer. $^1H$ NMR chemical shifts were referenced to the solvent signal in $C_6D_6$. Elemental analyses for C, H and N were performed with a Carlo-Erbo CHNO-S microanalyzer. The IR spectra were recorded with a Nicolet MagNa-IR550 FTIR spectrometer (4000–400 cm$^{-1}$). Molecular weight and molecular weight distributions were determined against a polystyrene standard by gel permeation chromatography (GPC) with a Waters 1515 apparatus with three HR columns (HR-1, HR-2 and HR-4); thf was used as an eluent.

**$[\{(Me_3Si)_2N\}_2Pr(\mu\text{-}S\mathit{t}Bu)]_2$ (3):** A solution of *t*BuSH (2.09 mmol) in thf (1.65 mL) was slowly added to a solution of **1** (1.31 g, 2.09 mmol) in thf (20 mL). The mixture was stirred at room temperature for 2 h, and then the solution was concentrated to dryness in vacuo. The resulting solid was extracted with *n*-hexane (10 mL) and toluene (20 mL) and then filtered. Compound **3**·$2(thf)_{0.5}$ (1.05 g, 43%) was isolated as light yellow crystals by cooling the filtrate to 2 °C for 3 d. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = –7.17 [br. s, $w_{1/2}$ = 40 Hz, 18 H, $C(CH_3)_3$], –10.92 [br. s, $w_{1/2}$ = 200 Hz, 72 H, $Si(CH_3)_3$] ppm. IR (KBr disc): $\tilde{\nu}$ = 2960 (s), 2902 (m), 1635 (m), 1385 (m), 1260 (s), 1189 (s), 1079 (m), 938 (s), 845 (s), 608 (w) cm$^{-1}$. $C_{36}H_{98}N_4Pr_2S_2OSi_8$ (1173.86): calcd. C 36.83, H 8.42, N, 4.77; found C 36.56, H 8.01, N 4.43.

**$[\{(Me_3Si)_2N\}_2Sm(\mu\text{-}S\mathit{t}Bu)]_2$ (4):** Compound **4** (0.78 g, 40%) was isolated as light yellow crystals from the reaction of **2** (1.12 g, 1.75 mmol) with *t*BuSH (1.75 mmol) in thf followed by a similar workup to that used in the isolation of **3**. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = –0.90 [br. s, $w_{1/2}$ = 32 Hz, 18 H, $C(CH_3)_3$], –2.00 [br. s, $w_{1/2}$ = 9 Hz, 72 H, $Si(CH_3)_3$] ppm. IR: $\tilde{\nu}$ = 2962 (s), 2903 (m), 1632 (m), 1385 (m), 1258 (s), 1185 (s), 1084 (m), 938 (s), 848 (s), 613 (w) cm$^{-1}$. $C_{32}H_{90}N_4S_2Si_8Sm_2$ (1120.66): calcd. C 37.89, H 8.42, N 4.42; found C 37.56, H 8.01, N 4.93.

**$[Li(thf)_4][\{(Me_3Si)_2N\}_4Pr_4(\mu_4\text{-}SEt)(\mu\text{-}SEt)_8]$ (5):** A solution of EtSH (1.85 mmol) in thf (0.88 mL) was added dropwise to a solution of **1** (1.12 g, 1.85 mmol) in thf (20 mL). After stirring at room temperature for 3 h, the volatile species were removed in vacuo, and the crude product was extracted with toluene (20 mL) and then filtered. The filtrate was kept at 2 °C for one week, which resulted in the formation of light yellow crystals of **5**·0.5$C_7H_8$ (0.440 g, 21%). $^1$H NMR (400 MHz, $C_6D_6$): $\delta$ = 3.25 (s, 32 H, thf), 1.27 (br. s, $w_{1/2}$ = 20 Hz, 27 H, $CH_3$), 0.71 (br. s, $w_{1/2}$ = 36 Hz, 18 H, $CH_2$), –1.45 [br. s, $w_{1/2}$ = 40 Hz, 72 H, $Si(CH_3)_3$] ppm. IR: $\tilde{\nu}$ = 2961 (s), 2901 (m), 2184 (w), 1658 (m), 1520 (s), 1475 (s), 1385 (s), 1256 (s), 1179 (s), 1048 (m), 992 (m), 949 (s), 841 (s), 756 (m), 604 (s) cm$^{-1}$. $C_{61.5}H_{153}LiN_4O_4Pr_4S_9Si_8$ (2088.66): calcd. C 35.23, H 7.36, N 2.67; found C 35.58, H 7.42, N 2.19.

**$[Li(thf)_4][\{(Me_3Si)_2N\}_4Sm_4(\mu_4\text{-}SEt)(\mu\text{-}SEt)_8]$ (6):** A solution of EtSH (2.02 mmol) in thf (0.96 mL) was added dropwise to a solution of **2** (1.29 g, 2.02 mmol) in thf (20 mL). After stirring at room temperature for 3 h, the volatile species were removed in vacuo, and the crude product was extracted with benzene (20 mL) and then filtered. The filtrate was kept at 2 °C for one week, which resulted in the formation of light yellow crystals of **6**·$C_6H_6$ (0.368 g, 17%). The $^1$H NMR spectrum in $C_6D_6$ showed broad uninterpretable signals. IR: $\tilde{\nu}$ = 2962 (s), 2905 (m), 2183 (w), 1655 (m), 1518 (s), 1482 (s), 1385 (s), 1248 (s), 1181 (s), 1053 (m), 995 (m), 937 (s), 841 (s), 753 (m), 610 (s) cm$^{-1}$. $C_{64}H_{155}LiN_4O_4S_9Si_8Sm_4$ (2158.59): calcd. C 36.61, H 6.86, N 2.60; found C 37.06, H 7.21, N 2.43.

**Crystal Structure Determination and Refinement:** All measurements were recorded with a Rigaku Mercury CCD X-ray diffractometer (3 kV, sealed tube) at 193 K by using graphite monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71070 Å) light. X-ray quality crystals of **3**·2(thf)$_{0.5}$, **4**, **5**·0.5$C_7H_8$ and **6**·$C_6H_6$ were obtained directly from the above preparations. A light yellow chunk of **3**·2(thf)$_{0.5}$ with dimensions 0.45 × 0.40 × 0.30 mm, a light yellow prism of **4** with dimensions 0.40 × 0.35 × 0.10 mm, a light yellow prism of **5**·0.5$C_7H_8$ with dimensions 0.22 × 0.47 × 0.30 mm and a light yellow prism of **6**·$C_6H_6$ with dimensions 0.14 × 0.50 × 0.30 mm were mounted in a sealed capillary, respectively. Diffraction data were collected with the $\omega$ mode with a detector distance of 35 mm to the crystals. A total of 720 oscillation images for each were collected in the range 6.04° < 2$\theta$ < 50.70° for **3**·2(thf)$_{0.5}$, 6.28° < 2$\theta$ < 50.70° for **4**, 6.10° < 2$\theta$ < 50.70° for **5**·0.5$C_7H_8$ and 6.18° < 2$\theta$ < 50.70° for **6**·$C_6H_6$. The collected data were reduced by using the program CrystalClear (Rigaku and MSC, ver. 1.3, 2001), and an absorption correction (multi-scan) was applied, which resulted in transmission factors ranging from 0.385 to 0.485 for **3**·2(thf)$_{0.5}$, from 0.406 to 0.799 for **4**, from 0.440 to 0.618 for **5**·0.5$C_7H_8$ and from 0.359 to 0.694 for **6**·$C_6H_6$. The reflection data were also corrected for Lorentz and polarization effects.

The structures of **3**·2(thf)$_{0.5}$, **4**, **5**·0.5$C_7H_8$, and **6**·$C_6H_6$ were solved by direct methods[25] and refined by full-matrix least-squares on $F^2$.[26] When crystals **3**·2(thf)$_{0.5}$ and **5**·0.5$C_7H_8$ were taken away from their mother liquors, rapid evaporation of part of the solvated molecules in these crystals was observed. Although we made numerous attempts, these crystals were always weakly diffracting, especially at high angles, which made the final R value relatively higher. In addition, in the structures of **3**·2(thf)$_{0.5}$, **5**·0.5$C_7H_8$ and **6**·$C_6H_6$, serious disorder problems derived from the solvated molecules and methyl groups from bis(trimethylsilyl)amide anions also contributed greatly to the high R value. Therefore, the thf and $C_7H_8$ molecules in **3**·2(thf)$_{0.5}$ and **5**·0.5$C_7H_8$ were fixed with constrained parameters and refined with an occupancy factor of 0.5. For **5**·0.5$C_7H_8$, three methyl groups bearing C(19), C(20) and C(21) atoms were found to be disordered over two positions with an occupancy ratio of 0.45:0.55 for C(19)/C(19A), C(20)/C(20A) and C(21)/C(21A). In the case of **6**·$C_6H_6$, a number of methyl groups were found to be disordered over two sites with an occupancy factor of 0.58:0.42 for C(12)/C(12A) and C(16)/C(16A) and 0.54:0.46 for C(19)/C(19A), C(25)/C(25A), C(28)/C(28A), C(31)/C(31A), C(34)/C(34A), C(35)/C(35A), C(36)/C(36A), C(38)/C(38A) and C(41)/C(41A). All non-hydrogen atoms, except for those from thf

solvent molecule in **3**·2(thf)$_{0.5}$, and those from $C_6H_6$ solvent molecule in **6**·$C_6H_6$, and those disordered C atoms in **5**·0.5$C_7H_8$, and part of disordered C atoms [C(12), C(16), C(19), C(25), C(28), C(31), C(38), C(41)] in **6**·$C_6H_6$ were refined anisotropically. Hydrogen atoms on C(43)–C(46) atoms in **5**·0.5$C_6H_5CH_3$ and C(43)–C(46) atoms in **6**·$C_6H_6$ were not located. All other hydrogen atoms were placed in geometrically idealized positions (C–H = 0.98 Å for methyl groups, C–H = 0.99 Å for methylene groups or C–H = 0.95 Å for phenyl groups) and constrained to ride on their parent atoms with $U_{iso}(H) = 1.2\ U_{eq}(C)$ or $1.5\ U_{eq}(C)$ for methyl groups. All the calculations were performed with a Dell workstation by using the CrystalStructure crystallographic software package (Rigaku and MSC, Ver.3.60, 2004). Crystal and data collection parameters for **3**·2(thf)$_{0.5}$, **4**, **5**·0.5$C_7H_8$ and **6**·$C_6H_6$ are summarized in Table 4.

CCDC-624794 (for **3**), -624795 (for **4**), -624796 (for **5**) and -624797 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via http://www.ccdc.cam.ac.uk/data_request/cif.

**A Typical Procedure for the ROP of ε-Caprolactone:** A 50-mL Schlenk flask equipped with a magnetic stir bar was charged with thf (0.33 mL), toluene (1.32 mL) and **5** (0.011 g). To this light yellow solution, ε-caprolactone (0.33 mL) was added at room temperature by using a syringe and with vigorous magnetic stirring. The stirring was ceased in a few minutes due to the viscosity. The reaction mixture was quenched by the addition of 1 M HCl in EtOH after a fixed interval. The solution was then poured into petroleum ether (20 mL) to precipitate the white oligomer. The resulting oligomer was washed with methanol three times, collected and dried in vacuo.

# Order and Disorder in Cluster Phases – The Case of $La_{\approx 0.7}(Al_{\approx 0.1}I_{\approx 0.9})$

**Lorenz Kienle,*[a] Oliver Oeckler,[b] Thomas Weber,[c] Viola Duppel,[a] Hansjürgen Mattausch,[a] and Arndt Simon[a]**

**Keywords:** Electron microscopy / X-ray diffraction / Rare earth metal compounds / Clusters / Halides / Disorder

The structure of the new partially ordered cluster phase $La_{0.69(1)}(Al_{0.12(1)}I_{0.88(1)})$ was determined by a combined methodical approach of electron microscopy techniques and X-ray diffraction. The structure is derived from the $Gd_3CCl_3$-type and ca. 50 % of the cluster positions in this structure type are occupied. The majority of the clusters are condensed via common edges, however, the degree of cluster condensation is low. The arrangement of neighboring clusters is comparable to chemically related, but strongly disordered cluster phases.

## Introduction

Many low-valent compounds of rare earth metals (Ln) are composed of discrete or condensed clusters[1] of the $Ln_6ZX_{12}$-type (X = Cl, Br, I). Endohedral species Z (Z = B, C, $C_2$, etc.) centering the octahedral $Ln_6$ core stabilize the valence electron-poor clusters.[2] Most phases with isolated or condensed $Ln_6ZX_{12}$-type clusters show a topological relationship with the NaCl-type structure thus following the general remark that rocksalt is everywhere.[3] The Z atoms replace a fraction of the X atoms on the anion positions, whereas Ln atoms and voids are located on the cation positions, and all Z atoms are surrounded by six Ln neighbors. The ratio Ln/Z determines the degree of cluster condensation with the maximum value of 6 for phases with discrete $Ln_6ZX_{12}$ clusters as in $Zr_6CI_{12}$[4] and decreased ratios for the condensed cluster phases, e.g. Ln/Z = 5 for $La_{10}(C_2)_2I_{18}$[5] containing double octahedra. As a rule, neighboring $Ln_6$ octahedra are connected via edges both in ordered and disordered phases. Well-documented examples for the first are the triple $Ln_{14}$ octahedra in $Ln_{14}(C_2)_3I_{20}$ (Ln = La, Ce; Ln/Z = 4.67)[6] and the linear chain of octahedra found in $Sc_4CCl_6$ (Ln/Z = 4).[7] Examples for the latter are $Ln_{13}B_3Br_{18}$ (Ln = Gd, Tb)[8] and $Ce_{29}Al_{14}I_{28}$[9] where discrete $Ln_{10}$ double octahedra are ordered in layers which, however, exhibit stacking disorder. The disordered intergrowth phases $Ln_{4n+2}(C_2)_nI_{5n+5}$[10] contain layers of linear oligomers with distinct numbers (*n*) of condensed octahedra.

Recently, we analyzed the connectivity of clusters in the highly disordered phase $La_{0.70}(Al_{0.14}I_{0.86})$ (**1**)[11] with average NaCl-type structure. Here, we report on $La_{0.70}(Al_{0.12}I_{0.88})$ (**2**) which is the first partially ordered cluster phase occurring in the system La–Al–I. In the context of the following, the structure of $Gd_3CCl_3$[12] is of particular importance ($Ca_3PI_3$-type,[13] $I4_132$). Each octahedron of the latter is connected to three neighboring ones; see Figure 1, producing a characteristic quadratic or hexagonal pattern of clusters in projections along <100> and

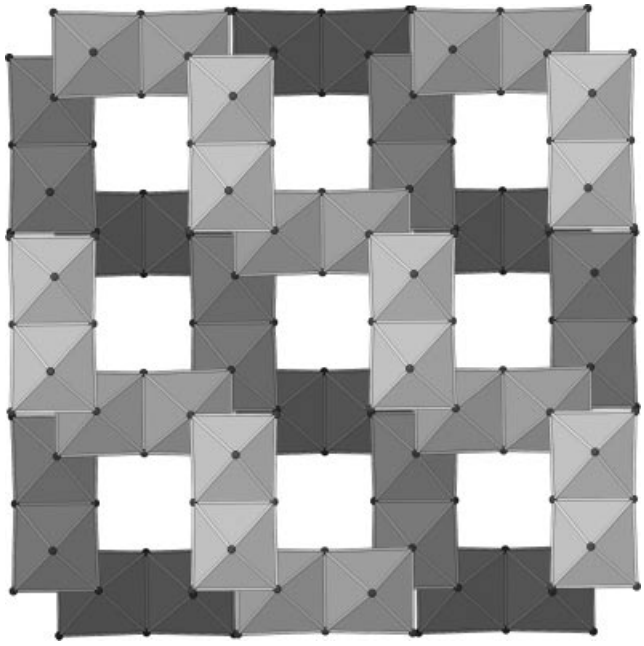

Figure 1. $CGd_6$ clusters in the structure of $Gd_3CCl_3$ along <100>, Cl atoms are omitted.

<111>, respectively. All known representatives of this structure type, including distorted ones,[14] are fully ordered.

## Results and Discussion

Despite the highly disordered real structure, neighboring clusters in **1** are far from a random arrangement. A structure refinement based on the intensity of the diffuse X-ray scattering had allowed the evaluation of relative cluster positions, indicating the presence of edge-condensed $La_6$ octahedra as expected from the ratio Ln/Z = 5, however, only as a small fraction. Crystals of **1** exhibit halo-shaped diffuse scattering around the Bragg reflections of electron and X-ray diffraction patterns. The new variant, **2** shows a segregation of the diffuse scattering into superstructure reflections indicating partial long-range ordering. The different degrees of structural disorder in **1** and **2** are exemplified by the SAED (selected area electron diffraction) patterns and electron micrographs of Figure 2. Both crystals were aligned along zone axis <111>, referring to the common NaCl-type subcell. The high resolution image for **1** (Figure 2, a) shows a strongly disordered, but non-random arrangement of dark and bright spots. The interpretation by simulated micrographs is based on the structural model derived from the diffuse X-ray scattering.[11] For $\Delta f \approx -70$ nm, low values of the projected potential produce dark spots, corresponding to the preferred cluster arrangement which leads to a superposition of Al atoms and voids along <111>, and bright spots represent high values of the projected potential resulting from <111> rows of La and I atoms. Following this analysis, **1** is characterized by pronounced correlations of the cluster positions. The interrelation of projected potential and image contrast is straightforward for all defocus values not only for Scherzer focus. The preferred cluster arrangement of **1** is imaged in the form of dark spots each surrounded by a hexagon of bright spots. Such hexagons can be seen in Figure 2 (a) bottom (see marks), however, they do not produce a periodic pattern due to the lack of perfect long range order in **1**. This contrasts the partially ordered crystallites of **2**, where ordering of the hexagons in {111} is observed, see Figure 2 (b) bottom. At the first glance, the HRTEM image seems to be entirely periodic, however, significant variations of the spot intensities are evident which disrupt the periodicity. In some cases, the partial order can also be demonstrated by faint diffuse intensities in Fourier transforms of HRTEM micrographs as seen in the electron-diffraction patterns (see Figure 2, b, top). SAED as well as corresponding zero layer X-ray patterns, like those along <100>, exhibit hardly any diffuse scattering. However, this observation does not unambiguously indicate long-range order of the 3D real structure, but a low significance of the disorder in the respective projection. A tilt from the precise zone axis orientation enables one to observe the diffuse intensity, and the existence of disorder becomes evident.

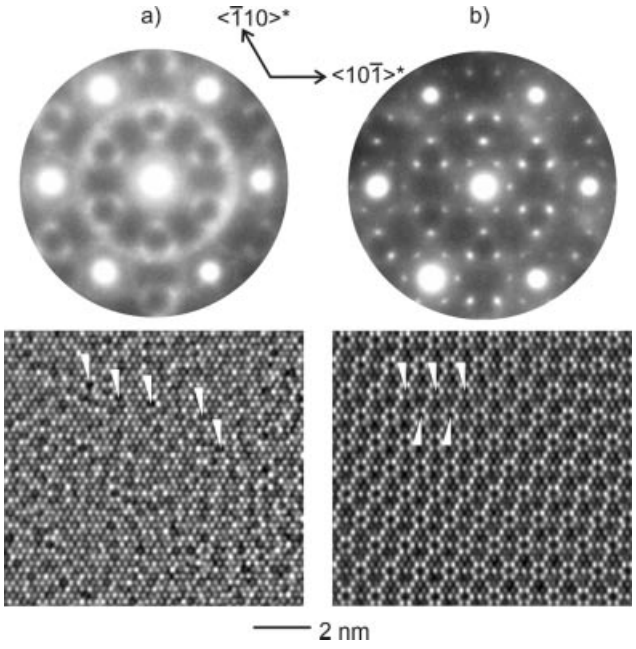

Figure 2. SAED pattern and HRTEM micrograph ($\Delta f \approx -70$ nm) for zone axis <111> recorded on a crystal of **1** (a), and **2** (b).

Such findings were the starting points for an interpretation of HRTEM micrographs and the corresponding SAED patterns of **2** in terms of the 3D structure, and they also entered the X-ray structure analysis. Two important aspects, the chemical composition and an average model need to be taken into account in order to derive a 3D structure of **2** before the real structure can be analyzed in detail. In order to elaborate the specific benefits, the information obtained by both approaches will be asserted separately first and then combined in the conclusion.

### Chemical Composition of 2

The chemical composition of **2** was determined by combining SAED and EDX. Both techniques allow nanoprobing and identification, whereas chemical analyses of probably inhomogeneous bulk samples are likely to fail due to averaging. The experimentally determined composition of $La_3I_3Al_2$,[15] taken as the standard, indicates only marginal correction factors as the average of 10 point measurements on 10 crystallites gave La 42.9(1.9) atom-%, Al 28.7(1.4) atom-% and I 28.4(1.0) atom-% (calculated values: 43.0 atom-%, 28.5 atom-%, 28.5 atom-%). For **2** we determined La 41.2(2.6) atom-%, Al 7.1(0.5) atom-% and I 51.7(2.9) atom-% (average of 7 point measurements on 7 crystallites), resulting in a composition $La_{0.70(4)}(Al_{0.12(1)}I_{0.88(5)})$. Point measurements on different regions of the same crystallite lead to variations of the composition within standard deviations.

### Symmetry of 2

X-ray measurements on single crystals of **2** yield an average unit cell with cubic metrics. A small amount of dif-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fuse scattering is present. The lattice parameter $a$ = 12.689(1) Å corresponds to a $2a2b2c$ supercell of the NaCl-type structure. This supercell has the Laue symmetry $m\bar{3}m$ and is body-centered. Reflections $h00$ are observed only for $h = 4n$, so the resulting space group is $I4_132$. As even small homogeneous selected areas of the crystallites yield tilting series of SAED patterns consistent with this symmetry, it is clear that the high symmetry is not due to twinning by (pseudo)-merohedry or reticular pseudo-merohedry (e.g. tetragonal with $c' = 2a$). Neither electron nor X-ray diffraction gave any indication of an even larger or not body-centered cell of **2**. Furthermore, the plane symmetry of electron micrographs ($p4mm$ for <100>, $p3m1$ for <111>, $p2mm$ for <110>, cf. Figure 5) in combination with the body-centered lattice is only allowed for the space groups $I432$ and $I4_132$.

### Structure Refinement from X-ray Data

For the structure refinement on the basis of X-ray data, diffuse scattering was not taken into account. As both the unit cell parameters and the space group $I4_132$ correspond to the $Gd_3CCl_3$ type,[12] initial refinements were started from an isotypic and hypothetical $La_3I_3Al$, although the chemical analysis contradicts this composition. The resulting $R$ value ($R_1$ = 0.21) was not convincing and the small displacement parameter of Al called for a mixed occupancy of this site by Al and I which was refined to an approximate ratio of 1. Hence, the structure contains only half the amount of $La_6Al$ units as compared to "$La_3I_3Al$". This does not necessarily lead to a lower La content, because all La atoms in the latter structure type belong to two $La_6$ octahedra. However, refining the occupancy of the La position yields a value of 87%. The model so far is only an approximation as residual electron density is found in the unoccupied octahedral voids of the $Gd_3CCl_3$ type, corresponding to ca. 15% occupancy with La. This means that a few cluster centers do not coincide with positions of the $Gd_3CCl_3$-type. Thus, the structure of **2** can be described as an approximately 50% thinned out variant of this structure type with many shared edges remaining and a few alternative cluster positions occupied. The $R$ values (e.g. $R_1$ = 0.044) for this structure model are satisfactory, in particular as the reflections to parameters ratio is 26 in spite of some disorder. The refinement in $Im\bar{3}m$ yields about the same $R$ values, however, the degree of disorder is higher and no centrosymmetric structure model can explain the $p3m1$ symmetry of electron micrographs for the <111> zone axis, where one would expect a $p6mm$ symmetry which is clearly absent, cf. Figure 5. For $I432$ which is consistent with the symmetry observed in HRTEM but not with all systematic absences, refinements yield a higher degree of disorder, too. Thus, the structure model derived from "$La_3I_3Al$" gives the best fit of the data with the highest degree of ordering. Based on the model assumptions, this refinement yields the chemical composition $La_{0.69}(I_{0.88}Al_{0.12})$ for **2** in good agreement with chemical analyses. Details are presented in Table 1, atomic parameters in Table 2.

Table 1. Crystal data of **2**.

| Formula | $La_{0.69(1)}(Al_{0.12(1)}I_{0.88(1)})$ |
|---|---|
| Formula weight | 210.75 [g mol$^{-1}$] |
| Crystal system | cubic |

### Structure Information from Electron Microscopy

In an independent approach, the combination of HRTEM and SAED served to derive structure models and to analyze structural defects of **2**. Particularly for the <111> zone axes, the HRTEM micrographs indicate a separation into high and low values of the projected potential, see text above as well as Figure 3, consistent with a disordered arrangement of clusters in a thinned out $Gd_3CCl_3$-type structure. The triangles highlight regions with high and low cluster concentration, and the corresponding triangles

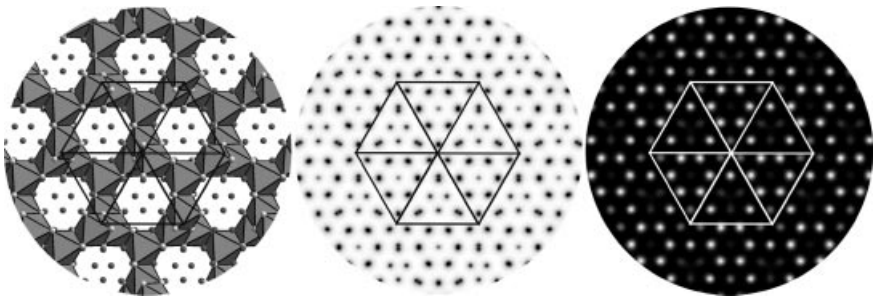

Figure 3. Correlation between projected potential based on the structure model of **2** (see text) and simulated micrograph for <111> ($\Delta f$ = –70 nm, $t$ = 3.5 nm). From left to right: projection of the structure model, projected potential, simulated micrograph. The triangles highlight regions with high and low cluster concentration.

in the projected potential and in the simulated micrograph give evidence for the experimental significance of such distribution.

In order to check the spatial 3D distribution of the clusters, all fundamental zone axes were investigated in an extended study. Neglecting faint diffuse intensities, experimental and calculated SAED patterns display a convincing agreement for different crystallites (see Figure 4). In addition tilting experiments performed on the same crystallite support the proposed model. As shown by simulations, aggregates of clusters could be identified by SAED and HRTEM; however, the lack of such correlations corresponds to the observed marginal diffuse intensity. Hypothetical structure models of a thinned out and ordered $Gd_3CCl_3$-type structure were also taken into account. Based on group-subgroup relations several ordering variants are possible, like a hypothetical phase $La_5AlI_7$ which would contain discrete clusters with edge-sharing double octahedral units. However, such orderings were never observed, even not in nanosized domains.

HRTEM gave additional evidence for the structure of **2**, as demonstrated by the simulated and experimental micrographs of Figure 5. However, a perfect match with simulations is impossible as the averaging is never complete for the transmittable regions of the crystallites. Of course, in very thin regions of the crystallites even an overall disordered distribution of clusters should separate into discernible aggregates. However, in the case of the extremely air-sensitive **2** those regions are already the subject of hydrolysis.

The real structure of **2** is further complicated by the presence of different domains. Firstly, **2** exhibits merohedrally twinned domains and antiphase boundaries, see relative positions of the high- and low intensity spots within the triangles of Figure 6. As the intensity of the spots correlates with the cluster concentration (cf. Figure 3 and Figure 5, bottom), domains with an inverted and shifted (bottom region of Figure 6) and a merely shifted arrangement of the clusters (top region of Figure 6) coexist. The diffraction patterns as well as Fourier transforms of HRTEM micrographs show a complete overlap of the reciprocal lattices for the different domains. Space-averaging of the cluster positions in different domains smaller than the X-ray coherence length could easily explain the detection of clusters on non-cluster positions of the thinned out $Gd_3CCl_3$-type as determined by XRD.

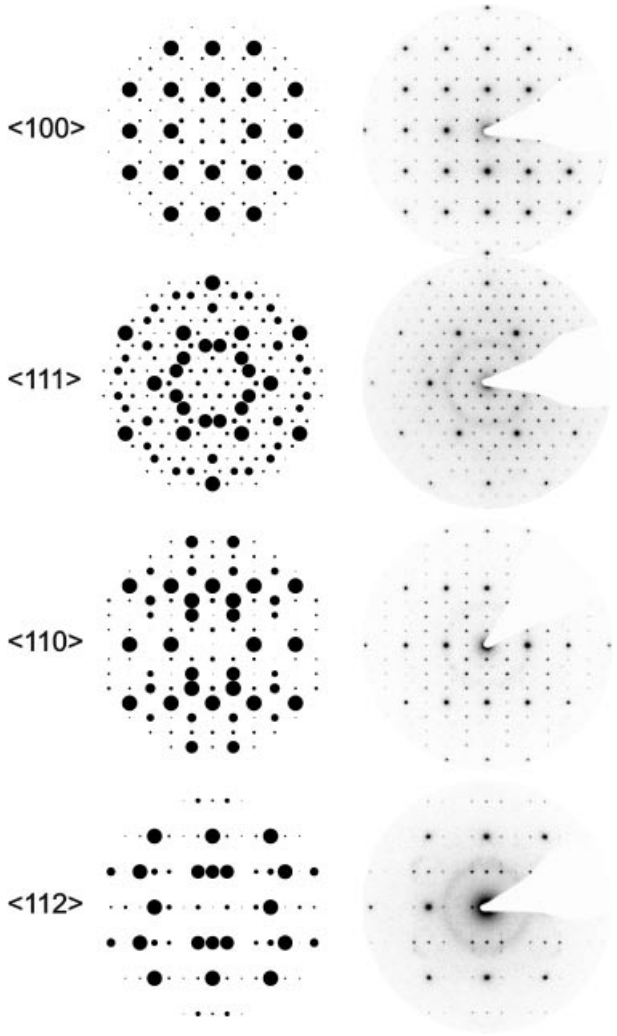

Figure 4. Calculated (left column) and experimental (right column) SAED patterns, zone axes are specified.

Secondly and more rarely, domains of **2** coexist with the domains of a byproduct. The intergrowth can easily by identified by sequentially recorded SAED patterns or the

corresponding superposition patterns, see Figure 7 (a). So far, the composition of the byproduct could not be analyzed reliably by EDX due to shading effects. The *d*-values and intensity distribution of the SAED patterns of the byproduct suggest a phase $La_{7+x}AlI_{12}$ related to $Sc_7CI_{12}$.[16] Furthermore, some crystallites of the byproduct exhibit the characteristic twinning frequently observed for phases $Ln_{7+x}ZX_{12}$, see superposition pattern in Figure 7 (b). In addition, an intergrowth of this phase and strongly disordered **1** occurs as demonstrated by the characteristic diffuse scattering in the SAED superposition pattern of Figure 7 (c). Hence, the byproduct forms intergrowth phases with both, the chemically related **1** and **2**.

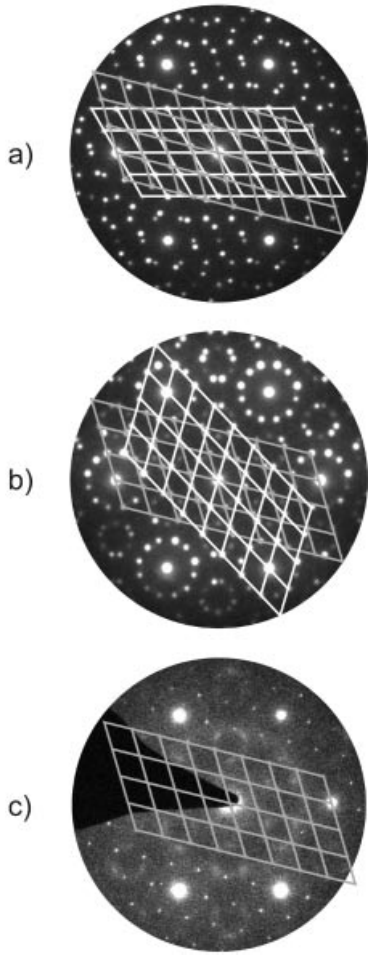

Figure 7. Distinct types of superposition patterns with the common zone axis <111> of **2**. a) Chemical intergrowth of **2** and the byproduct, b) twinning of the byproduct, c) intergrowth of the byproduct and **1**. The grey grids mark the unit cell of the byproduct.

## Conclusions

Conventional electron microscopy techniques allow the simultaneous determination of structure and composition of crystals on the nanoscale, however, they do not provide the precise localization of atoms as X-ray diffraction techniques do. Hence, a combined approach is of great value. The structural model for $La_{0.69(1)}(Al_{0.12(1)}I_{0.88(1)})$ determined from electron microscopy was used as the input for an accurate X-ray structure refinement. As X-ray data are

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

greatly influenced by averaging effects peculiarities of the refined model were then addressed and explained by local investigations in the electron microscope. The strongly disordered phase **1** and the partially ordered phase **2** are close in composition. As expected, they share certain structural properties, however, there are also distinctly different features. Both, the structures of **1** and **2** contain $La_6AlI_{12}$ clusters which are interconnected via I atoms in a rather defined way in spite of the disorder. **1** is arrived at by a systematic cation (La) depletion of a NaCl-type structure leaving the majority of $La_6$ units in an as far as possible distance from each other. One way of an ordered depletion follows the group-subgroup relation:

$Fm\bar{3}m$ ("Na": *4a*, "Cl": *4b*) $\xrightarrow{t2}$ $F432$ $\xrightarrow{k4}$ $P4_232$ $\xrightarrow{k4,\ a' = 2a}$ $I4_132$ (either La: *24h*, X: *24g*, □: *8a*, Z: *8b*, or La: *24g*, X: *24h*, □: *8b*, Z: *8a*) ending in the $Gd_3CCl_3$-type structure where close contacts between the metal atoms through edge-sharing of the $Ln_6$ units are still preserved. In the structure of **2**, this characteristic feature stays when the $Gd_3CCl_3$-type structure is further thinned out. Hence, the step from **1** via **2** to a $Gd_3CCl_3$-type structure marks a pathway from a discrete to a condensed cluster phase. As we were not able to change **1** into **2** by extended annealing, it still has to be elucidated which experimental parameters (composition, reaction temperature, etc.) lead along this pathway.

## Experimental Section

**Synthesis:** Powder samples of **2** were prepared by reaction of 500 mg $LaI_3$, 235 mg $AlI_3$ and 327 mg La (molar ratio La/Al/I = 18:3:24), pressed to pellets and heated 7 d at 870 °C in closed Ta-capsules.[17] After that the samples were ground and again heated at 900 °C for 8 d. From this batch the crystals were selected for X-ray and HRTEM investigations. All handlings were performed under inert (Ar) gas atmosphere.[18]

**X-ray Crystallography:** Powder diffractograms were recorded by modified Guinier technique[19] on fine powders sealed in glass capillaries (Cu-$K_{\alpha 1}$, Si as internal standard, Fuji™ film BAS-5000 image plate system). The lattice parameter of the NaCl-type subcell of **2** was determined to $a = 6.326(1)$ Å. Single-crystal X-ray data were collected on a STOE IPDS diffractometer (Mo-$K_\alpha$ radiation). The program package X-Area 1.18 (Stoe, Darmstadt, 2002) was used for data evaluation, SHELX97 was used for structure solution and refinement.[20] Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (Fax: +49-7247-808-666; E-mail: crysdata@fiz-karlsruhe.de) on quoting the depository number CSD-417290.

**Electron Microscopy and Chemical Analysis:** HRTEM and SAED were performed with a Philips CM30ST microscope (300 kV, $LaB_6$ cathode, $C_S = 1.15$ mm). All manipulations for the preparation and transfer of the sample were carried out under dry argon by applying Schlenk techniques.[21] A perforated carbon/copper net served as support of the crystallites. Simulations of HRTEM images (multislice formalism) and of SAED patterns (kinematical approximation) were calculated with the EMS program package[22] (spread of defocus: 70 Å, illumination semiangle: 1.2 mrad). All images were recorded with a Gatan Multiscan CCD camera and evaluated (including Fourier filtering) with the program Digital Micrograph 3.6.1 (Gatan). Chemical analyses by EDX were performed in the nanoprobe and in the scanning mode of CM30ST with a Si/Li detector (Noran, Vantage System).

# Tungsten(VI) and Molybdenum(VI) Complexes with Soft Thioether Ligand Coordination – Synthesis, Spectroscopic and Structural Studies

**Martin F. Davis,[a] William Levason,[a] Mark E. Light,[a] Raju Ratnani,[b] Gillian Reid,*[a] Keerti Saraswat,[b] and Michael Webster[a]**

**Keywords:** Tungsten / Thioether / Molybdenum

Reaction of $WX_6$ (X = Cl or Br) with $O(SiMe_3)_2$ in $CH_2Cl_2$, followed by addition of MeCN and a further equivalent of $O(SiMe_3)_2$ in $CH_2Cl_2$ gives $[WO_2X_2(MeCN)_2]$ in situ, which subsequently react with the dithioethers $MeS(CH_2)_2SMe$, $iPrS(CH_2)_2SiPr$ or 1,4-dithiane to afford the first series of $W^{VI}$ thioether complexes, $[WO_2X_2(dithioether)]$. The very moisture-sensitive yellow complexes have been characterised by microanalysis, IR, $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy, which indicate *cis*-dioxido and *trans*-dihalide arrangements in the monomers with two thioether donor atoms completing the very distorted octahedral geometry (confirmed by a crystal structure of $[WO_2Cl_2\{iPrS(CH_2)_2SiPr\}]$). The strongly polymerised $WO_2X_2$ compounds themselves are not useful synthons for the preparation of the $W^{VI}$ thioether complexes and substitution of the dimethoxyethane ligand in $[WO_2Cl_2\{MeO(CH_2)_2OMe\}]$ by dithioethers is also incomplete. Molybdenum(VI) dioxidodichloride thioether complexes of the form $[MoO_2Cl_2(L)]$ (L = $iPrS(CH_2)_2SiPr$, 1,4-dithiane, $\kappa^2$-[15]ane$S_2O_3$, $\kappa^2$-[14]ane$S_4$ and $\kappa^2$-[12]ane$S_4$) ([15]ane$S_2O_3$ = 1,4-dithia-7,10,13-trioxacyclopentadecane, [14]ane$S_4$ = 1,4,8,11-tetrathiacyclotetradecane, [12]ane$S_4$ = 1,4,7,10-tetrathiacyclododecane) and the unusual dinuclear $[Mo_2O_4Cl_4\{o\text{-}C_6H_4(CH_2SMe)_2\}_2]$ are obtained by direct treatment of $MoO_2Cl_2$ with the appropriate ligand. The $[Mo_2O_4Cl_4\{o\text{-}C_6H_4(CH_2SMe)_2\}_2]$ adopts an unexpected metallocyclic structure with *cis*-$MoCl_2$ units and bridging bidentate dithioether (confirmed crystallographically). The structure of a new polymorph of $[WO_2Cl_2\{MeO(CH_2)_2OMe\}]$ is also described.

## Introduction

While thioether coordination chemistry is dominated by complexes involving late transition metals in medium oxidation states, we and others have shown that under appropriate experimental conditions these soft and modest σ-donor ligands can also form complexes with hard, medium and high oxidation state early transition metal ions,[1] including for example $Sc^{III}$,[2] $La^{III}$ and $U^{III}$ [3] complexes with the trithioether macrocycle [9]ane$S_3$, and $Ti^{IV}$, $Zr^{IV}$, $Hf^{IV}$, $V^{III,IV}$ and $Cr^{III}$ complexes with both acyclic and macrocyclic thioethers.[4–7] We have also established that the choice of chalcogenoether ligand architecture plays a very important role in facilitating the stabilisation of these hard/soft metal/ligand combinations, with dimethylene-linkages between the S atoms leading to increased stability, and macrocyclic frameworks further stabilising the complexes. Further, we have shown that reaction of $Ti^{IV}$, $Cr^{III}$ and $V^{III}$ precursors with mixed thia-oxa macrocyclic ligands involving $C_2$-linkages between adjacent heteroatoms results in preferential coordination via the softer S-donor groups – an observation we have attributed to destabilisation of the M–O(ether) coordination due to ring strain in the five-membered chelate rings.[8,9]

The coordination chemistry of molybdenum and tungsten continues to attract considerable interest owing to the roles that these elements play in biologically important species, the molybdo- and tungsto-enzymes,[10] and also due to the use of high oxidation state Mo and W species in ring-opening metathesis catalysis.[11] The chemistry of medium and high oxidation state Mo centres with neutral sulfur donor ligands remains little studied, with some examples of $Mo^{III,IV,V}$ thioether complexes.[12–19] In 2004 we reported the preparations and spectroscopic characterisation of the first examples of $Mo^{VI}$ complexes involving thioether and selenoether coordination, including crystal structure determinations of representative examples of the form $[MoO_2X_2\{RS(CH_2)_2SR\}]$ (X = Cl or Br; R = Me or Et) which confirmed *cis*-oxido ligands, *trans*-halides and bidentate chelating dithioether.[20] We found that these species form only for a very limited range of dichalcogenoether ligands – $Me_2S$, $MeS(CH_2)_3SMe$, MeSCH=CHSMe and even the $PhS(CH_2)_2SPh$ all lead to reduction of the metal and give no evidence for $Mo^{VI}$ thioether complexes. Medium and high oxidation state tungsten thioether complexes

are even less explored than with molybdenum and, whereas direct reaction of $MoO_2X_2$ with the $RS(CH_2)_2SR$ (R = alkyl) in $CH_2Cl_2$ gives the requisite complexes, $WO_2X_2$ (X = Cl or Br) do not provide viable entries to this chemistry because they are unreactive and strongly polymerised.[21] We were interested in trying to extend the range of thioether and selenoether complexes of the hard, oxophilic $Mo^{VI}$ ion, to understand how the ligand donor properties and architecture influence the stability of the complexes, and also in developing synthetic routes to $W^{VI}$ analogues.

In order to investigate the chemistry of dioxidotungsten(VI) with thioether ligands and to widen the presently very limited range of thioether ligand types capable of coordinating to dioxidomolybdenum(VI), we report here the results of our studies on the preparations and properties of the first series of $W^{VI}$ dihalidedioxido complexes involving dithioether ligands and several new $Mo^{VI}$ dihalidedioxido complexes incorporating a range of ligand architectures and both thioether and mixed thia/oxa-macrocyclic ligands. The crystal structures of $[Mo_2O_4Cl_4\{o\text{-}C_6H_4(CH_2SMe)_2\}_2]$, $[WO_2Cl_2\{i\text{PrS}(CH_2)_2S i\text{Pr}\}]$ and a new polymorph of $[WO_2Cl_2\{MeO(CH_2)_2OMe\}]$ are reported and discussed.

## Results and Discussion

### Tungsten Thioether Complexes

Development of a synthetic route to give $W^{VI}$ complexes in respectable yields is much more difficult than for $Mo^{VI}$. The strongly polymerised nature of $WO_2Cl_2$[21] means that this is usually not a useful synthon for coordination complexes of $WO_2Cl_2$, hence alternative precursor compounds were sought. We have shown very recently that $WCl_6$ or $WBr_6$ react with two mol. equivs. of $O(SiMe_3)_2$ in $CH_2Cl_2$, followed by addition of two mol. equivs. of $OPR_3$ (R = Pr or Me) or one molar equivalent of $Ph_2P(O)(CH_2)_nP(O)Ph_2$ ($n$ = 1 or 2) or $o\text{-}C_6H_4(P(O)Ph_2)_2$, to give the distorted octahedral $[WO_2X_2(OPR_3)_2]$, $[WO_2X_2\{Ph_2P(O)(CH_2)_nP(O)Ph_2\}]$ or $[WO_2X_2\{o\text{-}C_6H_4(P(O)Ph_2)_2\}]$ respectively in good yields.[22] However, using this approach with $MeS(CH_2)_2SMe$ in place of the $OPR_3$ ligand gave mostly insoluble, polymeric $WO_2Cl_2$ (IR evidence) with only very weak bands in the IR spectrum corresponding to $[WO_2Cl_2(\text{dithioether})]$. We conclude from this that soft thioether ligands have less affinity for the hard $W^{VI}$ and are more dissociated in solution than the phosphane oxide complexes of $W^{VI}$, hence while the phosphane oxide "traps" the $WO_2Cl_2$ as a molecular complex, in the thioether ligand systems $(WO_2Cl_2)_n$ precipitates from the solution, removing it from the reaction.

Schulzke et al. have described the preparation of the only known thioether adduct of $W^{VI}$, $[WO_2Cl_2\{MeS(CH_2)_2SMe\}]$ by a closely related route, involving reaction of $WOCl_4$ with one molar equivalent of $O(SiMe_3)_2$ in $CH_2Cl_2$ solution, followed by addition of the dithioether. While the crystal structure of the distorted octahedral species was reported, no solution spectroscopic data were presented.[23] We have also investigated this reaction and in our hands it reproducibly leads to formation of a white solid which was very poorly soluble. While weak ν(W=O) and ν(W-Cl) bands consistent with the literature data were evident in the IR spectra of these products, strong, broad absorptions around 600–700 $cm^{-1}$ were also evident, which are indicative of polymeric $WO_2Cl_2$. The $^1H$ NMR spectra of the $CDCl_3$ soluble component of our reaction products from repeated attempts at this reaction consistently showed significant amounts of uncoordinated dithioether, and only very minor resonances for $[WO_2Cl_2\{MeS(CH_2)_2SMe\}]$ (ca. 10–15% by integration). Using $i\text{PrS}(CH_2)_2S i\text{Pr}$ gave similar results, although we were able to grow light yellow crystals of $[WO_2Cl_2\{i\text{PrS}(CH_2)_2S i\text{Pr}\}]$ by filtering the reaction mixture and cooling a $CH_2Cl_2$ solution of the complex in the freezer, however the yield based on tungsten was still very low. The crystal structure confirms the formation of the distorted octahedral $[WO_2Cl_2\{i\text{PrS}(CH_2)_2S i\text{Pr}\}]$ (Figure 1, Table 1) in which the W atom is bound to *cis*-oxido groups, *trans*-Cl ligands and the two S donor atoms of a chelating dithioether. An alternative description of the core geometry would be a distorted tetrahedral primary $O_2Cl_2$ coordination with additional weak $S_2$ coordination completing a very distorted six-coordination. The W–S bond lengths are 2.759(2) and 2.768(2) Å and compare with $d$(W–S) = 2.748 and 2.752 Å in $[WO_2Cl_2\{MeS(CH_2)_2SMe\}]$.[23] The complex adopts a DL configuration with the isopropyl substituents lying on opposite sides of the $WO_2S_2$ plane. The S–W–S chelate bite angle is 77.34(5)°, very similar to that in $[WO_2Cl_2\{MeS(CH_2)_2SMe\}]$ (77.4°) and $[MoO_2Cl_2\{RS(CH_2)_2SR\}]$; R = Me: 77.29(3)°; R = Et: 78.01(2)°.[20]

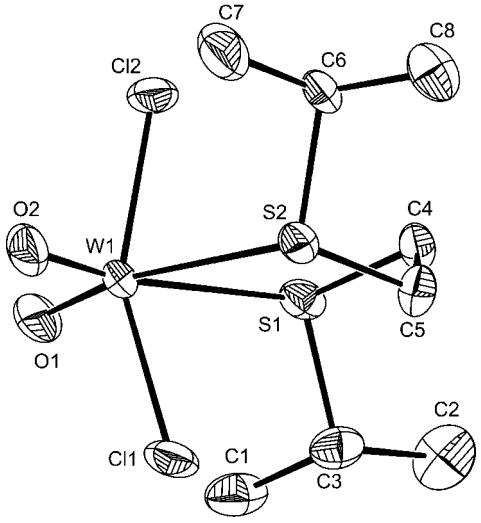

Figure 1. View of the structure of the $[WO_2Cl_2\{i\text{PrS}(CH_2)_2S i\text{Pr}\}]$ with numbering scheme adopted. Ellipsoids are drawn at 50% probability level and H atoms are omitted for clarity.

Small pale yellow crystals of the $Mo^{VI}$ analogue (below), $[MoO_2Cl_2\{i\text{PrS}(CH_2)_2S i\text{Pr}\}]$, were also obtained from $CH_2Cl_2$ solution. The structure determination shows that this compound is isostructural with the tungsten species ($C_8H_{18}Cl_2MoO_2S_2$, $MW$ = 377.18, $a$ = 11.838(2), $b$ = 13.034(2), $c$ = 18.951(3) Å, $\alpha = \beta = \gamma = 90°$, $V$ =

2924.3(8) Å$^3$, $Z$ = 8), although the crystal quality was poorer, giving rather high $R_1$ and $wR_2$ values ($R_1$ [$I_o > 2\sigma(I_o)$] = 0.0921, $wR_2$ [$I_o > 2\sigma(I_o)$] = 0.1814), with $d$(Mo–S) = 2.764(3), 2.783(4), $d$(Mo–O) = 1.673(12), 1.705(11), $d$(Mo–Cl) = 2.341(4), 2.345(4) Å and S1–Mo–S2 = 77.31(9)°.

The very poor yields from these tungsten reactions prompted further efforts to avoid formation of the insoluble by-products. We explored using the soluble and well-defined $[WO_2Cl_2\{MeO(CH_2)_2OMe\}]$,[24] however addition of the dithioether to a $CH_2Cl_2$ solution of this compound resulted in incomplete substitution of the dimethoxyethane, while treatment of $[WOCl_4]$ with one molar equivalent of $O(SiMe_3)_2$ in refluxing octane solution, followed by addition of dithioether gave light yellow insoluble, polymeric products with no evidence for thioether coordination. One route to $[WO_2X_2(\text{dithioether})]$ (X = Cl or Br) was via reaction of $[WOX_4]$ with $O(SiMe_3)_2$ in MeCN solution,[25] to give a colourless solution of $[WO_2X_2(MeCN)_2]$ in situ, followed by concentration of the solvent by ca. 50% in vacuo and addition of a solution of one molar equivalent of $RS(CH_2)_2SR$ (R = Me or *i*Pr) in anhydrous $CH_2Cl_2$. These reactions gave the desired compounds in good yields as yellow solids following removal of the solvent in vacuo and washing with hexane, with minimal polymer formation (and this could be removed by careful recrystallisation of the thioether complex from anhydrous $CH_2Cl_2$). The key to the success of this route is the clean formation of the molecular $[WO_2X_2(MeCN)_2]$ intermediates which seem to prevent the generation of the insoluble polymers. Using a similar approach we have found that the complexes may also be made in good yield from $WX_6$. Thus, reaction of $WX_6$ with one molar equivalent of $O(SiMe_3)_2$ in $CH_2Cl_2$ solution (to form $WOX_4$ in situ), followed by addition of ca. 0.5 mL MeCN, then another molar equivalent of $O(SiMe_3)_2$, and finally one equivalent of the dithioether gives yellow/brown solutions. Concentration of the solution in vacuo and cooling to ca. –15 °C (freezer) leads to deposition of the complexes as yellow (Cl) or yellow/brown (Br) precipitates. This approach was also used to obtain the 1,4-dithiane complexes, $[WO_2X_2(1,4\text{-dithiane})]$. We note that the dithiane complexes are relatively stable when stored as solids under a dry atmosphere, whereas the acyclic dithioether complexes are extremely moisture-sensitive and they also darken, turning blue-green over a few days, even when stored as powdered solids in the glove-box. The most sensitive is the light yellow $[WO_2Cl_2\{i\text{PrS}(CH_2)_2\text{S}i\text{Pr}\}]$ which develops an intense blue/green colour instantly on exposure to air and solutions of which become dark blue with trace water.

The IR spectra of the six $W^{VI}$ dithioether complexes show two strong ν(W=O) and one strong ν(W–X) bands, consistent with mutually *cis*-O and *trans*-X ligands. These are ca. 20–30 cm$^{-1}$ to high frequency of the corresponding Mo species.[20] This is typical of other series of $MO_2X_2$ compounds, e.g. $[MO_2X_2(OPR_3)_2]$ M = Mo or W,[23] although the difference is less in the phosphane oxide complexes. The higher frequency ν(M=O] for W is consistent with stronger metal-oxido bonds. The $^1$H and $^{13}$C{$^1$H} NMR spectra show small high frequency coordination shifts, although the patterns are indicative of fast pyramidal inversion. This was proven by obtaining spectra of representative examples at low temperature, whereupon resonances attributable to individual invertomers were observed. Samples containing added free ligand show resolved resonances for both coordinated and "free" ligand, demonstrating that intermolecular ligand exchange is slow on the NMR time scales at ambient temperatures.

In the course of our attempts to utilise $[WO_2Cl_2\{MeO(CH_2)_2OMe\}]$ as a molecular synthon for $W^{VI}$ thioether complexes we obtained colourless crystals. A structure analysis (120 K) revealed that these were in fact the $[WO_2Cl_2\{MeO(CH_2)_2OMe\}]$ precursor. A crystal structure of this species has been reported previously,[24] and while our cell is related to the published cell, we were unable to refine the structure using the published cell. Hence we conclude that this is a second polymorph. The new data refined very well, revealing (Figure 2, Table 2) a very similar distorted octahedral geometry based upon a W atom coordinated to *cis*-oxido groups, *trans*-Cl atoms and a chelating dimethoxyethane, giving a DL configuration. The bond lengths and angles are similar to those in the published structure.[24]

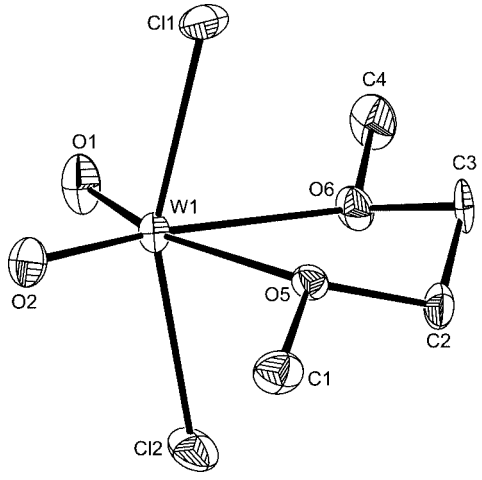

Figure 2. View of the structure of one of the two crystallographically independent $[WO_2Cl_2\{MeO(CH_2)_2OMe\}]$ molecules in the asymmetric unit with numbering scheme adopted. Ellipsoids are drawn at 50% probability level and H atoms are omitted for clarity. The second molecule is very similar.

### Molybdenum Thioether Complexes

The very unusual and highly sensitive metallocyclic compound $[Mo_2O_4Cl_4\{o\text{-}C_6H_4(CH_2SMe)_2\}_2]$ was prepared by treatment of $MoO_2Cl_2$ with one molar equivalent of *o*-$C_6H_4(CH_2SMe)_2$ in anhydrous $CH_2Cl_2$ or $Et_2O$. The formulation as a dinuclear complex follows from the spectroscopic and structural data. Two distinct ν(Mo–Cl) bands at 389 and 355 $cm^{-1}$ are evident, consistent with *cis*-Cl atoms, contrasting with the structures previously determined for $[MoO_2X_2\{RS(CH_2)_2SR\}]$ (X = Cl or Br; R = Me or Et) which have *trans*-halides and *cis*-oxido ligands.[20] The room temperature $^1H$ NMR spectrum of the $MoO_2Cl_2$-*o*-$C_6H_4(CH_2SMe)_2$ system is simple and little different from the thioether ligand itself. Upon cooling to 183 K the spectrum becomes more complex with high frequency coordination shifts with three δ(Me) resonances evident at low temperature, consistent with the presence of stereoisomers, indicating that the compound is undergoing reversible ligand dissociation and fast pyramidal inversion under ambient conditions. In order to identify unambiguously the structure of this complex, light yellow crystals which were extremely air and moisture-sensitive, were obtained by cooling a solution containing the complex dissolved in $CH_2Cl_2$. The structure shows (Figure 3, Table 3) an unusual centrosymmetric dinuclear metallocyclic species in which each formally $Mo^{VI}$ is in a distorted octahedral geometry, coordinated to *cis*-oxido, *cis*-chlorido and *cis*-thioether groups. The *o*-$C_6H_4(CH_2SMe)_2$ ligands are not chelating, but instead function as bridging bidentates, with one S atom *trans* to O and one *trans* to Cl. This represents the first metallocyclic species incorporating the *o*-xylyl dithioether ligand. The different *trans* influences of these ligands are very clearly reflected in the disparate bond lengths within pairs of ligands, e.g. Mo–Cl 2.278(3), 2.423(3) Å, the longer bond being associated with the Cl *trans* to O. Even the Mo=O bond lengths are disparate due to the *trans* ligands; Mo–O 1.726(7), 1.777(7) Å. The Mo–S distances are *d*(Mo–S) = 2.604(3), 2.826(3) Å, with the exceptionally long Mo–S bond lying *trans* to the oxido ligand. These compare with *d*(Mo–S) = 2.73–2.77 Å in the other structurally characterised $Mo^{VI}$ thioether complexes.[20] The angles involving the mutually *cis* pairs of ligands also show considerable variation, O1–Mo–O2 105.3(4), Cl1–Mo–Cl2 91.21(12), S1–Mo–S2a 82.52(9)°, and the S–Mo–S angle is some 4–5° larger than in the chelate complexes $[MoO_2Cl_2\{RS(CH_2)_2SR\}]$ (R = Me or Et). This is the first $Mo^{VI}$ complex incorporating other than a dimethylene-linked dithioether ligand and follows from our earlier work which has shown that the *o*-$C_6H_4(CH_2EMe)_2$ (E = S, Se, Te) are remarkably effective ligands for a range of late transition metal ions.[26] The occurrence of a metallocyclic structure with bridging bidentate *o*-$C_6H_4(CH_2SMe)_2$ ligands in the case of the $Mo^{VI}$ species, may be a consequence of the sterically demanding *o*-xylyl linkage and the small radius of $Mo^{VI}$. We have shown previously that the E–M–E chelate angle in transition metal complexes involving the *o*-$C_6H_4(CH_2EMe)_2$ (E = S, Se or Te) ligands is invariably close to 100°.[26] In the dinuclear $[Mo_2O_4Cl_4\{o\text{-}C_6H_4(CH_2SMe)_2\}_2]$ the Me groups within a single dithioether ligand are *anti* (the SMe group coordinated to one Mo atom lies on the opposite side of the $MoO_2S_2$ coordination plane to that on the other Mo atom), while the coordinated SMe groups on each individual Mo atom are *syn* (Me substituents on a single Mo atom lie on the same side of the $MoO_2S_2$ plane) – Figure 3. A similar reaction using $MoO_2Cl_2$ with *o*-$C_6H_4(CH_2SeMe)_2$ led to reduction of the metal centre.

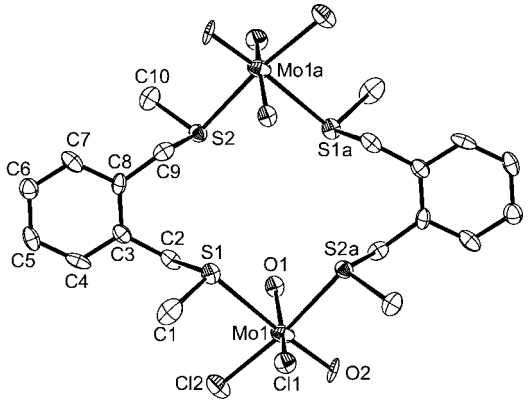

Figure 3. View of the structure of $[Mo_2O_4Cl_4\{o\text{-}C_6H_4(CH_2SMe)_2\}_2]$ with numbering scheme adopted. Ellipsoids are drawn at 50% probability level and H atoms are omitted for clarity. Symmetry operation *a* = 1 – *x*, 2 – *y*, –*z*.

The moisture-sensitive (macro)cyclic complexes of $Mo^{VI}$, $[MoO_2Cl_2(L)]$ (L = 1,4-dithiane, [15]ane$S_2O_3$, [12]ane$S_4$, [14]ane$S_4$), as well as $[MoO_2Cl_2\{iPrS(CH_2)_2SiPr\}]$ have been obtained similarly as light yellow solids in good yield. The isolated solids were stored in the glove box (<5 ppm $H_2O$) to prevent decomposition and have been characterised by microanalysis, IR, $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy. The IR spectra of these Mo species show evidence

for coordinated thioether ligand, and two strong bands in the region 900–950 $cm^{-1}$ indicative is the *cis*-dioxido unit. For the mononuclear species one strong absorption at ca. 350–360 $cm^{-1}$, suggesting mutually *trans* Cl ligands (and confirmed crystallographically for $[MoO_2Cl_2\{i\text{PrS}(CH_2)_2\text{-}S i\text{Pr}\}]$ – above). The $^1H$ NMR spectrum of $[MoO_2Cl_2\{i\text{PrS}(CH_2)_2S i\text{Pr}\}]$ is simple, with resonances to high frequency of $i\text{PrS}(CH_2)_2S i\text{Pr}$, consistent with coordination of the dithioether ligand to Mo, and fast pyramidal inversion – similar to the behaviour observed previously for $[MoO_2X_2\{RS(CH_2)_2SR\}]$.[20] Molybdenum-95 NMR spectroscopy reveals a resonance at $\delta$ = 225 ppm, also in the same range as for $[MoO_2Cl_2\{RS(CH_2)_2SR\}]$ (R = Me or Et) described previously, and an X-ray structure determination showed that $[MoO_2Cl_2\{i\text{PrS}(CH_2)_2S i\text{Pr}\}]$ is isostructural with its W analogue (above), based upon distorted octahedral Mo with *cis*-oxido and *trans*-Cl ligands and a chelating dithioether ligand. The dithiane complex $[MoO_2Cl_2(\text{dithiane})]$ exhibits a singlet methylene resonance in the $^1H$ NMR spectrum at ambient temperatures, indicating either bridging dithiane or reversible chelate ring opening. However, this broadens and splits into complex multiplets at low temperature (183 K), consistent with chelation for which an AA′BB′ pattern is expected.[27]

For the complex $[MoO_2Cl_2([15]aneS_2O_3)]$, assuming six-coordination, the possible macrocycle coordination modes are $S_2$, SO or $O_2$. The former would give rise to a symmetrical pattern, and hence five distinct $CH_2$ resonances, whereas SO or $O_2$ coordination would lead to a less symmetrical species and hence a more complicated $^1H$ NMR pattern. In fact, the $^1H$ NMR spectrum of $[MoO_2Cl_2([15]aneS_2O_3)]$ clearly reveals five resonances, and comparison with the spectrum of the parent macrocycle is also consistent with $S_2$ coordination to molybdenum. The $^{95}Mo$ NMR spectrum of $[MoO_2Cl_2([15]aneS_2O_3)]$ shows a single resonance at $\delta$ = 194 ppm, slightly to low frequency of $[MoO_2Cl_2\{\text{MeS}(CH_2)_2\text{SMe}\}]$ ($\delta$ = 210 ppm) and $[MoO_2Cl_2\{\text{EtS}(CH_2)_2\text{-SEt}\}]$ ($\delta$ = 225 ppm).[20]

The poor solubilities of the yellow $[MoO_2Cl_2([n]aneS_4)]$ ($n$ = 12 or 14) in solvents which would not react with the complex hindered attempts to obtain solution spectroscopic data for these species. However, the IR spectra are consistent with a $Cl_2O_2S_2$ coordination sphere at $Mo^{VI}$ in $[MoO_2Cl_2([n]aneS_4)]$ ($n$ = 12 or 14), with *cis*-oxido ligands and *trans*-chlorines; microanalyses confirm the formulation. The reaction of $MoO_2Cl_2$ with [14]$aneS_4$ has been mentioned previously.[19]

## Conclusions

The first series of dioxidotungsten(VI) complexes with soft dithioethers has been prepared in good yield and characterised structurally and spectroscopically. Successful formation of these compounds is very sensitive to the precise reaction conditions, and they appear to be much more reactive than their $Mo^{VI}$ analogues, consistent with dioxidotungsten(VI) being harder than dioxidomolybdenum(VI). Several new examples of dioxidomolybdenum(VI) thioether complexes, including the unique dinuclear metallocyclic $[Mo_2O_4Cl_4\{o\text{-}C_6H_4(CH_2SMe)_2\}_2]$ which involves the rare *cis*-$MoCl_2$ unit, and examples containing the small cyclic 1,4-dithiane ligand and several macrocyclic thia- and mixed S/O-ligands have also been prepared and characterised. Work involving other $W^{VI}$ species with neutral sulfur ligands and related $M^{IV}$ and $M^V$ (M = Mo or W) complexes which may be relevant as redox models for the molybdo- and tungsto-enzymes, is underway.

## Experimental Section

Infrared spectra were recorded as Nujol nulls between CsI discs using a Perkin–Elmer 983G spectrometer over the range 4000–200 $cm^{-1}$. $^1H$ NMR spectra were recorded using a Bruker AV300 spectrometer. $^{13}C\{^1H\}$ and $^{95}Mo$ NMR spectra were recorded using a Bruker DPX400 spectrometer operating at 100.6 and 26.1 MHz, respectively, and are referenced to TMS and 1 mol $dm^{-3}$ $Na_2[MoO_4]$ respectively. Microanalyses were undertaken by the University of Strathclyde microanalytical service.

Solvents were dried prior to use and all preparations were undertaken using standard Schlenk techniques under a $N_2$ atmosphere. $MoO_2Cl_2$, $WCl_6$ and $W(CO)_6$ were obtained from Aldrich and used as received. $WBr_6$ was prepared by treating $W(CO)_6$ with $Br_2$.[28] The ligands $MeS(CH_2)_2SMe$, $i\text{PrS}(CH_2)_2S i\text{Pr}$, $o\text{-}C_6H_4(CH_2SMe)_2$, $MeSe(CH_2)_2SeMe$, [12]$aneS_2O_2$ and [15]$aneS_2O_3$ were prepared as described previously,[26,29,30] while 1,4-dithiane, [12]$aneS_4$ and [14]-$aneS_4$ were obtained from Aldrich and the solids dried by heating in vacuo for ca. 1 h before use.

**$[WO_2Cl_2\{MeS(CH_2)_2SMe\}]$. Method 1:** An acetonitrile solution of $(Me_3Si)_2O$ (0.049 g, 0.3 mmol in 5 mL of $CH_3CN$) was added dropwise at room temperature to a stirred suspension of $WOCl_4$ (0.103 g, 0.3 mmol) in acetonitrile (5 mL) over a period of 10 min. The $WOCl_4$ was consumed to give a clear, colourless solution, which was stirred for a further 10 min. The solution was then concentrated to half volume in vacuo and a $CH_2Cl_2$ solution of $MeS(CH_2)_2SMe$ (0.037 g, 0.3 mmol) was added dropwise. After stirring for ca. 30 min the solvent was removed in vacuo, leaving a yellow precipitate, which was washed with *n*-hexane and dried in vacuo. Yield 0.094 g, 76%.

**Method 2:** A suspension of $WCl_6$ (0.50 g, 1.25 mmol) in dry $CH_2Cl_2$ (10 mL) was treated dropwise with $(Me_3Si)_2O$ (0.20 g, 1.25 mmol) in $CH_2Cl_2$ (5 mL) and the mixture stirred for 10 min during which

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

orange $WOCl_4$ deposited from the solution. Dry MeCN (0.5 mL) was added, followed by dropwise addition of $(Me_3Si)_2O$ (0.20 g, 1.25 mmol) and the solution stirred for 30 min when it became colourless (or sometimes very faintly blue). $MeS(CH_2)_2SMe$ (0.16 g, 1.3 mmol) in $CH_2Cl_2$ solution (2 mL) was added producing a pale yellowish solution. The solution was stirred for 10 min and then concentrated in vacuo to ca. 2 mL, and refrigerated overnight. The yellow powder deposited was separated by decantation of the solvent and dried in vacuo. Yield 0.30 g, 58%.

Both methods gave the same product as confirmed by spectroscopic studies. $C_4H_{10}Cl_2O_2S_2W$ (409.0): calcd. C 11.7, H 2.5; found C 11.0, H 2.9. IR (Nujol): $\tilde{\nu}$ = 956, 918 (W=O), 343 (W–Cl) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 300 K): $\delta$ = 3.24 (br. s, $CH_2S$, 4 H), 2.51 (br. s, Me, 6 H); (223 K): $\delta$ = 3.40–3.05 (m, $CH_2S$), 2.52 (s, Me, minor), 2.44 (s, Me, major). $^{13}C\{^1H\}$ ($CD_2Cl_2$, 300 K): br., ill-defined; (223 K): $\delta$ = 33.65 ($CH_2$), 18.1 (Me).

**[$WO_2Cl_2${*i*PrS$(CH_2)_2$S*i*Pr}]:** An acetonitrile solution of $(Me_3Si)_2O$ (0.048 g, 0.2 mmol in 5 mL of MeCN) was added dropwise at room temperature to a stirred suspension of $WOCl_4$ (0.102 g, 0.2 mmol) in acetonitrile (5 mL) over a period of 10 min to give a clear, colourless solution. After stirring for a further 10 min the solution was concentrated to half volume in vacuo and a $CH_2Cl_2$ solution of *i*PrS$(CH_2)_2$S*i*Pr (0.053 g, 0.2 mmol) was added dropwise at room temperature. The reaction mixture was stirred for ca. 30 min and then the solvent was evaporated to dryness in vacuo, leaving a yellow solid, which was washed with *n*-hexane and dried in vacuo. Yield 0.104 g, 75%. The compound was also prepared by method 2 used for [$WO_2Cl_2${$MeS(CH_2)_2SMe$}] above. Yield 55%. $C_8H_{18}Cl_2O_2S_2W{\cdot}CH_2Cl_2$ (550.0): calcd. C 19.6, H 3.7; found C 18.9, H 4.7. IR (Nujol): $\tilde{\nu}$ = 963, 923 (W=O), 338 (W–Cl) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 300 K): $\delta$ = 3.30 (br., CH, 2 H), 3.18 (br., $CH_2$, 4 H), 1.38 (br., $CHMe_2$, 12 H). $^{13}C\{^1H\}$ ($CDCl_3$, 300 K): $\delta$ = 36.6 (CH), 28.1($CH_2$), 23.2(Me).

**[$WO_2Cl_2$(1,4-dithiane)]:** A suspension of $WCl_6$ (0.50 g, 1.25 mmol) in dry $CH_2Cl_2$ (10 mL) was treated dropwise with $(Me_3Si)_2O$ (0.20 g, 1.25 mmol) in $CH_2Cl_2$ (5 mL) and the mixture stirred for 10 min. Dry MeCN (0.5 mL) was added to the orange suspension, followed by dropwise addition of $(Me_3Si)_2O$ (0.20 g, 1.25 mmol) and the solution stirred for 30 min when it became colourless. 1,4-Dithiane, which had been freshly sublimed in vacuo, (0.145 g, 1.2 mmol) in $CH_2Cl_2$ solution (5 mL) was added producing a pale yellowish solution. The solution was stirred for 10 min and then concentrated in vacuo to ca. 4 mL, and refrigerated for 48 h. The very fine yellow powder deposited was separated by decantation of the solvent and dried in vacuo. Yield 0.28 g, 55%. $C_4H_8Cl_2O_2S_2W$ (407.0): calcd. C 11.8, H 2.0; found C 11.5, H 2.9. IR (Nujol): $\tilde{\nu}$ = 940, 903 (W=O), 338 (W–Cl) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 300 K): $\delta$ = 2.91 (s, $CH_2$). $^{13}C\{^1H\}$ ($CDCl_3$, 300 K): $\delta$ = 29.3 ($CH_2$).

**[$WO_2Br_2${$MeS(CH_2)_2SMe$}]:** A suspension of $WBr_6$ (0.66 g, 1.0 mmol) in dry $CH_2Cl_2$ (10 mL) was treated dropwise with $(Me_3Si)_2O$ (0.16 g, 1.0 mmol) in $CH_2Cl_2$ (5 mL) and the mixture stirred for 10 min. Dry MeCN (0.5 mL) was added to the yellow-green suspension, followed by dropwise addition of $(Me_3Si)_2O$ (0.16 g, 1.0 mmol) and the solution stirred for 30 min when it became pale yellow-brown. $MeS(CH_2)_2SMe$ (0.12 g, 1.0 mmol) in $CH_2Cl_2$ solution (5 mL) was added producing a brown-yellow solution. The solution was stirred for 10 min and then concentrated in vacuo to ca. 5 mL, and refrigerated for 48 h. Only a small quantity of yellow-brown precipitate formed, so the solvent was removed in vacuo, and the residue stirred with hexane (10 mL). The powder deposited was separated by decantation of the solvent and dried in vacuo. Yield 0.3 g, 60%. $C_4H_{10}Br_2O_2S_2W$ (497.9): calcd. C 9.6, H 2.0; found C 10.2, H 1.3. IR (Nujol): $\tilde{\nu}$ = 965, 917 (W=O), 228 (W–Br) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 300 K): $\delta$ = 2.90 (s, $CH_2S$, 4 H), 2.43 (s, Me, 6 H). $^{13}C\{^1H\}$ ($CDCl_3$, 300 K): $\delta$ = 33.4 ($CH_2$), 18.4 (Me).

**[$WO_2Br_2${*i*PrS$(CH_2)_2$S*i*Pr}]:** An acetonitrile solution of $(Me_3Si)_2O$ (0.038 g, 0.2 mmol in 5 mL of MeCN) was added dropwise at room temperature to a stirred suspension of $WOBr_4$ (0.123 g, 0.2 mmol) in MeCN (5 mL) over a period of 10 min. The reaction mixture changed to a green coloured solution which was stirred for a further 10 min. The solution was concentrated to half volume in vacuo and a $CH_2Cl_2$ solution of *i*PrS$(CH_2)_2$S*i*Pr (0.042 g, 0.2 mmol) was added dropwise and the mixture was stirred for ca. 30 min. At this point the solvent was removed in vacuo, leaving a yellow-brown solid which was stirred with *n*-hexane (10 mL), separated by decantation and dried in vacuo. Yield 0.093 g, 71%. The compound was also prepared by method 2 used for [$WO_2Cl_2${$MeS(CH_2)_2SMe$}] above. $C_8H_{18}Br_2O_2S_2W{\cdot}1/4C_6H_{14}$ (575.7): calcd. C 19.8, H 3.8; found C 19.9, H 4.0. IR (Nujol): $\tilde{\nu}$ = 962, 920 (W=O), 230 (W–Br) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 300 K): $\delta$ = 3.48 (br. s, CH, 2 H) 3.30 (br. s, $CH_2$, 4 H), 1.46 (br. s, $CHMe_2$, 6 H); (223 K): $\delta$ = 3.01–3.53 (overlapping m, CH and $CH_2$), 1.43, 1.38 (s, Me). $^{13}C\{^1H\}$ ($CDCl_3$, 300 K): $\delta$ = 34.9 (CH), 30.7 ($CH_2$), 23.3 (Me).

**[$WO_2Br_2$(1,4-dithiane)]:** A suspension of $WBr_6$ (0.66 g, 1.0 mmol) in dry $CH_2Cl_2$ (10 mL) was treated dropwise with $(Me_3Si)_2O$ (0.16 g, 1.0 mmol) in $CH_2Cl_2$ (5 mL) and the mixture stirred for 10 min. Dry MeCN (0.5 mL) was added to the blue-green suspension, followed by dropwise addition of $(Me_3Si)_2O$ (0.16 g, 1.0 mmol) and the solution stirred for 30 min when it became pale yellow-brown. 1,4-Dithiane, which had been freshly sublimed in vacuo, (0.12 g, 1.0 mmol) in $CH_2Cl_2$ solution (5 mL) was added producing a brown-yellow solution. The solution was stirred for 10 min and then concentrated in vacuo to ca. 4 mL, and refrigerated for 48 h. The yellow-brown powder deposited was separated by decantation of the solvent, rinsed with dry hexane (5 mL) and dried in vacuo. Yield 0.35 g, 70%. $C_4H_8Br_2O_2S_2W$ (495.9): calcd. C 9.7, H 1.6; found C 9.0, H 1.7. IR (Nujol): $\tilde{\nu}$ = 961, 902 (W=O), 238 (W–Br) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 300 K): $\delta$ = 2.85 ($CH_2$). $^{13}C\{^1H\}$ ($CDCl_3$, 300 K): $\delta$ = 29.2 ($CH_2$).

**[$Mo_2O_4Cl_4${*o*-$C_6H_4(CH_2SMe)_2$}$_2$]:** A degassed ether solution of *o*-$C_6H_4(CH_2SMe)_2$ (0.104 g, 0.52 mmol) in 5 mL of $Et_2O$ was added dropwise at room temperature to a stirred solution of $MoO_2Cl_2$ (0.104 g, 0.52 mmol) in diethyl ether (10 mL) over a period of 5 min, giving a light yellow solution. The solution was stirred at room temperature for a further 30 min. The solution was then concentrated in vacuo by ca. 50% and placed in the freezer. This produced a yellow precipitate, which was collected by filtration and dried in vacuo. Yield 0.153 g, 74%. $C_{20}H_{28}Cl_4Mo_2O_4S_4$ (794.4): calcd. C 30.2, H 3.6; found C 29.2, H 3.8. IR (Nujol): $\tilde{\nu}$ = 933, 895 (Mo=O), 387, 355 (Mo–Cl) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 298 K): $\delta$ = 7.29 (br. s, *o*-$C_6H_4$, 4 H), 3.95 (br., $CH_2$, 4 H), 2.29 (br., Me, 6 H); (183 K): $\delta$ = 7.33–7.11 (m, *o*-$C_6H_4$, 4 H), 4.15, 3.74 (br., $CH_2$, 4 H), 2.64, 2.26, 1.94 (s, Me, 6 H). $^{13}C\{^1H\}$ NMR ($CDCl_3$, 298 K): no spectrum; (223 K): $\delta$ = 133.00 (*ipso*-C, *o*-$C_6H_4$), 132.67, 129.28 (*o*-$C_6H_4$), 37.21 ($CH_2$), 20.99 (Me).

**[$MoO_2Cl_2${*i*PrS$(CH_2)_2$S*i*Pr}]:** To a suspension of $MoO_2Cl_2$ (0.103 g, 0.52 mmol) in $CH_2Cl_2$ (20 mL) was added a $CH_2Cl_2$ solution (5 mL) of *i*PrS$(CH_2)_2$S*i*Pr (0.093 g, 0.52 mmol). Stirring the reaction mixture for ca. 15 min afforded a pale yellow solution which was reduced in vacuo to ca. 3 mL. Layering with anhydrous diethyl ether and storing the resulting mixture overnight at ca. –18 °C gave pale yellow crystals which were filtered, washed with diethyl ether and dried in vacuo. Yield 85%. $C_8H_{18}Cl_2MoO_2S_2$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(377.2): calcd. C 25.5, H 4.8; found C 25.3, H 5.1. IR (Nujol): $\tilde{\nu}$ = 944, 913 (Mo=O), 348 (Mo–Cl) $cm^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 300 K): $\delta$ = 3.30 (sept, CH, 2 H), 3.08 (s, $CH_2$, 4 H), 1.47 (d, $CHMe_2$, 12 H). $^{13}C\{^1H\}$ NMR ($CH_2Cl_2/CDCl_3$, 300 K): $\delta$ = 38.25 (CH), 31.01 ($CH_2$), 21.99 ($CHMe_2$) ppm. $^{95}Mo$ NMR ($CH_2Cl_2/CDCl_3$): $\delta$ = 225.

**[$MoO_2Cl_2$(1,4-dithiane)]:** A degassed diethyl ether (5 mL) solution of 1,4-dithiane (0.072 g, 0.6 mmol) was added dropwise at room temperature to a stirred solution of $MoO_2Cl_2$ (0.120 g, 0.6 mmol) in diethyl ether (10 mL) over a period of 5 min, giving a light yellow precipitate. The reaction mixture was stirred at room temperature for a further 1 h. The yellow precipitate was collected by filtration and dried in vacuo. Yield 0.128 g, 67%. $C_4H_8Cl_2MoO_2S_2$ (319.1): calcd. C 15.1, H 2.5; found C 15.4, H 2.4. IR (Nujol): $\tilde{\nu}$ = 946, 916 (Mo=O), 362 (Mo–Cl) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 298 K): $\delta$ = 2.98 (s, $CH_2$); (183 K): $\delta$ = 3.53–2.69 (br. m, $CH_2$).

**[$MoO_2Cl_2$([15]ane$S_2O_3$)]:** A dry, degassed $CH_2Cl_2$ solution (5 mL) of [15]ane$S_2O_3$ (0.010 g, 0.4 mmol) was added dropwise at room temperature to a stirred solution of $MoO_2Cl_2$ (0.080 g, 0.4 mmol) in degassed diethyl ether (10 mL) over a period of 5 min, giving a light yellow precipitate. The reaction mixture was stirred at room temperature for a further 3 h. The yellow precipitate was collected by filtration and dried in vacuo. Yield 0.124 g, 68%. $C_{10}H_{20}Cl_2MoO_5S_2$ (451.2): calcd. C 26.6, H 4.5; found C 26.6, H 4.5. IR (Nujol): $\tilde{\nu}$ = 939, 908 (Mo=O), 355 (Mo–Cl) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 300 K): $\delta$ = 3.97 (br. s, $CH_2O$, 4 H), 3.84 (s, $CH_2O$, 4 H), 3.77 (s, $CH_2O$, 4 H), 3.15 (s, $CH_2S$, 4 H), 3.02 (s, $CH_2S$, 4 H). $^{95}Mo$ NMR ($CH_2Cl_2/CDCl_3$, 300 K): $\delta$ = 194.

**[$MoO_2Cl_2$([14]ane$S_4$)]:** Addition of a solution of $MoO_2Cl_2$ (0.075 g, 0.38 mmol) in dry diethyl ether (5 mL) dropwise via a bypass funnel at room temperature to a solution of [14]ane$S_4$ (0.102 g, 0.38 mmol) in dry $CH_2Cl_2$ (10 mL) over a period of 5 min, produced a light yellow precipitate. The reaction mixture was stirred at room temperature for a further 60 min, and the yellow precipitate was collected by filtration and dried in vacuo. Yield 0.135 g, 76%. $C_{10}H_{20}Cl_2MoO_2S_4$ (467.4): calcd. C 25.7, H 4.3; found C 25.9, H 4.5. IR (Nujol): $\tilde{\nu}$ = 939, 913 (Mo=O), 359 (Mo–Cl) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, very poorly soluble, 300 K): $\delta$ = 2.72 (s, $SCH_2CH_2S$, 8 H), 2.61 (t, $SCH_2CH_2CH_2S$, 8 H), 1.88 (q, $SCH_2CH_2CH_2S$, 4 H) ([14]ane$S_4$).

**[$MoO_2Cl_2$([12]ane$S_4$)]:** Addition of a solution of $MoO_2Cl_2$ (0.084 g, 0.42 mmol) in dry diethyl ether (5 mL) dropwise via a bypass funnel at room temperature to a solution of [12]ane$S_4$ (0.102 g, 0.42 mmol) in dry $CH_2Cl_2$ (10 mL) over a period of 5 min, produced a light yellow precipitate. The reaction mixture was stirred at room temperature for a further 60 min. The yellow precipitate was collected by filtration and dried in vacuo. Yield 0.141 g, 76%. $C_8H_{16}Cl_2MoO_2S_4 \cdot CH_2Cl_2$ (524.2): calcd. C 20.6, H 3.5; found C 20.6, H 3.5. IR (Nujol): $\tilde{\nu}$ = 944, 919 (Mo=O), 358 (Mo–Cl) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, very poorly soluble, 300 K): $\delta$ = 2.72 (s, $CH_2$) ([12]ane$S_4$).

**X-ray Crystallography:** Details of the crystallographic data collection and refinement parameters are given in Table 4. Yellow crystals of [$WO_2Cl_2${*i*PrS$(CH_2)_2$S*i*Pr}], [$Mo_2O_4Cl_4${*o*-$C_6H_4(CH_2SMe)_2$}$_2$] and a new polymorph of [$WO_2Cl_2${MeO$(CH_2)_2$OMe}] were obtained by liquid diffusion of diethyl ether into a $CH_2Cl_2$ solution of the complex. The crystals of [$Mo_2O_4Cl_4${*o*-$C_6H_4(CH_2SMe)_2$}$_2$] were extremely moisture-sensitive and some degradation occurred during transfer from the Schlenk flask to the diffractometer – the data presented are those from the best crystal from several different crystals examined. Nevertheless the quality was rather poor and hence the residuals are higher than usually expected. Data collection used a Nonius Kappa CCD diffractometer ($T$ = 120 K) and with graphite-monochromated Mo-$K_\alpha$ X-radiation ($\lambda$ = 0.71073 Å). Structure solution and refinement were routine.[31,32] with H atoms being placed in geometrically calculated positions. Selected bond lengths and angles are given in Table 1, Table 2, and Table 3.

CCDC-626755 (for W/S), -626756 (for W/O), -626754 and -626757 (for Mo) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 4. Crystallographic parameters.[a]

| Compound | [$WO_2Cl_2${*i*PrS$(CH_2)_2$S*i*Pr}] | [$WO_2Cl_2${MeO$(CH_2)_2$OMe}] | [$(MoO_2Cl_2)_2${*o*-$C_6H_4(CH_2SMe)_2$}$_2$] |
|---|---|---|---|
| Formula | $C_8H_{18}Cl_2O_2S_2W$ | $C_4H_{10}Cl_2O_4W$ | $C_{20}H_{28}Cl_4Mo_2O_4S_4$ |

# Synthesis, Characterization, and DFT Investigation of $Ir^{III}$ Tolylterpyridine Complexes

Naokazu Yoshikawa,*[a] Shinichi Yamabe,[b] Nobuko Kanehisa,[c] Yasushi Kai,[c] Hiroshi Takashima,[a] and Keiichi Tsukahara[a]

**Keywords:** Iridium / Terpyridine / Absorption / Emission / Density functional calculations

Three new polypyridine iridium(III) complexes $[Ir^{III}Cl(L)(tterpy)](PF_6)_2$ {L = phen (**1**), dpphen (**2**), and dmbpy (**3**)} were prepared. Reference complexes $[Ir^{III}Cl(bpy)(tterpy)](PF_6)_2$ (**4**) and $[Ir^{III}(L)_2](PF_6)_3$ {L = tterpy (**5**) and terpy (**6**)} were also prepared. Abbreviations of the ligands used here are phen = 1,10-phenanthroline, dpphen = 4,7-diphenyl-1,10-phenanthroline, bpy = 2,2′-bipyridine, dmbpy = 4,4′-dimethyl-2,2′-bipyridine, tterpy = 4′-(4-tolyl)-2,2′:6′,2′′-terpyridine, and terpy = 2,2′:6′,2′′-terpyridine. The syntheses, which were accomplished in typical reaction times of fifteen minutes by using a microwave oven, were easier than a previous method. The complexes were characterized by electrospray mass spectrometry, UV/Vis spectroscopy, and cyclic voltammetry (CV). The X-ray structures of the two complexes **5** and **6** were also obtained. Cyclic voltammograms of all the $[Ir^{III}Cl(L)(tterpy)]^{2+}$ complexes showed that the first reduction occurred at around –0.67 V, which is attributed to the reduction of the tterpy ligand in $[Ir^{III}Cl(L)(tterpy)]^{2+}$. The electronic properties of complexes **5** and **6** were studied by using B3LYP functional calculations, and their optimized geometries were compared to those of the experimentally observed ones. Excited triplet and singlet states are also examined by using time-dependent density functional theory (TDDFT). The calculated energies of the lowest singlet and triplet states in the two complexes are in good agreement with the experimental absorption and phosphorescence spectra. In this study, it was found that $[Ir^{III}Cl(L)(tterpy)]^{2+}$ emits an intense phosphorescence at room temperature. Since the lowest unoccupied molecular orbitals (LUMOs) of all $[Ir^{III}Cl(L)(tterpy)]^{2+}$ complexes are composed of the $\pi^*$-system contribution of the tterpy ligand, the spectroscopic and electrochemical results are discussed comparatively.

## Introduction

Polypyridine complexes of $d^6$ transition metals have been studied extensively because of their useful spectroscopic and photophysical properties. In recent years, much interest has been devoted to $Ir^{III}$ complexes.[1–4] These iridium(III) complexes are known to exhibit high triplet quantum yields due to the mixing of the singlet and triplet excited states through spin-orbital coupling,[5] leading to high phosphorescence efficiencies. The attractive luminescence properties of $[Ir(terpy)_2]^{3+}$, particularly the long lifetime under aerated ambient conditions, render it of interest as the light-emitting component in sensory systems.[6] Bis(terpyridine) complexes of iridium(III) incorporating *meta*- or *para*-*N*-methylpyridyl substituents at the terpyridine 4′ position display long-lived luminescence in solution.[6,7] In particular, $Ir^{III}$ cyclometalated complexes have attracted great attention because of their applications in photonic devices and light-emitting diode (LED) displays.[8,9]

In our previous work, we synthesized and crystallized $[IrCl_2L_2]PF_6$ complexes {L = bqn, phen, dpphen, bpy, and dmbpy} to reveal their long-lived excited states and good photoluminescence efficiencies.[10–13] Abbreviations of the ligands used here are bqn = 2,2′-biquinoline, phen = 1,10-phenanthroline, dpphen = 4,7-diphenyl-1,10-phenanthroline, bpy = 2,2′-bipyridine, and dmbpy = 4,4′-dimethyl-2,2′-bipyridine. Recently, we focused on $Ir^{III}$ complexes with a 2,2′:6′,2′′-terpyridine (terpy) and a polypyridine ligand.[14,15] These iridium complexes have intense phosphorescence at room temperature and remarkably high quantum yields close to unity.[16]

Computational methods were used to predict or confirm photophysical properties of metal complexes. More recently, we designed and synthesized new $[Ru(CH_3CN)(L)(terpy)]^{2+}$ {L = phen, dpbpy, and bpm} complexes, bearing a labile $CH_3CN$ ligand, and their reference complexes $[RuCl(L)(terpy)]^+$ {L = phen, dpbpy, and dpphen}.[17] The time-dependent-density-functional-theory

(TDDFT) approach provided a good agreement between the computed and the experimental absorption spectra of these ruthenium complexes.[18]

To elucidate the source of intense emission and the electrochemical behavior of the $Ir^{III}$ polypyridine complex and confirm the positions of the HOMO and LUMO in the iridium complexes by using DFT and TDDFT calculations, we tried to synthesize several $Ir^{III}$ complexes with matrixes of a 4′-(4-tolyl)-2,2′:6′,2′′-terpyridine (tterpy) and a polypyridine ligand and also investigate the relations between the structures of a tterpy and a polypyridine ligand and the singlet and triplet electronic states in the iridium complexes. We also report an X-ray crystal structure of $[Ir(tterpy)_2](PF_6)_3$, because crystal structures of $Ir^{III}$-terpy complexes are very rare.[19,20]

## Results and Discussion

### X-ray Crystallographic Results

The structural formulae of all the complexes used in this work are shown in Figure 1. The structure of **5**, viz. $[Ir(tterpy)_2](PF_6)_3$, was confirmed by X-ray crystallography (Table 7). The ORTEP view of **5** is shown in Figure 2, and its selected bond lengths and angles are given in Table 1. The crystal structure of a mononuclear iridium compound, **5**, consists of a discrete $[Ir(tterpy)_2]^{3+}$ cation and three hexa-

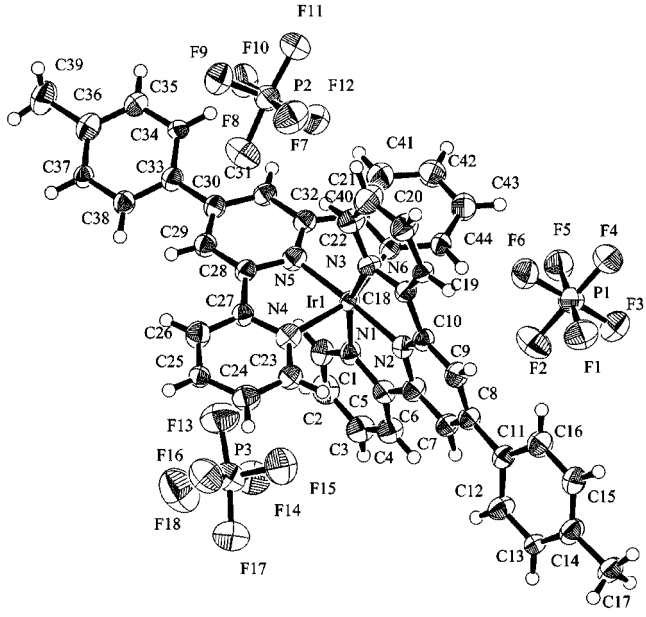

Figure 2. Molecular structure of $[Ir(tterpy)_2](PF_6)_3$ (**5**).

fluorophosphate anions. The $Ir^{III}$ atom is located in a distorted octahedral environment formed by the two tterpy ligands. The Ir–N bond lengths are in the range 1.94(2)–2.09(3) Å and the three *trans* angles are in the range 159.1(7)–176.8(9)°, which are similar to the values of 1.978–2.058 Å and 160.2–177.8° reported for $[Ir(terpy)_2](PF_6)_3$.[19] The Ir cation is coordinated by six N atoms from a pair of chelating tterpy ligands. An equatorial plane is formed by atoms N2, N4, N5, and N6, where the largest deviation from the mean plane is 0.035(4) Å and the Ir atom is out of this plane by 0.013(3) Å. In the case of complex **5**, the axial positions are occupied by the tterpy N1 atom and another tterpy N3 atom. The $PF_6^-$ is not coordinated to the iridium metal atom but hydrogen bonded to ring protons. The average length of the Ir–N bonds is 2.035(2) Å and the average value of the ligand angles, N1–Ir–N2 and N2–Ir–N3 is 79.6(8)°, which compare well with the values of 2.026 Å and 79.1° reported for $[Ir(bpy)_3](ClO_4)_3$.[21]

## Absorption Properties

The electronic absorption spectra for iridium(III) polypyridyl complexes contain typical π–π* and n–π* bands in the ultraviolet region. The electronic absorption spectra for **1**, **2**, and **5** are shown in Figure 3, and the spectroscopic data for the complexes **1**–**6** and the tterpy and terpy ligands are tabulated in Table 2.[22] While the shapes of the spectra are similar, the absorption band at 282 nm for **2** is red shifted relative to that at 272 nm for **1** (Figure 3), owing to the two phenyl groups attached to complex **2**. The absorption band at 272 nm in **1** has been assigned as a phen(π)–phen(π*) transition.[14] Similarly, the bands at 282 nm in **2** could be assigned as dpphen(π)–dpphen(π*) transitions.[10] The absorption bands at 311 nm in both **1** and **2** have been assigned as tterpy(π)–tterpy(π*) transitions. On the other hand, the absorption spectrum of **4** with a bpy ligand is very similar to that of **3** with a dmbpy ligand. This indicates that the two methyl groups introduced in the bpy ligand did not affect the absorption spectra of **3** and **4**. The absorption bands at 252, 278, and 306 nm in the free tterpy are the same as those in **5** (Table 2) and have been assigned as tterpy(π)–tterpy(π*) transitions.[10] Although the free tterpy ligand does not absorb around 320–500 nm, **5** exhibits large absorption bands at 346 and 374 nm. As a consequence of complex formation, the electronic charges are delocalized, and thus the absorption bands at 346 and 306 nm in **5** can be assigned as tterpy(π)–tterpy(π*) transitions. The *para*-tolyl group attached to the terpy ring has the role of expanding the conjugation.

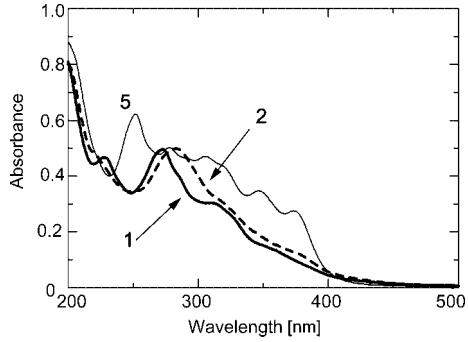

Figure 3. UV spectra of iridium complexes, **1**: $[IrCl(phen)(tterpy)]^{2+}$ (bold line), **2**: $[IrCl(dpphen)(tterpy)]^{2+}$ (broken line), and **5**: $[Ir(tterpy)_2]^{3+}$ (solid line) in $CH_3CN$ solution ($1.0 \times 10^{-5}$ M) at 25 °C.

## Electrochemistry

The electrochemical data obtained from cyclic voltammetry (CV) measurements are tabulated in Table 3. As for the complexes **5** and **6**, the first reductions occurred at the same potential (–0.67 V) and were assigned as tterpy/tterpy$^-$ and terpy/terpy$^-$ ligand-centered (LC) processes, respectively.[19] Two successive irreversible reductions of the ligand were then observed as shown in Figure 4. The similarity in

[a] $E_{pc}$ means the reduction peak potential. $\Delta E$ is a peak separation between the anodic and cathodic peak potentials. [b] Ref.[19] Potentials are vs. SCE.

these successive reduction potentials between **5** and **6** indicates that both of the reductions occur on the terpyridine ligand frame. Similarly, the first reduction waves of **1** and **2** were at –0.78 V, but the second and third ones appeared at different potentials, –1.06 and –1.27 V for **1** and –0.99 and –1.18 V for **2**. The slightly positive shift in the reduction potential of **2** compared to those in **1** is probably due to the effect of the dpphen ligand (electron-withdrawing ligand). Complexes **3** and **4** gave the second reduction waves at –1.06 and –1.00 V, respectively, as a result of the effect of the electron-donating dmbpy. From these results, both the first and the second reduction waves are assigned as tterpy-centered reductions.[21] Using an electron-donating ligand dmbpy the third reduction potential in **3** was cathodically shifted relative to the reduction potential of **4**, i.e. 140 mV, they can therefore be assigned as polybipyridine-centered reductions. The fourth reduction waves of **1**, **2**, **3**, and **4** occurred at around –1.68, –1.63, –1.70, and –1.65 V, respectively. These processes have also been assigned as tterpy ligand-centered reductions.[10]

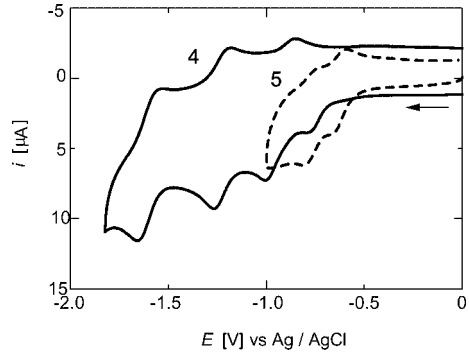

Figure 4. Cyclic voltammograms of **4**: $[IrCl(bpy)(tterpy)]^{2+}$ (bold line) and **5**: $[Ir(tterpy)_2]^{3+}$ (broken line) in $CH_3CN$ solution ($5.0 \times 10^{-4}$ M) at 25 °C with a scan rate of 100 mV $s^{-1}$.

The typical electrochemical behavior of iridium(III) polypyridine complexes are ligand-site oxidations and reductions. The highest occupied molecular orbital (HOMO) is localized on the ligand molecule, and the oxidative processes take place there. The six 5d lone-pair electrons on $Ir^{3+}$ are not involved in the HOMO, which leads to the absence of MLCT bands in the present six systems. The lowest unoccupied molecular orbital (LUMO) is also localized on the polypyridine ligand. In the case of the iridium complexes comprising a terpy and a bpy ligand, the LUMO is localized on the former ligand.[14]

## Emission Properties

The emission maxima and the excited-state lifetimes of the $[IrCl(L)(tterpy)]^{2+}$, $[Ir(tterpy)_2]^{3+}$, and $[Ir(terpy)_2]^{3+}$ systems are given in Table 4. Complex **1** has an intense phosphorescence band maximum at $\lambda_{em}$ = 537 nm ($\lambda_{ex}$ = 311 nm) in a solution at room temperature, whereas **2**, having a dpphen ligand, shows a slightly red shifted one at 539 nm (Figure 5). Complex **4** also displays strong phosphorescence at $\lambda_{em}$ = 542 nm ($\lambda_{ex}$ = 313 nm), whereas **3** with a dmbpy ligand exhibits a slight blue shift to 535 nm. It was found that the use of dpphen slightly extends the lifetime ($\tau$) of the $^3(\pi^*)$ excited state of the $Ir^{III}$ polypyridine complex ($\tau$ = 0.67 μs for **2**). However, in spite of the electron-withdrawing character of dpphen **2** gave a smaller emission quantum yield ($\phi$ = 0.096) relative to that of **1** ($\phi$ = 0.165). In complex **3**, the use of the dmbpy instead of the bpy ligand also resulted in the same lifetime as that of the π–π* transition in **3** ($\tau$ = 0.68 μs), and its emission quantum yield ($\phi$ = 0.110) was also similar to that of **4** ($\phi$ = 0.111). The emission spectrum of complex **5** shows a peak at 506 nm ($\lambda_{ex}$ = 305 nm) corresponding to the excited state of $^3$LC whenever the excitation is performed at 270 or 311 nm (Figure 5). This can be assigned to the phosphorescence from the tterpy* excited state (Table 4).[14]

Table 4. Emission properties and lifetimes of the $Ir^{III}$ complexes in $CH_3CN$ at 25 °C.

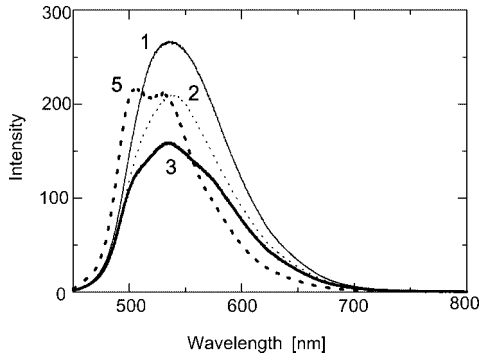

Figure 5. Emission spectra of iridium complexes in degassed $CH_3CN$ solution ($1.0 \times 10^{-5}$ M) at 25 °C. **1**: $[IrCl(phen)(tterpy)]^{2+}$ (bold line), **2**: $[IrCl(dpphen)(tterpy)]^{2+}$ (dotted line), **3**: $[IrCl(dpphen)(tterpy)]^{2+}$ (solid line), and **5**: $[Ir(tterpy)_2]^{2+}$ (broken line).

## DFT Calculations and Orbital Analyses

The experimental results obtained here suggest that the frontier orbitals (HOMO and LUMO) of the complexes are composed of the ligand π and π* components. The dπ components do not seem to be involved in the frontier orbitals. The absence of MLCT bands in Ir–terpyridine complexes has also been reported.[14,16] Apparently, the $Ir^{3+}$ cation works as a center of electrostatic stabilization in the complex, in addition to its role in spin-orbit coupling. In order to confirm the trend, DFT calculations were carried out for **5** and **6**. The geometries of $[Ir(tterpy)_2]^{3+}$ and $[Ir(terpy)_2]^{3+}$ were fully optimized in the closed-shell singlet and biradical triplet states. The calculated geometric values in the singlet state are comparable to the experimental ones determined in the present X-ray analyses (Table 5). Calculated metal–ligand bond lengths (angstroms) from singlet and triplet states (parentheses) for iridium complexes are shown in Figure S1. For instance, the calculated values for the Ir–N1 bond length (2.098 Å) and N1–Ir–N2 bond angle (80.2°) of **5** are comparable to the experimental values, 2.04 Å and 78.5°, determined from the X-ray structure, respectively. Calculated spin densities from the triplet state for iridium complexes are given in Figure S2. Table 6 exhibits the thirteen excited states of **6**, which result from low-energy one-electron transitions. The π–π* excitations occur between degenerate atomic orbitals of the tterpy ligand. The HOMO and HOMO–1 should be the frontier donor molecular orbitals, which were found not to be 5dπ but π MOs. The

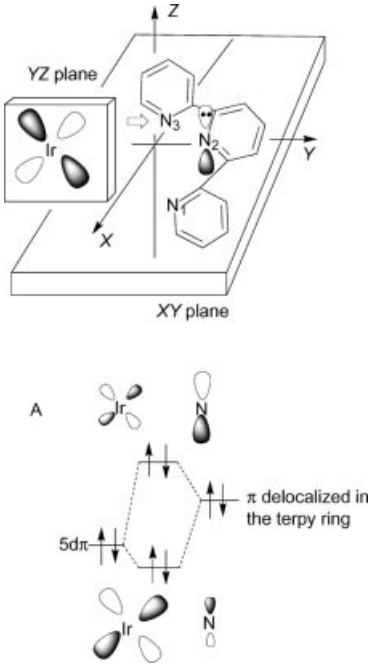
LUMO, LUMO+1, and LUMO+2 are the expected ligand π* orbitals. Thus, the low-energy one-electron transitions should be mainly HOMO→LUMO, LUMO+1, LUMO+2 and HOMO–1→LUMO, LUMO+1, LUMO+2, which are actually shown in Table 6.

The free terpy and tterpy molecules are nonplanar; the N–C–C–N dihedral angles are 32.1° and 32.02°, respectively. In complexes **5** and **6**, these molecules are fixed to be planar. The forced planarity raises the HOMO energy [–0.246 a.u. (nonplanar) → –0.238 a.u. (planar), by RHF/LANL2MB] and lowers the LUMO energy [+0.194 a.u. (nonplanar) → +0.184 a.u. (planar)]. That is, the forced planarity leads to a smaller HOMO–LUMO energy gap (the larger conjugation) and consequently to a larger $\lambda_{max}$ value. The question as to why MLCT bands are absent in the $Ir(terpy)_2^{3+}$ complex is considered. In the nearly octahedral geometry of $Ir(terpy)_2^{3+}$ the $5d_{z^2-(x^2+y^2)}$ and $5d_{x^2-y^2}$ atomic orbitals of Ir along the *x*, *y*, and *z* axes are vacant and the $5d_{xy}$, $5d_{yz}$, and $5d_{xz}$ (5dπ orbitals) are lone-pair orbitals. These lone-pair orbitals are low-lying (–1.657 a.u. by RHF/LAN2MB), because the metal center is $Ir^{3+}$. Scheme 1 illustrates the orbital mixing of the 5dπ-containing occupied MOs. In the Cartesian coordinate shown in Scheme 1, the HOMO of the terpy ring may overlap with the $5d_{xz}$ orbital. The shape of the HOMO is shown in Scheme 2. However, the mixing is very small because the 2pπ coefficient of N3 and N1 is only 0.172 in the terpy HOMO. The HOMO–1 of the terpy ligand may overlap with the $5d_{yz}$ orbital. But the nodal property inside 5dπ orbital again makes the overlap small (Scheme 3). The HOMO–2 cannot overlap with the $5d_{xz}$ (Scheme 4), and the HOMO–3 may overlap with the $5d_{xz}$ orbital. However, the overlap again suffers partial cancellation of Scheme 3. Thus, the MLCT pattern is absent owing to the low orbital energy of $Ir^{3+}$ and the ineffective 5dπ–π orbital overlap.



Scheme 1. One example of the orbital mixing that makes high-lying and 5dπ-containing occupied orbitals (A).

## Conclusions

Three new polypyridine iridium(III) complexes $[Ir^{II-I}Cl(L)(tterpy)](PF_6)_2$ were prepared {L = phen (**1**), dpphen (**2**), and dmbpy (**3**)}. Reference complexes $[Ir^{III}Cl(bpy)(tterpy)](PF_6)_2$ (**4**) and $[Ir^{III}(L)_2](PF_6)_3$ {L = tterpy (**5**) and terpy (**6**)} were also prepared and the X-ray structure of **5** was obtained. Cyclic voltammograms of all the $[Ir^{III}Cl(L)(tterpy)](PF_6)_2$ complexes showed that the first reduction occurred at around –0.67 V, which is attributed to the reduction of the tterpy ligand in $[Ir^{III}Cl(L)(tterpy)]^{2+}$. The electronic properties of complexes **5** and **6** were studied by using B3LYP functional calculations. Optimized geometries were compared to the experimentally observed structures. Excited singlet and triplet states were examined by using TDDFT. The calculated energies of the lowest singlet state of **6** are in good agreement with experimental absorption spectra. The LUMOs of all $[Ir^{III}Cl(L)(tterpy)]^{2+}$ complexes are composed of the π* system of the tterpy ligand. It was also found that $[Ir^{III}Cl(L)(tterpy)]^{2+}$ emits an intense phosphorescence at room temperature. The spectroscopic and electrochemical results were discussed comparatively. In the DFT calculations for the complexes **5** and **6** these molecules are fixed to be planar. The forced planarity raised the HOMO energy and lowered the LUMO energy, i.e., the forced planarity led to a smaller HOMO–LUMO energy gap (the larger conjugation) and consequently to a larger $\lambda_{max}$ value. However, the MLCT pattern was absent owing to the low orbital energy of $Ir^{3+}$ and the ineffective 5dπ–π orbital overlap.

## Experimental Section

**Reagents:** The materials used in the present experiments were of analytical reagent grade. The reagents are as follows: ammonium hexachloroiridate {$(NH_4)_3[IrCl_6]$, Aldrich}, bpy (Aldrich), dmbpy (Aldrich), phen (Aldrich), dpphen (Aldrich), tterpy (Aldrich), terpy (Aldrich), and potassium hexafluorophosphate ($KPF_6$, Wako). Tetrabutylammonium perchlorate {TBAP, $[(C_4H_9)_4N]ClO_4$, Aldrich} as a supporting electrolyte was purchased and used without further purification. $CH_3CN$ and *N*,*N*-dimethylformamide (DMF) used in spectroscopic and electrochemical studies were of spectroscopic grade obtained from Dojindo Laboratory. $[Ir(tterpy)_2](PF_6)_3$ (**5**) and $[Ir(terpy)_2](PF_6)_3$ (**6**) were prepared according to a previous method.[14] All other reagents and solvents were of guaranteed grade.

**Syntheses of the Mixed-Ligand Complexes $[IrCl(L)(tterpy)](PF_6)_2$ (1–4):** Syntheses of the complexes were undertaken by using a Mitsubishi Electric RR-12AF microwave oven (500 W, 2450 MHz) on medium-high power in a round-bottom flask fitted with a reflux condenser.[10,23] One target complex **3** (L = dmbpy), for example, was prepared by a sequential procedure with a ligand replacement. $(NH_4)_3[IrCl_6]$ (0.238 g, 0.500 mmol) and tterpy (0.161 g, 0.500 mmol) were mixed in ethylene glycol (15 mL). The suspended

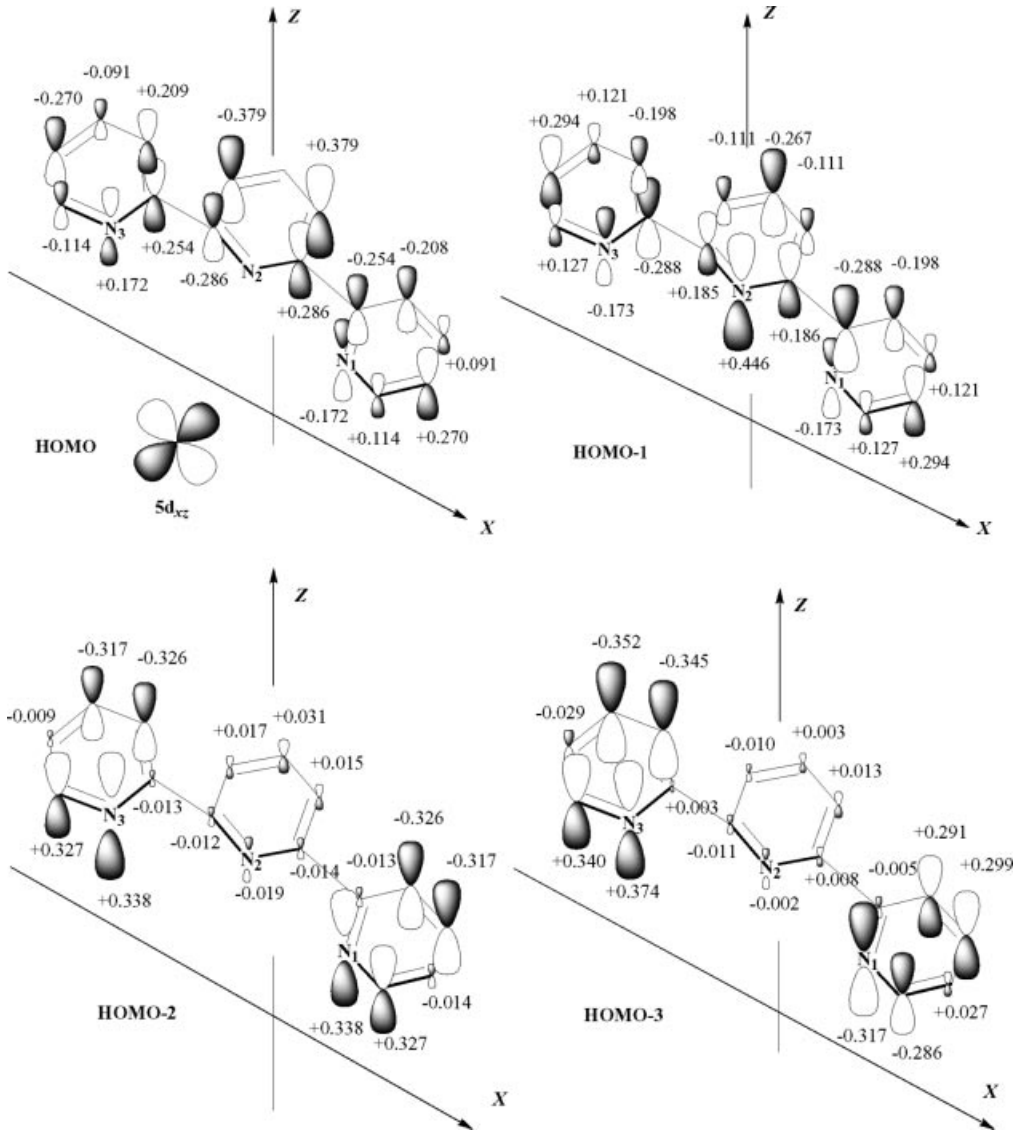
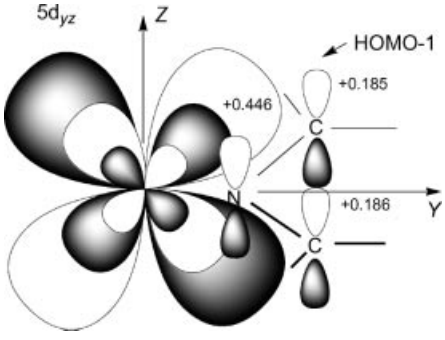
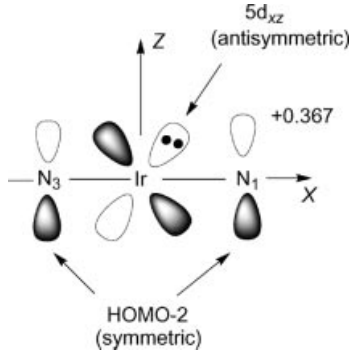


Scheme 2. MOs of the fixed planar terpyridine ligand.



Scheme 3. The overlap between the 5d$_{yz}$ of $Ir^{3+}$ and the HOMO–1 of terpy. The outer white-white overlap in the $Y > 0$, $Z > 0$ region is diminished by the inner shaded-white overlap.



Scheme 4. The overlap between the HOMO–2 and 5d$_{xz}$ is zero (out of phase).

mixture was heated under reflux for 3 min in a microwave oven under a purging nitrogen atmosphere. Next, dmbpy (0.092 g, 0.500 mmol) was added to the mixture, and the refluxing was continued for 12 min. The mixture was then cooled to room temperature. A saturated aqueous solution of $KPF_6$ (20 mL) was added to provide the counterion $PF_6^-$, and a light yellow product **3** began to precipitate and was collected by vacuum filtration. The residue was dissolved in a minimal amount of $CH_3CN$ and immediately precipitated in diethyl ether. The product was separated by vacuum filtration and was dried under a vacuum. The purity of the yellow

ESI MS {[IrCl(bpy)(tterpy)](PF$_6$)$_2$ in CH$_3$CN, positive}: $m/z$ = 353.53 {[M – (PF$_6$)$_2$]$^{2+}$ requires 353.62}, 851.51 ([M – PF$_6$]$^+$ requires 852.22).

**Measurements:** Electronic absorption spectra were recorded at room temperature in CH$_3$CN solution with a Shimadzu UV-2550 spectrophotometer. ESI-MS spectra were obtained by an Applied Biosystems Mariner spectrometer. All NMR spectra were recorded with a JEOL JNM-AL400 FT spectrometer. $^1$H NMR chemical shift values are reported in ppm with reference to the internal standard TMS. Cyclic voltammograms were measured with an ALS-610B electrochemical analyzer fitted with a three-electrode system consisting of a glassy carbon working electrode, a platinum auxiliary electrode, and a Ag/AgCl reference electrode (0.21 V vs. NHE at 3.5 M KCl). CV experiments were performed on DMF solution of the complexes ($5.0 \times 10^{-4}$ M) and 0.050 M TBAP under nitrogen at 25 °C with a scan rate of 100 mV s$^{-1}$. The emission lifetimes were measured in nitrogen-equilibrated CH$_3$CN solutions using a Horiba single-photon counting system (NAES-500). The emission quantum yields for the iridium complexes were determined in CH$_3$CN at room temperature relative to those of a solution containing [Ru(bpy)$_3$]$^{2+}$ and having the same absorbance. The emission quantum yields for the iridium complexes were determined by comparing the integrated emission spectra and using $\phi$ = 0.062 for the standard.[24]

**Crystallographic Data Collection and Structure Determination of 5:** Crystals for the X-ray diffraction study were mounted on glass fibers. All of the measurements were made with a Rigaku R-Axis-Rapid Imaging Plate diffractometer with graphite monochromated Mo-$K_\alpha$ radiation (see Table 7).[25] Indexing was performed from three oscillations. The camera radius was 127.40 mm. Readout was performed in the 0.100 mm pixel mode. The structures were solved by direct methods and were refined on $F^2$ by full-matrix least-squares methods using SHELXL-97.[26] The non-hydrogen atoms were refined anisotropically by the full-matrix least-squares method. All hydrogen atoms were anisotropically refined. CCDC-619118 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Methods:** DFT calculations of **5** and **6** were performed using the Gaussian 98 program package.[27] The Becke three parameters hybrid exchange and the Lee–Yang–Parr correlation functionals (B3LYP) were used.[28,29] Geometries of **5** and **6** in the singlet closed-shell and triplet biradical states were optimized by the R(U)B3LYP/LANL2MB method.[30] Absorption spectra were computed as vertical excitations from the $S_0$ PES using the TDDFT approach as implemented in the Gaussian 98 program. A double-$\xi$ quality LANL2DZ basis was used for the iridium atom,[31] and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the other atoms were described by a split valence Pople basis plus one polarization and one diffuse function (6-31+G*).[32]

# A Trinuclear Aqua Cyano-Bridged Ruthenium Complex $[\{(\eta^5\text{-}C_5H_5)(PPh_3)_2Ru(\mu\text{-}CN)\}_2RuCl_2(PPh_3)(H_2O)]PF_6$: Synthesis, Characterization and Crystal Structure

**Viatcheslav Vertlib,[a] João Figueira,[a] José Mesquita,[a] João Rodrigues,*[a] Kalle Nättinen,[b][‡] and Kari Rissanen*[b]**

**Keywords:** Ruthenium / Trinuclear complexes / Bridging ligands / X-ray structure / Metal–metal interactions / Chain structures

The organometallic trinuclear aqua cyano-bridged complex $[\{(\eta^5\text{-}C_5H_5)(PPh_3)_2Ru(\mu\text{-}CN)\}_2RuCl_2(PPh_3)(H_2O)]PF_6$ (**1**), in which the fragment $[RuCl_2(PPh_3)(H_2O)]$ acts as a bridge and an acceptor group between the two terminal cyclopentadienyl ruthenium cyano moieties, was isolated in moderate yield from the reaction of $[(\eta^5\text{-}C_5H_5)(PPh_3)_2RuCN]$ with $[RuCl_2(PPh_3)_3]$ in THF. To the best of our knowledge, compound **1** is one of the few examples of a trinuclear array of ruthenium fragments bridged by the nitrogen atom of the –C≡N– group (Ru–C≡**N**–Ru′–**N**≡C–Ru) with a Ru-coordinated water molecule. The new aqua complex was structurally characterized by FTIR, $^1H$, $^{13}C$, and $^{31}P$ NMR spectroscopy, mass spectrometry, elemental analysis, single-crystal X-ray diffraction, and cyclic voltammetry. The title complex crystallizes in a triclinic unit cell $a$ = 17.3477(6) Å, $b$ = 17.8551(5) Å, $c$ = 18.2460(7) Å, $\alpha$ = 95.693(2)°, $\beta$ = 111.648(2)°, and $\gamma$ = 97.839(2)° in the space group $P\bar{1}$ with $Z$ = 2.

## Introduction

Because of their interesting properties (such as conductivity, magnetic and spectral properties), di- and trinuclear complexes with bridging cyanide ligands have been widely studied and have been the object of a large number of publications in the last decades.[1] However, the number of trinuclear complexes reported is less than half of that reported for dinuclear cyanide-bridged complexes, because of difficulties in controlling the synthesis and the ease with which coordination polymers are formed.[2] The bonding characteristics of the cyanide anion make it a good donor at both its C and N atoms[3] – the C atom has a greater affinity for electron-rich metals (such as $M^{II}$), while the N atom for electron-deficient metals (such as $M^{III}$). The ability of the cyanide anion to bridge two metal centers and to mediate electronic communications between metal atoms (e.g. electron transfer)[4] led us recently to prepare and determine the X-ray structure of the dinuclear ruthenium cyano-bridged organometallic complex $[(\eta^5\text{-}C_5H_5)(PPh_3)_2Ru(\mu\text{-}CN)\text{-}Ru(PPh_3)_2(\eta^5\text{-}C_5H_5)]PF_6$.[5] As a natural extension of our previous work, we explored the properties of the –C≡N– bridging group in trinuclear complexes with linear arrays of ruthenium fragments (Ru–C≡**N**–Ru′–**N**≡C–Ru). Vahrenkamp et al.[4c,6] have systematically studied such trinuclear complexes, focusing mainly on the effects of the geometry and the oxidation state at the central metal and of the orientation of the bridges (cyanide vs. isocyanide) on the electronic communication between two terminal metallic fragments. Furthermore, while water is a very common ligand in classical Werner-type coordination chemistry, in 18-electron organometallic complexes coordinated water is relatively rare. This has two main reasons: (a) in organometallic compounds, the metal centers do not display either "hard" or "soft" character, (b) the oxygen atom has a hard donor capacity and binds weakly to most low-valent transition metals like $Ru^{II}$.[7] These labile complexes are frequently used as precursors for catalysts in organic reactions and in biological applications, viz. aqua complexes of ruthenium have proved to be effective for ring-opening metathesis polymerization (ROMP)[8] and as anti-tumor compounds.[9] In this paper, we report the preparation, structural characterization, and X-ray structure of a rare example of an organometallic trinuclear cyano-bridged ruthenium complex with Ru-coordinated water.

## Results and Discussion

The title organometallic trinuclear aqua complex was readily synthesized by treatment of the electron rich $Ru^{II}$ precursor unit $[(\eta^5\text{-}C_5H_5)(PPh_3)_2RuCN]$ with 1 equiv. $[RuCl_2(PPh_3)_3]$ in THF in the presence of $NH_4PF_6$ to yield $[\{(\eta^5\text{-}C_5H_5)(PPh_3)_2Ru(\mu\text{-}CN)\}_2RuCl_2(PPh_3)(H_2O)]PF_6$ (**1**). During the reaction, $[RuCl_2(PPh_3)_3]$, a well-known ruthenium catalyst for hydrogenation catalysis and an important starting material for the preparation of different types of complexes, dissociated extensively in solution[10] and the labile phosphanes were substituted to the central ruthenium unit $[RuCl_2(PPh_3)(H_2O)]$ in complex **1**. The resulting air stable, dark green-blue solid was recrystallized from a mixture of *n*-pentane/dichloromethane/diethyl ether and yielded dark blue crystals suitable for X-ray analysis. The compound was successfully characterized by FTIR, $^1H$, $^{13}C$, and $^{31}P$ NMR spectroscopy, mass spectrometry, elemental analysis, and cyclic voltammetry.

The UV/Vis spectrum of **1** (ca. $2\times10^{-4}$ M) was obtained in dichloromethane, chloroform, and dimethylformamide at room temperature and shows intense absorptions in the 250–420 nm region that arise from d–d transitions in the ruthenium moieties that are overlapped by the expected transitions in the aromatic ligands in the UV region. The mono- and the dinuclear compound $[(\eta^5\text{-}C_5H_5)(PPh_3)_2RuCN]$[5] and $[(\eta^5\text{-}C_5H_5)(PPh_3)_2Ru(\mu\text{-}CN)Ru(PPh_3)_2(\eta^5\text{-}C_5H_5)]PF_6$,[5] respectively, as well as the starting material $[RuCl_2(PPh_3)_3]$[10b] also show these absorption bands in their spectra. Additionally, a new broad band in the upper limit of the visible region with a tail in the NIR and a maximum at 658 nm (15200 $cm^{-1}$, $\varepsilon_{max}$ = 3937 $M^{-1}cm^{-1}$) was also observed (see Figure 1). This was interpreted according to the solvent dependence, bandwidth at half height, shape, and Hush theoretical formalism ($\Delta\nu_{1/2}° = 5925\ cm^{-1}$)[11] as a metal-to-metal charge transfer (MMCT) transition of low intensity from the terminal units $[(\eta^5\text{-}C_5H_5)(PPh_3)_2RuCN]$ to the central ruthenium fragment $[RuCl_2(PPh_3)(H_2O)]$.[4a,6e] A similar assignment has been made by Matsui et al.[12] in a related trinuclear system $[(NC)(bpy)_2Ru\text{-}CN\text{-}Ru(H_2dcbpy)_2\text{-}NC\text{-}Ru(bpy)_2(CN)]^+$ (dcbpy = 4,4′-dicarboxy-2,2′-bipyridine).

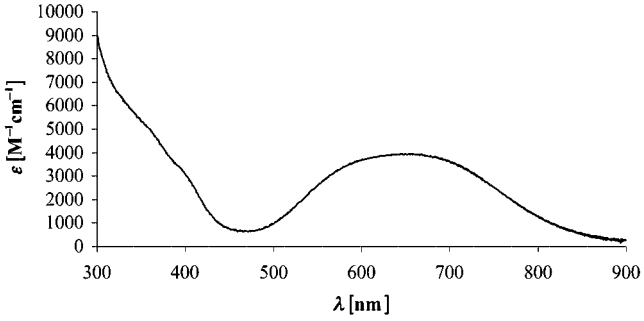

Figure 1. UV/Vis absorption spectrum of **1** (ca. $2\times10^{-4}$ M) recorded in $CH_2Cl_2$ at room temperature.

The IR spectrum shows two broad bands for the coordinated water at 3056 ($\upsilon_{OH}$) and 1635 $cm^{-1}$ ($\delta_{OH}$)[13] and two sharp bands for the counterion $PF_6^-$ at 841 and 520 $cm^{-1}$. As expected for a symmetrical cyanide arrangement in trinuclear complexes,[6d] compound **1** shows evidence of only one stretching frequency for the C≡N bonds in the IR spectrum at 2052 $cm^{-1}$, which occurs at a lower value than those for the mononuclear $[(\eta^5\text{-}C_5H_5)(PPh_3)_2RuCN]$ and dinuclear $[(\eta^5\text{-}C_5H_5)(PPh_3)_2Ru(\mu\text{-}CN)Ru(PPh_3)_2(\eta^5\text{-}C_5H_5)]PF_6$ complexes[5] (2072 and 2070 $cm^{-1}$, respectively). Usually a shift to higher frequency in the position of the $\nu_{CN}$ band is expected upon formation of the cyanide-bridged complex because of the kinematic effect (i.e. the restriction of the CN motion by simultaneous coordination of both N and C atoms).[6e] In the present case, a slight weakening of the CN bond can be observed with a band shift of about –20 $cm^{-1}$ relative to the mono- and dinuclear compounds. In spite of the fact that the central ruthenium fragment is a much stronger electron acceptor than the terminal ruthenium centers, this lowering of the position of the $\nu_{CN}$ band for the linear array Ru–C≡N–Ru′–N≡C–Ru is probably due to the π-back-donation from the terminal ruthenium to the CN-π* orbitals as well as due to the effect of the electron-donating aqua ligand bonded to the central ruthenium fragment, as was observed for the complex $[RuCl_2(PEt_3)_2(CO)(H_2O)]$.[14] In support of this observation, the $^1H$ NMR spectrum of the trinuclear complex **1** shows a general deshielding effect when compared with the mononuclear complex $[(\eta^5\text{-}C_5H_5)(PPh_3)_2RuCN]$; only one singlet of 10 protons for the two cyclopentadienyl ligands, which are deshielded by about 1 ppm, and a singlet at $\delta$ = 3.73 ppm for the coordinated water are observed in the spectrum of **1**. The $^{13}C\{^1H\}$ NMR spectrum shows a similar deshielding effect of about 5 ppm for the carbon signal of the CN bond. In the $^{31}P\{^1H\}$NMR spectrum, only two signals of different resonance intensities are observed; the four times more intense signal at $\delta$ = 30.0 ppm indicates the equivalency of the four phosphorus nuclei of the terminal ruthenium moieties, and the less intense signal at $\delta$ = 17.8 ppm is attributed to the phosphorus atom of the central ruthenium fragment and occurs more downfield relative to the signal arising from the basal $PPh_3$ group in the five-coordinate structure $[RuCl_2(PPh_3)_3]$ {$\delta(^{31}P)$ = 24.1 ppm}.[15] The NMR results show that the $[(\eta^5\text{-}C_5H_5)(PPh_3)_2RuCN]$ moieties are in a *trans* arrangement, which is also verified by the X-ray analysis (Figure 2). The redox behavior of complex **1** was investigated by cyclic voltammetry in the potential range 0–2.5 V (versus Ag/AgCl) with $CH_2Cl_2$ as solvent and *n*-$Bu_4NPF_6$ as the supporting electrolyte. No conclusive information was obtained because of the irreversible character of the observed processes (see Supporting Information).

The central ruthenium fragment is surrounded by six ligands in a slightly distorted octahedral coordination environment with O(48) *trans* to P(94) (Table 2, Figure 2). The Ru–Cl distances (2.327–2.348 Å) are in accordance with the normal, well-established range for $Ru^{III}$ chloride complexes.[16] The central Ru(2)–P(94) bond length (2.292 Å) is slightly shorter than the corresponding bond lengths at the terminal $Ru^{II}$ centers, which is expected for a relatively hard $Ru^{III}$ center. The Ru–$H_2O$ distance (2.215 Å) agrees well

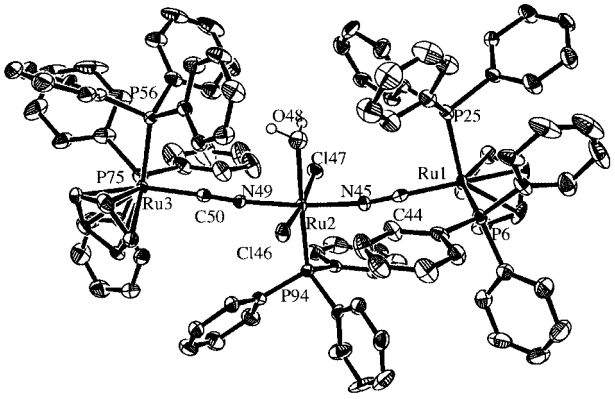

Figure 2. ORTEP[18] drawing at the 50% probability level for the cation of **1**. Solvent molecules and hydrogen atoms, except for the coordinated water, are omitted for clarity.

with the values in similar structural fragments.[16] The $H_2O$ ligand occupies a neat cavity formed by the bulky $PPh_3$ ligands [P(25) and P(56)]. One of the hydrogen atoms of water shows a weak O–H···π interaction, in which the H(48A)···C(68) distance is 2.52 Å. The Ru–C and Ru–N bond lengths in the terminal pseudo-tetrahedral ruthenium moieties are shorter than those in the dinuclear compound $[(\eta^5\text{-}C_5H_5)(PPh_3)_2Ru(\mu\text{-}CN)Ru(PPh_3)_2(\eta^5\text{-}C_5H_5)]PF_6$ and in the parent compound $[(\eta^5\text{-}C_5H_5)(PPh_3)_2RuCN]$, and are similar to those in the tetranuclear compound $Cl(CH_3CN)(PPh_3)Ru\{CNCuCl\}\{NCRu(PPh_3)_2Cp\}_2$.[17] A variation in the π-back-donation of the $[(\eta^5\text{-}C_5H_5)(PPh_3)_2$-Ru] unit can be observed on going from the mono- to the trinuclear complex. The two chlorine ligands are bent towards the water ligand with a Cl(47)–Ru(2)–Cl(46) angle of 171.39°. The cyclopentadienyl ligands are *trans* to each other, and the torsion angle [Ct(1)–Ru(1)–Ru(3)–Ct(2)] between the centroids of the cyclopentadienyl ligands and the metal centers is 123.8°. The most striking feature of the complex is the large deviation from linearity of the Ru–CN–Ru–NC–Ru chain; the Ru(1)–Ru(2)–Ru(3) angle is 164.8°. This is caused by the sterically bulky $PPh_3$ ligand that induces a steric strain on the other side of the complex – this strain is compensated by the curvature of the M–CN–M–NC–M chain (see Supporting Information). Crystallographic data for complex **1** are collected in Table 1, and the most relevant geometric parameters are shown in Table 2.

## Conclusions

We have prepared and fully characterized the new organometallic trinuclear ruthenium aqua complex $[\{(\eta^5\text{-}C_5H_5)(PPh_3)_2Ru(\mu\text{-}CN)\}_2RuCl_2(PPh_3)(H_2O)]PF_6$ and isolated it in moderate yield by using a relatively simple synthetic strategy and trivial starting materials. The structure of the complex was determined by X-ray diffraction, confirming the structural assignments obtained from the spectroscopic data. The isolated organometallic trinuclear aqua compound represents one of the few examples of a Ru–C≡**N**–Ru′–**N**≡C–Ru array with a metal–metal interaction across the cyanide bridges and probably over more than one CN linkage. Because of the steric strain imposed by the large $PPh_3$ ligand at the central ruthenium, the complex shows a marked deviation from the expected linearity of the Ru–C≡**N**–Ru′–**N**≡C–Ru array. The lability of the aqua ligand can lead to a convenient synthetic route for the preparation of other tri- and tetranuclear cyanide-bridged com-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plexes. Further studies on this organometallic trinuclear ruthenium aqua complex are in progress in order to explore fundamental properties such as its reactivity in selected transformations, for example in ring-opening metathesis polymerization (ROMP).

## Experimental Section

**General:** All the experiments were carried out under vacuum or a nitrogen atmosphere by use of standard vacuum line Schlenk-tube techniques. All the solvents used were distilled and dried according to the usual published methods.[19] The compounds [($\eta^5$-$C_5H_5$)($PPh_3$)$_2$RuCN][5,20] (**2**) and [$RuCl_2(PPh_3)_3$][21] (**3**) were prepared following methods described in the literature, and the spectroscopic data (UV/Vis and/or NMR) agreed with that reported. The UV/Vis spectra were recorded with a GBC-Cintra 40 UV/Vis spectrometer using 1 cm optical path quartz cells with freshly prepared solutions (ca. $2 \times 10^{-4}$ M) in dichloromethane (dcm), chloroform, and dimethylformamide (dmf). The spectrum is presented as $\lambda_{max}$ or shoulder (sh.) [nm] ($\varepsilon_{max}$ [$M^{-1}cm^{-1}$]). The mass spectra (TOF-MS) were recorded with a Micromass LCT; peaks are reported as *m*/*z* (assignment, relative intensity). IR spectra were recorded by using a Nicolet Avatar 360 FTIR spectrometer, calibrated with polystyrene, with KBr pellets; only significant bands are cited in the text. $^1$H, $^{13}$C{$^1$H} and $^{31}$P{$^1$H} NMR spectra were recorded with a Bruker AM500 spectrometer at 500.13 MHz ($^1$H), 125.76 MHz ($^{13}$C), and 202.46 MHz ($^{31}$P); probe temperature (30 °C) in $CDCl_3$. The $^1$H chemical shifts ($\delta$), reported in parts per million (ppm) downfield, are referenced to residual chloroform ($\delta$ = 7.24 ppm). The $^{13}$C{$^1$H} chemical shifts are reported in ppm relative to the carbon resonance of the deuterated NMR solvent: $CDCl_3$ ($\delta$ = 77.00 ppm). The $^{31}$P{$^1$H} NMR spectra are reported in ppm downfield from the external standard 85% $H_3PO_4$ at $\delta$ = 0.00 ppm. Melting points were obtained on a Leica Gallen instrument and were not corrected.

**Preparation of [{($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Ru(μ-CN)}$_2$$RuCl_2$($PPh_3$)($H_2O$)]-$PF_6$ (1)**: To a mixture of [($\eta^5$-$C_5H_5$)($PPh_3$)$_2$RuCN] (0.100 g, 0.14 mmol) and [$RuCl_2(PPh_3)_3$] (0.138 g, 0.14 mmol) in THF (30 mL) was added $NH_4PF_6$ (0.114 g, 0.7 mmol). The mixture was stirred at 60 °C for 3 h, then at 20 °C for 22 h. The color of the reaction mixture changed slowly from black-red to dark (almost black) green-blue. The solution was evaporated to dryness in vacuo. Dichloromethane (10 mL) was then added. The precipitate of ammonium salts was removed by cannula filtration, and the filtrate was evaporated to dryness and dried in vacuo. The resulting dark green-blue solid was recrystallized from a mixture of *n*-pentane/dichloromethane/diethyl ether (3 mL/6 mL/0.5 mL) to obtain dark blue crystals. Yield: 85 mg (59%). M.p. 184–187 °C. FTIR (KBr): $\upsilon_{OH}$ 3056 (br.), $\upsilon_{CN}$ 2052 (m), $\delta_{OH}$ 1635 (br.), $\upsilon_{PF6}$ 841 (s), 520 (s) $cm^{-1}$. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 7.57–7.30 (m, 75 H, Ph), 5.30 (s, 10 H, $C_5H_5$), 3.73 (s, $H_2O$) ppm. $^{13}$C{$^1$H} NMR (126 MHz, $CDCl_3$): $\delta$ = 146.7 (CN), 133.6–127.3 (Ph) ppm. $^{31}$P{$^1$H} NMR (202 MHz, $CDCl_3$): $\delta$ = 30.0 (s, 4 P, $PPh_3$), 17.8 (s, 1 P, $PPh_3$), –143.7 (m, $PF_6$) ppm. $C_{102}H_{87}Cl_2F_6N_2OP_6Ru_3$ (2030.74): calcd. C 60.3, H 4.3, N 1.4; found C 59.7, H 4.4, N 1.6. TOF-MS ($ES^+$): *m*/*z* (%) = calcd. 429.0, found 429.2 (84) [($\eta^5$-$C_5H_5$)$Ru(PPh_3)]^+$; calcd. 626.1, found 625.4 (100) $[Ru(PPh_3)_2]^+$; calcd. 1151.1, found 1151.7 (50) [($\eta^5$-$C_5H_5$)($PPh_3$)$_2$Ru(μ-CN)$RuCl_2(PPh_3)]^+$; calcd. 1868.2, found 1868.2 (75) $[M - PF_6 - H_2O]^+$; calcd. 1886.2, found 1886.2 (10) $[M - PF_6]^+$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon_{max}$, $M^{-1}cm^{-1}$) = 658 (3937).

**Single Crystal X-ray Diffraction:** Data were recorded with a Nonius Kappa Apex II diffractometer by using graphite monochromatized Mo-$K_\alpha$ radiation [$\lambda$(Mo-$K_\alpha$) = 0.71073 Å] and a temperature of 173.0 ± 0.1 K. The data were processed with Denzo-SMN v0.97.638.[22] The structure was solved by direct methods (SHELXS-97),[23] and refinements based on $F^2$ were made by full-matrix least-squares techniques (SHELXL-97).[24] Graphics program ORTEP3 for Windows[18] was executed through the WinGX-suite.[25] The hydrogen atoms were calculated to their idealized positions with isotropic temperature factors (1.2 or 1.5 times the C temperature factor) and as riding atoms. The water hydrogen atoms were located from the difference Fourier map, but refined as riding atoms with isotropic temperature factors 1.5 times the O temperature factor.

In the structure, only one of the approximately 3.5 dichloromethane (dcm) molecules was found to be non-disordered and was refined with full occupancy, one full dcm molecule was disordered over four sites, and one dcm molecule was refined with a one third occupancy. Residual electron density showed high peaks, which could not be modeled with any chemically reasonable model (they probably arise because of severely disordered dcm molecules) and were treated as Cl atoms with partial occupancy.

CCDC-626456 for **1** contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting information** (see footnote on the first page of this article): The cyclic voltammogram and van der Waals and ball-and-stick representations of compound **1** are available.

## Acknowledgments

The presented research was supported by Fundação para a Ciência e a Tecnologia (Portugal) through a FEDER funded project POCTI/CTM/41495/2001 (V. V. and J. R.) and by the sabbatical research grant SFRH/BSAB/632/2006 (J. R.). J. R. thanks the University of Jyväskylä for supporting his stay as a visiting professor at the Nanoscience Center, Department of Chemistry. The Academy of Finland (Proj. no. 205729) is gratefully acknowledged for a research grant (K. R. and K. N.). We also wish to thank Spec. Lab. Technicians Mirja Lahtiperä and Reijo Kauppinen for their help in running the MS and NMR spectra.

# Unusual T4(1) Water Chain Stabilized in the One-Dimensional Chains of a Copper(II) Coordination Polymer

Yi Jin,[a] Yunxia Che,[a] Stuart R. Batten,[b] Pangkuan Chen,[a] and Jimin Zheng*[a]

**Keywords:** Water chain / Self assembly / One dimensional / Coordination polymers

A novel T4(1) water chain in a new $Cu^{II}$ coordination polymer, $\{[Cu(C_4H_6N_2)_2(C_4H_2O_4)]\ (H_2O)_3\}_n$ (**1**, where $C_4H_6N_2$ = 2-methylimidazole, $C_4H_2O_4$ = maleate), has been synthesized and structurally characterized by single-crystal X-ray diffraction. Thermogravimetry, infrared spectroscopy, elemental analysis, and magnetic analysis have also been used to characterize **1**. Complex **1** crystallizes in the trigonal space group $P3_221$, and the 1-D chains composed of cyclic water tetramers play an important role in stabilizing the overall polymeric structure. Furthermore, this 1-D water chain presents an unusual association mode of water molecules.

## Introduction

Water in all its forms exhibits a mesmerizing collection of properties and functions. Because of its crucial role for life, its abundance in nature, and its importance in so many technological processes, many chemists, biochemists, and biologists study water in an attempt to achieve a comprehensive understanding of its properties.[1] The present upsurge in studying water clusters is aimed not only at understanding the "anomalous" behavior of bulk water but also in probing its possible roles in the stabilization and functioning of biomolecules[2] and in designing new materials.[3] Although considerable attention has been devoted to the theoretical and experimental investigation of water clusters, including a variety of oligomers and polymers consisting of the basis cyclic water subunits, they are still not fully understood. It is this realization that has prompted extensive investigations of water structures in recent years. Some discrete water clusters $(H_2O)_n$,[4–23] where $n$ = 2–10, 12, 16 and 18, in various crystal hosts at room temperature have been reported. Further attention has also been paid to the infinite one- and two-dimensional water morphologies, which structurally lie between small water clusters and bulk water/ice, while investigations of these clusters that are interlinked to form a larger network is much less[24–35] and infinite water chains consisting of cyclic water tetramers are rare.[26]

On the other hand, the investigations of novel metal–organic hybrid compounds have attracted considerable interest in recent years, not only because of their intriguing structural motifs and promising photochemical, electrochemical, and magnetic properties, but also their because of their potential applications in catalysis, medicine and host–guest chemistry.[36–42] It is noteworthy that the dicarboxylates such as malonate, fumarate, and 1,4-benzenedicarboxylate have been widely used in constructing novel different dimensional metal–organic hybrid compounds.[43] In contrast to the ligands mentioned above, maleate is rarely used. Of further interest is that few cases of such coordination polymers, especially those mixed with the other chelating N-donor imidazole ligands, have been document so far.

In this work we report the preparation, structural characterization, and properties of an unusual 1D water chain consisting of cyclic water tetramers in a new 1D dicarboxylate-bridged Cu(II) polymer, $\{[Cu(C_4H_2O_4)(C_4H_6N_2)_2](H_2O)_3\}_n$ (**1**, where $C_4H_6N_2$ = 2-methylimidazole, $C_4H_2O_4$ = maleate); the water chains are linked with the 1-D polymer through hydrogen-bonding interactions to form a 3D network structure. We believe that the water structure demonstrated herein brings to light yet another novel mode of the cooperative association of water molecules, and this discovery is helpful in improving the modeling of some of unexplained properties of water and in understanding better the structure and behavior of water molecules in biological systems.[25]

## Results and Discussion

### Crystal Structures

Single-crystal structure analysis reveals that compound **1** consists of a polymer $\{[Cu(C_4H_6N_2)_2(C_4H_2O_4)](H_2O)_3\}_n$, which crystallizes in the chiral space group $P3_221$. The asymmetric unit contains one $Cu^{II}$ ion, two 2-methylimid-

azole ligands, one maleate, and three independent water molecules (Figure 1). Each copper(II) ion lies on a twofold axis and exhibits a Jahn–Teller distorted $CuN_2O_4$ octahedral geometry. Two nitrogen atoms [N(2) and N(2A)] from two monodentate 2-methylimidazole groups and two carboxylate oxygen atoms [O(1) and O(1A)] from the maleate ligand occupy the equatorial sites, and the Cu–N bonds [1.9579(15) Å] are somewhat shorter than the Cu–O bonds [2.0283(12) Å]. The axial sites are occupied by the second carboxylate oxygen atom of each maleate [Cu(1)–O(2) = 2.4833(14) Å]; the chelating bite of the carboxylate group leads to a significant distortion from true octahedral geometry [O(2)–Cu(1)–Cu(2A) = 143.59(7)°]. The neighboring $Cu^{II}$ ions are connected through the dicarboxylate bridges to form a regular infinite 1D chain with a Cu···Cu distance of 6.977 Å (Figure 2). Simultaneously, the chains are interconnected though two types of hydrogen bonds to form a three-dimensional network, which involve the equatorial carboxyl oxygen atom O(1) of maleate and the O(3) atom of a water molecule [O(3)···O(1) = 2.879 Å] and the uncoordinated nitrogen atom N(1) from the 2-methylimidazole group and the carboxyl oxygen atom O(2) of maleate; the N(1)··· O(2) distance of 2.771 Å [$-x + y + 1$, $-x + 1$, $z + 1/3$] is shorter than those reported previously [N···O = 2.851(19) and 3.088(18) Å].[10a]

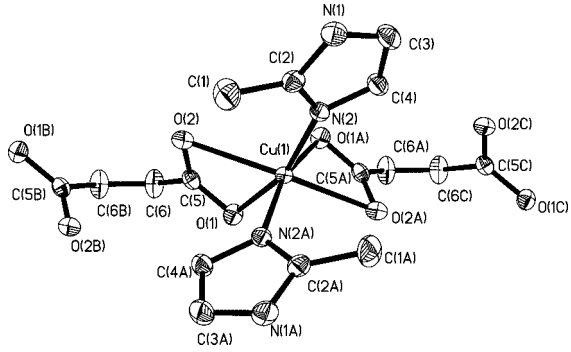

Figure 1. An ORTEP view of complex **1**, with selected atom numbering. The hydrogen atoms and uncoordinated water molecules are omitted for clarity.

Figure 2. Infinite 1D network of **1**. The hydrogen atoms and dissociated water molecules are omitted for clarity.

The most striking feature is that the structure contains extensive hydrogen bonding between the uncoordinated water molecules [O(3), O(4)] to form infinite 1D water chains containing cyclic water tetramers (Figure 3). The average O···O distance in the water chain is 2.790 Å, which is shorter than those observed in liquid water (2.854 Å) and comparable to those in the ice phase (2.77–2.84 Å).[32] However, this distance is a little longer than 2.768 Å[10a] and shorter than 2.95 Å[26] relative to the reported plane tetramer O···O distances.[26] The individual tetrameric clusters differ from the corner-sharing tetrameric and discrete tetrameric water clusters reported previously.[10,26] Two O(4) molecules form one side of the tetramer, and two O(3) molecules form the opposite side. The chains lie about the $3_2$ screw axes, and the tetramers are connected through the shared O(4) corners to give chains with a T4(1) symmetry[44] (Figure 4). The O(3) molecules lie on the periphery of the chain, and form hydrogen bonds with the coordinated O(1) carboxylate atoms of the coordination polymer chains (O···O = 2.879 Å); the $3_2$ screw axis means that each water chain is hydrogen bonded in this way to three adjoining coordination polymer chains. On a more local level, the two O(3) molecules within each tetramer bond to different coordination chains, whereas the two coordinated O(1) atoms in each Cu coordination environment form hydrogen bonds with the O(3) molecules belonging to two different (but adjoining) tetramers. Figure 5 displays the packing structure parallel to the *ab* plane of complex **1**. The water chains act as a "glue" to link the coordination polymer chains, forming an overall 3D structure.[32] Each water tetramer unit links two polymer chains, and each water chain links three 1D polymer chains through hydrogen bonds between the water molecules and the carboxyl groups. The T4(1) water chain is located in six polymer chains, and this plays a complementary role in stabilizing the network structure.

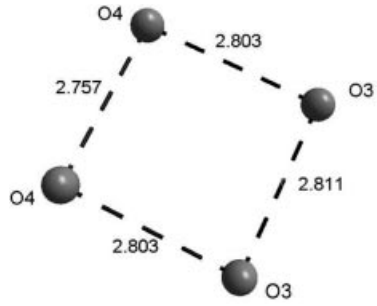

Figure 3. Tetrameric water cluster [O3···O3 = 2.811 Å, O4···O4 = 2.757 Å, O3···O4 = 2.803 Å].

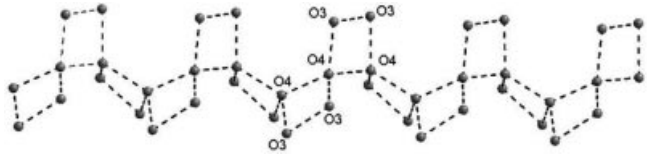

Figure 4. Hydrogen-bonding motif of the self-assembled infinite chain of water molecules.

The thermal stability of the water cluster was determined by thermogravimetric analysis (TGA) (see Figure S1 in the Supporting Information). TGA was performed at a heating rate of 10 °C/min with the single-crystal samples of **1**. Thermal analysis of the complex shows that the onset of water loss begins at 24 °C, and complete loss of water occurs within 200 °C. A 12.13-% weight loss was observed, which is almost equivalent to a loss of 2.7 water molecules – this value is lower than the calculated weight content of three water molecules (13.64%). In the infrared spectrum of **1**,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

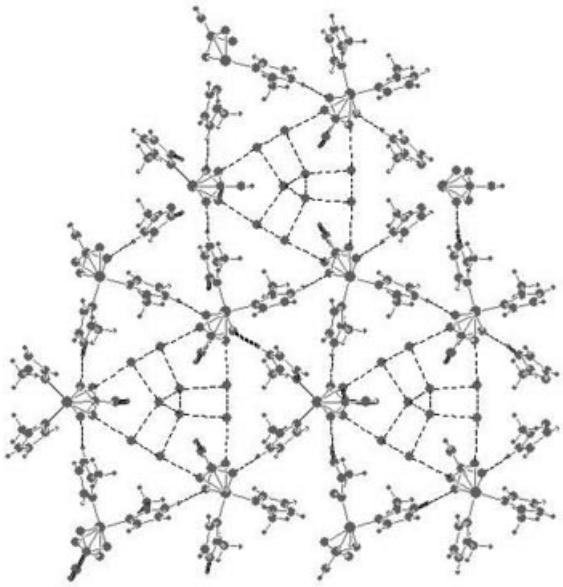

Figure 5. Packing diagram along the *c* axis of the supramolecular system for **1**.

the stretching frequency of the O–H bonds of the water cluster is observed as a band at about 3200 and 1631 $cm^{-1}$. The IR spectrum of ice shows the O–H stretching at 3220 $cm^{-1}$, while this stretching vibration in liquid water appears at 3490 and 3280 $cm^{-1}$.[16–18,29] This suggests that the water cluster in **1** shows an O–H stretching vibration similar to that of ice. It effectively proves that the O···O distance in the water chain is comparable to those in the ice phase (2.77–2.84 Å). In addition, there are several absorption bands observed at higher frequencies, 3133 $cm^{-1}$ and 3051.3 $cm^{-1}$, which are characteristic of the 2-MeIm groups. One strong peak corresponding to the $\nu(COO^-)$ vibration is observed at 1549 $cm^{-1}$ (see Figure S2 in the Supporting Information). The structural consistency and phase purity of compound **1** was confirmed by X-ray powder diffraction patterns (see Figure S3).

### Magnetic Properties

Magnetic measurement of **1** was carried out with a magnetic field of 500 Oe in the temperature range 2–300 K, and the results were presented in the form of a $\chi_M T$ vs. $T$ plot and $\chi_M^{-1}$ vs. $T$ plot (Figure 6), where $\chi_M$ is the corrected magnetic susceptibility per asymmetric $[Cu(C_4H_2O_4)(C_4H_6N_2)_2]$ unit.

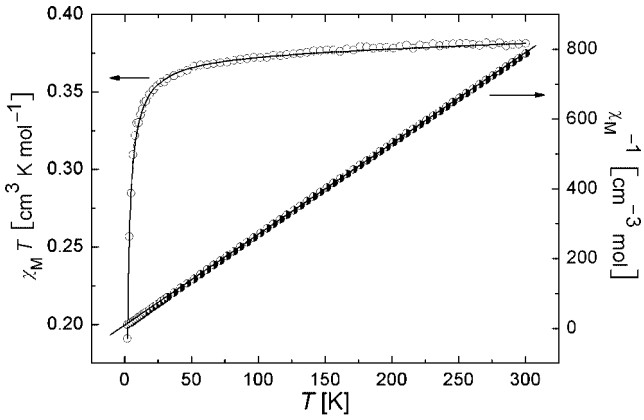

Figure 6. Plot of $\chi_M T$ vs. T and $\chi_M^{-1}$ vs. $T$ for **1**.

Magnetic susceptibility data per Cu unit for **1** can be fitted by the Curie–Weiss law: $\chi_M = C/(T - \theta)$ above 2 K, and this gives a Curie constant $C$ of 0.38 $cm^3 mol^{-1} K$ and a Weiss constant $\theta$ of –4.7 K. The $C$ value is slightly larger than that expected (0.375 $cm^3 mol^{-1} K$) for one $Cu^{II}$ ($S$ = 1/2) ion. The negative Weiss constant indicates that there are weak antiferromagnetic interactions between the $Cu^{II}$ ions through the maleate carboxyl bridge. The $\chi_M T$ value at room temperature is 0.38 $cm^3 mol^{-1} K$ and decreases gradually with decreasing temperature to a value of 0.35 $cm^3 mol^{-1} K$ at 25 K. The value then decreases sharply down to a minimum of 0.19 $cm^3 mol^{-1} K$ at 2 K, as shown Figure 6; this behavior is characteristic of an antiferromagnet.

The magnetic properties have been analyzed through the Bonner–Fisher result as shown in Equation (1), with $\chi = J/kT$ ($J$ is the intrachain magnetic coupling parameter). We take into account a proportion $\rho$ of a monomeric impurity, of which the susceptibility is assumed to follow the Curie law $Ng^2\beta^2S(S + 1)\rho/3kT$. The best fit obtained using a nonlinear regression analysis leads to $J$ = –1.54 $cm^{-1}$, $g$ = 2.05, $R = 7.105395 \times 10^{-5}$, and $\rho$ = 0.048; $R$ is the agreement factor defined as $\sum i[(\chi_M T)_{obs}(i) - (\chi_M T)_{calcd.}(i)]^2 / \sum[(\chi_M T)_{obs}(i)]^2$, $TIP$ is temperature-independent paramagnetism.

## Conclusions

An unusual 1D water chain with cyclic tetramers in a new 1D copper(II) coordination polymer chain has been successfully synthesized and structurally characterized. It is to be noted that the 1D water chain extends in an unusual association mode and is hydrogen bonded to surrounding 1D polymer chains to give a 3D network, thus highlighting

$$\chi = \frac{N g^2 \beta^2}{kT} \times \frac{0.25 + 0.074975x + 0.075235x^2}{1.0 + 0.9931x + 0.172135x^2 + 0.757825x^3} \times (1 - \rho) + Ng^2\beta^2 S(S+1)\rho / 3kT + TIP \quad (1)$$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the indispensable contribution to the stability of the coordination polymer frameworks. The unusual T4(1) water chain will enrich the water cluster family, and brings to light a novel mode for the cooperative association of water molecules and enhances the understanding of the 1D structural aspects of bulk water.

## Experimental Section

**Materials:** All reagents for syntheses were purchased from commercial sources and used as received.

**Physical Measurements:** Elemental analyses (C, H, N) were performed with an Elementar Vario EL instrument. Infrared spectra (KBr pellets) were measured on a MAGNA-IR 560 FTIR spectrometer in the 400–4000 $cm^{-1}$ region. Thermogravimetric analysis (TGA) was investigated with a standard TG-DTA analyzer under a flow of nitrogen at a heating rate of 10 °C$min^{-1}$ for all measurements. Magnetic studies were performed with MPMS SQUID and Maglab 2000 magnetometers in the temperature range 2–300 K. Powder diffraction data were collected with a Rigaku D/max-RC Diffractometer by using a Cu target ($\lambda$ = 1.54060 Å) operated at 45 KV and 180 mA.

**Synthesis of $\{[Cu(C_4H_2O_4)(C_4H_6N_2)_2](H_2O)_3\}_n$ (1):** $Cu(OAc)_2 \cdot H_2O$(0.20 g, 1 mmol), maleic acid (0.12 g, 1 mmol) and 2-methylimidazole (0.16 g, 2 mmol) in the molar ratio of 1:1:2 were dissolved in distilled water (25 mL). The pH value was then adjusted to about 7 with 2 M NaOH. The resulting solution was heated at 60 °C for 1 hr while stirring. The solvent was allowed to evaporate slowly at room temperature; small light blue single crystals appeared at the bottom of the cup. $C_{12}H_{20}CuN_4O_7$: C 36.41, H 5.09, N 14.15; found C 37.26, H 4.95, N 14.48%.

**X-ray Crystallography:** Single-crystal X-ray diffraction data for complex **1** was collected with a R-AXIS RAPID IP diffractometer, by using the $\omega$-scan technique with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods and refined on $F^2$ by full-matrix least-squares with SHELXTL-97.[45] Non-hydrogen atoms were refined with anisotropic temperature parameters and the hydrogen atoms of the ligands were refined as rigid groups; the hydrogen atoms of water were not found or assigned. Crystal data of **1**: $M$ = 395.86 g$mol^{-1}$, trigonal, space group $P3_221$, $a$ = 14.868(3), $b$ = 14.868(3), $c$ = 6.9774(14) Å, $\gamma$ = 120°, $V$ = 1335.8(5) $Å^3$, $Z$ = 3, $R_1$ = 0.0223, $wR_2$ = 0.0592, $d_{calcd.}$ = 1.476 g$cm^{-3}$, $\mu$ = 1.266 $mm^{-1}$, $F(000)$ = 615. A total of 12859 reflections were collected, of which 2049 unique reflections were used. The selected bond lengths and angles of **1** are presented in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] for **1**.[a]

# The Iminophosphorane-Phosphane $Ph_2PC_6H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2$: Synthesis, Reactivity, and Catalytic Activity in Suzuki Cross-Coupling and the Homogeneous Hydrogenation of Olefins

**Ramalingam Venkateswaran,[a] Maravanji S. Balakrishna,*[a] and Shaikh M. Mobin[b]**

**Keywords:** Monoimination / Monophosphane / Iminophosphorane-phosphane / Staudinger reaction / Suzuki cross-coupling

The iminophosphorane-phosphane ligand $Ph_2PC_6H_4OC_6H_4$-$PPh_2$=NP(O)$(OPh)_2$ (**1**) has been synthesized by partial imination of bis[2-(diphenylphosphanyl)phenyl] ether (DPEphos) with phosphoryl azide $(PhO)_2P(O)N_3$. A similar reaction in a 1:2 stoichiometry affords the bis(iminophosphorane) O-$\{C_6H_4PPh_2$=NP(O)$(OPh)_2\}_2$ (**2**). The chalcogen derivatives O$\{C_6H_4P(E)Ph_2\}_2$ [E = S (**3**) and Se (**4**)] and $Ph_2P(E)$-$C_6H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2$ [E = S (**5**) and Se (**6**)] are also synthesized by treating DPEphos and **1** with elemental sulfur and selenium, respectively. The mononuclear complexes *trans*-[$MCl_2\{\kappa^1$-*P*-$Ph_2PC_6H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2\}_2$] [M = Pt (**7**) Pd (**8**)] and *trans*-[Rh(CO)Cl{$\kappa^1$-*P*-$Ph_2PC_6$-$H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2\}_2$] (**12**) are prepared by the reaction of **1** with $[Pt(COD)Cl_2]$, $[Pd(COD)Cl_2]$, and $[\{Rh(CO)_2$-$Cl\}_2]$, respectively. Treatment of **1** with $[Pd_2(dba_3)]$ (dba = dibenzylideneacetone) affords the mononuclear complex $[Pd^0\{\kappa^2$-*P,O*-$Ph_2PC_6H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2\}_2]$ (**9**) in which ligand **1** coordinates through its P and O centers in a $\kappa^2$-*P,O* chelating fashion. The monocoordinated $Au^I$ complex [AuCl{$\kappa^1$-*P*-$Ph_2PC_6H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2\}$] (**10**) has been prepared by the reaction of **1** and $[AuCl(SMe_2)]$ and its structure has been confirmed by X-ray crystallography. The reaction of **1** with $[\{Rh(COD)Cl\}_2]$ in the presence of AgOTf affords the cationic $Rh^I$ complex *cis*-[Rh(COD)$\{\kappa^2$-*P,O*-$Ph_2PC_6H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2\}$][OTf] (**11**). The catalytic activity of the $Pd^0$ complex **9** has been investigated in Suzuki cross-coupling reactions. Homogeneous catalytic hydrogenation of olefins has also been studied using the cationic $Rh^I$ complex **11**.

## Introduction

There has been considerable interest in recent years in the chemistry of iminophosphorane-phosphane ligands due to their interesting coordination chemistry and applications in organic syntheses such as aza-Wittig reactions.[1] These iminophosphorane-phosphane ligands have been synthesized by selective imination of bis(phosphanes) in a Staudinger reaction.[2–4] Various types of organic azides have been employed for the synthesis of such ligands, including $R'_3SiN_3$ and $R'_2P(O)N_3$.[5–11] The monoimination of bis(phosphanes) with phosphoryl azide $R'_2P(O)N_3$ leads to the formation of the hemilabile iminophosphorane-phosphane ligands $R_2P$-X-P$\{$=NP(O)$R'_2\}R_2$ (X = divalent bridging group). These ligands have the ability to offer different coordination modes such as $\kappa^1$-*P*, $\kappa^2$-*P,N*, $\kappa^2$-*P,O*, and $\kappa^3$-*P,N,O*, and its hemilabile behavior has been successfully utilized in homogeneous catalysis such as hydrogenation of olefins,[12] olefin oligomerization,[13] transfer hydrogenation of ketones,[14,15] and cross-coupling of secondary amines with aryl halides.[16] Surprisingly, their involvement in Suzuki cross-coupling reaction still remains unexplored.

van Leeuwen and co-workers[17] and others[18] have extensively studied the coordination chemistry and the catalytic utility of the bis[2-(diphenylphosphanyl)phenyl] ether $Ph_2PC_6H_4OC_6H_4PPh_2$. The complexes of this large-bite bis(phosphane) are found to be very effective in catalyzing a variety of organic transformations.[19–21]As a continuation of our work in designing new phosphorus-based ligands in order to explore their coordination chemistry[22–29] and catalytic activity,[30–33] we report herein the synthesis, coordination chemistry, and catalytic activity of the iminophosphorane-phosphane $Ph_2PC_6H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2$ (**1**) derived from $Ph_2PC_6H_4OC_6H_4PPh_2$.

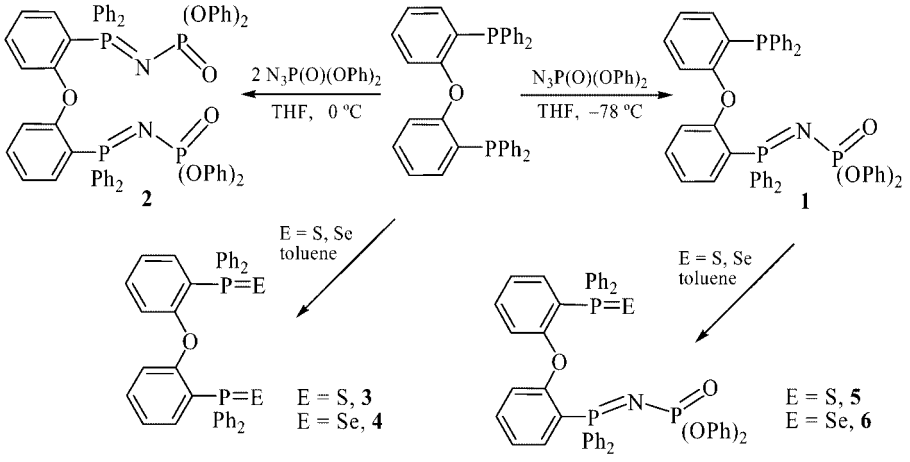
## Results and Discussion

### Synthesis of the Ligand and Chalcogen Derivatives

Reaction of the phosphoryl azide $(PhO)_2P(O)N_3$ with bis[2-(diphenylphosphanyl)phenyl] ether (DPEphos) (1:1 molar ratio) in thf at –78 °C affords the iminophos-



Scheme 1.

phorane-phosphane $Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2$ (**1**) in good yield. A similar reaction in a 2:1 molar ratio at 0 °C affords the bis(iminophosphorane) $O\{C_6H_4PPh_2{=}NP(O)(OPh)_2\}_2$ (**2**). Compounds **1** and **2** are moderately air stable and highly soluble in dichloromethane, diethyl ether, acetonitrile, and toluene.

The $^{31}P\{^1H\}$ NMR spectrum of ligand **1** shows three well-separated phosphorus signals with equal relative intensities. The terminal phosphoryl $P^V_{[O]}$ ($\delta$ = –10.5 ppm) and iminophosphorane $P^V_{[N]}$ ($\delta$ = 10.4 ppm) signals appear as simple doublets with a $^2J_{P,P}$ value of 37.7 Hz. The trivalent phosphorus appears as a singlet at $\delta$ = –20.1 ppm. The EI mass spectrum supports the structure as it shows the molecular ion peak at *m*/*z* 786.47 $[M + H]^+$. The $^{31}P\{^1H\}$ NMR spectrum of **2** shows two doublets of equal intensity [$\delta$ = 10.9 ($P^V_{[N]}$) and –10.6 ppm ($P^V_{[O]}$); $^2J_{P,P}$ = 40.4 Hz] with chemical shift values comparable to those described for analogous compounds of the type $[RNPPh_2NP(O)(OPh)_2]_2$.[8,10,11] The EI mass spectrum of compound **2** shows the molecular ion peak at *m*/*z* 1033.57 $[M + H]^+$. Treatment of DPEphos and **1** with elemental sulfur and selenium results in the isolation of the bis-chalcogenides $O\{C_6H_4P(E)Ph_2\}_2$ [E = S (**3**) and Se (**4**)] and the thio- and selenoyl derivatives $Ph_2P(E)$-$C_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2$ [E = S (**5**) and Se (**6**)], respectively, in good yield. The $^{31}P\{^1H\}$ NMR spectra of compounds **3** and **4** show single resonances at $\delta$ = 39.1 and 29.4 ppm ($^1J_{Se,P}$ = 734.1 Hz), respectively. The EI mass spectrum of **4** shows the molecular ion peak at *m*/*z* 699.04 $[M + H]^+$. The $^{31}P\{^1H\}$ NMR spectra of **5** and **6** show three resonances, similar to the parent compound **1**. The $^{31}P$ resonances due to the chalcogenide phosphorus centers in **5** and **6** show a considerable downfield shift and appear at $\delta$ = 37.7 and 27.6 ppm, respectively, whereas the chemical shift values of the other two phosphorus centers are almost the same as those of compound **1**. The selenoyl derivative **6** shows a $^1J_{Se,P}$ coupling of 744 Hz. The mass spectra of compounds **5** and **6** support their structure, with molecular ion peaks at *m*/*z* 818.15 $[M + H]^+$ and 866.13 $[M + H]^+$, respectively (Scheme 1).

## Synthesis of Metal Complexes

The reactions of **1** with $[M(COD)Cl_2]$ (M = Pt, Pd), irrespective of the stoichiometry, afford the mononuclear complexes *trans*-$[MCl_2\{\kappa^1$-*P*-$Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}_2]$ [M = Pt (**7**) and Pd (**8**)]. These complexes were therefore prepared in good yield from the reagents in 2:1 molar ratio. The $^{31}P\{^1H\}$ NMR spectroscopic data are very diagnostic for characterizing the complexes. The $^{31}P$ chemical shift due to the coordinated $PPh_2$ group is shifted considerably downfield as a result of coordination whereas the resonances due to the $P^V_{[N]}$ and $P^V_{[O]}$ groups do not exhibit such a large change in their chemical shift and $^2J_{P,P}$ values, thereby indicating their non-involvement in the complex formation. The $^{31}P\{^1H\}$ NMR spectrum of complex **7** shows a singlet at $\delta$ = 10.3 ppm corresponding to the coordinated phosphorus with a $^1J_{Pt,P}$ value of 2642 Hz and two doublets at $\delta$ = 11.4 (P=N) and –10.6 ppm (P=O) with a $^2J_{P,P}$ value of 37.9 Hz. The low $^1J_{Pt,P}$ value suggests a *trans* geometry for complex **7**.[34] The EI mass spectrum of complex **7** shows the molecular ion peak at *m*/*z* 1838.01 $[M + H]^+$. The $^{31}P\{^1H\}$ NMR spectrum of complex **8** shows one singlet at $\delta$ = 14.2 ppm for the coordinated phosphorus and two doublets at $\delta$ = 11.7 and –10.6 ppm ($^2J_{P,P}$ = 38.1 Hz) for the other two phosphorus centers.

The reaction of **1** with $[Pd_2(dba)_3]$ in a 2:1 molar ratio in toluene affords the $Pd^0$ complex **9** in good yield (Scheme 2). The $^{31}P\{^1H\}$ NMR spectrum of $[Pd\{\kappa^2$-*P*,*O*-$Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}_2]$ (**9**) shows three resonances at $\delta$ = 23.6, 11.7, and –7.8 ppm for the $PPh_2$, $P^V_{[N]}$, and $P^V_{[O]}$ centers, respectively. The reaction of **1** with $[AuCl(SMe_2)]$ in $CH_2Cl_2$ affords $[AuCl\{\kappa^1$-*P*-$Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}]$ (**10**) in quantitative yield as a colorless crystalline solid. The $^{31}P\{^1H\}$ NMR spectrum of complex **10** shows three well-separated signals with equal intensities. The coordinated phosphorus center exhibits a singlet at $\delta$ = 19.0 ppm; there is no major change in the chemical shift values for the other two phosphorus centers with respect to ligand **1**. The elemental analysis and

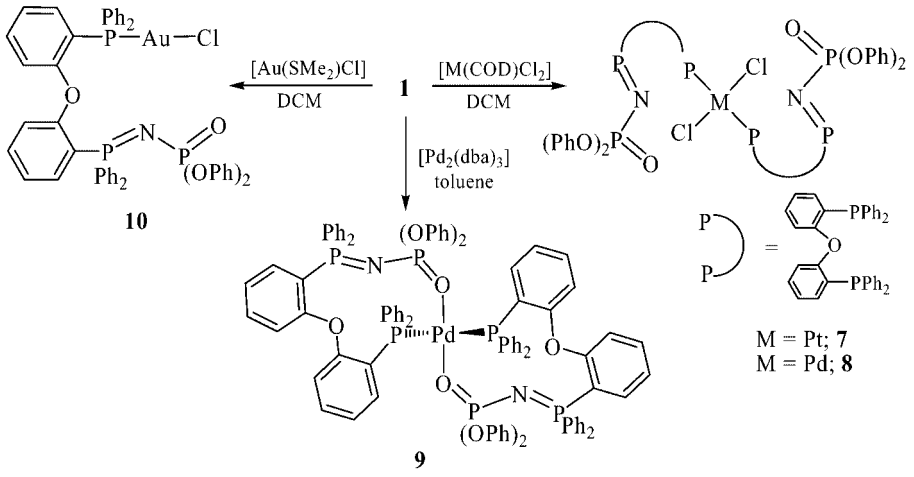

Scheme 2.

mass spectrum of complex **10** are in accordance with the proposed structure, which was further confirmed by single-crystal X-ray diffraction studies.

The mononuclear rhodium complex *cis*-[Rh(COD){κ²-*P*,*O*-$Ph_2PC_6H_4OC_6H_4PPh_2$=NP(O)$(OPh)_2$}][OTf] (**11**) was prepared by the reaction of **1** with [{Rh(COD)Cl}$_2$] followed by the addition of AgOTf in an equimolar ratio. The $^1$H NMR spectrum of **11** confirmed the presence of a cyclooctadiene group, which exhibits broad signals at around $\delta$ = 1.27–2.37 ppm for the four $CH_2$ groups and two doublets at $\delta$ = 2.90 and 5.13 ppm for the olefin protons with $^2J_{Rh,H}$ values of 119.2 and 115.6 Hz, respectively. The formation of an 11-membered chelate ring by binding of the P and O atoms of the phosphoryl group was confirmed by its $^{31}$P NMR spectroscopic data. The $^{31}$P{$^1$H} NMR spectrum of **11** consists of three resonances with equal intensities. The coordinated phosphorus appears as a doublet at $\delta$ = 12.9 ppm with a $^1J_{Rh,P}$ value of 149.3 Hz while the iminophosphorane and phosphoryl groups show mutually coupled doublets centered at $\delta$ = 8.8 and –11.1 ppm, respectively, with a $^2J_{P,P}$ value of 39 Hz. The doublet due to the phosphoryl group shows an additional $^2J_{Rh,P}$ coupling of 6.6 Hz, thus indicating the coordination of the phosphoryl oxygen to the rhodium center, similar to an analogous compound reported in the literature.[5b] The EI mass spectrum of cationic complex **11** shows the molecular ion peak at *m*/*z*

Table 1. Summary of $^{31}$P{$^1$H} NMR data for compounds **1**–**12** [$\delta$ in ppm and *J* in Hz].

| Compound | $\delta_{PPh_2}$ | $\delta_{Ph_2P=N}$ | $\delta_{(PhO)_2P=O}$ | $^2J_{P,P}$ |

996.2 $[M - OTf]^+$. The reaction of $[\{Rh(CO)_2Cl\}_2]$ with **1** in a 1:2 molar ratio affords *trans*-$[Rh(CO)Cl\{\kappa^1$-*P*-$Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}_2]$ (**12**), as is evident from the $^{31}P\{^1H\}$ NMR, mass, and elemental analysis data. The $^{31}P\{^1H\}$ NMR spectrum of complex **12** consists of three doublets. The doublet at $\delta$ = 22.5 ppm with a $^1J_{Rh,P}$ coupling of 140 Hz is due to the coordinated phosphorus whereas the remaining two doublets at $\delta$ = 11.3 and –10.6 ppm are assigned to $P^V_{[N]}$ and $P^V_{[O]}$, respectively, with a $^2J_{P,P}$ coupling of 37.9 Hz. The mass spectrum of **12** exhibits the molecular ion peak at *m*/*z* 1701.1 $[M - Cl]^+$. The IR spectrum of **12** shows $\nu_{CO}$ at 1958 $cm^{-1}$ (Table 1 and Scheme 3).

## Crystal Structure of Complex 10

A perspective view of the molecular structure of complex **10** with the atom numbering scheme is shown in Figure 1. Crystal data and details of crystal structure determination are given in the Experimental Section, while the selected bond lengths [Å] and bond angles [°] are displayed in Table 2. The P(1)–Au(1)–Cl(1) bond angle of 177.81(7)° indicates that the gold is in a slightly distorted linear geometry. The Au(1)–Cl(1) and Au(1)–P(1) bond lengths are 2.284(1) and 2.230(1) Å, respectively, and are close to the reported values for $[O(C_6H_4PPh_2AuCl)_2]$.[18b] There is an intermolecular interaction between O(2_j) and H(34), as is evident from the bond length of 2.402 Å (less than the sum of the van der Waal's radii)[35] and the C(34)–H(34)–O(2_j) bond angle of 172°.

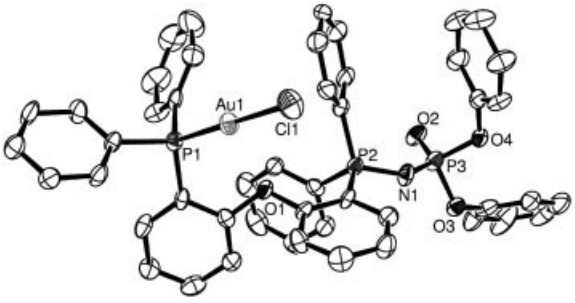

Figure 1. Molecular structure of $[AuCl\{\kappa^1$-*P*-$Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}]$ (**10**). All hydrogen atoms have been omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level.

Table 2. Selected bond lengths [Å] and bond angles [°] for **10**.

| Bond lengths | | Bond angles | |
|---|---|---|---|
| Au(1)–Cl(1) | 2.284(1) | Au(1)–P(1)–C(1) | 112.90(2) |
| Au(1)–P(1) | 2.230(1) | P(1)–Au(1)–Cl(1) | 177.81(7) |
| P(2)–N(1) | 1.586(5) | N(1)–P(3)–O(2) | 122.40(3) |

## Catalytic Studies

### *Suzuki Cross-Coupling Reactions*

Although iminophosphorane-phosphane ligands have been employed in homogeneous catalysis, there are no re-

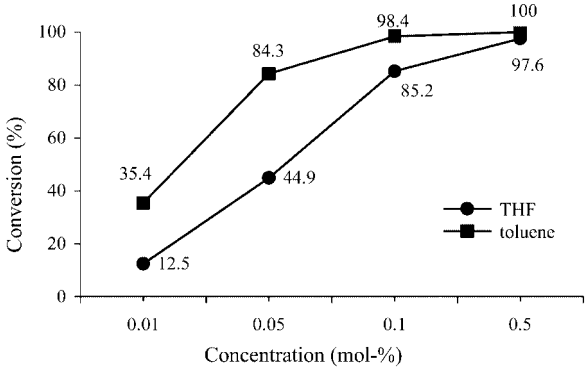

Figure 2. Influence of catalyst concentration on the coupling of 4-bromobenzaldehyde (1.0 mmol) and phenylboronic acid (1.5 mmol). Conditions: $K_3PO_4$ (2.0 mmol), toluene/thf (10 mL), *t* = 15 min, *T* = 70 °C.

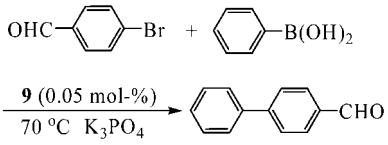
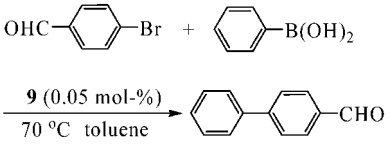
Table 3. Effect of solvent on the coupling of 4-bromobenzaldehyde with phenylboronic acid.



| Entry | Solvent | Base | Time [h] | Conversion [%][a] |
|---|---|---|---|---|
| 1 | tetrahydrofuran | $K_3PO_4$ | 2 | 84.6 |
| 2 | dioxane | $K_3PO_4$ | 2 | 63.2 |
| 3 | dimethylformamide | $K_3PO_4$ | 2 | 100 |
| 4 | toluene | $K_3PO_4$ | 2 | 100 |
| 5 | acetonitrile | $K_3PO_4$ | 2 | 63.7 |
| 6 | methanol | $K_3PO_4$ | 2 | 69.8 |

[a] Conversion to coupled product determined by GC, based on aryl halides; average of two runs.

Table 4. Effect of base on the coupling of 4-bromobenzaldehyde with phenylboronic acid.



| Entry | Base | Solvent | Time [h] | Conversion [%][a] |
|---|---|---|---|---|
| 1 | $Cs_2CO_3$ | toluene | 2 | 100 |
| 2 | $K_3PO_4$ | toluene | 2 | 100 |
| 3 | $K_2CO_3$ | toluene | 2 | 97.1 |

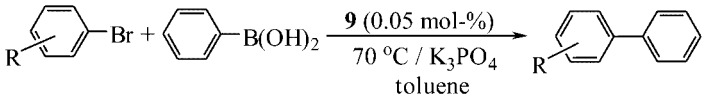
ports of their application in Suzuki cross-coupling reactions. Interestingly, the iminophosphorane-phosphane ligand **1** shows excellent activity for Suzuki cross-coupling reactions with high turnover numbers at very low catalyst concentrations. The $Pd^0$ complex **9** effectively catalyzes the Suzuki cross-coupling reactions of a variety of aryl bromides and phenylboronic acids to afford the desired biaryls in remarkably high yields. These reactions were studied systematically to find the optimal conditions to afford biaryls in good yield. It is important to achieve good yields using minimum amounts of catalyst, therefore we examined the effect of catalyst loading on the coupling between 4-bromobenzaldehyde and phenylboronic acid (Figure 2 and Tables 3, 4, and 5). Complete conversion of the starting materials into 4-phenylbenzaldehyde was achieved with 0.5 mol-% of catalyst in 1 h or 0.05 mol-% in 2 h, therefore a concentration of 0.05 mol-% was selected as the optimal concentration for catalytic loading.

Table 5. Suzuki cross-coupling of aryl halides (1 mmol) with phenylboronic acid (1.5 mmol) catalyzed by **9** in the presence of $K_3PO_4$ (2 mmol) in toluene (10 mL).



| Entry | Substrate | Product | Time (h) | Conversion[a] (%) | Yield (%) |
|---|---|---|---|---|---|
| 1 |  |  | 2 | 100 | 99 |
| 2 |  |  | 2 | 99.5 | 99 |
| 3 |  |  | 2 | 100 | 98 |
| 4 |  |  | 4 | 94.8 | 90 |
| 5 |  |  | 8 | 90.7 | 89 |

The above investigations showed that the reaction rate and the catalyst activity are significantly influenced by the base and the solvent employed. Various solvents were tested in the coupling reaction with $K_3PO_4$ as base. Toluene and dmf allowed complete conversion of 4-bromobenzaldehyde into 4-phenylbenzaldehyde. Considering the ease of separation of the product, toluene was chosen as the best solvent.

Inorganic bases such as $Cs_2CO_3$, $K_3PO_4$, $K_2CO_3$, and NaOH gave excellent yields whereas the reaction proceeded very slowly with TMEDA. Considering the high activity and cost effectiveness, $K_3PO_4$ was chosen as the base.

Under these optimized reaction conditions, a wide array of aryl bromides react with phenylboronic acid to provide the cross-coupling products in excellent yields (Table 5). The palladium(0) catalyst **9** is very effective in Suzuki cross-coupling reactions and exhibits remarkable tolerance towards both "deactivating" electron-donating substituents (Table 5, entries 7, 9 and 10) and sterically encumbering *ortho* substituents (Table 5, entry 5) on aryl bromides. The catalytic activity of **9** is found to be better than that of the catalyst $[Pd_2(dba)_3]$ + [1,1′-bis(diphenylphosphanyl)ferrocene (dppf)], which catalyzes the coupling of 4-bromoacetophenone and phenylboronic acid in toluene at 70 °C (2 h) in 86.5% yield,[36a] whereas it is similar to that of the parent compound DPEphos. However, DPEphos shows better activity only at higher temperature and higher catalytic loading.[36b]

### Catalytic Hydrogenation of Styrene

The cationic $Rh^I$ complex **11** was tested as a catalyst for the hydrogenation of styrene. The catalyst (0.0005 mol-%) shows effective conversions under mild conditions (4 atm of $H_2$ at room temperature). The conversion rate was monitored periodically by gas chromatography and the product formation was confirmed by $^1H$ NMR spectroscopy. The results are displayed in Figure 3.

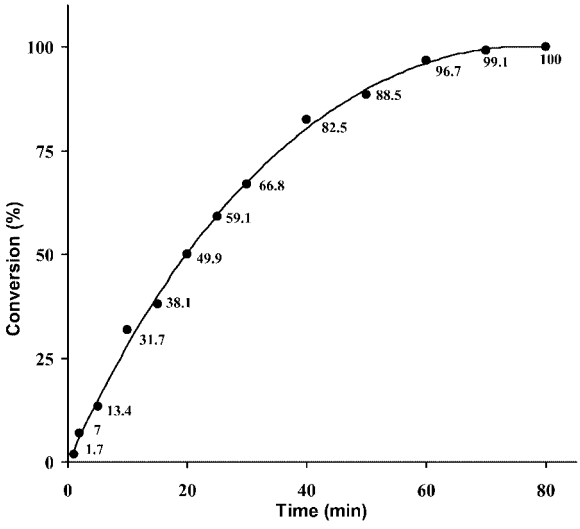

Figure 3. Hydrogenation of styrene. Conditions: styrene (1.0 mmol), $Et_3N$ (0.1 mmol), **11** (0.0005 mol-%), thf (20 mL); $H_2$ pressure: 4 atm; room temperature; stirring speed: 400 rpm.

The turnover number (TON) for the conversion of styrene to ethylbenzene was 200,000 and the turnover frequency (TOF) at 50% conversion was 300,000 $h^{-1}$. The TOF improved to 600,000 $h^{-1}$ when the pressure of $H_2$ was increased to 10 atm and the temperature to 70 °C. The catalytic activity was tested on other substrates such as α-methylstyrene, 4-methylstyrene, and phenylacetylene with a catalyst loading of 0.005 mol-%. The results are displayed in Table 6. Complex **11** was found to be more effective in homogeneous hydrogenation under mild conditions than $[RhCl(PPh_3)_3]$, for which complete conversion was observed under the following conditions: [styrene]/[catalyst] = 1200, $T$ = 80 °C, $t$ = 2 h, $H_2$ pressure: 28 atm.[37]

Table 6. Hydrogenation of olefins using complex **11**.[a]

| Entry | Substrate | Time [min] | Conversion [%] | TOF [$h^{-1}$] |
|---|---|---|---|---|
| 1 | styrene | 30 | 100 | 40,000 |
| 2 | α-methylstyrene | 40 | 100 | 30,000 |
| 3 | 4-methylstyrene | 30 | 100 | 40,000 |
| 4 | phenylacetylene | 70 | 100 | 17,143 |
| 5[b] | styrene | 20 | 100 | 600,000 |

[a] Conditions: olefin (1.0 mmol), $Et_3N$ (0.1 mmol), **11** (0.005 mol-%), thf (20 mL); $H_2$ pressure: 4 atm; room temp.; stirring speed: 400 rpm. [b] **11** (0.0005 mol-%), $H_2$ pressure: 10 atm; $T$: 70 °C.

## Summary

The hemilabile iminophosphorane-phosphane ligand **1** has been synthesized by monoimination of bis[2-(diphenylphosphanyl)phenyl] ether by a Staudinger reaction and its chalcogen derivatives **3**–**6** have been prepared and characterized. The imino-phosphorane shows both a monodentate and bidentate ($\kappa^2$-*P*,*O*) chelating coordination mode. The platinum(II), palladium(II), and rhodium(I) complexes **7**, **8**, and **12**, respectively, are obtained as *trans* isomers with simple monodentate coordination modes. The $Pd^0$ complex **9**, in which ligand **1** binds in a chelating ($\kappa^2$-*P*,*O*) fashion, has been synthesized by the reaction of **1** with $[Pd_2(dba)_3]$. The reaction of **1** with $[\{Rh(COD)Cl\}_2]$ and AgOTf affords the 11-membered macrocyclic square-planar complex **11** with the imino-phosphorane ligand showing a chelating bidentate mode of coordination. The cationic rhodium(I) complex **11** is catalytically active for the hydrogenation of olefins with a TON of $2\times10^5$ and a TOF of $6\times10^5$ $h^{-1}$. The $Pd^0$ complex **9** is catalytically active for Suzuki cross-coupling reactions of various aryl bromides and phenylboronic acid. A lower catalytic loading of 0.05 mol-% of **9** allows complete conversion of several aryl bromides into biaryls.

## Experimental Section

**Reagents and Techniques:** All manipulations were performed under an atmosphere of dry nitrogen using standard Schlenk techniques.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

All the solvents were purified by conventional procedures and distilled under nitrogen prior to use. The compounds DPEphos,[17a] $[M(COD)Cl_2]$ (M = Pd, Pt),[38] $[\{Rh(COD)(\mu\text{-}Cl)\}_2]$,[39] $[\{Rh(CO)_2(\mu\text{-}Cl)\}_2]$,[40] $[Pd_2(dba)_3]$,[41] and $[AuCl(SMe_2)]$[42] were prepared according to published procedures. $(PhO)_2P(O)N_3$ was purchased from Lancaster and used as received. The $^1H$ and $^{31}P\{^1H\}$ NMR spectra ($\delta$ in ppm) were recorded with Varian 300 or 400 mercury plus spectrometers operating at the appropriate frequencies using TMS and 85% $H_3PO_4$ as internal and external references, respectively. Microanalyses were performed with a Carlo–Erba Model 1112 elemental analyzer. The IR spectra were recorded with a Nicolet Impact 400 FT-IR instrument as KBr disc. Electrospray ionization (EI) mass spectrometry experiments were carried out with a Waters Q-Tof micro-YA-105 spectrometer. Melting points were recorded in capillary tubes and are uncorrected. GC analyses were performed with a Perkin–Elmer Clarus 500 GC fitted with a packed column.

**Synthesis of $Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2$ (1):** A thf solution (20 mL) of $(PhO)_2P(O)N_3$ (0.153 g, 0.557 mmol) was added dropwise to a solution of DPEphos (0.300 g, 0.557 mmol) in thf (20 mL) at –78 °C. After stirring the mixture for 8 h at room temperature, all the solvents were removed under vacuum and the residue washed with petroleum ether (b.p. 60–80 °C), then extracted with $Et_2O$ (15 mL) and dried to give an analytically pure white solid. Yield: 85% (0.372 g); m.p. 76–78 °C. $C_{48}H_{38}NO_4P_3$ (785.7): calcd. C 73.37, H 4.87, N 1.78; found C 72.81, H 4.43, N 1.93. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 5.93–8.18 (m, 38 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = –20.1 (s, $P^{III}$), 10.4 (d, $^2J_{P,P}$ = 37.7 Hz, $P^V_{[N]}$), –10.5 (d, $^2J_{P,P}$ = 37.7 Hz, $P^V_{[O]}$) ppm. MS (EI): *m*/*z* 786.47 $[M + H]^+$.

**Synthesis of $O\{C_6H_4PPh_2{=}NP(O)(OPh)_2\}_2$ (2):** A solution of DPEphos (0.2 g, 0.371 mmol) in thf (10 mL) was added dropwise to a solution of $(PhO)_2P(O)N_3$ (0.204 g, 0.742 mmol) in thf (10 mL) at 0 °C. After stirring the mixture for 8 h at room temperature, all the solvents were removed under vacuum and the residue washed with petroleum ether, then extracted with $Et_2O$ (10 mL) and dried to give **2** as a white solid. Yield: 90% (0.350 g); m.p. 72–74 °C. $C_{60}H_{48}N_2O_7P_4$ (1032.9): calcd. C 69.77, H 4.68, N 2.71; found C 70.26, H 4.51, N 2.84. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 6.12–7.65 (m, 48 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 10.9 (d, $^2J_{P,P}$ = 40.4 Hz, $P^V_{[N]}$), –10.6 (d, $^2J_{P,P}$ = 40.4 Hz, $P^V_{[O]}$) ppm. MS (EI): *m*/*z* 1033.57 $[M + H]^+$.

**Synthesis of $O\{C_6H_4P(S)Ph_2\}_2$ (3):** A mixture of DPEphos (0.200 g, 0.371 mmol) and sulfur (0.024 g, 0.093 mmol) was refluxed in toluene (10 mL) for 24 h with constant stirring to give a white precipitate of **3**. The solution was then cooled to room temperature, filtered, and recrystallized from hot $CHCl_3$. Yield: 92% (0.206 g); m.p. > 250 °C. $C_{36}H_{28}OP_2S_2$ (602.7): calcd. C 71.74, H 4.68, S 10.64; found C 71.62, H 4.81, S 10.88. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 6.20–7.68 (m, 28 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 39.1 (s) ppm.

**Synthesis of $O\{C_6H_4P(Se)Ph_2\}_2$ (4):** A mixture of DPEphos (0.200 g, 0.371 mmol) and selenium (0.059 g, 0.742 mmol) was refluxed in toluene (10 mL) for 24 h with constant stirring to give a white precipitate of **4**. The solution was then cooled to room temperature, filtered, and recrystallized from hot $CHCl_3$. Yield: 90% (0.233 g); m.p. > 250 °C. $C_{36}H_{28}OP_2S_2$ (696.5): calcd. C 62.08, H 4.05; found C 62.45, H 4.26. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 6.30–7.67 (m, 28 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 29.4 (s, $^1J_{Se,P}$ = 734.1 Hz) ppm. MS (EI): *m*/*z* 699.04 $[M + H]^+$.

**Synthesis of $Ph_2P(S)C_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2$ (5):** A mixture of **1** (0.100 g, 0.127 mmol) and sulfur (0.003 g, 0.016 mmol) was refluxed in toluene (5 mL) for 24 h with constant stirring. The solution was then cooled to room temperature and petroleum ether (5 mL) was added to give white precipitate **5**. Yield: 93% (0.096 g); m.p. 98–100 °C. $C_{48}H_{38}P_3O_4NS$ (817.8): calcd. C 70.49, H 4.68, N 1.71, S 3.92; found C 70.52, H 4.44, N 1.82, S 4.09. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 5.87–7.97 (m, 38 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 37.7 (s, $P^V_{[S]}$), 10.8 (d, $^2J_{P,P}$ = 38.9 Hz, $P^V_{[N]}$), –10.5 (d, $^2J_{P,P}$ = 38.9 Hz, $P^V_{[O]}$) ppm. MS (EI): *m*/*z* 818.15 $[M + H]^+$.

**Synthesis of $Ph_2P(Se)C_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2$ (6):** A mixture of **1** (0.100 g, 0.127 mmol) and Se (0.010 g, 0.127 mmol) was refluxed in toluene (5 mL) for 24 h with constant stirring. The solution was then cooled to room temperature and petroleum ether (5 mL) was added to give a white microcrystalline solid of **6**. Yield: 98% (0.108 g); m.p. 120–122 °C. $C_{48}H_{38}NO_4P_3Se$ (864.7): calcd. C 66.67, H 4.42, N 1.61; found C 66.97, H 4.21, N 1.73. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 5.89–7.92 (m, 38 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 27.6 (s, $^1J_{Se,P}$ = 744.0 Hz, $P^V_{[Se]}$), 10.8 (d, $^2J_{P,P}$ = 39.0 Hz, $P^V_{[N]}$), –10.5 (d, $^2J_{P,P}$ = 39.0 Hz, $P^V_{[O]}$) ppm. MS (EI): *m*/*z* 866.13 $[M + H]^+$.

**Synthesis of *trans*-$[PtCl_2\{\kappa^1\text{-}P\text{-}Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}_2]$ (7):** A solution of $[Pt(COD)Cl_2]$ (0.034 g, 0.091 mmol) in $CH_2Cl_2$ (5 mL) was added dropwise to a solution of **1** (0.144 g, 0.183 mmol) in $CH_2Cl_2$ (10 mL) at room temperature. The reaction mixture was stirred for 8 h to give a pale-yellow solution, which was concentrated to 5 mL. $Et_2O$ (10 mL) was added to give a pale-yellow precipitate of **7**, which was then filtered, washed, and dried. Yield: 87% (0.145 g); m.p. > 250 °C. $C_{96}H_{76}Cl_2N_2O_8P_6Pt$ (1837.5): calcd. C 62.75, H 4.16, N 1.52; found C 62.58, H 4.15, N 1.58. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 5.87–8.21 (m, 76 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 10.3 (s, $^1J_{Pt,P}$ = 2642 Hz, $P_{[Pt]}$), 11.4 (d, $^2J_{P,P}$ = 37.9 Hz, $P^V_{[N]}$), –10.6 (d, $^2J_{P,P}$ = 37.9 Hz, $P^V_{[O]}$) ppm. MS (EI): *m*/*z* 1838.01 $[M + H]^+$.

**Synthesis of *trans*-$[PdCl_2\{\kappa^1\text{-}P\text{-}Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}_2]$ (8):** A solution of $[Pd(COD)Cl_2]$ (0.031 g, 0.109 mmol) in $CH_2Cl_2$ (10 mL) was added dropwise to a solution of **1** (0.170 g, 0.217 mmol) in $CH_2Cl_2$ (10 mL) at room temperature. The bright yellow solution was stirred for 8 h then concentrated to 5 mL. Addition of $Et_2O$ (10 mL) gave the mononuclear *trans* complex **8** as a yellow solid. Yield: 83% (0.158); m.p. 210–212 °C. $C_{96}H_{76}Cl_2N_2O_8P_6Pd$ (1748.8): calcd. C 65.93, H 4.38, N 1.60; found C 65.24, H 3.99, N, 1.75. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 5.85–8.20 (m, 76 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = 14.2 (s, $P_{[Pd]}$), 11.7 (d, $^2J_{P,P}$ = 38.1 Hz, $P^V_{[N]}$), –10.6 (d, $^2J_{P,P}$ = 38.1 Hz, $P^V_{[O]}$) ppm.

**Synthesis of $[Pd\{\kappa^2\text{-}P,O\text{-}Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}_2]$ (9):** A solution of $[Pd_2(dba)_3]$ (0.05 g, 0.048 mmol) in toluene (20 mL) was added dropwise to a stirring solution of **1** (0.152 g, 0.193 mmol) in toluene (10 mL) at room temperature. After 4 h the solution had turned yellow and all the solvents were removed in vacuo. The residual solid was washed several times with petroleum ether to remove dba and dried. Yield: 78% (0.126 g); m.p. 112 °C (dec). $C_{96}H_{76}N_2O_8P_6Pd$ (1677.9): calcd. C 68.72, H 4.57, N 1.67; found C 68.48, H 4.76, N 1.80. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 5.93–8.30 (m, 38 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 23.6 (s, $P_{[Pd]}$), 11.7 (d, $^2J_{P,P}$ = 39.5 Hz, $P^V_{[N]}$), –7.8 (d, $^2J_{P,P}$ = 39.5 Hz, $P^V_{[O]}$) ppm.

**Synthesis of $[AuCl\{\kappa^1\text{-}P\text{-}Ph_2PC_6H_4OC_6H_4PPh_2{=}NP(O)(OPh)_2\}]$ (10):** A solution of $[AuCl(SMe_2)]$ (0.03 g, 0.102 mmol) in $CH_2Cl_2$ (5 mL) was added dropwise to a solution of **1** (0.08 g, 0.102 mmol)

in $CH_2Cl_2$ (10 mL) at room temperature. The reaction mixture was stirred for 12 h, then concentrated to 2 mL and layered with $Et_2O$ (5 mL) to give colorless crystals of analytical purity. Yield: 92% (0.095 g); m.p. 216–218 °C. $C_{48}H_{38}AuClNO_4P_3$ (1018.2): calcd. C 56.62, H 3.76, N 1.38; found C 56.64, H 3.79, N 1.38. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 6.15–7.88 (m, 38 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 19.0 (s, $P_{[Au]}$), 10.4 (d, $^2J_{P,P}$ = 37.9 Hz, $P^V_{[N]}$), –10.5 (d, $^2J_{P,P}$ = 37.9 Hz, $P^V_{[O]}$) ppm. MS (EI): *m*/*z* 982.49 $[M - Cl]^+$.

**Synthesis of *cis*-[Rh(COD){κ$^2$-*P*,*O*-$Ph_2PC_6H_4OC_6H_4PPh_2$=NP(O)-(OPh)$_2$}][OTf] (11):** A mixture of **1** (0.066 g, 0.083 mmol), [{Rh(COD)Cl}$_2$] (0.021 g, 0.042 mmol), and AgOTf (0.021, 0.083 mmol) in $CH_2Cl_2$ (10 mL) was stirred for 8 h at room temperature. The yellow solution was concentrated to 2 mL and $Et_2O$ (10 mL) added to give a yellow oily substance. The supernatant liquid was discarded and dried to give a yellow foamy substance **11**, which was washed with $Et_2O$ and dried. Yield: 78% (0.044 g, 0.025 mmol); m.p. 144–146 °C. $C_{57}H_{50}F_3NO_7P_3RhS$ (1145.9): calcd. C 59.74, H 4.39, N 1.22, S 2.80; found C 60.11, H 4.08, N 1.30, S 2.85. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.27–2.37 (br. m, 8 H, $CH_2$), 2.90 (br. d, $^2J_{Rh,H}$ = 119.2 Hz, 2 H, CH), 5.13 (br. d, $^2J_{Rh,H}$ = 115.6 Hz, 2 H, CH), 6.26–7.99 (m, 38 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 12.9 (d, $^1J_{Rh,P}$ = 149.3 Hz, $P_{[Rh]}$), 8.8 (d, $^2J_{P,P}$ = 39.0 Hz, $P^V_{[N]}$), –11.1 (dd, $^2J_{P,P}$ = 39.0, $^2J_{Rh,P}$ = 6.6 Hz, $P^V_{[O]}$) ppm. MS (EI): *m*/*z* 996.29 $[M - OTf]^+$.

**Synthesis of *trans*-[Rh(CO)Cl{κ$^1$-*P*-$Ph_2PC_6H_4OC_6H_4PPh_2$=NP-(O)(OPh)$_2$}$_2$] (12):** A $CH_3CN$ (8 mL) solution of [{$Rh(CO)_2Cl$}$_2$] (0.015 g, 0.039 mmol) was added dropwise to a solution of **1** (0.121 g, 0.154 mmol) in $CH_3CN$ (10 mL) at room temperature. The reaction mixture was stirred for 4 h to give the *trans* complex **12** as a yellow precipitate, which was then filtered, washed with $CH_3CN$ (2 mL), and dried. Yield: 88% (0.118 g, 0.068 mmol); m.p. 242–244 °C. $C_{97}H_{76}ClN_2O_9P_6Rh$ (1737.9): calcd. C 67.04, H 4.41, N 1.61; found C 66.37, H 4.80, N 1.82. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 6.77–8.12 (m, 76 H, Ph) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 22.5 (d, $^1J_{Rh,P}$ = 140.3 Hz, $P_{[Rh]}$), 11.3 (d, $^2J_{P,P}$ = 37.9 Hz, $P^V_{[N]}$), –10.6 (d, $^2J_{P,P}$ = 37.9 Hz, $P^V_{[O]}$) ppm. FT-IR (KBr disc): $\tilde{\nu}$ = 1958 cm$^{-1}$ [$\nu_{CO}$]. MS (EI): *m*/*z* 1701.70 $[M - Cl]^+$.

**Crystal Structure Determination:** Single crystals of **8** suitable for X-ray diffraction were grown by slow diffusion of diethyl ether into a dichloromethane solution and mounted on a glass fiber with epoxy resin. Unit cell determination and data collection of **8** were performed with an Oxford Diffraction XCALIBUR-S CCD system using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structure was solved and refined by full-matrix least-squares techniques on $F^2$ using the SHELX-97 (SHELXL program package).[43] The absorption corrections were done by multi-scan and all the data were corrected for Lorentz and polarization effects. The non-hydrogen atoms were refined with anisotropic thermal parameters. All the hydrogen atoms were geometrically fixed and allowed to refine using a riding model (Table 7).

CCDC-616229 (for **9**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Suzuki Cross-Coupling Reactions of Aryl halides with Boronic Acids:** The appropriate amount of catalyst **9** (0.05 mol-%) was placed into a two-necked, round-bottomed flask under an atmosphere of nitrogen and 10 mL of toluene was added. After stirring for 15 min, aryl halide (1.0 mmol), arylboronic acid (1.5 mmol), and $K_2CO_3$ (2 mmol) were added. The mixture was stirred at 70 °C under an atmosphere of nitrogen until the conversion stopped (the course of the reaction was monitored by GC analysis). The solvent was then removed under reduced pressure. The resultant residual mixture was quenched with $H_2O$ (10 mL) and extracted twice with $Et_2O$ (2 × 10 mL). The combined organic fraction was dried ($MgSO_4$), the solvent removed under vacuum, and the residue dissolved in $CH_2Cl_2$ (5 mL). An aliquot of the solution was subjected to GC analysis. Yields were calculated with respect to aryl halides or dodecane as an internal standard.

**Catalytic Hydrogenation of Olefins:** A mixture of Rh$^I$ complex **11** (0.0005 or 0.005 mol-%), olefin (1.0 mmol), and triethylamine (0.1 mmol) was dissolved in 20 mL of thf and was introduced into a 50-mL glass vessel, which was placed into a steel autoclave and the reactor sealed. The vessel was purged three times with hydrogen and then the autoclave was pressurized with 4 atm of hydrogen. The reaction mixture was stirred at a room temperature for the required time. The extent of conversion was determined by periodic GC analysis until complete conversion was observed.

Table 7. Crystallographic data for complex **10**.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** an apple snail (*Pomacea bridgesi*) and scanning electron micrographs of five different forms of calcium carbonate that were prepared in vitro (vaterite, calcite, monohydrocalcite, amorphous calcium carbonate, and aragonite). Details are discussed in the article by M. Neumann and M. Epple on p. 1953 ff.

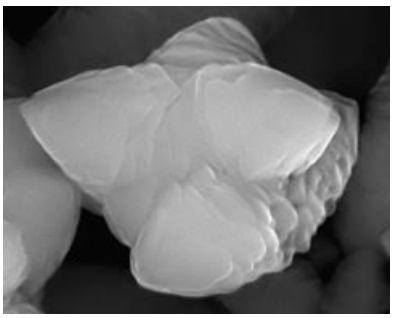
## FULL PAPERS

### Biominerals

**M. Neumann, M. Epple* ..... 1953–1957**

Monohydrocalcite and Its Relationship to Hydrated Amorphous Calcium Carbonate in Biominerals

**Keywords:** EXAFS spectroscopy / Biomineralisation / Materials science / Monohydrocalcite / Bioinorganic chemistry



Hydrated amorphous calcium carbonate (ACC) is often postulated as an intermediate and final phase in biomineralisation. The crystalline phase monohydrocalcite ($CaCO_3 \cdot H_2O$) is prepared, characterised and compared to biogenic calcium carbonate phases.

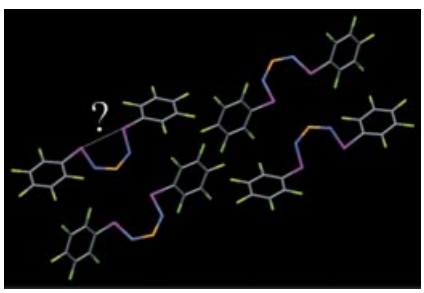
Insight Into the Intermolecular Factors Responsible for the *Z*,*Z* Configuration of Ar–X–N=S=N–X–Ar (X = S, Se) Derivatives in the Solid State

**Keywords:** Chalcogen-nitrogen chains / Crystal packing / Density functional theory / Molecular configurations / X-ray diffraction



For derivatives of Ph–X–N=S=N–X–Ph (X = S, Se) the predominance of the *Z*,*Z* configuration in the solid state can not be explained by intramolecular stereoelectronic effects. Calculation of the packing energies and densities reveals that the crystal packing of the structures in the *Z*,*Z* configuration has a systematic preference over the corresponding packing in the *Z*,*E* configuration. As a result, packing forces are most likely responsible for the dominance of the *Z*,*Z* configuration in the crystal.

### CuO Nanostructures

# Monohydrocalcite and Its Relationship to Hydrated Amorphous Calcium Carbonate in Biominerals

**Markus Neumann[a] and Matthias Epple*[a]**

**Keywords:** EXAFS spectroscopy / Biomineralisation / Materials science / Monohydrocalcite / Bioinorganic chemistry

Calcium carbonate monohydrate (monohydrocalcite) is prepared and structurally characterised by X-ray diffraction, X-ray absorption spectroscopy (EXAFS), thermal analysis, IR spectroscopy, and scanning electron microscopy. It is compared to hydrated phases of amorphous calcium carbonate (ACC) that have frequently been observed in biomineralisation. The crystal water is more strongly bound than in hydrated ACC phases, and monohydrocalcite can be distinguished from ACC by its IR spectrum. The EXAFS results suggest that monohydrocalcite is a suitable model for some biogenic and synthetic ACC phases, although not for all of them.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Monohydrocalcite, $CaCO_3 \cdot H_2O$, was first observed in 1930 during the dehydration of ikaite ($CaCO_3 \cdot 6H_2O$).[1] It was first observed in nature in 1959 in marine sediments,[2] and the first synthetic preparation was accomplished by Brooks et al. in 1950.[3] Under ambient conditions, this phase is metastable compared to the water-free calcium carbonate modifications calcite and aragonite, and upon dehydration, or at higher temperature, it transforms into these phases. Consequently, its solubility is higher than that of the water-free modifications (calcite, aragonite, vaterite).[4] Magnesium is generally incorporated into this phase in small quantities, therefore it is assumed that magnesium plays an important role during the crystallisation.[5–7] In nature, it is formed preferably in magnesium-rich marine locations.[8] The single crystal structure with trigonal symmetry (including a superstructure) was determined by Effenberger in 1981.[9]

Many living systems use inorganic minerals, for example for protection (shell, exoskeleton), as tools (teeth), for defence (spicule) or for internal stabilisation (bones forming an endoskeleton).[10–16] Calcium carbonate is the most prominent biomineral and is the main constituent of mollusc shells, crustacean cuticles, corals, skeletons of protozoa, etc.[17] In these cases, very delicate and often exceedingly mechanically stable structures are built by these organisms which (so far) cannot be mimicked in the laboratory. An exact control over the pathway of crystallisation lies at the centre of this process: There is a finely tuned interplay between the crystallising inorganic mineral and bio-organic compounds that control the crystallisation, both at the level of nucleation as well as during crystal growth.[10–17] The formation of mesocrystals has been proposed as a mechanism of how nanocrystals assemble into macroscopic crystals and aggregates.[18,19] In the case of calcium carbonate, there is increasing evidence that amorphous calcium carbonate (ACC) is first formed as a solid phase which then undergoes rearrangement/recrystallisation to one of the crystalline phases of calcium carbonate (calcite, aragonite and, much less frequently, vaterite). This is supported by studies of the mineral phase in developing organisms[20–32] and also by studies in vitro,[33–36] where ACC has been prepared synthetically. The role of ACC in biology was recently reviewed by Addadi et al.,[27] Meldrum,[17] and Weiner et al.[31] The thermodynamic[37] and structural[36] properties of synthetic ACC have been discussed by Günther et al.

When biogenic ACC is studied it usually contains some water, which suggests a hydrate-like structure. However, a distinction must be made between stable (permanent) forms of ACC and transient forms of ACC which transform into a crystalline phase. Addadi, Raz and Weiner have suggested that the stable forms are hydrated whereas the transient forms are not.[27] A water content of 15.7 wt.-% has been determined thermogravimetrically for hydrated ACC in the spicules of *Pyura pachydermatina*, which compares well to the stoichiometric formula for monohydrocalcite ($CaCO_3 \cdot H_2O$).[21] X-ray absorption spectroscopy (EXAFS) gave the best fit to the crystal structure of monohydrocalcite.[21] The monohydrocalcite EXAFS structure has also been found for ACC in cystoliths of *Ficus microcarpa* and *Ficus retusa*.[24]

We note here that all structural and thermal investigations that have suggested a similarity of hydrated ACC to monohydrocalcite refer only to literature data for monohydrocalcite, that is they use the crystal structure of monohy-

drocalcite for EXAFS fits. Monohydrocalcite itself has never been studied by EXAFS spectroscopy. We therefore considered it appropriate to prepare this phase in pure form, to characterise it by modern methods and compare it to biogenic ACC.

## Result and Discussion

Monohydrocalcite was synthesised by adding potassium carbonate to artificial seawater. It was clearly identified by X-ray diffractometry in a phase-pure form (Figure 1). A sample stored for three months at room temperature in a closed vial showed the same diffractogram, which means that monohydrocalcite is completely stable over that period and does not lose its water of crystallisation.

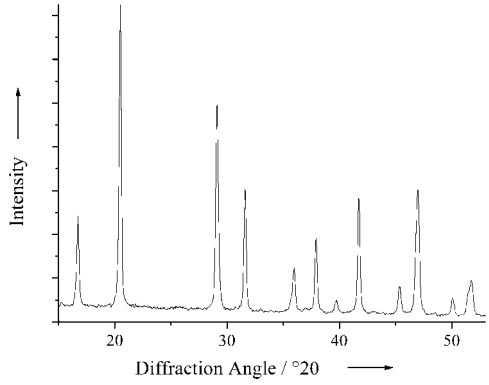

Figure 1. X-ray powder diffraction pattern of phase-pure monohydrocalcite.

The composition was studied by thermogravimetry, coupled with IR spectroscopic analysis of the released gases (Figure 2). A mass loss of 14.92 wt.-% from 140 to 205 °C was detected, which corresponds to the release of crystal water (theoretical value: 15.25 wt.-%). At higher temperatures (550 to 800 °C), decarboxylation occurred (observed mass loss: 36.44 wt.-%; theoretical value: 37.26 wt.-%). Released gaseous water and carbon dioxide, respectively, were detected in the connected IR spectrometer at the appropriate temperatures.

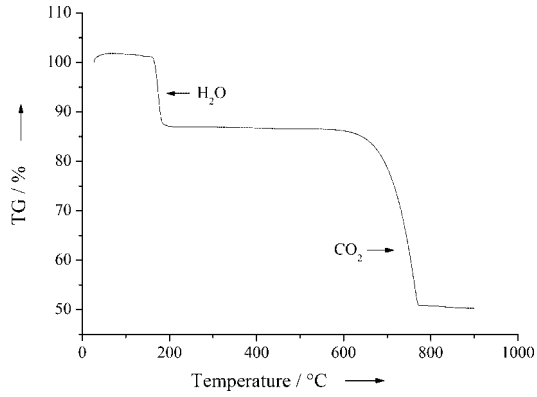

Figure 2. Thermogravimetric study of monohydrocalcite in a dynamic nitrogen atmosphere, showing first the dehydration and then the decarboxylation.

Synthetically prepared ACC has a water content of about 7.5 wt.-% (close to a hemihydrate), and about 1.5 wt.-% is released from 50–100 °C (loosely bound water) and about 6 wt.-% from 100–250 °C (structural water).[36] ACC from *Pyura pachydermatina* contains 15.7 wt.-% water (in good agreement with a monohydrate), which is released in the temperature range 20–200 °C.[21] We note that monohydrocalcite contains more strongly bound crystal water than ACC, a fact which is probably due to its higher crystallinity and its higher lattice energy.

Monohydrocalcite forms crystalline calcite after thermally induced loss of crystal water, as shown by X-ray powder diffraction (Figure 3). The fact that biogenic ACC can transform into calcite,[22,30,38] aragonite[20,26] and possibly vaterite[20] in vivo shows that there is a clear difference between a thermally induced dehydration and a biologically induced transformation at room temperature.

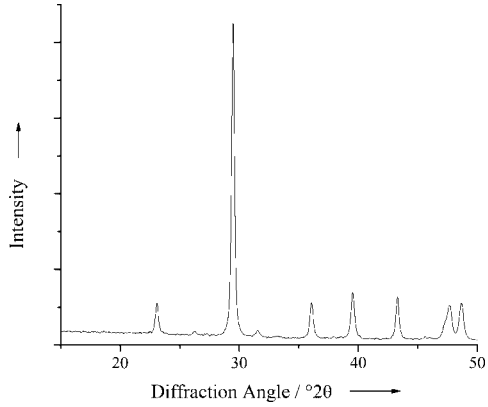

Figure 3. The X-ray powder diffractogram of monohydrocalcite after thermal dehydration (185 °C) shows only crystalline calcite.

The DSC curve shows an endothermal peak at 171.4 °C corresponding to the dehydration (Figure 4). The associated enthalpy change is +49.1 kJ mol$^{-1}$. Taking into account the enthalpy of evaporation of water [$\Delta_{vap}H_{373}°(H_2O)$ = 40.66 kJ mol$^{-1}$], the binding enthalpy of the water molecule is of the order of 8.5 kJ mol$^{-1}$.

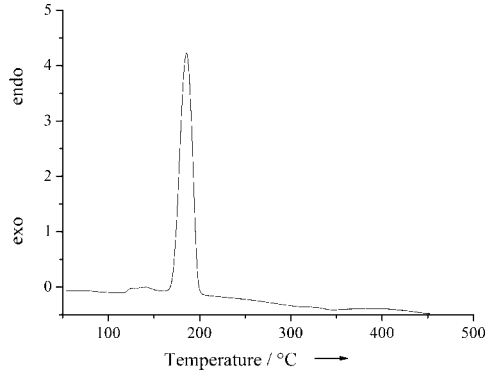

Figure 4. DSC curve of monohydrocalcite showing the endothermal peak associated with the dehydration. This is preceded by a broad endothermal peak which may be due to the release of water from disordered near-surface regions.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Monohydrocalcite was also characterised by IR spectroscopy (Figure 5). The asymmetric C–O stretching vibration is split (1408 and 1487 $cm^{-1}$). This is also observed for aragonite and vaterite, whereas calcite shows no splitting. In ACC from sternal deposits of the woodlouse *Porcellio scaber* we found an IR band at $\tilde{\nu}$ = 860 $cm^{-1}$ ($CO_3^{2-}$; $A_{2u}$).[28] The following values have been reported for this band in the literature: aragonite (860 $cm^{-1}$), calcite (876 $cm^{-1}$), and vaterite (877 $cm^{-1}$).[39] For biogenic ACC, a value of 866 $cm^{-1}$ has been reported.[27] Monohydrocalcite shows bands at 590 (lattice), 700/727 ($\nu_4$ of carbonate), 766 (lattice), 873 ($\nu_2$ of carbonate), 1068 ($\nu_1$ of carbonate), 1408/1487 ($\nu_3$ of carbonate), 1700 ($H_2O$ deformation), and 3235 $cm^{-1}$ (O–H stretch), in good agreement with the literature.[8,27,40,41] We therefore conclude that monohydrocalcite and ACC can be distinguished by IR spectroscopy by observing the carbonate band at around 870 $cm^{-1}$.

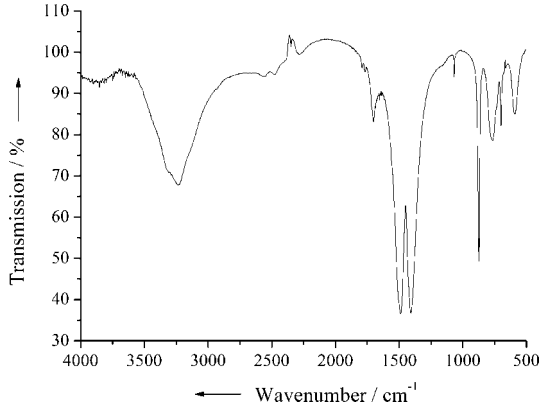

Figure 5. IR spectrum of monohydrocalcite.

The internal structure of monohydrocalcite was also studied by EXAFS, which examines the short-range order around Ca. Figure 6 shows the Fourier transform magnitude and the raw EXAFS data.

EXAFS is a versatile tool, especially for the analysis of amorphous materials which have short-range order but no long-range order. Investigations of amorphous calcium carbonates of different origin have shown that they differ in their short-range order.[27,36,43] The most stable forms of ACC contain one molecule of water per carbonate molecule, therefore monohydrocalcite has been suggested to be an appropriate model for hydrated ACC.[24,27] In the case of the ascidian *Pyura pachydermatina*, the best fit was actually obtained using monohydrocalcite as a model (see data in Table 1).[24] It is notable that no fit of the Ca–Ca coordination at around 4 Å was performed,[21] which shows that the disorder in ACC is much higher than in crystalline monohydrocalcite. The same situation has been observed for synthetic ACC, where only the first shell (Ca–O) could be fitted to the experimental data.[36] The transient amorphous calcium carbonate in the sternal deposits of the crustacean *Porcellio scaber* resembles either vaterite or monohydrocalcite.[28] Taylor et al. were the first to use EXAFS for the investigation of amorphous calcium carbonate from cystoliths of *Ficus retusa*. They showed that in the first coordination shell Ca is surrounded by eight O atoms, which is also the case for monohydrocalcite, and related it to ikaite ($CaCO_3 \cdot 6H_2O$).[42] However, this compound is very unstable and loses its crystal water even at 5 °C.[44] Note that the reference compound monohydrocalcite itself has never been studied by EXAFS until now, although its crystal structure has been used for EXAFS fits.[21,24,27] It must also be noted that the coordination number given by EXAFS is of limited accuracy due to its strong mathematical correlation with the Debye–Waller factor $\sigma^2$ and the amplitude reduction factor $S_0^2$.[45]

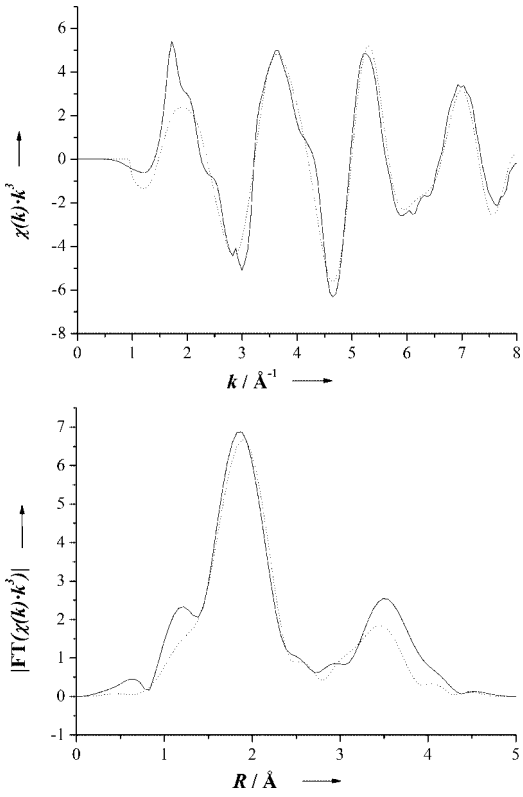

Figure 6. Ca *K*-edge EXAFS spectra of monohydrocalcite. Top: raw EXAFS data $\chi(k)$; bottom: Fourier transform magnitude. Solid line: experimental data; dotted line: fit data.

Crystallographically,[9] the environment of Ca in monohydrocalcite consists of eight oxygen atoms at distances of 2.41–2.49 Å (six from carbonate and two from hydrate water), two carbon atoms at a distance of 2.78–2.90 Å, two carbon atoms at a distance of 3.15–3.33 Å, one oxygen atom at a distance of 3.60 Å, and two calcium atoms at a distance of 3.86 Å. The higher coordination number in the first Ca–O shell (eight vs. six for calcite and vaterite, and nine for aragonite) and the lower coordination number in the outer Ca–Ca shell (two vs. six for calcite, aragonite and vaterite) distinguish monohydrocalcite from the water-free phases. The fact that the outer Ca–Ca shell in ACC is generally weak or not even present points to some similarity of monohydrocalcite to ACC, thus making it a useful structural model. An important difference, however, is the distance of the first Ca–O shell, which is very charac-

teristic and can be determined with high accuracy by EXAFS. This shows that not all ACC phases that have been described have a short range like that of monohydrocalcite.

Scanning electron microscopy on monohydrocalcite showed that it consists of platelets that are aggregated into larger particles (Figure 7), whereas the ACC prepared by Faatz et al.[35] and Günther et al.[36] shows a spherical morphology with sub-micrometer-sized particles, therefore there is no similarity in the morphology of monohydrocalcite and ACC prepared in vitro.

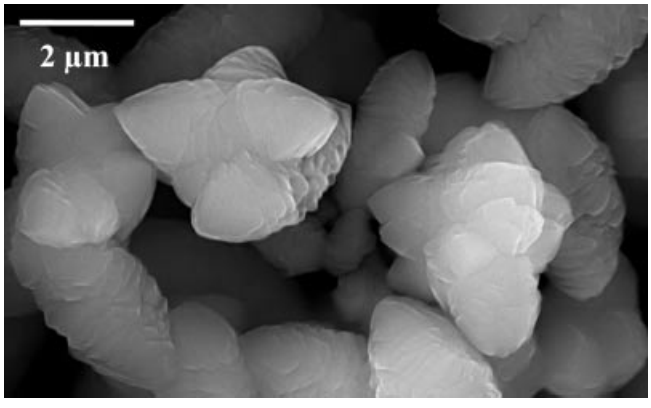

Figure 7. Scanning electron micrograph of synthetic monohydrocalcite.

## Conclusions

Monohydrocalcite as a stable hydrated phase of calcium carbonate is a suitable model for biogenic amorphous calcium carbonate (ACC) with regards to its composition (one water molecule per calcium carbonate unit). However, its microstructure, as determined by EXAFS, does not match the structure of all biogenic or synthetic ACC phases. This may be related to a higher degree of order in this crystalline phase, which also leads to a higher dehydration temperature compared to ACC. It may be assumed in the light of new theories on the formation of biominerals[18,19] that nanoscopic particles of hydrated calcium carbonate (resembling monohydrocalcite) assemble into water-containing ACC but do not crystallise (as shown by the fact that biogenic ACC is X-ray-amorphous), which means that the aggregates possess a higher energy than crystalline monohydrocalcite. Such biogenic assemblies always contain some organic material, which apparently prevents this ordering process. Unfortunately, no quantitative data on the content of organic matrix in biogenic ACC is available. The fact that many biogenic ACC phases are probably hydrated (although, to the best of our knowledge, this has only been quantified in one case by thermogravimetry[21] due to the small amount of sample material available) but structurally different[27,36,43] points to either different nanoscopic pre-

cursor particles or to a rearrangement during macroscopic assembly and ordering.

## Experimental Section

**Preparation of Monohydrocalcite:** Artificial seawater was prepared according to Kralj and Brecevic[4] by dissolving the following amounts of chemicals in 250 mL of doubly distilled water: 7.30 g of sodium chloride, 1.25 g of magnesium chloride, 0.370 g of calcium chloride dihydrate and 0.006 g of strontium chloride. Potassium carbonate (0.3 g) was then added and the solution was stirred until it had dissolved. The mixture was then placed in an ultrasonic bath for 10–15 s and left in a refrigerator at 6 °C overnight. The precipitate of monohydrocalcite obtained was filtered off and dried in air. Elemental analysis by combustion analysis (C, H) and atomic absorption spectroscopy (Ca, Mg) gave the following results: calcd. C 10.17, H 1.71, Ca 33.94, Mg 0; found C 10.06, H 1.83, Ca 33.67, Mg 0.32.

**Analytical Techniques:** Combined thermogravimetry/IR spectroscopy (TG-IR) was carried out with a Netzsch STA 209 TG-DTA/DSC instrument connected to a Bruker Vertex 70 IR spectrometer for gas analysis in situ. The sample was heated from 30 to 900 °C at a rate of 5 °C min$^{-1}$ under $N_2$ (50 mL min$^{-1}$). Scanning electron microscopy was carried out with a Zeiss DSM 962 instrument on Au-sputtered samples. X-ray powder diffractometry was carried out with a Stadi P instrument from STOE with Cu-$K_\alpha$ radiation. The DSC measurement was carried out with a Netzsch DSC 204 instrument. The sample was heated from 0 to 500 °C at a rate of 5 °C min$^{-1}$. Extended X-ray absorption fine structure (EXAFS) spectroscopy was carried out at beamline E4 at the Hamburger Synchrotronstrahlungslabor (HASYLAB) at the Deutsches Elektronen Synchrotron (DESY), Hamburg, Germany. The programs SPLINE/XFIT[46] and FEFF 6.01a[47] were used for quantitative data evaluation. The amplitude reduction factor $S_0^2$ was fixed to 0.8. Variation parameters were the bond lengths for all shells, the coordination numbers (only for the first shell), the Debye–Waller factors ($\sigma^2$) for all shells, and the zero-energy correction ($E_o$).

**Keywords:** Chalcogen-nitrogen chains / Crystal packing / Density functional theory / Molecular configurations / X-ray diffraction

The molecular and crystal structures of three new derivatives of Ph–S–N=S=N–S–Ph (**1**), with 2,4,6-(*tert*-$C_4H_9)_3C_6H_2$ (**4**), $C_6F_5$ (**5**) and 4-$CF_3C_6F_4$ (**6**) as peripheral rings, respectively, and one new derivative of Ph–Se–N=S=N–Se–Ph (**2**), with $C_6F_5$ (**7**) as peripheral rings, are reported and discussed in connection with those of the two parent structures **1** and **2** and those of the previously studied derivative of **1** containing 4-$ClC_6H_4$ (**3**) as peripheral rings. For these seven compounds the *Z*,*Z* configuration is the only one of the three theoretically possible configurations observed in the solid state and this configurational preference can not be explained by intramolecular stereoelectronic effects. Calculation of the packing energies and densities for the six most common space groups revealed that the crystal packing of the parent structure **1** in the *Z*,*Z* configuration has a systematic preference over the corresponding packing of **1** in the *Z*,*E* configuration by 0.3–4.9 kJ mol$^{-1}$. As a result, packing forces are most likely responsible for the dominance of the *Z*,*Z* configuration of the title compounds in the crystal.

## 1. Introduction

The molecular structures of chalcogen-nitrogen compounds are extremely diverse and continue to present a serious challenge to chemical theory in general.[1,2] Accurately predicting and rationalising these structures, both for isolated molecules and those arranged regularly in a crystal structure, remain of obvious fundamental interest.[3–5] This is particularly true when it comes to identifying and understanding the correlations that exist between molecular shape and the precise nature of the packing in the crystal. Within the family of chalcogen-nitrogen compounds, the oligomeric analogues of catenated sulfur nitride, $(SN)_x$, a metallic polymer and superconductor,[6] attract special attention due to possible applications as molecular wires in the field of molecular electronics. For this purpose, understanding the factors controlling molecular conformations is of the utmost importance.

Recently, we have shown[3] that the *Z*,*Z* configuration of $C_6H_5$–S–N=S=N–S–$C_6H_5$ (**1**)[7] and $C_6H_5$–Se–N=S=N–Se–$C_6H_5$ (**2**)[3] – and consequently that of 4-$ClC_6H_4$–S–N=S=N–S–$C_6H_4$Cl-4 (**3**)[8] – in the crystal can not be explained by the stabilising *intra*molecular interaction between the $X^{II}$ (X = S, Se) atoms, which had been suggested in the literature, and that *inter*molecular forces in the crystal must be the driving force behind the observed configuration. In particular, we have demonstrated that in the gas phase or in solution the *Z*,*Z* configuration is not stabilised to a greater extent than the *Z*,*E* configuration.

In this work we report the preparation and analysis of the crystal structures of four new substituted derivatives of **1** and **2**, including 2,4,6-(*tert*-$C_4H_9)_3C_6H_2$–S–N=S=N–S–$C_6H_2$(*tert*-$C_4H_9)_3$-2,4,6 (**4**), $C_6F_5$–S–N=S=N–S–$C_6F_5$ (**5**), 4-$CF_3C_6F_4$–S–N=S=N–S–$C_6F_4CF_3$-4 (**6**), and $C_6F_5$–Se–N=S=N–Se–$C_6F_5$ (**7**); see Figure 1 for structural formulas. For all these compounds only the *Z*,*Z* configuration is observed in the solid state.[9] Based on the results of quantum chemical calculations (i.e. energy differences, bond orders

and a topological analysis of the electron density) on 2,6-$(CH_3)_2C_6H_3$–S–N=S=N–S–$C_6H_3(CH_3)_2$-2,6 (**4′**) (as a model system for compound **4**) and **5**, using the same approach as we applied earlier,[3] *intra*molecular interactions can again be excluded as the reason for the observed *Z*,*Z* configurations. In order to shed more light on the possible *inter*molecular factors responsible for these observations, a number of simulations of the crystal packing of parent compound **1** were performed using the OPiX software.[10] The calculations show that for the six most common space groups ($P\bar{1}$, $P2_1/c$, $C2/c$, $Pbca$, $P2_1$, and $P2_12_12_1$) the crystal packing of **1** in the *Z*,*Z* configuration has a systematic preference over the packing of **1** in the *Z*,*E* configuration by 0.3–4.9 kJ mol$^{-1}$ and 0.010–0.025 g cm$^{-3}$ in energy and density, respectively. Based on this, we propose that the packing effects in the solid state are the driving force behind the observed *Z*,*Z* configuration of Ph–X–N=S=N–X–Ph (X = S, Se) and their derivatives.

## 2. Results and Discussion

### 2.1 Solid-State Molecular Structures

Previously, it was found that compounds **1**–**3** adopt the *Z*,*Z* configuration in the crystal.[3,7,8] This configuration features a virtually planar chalcogen-nitrogen fragment in which the $X^{II}\cdots X^{II}$ (X = S, Se) distance is significantly shorter than the sum of the van der Waals radii.[3,7,8] According to the XRD data we present here,[9] compounds **4**–**7** also exist in the *Z*,*Z* configuration in the crystal; see Figures 2, 3, 4, and 5 and Table 1 for geometrical data. For compound **4**, the –N=S=N– fragment is disordered over two sites (see Figure 2) in a ratio of 55:45. The chalcogen–nitrogen chain is planar to within ±0.012 and 0.032 Å for

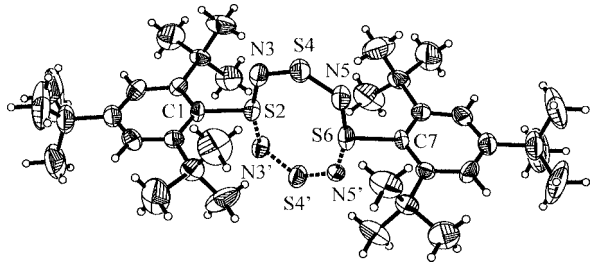

Figure 2. Molecular structure and partial numbering scheme of compound **4**. Displacement ellipsoids are at the 50% probability level; hydrogens are represented by spheres of arbitrary radius. Note that, for convenience, a unified numbering scheme has been used for compounds **4**–**7** in Figures 2, 3, 4, and 5; atoms S4 and S4′ of compound **4** actually lie on the $C_2$ symmetry axis.

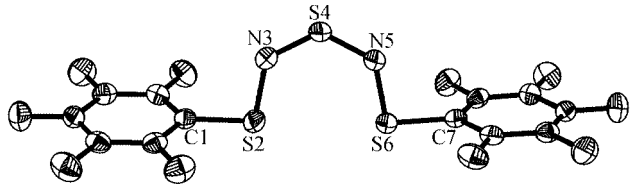

Figure 3. Molecular structure and partial numbering scheme of compound **5**. Displacement ellipsoids are at the 50% probability level.

[a] The –N=S=N– fragment is disordered over two sites in a ratio of 55:45. The abnormally long S2–N3 bond lengths obtained are attributed to the disorder. [b] Two crystallographically independent molecules.

the two disordered molecules of **4**, ±0.004 and 0.017 Å for the two crystallographically independent molecules of **5**, ±0.005 Å for **6** and ±0.055 Å for **7**. The bond lengths and angles in compounds **4**–**7** given in Table 1 are typical[11] and quite similar to those found for compounds **1**–**3**.[3,7,8] The intramolecular $X^{II}\cdots X^{II}$ distances are again significantly shorter than the sums of corresponding van der Waals radii, which are 3.60 Å for the S···S and 3.80 Å for the Se···Se contacts.[12,13]

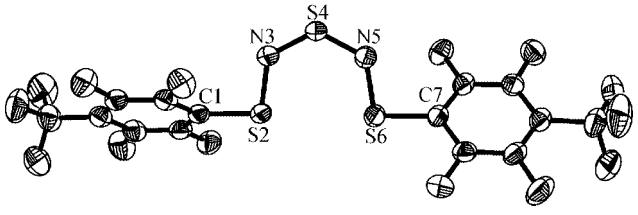

Figure 4. Molecular structure and partial numbering scheme of compound **6**. Displacement ellipsoids are at the 50% probability level.

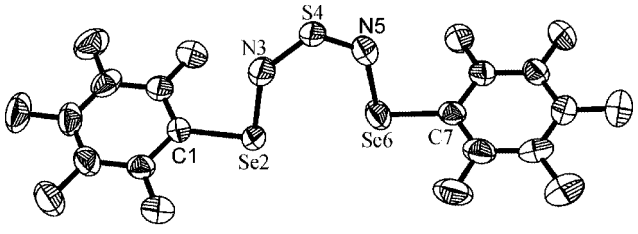

Figure 5. Molecular structure and partial numbering scheme of compound **7**. Displacement ellipsoids are at the 50% probability level.

Despite the fact that the seven compounds display the same *Z*,*Z* configuration, their particular molecular conformations are somewhat different. Molecules of compound **3** possess approximate $C_{2v}$ symmetry, while those of compound **1** display $C_2$ symmetry, since both phenyl rings are twisted away from the plane of the sulfur-nitrogen moiety by about 30°; the molecular conformation of **2** is very similar to that of **1**.[3] In contrast, the aromatic rings of compounds **4** and **5** are practically perpendicular to the plane of sulfur-nitrogen fragment: the corresponding dihedral angles in **4**, which displays $C_2$ symmetry, are 89.3(1)°. For the two crystallographically independent molecules of **5**, which possess $C_1$ symmetry, they are 79.9(1) and 76.6(1), and 73.7(1) and 71.5(1)°. For compound **6**, which also displays $C_2$ symmetry, the angles are 53.1(1)°, i.e. significantly smaller. The dihedral angles between the planes of the two aromatic rings are 10.6(1)° in **4**, 9.6(3)° and 9.3(3)° in **5**, and 10.4(5)° in **7**. Thus, the conformational changes observed on going from **2** to **7** are similar to those on going from **1** to **5**.

The above observations on compounds **1**–**7** provide clear evidence that the *Z*,*Z* configuration is the one which is generally favoured in the solid state, and that this configuration is stable towards intramolecular perturbations such as significant variations in the stereoelectronic demand of the terminal aromatic groups or the substitution of $S^{II}$ by $Se^{II}$ atoms. At the same time, the observed solid-state molecular conformations vary from practically coplanar to severely non-coplanar and it seems that these do depend greatly on the nature of the aromatic groups.

### 2.2 Gas-Phase Molecular Structures

The calculated relative energies of the three lowest-energy conformers [*Z*,*Z*-*anti*,*anti* ($C_2$), *Z*,*E*-*anti*,*anti* ($C_1$) and *Z*,*E*-*anti*,*syn* ($C_1$), see Figure 1] of compounds **4′** and **5** have been compiled in Table 2. We note that all other possible conformers have energies which are considerably higher ($> 20\ kJ\,mol^{-1}$), based on which they can be confidently excluded. The data in Table 2 indicate that the *Z*,*Z*-*anti*,*anti* conformer is the lowest-energy one; this is also the conformer that is found in the crystal. In analogy with the situation for the parent compounds **1** and **2**,[3] there are two *Z*,*E* conformers with an energy low enough so that they will be present in the gas phase (or in solution) at room

temperature. Based on the results of the calculations the equilibrium conformer compositions at 293 K are 87% $C_2$-*Z*,*Z*-*anti*,*anti*, 8% $C_1$-*Z*,*E*-*anti*,*anti* and 5% $C_1$-*Z*,*E*-*anti*,*syn* for compound **4′** and 73% $C_2$-*Z*,*Z*-*anti*,*anti*, 24% $C_1$-*Z*,*E*-*anti*,*anti*, and 3% $C_1$-*Z*,*E*-*anti*,*syn* for compound **5**.

Table 2. Calculated energies *E* [H] and relative energies Δ*E* [kJ mol$^{-1}$] of the three lowest-energy conformers [*Z*,*Z*-*anti*,*anti* ($C_2$), *Z*,*E*-*anti*,*anti* ($C_1$) and *Z*,*E*-*anti*,*syn* ($C_1$)] of compounds **4′** and **5** at the B3LYP/6-311+G* level of theory. See text for details.

The molecular geometries of the three conformers are given in Table 3. A comparison of the different calculated stable conformations of the two compounds reveals that when changing the conformation and/or configuration of the molecule the geometrical changes are quite substantial for the parameters directly involved in the change, i.e. S(4)–N(5), N(5)–S(6) and the three angles in the SNSNS fragment: differences of up to 0.056 Å for N(5)–S(6) and 15.7° for N(3)–S(4)–N(5) in **5** are found. These results are analogous to the ones found previously for the parent compounds **1** and **2**.[3] The changes in the non-bonded distances when going from one conformer to the other will be discussed in section 2.3. We note that conformational changes similar to the ones found in the solid state can be observed in the results of the calculations: while in the parent compounds **1** and **2** the benzene rings are twisted away from the plane of the XSNSX fragment by a mere 10.6 and 10.0°, respectively, for **4′** and **5** values of 70.1 and 69.1°, respectively, are found.

Comparing the XRD data of compounds **4** and **5** in Table 1 with those of the relevant gas-phase conformer (i.e. *Z*,*Z*-*anti*,*anti*) of compounds **4′** and **5** in Table 3 it is clear that the qualitative agreement between the calculated and experimental structures is quite good: the differences between single and double bonds are well reproduced, as are the different angles and torsion angles in the heteroatomic fragment. A quantitative comparison indicates that the calculations overestimate the bond lengths but this is mainly due to the fact that $r_{XRD}$ are $r_\alpha$-type distances while the $r_{calcd.}$ are $r_e$ distances by definition.[14,15]

### 2.3 Intramolecular S···S Interactions

As mentioned before, both in the crystal and in the lowest-energy conformer in the gas phase the distances between S(2) and S(6) [3.274(2) in **4** and 3.509 Å in **4′**, respectively, and 3.370(2)/3.220(2) and 3.424 Å in **5**, respectively] are well below the sum of the van der Waals radii (3.60 Å). This does suggest some sort of bonding interaction between those atoms. However, the energy difference between the conformer which has the interaction, i.e. $C_2$-*Z*,*Z*-*anti*,*anti*, and one which does not, e.g. $C_1$-*Z*,*E*-*anti*,*anti*, is only of the order of 5.98 kJ mol$^{-1}$ for **4′** and 2.65 kJ mol$^{-1}$ for **5** (Table 2). That the $C_1$-*Z*,*E*-*anti*,*anti* conformers do not display an interaction between S(2) and S(6) can be clearly seen from the S···S distances in Table 3 which are well above the sum of the van der Waals radii. These small energy differences suggest that the observed *Z*,*Z* configuration is not stabilised to a greater extent than the lowest-energy *Z*,*E* configuration and that the supposed S···S interactions do not play an important stabilising role.

Additional evidence comes from the calculated Hirshfeld bond orders of the different bonds in both molecules; the results are given in Table 4. The data reproduce the different types of bonding in the molecules equally well for the three conformers of **4′** and **5**: the XC bonds are clearly single while the S=N bonds are virtually double. The values for the S···S contacts are negative for all conformers of both compounds, which is a result of the scaling procedure,[16] and this indicates that the bond orders of these bonds are very small. The unscaled values for the *Z*,*Z*-*anti*,*anti* conformers of **4′** and **5** are 0.03 and 0.04, respectively, and these can be directly compared to the unscaled values for the XC bonds which are 0.38 and 0.39, respectively. The bonding in the S···S contacts is about thirteen and ten times lower, respectively, than in a regular single bond; the interaction between the two atoms must therefore be extremely

Table 4. Hirshfeld bond orders for the three lowest-energy conformers of compounds **4′** and **5**. See text for details.

weak. These values are of the same order of magnitude as for **1**, for which the scaled and unscaled bond orders are –0.52 and 0.04, respectively.[3]

Finally, a topological analysis of the total molecular electron density was performed using the Atoms In Molecules (AIM) theory.[17] The electron densities $\rho(r)$ of a number of relevant bond critical points (BCPs) and ring critical points (RCPs) of the three lowest-energy conformers of compounds **4′** and **5** were calculated and the results are given in Table 5. The topological analyses of **4′** and **5** show that there is an interaction between S(2) and S(6) but that this interaction is extremely weak. This conclusion is based on the fact that for **4′** the density in the BCP of the S···S bond is about 27 times lower than in the BCP of the SC single bond; for **5** this is 22 times. Moreover, the densities in the BCPs are 2.3 to 2.8 times lower than those found [calculated at the RI-BP86/TZVP level of theory] for the intermolecular S···S contacts (with a contact distance of about 3.0 Å) in a series of bis(thiocarbamoyl)disulfides.[18] The values of the density correlate well with those calculated for the parent compound **1**,[3] even though it seems that in compound **4′** the S···S interaction is slightly weaker than in **1** (0.0071 vs. 0.0078); in compound **5** the interaction seems slightly stronger (0.0087). The values of the RCPs confirm that the interaction should be very weak: the values of the phenyl rings are about three times larger those of the NSNS···S ring, for both compounds.

Table 5. Values of the electron density $\rho(r)$ (in au) of the relevant BCPs and RCPs for the three lowest-energy conformers of compounds **4′** and **5**. See text for details.

| | | **4′** | | | **5** | | |
|---|---|---|---|---|---|---|---|
| | | *Z,Z-a,a* | *Z,E-a,a* | *Z,E-a,s* | *Z,Z-a,a* | *Z,E-a,a* | *Z,E-a,s* |
| **BCP** | S2–C1 | 0.1887 | 0.1888 | 0.1889 | 0.1911 | 0.1911 | 0.1912 |
| | CH···N3 | 0.0081 | 0.0085 | 0.0086 | | | |
| | CH···N5 | 0.0081 | 0.0091 | | | | |
| | S2···S6 | 0.0071 | | | 0.0087 | | |
| **RCP** | $C_6Y_5$ | 0.0213 | 0.0213 | 0.0214 | 0.0192 | 0.0192 | 0.0193 |
| | SCCCH···N | 0.0080 | 0.0083 | 0.0082 | | | |
| | NSNS···S | 0.0064 | | | 0.0074 | | |

The combination of the above mentioned three criteria confirms the conclusion which was drawn for the parent compound: the proposed stabilising *intra*molecular interaction might not exist or at least be extremely weak, and *inter*molecular forces are the main cause of the observed *Z*,*Z* configuration in the solid.

### 2.4 Crystal Packing

Previously, it was hypothesized that in the crystal the *Z*,*Z* configuration of the title compounds allows a larger number of short intermolecular contacts per molecule, particularly via X···X (X = S, Se) contacts, than the corresponding *Z*,*E* configuration.[3] Naturally, this implies a closer packing. At present, though, the reliable ab initio prediction of a crystal packing remains practically very difficult, in particular for conformationally flexible molecules.[19–23] Still, we have been able to substantiate the idea that intermolecular (packing) forces are responsible for the preference of the *Z*,*Z* configuration, by performing simulations of the crystal packing of the parent compound **1** in both the *Z*,*Z* and *Z*,*E* configurations, using the OPiX software.[10] Starting from the atomic coordinates of a single molecule, this program generates[24–28] the solid-state packing for the six most common space groups ($P\bar{1}$, $P2_1/c$, $C2/c$, $Pbca$, $P2_1$, and $P2_12_12_1$), covering about 84% of the crystal structures deposited at the Cambridge Structural Database.[29,30] One limitation of the procedure, however, is the fact that the molecular geometry can not change during the optimization.[10] Even so, the energies of intermolecular interactions in molecular crystals are significantly smaller than the typical energies of intramolecular covalent interactions and, due to this, packing-induced molecular distortions are often limited.[31] Molecular structures calculated on higher levels of theory therefore often provide a good approximation to the structures observed in the crystal, and crystal structure predictions based on rigid calculated molecular structures is generally assumed to be reasonable.[32,33]

Also in the case of the parent Ph–S–N=S=N–S–Ph (**1**), the calculated gas-phase geometry of the *Z*,*Z-anti*,*anti* configuration seems to provide a useful model for the experimental geometry.[3] Therefore, the calculated molecular geometries of both configurations of **1** in the *anti,anti* conformation (i.e., *Z*,*Z-anti*,*anti* and *Z*,*E-anti*,*anti*, see Figure 1) were used in the OPiX calculations. However, to validate the simulation procedure and to investigate how well the method is able to reproduce experimentally observed unit cell dimensions, a first OPiX calculation was performed starting from the experimental geometry of **1** as it was reported by Leitch et al.[7] In the crystal (space group $C2/c$ and $Z = 4$) the molecules of **1** lie on $C_2$ axes. The OPiX software[10] allows using the corresponding subgroup which, in this case, is $P\bar{1}$. For this space group, the simulated unit cell of Ph–S–N=S=N–S–Ph (**1**) has a packing energy of –170.0 kJ mol$^{-1}$ and the following parameters: $a$ = 5.419 Å, $b$ = 7.584 Å, $c$ = 15.50 Å, $\alpha$ = 69.56°, $\beta$ = 79.94°, and $\gamma$ = 90.00°. The reduced unit cell parameters, calculated from the reported data,[7] are $a$ = 5.601(5) Å, $b$ = 7.792(8) Å, $c$ = 14.95(1) Å, $\alpha$ = 78.82(1)°, $\beta$ = 79.20(1)°, and $\gamma$ = 90.00°. As can be seen, there is a good agreement between calculated and experimental data.

The relevant results of the OPiX calculations performed using the molecular geometries of both the *Z*,*Z-anti*,*anti* and *Z*,*E-anti*,*anti* configurations of **1**, obtained from the quantum chemical calculations, are given in Table 6. From the packing energies and densities, given in Table 6, it can be seen that for all considered space groups the crystal packing of **1** in the *Z*,*Z* configuration has a systematic preference over the packing of **1** in the *Z*,*E* configuration by 0.3–4.9 kJ mol$^{-1}$ and 0.010–0.025 g cm$^{-3}$, respectively. In particular for the space group in which **1** crystallises, $C2/c$, the differences are 2.5 kJ mol$^{-1}$ and 0.012 g cm$^{-3}$ for the energy and density, respectively, in favour of the *Z*,*Z* configuration. It is interesting to note that for this space group the unit cell parameters simulated using the calculated *Z*,*Z*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

geometry ($a$ = 6.113 Å, $b$ = 6.848 Å, $c$ = 15.466 Å, $\alpha$ = 77.25°, $\beta$ = 83.10°, $\gamma$ = 87.20°) are likewise acceptably close to the experimental values given above. Furthermore, the calculated packing energy of the crystal based on **1** in its experimental geometry is 10.0 kJ mol$^{-1}$ lower than that of the crystal based on **1** in its gas-phase geometry, at least for the $P\bar{1}$ space group (see Table 6); it is 8.8 kJ mol$^{-1}$ lower than the most favourable packing based on the gas-phase geometry, i.e. that in the $P2_12_12_1$ space group.

Table 6. Packing energies ($E$ in kJ mol$^{-1}$) and densities ($D$ in g cm$^{-3}$)[a] of the crystal structures simulated by the OPiX suite of programs for the $Z$,$E$ and $Z$,$Z$ configurations of Ph–S–N=S=N–S–Ph **1**.

| | $Z$,$Z$-$a$,$a$ | | $Z$,$E$-$a$,$a$ | |
|---|---|---|---|---|
| Space group | $E$ | $D$ | $E$ | $D$ |
| $P\bar{1}$ | –160.0 | 1.495 | –156.4 | 1.476 |
| $P2_1/c$ | –158.7 | 1.496 | –158.4 | 1.486 |
| $C2/c$ | –154.5 | 1.445 | –152.0 | 1.433 |
| $Pbca$ | –152.0 | 1.459 | –150.2 | 1.437 |
| $P2_1$ | –158.6 | 1.487 | –153.7 | 1.462 |
| $P2_12_12_1$ | –161.2 | 1.501 | –158.8 | 1.489 |

[a] The experimental value is 1.471 g cm$^{-3}$.[7]

These findings can be considered as the manifestation of a trend to approach a close-packing regime via the $Z$,$Z$ configuration. In turn, this very favourable way of organising the crystal structure must then be largely responsible for the observed $Z$,$Z$ configurations of the title compounds **1**–**7**. Indeed, our theoretical and experimental work on isolated molecules of Ar–X–N=S=N–X–Ar (X = S, Se, and their derivatives) – in this work and in ref.[3] – suggests that even in the absence of stabilizing stereoelectronic interactions between the X$^{II}$ atoms the $Z$,$Z$ configuration has a minor thermodynamic preference over the $Z$,$E$ configuration (at least for the method/basis set combination used). As a consequence, both configurations coexist in the corresponding equilibria in the gas phase and in solution, but in the solid state only the $Z$,$Z$ configuration exists. Our OPiX calculations then suggest that the crystal packing of the discussed derivatives in the $Z$,$Z$ configuration has a further minor thermodynamic preference over that of the compounds in the $Z$,$E$ configuration. Both the intramolecular and the intermolecular effects seemingly act in the same direction, i.e., towards the packing of Ar–X–N=S=N–X–Ar (X = S, Se) in the $Z$,$Z$ configuration. Whereas in the gas phase or in solution the energy differences between the different isomers allows for the presence of the less stable isomer, the intermolecular (packing) forces seem to be critically important for the total domination of the $Z$,$Z$ configuration in the solid state. The idea that rather than *intra*molecular factors *inter*molecular ones (i.e. packing forces) are the main driving force behind the experimentally observed configurations, which was until now based on the results of the quantum chemical calculations, has thus been strengthened by the simulations of the crystal packing.

## 3. Conclusions

For Ph–S–N=S=N–S–Ph (**1**) and Ph–Se–N=S=N–Se–Ph (**2**) and their derivatives **3**–**7** the $Z$,$Z$ configuration is the only one of the three theoretically possible configurations observed in the solid state and this configurational preference can not be explained by intramolecular stereoelectronic effects, which is shown by three theoretical arguments at the B3LYP/6-311+G* level of theory. The analysis of the properties of the simulated crystal structures of two conformers of the parent compound Ph–S–N=S=N–S–Ph (**1**) strengthens the idea that rather than *intra*molecular factors *inter*molecular ones (that is packing forces) are the main driving force behind the experimentally observed $Z$,$Z$ configurations.

## Experimental Section

Compounds **4**[34] and **5**[35] were synthesized from $(Me_3SiN=)_2S$ and the corresponding ArSCl as described before. $^{15}$N and $^{77}$Se NMR spectra were recorded on a Bruker DRX-500 spectrometer at frequencies of 50.68 and 95.38 MHz, respectively, with $NH_3$ (liq.) and $Me_2Se$ as standards. $^{19}$F NMR spectra were recorded on a Bruker AC-200 spectrometer at a frequency of 188.20 MHz with $C_6F_6$ as the standard (the chemical shift of $C_6F_6$ with respect to $CFCl_3$ is –162.2 ppm). High-resolution mass spectra (EI, 70 eV) were recorded on a Finnigan MAT MS-8200 instrument. UV/Vis spectra were recorded on a Hewlett–Packard 8453 spectrophotometer. Synthetic procedures were carried out under an argon atmosphere in dried solvents with stirring. The reagents were added dropwise and solvents were always distilled off under reduced pressure.

### Syntheses

**1,5-Bis(heptafluoro-4-methylphenyl)-2,4-diaza-1,3,5-trihia-2,3-pentadiene (6):** Over a period of 1 h, a solution of 4-$CF_3C_6F_4SCl$[36] (2.85 g, 0.01 mol) in $CH_2Cl_2$ (15 mL) was added to a solution of $(Me_3SiN=)_2S$[37] (1.03 g, 0.005 mol) in $CH_2Cl_2$ (10 mL) at –30 °C. The reaction mixture was slowly warmed up to 20 °C, the solvent was distilled off and the residue was recrystallized from hexane. Compound **6** was obtained as bright yellow crystals in a yield of 2.23 g (80%), m.p. 75–76 °C. MS $m/z$: 557.9022 [M$^+$, calculated for $C_{14}F_{14}N_2S_3$ 557.9000]. NMR ($C_6D_6$): $\delta$ = $^{19}$F 106.5, 31.1, 23.7 ppm. UV/Vis (heptane) $\lambda_{max}$ (nm) (log $\varepsilon$): 412 (3.97). $C_{14}F_{14}N_2S_3$ (558.34): calcd. C 30.12, F 47.64, N 5.01, S 17.23; found C 30.09, F 47.62, N 4.84, S 17.35.

**1,5-Bis(pentafluorophenyl)-2,4-diaza-3-thia-1,5-diselena-2,3-pentadiene (7):** Over a period of 1 h, a solution of $C_6F_5SeCl$[38] (0.90 g, 0.0032 mol) in hexane (10 mL) was added to a solution of $(Me_3SiN=)_2S$[37] (0.32 g, 0.0016 mol) in hexane (20 mL) at 20 °C. After an additional hour the solvent was distilled off and the residue was recrystallized from hexane. Compound **7** was obtained as orange crystals in a yield of 0.56 g (62%), m.p. 42–43 °C. MS $m/z$: 553.8034 [M$^+$, calculated for $C_{12}F_{10}N_2SSe_2$ 553.7952]. NMR ($CDCl_3$): $\delta$ = $^{15}$N 302.1; $^{19}$F 36.5, 13.7, 2.7; $^{77}$Se 775 (broad, cf. ref.[2]) ppm. UV/Vis (heptane) $\lambda_{max}$ (nm) (log $\varepsilon$): 422 (3.68, sh), 370 (3.92). $C_{12}F_{10}N_2SSe_2$ (552.11): calcd. C 26.11, F 34.41, N 5.07; found C 25.93, F 34.45, N 5.11.

### Crystallographic Analyses

The single-crystal X-ray structure determinations (Table 7) were carried out on a Bruker P4 for compound **4**, a Stoe Stadi4 for compound **5** and a Syntex $P2_1$ diffractometer for compounds **6** and **7**, with graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) or Cu-$K_\alpha$ ($\lambda$ = 1.54178 Å) radiation. The structures were solved by direct methods using SHELXS-97[39] and refined by least-squares methods in the full-matrix anisotropic (isotropic for hydrogen atoms)

### Calculations

The DFT calculations were performed using Gaussian 03[40] applying standard gradient techniques at the B3LYP level of theory using the 6-311+G* basis set on all atoms; the basis set was used as it is implemented in the program. Calculations to determine the stability of the wave functions (or rather the mathematical constructions based on the Kohn–Sham orbitals) were performed using the same level and basis set and all wave functions were found to be stable. Force field calculations were used to ascertain whether the resulting structures were energy minima. All subsequent calculations of molecular properties were performed at the B3LYP/6-311+G* geometries. Bond orders (or rather overlap populations; see ref.[16]) were calculated according to the Hirshfeld Scheme.[16] QTAIM bond and ring properties were calculated using the AIMPAC suite of programs.[41] Crystal packing simulations were performed with the OPiX suite of programs[10] starting from the calculated (DFT/B3LYP/6-311+G*) geometries of the *Z*,*Z*-*anti,anti* and *Z*,*E*-*anti,anti* conformers of **1** (Figure 1). Initially, the recommended parameters were used in the optimizations, but in subsequent calculations these values were modified. In particular, the *energy threshold* parameter was lowered from the recommended value of 0.5 to 0.3 to obtain more detailed results. In the case of the *Pbca* space group the recommended values of the *energy threshold* and *step resolution* parameters were modified to 0.9 and 0.7, and 0.7 and 0.5 for the *Z*,*E* and *Z*,*Z* configurations, respectively.

## Acknowledgments

The authors are grateful to Prof. Angelo Gavezzotti for kindly providing the OPiX suite of programs, and to one referee for his or her valuable comments. The Novosibirsk authors are grateful to Dr. Vladimir V. Shcherbukhin for performing preliminary DFT calculations on the discussed compounds, to Mr. Mikhail K. Kovalev for his assistance in the syntheses, and to the Russian Foundation for Basic Research for financial support of their work (grant 06-03-32229).

# Controlled Synthesis and Characterization of CuO Nanostructures through a Facile Hydrothermal Route in the Presence of Sodium Citrate

**Hong-Mei Xiao,[a,b] Shao-Yun Fu,*[a] Lu-Ping Zhu,[a,b] Yuan-Qing Li,[a,b] and Guo Yang[a,b]**

**Keywords:** Hydrothermal synthesis / Nanostructures / Sodium citrate / Copper complexes

The controlled synthesis of one-dimensional, two dimensional, and three-dimensional CuO nanostructures has been achieved by a hydrothermal process in the presence of sodium citrate (SC) by simply controlling the reaction conditions. When the molar ratio of sodium citrate to $CuSO_4 \cdot 5H_2O$ (represented by SC/$Cu^{2+}$) is below 1.0, 1D CuO nanorods with 30–40 nm diameters and 100–200 nm lengths are formed. In the absence of citrate, 2D flakelike CuO nanostructures with 150–200 nm widths and 300–400 nm lengths are obtained. When the SC/$Cu^{2+}$ ratio is more than 1.0, 3D branchlike CuO nanostructures with lengths of hundreds of nanometers and diameters of 20–100 nm are attained. On the basis of the morphology and X-ray diffraction patterns of the samples, a possible growth mechanism for the CuO nanostructures is proposed. Moreover, it is shown that the optical bandgap energy ($E_g$) of resulting CuO nanostructures can be tuned through morphological control of the CuO nanostructures. Ultraviolet absorption measurements reveal that the estimated bandgap energy of the 1D rodlike, 2D flakelike, and 3D branchlike CuO nanostructures is 2.36, 1.60, and 1.40 eV, respectively.

## Introduction

Copper monoxide based materials are well known because of their relevance in high-temperature superconductivity and semiconducting antiferromagnetism.[1] CuO is a narrow bandgap ($E_g$ = 1.2 eV) *p*-type semiconductor and has been recognized as an industrially important material for a variety of practical applications, such as catalysis, solar energy conversion, gas sensing and field emission, in batteries, and in magnetic storage media.[2–14] Nanosized CuO may exhibit unique properties that can be significantly different from those of their bulk counterparts, for example, unusual optical, electrical, and catalytic properties, etc.[15a] Therefore, the synthesis and study of CuO nanostructures is both of practical and fundamental importance. In the last two decades, great efforts have been made to synthesize CuO nanostructures with various morphologies by a variety of wet chemical methods.[15–27] Among the various methods developed for fabrication of nanostructured CuO materials, the hydrothermal process has been considered as the most promising route because it is simple and can operate at low-temperatures and in a large scale.[16,19]

Besides the great interest in synthetic methods of the CuO nanostructures, there is a growing interest in the morphological control of CuO nanostructures.[18a,18d,28,29] Wet chemical methods, in which a water/ethanol mixture was used, were reported for the controlled synthesis of 1D CuO nanostructures, namely nanorods and nanoribbons, by controlling reagent concentrations.[18a] Controlled synthesis of CuO nanostructures such as nanoplatelets, nanoleaflets and nanowires was also realized by thermal dehydration of the as-prepared $Cu(OH)_2$ nanostructures in solution or in the solid state.[18d] CuO nanosheets and nanowhiskers were successfully obtained by controlling the liquid–solid reaction on copper surfaces under alkaline and oxidative conditions.[28] As mentioned above, the hydrothermal method is advantageous as it is simple and can operate at low temperatures and in a large scale, and hence should be more promising route for the controlled synthesis of CuO nanostructures, but this has not been reported previously.

It was claimed that semiconductors with bandgap energies in the range from 1 to 3 eV have important applications in solid-state photonic devices.[30] Various CuO nanostructures with different bandgap energies were reported.[15d,27b,29,31] A bandgap of 2.1 eV was reported for CuO nanoparticles,[15d] 2.78 eV for needle-shaped CuO nanocrystals,[31] 3.02 eV for CuO nanoplatelets,[27b] and 2.05 and 2.47 eV for CuO nanoellipsoids and nanosheets, respectively.[29] Moreover, the bandgap energy of CuO nanofibrils was estimated to be 1.67 eV.[32] Obviously, the bandgap energy depends on the morphology of CuO nanostructures. Thus, it can be expected that the bandgap energy of CuO nanostructures can be tuned by controlling the morphology of CuO nanostructures.

It is well known that sodium citrate (SC) is an important biological ligand for metal ions. It has been widely employed as a reductant and capping agent in the synthesis of elemental Ag, Au, and Ag–Au alloy nanoparticles.[33] It also serves as shape controller and stabilizer in the synthesis of $Ni(OH)_2$, calcite, coated CdSe colloids, doughnut-shaped ZnO microparticles, calcium phosphate and CuI crystals.[34] In this study, sodium citrate was employed for the first time for the controllable synthesis of CuO nanostructures with various morphologies using the hydrothermal process.

The controlled synthesis of nanostructured CuO samples with various morphologies was realized using the facile hydrothermal process through changing the molar ratio of sodium citrate to $CuSO_4 \cdot 5H_2O$ only. On the basis of the morphology and X- ray diffraction patterns of the samples, a possible growth mechanism for the CuO nanostructures was proposed. Moreover, UV absorption measurements show that CuO nanostructures display a blue shift of the bandgap relative to bulk CuO material and that the bandgap energy of the CuO nanostructures is tunable by controlling the morphology of the CuO nanostructures.

## Results and Discussion

### The Role of SC on Crystal Structure and Morphology

The control of the phase of the products through the hydrothermal route is shown in Figure 1. Figure 1a presents the XRD pattern of the product obtained without the addition of sodium citrate, and all peaks in the XRD patterns of the sample are consistent with the JCPDS (5–0661) data of copper oxide with a monoclinic phase.[35] When the SC/$Cu^{2+}$ ratio is 1.0, the XRD diffraction peaks can be indexed as the monoclinic phase of CuO (Figure 1b). The atomic ratio of Cu to O was estimated to be 1:1 by SEM-EDS elemental analysis (inset in Figure 1). However, when the SC/$Cu^{2+}$ is increased to 1.3, the XRD pattern of the obtained sample shows that the sample is no longer pure monoclinic CuO – a weak peak of cubic $Cu_2O$ also appears (Figure 1c). The above results indicate that citrate is very important in controlling the phase of the products during the hydrothermal process.

The influence of sodium citrate on the morphology of the CuO products was examined by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Figure 2a,b shows that the 2D flakelike CuO nanostructures with a width of 150–200 nm and a length of 300–400 nm were obtained by the hydrothermal process without citrate. Moreover, the 1D CuO nanorods with diameters of 30–40 nm and lengths of 100–120 nm were formed when the SC/$Cu^{2+}$ ratio was 1.0, as shown in Figure 2c,d. Figure 2e,f shows the 3D branchlike CuO nanostructures at a SC/$Cu^{2+}$ ratio of 1.3. The branchlike CuO nanostructures consist of sub-branched nanorods with diameters of about 20–100 nm, which radiate from the sides of the main stem of the branchlike CuO nanostructures.

The electron diffraction (ED) patterns of 1D (inset in Figure 2d), 2D (inset in Figure 2b), and 3D (inset in Figure 2f) CuO show that they are all single crystals.

### Formation Mechanism

Figure 3a shows the molecular structure of sodium citrate with three carbonyl groups and one hydroxy group. After the addition of sodium citrate to $CuSO_4 \cdot 5H_2O$, $Cu^{2+}$ and sodium citrate form a complex. Daniele et al. reported that the main component of citrate solutions of $Cu^{2+}$ in the

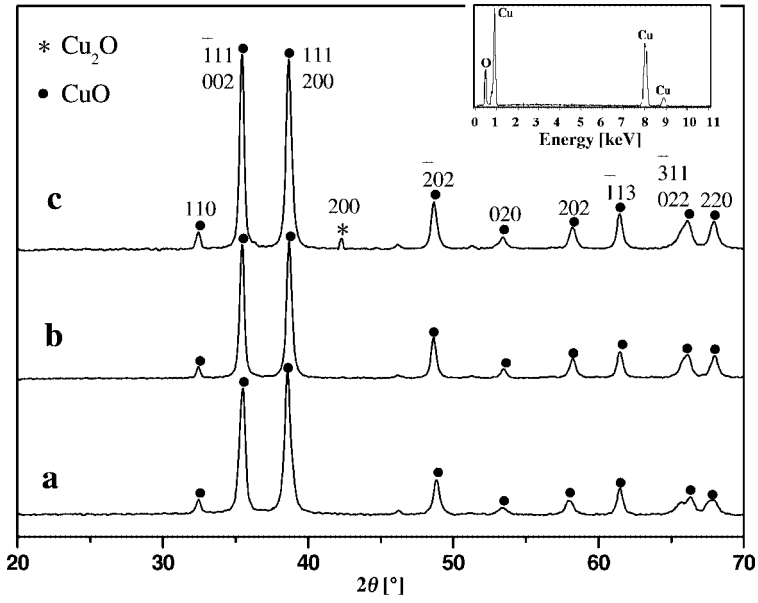

Figure 1. XRD patterns of the samples prepared by the hydrothermal route: (a) without sodium citrate, (b) SC/$Cu^{2+}$ = 1.0, and (c) SC/$Cu^{2+}$ = 1.3. The inset presents the SEM-EDS elemental analysis of the sample with SC/$Cu^{2+}$ = 1.0.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

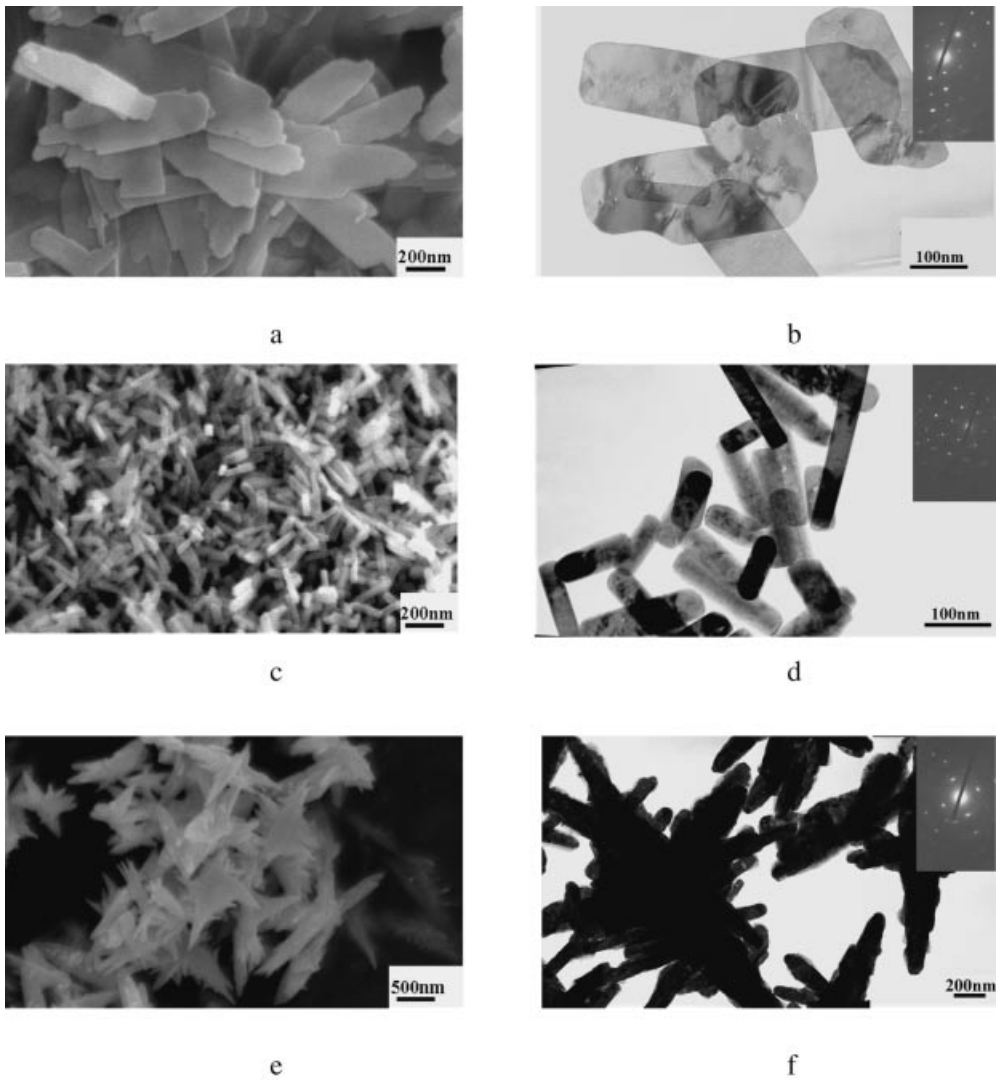

Figure 2. SEM images (a, c, e) and TEM images (b, d, f) of flakelike CuO (a and b, without sodium citrate), rodlike CuO (c and d, $SC/Cu^{2+}$ = 1.0), and branchlike CuO (e and f, $SC/Cu^{2+}$ = 1.3). The corresponding ED patterns of CuO are shown in the insets of the TEM images.

pH range 5–10 is the dimer $[Cu_2(cit)_2]^{4-}$ ($cit^{4-}$ = $[C_6H_4O_7]^{4-}$).[36] When the $SC/Cu^{2+}$ ratio is ≤1.0, the possible molecular structure of the citrate complex of $Cu^{2+}$ (complex **1**) is shown in the Figure 3b. Two $Cu^{2+}$ ions can form two six-membered rings and two seven-membered rings with two $cit^{4-}$ ions. As the $SC/Cu^{2+}$ ratio increases, the amount of complex **1** increases. Upon addition of NaOH solution, the formation of complex **1** delays the formation of $Cu(OH)_2$ nanoparticles and the crystal growth of $Cu(OH)_2$. Furthermore, the formation of complex **1** allows the elongation of the $Cu(OH)_2$ crystals in the direction perpendicular to the principal plane of the complex and elongation is inhibited in other directions. Therefore, the $Cu(OH)_2$ nanoparticles grow preferentially by the oriented attachment of the primary nanoparticles, which is coupled with coordination self-assembly thereby resulting in polycrystalline $Cu(OH)_2$ nanorods. With hydrothermal treatment the $Cu(OH)_2$ nanorods are transformed into CuO nanorods.

When the $SC/Cu^{2+}$ ratio is more than 1.0, another citrate complex of $Cu^{2+}$ (complex **2**, shown in the Figure 3c) appears. One $Cu^{2+}$ ion forms two six-membered rings with two $cit^{4-}$ ions. Strong H-bonds form between the carbonyl group ($-COO^-$) and the hydroxy group (–OH) in complex **2**. As the $SC/Cu^{2+}$ ratio increases, the amount of complex **2** also increases. Upon adding NaOH solution, the H-bonds in complex **2** attacks the hydroxy ion in complex **1** that protrudes out of the edge of the orthorhombic $Cu(OH)_2$ with the corrugated layer structure. Consequently, the orthorhombic $Cu(OH)_2$ is activated, and the dehydrated reaction takes place more easily at the positions attacked by complex **2**. With hydrothermal treatment, the preferential growth of CuO occurs easily in the direction of attack by complex **2**, and branched CuO therefore forms. The XRD patterns of the branched CuO samples show that they are not pure monoclinic CuO samples – a weak peak of cubic $Cu_2O$ also appears (Figure 1c). The appearance of the

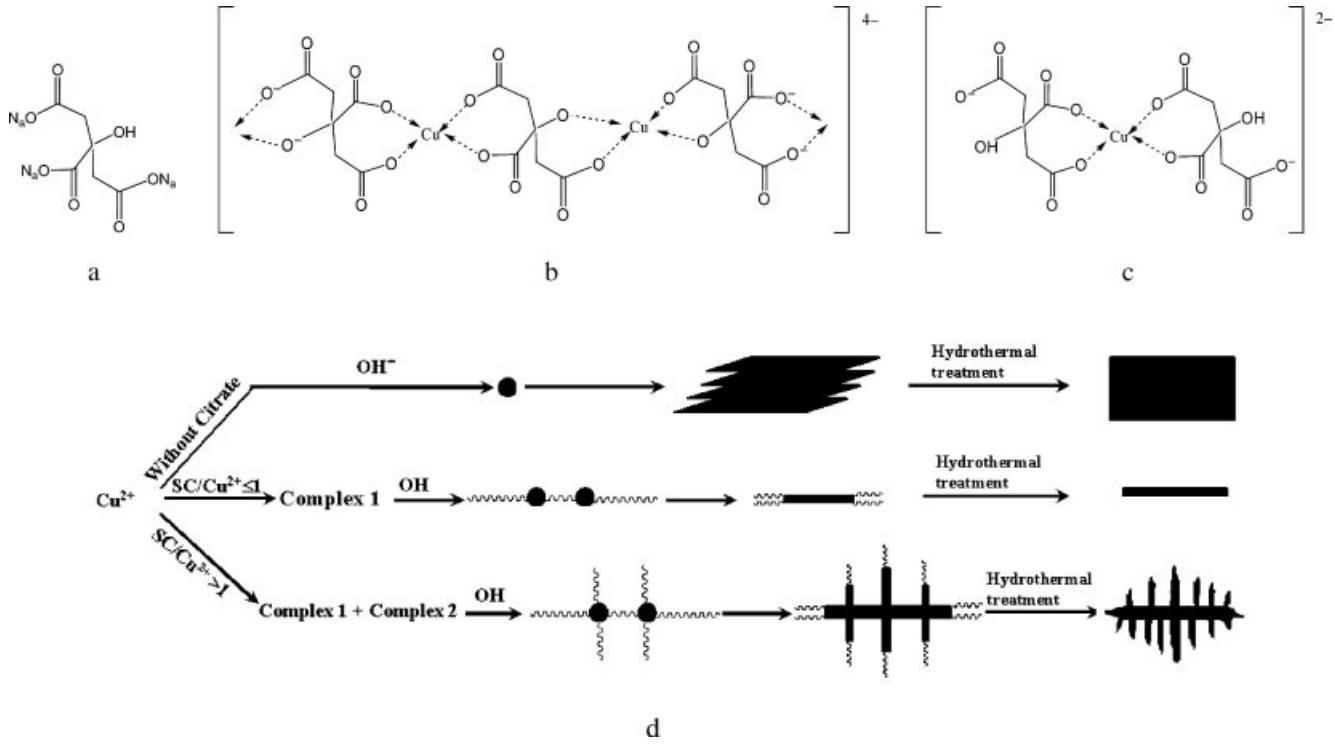

Figure 3. Molecular structures of (a) sodium citrate, (b) complex **1**, and (c) complex **2**, and (d) schematic illustration of the formation process for the as-prepared CuO nanostructures.

$Cu_2O$ phase shows that citrate has a reducing capability. The above-mentioned results indicate that citrate, which acts as a modifying and reducing agent, plays a critical role in the determination of the morphology and in the control of the phase of the CuO nanostructures during the hydrothermal process. Yang et al. reported a similar result in the presence of ethylene glycol.[19]

A schematic diagram of the proposed growth mechanism is shown in Figure 3d. The formation of the flakelike CuO nanostructures without sodium citrate is determined by the internal crystallographic structure of the $Cu(OH)_2$ precursor.[28] After the addition of $OH^-$, orthorhombic $Cu(OH)_2$ first precipitates in solution. The orthorhombic $Cu(OH)_2$ consists of chains in the (001) planes, which are oriented along [100] and characterized by the square-planar coordination of the $Cu^{2+}$ ions with strong H-bonds. By edge-sharing, a sheet of distorted $Cu(OH)_6$ octahedra is formed. The 2D layers of these sheets parallel to the (010) plane are connected through H-bonds. With hydrothermal treatment, orthorhombic $Cu(OH)_2$ transforms into flakelike, monoclinic CuO nanostructures by a dehydration reaction in which the interplanar H-bonds are broken. When the $SC/Cu^{2+}$ ratio is $\leq 1.0$, the formation of complex **1** leads to the formation of the rodlike CuO. When the $SC/Cu^{2+}$ ratio is $\geq 1.0$, the coexistence of complex **1** and complex **2** results in the appearance of branchlike CuO.

## Optical Properties

The UV/Vis absorption spectrum of the CuO samples dispersed in distilled water (the concentration was about 0.02 $mgmL^{-1}$) is presented in Figure 4, which shows a broad absorption peak centered at about 335 nm. In principle, the optical bandgap energy for a semiconductor can be estimated by Equation (1),[37] where $A$ is the absorbance, $K$ is a constant, and $m$ equals 1 for a direct transition.

$$A = \frac{K(hv - E_g)^{m/2}}{hv} \quad (1)$$

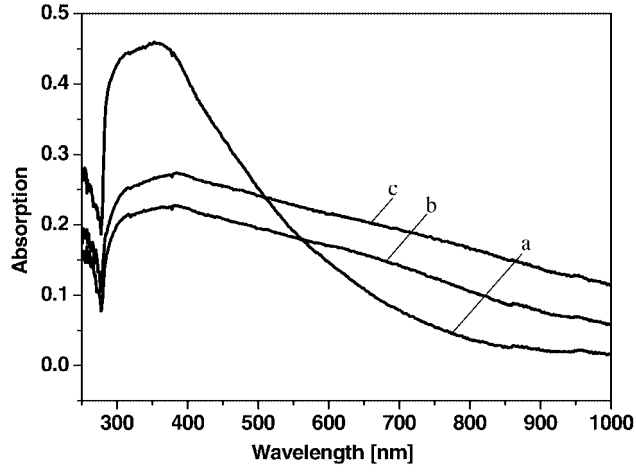

Figure 4. UV/Vis absorption spectrum of (a) rodlike CuO, (b) flakelike CuO, and (c) branchlike CuO.

Figure 5 shows a plot of $(A \cdot E_{phot})^2$ vs. photon energy ($E_{phot}$) for a direct transition. Extrapolation to $A = 0$ gives an absorption edge energy that corresponds to the bandgap energy $E_g$.[38] The bandgap energies of the 1D rodlike, 2D

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

flakelike, and 3D branchlike CuO samples were estimated to be 2.36, 1.60, and 1.40 eV, respectively, which are all larger than that reported for bulk CuO ($E_g$ = 1.2 eV).[18d] The result shows that the bandgap of the CuO samples strongly depends on the morphology of the CuO products. A large enhancement of the bandgap energy of the CuO nanorods is attributed to the well-known quantum size effect for nanostructured semiconductors.[39] In addition, the different values of the bandgap energy of the CuO nanostructures with various morphologies indicates that the bandgap can be tuned by controlling the morphology of the CuO nanostructures.

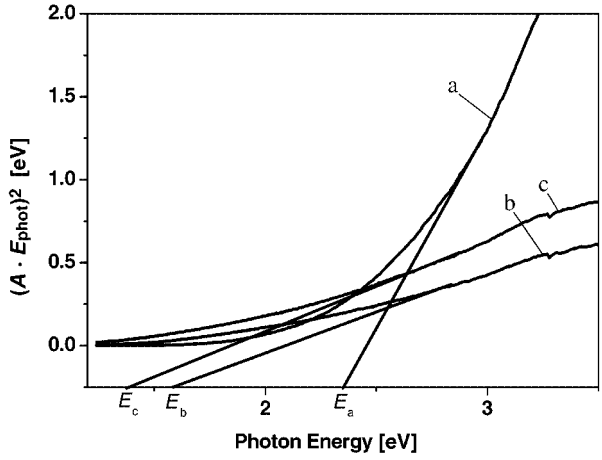

Figure 5. Plot of $(A \cdot E_{phot})^2$ vs. $E_{phot}$ for a direct transition for (a) 1D rodlike CuO, (b) 2D flakelike CuO, and (c) 3D branchlike CuO.

## Conclusions

The controlled synthesis of different nanostructured CuO samples has been achieved by a hydrothermal process in the presence of sodium citrate. It was found that the morphology of the CuO samples was affected by the SC/$Cu^{2+}$ ratio. When the SC/$Cu^{2+}$ ratio was below 1.0, 1D CuO nanorods with 30–40 nm diameters and 100–200 nm lengths were formed. In the absence of citrate, 2D flakelike CuO nanostructures were obtained. However, 3D branchlike CuO nanostructures were attained when the SC/$Cu^{2+}$ ratio was more than 1.0. It is proposed that the formation of different nanostructured CuO is influenced by the different citrate complex of $Cu^{2+}$ formed. The bandgap energies of the 1D rodlike, 2D flakelike, and 3D branchlike CuO nanostructures was estimated to be 2.36, 1.60, and 1.40 eV, respectively, which are all larger than that reported ($E_g$ = 1.2 eV) for bulk CuO material.

## Experimental Section

The chemical reagents including $CuSO_4 \cdot 5H_2O$, sodium citrate ($C_6H_5O_7Na_3 \cdot 2H_2O$), and sodium hydroxide were of analytical grade and used without further purification.

CuO nanostructures were synthesized by a hydrothermal process in the presence of sodium citrate. A typical synthesis of the CuO nanostructures is described as follows: $CuSO_4 \cdot 5H_2O$ (1.3 mmol) and a chosen amount of sodium citrate were dissolved in distilled water (40 mL), and the solution was constantly stirred for 15 min. NaOH (5.3 mmol) was then added to the above solution mixture. After 2.5 h of constant stirring, the final solution was transferred to a 50-mL Teflon-lined autoclave. The autoclave was then sealed in a stainless steel tank and kept at 160 °C for 12 h. The reactor was then naturally cooled to room temperature. The resulting samples were collected and washed with deionized water and dried at 50 °C in air. In order to investigate the influence of sodium citrate on the morphology of the final product, the molar ratio of sodium citrate to $CuSO_4 \cdot 5H_2O$ was changed from 0.1 to 1.5.

X-ray diffraction patterns [RINT 2000 Wilder-angel goniometer with Cu-$K_\alpha$ radiation ($\lambda$ = 1.5406 Å)] and UV/Vis absorption spectra (Lambda 900 spectrometer) were used to characterize the as-obtained CuO nanostructures. The morphology of the CuO nanostructures was studied using transmission electron microscopy (Hitachi H-600 with an accelerating voltage of 200 kV) and scanning electron microscopy (Hitachi S-4300 microscope). The electron diffraction patterns were recorded with a JEOL JEM-2010 transmission electron microscope at an accelerating voltage of 200 kV.

# Synthesis and Study of the Crystallographic and Magnetic Structure of $HoFeMnO_5$

**Angel Muñoz,*[a] José A. Alonso,[b] María J. Martínez-Lope,[b] and José L. Martínez[b]**

**Keywords:** Ferrimagnetic structure / Superexchange interactions / Neutron diffraction / High oxygen pressure

A new oxide of stoichiometry $HoFeMnO_5$ has been obtained by replacing $Mn^{3+}$ cations by $Fe^{3+}$ in the parent oxide $HoMn_2O_5$. The crystallographic and magnetic structures have been analyzed by neutron powder diffraction (NPD), which complements susceptibility and magnetization measurements. $HoFeMnO_5$ is orthorhombic, belonging to the *Pbam* space group like the parent compound. The crystal structure contains infinite chains of edge-sharing $Mn^{4+}O_6$ octahedra, interconnected by dimer units of $Fe^{3+}O_5$ square pyramids. In comparison with $HoMn_2O_5$, containing elongated $Mn^{3+}O_6$ pyramids, the $Fe^{3+}O_5$ units are flattened. The magnetization measurements show that $HoFeMnO_5$ presents a long-range magnetic order below $T_C \approx 153$ K. An NPD study shows that $HoFeMnO_5$ adopts a collinear ferrimagnetic structure: each of the $Mn^{4+}$ and $Fe^{3+}$ sublattices are ferromagnetically coupled, and the coupling between the two sublattices is antiferromagnetic; the magnetic moments are oriented along the *c* direction. The $Ho^{3+}$ cations also order below $T_C$, but with a very small magnetic moment; the $Ho^{3+}$ moments are parallel to the $Fe^{3+}$ magnetic sublattice. At $T = 2.7$ K, the ordered magnetic moments for the $Mn^{4+}$, $Fe^{3+}$ and $Ho^{3+}$ ions are 1.31(6), 3.20(10) and 0.36(7) $\mu_B$, respectively. In comparison with $ErFeMnO_5$, where $Er^{3+}$ cations are fully ordered at low temperatures, in $HoFeMnO_5$ there is a frustration concerning the long-range order of the $Ho^{3+}$ cations, which remain virtually paramagnetic over the whole temperature range.

## Introduction

In the last years, the interest in some rare-earth manganese oxide families such as $RMn_2O_5$ (R = rare earth, Y or Bi) has been revitalized, as different studies have shown a strong coupling between magnetism and ferroelectricity, also in the oxides that are in the select club of magnetoferroelectric materials.[1–6] For instance, in $TbMn_2O_5$, the application of an oscillating magnetic field can reverse the direction of the electrical polarization.[2,3,6] As it has been demonstrated for $(Tb,Dy,Ho)Mn_2O_5$,[5,6] an external magnetic field also gives rise to a strong increase in the dielectric constant near the order temperature $T_N$.

$RMn_2O_5$ compounds crystallize in an orthorhombic crystallographic structure having space group *Pbam*. The 4*f* and 4*h* sites are occupied by the $Mn^{4+}$ and $Mn^{3+}$ cations, respectively.[7–11] The structure contains infinite chains of edge-sharing $Mn^{4+}O_6$ octahedra arranged along the *c* axis; the chains are corner-linked by pairs of $Mn^{3+}O_5$ edge-sharing pyramids. Below $T_N$, in the temperature interval 39–45 K, most of the $RMn_2O_5$ compounds become magnetically ordered according to an incommensurate magnetic structure[12,13] defined by the propagation vector $\mathbf{k} = (k_x,0,k_z)$, with $k_x \approx 0.5$. A few compounds of this family present a commensurate magnetic structure such as $BiMn_2O_5$, $\mathbf{k} = (1/2,0,1/2)$,[14] and $LaMn_2O_5$, $\mathbf{k} = (0,0,1/2)$.[15] A few degrees below $T_N$, the onset of a ferroelectric transition takes place, with the polarization vector **P** oriented along the *b* axis. Very recently, it has been reported that $(Ho,Tb,Er,Y)Mn_2O_5$ presents a magnetic transition to a commensurate structure at the ferroelectric transition temperature $T_C$. Furthermore, on decreasing temperature, another magnetic transition to an incommensurate structure happens, which coincides with an anomaly in the dielectric constant.[4,16–19]

Recently, a new series of rare-earth manganese oxides has been derived from $RMn_2O_5$ by replacing $Mn^{3+}$ by $Fe^{3+}$ cations. The crystallographic structure and the magnetic behaviour of $YFeMnO_5$ and $ErFeMnO_5$ have already been reported.[20,21] The sample preparation requires a high-oxygen-pressure treatment, in order to stabilize $Mn^{4+}$ cations into the crystal structure. These novel $RFeMnO_5$ compounds keep the orthorhombic structure (space group *Pbam*) of the parent $RMn_2O_5$ oxides. However, important changes are observed in the magnetic behaviour, as both $YFeMnO_5$ and $ErFeMnO_5$ display ferrimagnetic behaviour below $T_C \approx 165$ K. The magnetic moments of the $Mn^{4+}$ and $Fe^{3+}$ cations are antiferromagnetically coupled along the *c* direction.

In this paper we describe a new phase of this family, $HoFeMnO_5$, for which we report the crystallographic structure and the magnetic properties, analyzed by neutron powder diffraction (NPD); the magnetic behaviour is also investigated by macroscopic magnetization measurements.

## Results

### Sample Preparation

Stoichiometric amounts of analytical grade $Ho_2O_3$, $FeC_2O_4{\cdot}2H_2O$ and $MnCO_3$ were dissolved in citric acid; the solvent was slowly evaporated, and the obtained organic resin was dried at 120 °C and slowly decomposed at temperatures up to 600 °C in air. High-oxygen-pressure treatments were performed in a VAS furnace. About 2 g of the precursor powder were placed in a gold can during the oxygenation process. The sample was slowly heated up to 900 °C at a final pressure of 200 bar and held at this temperature for 12 h. The product was finally cooled, under pressure, at 300 °C/h, down to room temperature. Finally, the oxygen pressure was slowly released.

### Magnetic Susceptibility and Magnetization

The magnetic measurements were performed in a commercial SQUID magnetometer from Quantum Design. The dc magnetic susceptibility was measured both in zero-field cooling (ZFC) and field cooling (FC) conditions in the temperature intervals $1.8 < T < 400$ K and $1.8 < T < 328$ K, respectively, under a magnetic field of 1 kOe. Ac magnetic susceptibility measurements were also carried out in the temperature range 50–250 K, the frequencies of the transversal oscillating magnetic field being 0.32, 7, 33, 321 and 997 Hz. As regards the isothermal magnetization curves, different hysteresis cycles were obtained at $T$ = 3, 50 and 225 K for a magnetic field ranging from –50 kOe to 50 kOe.

### Neutron Diffraction Data

The NPD experiments were carried out at the Institut Laue-Langevin, Grenoble (France). For the study of the crystallographic structure, two patterns, one at room temperature and one at 10 K were collected with the high-resolution D2B diffractometer, at a wavelength of 1.594 Å. For the magnetic structure resolution and the study of its thermal evolution, a set of NPD patterns were acquired with the high-flux D20 diffractometer at $\lambda$ = 2.418 Å and in the temperature interval $2.7 < T < 267$ K. The refinement of the different NPD diagrams was performed by the Rietveld method[22] with the Fullprof program.[23] A pseudo-Voigt function was used for the simulation of the profile of the Bragg peaks and a fifth-degree polynomial function was used for the fitting of the background. The coherent scattering lengths for Ho, Fe, Mn and O were 8.01, 9.45, –3.73 and 5.803 fm, respectively.

### Results of Magnetic Measurements

The ZFC and FC curves of the dc susceptibility are presented in Figure 1. Both curves coincide at high temperature, but below $T_C \approx 153$ K the two curves split at the onset of a magnetic ordering process. Below $T_C$, the ZFC susceptibility curve steadily increases and exhibits a maximum at $T$ = 100 K, which suggests the presence of antiferromagnetic interactions, and then a minimum at around 50 K, where a new change in the slope of the ZFC susceptibility indicates the presence of a remnant magnetization. The FC susceptibility curve continuously increases below $T_C$, also displaying a change in the slope at around 50 K. In the isothermal magnetization curves represented in Figure 2, a narrow hysteresis loop is observed at $T$ = 50 K and $T$ = 2 K with a remnant magnetization of 0.11 and 0.32 $\mu_B$ per formula, respectively. A maximum magnetization of 6.5 $\mu_B$/f.u. is reached for the maximum applied field of 5 T. The presence of a remnant magnetization is in good agreement with the thermal behaviour of the dc susceptibility below $T_C$ and with the ferrimagnetic order determined from the neutron diffraction data. At $T$ = 225 K, the isothermal magnetization curve presents linear behaviour, as it corresponds to a paramagnetic state.

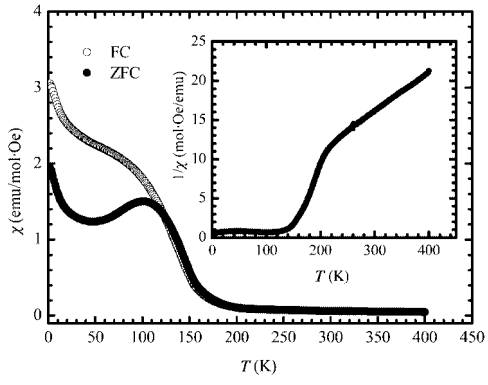

Figure 1. Thermal evolution of the field cooling (FC) and zero-field cooling (ZFC) dc susceptibility. Inset: inverse of the susceptibility (ZFC data).

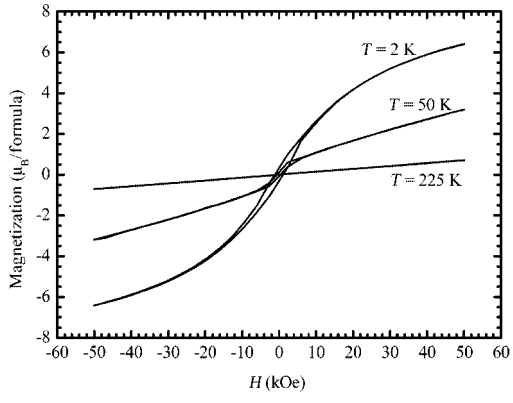

Figure 2. Magnetization vs. magnetic field isotherms at $T$ = 2, 50 and 225 K.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As it can be seen in the inset of Figure 1, the inverse of the susceptibility shows linear behaviour at high temperature; in the temperature interval $263 < T < 395$ K, the reciprocal susceptibility is fitted to a Curie–Weiss law, yielding a paramagnetic temperature $\Theta_P = -28.5(5)$ K and an effective paramagnetic moment of 12.16(1) $\mu_B$/f.u. The theoretical effective magnetic moment can be estimated by considering the expression $\mu_{eff} = [\mu_B(Mn^{4+})^2 + \mu_B(Fe^{3+})^2 + \mu_B(Ho^{3+})^2]^{1/2}$; the effective magnetic moments for spin-only $Mn^{4+}$, high-spin $Fe^{3+}$ and $Ho^{3+}$ ($^5I_8$ ground state configuration) are 3.87, 5.92 and 10.60 $\mu_B$, respectively, which implies an effective magnetic moment of 12.74 $\mu_B$, in good agreement with the experimental value.

The thermal evolution of the ac susceptibility is shown in Figure 3 for temperatures ranging from 50 to 250 K at different frequencies. $\chi'$ and $\chi''$ represent the real (in-phase) and imaginary (out-of-phase) components of the susceptibility, respectively. Both $\chi'$ and $\chi''$ present only one maximum at around the long-range ordering temperature $T_C \approx 153$ K, and the height of the peak decreases with increasing frequency; in both cases, the position of the maximum does not seem to shift upon varying the frequency.

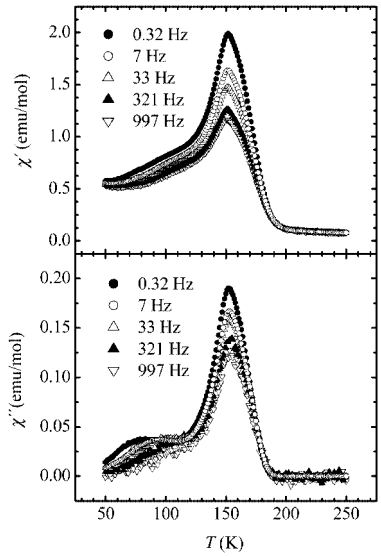

Figure 3. Thermal evolution of the real and imaginary parts of the ac susceptibility.

## Crystallographic Structure from Neutron Powder Diffraction

For the refinement of the crystallographic structure, two high-resolution NPD patterns, one acquired at room temperature and the other at $T = 10$ K, with $\lambda = 1.594$ Å were used. In the refinement carried out with the room temperature NPD pattern, all the Bragg peaks of the diagram could be indexed in the orthorhombic space group *Pbam*. Firstly, it was assumed that the Mn and Fe atoms occupy the 4*f* (*0*,1/2,*z*) and 4*h* (*x*,*y*,1/2) sites, respectively; however, a better fit was obtained if a certain anti-site disorder was allowed between Mn and Fe atoms. The lattice parameters obtained in the refinement and the corresponding discrepancy factors are shown in Table 1. In Table 2, the atomic positions and the occupancy of the Mn/Fe cations are presented. At room temperature, the 4*f* site is occupied at 94(2)% by the Mn atoms [6(2)% of Fe atoms]; in contrast, in the 4*h* site the disorder is slightly higher, since it is occupied at 86(2)% and 14(2)% by Fe and Mn atoms, respectively. Since a high oxygen pressure was necessary for the sample preparation, the possible deficiency in oxygen has also been checked by refining the oxygen occupancy at room temperature. As it is shown in Table 2, a small oxygen deficiency seems to ex-

ist, which is as high as 8(2)% for the O1 and O3 atoms. The crystallographic formula refined from NPD data is $HoFe_{0.92(2)}Mn_{1.08(2)}O_{4.74(10)}$, yielding a slightly Mn-rich compound with respect to the nominal stoichiometry. The most characteristic interatomic distances and bond angles are presented in Table 3. The good agreement between the experimental and calculated NPD patterns in the final Rietveld fit can be observed in Figure 4a.

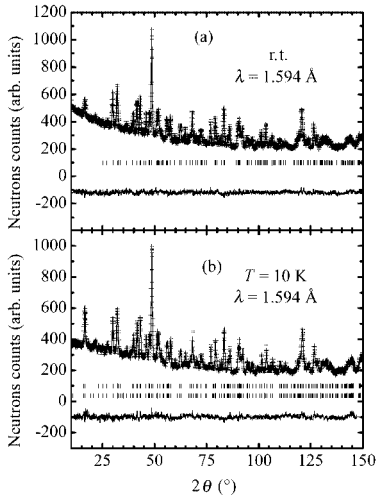

Figure 4. Comparison of the experimental (crosses), calculated (solid line) and difference (at the bottom) NPD patterns. (a) At room temperature; the tick marks correspond to the positions of the allowed Bragg reflections. (b) At $T$ = 10 K; the first and second rows of tick marks correspond to the nuclear and magnetic reflections, respectively.

The crystallographic structure at $T$ = 10 K has also been refined from high-resolution NPD data in the same orthorhombic space group *Pbam*. At this temperature $HoFeMnO_5$ is magnetically ordered; therefore, the magnetic contribution to the NPD pattern was taken into consideration. After including the magnetic structure described below, the refinement yielded the lattice parameters, atomic positions and discrepancy factors also included in Table 1 and Table 2; the most important interatomic distances and bond angles are listed in Table 3. As it can be observed in Table 2, the anti-site disorder between the Fe and Mn cations is very similar to that found at room temperature. The experimental and calculated NPD patterns are compared in Figure 4b.

In Figure 5, a projection of the crystallographic structure along the *c* axis is presented. $Mn^{4+}$ cations (4*f* site) are at the centre of $Mn^{4+}O_6$ octahedra which share edges via the equatorial O2 and O3 oxygen atoms, forming infinite chains along the *c* axis. The $Fe^{3+}$ cations (4*h* site) are coordinated to five closer neighbouring oxygen atoms in a pyramidal configuration; in the $Fe^{3+}O_5$ pyramids the O3 oxygen atom is in the axial position and the O1 and O4 oxygen atoms are in the equatorial plane. Two $Fe^{3+}O_5$ pyramids, doubly linked by O1 oxygen atoms, form a dimer unit $Fe_2O_{10}$. In this way, four $Mn^{4+}O_6$ octahedral chains are linked by these dimer units through the O3 and O4 oxygen atoms.

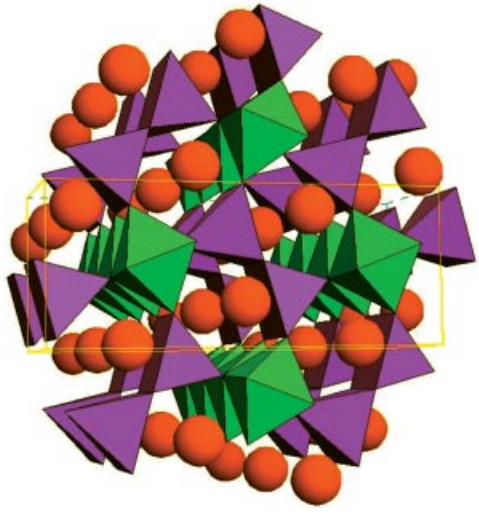

Figure 5. View of the crystallographic structure of $HoFeMnO_5$ along the *c* axis. Octahedra and tetragonal pyramids correspond to $Mn^{4+}O_6$ and $Fe^{3+}O_5$ polyhedra, respectively. The octahedra share edges, forming infinite chains along the *c* axis. The pyramids form dimer units, linking together the chains of octahedra. The spheres represent the Ho atoms.

### Determination of the Magnetic Structure

The determination of the magnetic structure and the analysis of its thermal evolution was carried out from a set of NPD patterns acquired in the temperature range from 267.0 to 2.7 K. The thermal evolution of the different NPD patterns is displayed in Figure 6; upon cooling below 153 K, the intensities of some Bragg peaks start to increase, indicating the onset of a magnetic order, in good agreement with the magnetization measurements. The magnetic struc-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ture is defined by the propagation vector **k** = 0, since there are no magnetic peaks outside the permitted Bragg positions. The thermal evolution of the integrated intensity for some Bragg reflections is shown in Figure 7; in the thermal evolution of the intensity, no changes are observed that could suggest a variation in the magnetic arrangement.

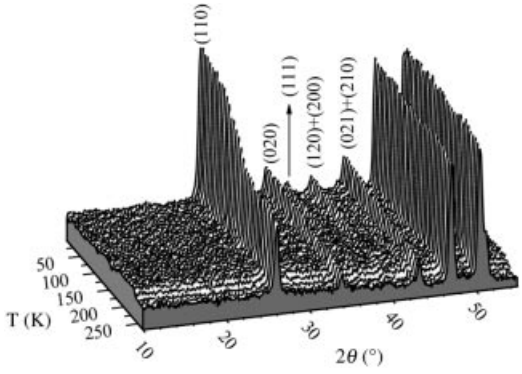

Figure 6. Thermal dependence of the NPD patterns collected with $\lambda$ = 2.418 Å.

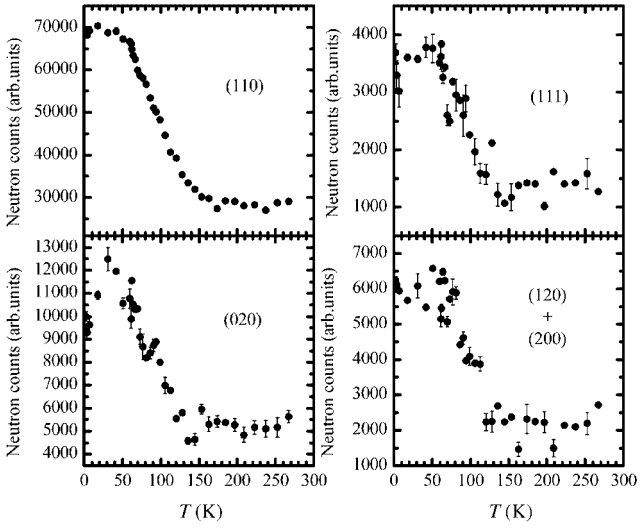

Figure 7. Thermal evolution of the integrated intensity of some magnetic reflections.

The different magnetic structure models, compatible with the crystallographic structure of the compound, have been determined from the representation analysis technique of group theory, by following the method described by Bertaut.[24] The possible magnetic structures corresponding to Mn (4*f* site), Fe (4*h* site) and Ho (4*g* site) atoms are those given in ref.[20]. The Mn atoms are labelled as 1(0,1/2,*z*), 2(1/2,0,–*z*), 3(0,1/2,–*z*) and 4(1/2,0,*z*); the notation for the Fe atoms is 5(*x*,*y*,1/2), 6(–*x*,–*y*,1/2), 7(–*x* + 1/2,*y* + 1/2,1/2) and 8(*x* + 1/2, –*y* + 1/2,1/2); the notation for the Ho atoms is 9(*x*,*y*,0), 10(–*x*,–*y*,0), 11(–*x* + 1/2,*y* + 1/2,0) and 12(*x* + 1/2, –*y* + 1/2,0).

After checking the different magnetic structure models, the solution that gives a better agreement with the experimental results corresponds to the basis vectors (0,0,$F_z$), (0,0,$F'_z$), and (0,0,$F''_z$) for the $Mn^{4+}$, $Fe^{3+}$ and $Ho^{3+}$ ions, respectively. For the $Fe^{3+}$ and $Ho^{3+}$ cations, the moments are oriented along the positive *z* direction, whereas for $Mn^{4+}$cations, the magnetic moments are directed along the negative *z* direction, in a global ferrimagnetic structure. At *T* = 2.7 K the magnetic moment values for $Mn^{4+}$, $Fe^{3+}$ and $Ho^{3+}$ ions are 1.31(6), 3.20(1) and 0.36(7) $\mu_B$, respectively (see Table 4). The good agreement between the experimental and calculated NPD patterns after the fitting of the magnetic structure at *T* = 2.7 K is shown in Figure 8; the discrepancy factors of the refinement are displayed in Table 4. A schematic plot of the ferrimagnetic order is presented in Figure 9. The thermal evolution of the magnetic moments for the magnetic ions is displayed in Figure 10; according to this figure, all the magnetic ions become ordered at the same temperature, but the magnetic moment of the $Ho^{3+}$ cations remains nearly constant (around 0.40 $\mu_B$) over the whole temperature range. As regards the magnetic moments of the $Mn^{4+}$ and $Fe^{3+}$ cations, they seem to reach saturation at around 60 K.

Table 4. Results obtained in the refinement of the magnetic structure at *T* = 2.7 K (angular range $2\Theta$ = 8–86°). Discrep. factors: $R_B$ = 3.9%, $R_{Mag}$ = 9.9%, $\chi^2$ = 3.1.

| | $Mn^{4+}$ | $Fe^{3+}$ | $Ho^{3+}$ |

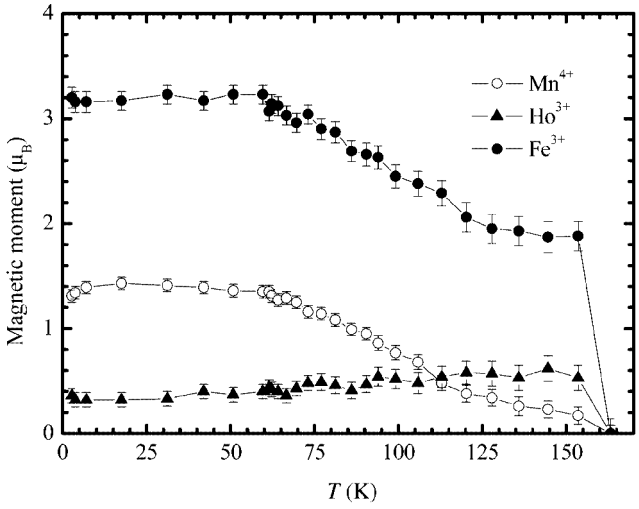

Figure 10. Thermal evolution of the module of the magnetic moments.

The thermal evolution of the lattice parameters has also been determined; as shown in Figure 11, the unit-cell volume progressively shrinks down to 130 K, and in the magnetically ordered regime, the volume remains nearly constant. The three lattice parameters *a*, *b* and *c* (not shown here) present a similar thermal variation.

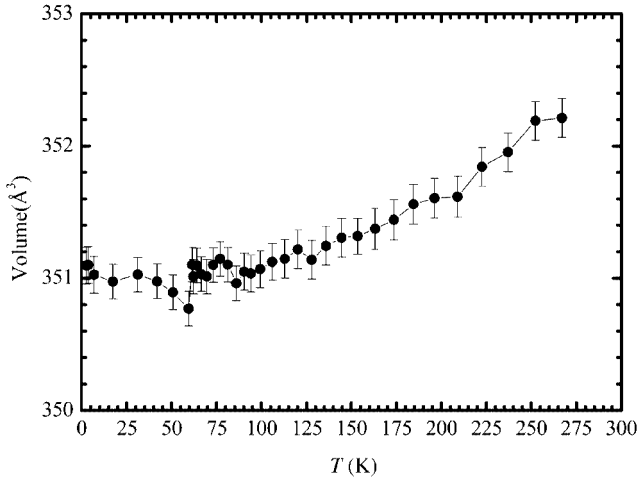

Figure 11. Thermal evolution of the volume of the unit cell.

## Discussion

The analysis of the crystallographic structure of $HoFeMnO_5$ by neutron diffraction indicates that this new oxide keeps the crystallographic structure of the parent $HoMn_2O_5$ oxide[11] (space group *Pbam*). Despite the fact that the ionic radii of the $Fe^{3+}$ and $Mn^{3+}$cations are very similar (0.645 Å in sixfold coordination and high-spin state[25]), some distinct features have been found both in the lattice parameters and in the interatomic distances of the $Mn^{4+}O_6$, $Fe^{3+}O_5$ and $Ho^{3+}O_8$ polyhedra. A comparison of the room-temperature lattice parameters of $HoMn_2O_5$,[11] *a* = 7.2643(3), *b* = 8.4768(3) and *c* = 5.6700(2) Å, with those of $HoFeMnO_5$, shows that the substitution of the $Mn^{3+}$ cations by $Fe^{3+}$ gives rise to an expansion of the unit-cell parameters. The changes in the interatomic distances in the $Mn^{4+}O_6$ octahedra are not very significant; the average bond length is 1.902(2) Å in $HoMn_2O_5$ and 1.891(9) Å in $HoFeMnO_5$. In both cases the $Mn^{4+}O_6$ octahedral are flattened, because the three Mn–O distances are different; the Mn–O3 and Mn–O2 bonds in the equatorial plane correspond to the shorter and longer bonds, respectively. In the tetragonal pyramids, the substitution of $Mn^{3+}$ by $Fe^{3+}$ causes a shortening of the axial bond length Fe–O3 and an elongation of the equatorial bond lengths Fe–O4 and Fe–O1, with a slight average expansion of the pyramidal units: the average bond length is 1.933(3) Å in $HoMn_2O_5$ and 1.947(4) Å in $HoFeMnO_5$. The changes observed in the tetragonal pyramids cannot be related to the ionic radii, because $Mn^{3+}$ and $Fe^{3+}$ have the same tabulated value. The changes are very possibly linked to the Jahn–Teller character of the $Mn^{3+}$ cations, which favour the lengthening of the axial interatomic distance in order to remove the degeneracy of the $t_{2g}$ and $e_{2g}$ energy levels; the $Fe^{3+}$ cations do not show such a Jahn–Teller character. Finally, in the $Ho^{3+}O_8$ polyhedron, although some slight variations in the individual Ho···O interatomic distances are observed, the average Ho···O distances are very similar, 2.381(2) Å in $HoMn_2O_5$ and 2.383(5) Å in $HoFeMnO_5$.

The magnetic structure of $HoFeMnO_5$ is similar to the magnetic structure of the previously described members of the $RFeMnO_5$ family, with R = Y and Er; the magnetic moments within the $Mn^{4+}$ and $Fe^{3+}$ sublattices are ferromagnetically coupled, and the two sublattices couple antiferromagnetically, giving rise to a global ferrimagnetic structure in such a way that the magnetic unit cell coincides with the crystallographic one. In all the mentioned compounds the magnetic moments are oriented along the *z* direction. However, $HoFeMnO_5$ presents certain features that distinguish it from other members of the series containing paramagnetic $R^{3+}$ cations, namely $ErFeMnO_5$. Firstly, the ordered magnetic moments of the $Mn^{4+}$ and $Fe^{3+}$ cations at 2 K, 1.31(6) and 3.20(10) $\mu_B$, respectively, are relatively small in comparison with the theoretical values of 3 and 5 $\mu_B$. Secondly, the ordered magnetic moment of $Ho^{3+}$ is very small relative to the magnetic moment reached by $Er^{3+}$ in $ErFeMnO_5$,[21] 8.59(7) $\mu_B$; in fact, it can be said that the $Ho^{3+}$ moments undergo a weak long-range magnetic order. The different magnetic behaviour of the $Er^{3+}$ and $Ho^{3+}$ sublattices is clearly exhibited by the different thermal evolution presented by the magnetic reflections (110) and (020): although in $ErFeMnO_5$[21] these magnetic reflections undergo a sharp increase below 75 K, in $HoFeMnO_5$ the integrated intensity of the mentioned reflections increase monotonically below $T_C \approx 153$ K, reaching saturation at around 50 K, much like the situation in $YFeMnO_5$.

The magnetic ordering of the $Mn^{4+}$ and $Fe^{3+}$ sublattices is defined by the superexchange interactions that appear between the $Mn^{4+}$···$Mn^{4+}$, $Mn^{4+}$···$Fe^{3+}$ and $Fe^{3+}$···$Fe^{3+}$ cations. The magnetic interactions between the $Mn^{4+}$···$Mn^{4+}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cations are characterized by the $J_1$ and $J_2$ superexchange interactions, which are associated with the $Mn^{4+}$–O2–$Mn^{4+}$ and $Mn^{4+}$–O3–$Mn^{4+}$ paths, with bond angles of 101.5(8)° and 94.6(9)°, respectively, at $T$ = 10 K. The Goodenough–Kanamori rules[26,27] for a 90° cation($d^3$)–anion–cation($d^3$) interaction indicate the presence of ferromagnetic (FM) and antiferromagnetic (AFM) interactions, the AFM interactions being mainly associated with a direct overlap of the $t_{2g}$ orbitals of the two cations, which strongly depends on the interatomic distance between the two cations. This subtle equilibrium between AFM and FM interactions along the chains of the $MnO_6$ octahedra, which in the case of the parent $RMn_2O_5$ compounds gives rise to incommensurate magnetic structures, is clearly broken by the presence of Fe at the pyramidal positions via strong Fe–O–Fe FM interactions followed by AFM Fe–O–Mn coupling, giving rise to positive $J_1$ and $J_2$ superexchange interactions along the chains of the octahedra.

It seems reasonable to think that the strong superexchange Fe–O–Fe interactions within the dimer $Fe_2O_{10}$ units trigger the onset of the magnetic ordering of the $Fe^{3+}$ spins immediately below $T_C$. There is an abrupt change in the reciprocal dc susceptibility at 220 K, as displayed in the inset of Figure 1, which plausibly coincides with the onset of Fe–O–Fe short-range interactions. In each dimer, the two $Fe^{3+}$ cations are linked through the O1 oxygen with a bond angle at $T$ = 10 K of 94.0(4)°. We can define $J_5$ as the superexchange interaction across the $Fe^{3+}$–O1–$Fe^{3+}$ path (Figure 12). On considering the Goodenough–Kanamori rules[26,27] for a 90° cation($d^5$)–anion–cation($d^5$) interaction, the coupling between the $Fe^{3+}$···$Fe^{3+}$ cations via O1 oxygen atoms would be FM ($J_5 > 0$), in accord with Hund's rule applied to the $p_x$ and $p_y$ orbitals of the central O1 oxygen, forming strong σ chemical bonds with the $d_{z^2-y^2}$ orbitals of neighbouring Fe atoms.

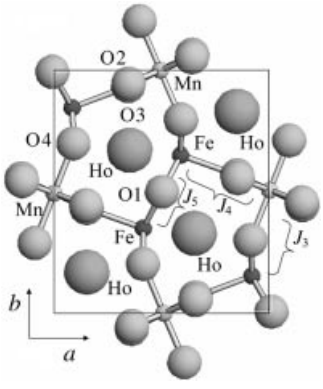

Figure 12. A view of the crystallographic structure along the [001] direction.

As it can be seen in Figure 12, the $Mn^{4+}$···$Fe^{3+}$ interactions are characterized by the superexchange $Fe^{3+}$–O4–$Mn^{4+}$ ($J_3$) and $Fe^{3+}$–O3–$Mn^{4+}$ ($J_4$) paths, whose bond angles are 121.4(3)° and 132.3(5)°, respectively, at $T$ = 10 K. The Goodenough–Kanamori rules[26,27] indicate that for a 180° cation($d^5$)–anion–cation($d^3$) interaction, the superexchange interactions are predominantly FM, whereas for a 90° bond there are FM and AFM interactions, the AFM interactions being more important. As the bond angles are closer to 90°, it seems that the superexchange interaction in the $Fe^{3+}$–O4–$Mn^{4+}$ and $Fe^{3+}$–O3–$Mn^{4+}$ bonds are mainly AFM ($J_3 < 0$, $J_4 < 0$). These interactions define the global AFM coupling between the Fe and Mn sublattices, giving rise to a ferrimagnetic structure.

As regards the ordering of the $Ho^{3+}$ sublattice, the experimental results suggest that the $Ho^{3+}$ moments are weakly polarized by the molecular field of the $Fe^{3+}$ magnetic sublattice immediately below $T_C$, giving rise to FM and AFM alignments with the $Fe^{3+}$ and $Mn^{4+}$ sublattices, respectively. In principle, a weak direct superexchange interaction is expected between the $Ho^{3+}$ cations via the $Ho^{3+}$···O1···$Ho^{3+}$, $Ho^{3+}$···O2···$Ho^{3+}$ and $Ho^{3+}$···O4···$Ho^{3+}$ paths (see Figure 12); therefore, the observed magnetic order at relatively high temperatures should be caused by the interaction with the $Mn^{4+}$ and $Fe^{3+}$ cations. The superexchange interactions would take place via the $Ho^{3+}$···O1–$Fe^{3+}$ ($J_6$), $Ho^{3+}$···O4–$Fe^{3+}$ ($J_7$), $Ho^{3+}$···O2–$Mn^{4+}$ ($J_8$) and $Ho^{3+}$···O4–$Mn^{4+}$ ($J_9$) paths; the interaction through the Ho···O1–Fe path involves the indirect interaction with the two $Fe^{3+}$ cations of the dimer. Besides, around the O1 oxygen there are two Ho atoms linked by an inversion centre and the $\mathbf{r} = \mathbf{a} + \mathbf{b}$ lattice translation; so, independently of the sign of $J_6$, both $Ho^{3+}$ cations must be ferromagnetically coupled. However, according to the magnetic structure, the interactions between $Ho^{3+}$ and the two $Fe^{3+}$ cations of the dimer are FM; therefore, $J_6$ is positive. In contrast, the coupling with the $Mn^{4+}$ cations is AFM, so $J_8$ and $J_9$ are negative. As regarding the sign of $J_7$ associated with the $Ho^{3+}$···O4–$Fe^{3+}$ path, it is very possible that $J_7$ is negative in contrast with the sign of $J_6$; it would contribute to the frustration of the long-range magnetic order of the $Ho^{3+}$ sublattice. In $ErFeMnO_5$, the scenario for the $Er^{3+}$ sublattice can be similar, but in this compound the <Er···O> interatomic distances are slightly shorter [2.363(2) Å at room temp.], so it seems that the direct Er···O···Er superexchange interactions play a more important role in the establishment of the long-range magnetic order. In $HoFeMnO_5$, with longer Ho···O interatomic distances, the participation of the direct superexchange interactions Ho···O···Ho in the long-range magnetic order seems to be much less important.

## Conclusions

By following a singular synthesis process that includes a thermal treatment under high oxygen pressure, it has been possible to obtain $HoFeMnO_5$. The crystallographic structure, investigated by NPD, is similar to that of $HoMn_2O_5$ (orthorhombic, space group *Pbam*), and can be described as infinite chains of edge-sharing $Mn^{4+}O_6$ octahedra running along the *c* axis; the chains are corner-linked by pairs of $Fe^{3+}O_5$ edge-sharing pyramids; the $Ho^{3+}$ cations are arranged in voids with eightfold oxygen coordination. A certain cationic disorder has been found over the 4*f* and 4*h* sites, ideally occupied by the $Mn^{4+}$ and $Fe^{3+}$ cations, respec-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tively: the crystallographic formula can be rewritten as $Ho(Fe_{0.86(2)}Mn_{0.14(2)})_{4h}(Mn_{0.94(2)}Fe_{0.06(2)})_{4f}O_{4.74(10)}$. In contrast with $HoMn_2O_5$, showing elongated $Mn^{3+}O_5$ pyramids, the $Fe^{3+}O_5$ units in $HoFeMnO_5$ are flattened; this difference is ascribed to the Jahn–Teller character of the $Mn^{3+}$ cations.

Magnetization and NPD data show that $HoFeMnO_5$ is a ferrimagnet with $T_C \approx 153$ K; the magnetic structure is characterized by $\mathbf{k} = 0$, consisting of an AFM arrangement of $Fe^{3+}$ and $Mn^{4+}$ spins, aligned along the *c* axis. $Ho^{3+}$ moments become slightly polarized below $T_C$, ferromagnetically coupled to the $Fe^{3+}$ sublattice and antiferromagnetically coupled to the $Mn^{4+}$ sublattice. At $T = 2.7$ K, the magnetic moment values for the $Mn^{4+}$, $Fe^{3+}$ and $Ho^{3+}$ ions are 1.31(6), 3.20(10) and 0.36(7) $\mu_B$, respectively. In contrast with the full long-range magnetic ordering of $Er^{3+}$ cations in $ErFeMnO_5$, where the initial polarization of Er moments immediately below $T_C$ is completed at lower temperatures by direct Er···O···Er interactions, in the present case it seems that the participation of direct Ho···O···Ho superexchange interactions in the long-range magnetic order is insignificant and the $Ho^{3+}$ moments remain in a quasi-paramagnetic state down to 2 K in $HoFeMnO_5$.

# The Relationship Between $^{27}Al$ Quadrupolar Parameters and $AlF_6^{3-}$ Octahedron Connectivity in Crystalline and Glassy Fluoroaluminates

**Monique Body,*[a] Christophe Legein,[b] Jean-Yves Buzaré,[a] and Gilles Silly[c]**

*This paper is dedicated to Professor Neil Bartlett on the occasion of his 75th birthday*

**Keywords:** Glasses / Fluorides / $^{27}Al$ NMR spectroscopy / Quadrupolar parameters

$^{27}Al$ SATRAS and MQ-MAS spectra were recorded for eight crystalline compounds, from the $CaF_2$–$AlF_3$ and $BaF_2$–$AlF_3$ binary and $BaF_2$–$CaF_2$–$AlF_3$ ternary systems, and four glass compositions with different $CaF_2$/$BaF_2$/$AlF_3$ contents. For the crystalline phases, the reconstruction of the spectra leads to the precise determination of the NMR parameters. For the glassy phases, the $^{27}Al$ SATRAS spectra have been reconstructed using quadrupolar parameter distributions. The main finding of this study is the dependence of the quadrupolar frequency on the type of $AlF_6^{3-}$ octahedron connectivity. For crystalline phases the experimental $\nu_Q$ values range between 75 kHz and 510 kHz for structures built up from isolated octahedra, and are between 560 kHz and 1250 kHz for structures built up from isolated chains of *cis*-connected octahedra, and are between 1530 kHz and 1580 kHz for structures built up from isolated chains of *trans*-connected octahedra. In the glassy phases the maximum of the quadrupolar frequency distribution shifts toward larger values and its width increases with increasing $AlF_3$ content, and subsequently with the number of connected octahedra. The range of the $\nu_Q$ values seems to indicate that when the octahedra are connected, *cis* connections occur most frequently.

## Introduction

The use of $^{27}Al$ NMR can provide important structural information relating to the local order around aluminium atoms in crystalline and disordered compounds. Numerous $^{27}Al$ NMR studies have been performed on a wide range of chemical systems. Oxide minerals have been particularly well studied. The isotropic chemical shifts observed in the spectra for these materials have been used to determine the nature of the Al coordination, and for obtaining information about the chemical environments of the Al atoms.

As aluminium atoms have a quadrupolar nucleus ($I$ = 5/2), other valuable structural information may also be obtained through the quadrupolar interactions. Actually, the $^{27}Al$ NMR spectra are broadened by this interaction even under Magic Angle Spinning (MAS) conditions. This hinders the precise determination of the quadrupolar parameters, especially when several crystallographically independent Al sites are present in the compound. However, the development of techniques such as SAtellite TRAnsition Spectroscopy (SATRAS),[1,2] and Multiple Quantum Magic Angle Spinning (MQ-MAS),[3] which are able to average first- and second-order broadenings, have allowed high-resolution $^{27}Al$ NMR spectra to be recorded from which the quadrupolar parameters in crystalline compounds,[4–20] and their distributions in disordered phases,[16,21–30] can be accurately determined.

In this paper we present a $^{27}Al$ NMR study of crystalline and glassy fluoride phases that are built up from $AlF_6^{3-}$ octahedra. The compounds under investigation are crystalline fluoridoaluminates of the $BaF_2$–$AlF_3$ (α-, β- and γ-$BaAlF_5$, $Ba_3Al_2F_{12}$, and $Ba_3AlF_9$-Ib) and $CaF_2$–$AlF_3$ binary systems (α-$CaAlF_5$, $Ca_2AlF_7$), α-$BaCaAlF_7$, and glassy phases of the corresponding $BaF_2$–$CaF_2$–$AlF_3$ ternary system ($50CaF_2$–$15BaF_2$–$35AlF_3$, $35CaF_2$–$25BaF_2$–$40AlF_3$, $35CaF_2$–$20BaF_2$–$45AlF_3$, and $35CaF_2$–$15BaF_2$-$50AlF_3$). We have already investigated β-$CaAlF_5$ and β-$Ba_3AlF_9$ by $^{27}Al$ NMR spectroscopy.[18,19] The crystalline compounds belonging to these systems that are not included in this study are as follows: $Ba_5AlF_{13}$ and $Ba_5Al_3F_{19}$, the crystal structures of which are unknown,[31] δ-$BaAlF_5$[32] which, to the best of our knowledge, cannot

be obtained by a solid-state reaction, and $Ba_3AlF_9$-Ia, which we were unable to synthesize.[33] SATRAS experiments were carried out for all the studied samples. For multi-site crystalline phases and glasses, MQ-MAS spectra were also recorded. The reconstruction of the NMR spectra leads to the determination of the quadrupolar parameters for the crystalline compounds. These quadrupolar parameters are then classified according to the $AlF_6^{3-}$ octahedron connectivities.

The reconstructions of the SATRAS spectra for the $BaF_2$–$CaF_2$–$AlF_3$ glassy phases lead to a determination of the quadrupolar parameter distributions in relation to the $AlF_3$ content. These results are discussed in the light of a recent $^{19}$F NMR study on the same glassy phases,[34] which led to the experimental determination of the mean number, $\beta$, of fluorine atoms per $AlF_6^{3-}$ octahedron. It was shown that the $\beta$ value is between 6 and 5 for the studied glasses, and is dependent on the amount of $AlF_3$ in the glass (35–50%). For $\beta$ = 6, the $AlF_6^{3-}$ octahedra are isolated, and $\beta$ = 5 may correspond to the presence of infinite chains of octahedra in the glass. Correlation of $^{27}$Al NMR results for glassy and crystalline phases with $^{19}$F NMR spectroscopic data analyses of the glassy phases enables an accurate picture to be gained of the glass network through the dependence of the quadrupolar parameters on the octahedron connectivity.

## Results

### $^{27}$Al Quadrupolar Parameters in Crystalline Compounds

All the compounds under investigation are built up from a framework of $AlF_6^{3-}$ octahedra. In α- and β-$CaAlF_5$[35,18] only infinite isolated chains of $AlF_6^{3-}$ octahedra sharing *trans*-fluorine atoms are present, as shown in Figure 1a. The chains are corrugated, and the F–Al–F angles are equal to 157.5° and 155.8° in α- and β-$CaAlF_5$, respectively. In α-,[36] β-, and γ-$BaAlF_5$[37], the octahedra share corners at the *cis* position to form infinite isolated chains as shown in Figure 1b. The Al–F–Al angles show small variations: 146.2° in α-$BaAlF_5$, 145.9° and 145.6° in β-$BaAlF_5$, and 144.5° and 139.5° in γ-$BaAlF_5$.

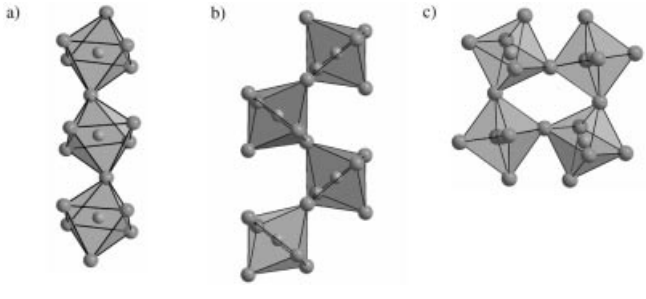

Figure 1. The different connectivities of the $AlF_6^{3-}$ octahedra encountered in the investigated crystalline phases: isolated chains of (a) *trans*-connected octahedra, (b) *cis*-connected octahedra and (c) tetrameric group of *cis*-connected octahedra.

There is only one unique aluminium site present in the α-$CaAlF_5$[35] and α-$BaAlF_5$[36] structures. Accordingly, for both compounds, the central transitions of the SATRAS spectra (Figure 2) correspond to one Al site. These central transitions present singularities that are characteristic of high quadrupolar frequency values. However, the line shape of the α-$CaAlF_5$ central transition is typical of an $\eta_Q$ value that is nearly equal to 1, whereas the central transition in the α-$BaAlF_5$ spectrum corresponds to a small $\eta_Q$ value. The method for extracting the NMR parameters has been described in detail for β-$CaAlF_5$;[16] an initial estimation of the quadrupolar parameters $\nu_Q$ and $\eta_Q$ is obtained from the reconstruction of the central transition line shape (Figure 2), and then precise values are given by the reconstruction of the overall spinning sideband envelope shape. $AlF_3$ is present as an impurity in α-$CaAlF_5$ and its contribution has been included in the reconstructed spectrum with a relative intensity of 0.5%, using the relevant NMR parameters previously determined by Silly et al.[15]. The NMR parameters leading to the best simulations are summarized in Table 1. $^{27}$Al MAS NMR spectra were previously recorded by Sakida et al.[38] for α-$CaAlF_5$ and α-$BaAlF_5$. However, these authors did not determine the quadrupolar parameter values, and they did not give the $\delta_{iso}$ value for α-$CaAlF_5$. However, they found $\delta_{iso}$ = –13.4 ppm for α-$BaAlF_5$, which is significantly different from our value. Their value is questionable since the experimental spectrum was not recon-

structed. We suggest that our results are more reliable as the experimental spectra were reconstructed taking into account all the interactions up to the second order.

Table 1. $AlF_6^{3-}$ octahedron connections, compounds, isotropic chemical shifts, $\delta_{iso}$ (ppm), quadrupolar frequencies, $\nu_Q$ (kHz), and asymmetry parameters, $\eta_Q$, from the reconstructions of the $^{27}Al$ NMR spectra.

| Connection | Compound | $\delta_{iso}$ (± 2) | $\nu_Q$ (± 5%) | $\eta_Q$ (± 0.05) |

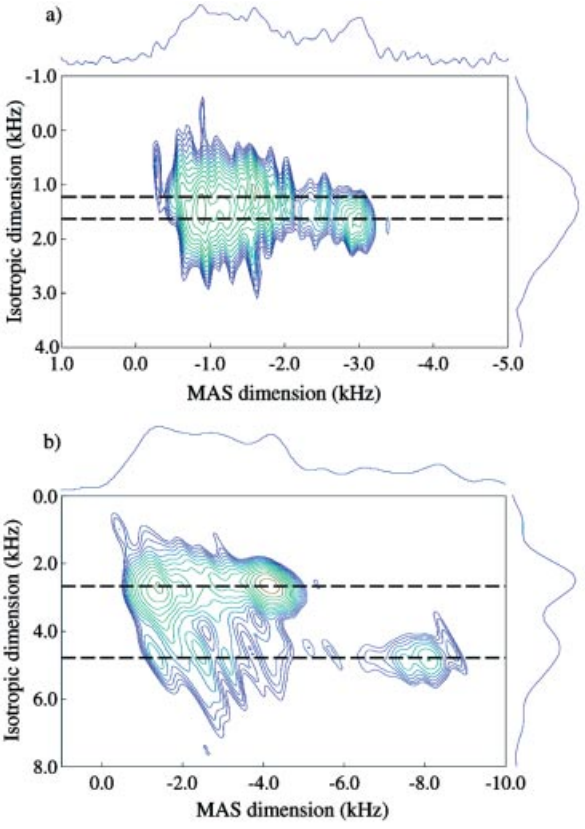

Figure 3. Experimental $^{27}Al$ 3Q-MAS NMR spectra for (a) β-$BaAlF_5$ and (b) γ-$BaAlF_5$ at 25 kHz. The curves at the top and to the right of the spectra are the projections of the spectra on to the MAS (*F2*) and isotropic (*F1*) axes, respectively. The dashed lines indicate the *F1* slices used for preliminary estimation of the NMR parameters.

Both the β- and γ-$BaAlF_5$ structures contain two symmetry-independent aluminium sites.[37] For these two compounds two aluminium sites can be resolved along the *F1* dimension in the 3Q-MAS spectra, as shown in Figure 3. As previously done for β-$Ba_3AlF_9$,[19] an initial estimation of the NMR parameters is given by the reconstruction of the *F1* slices. Then a precise determination of the NMR parameters is obtained from the reconstruction of the whole $^{27}Al$ SATRAS spectra. Two contributions of equal intensity are needed for the reconstruction of the β-$BaAlF_5$ SATRAS spectrum. Similarly, the two contributions used for the reconstruction of the γ-$BaAlF_5$ SATRAS spectrum have the same relative intensity. For both compounds the corresponding NMR parameters are listed in Table 1. The experimental and reconstructed central transitions are presented in Figure 4. In both compounds the Al sites have the same multiplicities, therefore ab initio calculations are required before any of these parameters can be attributed to the symmetry-independent Al atoms.

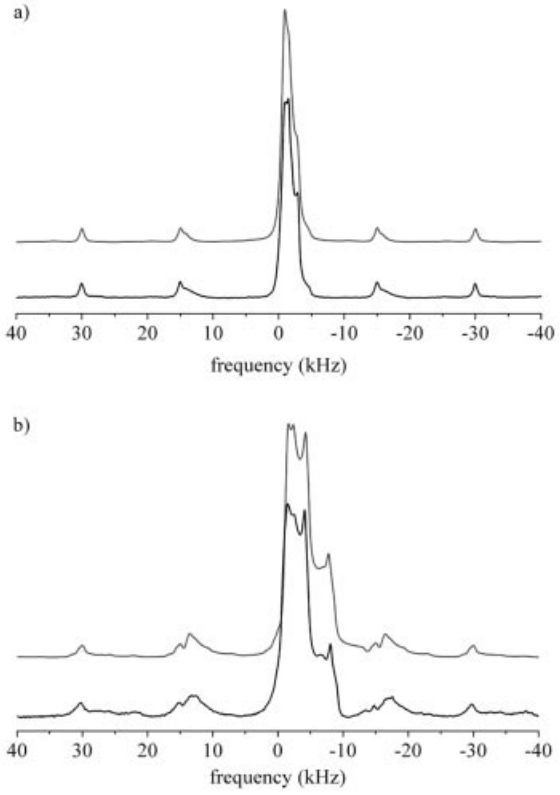

Figure 4. Experimental (bottom) and reconstructed (top) central transitions of the $^{27}Al$ SATRAS NMR spectra for (a) β-$BaAlF_5$ and (b) γ-$BaAlF_5$ at 15 kHz.

$Ba_3Al_2F_{12}$ comprises tetramers formed by four $AlF_6^{3-}$ octahedra sharing corners at the *cis* position,[39,40] as shown in Figure 1c. These tetrameric groups are separated from each other by barium and "free" fluorine ions (i.e. not linked to Al). Similarly, the NMR parameters were determined by first reconstructing the central transition, and then the whole experimental $^{27}Al$ SATRAS spectrum. These NMR parameters are given in Table 1. Experimental and reconstructed central transition and SATRAS spectra

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

are presented in Figure 5. Sakida et al.[38] determined an isotropic chemical shift value of $\delta_{iso}$ = –11.7 ppm for this compound. The comments made above with respect to α-$BaAlF_5$ hold for this compound as well.

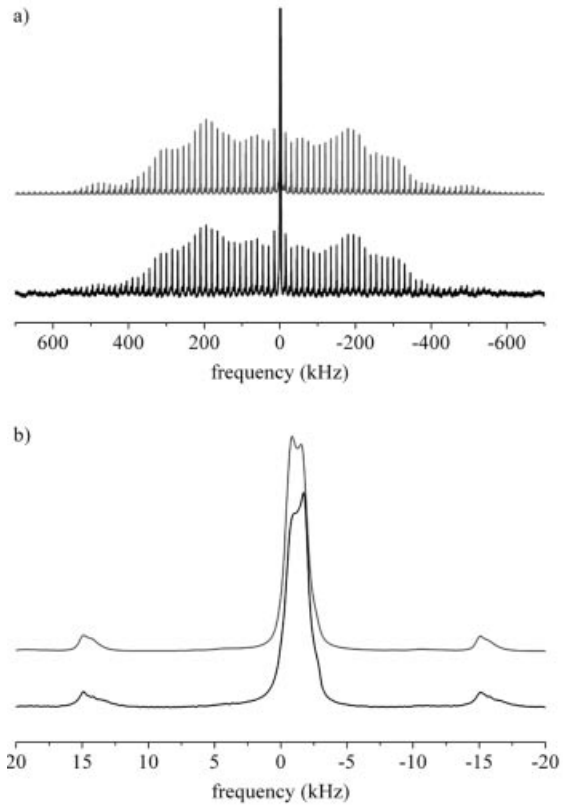

Figure 5. Experimental (bottom) and reconstructed (top) spectra: (a) $^{27}$Al SATRAS NMR spectra and (b) central transitions for $Ba_3Al_2F_{12}$ at 15 kHz. In the full SATRAS spectra the central transitions are truncated to improve the visiblity of the spinning sidebands.

$Ca_2AlF_7$,[41] $Ba_3AlF_9$-Ib,[42] β-$Ba_3AlF_9$,[43] and α-$BaCaAlF_7$[44] contain isolated $AlF_6^{3-}$ octahedra. $Ba_3AlF_9$-Ib and β-$Ba_3AlF_9$ are structurally quite different, even though they are both characterized by isolated $AlF_6^{3-}$ octahedra and $FBa_4^{7+}$ tetrahedra. β-$Ba_3AlF_9$ contains three aluminium sites; their corresponding NMR parameters have already been determined, and are reported in ref.[19] $Ca_2AlF_7$, $Ba_3AlF_9$-Ib, and α-$BaCaAlF_7$ contain one aluminium site, as confirmed by the $^{27}$Al SATRAS spectra presented in Figure 6. For these three spectra the central transitions are shapeless, and are therefore not shown. The shapeless central transitions, and the overall SATRAS spectrum expansions, may be related to low quadrupolar frequencies. The comparison between these three spectra indicates that $Ca_2AlF_7$ has the highest quadrupolar frequency, whereas $Ba_3AlF_9$-Ib has the lowest value. The NMR parameters leading to the best simulations are provided in Table 1. The $^{27}$Al MAS NMR spectrum of $Ca_2AlF_7$ previously recorded by Sakida et al.[38] presents two "split peaks" that we do not observe in our SATRAS spectrum.

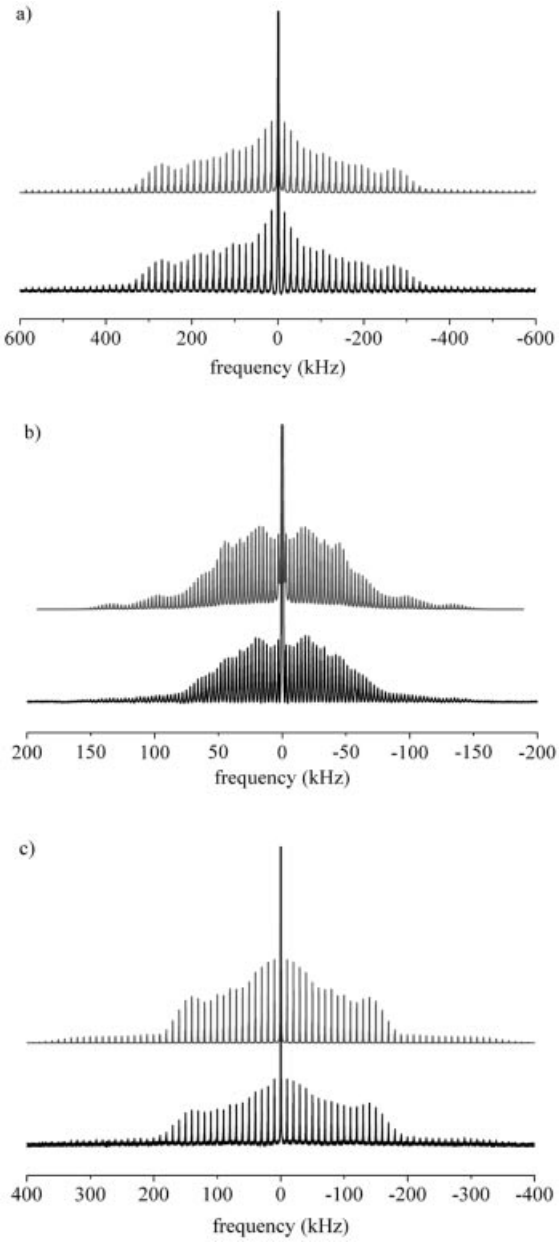

Figure 6. Experimental (bottom) and reconstructed (top) $^{27}$Al SATRAS NMR spectra for (a) $Ca_2AlF_7$ (15 kHz), (b) $Ba_3AlF_9$-Ib (3 kHz) and (c) α-$BaCaAlF_7$ (10 kHz). The central transitions are truncated to improve the visiblity of the spinning sidebands.

The previously published results for β-$CaAlF_5$[16] and β-$Ba_3AlF_9$[19] have been added to Table 1.

## Quadrupolar Parameters in Glassy Phases

For the $BaF_2$–$CaF_2$–$AlF_3$ ternary system several glass compositions have been synthesized in a previous study.[34] Four of these compositions have been chosen for this study, and contain 35–50% $AlF_3$. The selected glass compositions are given in Table 2.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2. Glass compositions (mol fractions), isotropic chemical shifts, $\delta_{iso}$ (ppm), $\sigma$ parameters (kHz), and $\beta$ parameters for the studied glasses.

| Composition | $\delta_{iso}$ (± 2) | $\sigma$ (±20) | $\beta$[a] |
|---|---|---|---|
| $50CaF_2$–$15BaF_2$–$35AlF_3$ | –3 | 370 | 6 |
| $35CaF_2$–$25BaF_2$–$40AlF_3$ | –4 | 420 | 5.76 |
| $35CaF_2$–$20BaF_2$–$45AlF_3$ | –3 | 440 | 5.44 |
| $35CaF_2$–$15BaF_2$–$50AlF_3$ | –7 | 470 | 5 |

[a] From ref.[34]

The $^{27}$Al 3Q-MAS spectra clearly show only one Al contribution, and are presented in Figure 7. These spectra are similar to the those reported by Chan and Eckert for a related glass composition.[45] A striking feature of the data is the broadening of the 3Q-MAS spectra, which is expected to mirror the broadening of the quadrupolar parameter distribution with increasing $AlF_3$ glass content.

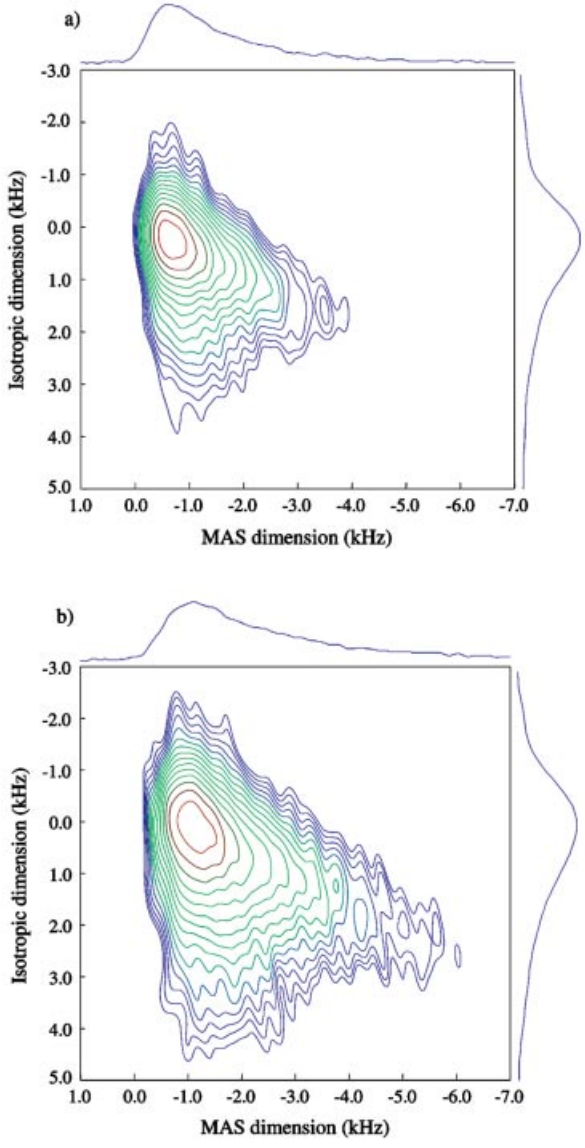

Figure 7. Experimental $^{27}$Al 3Q-MAS NMR spectra for (a) $50CaF_2$–$15BaF_2$–$35AlF_3$ and (b) $35CaF_2$–$15BaF_2$–$50AlF_3$ glasses at 25 kHz. The curves at the top and to the right of the spectra are the projections of the spectra on to the MAS (*F2*) and isotropic (*F1*) axes, respectively.

The $^{27}$Al SATRAS spectra, shown in Figure 8, were reconstructed using the Czjzek-like distribution[46,47] of the electric field gradients (EFG) [Equation (1)], where $\nu_Q = [3eQV_{zz}]/[2I(2I-1)h]$, $\eta_Q = [V_{xx} - V_{yy}]/V_{zz}$, $Q$ is the nuclear quadrupole moment, and $V_{ii}$ are the principal elements of the EFG tensor defined as $|V_{zz}| \geq |V_{yy}| \geq |V_{xx}|$.

$$P(\nu_Q, \eta_Q) = \frac{1}{\sqrt{2\pi}\sigma^d} \nu_Q^{d-1} \cdot \eta_Q \left(1 - \frac{\eta_Q^2}{9}\right) \cdot \exp\left(-\frac{\nu_Q^2\left(1 + \frac{\eta_Q^2}{3}\right)}{2\sigma^2}\right) \quad (1)$$

In Equation (1), $\sigma$ and $d$ are two adjustable parameters. The parameter $\sigma$ characterizes the strength of the quadrupolar interaction. When the five components of the quadrupolar tensor are independent, $d = 5$. In this case the distribution corresponds to the Gaussian Isotropic Model[48] in which the electric field gradient (EFG) distribution is assumed to correspond to statistical disorder.[28] Values of $d < 5$ account for local geometrical constraints.[47] Several tests have been performed for different $d$ values while assuming a unique value of the isotropic chemical shift. The best agreements between the experimental and reconstructed spectra were obtained with $d = 3$ and a line width equal to 350 Hz. This $d$ value is in agreement with previous studies on disordered and glassy aluminium and gallium phases, where good reconstructions of the $^{27}$Al and $^{69,71}$Ga NMR spectra were obtained with $d = 3$ corresponding to the metal atoms residing in octahedral environments.[26,49–51] The relevant parameters ($\delta_{iso}$, and $\sigma$) are given in Table 2. The $\delta_{iso}$ values are within the same range observed for the crystalline compounds, i.e. between –7 ppm and –2 ppm. The experimental and reconstructed $^{27}$Al SATRAS spectra for the glasses with lowest and highest $AlF_3$ contents are compared in Figure 8. The asymmetry of the central transitions is satisfactorily reproduced. The corresponding distributions $P(\nu_Q, \eta_Q)$ used for the reconstruction of these two spectra are shown in Figure 9. Most $\nu_Q$ values are within the range of 100–900 kHz for the 35% $AlF_3$ glass composition ($\sigma$ = 370 kHz and $d$ = 3), with a maximum around 450 kHz. For the 50% $AlF_3$ glass composition ($\sigma$ = 470 kHz and $d$ = 3), the distribution is enlarged, and most of the $\nu_Q$ values are between 100 kHz and 1200 kHz, with a maximum around 600 kHz. Moreover, these quadrupolar parameter distributions are nil when $\nu_Q$ and/or $\eta_Q$ are equal to zero. Therefore, high symmetrical EFGs are prohibited, as would be expected for materials exhibiting the level of disorder present in glassy phases.

## Discussion

For all the crystalline and glassy phases investigated, the isotropic chemical shift values are between –7 ppm and 1 ppm (Tables 1 and 2), which are typical $\delta_{iso}$ values for $Al^{3+}$ ions in $AlF_6^{3-}$ octahedra. The $\eta_Q$ values deviate from zero, which indicates that the $AlF_6^{3-}$ octahedra are rhombically distorted, in agreement with the crystal data.

For α- and β-$CaAlF_5$ the $\nu_Q$ values are equal to 1580 kHz and 1530 kHz, respectively. Both structures are built up by *trans*-connected $AlF_6^{3-}$ octahedra. The structures of α-, β- and γ-$BaAlF_5$, and $Ba_3Al_2F_{12}$ contain $AlF_6^{3-}$ octahedra that are *cis*-connected at the corners, and the $\nu_Q$ values are between 550 kHz and 1250 kHz. Isolated octahedra are encountered only in $Ca_2AlF_7$, $Ba_3AlF_9$-Ib, β-$Ba_3AlF_9$ and α-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$BaCaAlF_7$, and the $\nu_Q$ values range from 75 kHz to 510 kHz (Table 1).

It is well known that a bond involving a shared F ligand is usually longer than one involving an unshared F ligand. For example, in α-$CaAlF_5$[35] the Al-shared F distance is equal to 1.873 Å, and the Al-unshared F distances are equal to 1.806 Å and 1.749 Å. For *trans*-connected octahedron structures these bonds lie in opposite directions and the experimental $\nu_Q$ values are the highest of those measured. The charge distribution is expanded along the longest bond axis, which may correspond to the main *z* axis of the EFG. In the case of the *cis*-connected octahedron structures, the angle formed by the two longest bonds is around 90°, and the experimental $\nu_Q$ values are smaller than those measured for the *trans*-connected structures. We may assume that in this case the charge distribution is expanded along a direction that bisects the two longest bonds; as a result, the axial character of the charge distribution around the aluminium atom in the *cis*-connected octahedra is less pronounced than in the case of the *trans*-connected octahedra. For isolated octahedra the experimental $\nu_Q$ values are the smallest values measured, so in this case the axial character of the charge distributions around the Al atoms is even less pronounced than in the two previous cases, which may be related to smaller differences between the Al–F bond lengths. From these results it appears that the $\nu_Q$ value, which is related to the largest component of the EFG, could account for the way in which the $AlF_6^{3-}$ octahedra are connected i.e. in a *trans*, *cis* or isolated manner.

The main results for the glassy phases are as follows: (i) the low $\delta_{iso}$ values indicate that the $Al^{3+}$ ions are six-fold coordinated; (ii) the quadrupolar parameter distributions have $\nu_Q$ values that are usually encountered in cases where *cis*-connected and isolated octahedra are present in crystalline phases; (iii) the width of the $\nu_Q$ distribution increases with increasing $AlF_3$ content. In a previous $^{19}F$ NMR study[34] the $\beta$ parameter, which gives the mean number of F atoms per octahedron, was found to equal 6 for the glass with 35% $AlF_3$ content. Therefore, it can be stated that the glassy structure contains isolated $AlF_6^{3-}$ octahedra only. The reconstruction of the corresponding SATRAS spectrum indicates that most of the $\nu_Q$ values are between 100 kHz and 900 kHz (Figure 9). It is noticeable that these values appear to be slightly larger than for the crystalline phases containing isolated $AlF_6^{3-}$ octahedra (Table 1). Conversely, for the glass with a 50% $AlF_3$ content, the $\beta$ parameter was found to equal 5, which indicates that, on average, all octahedra are connected at two corners. The $\nu_Q$ range is enlarged to 1200 kHz, and accordingly the maximum $\nu_Q$ value increases from ca. 450 kHz to ca. 600 kHz (Figure 9). This increase in the $\nu_Q$ values with increasing $AlF_3$ content is in agreement with the previous observation based on the crystalline structures. The quadrupolar parameter distributions determined for the intermediate compositions confirm that the ratio of connected octahedra increases along with the $AlF_3$ content. In the glassy samples most of the $\nu_Q$ values range from 100 kHz to 1200 kHz, so we may infer that the *cis* connection is the favoured mode of bonding as far as the octahedra are connected. However, since low $\nu_Q$ values are observed for all the glasses investigated, we may infer that they contain isolated octahedra ($\beta$ = 6). For the glass comprising 50% $AlF_3$, we should assume the presence of ramified chains ($\beta < 5$) rather than infinite chains ($\beta$ = 5), as previously deduced from our $^{19}F$ NMR study.[34]

## Conclusion

$^{27}Al$ SATRAS and 3Q-MAS spectra (for compounds with several Al sites) were recorded for eight crystalline compounds from binary $CaF_2$–$AlF_3$ and $BaF_2$–$AlF_3$ and ternary $BaF_2$–$CaF_2$–$AlF_3$ systems, and four glass compositions with different $CaF_2/BaF_2/AlF_3$ contents.

For the crystalline phases the reconstruction of the spectra leads to the precise determination of the NMR parameters ($\delta_{iso}$, $\nu_Q$ and $\eta_Q$). For the glassy phases the $^{27}Al$ SATRAS spectra have been reconstructed using Czjzek distributions, and the relevant parameters ($\delta_{iso}$ and $\sigma$) were determined.

In agreement with the crystalline and glassy structures, the experimental $\delta_{iso}$ values are typical for $Al^{3+}$ ions in $AlF_6^{3-}$ octahedra. The measured $\eta_Q$ values are not equal to zero, which indicates that the $AlF_6^{3-}$ octahedra are rhombically distorted. It should be noted that despite of the precise determination of the quadrupolar parameters, it was impossible to relate these values to the two Al sites in β- and γ-$BaAlF_5$ both of which have the same multiplicity.

The most interesting finding from this study is the dependence of the quadrupolar frequency on the $AlF_6^{3-}$ octahedron connectivity. For crystalline phases the $\nu_Q$ values are measured between 75 kHz and 510 kHz for structures built up from isolated $AlF_6^{3-}$ octahedra, between 560 kHz and 1250 kHz for structures built up from isolated chains of *cis*-connected $AlF_6^{3-}$ octahedra, and between 1530 kHz and 1580 kHz for structures built up from isolated chains of *trans*-connected $AlF_6^{3-}$ octahedra. In the glassy phases the maximum of the quadrupolar frequency distribution is shifted towards larger values, and its width increases with increasing $AlF_3$ content and therefore the number of connected octahedra. The range of the $\nu_Q$ values seems to indicate that when the octahedra are connected, the most encountered connections are of the *cis* type.

In order to gain a deeper understanding of the dependence of the $\nu_Q$ values on the $AlF_6^{3-}$octahedron network connectivity, ab initio EFG calculations of $^{27}Al$ in crystalline phases are in progress. These calculations will provide important structural information about the sign and the orientation of the EFG tensors with respect to the crystallographic axes. They should also enable us to relate the quadrupolar parameters to the Al sites in the case of multi-site compounds such as β- and γ-$BaAlF_5$.

## Experimental Section

**Sample Preparation:** Owing to the fact that the fluoride compounds are moisture-sensitive, all weighting, mixing and grinding opera-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tions were done under anhydrous nitrogen. Before heating, the mixtures were introduced into Pt tubes sealed under anhydrous conditions. The crystalline compounds were synthesized as powders by solid-state reaction of mixtures containing the fluorides $AlF_3$, $CaF_2$ and/or $BaF_2$; the synthesis conditions are detailed in ref.[33] The purity and crystallinity of the phases were monitored by powder X-ray diffraction analysis. The glassy phases were obtained by heating $BaF_2/CaF_2/AlF_3$ mixtures at 1000 °C over a period of 1 h, followed by quenching in cold water. The glass formation was checked by powder X-ray diffraction (the XRD spectra should be featureless). Information regarding the glass formation area is reported in ref.[34]

**High-Resolution Solid-State NMR:** The high-resolution $^{27}$Al NMR spectra were recorded at 78.2 MHz with a Bruker Avance 300 spectrometer. CP MAS probes with 4 mm and 2.5 mm rotors were used for low and high spinning speeds, respectively. The $^{27}$Al isotropic chemical shifts were referenced to a 1 M aqueous solution of $Al(NO_3)_3$. $^{27}$Al SATRAS spectra[1,2] were recorded for all samples. To ensure a linear response regime[52] we chose the pulse duration and the RF field strength to equal 1 μs and 26 kHz, respectively. The recycle delay was set at 1 s. Under these experimental conditions the relative peak intensities are quantitative. The reconstructions of these spectra were achieved using an in-house FORTRAN 95 code based on the theoretical treatment developed by Skibsted et al.,[1,53] and including a correction for the second-order frequency shift, the formula for which is given in ref.[54,26] The adjustable parameters for the crystalline compounds are the quadrupolar frequency, $\nu_Q$, the asymmetry parameter, $\eta_Q$, and the chemical shift tensor, $\delta$. For the glassy phases the SATRAS spectra were reconstructed using the distributions of the quadrupolar parameters ($\nu_Q$, $\eta_Q$) implemented in the FORTRAN 95 code. For the crystalline multi-site compounds and for the glasses MQ-MAS experiments[3] were also carried out using a high-speed CP MAS probe with a 2.5 mm rotor. In the present case 3Q-MAS experiments were performed using a *z*-filter sequence without decoupling. The magnetic field strength was 188 kHz for the two hard pulses, and 8 kHz for the soft pulse. The pulse lengths were equal to 2.7 μs, 0.95 μs, and 10 μs, respectively. A two-dimensional Fourier transformation followed by a shearing[55] transformation gave 2D absorption spectra. For crystalline multi-site compounds an estimation of the quadrupolar parameters and chemical shift values of each contribution was obtained by simulating the corresponding *F1* slices with the DMFit[56] software.

## Acknowledgments

We thank A. Le Bail and A.-M. Mercier, from the Laboratoire des Oxydes et Fluorures, CNRS UMR 6010, who kindly supplied us with the three $BaAlF_5$ structural forms.

# Broadening the Scope of Ancillary Phosphane-Type Ligands: A Systematic Comparison of $PR_3$, $PR_2BH_3^-$, and $SiR_3^-$ and Their Chalcogen Derivatives

**Theresa I. Kückmann,[a] Franz Dornhaus,[a] Michael Bolte,[a] Hans-Wolfram Lerner,[a] Max C. Holthausen,*[a] and Matthias Wagner*[a]**

**Keywords:** Isoelectronic analogs / P ligands / Si ligands / Ligand design / Boron

This work describes a systematic experimental and theoretical study of the properties of two series of isoelectronic and largely isosteric ligands, namely $PPh_2Me$, $PPh_2BH_3^-$, and $SiPh_2Me^-$ and $SPtBu_3$, $SPtBu_2BH_3^-$, and $SSitBu_3^-$. In addition, we have also investigated the oxo derivatives $OPPh_2BH_3^-$ and $OSiPh_2Me^-$. Based on X-ray crystal structure determinations (Fe–CO and C–O bond lengths) as well as NMR [e.g. $\delta(^{13}CO)$] and IR [$\nu$(CO)] spectroscopic investigations of the corresponding $[CpFe(CO)_2]^+$ complexes, we can conclude that, with respect to electron donor strength, phosphanyl borohydrides occupy an intermediate position between phosphanes (weakest donors) and silyl ligands (strongest donors). The same is true for the thio derivatives, although the differences are smaller. In the reaction with $[CpFe(CO)_2]^+$, the oxo derivative $OPPh_2BH_3^-$ transfers a hydride ion rather than forming a stable $[CpFe(CO)_2(OPPh_2BH_3)]$ complex. The tendency to undergo hydride-transfer reactions was studied by density functional calculations for the series $PtBu_2BH_3^-$, $OPtBu_2BH_3^-$, and $SPtBu_2BH_3^-$. The results reveal that $OPtBu_2BH_3^-$ is the strongest and $SPtBu_2BH_3^-$ the weakest hydride donor, in accordance with the experimental observations. Theoretical analysis indicates that the three derivatives $PPh_2Me$, $PPh_2BH_3^-$, and $SiPh_2Me^-$ are truly isolobal species despite variations in their charge distributions.

## Introduction

The performance of a homogeneous catalyst depends critically on the steric and electronic properties of its ligands.[1,2] Intense research has therefore been devoted to the development of donor molecules specifically designed for the assembly of a particular catalyst with a well-defined purpose. As a result, homogeneous catalysis with transition-metal complexes has enjoyed enormous success, and catalyst research continues to gain momentum.[3] A wealth of information has been gathered on numerous individual ligand classes, which now must be compared in order to establish their relationship to one another. The goal is to create versatile toolboxes of ligands with smoothly varying donor properties so that the most suitable derivative can easily be selected for the rational de novo design of efficient catalysts.

We have a long-standing interest in the development of boron-based N-donor ligand systems [e.g. mono- and ditopic bis- and tris(pyrazol-1-yl)borates] for applications both in materials science and catalysis.[4–10] In order to extend the range of accessible complexes, we are presently broadening our focus to include negatively charged boron-based P-donor ligands and their isoelectronic silyl analogs. The purpose of this paper is to reveal the underlying relationship between two representatives of these ligand classes, namely phosphanyl borohydrides $PR_2BH_3^-$ and triorganylsilanides $SiR_3^-$, and to compare them with the well established phosphane ligands $PR_3$.

A generic methyldiorganylphosphane **A** is shown in Figure 1. On moving to the phosphanyl borohydride **B**, the phosphane methyl group is replaced by a $BH_3$ moiety. This leaves the central atom unchanged but results in a negatively charged ligand. The substitution pattern is conserved in the corresponding silyl compound **C** but the central phosphorus atom is replaced by silicon, which again introduces a negative charge. The same relationship holds true for the chalcogen derivatives of these compounds (**D**–**F**; Figure 1), which have been the subject of two recent studies.[11,12] We are interested in investigating the similarities as well as the fundamental differences between these three related species. We commence with a brief review of selected literature relevant to this pursuit.

Phosphanes are ubiquitous ligands in coordination chemistry due to their σ-donating and π-accepting properties.[13,14] The degree to which these σ and π components influence the overall coordination characteristics of a given phosphane depends on the phosphorus-bound substituents. The π-acceptor strength of $PF_3$, for example, is comparable to that of CO, which is often considered the archetypical π-

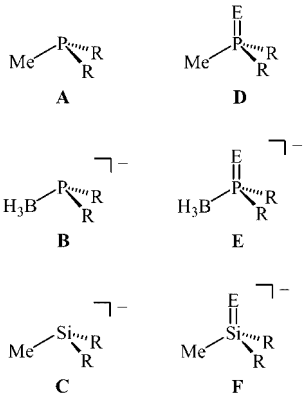

Figure 1. Isoelectronic phosphanes, phosphanyl borohydrides, and silanides, and their chalcogen derivatives.

acceptor ligand. Trialkylphosphanes, on the other hand, are primarily σ-donors and participate to only a small degree in π-backbonding.

Transition metal complexes with silyl ligands, while not as widespread as phosphane complexes, have also received significant attention in the literature.[15,16] Such studies have focused primarily on the reactivity of the Si–M bond, for example in transition-metal-catalyzed hydrosilylation or C–Si bond formation.[15,17] Recently, silyl derivatives have also generated increasing interest as ancillary ligands.[18] Indeed, it has been suggested that silyl ligands might enhance the performance of soluble catalytic systems for hydrogenation or hydroformylation reactions.[19] Silyl ligands are strongly electron-releasing with comparatively poor π-accepting properties and display a pronounced *trans* effect, which makes them potentially complementary ligands to phosphanes.[18,20–22] It is clear, however, that the properties of formally isoelectronic silyl and phosphane ligands differ significantly and that this difference is too large to be considered a gradual transition.

Phosphanyl borohydrides $PR_2BH_3^-$ are intermediate species in which the donor phosphorus atom remains as in phosphanes, but which contain a negative charge, as do silyl ligands. To date, these anionic phosphane analogues have mainly been generated in situ and used as building blocks for the preparation of chiral organophosphanes.[23–26] However, there is a growing number of phosphanyl borohydride transition metal complexes in the literature. Manners et al., for example, have exploited the regioselective insertion of the $Pt(PEt_3)_2$ fragment into the P–H bond of $PPhBH_3(H)_2$ or $PPh_2BH_3(H)$ in order to prepare the platinum phosphanyl borohydride complexes *trans*-[PtH(PPhRBH$_3$)-$(PEt_3)_2$] (R = H, Ph).[27] Other examples of structurally characterized phosphanyl borohydride complexes include the compounds $[(dppp)Pd(C_6F_5)(PPh_2BH_3)]$[28] and $[(C_5Me_5)Fe(CO)_2(PPh_2BH_3)]$.[29] In a 1996 paper, Fu and co-workers described diphenylphosphidoboratabenzene, $PPh_2(BC_5H_5)^-$, as the anionic analog of triphenylphosphane and investigated its coordination chemistry.[30]

While not as common as the parent phosphanes, phosphane oxides also play an important role as ancillary ligands in coordination chemistry,[13] especially in the form of bidentate bisphosphane monooxides [P(O)–P] or P(O)–O and P(O)–N type ligands, which form part of efficient catalytic systems for rhodium- and cobalt-catalyzed hydroformylation reactions.[31–33]

Transition metal siloxide complexes have also been investigated.[34–38] For example, rhodium siloxides are active in catalytic hydrosilylation reactions,[34,39] and titanium, niobium, and tantalum siloxide systems have been used to investigate C–H activation[37] and olefin-to-alkylidene rearrangement.[38]

The corresponding chalcogen derivatives of phosphanyl borohydrides, $EPR_2BH_3^-$ (E = O–Te), have only recently been reported in the literature,[12] and their application as ligands for transition metals has yet to be explored.

In order to shed more light on the relative importance of donor atom and electronic structure for the ligand properties of phosphanes, phosphanyl borohydrides, and silanides, we have investigated two series of isoelectronic, isosteric compounds (Figure 2). In the case of the non-chalcogen species, the diphenyl derivatives **1**, **2a**, and **3a** were chosen for detailed study. In order to still be able to evaluate the effect of increased steric demand, P*t*Bu$_2$BH$_3^-$ (**2b**) was also investigated. For the chalcogen derivatives, both the phenyl and *tert*-butyl systems **4**–**8** were studied.

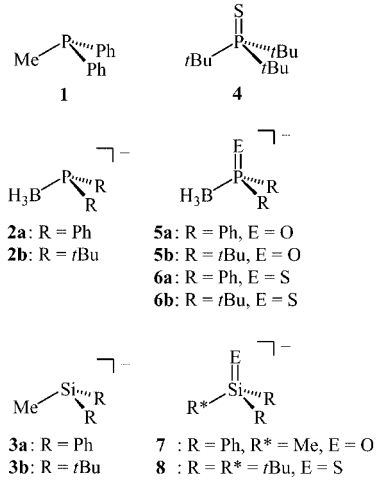

Figure 2. Ligand numbering scheme for isoelectronic species **1**–**3** and **4**–**8**.

For the transition metal site, we chose the cyclopentadienidoiron dicarbonyl fragment $[CpFe(CO)_2]^+$ (in future referred to as $Fp^+$) as a model system. This fragment is an ideal candidate for our pursuit because it has a single vacant coordination site (often occupied by halides or donor solvent molecules in its isolable derivatives) and all of the ligands in question can be expected to coordinate to it in a similar fashion, regardless of whether the result is a neutral or cationic complex. In addition, its electronic properties can be related to the carbonyl IR stretching frequencies[40] as well as to the $^{13}C$ NMR shifts of the carbonyl[41] and cyclopentadienido[42] carbon atoms.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Terminal, unbridged phosphane complexes of the $Fp^+$ fragment are well known in the literature, with one of two synthetic routes generally being applied. The first involves treating $Fp^+$ complexes containing labile ligands such as thf or $I^-$ with phosphanes.[43–46] In the second, $Fp_2$ is oxidized in the presence of phosphane ligand, typically with ferrocenium or cobaltocenium ions.[47–49] Using a different approach, Malisch has succeeded in isolating $[(C_5Me_5)Fe(CO)_2(PPh_2Me)]I$, which was prepared by reaction of the corresponding diphenylphosphido complex with MeI and characterized spectroscopically.[29]

To the best of our knowledge, no structurally characterized monomeric $FpSiR_3$ complexes in which the silyl ligand bears only alkyl and/or aryl substituents R have been previously reported. Nevertheless, there are a number of silyl complexes with known molecular structures where the silicon atom is bound to electron-withdrawing functional groups.[50–53] Complexes of $Fp^+$ bearing silyl ligands with solely aryl and/or alkyl substituents have, however, been spectroscopically characterized and are typically obtained by treating NaFp with a triorganylsilyl chloride.[54–57]

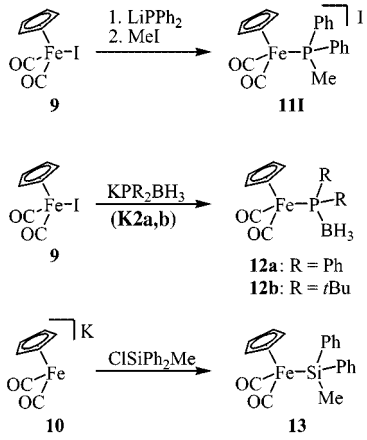
The σ-donor properties of the phosphanyl borohydride **2a** (Figure 2) towards selected main group Lewis acids have already been explored.[58] It was found that **2a** forms stronger Lewis acid–base adducts than the related phosphane $PPh_2Me$ (**1**). Transition metal complexes of phosphanyl borohydrides are rare in the literature, with only a handful of structurally characterized complexes {e.g. $[FpPPh_2(BC_5H_5)]$ and $[(C_5Me_5)Fe(CO)_2(PPh_2BH_3)]$}.[27–30] The complex $[FpPPh_2BH_3]$ was prepared from $FpPPh_2$ and $BH_3$·thf and was characterized spectroscopically.[59]

The few examples of Fp-phosphane chalcogenide complexes with trialkyl- and triarylphosphane chalcogenides $EPR_3$ (R = *i*Pr, *t*Bu, Ph; E = O, S, Se) were prepared by reaction with $[Fp(thf)]BF_4$ and characterized spectroscopically[60] and, in part, by cyclic voltammetry.[61] The same synthetic route can be followed for silyl thiolates, and a small number of complexes of the type $FpSSiR_3$ have been isolated.[62] The coordination of chalcogenated phosphanyl borohydrides to the $Fp^+$ fragment has not been described previously.

## Results and Discussion

### Synthesis

In order to conduct a detailed comparison of transition metal complexes of the non-chalcogen ligands, compounds $[FpPPh_2Me]I$ (**11I**), $[FpPPh_2BH_3]$ (**12a**), $[FpPtBu_2BH_3]$ (**12b**), and $[FpSiPh_2Me]$ (**13**) were synthesized (Scheme 1). Compound **11I** was prepared from FpI (**9**), $LiPPh_2$, and MeI in thf. Reports of the synthesis of this complex directly from FpI and $PPh_2Me$ (**1**) describe impurities due to the CO-substitution product $[CpFe(CO)(PPh_2Me)I]$.[63] In contrast, the procedure followed here produces the product as a yellow solid in high purity and good yield. Complex **11I** is, however, sensitive to light, and photochemical decomposition can be observed, which proceeds more quickly in solution than in the solid state. When the solid is stored under inert atmosphere and protected from light, the compound is stable for several months. X-ray quality crystals can be obtained by gas-phase diffusion of diethyl ether into an acetonitrile solution of the complex.



Scheme 1. Complexes of a phosphane and its isoelectronic analogues, **11I**–**13**.

Preparation of the phosphanyl borohydride homologue **12a** in an analogous reaction using $BH_3$·thf instead of MeI has been reported.[59] However, the general utility of phosphanyl borohydrides as ligands can best be achieved if it is possible to form metal complexes by introducing the preformed ligands, rather than assembling them with the phosphorus atom connected to a metal fragment. With this goal in mind, FpI was treated with $KPPh_2BH_3$ (**K2a**) in thf, which resulted in nearly quantitative formation of the desired compound **12a**. It also proved possible to synthesize $[FpPtBu_2BH_3]$ (**12b**) by the same method. Both complexes were isolated as X-ray quality crystals by gas-phase diffusion of pentane into a concentrated toluene solution of **12a** or **12b**. The yellow solids can be handled in air for short periods of time but decompose upon longer exposure.

Considering the similarities between silanides and phosphanyl borohydrides, it would be desirable to apply the same synthetic route used for complexes of the latter to the preparation of complexes of the former. The sodium silanides $NaSiPh_2Me$[64] (**Na3a**) and $NaSitBu_2Me$[65] (**Na3b**) are both known in the literature, although the former has been characterized only by boiling point determination of the corresponding silane after hydrolysis. The di-*tert*-butyl species **Na3b** is well documented, but the synthesis of the donor-free compound as described by Sekiguchi, which involves reduction of the bromosilane with elemental sodium in boiling heptane, results in a significant amount of disilane impurity.[65] Another common synthesis of sterically hindered sodium silanides, in this case donor-supported, involves the reduction of the corresponding bromosilanes with sodium metal in thf.[66] Biphenyl can be used as a redox catalyst to allow lower reaction temperatures. In an effort to avoid unnecessary and unwanted by-products, this method was used to prepare $(thf)_xNaSitBu_2Me$. The NMR

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chemical shifts ($^1$H, $^{13}$C, $^{29}$Si) of the sodium silanide produced by this route were in good agreement with the published values. Slight variations can be attributed to the fact that the procedure reported here results in a donor-supported silanide, while the literature describes the synthesis of the donor-free compound. Unfortunately, this synthetic method led to unexpected side products. In an attempt to grow crystals of the silanide, dark green blocks of the silylated biphenyl radical [(18-crown-6)(thf)$_2$Na][4,4′-(Si*t*Bu$_2$Me)$_2$(C$_6$H$_4$)$_2$] were isolated.[67] In light of this result and the poor characterization of NaSiPh$_2$Me in the literature, no further attempts to synthesize [FpSiR$_2$Me] (R = Ph, *t*Bu) from Fp$^+$ and SiR$_2$Me$^-$ were undertaken.

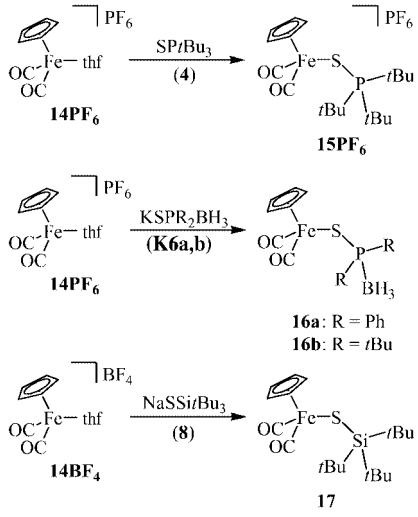
As described above, a number of [FpSiR$_3$] complexes have been reported in the literature. Due to the low electronegativity of silicon, these reactions generally proceed with silyl chlorides. This, in essence, represents the umpolung of the procedure used with phosphanyl borohydrides **2a** and **2b**. The synthesis of [FpSiPh$_2$Me] (**13**) by this method has been described.[57] When KFp (**10**) is treated with ClSiPh$_2$Me in thf, the desired complex is formed in nearly quantitative yield (Scheme 1). Impurities can be removed by filtration through silica gel using hexane/CH$_2$Cl$_2$ (2:1) as the eluent. Recrystallization from hexane at –25 °C yields the complex as light-brown plates.

Considering the success achieved with the parent compounds, it was logical to explore the behavior of the chalcogen derivatives KOPPh$_2$BH$_3$ (**K5a**), NaOSiPh$_2$Me (**Na7**), and KSPPh$_2$BH$_3$ (**K6a**) with the Fp$^+$ fragment (the silyl thiolate NaSSiPh$_2$Me is not readily accessible).

When FpI was treated with **K5a** in thf, a colorless solid was slowly deposited over the course of several days. NMR analysis of the resulting mixture revealed conversion of FpI to Fp$_2$ and the appearance of unidentified components in the $^{31}$P and $^{11}$B NMR spectra. Upon closer inspection of the hydride region of the $^1$H NMR spectrum, a small amount of FpH[68] could be identified, which is known to be an unstable intermediate that decomposes to Fp$_2$ and H$_2$.[69,70] This finding suggests that rather than forming an Fe–O bond, the iron atom interacts with the borohydride moiety of the ligand, ultimately resulting in hydride transfer. Although the fate of the ligand after hydride transfer remains unclear, it seems likely that oligomeric or polymeric compounds of the type [OPPh$_2$BH$_2$]$_n$ are formed.

The observation of a hydride-transfer product with **K5a** is particularly interesting in light of a comparison with the siloxide **Na7**, since it is unlikely that the methyl moiety would engage in the same kind of behavior. However, when a thf solution of FpI is treated with **Na7**, Fp$_2$ is the only Cp-containing product. In the $^{29}$Si NMR spectrum, O(SiPh$_2$Me)$_2$ can be identified as the major silicon-containing product (its $^1$H, $^{13}$C, and $^{29}$Si NMR shifts correspond to an authentic sample prepared from ClSiPh$_2$Me and NaOSiPh$_2$Me).[71–73] A similar reaction to that with FpI was observed when the alternative starting material [Fp(thf)]PF$_6$ was treated with **K5a** and **Na7**. However, in the latter case a significant amount of ferrocene was formed in addition to Fp$_2$.

The reaction of KSPPh$_2$BH$_3$ (**K6a**) with [Fp(thf)]PF$_6$ (**14PF$_6$**) was more successful. Thus, when the reactants were combined in CH$_2$Cl$_2$ at –78 °C and warmed to room temperature overnight, a colorless precipitate (KPF$_6$) formed. Changing the solvent to toluene with subsequent filtration through a plug of silica gel on a frit allowed the product complex [FpSPPh$_2$BH$_3$] (**16a**, Scheme 2) to be isolated as an orange oil. Although the NMR and IR data clearly indicate the formation of the complex, attempts to obtain single crystals of **16a** failed.



Scheme 2. Complexes of a phosphane sulfide and its isoelectronic analogs, **15PF$_6$**–**17**.

In the hope of isolating a crystalline product, the same reaction was carried out using the *tert*-butyl derivative **K6b** rather than the phenyl derivative **K6a**. In this case, filtration of the crude product through silica gel and recrystallization from benzene yielded orange X-ray quality needles of [FpSP*t*Bu$_2$BH$_3$] (**16b**).

Since the isosteric silyl thiolate NaSSi*t*Bu$_2$Me is not easily accessible, we turned to the sterically more hindered NaSSi*t*Bu$_3$ (**Na8**). This compound reacts readily with [Fp(thf)]BF$_4$ (**14BF$_4$**) in CH$_2$Cl$_2$ at room temperature to give the desired complex [FpSSi*t*Bu$_3$] (**17**; Scheme 2). Recrystallization from a concentrated pentane solution yielded X-ray quality crystals.

The complex of the analogous phosphane sulfide **4**, [FpSP*t*Bu$_3$]BF$_4$ (**15BF$_4$**), has been described in the literature.[60] Using the PF$_6^-$ salt **14PF$_6$**, we were able to isolate X-ray quality crystals of the compound by gas-phase diffusion of pentane into a solution of [FpSP*t*Bu$_3$]PF$_6$ (**15PF$_6$**) in CHCl$_3$ (Scheme 2).

It was thus possible to prepare two series of three isoelectronic compounds each in which all six compounds were characterized by X-ray crystal structure analysis and NMR and IR spectroscopy. Complexes **11I**, **12a**, and **13** are derived from the phosphane PPh$_2$Me, while complexes **15PF$_6$**, **16b**, and **17** are related to the phosphane sulfide SP*t*Bu$_3$. A comparison of these two sets of isoelectronic complexes grants insight into the electronic differences between the ligands.

### Structural and Spectroscopic Comparison of 11I, 12a, 12b, and 13

Selected bond lengths and angles for **11I**, **12a**, **12b**, and **13** are compiled in Table 1. Details of the X-ray crystal structure analyses of these compounds are summarized in Table 5.

Table 1. Selected bond lengths [Å] for compounds **11I**–**13**; calculated values in italics.

| | Fe–P/Si | Fe–CO (av.) | C–O (av.) |
|---|---|---|---|
| **11I** | 2.236(2) | 1.779(9) | 1.146(10) |
| *calc.* | *2.338* | *1.787* | *1.158* |
| **12a** | 2.2705(6) | 1.772(2) | 1.141(2) |
| *calc.* | *2.367* | *1.772* | *1.163* |
| **12b** | 2.3404(6) | 1.756(3) | 1.142(3) |
| **13** | 2.3353(5) | 1.755(2) | 1.160(3) |
| *calc.* | *2.389* | *1.757* | *1.168* |

Phosphane compound **11I** crystallizes in the triclinic space group $P\bar{1}$ with well-separated complex cations and iodide anions (Figure 3). The Fe–P bond [2.236(2) Å] is in the range of Fe–P distances found for other $[FpPR_3]^+$ complex cations.[74]

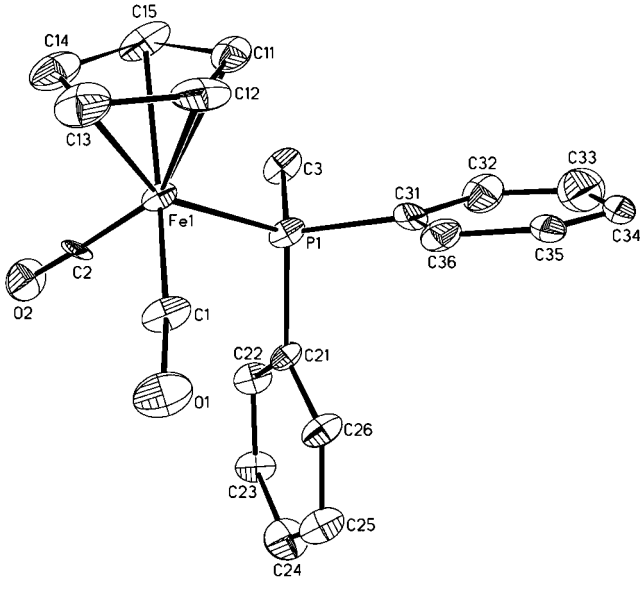

Figure 3. Solid-state structure of the complex cation of **11I**. Thermal ellipsoids are drawn at the 50% probability level. H atoms have been omitted for clarity.

Both phosphanyl borohydride complexes **12a** and **12b** crystallize in the orthorhombic space group $P2_12_12_1$ (Figures 4 and 5, respectively). Their structural parameters are similar, although **12b** shows signs of the higher steric demand of the *tert*-butyl substituents: the Fe–P bond [2.3404(6) Å] is somewhat longer than in the diphenyl derivative **12a** [2.2705(6) Å]. The Fe–CO bonds, on the other hand, are slightly shorter in **12b** (Table 1). Furthermore, the B–P–Fe–COG torsion angles (COG = center of gravity of the Cp ring) differ significantly: the torsion angle is 56.8° for **12a** and –175.9° for **12b**. The only other structurally characterized Fp complex with an anionic phosphorus/boron ligand was reported by Fu and co-workers and contains coordinated diphenylphosphidoboratabenzene.[30] This complex has an Fe–P bond of 2.276(2) Å, which is similar to that in **12a** [2.2705(6) Å]. The Fe–CO distances in Fu's compound [av. 1.742(10) Å] are slightly shorter than in **12a** [av. 1.772(2) Å] but similar to those in **12b** [av. 1.756(3) Å]. The C–O distances [av. 1.169(9) Å] are longer than in both of the phosphanyl borohydride complexes [**12a**: av. 1.141(2) Å; **12b**: av. 1.142(3) Å].

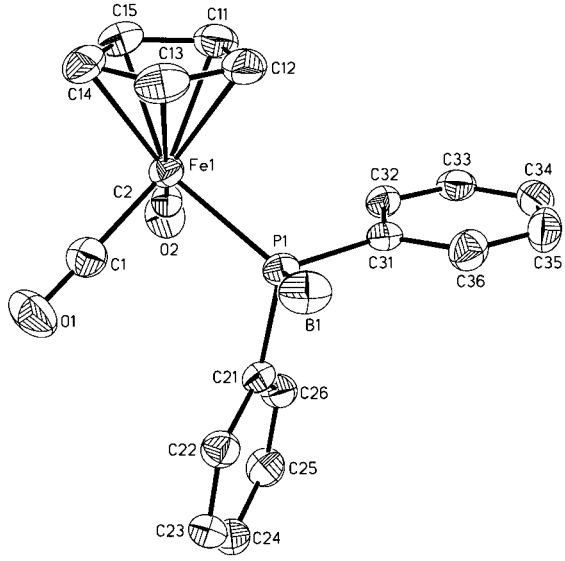

Figure 4. Solid-state structure of **12a**. Ellipsoids are drawn at the 50% probability level. H atoms have been omitted for clarity.

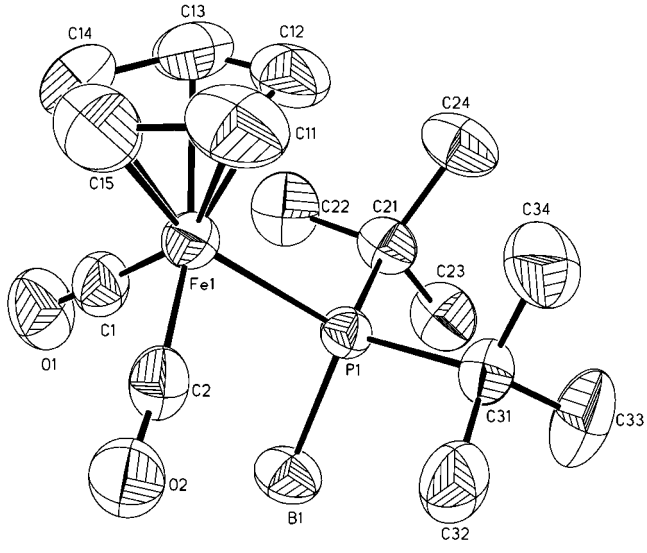

Figure 5. Solid-state structure of **12b**. Ellipsoids are drawn at the 50% probability level. H atoms have been omitted for clarity.

Complex **13** (orthorhombic, $P2_12_12_1$; Figure 6) has the longest Fe–Si bond [2.3353(5) Å] of the structurally characterized Fp-silyl complexes in the literature, with the exception of those complexes with donor silicon atoms bound to silyl residues without electron-withdrawing substituents (cf. $[FpSiMe_2SiPh_3]$: Fe–Si = 2.346(1) Å;[75] $[FpSiPh(SiMe_3)_2]$: Fe–Si = 2.366(1) and 2.355(1) Å in two crystallographically independent molecules[76]). The Fe–Si bond in **13** cannot, of course, be compared directly to the Fe–P bonds in complexes **11I**, **12a**, and **12b**. However, the difference between the Fe–P bond length in **12a** and the Fe–Si bond length in **13** is roughly equivalent to the difference in the covalent radii[71] of P and Si. The Fe–CO distances in **13** are comparable to those found in other Fp-silyl complexes[74] but shorter than those in complexes **11I** and **12a** (Table 1). The C–O bonds found in silyl complex **13** [av. 1.160(3) Å] are roughly 0.015 Å longer than in the complexes **11I** and **12**. This indicates that the π-backbonding from the iron center to the CO ligands is most pronounced in the silyl complex and suggests that **3a** is the strongest donor of the isoelectronic series **1**, **2a**, and **3a**.

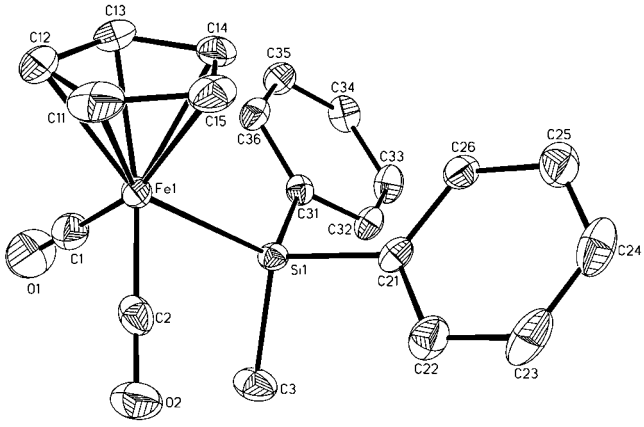

Figure 6. Solid-state structure of **13**. Ellipsoids are drawn at the 50% probability level. H atoms have been omitted for clarity.

This interpretation of relative donor strengths is supported by the $^{13}C$ NMR chemical shifts of the carbonyl carbon atoms. A summary of spectroscopic data can be found in Table 2. It has been shown in the literature that an increase in the donor capacity of an ancillary ligand in a carbonyl complex leads to a shift of the carbonyl carbon atom resonance to lower field.[41,49,77] The carbonyl carbon atom of silyl complex **13** resonates at $\delta$ = 215.8 ppm. The corresponding signals for **12a** and **11I** are found at $\delta$ = 213.5 and 210.4 ppm, respectively. The $^{13}C$ NMR chemical shifts of the cyclopentadienido ligands in metal carbonyl complexes also correlate to the electron density at the metal center, although in this case higher electron density corresponds to a shift to higher field.[42,49,77] Phosphane complex **11I** contains the Cp ring with the most deshielded carbon nuclei ($\delta$ = 89.1 ppm). The cyclopentadienido ring of **12a** resonates at $\delta$ = 86.8 ppm (**12b**: $\delta$ = 86.5 ppm), and the corresponding signal for silyl complex **13** can be seen at $\delta$ = 84.4 ppm. In summary, the NMR spectroscopic data also support the conclusion that the following trend can be established for the donor strengths of the isoelectronic, isosteric ligands: **3a** > **2a** > **1**.

In the $^{31}P$ NMR spectrum, the resonance of the P atom in **12b** is found at $\delta$ = 81.4 ppm, a shift to considerably lower field compared to **11I** ($\delta$ = 48.6 ppm) and **12a** ($\delta$ = 34.3 ppm). This is attributable to the difference in steric demand between the two complexes. This effect has already been observed for potassium phosphanyl borohydrides **K2a** and **K2b**[78] as well as for the parent phosphanes $PPh_3$ and $PtBu_3$.[79] The $^1J_{P,C}$ coupling constants can be correlated to the degree of s character in the P–C bonding orbital.[79] For the two isosteric compounds **11I** and **12a**, $^1J_{P,C}$ (C-*i*) is significantly larger for the phosphane complex (**11I**: 52.9 Hz; **12a**: 27.8 Hz), thereby indicating a larger degree of s character in the P–C-*i* bonding orbital of **11I**. A similar relationship between the $^1J_{P,C}$ values is observed for the free ligands and can easily be explained by Bent's rule.[58,80]

Comparison of the carbonyl IR stretching frequencies is, of course, also an important measure of donor strength in carbonyl complexes (Table 2). In accordance with the interpretation of the $^{13}C$ NMR spectra, complex **11I** is found to have the highest CO stretching frequencies (2055 and 2011 $cm^{-1}$ in MeCN solution). These values compare favorably with those found in the literature for similar complexes.[81–83] Introduction of the $BH_3$ moiety and consequently of a negative charge in **12a** leads to a marked decrease in the frequencies of these vibrations to 2030 and 1982 $cm^{-1}$ (MeCN solution). The relatively low-energy bands found for complex **13** (1994 and 1938 $cm^{-1}$; MeCN

solution) are consistent with the NMR spectroscopic data, which indicate that the silyl ligand is the strongest donor of the three.

When moving from **1** to **2a** to **3a** within the $Fp^+$ system, it is also interesting to consider the effect of exchanging the Cp ligand for Cp* (Cp* = $C_5Me_5^-$) while leaving the other ligands unchanged. While the Cp* silyl complex has not been described in the literature, both the phosphane and phosphanyl borohydride adducts have been reported by Malisch and co-workers.[29] In $CH_2Cl_2$ solution, the CO stretching frequencies are observed at 2029 and 1987 $cm^{-1}$ for the phosphane complex [Cp*Fe(CO)$_2$(PPh$_2$Me)]I, thereby demonstrating that the effect of exchanging Cp for Cp* is comparable to exchanging the phosphane ligand for the corresponding phosphanyl borohydride. Bands attributable to the CO ligands in [Cp*Fe(CO)$_2$(PPh$_2$BH$_3$)], on the other hand, are found at 2007 and 1959 $cm^{-1}$ ($CH_2Cl_2$ solution). These frequencies lie above those seen for complex **13**, thus indicating that moving from the phosphanyl borohydride to the silyl ligand has a more dramatic effect on the electronic structure of the compound than replacing Cp with Cp*. Taken together, these results suggest that, when viewed electronically, the difference between the phosphane and phosphanyl borohydride ligands is somewhat smaller than between the phosphanyl borohydride and silyl ligands.

### Structural and Spectroscopic Comparison of 15PF$_6$, 16b, and 17

Selected bond lengths and angles for **15PF$_6$**, **16b**, and **17** are compiled in Table 3. Details of the X-ray crystal structure analyses of these compounds are summarized in Table 6.

The three iron–sulfur complexes [FpSP*t*Bu$_3$]PF$_6$ (**15PF$_6$**; orthorhombic, $P2_12_12_1$, Figure 7), [FpSP*t*Bu$_2$BH$_3$] (**16b**; orthorhombic, *Pbca*, Figure 8) and [FpSSi*t*Bu$_3$] (**17**; triclinic, $P\bar{1}$, Figure 9) all adopt the expected structure with monodentate, end-on coordination of the sulfide ligands. Separated ion pairs are found in **15PF$_6$**. The effect of the increased steric bulk of **15PF$_6$** and **17** compared to **16b** is most noticeable in the Fe–S–P/Si bond angle, which is nearly 130° in the tri-*tert*-butyl derivatives **15PF$_6$** [127.88(2)°] and **17** [129.01(7)°], compared to 115.86(4)° in **16b**. The Fe–S bond is also affected by the steric strain: **15PF$_6$** and **17** possess the longest reported Fe–S bonds of all Fp complexes with terminal sulfur ligands [2.3469(4) and 2.345(2) Å, respectively].[74] The less sterically hindered complex **16b**, on the other hand, has an Fe–S bond of 2.3125(8) Å. This complex also displays an OC–Fe–CO angle of 98.0(2)°, nearly 5° larger than those found for the two related complexes with three *t*Bu residues.

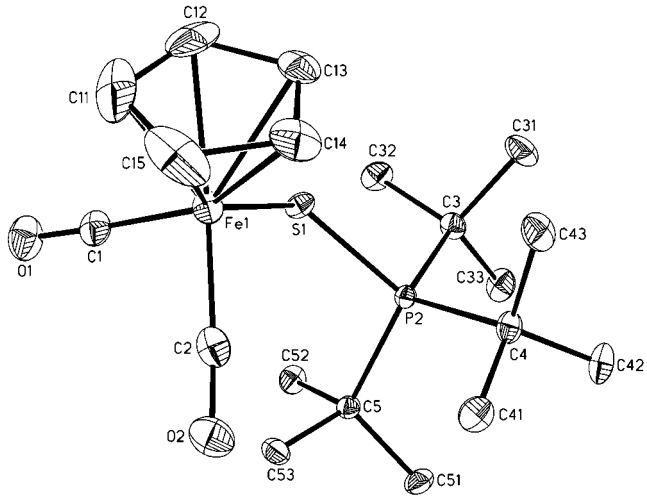

Figure 7. Solid-state structure of the complex cation of **15PF$_6$**. Ellipsoids are drawn at the 50% probability level. H atoms have been omitted for clarity.

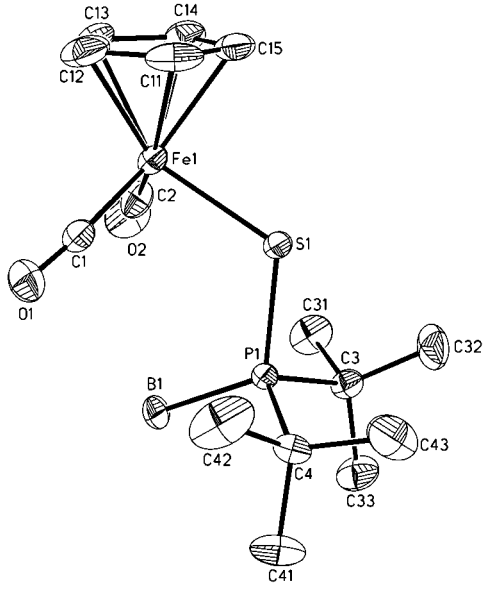

Figure 8. Solid-state structure of **16b**. Ellipsoids are drawn at the 50% probability level. H atoms have been omitted for clarity.

The iron–carbonyl bond lengths and the C–O distances in the carbonyl ligands, however, seem to follow trends that are independent of steric hindrance. Of complexes **15PF$_6$**,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

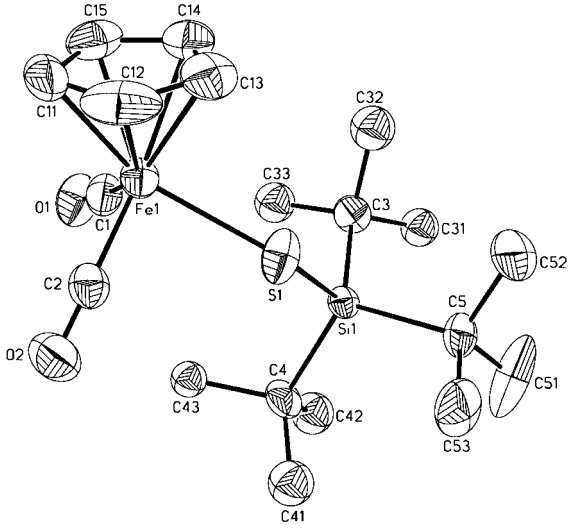

Figure 9. Solid-state structure of **17**. Ellipsoids are drawn at the 50% probability level. H atoms have been omitted for clarity.

**16b**, and **17**, for example, $[FpSPtBu_3]PF_6$ (**15PF$_6$**) displays the longest Fe–CO and the shortest C–O distances [an average of 1.799(2) and 1.139(3) Å, respectively]. The equally sterically hindered silyl thiolate complex **17**, on the other hand, has the shortest Fe–CO and the longest C–O bond [an average of 1.776(5) and 1.151(6) Å, respectively], although the individual C–O distances for this complex are quite different [1.139(6) and 1.163(6) Å]. The phosphanyl borohydride sulfide complex **16b** displays intermediate average bond lengths of 1.784(3) (Fe–CO) and 1.144(4) Å (C–O). These results indicate that the donor-strength trends observed for the non-chalcogen complexes **11I**–**13** also hold true for the thio derivatives. The silyl thiolate **8** appears to be the strongest donor, causing increased Fe–CO backbonding, which leads to a shortening of the Fe–CO bonds and lengthening of the C–O bonds, followed by **6b** and finally phosphane sulfide **4**.

This general trend is also supported by the chemical shifts of the CO carbon atoms in the $^{13}C$ NMR spectra (Table 4). As explained above, a more deshielded CO carbon atom correlates to a stronger donor ligand being attached to the same metal center.[41,42,49,77] The silyl thiolate complex **17** has the furthest downfield CO signal ($\delta$ = 215.1 ppm), while the carbonyl ligands of **16b** and **15PF$_6$** resonate at $\delta$ = 213.1 and 211.5 ppm, respectively (cf. $[FpSSiiPr_3]$: $\delta$ = 214.7;[62] $[FpSPPh_3]PF_6$: $\delta$ = 211.3 ppm[61]). In contrast to complexes **11I**–**13**, the differences in the chemical shifts of the carbon atoms in the Cp rings of complexes **15PF$_6$**–**17** are too small to discern any meaningful trends.

When considering the IR data (Table 4), silyl thiolate complex **17** is found to have CO vibrations at 2030 and 1982 cm$^{-1}$, compared to 2040 and 1994 cm$^{-1}$ for **16b** and 2054 and 2010 cm$^{-1}$ for **15BF$_4$**. The steric influence on the IR stretching frequencies appears to be minimal, as $[FpSPPh_2BH_3]$ (**16a**) displays bands at 2042 and 1998 cm$^{-1}$, which vary only slightly from those of the corresponding *tert*-butyl species **16b**. These results correspond well with published data.[60,62] It can thus be concluded that the CO stretching frequencies in the IR spectra clearly indicate that the silyl thiolate is the strongest donor of the three, while the phosphane sulfide is the weakest.

In summary, X-ray, IR, and NMR spectroscopic data indicate that differences in the electron densities of the non-chalcogen complexes **11I**–**13** on the one hand and the thio complexes **15PF$_6$**–**17** on the other follow the same qualitative trend. However, the differences found for **15PF$_6$**–**17** are less than half as large as those for **11I**–**13**.

## Quantum Chemical Calculations

The experimental studies described thus far were augmented by quantum chemical calculations in order to learn more about qualitative differences in the charge density distribution between formally isoelectronic ligands as well as between the $[CpFe(CO)_2]^+$ complexes of these ligands and also about the hydride-donor capacities of phosphanyl borohydrides compared to their chalcogen derivatives. The latter computations were inspired by the experimental observation that the parent phosphanyl borohydride $PtBu_2BH_3^-$ (**2b**) and the corresponding thio derivative **6b** react with the $CpFe(CO)_2$ fragment with formation of a coordinative Fe–P and Fe–S bond, respectively. In contrast, the oxo derivative $OPPh_2BH_3^-$ (**5a**) does not form stable complexes. Instead, we identified the hydride species FpH in the reaction mixture, which is most likely generated by hydride transfer from the $BH_3$ group.

For the calculation of complex structures and vibrational frequencies, we employed the BP86 functional in combination with the SVP valence double-zeta basis of Ahlrichs and

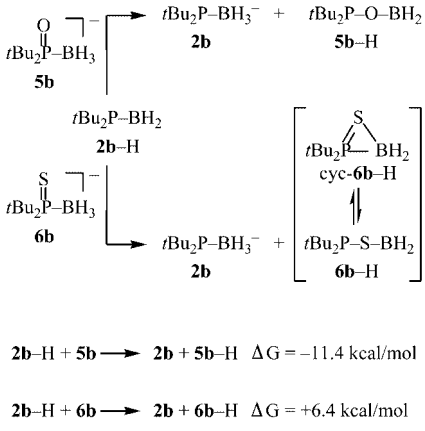
co-workers.[84] The good agreement between computed and experimental values for key geometric data (cf. Tables 1 and 3), as well as for characteristic spectroscopic parameters (cf. Tables 2 and 4) validates this level of density functional theory for an adequate description of electronic structures of the class of compounds studied here.[85,86] For the computation of thermodynamic data for the hypothetical hydride transfer reaction sketched in Scheme 3, we employed the more reliable B3LYP functional in combination with the TZVP valence triple-zeta basis set of Ahlrichs et al.[87] All computations were performed with the Gaussian03 program.[88] Electrostatic potential surfaces were obtained from analogous computations employing the SPARTAN program.[89]



Scheme 3. Isodesmic reactions to assess the relative hydride donor strengths of P*t*Bu$_2$BH$_3^-$ (**2b**), OP*t*Bu$_2$BH$_3^-$ (**5b**), and SP*t*Bu$_2$BH$_3^-$ (**6b**).

An inspection of the electrostatic potential surfaces of PPh$_2$BH$_3^-$ (**2a**) and SiPh$_2$Me$^-$ (**3a**; Figure 10) clearly reveals an accumulation of negative charge concentrated on the BH$_3$ fragment for the phosphanyl borohydride and on the silicon atom for the silyl ligand. In contrast, all of the chalcogen derivatives OP*t*Bu$_2$BH$_3^-$ (**5b**), SP*t*Bu$_2$BH$_3^-$ (**6b**), OSi*t*Bu$_3^-$, and SSi*t*Bu$_3^-$ (**8**) bear the bulk of their negative charge on the chalcogen atom (Figure 10).

Given this qualitative background, it is at first glance surprising to see that **2a** and **2b** react with FpI to give complexes **12a** and **12b**, respectively, whereas treatment of FpI with **5a** leads to hydride transfer and formation of FpH and ultimately of Fp$_2$. The reactivities of **2a/2b** and **5a** with respect to FpI are obviously not governed simply by electrostatic attraction between the positively charged iron center and the most negatively charged part of the ligand molecule; other factors appear to play an important role. We suspected that in the case of ligand **5a**, a neighboring group effect might be responsible for the facile hydride abstraction, because the resulting borane OPPh$_2$BH$_2$ (**5a**-H) can stabilize itself by intramolecular O–B adduct formation leading to a three-membered P–O–B ring. In the case of PR$_2$BH$_2$, the electron deficiency of the boron atom can only be alleviated by P–B pπ–pπ bonding, which is not very efficient.[90]

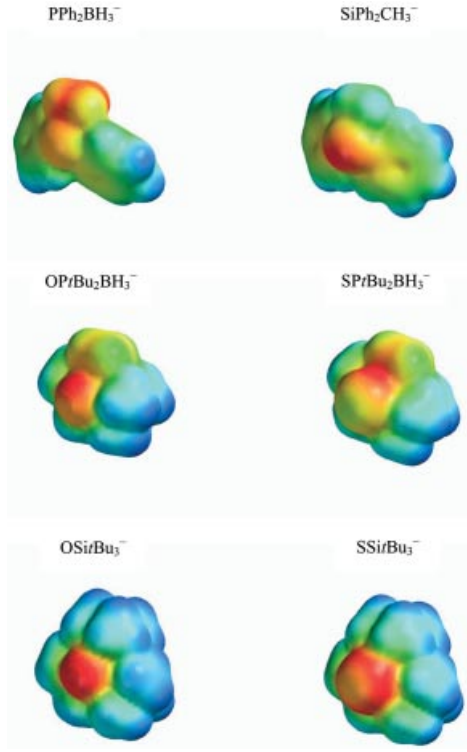


Figure 10. Electrostatic potential surfaces of the anionic ligands PPh$_2$BH$_3^-$ (**2a**), SiPh$_2$Me$^-$ (**3a**), OP*t*Bu$_2$BH$_3^-$ (**5b**), SP*t*Bu$_2$BH$_3^-$ (**6b**), OSi*t*Bu$_3^-$, and SSi*t*Bu$_3^-$ (**8**); color code: red = negative potential; blue = positive potential.

To test the relevance of a possible neighboring group effect, we calculated the molecular structures of the monomeric products of hydride abstraction from P*t*Bu$_2$BH$_3^-$ (**2b**), OP*t*Bu$_2$BH$_3^-$ (**5b**), and SP*t*Bu$_2$BH$_3^-$ (**6b**) (Scheme 3). After geometry optimization, the P–B length in P*t*Bu$_2$BH$_2$ (**2b**-H; 1.818 Å) indicates very little double-bond character between the two atoms. In the case of the oxo derivative OP*t*Bu$_2$BH$_2$, an interesting rearrangement is observed computationally which leads to a migration of the BH$_2$ fragment from phosphorus to oxygen via the anticipated three-membered P–O–B ring (Scheme 3). In the resulting isomer *t*Bu$_2$P–O–BH$_2$ (**5b**-H), pronounced O–B π-bonding aids in the stabilization of the BH$_2$ fragment (O–B = 1.352 Å). To assess the relative stabilities of P*t*Bu$_2$BH$_2$ and *t*Bu$_2$P–O–BH$_2$, we computed the free reaction energy for the isodesmic reaction P*t*Bu$_2$BH$_2$ + OP*t*Bu$_2$BH$_3^-$ → P*t*Bu$_2$BH$_3^-$ + *t*Bu$_2$P–O–BH$_2$ and obtained a value of –11.4 kcal mol$^{-1}$ (Scheme 3). A neighboring group effect similar to the one suggested for hydride-transfer reactions of **5b** may also be operative in the thio derivative **6b**. This in turn raises the question as to why this ligand reacts with [Fp(thf)]$^+$ to form [FpSP*t*Bu$_2$BH$_3$] (**16b**) rather than [FpH]. To address this point, we also calculated the molecular structure of SP*t*Bu$_2$BH$_2$ and found two minima, one containing a three-membered P–S–B ring and the other being the open-chain isomer (Scheme 3). Both isomers are similar in energy, with cyc-**6b**-H being less stable than the open chain species **6b**-H by merely 2.6 kcal mol$^{-1}$. We interpret this result as fol-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lows: due to poor orbital overlap, S–B π-bonding is less favorable than O–B π-bonding, and consequently S–B σ-donation becomes competitive, even though the resulting cyclic structure suffers from severe Baeyer strain. As before, we computed the free reaction energy for the isodesmic reaction $PtBu_2BH_2 + SPtBu_2BH_3^- \rightarrow PtBu_2BH_3^- + tBu_2P–S–BH_2$ (Scheme 3). Contrary to our results for the O-containing analogs, we found this process to be endergonic by +6.4 kcal mol$^{-1}$ relative to the more stable open-chain isomer. Hence, we conclude that hydride abstraction from $OPtBu_2BH_3^-$ (**5b**) is significantly more facile (by 17.8 kcal mol$^{-1}$) than from $SPtBu_2BH_3^-$ (**6b**). These theoretical findings agree very well with our experimental observations.

In all three compounds [**11**]$^+$, **12a**, and **13**, the CpFe(CO)$_2$ fragment bears a positive charge $q$ (obtained from NPA analyses) which is largest in the cationic phosphane complex [**11**]$^+$ ($q$ = + 0.486), intermediate in the phosphanyl borohydride complex **12a** [$q$ = +0.302; $\Delta q$([**11**]$^+$ – **12a**) = 0.184], and smallest in the silyl complex **13** [$q$ = +0.072; $\Delta q$(**12a** – **13**) = 0.230]. This finding supports the conclusion drawn from inspection of the IR and NMR spectroscopic data that silyl ligand **3a** is a significantly stronger electron donor than phosphanyl borohydride ligand **2a**. A similar trend is also visible for the series of complexes [**15**]$^+$ ($q$ = +0.576), **16b** [$q$ = +0.435; $\Delta q$([**15**]$^+$ – **16b**) = 0.141], and **17** [$q$ = +0.353; $\Delta q$(**16b** – **17**) = 0.082], even though the differences in the computed NPA charges on the three CpFe(CO)$_2$ fragments are less pronounced with a sulfur atom between the iron center and the P/Si atom. Again, these results are nicely reflected by the changes of the CO stretching frequencies: The highest wavenumbers are found for [**15**]$^+$, while a shift to lower wavenumbers is observed for **17** (Table 4), although this difference is much smaller than in the case of [**11**]$^+$ and **13** (Table 2). An inspection of the HOMOs of the three isoelectronic ligands **1**, **2a**, and **3a** reveals very similar topologies, all of which correspond to the lone pair being located on the donor atoms P or Si (Figure 11). This finding provides convincing evidence that the interaction of these ligands with transition metal ions will be of essentially the same nature and implies that these ligands are truly isolobal species. Quantitatively, however, the degree of charge transfer is different for the different ligand classes, with phosphanes being the weakest and silyl ligands being the strongest donors.

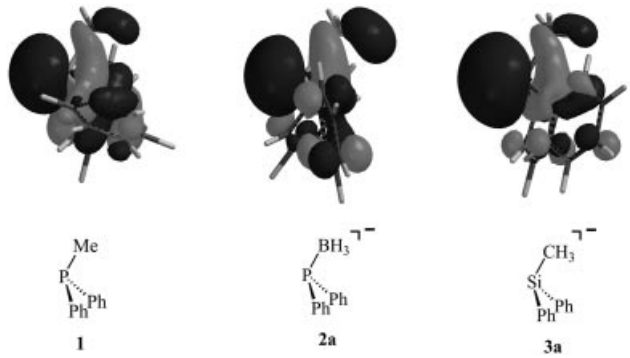

Figure 11. HOMOs of the series of isoelectronic ligands $PPh_2Me$ (**1**), $PPh_2BH_3^-$ (**2a**), and $SiPh_2Me^-$ (**3a**).

## Conclusions

A series of isoelectronic and isosteric iron complexes [CpFe(CO)$_2$(EPh$_2$XH$_3$)]$^{n+}$ (E = Si, X = C; E = P, X = C, B; $n$ = 0, 1) **11I**, **12a**, and **13** has been synthesized and characterized by X-ray crystallography and $^1$H and heteronuclear NMR and IR spectroscopy. A comparison of the structural and spectroscopic properties of compounds **11I**–**13** indicates that the silyl ligand **3a** displays the highest propensity towards electron donation, followed by the anionic phosphanyl borohydride ligand **2a**. The phosphane ligand **1** is the weakest donor.

In addition, the reactivity of phosphane chalcogenides, phosphanyl borohydride chalcogenides, and silyl chalcogenolates with the [CpFe(CO)$_2$]$^+$ fragment has been investigated. A second series of isoelectronic complexes [CpFe(CO)$_2$(SE*t*Bu$_2$XH$_3$)]$^{n+}$ (E = Si, X = C; E = P, X = C, B; $n$ = 0, 1) **15PF$_6$**–**17** has been isolated with *tert*-butyl rather than phenyl residues and fully characterized. The conclusion that the silyl species is the strongest donor of the sulfur-containing ligands can be drawn, but this effect, now mediated by the sulfur atom, is not as pronounced as for the non-chalcogen species **11I**–**13**, and the differences in the CO stretching frequencies in the IR spectra and the $^{13}$C NMR resonances of the CO carbon atoms are about half as large in **15PF$_6$**–**17** as in **11I**–**13**. The molecular structures of all crystallographically characterized compounds as well as key spectroscopic parameters have been calculated by DFT. Overall, an excellent agreement was found between experimentally and theoretically derived data. In the reaction with [CpFe(CO)$_2$]$^+$, the oxo derivative $OPPh_2BH_3^-$ transfers a hydride ion rather than forming a stable [CpFe(CO)$_2$(OPPh$_2$BH$_3$)] complex. The tendency to undergo hydride transfer reactions has been studied by DFT calculations for the series $PtBu_2BH_3^-$, $OPtBu_2BH_3^-$, and $SPtBu_2BH_3^-$. The results reveal that $OPtBu_2BH_3^-$ is the strongest and $SPtBu_2BH_3^-$ the weakest hydride donor, in agreement with experimental observations. Further theoretical analysis indicates that the three derivatives $PPh_2Me$, $PPh_2BH_3^-$, and $SiPh_2Me^-$ are truly isolobal species, despite variations in their charge distributions.

## Experimental Section

**General Considerations:** All reactions and manipulations of air-sensitive compounds were carried out under an atmosphere of dry nitrogen using standard Schlenk techniques. Solvents were freshly distilled under argon from sodium/benzophenone (thf, diethyl ether, toluene, $C_6D_6$) or sodium-lead alloy (pentane, hexane) prior to use. MeCN, $CD_3CN$, $CH_2Cl_2$, $CD_2Cl_2$, and $CDCl_3$ were dried with molecular sieves (4 Å) and degassed. NMR spectra were recorded with Bruker AMX 250, DPX 250, Avance 300, or Avance 400 spectrometers. $^1$H and $^{13}$C chemical shifts are reported relative to tetramethylsilane and were referenced against residual solvent

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

peaks ($C_6D_5H$: $\delta$ = 7.16; $C_6D_6$: $\delta$ = 128.06; $CHCl_3$: $\delta$ = 7.26; $CDCl_3$: $\delta$ = 77.16 ppm).[91] $^{11}B$ NMR spectra were referenced against external $BF_3{\cdot}OEt_2$. $^{31}P$ NMR spectra are reported relative to external $H_3PO_4$ (85%). $^{29}Si$ NMR spectra were referenced against external TMS and recorded using the INEPT pulse sequence with empirically optimized parameters for polarization transfer from the methyl and phenyl substituents (**13**) or the *t*Bu substituents (**Na3b** and **17**). Abbreviations: Fp = $CpFe(CO)_2$, n.r. = multiplet expected but not resolved. IR spectra were recorded with a Perkin–Elmer 1650 FTIR spectrophotometer or a Jasco FT/IR-420 spectrophotometer. Elemental analyses were performed by the microanalytical laboratory of the J. W. Goethe University, Frankfurt(Main).

**Materials:** Li, Na, KH, *n*BuLi solution (ca. 1.6 M in hexane), $BH_3$·thf solution (1 M in thf), $PPh_3$, $ClSiPh_2Me$, biphenyl, FpI, and MeI were obtained from commercial sources (Aldrich, Fluka, Acros or Chemetall) and used as received. $HPPh_2$ was obtained by reductive cleavage of $PPh_3$ with Li powder in thf and subsequent hydrolysis and distillation, as described by Bianco and Doronzo.[92] Deprotonation of $HPPh_2$ with *n*BuLi yields $LiPPh_2$;[93] employing hexane leads to precipitation of solvent-free $LiPPh_2$. Bromination of $HSitBu_2Me$[94] according to the literature method[95] yields $BrSitBu_2Me$. KFp (**10**),[96] $KPPh_2BH_3$ (**K2a**),[12,58] and $KPtBu_2BH_3$ (**K2b**)[12,58] were prepared by literature methods. $[Fp(thf)]PF_6$ (**14PF$_6$**) was obtained by treating $[Cp_2Fe]PF_6$ with $Fp_2$ as reported by Catheline and Astruc.[97] $[Fp(thf)]BF_4$ (**14BF$_4$**) was prepared from FpI and $AgBF_4$.[98]

**Synthesis of (thf)$_x$NaSi*t*Bu$_2$Me (Na3b):** Na (2.0 g, 87.0 mmol) and biphenyl (1.29 g, 8.4 mmol) were stirred overnight in thf (20 mL) to give a dark green solution surrounding blocks of unreacted sodium. A solution of $BrSitBu_2Me$ (3.38 g, 14.2 mmol) in thf (15 mL) was then added dropwise to this mixture over 2.5 h. After stirring for 16 h, all volatiles were removed in vacuo, and the dark brown residue was extracted with pentane (25 mL). After filtration, the filter cake was washed with pentane (10 mL). Volatiles were removed in vacuo overnight from the dark brown filtrate, and the resulting brown residue was dissolved in thf (30 mL) to give a 0.305 M solution of the product in thf (9.15 mmol, 64%). $^1H$ NMR ($C_6D_6$, 250.13 MHz): $\delta$ = 0.33 (s, 3 H, $SiCH_3$), 1.35 ppm (s, 18 H, $CCH_3$). $^{13}C\{^1H\}$ NMR ($C_6D_6$, 62.90 MHz): $\delta$ = 0.3 ($SiCH_3$), 21.3 ($CCH_3$), 32.2 ppm (s, $CCH_3$). $^{29}Si\{^1H\}$ NMR ($C_6D_6$, 49.7 MHz): $\delta$ = 14.4 ppm.

**Synthesis of [FpPPh$_2$Me]I (11I):** A solution of $LiPPh_2$ (0.147 g, 0.77 mmol) in thf (6 mL) was added with stirring to a solution of FpI (**9**, 0.233 g, 0.77 mmol) in thf (8 mL) at –78 °C. Slowly warming to ambient temperature overnight resulted in a color change from black to dark red and the formation of a colorless precipitate (LiI). The mixture was filtered and the filtrate treated with a solution of MeI (0.112 g, 0.79 mmol) in thf (3 mL). The resulting dark yellow precipitate was washed with thf (2 × 5 mL) and dried in vacuo. Yield: 0.243 g (63%). X-ray quality crystals were obtained by gas-phase diffusion of diethyl ether into a solution of **11I** in MeCN. $^1H$ NMR ($CD_3CN$, 400.13 MHz): $\delta$ = 2.38 (d, $^2J_{P,H}$ = 10.5 Hz, 3 H, $CH_3$), 5.38 (d, $^3J_{P,H}$ = 1.6 Hz, 5 H, Cp), 7.50–7.64 ppm (m, 10 H, H-*o,m,p*). $^{13}C\{^1H\}$ NMR ($CD_3CN$, 100.63 MHz): $\delta$ = 19.5 (d, $^1J_{P,C}$ = 35.4 Hz, $CH_3$), 89.1 (d, $^2J_{P,C}$ = 0.5 Hz, Cp), 130.4 (d, $^3J_{P,C}$ = 11.0 Hz, C-*m*), 132.3 (d, $^2J_{P,C}$ = 10.2 Hz, C-*o*), 132.9 (d, $^4J_{P,C}$ = 2.8 Hz, C-*p*), 134.1 (d, $^1J_{P,C}$ = 52.9 Hz, C-*i*), 210.4 ppm (d, $^2J_{P,C}$ = 24.2 Hz, CO). $^{31}P\{^1H\}$ NMR ($CD_3CN$, 161.98 MHz): $\delta$ = 48.6 ppm (s). IR (MeCN): $\tilde{\nu}$ = 2055, 2011 $cm^{-1}$ (CO). $C_{20}H_{18}FeIO_2P$ (504.06): calcd. C 47.65, H 3.60; found C 47.46, H 3.65.

**Synthesis of [FpPPh$_2$BH$_3$] (12a):** A solution of $KPPh_2BH_3$ (**K2a**; 0.239 g, 1.00 mmol) in thf (10 mL) was added with stirring to a solution of FpI (**9**, 0.304 g, 1.00 mmol) in thf (10 mL) at –78 °C. Slowly warming to ambient temperature overnight resulted in a color change from black to light brown and formation of a colorless precipitate (KI). The mixture was filtered and the solvent removed from the filtrate in vacuo. The resulting brown solid residue was washed with pentane (5 mL) and extracted with toluene (10 mL). The toluene was removed from the filtrate in vacuo to give the product as a yellow crystalline material. Yield: 0.274 g (73%). X-ray quality crystals were obtained by gas-phase diffusion of pentane into a solution of **12a** in toluene. $^1H$ NMR ($C_6D_6$, 250.13 MHz): $\delta$ = 2.3 (m, 3 H, $BH_3$), 4.16 (d, $^3J_{P,H}$ = 1.6 Hz, 5 H, Cp), 6.97–7.16 (m, 6 H, H-*m,p*), 7.93–8.02 ppm (m, 4 H, H-*o*). $^{11}B\{^1H\}$ NMR ($C_6D_6$, 128.37 MHz): $\delta$ = –28.0 ppm (d, $^1J_{P,B}$ = 44 Hz). $^{13}C\{^1H\}$ NMR ($C_6D_6$, 62.90 MHz): $\delta$ = 86.8 (n.r., Cp), 128.3 (d, $^3J_{P,C}$ = 8.7 Hz, C-*m*), 129.3 (d, $^4J_{P,C}$ = 2.3 Hz, C-*p*), 133.3 (d, $^2J_{P,C}$ = 8.0 Hz, C-*o*), 140.2 (d, $^1J_{P,C}$ = 27.8 Hz, C-*i*), 213.5 ppm (d, $^2J_{P,C}$ = 18.0 Hz, CO). $^{31}P\{^1H\}$ NMR ($C_6D_6$, 161.98 MHz): $\delta$ = 34.3 ppm (m). IR (MeCN): $\tilde{\nu}$ = 2030, 1982 $cm^{-1}$ (CO). $C_{19}H_{18}BFeO_2P$ (375.96): calcd. C 60.74, H 4.83; found C 60.58, H 4.73.

**Synthesis of [FpP*t*Bu$_2$BH$_3$] (12b):** A solution of $KPtBu_2BH_3$ (**K2b**, 0.291 g, 1.47 mmol) in thf (10 mL) was added with stirring to a solution of FpI (**9**, 0.446 g, 1.47 mmol) in thf (10 mL) at –78 °C. Slowly warming to ambient temperature overnight resulted in a color change from black to yellow and formation of a colorless precipitate (KI). The mixture was filtered and the solvent removed from the filtrate in vacuo. The resulting brown solid residue was washed with pentane (5 mL) and extracted with toluene (10 mL). The toluene was removed from the filtrate in vacuo to give the product as a yellow crystalline material. Yield: 0.355 g (72%). X-ray quality crystals were obtained by gas-phase diffusion of pentane into a solution of **12b** in toluene. $^1H$ NMR ($C_6D_6$, 250.13 MHz): $\delta$ = 1.35 (d, $^3J_{P,H}$ = 11.9 Hz, 18 H, $CH_3$), 1.60 (q, $^1J_{B,H}$ = 93.6 Hz, 3 H, $BH_3$), 4.33 ppm (s, 5 H, Cp). $^{11}B\{^1H\}$ NMR ($C_6D_6$, 128.37 MHz): $\delta$ = –30.0 ppm (d, $^1J_{P,B}$ = 49 Hz). $^{13}C\{^1H\}$ NMR ($C_6D_6$, 62.90 MHz): $\delta$ = 31.2 (d, $^2J_{P,C}$ = 2.0 Hz, $CH_3$), 37.4 (d, $^1J_{P,C}$ = 6.6 Hz, $CCH_3$), 86.5 (n.r., Cp), 215.5 ppm (d, $^2J_{P,C}$ = 17.0 Hz, CO). $^{31}P\{^1H\}$ NMR ($C_6D_6$, 161.98 MHz): $\delta$ = 81.4 ppm (m). IR (MeCN): $\tilde{\nu}$ = 2029, 1982 $cm^{-1}$ (CO). $C_{15}H_{26}BFeO_2P$ (335.99): calcd. C 53.62, H 7.80; found C 53.48, H 7.69.

**Synthesis of [FpSiPh$_2$Me] (13):** A solution of $ClSiPh_2Me$ (0.33 mL, 0.367 g, 1.57 mmol) in thf (8 mL) was added dropwise to a suspension of KFp (0.307 g, 1.42 mmol) in thf (10 mL). After stirring overnight, volatiles were removed in vacuo, then the brown residue was extracted with pentane (4 × 10 mL) and filtered. Removal of the solvent yielded the crude product as a brown oil (0.392 g, 74%). The crude product was purified by filtration through silica gel under an inert atmosphere using hexane/$CH_2Cl_2$ (2:1) as the eluent, which yielded the product as a yellow solid after removal of the volatiles in vacuo. X-ray quality crystals were obtained from hexane solution at –25 °C. $^1H$ NMR (300.0 MHz, $C_6D_6$): $\delta$ = 0.95 (s, 3 H, $CH_3$), 3.97 (s, 5 H, Cp), 7.21, 7.69 ppm (2 × m, 6 H, 4 H, H-*o,m,p*). $^{13}C\{^1H\}$ NMR (75.4 MHz, $C_6D_6$): $\delta$ = 5.5 ($CH_3$), 84.4 (s, Cp), 128.0 (C-*m* or C-*o*), 128.4 (s, C-*p*), 134.6 (C-*m* or C-*o*), 144.6 (C-*i*), 215.8 ppm (CO). $^{29}Si\{^1H\}$ NMR (59.6 MHz, $C_6D_6$): $\delta$ = 35.1 ppm. IR (MeCN): $\tilde{\nu}$ = 1994, 1938 $cm^{-1}$ (CO). $C_{20}H_{18}FeO_2Si$ (374.28): calcd. C 64.18, H 4.85; found C 64.14, H 4.88.

**Reaction of KOPPh$_2$BH$_3$ (K5a) with FpI (9):** An NMR tube was charged with **K5a** (0.05 g, 0.2 mmol), FpI (**9**; 0.06 g, 0.2 mmol), and [D$_8$]thf (0.6 mL), and the tube was flame-sealed and shaken

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

until all the solids had dissolved. Slow deposition of a colorless precipitate (KI) took place over several days. Analysis by NMR spectroscopy showed slow formation of $Fp_2$ and several unidentified phosphorus- and boron-containing products. The integrals of the $^1H$ NMR Cp resonances of $Fp_2$ and FpI account for over 95% of the total Cp region integral. Main phosphorus-containing product, approx. 60% yield by $^{31}P$ NMR: $^{31}P\{^1H\}$ NMR ([D$_8$]thf, 161.98 MHz): $\delta$ = 80.8 ppm (m); $^{11}B$ NMR ([D$_8$]thf, 128.37 MHz): $\delta$ = –37.5 ppm (m). Analysis of the hydride region of the $^1H$ NMR spectrum showed small amounts of FpH at $\delta$ = –11.7 ppm.[68]

**Reaction of $NaOSiPh_2Me$ (Na7) with FpI (9):** A Schlenk flask was charged with FpI (**9**; 0.220 g, 0.72 mmol) in thf (5 mL), cooled to –78 °C, and a solution of **Na7** (0.170 g, 0.72 mmol) in thf (5 mL) was added dropwise to this solution. The mixture was then warmed to room temperature overnight. All volatiles were removed in vacuo, and the brown residue was extracted with toluene and filtered. The only major Cp-containing product in the filtrate was $Fp_2$ and the only major Si-containing product $O(SiPh_2Me)_2$, both of which were identified by comparison with authentic samples. Red crystals of $[(NaOSiPh_2Me)_4(Fp_2)_2]$ were isolated by removing toluene from the filtrate, washing the residue with benzene, and recrystallizing from toluene. It should be noted that the solubility of the adduct is significantly higher in toluene than in benzene. IR $[(NaOSiPh_2Me)_4(Fp_2)_2]$ (KBr): $\tilde{\nu}$ = 2005 (m), 1957 (s), 1932 (m), 1756 (m), 1735 (s) cm$^{-1}$ (CO).

**Synthesis of $[FpSPtBu_3]PF_6$ (15PF$_6$):** The synthesis and NMR and IR data of the complex cation as its $BF_4$ salt have been reported by Kuhn and Schumann (data given in Table 4 are for the $PF_6$ salt).[60] We modified their procedure by using $[Fp(thf)]PF_6$ instead of the $BF_4^-$ salt, as described in the literature.[97] X-ray quality crystals were obtained by gas-phase diffusion of pentane into a solution of **15PF$_6$** in $CHCl_3$. $C_{19}H_{32}F_6FeO_2P_2S$ (556.30): calcd. C 41.02, H 5.80; found C 40.97, H 5.81.

**Synthesis of $[FpSPPh_2BH_3]$ (16a):** A solution of $KSPPh_2BH_3$ (**K6a**; 0.098 g, 0.36 mmol) in thf (3 mL) was added to a solution of $[Fp(thf)]PF_6$ (**14PF$_6$**; 0.143 g, 0.36 mmol) in $CH_2Cl_2$ (30 mL) with stirring at –78 °C. As the mixture warmed to ambient temperature overnight, the color lightened from dark red to orange. The solvent was removed in vacuo and the resulting red-brown solid residue washed with pentane (2 × 5 mL) and extracted with toluene (2 × 10 mL). The extracts were filtered through silica gel, and the toluene was removed from the filtrate in vacuo to give the product as an orange oil. Yield: 0.106 g (72%). $^1H$ NMR ($CD_2Cl_2$, 300.03 MHz): $\delta$ = 1.25 (br. m, 3 H, $BH_3$), 5.08 (s, 5 H, Cp), 7.1–7.9 ppm (m, 10 H, H-*o,m,p*). $^{11}B\{^1H\}$ NMR ($CD_2Cl_2$, 96.26 MHz): $\delta$ = –33.8 ppm (d, $^1J_{P,B}$ = 55 Hz). $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75.45 MHz): $\delta$ = 86.3 (s, Cp), 128.5 (d, $^3J_{P,C}$ = 9.9 Hz, C-*m*), 130.6 (d, $^4J_{P,C}$ = 2.5 Hz, C-*p*), 132.0 (d, $^2J_{P,C}$ = 9.9 Hz, C-*o*), 136.2 (d, $^1J_{P,C}$ = 46.4 Hz, C-*i*), 212.1 ppm (d, $^3J_{P,C}$ = 4.4 Hz, CO). $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$, 121.46 MHz): $\delta$ = 48.3 ppm (br. m). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2042, 1998 cm$^{-1}$ (CO). A correct elemental analysis could not be obtained due to residual solvent and an unidentified impurity that could not be removed.

**Synthesis of $[FpSPtBu_2BH_3]$ (16b):** A solution of $KSPtBu_2BH_3$ (**K6b**; 0.137 g, 0.60 mmol) in thf (3 mL) was added to a solution of $[Fp(thf)]PF_6$ (**14PF$_6$**; 0.185 g, 0.47 mmol) in $CH_2Cl_2$ (40 mL) with stirring at –78 °C. As the mixture warmed to ambient temperature overnight, the color lightened from dark red to orange, and a colorless precipitate ($KPF_6$) formed. The solvent was removed in vacuo and the resulting red-brown semi-solid residue was extracted with pentane (2 × 10 mL). The extracts were filtered through silica gel (approx. 1 cm) on a Schlenk frit. The product adsorbed completely on the silica gel and was subsequently washed with 30 mL of pentane. It was eluted with benzene, and all volatiles were removed in vacuo to give a dark red oil. Upon standing overnight, fine orange needles of **16b** formed in X-ray quality. Yield: 0.100 g (58%). $^1H$

NMR ($CD_2Cl_2$, 300.03 MHz): $\delta$ = 0.68 (m, 3 H, $BH_3$), 1.27 (d, $^3J_{P,H}$ = 13.2 Hz, 18 H, $CH_3$), 5.12 ppm (s, 5 H, Cp). $^{11}B\{^1H\}$ NMR ($CD_2Cl_2$, 96.26 MHz): $\delta$ = –37.1 ppm (d, $^1J_{P,B}$ = 55 Hz). $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75.45 MHz): $\delta$ = 28.4 (d, $^2J_{P,C}$ = 2.3 Hz, $CH_3$), 36.8 (d, $^1J_{P,C}$ = 20.7 Hz, *C*$CH_3$), 86.5 (s, Cp), 213.1 ppm (d, $^3J_{P,C}$ = 3.1 Hz, CO). $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$, 121.46 MHz): $\delta$ = 86.8 ppm (br. m). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2040, 1994 cm$^{-1}$ (CO). $C_{15}H_{26}BFeO_2PS$ (368.05): calcd. C 48.95, H 7.12; found C 48.06, H 7.12.

**Synthesis of [FpSSi*t*Bu$_3$] (17):** Solid $(thf)_2NaSSitBu_3$ (**Na8**, 0.155 g, 0.39 mmol) was added in one portion to a solution of $[Fp(thf)]BF_4$ (**14BF$_4$**; 0.131 g, 0.39 mmol) in $CH_2Cl_2$ (12 mL). After 4 h stirring, the volatiles were removed from the reaction mixture and the brown residue was extracted with pentane (5 mL) and filtered through Celite® on a frit. The filter cake was then washed with pentane (2 × 5 mL). Slow concentration of the filtrate yielded a dark brown, microcrystalline solid. Yield: 0.156 g (98%). Recrystallization from pentane yielded X-ray quality crystals. $^1H$ NMR ($C_6D_6$, 400.13 MHz): $\delta$ = 1.39 (s, 27 H, $CH_3$), 4.11 ppm (s, 5 H, Cp). $^{13}C\{^1H\}$ NMR ($C_6D_6$, 100.63 MHz): $\delta$ = 25.5 (*C*$CH_3$), 31.6 ($CH_3$), 86.2 (Cp), 215.1 ppm (CO). $^{29}Si\{^1H\}$ NMR ($C_6D_6$, 59.6 MHz): $\delta$ = 29.2 ppm. $^1H$ NMR ($CD_2Cl_2$, 300.0 MHz): $\delta$ = 1.13 (s, 27 H, $CH_3$), 5.02 ppm (s, 5 H, Cp). $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75.4 MHz): $\delta$ = 25.3 (*C*$CH_3$), 31.3 ($CH_3$), 86.9 (Cp), 215.1 ppm (CO). IR (hexane): $\tilde{\nu}$ = 2035 (s), 1988 (s) cm$^{-1}$ (CO). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2030 (s), 1982 (s) cm$^{-1}$ (CO). $C_{19}H_{32}FeO_2SSi$ (408.45): calcd. C 55.87, H 7.90; found C 54.59, H 7.85.

**X-ray Structural Characterization:** Data were collected with a Stoe IPDS-II two circle diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation. Empirical absorption corrections were performed with the MULABS option[99] in the program PLATON.[100] Equivalent reflections were averaged. The structures were solved by direct methods[101] and refined with full-matrix least-squares on $F^2$ using the program SHELXL-97.[102] Hydrogen atoms were placed at ideal positions and refined with fixed isotropic displacement parameters using a riding model. Complex **17**: Two of the three *t*Bu substituents are disordered over two sites and were refined isotropically. In order to keep the geometric parameters in reasonable ranges, similarity restraints were applied for bond lengths and bond angles. Details of the X-ray crystal structure analyses of compounds **11I**, **12a**, **12b**, and **13** are summarized in Table 5 and compounds **15PF$_6$**, **16b**, and **17** in Table 6.

CCDC-628090 (**11I**), -628087 (**12a**), -628088 (**12b**), -628091 (**13**), -628094 (**15PF$_6$**), -628093 (**16b**), -628092 (**17**), and -628089 ([(18-crown-6)$(thf)_2$Na][4,4′-$(SitBu_2Me)_2(C_6H_4)_2$]) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Calculated molecular structures of compounds **2b**, **2b**-H, **5b**, **5b**-H, **6b**, and **6b**-H (Figure S1).

[72] It appears that rather than attacking the iron atom, the nucleophilic siloxide reacts with the iodide ligand to form an $[Fp]^-$ fragment and intermediate $IOSiPh_2Me$. The complex iron anion subsequently reacts with one equivalent of FpI to give $Fp_2$. We speculate that the intermediate silicon-containing species reacts with one equivalent of siloxide ligand to give disiloxane $O(SiPh_2Me)_2$ and NaIO. The disiloxane is also the major product when **Na7** is treated with $I_2$. This can be thought of as analogous to the reaction of $I_2$ with $OH^-$, which results in $IO_3^-$, $I^-$, and $H_2O$.[71] When the same reaction is carried out using FpBr rather than FpI, an identical outcome is observed. However, the formation of $Fp_2$ and $O(SiPh_2Me)_2$ from **Na7** and FpI is slow, with about 50% of the starting material left after stirring for two weeks at room temperature. This slow reaction rate allows for the isolation of an adduct of **Na7** and $Fp_2$ in which the siloxide sodium atoms are supported by donor–acceptor interactions with the oxygen atoms of the bridging carbonyl ligands in $Fp_2$. The details of this adduct formation have been discussed recently in another context.[73]

# Synthesis, Structures and Optical Power Limiting of Some Transition Metal and Lanthanide Monoporphyrinate Complexes Containing Electron-Rich Diphenylamino Substituents

**Shitao Fu,[a,b] Xunjin Zhu,[b] Guijiang Zhou,[b] Wai-Yeung Wong,[b] Cheng Ye,[c] Wai-Kwok Wong,*[b] and Zaoying Li*[a]**

**Keywords:** Lanthanides / Optical limiting / Photoluminescence / Porphyrins / Transition metals

Transition metal and lanthanide monoporphyrinate complexes based on 5,10,15,20-tetrakis[*p*-(diphenylamino)-phenyl]-21*H*,23*H*-porphine ($H_2$tdpapp) have been synthesized and characterized and the X-ray crystal structures of the palladium and platinum analogues [M(tdpapp)] (M = Pd, Pt) determined. Experimental investigations of the nonlinear optical transmittance characteristics at 532 nm show that most of these new metalated porphyrinate complexes are excellent optical limiters with performances comparable or superior to those of the benchmark reverse saturable absorption dyes such as fullerene $C_{60}$ and (phthalocyanine)metal complexes. The nonlinear optical measurements reveal that the optical-limiting effects of porphyrins can be enhanced greatly by incorporation of lanthanide ions and covalent attachment of the electron-donating diphenylamino moieties to the parent porphyrinate ring. The optical-limiting thresholds for these lanthanide monoporphyrinate complexes range from 0.09 to 0.30 J cm$^{-2}$ at 82 % linear transmittance, which makes them attractive candidates as optical-limiting materials for the protection of various optical devices.

## Introduction

With the rapid development of laser technology, the damage to human eyes, optical sensors, and optical components caused by exposure to sudden, intense laser pulses has driven the search for effective optical limiters that display fast response speeds and relatively high linear transmissions.[1,2] Optical limiters are materials that are transparent at normal light intensities but opaque to very bright light.[3–5] Over the last decade, interest has focused on materials with weak ground-state absorption and strong excited-state absorption, which typically achieve optical limiting by a mechanism known as reverse saturable absorption (RSA). An ideal material would have a low ground-state absorption over a wide spectral bandwidth and strong excited-state absorption across the same region.[6]

At present, the materials employed for optical power limiting (OPL) are mainly composed of small molecules, such as fullerene ($C_{60}$),[7,8] phthalocyanines,[9,10] diacetylenes,[11] nanotubes,[12] and organometallic compounds.[13,14] Some conjugated organic polyynes also exhibit good optical-limiting capabilities.[15] Metalloporphyrins are among the most effective optical limiters[6,16–20] because their ground-state absorption is mostly confined to a few narrow regions (Soret and Q-bands), which allows high transmission in the spectral window between these bands. In addition, these macrocycles present a highly developed π-conjugation system which contributes to strong excited-state absorption, high triplet yields, long excited line-like spectra, and long luminescence lifetimes. Porphyrins and metalloporphyrins are known to exhibit RSA at 532 nm. Molecular modifications, for example by incorporating functional groups on the porphyrin ring or inserting metal ions in the ring, are commonly adopted to improve their OPL properties.

Recent investigations on the use of metalloporphyrins for optical limiting have focused on the transition metals,[16] phosphorus(V),[17] and group III and IV metals.[6,18] Wang and co-workers, for example, have reported a series of pentaazadentate porphyrin-like metal complexes with potential uses as optical-limiting materials where the metal ion is $Sm^{3+}$ or $Gd^{3+}$.[19] A europium(III) tetraphenylporphyrinate complex with OPL capability has also been reported by Kuznetsova et al.[20] It is well known that insertion of the lanthanide ion into the porphyrin core allows the energy of the ligand's triplet state to transfer efficiently to the excited state of the lanthanide ion, thus enabling this ion to emit light.[21] While triarylamine-derived organic materials have been investigated extensively because of their potential applications in various areas of optoelectronic devices,[22] there are only a few reports of porphyrin/triarylamine hybrids.[23] In this paper, we describe the synthesis and charac-

terization of a series of lanthanide monoporphyrinate complexes [(tdpapp)Ln($L_{OMe}$)] {Ln = Yb, Er, and Gd; $L_{OMe}^-$ = ($\eta^5$-$C_5H_5$)Co[P(=O)(OMe)$_2$]$^-$, $H_2$tdpapp = 5,10,15,20-tetrakis[*p*-(diphenylamino)phenyl]-21*H*,23*H*-porphine} and their late transition metal analogues [M(tdpapp)] (M = Ni, Zn, Pd, Pt) which show large optical-limiting capabilities; the mechanisms pertaining to their nonlinear optical behavior are critically discussed.

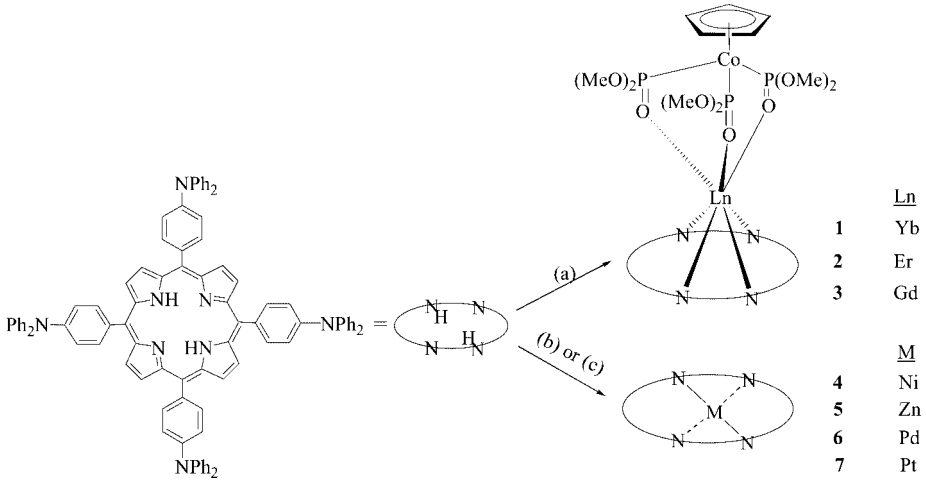
## Results and Discussion

### Synthesis and Characterization

Scheme 1 shows the chemical structures and the synthetic strategies of the metal monoporphyrinate complexes discussed in the present study. The porphyrin free-base ($H_2$tdpapp) containing diphenylamino (DPA) units was prepared according to a literature procedure.[24] When the molar ratio of pyrrole/DDQ (DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone) was set at 4:3, the synthetic yield improved by up to 52%. The precursor complex Ln[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)$_3$] (Ln = Yb, Er, and Gd) was generated from the reaction of anhydrous $LnCl_3$ with 3 equiv. of Li[N(SiMe$_3$)$_2$] in thf. An excess of the precursor complex was treated with the porphyrin free-base under nitrogen, and the mixture was refluxed in toluene for 12 h. Excess $NaL_{OMe}$ was then added to the reaction mixture at room temperature. This procedure gave green crystals of [(tdpapp)Ln($L_{OMe}$)] [Ln = Yb (**1**), Er (**2**), Gd (**3**)] in about 80% yield. These lanthanide complexes are thermally and air-stable, and could be purified by column chromatography, which indicates that the tripodal anion is capable of stabilizing labile normal lanthanide(III) porphyrinate complexes by effectively encapsulating the lanthanide(III) ion and thereby shielding it from interactions with the environment. The transition metal porphyrinate complexes [M(tdpapp)] [M = Ni (**4**), Zn (**5**), Pd (**6**), Pt (**7**)] were synthesized by refluxing the porphyrin free-base with 1 equiv. of the metal salts in an appropriate solvent. Purification was effected by preparative thin layer chromatography (TLC) with high isolated yields of 87–96%. All of these metal monoporphyrinate complexes were characterized by accurate mass spectrometric and spectroscopic techniques. The electrospray ionization high-resolution (ESI-HR) mass spectra of **1**–**3** exhibit the $[M + 1]^+$ or $[M]^+$ peak at *m*/*z* = 1906.4548, 1899.4461, and 1890.4455, respectively, which deviate by less than 5 ppm from the theoretical values of 1906.4627, 1899.4488, and 1890.2683; their isotopic distribution patterns match the theoretical fittings very well. The $^{31}$P NMR spectra (vs. 85% $H_3PO_4$) of **1** and **2** display a single peak at $\delta$ = 68.29 and –166.01 ppm, respectively.

The solid-state structures of complexes **6** and **7** were also confirmed by X-ray crystallographic studies. Perspective drawings of **6** and **7** are displayed in Figure 1, and Table 1 lists selected bond lengths and angles. There is only half of the molecule per asymmetric unit in the unit cell in each case, and the porphyrin framework is essentially planar. The group 10 metal ion is coordinated to the four pyrrolic nitrogen atoms, as is typical of other normal metalated porphyrinates. The bond lengths and angles in the porphyrin ring are also similar to those observed in the 5,10,15,20-tetraarylporphyrin system.[25,26]

The absorption spectra of all the new complexes were also measured and, in general, show a bathochromic shift in the absorption features after adding the diphenylamino chromophores (see Exp. Sect.). For example, complexes **1**–**3** show typical Soret and Q-bands for the lanthanide monoporphyrinate complexes at about 441, 564, and 607 nm, which are redshifted by at least 10 nm compared to those of the unsubstituted lanthanide tetraphenylporphyrinate (TPP) complexes. The large red shifts of both the Soret and Q-bands indicate a decreased energy gap between the HOMO and LUMOs as a consequence of the expanded π-conjugation. This can be attributed to the strong electron-donating ability of the DPA substituents, which produces a profound perturbation of the ground-state properties of the porphyrin TPP.



Scheme 1. Synthesis of lanthanide and transition metal monoporphyrinate complexes: (a) Ln[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)], reflux in toluene, then $NaL_{OMe}$; (b) M(OAc)$_2$, $CHCl_3$/MeOH (M = Ni, Zn, Pd); (c) [$PtCl_2$(PhCN)$_2$], reflux in PhCN.

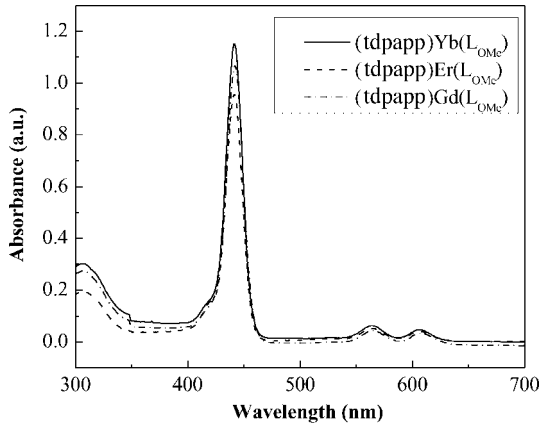
## Optical-Limiting Properties of Lanthanide Monoporphyrinate Complexes

All the samples are stable toward air and laser light under our experimental conditions. In order to characterize the OPL properties at 532 nm excitation, the materials should show weak ground-state absorption at this wavelength. The UV/Vis spectra of the complexes in toluene at room temperature are shown in Figure 2; there is clearly a transparent window at 532 nm for the lanthanide monoporphyrinate complexes.



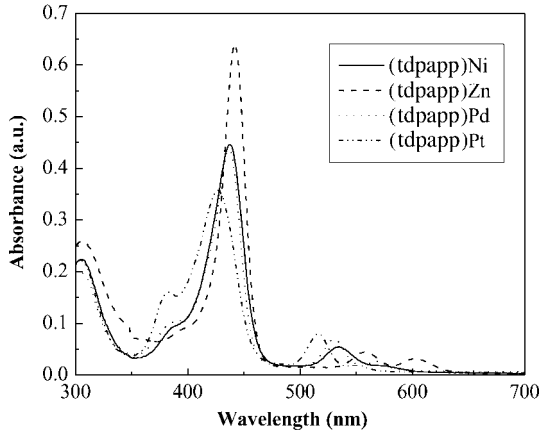


Figure 2. UV/Vis linear-absorption spectra of all the complexes in dilute toluene solution at room temperature.

According to the *Z*-scan curves for all the complexes measured in $CH_2Cl_2$ (Figure 3), the three lanthanide monoporphyrinate complexes show excellent OPL behavior relative to the benchmark material $C_{60}$, while the effect is only moderate for the transition metal complexes. Experiments with $CH_2Cl_2$ alone showed no detectable OPL effect, which indicates that there is a negligible contribution of solvent. When each sample is far from the focus ($Z/Z_0 = 0$) and the incident irradiance upon it is weak, the transmittance of the sample remains almost constant and shows a linear behavior (obeying Beer's law). When the sample is close to the focus, however, and the incident irradiance is strong, the transmittance of the sample decreases rapidly and an OPL

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

effect appears. It is clear that complex **2** shows the strongest optical-limiting capability, superior even to that of $C_{60}$, which is generally regarded as an excellent optical limiter. Complexes **1** and **3** also exhibit good OPL properties similar to those of $C_{60}$. As anticipated, compound **4** with the lighter nickel ion only showed a relatively weaker OPL response among **4**–**7**. On the other hand, we observe that incorporation of DPA units to the porphyrin ring leads to enhanced OPL responses (Figure 4), indicative of strong electronic interaction between the porphyrin and DPA moieties in the present system.

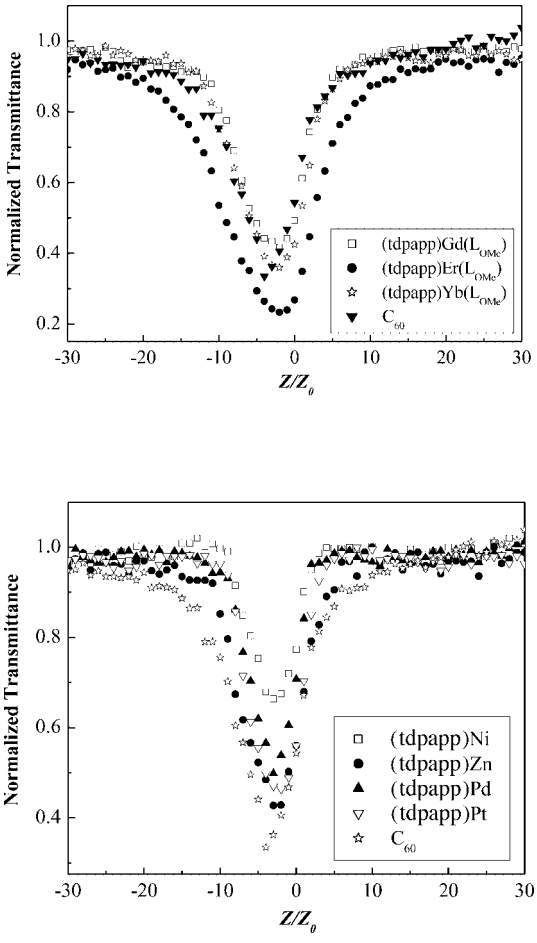

Figure 3. Open-aperture *Z*-scan results for the metal monoporphyrinate complexes and $C_{60}$ solutions at $T_o$ = 82%.

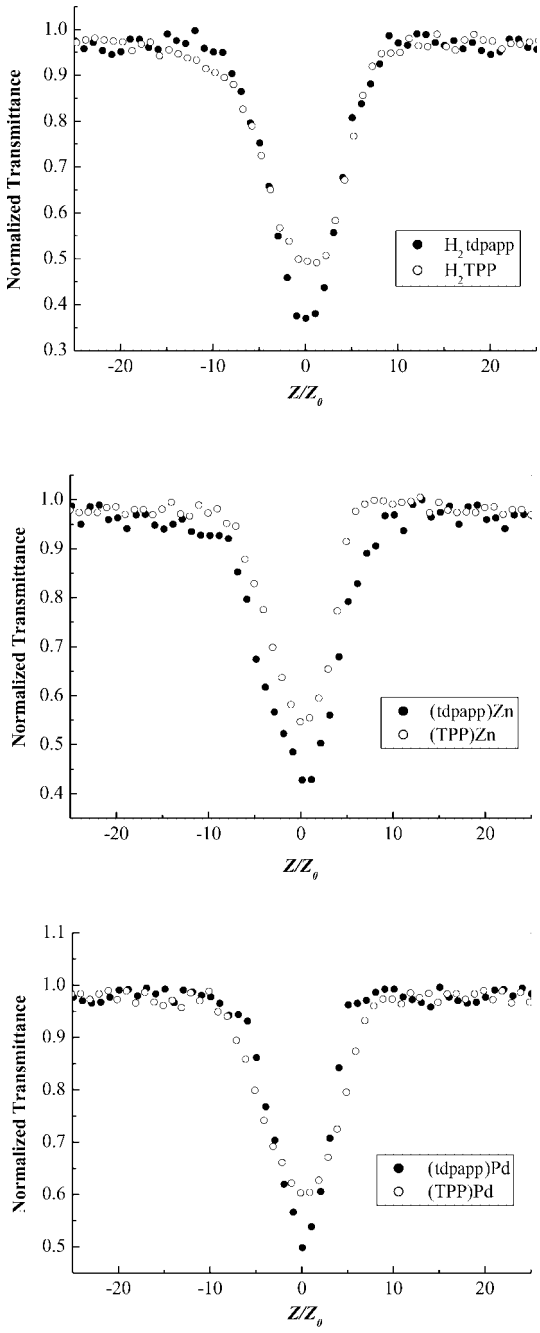

Figure 4. The effect of diphenylamino groups on the open-aperture *Z*-scan results for the free porphyrin and its metal complexes at $T_o$ = 82%.

In order to explain the *Z*-scan data obtained, we must consider the optical-limiting mechanism. According to the five-level model for the RSA mechanism (see Figure 5),[27] the molecules in the ground state ($S_0$) initially absorb optical energy and are excited to the first singlet state ($S_1$). After the $S_1$ state reaches a certain population, it can absorb optical energy strongly and leap to a higher singlet state ($S_n$), where it can induce an optical-limiting effect or undergo intersystem crossing (ISC) to the first triplet state ($T_1$). This can then also absorb optical energy strongly to reach a higher triplet state ($T_n$), which leads to optical-limiting action. Owing to the short lifetime (<10 ns) of the singlet state (see Table 2), it is the triplet-state absorption that contributes to the nanosecond optical-limiting process.[15b,27] To support this, the photoluminescence (PL) spectra for the singlet and triplet states of all complexes were measured (see Figures 6, 7, 8, and 9). At 77 K, the PL spectrum for **3** shows an obvious triplet emission at 815 nm with a measured triplet lifetime of 109 ms. The singlet-state lifetime for **3** is 3.23 ns. Since the pulse lengths are shorter than the lifetime of the triplet state, it acts as an accumulation site. This could confirm that the OPL effect of **3** is mainly induced by the triplet-state absorption. While a more complicated discussion may be invoked for the other

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

two lanthanide porphyrinate complexes, there is no apparent triplet emission for **1** and **2**, even at 77 K (Figure 6a and b), which suggests that the OPL effects of the Er and Yb complexes are not induced by the triplet-state absorption of the ligands. It is well known that there are efficient energy-transfer processes from the triplet state of the porphyrinate ligand to the excited states of the central lanthanide ions, thus enabling the ion to emit light. The energy absorption that accompanies the transition processes from the lower excited states of the lanthanide ion to the higher energy ones will therefore contribute to the OPL effect of the lanthanide complexes. Owing to the presence of its multiple excited states, the porphyrinate ligand will provide more possible energy absorption transitions in **2** than its Yb counterpart **1**. Complex **2** therefore shows a much better optical-limiting performance than **1**. It can be concluded that the OPL effects of **1** and **2** are predominantly caused by the excited state absorption of the central lanthanide ion. As trivalent lanthanide ions, $Yb^{3+}$ and $Er^{3+}$ should show strong near-infrared (NIR) emission bands.[21a,28] To support this, the NIR PL spectra of **1** and **2** (Figure 7) were measured. Our previous PL studies on related lanthanide porphyrinate complexes have shown that the excitation of $Yb^{3+}$ is due to the $\pi \rightarrow \pi^*$ transitions of the porphyrinate antenna, and that the porphyrinate antenna transfers its absorbed visible energy of the Q-bands to the excited state of the lanthanide ion, which then relaxes through emission in the NIR region.[21a,28b] A strong emission due to the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition is observed at 995 nm for the $Yb^{3+}$ complex **1**, whereas for the $Er^{3+}$ complex **2**, the emission at 1529 nm can be assigned to the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition. The NIR lifetime of **1** in toluene at room temperature is 30 μs, which also confirms that the excited state of the $Yb^{3+}$ ion should play a major role in the OPL effect of **1**. However, we were unable to measure the NIR lifetime of **2** due to the limitations of the instrument. Unlike **1** and **2**, the OPL effect of **3** should be due to the triplet state of the ligand which can be corroborated by the observation of an obvious triplet emission at 77 K (Figure 6c). Furthermore, the absence of an NIR emission for the $Gd^{3+}$ ion will also preclude the involvement of the excited state of the central Gd ion in the OPL phenomenon. In other words, the OPL effect of **3** is likely dominated by the triplet excited state absorption of the ligand. In view of these factors, complex **3** can be anticipated to show an inferior OPL effect than the free ligand.

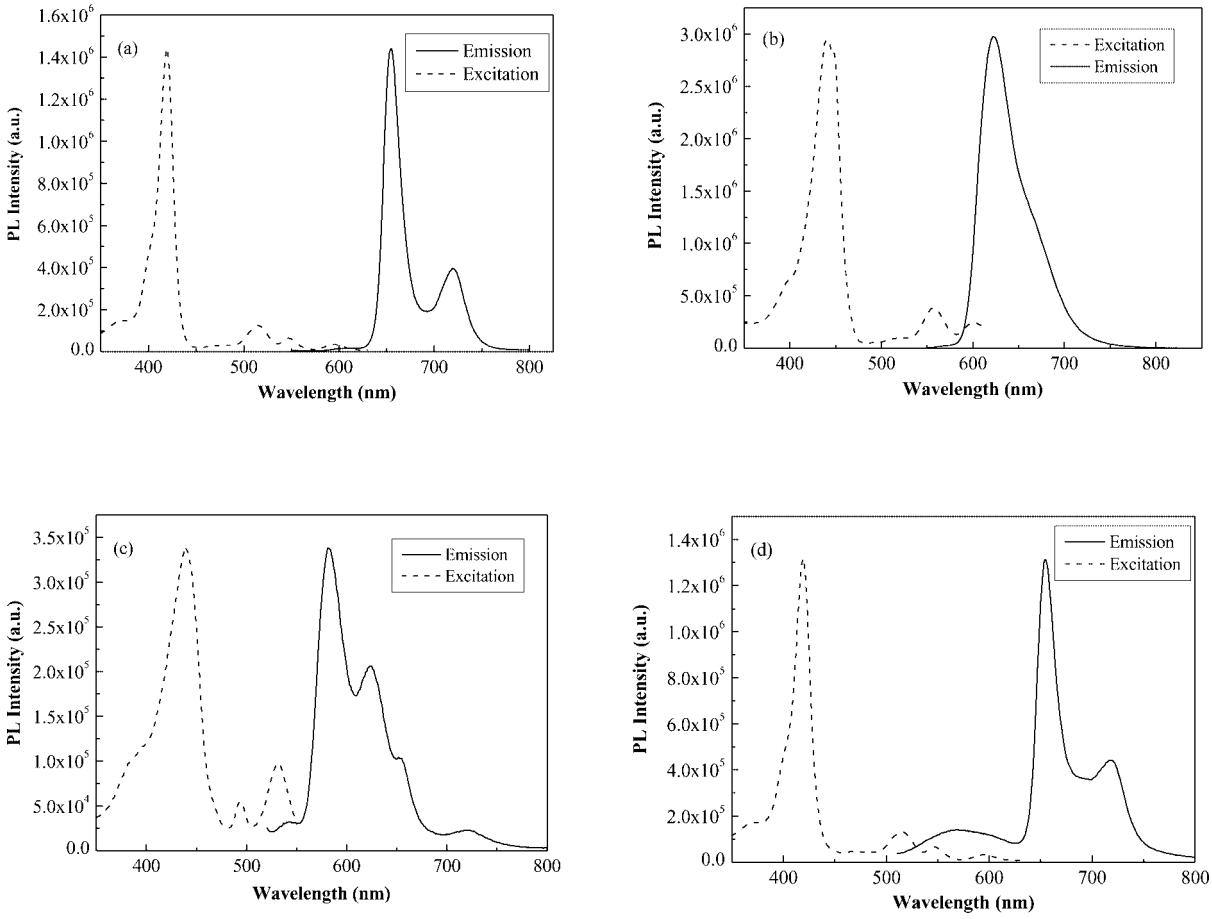

Figure 8. PL spectra for **4** (a), **5** (b), **6** (c), and **7** (d) at 298 K in toluene.

scribed by the typical RSA mechanism (Figure 5) and is typical of other known transition metal porphyrins reported in the literature. The PL spectra of **4**–**7** in toluene at 298 and 77 K are depicted in Figures 8 and 9, respectively. Owing to the much stronger triplet emission at 77 K for **6** ($\lambda_{em}$ = 723 nm) and **7** ($\lambda_{em}$ = 689 nm) and their long lifetimes (890 and 80 μs, respectively), both of them show a stronger OPL effect than **4** according to the RSA mechanism stated above. As complex **4** contains the light Ni ion, it is not phosphorescent even at 77 K. The observation of a reasonably strong OPL response for **5**, which also shows no triplet emission at 77 K but only a singlet emission at 630 nm with a lifetime of 7.78 ns at 77 K, can be ascribed to its higher transparency at 532 nm compared with that of other three transition metal complexes (as revealed clearly from the UV/Vis spectra shown in Figure 2). In view of its better transparency, the Zn complex **5** should possess a higher concentration than the others when the OPL signal is measured at the same linear transmittance. As there should be more molecules contributing to its OPL effect,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

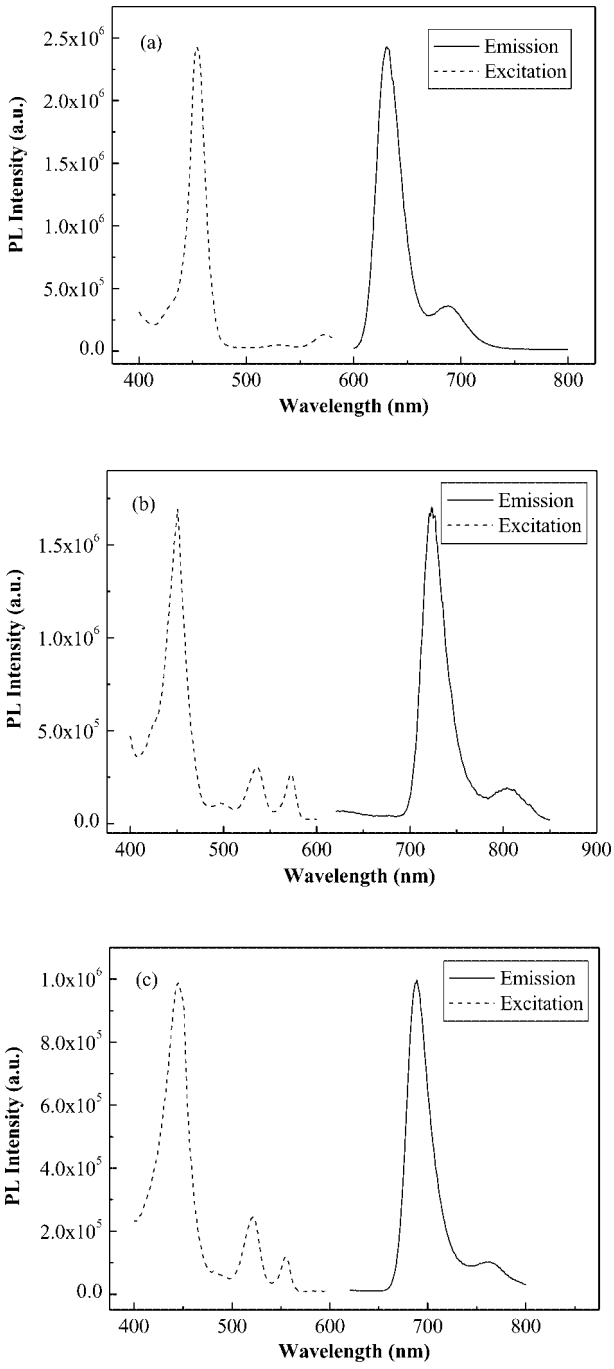

Figure 9. PL spectra for **5** (a), **6** (b), and **7** (c) at 77 K in toluene.

this will compensate for the loss in contribution due to the triplet-state absorption. Hence, despite its low triplet yield, complex **5** can still show an OPL close to those of **6** and **7**.

Figure 10 shows a simple, widely accepted photophysical model of the sensitization process in some (Por)Ln($L_{OMe}$)-type compounds (Por = porphyrinate anion).[28c,28d,29] In this process, the porphyrin absorbs light and is excited to its singlet state ($S_1$). The energy is then transferred to its triplet state ($T_1$), which is, in part, transferred to the excited state of the lanthanide ion ($Ln^{3+}$)* to produce the final luminescence. The $Er^{3+}$ ion is clearly able to introduce more low-lying states in the HOMO–LUMO gap to perturb the ring π-electron system,[16f] which might explain why **2** has the strongest optical-limiting yield of the three lanthanide monoporphyrinate complexes.

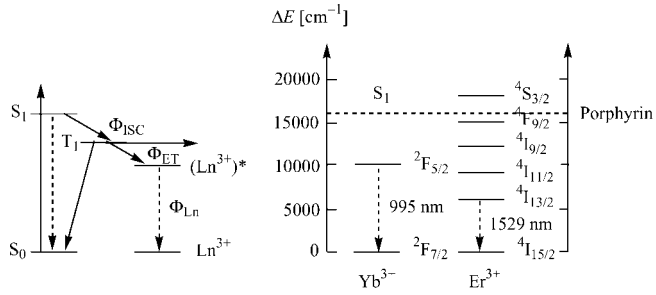

Figure 10. Schematic energy diagram of (Por)Ln($L_{OMe}$) complexes. The arrows indicate the excitation mechanism of lanthanide ions by the porphyrin sensitizer ($S_0 \rightarrow S_1$ transition followed by intersystem crossing and energy transfer).

Table 3 lists the optical-limiting thresholds of the three lanthanide monoporphyrinate complexes, which is an important parameter in characterizing the merit of these optical limiters. All three complexes possess low optical-limiting thresholds at 82% linear transmittance. Complex **2** shows a lower optical-limiting threshold than fullerene $C_{60}$ that is even comparable to those of some state-of-the-art phthalocyanine dyes. The optical-limiting thresholds of the transition metal analogues **4**–**7** are, however, less attractive than the lanthanide congeners. Hence, the OPL effects of the functionalized porphyrin $H_2$tdpapp can be enhanced greatly by the incorporation of trivalent lanthanide ions.

## Concluding Remarks

We have reported a series of new lanthanide monoporphyrinate complexes that exhibit excellent optical-limiting capabilities for a nanosecond laser pulse at 532 nm and display optical-limiting thresholds comparable to or lower than those reported for optical-limiting materials currently in use. Experimental investigations on their photophysics suggest that these complexes show optical-limiting effects following the standard five-level RSA mechanism. The optical-limiting effects of porphyrins can be enhanced greatly by the addition of electron-rich $Ph_2N$ groups and the incorporation of lanthanide ions, which can make the energy of the porphyrin triplet state transfer efficiently to the excited state of the lanthanide ions. We have shown that the three monoporphyrinate lanthanide complexes have an excellent optical-limiting performance and are very promising candidates for practical use as optical-limiting materials for the protection of optical devices. Solid films are desirable for many optical power-limiting applications, therefore further work will be carried out to determine the response of polymer films to an optical pulse for use in practical devices.

[a] $\sigma_{ex}/\sigma_o = \ln T_{sat}/\ln T_o$, where $\sigma_{ex}$ is the effective excited-state absorption cross-section, $\sigma_o$ is the ground-state absorption cross-section, and $T_{sat}$ is the transmittance at the saturation fluence. [b] The optical-limiting threshold is defined as the input light fluence at which the output light fluence is 50% of that predicted by linear transmittance. [c] Linear transmittance. [d] Not reported. [e] R = pentyloxy. [f] Predicted by theoretical fitting.

## Experimental Section

**General:** All reactions were carried out under dry nitrogen. Solvents were dried by standard procedures, distilled, and degassed prior to use. All chemicals used were purchased from Aldrich or Acros. 4-(Diphenylamino)benzaldehyde was prepared according to a literature method by formylation of triphenylamine with dmf and $POCl_3$.[34] 5,10,15,20-Tetrakis[*p*-(diphenylamino)phenyl]-21*H*,23*H*-porphine ($H_2$tdpapp) was also prepared according to a literature method by condensing pyrrole and 4-(diphenylamino)benzaldehyde.[24] NMR spectra were measured in $CDCl_3$ with a JEOL EX270 or a Varian Inova 400 MHz FT-NMR spectrometer, with the $^1$H NMR chemical shifts quoted relative to $SiMe_4$ and the $^{31}$P NMR chemical shifts relative to 85% $H_3PO_4$ as external standard. Electrospray ionization high-resolution mass spectra were recorded with a QSTAR mass spectrometer. The electronic absorption spectra in the UV/Vis region were obtained with a Hewlett Packard 8453 spectrophotometer. The photoluminescent properties and lifetimes of the complexes were determined with a Photon Technology International (PTI) spectrophotometer. NIR emission was detected by a liquid-nitrogen-cooled InSb IR detector (EG & G) with a preamplifier, and recorded by a lock-in amplifier system. The third harmonic of the 355-nm line of an Nd:YAG laser (Quantel Brilliant B) was used as the excitation light source. Infrared spectra were obtained with a Nicolet Magna 550 series II FTIR spectrometer in KBr pellets.

**Optical-Limiting Measurements:** To study the optical-limiting properties, intensity-dependent transmittance and *Z*-scan measurements were performed with a Q-switched Nd:YAG laser at a repetition rate of 10 Hz. The laser frequency was doubled with an output wavelength of 532 nm and a 10-ns pulse width for the Gaussian mode by a frequency double crystal. The laser beam was then split into two by a beam splitter. One was used as the reference beam, which was received by a detector ($D_1$), and the other was used for the sample measurement, and was focused with a lens ($f$ = 20 cm). After transmitting through the sample, the light beam entered another detector ($D_2$). The sample to be measured was moved along a rail to change the incident irradiance on it. The incident and transmitted energies were detected simultaneously by the two detectors $D_1$ and $D_2$ (LPE-1A). The performance of each sample was measured as an 82% transmitting solution at 532 nm in $CH_2Cl_2$ in a 1-mm quartz cell.

**Preparation of Precursor Complexes:** Stock solutions of the precursor complexes, Ln[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)$_3$] (Ln = Yb$^{3+}$, Er$^{3+}$ and Gd$^{3+}$), were prepared in a similar manner. A detailed description is given for the Yb$^{3+}$ complex.

**Yb[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)$_3$] (Solution A):** HN(SiMe$_3$)$_2$ (5.06 mL, 0.024 mol) was dissolved in thf (10 mL) in an ice bath, then *n*BuLi (1.6 M in hexane; 15.0 mL, 0.024 mol) was added slowly over a period of 30 min. The resulting solution was magnetically stirred for 12 h until a clear pale yellow solution was obtained. The solution was then transferred slowly into a Schlenk flask containing $YbCl_3$ (2.24 g, 0.008 mol) suspended in thf (20 mL). The resulting mixture was magnetically stirred for 24 h until all of the solid $YbCl_3$ had disappeared. The resulting solution A contains Yb[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)] (*x* = 3–5).

**Er[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)$_3$] (Solution B):** Er[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)$_3$] was prepared by the same method as for solution A except that HN(SiMe$_3$)$_2$ (5.06 mL, 0.024 mol), *n*BuLi (1.6 M in hexane; 15.0 mL, 0.024 mol), and $ErCl_3$ (2.18 g, 0.008 mol) in thf were used.

**Gd[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)$_3$] (Solution C):** Gd[N(SiMe$_3$)$_2$]$_3$·*x*[LiCl(thf)$_3$] was prepared similarly as for solution A except that HN(SiMe$_3$)$_2$ (5.06 mL, 0.024 mol), *n*BuLi (1.6 M in hexane; 15.0 mL, 0.024 mol), and $GdCl_3$ (2.11 g, 0.008 mol) in thf were used.

**Synthesis of Complexes 1–3:** Compounds **1**–**3** were prepared according to the same procedure. A typical procedure is given for **1**. We used the tripodal anion $L_{OMe}^-$ {$L_{OMe}^-$ = ($\eta^5$-$C_5H_5$)Co[P(=O)(OMe)$_2$]$_3^-$} to stabilize labile normal lanthanide(III) porphyrinate complexes.

**[(tdpapp)Yb($L_{OMe}$)] (1):** Solution A (2.0 mL, 0.32 mmol) was transferred into a Schlenk flask and the solvent was removed under vacuum. Dichloromethane (10 mL) was then added to precipitate LiCl. The mixture was centrifuged and the clear layer was transferred to another Schlenk flask containing dry $H_2$tdpapp (50 mg, 0.039 mmol) dissolved in toluene (15 mL). The progress of the reaction was monitored by UV/Vis spectroscopy. The resulting solution was refluxed for 12 h until most of the free base had coordinated to the metal ion. Upon cooling of the reaction mixture to room temperature, solid $NaL_{OMe}$ (0.1 g, 0.22 mmol) was added and the resultant solution was magnetically stirred for another 24 h. The

solvent was removed in vacuo, and the residue was dissolved in chloroform, filtered, and chromatographed on silica gel using chloroform/petroleum ether (1:1, v/v) as the eluent. Complex **1** was obtained in 75% yield (56 mg). IR (KBr): $\tilde{\nu}$ = 3445 m, 2940 m, 1591 s, 1490 s, 1276 m, 1143 s, 1006 m, 752 m, 696 m cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 16.39 (s, 4 H, Ar), 15.57 (s, 8 H, β-H), 10.30 (s, 4 H, Ar), 8.58–8.56 (m, 24 H, Ar), 8.11–8.07 (m, 16 H, Ar), 7.63–7.61 (m, 8 H, Ar), 6.44 (s, 18 H, OMe), –4.71 (s, 5 H, $\eta^5$-$C_5H_5$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 68.29 (s) ppm. UV/Vis (toluene, 20 °C): $\lambda_{max}$ (log$\varepsilon$) = 307 (5.18), 441 (5.76), 564 (4.50), 607 (4.38 M$^{-1}$cm$^{-1}$) nm. ESI-HRMS ($CHCl_3$): *m*/*z* = 1906.4548 [M + H]$^+$.

**[(tdpapp)Er($L_{OMe}$)] (2):** Solution B (2.0 mL, 0.32 mmol), $H_2$tdpapp (100 mg, 0.078 mmol), and $NaL_{OMe}$ (0.1 g, 0.22 mmol) were used. Yield: 81% (120 mg). IR (KBr): $\tilde{\nu}$ = 3445 m, 2940 m, 1591 s, 1490 s, 1277 s, 1141 s, 1006 s, 796 m, 752 m, 696 m cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 45.59 (s, 4 H, Ar), 35.09 (s, 8 H, β-H), 20.64–19.99 (m, 24 H, Ar), 12.56 (s, 18 H, OMe), 12.14 (s, 4 H, Ar), 10.39 (s, 16H, Ar), 9.43 (s, 8 H, Ar), –34.16 (s, 5 H, $\eta^5$-$C_5H_5$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = –166.01 (s) ppm. UV/Vis (toluene, 20 °C): $\lambda_{max}$ (log$\varepsilon$) = 307 (4.99), 441 (5.68), 564 (4.41), 606 (4.31 M$^{-1}$cm$^{-1}$) nm. ESI-HRMS ($CHCl_3$): *m*/*z* = 1899.4461 [M]$^+$.

**[(tdpapp)Gd($L_{OMe}$)] (3):** Solution C (2.0 mL, 0.32 mmol), $H_2$tdpapp (100 mg, 0.078 mmol), and $NaL_{OMe}$ (0.1 g, 0.22 mmol) were used. Yield: 76% (112 mg). IR (KBr): $\tilde{\nu}$ = 3449 m, 2940 m, 1591 s, 1491 s, 1277 m, 1137 s, 1006 m, 752 m, 696 m cm$^{-1}$. UV/Vis (toluene, 20 °C): $\lambda_{max}$ (log$\varepsilon$) = 307 (5.14), 442 (5.73), 566 (4.35), 608 (4.24 M$^{-1}$cm$^{-1}$) nm. ESI-HRMS ($CHCl_3$): *m*/*z* = 1890.4455 [M + H]$^+$.

**Synthesis of Complexes 4–7:** Transition metal porphyrinate complexes **4**–**7** were prepared by refluxing the porphyrin free-base with 1 equiv. of the metal salts in an appropriate solvent. The typical procedure is described in detail for **4**.

**[Ni(tdpapp)] (4):** $Ni(OAc)_2$·$4H_2O$ (100 mg, 0.4 mmol) dissolved in MeOH (8 mL) was added to a solution of $H_2$tdpapp (50 mg, 0.039 mmol) in $CHCl_3$ (30 mL). The mixture was then refluxed until the reaction was complete, as revealed by TLC. The product was purified on silica gel using chloroform/petroleum ether (2:1, v/v) as the eluent. The title product was obtained in 92% yield (48 mg). IR (KBr): $\tilde{\nu}$ = 3444 m, 3029 w, 1591 s, 1491 s, 1280 s, 1177 w, 1002 m, 800 m, 753 m, 695 m cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 8.81 (s, 8 H, β-H), 7.78 (d, *J* = 8.4 Hz, 8 H, Ar), 7.34–7.28 (m, 40 H, Ar), 7.06–7.01 (m, 8 H, Ar) ppm. UV/Vis (toluene, 20 °C): $\lambda_{max}$ (log$\varepsilon$) = 304 (5.05), 437 (5.35), 534 (4.44 M$^{-1}$cm$^{-1}$) nm. ESI-HRMS ($CHCl_3$): *m*/*z* = 1339.4674 [M]$^+$.

**[Zn(tdpapp)] (5):** $H_2$tdpapp (50 mg, 0.039 mmol) and $Zn(OAc)_2$·$2H_2O$ (50 mg, 0.23 mmol) were used. Yield: 96% (50 mg). IR (KBr): $\tilde{\nu}$ = 3446 m, 3027 w, 1590 s, 1489 s, 1279 s, 1176 w, 999 m, 798 m, 753 m, 695 m cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 9.03 (s, 8 H, β-H), 8.01 (d, *J* = 8.4 Hz, 8 H, Ar), 7.40–7.33 (m, 40 H, Ar), 7.07–7.04 (m, 8 H, Ar) ppm. UV/Vis (toluene, 20 °C): $\lambda_{max}$ (log$\varepsilon$) = 306 (5.11), 442 (5.51), 558 (4.35), 603 (4.20 M$^{-1}$cm$^{-1}$) nm. ESI-HRMS ($CHCl_3$): *m*/*z* = 1346.4536 [M]$^+$.

**[Pd(tdpapp)] (6):** $H_2$tdpapp (50 mg, 0.039 mmol) and $Pd(OAc)_2$ (50 mg, 0.22 mmol) were used. Yield: 89% (48 mg). IR (KBr): $\tilde{\nu}$ = 3443 m, 3029 w, 1591 s, 1491 s, 1278 s, 1175 w, 1014 m, 805 w, 751 m, 695 m cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 8.90 (s, 8 H, β-H), 7.96 (d, *J* = 8.4 Hz, 8 H, Ar), 7.39–7.33 (m, 40 H, Ar), 7.09–7.07 (m, 8 H, Ar) ppm. UV/Vis (toluene, 20 °C): $\lambda_{max}$ (log$\varepsilon$) = 307 (4.99), 437 (5.34), 530 (4.54), 569 (4.13 M$^{-1}$cm$^{-1}$) nm. ESI-HRMS ($CHCl_3$): *m*/*z* = 1386.4327 [M]$^+$.

**[Pt(tdpapp)] (7):** A solution of $H_2$tdpapp (100 mg, 0.078 mmol) and $PtCl_2(PhCN)_2$ (74 mg, 0.156 mmol) in benzonitrile (10 mL) was heated at reflux to afford **7** in 87% yield (100 mg).[35] IR (KBr): $\tilde{\nu}$ = 3444 m, 3029 w, 1591 s, 1491 s, 1281 s, 1177 w, 1021 m, 803 w, 753 m, 695 m cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 8.85 (s, 8 H, β-H), 7.93 (d, *J* = 8.1 Hz, 8 H, Ar), 7.38–7.33 (m, 40 H, Ar), 7.08–7.06 (m, 8 H, Ar) ppm. UV/Vis (toluene, 20 °C): $\lambda_{max}$ (log$\varepsilon$) = 305 (5.16), 428 (5.25), 516 (4.58), 551 (3.94 M$^{-1}$cm$^{-1}$) nm. ESI-HRMS ($CHCl_3$): *m*/*z* = 1476.4990 [M]$^+$.

**X-ray Crystallography:** Crystals of **6**·$2CHCl_3$ and **7**·$2CHCl_3$ suitable for X-ray diffraction were grown by slow concentration of chloroform solutions of these compounds in air. Because of severe solvent loss, the selected crystals were mounted in sealed capillary tubes for diffraction experiments. The intensity data were collected at 293 K with a Bruker AXS SMART 1000 CCD area-detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The collected frames were processed with proprietary software (SAINT[36]) and an absorption correction was applied (SADABS[37]) to the collected reflections. The structures of these molecules were solved by direct methods and expanded by standard difference Fourier syntheses using the software SHELXTL.[38] Structure refinements were made on $F^2$ using the full-matrix least-squares technique. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were placed in their idealized positions and allowed to ride on the respective carbon atoms. Pertinent crystallographic data and other experimental details are summarized in Table 4. CCDC-628463 (**6**) and -628464 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Conformational Analysis of Heteroannularly Substituted Ferrocene Oligoamides

Jasmina Lapić,[a] Daniel Siebler,[b] Katja Heinze,*[b] and Vladimir Rapić*[a]

**Keywords:** Conformation analysis / Density functional calculations / Hydrogen bonds / Metallocenes / Molecular modelling

The main conformer of symmetrical conjugates of ferrocene-1,1′-dicarboxylic acid with natural amino acids – Fn(CO–$AA_{1–2}$–$OMe)_2$ (type I, Fn = ferrocene-1,1′-diyl, AA = L-α-amino acid) – is supported by two hydrogen bonds between the peptide substituents. To compare intramolecular hydrogen bond patterns of type I conjugates with related asymmetrically substituted derivatives, type II (MeNHCO–Fn–CO–AA–OMe) and type III conjugates (MeNHCO–Fn–CO–AA–NHMe) were prepared in moderate-to-good yields in a few steps starting from 1′-(methoxycarbonyl)ferrocene-1-carboxylic acid by using the HOBt/EDC method (AA = Gly, Ala, Val). $^1$H NMR spectroscopic variation ratio analysis suggests that an increase in the steric demand of the amino acid side chains favours conformations with hydrogen-bonded FnCO*NH*Me groups. CD spectroscopy of chiral derivatives reveals that (*P*)-helical conformations predominate in solution. The experimental findings are in accordance with DFT calculations.

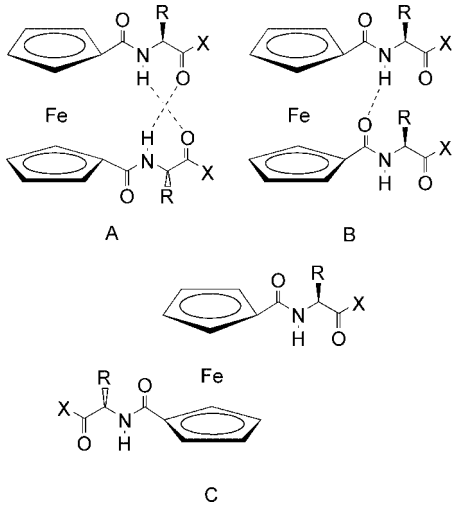
## Introduction

Symmetrically substituted bioconjugates of ferrocene-1,1′-dicarboxylic acid − Fn(CO–$AA_n$–$OMe)_2$ (Fn = ferrocene-1,1′-diyl, AA = L-α-amino acid, $n$ = 1–2) (type I conjugates) − have been extensively studied, especially with the focus on applications as turn mimetica. Depending on the amino acid employed, these molecules adopt different conformations, A, B or C in the solid state, as well as in solution (Scheme 1).

In the solid state, the majority of type I conjugates form two intramolecular hydrogen bonds, which results in two 10-membered rings (conformation A, β-turn, "Herrick conformation"). If these intramolecular hydrogen bonds are sufficiently strong, conformation A is even retained in chloroform solution.[1–11] The bis(phenylalanine) derivative Fn(CO–Phe–$OMe)_2$ crystallises in asymmetrical form B characterised by a single seven-membered intramolecular hydrogen-bonded ring (γ-turn, "van Staveren conformation"), whereas conformation A presumably predominates in solution.[12] The derivatives Fn(CO–AA–$OMe)_2$ (AA = Pro, Cys(Bzl), Val) provide examples of open "Xu conformations" C in the solid state.[13–16] However, conformations found in the solid state can be substantially different from solution conformations as intermolecular hydrogen bonds are usually additionally present in the solid state. Therefore, with respect to chemical reactivity, the conformations adopted in solution are of importance. A systematic description of the structural motifs and a suitable nomenclature of 1,1′-disubstituted ferrocenes has been recently put forward.[17]



Scheme 1. Intramolecular hydrogen bond patterns in symmetrical ferrocene peptides (type I) [X = OMe, L–AA–OMe].

Having in mind the conformational characteristics of type I conjugates, we aimed to investigate the hydrogen bonding patterns of related asymmetrically substituted derivatives of ferrocene-1,1′-dicarboxylic acid belonging to

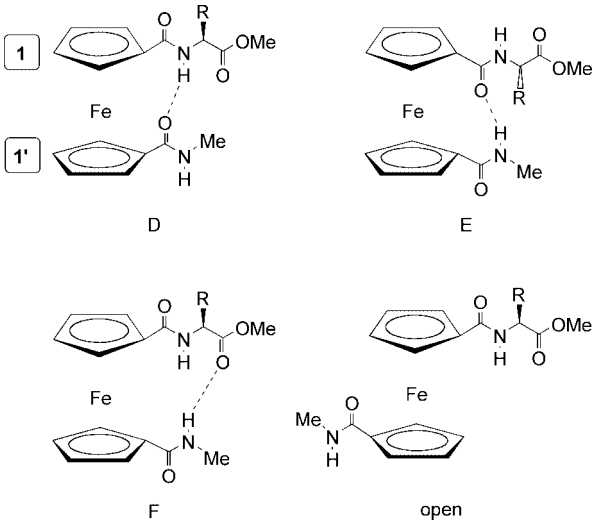
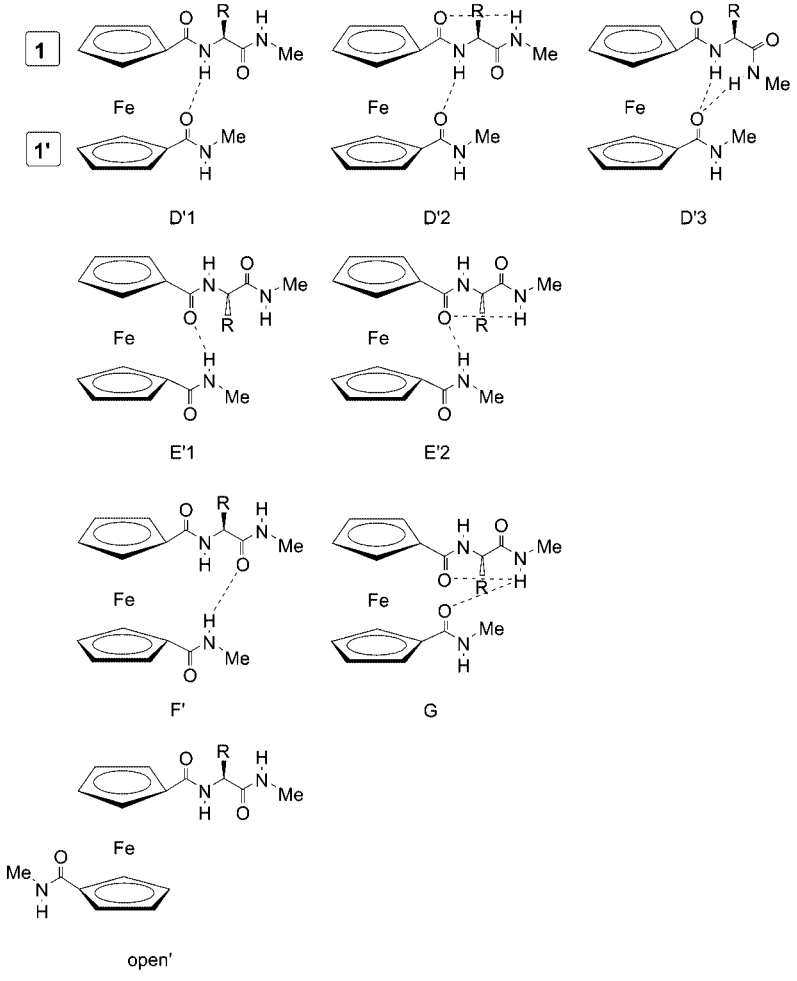
type II (MeNHCO–Fn–CO–AA–OMe) and type III (MeNHCO–Fn–CO–AA–NHMe) (AA = Gly, L-Ala, L-Val) to understand individual conformational preferences in solution with respect to the amino acid employed (i.e. the size of their side chains). Here we describe the conformational analyses based on a combined experimental (NMR, IR and CD spectroscopy) and theoretical approach (DFT calculations).

## Results and Discussion

Scheme 2 depicts three possible hydrogen bonded conformations, D, E and F, with (*P*)-helical stereochemistry at the ferrocene as well as an open form of type II conjugates. The corresponding (*M*)-helical diastereomeric conformations can be derived from the mirror images and by changing the resulting D-configuration of the amino acid to L. Descriptor "1-" denotes the amino acid containing the substituent and descriptor "1′-" denotes the CONHMe part of the compounds. Conformations D and E can be described by seven-membered "van Staveren"-like intramolecular hydrogen bonds (Scheme 1, B), whereas form F is stabilised by a 10-membered intramolecular hydrogen bonded ring, which can be considered as half of a "Herrick's" motive (Scheme 1, A). These patterns represent γ- and β-turn structures, and it is expected that their relative population depends on the



Scheme 2. Possible intramolecular hydrogen bond patterns in diamide esters (type II).



Scheme 3. Possible intramolecular hydrogen bond patterns in triamides (type III).

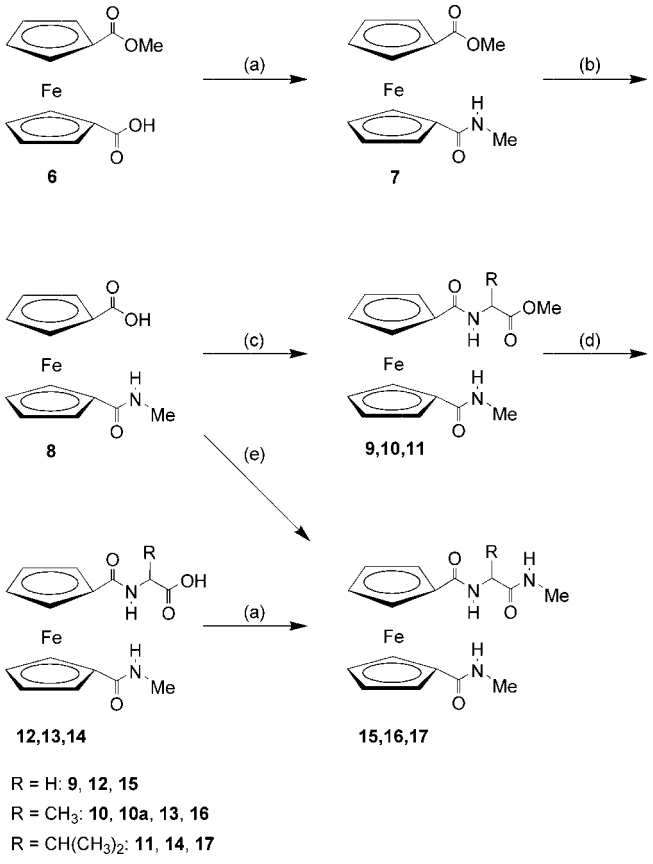
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

steric demand of the amino acid side chain (R). Conformation E was recently observed in the solid state and in a $CDCl_3$ solution of 1′-(butylcarbamoyl)-*N*-morpholinoferrocene-1-carboxamide.[18]

Intramolecular hydrogen bonding patterns possible in type III conjugates are shown in Scheme 3. Three conformations are analogous to forms D, E and F of amide esters and for clarity, they are denoted as D′, E′ and F′. However, owing to the additional 1-NHMe group, a further hydrogen bond between 1-NHMe and 1-CO in D′2, E′2 and F′ or between 1-NHMe and 1′-CO in D′3 is possible. In theoretically possible conformation G, a 10-membered hydrogen bonded ring between 1′-CO and 1-NHMe occurs together with an intrachain hydrogen bond between 1-NHMe and 1-CO. Thus, the conformational space of type III conjugates is considerably expanded relative to type II conjugates.

## Synthesis of Type II and Type III Conjugates

The syntheses of diamide esters **9**–**11** and triamides **15**–**17** are depicted in Scheme 4. The starting compound, 1′-(methoxycarbonyl)ferocene-1-carboxylic acid (**6**), was prepared according to a previously described procedure.[30] Activation of acid **6** with HOBt/EDC (HOBt = 1-hydroxybenzotriazole, EDC = *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride) in $CH_2Cl_2$ solution, followed by treatment with $NH_2Me$ (obtained from $NH_2Me{\cdot}HCl$ and $NEt_3$) gave 45% of methyl 1′-(methylcarbamoyl)ferrocene-1-carboxylate (**7**). Amide ester **7** was hydrolysed with $NaOH/H_2O$ in MeOH to give 1′-(methylcarbamoyl)ferrocene-1-carboxylic acid (**8**) (97% yield). Acid **8** was activated by HOBt/EDC and coupled with Gly–OMe, L-Ala–OMe, D-Ala–OMe and L-Val–OMe (obtained from AA–OMe·HCl by treatment with $NEt_3$), which resulted in the formation of diamide esters **9** (42%), **10** (60%), **10a** (54%) and **11** (46%), respectively. Hydrolysis of diamide esters **9**–**11** gave MeNHCO–Fn–CO–AA–OH in good yields [**12** (94%), **13** (81%) and **14** (94%)] which were subsequently transformed into triamides **15** (24%) **16** (56%) and **17** (20%), respectively, in a manner analogous to that described for the preparation of **7**. Unexpectedly, compounds **16** and **17** thus obtained had racemized during hydrolysis as they displayed only a negligible Cotton effect (in contrast to **10** and **11**, Table 6). Therefore, **8** was directly coupled with AA–NHMe (AA = Gly, L-Ala, L-Val) to give triamide **15** (45%), as well as optically pure triamides **16** (45%) and **17** (34%).



Scheme 4. Synthesis of $Fn(COOH)_2$-derived oligoamides. a) 1. HOBt/EDC, $CH_2Cl_2$, 2. $NH_2Me{\cdot}HCl$, $NEt_3$, $CH_2Cl_2$; b) $NaOH/H_2O$, MeOH; c) 1. HOBt/EDC, $CH_2Cl_2$, 2. L-AA–OMe·HCl, $NEt_3$, $CH_2Cl_2$; d) $NaOH/H_2O$, dioxane; e) 1. HOBt/EDC, $CH_2Cl_2$, 2. L-AA–NHMe·HCl, $NEt_3$, $CH_2Cl_2$.

## Spectroscopy of Type II and Type III Conjugates

Intramolecular hydrogen bonds found in the solid state often undergo cleavage even in weakly coordinating solvents (e.g. chloroform, dichloromethane) with competitive formation of hydrogen-bond-free states and species with hydrogen bonded rings of different sizes. The conformational equilibria are usually fast on the NMR timescale, which results in time-averaged and population-weighted chemical shifts, but in some cases, barriers are high enough to allow the detection of individual conformers or conformer groups.[19] On the faster IR timescale, however, absorptions for NH and CO stretching vibrations are detected for each conformer present in solution (unfortunately with severe overlap, which often precludes detailed assignment).[20] In chiroptical experiments (CD spectroscopy) the measured signal represents the sum of signals for all species present in solution.

To elucidate the conformational equilibria of **9**–**11** and **15**–**17** in solution and to probe the influence of the amino acid side chain [R = H, $CH_3$, $CH(CH_3)_2$], we used IR and CD spectroscopy, NMR spectroscopy (solvent-dependent, temperature-dependent) and DFT calculations (B3LYP, LanL2DZ[19,21–24]).

IR spectra of **7**, **9**–**11** and **15**–**17** were measured in $CH_2Cl_2$ solution at different concentrations (Table 1). The characteristic signals (NH, CO) were unchanged in the concentration range $0.5\times10^{-2}$ to $2.5\times10^{-2}$ M, which confirms

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

that intermolecular interactions are absent under these conditions. Signals for non-hydrogen-bonded NH groups as well as hydrogen bonded NH groups are observed. For **7**, the low-energy $CO_{ester}$ absorption indicates a quite strong hydrogen bond from 1′-NH to the ester carbonyl group, which corresponds to the only possible hydrogen bonded conformation E. Thus, **7** exists in solution as conformer E in equilibrium with the open form.

Table 1. IR data [$cm^{-1}$] for **7**, **9**–**11** and **15**–**17** in $CH_2Cl_2$ ($c$ = $10^{-2}$ M).

Chiral amide esters **10** and **11** display Cotton effects at about 350 (300 nm), –275 (348 nm), –155 (411 nm), and 395° $M^{-1}cm^{-1}$ (470 nm) in acetonitrile. For chiral triamides **16** and **17**, the following Cotton effects were observed: 825 (305 nm), –410 (352 nm), –230 (417 nm) and 470° $M^{-1}cm^{-1}$ (480 nm) (Experimental Section, Table 6). The spectra are very similar to those of type I derivatives with "Herrick conformations" (Scheme 1, A). A positive Cotton effect around the ferrocene absorption ($\lambda_{max} \approx 440$ nm; Experimental Section, Table 6) was previously interpreted as being indicative of (*P*)-enantiomers of the helically ordered ferrocenes.[9,17] However, the CD intensities of **10**, **11**, **16** and **17** are one order of magnitude lower than those found for type I (*P*)-helical "Herrick conformations" (Scheme 1, A; $M_\theta \approx$ 5000° $M^{-1}cm^{-1}$) with two intramolecular hydrogen bonds between the L-amino acid side arms. Thus, CD spectroscopy of L-amino acid derivatives suggests that (*P*)-helical conformations are present in slight excess over (*M*)-helical and open conformations, whereas (*M*)-helical conformations are slightly preferred for D-Ala derivative **10a** (Figure 1, Experimental Section, Table 6). As expected, CD spectra of amide esters **10** and **10a** derived from L- and D-Ala, respectively, are mirror images of each other (Figure 1). Interestingly, the positive Cotton effects increase for amide esters **10** and **11** from 360 to 430° $M^{-1}cm^{-1}$ (470 nm) as well as for triamides **16** and **17** from 410 to 530° $M^{-1}cm^{-1}$ (480 nm). This slight enhancement could be attributed to an increased amount of (*P*)-helical ferrocenes present in solution, which results from an increase in the size of the amino acid side chain from R = $CH_3$ to R = $CH(CH_3)_2$.

To address the engagement of specific NH protons (1-NH, 1′-NH, 1-NHMe) in hydrogen bonding by $^1H$ NMR spectroscopy, all the NH proton signals have to be correctly assigned. NOE spectroscopy allowed all NH proton signals to be distinguished as specific NOE cross peaks are observed to cyclopentadienyl protons and $CH_\alpha$ of the amino acid as shown exemplarily for **16** in Figure 2. NH protons

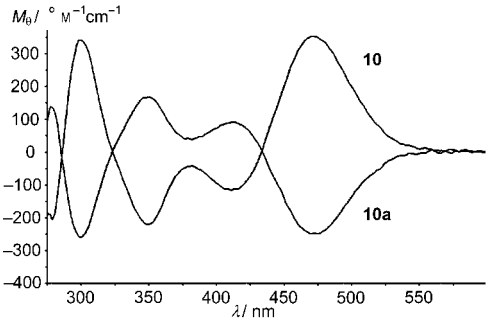

Figure 1. CD spectra of **10** and **10a** in $CH_3CN$.

adjacent to ferrocene carbonyl (1-NH, 1′-NH) display NOE cross peaks to two Cp protons, while 1-NHMe shows an NOE contact to $CH_\alpha$.

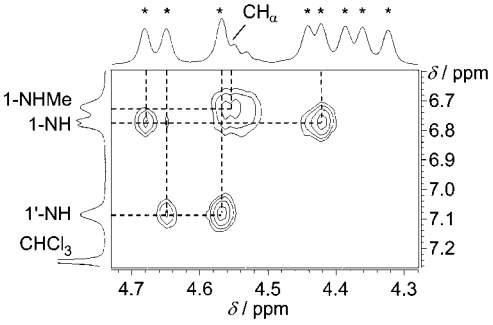

Figure 2. Part of the NOESY spectrum of **16**, which indicates NOE contacts between NH protons and Cp-H and $CH_\alpha$ (* denotes Cp-H).

To address the question as to which NH group preferentially participates in hydrogen bonds, NH chemical shifts were measured in different solvents ["variation ratio" (v.r.) method][25] and at different temperatures (VT $^1H$ NMR spectroscopy). For interpretation of the observed $\delta_{NH}$ values, it has proven useful to compare them to those of standard (reference) compounds. The standard compounds possess NH groups in a comparable chemical environment but without any intramolecular hydrogen bonds (non-hydrogen-bonded reference state) in noncoordinating solvents (e.g. $CDCl_3$). The fully hydrogen-bonded reference state is simulated by measuring the $^1H$ NMR spectrum in the strongly coordinating solvent [$D_6$]DMSO (Experimental Section, Tables 4 and 5).

Chemical shift variation from [$D_6$]DMSO to $CDCl_3$ ($\Delta\delta_{NH}$) provides a measure of the extent to which an amide proton takes part in an intramolecular hydrogen bond. If the shift variation of a particular NH proton is distinctly smaller than that of the hydrogen-bond-free reference, the NH proton is considered to be intramolecularly hydrogen bonded in $CDCl_3$ solution. The variation ratio v.r. = $\Delta\delta_{NH}$(substrate)/$\Delta\delta_{NH}$(reference) describes the involvement of the considered proton in an intramolecular hydrogen bond. Small v.r. values indicate strong hydrogen bonds whereas larger v.r. values suggest weak hydrogen bonds.[25] We, and others, have previously synthesised a number of peptides derived from 1′-aminoferrocene-1-carboxylic acid

[a] All values are given in the sequence 1′-NH, 1-NH and 1-NHMe. [b] $\delta_{NH}$ ($CDCl_3$) and $\delta_{NH}$ ([$D_6$]DMSO) for compounds **1**–**5** are taken from refs.[25,26] [c] $1.0\times10^{-4}$ M in $CDCl_3$. [d] Sample precipitates under these conditions.

(Fca)[21,27] and natural amino acids.[19,24,26,28,29] In this context, we have successfully employed the v.r. method in the estimation of intramolecular hydrogen bond strengths and conformer populations in Fca–AA conjugates.[24,26]

Suitable reference compounds for amide esters **9**–**11** are Ac–AA–OEt (AA = Gly, Ala, Val; **2**–**4**) for the amino acid containing substituent in position 1- and *N*-methylferrocenecarboxamide Fc–CONHMe (**5**) for the 1′-NHMe part. For the 1-NHMe moiety of triamides **15**–**17**, *N*-methylacetamide (MeCONHMe, **1**) is used as a reference compound. As mentioned above, the reference compounds are unable to engage in intramolecular hydrogen bonds and exhibit chemical shifts of the amide protons at positions well below $\delta = 7$ ppm in $CDCl_3$. In [$D_6$]DMSO solution, the signals are shifted to lower field ($\delta \approx 8$ ppm), which indicates intermolecular hydrogen bonds to the solvent ($\Delta\delta_{NH} \geq 2.0$ ppm, Table 2).

To exemplify this approach, v.r. calculations for ester amide **9** will be described. In $CDCl_3$ solution, compound **9** exhibits amide resonances at $\delta = 6.72$ ppm for 1′-NH and $\delta = 7.39$ ppm for 1-NH groups (unambiguously assigned by NOESY experiments and coupling patterns). In [$D_6$]-DMSO, the corresponding resonances appear at $\delta = 7.73$ ppm and $\delta = 8.40$ ppm (Figure 3). The difference in the chemical shifts of the two amide protons in the two solvents is $\Delta\delta = 1.01$ ppm for both protons. A suitable standard (reference) for 1′-NH is FcCONHMe (**5**) with $\Delta\delta = 2.00$ ppm, and for 1-NH Ac–Gly–OEt (**2**) with $\Delta\delta = 2.17$ ppm was chosen. Thus, v.r. (1′-NH) = 0.51 and v.r. (1-NH) = 0.47 can be calculated for **9**, and these values indicate medium–strong hydrogen bonds for both protons. This finding can only be explained by the presence of several conformations which are in equilibrium in solution. As only conformer D possesses a hydrogen bonded 1-NH group, this species is surely present in solution, whereas the v.r. data do not discriminate between conformations E and F as both possess 1′-NH involved in hydrogen bonds (Scheme 2).

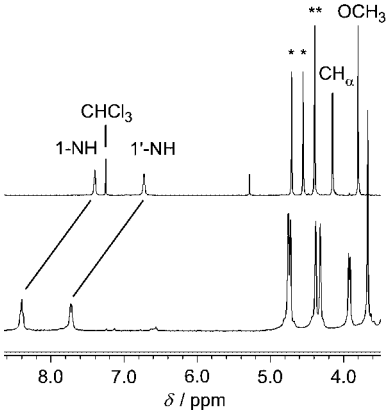

Figure 3. Part of the $^1$H NMR spectra of **9** in $CDCl_3$ (top) and [$D_6$]DMSO (bottom) (* denotes Cp-H).

In the sequence **9**, **10**, **11**, a monotonous lowering of v.r. values of the 1′-NH protons occurred ($0.51 > 0.44 > 0.32$), which indicates an enrichment of conformations E and/or F displaying 1′-NH···O bonds. Concomitantly, conformations with 1-NH···O bonds (D) are less populated (v.r. values: $0.47 < 0.55 < 0.57$). Similar to amide esters **9**–**11**, in the order **15**, **16**, **17**, v.r. values for 1′-NH protons decrease ($0.55 > 0.45 > 0.34$) and increase for 1-NH protons ($0.47 < 0.50 < 0.52$). 1-NHMe protons show increasing v.r. values ($0.34 < 0.52 < 0.62$). Once again, these findings indicate enrichment of E′ and/or F′ forms at the expense of conformers D′ and G (Scheme 3).

Additionally, variable temperature NMR experiments were undertaken in $CDCl_3$ solution (Figure 4). However, valine derivative **11** visibly precipitates upon cooling (presumably by association through intermolecular hydrogen bonds). For **9** and **16**, the large temperature shifts $\Delta\delta/T$ of NH protons are indicative of beginning intermolecular hydrogen bonding upon cooling (Table 2). Thus, temperature shifts $\Delta\delta/T$ of **9**, **16** and **17** are clearly not interpretable in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

terms of intramolecular hydrogen bonding. Thus, for **10** and **15**, it should also be considered that intermolecular interactions (especially through 1′-NH and 1-NHMe) are highly probable at lower temperatures.

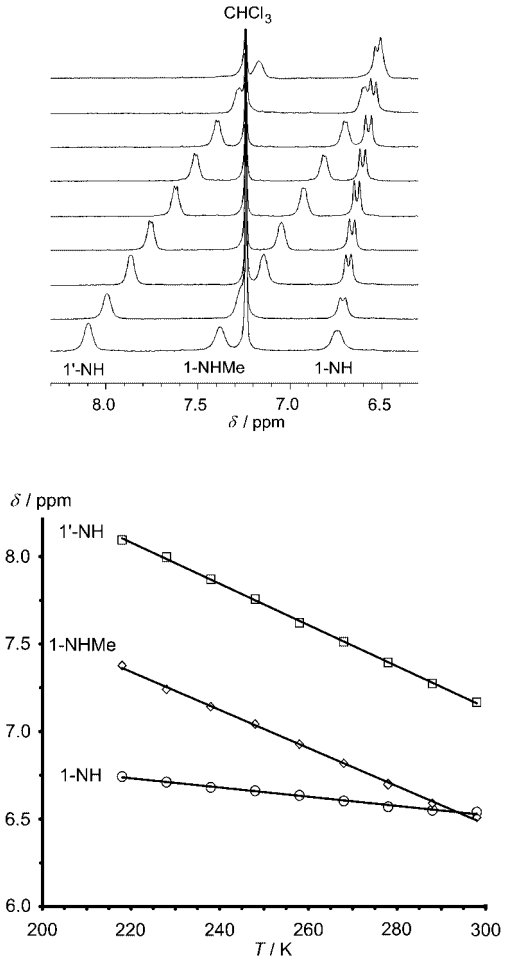

Figure 4. Partial VT $^1$H NMR spectra of **17** in $CDCl_3$ (top) and $\delta$ versus $T$ plot of the amide protons.

The combined experimental data can be summarised as follows: (1) chiral L-amino acid conjugates form predominantly (*P*)-helical conformations in solution for both type II and III conjugates, (2) all NH protons are involved in intramolecular hydrogen bonding in the ensemble, (3) according to NH v.r. values for types II and III, increasing the steric bulk of the amino acid side chain (R) results in a larger fraction of conformers with 1′-NH···O hydrogen bonds and a smaller fraction of conformers with 1-NH···O hydrogen bonds, (4) for type III conjugates, an increase in the steric bulk of the amino acid side chain (R) leads to a depletion of conformers with 1-NHMe···O hydrogen bonds in the ensemble.

## DFT Calculations

To gain deeper insight into the possible conformations, the geometries of compounds **9**–**11** and **15**–**17** were optimised by DFT calculations without symmetry constraints (B3LYP, LanL2DZ) in different conformations, that is, with respect to hydrogen bonding patterns (D, E, F, open, D′, E′, F′, G′ and open′) and ferrocene helicity (*P*, *M*) (Table 3, Figures 5 and 6). In all cases, the open form is calculated to be higher in energy by 13–19 kJ mol$^{-1}$ relative to the calculated minimum geometry. Type II compounds **9**–**11** with two hydrogen-donors and three hydrogen-acceptors will be discussed before type III conjugates **15**–**17** with three donors and three acceptors are addressed.

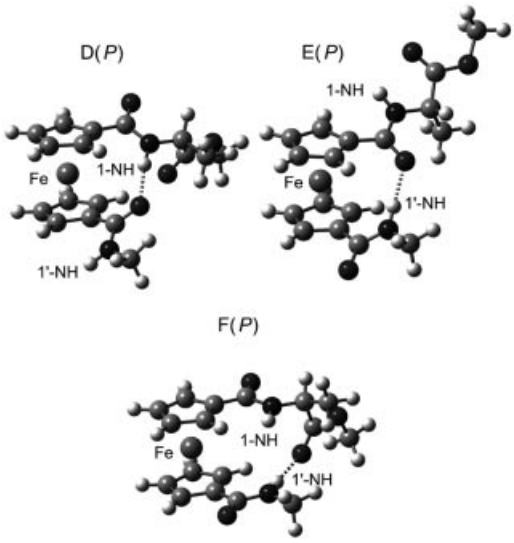

Figure 5. DFT-calculated (*P*)-helical minimum structures of **10**.

For glycine derivative **9**, all conformations D, E and F are local minima with marginal energy differences, which confirms that no conformation is especially preferred over the others and also substantiates conclusion (2) above. In sterically more demanding conjugates **10** and **11**, conformations D(*M*) and F(*M*) are destabilised by the larger substituent R (Figure 7). Thus, less (*M*)-helical ferrocenes equalling more (*P*)-helical conformers are present in the ensemble in accordance with conclusion (1) above. According to the calculations, the ensemble is enriched in E conformers as D(*M*) and F(*M*) are energetically unfavourable for **10** and **11**. Conformers E exhibit 1′-NH···O hydrogen bonds, which accounts for conclusion (3). Additionally, F(*P*) becomes the most stable conformation for **11**, which also shows 1′-NH···O hydrogen bonds and furthermore explains the lower $C{=}O_{ester}$ stretching vibration frequency of **11** relative to that of **9** (Table 1).

Type III conjugates show a more complicated behaviour as the number of possible conformations with hydrogen bonds has doubled relative to type II compounds. No stable minimum structure could be obtained for the G conformation shown in Scheme 3 as the 1-NHMe···1′-CO hydrogen bond is disrupted, which leaves only the intrachain hydrogen bond between 1-NHMe and 1-CO. This conformation is almost as high in energy as the open form and rules out a significant contribution (Table 3). Glycine conjugate **15** shows no conformational preference as does its type II counterpart **9**, that is, all conformations D′1, D′2, D′3, E′1, E′2 and F′ with (*P*) and (*M*) helical ferrocenes are present

in the ensemble (Figure 7). An increase in the size of R in the L-amino acid destabilises conformations D′1(*P*), D′1(*M*), D′3(*P*), D′3(*M*), E′2(*M*) and F′(*M*). Thus, in the ensemble, conformers D′2(*P*), D′2(*M*), E′1(*P*), E′1(*M*), E′2(*P*) and F′(*P*) are still present, which results in an excess of (*P*)-helical ferrocenes for **16** and **17** and corroborates

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

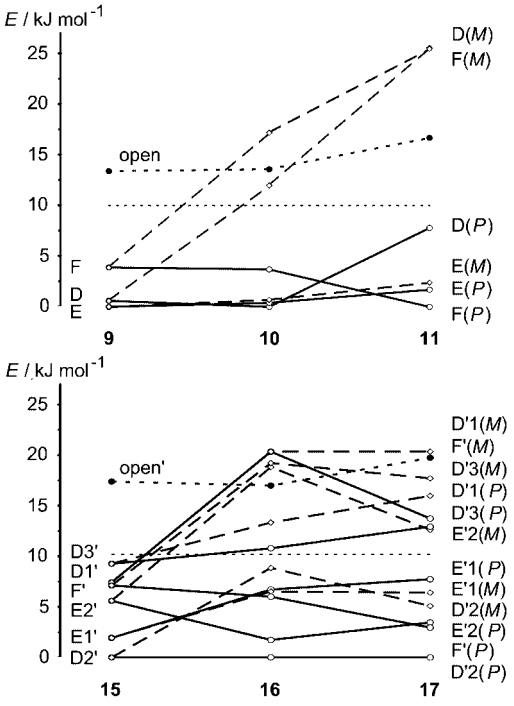

Figure 7. Relative energies of conformations of type II conjugates **9**–**11** (top) and of conformations of type III conjugates **15**–**17** (bottom) [for 16D′1(*P*), 16D′1(*M*) and 17D′1(*M*), the relative energy must be arbitrarily set to 20 kJ mol$^{-1}$; the dotted lines at 10 kJ mol$^{-1}$ are a guide for the eye].

conclusion (1) above. Analogously to type II conjugates, the ensembles of **16** and **17** contain more E conformers relative to the ensemble of glycine derivative **15**. This confirms conclusion (3), which states that a larger fraction of conformers with 1′-NH···O hydrogen bonds exists for derivatives with larger R substituents. As for type II derivatives, F′(*P*) conformations (with 1′-NH···O hydrogen bonds) are increasingly stabilised by larger R side chains.

Interchain 1-NHMe hydrogen bonds are only present in conformations D′3 and G (Scheme 3), which are quite high in energy. Thus, 1-NHMe hydrogen bonds are mainly intrachain in nature and occur in conformations D′2, E′2 and 17F′(*M*) (Table 3). As E′2(*M*) and F′(*M*) are destabilised for **16** and **17**, the number of conformations with 1-NHMe hydrogen bonds is reduced relative to the ensemble of **15**. This accounts for the observed weakening of 1-NHMe hydrogen bonds [conclusion (4) above].

## Conclusions

It was shown that ferrocene-1,1′-dicarboxylic acid conjugates of types II and III form an ensemble of conformations in weakly coordinating solvents without a preference for one specific conformer. However, an increase in the steric demand of the L-amino acid side chain reduces the number of conformations [especially with respect to (*M*)-helical ferrocenes] in solution, which provides an explanation for the observed positive Cotton effect at the ferrocene absorption in the CD spectra. Furthermore, large amino acid side chains favour conformations with 1′-NH···O hydrogen bonds (conformations E/E′ and F/F′) as shown by NMR spectroscopic techniques (v.r. method) and DFT calculations.

A single hydrogen bond spanning the 1- and 1′-substituents already provides an explanation for the preference of (*P*)-helical ferrocenes in asymmetrical type II and III conjugates with one L-amino acid attached. This effect is even more pronounced in symmetrically substituted type I conjugates with two L-amino acids and two hydrogen bonds between the ferrocene substituents. For Fn(CO–Ala–OMe)$_2$, the energy difference between (*P*)- and (*M*)-"Herrick" conformers was calculated as 17.3 kJ mol$^{-1}$ by DFT methods.[22] However, in these systems, an increase in the number of L-amino acids has no further stabilising effect.

On the basis of the results obtained in this study, it is expected that an increase in the size of the amino acid side chains adjacent to the ferrocene carbonyl might be a means to further stabilise chiral secondary structures, for example, turn motifs.

## Experimental Section

**General:** The syntheses were carried out under an atmosphere of argon. $CH_2Cl_2$ that was used for syntheses and FTIR spectroscopy was dried ($P_2O_5$), distilled from $CaH_2$ and stored over molecular sieves (4 Å). EDC, HOBt (Aldrich) and amino acid esters and amides (Merck) were used as received. NMR spectroscopic data for compounds **1**–**5** were taken from refs.[25,26]. Products were purified by preparative thin layer chromatography on silica gel (Merck, Kieselgel 60 $HF_{254}$) by using $CH_2Cl_2$/EtOAc or $CH_2Cl_2$/MeOH. Melting points were determined with a Buechi apparatus. IR spectra were recorded as $CH_2Cl_2$ solutions with a Bomem MB 100 mid FTIR spectrophotometer. $^1$H- and $^{13}$C{$^1$H}-NMR spectra were recorded with a Varian EM 360 or Varian Gemini 300 spectrometer in $CDCl_3$ and [$D_6$]DMSO solutions with $Me_4Si$ as the internal standard or with a Varian Unity Plus 400 spectrometer. ESI mass spectra were recorded with a Finnigan TSQ 700 spectrometer. High resolution FAB mass spectra were recorded with a JEOL JMS-700. CD spectra were recorded as $CH_3CN$ solutions with CD spectrophotometer Jasco-810. 1′-(Methoxycarbonyl)ferrocene-1-carboxylic acid (**6**) was prepared according to a literature procedure.[30]

**Computational Method:** Density functional calculations were carried out with the Gaussian03/DFT[31] series of programs. The B3LYP formulation of density functional theory was used by employing the LanL2DZ basis set.[31] All points were characterised as minima ($N_{imag}$ = 0) by frequency analysis.

**Methyl 1′-(methylcarbamoyl)ferrocene-1-carboxylate (7):** EDC (1.7 g, 9.1 mmol) and HOBt (1.2 g, 9.1 mmol) were added to a suspension of 1′-(methoxycarbonyl)ferrocene-1-carboxylic acid (**6**; 2 g, 7 mmol) in dry dichloromethane (20 mL), and the solution was stirred for 1 h at room temp. $MeNH_2$·HCl (682.5 mg, 10.5 mmol) was suspended in dichloromethane (5 mL) at 0 °C and dissolved by the addition of dry $NEt_3$ until ca. pH 8. This solution was added to the solution of activated **6**. After stirring for 1 h at room temp., the reaction mixture was washed with saturated aqueous $NaHCO_3$ and water. The organic layer was dried with $Na_2SO_4$ and evaporated in vacuo. TLC purification of the crude product with $CH_2Cl_2$/EtOAc (10:1) gave 900 mg (45%) of orange crystals. M.p. 135–

137 °C. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 6.16 (br. s, 1 H, NH), 4.77 (pt, 2 H, $H^{2,5}$), 4.59 (pt, 2 H, $H^{2',5'}$), 4.46 (pt, 2 H, $H^{3,4}$), 4.37 (pt, 2 H, $H^{3',4'}$), 3.85 (s, 3 H, $COOCH_3$), 2.98 (d, $^3J_{HH}$ = 4.9 Hz, 3 H, $NHCH_3$) ppm. $^1$H NMR (300 MHz, [$D_6$]-DMSO): $\delta$ = 7.75 (br. q, 1 H, NH), 4.80 (s, 2 H, $H^{2,5}$), 4.71 (s, 2 H, $H^{2',5'}$), 4.44 (s, 2 H, $H^{3,4}$), 4.36 (s, 2 H, $H^{3',4'}$), 3.71 (s, 3 H, $COOCH_3$), 2.32 (d, $^3J_{HH}$ = 4.5 Hz, 3 H, $NHCH_3$) ppm. $^{13}$C NMR, APT (75 MHz, $CDCl_3$): $\delta$ = 172.0 (s, $COOCH_3$), 169.72 (s, C=O), 78.66 (s, $C^{1'}$), 71.99 (s, $C^1$), 72.64 (s, $C^{2,5}$), 71.84 (s, $C^{2',5'}$), 71.31 (s, $C^{3,4}$), 70.06 (s, $C^{3',4'}$), 51.96 (s, $OCH_3$), 26.55 (s, $NHCH_3$) ppm. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 3462 (s, NH, free), 3373 (vw, NH, assoc.), 1712 (s, $CO_{ester}$), 1659 (s, amide I) 1606 (m), 1530 (s, amide II) cm$^{-1}$.

**1′-(Methylcarbamoyl)ferrocene-1-carboxylic acid (8):** A solution of NaOH (140 mg, 3.5 mmol) in water (5 mL) was added to a solution of amide ester **7** (900 mg, 3 mmol) in methanol (20 mL). After heating to 80 °C for 50 min, the reaction mixture was extracted with $CH_2Cl_2$. The alkaline aqueous layer was treated with conc. HCl (pH = 1–2), extracted with EtOAc and washed with water. The organic layer was dried with $Na_2SO_4$ and evaporated in vacuo to afford 840 mg (97%) of orange crystals. M.p. 146–149 °C. IR (KBr): $\tilde{\nu}$ = 3334 (s, NH), 3089 (s, OH), 1676 (s, $CO_{acid}$), 1637 (s, amide I), 1550 (s, amide II) cm$^{-1}$.

**MeNHCO–Fn–CO–AA–OMe (9–11):** Compound **8** (200 mg, 0.7 mmol) was activated by using EDC/HOBt (as described for the preparation of **7**). The solution was cooled to 0 °C and AA–OMe (obtained from AA–OMe·HCl by treatment with $NEt_3$ in $CH_2Cl_2$, pH ca. 8) was added. The reaction mixture was stirred for 1 h at room temp., washed thrice with a saturated aqueous solution of $NaHCO_3$, 10% aqueous solution of citric acid, and $H_2O$. After drying over $Na_2SO_4$ and evaporating in vacuo, the crude products were TLC-purified with EtOAc as eluent. **9** (AA = Gly): Yield: 110 mg (42%), orange crystals. M.p. 149–152 °C. $^{13}$C NMR, APT (75 MHz, $CDCl_3$): $\delta$ = 170.49 (s, $CONHCH_3$), 170.48 (s, $COOCH_3$), 170.44 (s, C=O), 78.07 (s, $C^{1'}$), 76.62 (s, $C^1$), 70.69 (s, $C^{2,5}$), 70.59 (s, $C^{2',5'}$), 70.40 (s, $C^{3,4}$), 70.29 (s, $C^{3',4'}$), 51.85 (s, $OCH_3$), 40.85 (s, $CH_{2Gly}$), 26.07 (s, $NHCH_3$) ppm. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 3446 (m, NH, free), 3259 (w, NH, assoc.), 1742 (s, $CO_{ester}$) 1650 (s, amide I), 1609 (m), 1535 (s, amide II) cm$^{-1}$. IR (KBr): $\tilde{\nu}$ = 3401 (s, NH, free), 3273 (s, NH, assoc.), 1737 (s, $CO_{ester}$), 1634 (s, amide I), 1540 (s, amide II) cm$^{-1}$. MS (ESI+, $CH_3CN$): *m*/*z* (%) = 359.3 (100) [M + H]$^+$, 381.3 (7) [M + Na]$^+$, 397.2 (5) [M + K]$^+$, 717.3 (14) [2M + H]$^+$, 739.3 (4) [2M + Na]$^+$, 755.3 (2) [2M + K]$^+$. HRMS (FAB): calcd. for $C_{16}H_{18}FeN_2O_4$ 358.0616; found 358.0619. **10** (AA = L-Ala): Yield: 157 mg (61%), orange resin. $^{13}$C NMR, APT (75 MHz, $CDCl_3$): $\delta$ = 174.25 (s, $COOCH_3$), 170.82 (s, $CONHCH_3$), 170.39 (s, C=O), 78.54 (s, $C^{1'}$), 76.75 (s, $C^1$), 71.37 (s, $C^2$), 71.32 (s, $C^5$), 71.28 (s, $C^{2'}$), 71.26 (s, $C^{5'}$), 70.89 (s, $C^3$), 70.83 (s, $C^4$), 70.77 (s, $C^{3'}$), 70.09 (s, $C^{4'}$), 52.57 (s, $OCH_3$), 48.39 (s, $CH_{Ala}$), 26.58 (s, $NHCH_3$), 17.71 (s, $CH_{3Ala}$) ppm. dition of NaOH (23 mg, 0.6 mmol), the reaction mixture was stirred at room temp. for 10 min. The solution was treated with conc. HCl to pH = 2–3, extracted with EtOAc, washed with saturated aqueous $NaHCO_3$ and water. The organic layer was dried with $Na_2SO_4$ and evaporated in vacuo. Compounds **12**–**14** were used without purification for further transformation. **12** (AA = Gly): Yield: 100 mg (94%), orange crystals. M.p. 115–117 °C. IR (KBr): $\tilde{\nu}$ = 3458 (m, NH, free), 3092 (s, OH), 1630 (s, amide I), 1534 (s, amide II) cm$^{-1}$. **13** (AA = L-Ala): Yield: 94 mg (81%), orange resin. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 3450 (m, NH, free), 3100 (s, OH), 1655 (s, amide I), 1534 (s, amide II) cm$^{-1}$. **14** (AA = L-Val): Yield: 96 mg (94%), orange resin. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 3453 (m, NH, free), 3110 (s, OH), 1650 (s, amide I), 1534 (s, amide II) cm$^{-1}$.

**MeNHCO–Fn–CO–AA–NHMe (15–17). Procedure A:** MeNHCO–Fn–CO–AA–OH (**12**–**14**; 0.25 mmol) was activated (as described for **7**) and reacted with $MeNH_2$·HCl (cf. preparation of **9**–**11**). The crude products were purified by TLC using EtOAc as the eluent to give orange resins **15** (24%), **16** (56%) and **17** (20%), respectively. **Procedure B:** Acid amide **8** (150 mg, 0.526 mmol) was activated by using EDC/HOBt as described for **7** and reacted with AA–NHMe (obtained from AA–NHMe·HCl similarly as in preparation of **9**–**11**). The products were purified by TLC using EtOAc as the eluent to give orange resins **15** (45%), **16** (45%), **17** (34%). The compounds prepared by these alternative procedures display identical NMR and IR spectra. **15** (AA = Gly): orange resin. $^{13}$C NMR, APT (75 MHz, $CDCl_3$): $\delta$ = 170.31 (s, $CONHCH_3$), 170.22 (s, $CONHCH_3$), 169.72 (s, C=O), 77.75 (s, C$^{1'}$), 76.25 (s, C$^1$), 70.93 (s, C$^{2,5}$), 70.75 (s, C$^{2',5'}$), 70.12 (s, C$^{3,4}$), 69.92 (s, C$^{3',4'}$), 43.01 (s, $CH_{2Gly}$), 26.08 (s, $NHCH_3$), 25.85 (s, $NHCH_3$) ppm. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 3449 (m, NH, free), 3341 (w, NH, assoc.), 1655 (s, amide I), 1607 (s), 1534 (s, amide II) cm$^{-1}$. # Synthesis and Characterization of New Energetic Nitroformate Salts

Yangen Huang,[a] Haixiang Gao,[a] Brendan Twamley,[a] and Jean'ne M. Shreeve*[a]

**Keywords:** Nitroform / Energetic salt / Oxygen balance

New energetic nitroformate salts that contain high-nitrogen cations were synthesized by taking advantage of the relatively high acidity of nitroform. All of the new salts have been characterized by elemental, spectral, and thermal analyses. Single-crystal X-ray analysis of **2** shows that it is a co-crystal of a neutral 4-amino-1,2,4-triazole molecule with the 4-amino-1,2,4-triazolium nitroformate ion pair. The presence of the neutral molecule appears to lend stability to the salt. The structure of 3,6-diguanidino-1,2,4,5-tetrazinium nitroformate (**10**) was also confirmed by single-crystal X-ray analysis. Theoretical performance calculations indicate that these materials have properties which compare favorably with hydrazinium nitroformate, TNT and Tetryl suggesting potential applications as eco-friendly oxidizers.

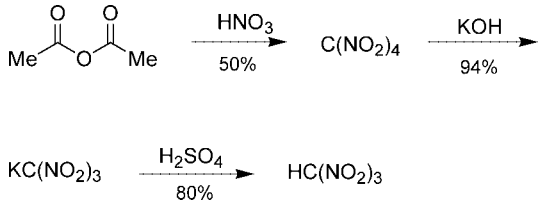
## Introduction

On the basis of their special properties such as lower vapor pressures and higher densities than their atomically similar non-ionic analogues, the synthesis of energetic salts as a unique class of high energetic materials has attracted considerable interest over the past decade.[1] Recently, the syntheses of new members of heterocyclic-based energetic, low-melting salts were reported.[2] Some of them display attractive energetic properties including high positive heats of formation and high density, e.g., the salt of 3-amino-6-(nitroamino)tetrazine (ANAT) with 3,6-diguanidinotetrazine exhibits a heat of formation of +1089 kJ mol$^{-1}$.[2a] Due to its high oxygen content and labile hydrogen atom which facilitates the preparation of nitroformate derivatives, nitroform (trinitromethane) is a very valuable compound for use in the preparation of ingredients with good explosive and propellant properties. A number of nitroform derivatives including those with potassium, silver, pyridinium, piperidinium, ammonium, guanidinium, aminoguanidinium, diaminoguanidinium, triaminoguanidinium, and hydrazinium cations have been reported.[3] Among them, hydrazinium nitroformate (HNF) has received considerable attention as an effective oxidizer.[4]

High-energy solid oxygen oxidizers which possess useful propellant properties such as high density, good thermal stability and high impact resistance continue to be sought. Ammonium nitrate (AN) and ammonium perchlorate (AP) are two oxidizers widely used in military and civilian applications. HNF has a higher heat of formation than AP ($\Delta H_f$ = –71 kJ mol$^{-1}$ compared to –292.88 kJ mol$^{-1}$), is relatively dense (1.86 g cm$^{-3}$) and is more environmentally friendly making it a suitable substitute. Because of its rather high thermal stability ($T_d$ = 123 °C),[4c] HNF is in the minority relative to most nitroform salts which often decompose rapidly at ≤25 °C. However, hydrazine hydrate, the precursor to HNF, is a probable human carcinogen. Therefore, it was worthwhile to attempt to design benign energetic salts with trinitromethanide as the anion. With respect to this need, we have prepared several high-nitrogen energetic salts with the highly oxidizing trinitromethanide anion, two of which appear to exhibit considerable promise.

## Results and Discussion

The key synthon, nitroform (NF), was prepared from acetic anhydride through a three-step process in 38% overall yield (Scheme 1)[5] (m.p. 22 °C; reported m.p. 15–26 °C mainly due to the degree of purity of the product)[4c,6] (see Supporting Information).



Scheme 1.

Due to the high acidity of nitroform (p$K_a$ = 0),[4c] which is comparable to mineral acids, a series of nitrogen-rich compounds were protonated in methanol or water at 25 °C or below (Scheme 2). All of the nitroform salts **1**, **3**–**11** are formed in nearly quantitative yields and in high purity.

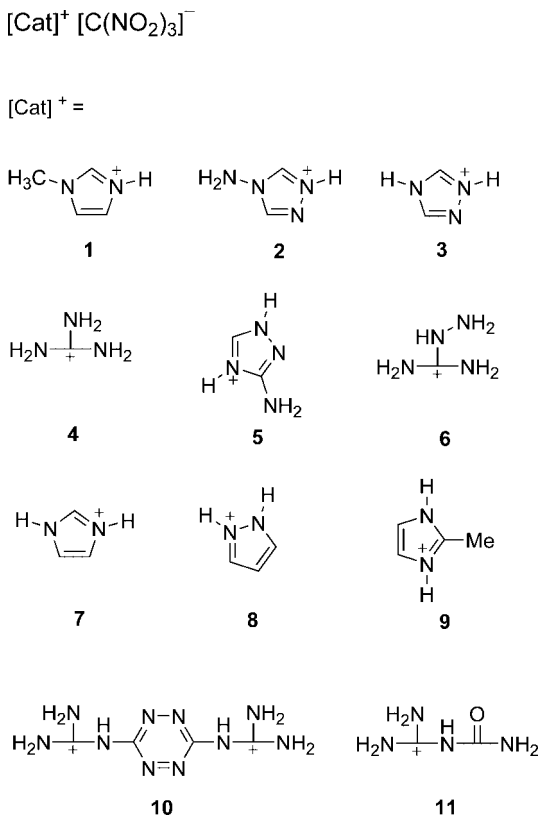
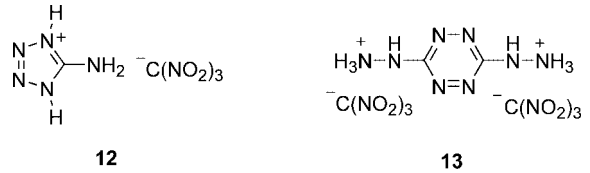


Scheme 2.

While attempting to synthesize 4-amino-1,2,4-triazolium nitroformate, the product which was obtained after recrystallization from methanol and diethyl ether was found to be molecular 4-amino-1,2,4-triazole combined with the 4-amino-1,2,4-triazolium nitroformate in a novel co-crystal **2**. The same product was obtained even after a prolonged reaction time (36 h) or by increasing the equivalent ratio of nitroform from 1 to 5 and reaction temperature from 25 °C to 50 °C. Using water as solvent did not affect the results. However, the expected 1:1 salt **5** was obtained when the 3-amino isomer, 3-amino-1,2,4-triazole, and nitroform were reacted. Guanylurea nitroformate (**11**) was synthesized by reaction of guanylurea carbonate with nitroform in methanol. Meanwhile, all attempts to isolate the corresponding nitroformate salts with 5-amino-1*H*-tetrazole (**12**) and 3,6-dihydrazinotetrazine (**13**) were unsuccessful due to their extremely low thermal stability. The reaction mixture foamed dramatically even at 0 °C which suggested that the desired product decomposed immediately (Scheme 3).



Scheme 3.

All the new salts, namely, 1-methylimidazolium, 3-amino-1,2,4-triazolium, 1,2,4-triazolium, guanidinium, 4-amino-1,2,4-triazolium, aminoguanidinium, imidazolium, pyrazolium, 2-methylimidazolium, 3,6-diguanidino-1,2,4,5-tetrazinium and *N*-guanylurea nitroformate (**1**–**11**) were characterized by IR, and $^{1}H$ and $^{13}C$ NMR spectral and elemental analyses. The IR spectra of these salts exhibit absorption bands in the range 1510–1590 $cm^{-1}$ which are attributed to the presence of nitro groups. The several main absorption bands in the range 3100–3430 $cm^{-1}$ can be assigned to the N–H bonds. It was not possible to locate the $^{13}C$ NMR signal of the nitroformate anion in **1**–**11**.

Crystals suitable for single-crystal X-ray analysis were obtained by crystallization from methanol and diethyl ether for **2** and water for **10**. The structure of **2** (Figure 1) consists of a co-crystal of a neutral 4-amino-1,2,4-triazole with the 4-amino-1,2,4-triazolium nitroformate ion pair. The tetrahedral geometry and bond length [1.412(1) Å] of the amino group of the triazolium cation indicates little interaction by the N1 lone pair and the triazolium ring pi system, similar to other triazolium species.[2b,7] However, there are many strong hydrogen bonds which stabilize this structure and assist with charge delocalization. The extended structure of

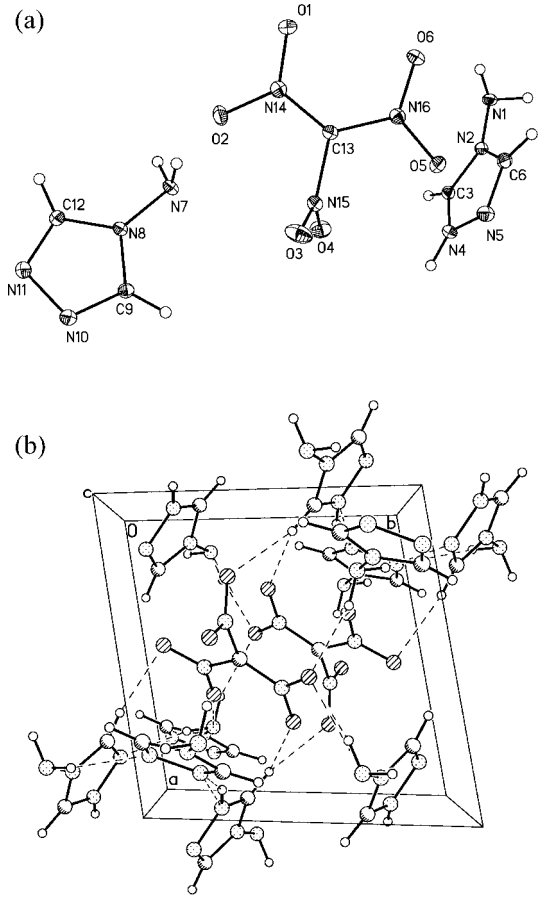


Figure 1. (a) Thermal ellipsoid plot (30%) and labeling scheme for 4-amino-1,2,4-triazolium nitroformate (**2**). Hydrogen atoms included but are unlabelled for clarity. (b) Ball and stick packing diagram of **2** viewed down the *c* axis. Dashed lines indicate strong hydrogen bonding.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**2** (Figure 1, b) shows some of these strong hydrogen bonds and indicates the layer structure formed by alternating nitroformate anions and cationic triazolium/neutral triazole. The triazolium/neutral triazole pair hydrogen bond into an oblique square which stacks to form a four-sided channel with an approximate diameter of 3.8 Å. Although an anhydrous salt of **10** could be obtained by dehydration in vacuo at room temperature (confirmed by elemental analyses), the structure of **10** (Figure 2) is a dihydrate and consists of a 3,6-diguanidino-1,2,4,5-tetrazinium dication with two nitroformate anions.

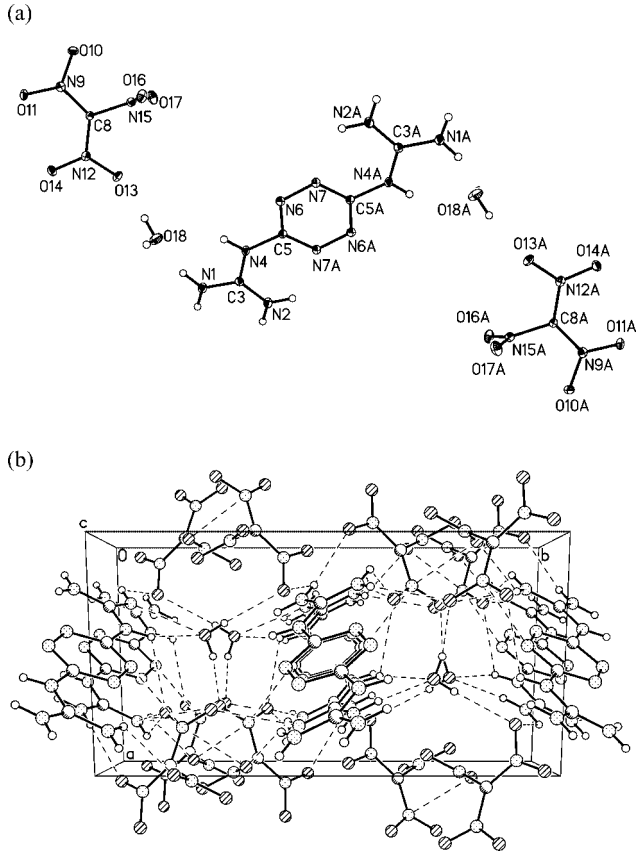

Figure 2. (a) Thermal ellipsoid plot (30%) and labeling scheme for 3,6-diguanidino-1,2,4,5-tetrazinium nitroformate (**10**). Hydrogen atoms included but are unlabelled for clarity. (b) Ball and stick packing diagram of **10** viewed down the *c* axis. Dashed lines indicate strong hydrogen bonding.

In this structure, the guanidine moieties are planar with an 8.7° dihedral angle to the central tetrazinium ring. This indicates a stabilization of the cation via delocalization of the charge over the entire diguanidino tetrazinium moiety. The extended structure also forms a strongly hydrogen-bonded network with alternating anionic nitroformate/water and cationic tetrazinium layers parallel to the *a* axis (Figure 2, b). There are few known nitroformate structures.[7a,8] In **2** and **10**, one nitro group is ca. 73° and 85° degrees, respectively, to the main plane of the anion. This angle varies in the other published structures from planar[8b] to 90°.[8d]

Densities and thermochemical data for **1**–**11** are summarized in Table 1. DSC and TGA were used to evaluate the relative thermal stabilities of **1**–**11** and are measured under comparable conditions. In the DSC thermograms, most of the salts (**1**, **3**–**11**) decomposed at their melting points except for **2** which melted sharply at 92 °C. The results from DSC are consistent with those obtained using TGA. The decomposition temperatures of **1**–**11** occur over the range of 74–167 °C with **2** displaying the highest decomposition temperature (167 °C). The results indicate that the neutral 4-amino-1,2,4-triazole contained in the 4-amino-1,2,4-triazolium nitroformate crystal may have a stabilizing effect on the product. Comparison of guanylurea nitroformate (**11**) with guanylurea dinitramide (FOX-12),[9] showed that the stability of **11** is slightly lower than FOX-12 ($T_d$ = 153 °C vs. 216 °C), but they have essentially the same density, detonation pressure and detonation velocity (Table 2). The low decomposition temperature of nitroform salts **1**, **3**–**11** and HNF ($T_d$ = 120–153 °C) confirmed further that the thermal stability of compounds with the trinitromethanide anion is low.

[a] Ref.[4c], ref.[9] for FOX-12.

As one of the important physical properties of energetic salts, the densities of **1**–**10** were measured by using helium displacement methods to yield results shown in Table 1. All of the compounds had densities > 1.50 g/cm$^3$ with **10** exhibiting a density of 1.79 g/cm$^3$ which is comparable with HNF (1.86 g/cm$^3$). The performance of a high explosive is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

measured by its detonation velocity, $vD$ (m/s), detonation pressure, $P$ (Gpa), and specific impulse $I_{sp}$ (s).[10] These parameters are directly related to oxygen balance (OB), density, and heat of formation. The detonation pressure and velocity (based on traditional Chapman–Jouget thermodynamic detonation theory) and specific impulse ($I_{sp}$) were obtained by using Cheetah 4.0 (Table 1).[11]

For the compounds **1**–**11** the calculated detonation pressures lie in the range between $P$ = 19.6 GPa (**9**) and $P$ = 33.9 GPa (**6**). Detonation velocities are distributed from $D$ = 7230 m s$^{-1}$ (**8**) to $D$ = 9145 m s$^{-1}$ (**6**). Substituents on the nitrogen-containing heterocycle lower the density and detonation performance of the corresponding nitroform salts (**2** to **3**, **1** to **7**). Aminoguanidinium nitroformate (**6**) has the highest density and best performance among these salts; however, it decomposes within 36 h at 25 °C with loss of color. The salts **2** and **10** show the best stability being storable at 25 °C for several weeks. In addition, the performance potential of salts **2** and **10** are superior to the conventional explosives TNT and Tetryl as shown in Table 2.

## Conclusions

In conclusion, several energetic salts with the nitroformate anion have been synthesized and characterized. The neutral molecule contained in the crystalline salt **2** exhibits a stabilizing effect on the corresponding ion pair. This may offer a new way to stabilize energetic salts by designing co-crystals. In addition, thermal computations indicate that the performance potentials of **2** and **10** are better than the conventional explosives, TNT and Tetryl, which suggests their potential as eco-friendly oxidizers.

## Experimental Section

***Caution:*** Although none of the compounds described herein has exploded or detonated in the course of this research, these materials should be handled with extreme care using the best safety practices because their shock and impact sensitivities have not been determined. All nitroform salts should be stored at lower temperatures (–18 °C) to preclude decomposition.

**General Methods:** $^1$H and $^{13}$C NMR spectra were recorded with a 300-MHz NMR spectrometer operating at 300.13, and 75.48 MHz, respectively, using $CD_3CN$ as solvent unless otherwise indicated. Chemical shifts were reported relative to $Me_4Si$. The melting and decomposition points were recorded with a differential scanning calorimeter (DSC) and a thermogravimetric analyzer (TGA) at a scan rate of 10 °C/min, respectively. IR spectra were recorded using KBr pellets for solids. Densities were measured at room temperature using a Micromeritics Accupyc 1330 gas pycnometer. Elemental analyses were obtained by with a CE-440 elemental analyzer (EAI Exeter Analytical).

**Computational Details:** Computations were performed with the Gaussian03 (Revision D.01) suite of programs.[12] The geometric optimization of the structures based on single-crystal structures, where available, and frequency analyses are carried out using B3-LYP functional with 6-31+G** basis set,[13] and single energy points were calculated at the $MP_2$(full)/6-311++G** level. All of the optimized structures were characterized to be true local energy minima on the potential energy surface without imaginary frequencies.

On the basis of Born–Haber energy cycles, the heat of formation of an ionic salt can be simplified by the formula:

$\Delta H_f°$(ionic salt, 298 K) = $\Delta H_f°$(cation, 298 K) + $\Delta H_f°$(anion, 298 K) – $\Delta H_L$

where $\Delta H_L$ is the lattice energy of the ionic salts which could be predicted by the formula suggested by Jenkins et al.[14] as:

$\Delta H_L = U_{POT} + [p(nM/2 - 2) + q(nX/2 - 2)]RT$ (**A**)

where $n_M$ and $n_X$ depend on the nature of the ions $M_p^+$ and $Xq^-$, respectively, and are equal to **3** for monatomic ions, **5** for linear polyatomic ions, and **6** for nonlinear polyatomic ions. The equation for lattice potential energy $U_{POT}$ (Equation **B**) has the form:

$U_{POT}$/kJ mol$^{-1}$ = $\gamma$ $(\rho_m/M_m)^{1/3}$ + $\delta$ (**B**)

where $\rho_m$/g cm$^{-3}$ is the density, $M_m$ is the chemical formula mass of the ionic material, values for $g$ and the coefficients $\gamma$/kJ mol$^{-1}$ cm and $\delta$/kJ mol$^{-1}$ were taken from ref.[14]

The remaining task is to determine the heat of formation of the cation, which is computed using the method of isodesmic reactions.[2c] The enthalpy of reaction ($\Delta H_r°_{298}$) is obtained by combining the MP2(full)/6-311++G** energy difference for the reaction, the scaled zero point energies, and other thermal factors. Thus, the heat of formation of the cation being investigated can be readily extracted.

With the value of the heats of formation and density of energetic salts, the expected detonation pressures ($P$) and detonation velocities ($D$) were calculated based on the traditional Chapman–Jouget thermodynamic detonation theory.[11a]

**X-ray Analyses:** Crystals of compound **2** (**10**) were removed from the flask, a suitable crystal selected, attached to a glass fiber, and data were collected at 90(2) K with a Bruker/Siemens SMART APEX instrument (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) equipped with a Cryocool NeverIce low-temperature device. Data were measured using omega scans 0.3° (0.5°) per frame for 5 (20) s, and a full sphere of data was collected. A total of 2400 (1065) frames were collected with a final resolution of 0.83 Å. Cell parameters were retrieved using SMART[15] (APEX2)[16] software for **2** (**10**), and refined using SAINTPlus[17] on all observed reflections. Data reduction and correction for Lp and decay were performed using SAINTPlus software. Absorption corrections were applied using SADABS.[18] The structures were solved by direct methods and refined by least-squares method on $F^2$ using the SHELXTL program package.[19] Structure were solved in the space group $P\bar{1}$ and $P2_1/c$ for compounds **2** and **10**, respectively, by analysis of systematic absences. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located and refined independently for the amino groups in **2**. No decomposition was observed during data collection. CCDC-628775 and -628776 contain the supplementary crystallographic data for **2** and **10**. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Nitroform:** The synthesis of nitroform is carried out as described in the literature (Supporting Information).[5]

**General Procedure for the Preparation of Nitroformate Salts. 1-Methylimidazolium Nitroformate (1):** A solution of nitroform (151 mg, 1.0 mmol) in methanol (2 mL) was slowly added to a solution of 1-methylimidazole (82 mg, 1.0 mmol) in methanol (2 mL) at 25 °C with stirring. After stirring for 3 h at room temperature,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the solvent was removed in vacuo to leave the desired product **1** (233 mg, 96%) as a yellow crystalline solid. IR (KBr): $\tilde{\nu}$ = 3415, 3150, 1584, 1535, 1484, 1277, 1153, 805 $cm^{-1}$. $^1H$ NMR: $\delta$ = 8.48 (s, 1 H), 7.39 (s, 2 H), 3.88 (s, 3 H) ppm. $^{13}C$ NMR: $\delta$ = 136.2, 124.2, 120.5, 36.6 ppm. $C_5H_7N_5O_6$ (233.14): calcd. C 25.76, H 3.03, N 30.04; found C 25.81, H 2.67, N 30.05.

**4-Amino-1,2,4-triazolium Nitroformate (2):** IR (KBr): $\tilde{\nu}$ = 3418, 3131, 1628, 1532, 1486, 1272, 1155, 617 $cm^{-1}$. $^1H$ NMR: $\delta$ = 8.68 (s, 4 H), 7.42 (br., 4 H) ppm. $^{13}C$ NMR: $\delta$ = 145.3, 151.2 ppm. $C_5H_9N_{11}O_6$ (319.07): calcd. C 18.81, H 2.84, N 48.27; found C 18.88, H 2.71, N 48.32.

**1,2,4-Triazolium Nitroformate (3):** IR (KBr): $\tilde{\nu}$ = 3424, 3130, 2793, 1572, 1536, 1404, 1335, 1159, 825 $cm^{-1}$. $^1H$ NMR: $\delta$ = 8.92 (br., 2 H) ppm. $^{13}C$ NMR: $\delta$ = 143.3, 39.8 ppm. $C_3H_4N_6O_6$ (220.11): calcd. C 16.37, H 1.83, N 38.18; found C 16.55, H 2.21, N 38.53.

**Guanidinium Nitroformate (4):** IR (KBr): $\tilde{\nu}$ = 3398, 1642, 1533, 1495, 1409, 1283, 868, 787 $cm^{-1}$. $^1H$ NMR: $\delta$ = 6.0 (br., 6 H) ppm. $C_2H_6N_6O_6$ (210.11): calcd. C 11.43, H 2.88, N 40.00; found C 11.49, H 2.72, N 39.27.

**3-Amino-1,2,4-triazolium Nitroformate (5):** IR (KBr): $\tilde{\nu}$ = 3360, 3152, 2765, 1686, 1561, 1482, 1284, 1153, 951, 785 $cm^{-1}$. $^1H$ NMR: $\delta$ = 10.12 (br., 4 H), 8.66 (s, 1 H) ppm. $^{13}C$ NMR: $\delta$ = 143.3 ppm. $C_3H_5N_7O_6$ (235.12): calcd. C 15.33, H 2.14, N 41.70; found C 15.44, H 1.94, N 41.72.

**Aminoguanidinium Nitroformate (6):** IR (KBr): $\tilde{\nu}$ = 3406, 3277, 3168, 1678, 1554, 1484, 1315, 1157, 787 $cm^{-1}$. $^1H$ NMR: $\delta$ = 7.41 (br., 1 H), 6.51 (br., 2 H), 5.92 (br., 2 H), 4.14 (br., 2 H) ppm. $C_2H_7N_7O_6$ (225.12): calcd. C 10.67, H 3.13, N 43.55; found C 10.80, H 2.87, N 43.01.

**Imidizolium Nitroformate (7):** IR (KBr): $\tilde{\nu}$ = 3398, 3150, 2983, 1587, 1537, 1484, 1370, 1285, 1157, 829 $cm^{-1}$. $^1H$ NMR: $\delta$ = 10.75 (br., 2 H), 8.57 (s, 1 H), 7.45 (s, 2 H) ppm. $^{13}C$ NMR: $\delta$ = 135.0, 120.2 ppm. $C_4H_5N_5O_6$ (219.11): calcd. C 21.93, H 2.30, N 31.96; found C 22.27, H 2.39, N 31.32.

**Pyrazolium Nitroformate (8):** IR (KBr): $\tilde{\nu}$ = 3131, 3061, 2839, 1763, 1561, 1391, 1245, 1040, 825 $cm^{-1}$. $^1H$ NMR: $\delta$ = 8.00 (s, 2 H), 6.65 (s, 1 H) ppm. $^{13}C$ NMR: $\delta$ = 135.0, 107.7 ppm. $C_4H_5N_5O_6$ (219.11): calcd. C 21.93, H 2.30, N 31.96; found C 21.88, H 2.11, N 31.83.

**2-Methylimidazolium Nitroformate (9):** IR (KBr): $\tilde{\nu}$ = 3403, 3121, 2993, 2721, 1625, 1537, 1483, 1269, 1157, 756 $cm^{-1}$. $^1H$ NMR: $\delta$ = 7.28 (s, 2 H), 2.61 (s, 3 H) ppm. $^{13}C$ NMR: $\delta$ = 119.4, 11.7 ppm. $C_5H_7N_5O_6$ (233.14): calcd. C 25.76, H 3.03, N 30.04; found C 25.54, H 2.70, N 29.86.

**3,6-Diguanidino-1,2,4,5-tetrazinium Nitroformate (10):** IR (KBr): $\tilde{\nu}$ = 3400, 3345, 3281, 2945, 2872, 1703, 1592, 1417, 947 $cm^{-1}$. $^1H$ NMR: $\delta$ = 7.79 (br., 10 H) ppm. $^{13}C$ NMR: $\delta$ = 159.6, 155.9 ppm. $C_6H_{10}N_{16}O_{12}$ (498.24): calcd. C 14.46, H 2.02, N 44.98; found C 14.26, H 2.18, N 45.64.

***N*-Guanylurea Nitroformate (11):** IR (KBr): $\tilde{\nu}$ = 3400, 3345, 3281, 2945, 2872, 1703, 1592, 1417, 947 $cm^{-1}$. $^1H$ NMR: $\delta$ = 7.29 (br., 5 H), 5.90 (br., 2 H) ppm. $^{13}C$ NMR: $\delta$ = 156.7, 154.7 ppm. $C_3H_7N_7O_7$ (253.13): calcd. C 14.23, H 2.79, N 38.73; found C 14.22, H 2.59, N 37.94.

**Supporting Information** (see also the footnote on the first page of this article): Synthesis of nitroform.

## Acknowledgments

We gratefully acknowledge the support of Air Force Office of Scientific Research (AFOSR) (F49620-03-1-0209), National Science Foundation (NSF) (CHE0315275), and Office of Naval Research (ONR) (N00014-06-1-1032). We appreciate the work of Drs. Gary Knerr and Alex Blumenfeld for mass spectra and NMR analyses, respectively. # Mixed-Valent Linear Chain $Pt_2PdPt_2$ Complexes

Saiko Arai,[a] Masahiko Ochiai,[a] Koji Ishihara,*[a,b] and Kazuko Matsumoto*[a]

**Keywords:** Platinum / Palladium / Chain structures / Metal–metal interactions / Mixed-valent compounds

Pentanuclear linear-chain PtPd complexes $\{[Pt_2(NH_3)_2X_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[PdX'_4]\}\cdot 2CH_3COCH_3$ (X = X′ = Cl (**1a**), X = Cl, X′ = Br (**1b**), X = Br, X′ = Cl (**1c**), X = X′ = Br (**1d**)) composed of a monomeric $Pd^{II}$ complex sandwiched by two amidato-bridged dimeric $Pt^{III}$ units were synthesized from the reaction between the acetonyl dinuclear $Pt^{III}$ complexes having equatorial halide ligands $[Pt_2(NH_3)_2X_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]X''$ (X = Cl (**2a**), Br (**2b**), X″ = $NO_3^-$, $CH_3C_6H_4SO_3^-$) and $K_2[PdX'_4]$ (X′ = Cl, Br). The X-ray crystallographic analysis of **1a**–**1d** shows that the complexes have metal–metal bonded linear $Pt_2PdPt_2$ structures. The pentanuclear PtPd complexes have either an arch backbone structure or a sigmoid backbone structure, depending on the solvent of crystallization. The UV/Vis/NIR spectra clearly show the existence of a rare charge-transfer band from Pd to Pt in the pentanuclear PtPd complexes.

## Introduction

Discrete metal chains composed of direct metal–metal interactions are of current interest from both theoretical and practical points of view.[1] One of the synthetic methods for this class of compounds is based on ligand-assisted metal–metal bond formation reactions by using polydentate ligands.[2,3] In this case, the number of the available coordination atoms of the ligand determines the length of the metal–metal chain. One of the representative cases is the family of metal string complexes supported by oligo-α-pyridylamido ligands.[2] A second approach involves the formation of metal–metal bonds by oxidation of $d^8$ square-planar complexes or by reduction of $d^7$ octahedral complexes, in which mixed-valent metal chain complexes are formed, such as platinum,[4–6] rhodium, and iridium blues.[7] The latter approach recently successfully extended the chain length to infinity, and allowed the isolation of the rare rhodium[8] and platinum one-dimensional mixed-valence compounds.[9,10] One-dimensional infinite platinum chain compounds,[11–13] such as Magnus' green salt[12] are another well known class of compounds, in which the metal–metal bond interactions rely upon self-stacking of square-planar complexes. Apart from these approaches, we previously reported pentanuclear Pt chain complexes $\{[Pt_2(NH_3)_2X_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[PtX'_4]\}\cdot n CH_3COCH_3$ (X = X′ = Cl, $n$ = 2 (**3a**), X = Cl, X′ = Br, $n$ = 1 (**3b**), X = Br, X′ = Cl, $n$ = 2 (**3c**), X = X′ = Br, $n$ = 1 (**3d**))[14] having Pt–Pt···Pt···Pt–Pt structures with strong $Pt^{III}$···$Pt^{II}$ interactions between the $Pt^{III}$ dinuclear and $[PtX'_4]^{2-}$ units. The pentanuclear structures are maintained even in solution.

The number of $Pd^{III}$ complexes that have been isolated and characterized is very limited, compared to the number of the mixed-valence Pt(II,III) chain species such as platinum blues.[4–6] Although paddlewheel compounds are known for most of the transition elements, there are only two types of structurally characterized Pd compounds having $Pd^{III}_2$ cores.[15] Palladium hardly makes a $Pd^{III}$–$Pd^{III}$ σ bond based on the $d_{z^2}$–$d_{z^2}$ overlap; if any it would be hard to observe experimentally.[15c] Attempts to generate a seemingly less difficult heterodinuclear $Pt^{III}Pd^{III}$ system have so far failed; oxidation of the dinuclear $Pt^{II}Pd^{II}$ complex $[(X_2)Pt(1\text{-MeU})_2Pd(Y_2)]Z$ ($X_2$, $Y_2$ = $(NH_3)_2$, en, or bpy; Z = $(NO_3)_2$, $(ClO_4)_2$, or $SO_4$) resulted in cleavage of the dinuclear complex into mononuclear $Pt^{IV}$ and $Pd^{II}$ complexes.[16] The dinuclear $Pt^{II}Pd^{II}$ complexes with Pt→Pd dative bonds, *trans*-$[(RNH_2)_2Pt(amidato)_2PdCl]^+$ (R = H, $CH_3$) or *trans*-$[(RNH_2)_2Pt(amidato)_2Pd(NH_3)]^{2+}$ (R = H, $CH_3$), have been reported, in which the coordination planes of Pt and Pd are perpendicular to each other and Pd is coordinated by Pt.[17] Only two trinuclear $Pt^{II}Pd^{III}Pt^{II}$ complexes with charge transfer from Pt to Pd have been reported, in which Pt–Pd σ bonds by the $d_{z^2}$–$d_{z^2}$ overlap are involved.[18]

We report here the synthesis of the novel pentanuclear PtPd complexes $\{[Pt_2(NH_3)_2X_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[PdX'_4]\}\cdot 2CH_3COCH_3$ (X = X′ = Cl (**1a**), X = Cl, X′ = Br (**1b**), X = Br, X′ = Cl (**1c**), X = X′ = Br (**1d**)) and $\{[Pt_2(NH_3)_2Cl_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[PdCl_4]\}\cdot H_2O$ (**1a′**) having Pt–Pt–Pd–Pt–Pt structures with strong Pt–Pd interactions maintained by novel charge transfer from Pd to Pt (Scheme 1).

## Results and Discussion

### Synthesis and Characterization

The pivalamidato-bridged pentanuclear linear chain $Pt_2PdPt_2$ complexes **1a**–**1d** were synthesized in the same way as **3a**–**3d**[14a] from the reaction of 2 equiv. of **2a** or **2b** with 1 equiv. of $K_2[PdX'_4]$ (X′ = Cl, Br). The FAB-MS spectra of **1a**–**1d** showed the presence of molecular ions of **1a**–**1d**. Considering the fact that weak bonds such as ionic bonds are usually fragmented in FAB-MS spectra, the Pt···Pd interactions between the dinuclear units and the mononuclear unit seem to be substantially strong. The $^{195}Pt\{^1H\}$ NMR spectroscopic data of **1a**, **1d**, and related compounds including **3a** and **3d** are listed in Table 1. In Table 1, only one signal was observed for **1d**, and the satellite signals due to Pt–Pt coupling were not observed for **3a**, whereas all the signals were observed for **1a** and **3d**. The $^{195}Pt$ NMR spectra of **1a** and **3d** are shown in Figure 1. For **1a** and **3d**, the least-shielded signals at $\delta$ = 269 ppm (**1a**) and –230 ppm (**3d**) can be assigned to the $Pt(X_2O_2)$ atom (the elements in the parenthesis are coordination atoms), while the more- and most-shielded signals at $\delta$ = –2173 ppm (**1a**) and –2254 ppm (**3d**), and –2689 ppm (**3d**) can be assigned to the $Pt(N_4)$ and the $Pt(Br_4)$, according to the results of the $^{195}Pt$ NMR measurements for the related amidato-bridged $Pt^{III}$ dinuclear complexes.[14,19] In fact, the peaks at $\delta$ = –2173 ppm (**1a**) and –2254 ppm (**3d**), and –2689 ppm (**3d**) are broader than those at $\delta$ = 269 ppm (**1a**) and –230 ppm (**3d**), and would be caused by quadrupole moments of the N atom and Br atoms [the nuclear spin quantum numbers (*I*) of $^{14}N$ and $^{81}Br$ are 1 and 3/2, respectively] coordinated to the Pt atom. The assignment of the broad peaks at $\delta$ = –2173 ppm (**1a**) and –2254 ppm (**3d**) is also supported by the fact that the $Pt(N_4)$ peak is split and most broadened because of the Pt–Pd (**1a**) or Pt–Pt (**3d**) coupling in addition to the Pt–N coupling. In **1d**, the peak of the $Pt(N_4)$ was more broadened than the corresponding $Pt(N_4)$ peak in **3d** because of the coupling with the Pd atom ($^{105}Pd$, $I$ = 5/2).

Table 1. The $^{195}Pt$ NMR chemical shifts of the pentanuclear complexes and related compounds.

| Complexes[a] | Coordinated atoms | $\delta(^{195}Pt)$ [ppm] |
|---|---|---|
| **1a**[b] | $Cl_2O_2$ | 269 |
| | $N_4$ | –2173 |
| | $Cl_4$ | ND |
| **1d**[b] | $Br_2O_2$ | –231 |
| | $N_4$ | ND |
| | $Br_4$ | ND |
| **3a**[b] | $Cl_2O_2$ | 268 |
| | $N_4$ | –2208 |
| | $Cl_4$ | –1888 |
| **3d**[b] | $Br_2O_2$ | –230 |
| | $N_4$ | –2254 |
| | $Br_4$ | –2689 |
| **2a**[c] | $Cl_2O_2$ | 253 |

| $K_2[Pt^{II}Cl_4]$[d] | $Cl_4$ | –1623 |
| $K_2[Pt^{II}Br_4]$[d] | $Br_4$ | –2672 |

[a] PVM: $(CH_3)_3CCONH$; X′′′ = $p$-$CH_3C_6H_4SO_3^-$, $NO_3^-$. [b] Measured in $[D_6]$acetone/$D_2O$ (9:1), and locked with $D_2O$ in an inner tube. [c] Measured in $[D_6]$acetone, and locked with $D_2O$ in an inner tube. [d] Measured in $D_2O$.

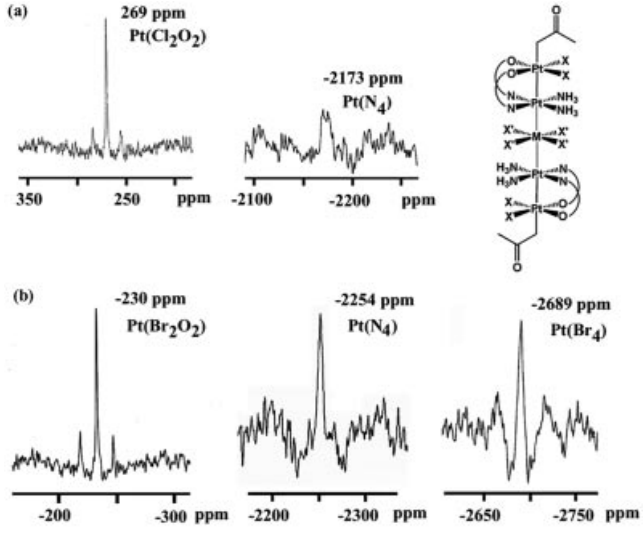

Figure 1. The $^{195}Pt$ NMR spectra of the pentanuclear PtPd complex (**1a**) and the pentanuclear Pt complex (**3d**): (a) $\{[Pt_2(NH_3)_2Cl_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[PdCl_4]\}\cdot 2CH_3COCH_3$ (**1a**), (b) $\{[Pt_2(NH_3)_2Br_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[PdBr_4]\}\cdot 2CH_3COCH_3$ (**3d**).

The broadenings caused by the couplings suggest that the $Pt_2MPt_2$ (M = Pt, Pd) backbones are retained even in solution. The UV/Vis/NIR spectra also showed the formation of the $Pt_2PdPt_2$ structures in the reaction solutions (see below).

Gradual evaporation of acetone from the reaction solution of **1a** gave two types of complexes from the same reaction solution, one with the arch structure (**1a**) and another

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with the sigmoid structure (**1a′**). Crystallization of **1b** gave only one product as orange microcrystals because **1b** was quickly evaporated to avoid decomposition to black precipitate. The FAB-MS spectrum of the orange microcrystals showed the presence of molecular ions, and the elemental analysis approximately corresponded to **1b** with two molecules of acetone solvent. Crystallizations of **1c** and **1d** were carried out similarly to **1a**, however, **1c** and **1d** gave complexes of the arch structure and the sigmoid structure, respectively. In the case of **1d**, black precipitate was also obtained.

### Crystal Structures

The X-ray structures of **1a** and **1a′** are shown in Figure 2. The structural parameters of **1a**, **1a′**, **1c**, **1d**, and **4b** are listed in Table 2. We have already reported that the equatorial halide ligands in the dimer units of **3a**–**3d** polarize the $R–Pt^{III}–Pt^{III}$ (R is acetonyl) in the amidato-bridged dimer approximately to $R–Pt^{IV}–Pt^{II}$ and induce the electron transfer from the monomer unit to the dimer units having the axial acetonyl ligands to stabilize the Pt–Pt bonds between the dimer and monomer units.[14,20] The same polarization of the Pt–Pt bonds in the dimer units of **1a**, **1a′**, **1c**, and **1d** is considered to work similarly in the pentanuclear structures of **1a**, **1a′**, **1c**, and **1d**. Such polarization of the Pt–Pt bonds in the dimer units is proved by the $^{195}Pt$ NMR spectra of both PtPd and PtPt complexes.

Two types of PtPd backbones, the arch structure (**1a**) and the sigmoid structure (**1a′**), were obtained from the same mother liquor as mentioned above. We previously reported that **3a** also had both arch and sigmoid backbones,[14a] but they were obtained from different mother liquors. In the present case, **1a**, which has two acetone molecules of crystallization, is formed preferentially from the mother liquor when acetone is moderately evaporated, while **1a′** is preferentially formed when the evaporation of acetone is either depressed or very rapid. In the crystals of **1a** two molecules of the arch PtPd complex exist facing each other probably by hydrophobic interaction. In the crystals of **1a** the pentanuclear $Pt_4Pd$ molecules are regularly arranged by both intermolecular hydrophobic and hydrophilic interactions. As will be mentioned later, once-separated and redissolved solutions of **1a** and **1a′** showed the same spectral and chemical behavior. So the formation of **1a** and **1a′** would be explained as follows. The symmetrical sigmoid structure of **1a′** would be energetically favored and exist predominantly in the acetone-rich aqueous solution, because **1a′** would be favorably solvated by the moderately polar solvent, acetone in acetone-rich aqueous solution. So **1a′** crystallizes out by itself when the evaporation of acetone does not occur or occurs rapidly. On the other hand, in view of the fact that solubilities of **1a** and **1a′** into water are very low, **1a′** cannot gain such solvation energy in acetone-poor aqueous solution, so that **1a′** transforms into **1a** to gain stabilization energy from intermolecular interaction. Thus, when acetone evaporates gradually to make

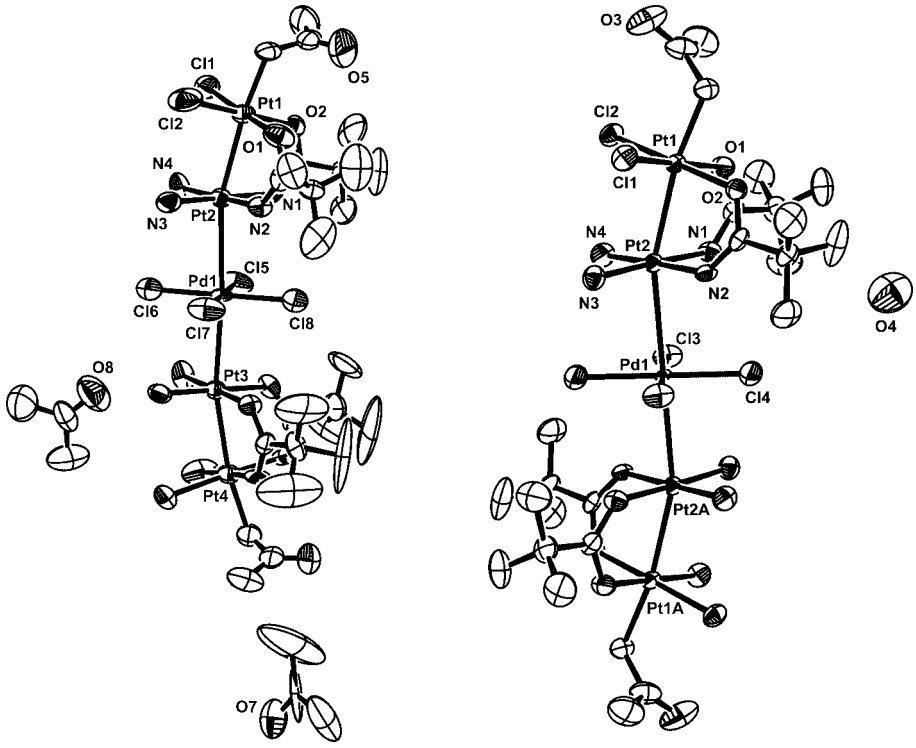

Figure 2. Crystal structures of the arch PtPd backbone complex (**1a**) and the sigmoid PtPd backbone complex (**1a′**): (a) $\{[Pt_2(NH_3)_2Cl_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[PdCl_4]\}\cdot 2CH_3COCH_3$ (**1a**), (b) $\{[Pt_2(NH_3)_2Cl_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[PdCl_4]\}\cdot H_2O$ (**1a′**). H atoms are omitted for clarity.

the acetone-rich aqueous solution into an acetone-poor aqueous solution, **1a** comes out.

In the previous paper, it was concluded that the charges of the Pt atoms in **3a**–**3d** are not delocalized as in the platinum blues[4–6] but are localized approximately to $Pt^{III}_2Pt^{II}Pt^{III}_2$. The distances of $Pt(N_4)$–$Pt(X_4)$ [3.0054(11)–3.1109(15) Å] in **3a**–**3d** are significantly shorter than the $Pt(N_4)$–$Pt(Cl_4)$ distance (3.24 Å)[9] in Magnus' green salt, so the interactions between $Pt(N_4)$ and $Pt(X_4)$ are stronger in **3a**–**3d**, though the distances are slightly longer than a typical Pt–Pt single bond. However, it was found in the present study that the charges of the Pt atoms in **1a**, **1a′**, **1c**, **1d**, **4b**, and **3a**–**3d** are much more delocalized through the Pt backbones, as shown by the UV/Vis/NIR spectra (see below).

The X-ray structure of $[Pt_2(NH_3)_2Br_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[Pt(NO_2)_4]$ (**4b**) is shown in Figure S3 (Supporting Information). The structural parameters of **4b** are listed in Table 2. The distances of $Pt(N_4)$–$Pt(X_4)$ in **4b** are too long to be a significant Pt–Pt interaction, so **4b** would not have a Pt–Pt bond between the monomer unit and the dimer units (see below).

## Observation of Charge Transfers with UV/Vis/NIR Measurements

Long-wavelength absorption bands are known for the mixed-valence species such as tetranuclear platinum blues ($\lambda_{max}$ = about 500 nm and 680–750 nm)[5] and the octanuclear platinum blue ($\lambda_{max}$ = 540 nm and 1140 nm).[6] In these platinum blues, the latter bands are assigned to intervalence excitation from the inner Pt–Pt σ orbital to the inner Pt–Pt σ* orbital.[5c,6c] The present pentanuclear $Pt_4Pd$ complexes **1a**–**1d** also have the intervalence charge transfer (IVCT) bands, which are similar to those of **3a**–**3d** (Table 3).

The absorption spectra of **2a** and $K_2[PdCl_4]$ are shown in Figure 3. The broad band ($\lambda_{max}$ = 423 nm) in the $K_2[PdCl_4]$ spectrum is assigned to Cl → Pd LMCT transitions.[21] Complex **2a** has two strong absorption bands at $\lambda_{max}$ = 325 and 434 nm. The former band is assigned to Pt → Pt MMCT transitions as judged from the comparison with other amidato-bridged $Pt^{III}$ dinuclear complexes,[22] and the latter is assigned to Cl → Pt LMCT transitions. Obviously, there is no absorption band above 650 nm in the spectra. Figure 4 shows the time course of the UV/Vis/NIR spectral change during the reaction between **2a** and $K_2[PdCl_4]$ in aqueous acetone solution. The spectral change shows the process of **1a** formation. Little occurred until about 7 h after mixing, when the reaction started with a gradual rise of the IVCT absorption band at $\lambda_{max}$ = 735 nm, and was complete after about 10 h. This absorption band was also observed when the crystals of **1a** or **1a′** were dissolved into the aqueous acetone solvent, and both solutions of **1a** and **1a′** showed an identical spectrum.

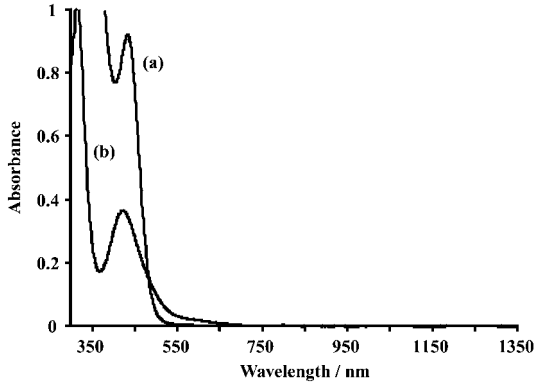

Figure 3. The UV/Vis/NIR spectra of **2a** and $K_2[PdCl_4]$: (a) acetone/water (9:1) solution of **2a** ($4.5 \times 10^{-4}$ M), (b) aqueous solution of $K_2[PdCl_4]$ ($2.5 \times 10^{-3}$ M).

Table 3. Absorption bands of **1a**–**1d** and **3a**–**3d** at various conditions.[a]

| | **1a**, **1a′** | **1b** | **1c** | **1d** | **3a** | **3b** | **3c** | **3d** |
|---|---|---|---|---|---|---|---|---|

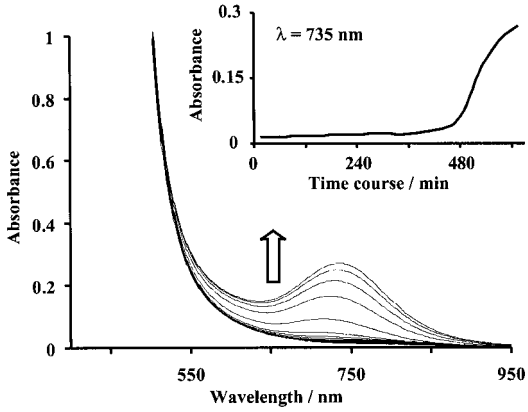

Figure 4. The time-course UV/Vis spectra for the pentanuclear PtPd backbone formation of **1a**. Spectra were recorded every 30 min after mixing solutions (a) and (b) in a quartz cell with 5-mm pathlength at room temperature. (a) 1.8 mL of the acetone solution of **2a** ($1.0 \times 10^{-2}$ M), (b) 0.2 mL of the aqueous solution of $K_2[PdCl_4]$ ($4.5 \times 10^{-2}$ M).

After reaction completion, the solution of **1a** was several-fold diluted and the spectrum was measured as shown in Figure 5. It is obvious that the original absorption bands at $\lambda_{max}$ = 382 and 735 nm remain up to about 30-fold dilution. It is noteworthy that the Pt–Pd σ bonds are kept even in such a dilute solution of $1.5 \times 10^{-4}$ M.

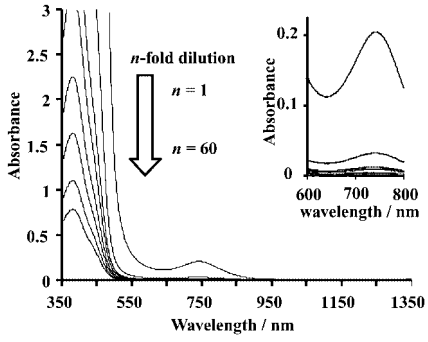

Figure 5. The UV/Vis/NIR spectra of **1a** with different concentrations. The acetone/water (9:1) solution of **1a** ($4.5 \times 10^{-3}$ M) was *n*-fold diluted with acetone/water (9:1) mixed solvent: $n$ = 1 (no dilution), 5, 10, 15, 20, 30, 40, and 60.

Similar measurements were carried out for **1b**–**1d** and **3a**–**3d**, and similar results were obtained (see Figures S4–S17, Supporting Information).

The diffuse reflectance spectra of the microcrystals of **1a** and **1a′** in the range of 200–2000 nm were measured, and are shown in Figure 6 along with the spectra of **2a** and $K_2[PtCl_4]$. Figure 6 clearly shows the IVCT absorption band at around 850 nm. Complexes **3a**–**3d** and **1b**–**1d** also show the IVCT bands, as shown in Figures S18 and S19.

Recently, sensitivity of diffuse reflectance spectroscopy has greatly improved. We used the Kubelka–Munk transformation,[23] which can convert a reflectance spectrum into a spectrum similar to a conventional absorption spectrum for solution samples, to compare the reflectance and absorption spectra to each other. According to the Kubelka–Munk theory,[23] the Kubelka–Munk function $F(R_\infty)$ is

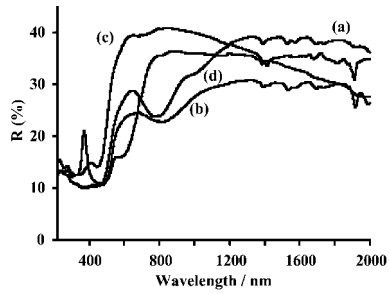

Figure 6. The diffuse reflectance spectra of **3a**, **2a**, $K_2PtCl_4$, and **1a**: (a) red-orange crystals of **3a**, (b) yellow powders of **2a**, (c) pale red powders of $K_2[PtCl_4]$, (d) yellow-orange crystals of **1a**.

given by the following equation for "infinitely thick" layers. In the equation $R_\infty$ is the absolute reflectance for an infinitely thick sample and $k$ is the absorption coefficient of the layer at a given wavelength,

$$F(R_\infty) = \frac{(1-R_\infty)^2}{2R_\infty} = \frac{k}{S} = \frac{\varepsilon c}{S}$$

$S$ is the scattering coefficient (depending on the size and form of the particles), $\varepsilon$ is the molar extinction coefficient of the analyte, and $c$ is the molar concentration. The converted Kubelka–Munk spectra and the absorption spectra of **1a** and **1a′** in solution are shown in Figure 7 (see also Figures S20, S21 in the Supporting Information).

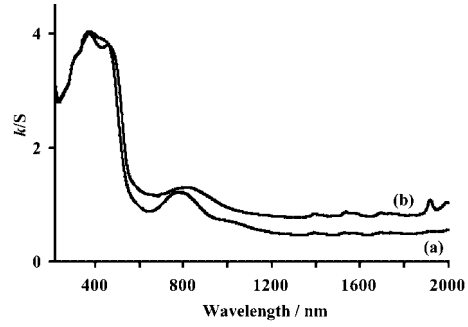

Figure 7. The transformed diffuse reflectance spectra of **1a** and **1a′**: (a) the arch PtPd backbone structure of **1a**, (b) the sigmoid PtPd backbone structure of **1a′**.

The band of the sigmoid backbone structure **1a′** in Figure 7 appeared at a longer wavelength than the arch one (**1a**), probably because the overlaps of $d_{z^2}$ orbitals of Pt and Pd in **1a′** are more linear and therefore more efficient than in **1a**. The close similarity of the spectra in Figures 7 and 5 supports the assumption that the pentanuclear $Pt_2MPt_2$ structure is maintained, even in dilute solution.

### Synthetic Elucidation of the Charge Transfer

In our previous article[14a] it was shown by the DFT calculation for **3a**–**3d** that the Pt···Pt interactions consist of the electron transfer from the monomer to the dimers. In the present study we prepared several pentanuclear $Pt_4Pd$ complexes with different mononuclear complexes to examine

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

whether the same electron transfer as in **3a**–**3d** exists in **1a**–**1d** or not.

According to the DFT calculation of **3a**–**3d**, the p orbitals of halide ligands of the monomer unit, especially $p_y$ orbital, donate electrons to the $Pt(X_4)$, and the $d_{z^2}$ orbital of the $Pt(X_4)$ donates electrons to the Pt dimeric units.[14a] The π donor ability of the halide ligands would play a role in the electron flows through the Pt chains.

At first, we tried to prepare the pentanuclear analogues by using $[M(dmit)_2]^{2-}$ (M = Pt, Pd; dmit = 2-thioxo-1,3-dithiole-4,5-dithiolate) as a monomer complex, in which dmit is a σ donor and weak π acceptor contrary to halide ligands.[24] The metal complexes with dmit ligand are used to prepare charge transfer (CT) complexes similar to the organic CT compounds, such as BEDT-TTF, a well-known molecular metal and molecular superconductor.[25] As a result, pentanuclear complexes could not be synthesized, because dmit is a weak π acceptor.

In another attempt, we used $[M(CN)_4]^{2-}$ (M = Pt, Pd) as a monomer complex. $CN^-$ is a weaker σ donor and weaker π acceptor than dmit.[24] The monomeric complex $K_2[Pt(CN)_4]$ is used to prepare the well-known Krogmann salt (KCP).[11] No pentanuclear complex was synthesized from the reaction of **2a** or **2b** with $[M(CN)_4]^{2-}$ (M = Pt, Pd), as shown in the VIS/NIR spectra (Figure S22).

Further, we used the $NO_2^-$ ligand, which is a weaker σ donor and weaker π acceptor than the $CN^-$ ligand.[24] Arch-like poor crystals of **4a** and needle crystals of **4b** were obtained. The former crystals would be $[Pt_2(NH_3)_2Cl_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[Pt(NO_2)_4]$ (**4a**), though the structure could not be confirmed by X-ray analysis because of their poor crystallinity. The latter was $[Pt_2(NH_3)_2Br_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[Pt(NO_2)_4]$ (**4b**), as confirmed by X-ray analysis. The distances of $Pt(N_4)$–$Pt(X_4)$ in **4b** are too long to be significant Pt–Pt interactions (about 3.4 Å), and correspondingly the reaction solutions did not show any absorption bands in the NIR region (Figures S23 and S24). The relative bulkiness of $NO_2^-$ compared with halide would not be responsible for the long $Pt(N_4)$–$Pt(X_4)$ distance, because the coordination planes of the dimer units and the monomer unit are rotated to each other in a staggered form, as in all other pentanuclear complexes, to avoid steric hindrance among the coordinating ligands (Figure 8). The FAB-MS spectrum of the saturated solution of **4b** shows the small peaks of its molecular ion.

Thus, it seems that $[PtX'_4]^{2-}$, as well as other mononuclear complexes with ligands having considerable π donor ability, can form pentanuclear complexes, and the electron flow from the $Pd(X_4)$ to the $Pt(N_4)$ creates a strong $Pt_{dimer}$–$Pd_{monomer}$ interaction in **1a**–**1d**, which is similar to the interaction of $Pt_{dimer}$–$Pt_{monomer}$ in **3a**–**3d**.

## Concluding Remarks

Novel linear pentanuclear complexes having $Pt_2PdPt_2$ chain backbones have been synthesized from the reaction between the amidato-bridged $Pt^{III}$ dimer complexes and $[PdX_4]^{2-}$. The pentanuclear complexes are composed of two units of the amidato-bridged $Pt^{III}$ dimer complexes sandwiching one unit of $[PdX_4]^{2-}$. The interactions between the $Pt^{III}$ dimer units and the $Pd^{II}$ monomer unit are strong enough to hold the linear pentanuclear chain structure retained in solution. The UV/Vis/NIR spectra clearly showed the charge transfer from the π donor chloride ligands of the Pd or Pt monomer unit to the $Pt^{III}$ dinuclear units with axial acetonyl ligands. Such charge transfer from Pd to Pt is quite rare, and in fact multinuclear complexes involving a Pd→Pt dative bond are not known. It is noteworthy that the Pd–Pt bond is maintained even in highly diluted solution.

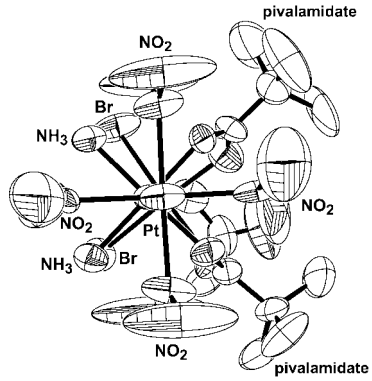

Figure 8. The structure of $[Pt_2(NH_3)_2Br_2(\mu\text{-pivalamidato})_2(CH_2COCH_3)]_2[Pt(NO_2)_4]$ (**4b**) viewed along the Pt axis from the monomer unit to the dimer unit.

## Experimental Section

**Materials and Methods:** All the reactions and manipulations were performed in air and in the dark. Solvents were used as received. All the reagents were purchased from commercial sources and used as received. The complexes, $[Pt_2(NH_3)_2X_2\{(CH_3)_3CCONH\}_2(CH_2COCH_3)]X''$ (X = Cl, X'' = $NO_3^-$ or $CH_3C_6H_4SO_3^-$ (**2a**), X = Br, X'' = $NO_3^-$ or $CH_3C_6H_4SO_3^-$ (**2b**)), $[\{Pt_2(NH_3)_2X_2\{(CH_3)_3CCONH\}_2(CH_2COCH_3)]_2\}][PtX'_4]\cdot n CH_3COCH_3$ (X = X' = Cl, *n* = 2 (**3a**), X = Cl, X' = Br, *n* = 1 (**3b**), X = Br, X' = Cl, *n* = 2 (**3c**), X = X' = Br, *n* = 1 (**3d**)), and $K_2[Pt(NO_2)_4]$, were prepared as reported.[14,26]

Elemental analyses were carried out on a Perkin–Elmer PE 2400II. The $^1H$ NMR spectra were recorded with a JEOL Lambda 270 spectrometer and a Bruker AVANCE 400 spectrometer operating at 270 MHz and 400 MHz for $^1H$, respectively. The $^{195}Pt\{^1H\}$ NMR spectra were recorded with a JEOL Lambda 500 spectrometer operating at 107.3 MHz for $^{195}Pt$. Chemical shifts are in $\delta$ unit (parts per million, ppm) referenced to $(CD_3)_2CO$ at $\delta$ = 2.04 ppm for $^1H$ and to $H_2[PtCl_6]$ (external reference, 0 ppm) or $K_2[PtCl_4]$ (external reference, –1622 ppm) for $^{195}Pt$. The mass spectra were measured with a JEOL JMS-SX102A spectrometer (FAB) and Thermo Quest LCQ-Deca spectrometer (ESI). The UV/Vis/NIR absorption spectra were measured with a JASCO Ubest V-570 with a cell holder for 5-mm pathlength. The diffuse reflectance spectra were measured with a JASCO Ubest V-570 with the custom-tailored integrating sphere unit.

**Preparation of {[$Pt_2(NH_3)_2Cl_2$(μ-pivalamidato)$_2(CH_2COCH_3)$]$_2$-[$PdCl_4$]}·$2CH_3COCH_3$ (1a):** A solution of **2a** (0.02 mmol) in acetone (2.0 mL) was added into an aqueous solution of $K_2[PdCl_4]$ (6.52 mg, 0.02 mmol, in 0.4 mL of water). The color of the reaction solution immediately changed from yellow to red. Yellow-orange crystals were obtained by slow evaporation of acetone in the dark. Yield: 8.49 mg, 45% (as crystals). $C_{32}H_{74}Cl_8N_8O_8PdPt_4$ (1869.3): C 20.56, H 3.99, N 5.99; found C 20.48, H 3.67, N 5.54. $^1$H NMR (400 MHz, [D$_6$]acetone, 23 °C): $\delta$ = 5.20 (s, 4 H, $CH_2$), 2.25 (s, 6 H, $CH_3$), 1.16 (s, 36 H, $CH_3$). FAB-MS (positive) 1753.1 (molecule + $H^+$).

**Preparation of {[$Pt_2(NH_3)_2Cl_2$(μ-pivalamidato)$_2(CH_2COCH_3)$]$_2$-[$PdCl_4$]}·$H_2O$ (1a′):** Dark orange crystals of **1a′** were obtained from the mother solution of **1a**. The evaporation conditions to sort the conformation of the PtPd backbones are shown in the text. Yield: 9.61 mg, 54% (as crystals). $C_{26}H_{64}Cl_8N_8O_7PdPt_4$ (1771.2): C 17.63, H 3.64, N 6.33; found C 17.65, H 3.43, N 6.05. $^1$H NMR (400 MHz, [D$_6$]acetone, 23 °C): $\delta$ = 5.20 [s, $^2J$(Pt,H) = 78.8 Hz, 4 H, $CH_2$], 2.26 (s, 6 H, $CH_3$), 1.17 (s, 36 H, $CH_3$) ppm.

**Preparation of {[$Pt_2(NH_3)_2Cl_2$(μ-pivalamidato)$_2(CH_2COCH_3)$]$_2$-[$PdBr_4$]}·$2CH_3COCH_3$ (1b):** The reaction solution of complex **1b** was prepared by the reaction of **2a** with $K_2[PdBr_4]$ (10.08 mg, 0.02 mmol). Orange microcrystals were obtained by speedy evaporation with a rotary evaporator to avoid decomposition. Yield 10.17 mg, 53%. $C_{32}H_{74}Br_4Cl_4N_8O_8PdPt_4$ (2047.1): C 18.77, H 3.64, N 5.47; found C 18.74, H 3.17, N 4.89. $^1$H NMR (400 MHz, [D$_6$]-acetone, 23 °C): $\delta$ = 5.22 (s, 4 H, $CH_2$), 2.26 (s, 6 H, $CH_3$), 1.21 (s, 36 H, $CH_3$). FAB-MS (positive) 1931.9 (molecule + $H^+$).

**Preparation of {[$Pt_2(NH_3)_2Br_2$(μ-pivalamidato)$_2(CH_2COCH_3)$]$_2$-[$PdCl_4$]}·$2CH_3COCH_3$ (1c):** Complex **1c** was prepared in the same way as **1a** by the reaction of **2b** with $K_2[PdCl_4]$ (6.52 mg, 0.02 mmol), and was obtained as yellow-orange crystals. Yield 8.88 mg, 43% (as crystals). $C_{32}H_{74}Br_4Cl_4N_8O_8PdPt_4$ (2047.1): C 18.77, H 3.64, N 5.47; found C 18.82, H 3.69, N 5.19. $^1$H NMR (400 MHz, [D$_6$]acetone, 23 °C): $\delta$ = 5.27 [s, $^2J$(Pt,H) = 84.0 Hz, 4 H, $CH_2$], 2.28 (s, 6 H, $CH_3$), 1.17 (s, 36 H, $CH_3$). FAB-MS (positive) 1932.0 (molecule + $H^+$).

**Preparation of {[$Pt_2(NH_3)_2Br_2$(μ-pivalamidato)$_2(CH_2COCH_3)$]$_2$-[$PdBr_4$]}·$2CH_3COCH_3$ (1d):** Complex **1d** was prepared in the same way as **1a** by the reaction of **2b** with $K_2[PdBr_4]$ (10.08 mg, 0.02 mmol), and was obtained as red-orange crystals. Yield 5.27 mg, 24% (as crystals). $C_{32}H_{74}Br_8N_8O_8PdPt_4$ (2224.9): C 17.27, H 3.35, N 5.04; found C 17.02, H 3.28, N 4.85. $^1$H NMR (400 MHz, [D$_6$]acetone, 23 °C): $\delta$ = 5.30 (s, 4 H, $CH_2$), 2.28 (s, 6 H, $CH_3$), 1.19 (s, 36 H, $CH_3$). FAB-MS (positive) 2109.3 (molecule + $H^+$).

**Preparation of [$Pt_2(NH_3)_2Cl_2$(μ-pivalamidato)$_2(CH_2COCH_3)$]$_2$-[$Pt(NO_2)_4$] (4a):** Complex **4a** was prepared in the same way as **1a** by the reaction of **2a** with $K_2[Pt(NO_2)_4]$ (2.29 mg, 0.005 mmol), and was obtained as poor yellow arch crystals. Yield 1.26 mg, 13% (as poor crystals).

**Preparation of {[$Pt_2(NH_3)_2Br_2$(μ-pivalamidato)$_2(CH_2COCH_3)$]$_2$-[$Pt(NO_2)_4$]}·$2CH_3COCH_3$ (4b):** Complex **4b** was prepared in the same way as **1a** by the reaction of **2b** with $K_2[Pt(NO_2)_4]$ (4.57 mg, 0.01 mmol). $C_{29}H_{68}Br_4N_{12}O_{15}Pt_5$ (2178.0): C 16.43, H 3.23, N 7.93; found C 16.79, H 3.13, N 7.19. FAB-MS (positive) 2062.8 (molecule + $H^+$).

**X-ray Structure Determination:** The data were collected on a Bruker SMART 1000 CCD diffractometer. The cell parameters were determined by using the programs SMART[27] and R-LATT.[28] Data reduction and integration were performed with the software package SAINT,[29] whereas the absorption collection was applied by using the program SADABS.[30] The structures were solved by full-matrix least-squares on $F^2$, and were refined with SHELXTL.[31] Hydrogen atoms were added in the idealized positions. Non-hydrogen atoms were refined with anisotropic temperature parameters. The crystal data are given in Table 4.

CCDC-631866 (for **1a**), -631865 (for **1a′**), -631867 (for **1c**), -631868 (for **1d**), and -631869 (for **4b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Full tables of the data collection parameters, anisotropic temperature factors, and bond lengths and angles for **1a**, **1a′**, **1c**, **1d**, and **4b**. Crystal structures of **1b**, **1c**, and **1d** are included. The UV/Vis/NIR spectra are also available.

## Acknowledgments

We wish to express our thanks for financial support from the 21COE "Practical Nano-Chemistry" project from MEXT, Japan and from a Waseda University Grant for Special Research Projects.

Table 4. Crystallographic data for **1a**, **1a′**, **1c**, **1d**, and **4b**.

# Synthesis, Crystal Structure, and Magnetic Properties of Two Manganese(II) Polymers Bearing Ferrocenecarboxylato Ligands

Zilu Chen,[a] Yunsheng Ma,[a] Fupei Liang,*[a] and Zhaohui Zhou[b]

**Keywords:** Manganese / Crystal structure / Ferrocenecarboxylato / Magnetic properties

Reactions of $Mn(ClO_4)_2{\cdot}6H_2O$ with $FcCO_2Na$ [Fc = ($\eta^5$-$C_5H_4$)Fe($\eta^5$-$C_5H_5$)] in methanol solution gave $[Mn_3(FcCO_2)_6(CH_3OH)_4]_n$ (**1**), and, in the presence of 4,4′-bipyridine (4,4′-bpy), $[Mn_3(FcCO_2)_6(H_2O)_2(4,4'\text{-bpy})]_n$ (**2**). Both complexes have the similar chains with a sequence of –Mn–($\mu_2$-COO)$_n$–Mn–($\mu_2$-COO)–Mn–($\mu_2$-COO)–Mn–($\mu_2$-COO)$_n$–Mn– ($n$ = 4 and 2 for complex **1** and **2**, respectively), which are constructed alternatively from mononuclear [$Mn^{II}$] units and dinuclear $[Mn_2(FcCO_2)_4]$ units by $\mu_2$-ferrocenecarboxylato-$O,O'$ bridging. The two $Mn^{II}$ ions in the dinuclear $[Mn_2(FcCO_2)_4]$ units of complex **1** are connected by four ferrocenecarboxylato ligands to form a swastika-like shaped skeleton, which is rare in metallocenecarboxylato complexes. However, the two $Mn^{II}$ ions in the dinuclear $[Mn_2(FcCO_2)_4]$ units of complex **2** are bridged only by two carboxylato ligands, and the other two ferrocenecarboxylato ligands in this unit bind in a chelating mode. The chains in complex **2** are further interconnected by the coordinated 4,4′-bipyridine molecules to form two-dimensional coordination sheets. Magnetic susceptibility measurements revealed a weak antiferromagnetic coupling for both complexes. A model Heisenberg chain comprising classical spins coupled through alternating exchange interactions $J_1$–$J_1$–$J_2$ (AF1–AF1–AF2) is proposed to describe the magnetic behavior.

## Introduction

The chemistry of polynuclear manganese complexes has drawn significant research interest in the recent years due to their intriguing network topologies and their potential use as precursors for molecule-based magnetic materials.[1] To elucidate the fundamental relationship between the structures and the magnetic properties, a number of polynuclear manganese(II) complexes with various types of ligands have been synthesized and characterized in addition to the theoretical treatment provided in this paper.[2] Many factors govern the assembly process, and it is desirable to select the appropriate extended bridging ligands that can transmit magnetic interactions and bind several metal centers through various bonding modes and also to introduce some chelating or linear ditopic ancillary ligands to tune the composition and structure.[3,4] Carboxylato ligands have been widely used because they can exist in diverse coordination modes such as terminal monodentate, chelating to one metal center, and bridging bidentate, in a *syn-syn*, *syn-anti*, or *anti-anti* configuration to two metal centers.[5,6] However, most of the work has been focused on organic carboxylates such as oxalate, malonate, succinate, fumarate, maleate, terephthalate, 1,3,5-benzenetricarboxylate, and reports on organometallic carboxylates are limited. From the viewpoint of constructing functional manganese compounds, it may be interesting to incorporate the carboxyl group with the ferrocene moiety, for it was thought that, in addition to the electronic factors that are operative, the ferrocene moiety might introduce steric restrictions which might affect the nature of the adducts formed. Furthermore, the multicentered adducts may present opportunities for studying electronic interactions between the manganese center and the ferrocenyl groups. Ferrocenes not only show good redox activity but also play important roles in the field of materials science, as components of catalysts, molecular magnets, and nonlinear optical materials.[7] To the best of our knowledge, only three papers have been published on manganese complexes with ferrocene-involving carboxylate groups as ligands.[8–10] Among them, only the study reported by Hou, et al. includes some investigation of the magnetic properties of the manganese complex with a *p*-ferrocenylbenzoato ligand.[9] In the other two cases, Tian, et al.[8] and Kondo et al.[10] described the redox properties of a dinuclear complex cation $[Mn_2(phen)_4(FCA)_2]^{2+}$ (FCA = dianion of 3-ferrocenyl-2-crotonic acid, phen = 1,10-phenanthroline) and a manganese supercubane $[Mn_{13}O_8(OCH_3)_6(fcdc)_6]{\cdot}8H_2O{\cdot}2CH_3OH{\cdot}2(CH_3)_2CO$ (fcdc = 1, 1′-ferrocenedicarboxylato), respectively. This information led us to pursue the design and synthesis of manganese complexes with the participa-

tion of ferrocene-involving carboxylato ligands and to investigate the magnetic properties of the compounds formed.

In this work, we chose ferrocenecarboxylato as the main ligand with the aim of investigating its ability to tune the structure and magnetic properties of $Mn^{II}$ complexes. We present here the synthesis and characterization of two antiferromagnetic manganese coordination polymers, $[Mn_3(FcCO_2)_6(CH_3OH)_4]_n$ (**1**) and $[Mn_3(FcCO_2)_6(H_2O)_4(4,4'\text{-bpy})]_n$ (**2**). Both exhibit similar antiferromagnetic chains with a $J_1$–$J_1$–$J_2$ (AF1–AF1–AF2) repeating sequence, which is unprecedented in $Mn^{II}$–carboxylato complexes. The only reported $Mn^{II}$–carboxylato complexes with a $J_1$–$J_1$–$J_2$ repeating sequence exhibit ferrimagnetic properties with an AF–AF–F repeating sequence.[11]

## Results and Discussion

### Description of the Structure of Complexes 1 and 2

The X-ray diffraction analysis of complex **1** reveals an infinite 1D chain structure (Figure 1) with repeating linear trinuclear units $[Mn_3(FcCO_2)_6(CH_3OH)_4]$. It is shown in the structure that there are two kinds of coordination modes for the $Mn^{II}$ ions. The $Mn2^{II}$ ion is six-coordinate in a distorted octahedral geometry and is coordinated by four oxygen atoms from four methanol molecules and two oxygen atoms from two ferrocenecarboxylato ligands (Figure 1). However, a distorted square-pyramidal coordination mode is established for the $Mn1^{II}$ ion, which is coordinated by five oxygen atoms from five ferrocenecarboxylato ligands. The Mn–O bond lengths of complex **1** are in the range 2.035(2)–2.227(3) Å (Table 1), which is comparable to those in related complexes.[3,12] The O–Mn–O angles range from 83.18 to 180.0° (Table 1). An interesting feature is the construction of the $[Mn_2(FcCO_2)_4]$ building block as shown in Figure 2. Two $Mn1^{II}$ ions are connected by four *syn-syn* $\mu_2$-ferrocenecarboxylato ligands with a Mn···Mn separation of 3.0767(1) Å, and each ferrocenyl group points away from its neighbor. This gives a swastika-like shaped skeleton for the dimer structure when viewed down the Mn···Mn axis. To the best of our knowledge, only a few structures with Cu, Zn, Ru, and Mo were reported to have this kind of dimer skeleton with four $\mu_2$-metallocenecarboxylato ligands.[13] This is the first report of such a structure for a $Mn^{II}$–metallocenecarboxylato complex. The short intradimer Mn···Mn separation is comparable to those reported for dinuclear $Mn^{II}$ complexes bridged by four organic carboxylato ligands,[14] suggesting a nonbonding interaction between two $Mn^{II}$ ions. Each $Mn1^{II}$ ion of the $[Mn_2(FcCO_2)_4]$ building block are connected to a $Mn2^{II}$ ion by one *syn-anti* ferrocenecarboxylato ligand with a Mn···Mn separation of 4.7884(3) Å, which is much larger than the intradimer Mn···Mn separation in the $[Mn_2(FcCO_2)_4]$ building block. A 1D infinite chain with repeating linear $[Mn_3(FcCO_2)_6(CH_3OH)_4]$ trinuclear units is thus formed along the *b* axis, in which both the $Mn2^{II}$ ion and the midpoint of the two $Mn1^{II}$ ions in the $[Mn_2(FcCO_2)_4]$ building block are located on the centers of symmetry. It is easy to see that all of the ferrocenecarboxylato ligands in the complex act as $\mu_2$-bridges.

[a] Symmetry operations: (A) $-x + 2, -y + 1, -z$, (B) $-x + 2, -y + 2, -z$.

Complex **2** is different from complex **1**, and it displays a 2D layered structure parallel to the *ab* plane with the composition $[Mn_3(FcCO_2)_6(H_2O)_2(4,4'\text{-bpy})]_n$, as depicted in Figure 3. The coordination modes of the $Mn^{II}$ ions in complex **2** (Figure 4) are similar to those in complex **1**. The $Mn2^{II}$ ion is coordinated in a distorted octahedral geometry by two oxygen atoms from water molecules, two nitrogen atoms from two 4,4′-bpy ligands, and two oxygen atoms from two ferrocenecarboxylato ligands. The $Mn1^{II}$ ion is in a distorted square-pyramidal environment and is coordinated by five oxygen atoms from four ferrocenecarboxylato ligands. Thus, there are two kinds of coordination modes (chelating and *syn-anti* $\mu_2$-bridging) for the ferrocenecarboxylato ligands in complex **2**. The Mn–O bond lengths are in the range 2.056(5)–2.257(5) Å, and the O–Mn–O bond angles vary from 58.50(19) to 180.0° (Table 2). Two $Mn1^{II}$ ions of complex **2** are bridged by two *syn-anti* $\mu_2$-ferrocenecarboxylato ligands to form a dimer building block $[Mn_2(FcCO_2)_4]$ with a Mn···Mn separation of 3.7757(2) Å, which is shorter than those for the reported dimers with two $\mu_2$-carboxylato-*O*,*O*′ ligands.[15–17] It is noteworthy that

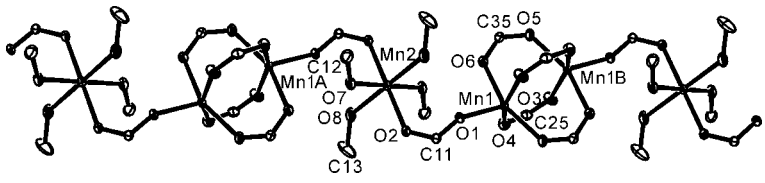

Figure 1. 1D infinite chain of complex **1** showing 30% probability ellipsoids. For clarity, ferrocenyl groups and hydrogen atoms are omitted. Symmetry operations: (A) $-x + 2, -y + 1, -z$, (B) $-x + 2, -y + 2, -z$.

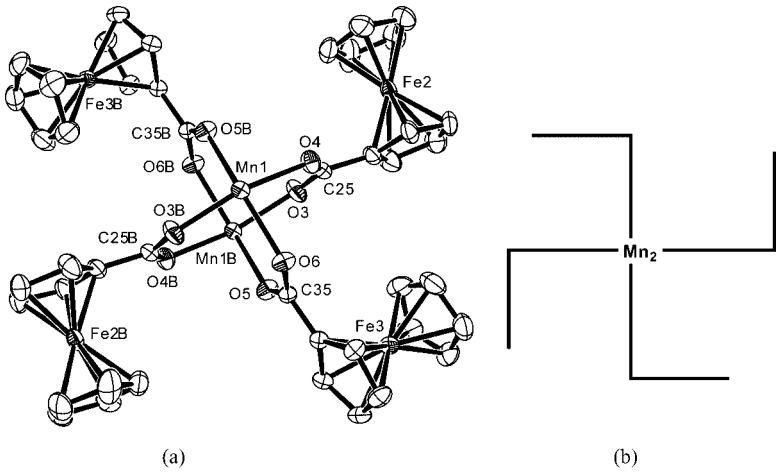

Figure 2. (a) The $[Mn_2(FcCO_2)_4]$ building block of complex **1**. Symmetry operations: (B) $-x + 2, -y + 2, -z$. (b) The skeletal swastika-like shape of $[Mn_2(FcCO_2)_4]$ of complex **1** when viewed down the Mn···Mn axis.

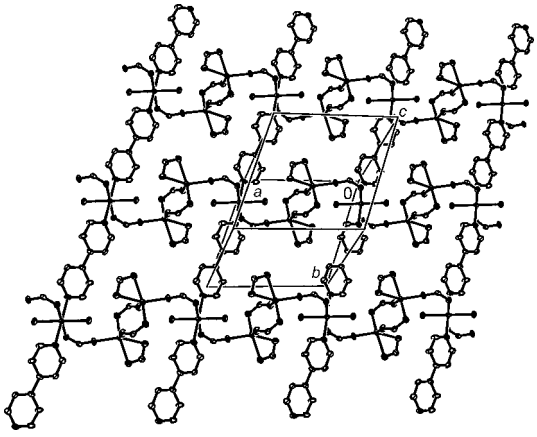

Figure 3. 2D network of complex **2**. Ferrocenyl groups and hydrogen atoms are omitted for clarity.

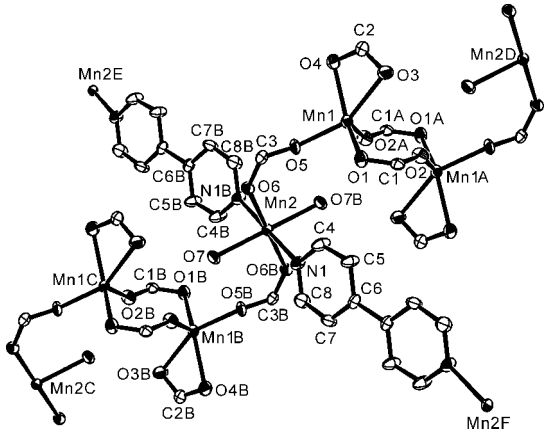

Figure 4. ORTEP drawing of complex **2** showing 30% probability ellipsoids. For clarity, ferrocenyl groups and hydrogen atoms are omitted and only selected atoms are labeled. Symmetry operations: (A) $-1 - x, 1 - y, 1 - z$, (B) $-x, 1 - y, 1 - z$, (C) $1 + x, y, z$, (D) $-1 + x, y, z$, (E) $x, 1 + y, z$, (F) $x, -1 + y, z$.

the dimer building blocks in complex **1** and **2** have the same composition but different structures. All of the ferrocenecarboxylato ligands in the dimer of complex **1** behave as *syn-syn* $\mu_2$-bridging ligands to bridge the two $Mn^{II}$ ions. However, only two ferrocenecarboxylato ligands in the dimer of **2** act as *syn-anti* $\mu_2$-bridging ligands, the other two chelate to $Mn^{II}$ ions. This results in a much shorter Mn···Mn separation for complex **1** than that for complex **2**. Each $Mn1^{II}$ ion of the dimer building block in complex **2** is further connected to one $Mn2^{II}$ ion by one *syn-anti* $\mu_2$-ferrocenecarboxylato bridge with a Mn···Mn separation of 5.1268(3) Å. This leads to the formation of an infinite 1D chain along the *a* axis, which has linear trimer repeating units of $[Mn_3(FcCO_2)_6(H_2O)_2]$. The 1D chains are further connected by the coordination of 4,4′-bpy molecules to $Mn2^{II}$ ions from adjacent chains with an interchain Mn···Mn separation of 11.493 Å, resulting in the construction of a 2D coordination sheet in the *ab* plane, as shown in Figure 3. The two pyridine rings of the 4,4′-bpy molecule are parallel to each other. In the structure of complex **2**, both the $Mn2^{II}$ ion and the midpoint of two $Mn1^{II}$ ions in the dimer are located on the centers of symmetry.

It is of great interest that both compounds have similar chains constructed from alternately repeating mononuclear [$Mn^{II}$] units and dinuclear [$Mn_2(FcCO_2)_4$] units. The big difference is that the two $Mn^{II}$ ions in the dinuclear [$Mn_2(FcCO_2)_4$] units of compound **2** are bridged only by two *syn-anti* carboxylato ligands; the other two carboxylato ligands in this unit act as chelating ligands. However, the two $Mn^{II}$ ions in the dinuclear [$Mn_2(FcCO_2)_4$] units of compound **1** are connected by four *syn-syn* carboxylato ligands, that is to say, all of the ferrocenecarboxylato ligands in the dinuclear unit of compound **1** behave as $\mu_2$-bridging ligands. Another difference is that the chains in compound **2** are further interconnected by the coordinated 4,4′-bipyridine molecules to form two-dimensional coordination sheets.

## Magnetic Properties

The magnetic properties of complexes **1** and **2** were investigated by solid-state magnetic susceptibility ($\chi_m$) measurements in the 2.0–300 K range in a DC field of 2000 Oe; the resulting data are shown in Figure 5 and Figure 6 as $\chi_m$ and $\chi_mT$ vs. $T$ plots. The $\chi_m$ value decreases monotonously with $T$ for both compounds. Its values at 300 K and 2 K are 0.03274 and 1.8322 $cm^3 mol^{-1}$, respectively, for compound **1**, and 0.04101 and 1.331 $cm^3 mol^{-1}$, respectively, for compound **2**. The values of $\chi_mT$ at 300 K for compounds **1** and **2** are 9.82 and 12.30 $cm^3 mol^{-1}$ K, respectively, which are lower than that (13.1 $cm^3 mol^{-1}$ K) expected for three magnetically isolated high-spin $Mn^{II}$ ions. This indicates the presence of antiferromagnetic coupling. With decreasing temperature, the $\chi_mT$ of **1** and **2** gradually decrease, reaching 3.66 and 2.66 $cm^3 mol^{-1}$ K, respectively, at 2.0 K. The shapes of these curves are also characteristic of weak antiferromagnetic interactions between the $Mn^{II}$ centers.

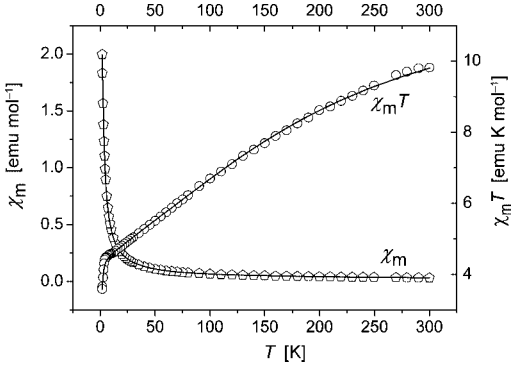

Figure 5. Plot of $\chi_m$ and $\chi_mT$ vs. $T$ for **1**. Solid lines show the best fit of the data according to the proposed model.

There are two sets of magnetic exchange pathways within the chain in both compounds. One consists of one *syn-anti* $\mu_2$-1,3-carboxylato bridge. The other mainly consists of four *syn-syn* $\mu_2$-1,3-carboxylato bridges for compound **1** and two *syn-anti* $\mu_2$-1,3-carboxylato bridges for compound **2**. The interactions alternate according to a $J_1$–$J_1$–$J_2$ repeating sequence to yield an antiferromagnetic chain (AF1–AF1–AF2) as shown in Scheme 1. This unprecedented antiferromagnetic chain is different from the reported AF–AF–F ferrimagnetic chains.[11,18] The ground state is $S$ = 5/2 for each trinuclear $Mn_3$ unit.

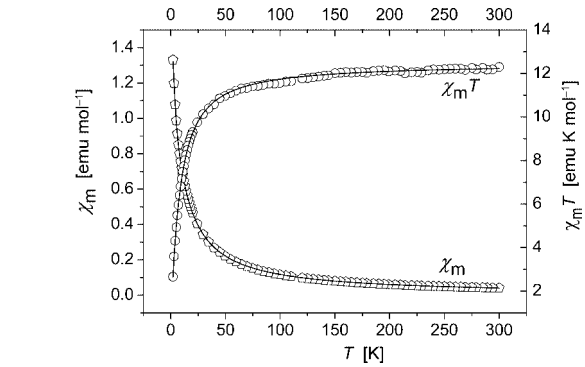

Figure 6. Plot of $\chi_m$ and $\chi_mT$ vs. $T$ for **2**. Solid lines show the best fit of the data according to the proposed model.

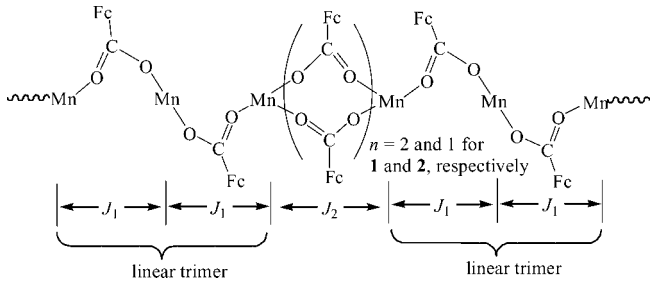

Scheme 1.

The theoretical expression proposed by Escuer and Ribas et al.[11,18] was employed to fit the observed magnetic data for complexes **1** and **2**:

$$H = -J_1\Sigma(S_{3i}\cdot S_{3i+1} + S_{3i+1}\cdot S_{3i+2}) - J_2\Sigma S_{3i-1}\cdot S_{3i}$$

$$\chi_{chain} = \frac{Ng^2\mu_B^2}{3kT}\,\frac{3(1-\mu_1^4\mu_2^2)+4\mu_1(1-\mu_1^2\mu_2^2)+2\mu_2(1+\mu_1)^2(1-\mu_1^2)+2\mu_1^2(1-\mu_2^2)}{(1-\mu_1^2\mu_2)^2}$$

where $\mu_1 = \coth(J_1/kT) - kT/J_1$, $\mu_2 = \coth(J_2/kT) - kT/J_2$, $J_i = J_iS(S + 1)$ and $g_i = g_i[S(S + 1)]^{1/2}$. The best fitting parameters obtained for **1** are $J_1$ = –0.15 $cm^{-1}$, $J_2$ = –29.56 $cm^{-1}$, and $g$ = 2.00 with $R = 3.73\times10^{-4}$.

For complex **2**, the fitting was carried out by employing a molecular field approximation, assuming that there is an interchain interaction ($zJ'$) through the 4,4′-bpy bridge. With this assumption, the final susceptibilities for **2** are shown below:

$$\chi_M = \frac{\chi_{chain}}{1-(zJ'/Ng^2\beta^2)\chi_{chain}}$$

The best fitting parameters for **2** were found to be $J_1$ = –0.27 $cm^{-1}$, $J_2$ = –1.28 $cm^{-1}$, $zJ'$ = –0.081 $cm^{-1}$, $g$ = 1.95 with $R = 1.32\times10^{-5}$. This fit gives a nice agreement factor $R$. It was revealed that the 4,4′-bpy ligand (between the chains) mediates a very weak antiferromagnetic interaction ($zJ'$ = –0.081 $cm^{-1}$), in agreement with the large Mn···Mn separation (11.493 Å).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

These $J$ values are comparable to those of compounds with similar bridging modes and also confirm the dependence of $J$ on the nature of the carboxylato bridges.[19,20] The adjacent trinuclear units of **1** are bridged by four *syn-syn* $\mu_2$-1,3-carboxylato ligands which are much more efficient pathways for superexchange than *syn-anti* $\mu_2$-1,3-carboxylato bridges. Thus, they induce a much larger $|J|$ ($J_2$ = –29.56 cm$^{-1}$) than that ($J_1$ = –0.15 cm$^{-1}$) in the trimer of **1** and those ($J_1$ = –0.27 cm$^{-1}$, $J_2$ = –1.28 cm$^{-1}$) in **2**. The intratrimer $J$ ($J_1$ = –0.27 cm$^{-1}$) and intertrimer $J$ ($J_2$ = –1.28 cm$^{-1}$) of **2** are in the range reported for one *syn-anti* carboxylato bridge (–0.1 to –0.4 cm$^{-1}$)[5,17,21] and two *syn-anti* carboxylato bridges (–0.9 to –1.7 cm$^{-1}$),[16,17,20] respectively. This confirms again that the magnitude of $|J|$ increases with the number of carboxylato bridges.

## Conclusions

Two manganese(II) complexes bearing the organometallic ligand ferrocenecarboxylato have been synthesized and characterized crystallographically and magnetically. Both complexes have similar chains constructed by $\mu_2$-ferrocenecarboxylato-*O*,*O*′ bridging from alternately repeating mononuclear [Mn$^{II}$] units and dinuclear [$Mn_2(FcCO_2)_4$] units. The dinuclear [$Mn_2(FcCO_2)_4$] unit of complex **1** presents a swastika-like shaped skeleton, which is rare in metallocenecarboxylato complexes. Both compounds show antiferromagnetic interactions with a $J_1$–$J_1$–$J_2$ repeating sequence. To the best of our knowledge, this is the first AF1–AF1–AF2 antiferromagnetic chain with an organometallic carboxylato bridge. The analysis of the magnetic properties also confirms that the exchange coupling through the carboxylato bridge is highly dependent on the conformation modes of the bridge between the metal atoms. The *syn-syn* mode usually induces a much larger $|J|$ value than the *syn-anti* mode, and the magnitude of $|J|$ increases with the number of carboxylato bridges.

## Experimental Section

**General:** Sodium ferrocenecarboxylate was prepared according to the literature method.[22] The other starting materials were commercially available and were used without further purification. Elemental analyses (C, H, and N) were performed with a Vario EL analyzer. Infrared spectra were recorded with KBr pellets by using a Nicolet 360 FT-IR spectrometer in the region 400–4000 cm$^{-1}$. Variable-temperature magnetic susceptibility data were obtained with a SQUID magnetometer (MPMS XL-5) in the temperature range 2–300 K with an applied magnetic field of 2000 Oe.

**CAUTION:** Although no problems were encountered in this work, perchlorate salts are potentially explosive. They should be prepared in small quantities and handled with great care.

**Preparation of $[Mn_3(FcCO_2)_6(CH_3OH)_4]_n$ (1):** A methanol solution (5 mL) of $FcCO_2Na$ (0.0251 g; 0.1 mmol) was added dropwise to a methanol solution (5 mL) of $Mn(ClO_4)_2{\cdot}6H_2O$ (0.0362 g; 0.1 mmol). The resulting mixture was stirred at room temperature for 10 h and filtered. The filtrate was allowed to condense at ambient temperature to give orange crystals. Yield: 0.0584 g (70%). $C_{70}H_{70}Fe_6Mn_3O_{16}$ (1667.18): calcd. C 50.38, H 4.20; found C 50.67, H 4.24. IR (KBr): $\tilde{\nu}$ = 3431 (m), 1533 (s), 1391 (s), 1360 (s), 1105 (w), 1001 (w), 816 (m), 506 (m), 486 (m) cm$^{-1}$.

**Preparation of $[Mn_3(FcCO_2)_6(H_2O)_2(4,4'\text{-bpy})]_n$ (2):** A methanol solution (5 mL) of $FcCO_2Na$ (0.0251 g; 0.1 mmol) was added dropwise to a methanol solution (10 mL) of 4,4′-bpy (0.0156 g, 0.1 mmol) and $Mn(ClO_4)_2{\cdot}6H_2O$ (0.0362 g; 0.1 mmol). The resulting solution was stirred at ambient temperature for 10 h and filtered. The filtrate was allowed to condense at ambient temperature to give orange crystals. Yield: 0.0519 g (60%). $C_{76}H_{66}Fe_6Mn_3N_2O_{14}$ (1731.23): calcd. C 52.68, H 3.81, N 1.61; found C 53.01, H 3.97, N 1.47. IR (KBr): $\tilde{\nu}$ = 3431 (m), 1607 (w), 1577 (s), 1531 (s), 1391 (s), 1359 (s), 1218 (w), 1105 (w), 1002 (w), 811 (m), 508 (m), 487 (w) cm$^{-1}$.

**X-ray Crystallography:** All the data for complexes **1** and **2** were collected with a Bruker APEX CCD diffractometer by using graphite monochromatic Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). A prismatic single crystal was mounted on a glass fiber. The data were collected at 296(2) K. Absorption effects were corrected by semi-empirical methods. The structure was solved by direct methods with the program SHELXS-97[23] and refined by full-matrix least-squares methods on all $F^2$ data with SHELXL-97.[24] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms of water molecules and hydroxyl groups were located in a difference Fourier map and refined isotropically in the final refinement cycles. Other hydrogen atoms were placed in calculated positions and refined by using a riding model. The final cycle of full-matrix least-squares refinement was based on observed reflections and variable parameters. The molecular illustrations were drawn with the program XP.[25] All cal-

Table 3. Crystal data and refinement details of complexes **1** and **2**.

| | **1** | **2** |
|---|---|---|
| Formula | $C_{70}H_{70}Fe_6Mn_3O_{16}$ | $C_{76}H_{66}Fe_6Mn_3N_2O_{14}$ |

# Mechanisms of $H_2$, $H_2C{=}CH_2$, and $O{=}CH_2$ Insertion into $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(PMe_3)$

**Siwei Bi,*[a] Shufen Zhu,[a] and Zhenwei Zhang[a]**

**Keywords:** Zirconium / Silanimines / Insertion / Mechanism

In this paper, the mechanisms for the insertion of $H_2$, $H_2C{=}CH_2$, and $O{=}CH_2$ into the Zr–Si bond of $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(PMe_3)$ (**R**) are theoretically investigated with the aid of density functional theory (DFT) calculations. The structure of the $H_2$ insertion product **P** is discussed on the basis of our calculations, and its bonding features are rationalized in terms of molecular orbital theory. The regiochemistry for insertion of $O{=}CH_2$ has also been theoretically investigated. It is found that the relative stabilities of the three insertion products of **R** are in the order $\mathbf{P} < \mathbf{P}' < \mathbf{P}''$. For the reactions of **R** with $H_2$ and $CH_2{=}CH_2$, the rate-determining steps are the insertions of $H_2$ and $CH_2{=}CH_2$ into the Zr–Si bond of $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)$ (**Int1**), whereas $PMe_3$ dissociation is the rate-determining step for the reaction of **R** with $O{=}CH_2$. Only the precursor **Int2**′′, formed by the coordination of $O{=}CH_2$ to the Zr atom, is located; those formed by the coordination of $H_2$ and $CH_2{=}CH_2$ to **Int1** are not found.

## 1. Introduction

Free unsaturated silicon substrates are very reactive and usually exhibit unsaturation at the Si atom. However, they can be stabilized by coordination to transition metals. Metal complexes of silicon analogs of common carbon-based ligands such as silylenes and silaolefins were prepared, but remained quite rare despite their unusual reactivity in chemical transformations, their proposed role in metal-catalyzed transformations at silicon, and their potential utility in the selective formation of silicon-based polymers. Transition-metal complexes of unsaturated silicon compounds such as silenes ($R_2Si{=}CR'_2$), disilenes ($R_2Si{=}SiR_2$), and silanimines ($R_2Si{=}NR'$) are important candidates for experimental and theoretical investigation. The reactions of these complexes with a range of organic and inorganic reagents afford interesting products and provide further insight into the role of such species in catalytic reactions. Remarkable progress has been made over more than ten years in the synthesis of stable transition-metal complexes of unsaturated silicon ligands. In 1988, Tilley and co-workers reported the first stable unsaturated silene complex, $(C_5Me_5)Ru(PR_3)(H)(\eta^2\text{-}R'_2Si{=}CH_2)$.[1,2] Stable mononuclear and binuclear complexes of disilenes were subsequently prepared.[3–8] Okazaki and co-workers prepared a three-membered silametallacyclic complex, $Cp^*Fe(CO)\{\kappa^2(Si,P)\text{-}SiMe_2PPh_2\}$ and studied its reactivity toward MeOH.[9] We have theoretically investigated the mechanisms of formation of the ring-opening products of this reaction.[10] Berry introduced the first unsaturated silanimine complex, $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(PMe_3)$,[11] and investigated some chemical reactivity experimentally in 1991. As depicted in Scheme 1, $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)L$ (L = $PMe_3$, CO) can react with $H_2$ by α-bond metathesis, and with olefins, alkynes, aldehydes, or ketones[11,12] by unsaturated bond insertion leading to ring expansion. For these reactions, only the structures of the complexes $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(PMe_3)$ and $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(CO)$ were determined by single-crystal X-ray diffraction analyses.[11,13] For the complex $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(CO)$, the origin of π-back-bonding to the carbonyl ligand directly from an orbital on the adjacent silicon atom has been theoretically investigated by ZINDO molecular orbital calculations.[13] To the best of our knowledge, theoretical studies on the reactions of $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(PMe_3)$ with $H_2$, olefins, alkynes, and aldehydes or ketones have been very limited. For example, the reaction of $[Cp_2ZrHCl]_n$ with $LiNtBuSiMe_2H{\cdot}THF$ in benzene yields $Cp_2ZrH(NtBuSiMe_2H)$, whose structure was characterized by single-crystal X-ray diffraction. The same molecular formalism was afforded by $H_2$ insertion into the Zr–Si bond of $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(PMe_3)$; the product of this reaction has not been analyzed by single-crystal X-ray diffraction. Are the two products obtained from these two reactions the same or different? What structural and bonding features are involved in the product obtained by $H_2$ insertion? For the reaction of $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(PMe_3)$ with $CH_2{=}O$, chemoselectivity clearly appears. Why does the O atom, and not the C atom, of $CH_2{=}O$ bind to the Zr center? In addition, it is necessary to study the reactions in

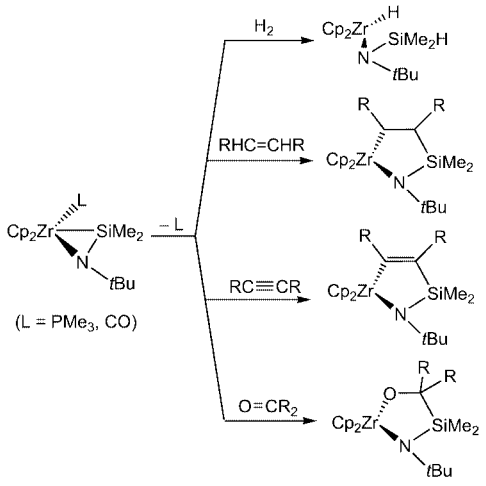
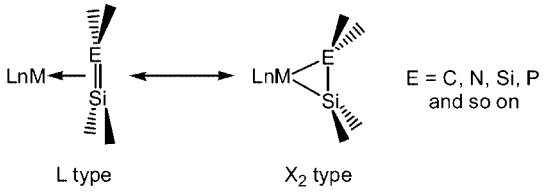
more detail in order to gain an insight into the mechanisms on these reactions. In this work, theoretical calculations based on the B3LYP DFT have been carried out to examine the structural, bonding, and energetic aspects related to these reaction pathways.



Scheme 1.

As known, the bonding of the silanimine fragment to the metal falls between two resonance extremes. One is a metallacycle in which Si has $sp^3$ hybridization ($X_2$ type), and the other is a π-donor complex in which Si has $sp^2$ hybridization (L type) as shown in the diagram. We will give further evidence for the bonding of the silanimine fragment to the metal on the basis of the results of our calculations.



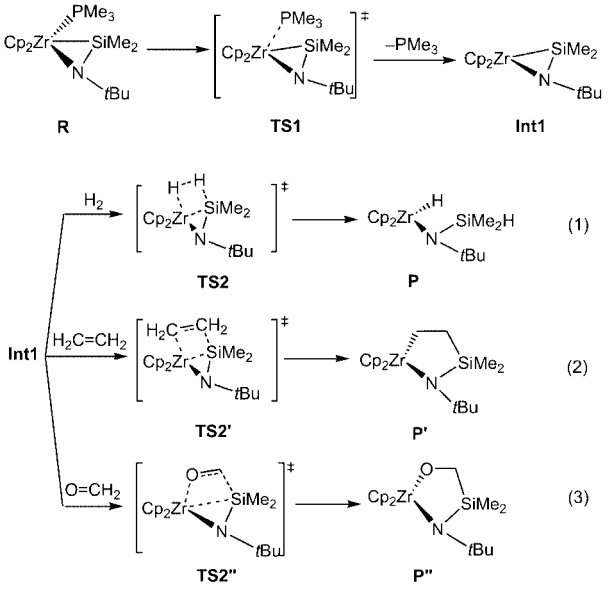
## 2. Computational Details

All molecular geometries were optimized at the Becke-3LYP (B3LYP) level of DFT.[14–16] Frequency calculations at the same level of theory have also been performed to identify all stationary points as minima (zero imaginary frequencies) or transition states (one imaginary frequency). The transition states involved were checked by IRC (Intrinsic Reaction Coordinate) analysis.[17,18] The effective core potentials (ECPS) of Hay and Wadt with double-ζ valence basis sets (LanL2DZ) were used to describe Zr, Si, and P atoms, while the standard 6-31G basis set was used to describe C, N, and H atoms. Polarization functions were added for P(ζ $d$ = 0.34), Si(ζ $d$ = 0.262), N(ζ $d$ = 0.8), and those atoms directly involved in bond-forming and bond-breaking processes, C(ζ $d$ = 0.8), H(ζ $p$ = 0.11). All the calculations were performed with the Gaussian 98 software package.[19]

For examining the feasibility of the B3LYP level of DFT, the computed geometrical structure of the reactant **R** was compared to the original X-ray diffraction structure. Selected calculated and experimental (in brackets) bond lengths are shown in Figure 2. The calculated values and the geometrical parameters obtained from X-ray diffraction are close enough, indicating that our calculations at the B3LYP level of DFT are reliable. We have also used this computational method to investigate other organometallic systems.[20–23]

## 3. Results and Discussion

For investigating the mechanisms, the structures, and the bonding features involved in the reactions mentioned above, we chose $H_2$, $H_2C{=}CH_2$, and $O{=}CH_2$ as substrates to react with $Cp_2Zr(\eta^2\text{-}SiMe_2{=}N\mathit{t}Bu)(PMe_3)$ (**R**). The mechanisms for the three reactions are theoretically proposed as shown in Scheme 2. Since the reactant **R** is coordinatively saturated, it is proposed that **R** first loses the phosphane ligand, $PMe_3$, through a transition state **TS1**, to form a 16-electron intermediate **Int1**. In reaction (1), **Int1** reacts with $H_2$ to yield the product **P** via a transition state **TS2**. In reaction (2), **Int1** reacts with ethylene to give the product **P′** via a transition state **TS2′**. In reaction (3), **Int1** reacts with formaldehyde to afford the product **P′′** via a transition state **TS2′′**.



Scheme 2.

### 3.1 Insertion of $H_2$

Figure 1a shows the calculated potential energy profile corresponding to the reaction of **R** with $H_2$ by the mechanism shown in Scheme 2. Figure 2 shows all the B3LYP-optimized geometrical structures with selected structural parameters. The first step is the dissociation of $PMe_3$. In **R**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and **TS1**, the calculated Zr–P bond lengths are 2.76 and 3.73 Å, respectively, indicating that the $PMe_3$ leaves from the metal center. Table 1 indicates that the Zr–Si and Zr–N bond lengths decrease and the Si–N bond length increases in going from **R** via **TS1** to **Int1**. This means that, with the dissociation of $PMe_3$, the $Me_2SiNtBu$ unit tends to be closer to the Zr center, and correspondingly the interaction between the $Me_2SiNtBu$ unit and Zr is enhanced. The Si–N bond is then weakened with the increasing interaction of the Zr center with the $Me_2SiNtBu$ unit, and hence the Si–N bond length increases in going from **R** via **TS1** to **Int1**, as shown in Table 1. Also, as the $Me_2SiNtBu$ unit approaches the Zr atom, the increasing strain in the Zr–Si–N ring in going from **R** to **Int1** can make the Si–N bond longer. Clearly, this structural variation results from the loss of the $PMe_3$ ligand. The activation energy for the step from **R** to **Int1** is calculated to be 9.2 kcal/mol. **Int1** is higher than **R** in energy by 5.9 kcal/mol, indicating that this step is thermodynamically unfavorable. The reason for the instability of **Int1** compared with **R** is the transformation from the 18-electron species **R** to the 16-electron species **Int1**.

Table 1. Zr–N, Zr–Si, and Si–N bond lengths [Å] in all the species involved in the reaction mechanism shown in Figure 1a.

| | Zr–N | Zr–Si | Si–N |
|---|---|---|---|
| **R** | 2.16 | 2.67 | 1.72 |
| **TS1** | 2.09 | 2.62 | 1.76 |
| **Int1** | 2.07 | 2.60 | 1.77 |
| **TS2** | 2.09 | 2.62 | 1.75 |
| **P** | 2.20 | 2.94 | 1.71 |

As for step two (**Int1** to **P**), the results of our calculations indicate that insertion of $H_2$ into the Zr–Si bond becomes energetically accessible as shown in Figure 1a. The H–H bond length in free $H_2$ is calculated to be 0.74 Å. In **TS2**, the calculated H1–H2, Zr–Si, Zr–H1, and Si–H2 bond lengths are 0.76, 2.62, 2.72, and 2.89 Å, respectively. As $H_2$ approaches the metal center in **TS2**, the H1–H2 and Zr–Si bonds are elongated with respect to their values in **Int1**. The activation energy for the step is calculated to be 7.8 kcal/mol. In the product **P**, the H1–H2 and Zr–Si bonds are broken, and Zr–H1 and Si–H2 σ bonds are formed. As shown in Table 1, the Zr–Si bond length increases in going from **Int1** via **TS2** to **P** as a result of the insertion of $H_2$. The Si–N bond strength is enhanced as a result of the decrease in the π-back-donation from the metal center to the Si–N unit and the release of the ring strain. As indicated in Table 1, the Si–N bond length decreases in going from **Int1** via **TS2** to **P**. The Zr–N bond length increases slightly as shown in Table 1, which arises mainly from two factors. One is the decrease in the π-back-donation, which weakens the Zr–N bond. The other is the increasing steric hindrance of the *t*Bu group attached to the N atom by the two Cp rings because of the increase in the Zr–N–Si bond angle. The energy difference for the step is calculated to be –17.7 kcal/mol, indicating that this step is very much favored thermodynamically.

Examining carefully the structure of **P**, we predict the presence of an agostic interaction between the Si–H bond and the metal center. Evidence offered by our calculations is as follows: (i) The Zr, N, Si, and C1 atoms are coplanar, and hence the N atom has $sp^2$ hybridization. Thus, the Zr–N–Si bond angle could be predicted to be about 120°. However, this angle is calculated to be 96.4°, supporting the occurrence of an interaction between the Zr atom and the Si–H bond. (ii) The Si atom has $sp^3$ hybridization, and hence the N–Si–H2 bond angle could be predicted to be about 109°. In fact, the bond angle is calculated to be 95.2°, also providing evidence for the agostic interaction. (iii) The Si–H2 bond length is calculated to be 1.54 Å. This bond could be expected to be longer in the absence of an agostic interaction. For investigating the Si–H2 bond length, we designed a model complex, **A**, as shown in Figure 2. **A** is derived from the product **P** by the replacement of the two methyl groups attached to the Si atom by two hydrogen atoms. The Si–H3 and Si–H4 bond lengths in **A** are calculated to be 1.49 Å, and the Si–H2 bond length in **A** is 1.52 Å. Clearly, the Si–H2 bond is longer than both the Si–H3 and the Si–H4 bonds, implying the presence of an agostic interaction between the Si–H2 bond and the Zr atom in **A**, and further supporting the prediction of an agostic interaction in **P**. Even though Zr has $d^0$ configuration, meaning that little back-donation from Zr to the σ* orbital of Si–H is present, the agostic interaction is still present. The greater stability of **P** compared with **Int1** has two main reasons. One is the release of the strain in the Zr–N–Si three-membered ring. The other is the presence of the agostic interaction mentioned above. The agostic interaction helps the complex achieve a formal 18-electron configuration, and hence makes some contribution to the stability of **P**. To the best of our knowledge, the structure of **P** has not been characterized by single-crystal X-ray diffraction. However, the structure of an isomer of **P**, represented by **P**-isomer in this paper, was analyzed by single-crystal X-ray diffraction.[24] **P**-isomer was prepared from the reaction of $[Cp_2ZrHCl]_n$ with $LiNtBuSiMe_2H{\cdot}THF$ in benzene as shown in Scheme 3. The structure of **P**-isomer is optimized at the same level of B3LYP, which is illustrated in Figure 2 with selected bond lengths. The calculated Zr–N and N–Si bond lengths (2.17, 1.72 Å, respectively) are close to the experimental observations (2.14, 1.71 Å). The results of our calculations are consistent with the experimental analysis results that an agostic interaction between Zr and the Si–H bond is present in the compound. The Zr···H1 distance and the N–Si–H1 angle in **P**-isomer are calculated to be 2.29 Å and 95.7°, respectively; these values are similar to those in **P** (2.20 Å, 95.2°). The calculated Zr–N–Si bond angle is 98.8°, which is close to that in **P** (96.4°) and to the experimental result (95.1°).[24] On the basis of the structural parameters above, we can also theoretically support the presence of the β-agostic interaction mentioned above. **P**-isomer is calculated to be more stable than **P** by –2.0 kcal/mol. The weaker steric hindrance in **P**-isomer compared with that in **P** may be responsible for its relative stability. Theoretically, **P** could be converted into the more stable **P**-isomer by rota-

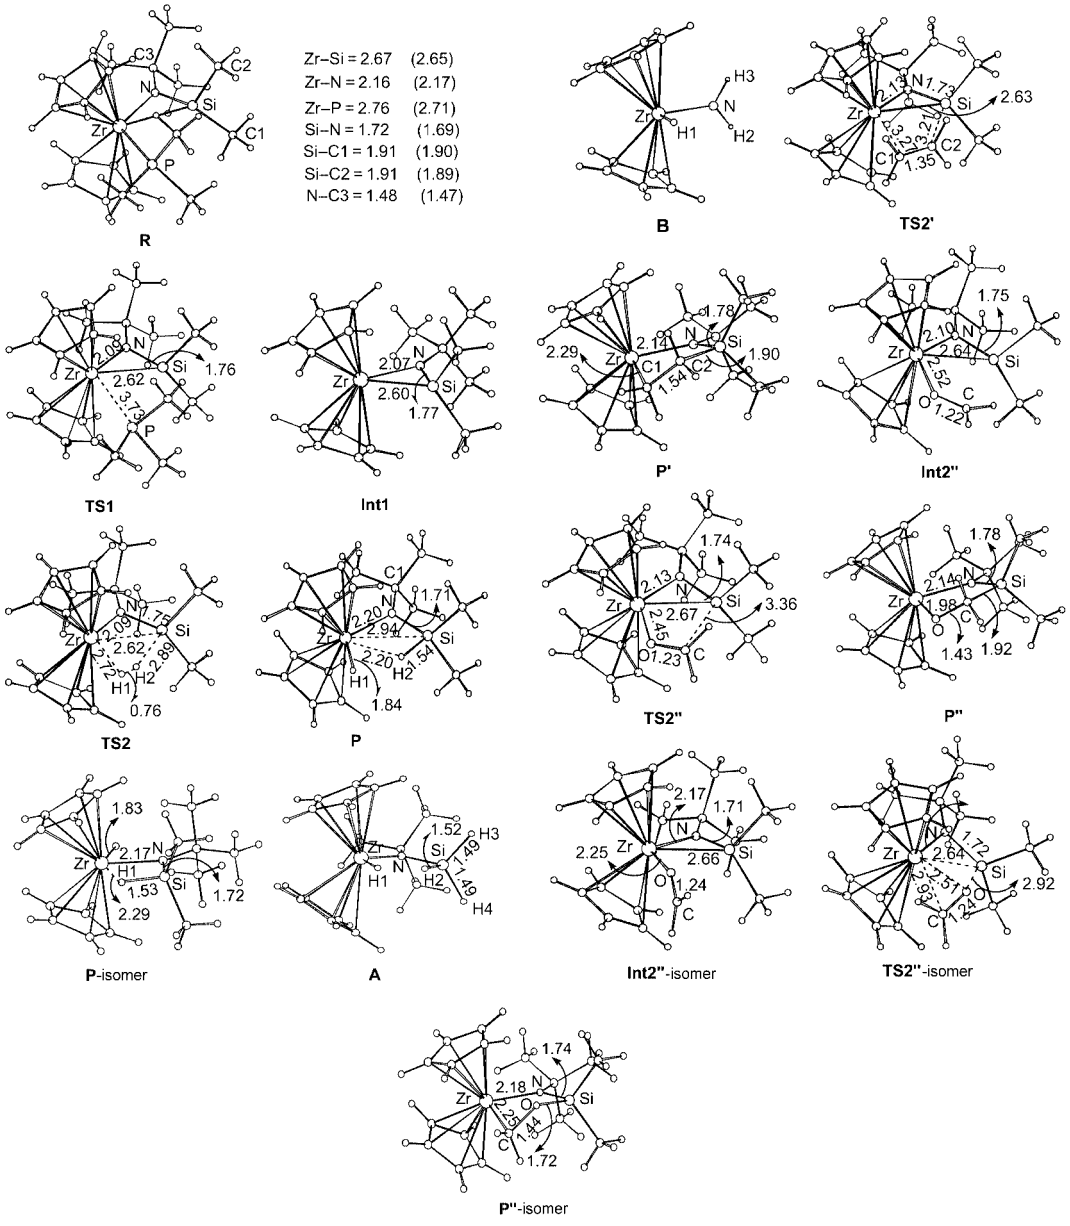

Figure 2. B3LYP-optimized structures of all related compounds with selected structural parameters. The experimental data are given in brackets. Bond lengths are in Å.

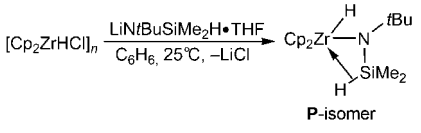
tion of –N(*t*Bu)($SiMe_2H$) about the Zr–N axis. However, the conversion through rotation is very difficult because of the agostic interaction and the steric hindrance as mentioned above. So, we suggest theoretically that the final product for reaction (1) in Scheme 2 is **P** but not **P**-isomer.

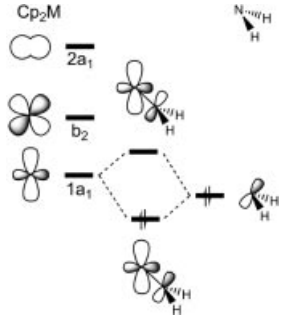


Scheme 3.

It is interesting to further discuss the structure of the product **P** and the bonding features involved. If the *t*Bu and $SiHMe_2$ groups are substituted by two hydrogen atoms, the B3LYP-optimized structure of the derived model complex, $Cp_2ZrH(NH_2)$ (**B**), shown in Figure 2, is different from that of **P**. The Zr, N, H2, and H3 atoms are coplanar, meaning that the N atom has $sp^2$ hybridization, and one lone pair is on the p orbital of the N atom perpendicular to the Zr–N–H2–H3 plane. The H1–Zr–N–H2 and H1–Zr–N–H3 dihedral angles are calculated to be equal (89.4°). In other words, the H2–N–H3 plane is perpendicular to the H1–Zr–N plane in **B**, whereas H1, Zr, N, C1, and Si are coplanar in **P**. The structural difference between **P** and **B** is worth to explore in terms of molecular orbital interactions. For the model complex $Cp_2ZrH(NH_2)$, only if the H2–N–H3 plane is perpendicular to the H1–Zr–N plane can the lone pair on the N atom have the same symmetry with one

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

LUMO ($1a_1$) of the fragment $Cp_2M$, as shown in Scheme 4.[25] Thus, the π interaction between $1a_1$ and the p orbital takes effect, and the Zr–N bond is further stabilized. Therefore, the π interaction between the $1a_1$ orbital of the fragment $Cp_2M$ and the p orbital on the N atom is responsible for the orientation of the H2–N–H3 plane. In contrast, the C1–N–Si plane in **P** is wedged into the two Cp rings. Clearly, the π interaction mentioned above is not present in **P**, since the LUMO ($1a_1$) is not symmetric to the p orbital on the N atom. Other factors play a dominant role in controlling the geometrical structure. One is the agostic interaction between Zr and the Si–H bond, which prevents the rotation of the C1–N–Si plane around the Zr–N axis. Another is the steric hindrance of the two Cp rings, affecting the bulky *t*Bu and $SiHMe_2$ groups, which also blocks the rotation of the C1–N–Si plane around the Zr–N axis. Only when the C1–N–Si plane is wedged into the two Cp rings can the steric effect be reduced to the least possible amount.



Scheme 4.

Figure 1a shows that the rate-determining step is the insertion of $H_2$ into the Zr–Si bond. The reaction activation energy is calculated to be 13.7 kcal/mol. The product **P** is lower in energy than the reactant **R** by 11.8 kcal/mol, indicating that the reaction is thermodynamically favorable. The high stability of the product **P** relative to the reactant **R** arises mainly from the release of the strong ring strain in going from **R** to **P**, the formation of the relatively strong Zr–H bond, and the agostic interaction of the Si–H bond with the metal center.

The bonding between Zr and the Si–N is also worth discussing. As mentioned in the introduction, there are two extremes for the structure of the Zr–Si–N three-membered ring, the L type and the $X_2$ type. What we want to know is which one is the major type in the reactant **R**. First, we take a look at the structure of the product **P**. The Si atom in **P** has $sp^3$ hybridization, and hence the Si–N bond is a σ bond. The bond length is calculated to be 1.71 Å. In the reactant **R**, both N and Si atoms bind to the metal, and the Si–N bond length is calculated to be 1.72 Å, which is even slightly longer than that in **P**, suggesting that the Zr–Si–N unit has $X_2$-type bonding. This is a result of the fact that the remaining $d^2$ electrons in the fragment $Cp_2Zr$ are very reactive, and hence the $Cp_2Zr$ fragment is a very good π base. The two methyl groups attached to the Si atom are bent far away from the metal, which is also consistent with the $X_2$-type structure. The Zr–N bond in **P** is a σ bond, which is longer than that in **R** only by 0.04 Å, also suggesting that the Zr–N bond in **R** is a σ bond.

### 3.2 Insertion of $CH_2{=}CH_2$

Reaction (2) in Scheme 2 is the insertion of ethene into the Zr–Si bond. Figure 1b shows the energy profile corresponding to the reaction mechanism. Related geometrical structures with selected structural parameters are also illustrated in Figure 2. The first step is the same as that in reaction (1). The second step is the insertion of the C=C double bond into the Zr–Si bond. In **TS2′**, the calculated Zr···C1 and Si···C2 distances are 3.27 and 3.21 Å, respectively. The Zr–Si bond length is 2.63 Å, which is slightly larger than that in **Int1** (2.60 Å). The C1–C2 bond length (1.35 Å) is almost the same as the free ethylene C–C bond length, indicating that the C1 and C2 atoms keep nearly $sp^2$ hybridization. Clearly, **TS2′** is a very early transition state. IRC analysis confirms that **TS2′** directly connects to **Int1** and the product **P′**. In other words, along the reaction coordinate, no precursor in which ethylene is coordinated to the metal center can be located as a minimum on the potential energy profile. The reason is probably that the $d^0$ metal center cannot stabilize an olefin complex because of lack of back-donation. The activation energy for the step is calculated to be 8.5 kcal/mol. When the ethylene ligand is inserted into the Zr–Si bond, a five-membered metallacycle is formed in the product **P′**. The hybridizations of C1 and C2 are changed from $sp^2$ to $sp^3$, which is supported by change in the C1–C2 bond length from 1.35 Å in **TS2′** to 1.54 Å in **P′**. No agostic interaction between C–H and Zr is found because of the formation of the metallacycle. The energy difference for the step is calculated to be –28.1 kcal/mol, indicating that this step is thermodynamically very favorable . The high stability of **P′** relative to **Int1** is a result of the chelating effect involved and the releasing of ring strain.

As shown in Figure 1b, the rate-determining step is the insertion of ethylene into the Zr–Si bond. The reaction activation energy is calculated to be 14.4 kcal/mol, which is slightly higher than that for $H_2$ insertion. The reaction energy difference is –22.2 kcal/mol. Although the reactant **R** is an 18-electron species, **R** is much less stable than the 16-electron product **P′**. The reasons for the energy difference are the releasing of ring strain from **R** to **P′** and the chelating effect involved in **P′**.

### 3.3 Insertion of $CH_2{=}O$

Figure 1c shows the energy profile for the reaction of **R** with the substrate formaldehyde. Related B3LYP geometrical structures are illustrated in Figure 2. In contrast to the insertion of $H_2$ and ethylene, a precursor, **Int2′′**, is located for the insertion of formaldehyde. In the structure of **Int2′′** shown in Figure 2, the Zr–O bond length is calculated to be 2.52 Å. The C–O bond length in the coordinated $CH_2O$ is 1.22 Å, while that in free $CH_2O$ is 1.21 Å, calculated at

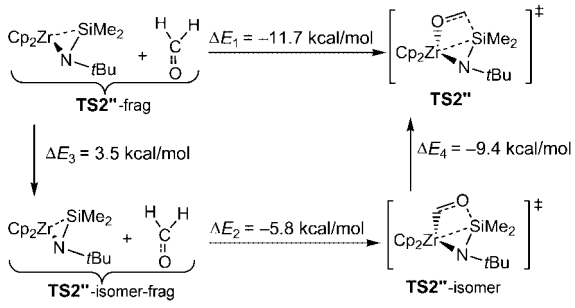
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the same level of theory, which supports the coordination of $CH_2O$ to the metal center. The calculated distance between the Zr atom and the C atom of $CH_2$=O is 3.44 Å, indicating that the O atom is coordinated to the metal center rather than the $CH_2$=O π bond. This means that the binding of the terminal oxygen coordination is stronger than that of the side C=O coordination. The reason for the different binding ability is that the metal center $Zr^{IV}$ is a hard acid and the O atom is a hard base, which can form a relatively strong σ coordination bond to afford an 18-electron intermediate. **Int2′′** is more stable than **Int1** by 1.7 kcal/mol. The coordination of $CH_2O$ to the metal to achieve an 18-electron species may be responsible for the relatively high stability of **Int2′′** relative to **Int1**. The coordination abilities of the substrates studied in this paper to the Zr center are in the order $PMe_3$ > $CH_2O$ > $CH_2$=$CH_2$ > $H_2$. The calculated results show that **R** is more stable than **Int2′′**, whereas the precursors formed by the coordination of ethylene and dihydrogen to the Zr atom are not present.

Ring expansion from **Int2′′** to **P′′** results from the insertion of the C=O bond of $CH_2$=O into the Zr–Si bond. Obviously, the regiochemistry of the C=O insertion could occur in two modes: one would be the binding of the Zr with the O atom and Si with the C atom, and the other would be the binding of the Zr with the C atom and Si with the O atom. Experiments confirmed that the O atom is coordinated to the Zr atom to afford a five-membered metallacycle in **P′′**. This results from the fact that the $Zr^{IV}$ is a hard acid and the O atom is a hard base in terms of the so-called "hard soft acid base theory", leading to the relatively strong interaction between the Zr and O atoms.

In the calculated insertion transition state **TS2′′**, the calculated Zr–O bond length is 2.45 Å, and the Si···C distance is 3.36 Å. IRC calculations confirmed that **TS2′′** directly connects to **Int2′′** and **P′′**. The longer Zr–N and Zr–Si bond lengths than those in **Int2′′** indicate a decrease in π-back-donation from the metal to the Si–N unit. Consequently, the Si–N bond becomes slightly shorter than that in **Int2′′**. The C–O bond length in **TS2′′** is calculated to be 1.23 Å, which is larger than that in **Int2′′**. The longer Zr–Si and C–O bonds and shorter Zr–O and Si–C bonds imply stronger interaction between the latter two bonds relative to that in **Int2′′**. In the structure of **P′′**, a five-membered ring containing the metal center is formed. The Si atom is far away from the metal center, and the three σ bonds (Zr–O, O–C, and C–Si) are formed; this can be confirmed by the structural parameters of **P′′** shown in Figure 2. The activation energy for the step is calculated to be 2.7 kcal/mol, indicating the insertion of formaldehyde is kinetically much favorable. The energy difference for the step is calculated to be –52.0 kcal/mol. In contrast to the insertion of $H_2$ and ethylene, the rate-determining step of Reaction (3) in Scheme 2 is theoretically predicted to be the dissociation of the phosphane ligand $PMe_3$ and not the insertion of C=O into the Zr–Si bond. The strong interaction between the Zr and O atoms plays a crucial role in stabilizing the transition state **TS2′′**. The reaction energy is calculated to be –47.8 kcal/mol, indicating that this reaction is much favorable thermodynamically. Releasing of ring strain and the chelating effect due to the formation of the five-membered metallacycle are responsible for the favored thermodynamics.

Clearly, there is regioselectivity in the insertion of O=$CH_2$. The metal could be attacked by the O atom of O=$CH_2$ or by the C atom. As shown in Figure 1c, the transition state **TS2′′**-isomer is located, which connects an intermediate **Int2′′**-isomer and a proposed product **P′′**-isomer. In this step, the C atom is bound to Zr and the O atom bound to Si. Calculations show that **Int2′′**-isomer is more stable than **Int2′′** by 0.7 kcal/mol. This arises from the stronger Zr–O bond in **Int2′′**-isomer than that in **Int2′′**, since the Zr–O bond length is shorter in the former (2.25 Å) than in the latter (2.52 Å). The **TS2′′**-isomer is calculated to be higher in energy than **TS2′′** by 9.3 kcal/mol. The reason for this energy difference can be understood by an energy-decomposition analysis of reaction barriers.[26,27] As shown in Scheme 5, $\Delta E_1$ and $\Delta E_2$ represent the binding energies between **TS2′′**-frag and **TS2′′**, and **TS2′′**-isomer-frag and **TS2′′**-isomer, respectively. $\Delta E_3$ is the energy difference between the two kinds of fragments. $\Delta E_4$ is the activation energy difference between **TS2′′** and **TS2′′**-isomer. It can be seen in Scheme 5 that $\Delta E_4 = (\Delta E_1 - \Delta E_2) - \Delta E_3$ = –5.9–3.5 = –9.4 (kcal/mol). The binding energy difference (–5.9 kcal/mol) plays a dominant role in the difference between the activation energies. Clearly, the stronger Zr–O bond in **TS2′′** relative to the Zr–C bond in **TS2′′**-isomer is responsible for the activation energy difference. The isomer of **P′′**, **P′′**-isomer, is 5.6 kcal/mol higher in energy than **P′′**. The driving force from **Int2′′** to **P′′**, but not to **P′′**-isomer is still the strong interaction of the O atom with the metal center.



Scheme 5.

### 3.4 Comparison of the Insertions of $H_2$, $CH_2$=$CH_2$, and $CH_2$=O

In a comparison of the three reactions, insertion of $H_2$ can be regarded as a σ-bond metathesis, while insertion of ethylene and formaldehyde are processes of ring expansion. The reactant **R** is an 18-electron species, so we propose that the first step is the dissociation of $PMe_3$ to give a 16-electron intermediate. Among the insertions of the three substrates, only that of formaldehyde involves a precursor formed by the coordination of formaldehyde to the Zr cen-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ter as a result of the strong interaction between the so-called "hard acid" $Zr^{IV}$ center and the so-called "hard base" O atom of $CH_2$=O. The precursors formed by coordination of $H_2$ and $CH_2$=$CH_2$ are theoretically predicted to be nonexistent, mainly owing to the lack of back-donation, as the Zr center has $d^0$ configuration. As for the three transition states, **TS2**, **TS2′**, and **TS2′′**, the former two are relatively close to each other. $H_2$ has a higher bond energy than the ethylene π bond, indicating that the H–H σ bond is more difficult to break than the C=C π bond. However, ethylene engages in a larger steric repulsive interaction as it approaches the metal center, while $H_2$ can easily reach the metal center with its much less bulky structure. These two factors lead to similar activation energies for the two insertions. In comparison, the transition state **TS2′′** for the insertion of formaldehyde is much lower than **TS2** and **TS2′** in energy, and even lower than the dissociation barrier of $PMe_3$, as a result of the strong interaction between the Zr and O atoms. Therefore, in contrast to the insertion of $H_2$ and ethylene, the rate-determining step for reaction (3) in Scheme 2 becomes the dissociation of $PMe_3$ and not the insertion of formaldehyde. Figure 1 indicates that the relative stability of the three products with respect to the reactant **R** is in the order **P** < **P′** < **P′′**. A chelating effect due to the formation of the five-membered metallacycle in **P′** and **P′′** leads to the higher stability of **P′** and **P′′** relative to **P**. For early transition metals, M–X (X is a heteroatom) bonds are much stronger than M–C bonds.[28] For example, calculated results show that the bonding energy difference between Ta–OH and Ta–C bonds is about 53.1 kcal/mol, and the difference between Ta–Cl and Ta–C bonds is about 35.6 kcal/mol. For late transition metals, M–X bonds are a little stronger than M–C bonds. For example, the bond dissociation energy of a Pt–Cl bond is estimated to be only about 10.0 kcal/mol larger than that of a Pt–C bond.[29,30] The energy of **P′** is calculated to be –22.2 kcal/mol, while that of **P′′** is –47.8 kcal/mol with respect to the reactant **R**. **P′′** is much more stable than **P′**. Clearly, the reason for the higher stability of **P′′** is the formation of the strong Zr–O σ bond.

## 4. Conclusions

Metal complexes of silanimines ($R_2Si{=}NR'$) exhibit unusual reactivity in chemical transformations. The reactions of these complexes with a range of organic and inorganic reagents yield interesting products and provide further insight into the role of such species in catalytic reactions. Three typical insertion reactions, those of $H_2$, $CH_2$=$CH_2$, and $CH_2$=O into the Zr–Si bond of $Cp_2Zr(\eta^2\text{-}SiMe_2{=}NtBu)(PMe_3)$ were chosen to investigate their reaction mechanisms and the structural and bonding features involved in these reactions. The product of $H_2$ insertion, **P**, is structurally discussed, and we find that a Zr···H–Si agostic interaction is present. The bonding feature in **P** is analyzed in comparison to the designed model complex $Cp_2Zr(NH_2)H$ (**B**). The geometrical structural difference between **P** and **B** results from their different bonding properties and steric environments. We also predict that the $H_2$ insertion product, **P**, is different from **P**-isomer, the product obtained from the reaction of $[Cp_2ZrHCl]_n$ with $LiNtBuSiMe_2H{\cdot}THF$. The results of our calculations also confirm that the product of $CH_2$=O insertion contains the Zr–O bond and not the Zr–C bond as a result of the stronger interaction of Zr with the O atom than with the C atom.

The reaction mechanisms are confirmed theoretically to comprise two steps, dissociation of $PMe_3$ and insertion of $H_2$, $CH_2$=$CH_2$, and $CH_2$=O. Theoretical findings are: (i) the relative stabilities of the three insertion products of **R** are in the order **P** < **P′** < **P′′**; (ii) the rate-determining step is $H_2$ insertion in reaction (1) and $CH_2$=$CH_2$ insertion in reaction (2), whereas it is $PMe_3$ dissociation in reaction (3); (iii) only the precursor **Int2′′** is located, while those formed by the coordination of $H_2$ and $CH_2$=$CH_2$ to **Int1** are not found.

**Keywords:** Cluster compounds / Molybdenum / Rhenium / Triphenylphosphane oxide / Crystal structure / NMR spectroscopy / Hydrogen bonding

New cluster compounds $[H_3O(Ph_3PO)_3]_2[Mo_6Cl_{14}]$ (**I**) and $[H(Ph_3PO)_2]_2[Re_6S_6Br_8]$ (**II**) have been prepared by the reaction of a acetonitrile solution of triphenylphosphane oxide $Ph_3PO$ with octahedral cluster complexes of molybdenum $(H_3O)_2Mo_6Cl_{14}\cdot 6H_2O$ and rhenium $K_2Re_6S_6Br_8$, respectively, (with addition of several drops of HBr). The structures and properties of the products were studied by single-crystal X-ray diffraction and NMR and luminescence spectroscopic methods. The compounds studied are characterized by strong hydrogen bonds with O–O distances of 2.45–2.51 Å (**I**) and 2.34–2.41 Å (**II**); unusual H-bonded cationic trimers, $[H_3O(Ph_3PO)_3]^+$, were found in compound **I**.

## Introduction

The reactions of triphenylphosphane oxide ($Ph_3PO$) with various acids give molecular compounds of different types. Compounds with the stoichiometry $Ph_3PO$/acid = 1:1 are formed for the reactions with $HNO_3$,[1] HF,[2] HCl,[3] HBr,[4] $CCl_3COOH$.[5] Compounds with a $Ph_3PO$/acid ratio of 2:1 are also found – $(Ph_3PO)_2\cdot H_2O\cdot HBr$,[6] $(Ph_3PO)_2\cdot(CH_3)_2C(COOH)$,[7] $(Ph_3PO)_2\cdot HAuCl_4$,[8] $(Ph_3PO)_2\cdot HClO_4$.[9] The compounds that form from triphenylphosphane oxide and acids can be separated into three main groups depending on the nature of the interaction between the acidic protons and the $Ph_3PO$ molecules.[9] The first group includes compounds in which the hydrogen atoms belong more to the acid than to the $Ph_3PO$ molecule, as, for example, in the case of $Ph_3PO\cdot CCl_3COOH$. In such compounds, the lengths of the P=O bonds are close to those observed in the free $Ph_3PO$ molecule (1.487 Å).[10] In the second group, on the contrary, the proton lies more towards $Ph_3PO$, which results in a remarkable lengthening of the P=O bond. Such compounds can be considered as ionic pairs (e.g. $[Ph_3POH]^+Cl^-$), and their formation is typical of non-oxygen acids. The third group combines the compounds in which the $Ph_3PO$ molecules are bound together by strong symmetrical or non-symmetrical hydrogen bonds, but the anions do not participate in the hydrogen bonding. A typical example of such compounds is $(Ph_3PO)_2HClO_4$, where the two triphenylphosphane oxide fragments are bound together by very short (2.41 Å) hydrogen bonds to form a dimer cation $[Ph_3PO\cdots H\cdots OPPh_3]^+$.[9]

The interaction of chloromolybdenic(II) acid $(H_3O)_2Mo_6Cl_{14}$ with triphenylphosphane oxide was first studied by Sheldon,[11] but the reaction products were not described thoroughly enough and their structure was not studied.

In this paper we present the synthesis of two novel cluster compounds containing $Ph_3PO$ molecules: $[H_3O(Ph_3PO)_3]_2[Mo_6Cl_{14}]$ (**I**) and $[H(Ph_3PO)_2]_2[Re_6S_6Br_8]$ (**II**). In the frame of the above classification, these compounds can be assigned to the third group, since their triphenylphosphane oxide molecules are connected by strong hydrogen bonds to form large cationic complexes: dimers $[H(Ph_3PO)_2]^+$ (in **II**) and unusual trimers $[H_3O(Ph_3PO)_3]^+$ (in **I**). Inspection of the Cambridge crystallographic database showed that the trimeric cation, namely tris(oxotriphenylphosphane)-oxonium, has not been mentioned in the literature so far. Therefore, it is interesting to consider its structure in detail. The structures of the H-bonded complexes **I** and **II** were solved by single-crystal X-ray diffraction and examined by solid-state NMR spectroscopy.

## Results and Discussion

The interaction of the cluster acid $(H_3O)_2Mo_6Cl_{14}$ and triphenylphosphane oxide gives a complex compound $[H_3O(Ph_3PO)_3]_2[Mo_6Cl_{14}]$ (**I**). The unit cell of compound **I** contains one centrosymmetrical and two noncentrosymmetrical $[Mo_6Cl_{14}]^{2-}$ anions formed by slightly distorted $Mo_6$ octahedrons with Mo–Mo distances of 2.594–2.608 Å (Table 1, Figure 1, Figure 2). The lengths of the Mo–Cl

bonds, 2.421(8) Å and 2.472(5) Å for terminal and bridged ligands, respectively, are typical of those observed in related clusters.[12–14] The formation of the unusual cationic complex ion $[H_3O(Ph_3PO)_3]^+$ (Figure 3) is a distinctive feature of the structure. Such structures consist of three triphenylphosphane oxide molecules that are H-bonded to a central oxygen atom ($O_W$) to form a trigonal pyramid $\{O_3O_W\}$ (see the inset in Figure 3). The O–$O_W$ lengths (Table 2) range between 2.449 Å and 2.504 Å, which indicates relatively strong hydrogen bonding. The angles O–$O_W$–O are within the range 99.1–110.4°. However, as is evident from Table 2, the H-bonding does not lead to considerable deformation of the P=O bonds. Relative to unbound $Ph_3PO$,[10,15] the bonds are approximately 0.01 Å longer. This fact might be indicative of a shift in the positions of the protons towards the central oxygen atom to form the $H_3O^+$ ion as a cation–complex core.

We studied the H-bond geometry by $^1$H NMR wide-line spectroscopy. The NMR spectrum of the compound **I** (Figure 4) is determined mainly by magnetic dipole–dipole interactions of the $C_6H_5$ ring protons, whereas the protons involved in the hydrogen bonds, which are closer together and therefore coupled more strongly, are represented as very feeble tails at the absorption edges. In this regard, we considered the spectral domains at frequencies $|\Delta f|$ = (25 – 60) kHz where the influence of the aromatic protons is not overwhelming. The spectra recorded below 200 K were chosen for analysis since higher temperatures result in significant narrowing of the NMR spectra because of increased proton mobility. The simulation of the spectrum was performed by an approach outlined in the Experimental Section. The best fits to the experimental spectra were obtained for a three-spin configuration close to equilateral (the distortion of the triangle sides does not exceed 2%), with an average proton–proton distance of 1.76(1) Å. On the basis of these assessments and by supposing the linearity of the

[a] Values obtained from crystal structure determination. [b] Values estimated from NMR spectroscopic data (no corrections for the $H_3O$ librations were made).

O–H···O bonds, we estimated the proton positions in the hydrogen bonds. On the whole, the obtained proton arrangement (Table 2) corresponds to asymmetrical H-bonding with the mean distances of 1.11(2) and 1.37(3) Å for $O_W$–H and H···O, respectively, which are in satisfactory agreement with the experimental correlation of O–H vs. H···O found for the oxonium ions in inorganic crystals.[16] Therefore, the discussed complex ion can be named *tris-(oxotriphenylphosphane)oxonium*.

The complex $[H_3O(Ph_3PO)_3]_2[Mo_6Cl_{14}]$ is brightly luminescent in the red and near infrared regions of the emission spectrum (Figure 5). It is interesting to note that the intensity of its emission is almost twice as high as that for the initial compound $(H_3O)_2Mo_6Cl_{14}\cdot 6H_2O$. Recently we observed similar luminescence behaviour in some related complexes $[Ca(DMF)_6][Mo_6Cl_{14}]$ and $[Ca(Ph_3PO)_4][Mo_6Cl_{14}]$;[15] the emission intensities for these two complexes are four and six times higher than that for $(H_3O)_2Mo_6Cl_{14}\cdot 6H_2O$.

We tried to find a similar cationic complex ion (as in **I**) in the related rhenium system containing the isoelectronic cluster complex $[Re_6S_6Br_8]^{2-}$ with similar geometric characteristics. The interaction of the rhenium complex $K_2Re_6S_6Br_8$ with triphenylphosphane oxide was carried out in acetonitrile solution with the addition of several drops of HBr. Indeed, we succeeded in obtaining a similar complex

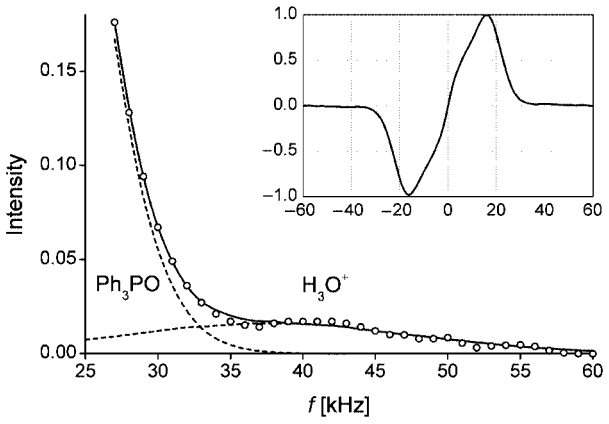

Figure 4. Fragment of the $^1H$ NMR absorption derivative for $[H_3O(Ph_3PO)_3]_2[Mo_6Cl_{14}]$ at 180 K (○) (the complete spectrum is illustrated in the inset). The best fit to the experimental spectrum is shown as a solid line. The dashed curves correspond to the contributions of the $H_3O^+$ and the $Ph_3PO$ protons.

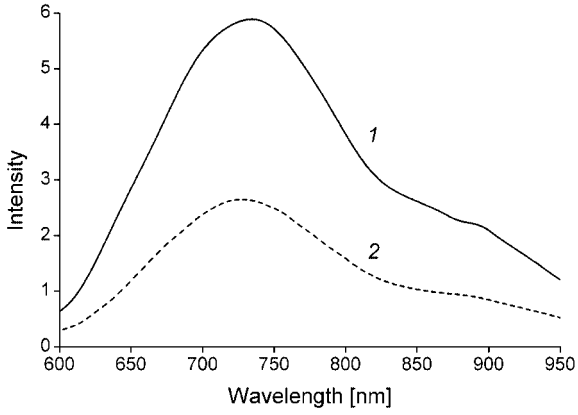

Figure 5. Luminescence spectrum of $[H_3O(OPPh_3)_3]_2[Mo_6Cl_{14}]$ (1) and $(H_3O)_2Mo_6Cl_{14}\cdot 6H_2O$ (2).

$[H_3O(Ph_3PO)_3]_2[Re_6S_6Br_8]$ (**III**) with unit-cell parameters [$a$ = 13.699(3) Å, $b$ = 22.731 Å, $c$ = 29.596(5) Å, $\alpha$ = 102.889(8)°, $\beta$ = 99.129(5)°, $\gamma$ = 92.202(5)°] similar to those observed for **I** (Table 1). Unfortunately, compound **III** crystallized with a very small yield, and several crystals that were isolated had poor quality and were therefore unsuitable for single-crystal X-ray analysis.

In the $K_2Re_6S_6Br_8$–$Ph_3PO$–HBr system, another new complex with the composition $[H(Ph_3PO)_2]_2[Re_6S_6Br_8]$ (**II**) was obtained in a high yield (Table 1, Figure 6). In **II**, there are two types of cluster anions, $[Re_6S_2(S_{2/3}Br_{1/3})_6Br_6]^{2-}$ and $[Re_6S_4(S_{1/2}Br_{1/2})_4Br_6]^{2-}$, with different distributions of the $\mu_3$ ligands (Figure 7). In $[Re_6S_2(S_{2/3}Br_{1/3})_6Br_6]^{2-}$, four sulfur and two bromine atoms alternatively occupy six corners of a cube; in $[Re_6S_4(S_{1/2}Br_{1/2})_4Br_6]^{2-}$, two sulfur and two bromine atoms are distributed over four positions. The interatomic distances for both isomers are summarized in Table 3. The observation of similar cluster isomers among octahedral cluster complexes is not unexpected. In particular, it was shown[17] that in the related complex $[\{Re_6Se_6Br_2\}Br_6]^{2-}$, the cluster core $[Re_6Se_6Br_2]^{4+}$ is repre-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sented by three isomers that can be identified in solution by $^{77}Se$ NMR spectroscopy.

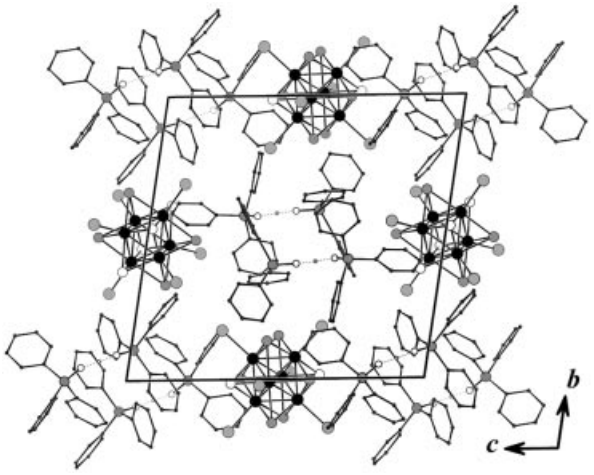

Figure 6. Packing in the crystal structure of $[H(Ph_3PO)_2]_2$-$[Re_6S_6Br_8]$.

In compound **II**, the triphenylphosphane oxide molecules are integrated into H-bonded dimers $[H(OPPh_3)_2]^+$ (Figure 8) with very short O–O distances of 2.34(1) Å and 2.41(1) Å for the two structurally nonequivalent dimers in the unit cell. Note that one of these distances is even less than the known limit (2.39 Å) usually associated with the formation of the symmetric O–H–O bond.[16] The P=O bond lengths are essentially different in each of the dimers: 1.483(8) and 1.549(7) Å, 1.488(10) and 1.523(8) Å. This difference might possibly be explained by the asymmetric proton positions in the hydrogen bonds, i.e. the protons are shifted from the bond centres towards the oxygen atoms with longer P=O contacts.[9] In this regard, of interest is the MAS $^1H$ NMR spectrum (Figure 9): the protons involved in H-bond formation give rise to a diffuse peak with a chemical shift $\delta$ of 17.5(5) ppm. The observed $\delta$ value differs noticeably from the shift of 21.6 ppm expected for a symmetrical bond.[18] On the basis of the various experimental correlations between the chemical shift and hydrogen-bond geometry,[18,19] the proton displacements from the bond

centre were estimated to fall in the range from 0.13 to 0.17 Å.

The obtained experimental results together with those cited in the literature allow us to predict that triphenylphosphane oxide in acid solutions is able to form several protonated complex ions, namely $[HOPPh_3]^+$, $[H(OPPh_3)_2]^+$, $[(H_3O)(OPPh_3)_2]^+$ and $[(H_3O)(OPPh_3)_3]^+$, which can exist simultaneously in chemical equilibrium with each other. The question "What forms can be isolated in proper complexes?" can be answered differently depending on the specific chemical system to be studied. The oxonium ion $H_3O^+$ plays a key role in the formation of cationic trimeric complex ion $[H_3O(OPPh_3)_3]^+$ (a single proton involved in the formation of $[HOPPh_3]^+$ or $[H(OPPh_3)_2]^+$ is obviously not able to interact with a third oxygen atom). In solids containing $OPPh_3$ and large cluster anions, we have discovered the cationic complex ion $[H(OPPh_3)_2]^+$ (observed earlier[9]) and a novel complex ion $[H_3O(OPPh_3)_3]^+$. These complex ions resemble well-known protonated complexes inherent to hydrated systems (Zundel complex $[H_5O_2]^+$[20] and Eigen complex $[H_9O_4]^+$[21] in which the $H_2O$ molecules are replaced by $OPPh_3$) owing to the type of solvation observed in these complexes.

## Experimental Section

**Materials and Methods:** Starting compounds were prepared by known methods described in the literature. $Mo_6Cl_{12}$ was synthesized by the method described previously.[22] $(H_3O)_2Mo_6Cl_{14}\cdot 6H_2O$ was prepared by dissolution of $Mo_6Cl_{12}$ in hot concentrated HCl. The solution was filtered and $(H_3O)_2Mo_6Cl_{14}\cdot 6H_2O$ was crystallized by cooling of the solution. The precipitate was washed with cold water and dried in air. $K_2[Re_6S_6Br_8]$ was synthesized as described previously.[23] Other reagents were purchased from Aldrich and used as received without additional treatment. Elemental analyses (Carlo Erba Instrument EA1106) were performed by the laboratory of microanalysis at the Vorozhtsov Institute of Organic Chemistry, Siberian Branch of Russian Academy of Sciences.

**Synthesis of $[H_3O(Ph_3PO)_3]_2[Mo_6Cl_{14}]$ (I):** $(H_3O)_2Mo_6Cl_{14}\cdot 6H_2O$ (100 mg, 0.08 mmol) was dissolved in acetonitrile (10 mL), and $Ph_3PO$ (300 mg, 1.1 mmol) was dissolved in acetonitrile (10 mL). The solutions obtained were mixed, boiled for 5 min and evaporated until a crystalline precipitate began to form. Then the solution was cooled. The crystals were filtered and washed with diethyl ether (5 mL). Yield: 170 mg (61%). Single crystals for X-ray diffraction analysis were separated from the precipitate. The XPD pattern of solid **I** agreed well with the pattern calculated from the single-crystal parameters. $C_{108}H_{96}Cl_{14}Mo_6O_8P_6$ (2779.61): calcd. C 46.67, H 3.48; found C 46.61, H 3.60%.

**Synthesis of $[H(Ph_3PO)_2]_2[Re_6S_6Br_8]$ (II):** $K_2Re_6S_6Br_8$ (100 mg, 0.04 mmol) was dissolved in acetonitrile (10 mL), and $Ph_3PO$ (100 mg, 0.36 mmol) was dissolved in acetonitrile (10 mL). The solutions obtained were mixed, a drop of HBr was added and the solution boiled for 2–3 min. The solution was filtered, and the filtrate was evaporated to a volume of 10 mL, after which diffusion was carried out using ether. Bright red vinous crystals precipitated, which were collected. Single crystals for X-ray diffraction analysis were separated from the precipitate manually. Yield 95 mg (63%). A further amount of the compound could be obtained from the mother liquor by evaporation. The XPD pattern of solid **II** agreed with the pattern calculated from the single-crystal parameters. $C_{72}H_{62}Br_8O_4P_4Re_6S_6$ (3063.94): calcd. C 28.22, H 2.04; found C 28.39, H 2.18%.

**Crystallography:** The structures of complexes **I** and **II** were solved by X-ray diffraction analysis of single crystals. The diffraction data were collected on a Bruker-Nonius X8APEX CCD diffractometer by using Mo-$K_\alpha$ (0.71073 Å) radiation and a graphite monochromator. The absorption corrections were semiempirical using the intensities of equivalent reflections and the SADABS software.[24] The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$; anisotropic approximation for non-hydrogen atoms using the program package SHELXL.[25] The crystallographic and experimental details are given in Table 1. CCDC 614149 (**I**) and 614150 (**II**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**NMR Spectroscopy:** MAS $^1$H NMR measurements for **II** were performed at room temperature with a Bruker Advance 400 spectrometer at 400.13 MHz. The π/2 rf-pulse width and the recycle delay were 10 μs and 60 s, respectively. The spectra were recorded at rotation frequencies in the range 10–20 kHz using a 4-mm $ZrO_2$ rotor. The powder sample was prepared by several synthesis cycles described above. The $^1$H chemical shift was measured relative to the resonance of TMS. The wide-line $^1$H NMR spectrum of **I** was recorded in the form of the first derivative of the NMR absorption line by sweeping the frequency in the neighbourhood of 25 MHz in the temperature range 180–350 K with a home-made NMR spectrometer with signal accumulation. For the analyzed spectra, the signal/noise ratio reached about $3\times10^3$. The $H_3O^+$ spectra, as a function of the proton–proton distances $r_1$, $r_2$ and $r_3$, were simulated with a known three-spin approximation.[26,27] The contribution of the aromatic protons in the analyzed frequency region was approximated by a rectangle-Gaussian convolution function[28] determined by two parameters: $a$ and $b$ for the rectangle and Gaussian, respectively. This gives the NMR absorption derivative for a powder in the form:

$$F(f) \sim -c/(4\pi\beta^3)\int\sum J_i(f-\delta_i)\exp[-(f-\delta_i)^2/2\beta^2]d\Omega$$

$$+ (1-c)/(2ab)\{\exp[-(f+a)^2/2b^2] - \exp[-(f-a)^2/2b^2]\}$$

where $J_i$ and $\delta_i$ are corresponding intensities and line positions of the $H_3O^+$ NMR septet,[27] which depend on $r_i$ and the orientation (Ω) of the proton triangle with respect to the external magnetic field; $\beta$ is the parameter of the spectral broadening due to the di-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

polar interactions of the $H_3O^+$ group with surrounding protons; $c$ is the concentration of the $H_3O^+$ protons. In the frequency ranges $|\Delta f| = (25 - 60)$ kHz, the discrepancy between the experimental spectra and the best fits obtained with this equation is about 2.5%.

**Luminescence Spectroscopy:** Luminescence spectra were recorded at room temperature by using the spectrometer SDL-1 with the photoelectron multiplier PEM-62. The excitation source was a mercury lamp of type DRSH-250 with a 365-nm filter. The measured samples had the shape of square pellets of equal size.

## Acknowledgments

This work was supported by the Russian Foundation for Basic Research, projects no. 05–03–32123, 05–03–08090 and 06–03–89503-HHC. The authors thank Prof. O. Lapina and Dr. K. Romanenko for recording MAS $^1$H NMR spectra.

# Bis(phenylethylamide) Derivatives of Gd-DTPA as Potential Receptor-Specific MRI Contrast Agents

**Sophie Laurent,[a] Tatjana N. Parac-Vogt,*[b] Kristof Kimpe,[b] Coralie Thirifays,[a] Koen Binnemans,[b] Robert N. Muller,[a] and Luce Vander Elst*[a]**

**Keywords:** Lanthanides / MRI contrast agents / N,O ligands / NMRD / $^{17}O$ NMR spectroscopy

DTPA-bis(amide) derivatives bearing phenyl, phenol or catechol groups that mimic side chains of naturally occurring amino acids, such as phenylalanine, tyrosine or dopamine, were synthesized and characterized by elemental analysis, electrospray mass spectrometry, NMR spectroscopy and IR spectroscopy. The gadolinium(III) complexes of the ligands DTPA-bis(tyramide) [DTPA-$(TA)_2$], DTPA-bis(3-hydroxytyramide) [DTPA-$(HTA)_2$] and DTPA-bis(phenylalanine ethyl ester) [DTPA-$(PAE)_2$], were prepared and then studied in vitro by $^{17}O$ NMR spectroscopy and by nuclear magnetic relaxation dispersion (NMRD) measurements. The residence time of the coordinated water in gadolinium(III) complexes was obtained from $^{17}O$ NMR relaxometric $T_2$ measurements. At 310 K, the following $\tau_M$ values were obtained: Gd-DTPA-$(TA)_2$ 582 ns, Gd-DTPA-$(HTA)_2$ 372 ns and Gd-DTPA-$(PAE)_2$ 809 ns. As shown by the analysis of the proton NMRD profiles, the larger proton relaxivities of the gadolinium(III) complexes at 310 K relative to that of the parent Gd-DTPA complex are mainly because of the increase in the rotational correlation time.

## Introduction

Magnetic resonance imaging (MRI) is a powerful diagnostic technique which is used for obtaining images of internal organs and tissues.[1] Nowadays, an increasing number of MRI scans are performed employing contrast agents, which are able to greatly increase the contrast between tissues in magnetic resonance images.[2] The efficiency of contrast agents is related to their ability to enhance the proton relaxation of water tissues. This property, called *relaxivity*, depends on different factors such as the molecular mobility of the contrast agent, the water dynamics and the noncovalent binding of the contrast agent to endogenous proteins.[3,4] In recent years, new developments in molecular imaging applications have prompted the development of a novel class of contrast agents characterized by a higher contrasting ability and improved targeting capabilities.

Several strategies have been explored in order to slow down the rotational motion of the gadolinium(III)-based contrast agents and thus to increase their relaxation efficiency. These approaches include (i) the synthesis of covalently or noncovalently bound macromolecular gadolinium(III) chelates such as dendrimers, linear polymers or proteins;[5–7] (ii) the synthesis of amphiphilic gadolinium(III) complexes which can self-assemble to micelles;[8,9] (iii) lipophilic gadolinium(III) complexes incorporated in supramolecular systems with a better control of the size such as mixed micelles;[10–12] and (iv) incorporation of amphipathic gadolinium(III) complexes into the membranes of liposomes.[13–17]

The properties of the contrast agents that are important for the tissue specificity include molecular size, charge and lipophilicity. Since most of the specific cell-cell interactions or recognitions are regulated by special proteins, receptor targeting can be attained by mimicking signal peptides. For example, adhesive proteins present in extracellular matrices and in blood, such as fibrinogen and collagens, contain the tripeptide arginine–glycine–aspartic acid as the cell recognition site.[18] Using this binding domain or similar sequences, small peptides can be designed to target receptors.[19] Additionally, some receptors have an affinity for certain classes of substrates such as amino acids or catechol amines.[20] These receptors may also bind molecules that resemble the substrate, for example, a derivative of an amino acid that is present in a peptide substrate or an amide derivative of a naturally occurring catechol amine such as dopamine. The coupling of these potential recognition groups to high relaxivity moieties such as $[Gd(DTPA)(H_2O)]^{2-}$ could thus lead to tissue specificity of the contrast agent.

In this paper we report on ligands based on bis(amide) derivatives of DTPA bearing phenyl, phenol or catechol groups that mimic the side chains of naturally occurring

amino acids such as phenylalanine, tyrosine and dopamine. The gadolinium(III) complexes of these ligands were synthesized and then studied in vitro. The residence time of the coordinated water molecule was studied by means of $^{17}O$ NMR spectroscopy, and nuclear magnetic relaxation dispersion (NMRD) measurements were performed in order to test the efficiency of these complexes as potential MRI contrast agents.

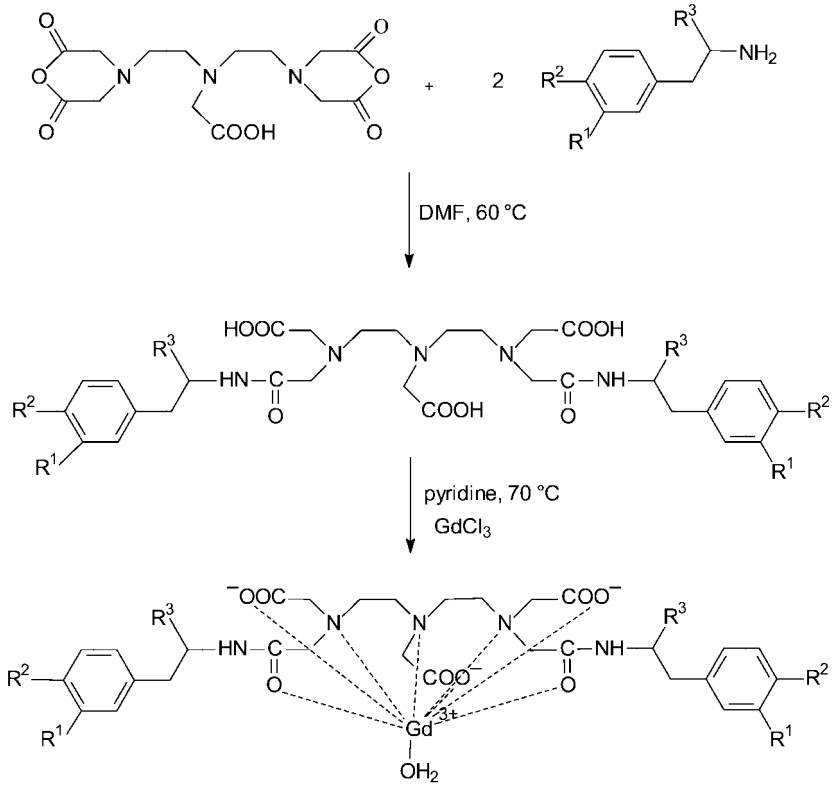
## Results and Discussion

### Ligands and Complexes

The ligands DTPA-bis(tyramide) [DTPA-$(TA)_2$], DTPA-bis(3-hydroxytyramide) [DTPA-$(HTA)_2$] and DTPA-bis-(phenylalanine ethyl ester) [DTPA-$(PAE)_2$] were synthesized by the reaction between DTPA-bis(anhydride) and the corresponding amine in DMF. In pyridine, the ligands readily formed complexes with gadolinium(III) ions (Scheme 1). Infrared absorption data of all ligands show strong absorptions in the region 1630–1650 $cm^{-1}$, corresponding to the CO stretching modes.[21] Shifts of ca. 10 to 20 $cm^{-1}$ to lower wavenumber were observed for the carbonyl stretching frequencies upon complexation. This indicates amide oxygen coordination to the gadolinium(III) ion. These findings are consistent with previous studies which have shown that DTPA-bis(amide) derivatives coordinate to trivalent lanthanide ions by three acetate oxygen atoms, three nitrogen atoms and two carbonyl oxygen atoms of the amide groups, while the ninth coordination site is occupied by a water molecule.[22–25] In the case of DTPA-$(TA)_2$ and DTPA-$(HTA)_2$ ligands, no evidence for the coordination of phenol oxygen to gadolinium(III) was observed. Positive-mode electrospray ionization mass spectroscopy (ESI-MS) of the Gd-DTPA-$(TA)_2$, Gd-DTPA-$(HTA)_2$ and Gd-DTPA-$(PAE)_2$ complexes indicate the presence of fully complexed species in the solution (see Experimental Section and Scheme 1).

### Estimation of $\tau_M$: $^{17}O$ NMR and Proton Relaxometric Measurements

The value of the residence time of the coordinated water molecule, $\tau_M$, was classically obtained by analysis of the temperature dependence of the reduced transverse relaxation rate of the water $^{17}O$ nucleus in solutions containing the gadolinium(III) complexes. The procedure has been described previously.[26,27] As expected for bis(amide) derivatives of Gd-DTPA,[28] the curves representing the reduced transverse relaxation rates versus the reciprocal of the tem-



Scheme 1. Synthesis of the ligands and corresponding gadolinium(III) complexes.

perature are closer to the data obtained for Gd-DTPA-BMA than to those of Gd-DTPA (Figure 1). Theoretical adjustment of these experimental data was performed as described previously, assuming the presence of one water molecule in the first coordination sphere.[26,27] This procedure allows for the determination of (i) $A/\hbar$, the hyperfine coupling constant between the oxygen nucleus of bound water molecules and the gadolinium(III) ion; (ii) the parameters describing the electronic relaxation times of gadolinium(III), that is, the correlation time modulating the electronic relaxation, $\tau_V$, its activation energy, $E_v$, and a parameter related to the mean-square of the zero-field splitting energy, $B$ ($B = 2.4\Delta^2$); and (iii) parameters related to the water exchange, that is, the enthalpy ($\Delta H^{\#}$) and entropy ($\Delta S^{\#}$) of the process. A second fitting was performed with the value of $A/\hbar$ set to $-3.8 \times 10^6$ rad s$^{-1}$. Similar values of $\tau_M$ were obtained by both procedures. At 310 K, the water residence time of Gd-DTPA-$(PAE)_2$ [$\tau_M{}^{310}$ = (809 ± 46) or (811 ± 72) ns], is quite similar to that reported[28] for the bis(methylamide) derivative of Gd-DTPA, Gd-DTPA-BMA [$\tau_M{}^{310}$ = (967 ± 36) ns], whereas smaller values are obtained for the two other complexes [$\tau_M{}^{310}$ = (582 ± 149) or (545 ± 24) ns for Gd-DTPA-$(TA)_2$ and $\tau_M{}^{310}$ = (372 ± 18) or (404 ± 18) ns for Gd-DTPA-$(HTA)_2$] (Table 1). The presence of an ethyl ester group on the ethylene chain of the amide substituent seems thus to have a harmful effect on the water exchange rate. This could be related to the steric hindrance and the hydrophobicity of the ethyl chains and/or to the possible formation of hydrogen bonds between the ester function and the coordinated water molecule leading to stabilization of the hydrated state and thus to a slowing down of the water exchange. On the other hand, the presence of two hydroxy groups on the aromatic ring has a beneficial effect on the water exchange rate.

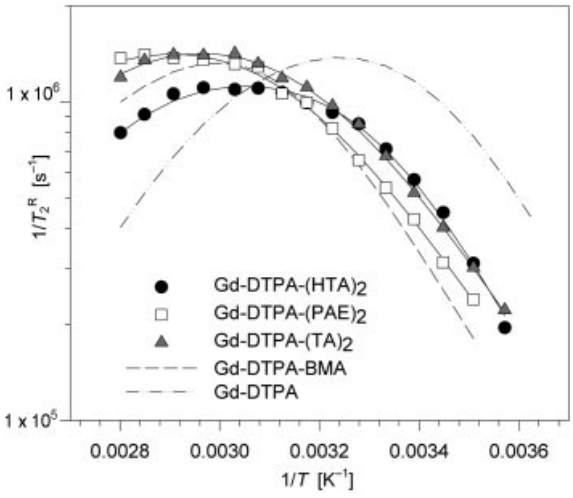

Figure 1. $^{17}$O transverse reduced relaxation rate ($1/T_2{}^R$ = 55.55/{$T_2{}^P$[Gd complex]}) of aqueous solutions of the gadolinium(III) complexes as a function of the reciprocal of temperature.

Such values of $\tau_M$ are not expected to significantly influence the relaxivity of small complexes at 310 K and 20 MHz, but at lower temperatures the relaxivity should be quenched. This is confirmed by the similarity of the proton relaxivities measured at 298 and 278 K (Figure 2) and their very small variations (less than 10%) observed in the temperature range extending between 310 and 278 K.

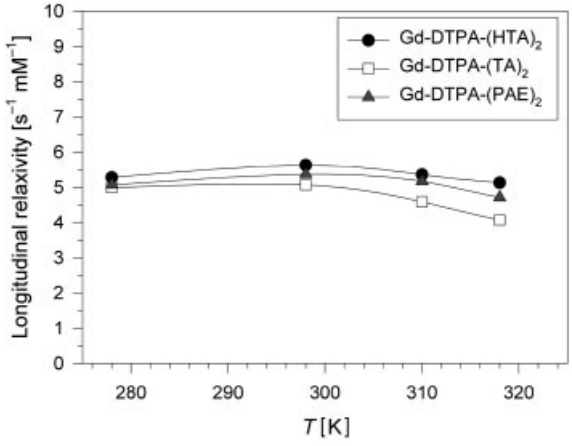

Figure 2. Evolution of the proton longitudinal relaxivity of Gd-DTPA-$(TA)_2$, Gd-DTPA-$(HTA)_2$ and Gd-DTPA-$(PAE)_2$ as a function of the temperature ($B$ = 0.47 T).

It should be pointed out that such $\tau_M$ values are unfavourable in the context of the design of tracers for molecular imaging if covalent coupling of the chelate to a vector is considered.

Table 1. Parameters obtained from the theoretical fitting of the $^{17}$O NMR spectroscopic data.[a]

| Parameter | Gd-DTPA-$(TA)_2$ | Gd-DTPA-$(HTA)_2$ | Gd-DTPA-$(PAE)_2$ |
|---|---|---|---|
| $\tau_V{}^{298}$ [ps] | 12.9 ± 2.7 (22.0 ± 0.5) | 21.1 ± 0.5 (24.1 ± 0.5) | 12.9 ± 0.4 (20.5 ± 1.6) |
| $B$ [$10^{20}$ s$^{-2}$] | 2.85 ± 0.57 (6.22 ± 0.15) | 1.36 ± 0.03 (9.50 ± 0.2) | 3.57 ± 0.10 (4.70 ± 0.40) |
| $E_v$ [kJ mol$^{-1}$] | 1.8 ± 4.5 (0.1 ± 18.8) | 0.1 ± 3.0 (0.1 ± 12.4) | 4.8 ± 3.7 (3.8 ± 2.6) |
| $\tau_{SO}{}^{310}$ [ps][b] | 54 ± 22 (15 ± 1) | 70 ± 3 (9 ± 0.4) | 43 ± 3 (21 ± 4) |
| $A/\hbar$ [$10^6$ rad s$^{-1}$] | –3.6 ± 0.7 (–3.8) | –4.5 ± 1.4 (–3.8) | –4.2 ± 0.4 (–3.8) |
| $\Delta H^{\#}$ [kJ mol$^{-1}$] | 44.6 ± 0.4 (46.1 ± 0.1) | 55.8 ± 0.1 (53.3 ± 0.1) | 43.6 ± 0.1 (42.2 ± 0.2) |
| $\Delta S^{\#}$ [J mol$^{-1}$ K$^{-1}$] | 18.2 ± 1.0 (23.4 ± 0.2) | 58.1 ± 0.2 (49.2 ± 0.2) | 12.2 ± 0.3 (7.6 ± 0.3) |
| $\tau_M{}^{310}$ [ns] | 582 ± 149 (545 ± 24) | 372 ± 18 (404 ± 18) | 809 ± 46 (811 ± 72) |

[a] The values in parentheses correspond to the second type of fitting ($A/\hbar$ fixed to $-3.8 \times 10^6$ rad s$^{-1}$), whereas the other values correspond to the first type of fitting ($A/\hbar$ fitted). [b] Values calculated using the equation: $\tau_{S0} = (5B\tau_v)^{-1}$.

### Influence of pH on Proton Relaxivity

In a pH range extending from 4 to 8, no significant change in the proton relaxivity at 20 MHz and 310 K was noticed ($r_1$ varies by less than 8%). These results show that no decomplexation occurs in this pH range and that the possible acceleration of the exchange rate of the water protons in acidic or basic media induce no or very little change in the proton relaxivity of the complexes. Since the hydrogen bonding is pH dependent, the absence of pH dependence of the Gd-DTPA-$(PAE)_2$ proton relaxivity could suggest the absence of a hydrogen bond between the ester function and the coordinated water molecule.[29] However, one can not exclude the existence of this hydrogen bond, since it has been established that the hydrogen bonding between neutral groups is usually insensitive to pH over the wide range in which no protonation or deprotonation of the hydrogen-bond acceptor or donor occurs.[29]

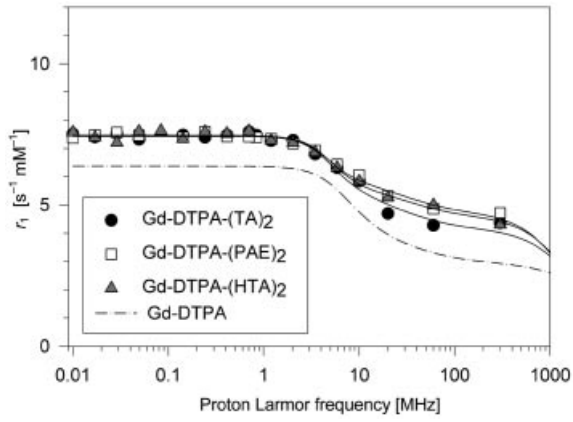

Figure 3. Proton NMRD profiles of the relaxivity of Gd-DTPA-$(TA)_2$, Gd-DTPA-$(HTA)_2$ and Gd-DTPA-$(PAE)_2$ at 37 °C. [Gd-DTPA-$(TA)_2$] = 3.22 mM, [Gd-DTPA-$(HTA)_2$] = 3.65 mM and [Gd-DTPA-$(PAE)_2$] = 2.84 mM. The NMRD profile of Gd-DTPA was added for comparison.[34]

### Proton NMRD Measurements

The proton NMRD relaxivities of the three gadolinium(III) complexes recorded at 310 K are quite similar and 20 to 36% larger than that for Gd-DTPA at 20 MHz (Figure 3, Table 2). The fittings of the proton NMRD profiles were performed as described in the Exp. Sect. and include both inner-sphere and outer-sphere interactions.[30–32] Some parameters were fixed during the fitting procedure: *d*, the distance of closest approach for the outer-sphere contribution was set at 0.36 nm, *D*, the relative diffusion constant was set to $3.3 \times 10^{-9}$ m$^2$ s$^{-1}$,[33] $\tau_M^{310}$ values were those obtained by $^{17}$O NMR spectroscopy, and the number of water molecules in the first coordination sphere of gadolinium(III) was set to one. $\tau_V^{310}$ and $\tau_{S0}^{310}$ (the electronic relaxation time at zero field) were optimized for the outer-sphere and the inner-sphere contributions simultaneously. The distance *r* between the protons of the coordinated water molecule and the gadolinium(III) ion was set to 0.31 nm.

The fitting of the experimental data of the three complexes gave values of $\tau_{S0}$ and $\tau_V$ close to those of Gd-DTPA. However, the $\tau_{S0}$ values calculated from the $^{17}$O NMR spectroscopic data or obtained from the fitting of the proton NMRD profiles are quite different. This can be related to the fact that $^{17}$O data are obtained at high magnetic field where $\tau_{S1}$ values are quite large (of the order of $10^{-8}$ s), whereas the $\tau_{S0}$ values estimated from the proton relaxometric NMRD data of small complexes are predominantly determined from the low-field data (where $\tau_{S1}$ values are of the order of $10^{-10}$ s). The rotational correlation times $\tau_R$ are, as expected, somewhat larger (Table 2) than the value found for Gd-DTPA and agree with the increase in molecular weight on going from Gd-DTPA-$(TA)_2$ to Gd-DTPA-$(PAE)_2$.

### Transmetallation

The transmetallation by zinc(II) ions was assessed in order to test the stability of the complexes. The procedure is based on the very low solubility of gadolinium(III) ions in phosphate solution and on the subsequent decrease of the proton paramagnetic relaxation rate during the transmetallation process. The data are shown in Figure 4 and are compared to those of Gd-DTPA and Gd-DTPA-BMA. The "ratio index" is defined as the time ($t$) required to reach a ratio $R_1^P(t)/R_1^P(0) = 80\%$,[34] and is larger for the three complexes than that of the commercial Gd-DTPA-BMA. After 50 hours, the ratio $R_1^P(t = 3000)/R_1^P(0)$ of Gd-DTPA-$(TA)_2$ and Gd-DTPA-$(PAE)_2$ is still better or similar to that of Gd-DTPA-BMA, whereas for Gd-DTPA-$(HTA)_2$ a

[a] Relaxivity in water. [b] Apparent relaxivity in 4% HSA (i.e., paramagnetic relaxation rate of 1 mM solution of the complex in 4% HSA). [c] Obtained from $^{17}$O relaxometry. [d] From ref.[34]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lower ratio is obtained. The complexes reported in the present work thus undergo a slower transmetallation than Gd-DTPA-BMA within the first five hours. However, after 50 hours the extent of the transmetallation process is more pronounced for Gd-DTPA-$(HTA)_2$ (Figure 4).

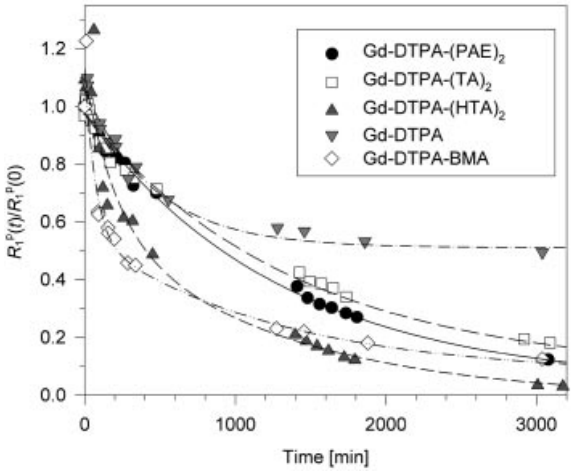

Figure 4. Evolution of $R_1^P(t)/R_1^P(0)$ vs. time for Gd-DTPA-$(TA)_2$, Gd-DTPA-$(HTA)_2$, Gd-DTPA-$(PAE)_2$, Gd-DTPA and Gd-DTPA-BMA (initial concentrations of Gd complexes and $ZnCl_2$ are 2.5 mM in phosphate buffer pH = 7, $T$ = 37 °C, $B$ = 0.47 T).

### Interaction with Human Serum Albumin

The interaction of a small gadolinium(III) complex with human serum albumin (HSA) increases its rotational correlation time and subsequently enhances its paramagnetic relaxation rate and its vascular remanence. A quick insight into the strength of the interaction can be obtained by the measurement of the paramagnetic relaxation rate of a solution (1 mM) of the complex in the presence of HSA (4%) at 20 MHz. An increase in the relaxation rate larger than 60% attests to a significant interaction between the gadolinium complex and the protein.[34] Such experiments performed with all three complexes showed maximum increases of 40% at 0.41 T and smaller values of the paramagnetic relaxation rate at 1.4 T (Table 2), testifying to the absence of a significant binding of these complexes with HSA.

## Conclusions

DTPA-bis(amide) derivatives bearing phenyl, phenol or catechol groups were synthesized in high yields and complexed to gadolinium(III) ions. As expected for bis(amide) derivatives of Gd-DTPA, the residence time of the coordinated water, as obtained from $^{17}O$ NMR relaxometric $T_2$ data, is longer than that for the parent Gd-DTPA complex. Surprisingly, a significantly longer residence time of the coordinated water was observed for the complex bearing an ethyl ester substituent. This could be caused by the existence of a hydrogen bond between the ester function and the water molecule, which can result in the stabilization of the hydrated state, or by the steric hindrance and the hydrophobicity of the ethyl groups. The larger proton relaxivity of all three complexes relative to that of Gd-DTPA is mainly because of the increase in the rotational correlation time. The stability of these new paramagnetic complexes tested in the presence of zinc(II) ions is better than that of Gd-DTPA-BMA within the first five hours. Taking into account the water residence time and the stability compared with zinc(II) transmetallation, the best candidate as a potential MRI contrast agent is thus Gd-DTPA-$(TA)_2$. The lack of significant interaction with HSA could be favourable to their use as receptor-specific contrast agents. In a next step, these contrast agents should be tested in the presence of catechol receptors and characterized in vivo in animal models.

## Experimental Section

**Chemicals:** Reagents were obtained from Aldrich Chemical Co. Inc., Acros Organics and Fluka, and were used without further purification. DTPA-bis(anhydride) was prepared by the published procedure.[35]

**Instruments:** Elemental analysis was performed with a CE Instruments EA-1110 elemental analyzer. $^1H$- and $^{13}C$ NMR spectra were recorded with a Bruker AMX-300 spectrometer, operating at 7.05 T. For $^{13}C$ NMR spectra, methanol was used as the internal reference. IR spectra were measured with a FTIR spectrometer Bruker IFS66, using KBr discs. Mass spectra were recorded with a Q-tof 2 (Micromass, Manchester UK). Samples for the mass spectra were prepared as follows. The complex (2 mg) was dissolved in methanol (1 mL). A sample of this solution (200 μL) was added to a 50:50 water/methanol solution (800 μL). The resulting solution was injected with a flow rate of 5 μL min$^{-1}$.

**Synthesis of the Ligands:** Ligands DTPA-$(PAE)_2$, DTPA-$(TA)_2$ and DTPA-$(HTA)_2$ were synthesized by the following general procedure. To a solution of DTPA-bis(anhydride) (0.357 g, 1 mmol) in dry DMF (30 mL) was added the corresponding amine (2.5 mmol), and the reaction mixture was heated overnight at 60 °C under nitrogen.[35] For the ligand DTPA-$(HTA)_2$, a small amount of ascorbic acid (50 mg) was added to the mixture to prevent oxidation. After the removal of the solvent, the product was re-dissolved in ethanol and precipitated by addition of diethyl ether. The precipitate was filtered off and dried in vacuo overnight.

#### Analytical Data for the Ligands

**DTPA-$(PAE)_2$:** Yield: 89% (661 mg). $C_{34}H_{49}N_5O_{12}$ (743.81): calcd. C 58.12, H 6.64, N 9.42; found C 58.55, H 6.61, N 9.40. $^1H$ NMR ([D$_6$]dmso): $\delta$ = 1.10 (t, 6 H, $CH_3$), 2.72 (m, 4 H, 2 × N–$CH_2$), 2.81 (m, 4 H, 2 × N–$CH_2$), 3.01 (m, 2 H, N–$CH_2$), 3.25 (s, 4 H, 2 × N–$CH_2$), 3.32 (s, 4 H, 2 × N–$CH_2$), 3.48 (d, 4 H, 2 × $CH_2$–Ph), 4.05 (q, 4 H, $CH_2$–O), 4.52 (m, 2 H, 2 × CH), 7.19–7.43 (m, 10 H, Ph), 8.32 (d, 2 H, 2 × NH) ppm. $^{13}C$ NMR ([D$_6$]dmso): $\delta$ = 172.8, 171.5, 170.7, 168.9, 137.4, 129.3, 128.4, 126.7, 60.8, 56.6, 56.2, 52.2, 48.7, 45.5, 38.9, 35.9, 14.0 ppm. IR: $\tilde{\nu}$ = 2972, 2952, 2876 (CH alkyl), 1733 (CO ester), 1677 (CO acid), 1633 (CO amide I), 1534 (CO amide II) cm$^{-1}$. ESI-MS(+) ($C_{36}H_{49}N_5O_{12}$: $M_{calcd.}$ = 743): $m/z$ = 744 [M + H]$^+$, 766 [M + Na]$^+$.

**DTPA-$(TA)_2$:** Yield: 85% (536 mg). $C_{30}H_{41}N_5O_{10}$ (631.68): calcd. C 57.04, H 6.54, N 11.09; found C 57.36, H 6.68, N 11.38. $^1H$ NMR ($D_2O$): $\delta$ = 2.64 (t, 4 H, 2 × N–$CH_2$), 2.97 (t, 4 H, 2 × N–$CH_2$), 3.11 (m, 4 H, 2 × $CH_2$–NH–CO), 3.35 (m, 4 H, 2 × $CH_2$–

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Ph), 3.50 (s, 2 H, $CH_2$–COOH), 3.57 (s, 4 H, 2 × $CH_2$–COOH), 3.69 (s, 4 H, 2 × $CH_2$–CO–NH), 6.60–6.92 (AA′BB′, 8 H, 2 × Ph) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 173.2, 172.1, 169.4, 154.4, 131.2, 130.6, 115.7, 57.2, 54.7, 51.9, 51.4, 51.3, 40.8, 33.9 ppm. IR: $\tilde{\nu}$ = 1635 (CO amide I), 1510 (CO amide II) cm$^{-1}$. ESI-MS(+) ($C_{30}H_{41}N_5O_{10}$: $M_{calcd.}$ = 631): $m/z$ = 632 [M + H]$^+$, 654 [M + Na]$^+$.

**DTPA-(HTA)$_2$:** Yield: 79% (630 mg). $C_{30}H_{38}N_5O_{12}Na_3(H_2O)$ (747.64): calcd. C 48.18, H 5.39, N 9.37; found C 48.63, H 5.60, N 8.97. $^1$H NMR ($D_2O$): $\delta$ = 2.61 (t, 4 H, 2 × N–$CH_2$), 2.95 (t, 4 H, 2 × N–$CH_2$), 3.10 (m, 4 H, 2 × $CH_2$–NH–CO), 3.37 (m, 4 H, 2 × $CH_2$–Ph), 3.50 (s, 2 H, $CH_2$–COOH), 3.56 (s, 4 H, 2 × $CH_2$–COOH), 3.68 (s, 4 H, 2 × $CH_2$–CO–NH), 6.56–6.82 (m, 6 H, Ph) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 179.6, 174.4, 171.4, 152.3, 149.5, 128.9, 117.5, 116.7, 115.7, 59.4, 57.8, 52.1, 48.1, 46.5, 40.9, 35.5 ppm. IR: $\tilde{\nu}$ = 1740 (CO acid), 1647 (CO amide I), 1521 (CO amide II) cm$^{-1}$. ESI-MS(+) ($C_{30}H_{41}N_5O_{12}$: $M_{calcd.}$ = 663): $m/z$ = 664 [M + H]$^+$, 686 [M + Na]$^+$.

**Synthesis of the Gadolinium(III) Complexes:** All complexes were synthesized according to the following general procedure. A solution of hydrated $GdCl_3$ salt (1 mmol) in $H_2O$ (1 mL) was added to the ligand (1 mmol) dissolved in pyridine (30 mL), and the mixture was heated at 70 °C for 3 h. Because of the basicity of pyridine, the addition of extra base for the deprotonation of the ligand was not necessary.The solvents were evaporated under reduced pressure, and the crude product was then refluxed in ethanol for 1 h. After cooling to room temp., the complex was filtered off and dried in vacuo. The absence of free gadolinium(III) ions was checked with xylenol orange indicator.[36]

**Analytical Data for the Gadolinium(III) Complexes**

**Gd-DTPA-(PAE)$_2$:** Yield: 35% (315 mg). IR: $\tilde{\nu}$ = 1733 (CO ester), 1622 (CO amide I), 1589 ($COO^-$ asym. stretch), 1388 ($COO^-$ sym. stretch) cm$^{-1}$. ESI-MS(+) ($C_{36}H_{46}GdN_5O_{12}$: $M_{calcd.}$ = 897): $m/z$ = 898 [M + H]$^+$.

**Gd-DTPA-(TA)$_2$:** Yield: 53% (417 mg). IR: $\tilde{\nu}$ = 1627 (CO amide I), 1595 ($COO^-$ asym. stretch), 1399 ($COO^-$ sym. stretch) cm$^{-1}$. ESI-MS(+) ($C_{30}H_{38}GdN_5O_{10}$: $M_{calcd.}$ = 785): $m/z$ = 786 [M + H]$^+$, 809 [M + Na]$^+$.

**Gd-DTPA-(HTA)$_2$:** Yield: 95% (770 mg). IR: $\tilde{\nu}$ = 2923, 2852 (CH alkyl), 1628 (CO amide I), 1602 ($COO^-$ asym. stretch), 1408 ($COO^-$ sym. stretch) cm$^{-1}$. ESI-MS(+) ($C_{30}H_{38}GdN_5O_{12}$: $M_{calcd.}$ = 817): $m/z$ = 840 [M + Na]$^+$.

**Sodium and Potassium Ion Content Measurements:** The potassium and sodium ion content of the solutions was checked by flame photometry (IL 943, Instrumentation Laboratories, Massachusetts, USA). $Na^+$ content (mmol per mol of the complex): Gd-DTPA-(PAE)$_2$: 0.7; Gd-DTPA-(TA)$_2$: 0.0; Gd-DTPA-(HTA)$_2$: 0.0. $K^+$ content: no $K^+$ could be detected in any of the complexes.

**Proton $T_1$ Measurements:** Proton nuclear magnetic relaxation dispersion (NMRD) profiles were recorded at 310 K between 0.24 mT and 0.24 T with a Field Cycling Relaxometer (Stelar Spinmaster FFC-2000, Stelar S. R. L., Mede, Italy) on solutions (0.6 mL) contained in 10-mm o.d. tubes. Proton relaxation rates were also measured at 0.47, 1.5 and 7.05 T on Minispec PC-120, mq-60 and AMX-300 spectrometers (Bruker, Karlsruhe, Germany), respectively. $^1$H NMRD data were fitted according to the theoretical inner-sphere model described by Solomon[30] and Bloembergen[31] and to the outer-sphere contribution described by Freed.[32] Calculations were performed with a previously described software.[26]

**$^{17}$O NMR Measurements:** $^{17}$O NMR measurements of solutions were performed on samples (2 mL) contained in 10-mm external diameter tubes with a Bruker AMX-300 spectrometer. The temperature was regulated by air or nitrogen flow controlled by a BVT 2000 unit. No field frequency lock was used. $^{17}$O transverse relaxation times of distilled water (pH = 6.5–7) were measured using a CPMG sequence and a subsequent two-parameter fit of the data points. The 90° and 180° pulse lengths were 25 and 50 μs, respectively. $^{17}$O $T_2$ values of water in complex solution were obtained from line-width measurement. Concentrations of the samples were less than 25 mM {[Gd-DTPA-(TA)$_2$] = 20.1 mM, [Gd-DTPA-(HTA)$_2$] = 20.0 mM and [Gd-DTPA-(PAE)$_2$] = 20.3 mM}. The data were treated as described elsewhere.[26–28,34]

**Transmetallation Kinetics:** The technique is based on the measurement of the evolution of the water proton paramagnetic longitudinal relaxation rate ($R_1^P$) of a buffered solution ([$KH_2PO_4$] = 0.026 mol L$^{-1}$, [$Na_2HPO_4$] = 0.041 mol L$^{-1}$, pH = 7) containing the gadolinium(III) complex (2.5 mM) and $ZnCl_2$ (2.5 mM).[37] The measurements were performed with a spin analyzer Minispec PC-120 (Bruker, Karlsruhe, Germany) at 20 MHz and 310 K. The samples (0.3 mL) were contained in 7-mm o.d. Pyrex™ tubes and kept at 310 K in a dry block between measurements (up to 4 d).

## Acknowledgments

T. N. P.-V., K. K. and K. B. thank the K. U. Leuven for financial support (VIS/01/006.01/20002-06/2004 and GOA 03/03). T. N. P.-V. acknowledges the F. W. O.-Flanders (Belgium) for a Postdoctoral Fellowship. C,H,N microanalyses were performed by Mrs. Petra Bloemen. This work was supported by the ARC Program (contracts number 95/00-194 and 00-05/258) of the French Community of Belgium. L. V. E., S. L., C. T. and R. N. M. kindly acknowledge the support and sponsorship concerted by COST Action D18 "Lanthanide Chemistry for Diagnosis and Therapy", and the EMIL NoE of the FP6 of the EC.

# Structural Chemistry of an $n = 1$ Member of the Ruddlesden–Popper $Sr_{n+1}(Co_{0.5}Ta_{0.5})_nO_{3n+1}$ Homologous Series: $Sr_4CoTaO_8$

**Khalid Boulahya,[a] Marina Parras,[a] and José María González-Calbet*[a]**

**Keywords:** Electron diffraction / X-ray diffraction / Electron microscopy / Magnetic properties

A layered perovskite related compound with the $Sr_4CoTaO_8$ composition was isolated. This material constitutes the $n = 1$ member of the recently reported $[Sr_{n+1}(Co_{0.5}Ta_{0.5})_nO_{3n+1}]$ Ruddlesden–Popper series. XRPD, SAED and HREM reveal that this compound crystallizes as a $K_2NiF_4$-type with space group $I4/mmm$. The structure is formed by one $Sr_2CoTaO_6$ perovskite block that intergrows with one SrO rock salt layer; no ordering between the Co and Ta cations was established. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Main-layered perovskites and their derivatives are characterized by an excess of anions relative to the ideal perovskite, and they constitute homologous series that are defined on the basis of the interslab composition and orientation of the layer plane relative to the aristotype cubic lattice. When this layer is parallel to the (001) plane of the cubic perovskite, the $(ABO_3)_nAO$ Ruddlesden–Popper (RP) series[1] arises. Most of the RP phases described up to now contain B cations of the first transition series, such as Ti, Ni, Cu, ...; however, structures related to the $n = 2$ member of this series, $Sr_3Co_2O_{7-\delta}$, which involves the substitution of Co by other metals of the later transition series, have been recently reported.[2] Indeed, a broad range of complex tantalum oxides have been reported to exhibit very high photocatalytic activities for the decomposition of water into $H_2$ and $O_2$; this is one of the most promising pathways for the conversion of photon energy into chemical energy.[3] For instance, $A_2SrTa_2O_7$ (A = H, K, Rb)[4] is the $n = 2$ member of the RP-layered series whose structure is built up of two cubic perovskite blocks that intergrow with a SrO rock-salt-type layer. The substitution of a monovalent cation by a divalent cation in the A sublattice must be accompanied by the partial substitution of Ta by other metals that stabilize lower oxidation states. In an attempt to stabilize homologous series with cations of later transition-metal series, and taking into account the versatility of cobalt, we recently isolated the $n = 2$ and $n = \infty$ members of the $Sr_{n+1}(CoTa)_nO_{3n+1}$[5] family with a Co/Ta ratio of 1:1.

Cobalt-containing systems present a particular behaviour when compared with other RP series, and this difference in behaviour is related to the difficulty in stabilizing the $n = 1$ term. In fact, $Sr_2CoO_4$ can only be stabilized under high pressure conditions[6] whereas the upper $n$ terms can be easily prepared under atmospheric pressure. In a somewhat similar way, the high temperatures used to stabilize the different members of the $Sr_{n+1}(CoTa)_nO_{3n+1}$ series were not adequate to isolate the first member ($n = 1$) because disordered intergrowths of upper members ($n > 1$) were usually obtained. Lower synthetic temperatures combined with longer annealing times allowed us to successfully stabilize, for the first time, this $n = 1$ member. In this paper, we describe the synthetic conditions and microstructural characterization of the $n = 1$ member of this series, which possesses the composition $Sr_2(Co_{0.5}Ta_{0.5})O_4$ (i.e. $Sr_4CoTaO_8$). This is the end, in the absence of tilting, members of the series belong to the $I4/mmm$ $K_2NiF_4$ structural type with the layer sequence ($ABO_3$) perovskite-(AO) rock salt. To fully determine the structural details and physical properties of the series, X-ray powder diffraction (XRPD), selected area electron diffraction (SAED), high resolution electron microscopy (HREM) and magnetic properties were investigated.

## Results and Discussion

The synthetic pathway to $Sr_4CoTaO_8$ was followed by XRPD. After annealing for three days, the XRPD pattern can be indexed on the basis of a single $A_2BO_4$, $n = 1$ RP single phase. As it is well known, different members of the RP series ranging from $n = 1$ to $n = \infty$ (the $ABO_3$ perovskite structure) can be isolated. However, the presence of disorder in the stacking of the perovskite and SrO blocks is not unusual and it is not always detected by powder X-ray diffraction, and therefore, careful microstructural study of these phases is always advisable. In fact, the microstructural study of $Sr_4CoTaO_8$ by HREM confirms that most of the

[a] Departamento de Química Inorgánica, Facultad de Químicas, Universidad Complutense de Madrid

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

crystals are constituted by intergrowth of $n = 1$ and $n = \infty$ members of the RP series.

Actually, in the [010] zone image (Figure 1), $n = 1$ regions, $A_2BO_4$ structural blocks intergrow with isolated lamellae of the cubic perovskite $n = \infty$ member of the mentioned series. Moreover, in some crystals, the intergrowth of the $n = 1$ member with other related superstructures, which correspond to other terms of the RP series, is apparent. The presence of this type of disorder was attributed to kinetic reasons. In fact, sintering times play an important role in the stabilization of single phases and, usually, long times are necessary to avoid intergrowths of different members of the series. Therefore, to attain a long range ordered material, the sample was reannealed. After seven days at 1000 °C, a fully ordered $Sr_4CoTaO_8$ single phase was isolated as revealed by XRPD, SAED and HREM.

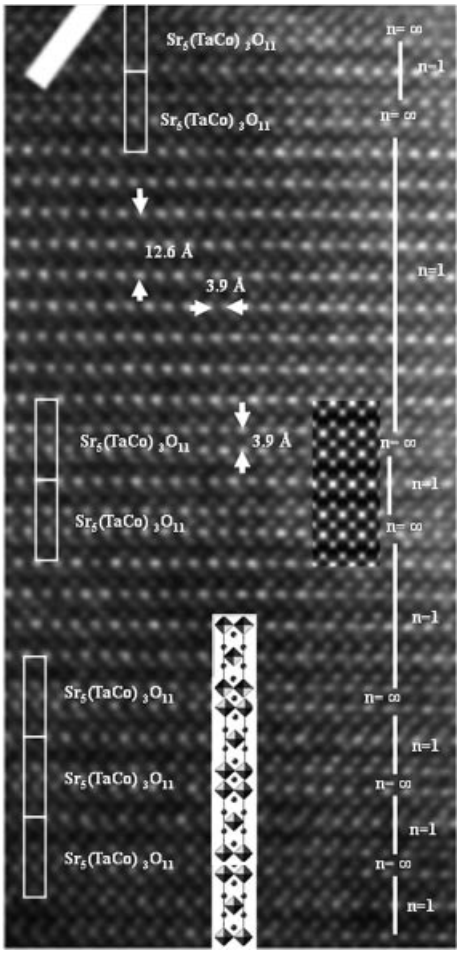

Figure 1. HRTEM image along the [010] zone axis that corresponds to a sample with nominal composition $Sr_4CoTaO_8$ after 3 d annealing. $Sr_5(CoTa)_3O_{11}$ ($n = 1.5$) member of $Sr_{n+1}(Co_{0.5}Ta_{0.5})_nO_{3n+1}$ series intergrows in a disordered way with $n = 1$ regions. Ideal structural model of $Sr_5(CoTa)_3O_{11}$ and calculated image from the model are shown in the inset.

The whole XRPD pattern (Figure 2) can be indexed on the basis of a tetragonal unit cell with lattice parameters $a = b = 3.8991(1)$ and $c = 12.6264(8)$ Å, no extra reflections are detected. SAED was used to fully reconstruct the reciprocal space. The most relevant zone axes, [001] and [010], are depicted in Figure 3. The diffraction spots are always sharp; streaking or diffuse intensity, which are indicative of some disorder, are not observed. All reflections can be indexed on the basis of the above tetragonal unit cell. Besides, the reflection conditions are compatible with the *I*4/*mmm* (139) space group, which was previously proposed for other $n = 1$ members of the RP family.[9]

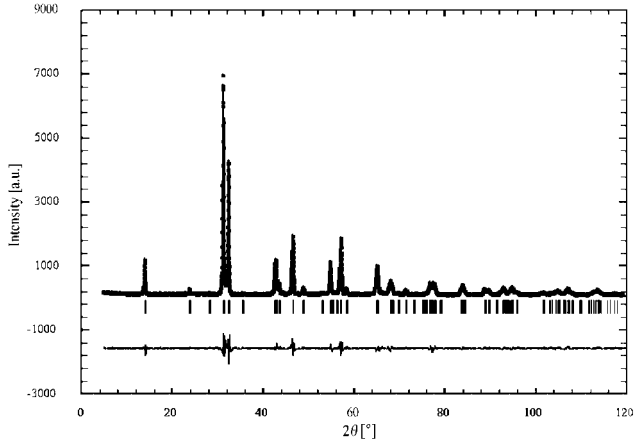

Figure 2. Graphic results of the fitting of the XRPD powder data of $Sr_4CoTaO_8$: experimental (points), calculated (solid line) and difference (bottom).

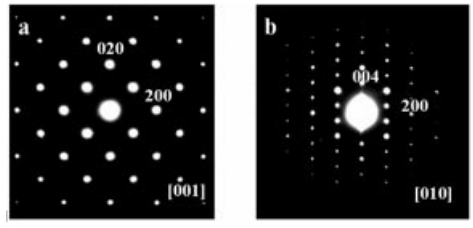

Figure 3. SAED patterns corresponding to $Sr_4CoTaO_8$ along (a) [001] and (b) [010] zone axes.

The [010] HREM image (Figure 4) corresponds to an apparently well-ordered material that shows *d*-spacing of 3.9 Å and 12.6 Å, which corresponds to $d_{100}$ and $d_{001}$, respectively. The contrast variation in this image corresponds to two layers with black dots that are marked by an arrow, which can be associated to Sr atoms of the rock salt blocks; these layers are separated by one layer with less intense dots that are marked by a dashed arrow, which correspond to Co/Ta atoms of the perovskite blocks. This configuration is shown in the enlarged image of Figure 4 and corresponds to the structural model depicted in Figure 5. Fourier transform was performed on the HREM micrograph to look for the existence of different domains that could indicate the presence of additional Co/Ta ordering in the structure. However, the whole crystal is homogeneous and no additional ordering was observed. Therefore, from the corresponding ideal atomic coordinates, an image calculation was performed. The simulated image fits nicely to the experimental one for $\Delta f = -50$ nm and $\Delta t = 6$ nm (see Figure 4).

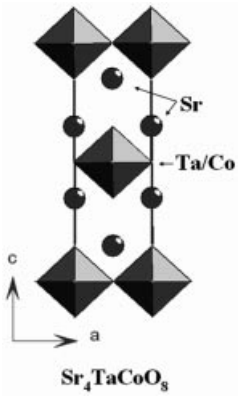

Figure 5. Structural model of $Sr_4CoTaO_8$ along the *b* axis.

B-site ordering for Co compounds has only been reported in $K_2NiF_4$-related materials when monovalent and trivalent cations occupy this site. For instance, Abou-Warda et al.[10] suggest that ordering of Co and Li in $La_2Li_{0.5}Co_{0.5}O_4$ is due to size rather than charge differences [$^{VI}r_{Li^+}$ = 0.76 Å; $^{VI}r_{Co^{3+}}$ = 0.545 Å (low-spin)]. In our case, the smaller difference between the $Co^{3+}$ and $Ta^{5+}$ radii ($^{VI}r_{Ta^{5+}}$ = 0.76 Å) could justify the disorder between the $[CoO]_6$ and $[TaO]_6$ octahedra.

According to the above results, an X-ray profile refinement of $Sr_4CoTaO_8$ was performed. The structure was solved in the *I*4/*mmm* space group by taking the crystallographic data corresponding to an $n$ = 1 member of this layered family as a starting point.[11] Because no evidence for the presence of Co/Ta order in the B sublattice was detected, both cations were randomly distributed over the octahedral sites in a first stage. Peak shapes were described by pseudo-Voigt functions. Figure 2 shows the graphic results of the fitting of the experimental X-ray diffraction pattern and the difference between observed and calculated data. The refinement was stable, and it was possible to refine the positions of the oxygen atoms provided that a temperature factor for each type of atom was used. Structure refinement confirms isotypism with $Sr_2TiO_4$.[11] The final structural parameters are collected in Table 1, and Table 2 shows some selected interatomic distances.

Table 1. Final structural parameters of $Sr_4CoTaO_8$.[a]

| Atom | *x*/*a* | *y*/*b* | *z*/*c* | $B_{iso}$ | *Occ* |

| O2 | 0.00000 | 0.00000 | 0.1684(8) | 1.85(13) | 1.00000 |

[a] S.G. *I*4/*mmm* (139), $a$ = 3.8991(1) Å, $a$ = 12.6264(8) Å, $V$ = 191.962(2) Å$^3$. $R_{wp}$ = 0.118, $R_{exp}$ = 0.070, $R_B$ = 0.038, $\chi^2$ = 2.6.

Table 2. Selected interatomic distances [Å] in $Sr_4CoTaO_8$.

| | |
|---|---|
| Sr1–O1: 2.688(1) × 4 | Co/Ta–O1: 1.950(0) × 4 |
| Sr1–O2: 2.336(1) | Co/Ta–O2: 2.126(1) × 2 |
| Sr1–O2: 2.771(1) × 4 | |

Refinement of the XRPD pattern confirms that $Sr_4TaCoO_8$ constitutes a new example of an $n$ = 1 term of the layered RP family. The structure consists of layers of corner-sharing $[Co/TaO_6]$ octahedra running perpendicular to the *c* axis and separated by Sr atoms. Adjacent sets of layers are staggered as shown in Figure 5. The observed Co/Ta–O(1) and Co/Ta–O(2) bond lengths of 1.950(0) and 2.126(1) Å indicate that the octahedra are tetragonally distorted along the *c* axis. These interatomic Co/Ta–O distances fit well with those of analogous oxides as $K_2SrTa_2O_7$[12] [distances Ta–O, 2.102(1)–1.812(1) Å] or $Sr_3Co_2O_{7-\delta}$[2] where the Co–O interatomic distances range from 1.92 to 2.00(1) Å. Finally, the Sr–O [2.771(1)–2.336(1) Å] distances are similar to those observed in other Sr oxides. At this point, it is worth remembering that the analogous $Sr_2CoO_4$ phase is only stabilized under high pressure. The partial substitution of Co by $Ta^V$ reduces the oxidation state of Co from IV to III in $Sr_4CoTaO_8$, which allows their stabilization under ambient pressure.

Figure 6 shows the temperature dependence of the magnetic susceptibility for $Sr_4CoTaO_8$ in the temperature range from 150 to 300 K. $Sr_4CoTaO_8$ exhibits a small and flat

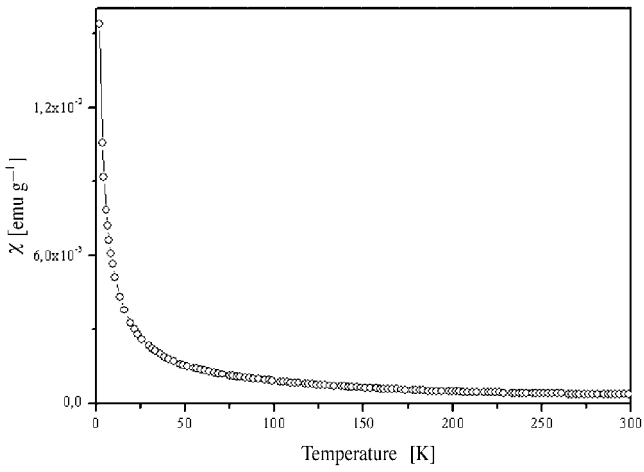

Figure 6. Magnetic susceptibility versus temperature plot corresponding to $Sr_4CoTaO_8$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

susceptibility, with a significant increase only at low temperatures. This low-temperature tail is usually attributed to spurious local paramagnetic moments. A similar behaviour was reported for $NaCoO_2$,[13] with all Co as low spin $Co^{III}$.

## Conclusions

The $n = 1$ member of the $[Sr_{n+1}(Co_{0.5}Ta_{0.5})_nO_{3n+1}]$ Ruddlesden–Popper series was successfully isolated. Large annealing times were necessary because SAED and HREM show that the first stage of the synthesis of $Sr_4CoTaO_8$ requires the initial formation of intergrowths of different members of the series. In this case, $Sr_4CoTaO_8$ intergrowths with the $n = \infty$ term is observed in most of the crystals.

A very interesting point of this work arises from this result. From the micrograph shown in Figure 1 it is clear that the existence of a new stable term of the series, formed by the ordered stacks of one $Sr_4CoTaO_8$ and one $SrCo_{0.5}Ta_{0.5}O_3$ structural block is possible and this corresponds to a chemical composition of $Sr_5(Co_{0.5}Ta_{0.5})_3O_{11}$. This recurrent intergrowth constitutes the $n = 1.5$ term, and this is the first example of a noninteger member of a RP series. This result opens the route to the research of new members of this series. We are currently investigating the synthetic conditions necessary to stabilize this new series member, and we hope to publish the results of this study in the near future.

## Experimental Section

Polycrystalline $Sr_4CoTaO_8$ was synthesized by heating stoichiometric amounts of $SrCO_3$ (Aldrich 99.98%), $Co_3O_4$ (Aldrich 99.9%) and $Ta_2O_5$ (Aldrich 99+%) at 1000 °C for 7 d. Annealing at higher temperatures does not lead to an ordered situation. In fact, the microstructural study shows that most parts of the crystals are constituted by disordered intergrowths of different members of the RP series, which results from the loss of SrO layers. X-ray powder diffraction (XRPD) patterns were collected by using Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å) at room temperature with a PHILIPS X'PERT diffractometer equipped with a graphite monochromator. Diffraction data were analyzed by the Rietveld method[7] with the use of the Fullprof program.[8] The sample was characterized by selected area electron diffraction (SAED) and high resolution electron microscopy (HREM) with a JEOL 3000 FEG electron microscope, fitted with a double tilting goniometer stage (±20°, ±20°). Local composition was analyzed by energy-dispersive X-ray spectroscopy (EDS) with an Oxford analyzer system attached to the above-described electron microscope. Magnetization was measured with a SQUID Quantum Design MPMS magnetometer, in a temperature range from 2 to 300 K, and magnetic field of 1000 Oe.

# Osmium(II) and Osmium(IV) Complexes with Phosphane–Ethers, –Esters, and –Amines as Mono- and Bidentate Ligands

**Birgit Weber[a] and Helmut Werner*[a]**

*Dedicated to Professor Max Herberhold on the occasion of his 70th birthday*

**Keywords:** Osmium / Phosphane–Ethers / Phosphane–Esters / Phosphane–Amines / Vinylidene complexes

The six-coordinate dihydridoosmium(IV) complex $[OsH_2Cl_2(PiPr_3)_2]$ (**1**) reacted with the hemilabile chelating phosphanes $iPr_2PCH_2CH_2OMe$ and $iPr_2PCH_2CO_2R$ (R = Me, Et) at room temperature to give the substitution products $[OsH_2Cl_2(iPr_2PCH_2CH_2OMe)_2]$ (**2**) and $[OsH_2Cl_2\{\kappa^2(P,O)\text{-}iPr_2PCH_2C(=O)OR\}\{\kappa(P)\text{-}iPr_2PCH_2CO_2R\}]$ (**3**, **4**) in good to excellent yields. Treatment of **1** with $iPr_2PCH_2CH_2NMe_2$ led to the displacement of only one $PiPr_3$ ligand and gave $[OsH_2Cl_2(PiPr_3)(iPr_2PCH_2CH_2NMe_2)]$ (**5**). The reaction of **1** with $iPr_2PCH_2CH_2OMe$ and $iPr_2PCH_2CO_2R$ (R = Me, Et) at elevated temperature afforded the osmium(II) complexes $[OsCl_2\{\kappa^2(P,O)\text{-}iPr_2PCH_2CH_2OMe\}_2]$ (**6**) and $[OsCl_2\{\kappa^2(P,O)\text{-}iPr_2PCH_2C(=O)OR\}_2]$ (**7**, **8**), which were also obtained on heating the osmium(IV) precursor **3** or the labile 1:1 adducts of **3** and **4** with ethene in benzene under reflux. The dihydrido compounds **2** and **3** reacted with CO at room temperature to give initially the octahedral all-*cis*-configured complexes $[OsCl_2(CO)_2\{\kappa(P)\text{-}iPr_2PCH_2CH_2OMe\}_2]$ (**11a**) and $[OsCl_2(CO)_2\{\kappa(P)\text{-}iPr_2PCH_2CO_2Me\}_2]$ (**12a**), which rearrange to the more stable *cis*,*cis*,*trans* isomers **11b** and **12b** in benzene under reflux. The all-*trans* isomer **11c** and the monocarbonyl complexes *trans*,*trans*-$[OsCl_2(CO)\{\kappa^2(P,O)\text{-}iPr_2PCH_2C(=O)OR\}\{\kappa(P)\text{-}iPr_2PCH_2CO_2R\}]$ (**13**, **14**) were prepared by passing CO through a solution of **6**–**8** in benzene or toluene/dichloromethane at room temperature. While the osmium(IV) compounds **3**, **4** as well as the osmium(II) complexes **7**, **8** reacted with CN*t*Bu to give the neutral complexes *cis*,*cis*,*trans*-$[OsCl_2(CNtBu)_2\{\kappa(P)\text{-}iPr_2PCH_2CO_2R\}_2]$ (**15**, **16**), treatment of **5** with CN*t*Bu afforded the ionic product $[OsHCl(CNtBu)_2(PiPr_3)(iPr_2PCH_2CH_2NHMe_2)]Cl$ (**17**). The reaction of **7** with $Ph_2CN_2$ did not lead to the formation of a (carbene)osmium(II) compound but gave the dinitrogen complex *trans*,*trans*-$[OsCl_2(N_2)\{\kappa^2(P,O)\text{-}iPr_2PCH_2C(=O)OMe\}(\kappa(P)\text{-}iPr_2PCH_2CO_2Me)]$ (**18**) instead. The structurally related vinylidene complexes *trans*,*trans*-$[OsCl_2(=C=CHPh)\{\kappa^2(P,O)\text{-}iPr_2PCH_2CH_2OMe\}\{\kappa(P)\text{-}iPr_2PCH_2CH_2OMe\}]$ (**19a**) and *trans*,*trans*-$[OsCl_2(=C=CHPh)\{\kappa^2(P,O)\text{-}iPr_2PCH_2C(=O)OR\}\{\kappa(P)\text{-}iPr_2PCH_2CO_2R\}]$ (**20**, **21**) were prepared from **6**–**8** and PhC≡CH as starting materials. The *cis*,*cis*-configured compound $[OsCl_2(=C=CHPh)(PiPr_3)\{\kappa^2(P,N)\text{-}iPr_2PCH_2CH_2NMe_2\}]$ (**22**) was obtained analogously from **5** and phenylacetylene.

## Introduction

In the context of our investigations to prepare highly reactive transition-metal complexes with coordinatively unsaturated metal centers, we reported the synthesis of the dichloridodihydridoosmium(IV) compounds $[OsH_2Cl_2(PR_3)_2]$ ($PR_3$ = $PiPr_3$, $PtBu_2Me$, $PCy_3$), in which the osmium atom, although six-coordinate, has only 16 instead of 18 electrons in its valence shell.[1,2] We as well as Esteruelas, Caulton and co-workers showed that these compounds have a diverse chemistry which opened the gate not only to (carbyne)- but also to (vinylidene)osmium complexes.[3,4]

The aim of the present work was to find out whether dichloridodihydridoosmium(IV) compounds containing hemilabile, potentially chelating phosphane ligands were also accessible and could be converted into the osmium(II) compounds $[OsCl_2(P\text{–}X)_2]$ (P–X = $iPr_2PCH_2CH_2OR$, $iPr_2PCH_2CO_2R$, $iPr_2PCH_2CH_2NMe_2$). Previous attempts in our laboratory to prepare the corresponding phosphane–ether complex $[OsCl_2(P\text{–}O)_2]$ (P–O = $iPr_2PCH_2CH_2OMe$) from $[OsCl_2(PPh_3)_3]$ and $iPr_2PCH_2CH_2OMe$ led unexpectedly to the formation of the (carbene)osmium complex $[OsCl_2\{\kappa^2(P,C)\text{-}(=CHOCH_2CH_2PiPr_2)\}\{\kappa^2(P,O)\text{-}iPr_2PCH_2CH_2OMe\}]$ by double metalation of the methoxy group of the phosphane.[5] The phosphane–amine $iPr_2PCH_2CH_2NMe_2$ behaves similarly.

In this paper we describe the synthesis of a series of osmium(II) and osmium(IV) compounds with hemilabile phosphane ligands which, as expected, are highly reactive and can serve as starting materials for the preparation of new carbonyl-, (isocyanide)- and (vinylidene)osmium(II) complexes.[6]

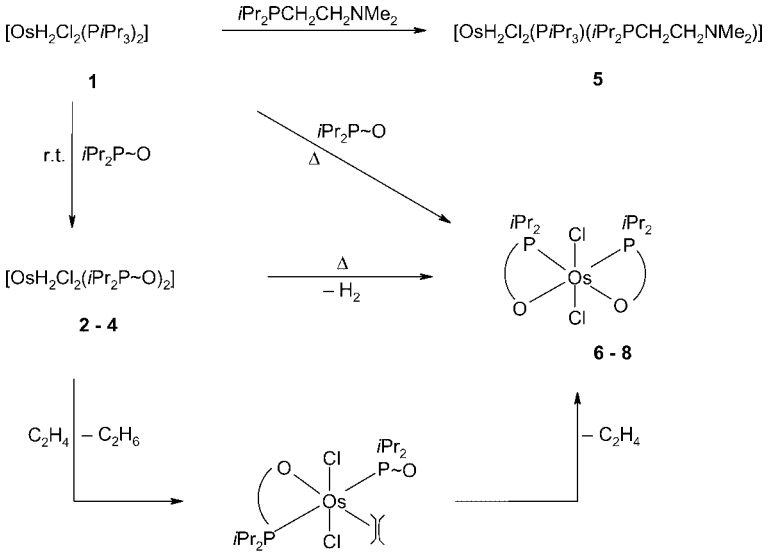
## Results and Discussion

The reactions of the dichloridodihydridoosmium(IV) complex $[OsH_2Cl_2(PiPr_3)_2]$ (**1**) with the phosphane–ether $iPr_2PCH_2CH_2OMe$ and the phosphane–esters $iPr_2PCH_2CO_2R$ (R = Me, Et) in pentane or hexane at room temperature proceed smoothly and give the substitution products **2**–**4** in good to excellent yields (Scheme 1). These compounds are pale-yellow or colorless, only moderately air-sensitive solids, for which correct elemental analyses were obtained. The $^1H$ and $^{13}C$ NMR spectra of **2**–**4** in $CDCl_3$ or $C_6D_6$ display at room temperature only one set of signals for the protons and carbon atoms of the phosphane ligands, indicating that these are stereochemically equivalent under those conditions. The $^{31}P$ NMR spectra of **2**–**4** show in each case one singlet which, due to $^1H,^{31}P$ coupling, becomes a triplet in off-resonance.

The IR spectra of the phosphane–ester complexes **3** and **4** display two equally strong ν(C=O) stretching modes at 1720 and 1630 $cm^{-1}$ (for **3**) and 1755 and 1665 $cm^{-1}$ (for **4**), of which those at higher wavenumbers are assigned in analogy to the data of the phosphane–esters $iPr_2PCH_2CO_2R$ (R = Me, Et) to a free, noncoordinated C=O unit.[7] This indicates that in the ground state of compounds **3** and **4** one phosphane ligand is coordinated in a monodentate and the other in a bidentate fashion. In agreement with this proposal, the singlets observed in the room-temperature $^{31}P$ NMR spectra of **3** and **4** are split at –90 °C into two slightly broadened resonances at $\delta$ = 18.0 and 9.7 ppm (for **3**) and $\delta$ = 19.0 and 9.8 ppm (for **4**) of about equal intensity. The small $^{31}P,^{31}P$ coupling is consistent with a *cis* position of the $iPr_2PCH_2CO_2R$ ligands. The $^1H$ NMR spectrum of **3** at –90 °C in $[D_8]$toluene shows two singlets for the methoxy protons of the ester functionality, which supports the proposed different coordination mode of the phosphanes. It is conceivable that not only the phosphane–ester complexes **3** and **4** but also the phosphane–ether analogue **2** is fluxional on the NMR time scale in solution at room temperature.

In contrast to $iPr_2PCH_2CH_2OMe$ and $iPr_2PCH_2CO_2R$, the phosphane–amine $iPr_2PCH_2CH_2NMe_2$ reacts with the starting material **1** at room temperature to give compound **5**, which still contains one $PiPr_3$ ligand. Even with an excess of the phosphane–amine, the coordinated triisopropylphosphane could not be displaced. Treatment of **1** with $iPr_2PCH_2CH_2NMe_2$ in refluxing hexane or benzene did also not lead to the formation of $[OsH_2Cl_2(iPr_2PCH_2CH_2NMe_2)_2]$ or $[OsCl_2(iPr_2PCH_2CH_2NMe_2)_2]$, but afforded the aminocarbene complex $[OsCl_2\{\kappa^2(C,N)\text{-}(=CHN(Me)CH_2CH_2PiPr_2)\}\{\kappa^2(P,N)\text{-}iPr_2PCH_2CH_2NMe_2\}]$, probably via $[OsCl_2(iPr_2PCH_2CH_2NMe_2)_2]$ as the intermediate.[5] The $^{31}P$ NMR spectrum of **5** displays two broadened resonances at $\delta$ = 30.8 and 14.2 ppm, which indicates the coordination of two different phosphane ligands. The $^1H$ NMR spectrum of **5** shows a sharp triplet for the two hydrido ligands, the chemical shift of which ($\delta$ = –12.22 ppm) is nearly identical to that of the hydrido signal of **2** ($\delta$ = –12.39 ppm). Therefore, it is likely that the stereochemistry of compounds **2** and **5** is the same.

The reaction of **1** with $iPr_2PCH_2CH_2OMe$ and $iPr_2PCH_2CO_2R$ (R = Me, Et) in hexane at 110 °C in a closed vessel gave instead of the osmium(IV) compounds **2**–**4** the osmium(II) complexes **6**–**8** by elimination of dihydrogen. They are probably formed via the osmium(IV)



| | P~O |
|---|---|
| **2, 6** | $PCH_2CH_2OMe$ |
| **3, 7, 9** | $PCH_2CO_2Me$ |
| **4, 8, 10** | $PCH_2CO_2Et$ |

Scheme 1.

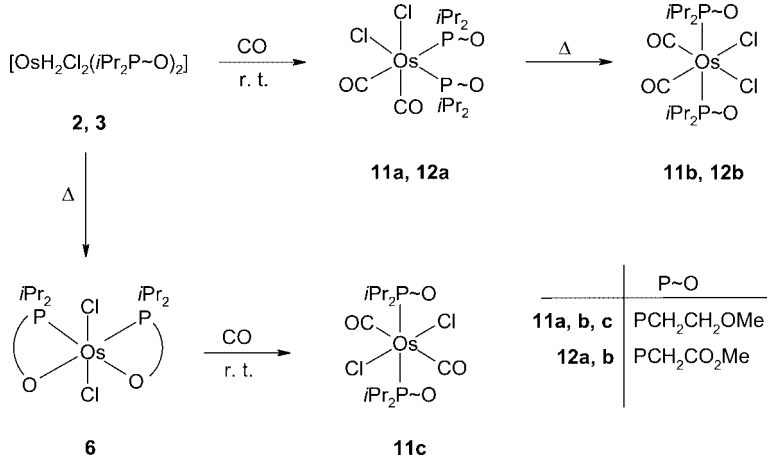
compounds **2**–**4**, as was shown by the thermal conversion of **3** to **6** in benzene under reflux. An alternative method of synthesis of **6**–**8** consists of the reaction of **2**–**4** in benzene in the presence of ethene, which affords the required osmium(II) complexes in nearly quantitative yield. If the conversion was carried out in $C_6D_6$ in an NMR tube, ethane could be detected as a by-product. Under these conditions it was also possible to observe the formation of the ethene derivatives **9** and **10** as intermediates. Similar to the IR spectra of **3** and **4**, those of **9** and **10** also display two ν(C=O) stretching modes at 1710 and 1605 $cm^{-1}$ (for **9**) and 1705 and 1610 $cm^{-1}$ (for **10**), which is consistent with the coordination of one monodentate and one bidentate $iPr_2PCH_2CO_2R$ ligand. This proposal is supported by the $^{31}P$ NMR spectra of **9** and **10**, in which two signals corresponding to an AB spin system are observed. The large $^{31}P,^{31}P$ coupling constants of 324.0 Hz (for **9**) and 325.6 Hz (for **10**) suggest that the two phosphorus atoms are *trans*-disposed. The $^1H$ NMR spectra of **9** and **10** show in each case a single resonance at $\delta$ = 4.01 ppm (for **9**) and $\delta$ = 4.05 ppm (for **10**), which is split into a triplet due to $^1H,^{31}P$ coupling. Since for a rigid structure two signals for the ethene protons should be observed, we assume that a rapid rotation of the ethene ligand around the metal–olefin axis occurs, making these protons equivalent. With regard to the stereochemistry of the six-coordinate osmium(II) complexes **6**–**8**, we favor a *cis*,*cis*,*trans* configuration (see Scheme 1), which is not only consistent with the spectroscopic data but also with the molecular structure of the related ruthenium(II) compound $[RuCl_2\{\kappa^2(P,O)\text{-}Ph_2PCH_2CH_2OMe\}_2]$.[8]

Similar to $[OsH_2Cl_2(PtBu_2Me)_2]$,[1] the osmium(IV) complexes **2** and **3** react with CO at room temperature within a few minutes by elimination of $H_2$. While with **2** as starting material the all-*cis* isomer **11a** (Scheme 2) is exclusively formed, in the case of **3** a mixture of **12a** (all-*cis*) and **12b** (*cis*,*cis*,*trans*) is generated under these conditions. Typical spectroscopic features for **11a** are two CO stretching modes in the IR spectrum, two doublet resonances in the $^{31}P$ NMR spectrum, two singlets for the methoxy protons in the $^1H$ NMR spectrum, and two signals for the carbon atoms of the stereochemically different CO ligands in the $^{13}C$ NMR spectrum. One of these $^{13}C$ NMR signals is split into a triplet and assigned to the carbonyl ligand *trans* to the chlorido ligand, while the other is split into a doublet of doublets and assigned to the carbonyl ligand *cis*-disposed to one and *trans*-disposed to the other phosphorus atom. The $^1H$ and $^{31}P$ NMR spectroscopic data of **12a** are very similar to those of **11a**.

If a solution of **11a** in benzene is stirred under reflux for 3 h, a complete conversion of the all-*cis* to the *cis*,*cis*,*trans* isomer **11b** occurs. The related complex **12b** is obtained upon heating a solution of the isomeric mixture of **12a** and **12b** in refluxing benzene for 5 h. Like the dibromidoosmium(II) compounds all-*trans*-$[OsBr_2(CO)_2\{\kappa(P)\text{-}R_2PCH_2CH_2OMe\}_2]$ (R = Ph, Cy), prepared by Lindner and co-workers,[9] the stereochemically different dichlorido complexes **11a**,**12a** and **11b**,**12b** are white solids, which are air-stable and readily soluble in benzene, toluene and chlorinated aliphatic hydrocarbons. In contrast to **11a** and **12a**, the $^{31}P$ NMR spectra of **11b** and **12b** display only one resonance for the equivalent phosphorus atoms and the $^1H$ NMR spectra of **11b** and **12b** only one signal for the methoxy protons. The IR spectra of **11b** and **12b** show two CO stretching modes, which is in agreement with a *cis* disposition of the carbonyl ligands.

In addition to **11a** and **11b** a third isomer **11c** of the general composition $[OsCl_2(CO)_2\{\kappa(P)\text{-}iPr_2PCH_2CH_2OMe\}_2]$ was obtained by passing a slow stream of CO through a solution of **6** in benzene at room temperature. The proposed all-*trans* configuration of **11c** is supported by the appearance of only one ν(C=O) band in the IR spectrum and of a single resonance in the $^{31}P$ NMR spectrum. The $^{31}P,^{187}Os$ coupling constant of 162.8 Hz is also in agreement with the *trans* position of the phosphorus atoms.[10]

In contrast to **6**, the corresponding phosphane–ester complexes **7** and **8** react with CO in toluene/dichloromethane at room temperature to give the monocarbonyl compounds **13** and **14** as yellow, air-stable solids in about 75% yield. Even if the solutions are stirred under CO for 12 h,



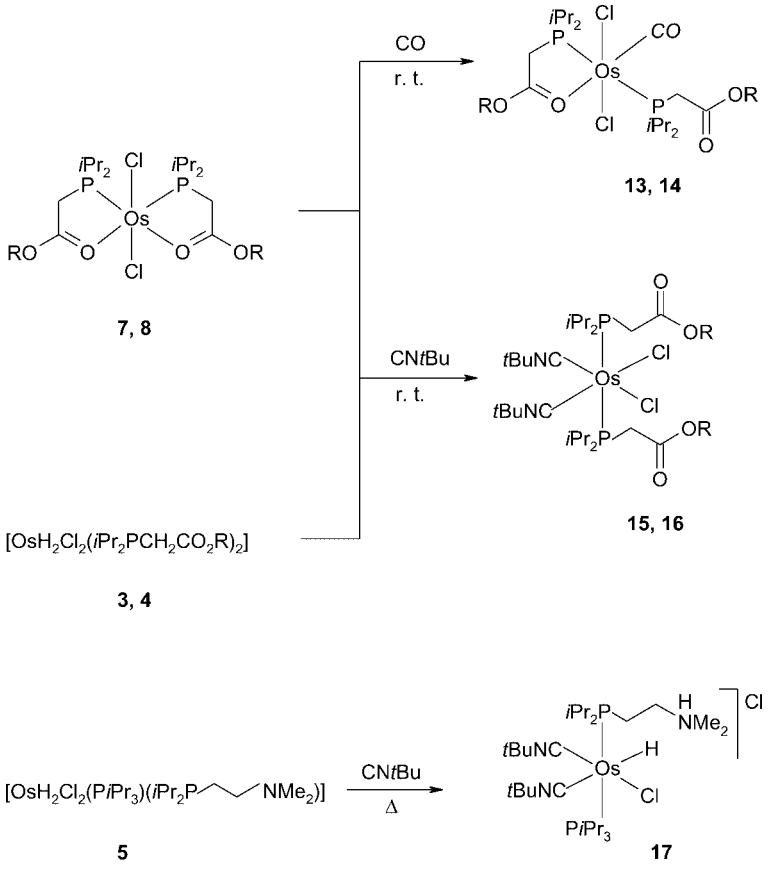
Scheme 2.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the expected dicarbonyl complexes, structurally related to **11a**, **11b** or **11c**, are not formed. The IR spectra of **13** and **14** display besides the strong ν(CO) band for the carbonyl ligand at 1915 $cm^{-1}$ (for **13**) and 1905 $cm^{-1}$ (for **14**) two ν(C=O) stretching modes for the free and the coordinated C=O ester function at 1710 and 1615 $cm^{-1}$ (for **13**) and 1705 and 1610 $cm^{-1}$ (for **14**). The observation of an AB spin system in the $^{31}P$ NMR spectra supports the different bonding mode of the $iPr_2PCH_2CO_2R$ ligands and the size of the $^{31}P,^{187}Os$ coupling constant the *trans* position of the phosphorus atoms. If we take this (and the supposed octahedral structure) into consideration, there remain two alternatives for the coordination site of the carbonyl ligand: it could be *trans* to the chlorido ligand or *trans* to the oxygen atom of the C=O ester group. Since the splitting pattern of the signals of the $CHCH_3$ protons and the $CHCH_3$ carbon atoms in the $^1H$ and $^{13}C$ NMR spectra of **13** and **14** indicate the presence of a mirror plane in the molecules, the second alternative, shown in Scheme 3, should be correct.

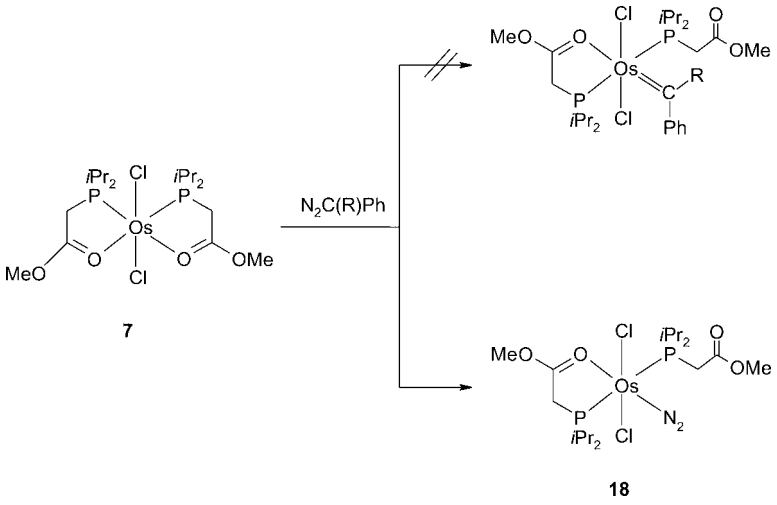
Under the same conditions, under which the monocarbonyl complexes **13** and **14** are obtained, the osmium(II) precursors **7** and **8** react with *tert*-butyl isocyanide to afford the disubstituted compounds **15** and **16**. Based on the NMR spectroscopic data, we assume that exclusively the *cis*,*cis*,*trans* isomers are formed. In analogy to the structurally related dicarbonyl derivatives **11b** and **12b**, the $^{31}P$ NMR spectra of **15** and **16** display one singlet for the equivalent phosphorus atoms, while the IR spectra show two ν(C≡N) stretching modes in the expected region. We note that prior to our work on the reactivity of the osmium(II) compounds **7** and **8**, we found that the analogous ruthenium(II) complex $[RuCl_2\{\kappa^2(P,O)\text{-}iPr_2PCH_2CO_2Me\}_2]$ reacts with CO to give the monocarbonyl compound $[RuCl_2(CO)\{\kappa(P)\text{-}iPr_2PCH_2CO_2Me\}\{\kappa^2(P,O)\text{-}iPr_2PCH_2CO_2Me\}]$ whereas with *t*BuNC the bis(isocyanide) complex $[RuCl_2(CNtBu)_2\{\kappa(P)\text{-}iPr_2PCH_2CO_2Me\}_2]$ (having in contrast to **15** the all-*trans* configuration) was obtained. The corresponding 1:1 adduct $[RuCl_2(CNtBu)\{\kappa(P)\text{-}iPr_2PCH_2CO_2Me\}\{\kappa^2(P,O)\text{-}iPr_2PCH_2CO_2Me\}]$ was isolated as an intermediate.[11]

The dihydridoosmium(IV) compounds **3** and **4** behave similarly to **7** and **8** and upon treatment with excess *t*BuNC in benzene at room temperature give the bis(isocyanide) complexes **15** and **16** in good to excellent yield. In contrast, the reaction of the phosphane–amine complex **5** with *tert*-butyl isocyanide in benzene under reflux led to the formation of the ionic product **17**, the conductivity of which in nitromethane is in agreement with that of a 1:1 electrolyte.



Scheme 3.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

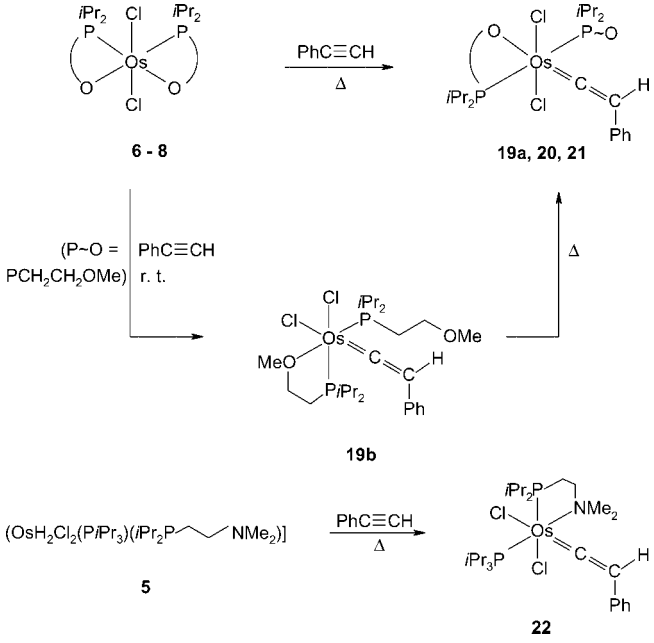


Scheme 4.

The $^1$H NMR spectrum of **17** displays for the hydrido ligand a resonance at $\delta$ = –7.48 ppm, which due to the coupling with two different $^{31}$P nuclei is split into a doublet of doublets. The presence of the OsH unit is also indicated by the {$^1$H}-decoupled $^{31}$P NMR spectrum, in which the two singlet signals of the AB spin system are split into doublets. The large $^{31}$P,$^{31}$P coupling constant of 245.8 Hz supports the *trans* position of the two phosphane ligands.

Attempts to prepare a (carbene)osmium(II) complex [$OsCl_2$(=CRPh){κ(*P*)-*i*$Pr_2PCH_2CO_2Me$}{κ$^2$(*P*,*O*)-*i*$Pr_2PCH_2CO_2Me$}] (R = H, Ph) from **6** and phenyl- or diphenyldiazomethane led unexpectedly to the formation of the dinitrogen compound **18** (see Scheme 4). A similar observation was already made in the course of studies on the reactivity of the dimer [RhCl(P*i*$Pr_3)_2]_2$, which upon treatment with $PhCHN_2$ gave the mononuclear complex *trans*-[RhCl($N_2$)(P*i*$Pr_3)_2$].[12] As we failed to separate **18** from organic by-products by column chromatography or fractional crystallization, the dinitrogenosmium(II) compound was characterized spectroscopically. Diagnostic for the coordination of the $N_2$ ligand is the N–N stretching mode at 2060 cm$^{-1}$ in the IR spectrum, which appears at a similar position as for the complexes [$OsCl_2(N_2)(L_3)$] (L = $PMe_2Ph$, $PEt_2Ph$, $PEt_3$)[13] and is consistent with an "end-on" coordination of the dinitrogen molecule.[14] Since the IR spectrum of **18** displays two ν(C=O) stretching modes at almost the same wavenumbers as for the monocarbonyl complex **13**, and since also the $^1$H, $^{13}$C and $^{31}$P NMR spectroscopic data of the two compounds are quite similar, we assume that the two chlorido ligands, the two phosphorus atoms, and the ester C=O group and the $N_2$ ligand are *trans*-disposed.

The reactions of the bis(chelate) osmium(II) precursors **6**–**8** with phenylacetylene in benzene under reflux gave the six-coordinate vinylidene complexes **19a**, **20** and **21** in 48–95% yield (Scheme 5). They are possibly formed via the isomeric alkyne- and alkynyl(hydrido) compounds as intermediates, although in contrast to the reactions of [RhCl{κ(*P*)-*i*$Pr_2PCH_2CH_2OMe$}{κ$^2$(*P*,*O*)-*i*$Pr_2PCH_2CH_2OMe$}] and [IrCl($C_2H_4$){κ(*P*)-*i*$Pr_2PCH_2CO_2Me$}$_2$] with phenylacetylene,[15,16] species with an Os(PhC≡CH) or OsH(C≡CPh) unit could not be observed. The most characteristic spectroscopic features of **19a**, **20** and **21** are (1) the signal of the =C*H*Ph proton at $\delta \approx$ 2.0–2.6 ppm in the $^1$H NMR spectra and (2) the low-field resonances at $\delta$ = 291.8 and 108.9 ppm (for **19a**), 297.1 and 109.3 ppm (for **20**), and 297.3 and 108.3 ppm (for **21**) in the $^{13}$C NMR spectra. The latter are assigned to the α-C and β-C vinylidene carbon atoms. The chemical shifts of the $^1$H and $^{13}$C NMR signals are quite similar to those of the related five-coordinate phenylvinylidene complexes [$OsCl_2$(=C=CHPh)(P*i*$Pr_3)_2$][17] and [$OsCl_2$(=C=CHPh)($PPh_3)_2$].[18]



Scheme 5.

At room temperature, compounds **19a**, **20** and **21** are fluxional in solution, as can be seen by the appearance of one broad singlet in the $^{31}$P NMR spectra. The dynamic

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

process is frozen out at low temperature, and thus in the spectra of **19a** (in $CDCl_3$ at –90 °C), **20** (in $C_6D_5CD_3$ at –80 °C), and **21** (in $C_6D_5CD_3$ at –20 °C) the typical pattern of an AB spin system is observed. The large $^{31}P,^{31}P$ coupling constants of about 320–333 Hz are consistent with the *trans* position of the phosphorus atoms. From the coalescence temperatures and the difference in the chemical shifts of the two signals $\Delta G^{\neq}$ values of approximately 40 kJ mol$^{-1}$ (for **19a**), 51 kJ mol$^{-1}$ (for **20**), and 54 kJ mol$^{-1}$ (for **21**) can be calculated. The observed phenomenon is reversible and explained by a rapid exchange in the chelating behavior of the two phosphane ligands. It is interesting to note that neither the monocarbonyl complexes **13** and **14** nor the dinitrogen derivative **18** are fluxional in solution at room temperature.

The proposed stereochemistry of **20** with the phosphanes and the chlorido ligands in *trans* disposition was confirmed by a single-crystal X-ray diffraction investigation.[19] The Os–C–C unit is almost linear [176.7(5)°] and the Os–C bond length [1.802(6) Å] slightly shorter than in some other (vinylidene)osmium(II) complexes such as $[OsCl_2(=C=CHPh)(P\textit{i}Pr_3)\{\kappa^2(\textit{P},\textit{N})\text{-}\textit{i}Pr_2PCH_2CH_2NMe_2\}]$ [1.82(1) Å],[3b] $[OsCl(=C=CHSiMe_3)(CH=CHSiMe_3)(P\textit{i}Pr_3)_2]$ [1.82(3) Å],[20] $[OsCl(=C=CHPh)(PPh_3)\{1,3\text{-}(PPh_2CH_2)_2C_6H_4\}]$ [1.819(6) Å],[21] and $[OsCl_2(=C=CHPh)(H_2O)(PPh_3)_2]$ [1.812(7) Å].[18] The smallest corner–center–corner angle of the octahedron is found for P–Os–O (80.0(1)°], which is probably due to the ring strain in the five-membered $OsPC_2O$ chelating system.

If the reaction of **6** with phenylacetylene in benzene was carried out at room temperature instead of under reflux, the red, moderately air-stable *cis,cis*-configured compound **19b** was generated (see Scheme 5). Under the same conditions, **7** and **8** are inert towards PhC≡CH. Upon heating, **19b** rearranges quickly to the thermodynamically preferred isomer **19a**. In contrast to **19a**, the $^{31}P$ NMR spectrum of **19b** displays two sharp doublets at room temperature, which indicates that in solution the molecule is non-fluxional on the NMR time scale under these conditions. The chemical shift of the two doublets ($\delta$ = 19.0 and –10.4 ppm) and the $^{31}P,^{31}P$ coupling constant (9.2 Hz) are similar to those of the phenylvinylidene complex **22** ($\delta$ = 15.4 and –11.2 ppm, $^2J_{P,P}$ = 6.7 Hz), which was prepared from **5** and excess phenylacetylene in benzene under reflux and characterized crystallographically.[3b] The X-ray crystal structure analysis of **22** revealed a slightly distorted octahedral geometry with the phosphorus atoms and the chlorido ligands in *cis* disposition and bond angles Cl–Os–Cl and P–Os–P of 85.10(9)° and 105.80(9)°, respectively. The P–Os–N angle of the chelate ring amounts to 82.4(1)° and is thus similar to the corresponding P–Os–O angle of **20**.

## Conclusion

The present work has shown that osmium(II) complexes of the general composition $[OsCl_2(P\text{–}O)_2]$ with the phosphane–ether $\textit{i}Pr_2PCH_2CH_2OMe$ and the phosphane–esters $\textit{i}Pr_2PCH_2CO_2R$ (R = Me, Et) as chelate ligands are accessible from dichloridodihydridoosmium(IV) compounds as precursors. Due to the lability of the Os–O bond, the osmium(II) complexes react smoothly with carbon monoxide and *tert*-butyl isocyanide by partial opening of the chelate ring. Depending on the reaction conditions, different isomers of the dicarbonyl compounds $[OsCl_2(CO)_2(\textit{i}Pr_2PCH_2CH_2OMe)_2]$ and $[OsCl_2(CO)_2(\textit{i}Pr_2PCH_2CO_2Me)_2]$ are formed. The monocarbonyl complexes $[OsCl_2(CO)(\textit{i}Pr_2PCH_2CO_2R)_2]$ and the dinitrogen derivative $[OsCl_2(N_2)(\textit{i}Pr_2PCH_2CO_2Me)_2]$, each of them containing one monodentate and one bidentate phosphane ligand, have also been obtained. The reactions of the chelate compounds $[OsCl_2(P\text{–}O)_2]$ with phenylacetylene afford the phenylvinylidene complexes $[OsCl_2(=C=CHPh)(P\text{–}O)_2]$, which in solution at room temperature are fluxional on the NMR time scale. The phosphane–amine complex $[OsCl_2(=C=CHPh)(P\textit{i}Pr_3)(\textit{i}Pr_2PCH_2CH_2NMe_2)]$ was prepared from $[OsH_2Cl_2(P\textit{i}Pr_3)(\textit{i}Pr_2PCH_2CH_2NMe_2)]$ and phenylacetylene and characterized crystallographically.

## Experimental Section

**General:** All operations were carried out under argon using Schlenk techniques. The osmium complex **1**[1] and the phosphane derivatives $\textit{i}Pr_2PCH_2CH_2OMe$,[16] $\textit{i}Pr_2PCH_2CH_2NMe_2$,[16] and $\textit{i}Pr_2PCH_2CO_2R$ (R = Me, Et)[7] were prepared as described in the literature. NMR: Bruker AC 200 and AMX 400. IR: Perkin–Elmer 397 and 1320. MS: Varian CH 7 MAT (70 eV). The molar conductivity $\Lambda_M$ was determined in nitromethane. Melting points were determined by DTA. Abbreviations used: s: singlet; d: doublet; t: triplet; q: quartet; m: multiplet; vt: virtual triplet; br.: broad signal; $N = {}^3J_{P,H} + {}^5J_{P,H}$ or ${}^2J_{P,C} + {}^4J_{P,C}$.

**1. Preparation of $[OsH_2Cl_2(\textit{i}Pr_2PCH_2CH_2OMe)_2]$ (2):** A suspension of **1** (145 mg, 0.25 mmol) in pentane (10 mL) was treated with $\textit{i}Pr_2PCH_2CH_2OMe$ (142 μL, 0.75 mmol) and stirred at room temperature for 24 h. A pale-yellow solid precipitated, which was filtered, washed three times with 5-mL portions of pentane and dried; yield 144 mg (94%); m.p. 65 °C (decomp.). MS: *m*/*z* ($I_r$) = 614 (0.4) [$M^+$], 578 (2.8) [$M^+$ – HCl], 542 (2.4) [$M^+$ – 2 HCl]. IR (KBr): $\tilde{\nu}$ = 2225 [ν(OsH)] cm$^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 3.65 (m, 4 H, $OCH_2$), 3.49 (s, 6 H, $OCH_3$), 2.53 (m, 4 H, $PCHCH_3$), 1.99 (m, 4 H, $PCH_2$), 1.24 (dd, $^3J_{P,H}$ = 16.2, $^3J_{H,H}$ = 7.1 Hz, 12 H, $PCHCH_3$), 1.23 (dd, $^3J_{P,H}$ = 13.9, $^3J_{H,H}$ = 7.0 Hz, 12 H, $PCHCH_3$), –12.39 (t, $^2J_{P,H}$ = 26.8 Hz, 2 H, $OsH_2$) ppm. $^{13}C$ NMR (50.3 MHz, $C_6D_6$): $\delta$ = 72.4 (s, $OCH_2$), 60.5 (s, $OCH_3$), 28.0 (d, $^1J_{P,C}$ = 35.7 Hz, $PCHCH_3$), 27.3 (d, $^1J_{P,C}$ = 33.7 Hz, $PCH_2$), 19.2, 18.8 (2 s, $PCHCH_3$) ppm. $^{31}P$ NMR (81.0 MHz, $C_6D_6$): $\delta$ = 25.2 (s, t in off-resonance) ppm. $C_{18}H_{44}Cl_2O_2OsP_2$ (615.7): calcd. C 35.11, H 7.20; found C 35.38, H 7.32.

**2. Preparation of $[OsH_2Cl_2\{\kappa^2(\textit{P},\textit{O})\text{-}\textit{i}Pr_2PCH_2C(=O)OMe\}\{\kappa(\textit{P})\text{-}\textit{i}Pr_2PCH_2CO_2Me\}]$ (3):** This compound was prepared as described for **2**, with **1** (134 mg, 0.29 mmol) and $\textit{i}Pr_2PCH_2CO_2Me$ (135 μL, 0.69 mmol) as starting materials and hexane (10 mL) as solvent. Colorless solid; yield 106 mg (72%); m.p. 80 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 2140 [ν(OsH)], 1720, 1630 [ν(C=O)] cm$^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 3.75 (s, 6 H, $OCH_3$), 3.31 (d, $^2J_{P,H}$ = 9.9 Hz, 4 H, $PCH_2$), 2.38 (m, 4 H, $PCHCH_3$), 1.29 (dd, $^3J_{P,H}$ = 15.9, $^3J_{H,H}$ = 7.0 Hz, 12 H, $PCHCH_3$), 1.13 (dd, $^3J_{P,H}$ = 14.5, $^3J_{H,H}$ = 6.7 Hz, 12 H, $PCHCH_3$), –9.97 (t, $^2J_{P,H}$ = 18.2 Hz, 2 H, $OsH_2$)

ppm. $^{13}$C NMR (100.6 MHz, $C_6D_6$): $\delta$ = 177.4 (s, *C*$O_2$Me), 53.9 (s, $OCH_3$), 31.8 (d, $^1J_{P,C}$ = 25.0 Hz, $PCH_2$), 27.8 (d, $^1J_{P,C}$ = 32.7 Hz, P*C*HCH$_3$), 18.8, 18.5 (2 s, PCH*C*H$_3$) ppm. $^{31}$P NMR (36.2 MHz, $C_6D_6$, 295 K): $\delta$ = 15.8 (s, t in off-resonance) ppm. $^{31}$P NMR (36.2 MHz, $C_6D_5CD_3$, 183 K): $\delta$ = 18.0, 9.7 (2 br., $J_{P,P}$ not resolved) ppm. $C_{18}H_{40}Cl_2O_4OsP_2$ (643.6): calcd. C 33.59, H 6.26; found C 33.54, H 6.22.

**3. Preparation of [OsH$_2$Cl$_2${κ$^2$(*P*,*O*)-*i*Pr$_2$PCH$_2$C(=O)OEt}{κ(*P*)-*i*Pr$_2$PCH$_2$CO$_2$Et}] (4):** This compound was prepared as described for **2**, with **1** (98 mg, 0.17 mmol) and *i*Pr$_2$PCH$_2$CO$_2$Et (120 μL, 0.51 mmol) as starting materials and hexane (10 mL) as solvent. Colorless solid; yield 99 mg (88%); m.p. 112 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 2140 [ν(OsH)], 1755, 1665 [ν(C=O)] cm$^{-1}$. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 4.25 (q, $J$ = 4 H, $^3H_{H,H}$ = 7.1 Hz, OC*H*$_2$CH$_3$), 3.29 (d, $^2J_{P,H}$ = 9.8 Hz, 4 H, $PCH_2$), 2.32 (m, 4 H, PC*H*CH$_3$), 1.28 (dd, $^3J_{P,H}$ = 16.4, $^3J_{H,H}$ = 7.0 Hz, 12 H, PCHC*H*$_3$), 1.26 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, OCH$_2$C*H*$_3$), 1.11 (dd, $^3J_{P,H}$ = 14.3, $^3J_{H,H}$ = 6.9 Hz, 12 H, PCHC*H*$_3$), –9.90 (t, $^2J_{P,H}$ = 18.3 Hz, 2 H, OsH$_2$) ppm. $^{31}$P NMR (36.2 MHz, $C_6D_6$, 295 K): $\delta$ = 15.5 (s, t in off-resonance) ppm. $^{31}$P NMR (36.2 MHz, $C_6D_5CD_3$, 183 K): $\delta$ = 19.0, 9.8 (2 br., $J_{P,P}$ not resolved) ppm. $C_{20}H_{44}Cl_2O_4OsP_2$ (671.6): calcd. C 35.77, H 6.60; found C 35.43, H 6.63.

**4. Preparation of [OsH$_2$Cl$_2$(P*i*Pr$_3$)(*i*Pr$_2$PCH$_2$CH$_2$NMe$_2$)] (5):** This compound was prepared as described for **2**, with **1** (200 mg, 0.35 mmol) and *i*Pr$_2$PCH$_2$CH$_2$NMe$_2$ (218 μL, 1.03 mmol) as starting materials and benzene (8 mL) as solvent. Time of reaction 3 h. Pale-yellow solid; yield 185 mg (88%); m.p. 98 °C (decomp.). MS: *m*/*z* ($I_r$) = 576 (17.6) [M$^+$ – HCl)], 540 (0.8) [M$^+$ – 2 HCl]. IR (KBr): $\tilde{\nu}$ = 2180, 2140 [ν(OsH)] cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 2.80 (s, 6 H, $NCH_3$), 2.71, 2.57, 2.53 (3 m, 7 H, C*H*$_2$NMe$_2$ and PC*H*CH$_3$), 1.78 (m, 2 H, $PCH_2$), 1.30 (dd, $^3J_{P,H}$ = 13.2, $^3J_{H,H}$ = 7.2 Hz, 12 H, PCHC*H*$_3$ of P*i*Pr$_3$), 1.24 (dd, $^3J_{P,H}$ = 13.2, $^3J_{H,H}$ = 7.1 Hz, 6 H, PCHC*H*$_3$ of P*i*Pr$_2$), 1.21 (dd, $^3J_{P,H}$ = 14.5, $^3J_{H,H}$ = 7.2 Hz, 6 H, PCHC*H*$_3$ of P*i*Pr$_2$), –12.22 (dd, $^2J_{P,H}$ = $^2J_{P',H}$ = 18.2 Hz, 2 H, OsH$_2$) ppm. $^{13}$C NMR (50.3 MHz, $CDCl_3$): $\delta$ = 63.3 (s, $NCH_2$), 54.0 (s, $NCH_3$), 30.2 (d, $^1J_{P,C}$ = 33.5 Hz, P*C*HCH$_3$ of P*i*Pr$_2$), 26.4 (d, $^1J_{P,C}$ = 31.5 Hz, P*C*HCH$_3$ of P*i*Pr$_3$), 20.9 (d, $^1J_{P,C}$ = 27.7 Hz, $PCH_2$), 19.7 (s, PCH*C*H$_3$ of P*i*Pr$_3$), 18.7, 18.6 (2 s, PCH*C*H$_3$ of P*i*Pr$_2$) ppm. $^{31}$P NMR (162.0 MHz, $CDCl_3$, 295 K): $\delta$ = 30.8, 14.2 (2 br. s, both t in off-resonance) ppm. $C_{19}H_{47}Cl_2NOsP_2$ (612.6): calcd. C 37.25, H 7.73, N 2.29; found C 37.03, H 7.75, N 2.25.

**5. Preparation of [OsCl$_2${κ$^2$(*P*,*O*)-*i*Pr$_2$PCH$_2$CH$_2$OMe}$_2$] (6). (a)** A suspension of **1** (305 mg, 0.52 mmol) in hexane (70 mL) was treated dropwise with *i*Pr$_2$PCH$_2$CH$_2$OMe (351 μL, 1.57 mmol) and heated at 110 °C in a closed vessel for 4 h. After the reaction mixture was cooled to room temperature, an orange solid precipitated. The solution was concentrated to ca. 2 mL, the yellow precipitate was filtered, washed twice with 5-mL portions of pentane (0 °C) and dried; yield 154 mg (48%). **(b)** A stream of ethene was passed through a solution of **2** (206 mg, 0.34 mmol) in benzene (10 mL) for 1 min and, after the ethene was replaced by argon, the solution was stirred under reflux for 30 min. After the reaction mixture was cooled to room temperature, the solvent was evaporated. The remaining oily residue was suspended in pentane (5 mL, 0 °C) and the suspension was stirred until an orange solid precipitated. The isolation of the product was analogous to the one described in (a); yield 156 mg (76%); m.p. 96 °C (decomp.). $^1$H NMR (200 MHz, $C_6D_6$): $\delta$ = 3.60 (s, 6 H, $OCH_3$), 3.56 (m, 4 H, $OCH_2$), 2.78 (m, 4 H, PC*H*CH$_3$), 1.84 (m, 4 H, $PCH_2$), 1.21 (dvt, PCHC*H*$_3$, $^3J_{H,H}$ = 7.3 Hz, 12 H, $N$ = 13.2 Hz), 1.19 (dvt, PCHC*H*$_3$, $^3J_{H,H}$ = 7.4 Hz, 12 H, $N$ = 13.0 Hz) ppm. $^{13}$C NMR (50.3 MHz, $C_6D_6$): $\delta$ = 75.0 (s, $CH_2O$), 62.6 (s, $OCH_3$), 29.0 (X part of an ABX spin system, $J_{A,X}$ = 28.6 Hz, P*C*HCH$_3$), 26.3 (X part of an ABX spin system, $J_{A,X}$ = 23.0 Hz, $PCH_2$), 20.7, 20.5 (2 s, PCH*C*H$_3$) ppm. $^{31}$P NMR (81.0 MHz, $C_6D_6$): $\delta$ = –0.6 (s, $^1J_{Os,P}$ = 361.8 Hz) ppm. $C_{18}H_{42}Cl_2O_2OsP_2$ (613.6): calcd. C 35.23, H 6.86; found C 35.22, H 6.90.

**6. Preparation of [OsCl$_2${κ$^2$(*P*,*O*)-*i*Pr$_2$PCH$_2$C(=O)OMe}$_2$] (7). (a)** A suspension of **1** (119 mg, 0.20 mmol) in hexane (15 mL) was treated dropwise with *i*Pr$_2$PCH$_2$CO$_2$Me (120 μL, 0.16 mmol) and heated at 110 °C in a closed vessel for 4 h. The reaction mixture was worked up as described for **6**; yield 118 mg (90%). **(b)** A stream of ethene was passed through a solution of **3** (515 mg, 0.80 mmol) in benzene (20 mL) for 1 min and, after the ethene was replaced by argon, the solution was stirred under reflux for 1 h. After the reaction mixture was cooled to room temperature, the solvent was evaporated. The remaining oily residue was dissolved in benzene (20 mL) and the solution refluxed again for 1 h. After the solution was cooled and the solvent removed, the residue was suspended in pentane (5 mL, 0 °C) and the suspension was stirred until an orange solid precipitated; yield 467 mg (91%). **(c)** A suspension of **3** (101 mg, 0.17 mmol) in benzene (20 mL) was heated under reflux for 12 h. The hot reaction mixture was filtered, the filtrate was brought to drynes in vacuo, and the oily residue worked up as described for **6**. Orange microcrystalline solid; yield 96 mg (87%); m.p. 69 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 1630 [ν(C=O)] cm$^{-1}$. $^1$H NMR (400 MHz, $C_6D_6$): $\delta$ = 3.41 (s, 6 H, $OCH_3$), 3.13 (d, $^2J_{P,H}$ = 9.1 Hz, 4 H, $PCH_2$), 2.43 (m, 4 H, PC*H*CH$_3$), 1.21 (dd, $^3J_{P,H}$ = 14.3, $^3J_{H,H}$ = 7.1 Hz, 12 H, PCHC*H*$_3$), 1.15 (dd, $^3J_{P,H}$ = 13.6, $^3J_{H,H}$ = 7.1 Hz, 12 H, PCHC*H*$_3$) ppm. $^{13}$C NMR (100.6 MHz, $C_6D_6$): $\delta$ = 185.3 (s, *C*$O_2$Me), 55.0 (s, $OCH_3$), 35.7 (X part of an ABX spin system, $J_{A,X}$ = 23.7 Hz, $PCH_2$), 28.3 (X part of an ABX spin system, $J_{A,X}$ = 29.5 Hz, P*C*HCH$_3$), 19.1, 18.8 (2 s, PCH*C*H$_3$) ppm. $^{31}$P NMR (162.0 MHz, $C_6D_6$): $\delta$ = 2.8 (s, $^1J_{Os,P}$ = 341.4 Hz) ppm. $C_{18}H_{38}Cl_2O_4OsP_2$ (641.5): calcd. C 33.70, H 5.97; found C 34.02, H 6.15.

**7. Preparation of [OsCl$_2${κ$^2$(*P*,*O*)-*i*Pr$_2$PCH$_2$C(=O)OEt}$_2$] (8). (a)** A suspension of **1** (353 mg, 0.61 mmol) in hexane (60 mL) was treated dropwise with *i*Pr$_2$PCH$_2$CO$_2$Et (434 μL, 1.82 mmol) and heated at 110 °C in a closed vessel for 4 h. The reaction mixture was worked up as described for **6**; yield 180 mg (44%). **(b)** A stream of ethene was passed through a solution of **4** (150 mg, 0.22 mmol) in benzene (10 mL) for 1 min and, after the ethene was replaced by argon, the solution was stirred under reflux for 1 h. The reaction mixture was worked up as described for **6**. Orange microcrystalline solid; yield 133 mg (89%); m.p. 56 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 1630 [ν(C=O] cm$^{-1}$. $^1$H NMR (200 MHz, $C_6D_6$): $\delta$ = 4.05 (q, $^3J_{H,H}$ = 7.1 Hz, 4 H, OC*H*$_2$CH$_3$), 3.14 (d, $^2J_{P,H}$ = 9.1 Hz, 4 H, $PCH_2$), 2.43 (m, 4 H, PC*H*CH$_3$), 1.22 (dvt, PCHC*H*$_3$, $^3J_{H,H}$ = 7.7 Hz, 12 H, $N$ = 14.6 Hz), 1.15 (dvt, PCHC*H*$_3$, $^3J_{H,H}$ = 6.8 Hz, 12 H, $N$ = 13.9 Hz), 0.88 (t, $^3J_{H,H}$ = 7.1 Hz, 6 H, OC*H*$_2$CH$_3$) ppm. $^{13}$C NMR (50.3 MHz, $C_6D_6$): $\delta$ = 185.3 (t, $^2J_{P,C}$ = 3.3 Hz, *C*$O_2$Et), 65.4 (s, O*C*H$_2$CH$_3$), 36.6 (X part of an ABX spin system, $J_{A,X}$ = 23.1 Hz, $PCH_2$), 30.0 (X part of an ABX spin system, $J_{A,X}$ = 29.6 Hz, P*C*HCH$_3$), 19.8, 19.6 (2 s, PCH*C*H$_3$), 14.5 (s, $OCH_2CH_3$) ppm. $^{31}$P NMR (81.0 MHz, $C_6D_6$): $\delta$ = 3.2 (s, $^1J_{Os,P}$ = 341.4 Hz) ppm. $C_{20}H_{42}Cl_2O_4OsP_2$ (669.6): calcd. C 35.87, H 6.32; found C 36.26, H 6.85.

**8. Generation of [OsCl$_2$(C$_2$H$_4$){κ$^2$(*P*,*O*)-*i*Pr$_2$PCH$_2$C(=O)OMe}-{κ(*P*)-*i*Pr$_2$PCH$_2$CO$_2$Me}] (9):** A slow stream of ethene was passed through a solution of **3** (40 mg, 0.06 mmol) in $C_6D_6$ (1 mL) in an NMR tube for 1 min. The ethene was replaced by argon, and the solution was stirred at 70 °C for 5 min. After it was cooled to room

temperature, the $^1H$ NMR spectrum indicated that a 1:1 mixture of **7** and **9** had formed. Attempts to separate the two compounds by chromatography or fractional crystallization failed. Data for **9**: IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1710, 1605 [ν(C=O)], 1590 [ν(C=C)] $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 4.01 (t, $^3J_{P,H}$ = 3.7 Hz, 4 H, $C_2H_4$), 3.60 (br. d, $^2J_{P,H}$ = 6.6 Hz, 2 H, $PCH_2$), 3.29 (s, 6 H, $OCH_3$), 2.90, 2.61 (2 m, 2 H each, $PCHCH_3$), 2.89 (br. d, $^2J_{P,H}$ = 9.1 Hz, 2 H, $PCH_2$), 1.45, 1.15 (2 m, 12 H each, $PCHCH_3$) ppm. $^{31}P$ NMR (81.0 MHz, $C_6D_6$): AB spin system: $\delta_A$ = –0.1, $\delta_B$ = –15.3 ($^2J_{P,P}$ = 324.0 Hz) ppm.

**9. Generation of [$OsCl_2(C_2H_4)$\{κ²(*P*,*O*)-*i*$Pr_2PCH_2C(=O)OEt$\}-\{κ(*P*)-*i*$Pr_2PCH_2CO_2Et$\}] (10):** This compound was generated as described for **9**, with **4** (38 mg, 0.05 mmol) and ethene as starting materials. The $^1H$ NMR spectrum indicated that a 2:1 mixture of **8** and **10** had formed. Attempts to separate the two compounds by chromatography or fractional crystallization failed. Data for **10**: IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1705, 1610 [ν(C=O)], 1585 [ν(C=C)] $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 4.05 (t, $^3J_{P,H}$ = 3.1 Hz, 4 H, $C_2H_4$), 3.64 (d, $^2J_{P,H}$ = 7.2 Hz, 2 H, $PCH_2$), 2.95, 2.64 (2 m, 2 H each, $PCHCH_3$), 2.93 (br. d, $^2J_{P,H}$ = 9.0 Hz, 2 H, $PCH_2$), 1.50, 1.08 (2 m, 12 H each, $PCHCH_3$), 0.97 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H, $OCH_2CH_3$) ppm. $^{31}P$ NMR (81.0 MHz, $C_6D_6$): AB spin system: $\delta_A$ = –0.5, $\delta_B$ = –15.4 ($^2J_{P,P}$ = 325.6 Hz) ppm.

**10. Preparation of all-*cis*-[$OsCl_2(CO)_2$\{κ(*P*)-*i*$Pr_2PCH_2CH_2OMe$\}$_2$] (11a):** A slow stream of CO was passed through a solution of **2** (96 mg, 0.16 mmol) in a 5:1 mixture of toluene and dichloromethane (12 mL) at room temperature for 10 min. The solvent was evaporated in vacuo and the oily residue dissolved in a 1:10 mixture of acetone/diethyl ether (5 mL). After the solution had been stored at –78 °C for 12 h, colorless crystals precipitated, which were washed twice with 2-mL portions of hexane and dried; yield 48 mg (46%); m.p. 102 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 2005, 1940 [ν(CO)] $cm^{-1}$. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 3.76 (m, 4 H, $OCH_2$), 3.40, 3.38 (2 s, 3 H each, $OCH_3$), 3.02, 2.82, 2.64, 2.56 (4 m, 8 H, $PCH_2$ and $PCHCH_3$), 1.50–1.22 (br. m, 24 H, $PCHCH_3$) ppm. $^{13}C$ NMR (50.3 MHz, $C_6D_6$): $\delta$ = 175.2 (t, $^2J_{P,C}$ = 8.9 Hz, OsCO *trans* to Cl), 174.8 (dd, $^2J_{P,C}$ = 100.5 and 8.9 Hz, OsCO *trans* to P), 68.8, 68.7 (2 s, $OCH_2$), 59.0, 58.9 (2 s, $OCH_3$), 28.6 (d, $^1J_{P,C}$ = 25.4 Hz, $PCHCH_3$), 27.9 (d, $^1J_{P,C}$ = 28.0 Hz, $PCHCH_3$), 26.8 (d, $^1J_{P,C}$ = 29.2 Hz, $PCH_2$), 25.0, 23.7 (2 d, $^1J_{P,C}$ = 25.4 Hz, $PCHCH_3$), 21.5 (d, $^1J_{P,C}$ = 22.9 Hz, $PCH_2$), 20.2, 20.0, 19.7, 19.3, 18.9 (5 s, $PCHCH_3$), 19.1 (br., $PCHCH_3$) ppm. $^{31}P$ NMR (81.0 MHz, $CDCl_3$): $\delta$ = 2.3 (d, $^2J_{P,P}$ = 14.5, $^1J_{Os,P}$ = 222.0 Hz), –12.3 (d, $J_{P,P}$ = 14.5, $J_{Os,P}$ = 151.3 Hz) ppm. $C_{20}H_{42}Cl_2O_4OsP_2$ (669.6): calcd. C 35.88, H 6.32; found C 36.20, H 6.47.

**11. Preparation of *cis*,*cis*,*trans*-[$OsCl_2(CO)_2$\{κ(*P*)-*i*$Pr_2PCH_2CH_2OMe$\}$_2$] (11b):** A solution of **11a** (48 mg, 0.07 mmol) in benzene (10 mL) was stirred under reflux for 3 h. After the solution had cooled to room temperature, the solvent was evaporated in vacuo. The oily residue was treated with a small quantity of hexane (ca. 2 mL) and stirred until small crystals precipitated. The crystallization was completed while the mixture was stored at –78 °C for 12 h. The colorless solid was filtered, washed twice with 2-mL portions of hexane and dried; yield 45 mg (94%); m.p. 98 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 2000, 1940 [ν(CO)] $cm^{-1}$. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 3.73 (m, 4 H, $OCH_2$), 3.31 (s, 6 H, $OCH_3$), 2.74, 2.67 (2 m, 4 H each, $PCH_2$ and $PCHCH_3$), 1.31 (m, 24 H, $PCHCH_3$) ppm. $^{13}C$ NMR (50.3 MHz, $C_6D_6$): $\delta$ = 176.4 (t, $^2J_{P,C}$ = 7.4 Hz, OsCO), 69.0 (s, $OCH_2$), 59.1 (s, $OCH_3$), 25.3 (vt, *N* = 13.8 Hz, $PCH_2$), 20.8 (vt, *N* = 13.4 Hz, $PCHCH_3$), 19.4, 19.1 (2 s, $PCHCH_3$) ppm. $^{31}P$ NMR (81.0 MHz, $CDCl_3$): $\delta$ = 3.6 (s, $^1J_{Os,P}$ = 149.7 Hz) ppm. $C_{20}H_{42}Cl_2O_4OsP_2$ (669.6): calcd. C 35.88, H 6.32; found C 36.14, H 6.53.

**12. Preparation of all-*trans*-[$OsCl_2(CO)_2$\{κ(*P*)-*i*$Pr_2PCH_2CH_2OMe$\}$_2$] (11c):** A slow stream of CO was passed through a solution of **6** (50 mg, 0.08 mmol) in benzene (10 mL) at room temperature for 5 min. The solvent was evaporated in vacuo and the oily residue worked up as described for **11b**. Pale-orange crystals; yield 34 mg (63%); m.p. 105 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 1960 [ν(CO)] $cm^{-1}$. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 3.71 (m, 4 H, $OCH_2$), 3.32 (s, 6 H, $OCH_3$), 2.66 (m, 4 H, $PCH_2$), 2.48 (m, 4 H, $PCHCH_3$), 1.32 (m, 24 H, $PCHCH_3$) ppm. $^{31}P$ NMR (81.0 MHz, $CDCl_3$): $\delta$ = –4.7 (s, $^1J_{Os,P}$ = 162.8 Hz) ppm. $C_{20}H_{42}Cl_2O_4OsP_2$ (669.6): calcd. C 35.88, H 6.32; found C 35.41, H 6.65.

**13. Preparation of a Mixture of all-*cis*- and *cis*,*cis*,*trans*-[$OsCl_2(CO)_2$\{κ(*P*)-*i*$Pr_2PCH_2CO_2Me$\}$_2$] (12a,b):** A slow stream of CO was passed through a solution of **3** (46 mg, 0.07 mmol) in a 1:1 mixture of toluene/dichloromethane (4 mL) at room temperature for 10 min. The solvent was evaporated in vacuo, and the oily residue dissolved in diethyl ether (1 mL). After the solution had been stored at –78 °C for 24 h, a colorless solid precipitated which was filtered, washed twice with 2-mL portions of pentane and dried. According to the NMR spectroscopic data, the product consisted of a mixture of **12a** and **12b** in a ratio of 7:3; yield 32 mg (65%). IR (KBr): $\tilde{\nu}$ = 2060, 1965 [ν(CO)], 1725, 1715 [ν(C=O)] $cm^{-1}$. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 4.11 (dd, $^2J_{P,H}$ = 15.1, $^4J_{H,H}$ = 12.2 Hz, $PCH_2$ of **12a**), 3.81 (m, $PCH_2$ of **12a/b**), 3.25 (dd, $^2J_{P,H}$ = 14.6, $^4J_{H,H}$ = 9.4 Hz, $PCH_2$ of **12a**), 3.17, 3.16, 3.15 (3 s, $OCH_3$), 2.83, 2.51, 2.33 (3 m, $PCHCH_3$ of **12a**), 2.74 (m, $PCHCH_3$ of **12b**), 1.49 (dd, $^3J_{P,H}$ = 15.4, $^3J_{H,H}$ = 7.2 Hz, $PCHCH_3$ of **12a**), 1.48 (dd, $^3J_{P,H}$ = 14.1, $^3J_{H,H}$ = 7.0 Hz, $PCHCH_3$ of **12a**), 1.32 (dvt, *N* = 16.1 Hz, $^3J_{H,H}$ = 7.3 Hz, $PCHCH_3$ of **12b**), 1.17 (dvt, *N* = 14.6 Hz, $^3J_{H,H}$ = 7.5 Hz, $PCHCH_3$ of **12b**), 1.18–0.96 (br. m, $PCHCH_3$ of **12a**) ppm. $^{31}P$ NMR (162.0 MHz, $C_6D_6$): $\delta$ = 6.2 (s, P of **12b**), 4.9, –9.0 (2 d, $^2J_{P,P}$ = 15.2 Hz, P of **12a**) ppm. $C_{20}H_{38}Cl_2O_6OsP_2$ (697.6): calcd. C 34.44, H 5.49; found C 34.12, H 5.15.

**14. Preparation of *cis*,*cis*,*trans*-[$OsCl_2(CO)_2$\{κ(*P*)-*i*$Pr_2PCH_2CO_2Me$\}$_2$] (12b):** A solution of **12a**,**b** (32 mg, 0.05 mmol) in benzene (3 mL) was stirred under reflux for 5 h. After the solution had cooled to room temperature, the solvent was evaporated in vacuo, and the oily residue layered with diethyl ether (1 mL). The mixture was vigorously stirred until a colorless solid precipitated. The precipitate was filtered, washed twice with 2-mL portions of pentane and dried; yield 12 mg (39%); m.p. 85 °C (decomp). IR (KBr): $\tilde{\nu}$ = 2020, 1945 [ν(CO)], 1710 [ν(C=O)] $cm^{-1}$. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 3.81 (vt, 4 H, *N* = 9.5 Hz, $PCH_2$), 3.15 (s, 6 H, $OCH_3$), 2.74 (m, 4 H, $PCHCH_3$), 1.32 (dvt, $PCHCH_3$, $^3J_{H,H}$ = 7.3 Hz, 12 H, *N* = 16.1 Hz), 1.17 (dvt, $PCHCH_3$, $^3J_{H,H}$ = 7.5 Hz, 12 H, *N* = 14.6 Hz) ppm. $^{31}P$ NMR (162.0 MHz, $C_6D_6$): $\delta$ = 6.2 (s, $^1J_{Os,P}$ = 151.6 Hz) ppm. $C_{20}H_{38}Cl_2O_6OsP_2$ (697.6): calcd. C 34.44, H 5.49; found C 33.99, H 5.43.

**15. Preparation of *trans*,*trans*-[$OsCl_2(CO)$\{κ²(*P*,*O*)-*i*$Pr_2PCH_2C(=O)OMe$\}\{κ(*P*)-*i*$Pr_2PCH_2CO_2Me$\}] (13):** A slow stream of CO was passed through a solution of **7** (52 mg, 0.08 mmol) in a 3:2 mixture of toluene/dichloromethane (10 mL) at room temperature for 10 min. A change of color from orange to yellow occurred. The solvent was evaporated in vacuo, the remaining yellow oil was dissolved in methanol (2 mL) and the solution was layered with diethyl ether (4 mL). After the mixture had been stored at –78 °C for 12 h, a lemon-yellow microcrystalline solid precipitated, which was filtered, washed twice with 2-mL portions of diethyl ether and dried; yield 42 mg (77%); m.p. 116 °C (decomp.). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1915 [ν(CO)], 1710, 1615 [ν(C=O)] $cm^{-1}$. $^1H$ NMR (400 MHz, $C_6D_5CD_3$): $\delta$ = 3.83 (d, $^2J_{P,H}$ = 8.4 Hz, 2 H, $PCH_2$), 3.53, 3.52 (2 s, 3 H each, $OCH_3$), 3.31, 2.97 (2 m, 2 H each, $PCHCH_3$), 2.94 (d,

# Synthesis, X-ray Structure, Thermal and Magnetic Behavior of $[(bipy)_2Ni_2(\mu\text{-}Cl)_2Cl_2(H_2O)_2]$: The First Neutral Ferromagnetically Coupled Six-Coordinate Dichlorido-Bridged Nickel(II) Dimer

**Oluwatayo F. Ikotun,[a] Wayne Ouellette,[a] Francesc Lloret,[b] Miguel Julve,*[b] and Robert P. Doyle*[a]**

**Keywords:** Crystal structures / Nickel complexes / Ferromagnetic coupling / Thermal analysis

$NiCl_2 \cdot 6H_2O$ and 2,2′-bipyridine (bipy) (1:1) were allowed to react under ambient conditions in dimethyl sulfoxide in the presence of acetylacetone (Hacac). The resulting green solution was concentrated in vacuo, and a green solid was isolated by precipitation with cold acetone. X-ray quality crystals of $[(bipy)_2Ni_2(\mu\text{-}Cl)_2(Cl)_2(H_2O)_2]$ (**1**) were grown by subsequent vapor/liquid diffusion of acetonitrile into a methanolic solution for one week. The structure of **1** consists of a dimeric nickel system with each metal atom in an octahedral geometry. Both equatorial bridging and axial chlorine atoms are present in this neutral species. The nickel–nickel distance (3.441 Å) is the shortest reported to date for this class of complexes and the bridging chlorido angles at 91.5° are the most acute. Variable-temperature magnetic susceptibility measurements reveal the complex to have the strongest ferromagnetic interaction reported to date ($J$ = +16.8 $cm^{-1}$, the Hamiltonian being defined as $H = -JS_A \cdot S_B$) for this family of complexes.

## Introduction

Multimetallic nickel(II) species occupy an important position in modern inorganic and materials chemistry. They are ubiquitous in nature as active sites in a variety of metallo-enzymes and this recognition has fuelled the development of numerous low molecular weight model compounds.[1] In addition, they have been investigated from the viewpoint of magnetochemistry, in particular in the prediction of superexchange coupling between paramagnetic centers.[2] In this field the seminal work on structure/function correlation remains that by Hatfield and Hodgson who found a linear correlation between the strength and sign of the magnetic interaction and the bridging angle, $\theta$, for eight, essentially planar, di-μ-hydroxidodicopper(II) complexes.[3] This was further expanded by Ruiz et al. to include the effects of the out-of-plane dispersion of the hydroxido hydrogen atom resulting in a highly successful predictor of magnetic behaviour in this class of compounds.[1] Such a correlation, with clear predictors, has yet to be established for five- and six-coordinate di-μ-chloridodinickel(II) complexes. Reedijk et al. have produced a comprehensive review of such structures and their magnetic behaviour[4] but attempts to produce a structure/function correlation have been hampered by the dearth of such complexes in the literature, especially complexes that are unique or extreme in geometry, bridging angle, nickel–nickel distance, charge, etc. Goodenough, Kanamori, and Anderson predicted that with an octahedral geometry and an M–X–M bridging angle close to 90°, a ferromagnetic coupling between two $d^8$ metal ions would be observed.[5] Theoretical studies by Barraclough and Brookes[6] and work by Gatteschi et al.[7] have also concluded that close proximity of the bridging Ni–Cl–Ni angle to 90° was a strong predictor of a ferromagnetic interaction. They also noted, however, that distortions about the octahedral metal ion would increase antiferromagnetic character by mixing d orbitals, and this sensitivity would make predicting the coupling strength and sign difficult for such systems. A search of the literature revealed only six ferromagnetic di-μ-chloridodinickel(II) complexes that have been both magnetically and structurally characterized with the most acute bridging angle noted to date between the Ni–Cl–Ni atoms being 93.03°.[8] Two of the six complexes with intramolecular ferromagnetic coupling are five-coordinate, distorted trigonal-bipyramidal with the remaining four having octahedral geometry. Both the five-coordinate structures show a high degree of distortion from perfect square-pyramidal geometry (as measured by $\tau$ and compared to analogous complexes displaying antiferromagnetic behaviour).[9] Reedijk et al. have noted this may be the

source of the strengthening of the ferromagnetic coupling in five-coordinate structures (again distortion playing an important role).[4] All the octahedral ferromagnetic complexes are charged and no such neutral structures have been characterized. Such a structure, devoid of counterion-induced distortions, that exhibits close proximity to 90°, would be an intriguing result, because current predictors would charge that this structure be strongly ferromagnetic (certainly stronger than any such value of ferromagnetic coupling reported to date). In this paper we present a new octahedral dichlorido-bridged nickel(II) dimer, $[(bipy)_2Ni_2(\mu\text{-}Cl)_2(Cl)_2(H_2O)_2]$ (**1**), with the most acute Ni–Cl–Ni bridging angle (91.5°) and the shortest intramolecular Ni···Ni distance (3.44 Å) observed to date. These extremes and the fact that it is the first neutral octahedral complex in this family, makes this structure somewhat of a "missing link" for such di-μ-chloridodinickel(II) complexes.

## Results and Discussion

### Synthesis of $[(bipy)_2Ni_2(\mu\text{-}Cl)_2(Cl)_2(H_2O)_2]$ (1)

The compound was synthesized from nickel(II) chloride hexahydrate and 2,2′-bipyridine (bipy) in a stoichiometric ratio of 1:1 in the presence of acetylacetone (Hacac). Interestingly, attempts to obtain **1** without the presence of Hacac failed, instead producing a blue solid for which a crystal structure is currently being sought. Our desire to follow this reaction stems from our observation that in reactions involving attempts to incorporate pyrophosphate ($P_2O_7^{4-}$) into $(bipy)Ni^{II}$ systems, dichlorido "impurities" were observed when the chloride salt was used. We wanted to know if we could prepare this complex directly and subsequently conduct full structural and functional characterization.

### Characterization of 1

The IR spectrum of **1** is consistent with the presence of coordinated 2,2′-bipyridine.[17] Electrospray mass spectrometry revealed the presence of Cl isotopes and is consistent with the presence of **1** as the monocationic acetonitrile solvate $\{[(bipy)_2Ni_2(\mu\text{-}Cl)_2Cl(H_2O)_2]\cdot MeCN\}^+$. Elemental analysis (C, H, N) is also consistent with the formula of **1**. The extinction coefficient ($H_2O$) was calculated to be 3.4 $M^{-1}\,cm^{-1}$ for both $Ni^{II}$ atoms, a value, which is indicative of the presence of an octahedral structure in solution.

### Description of the Crystal Structure of 1

The structure of **1** consists of neutral $(bipy)NiCl_2(H_2O)$ units, which are related by the crystallographic center of symmetry, as shown in Figure 1.

The crystallographically independent unit consists of an $Ni^{II}$ ion, octahedrally surrounded by two N atoms from the bipyridine ligand [Ni(1)–N(1) = 2.048 Å and Ni(1)–N(2) = 2.053 Å], one coordinated water molecule [Ni(1)–O(90) = 2.14 Å], and three chlorine atoms (one axial chlorido group [Ni(1)–Cl(2)] and two bridging equatorial chlorido groups [Ni(1)–Cl(1) and Ni(1)–Cl(1a)]). The *trans*-axial bridging angles [Cl(2)–Ni(1)–O(90)] show only a slight deviation from linearity at 176°. The Ni–Cl–Ni bridging unit is practically planar and the dimer is located on an inversion center.

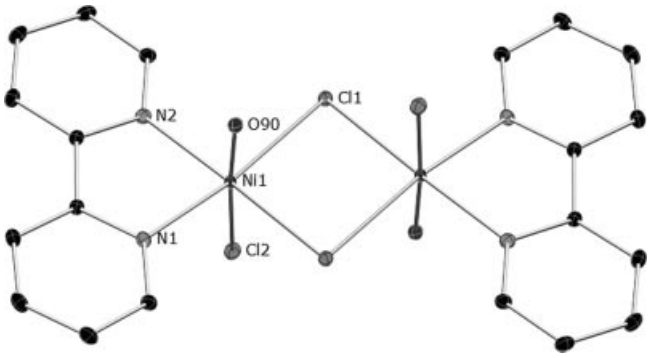

Figure 1. ORTEP plot of **1** with the atom labeling scheme; hydrogen atoms have been removed for clarity; the unlabeled atoms are generated by an inversion center. Thermal ellipsoids are plotted at 50% probability level.

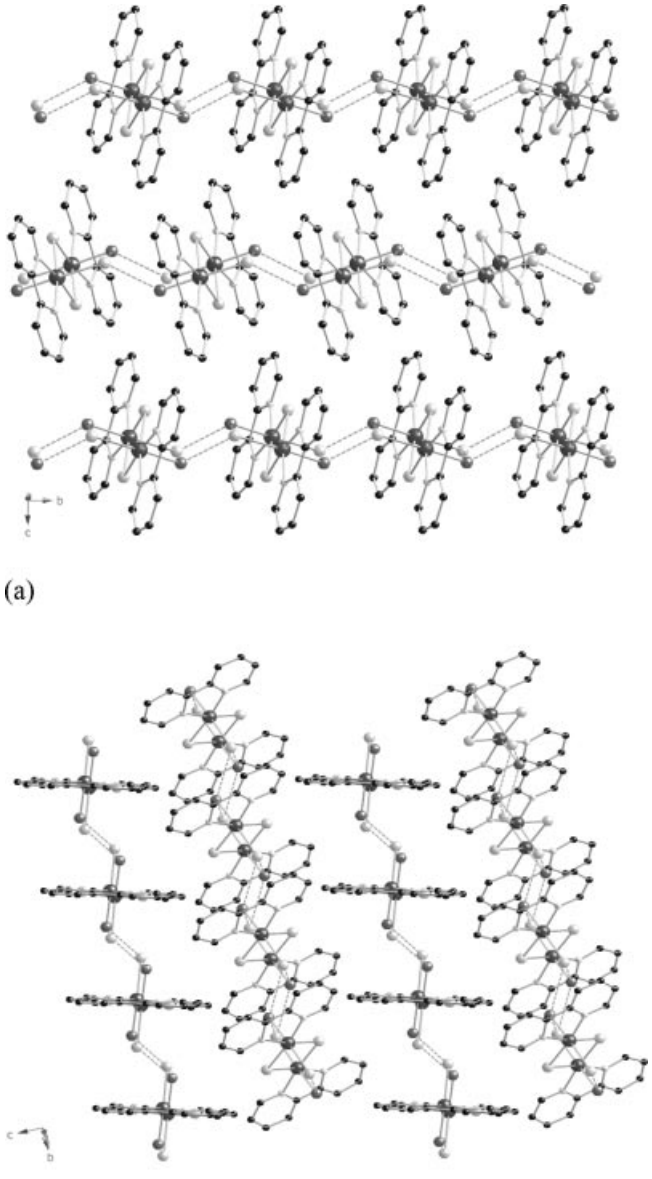

Figure 2. (a) Packing diagram of **1** looking along the crystallographic *b* axis; note the alternating arrangement of intermolecular hydrogen bonds. (b) Looking along the crystallographic *c* axis. Hydrogen atoms have been omitted for clarity.

Average carbon–carbon and carbon–nitrogen bond lengths of the coordinated 2,2′- bipyridine are close to those reported for the free molecule.[18] The significant deviation of the N(1)–Ni–N(2) angle [79.60(5)°] from the ideal value (90°) is due to steric requirements of a bipyridine ring ligand. Interestingly, complex **1** packs to produce 1-dimensional alternating ABAB layers of asymmetric units along the crystallographic *b* axis. Within each individual layer the asymmetric units are connected through intermolecular hydrogen bonds between the coordinated water and chlorine atoms of adjacent dimers. The intermolecular $O_w$···Cl distance of 3.195 Å is typical of an O–H···Cl interaction (range of 2.95–3.30 Å). The torsional angle between intralayer bipyridine rings is ca. 180°, indicating a near perfect parallel alignment within each layer. Closest distance between such bipyridine rings, however, is ca. 6.4 Å indicating that intralayer π–π stacking is not present in **1**. Interlayer distances, however, approach 3.7 Å with the phenanthroline rings interleaving such that the edge of one ring interacts with the face of another, both consistent with *phenyl embraces*.[19] Certainly, the complex packs to produce clear hydrophobic and hydrophilic regions, and their combination helps to explain the "twist" between layers in **1** as shown in Figure 2 (b).

### Magnetic Behavior of 1

Variable-temperature magnetic susceptibility studies were carried out on a powdered sample of the crystalline complex **1** over the temperature range 1.9–300 K. The magnetic behavior of **1** is shown in Figure 3 in the form of a $\chi_M T$ vs. $T$ plot [$\chi_M$ being the magnetic susceptibility per two nickel(II) ions]. The value of $\chi_M T$ at room temperature, ca. 2.30 $cm^3 mol^{-1}$ K, is as expected for two single-ion triplet states magnetically isolated ($\chi_M T$ = 2.31 $cm^3 mol^{-1}$ K with $g$ = 2.15). This value continuously increases upon cooling to reach a maximum of 4.10 $cm^3 mol^{-1}$ K at 5.0 K and then further decreases to 3.68 $cm^3 mol^{-1}$ K at 1.9 K. The shape of this curve is typical of a significant ferromagnetic coupling in **1**, the decrease of $\chi_M T$ at low temperatures being due to zero-field splitting effects and/or intermolecular interactions. In addition, the fact that $\chi_M T$ at low temperatures reaches values larger than 3.50 $cm^3 mol^{-1}$ K (the calculated value for a magnetically isolated quintet spin state with $g$ = 2.09) supports the occurrence of interdimer ferromagnetic interactions in **1**. Most likely, the hydrogen bonds, which link the dimers to afford a chain of dinuclear nickel(II) units along the crystallographic *a* axis [see Figure 2 (a)] provide the exchange pathway for this additional ferromagnetic interaction.

Keeping in mind the dinuclear structure of **1** and the fact that the ground state for a nickel(II) ion in an octahedral environment is orbitally nondegenerate, it is possible to represent the intradimer magnetic interaction $J$ with the iso-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

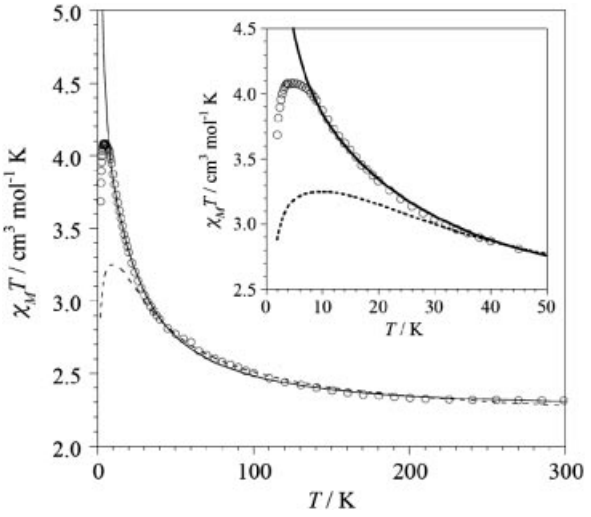

Figure 3. $\chi_M T$ vs. $T$ plot for **1**: experimental data (circles); best-fit curve for a nickel(II) dimer with $J$, $g$ and $D$ as variable parameters (dashed line); best-fit curve for a uniform chain of nickel(II) dimers (solid line) (see text). The inset shows the low-temperature region in detail.

tropic spin Hamiltonian $H = -JS_A \cdot S_B$. This approach works well for the cases where a relatively strong antiferromagnetic coupling is involved. However, when a weak antiferromagnetic interaction occurs or when the coupling is ferromagnetic (as in **1**), the effect of $D$ [zero-field splitting of the octahedral nickel(II) ion] has to be taken into account to describe the magnetic behaviour at low temperatures.[20]

We have then analyzed the magnetic susceptibility data of **1** in the high-temperature range by the corresponding expression derived through the Hamiltonian of Equation (1).[20]

$$H = -JS_A \cdot S_B + D(S_{zA}^2 + S_{zB}^2) \quad (1)$$

The best-fit values are: $J = +16.8$ cm$^{-1}$, $g = 2.09$ and $D = 3.5$ cm$^{-1}$. The calculated plot corresponds to the dashed line in Figure 3. The theoretical curve reproduces the experimental data from room temperature to $T = 40$ K. At $T < 40$ K, there is a clear mismatch between the experimental data and the theoretical plot, the former being above the calculated curve. This is in agreement with the additional ferromagnetic interaction between the nickel(II) dimers through the hydrogen bonds mentioned above. As the spin of the ferromagnetically coupled nickel(II) dimer at $T \leq 40$ K is large enough ($S \approx 2.0$) to be considered as a classic one, the magnetic data of **1** in the low-temperature range could be modelled through a uniform chain of hydrogen-bonded nickel(II) dimers (denoted $P$) with an interdimer ferromagnetic coupling $j_{eff}$, the Hamiltonian being defined by Equation (2).

$$H_{eff} = -j_{eff} \Sigma_i (S_{P,i} \cdot S_{P,i+1}) \quad (2)$$

The value of the spin of each $P$ unit ($S_P$) is given by Equation (3), where $\chi_P$ is the magnetic susceptibility for the nickel(II) dimer derived through Equation (1)[19] and $g_P$ is the $g$ factor for the ground spin sate of the dimer which is the local $g$ factor of the nickel(II) ion.

$$S_P(S_P + 1) = 8\chi_P T/g_P \quad (3)$$

In such an approach of a classical spin Heisenberg chain model,[21] the expression for the magnetic susceptibility per $P$ unit is given by Equations (4), (5) and (6).

$$\chi_P = [N\beta^2 g_P^2 S_P(S_P + 1)/3kT]\{[1 + u(K)]/[1 - u(K)]\} \quad (4)$$

$$u(K) = \coth(K - 1)/K \quad (5)$$

$$K = j_{eff} S_P(S_P + 1)/kT \quad (6)$$

This approach allowed us to fit the magnetic data of **1** from room temperature to $T = 8.0$ K (solid line in the inset of Figure 3), the values of the best-fit parameters being $J_P = +16.8$ cm$^{-1}$, $g_P = 2.09$, $D = 3.5$ cm$^{-1}$ and $j_{eff} = +0.37$ cm$^{-1}$. The previous values of $J$, $g$ and $D$ remain unchanged in the new fit and the weak ferromagnetic coupling ($j_{eff}$) between the nickel(II) dimers through the hydrogen bonds is evaluated. The very small $j_{eff}/J_P$ ratio (ca. 0.02) supports the validity of the perturbational model used here.

Such an approach was successfully used by some of us in other magnetic systems.[22–26] The mismatch between the calculated curve and the experimental data at $T < 8.0$ K for **1** in Figure 3 is most likely due to weak interchain antiferromagnetic interactions, which certainly would cause a decrease of the magnetic moment in the very-low-temperature region. We should also note that although the simulation of the magnetisation ($M$) vs. the applied magnetic field ($H$) plots for a discrete molecule with $J$ (magnetic coupling) and $D$ (zero-field splitting) as variable parameters is possible for a discrete molecule, it cannot be used for a chain (as is the case here). Consequently, $M$ vs. $H$ plots for **1** were discarded. Finally, the decrease of the $\chi_M T$ product being due to saturation phenomena (Zeeman level depopulation effects) was also discarded because the plots for three $H$ values less than 500 G (that is 250, 100 and 50 G) provided the same susceptibility curve.

## Conclusion

We report the first neutral octahedral di-μ-chloridodinickel(II) complex with the most acute Ni–Cl–Ni bridging angle to date. The complex exhibits the strongest intramolecular ferromagnetic interaction for this family, as expected given the acute bridging angle and quasi-planarity of the bridging unit, and is an important addition to this family of complexes.

## Experimental Section

**General:** Solvents and chemicals were of laboratory grade and were used as received except dimethyl sulfoxide, which was dried with molecular sieves (4 Å) under dry dinitrogen. Electrospray mass spectrometry was performed with a Shimadzu LCMS-2010 A system at a cone voltage of 5 kV. Infrared spectra were recorded with a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Nicolet Magna-IR 850 Series II spectrophotometer as KBr pellets. Thermal analysis was performed with a TA instruments TGA Q500 using 2–6 mg samples placed on platinum pans and ran under nitrogen (40 mL/min). The temperature was ramped from ca. 25 to 500 °C at a rate of 10 °C/min. Analysis was performed using the TA instruments Universal Analysis 2000 software program. Elemental analysis (C, H, N) was performed by Quantitative Technologies Inc., Whitehouse, NJ. Water was distilled and deionized to 18.6 MΩ using a Barnstead Diamond RO Reverse Osmosis machine coupled to a Barnstead Nano Diamond ultrapurification machine. Variable-temperature magnetic susceptibility measurements were performed with a Quantum design SQUID susceptometer in the temperature range 1.9–300 K with an applied magnetic field of $H$ = 1000 G ($T \geq 100$ K) and 50 G ($T < 100$ K). Crystalline samples were obtained directly from the reaction mixture, air-dried and powdered in a mortar. Diamagnetic corrections for the constituent atoms were estimated using Pascal's constants and corrections for the sample holder and the temperature-independent paramagnetism were also performed. Electronic absorption spectra were obtained with a Varian Cary 50 Bio spectrophotometer in 1-mL Quartz cuvettes between 200 and 800 nm at ambient temperature.

**Synthesis and Characterization of $[(bipy)_2Ni_2(\mu\text{-}Cl)_2(Cl)_2(H_2O)_2]$ (1):** $NiCl_2$ (0.48 g, 2.0 mmol) was suspended in dimethyl sulfoxide (DMSO) (10 mL). To this was added acetylacetone (10 mL, 99.3%) and then 2,2′-bipyridine (0.31 g; 2.0 mmol) was added as a 10-mL solution in DMSO. The volume of the solution was reduced in vacuo to approximately 5 mL, and a green solid was precipitated with chilled acetone. The precipitate was subsequently dissolved in a minimum amount of methanol and filtered (0.45 μm Fisher). Crystallization was conducted by an acetonitrile/methanol diffusion performed under ambient conditions. Green block-shaped crystals grew over ca. 8 d. Yield 0.941 g (41% based on $Ni^{II}$). $C_{20}H_{20}Cl_4N_4Ni_2O_2$ (607.6): calcd. C 39.50, H 3.32, N 9.22; found C 39.24, H 3.18, N 9.06. $\lambda_{max}$ ($H_2O$) = 612 nm (3.4 $M^{-1}cm^{-1}$). FT-IR (KBr): $\tilde{\nu}$ = 1598 (s), 1475 (s), 1445 (s), 1313 (m), 1115 (w), 1057 (w), 1027 (w), 775 (s), 736 (m), 654 (w) $cm^{-1}$. ES-MS (90% MeOH/10% $H_2O$): $m/z$ = 612 $\{[(bipy)_2Ni_2(\mu\text{-}Cl)_2(Cl)(H_2O)_2]\cdot MeCN\}^+$.

**Crystal-Structure Determination and Refinement for 1:** Structural measurements were performed with a Bruker-AXS SMART-CCD diffractometer at low temperature (90 K) using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Absorption correction was applied using SADABS and SHELXTL and the structure was solved by direct methods and refined using the SHELXTL program package.[27] Key crystallographic data are given in Table 3. CCDC-631084 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The Thermal Decomposition of Three Magnetic Acetates at Their Autogenic Pressure Yields Different Products. Why?

**Swati V. Pol,[a] Vilas G. Pol,[a] Israel Felner,[b] and Aharon Gedanken*[a]**

**Keywords:** Decomposition / Acetates / Magnetic properties / Core-shell nanostructures

We report on the one-stage, reproducible, solvent-free, competent and straightforward approach for the synthesis of fullerene-like Ni@C, Co@C, and $Fe_3O_4$@C core-shell nanostructures that can be scaled up. The single precursor reactions of low cost acetates of Fe, Co and Ni are separately conducted at a relatively low temperature (700 °C) in a closed Swagelok reactor, as compared to other methods for the formation of graphitic layers. It is worth mentioning that although identical reaction parameters are employed, using the three acetate precursors, the graphitic carbon is coated on nanosized metallic Ni and Co cores, while Fe tends to form $Fe_3O_4$, maintaining the same core-shell morphology. The systematic morphological, compositional, structural characterization and the room temperature magnetic susceptibility measurements of the as-made particles are carried out on a vibrating sample magnetometer. The plausible mechanism is based on the comparison between the dissociation products of three acetate precursors, their obtained experimental data, and calculations on the enthalpy and free energy changes.

## Introduction

The studies of magnetic nanoparticles and nanostructures combine a broad range of synthetic and investigative techniques from physics, chemistry, and materials science. Ultra fine magnetic particles have been the subject of intense scientific research in recent years with respect to their novel properties and commercially-potential valuable applications.[1] The application of the encapsulated magnetic nanomaterials ranges from magnetic inks, magnetic recording media, toners for xerography, and ferrofluids for biomedical applications, such as contrast agents in magnetic resonance imaging.[2] Single- and multi-walled carbon nanotubes filled with ferromagnetic materials (Fe, Co, Ni) showed significant potential in data storage.[3] The ferromagnetic nanosized Fe, Ni, or Co coated with carbon constitute a group of especially interesting magnetic nanomaterials. This is because of their fascinating magnetic properties, and the carbon coating that protects the magnetic nanoparticles against environmental degradation.[3] The discovery of fullerenes and carbon-coated materials accelerated extensive investigation on nanoparticles, carbon-coated nanomaterials, and a wide range of carbon-based materials.[4] Some of the standard problems encountered in the synthesis of nanoparticles are those of good control of composition, particle size and morphology, a narrow monodisperse size distribution, and stabilization against oxidation in the case of reactive metals.

Various synthetic methods of magnetic nanoparticles have been reported in recent times, e.g., wet chemical processes,[5–6] inert gas condensation,[7] ultra-rapid quenching and vacuum-based deposition.[8] Carbon nanotubes and filled carbon nanostructures such as onions, wires, and rods, have been prepared by the pyrolysis of metallocene.[9–10] Using Ni(acac) and Cu(acac) as catalyst precursors, carbon nanotubes and onions from carbon monoxide were produced previously.[11] An arc-discharge process[12] was employed for the preparation of ferromagnetic carbon-coated Fe, Co, and Ni nanoparticles. The major problem with the synthesis of graphite-encapsulated nanocrystals by using the standard arc method has been the production of large amounts of unwanted carbonaceous debris.[13] This causes the reduction of particle-exchange coupling, which is an important issue in the ongoing attempt to synthesize high density magnetic recording media.[14a] Vivekchand et al. recently developed a new method for the preparation of metal nanowires by the nebulized spray pyrolysis of precursors.[14b] The arc evaporation method is also successfully demonstrated for the encapsulation of ferromagnetic metals (iron, cobalt, and nickel) nanoparticles in graphitic carbon.[14c] Chemical vapor synthesis (CVS) is becoming increasingly important because of its potential for producing nanomaterials in a controlled and scalable way with a low degree of agglomeration.[15] Each technique has its own advantages and disadvantages. However, most of the techniques require a high energy input and are not suitable for

mass production because of the low yield and the complicated process control. The research community is seeking methods for producing carbon nanomaterials with specific properties and on an industrial scale. Thus, further experimental research on their synthesis is needed.

Herein, we report on a one-stage, reproducible, solvent-free, competent, and straightforward approach for the synthesis of fullerene-like Ni@C, Co@C, and $Fe_3O_4$@C core-shell nanostructures that can be scaled up. The single precursor reactions of low-cost acetates of Fe, Co and Ni are conducted separately at a relatively low temperature (700 °C) in a closed Swagelok reactor, as compared to other methods for the formation of graphitic layers. It is worth mentioning that although identical reaction parameters are employed, using the three acetate precursors, graphitic carbon-coated nanosize metals are obtained for Ni and Co, while Fe tends to form $Fe_3O_4$, maintaining the same core-shell morphology. Early results on a similar reaction of $Ni(AcAc)_2$ have been reported.[16] This publication extends this report and also includes a comparison between $Fe^{II}$, $Ni^{II}$, and $Co^{II}$ acetates, which yield different products. This manuscript also attempts to account for and explain the formation of different products. The systematic morphological, compositional, structural characterization and room temperature magnetic susceptibility measurements of the as-made particles are measured by using a vibrating sample magnetometer. The suggested mechanism is supported by the obtained experimental data and calculations on enthalpy, as well as free energy changes.

## Results and Discussion

### 1. C, H, N, S, and O Analysis, X-ray Diffraction, Mössbauer, and BET Surface Area Measurements

Here we present and compare the results related to the three metal acetates that produce core/shell structures of metal/metal oxide surrounded by carbon. The carbon and hydrogen content in the product/carbonaceous material is determined by elemental analysis measurements (Table 1). The calculated element percentages of carbon in Ni, Co and Fe acetates are 27.2, 27.1, and 27.6%, while the element percentages of hydrogen are 3.4, 3.4, and 3.5%, respectively. The measured percentage of carbon in Ni@C, Co@C, and $Fe_3O_4$@C products are 11.78, 15.25, and 22.3 wt.-%, while the percentages of hydrogen are 0.18, 0.1, and 0.12%, respectively. The calculated oxygen percentage for Ni, Co, and Fe acetates is almost the same (ca. 36 wt.-%). The measured oxygen percentages are 0.2, 0.3, and 21.43 wt.-% for Ni@C, Co@C, and $Fe_3O_4$@C products, respectively. The calculated weight of metal Ni, Co, and Fe is 332 mg, 333 mg, and 321 mg in 1 g of nickel(II) acetate, cobalt(II) acetate, and iron(II) acetate precursors, while 337 mg, 339 mg, and 315 mg account for the 382 mg, 400 mg, and 560 mg of the Ni@C, Co@C, and $Fe_3O_4$@C products, respectively. It is obvious that the products show less carbon than the reactants, while the percent of hydrogen is almost negligible. This means that some of the carbon is bonded to the hydrogen in the form of hydrocarbons and/or to oxygen to form carbon oxides. Furthermore, the reduction in the transition metal is observed in both Ni@C and Co@C. This reduction might have occurred due to carbon monoxide. Jesus et al. reported on the thermal decomposition[17] process of the nickel acetate precursor under inert atmosphere. Our obtained coupled TGA-Mass spectroscopy analysis data for Ni acetate salt are in agreement with this. The TGA spectra of all the three acetates are shown in Figure 1.

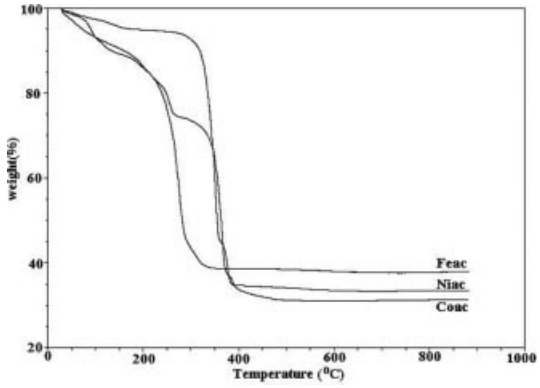

Figure 1. The TGA curve of Fe, Co, and Ni acetates.

The complete decomposition of all the acetates is observed at about 400 °C. The higher weight loss is observed for Ni and Co acetates (68%), while early (ca. 300 °C) and less weight loss (60%) accounts for Fe acetate. The residual weight of about 32% corresponds to the metallic Ni and Co for the related acetates, while the 40% for Fe acetate corresponds to FeO. The gaseous content of the dissociation products of these acetates at 350 °C is monitored by an MS. The gases detected by the instrument are acetone, $CH_3COCH_3$ ($m/z$ = 58), acetic acid, $CH_3COOH$ (60), $CO_2$ (44), CO (28), $CH_4$ (16), $C_2H_6$ (30), and $C_2H_2$ (26).

Conducting the RAPET reaction of all three acetates at 650 °C does not lead to any crystalline products, and only amorphous products are obtained, based on XRD mea-

Table 1. The obtained products, % yield, morphology, crystal structure, percent of carbon, hydrogen and oxygen and BET surface area are illustrated.

| Sample name | % Yield | XRD | Morphology (TEM) | wt.-% C | wt.-% H | wt.-% O | BET Surface area $m^2/g$ |
|---|---|---|---|---|---|---|---|
| Ni@C | 38.2 | Ni | core-shell | 11.78 | 0.18 | 0.2 | 1 |
| Co@C | 40 | Co | core-shell | 15.25 | 0.10 | 0.3 | 3 |
| $Fe_3O_4$@C | 56 | $Fe_3O_4$ | core-shell | 22.3 | 0.12 | 21.43 | 2 |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

surements. The first crystalline products for the RAPET of the acetates appear at 700 °C. The RAPET of Ni and Co acetates in a closed cell at 700 °C yields 38.2% and 40% of products containing metallic Ni and Co, respectively coated with carbon. The dissociation of Fe acetate in a closed RAPET system confirms the weight loss of 44%, keeping about 56% of a solid product consisting of $Fe_3O_4$ and carbon. The rest of the weight loss is due to the formation of hydrocarbons and carbon oxides. In the case of the RAPET of Fe acetate, the reactant possesses a +2 oxidation state, while the product has a 2.66 oxidation state. This means that unlike Co and Ni ions, which undergo a reduction to the corresponding metals, the $Fe^{+2}$ is partially oxidized to $Fe_3O_4$ before being coated by carbon. Since the particles are densely coated with graphitic carbon, the oxidation of the product due to handling under air atmosphere is impossible. It is noticeable that the Fe is more facile to oxidation than Ni and Co. The measured surface areas for the Ni@C, Co@C and $Fe_3O_4$@C products are 1, 3, and 2 $m^2/g$, respectively.

The XRD pattern of the as-prepared Ni@C sample is presented in Figure 2 (top). The diffraction peaks, observed at $2\theta$ = 44.49, 51.85, and 76.38, are assigned as (111), (200), and (220) reflection lines of the face-centered cubic phase of Ni (space group: *Fm-3m*). These values are in good agreement with the diffraction peaks, peak intensities and cell parameters of crystalline Ni (PDF No. 87-712). The diffraction patterns of the as-prepared Co@C sample (middle) can be indexed to fcc (space group: *Fm-3m*) Co, and matches well with PDF No. 89-4307. The diffraction peaks observed at $2\theta$ = 44.22, 51. 35, and 75.86 are assigned as (111), (200), and (220) reflection lines. The XRD pattern of the as-prepared $Fe_3O_4$@C sample is presented at the bottom of Figure 2. The major diffraction peaks are observed at $2\theta$ = 30.10, 35.45, 37.08, 43.08, 53.45, 56.98, 62.57, and 74.02 and are assigned as (220), (311), (222), (400), (422), (511), (440) and (533) reflection lines. These values are in good agreement with the diffraction peaks, peak intensities and cell parameters of crystalline $Fe_3O_4$ (PDF No. 65-3107). However, since the XRD of $\gamma$-$Fe_2O_3$ is very similar to that of magnetite, we also used Mössbauer spectroscopy to further substantiate our assignment. In none of the three cases is a carbide phase detected. The small diffraction peak at $2\theta$ = 26.6°, assigned to graphitic carbon, is only detected for Co@C, and is suppressed in Ni and $Fe_3O_4$.

The Mössbauer spectra of $Fe_3O_4$ at 298 K are shown in Figure 3. The spectra show two hyperfine magnetic splits, which are clear evidence for the existence of $Fe_3O_4$ (magnetite). In the transmission spectrum, the hyperfine split arises due to a nuclear quadrupole interaction. This indicates that there is some departure from the cubic symmetry of the electric field due to the existence of an electric field gradient at the nucleus. It means that the $^{57}Fe$ excited level ($I = {}^3/_2$) has split, whereas the ground state ($I = {}^1/_2$) remains whole/intact. The difference in energy levels is only due to different electronic densities of the Fe atoms at the source, and the absorber. $Fe_3O_4$ can be written as $[(Fe^{3+})(Fe^{2+}Fe^{3+})]O_4$. The magnetic hyperfine fields of 455 and 487 kOe and the

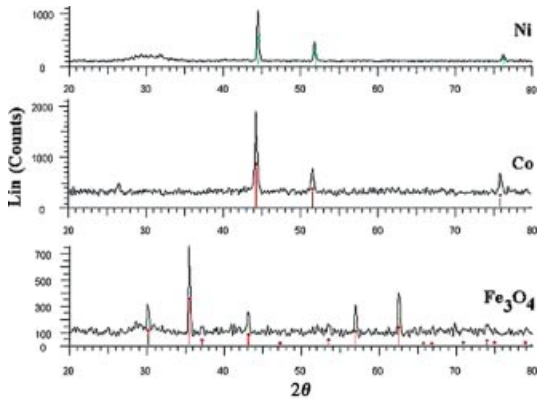

Figure 2. XRD patterns of as-prepared Ni@C (top), Co@C (middle), and $Fe_3O_4$@C (bottom) samples.

two isomer shift values, 0.67 and 0.37 mm/s, correspond to site A ($Fe^{3+}$) ions and to site B ($Fe^{2+}$, $Fe^{3+}$) ions, respectively. The high isomer shift for the B site is typical for $Fe^{2+}$. The resultant parameters are given in Table 2.

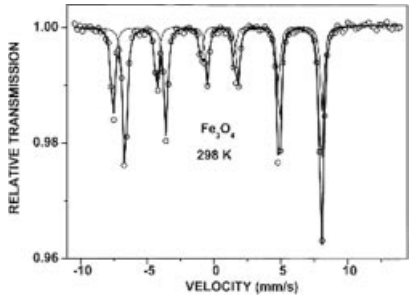

Figure 3. The Mössbauer spectrum of a $Fe_3O_4$@C sample at room temperature.

Table 2. The Mössbauer parameters of $Fe_3O_4$@C sample: isomeric shift (mm/s), quadrupole moment (mm/s) and effective field (kOe) for site A and site B.

| | I.S. (mm/s) | eQ (mm/s) | $H_{eff}$ (kOe) |
|---|---|---|---|
| Site A | 0.67 | 0.028 | 455 |
| Site B | 0.37 | – | 487 |

The nature of the coated carbon for all of three samples is also studied by employing Raman spectroscopy and HR-TEM measurements.

## 2. TEM, SEM, EDS, Raman, and HR-TEM Measurements

The morphology of all the samples is studied by TEM measurements. The transmission electron micrograph of Ni@C core-shell structures is shown in part a of Figure 4. The thermal dissociation of Ni acetate favors the formation of the dark particles of Ni, which are coated with carbon layers. We assume that the thermal decomposition of $Ni(CH_3COO)_2$, leads to dissociation into carbon, hydrogen, oxygen and nickel atoms at 700 °C. The Ni atoms forms the Ni core. The particle diameters range from 20 nm to 160 nm. The high resolution image (Figure 4b) taken on a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

single particle revealed that the 25 nm dark core of Ni is encapsulated in 5–10 nm carbon layers. Using the SAEDS technique, the identification of the dark cores as Ni, Co and iron oxide, which are covered by carbon, is confirmed for all the three products of (Ni, Co, and Fe) acetates. The TEM image of the Co@C sample demonstrates (Figure 4c) that the particles, whose diameters range from 30 to 230 nm, are covered with in situ formed carbon layers after the dissociation of cobalt acetate. The central 110 nm diameter cobalt particle is uniformly surrounded by a 20 nm carbon layer (Figure 4d). Thus, a similar trend is observed for the thermal decomposition of $Co(CH_3COO)_2$ and $Ni(CH_3COO)_2$, resulting in a metallic core and a carbon shell structure. Part e of Figure 4 shows that the 5 to 20 nm particles of $Fe_3O_4$ are densely covered with carbon. The HR-TEM image (Figure 4f) of a 10 nm $Fe_3O_4$ particle is surrounded by a thick layer of carbon. The thermal dissociation of Fe acetate favors the formation of a $Fe_3O_4$ core, which is coated with carbon layers after the decomposition of $Fe(CH_3COO)_2$. This means that the produced carbon, hydrogen, oxygen and FeO facilitate the FeO to react with oxygen to form $Fe_3O_4$, thus hindering the reduction.

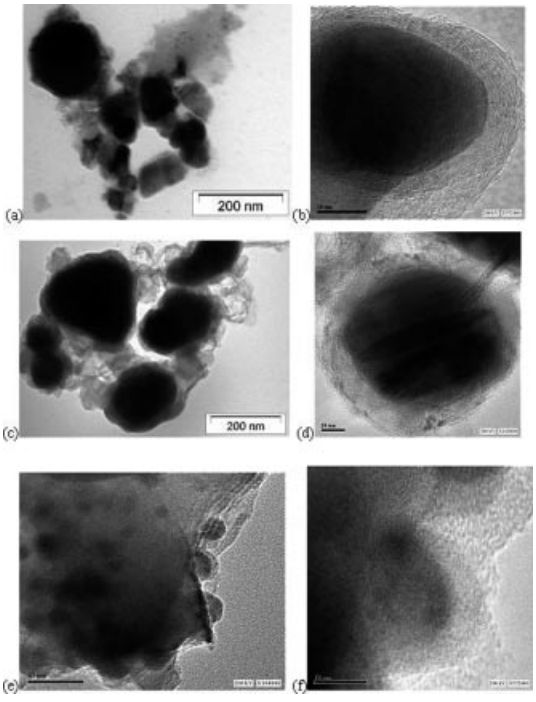

Figure 4. Transmission electron micrographs of (a) Ni@C sample, (b) single Ni@C particle at high resolution, (c) Co@C sample, (d) single Co@C particle at high resolution, (e) $Fe_3O_4$@C sample, and (f) single $Fe_3O_4$@C particle at high resolution.

The SEM image shown in Figure 5a indicates the spherical morphology of the Ni@C. The Ni-C particles have a tendency to form a few agglomerates, which are observed in addition to the individual particles. The aggregation is attributed to their magnetic nature. The diameters of the separated individual particles are in the range of 40–160 nm. The EDS of the Ni@C particles is presented in Figure 5b, and confirms the presence of Ni and C. No additional peak is detected, which verifies the purity of the Ni@C sample.

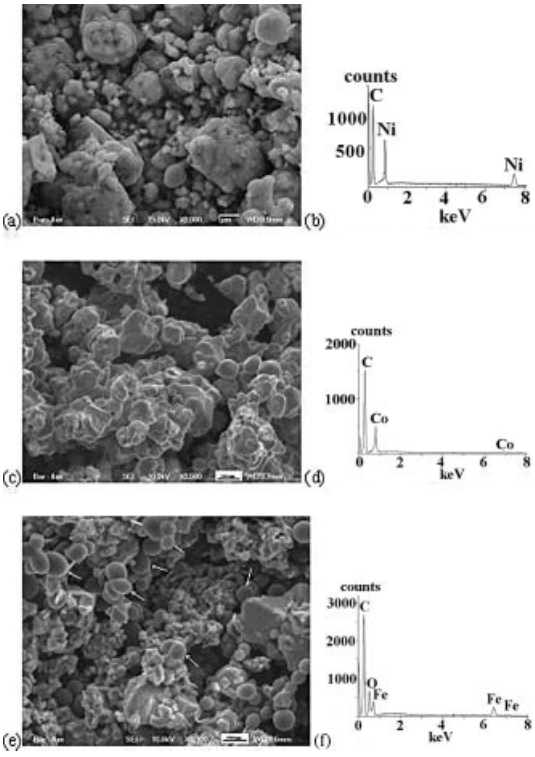

Figure 5. Scanning electron micrographs of (a) Ni@C sample, (b) EDS of Ni@C sample, (c) Co@C sample, (d) EDS of Co@C sample, (e) $Fe_3O_4$@C sample [arrow indicates egg-like carbon entities], and (f) EDS of $Fe_3O_4$@C sample.

The SEM image of the Co@C sample demonstrates (Figure 5c) that the particle diameter ranges from 50 to 200 nm. In addition, the obvious aggregating tendency of magnetic Co@C particles is observed. The EDS analysis of the Co@C sample (Figure 5d) detected only the presence of cobalt and carbon, without additional impurities. Negligible amounts of oxygen are detected in Ni@C and Co@C samples.

The $Fe_3O_4$@C sample possesses an oval shaped mixture of about 400 nm and aggregates of about 100 nm particles (Figure 5e). The SAEDS confirm that the oval shaped particles, indicated by an arrow, are composed solely of carbon, while the smaller particles are composed of $Fe_3O_4$ and carbon. The core-shell nature of $Fe_3O_4$ surrounded by C is substantiated by TEM measurements. The excess of carbon might have lead to the formation of egg-like carbon entities in the $Fe_3O_4$@C sample. The bulk EDS analysis of the $Fe_3O_4$@C sample is shown in part f of Figure 5, presented Fe, O, and carbon occurrence. The formation of $Fe_3O_4$ and carbon without additional impurities is confirmed by the EDS spectrum shown in Figure 5f.

The nature of the carbon shell is investigated by Raman spectroscopy. The Raman spectra (Figure 6) are the charac-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

teristics of disordered graphitic carbon with nanosized graphitic crystals. The first D peak, located at ca. 1330 $cm^{-1}$, originates from the in-plane lattice vibrations. The second G peak is located at ca. 1595 $cm^{-1}$, and only occurs when small, crystal-size graphitic particles are present.[18] The D band is associated with graphitic edge-planes and defects in the graphitic lattice. The relative intensity of the D and G bands is generally used to estimate the size of graphitic clusters in the hexagonal plane, *La*. Although all the samples are prepared at 700 °C, the intensity of graphitic carbon is much higher than the disordered carbon for the Ni@C sample. Almost the same intensity is observed for the Co@C and $Fe_3O_4$@C samples. The results indicate that Ni is the best catalyst for the preparation of high order graphitic planes. This is also manifested in the relatively low temperature that the graphitic layers reach.

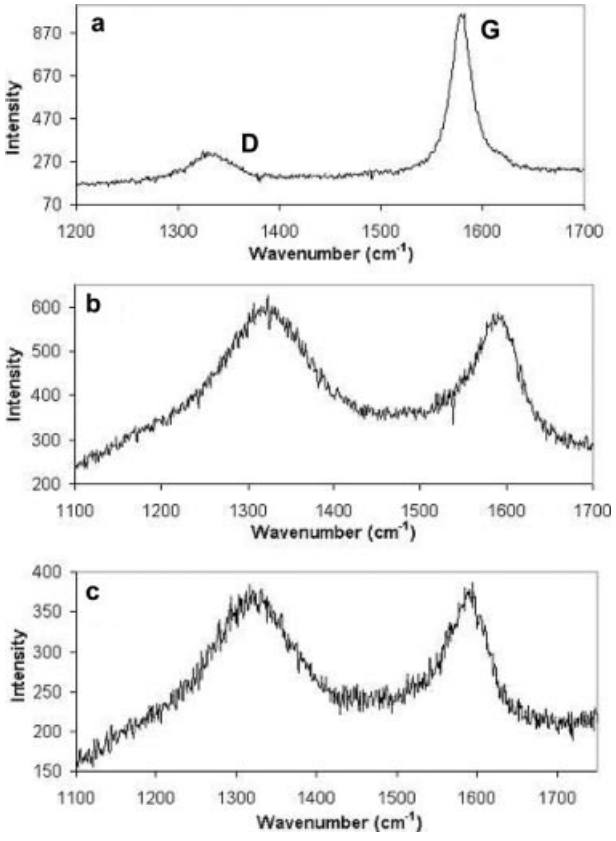

Figure 6. Raman spectra of a) Ni@C, b) Co@C, and c) $Fe_3O_4$@C samples.

In order to understand the graphitization of formed carbon layers around the cores, HR-TEM measurements of the carbon-shells are carried out for the Ni@C, Co@C, and $Fe_3O_4$@C samples. The measured interlayer spacings between these graphitic planes are 0.345, 0.337, and 0.341 nm for Ni@C (Figure 7a), Co@C (Figure 7b), and $Fe_3O_4$@C (Figure 7c) samples, respectively, which are very close to that of the graphitic layers. It should be noted that the graphitic ordering is much better in Ni than in the Co and $Fe_3O_4$.

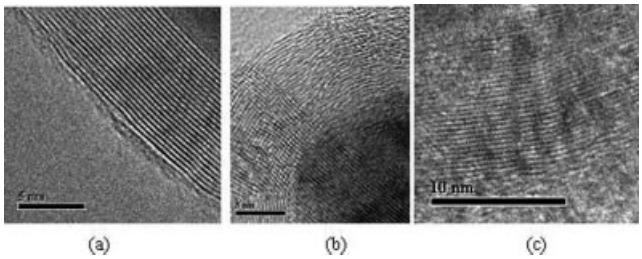

Figure 7. HR-TEM images of a) carbon layer coated on the Ni core, b) carbon coated on the Co core, and c) carbon layer on the surface of $Fe_3O_4$ core.

To summarize, the few points that need further clarification and discussion on the results reported for the decomposition of all three acetates (Co, Ni, and Fe) are: 1) The cores of Co, Ni, and iron oxide are surrounded by graphitic carbon (interlayer spacing ≈ 0.34 nm). 2) A wide particle size distribution is observed. 3) The thickness of the carbon coating around the cores is proportional to the percentage of carbon present in the product (see Table 1). 4) Although the graphitic carbon encapsulates the cores, nanosize Ni and Co are obtained in metallic form, while Fe tends to form $Fe_3O_4$ (confirmed by XRD, EDS, and SAEDS), maintaining the core-shell morphology. The three-dimensionality of the onion-like structures of Ni@C, Co@C, and $Fe_3O_4$@C products is confirmed by tilting the TEM grid during HR-TEM measurements, when the pictures remained unchanged.

## 3. Magnetic Properties

A room temperature magnetic susceptibility measurement of Ni@C, Co@C, and $Fe_3O_4$@C samples is conducted by employing a vibrating sample magnetometer. A small amount of material, ca. 20 mg, is inserted into a plastic capsule. Cotton wool is placed on the top of the sample and the capsule is sealed. This prevents the particles from any movement caused by the vibration of a VSM sample holder rod, or by a variation in the applied magnetic field during measurements. The magnetization vs. magnetic field curves are measured for all the samples (Figure 8a–c) in the range of –15800 to 16000 Oe.

The Ni@C sample exhibits typical hysteresis with a saturation magnetization of 21.7 emu/g (Figure 8a). Taking into account the fact that the sample contains 11.78% carbon and the remaining 88.22% Ni, this yields a value of 24.6 emu/g for 100% Ni. A 151 Oe coercive field is obtained for the Ni@C sample. The Co@C sample shows a saturation magnetization of 21.87 emu/g (Figure 8b). When considering that the sample contains 84.75% of Co, this gives a value of 25.81 emu/g for 100% Co. This sample shows the coercivity of 97 Oe with a remanent magnetization of 2.6 emu/g. Figure 8c shows the magnetization curve of the $Fe_3O_4$@C sample. Unlike the ferromagnetic behavior detected for Ni@C and the Co@C, the characteristic behavior of superparamagnetic particles is detected for $Fe_3O_4$@C. The magnetization curve does not show hysteresis and does

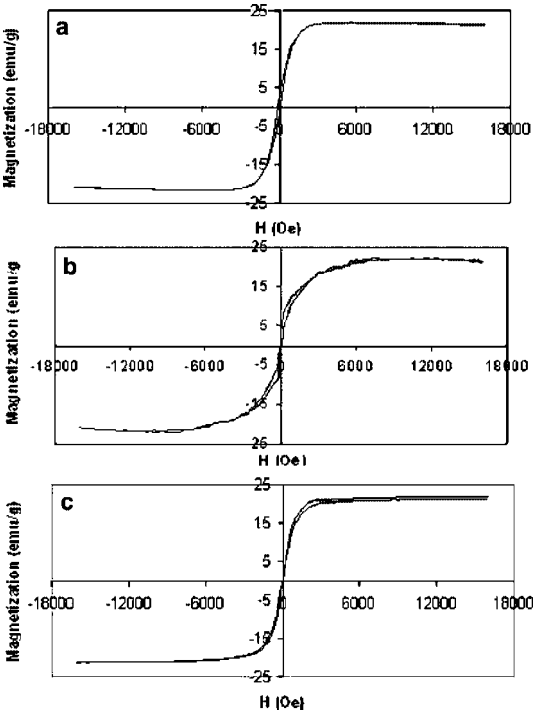

Figure 8. Magnetization vs. magnetic field curves for a) Ni@C, b) Co@C, and c) $Fe_3O_4$@C samples.

not saturate (a small increase in magnetization is measured between 12–16 kOe), even at 16 kOe. This is due to the $Fe_3O_4$ core, which is comprised of small 5–20 nm crystallites (shown in the TEM measurements). The magnetization of ferromagnetic materials is very sensitive to the microstructure of a sample. If a specimen consists of small particles, its total magnetization decreases with decreasing particle size due to the increased dispersion in the exchange integral,[19] finally reaching the superparamagnetic state, when each particle acts as a big 'spin' with suppressed exchange interaction between the particles, which is more hindered because of the presence of the carbon shell. Nanomagnetic particles are expected to exhibit reduced magnetization due to the large percentage of surface spins with disordered magnetization orientation.[20] In fact, the magnetization is smaller than the bare particles, indicating that there is no magnetic proximity effect between the magnetic (Ni, Co, or $Fe_3O_4$) particles and carbon, which is consistent with recent experiments.[21]

The main question remaining now is why are Ni and Co obtained in the metallic form, while Fe tends to form $Fe_3O_4$, maintaining a carbon shell in all three cases. The thermal decomposition of $Ni(CH_3COO)_2$ at 350 °C[17] leads to dissociation into nickel oxide and oxygenates like acetone and acetic acid, as perceived by TGA coupled with MS. It is worth mentioning that both, Jesus et al.[17] and our own TGA + MS results show that CO is one of the intermediates in the decomposition of the Ni acetate. We attribute the reduction of nickel oxide to carbon monoxide. The product of the reduction is the Ni atom, forming the Ni core, while the oxygenate molecule decomposes to hydrocarbon, and further to carbon. In our previous RAPET reactions of various organic or organometallic materials, we observed the appearance of carbon above 550 °C.[22–24]

The decomposition of $Co(ac)_2$ and $Ni(ac)_2$ results in a metallic core and carbon shell structures, while the thermal dissociation of Fe acetate favors the formation of a $Fe_3O_4$ core, which is coated with graphitic and disordered carbon layers. It should be noted that the only source of oxygen is the acetate ion, and its quantity in all three acetates is almost the same (36 wt.-%).

Based on the obtained MS data, we propose the dissociation of acetates as follows:

$$M(CH_3COO)_2 \rightarrow MCO_3 + CH_3COCH_3 \quad (1)$$

$$MCO_3 \rightarrow MO + CO_2 \quad (2)$$

$$CH_3COCH_3 \rightarrow CO + C_2H_6 \quad (3)$$

$$MO + CO \rightarrow M + CO_2 \quad (4)$$

where M = Ni, Co, Fe.

The formation of the first oxygenated product, acetone, occurs by Equation (1). The metal carbonate,[17,25] which is a short-lived intermediate, immediately decarboxylates to give a metal oxide at 350 °C. This metal oxide, in the case of Ni and Co acetates, gets reduced by carbon monoxide, while the Fe atoms prefer to stay as FeO. It further is oxidized to form $Fe_3O_4$ and then coated by carbon to form the core-shell structure during solidification. This can be explained by the reduction potential values of Ni, Co, and Fe. The well-known standard reduction potentials[26] at 25 °C for Ni, Co and Fe are –0.25, –0.27, and –0.44 V, respectively, for the metal–metal ion equilibrium. These numbers indicate that iron is less favorably reduced than cobalt and nickel.

Thus, all three acetates decompose into their corresponding oxides, which further get reduced by carbon monoxide to a metallic form. The values for the enthalpy change, $\Delta H^0$, and free energy change, $\Delta G^0$, are calculated to form the respective metals from the corresponding oxide[27] in the presence of carbon monoxide at 700 K. Since the cases of Ni and Co are similar, the values are calculated for the representative Co@C case and, for simplicity, are compared with the case of $Fe_3O_4$@C.

$FeO(s) + CO(s) \rightarrow Fe_{(s)} + CO_2(g)$
$\Delta H^0$ = –14.7 kJ/mol at 700 K
$\Delta G^0$ = +3.55 kJ/mol at 700 K
$CoO(s) + CO(s) \rightarrow Co(s) + CO_2(g)$
$\Delta H^0$ = –49.89 kJ/mol at 700 K
$\Delta G^0$ = –37.61 kJ/mol at 700 K

The positive value obtained for the $\Delta G^0$ of formation of Fe from $Fe^{II}$ acetate, unlike Ni and Co, indicates that thermodynamically, the reduction to the metallic state is not favorable. Therefore, the alternative is its partial oxidation and the kinetically-controlled coating by the carbon surrounding it, forming the $Fe_3O_4$@C. On the other hand, the $\Delta G^0$ value is negative for the formation of metallic cobalt and Ni, and we assume that the reaction is also fast. Thus the core of metallic Co or Ni is formed in this way in Co@C and Ni@C particles.

## Conclusions

In summary, using low cost, transition metal acetate precursors and employing identical reaction parameters, graphitic carbon-coated nanosize Ni, Co are obtained in the metallic form. Metallic Fe is not obtained, and instead it forms $Fe_3O_4$, maintaining the core-shell morphology. A broad particle size distribution is observed. Graphite-encapsulated Ni, Co, and $Fe_3O_4$ fullerene-like core-shell nanostructures could be obtained at a relatively low temperature (700 °C) in a closed Swagelok reactor, as compared to other methods for the formation of graphitic layers. The one-stage, reproducible, solvent-free, competent and straightforward approach for the synthesis of Ni@C, Co@C, and $Fe_3O_4$@C core-shell nanostructures can be scaled up.

## Experimental Section

**Synthesis of Fullerene-like Ni@C, Co@C and $Fe_3O_4$@C Core-Shell Nanostructures:** Acetates of $Fe^{II}$ (Aldrich), $Co^{II}$ (Aldrich) and $Ni^{II}$ (Alfa Aesar), were purchased with > 99% purity and used as received. In the fabrication of Ni@C, Co@C, and $Fe_3O_4$@C core-shell nanostructures, 1 g of the acetate of Ni, Co and Fe are introduced separately into a 3 mL stainless steel reactor at room temperature in a nitrogen-filled glove box. The filled Swagelok reactors are closed tightly with the other plug.[22] The temperature of the tube furnace is raised to 700 °C at a rate of 10 °C/min, and the temperature is maintained at 700 °C for 3 h. The Swagelok-reactors heated at 700 °C are gradually cooled (ca. 6 h) to room temperature and opened. A black powders of Ni@C (0.382 g), Co@C (0.400 g) and $Fe_3O_4$@C (0.560 g) is obtained. The obtained products, their morphology, crystal structure, carbon percent are shown in Table 1. Earlier, such a one-stage, efficient, and the simplest economic RAPET (Reactions under Autogenic Pressure at Elevated Temperature) technique was employed for the fabrication of various interesting nanostructures.[22–24]

**Characterization:** Various analytical techniques are used to identify and characterize the as-prepared RAPET products of the Ni, Co and Fe acetate reactions. To understand the purity of the crystal structure (the interatomic distance, and angle) of the as-prepared products, the X-ray diffraction patterns are measured with a Bruker AXS D* Advance Powder X-ray diffractometer [$\lambda$(Cu-$K_a$) = 1.5418 Å]. Since all the acetate contains C, H, and O, in addition to metal, C, H, N, S and O analyses are carried out for the as-prepared products on an Eager 200 C,H,N,S analyzer and an EA1110, oxygen analyzer, respectively. The morphology, grain size, and chemical composition in a selected area are measured for the fullerene-like Ni@C, Co@C, and $Fe_3O_4$@C core-shell nanostructures by employing transmission electron microscopy (TEM) (JEM-1200EX) and high-resolution transmission electron microscopy (HRTEM) (JOEL 2010), working at acceleration voltages of 80 kV and 200 kV, respectively. The morphology and energy dispersive X-ray analysis (EDX) of the materials are investigated by high resolution scanning electron microscopy (HR-SEM, JSM, 7000 F). The Mössbauer spectroscopy (MS) studies are carried out at room temp. using a conventional constant acceleration spectrometer. The $^{57}$Fe MS are measured with a 50 mCi $^{57}$Co:Rh source and the spectra were least square fitted with two sub spectra. The isomer shift (IS) values are relative to Fe metal at 300 K. A Micromeritics (Gemini 2375) surface area analyzer is used to measure the surface area of the samples. An Olympus BX41 (Jobin–Yvon–Horiba) Raman spectrometer is employed, using the 514.5 nm line of an Ar ion laser as the excitation source to analyze the nature of the carbon present in the samples. A vibrating sample magnetometer (VSM-Oxford-3001) is used for the magnetic susceptibility measurements for Ni@C, Co@C, and $Fe_3O_4$@C samples at room temperature.

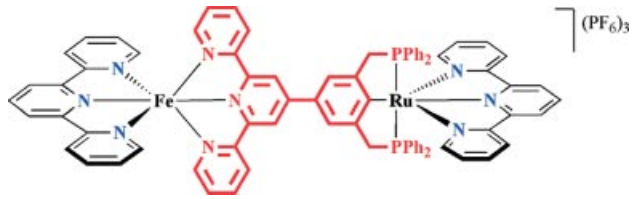
## FULL PAPERS

### Pincer Ligands

**M. Gagliardo, J. Perelaer, F. Hartl, G. P. M. van Klink, G. van Koten* ..... 2111–2120**

Mono- and Heterodimetallic $Fe^{II}$ and $Ru^{II}$ Complexes Based on a Novel Heteroditopic 4′-{Bis(phosphanyl)aryl}-2,2′:6′,2′′-terpyridine Ligand

**Keywords:** Ruthenium / Iron / Terpyridine ligands / Pincer ligands / Spectroelectrochemistry



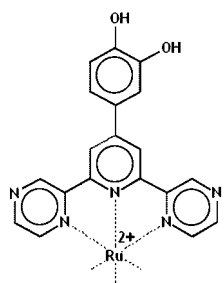
The redox and spectroscopic properties of the mono- and dimetallic complexes of the heteroditopic ligand 4′-{$C_6H_3(CH_2PPh_2)_2$-3,5}-2,2′:6′,2′′-terpyridine have been investigated in detail. The degree of electronic communication between the $Ru^{II}$ and $Fe^{II}$ centres in the heterodimetallic complex was probed. The electronic interaction between the metal centres appears to be very limited.

### Photosensitizers

**F. A. Al-mutlaq, P. G. Potvin,* A. I. Philippopoulos, P. Falaras ..... 2121–2128**

Catechol-Bearing Dipyrazinylpyridine Complexes of Ruthenium(II)

**Keywords:** Ruthenium / Tridentate ligands / Photosensitizers / Electron transfer / Energy conversion



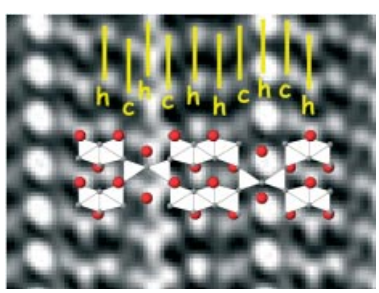
Homoleptic and heteroleptic dipyrazinylpyridine complexes of $Ru^{II}$ with one or two peripheral catechol groups were prepared via protected forms. They were characterized by electronic spectra and cyclic voltammetry, then assessed as photosensitizers in homogeneous solutions and in photovoltaic devices.

### Hexagonal Perovskite Oxides

**L. Miranda, J. Ramírez-Castellanos, M. Hernando, A. Varela, J. M. González-Calbet, M. Parras* ..... 2129–2135**

Structural Chemistry of a New 10H Hexagonal Perovskite: $BaMn_{0.4}Fe_{0.6}O_{2.73}$

**Keywords:** Hexagonal perovskites / Magnetic properties / Mn polytypes / High-resolution electron microscopy



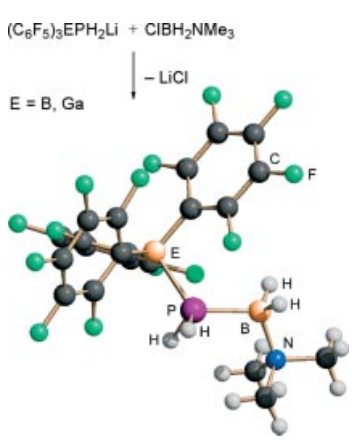
A new 10H polytype has been stabilized in the $BaMn_{1-x}Fe_xO_{3-y}$ system with the composition $BaMn_{0.4}Fe_{0.6}O_{2.73}$. The anionic composition has been established by a reduction and re-oxidation cycle in the stability range of this phase. The structure can be described by the stacking of cubic (c) and hexagonal (h) $BaO_3$ layers with oxygen-deficient hexagonal (h′) $BaO_{2-y}$ layers according to the sequence $(hch'ch)_2$.

### Phosphanylboranes

**A. Adolf, M. Zabel, M. Scheer* ..... 2136–2143**

Main Group Lewis Acid/Base-Stabilised Phosphanylboranes

**Keywords:** Boron / Phosphorus / Hydrides / Lewis acids / Lewis bases



The synthesis of the novel parent compounds of the phosphanylboranes stabilised by Lewis acid/Lewis base is described, where the perfluorinated main group moieties $B(C_6F_5)_3$ and $Ga(C_6F_5)_3$, respectively, were used as Lewis acids for the first time. These are stable compounds which do not show any tendency of dehydrocoupling to form polymerisation products.

## Markovnikov Addition

A simple but efficient method for synthesizing stable azaplatinacyclobutanes containing platinum(II) is reported together with two crystal structures. The influence of the substituents on the parent complexes on the molar ratios of the anti-Markovnikov/Markovnikov isomers formed is highlighted and interpreted in terms of electronic and steric factors. These reactions can serve as models for metal-catalyzed amination of alkenes.

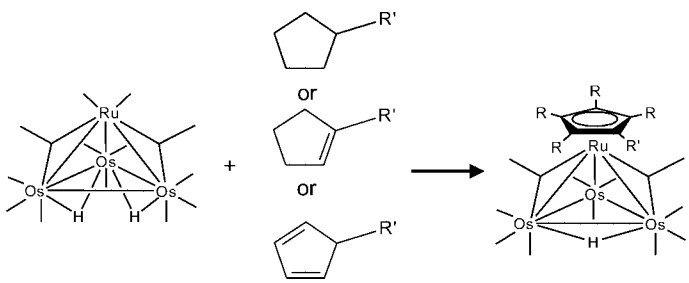
## Aromatization of $C_5$ Rings



The reaction of $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ with saturated and unsaturated $C_5$ rings led to the aromatization of the rings to afford the clusters $RuOs_3(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_2(\eta^5\text{-}C_5R_4R')$. However, the reaction with cyclopentene gave the cluster $RuOs_3(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}C_5H_7)$ via C–H activation of an $sp^2$ carbon instead. Thermolysis of two of the products led to their isomerization to butterfly clusters.

**Keywords:** Nickel / Copper / Dinuclear complexes / Pyrazolate bridge / $Ni^{III}$-$Ni^{II}$ species

## Black Dye

Ruthenium(II) "black dye" complexes are investigated by DFT and TD-DFT methods. In the calculated absorption spectra, the first four bands have MLCT/LLCT nature, whereas the fifth band, the one with the strongest intensity, arises from an intraligand tricarboxyterpyridine π → π* charge transfer (ILCT) with some LLCT character.

# Mono- and Heterodimetallic $Fe^{II}$ and $Ru^{II}$ Complexes Based on a Novel Heteroditopic 4′-{Bis(phosphanyl)aryl}-2,2′:6′,2′′-terpyridine Ligand

**Marcella Gagliardo,[a] Jolke Perelaer,[a] František Hartl,[b] Gerard P. M. van Klink,[a] and Gerard van Koten*[a]**

**Keywords:** Ruthenium / Iron / Terpyridine ligands / Pincer ligands / Spectroelectrochemistry

In the search for a versatile building block that allows the preparation of heteroditopic tpy-pincer bridging ligands, the synthon {4′-[$C_6H_3(CH_2Br)_2$-3,5]-2,2′:6′,2′′-terpyridine} was synthesized. Facile introduction of diphenylphosphanyl groups in this synthon gave the ligand {4′-[$C_6H_3(CH_2PPh_2)_2$-3,5]-2,2′:6′,2′′-terpyridine} ([**tpyPC(H)P**]). The asymmetric mononuclear complex [Fe(tpy){**tpyPC(H)P**}]$(PF_6)_2$, prepared by selective coordination of [$Fe(tpy)Cl_3$] to the tpy moiety of [**tpyPC(H)P**], was used for the synthesis of the heterodimetallic complex [Fe(tpy)(**tpyPCP**)Ru(tpy)]$(PF_6)_3$, which applies the "complex as ligand" approach. Coordination of the ruthenium centre at the PC(H)P-pincer moiety of [Fe(tpy){**tpyPC(H)P**}]$(PF_6)_2$ has been achieved by applying a transcyclometallation procedure. The ground-state electronic properties of both complexes, investigated by cyclic and square-wave voltammetries and UV/Vis spectroscopy, are discussed and compared with those of $[Fe(tpy)_2](PF_6)_2$ and [Ru(PCP)(tpy)]Cl, which represent the mononuclear components of the heterodinuclear species. An in situ UV/Vis spectroelectrochemical study was performed in order to localize the oxidation and reduction steps and to gain information about the $Fe^{II}$–$Ru^{II}$ communication in the heterodimetallic system [Fe(tpy)(**tpyPCP**)Ru(tpy)]$(PF_6)_3$ mediated by the bridging ligand [**tpyPCP**]. Both the voltammetric and spectroelectrochemical results point to only very limited electronic interaction between the metal centres in the ground state.

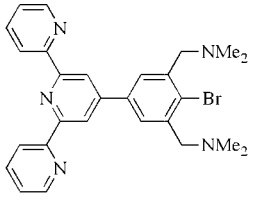
## Introduction

In the past decades, much attention was devoted to the field of coordination chemistry of substituted terpyridines. Currently, a significant amount of research is devoted to the preparation of mononuclear terpyridine complexes bearing an externally oriented vacant binding site. A huge potential is concealed in these compounds with tuneable redox and photophysical properties, which can be used as building blocks for the construction of molecular devices,[1] metal-containing dendrimers[2] and one-dimensional polymers.[3]

Only a few examples have been reported in which metal–tpy and organometallic subunits are incorporated into a single molecule.[4] Bridging ligands based on 2,2′:6′,2′′-terpyridine (tpy) functionalized at the 4′-position with a cyclometallating unit proved to have a high potential for linking chromophoric Ru–tpy centres and robust organometallic units containing a stable M–C σ-bond.[1b,5] Recently, we described the synthesis of the heteroditopic ligand 4′-{4-Br-$C_6H_3(CH_2NMe_2)_2$-3,5}-2,2′:6′,2′′-terpyridine [**tpyNCNBr** (**1**)], which combines the properties of the tpy and NCNBr-pincer {$BrC_6H_3(CH_2NMe_2)$-2,6} ligands.[6] It was shown that selective metallation and coordination of the NCNBr and tpy moieties, respectively, affords monometallic species that can be further used as building blocks for the construction of heterodi- and trimetallic complexes containing covalently linked photosensitizing octahedral $[Ru(tpy)_2]^{2+}$ and cyclometalated NCN–$Pd^{II}$ domains.[6]



**1**

Metallation of the NCNBr moiety in **1** can be performed only by oxidative addition of the C–Br bond to transition-metal salts.[7] For a broader application in template-directed synthesis of multimetallic systems based on metal–tpy binding domains containing aryl pincer components, we extended our studies to the preparation of the versatile tpy-pincer building block 4′-{$C_6H_3(CH_2Br)_2$-3,5}-2,2′:6′,2′′-terpyridine (**5**). Interestingly, **5** can be used as a precursor for several tpy-pincer ligand systems because the bromo

substituents at the benzylic arms can be easily converted into $ER_2$ groups, where E = N, P, S, O and R = alkyl or aryl.[8] In the pincer moiety, several parameters (e.g. nature of the donor atoms, size and electron-withdrawing or releasing character of the donor substituents) can readily be varied. This allows for fine-tuning of the target ligand depending on its envisaged application.[9] Moreover, incorporation of a wider range of transition metals into the pincer moiety can at the same time be achieved through C–H activation,[10] transmetallation[11] and transcyclometallation[12] procedures.

In our previous work, we described a heterometallic system with weak electronic interactions between the $Ru^{II}$ and $Pd^{II}$ centres mediated by tpy-pincer ligand **1**.[6] However, this study was hampered by the low redox activity of the $Pd^{II}$ centre and by the instability of the NCN–Pd pincer moiety upon electrochemical reduction.[6] Aimed at continuing these physicochemical investigations and with synthon **5** in hand, we focused our attention on its derivatization to form the heteroditopic ligand 4′-{$C_6H_3(CH_2PPh_2)_2$-3,5}-2,2′:6′,2′′-terpyridine {[**tpyPC(H)P**] (**7**, see Scheme 1} containing P-donor atoms. Facile attachment of redox active $Fe^{II}$ and $Ru^{II}$ centres to the tpy and PCP-pincer moieties of **7**, respectively, led to the formation of the heterodimetallic complex [Fe(tpy)(**tpyPCP**)Ru(tpy)]$(PF_6)_3$ (**11**). For the purpose of comparison, the mononuclear complex [Fe(tpy){**tpyPC(H)P**}]$(PF_6)_2$ (**9**) was also prepared. Our main goal was to investigate the spectroelectrochemical behaviour of **11** and the known reference complexes [Fe(tpy)$_2$]$^{2+}$[13] and [Ru(PCP)(tpy)]Cl (PCP = [$C_6H_3(CH_2PPh_2)_2$-2,6]$^-$)[14] to probe the degree of intramolecular electronic interaction between the metal centres in the novel dinuclear species mediated by the **tpyPCP** bridging ligand.

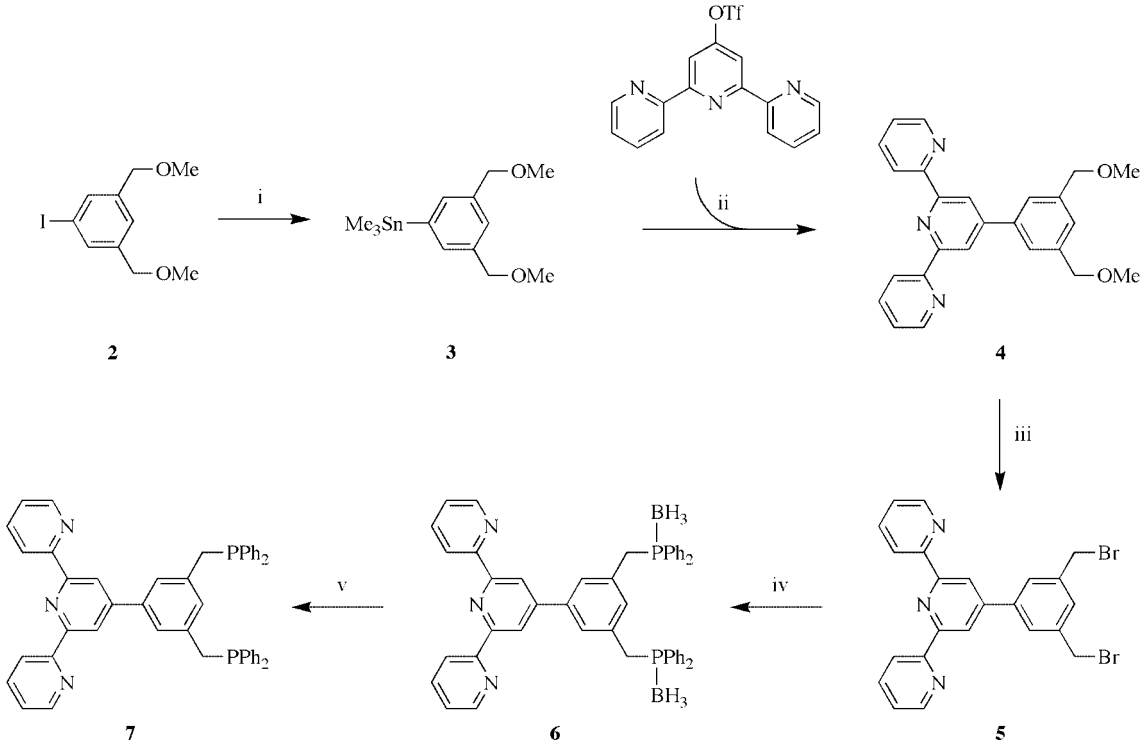
## Results and Discussion

### Synthesis of the [tpyPC(H)P] Ligand

The starting point for the synthesis of the building block 4′-{$C_6H_3(CH_2Br)_2$-3,5}-2,2′:6′,2′′-terpyridine (**5**) (Scheme 1) is the preparation of the stannane pincer compound {$C_6H_3(CH_2OMe)_2$-3,5}-$SnMe_3$ (**3**). Chemoselective lithiation of 3,5-bis(methoxymethyl)iodobenzene **2**[15] at the C–I position was achieved by reaction of **2** with 2 equiv. of *t*BuLi in $Et_2O$ at –100 °C. Subsequent quenching with $Me_3SnCl$ followed by slow warming of the reaction mixture to room temperature resulted in the formation of **3** in good yield. Pd-catalyzed Stille cross-coupling[16] of **3** with 4′-triflato-2,2′:6′,2′′-terpyridine[17] gave **4** in moderate yield after chromatographic purification.

First attempts to replace the methoxy groups in **4** with bromide substituents by using $BF_3{\cdot}EtO_2$/AcBr in $CH_2Cl_2$[18] mainly resulted in the formation of unwanted side products and only small amounts of **5**. However, **5** was conveniently prepared by treatment of **4** with an excess amount of HBr·AcOH in dichloromethane.

Subsequently, a two-step procedure was employed for the preparation of **7**. First, treatment of **5** with 2 equiv. of in situ prepared $LiPPh_2{\cdot}BH_3$ afforded **6**. Deprotection of the diphenylphopshine–$BH_3$ moieties with $Et_2NH$ yielded **7** as



Scheme 1. Synthesis of [**tpyPC(H)P**] ligand **7**. Reagents and conditions: i) (a) 2 equiv. *t*BuLi, $Et_2O$, –100 °C, 0.5 h.  © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

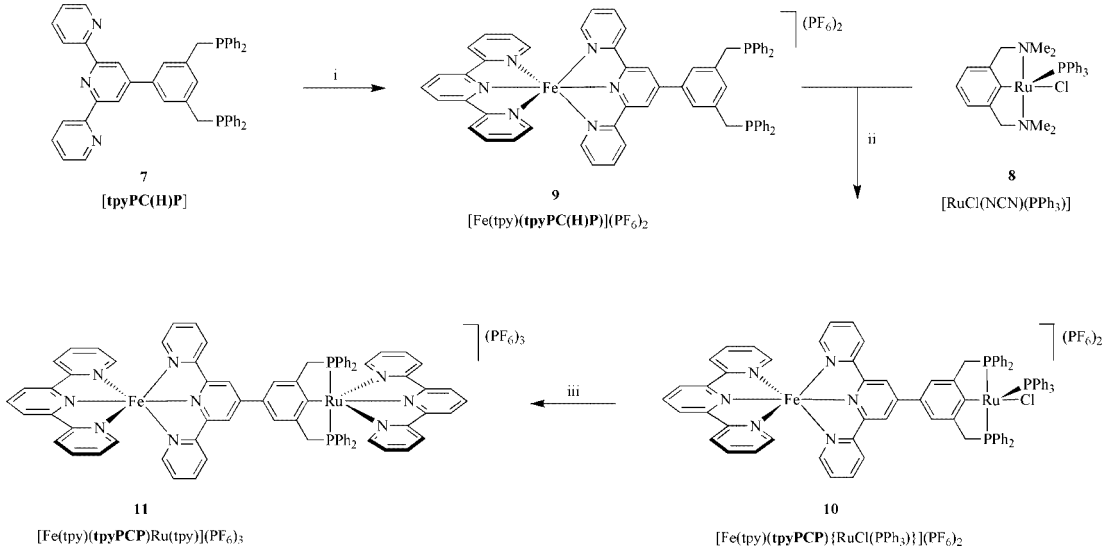
an air- and moisture-sensitive sticky white solid. Notably, both the tpy and PCP-pincer moieties of **7** proved to be stable both in acidic and basic media during the entire synthetic procedure. All the intermediates and ligand **7** have been fully characterized by analytical and spectroscopic methods. The $^1H$ and $^{13}C$ NMR spectra of **7** show the characteristic coupling between the benzylic proton and carbon atoms, of the $PPh_2$ groups, respectively. The $^{31}P\{^1H\}$ NMR spectrum exhibits a signal at $\delta$ = –8.5 ppm typical for the diphenylphosphanyl groups.

### Syntheses of Mono- and Heterodimetallic Complexes

Previous work carried out by Constable and coworkers[19] showed the high potential of the phosphane-functionalized terpyridine ligand 4′-($PPh_2$)-2,2′:6′,2′′-terpyridine to link $M^{II}$ coordination centres (M = Fe, Ru) and organometallic units through the N,N,N- and P-donor domains, respectively. Because it was demonstrated that reaction of ruthenium(III) chloro complexes with this ligand leads to partial or complete oxidation of the $PPh_2$ group,[19a] it was decided to employ different ruthenium starting materials to produce the (**tpyPCP**)Ru-containing species. The use of $[RuCl_2(PPh_3)_3]$ gave a mixture of N,N,N- and P-bound compounds. Confident that a selective and quantitative transfer of the $RuClPPh_3$-moiey into the PCP-pincer unit of **7** could be achieved by a transcyclometallation (TCM) procedure developed in our laboratories for the synthesisofmulti(pincer–metal)complexes,[12,20]wereactedthe ruthenium precursor $[RuCl(NCN)(PPh_3)]$[21] (NCN = $[C_6H_3(CH_2NMe_2)_2$-2,6$]^-$) (**8**, Scheme 2) with **7** in refluxing benzene. Resonances of free **7** or unreacted **8** (singlet at $\delta$ = 90.2 ppm) were subsequently not detected in the $^{31}P\{^1H\}$ NMR spectrum. The main signals present in the spectrum, a triplet at $\delta$ = 83.2 ppm ($PPh_3$, $^2J_{PP}$ = 31.8 Hz) and a doublet at $\delta$ = 37.9 ppm (PCP, $^2J_{PP}$ = 31.8 Hz), together with a large amount of free $PPh_3$, are consistent with the incorporation of the ruthenium centre into the PCP-pincer unit by TCM.[12a] However, the presence of a singlet at $\delta$ = 41.82 ppm indicated that an unwanted reaction concomitant to the TCM procedure occurred. The ruthenium centre of the {(PCP)$RuCl(PPh_3)$} moiety partly reacted with the tpy site of another molecule of the bridging ligand, which produced an oligonuclear species containing the unit [(PCP)Ru(**tpyPCP**)$RuCl(PPh_3)$]. The nature of this material was not investigated in detail. However, fine-tuning of the reaction conditions, as well as the introduction of solubilizing substituents at the phosphorus atoms, may give rise to the formation of soluble redox- and photoactive organometallic molecular wires. Because the synthesis of mononuclear complexes incorporating **7** failed as a result of the affinity of both PCP-pincer and tpy sites for ruthenium, we decided to choose a different approach: to first coordinate an iron centre to the tpy unit in **7**, and then to bind the ruthenium centre at the PCP-site through a TCM reaction.

The reaction of equivalent amounts of $[Fe(tpy)Cl_3]$[22] and **7** in refluxing methanol resulted in the formation of an intensely purple-coloured solution, from which the cation $[Fe\{\mathbf{tpyPC(H)P}\}(tpy)]^{2+}$ could be isolated as the diamagnetic $PF_6$-salt **9** (Scheme 2). Similarly to what was found for **7**, complex **9** is highly air and moisture-sensitive and has to be handled under strictly anaerobic conditions. This sensitivity hampered the removal of small amounts of tpy-containing impurities by chromatography. Attempts to obtain single-crystals suitable for X-ray diffraction analysis were, unfortunately, also unsuccessful. However, complex **9** was sufficiently characterized by NMR spectroscopy and high-resolution ESI-MS analysis. In the ESI-MS spectrum of **9**, the highest mass peak at $m/z$ = 497.20 corresponds to $[M - 2\ PF_6]^{2+}$, which shows the correct isotopic pattern for this formulation. The resonances in the aromatic region of the $^1H$ NMR spectrum could be unequivocally assigned to the protons of the complexed tpy moieties. A single resonance



Scheme 2. Synthesis of **9** and heterodimetallic **11**. Reagents and conditions: i) (a) 1 equiv. $[Fe(tpy)Cl_3]$, MeOH, reflux, 4 h. (b) Excess $NH_4PF_6$. ii) **8**, THF/MeCN, reflux, 2 d. iii) (a) tpy, MeOH. (b) Excess $NH_4PF_6$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in the $^{31}P\{^1H\}$ NMR spectrum ($\delta$ = –4.9 ppm in $CD_3CN$) for the equivalent diphenylphosphanyl groups clearly indicates that the iron centre is selectively coordinated to the tpy moiety.

Ruthenation of the PCP-pincer unit of **9** was achieved by the TCM procedure: the reaction of **9** with an equivalent amount of **8** in refluxing THF/MeCN (8:3 v/v). Removal of the volatiles gave intermediate species **10** (Scheme 2) that was subsequently treated with tpy in refuxing methanol. Addition of aqueous $NH_4PF_6$ to the red–purple methanolic solution resulted in the precipitation of **11** as a wine-red solid.

The presence of the $PPh_2$ groups and three nonequivalent tpy ligands results in a complicated $^1H$ NMR spectrum in the aromatic region. Nevertheless, the resonances of **11** could be assigned by comparison with the data obtained for **9** and [Ru(PCP)(tpy)]Cl.[14] The $^1H$ and $^{31}P\{^1H\}$ NMR spectra reveal a high degree of symmetry for the {(PCP)-Ru(tpy)} unit in **11**, with the geometry in solution probably very close to that of [Ru(PCP)(tpy)]Cl. The aliphatic region of the $^1H$ NMR spectrum shows a singlet resonance for the equivalent benzylic hydrogens, which is indicative of a molecular mirror plane containing the benzylic carbon atoms. These data, together with the peak at $\delta$ = 41.82 ppm in the $^{31}P\{^1H\}$ NMR spectrum for the equivalent phosphorus nuclei, suggest an octahedral geometry of the ruthenium coordination sphere, with both the PCP-pincer and tpy ligands coordinated in a meridional fashion. The ESI-MS spectrum of **11** displays $[M - 3PF_6]^{3+}$ ($m/z$ = 442.75) and $[M - 2PF_6]^{2+}$ ($m/z$ = 736.67) for the heterodinuclear complex with good isotopic matching to the simulated spectrum.

### Redox Behaviour and Electronic Absorption Spectra

The electrochemical and spectroscopic properties of the prepared compounds were studied with the aim to estimate the extent of the $Fe^{II}$–$Ru^{II}$ interactions within **11**, mediated by bridging ligand **7**. The redox behaviour of **9** and **11** was investigated by cyclic and square-wave voltammetries (CV and SWV) in MeCN at room temperature. Pertinent electrochemical data are collected in Table 1. Literature data for $[Fe(tpy)_2](PF_6)_2$[13] and [Ru(PCP)(tpy)]Cl[14] have been included for reference purposes.

Table 1. Electrochemical data for complexes **9** and **11**, and reference compounds.[a]

| Complex | $E_{1/2}$ [V] (oxidation) | $E_{1/2}$ [V] (reduction) |
|---|---|---|
| $[Fe(tpy)_2](PF_6)_2$[b] | 0.74 | –1.64, –1.82 |
| [Ru(PCP)(tpy)]Cl[c] | 0.17 | –1.95 |
| [Fe(tpy){**tpyPC(H)P**}]$(PF_6)_2$ (**9**) | 0.74 | –1.59; –1.69 |
| [Fe(tpy)(**tpyPCP**)Ru(tpy)]$(PF_6)_3$ (**11**) | 0.16 | –1.93 |
| | 0.71 | –1.62; –1.77 |

[a] Measured in MeCN containing $10^{-1}$ M TBAH at 298 K. Electrode potentials are given in Volt versus $Fc/Fc^+$. Scan rate = 100 mV $s^{-1}$. [b] Ref.[13] [c] Ref.[14]

It is well known that redox processes for common $Ru^{II}$–polypyridine complexes are mainly localized either on the metal centres (oxidations) or the ligands (reductions).[23] According to experimental results previously reported,[13a,13b] oxidation of the $Fe^{II}$-tpy complexes can be assigned as metal-localized.[13c] However, DFT calculations performed on the complexes $[Fe(tpy)_2]^{2+}$ and $[Fe(B\text{-}ptpy)_2]^{2+}$ {B-ptpy = 4′-(*tert*-butyl-phenyl)-2,2′:6′,2′′-terpyridine} showed that the highest molecular orbital (HOMO) of these compounds is not solely iron-based.[13c] In fact, the HOMO of the complex $[Fe(tpy)_2]^{2+}$ resides mainly on one of the tpy ligands and partly on the iron. Introduction of a substituted phenyl group at the 4′-position of the terpyridine ligands in $[Fe(B\text{-}ptpy)_2]^{2+}$ significantly changes the HOMO character relative to that of $[Fe(tpy)_2]^{2+}$, which has a stronger metal dπ component, with a contribution from the phenyl π orbitals.[13c] The lowest unoccupied molecular orbital (LUMO) of $[Fe(tpy)_2]^{2+}$ is localized on both tpy ligands, whereas the LUMO of $[Fe(B\text{-}ptpy)_2]^{2+}$ is mainly localized on only one of the B-ptpy ligands and partly on the metal.[13c]

The redox potentials determined for **9** and **11** are close to those reported for other $Fe^{II}$–tpy complexes (Table 1). This indicates that the oxidation and reduction of these species involve frontier orbitals having comparable energy and probably also similar character to those calculated for $[Fe(B\text{-}ptpy)_2]^{2+}$. Thus, the reversible anodic wave at $E_{1/2}$ = 0.74 V ($\Delta E_p$ = 0.60 mV) in the cyclic voltammogram of **9** corresponds to a one-electron oxidation of the $Fe^{II}$–tpy moiety. In the cathodic region, two reversible one-electron waves at –1.59 V ($\Delta E_p$ = 0.58 mV) and –1.69 V ($\Delta E_p$ = 0.54 mV) belong to the sequential reduction of the tpy ligands. By comparison with $[Fe(tpy)_2]^{2+}$,[13b] we assign the first and second reduction steps in **9** to the pincer-substituted and terminal tpy ligands, respectively. The electron-withdrawing character of the phenyl moiety renders the substituted tpy less electron rich, thereby decreasing its reduction potential. The anodic potential region of the heterodimetallic complex **11** exhibits two reversible, one-electron anodic waves due to the $Ru^{II}$ centre at $E_{1/2}$ = 0.16 V ($\Delta E_p$ = 0.56 mV) and the $Fe^{II}$–tpy moiety at $E_{1/2}$ = 0.71 V, respectively. These values are nearly identical with the electrode potentials of the $Fe^{II}$–tpy and $Ru^{II}$-based oxidations of complex **9** and [Ru(PCP)(tpy)Cl], respectively. Apparently, the electronic communication between the metal centres is very limited. In the cathodic region, complex **11** undergoes three ligand-centred reduction processes. The first two cathodic waves lie at –1.62 V and –1.77 V. The initial reduction is fully reversible ($\Delta E_p$ = 0.54 mV). The second cathodic step, however, is characterized by slower electron transfer as indicated by decreased peak currents in both voltammetric (CV and SWV) records. More information about this behaviour has been obtained from the corresponding spectroelectrochemical experiments (see below). According to the reference data in Table 1, these reductions are localized at the terminal and substituted tpy ligands that are coordinated to the iron centre, respectively. The third cathodic step at –1.92 V ($\Delta E_p$ = 0.60 mV), which is fully reversible, can be readily assigned to the reduction of the terminal tpy ligand bound to the ruthenium centre. The reduction

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

potential is only slightly less negative than that of the tpy ligand in [Ru(PCP)(tpy)]Cl (Table 1). These observations are consistent with a negligible electronic communication between the Ru(tpy) and the doubly reduced (tpy)Fe(**tpyPCP**) moieties.

The electronic absorption spectra of **9** and **11** were recorded in MeCN solution at room temperature. Absorption maxima ($\lambda_{max}$) and molar absorption coefficients ($\varepsilon_{max}$) for both compounds are listed in Table 2, together with the reference data for $[Fe(tpy)_2](PF_6)_2$[13] and [Ru(PCP)(tpy)]Cl.[14] The UV/Vis spectra of **9** and **11** show features typical for other $Fe^{II}$– and $Ru^{II}$–tpy compounds,[13,23] in particular intense $\pi\rightarrow\pi^*$ intraligand (IL) transitions in the UV region, 320 and 280 nm for **9**, and at 308, 319 and 275 nm for **11**. In the visible spectral region, complexes **9** and **11** exhibit moderately intense visible absorption bands (Figure 1) that are tentatively attributed to electronic transitions having a mixed $\pi$(tpy)$\rightarrow\pi^*$(tpy) IL and d$\pi$(Ru)$\rightarrow\pi^*$(ph) MLCT character by comparison with literature data on the basis of the TD-DFT calculations performed on the complexes $[Fe(tpy)_2]^{2+}$ and $[Fe(B\text{-}ptpy)_2]^{2+}$ (B-ptpy = 4′-(*n*-butylphenyl)-2,2′:6′,2′′-terpyridine) (vide supra).[13c,23] The small shift in the lowest absorption of **9** and **11** (Figure 1) to a lower energy relative to $[Fe(tpy)_2](PF_6)_2$ is consistent with the electrochemical results. The lowest transition of **9** is only slightly affected by the incorporation of the ruthenium centre into the PCP-pincer unit (Table 2).

Table 2. UV/Vis absorption maxima ($\lambda_{max}$) and molar absorption coefficients ($\varepsilon_{max}$) of complexes **9** and **11**, and reference compounds.[a]

| Compound | $\lambda_{max}$ [nm] ($\varepsilon_{max}$ $10^{-4}$ [$M^{-1}$ $cm^{-1}$]) |
|---|---|
| $[Fe(tpy)_2](PF_6)_2$[b] | 548 (1.4) |
| [Ru(PCP)(tpy)]Cl[c] | 275 (3.7), 305 (3.9), 479 (0.8) |
| $[Fe(tpy)\{(tpyPC(H)P\})](PF_6)_2$ (**9**) | 280 (5.9), 320 (5.6), 563 (1.0) |
| $[Fe(tpy)(tpyPCP)Ru(tpy)](PF_6)_3$ (**11**) | 275 (5.1), 308 (4.1), 319 (4.0), 489 (0.8), 563 (1.0) |

[a] Measured at 298 K in MeCN. [b] Ref.[13] [c] Ref.[14]

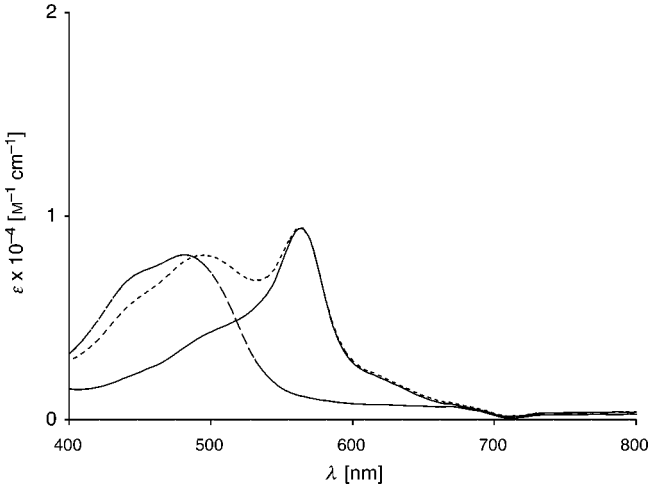


Figure 1. Visible region of the absorption spectra of complexes [Ru(PCP)(tpy)]Cl (– – –), **9** (——), and **11** (-----) recorded in MeCN at 298 K.

For the ruthenium centre in [Ru(PCP)(tpy)]Cl, it is expected that the lowest MLCT excited state involves the coordinated tpy ligands rather than the strongly donating cyclometallated PCP-pincer ligand.[14] The Ru-to-tpy CT band of complex **11** at 489 nm is only slightly shifted to a lower energy relative to the mononuclear [Ru(PCP)(tpy)]Cl (Table 2). This shift, although small, is in agreement with the less positive oxidation and less negative reduction potentials of the Ru(tpy) moiety in the latter complex (Table 1), that is, with a slightly larger HOMO – LUMO gap: $\Delta E$ = 0.03 eV. These results again reveal that the electronic communication between the **tpyPCP**-bridged Ru(tpy) and Fe(tpy) moieties in complex **11** is very limited. A large dihedral angle between the tpy and the PCP-pincer units of the bridging ligand is the most likely reason for the lack of electronic coupling between the two motifs.[24]

However, it cannot be excluded that stabilization of the ruthenium orbitals by $\pi$-back donation to the $PPh_2$ moieties to some extent contributes to a decrease in the mixing between the d$\pi$(Ru)- and the bridging ligand-based orbitals, and thus, the metal-coupling in the studied heterodimetallic complex.

### UV/Vis Spectroelectrochemistry

UV/Vis spectroelectrochemical studies of heterodimetallic complex **11** were performed in MeCN at room temperature within an optically-transparent thin-layer electrochemical (OTTLE)[25] cell. These investigations were mainly aimed at gaining more information about the degree of the $Fe^{II}$–$Ru^{II}$ interaction mediated by the twisted bridging ligand [**tpy(PCP)**]. In addition, the spectral changes recorded during the oxidation and reduction steps help to more accurately appoint their assignment in the preceding section.

Electrochemical oxidation of **11** to $\mathbf{11}^+$ at 0.16 V caused flattening of the band at 500 nm (Figure 2), consistent with

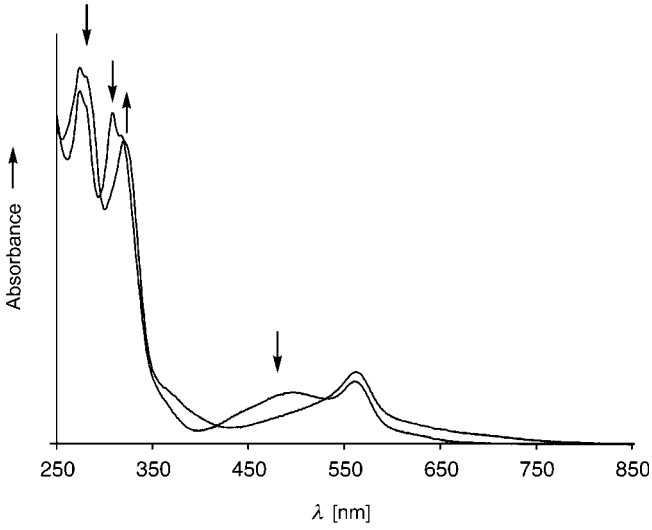

Figure 2. UV/Vis spectra recorded during one-electron oxidation of the $Ru^{II}$ centre in complex **11**. Conditions: OTTLE cell, MeCN/$10^{-1}$ M TBAH, 293 K.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

its assignment to the MLCT transition in the {Ru(tpy)} moiety. Further oxidation of $\mathbf{11}^{+}$ to $\mathbf{11}^{2+}$ at 0.70 V then resulted in disappearance of the composed absorption band at 565 nm (Figure 3), which agrees with the oxidation of the Fe(tpy) moiety. The formation of $\mathbf{11}^{+}$ and $\mathbf{11}^{2+}$ is also accompanied by stepwise disappearance of the π→π* absorption bands at 308 and 319 nm, respectively. Accordingly, they can be attributed to intraligand Ru(tpy) and Fe(tpy) transitions, respectively. This assignment, supported also by the reference data ([Ru(PCP)(tpy)]Cl and complex **9** in Table 2), is also important for the discussion of the cathodic steps (see below). Reduction of $\mathbf{11}^{2+}$ at 0.16 V led to full recovery of the electronic absorption spectrum of **11**.

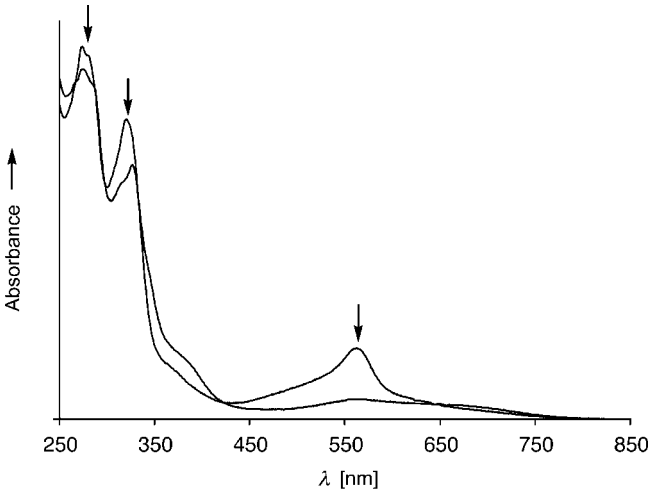

Figure 3. UV/Vis spectra recorded during one-electron oxidation of complex $\mathbf{11}^{+}$, which is probably localized at the Fe(tpy) moiety.[13c] The preceding anodic step is depicted in Figure 2. Conditions: OTTLE cell, MeCN/$10^{-1}$ M TBAH, 293 K.

The spectroscopic changes observed during one-electron reduction of the heterodinuclear complex **11** to $\mathbf{11}^{-}$ were very similar to those observed in the UV/Vis spectra of the singly and doubly reduced complex $[Fe(tpy)_2]^{2+}$.[13b] Reduction of **11** at –1.73 V led to the disappearance of the mixed IL/MLCT band at 565 nm (Figure 4). New low-lying absorption bands due to π*→π*($tpy^{-}$) transitions[13b] arose at 641, 736 and 905 nm (Figure 4). The persisting Ru-to-tpy CT transition of $\mathbf{11}^{-}$ at 498 nm, as well as the unaffected intraligand Ru(tpy) transition at 308 nm also prove that the first reduction step is localized on the terminal tpy ligand coordinated at the iron(II) centre. The slightly decreased intensity of the band at 498 nm in the UV/Vis spectrum of $\mathbf{11}^{-}$ is most probably caused by the disappearance of the underlying shoulder of the composed IL/MLCT Fe(tpy)-band (Figure 1).[13c] Unlike that reported for $[Fe(tpy)_2]^{2+}$,[13b] the addition of the second electron did not result in a shift of the π*→π*($tpy^{-}$) transitions to lower energies. Instead, the formation of $\mathbf{11}^{2-}$ resulted in the increasing intensity of the broad π*→π* absorption between 550–900 nm, with the main absorption maximum at 732 nm (Figure 4).

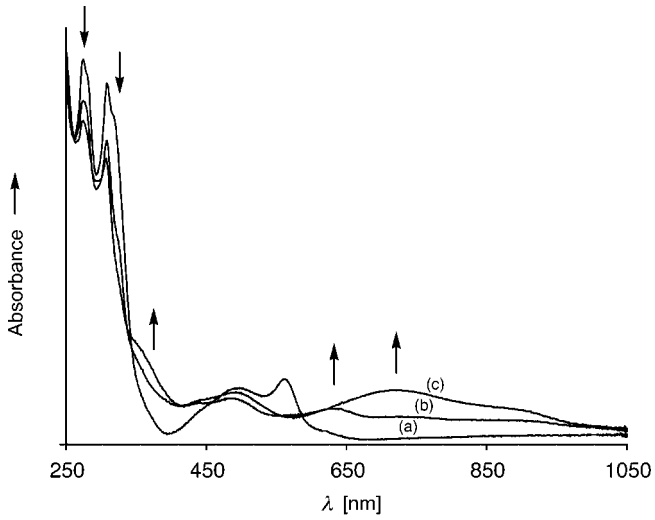

Figure 4. UV/Vis spectral changes accompanying reduction of complex **11** (a) to $\mathbf{11}^{-}$ (b) and $\mathbf{11}^{2-}$ (c) in two tpy(Fe)-localized steps. Conditions: OTTLE cell, MeCN/$10^{-1}$ M TBAH, 293 K.

Importantly, the Ru-to-tpy CT and π→π* Ru(tpy) bands also do not change during the second cathodic step, which indicates that this step is localized on the substituted tpy part of the bridging [**tpyPCP**] ligand. These findings again reveal only a weak communication between the two metal centres through the **tpyPCP** bridge. The qualitatively different changes in the visible spectral region upon the formation of $\mathbf{11}^{2-}$ compared with the doubly reduced reference $[Fe(tpy)_2]$[13b] may reflect some involvement of the phenyl ring of the pincer part of the bridging ligand in the occupied π* system, possibly due to some variation in the central twist angle caused by the second reduction. This observation may explain the slower voltammetric response to the second electron transfer than the first, electrochemically reversible cathodic step of **11**. The third one-electron reduction producing $\mathbf{11}^{3-}$ caused flattening of the Ru-to-tpy CT band. The π→π* Ru(tpy) absorption band at 308 nm

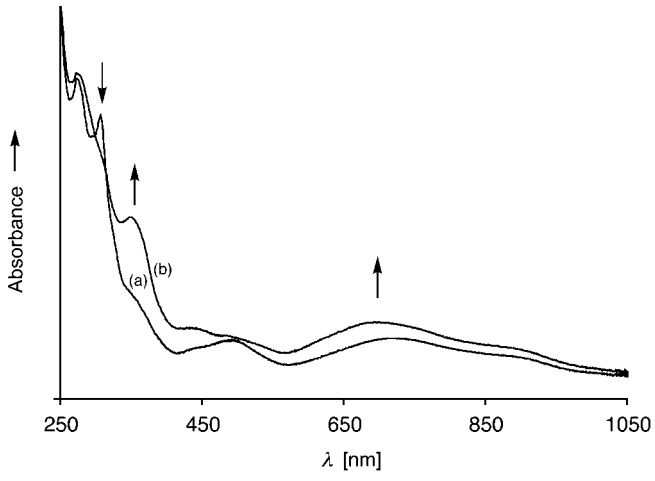

Figure 5. UV/Vis spectrum of $\mathbf{11}^{3-}$ (b) formed from $\mathbf{11}^{2-}$ (a) in the third, tpy(Ru)-localized cathodic step. Conditions: OTTLE cell, MeCN/$10^{-1}$ M TBAH, 293 K.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

also became affected (Figure 5). Importantly, a new $\pi^*\rightarrow\pi^*(tpy^{-})$ absorption appeared around 550 nm.

Similar spectral changes are characteristic for the one-electron reduction of the reference complex [Ru(PCP)(tpy)]Cl (Figure 6), which confirms that the third reduction step of complex **11** involves occupation of the lowest $\pi^*$ orbital that is essentially localized on the Ru-bound terminal terpyridine ligand, tpy(Ru).

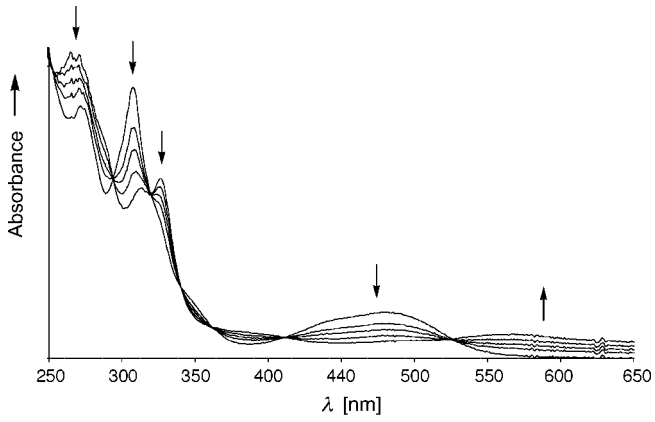

Figure 6. UV/Vis spectral changes accompanying the tpy-localized one-electron reduction of the reference complex [Ru(PCP)(tpy)]Cl. Conditions: OTTLE cell, MeCN/$10^{-1}$ M TBAH, 293 K.

Reoxidation of all three one-electron-reduced species, $\mathbf{11}^{n-}$ ($n$ = 1, 2, 3), fully regenerated the UV/Vis spectrum of parent **11**. It is clear that the reduction steps are largely tpy-localized. The stability of the Ru–C σ-bond during the second and third cathodic steps is remarkable and is a consequence of this localization. In fact, significant delocalization of the added electron density over the PCP-pincer moiety would most likely break the Ru–C σ-bond.[6]

## Conclusions

In this work, the synthesis of novel building block 4′-{$C_6H_3(CH_2Br)_2$-3,5}-2,2′:6′,2′′-terpyridine is presented, which can be used as a precursor for bridging ligands containing an N,N,N-domain and an E,C,E-coordination (E = N, P, S, O) motive. Heteroditopic tpy-pincer ligands are interesting from different viewpoints. In particular, electronic and steric properties of the pincer moiety, in which several transition metals can be incorporated by applying various metallation procedures, can easily be tuned.

Incorporation of diphenylphosphanyl groups gave the 4′-{$C_6H_3(CH_2PPh_2)_2$-3,5}-2,2′:6′,2′′-terpyridine [**tpyPC(H)P**] ligand. The asymmetric complex [Fe(tpy){**tpyPC(H)P**}]-$(PF_6)_2$, prepared by reaction of [**tpyPC(H)P**] with 1 equiv. of [Fe(tpy)$Cl_3$], was used for the construction of the heterodimetallic complex [Fe(tpy)(**tpyPCP**)Ru(tpy)]$(PF_6)_3$, which follows the "complex as ligand" approach.

For both complexes, the oxidation and reduction processes have been assigned by comparison with literature data reported for related $Fe^{II}$–tpy compounds and with [Ru(PCP)(tpy)]Cl, which was extensively studied in this work. The redox potentials do not significantly change on passing from the mononuclear $Fe^{II}$ to the heterodimetallic $Fe^{II}$–$Ru^{II}$ complex. UV/Vis spectroelectrochemical studies of the heterodimetallic complex confirm the voltammetric results. The spectral changes allow the stepwise $Ru^{II}$– and $Fe^{II}$–tpy oxidations to be distinguished. The first and second reduction steps are localized at the terminal and pincer-substituted tpy ligands coordinated at the iron centre, respectively. The third reduction resides at the tpy ligand coordinated at the ruthenium centre.

Apparently, despite the relatively moderate internuclear separation, only a very weak electronic interaction exists between the {Fe(tpy)$_2$} and {(PCP)Ru(tpy)} fragments. This can be rationalized in terms of the very limited ability of the nonplanar (twisted) [**tpyPCP**] bridging ligand to mediate electronic communication between the metal centres. However, stabilization of the dπ(Ru) orbitals as a result of the π-accepting properties of the $PPh_2$ moieties may also cause a decrease in the Fe–Ru coupling by limiting the overlap between the ruthenium orbitals and the bridging ligand orbitals. Connection of the {Fe(tpy)$_2$} and {(PCP)Ru(tpy)} fragments through a bridge capable of achieving a more effective aromatic conjugation would be highly desirable.[26]

## Experimental Section

**General:** All experiments were carried out under a dry nitrogen atmosphere by using standard Schlenk techniques. Benzene, toluene, pentane, hexane and diethyl ether ($Et_2O$) were distilled from sodium/benzophenone. Dichloromethane and methanol were dried with $CaH_2$ and magnesium, respectively. All solvents were freshly distilled under a nitrogen atmosphere prior to use. 1D NMR spectra were recorded with a Varian Inova 300 MHz spectrometer. Chemical shifts are given in ppm relative to the residual solvent signal ($^1$H and $^{13}$C NMR spectra) or 85% $H_3PO_4$ external reference ($^{31}P\{^1H\}$ NMR spectra). EtOAc and all reagents were purchased from Acros or Aldrich and used as received. Compounds **2**,[15] 4′-trifluoromethylsulfonato-2,2′:6′,2′′-terpyridine,[17] **8**[21] and [Fe(tpy)$Cl_3$][22] were synthesized according to literature procedures. Elemental analyses were performed by Dornis und Kolbe, Mikroanalytisches Laboratorium, Mülheim a. d. Ruhr, Germany. Electron spray ionization (ESI) mass spectra were recorded with a Micromass LC-TOF mass spectrometer by the Department of Biomolecular Mass Spectrometry, Utrecht University.

**Electrochemical Measurements:** Cyclic and square-wave voltammetric scans were performed with a gas-tight single compartment cell under a dry nitrogen atmosphere. The cell was equipped with a Pt microdisk working electrode (apparent surface area of 0.42 mm$^2$), Pt wire auxiliary electrode and a Ag wire pseudoreference electrode. The working electrode was carefully polished with a 0.25 μm-grain diamond paste between scans. The potential control was achieved with a PAR Model 283 potentiostat. All redox potentials are reported against the ferrocene–ferrocenium ($Fc/Fc^+$) redox couple used as an internal standard[27] ($E_{1/2}$ = +0.63 V versus NHE[28]). All electrochemical samples were $5\times10^{-4}$ M in the studies complexes and $10^{-1}$ M in $Bu_4NPF_6$ used as the supporting electrolyte.

**Electronic Spectroscopic Measurements:** UV/Vis absorption spectra were obtained with a Varian Cary 1 spectrophotometer by using matched 1 cm cells and operating with a 0.5 nm spectral resolution. Peak positions are given within 0.5 nm accuracy.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**UV/Vis Spectroelectrochemical Measurements:** All the experiments were performed with an optically transparent thin-layer electrochemical (OTTLE)[25] cell, equipped with a Pt minigrid working electrode and quartz optical windows. The controlled-potential electrolyses were carried out with a PA4 potentiostat (EKOM, Polná, Czech Republic). All electrochemical samples were $5 \times 10^{-4}$ M in the studied complex and $10^{-1}$ M in $Bu_4NPF_6$. UV/Vis spectra were recorded with a Hewlett Packard 8453 diode-array spectrophotometer.

**[$C_6H_3(CH_2OMe)_2$-3,5]-$SnMe_3$ (3):** A solution of *t*BuLi (13.0 mL, 1.5 M in pentane, 19.52 mmol) was added dropwise to a solution of **2** (3.00 g, 10.27 mmol) in $Et_2O$ (75 mL) at –100 °C with vigorous stirring. After 0.5 h, a solution of $Me_3SnCl$ (3.07 g, 15.41 mmol) in $Et_2O$ (35 mL) was slowly added. The resulting pale yellow coloured suspension was warmed to room temperature and stirring was continued for another 15 h. Subsequently, water was added, and the obtained mixture was treated with a NaOH solution (0.1 M, $2 \times 50$ mL). The $Et_2O$ layer was separated, and the water layer was washed with $Et_2O$ ($2 \times 50$ mL). The organic layers were combined, washed with brine, dried with $MgSO_4$, filtered and concentrated to afford **3** as a colourless oil. Yield: 2.95 g, 85%. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.37 (s, 2 H, Ar), 7.26 (s, $^2J_{Sn,H}$ = 21.7 Hz, 1 H, Ar), 4.43 (s, 4 H, $OCH_2$), 3.34 (s, 6 H, $OCH_3$), 0.29 [s, $^2J_{Sn,H}$ = 27.0 Hz, 9 H, $Sn(CH_3)_3$] ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 142.9 ($^1J_{Sn,C}$ = 228.3 and 451 Hz), 137.9 ($^2J_{Sn,C}$ = 18.3 Hz), 134.7 ($^2J_{Sn,C}$ = 22.3 Hz, ArH), 127.5, 75.0 ($OCH_3$), 58.4 [$CH_2$, Sn-$(CH_3)_3$], –9.3 [$^1J_{Sn,C}$ = 171.5 Hz, $Sn(CH_3)_3$] ppm. ESI-MS: *m*/*z* 331.05 $[M - H]^+$. $C_{13}H_{22}O_2Sn$ (329.02): calcd. C 47.46, H 6.74; found C 47.55, H 6.62.

**4′-{$C_6H_3(CH_2OMe)_2$-3,5}-2,2′:6′,2″-terpyridine (4):** 4′-Trifluoromethylsulfonato-2,2′:6′,2″-terpyridine (2.66 g, 6.99 mmol), **3** (2.315 g, 6.99 mmol), $[PdCl_2(PPh_3)_2]$ (0.41 g, 0.58 mmol) and dried LiCl (1.72 g, 40.6 mmol) were heated at reflux in dry toluene (100 mL) for 20 h in a 100-mL round-bottomed flask under a nitrogen atmosphere. Subsequently, the solvent was removed in vacuo, and the residue was redissolved in $CH_2Cl_2$. The $CH_2Cl_2$ solution was washed with water, filtered through Celite and dried with $MgSO_4$. The crude product was obtained as a light yellow oil after removal of the solvent as purified by silica gel column chromatography (EtOAc/MeOH 8:1). The fractions containing **4** were collected, concentrated and cooled to –30 °C. Product **4** precipitated as a white crystalline solid and was collected and dried in vacuo. Yield: 1.02, g, 40%. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.75 [s, 2 H, tpy(3′, 5′)], 8.73 [d, $J_{H,H}$ = 4.3 Hz, 2 H, tpyH(6, 6″)], 8.67 [d, $J_{H,H}$ = 9.0 Hz, 2 H, tpyH(3, 3″)], 7.88 [td, $J_{H,H}$ = 7.89, 1.61 Hz, 2 H, tpyH(4, 4″)], 7.80 (s, 2 H, ArH), 7.43 (s, 1 H, Ar), 7.35 [m, 2 H, tpyH(5, 5″)], 4.57 (s, 4 H, $CH_2$), 3.44 (s, 12 H, $OCH_3$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 156.4, 156.0, 150.4, 149.2, 139.6, 139.0, 137.3, 127.8, 126.2, 124.0, 121.7, 119.3, 74.6 ($OCH_3$), 58.5 ($CH_2$) ppm. $C_{25}H_{23}N_3O_2$ (397.47): calcd. C 75.54, H 5.83, N 10.57; found C 75.63, H 5.88, N 10.62.

**4′-{$C_6H_3(CH_2Br)_2$-3,5}-2,2′:6′,2″-tpy (5)**: Compound **4** (0.25 g, 0.7 mmol) was dissolved in dry $CH_2Cl_2$ (20 mL) under a nitrogen atmosphere. The temperature of the solution was lowered with an ice bath and excess HBr·AcOH (110 mL, 33%) was slowly added. The mixture was then stirred at room temperature for 15 h and then cooled to 0 °C. Subsequently, aqueous 6 M $K_2CO_3$ was slowly added until the solution reached a pH of 8. The organic layer was then collected, washed with water and brine, dried with $MgSO_4$, filtered and concentrated to ca. 5 mL. Addition of hexane caused the precipitation of **5** as a white crystalline material. The crystals were collected by filtration, washed with cold hexane and dried in vacuo. Yield: 0.31 g, 64%. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.75 [d, $J_{H,H}$ = 4.8 Hz, 2 H, tpyH(6, 6″)], 8.73 [s, 2 H, tpy(3′, 5′)], 8.69 [d, $J_{H,H}$ = 8.1 Hz, 2 H, tpy(3, 3″)], 7.90 [td, $J_{H,H}$ = 7.80, 1.60 Hz, 2 H, tpy(4, 4″)], 7.85 (s, 2 H, ArH), 7.53 (s, 1 H, Ar), 7.38 [t, $J_{HH}$ = 6.13 Hz, 2 H, tpy(5, 5″)], 4.58 (s, 4 H, $CH_2$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 156.3, 156.1, 149.3, 149.2, 139.9, 139.5, 137.2, 130.5, 128.1, 124.2, 121.7, 118.9, 32.7 ($CH_2$) ppm. Because of its toxicity, elemental and ESI analyses were not carried out. *Caution: Substituted benzyl bromides can be powerful lachrymators and should be used with adequate ventilation and precaution against skin contact or ingestion.*

**4′-{$C_6H_3\{CH_2P(BH_3)Ph_2\}_2$-3,5}-2,2′:6′,2″-terpyridine ([tpyPC(H)P]·$2BH_3$, 6):** *n*BuLi (0.8 mL, 1.34 mmol) was added to $HPPh_2{\cdot}BH_3$ (0.27 g, 1.34 mmol) in dry THF (30 mL) at –78 °C. The temperature was allowed to rise to room temperature and stirring was continued overnight. A solution of **5** (0.32 g, 0.67 mmol) in dry THF (20 mL) was then added at –78 °C. The mixture was warmed to room temperature and stirred for ca. 20 h. All volatiles were then removed in vacuo, and the obtained residue was dissolved in $CH_2Cl_2$. The organic layer was washed with water and brine and dried with $MgSO_4$. Product **6** was obtained after evaporation of $CH_2Cl_2$ as a white solid that was washed with hot EtOH and hexane and dried in vacuo. Yield: 0.63 g, 64%. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.77 [d, $J_{H,H}$ = 4.0 Hz, 2 H, tpyH(6, 6″)], 8.60 [d, $J_{H,H}$ = 7.8 Hz, 2 H, tpyH(3, 3″)], 8.19 [s, 2 H, PyrH(3′, 5′)], 7.86 [td, $J_{H,H}$ = 7.8, 1.6 Hz, 2 H, tpyH(4, 4″)], 7.63 (m, 8 H, *meta*-H PAr), 7.47 (m, 12 H, *ortho*- and *para*-H PAr), 7.35 [t, $J_{H,H}$ = 6.13 Hz, 2 H, tpyH(5, 5″)], 7.15 (s, 2 H, ArH), 6.95 (s, 1 H, Ar), 3.58 (d, $^2J_{H,P}$ = 11.0 Hz, 4 H, $CH_2$), 0.90 (br. m, 6 H, $BH_3$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 156.3, 155.9, 149.8, 149.0, 138.3, 137.2, 133.3, 132.9 (d, $^1J_{C,P}$ = 8.5 Hz, $C_{quat.}$, PAr), 131.7, 129.0 (d, $^2J_{C,P}$ = 9.2 Hz, PAr), 128.2, 128.0, 124.0, 121.7, 119.2, 34.2 (d, $^1J_{C,P}$ = 31.7 Hz, $CH_2$) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = (121.4 MHz, $CDCl_3$): $\delta$ = 19.3 (br. m) ppm. $C_{35}H_{33}B_2N_3P$ (548.25): calcd. C 76.97, H 5.91, N 5.73, B 2.95, P 8.45; found C 76.78, H 6.10, N 5.59, B 3.01, P 8.50.

**4′-{$C_6H_3(CH_2PPh_2)_2$-3,5}-2,2′:6′,2″-terpyridine ([tpyPC(H)P], 7):** Freshly distilled $Et_2NH$ (5 mL) was added to a solution of **6** in $CH_2Cl_2$. The mixture was stirred at reflux for 4 h. All the volatiles were removed in vacuo, and the obtained white solid was redissolved in dry $CH_2Cl_2$ (10 mL). The organic layer was collected, washed with degassed water and brine and dried with $MgSO_4$. After evaporation of the $CH_2Cl_2$ in vacuo, product **7** was obtained as an extremely air- and moisture-sensitive white sticky solid. This product was used without further purification. Yield: 0.54 g, 88%. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.76 [d, $J_{H,H}$ = 3.0 Hz, 2 H, tpyH(6, 6″)], 8.75 [d, $J_{H,H}$ = 3.0 Hz, 2 H, tpyH(3, 3″)], 8.38 [s, 2 H, tpyH(3′, 5′)], 7.86 [td, $J_{H,H}$ = 7.5, 1.6 Hz, 2 H, tpyH(4, 4″)], 7.37 [m, 2 H, tpyH(5, 5″) and PAr], 7.18 (s, 2 H, ArH), 6.93 (s, 1 H, Ar), 3.39 (s, 4 H, $CH_2$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 156.6, 155.9, 150.6, 149.2, 138.3, 138.2, 136.9, 133.2 (d, $^1J_{C,P}$ = 18.0 Hz, $C_{quat.}$, PAr), 131.2, 129.0, 128.6 (d, $^2J_{C,P}$ = 6.0 Hz, PAr), 126.4, 123.9, 121.6, 119.2, 36.2 (d, $^1J_{C,P}$ = 16.0 Hz, $CH_2$) ppm. $^{31}$P{$^1$H} NMR (121.4 MHz, $CDCl_3$): $\delta$ = –8.5 (s) ppm.

**[Fe(tpy){tpyPC(H)P}]$(PF_6)_2$ (9):** Ligand **7** (0.17 g, 0.25 mmol) and $[Fe(tpy)Cl_3]$ (0.095 g, 0.25 mmol) were heated at reflux in dry MeOH for 4 h. The yellow mixture rapidly turned purple upon heating. The solution was then cooled down to room temperature, filtered and excess $NH_4PF_6$ in degassed water was added. The formed deep purple precipitate was filtered off, washed with degassed water and dried in vacuo. Yield: 0.10 g, 40%. Removal of a small amount of a tpy-containing impurity by chromatography

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

could not be carried out because of the high sensitivity to air and moisture of the $PPh_2$ moieties. Complex **9** was used in the next reaction without further purification. $^1H$ NMR (300 MHz, $CD_3CN$): $\delta$ = 8.96 [d, $J_{H,H}$ = 7.8 Hz, 2 H, tpyA(3′, 5′)], 8.70 [t, $J_{H,H}$ = 8.1 Hz, 1 H, tpyA(4′)], 8.51 [d, $J_{H,H}$ = 8.4 Hz, 4 H, tpyA(3, 3′′) + tpyA(3, 3′′)], 7.98 [s, 2 H, tpyB(3′, 5′)], 7.91–7.86 [m, 4 H, tpyA(4, 4′′) + tpyA(4, 4′′)], 7.71 [d, $J_{HH}$ = 7.8 Hz, 2 H, tpyA(6, 6′′)], 7.61 [d, $J_{H,H}$ = 8.0 Hz, 2 H, tpyB(6, 6′′)], 7.43–7.39 (m, 12 H, *para*-H + *meta*-H PAr), 7.34–7.28 [m, 6 H, Ar + tpyA(5, 5′′) + tpyA(5, 5′′)], 7.09 (m, 9 H, Ar + *ortho*-H PAr), 2.7 (s, 4 H, $CH_2$) ppm. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CD_3CN$): $\delta$ = –4.9 (s, 2 P), –143.28 (sept, $^1J_{P,F}$ = 705 Hz, $[PF_6]^-$) ppm. ESI-MS: *m/z* = 497.20 $[M - 2\ PF_6]^{2+}$.

**$[Fe(tpy)(tpyPCP)Ru(tpy)](PF_6)_3$ (11):** Compounds **8** (0.10 g, 0.08 mmol) and **9** (0.05 g, 0.08 mmol) were dissolved in THF/MeCN (2:1, 30 mL). The solution was stirred at reflux for 10 h. The solvent was evaporated in vacuo. The deep purple residue was washed several times with hexane until no more free bis(amino)-arene (NCN) ligand could be detected by $^1H$ NMR spectroscopy, and then dried in vacuo. The obtained deep purple solid (**10**), characterized only by NMR spectroscopy, was added to 2,2′:6′,2′′-terpyridine (0.02 g, 0.08 mmol) dissolved in dry MeOH (25 mL). The mixture was heated at reflux for 2 d. Subsequently, the methanolic solution was cooled to room temperature, filtered, and concentrated until a small residual amount remained. Addition of aqueous $NH_4PF_6$ resulted in the precipitation of **11** as an air-stable red–purple solid that was collected by filtration, washed with water, hexane and dried in vacuo. The crude product was purified by column chromatography on silica gel (MeCN/water/saturated $NaNO_3$ solution 70:25:5). The major fraction was dried to afford **11** as a red-purple solid. Yield: 0.07 g, 52%. $^1H$ NMR (300 MHz, $CD_3COCD_3$): $\delta$ = 9.07 [d, $J_{H,H}$ = 8.1 Hz, 2 H, tpyC(3′, 5′)], 8.86 [d, $J_{H,H}$ = 8.1 Hz, 2 H, tpyA(3′, 5′)], 8.82–8.70 [m, 3 H, tpyA(4′) + tpyC(3, 3′′)], 8.58 [t, $J_{H,H}$ = 8.5 Hz, 1 H, tpyC(4′)], 8.48 [d, $J_{H,H}$ = 8.1 Hz, 4 H, tpyA(3, 3′′) + tpyB(3, 3′′)], 8.09 [s, 2 H, tpyB(3′, 5′)], 8.06–8.00 [m, 8 H, Ar + tpyA(4, 4′′) + tpyB(4, 4′′) + tpyC(4, 4′′)], 7.69 [d, $J_{H,H}$ = 5.4 Hz, 2 H, tpyC(6, 6′′)], 7.42 [d, $J_{H,H}$ = 5.1 Hz, 4 H, tpyA(6, 6′′) + tpyA(6, 6′′)], 7.64–7.53 [m, 6 H, tpyA(5, 5′′) + tpyB(5, 5′′) + tpyC(5, 5′′)], 7.35–6.77 (m, 20 H, PAr) ppm. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CD_3CN$): $\delta$ = 41.82 (s, 2 P), –142.92 (sept, $^1J_{P,F}$ = 705 Hz, $[PF_6]^-$) ppm. ESI-MS: *m/z* = 442.75 $[M - 3\ PF_6]^{3+}$, 736.67 $[M - 2\ PF_6]^{2+}$.

# Catechol-Bearing Dipyrazinylpyridine Complexes of Ruthenium(II)

**Fahad A. Al-mutlaq,[a] Pierre G. Potvin,*[a] Athanassios I. Philippopoulos,[b] and Polycarpos Falaras[b]**

**Keywords:** Ruthenium / Tridentate ligands / Photosensitizers / Electron transfer / Energy conversion

The new tridentate ligand 4-(3,4-methylenedioxyphenyl)-2,6-dipyrazinylpyridine (**2**) was prepared in good yield in a one-pot reaction. The $Ru^{II}$ complexes $[Ru(\mathbf{2})_2](PF_6)_2$ and $[Ru(\mathbf{1})(\mathbf{2})](PF_6)_2$ [**1** is 2,6-dipyrazinyl-4-(4-tolyl)pyridine] were prepared in good yields and tested as photosensitizers against $[Ru(\mathbf{1})_2](PF_6)_2$ and $[Ru(ttpy)_2](PF_6)_2$ [ttpy is 4′-(4-tolyl)-2,2′:6′,2′′-terpyridine]. The photosensitization ability follows the order $[Ru(\mathbf{1})_2](PF_6)_2 > [Ru(\mathbf{1})(\mathbf{2})](PF_6)_2 > [Ru(\mathbf{2})_2](PF_6)_2 >> [Ru(ttpy)_2](PF_6)_2$, which is explainable in terms of mechanism and driving force. Hydrolysis of the methylene acetal function affords the catechol-appended complexes $[Ru(\mathbf{3})_2](PF_6)_2$ and $[Ru(\mathbf{1})(\mathbf{3})](PF_6)_2$ [**3** is 4-(3,4-dihydroxyphenyl)-2,6-dipyrazinylpyridine] in excellent yields. These insoluble, paramagnetic precipitates when tested as photosensitizers in homogeneous solution and in one case adsorbed on titania are able to generate photocurrents in a photovoltaic cell, albeit more weakly compared to the so-called N719 dye.

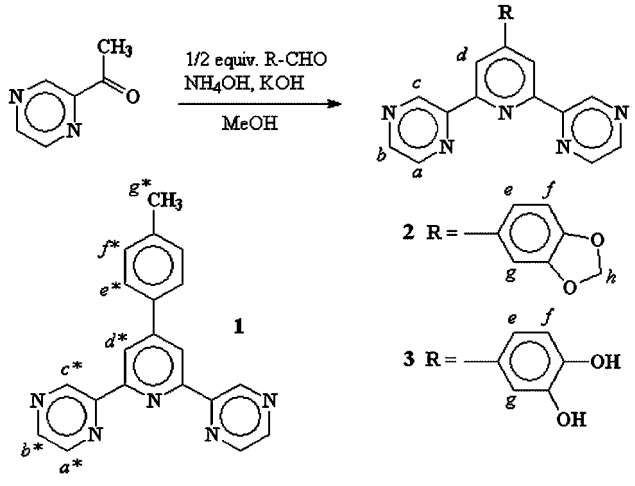
## Introduction

$Ru^{II}$ complexes of polypyridine-type ligands continue to enjoy great interest as photosensitizers,[1,2] owing to strong absorption of visible light, favourable redox potentials, appreciable excited state lifetimes and the ability of the excited states to transfer an electron to acceptor molecules or electrodes.[3–5] We have a long-standing interest in discovering non-stereogenic ligands that promote these properties. The present work arises from a desire to incorporate three promising phenomena into the design of a new ligand.

Firstly, we devised sometime ago a new tridentate ligand family with promising features. The first member of the dipyrazinylpyridine (dpp) family of ligands, the 4-*p*-tolyl derivative **1** (Scheme 1), was prepared in a remarkable one-step reaction of commercial materials, in excellent yield and without purification.[6] We have since used this procedure to prepare other dpp examples,[7–9] and extended it to terpyridine synthesis, although those reactions were slower.[9,10] Besides their easier syntheses, the homoleptic $Ru^{II}$ complex $[Ru(\mathbf{1})_2]^{2+}$ revealed an additional advantage of dpp ligands over other tridentates: a longer excited-state lifetime, $\tau$ (18 ns at room temperature),[6] compared to that of the analogous terpyridine complex $[Ru(ttpy)_2]^{2+}$ [0.95 ns,[11] ttpy is 4′-(4-tolyl)-2,2′:6′,2′′-terpyridine], a result which can be attributed to the electron-withdrawing effect of the additional nitrogen atoms in stabilizing the ligand π* orbital relative to metal-centred orbitals. At the same time, its absorption (498 nm) and emission (667 nm) were only of slightly lower energy (cf. 490 nm[12] and 640 nm,[11] respectively, for the ttpy analogue), and the shift is the direction favouring the more efficient harvesting of visible light. The $Ru^{III/II}$ oxidation potential was comparatively very high (1.62 V vs. SCE; cf. 1.25 V[13] for the ttpy analogue), again because of the additional nitrogens. This enabled the operation of an electrostatically advantaged reductive quenching mechanism in photosensitization experiments using other dpp complexes.[9]



Scheme 1.

Secondly, we recently demonstrated the significant benefit conferred by peripheral carboxylate groups in establishing a binding site for a cationic electron acceptor during oxidative quenching in organic solvents.[14] We wished to

gauge the extent of this benefit during reductive quenching with dpp complexes, and to explore the utility of peripheral catecholate groups in supramolecularly binding an electron acceptor.

Thirdly, we knew that catechols form relatively stable complexes with $Ti^{IV}$.[15–17] As mesoporous $TiO_2$ is the anchoring substrate for carboxylated $Ru^{II}$ sensitizers on nanocrystalline solar cells,[3] we reasoned that catechol groups would enable stronger, more covalent anchoring to the surface. Indeed, catechol is known to chemisorb to particulate $TiO_2$[18,19] and Rice et al. have indeed found stronger and faster grafting with catechol-bearing terpyridine complexes on $TiO_2$-coated electrodes.[20]

Therefore, this paper reports the preparation of a ligand with a dpp core and a peripheral catechol group, the synthesis of its $Ru^{II}$ complexes in both homo- and heteroleptic forms, and an assessment of the photosensitization ability of its $Ru^{II}$ complexes both in solution and while attached to an electrode surface in a photovoltaic cell.

## Results

### Synthesis

As with the terpyridine analogues,[21] the catechol function was introduced in protected form and deprotected after binding to the metal, this time using the methylene acetal for a less harsh deprotection. As shown in Scheme 1, methylenedioxy ligand **2** was prepared from commercial materials (piperonal, acetylpyrazine and ammonia) in a remarkable one-pot reaction from which it precipitated in good yield (75%, after recrystallization). This compares very favourably with the two-step preparation of the (dimethoxyphenyl)terpyridine analogue in 21–36% overall yield.[21]

The complex $[Ru(\mathbf{2})_2]^{2+}$ was prepared by three procedures with varying results. The direct reaction of $RuCl_3$ with two equiv. of **2** in hot ethylene glycol, followed by isolation of the product by precipitation as the $PF_6^-$ salt using aqueous $NH_4PF_6$, proceeded in 55–65% yields, but the product contained unacceptable amounts of unidentified impurities. If, instead, the intermediate $Ru(\mathbf{2})Cl_3$ was first prepared in $CH_3CN$ from one equiv. of **2** and $RuCl_3$, then treated with 3 equiv. of $AgBF_4$ to precipitate AgCl and activate the $Ru^{III}$ centre for substitution with a second equiv. of **2** in ethylene glycol, the final $[Ru(\mathbf{2})_2](PF_6)_2$ product was isolated in better yields (65–75%) with less impurity, even though this three-step procedure was more tedious. In a shortened variant, $RuCl_3$ was activated in $CH_3CN$ with 3 equiv. of $AgBF_4$ before reaction with two equiv. of **2** in ethylene glycol, followed by treatment with $NH_4PF_6$, for a final yield of 75–85% of the purest product yet.

The mixed-ligand species $[Ru(\mathbf{1})(\mathbf{2})]^{2+}$ was also prepared with and without $Ag^+$ activation.

The $Ru(\mathbf{2})Cl_3$ intermediate was prepared as before, then treated with **1** in ethylene glycol to afford, after the usual work-up, $[Ru(\mathbf{1})(\mathbf{2})](PF_6)_2$ in 45–50% yields, but this product of direct reaction was even less pure than in the homoleptic case. Treatment of $Ru(\mathbf{2})Cl_3$ with 3 equiv. of $AgBF_4$ in ethylene glycol, followed by reaction with one equiv. of **1** in the same solvent and precipitation of the $PF_6^-$ salt, produced $[Ru(\mathbf{1})(\mathbf{2})](PF_6)_2$ in purer form and in better yields (65–70%).

Deprotection of the acetal function proved to be incomplete and slow with plain aqueous acid. Heating with HBr in HOAc afforded complete deprotection in 3–4 d, and proceeded in very high yields (90–95% for $[Ru(\mathbf{3})_2](PF_6)_2$ and 85–90% for $[Ru(\mathbf{1})(\mathbf{3})](PF_6)_2$, after anion exchange with $NH_4PF_6$).

Despite repeated crystal growth attempts with the four new complexes, only microcrystals or powders were obtained. Upon prolonged standing in $CH_3CN$ solutions, the deprotected salts tended to lose the elements of $HPF_6$ and form amorphous precipitates that resisted redissolution with heat, but these were easily rescued by redissolving with a small excess of 60% aqueous $HPF_6$, then diluting with water to re-precipitate the original salts.

### Proofs of Identity

$^1H$ NMR spectroscopy was able to verify the identities of the new complexes. While three aromatic signals in free **2** were fortuitously overlapped, they were well separated in the complexes of **2** and **3**. COSY spectra were used in the assignments but, in the heteroleptic cases, many of the signals from one ligand were unfortunately overlapped with the corresponding signals from the other ligand, making individual assignments impossible.

The coordinating nitrogen atoms of heteroaromatic bi- and tridentate ligands are actually in *anti* conformations to minimize dipole–dipole repulsions.[22] Complexation causes a change to *syn* binding conformations and, commonly, the signals adjoining the coordinated nitrogen atoms on the end rings are shifted upfield owing to magnetic anisotropy from the ring current of the perpendicular ligand, while other signals are shifted downfield due to the electron-withdrawing effect of the metal ion. In the present case, the fine doublets due to 5-H and 6-H of the pyrazine rings (which often appeared as broad singlets) were shifted upfield (by 0.8 and 0.3 ppm, respectively) upon complexation, and remained so upon deprotection. However, deprotection predictably caused the disappearance of the distinctive methylene singlets at 6.1–6.2 ppm.

Mass spectrometry confirmed the complex formulations. ES-MS of $[Ru(\mathbf{2})_2]^{2+}$ showed two high-mass clusters, one at *m*/*z* 406 corresponding to the dicationic molecular ion, and a smaller one at *m*/*z* 400 due to partial hydrolysis of the protecting group. With $[Ru(\mathbf{1})(\mathbf{2})]^{2+}$, there was a similar pair of clusters at *m*/*z* 391 and 385. LDI-TOF was used with the deprotected complexes, and both $[Ru(\mathbf{3})_2]^{2+}$ and $[Ru(\mathbf{1})(\mathbf{3})]^{2+}$ showed monocationic molecular ions at *m*/*z* 788 and 769, respectively. While this was the base peak in the former case, a fragment ion dominated the spectrum of the latter (at M-17). In all cases, the mass distributions within each cluster of peaks owing to isotopic diversity was well matched by computed spectra.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Finally, the formulae of all of the new materials were also confirmed by elemental analyses.

### UV/Vis Spectroscopy

The UV/Vis spectrum of free **2** showed only n→π* and π→π* transitions in the 200–300 nm range, as is usual with polypyridine-type ligands, but with extended tailing into the visible region. In addition to this same sort of transition, all four complexes showed a similar metal-to-ligand charge transfer (MLCT) band at $\lambda_{max}$ 500–502 nm (Table 1), as well as a much smaller feature near 405 nm. The MLCT bands were typical of complexes of this type and virtually the same as that of the analogous $[Ru(\mathbf{1})_2]^{2+}$.[6] The influence of the oxygen functionalities is apparently weak, shifting the peak positions only slightly toward the red, in agreement with their π-donating character. The only significant difference between them was that the catechol forms were more strongly absorbing than were the protected forms, with a molar extinction coefficient ($\varepsilon$) value 37% larger with one catechol unit, and 53% larger with two. The terpyridine analogues[21] behaved differently in that deprotection to the catechol forms caused 8 nm red shifts in $\lambda_{max}$ and much larger increases in $\varepsilon$ (by 133% and 57% for homo- and heteroleptic varieties, respectively) than with our complexes.

We also explored the effect of deprotonation of the catechol units on the MLCT transitions, using sample solutions of the two deprotected complexes prepared at various [$Et_3N$]:[Ru] ratios in $CH_3CN$. The effect was mild: the red color of the pure complexes changed to a light brown, as the MLCT $\lambda_{max}$ drifted slightly with $[Ru(\mathbf{3})_2]^{2+}$ (from 502 to 506 nm with 0–6 equiv. of $Et_3N$) but held steady at 500 nm with $[Ru(\mathbf{1})(\mathbf{3})]^{2+}$ (with 0–4 equiv. of base), while the band tails lengthened toward the red and the $\varepsilon$ values at $\lambda_{max}$ decreased gently in lock-step with increasing [$Et_3N$]:[Ru].

### Cyclic Voltammetry

Cyclic voltammograms were obtained for all four complexes in degassed $CH_3CN$ and DMF (Figure 1 is representative). Oxidation was only detected in $CH_3CN$ but was irreversible in all cases. Limited-range scans did not improve the reversibility. Some of the features in the negative range appeared only after first scanning positive, so were probably reductions of oxidation products having undergone subsequent chemical transformations. Therefore DPV scans were employed to help determine $E_{1/2}$ values. Except for more positive potentials owing to the electron-poorer pyrazine rings, the results (Table 1) mimicked the behaviour

Table 1. Spectroscopic, electrochemical and photochemical data in $CH_3CN$ solutions.

of the terpyridine analogues,[21] in that metal oxidation was followed by a more positive ligand oxidation when in protected form, and a less positive one after deprotection to catechol forms. Both metal oxidation and first ligand reduction potentials occurred near those previously measured for the dpp complex $[Ru(\mathbf{1})_2]^{2+}$ lacking a catechol unit,[6] and up to three further reduction waves occurred at 100–340 mV intervals.

### Photosensitization

Samples of all four new complexes were submitted to the assessment protocol[23] that we have used several times to gauge photosensitizer ability[9,12,14,24,25] by monitoring the rate of accumulation of the methyl viologen cation radical ($MV^{\cdot+}$) arising by electron transfer from the photo-excited state to methyl viologen ($MV^{2+}$) in the presence of a sacrificial reductant, triethanolamine (TEOA), which is used to reduce the $Ru^{III}$ photoproduct back to the starting $Ru^{II}$ state. When a mixture of $[Ru(\mathbf{3})_2]^{2+}$, $MV(PF_6)_2$ and TEOA in $CH_3CN$ was irradiated at 400–600 nm, the Ru complex quantitatively formed a dark precipitate and very little $MV^{\cdot+}$ accumulated in the supernatant, as judged by the absorption spectrum. This precipitation recurred with repeated trials. The precipitate was isolated by filtration, but the material was insoluble in most solvents, including $CH_3CN$ and DMF. It was soluble in TFA, but it was NMR-silent in [D]TFA, suggesting that it was paramagnetic. Its LDI-TOF mass spectrum was very noisy and generally uninformative, showing very few peaks and these were not attributable to any reasonable formulation. No further characterization was carried out, but control experiments revealed that the three chemical components, the $Ru^{II}$ complex, $MV^{2+}$ and TEOA, were all required to produce the precipitation. We also found that no precipitation occurred in the dark; light – even sunlight through a window – was required. This precipitation behaviour was also noted with $[Ru(\mathbf{1})(\mathbf{3})]^{2+}$, but we did not carry out control experiments in that case.

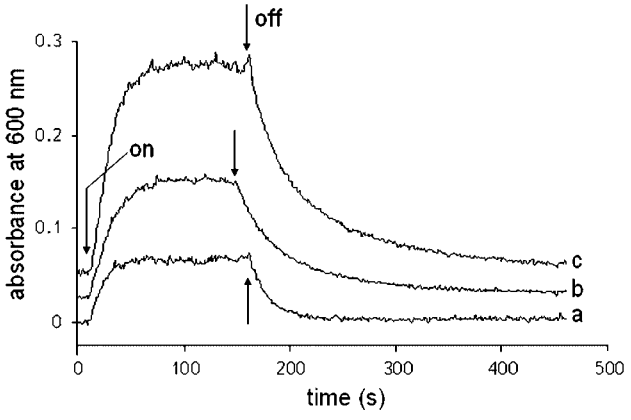

Figure 2. Plots of absorbance at 600 nm over time for (a) $[Ru(\mathbf{3})_2]^{2+}$, (b) $[Ru(\mathbf{1})(\mathbf{3})]^{2+}$, offset by 0.025 absorbance units, and (c) $[Ru(\mathbf{1})_2]^{2+}$, offset by 0.05 absorbance units. Arrows indicate the start and end of irradiation.

In contrast, the protected forms, $[Ru(\mathbf{2})_2]^{2+}$and $[Ru(\mathbf{1})(\mathbf{2})]^{2+}$, behaved normally, showing the same pattern as had been seen with other sensitizers (Figure 2): a rapid, steady rise in absorbance at 600 nm owing to $MV^{\cdot+}$, followed by a levelling off and, after turning off the light, a slow aerobic decay back to the starting absorbance. For comparison, $[Ru(\mathbf{1})_2]^{2+}$ was assessed in the same manner. The data were treated as before,[23] and the first-order rate constants $k_f$ for $MV^{\cdot+}$ accumulation are reported in Table 1. These clearly show that all three species were significantly better sensitizers than was the terpyridine complex $[Ru(ttpy)_2]^{2+}$, and that $[Ru(\mathbf{1})_2]^{2+}$ was a better sensitizer than the catechol-containing species.

### Photovoltaic Performance

A photovoltaic cell was assembled for each of the two catechol-bearing complexes. The sensitizer was adsorbed from a $CH_3CN$ solution onto a titania-coated conductive glass plate. A solid-state electrolyte film was sandwiched between this and a platinized counter-electrode. The current and potential between the electrodes were monitored while the assembly was irradiated using a "standard" light source approximating the sun's spectrum and density (per unit area) at the Earth's surface. Another assembly was similarly prepared using the so-called N719 dye, the bis(tetrabutylammonium) salt of *cis*-bis(2,2′-bipyridyl-4,4′-dicarboxylic acid)bis(thiocyanato)ruthenium(II), to serve as a comparison. The results are presented in Table 2 in terms of the four quantities of importance for solar cells: the open-circuit potential $V_{oc}$, the short-circuit current density $I_{sc}$, the "fill factor" (*FF*), which is the maximum or peak power ($V \times I$) divided by $V_{oc}$ and by $I_{sc}$, and the photon-to-electron conversion efficiency $\eta$.

Table 2. Photovoltaic characteristics.

| Sensitizer | $I_{sc}$ [mA cm$^{-2}$] | $V_{oc}$ [mV] | *FF* | $\eta$ [%] |
|---|---|---|---|---|
| $[Ru(\mathbf{3})_2]^{2+}$ | 0.297 | 337 | 0.52 | 0.05 |
| $[Ru(\mathbf{1})(\mathbf{3})]^{2+}$ | 1.006 | 348 | 0.52 | 0.19 |
| N719 | 9.29 | 583 | 0.53 | 2.87 |

Gratifyingly, the new catechol dyes both were able to generate a current when irradiated under these conditions. However, they showed significantly lower efficiencies ($\eta$) than the well studied N719 dye, which generated a stronger $V_{oc}$ and a much larger $I_{sc}$ under the same conditions, while *FF* was virtually the same for all three sensitizers. Interestingly, it appears that the asymmetric catechol complex is about four times more efficient than the symmetrical bis(catechol) one, in spite of the latter's ability to absorb more light (higher $\varepsilon$). Two catechol-bearing terpyridine complexes have previously been tested in photovoltaic cells, with moderately good results.[20] The cell constitution was different in that a liquid electrolyte was used, and the results are not directly comparable to ours, but the $\eta$ values were also

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

significantly lower than for carboxylated sensitizers like the N719 dye, in spite of the determination that the surface grafting was superior and faster with catechol than with carboxylate groups.

## Discussion

The weak base-dependence of the position and intensity of the MLCT absorption of the two catechol-bearing complexes, and the similarity in the $E_{1/2}(Ru^{II/I})$ values of all dpp complexes is consistent with the LUMO in dpp complexes being centred over a pyrazine ring. This is reasonable, since pyrazine rings are the most electron-poor and are π-disconnected from each other and from the 4-substituent on the central pyridine ring. Moreover, pyrazine rings on the less π-rich ligand **1** are expected to be of lower energy than those of the oxygenated **2** or **3**. In contrast, the LUMO of a tpy ligand is likely centred over the central pyridine ring, more strongly influenced, therefore, by a 4′-substituent on that ring, as demonstrated by the MLCT absorptions of the tpy analogues.[21]

According to its very positive $E_{1/2}(Ru^{III/II})$ value, $[Ru(\mathbf{1})_2]^{2+}$ can undergo reductive quenching, and the other dpp complexes should also have been capable of reductive quenching. However, they would not benefit from the same driving force. In comparison with the *p*-tolyl groups in $[Ru(\mathbf{1})_2]^{2+}$, the methylenedioxy group in **2** is much more strongly electron-donating in character. Since electron-donating substituents destabilize the metal-centered orbitals to a greater degree than they destabilize the pyrazine-centered LUMO, and especially since the electron-donating substituents are π-disconnected from the pyrazines, $E(Ru^{III/II})$ should be much more affected than $E(Ru^{II/I})$ and shifted to less positive values. Consequently, both absorption and emission (and $E_{00}$) will shift to lower energies, as the gaps between the ground state and $^1$MLCT or $^3$MLCT states become narrower as a result. Since both $E(Ru^{III/II})$ and $E_{00}$ will be depressed by the same HOMO destabilization, $E(Ru^{III/II*}) = E(Ru^{III/II}) - E_{00}$ will be little changed and oxidative quenching will remain impossible. However, $E(Ru^{II*/I}) = E_{00} + E(Ru^{II/I})$ will decrease. While this decrease may not be sufficient to prevent reductive quenching from occurring, it will certainly reduce the driving force for the initial reaction of the excited state with TEOA. According to Marcus–Hush theory, that driving force determines the rate of the electron transfer reaction.[26] This then explains the stronger photosensitization in the order $[Ru(\mathbf{1})_2]^{2+} > [Ru(\mathbf{1})(\mathbf{2})]^{2+} > [Ru(\mathbf{2})_2]^{2+}$.

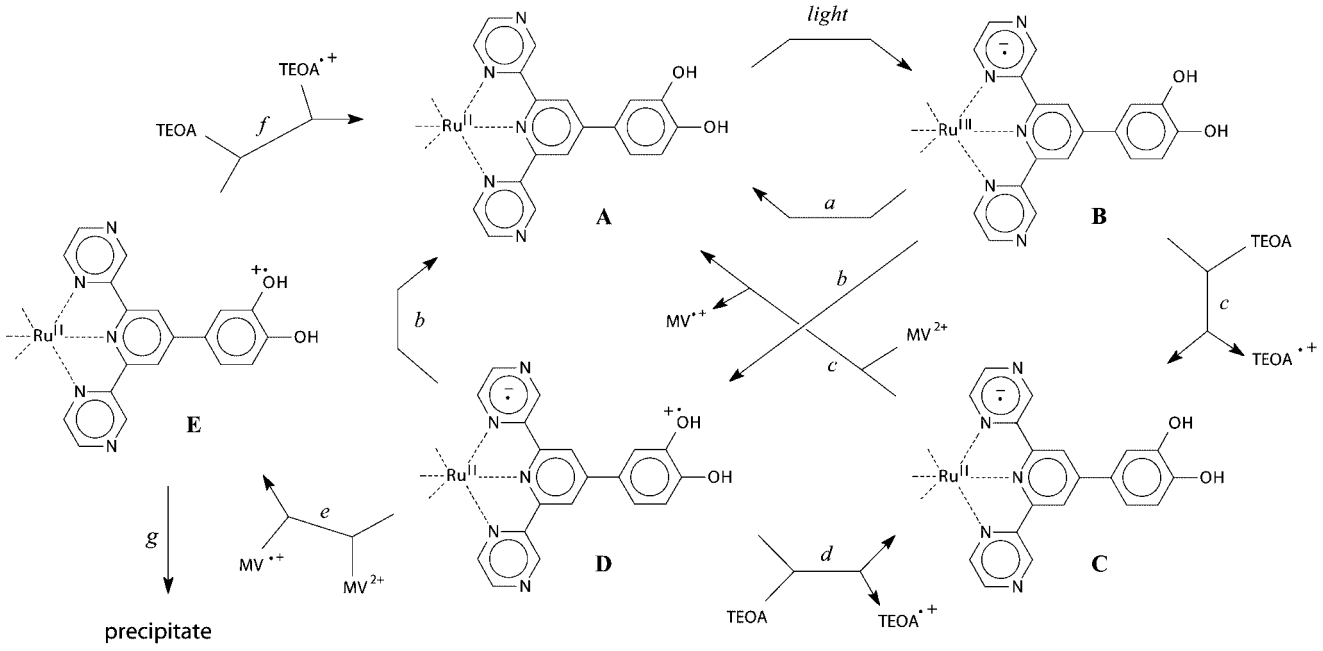
Yet all three dpp complexes were better than $[Ru(ttpy)_2]^{2+}$. We can identify two reasons for this. Firstly, we can expect enhanced steady-state concentrations of the excited states with dpp sensitizers, owing to three factors: the absorption bands are more centred in the 400–600 nm irradiation window, there is increased light absorption (higher ε values) and, because $[Ru(\mathbf{1})_2]^{2+}$ was previously found to have a higher τ value than had $[Ru(ttpy)_2]^{2+}$, as mentioned earlier, it is reasonable to expect similarly higher values for the other dpp complexes. Secondly, and perhaps most importantly, the dpp-containing complexes are expected to follow a reductive quenching mechanism while $[Ru(ttpy)_2]^{2+}$ can only undergo oxidative quenching. As the crucial step involves a reaction of the excited state with the neutral TEOA in reductive quenching, or with the dicationic $MV^{2+}$ during oxidative quenching, reductive quenching is electrostatically advantaged.

In light of this, we can postulate a reason for precipitate formation during irradiation of the complexes of **3**. With the additional nitrogens present, catechol oxidation would have occurred at a slightly more positive potential with these than that measured for the *tpy* analogues (1.21 V vs. SCE),[21] but this would probably still remain below $E(Ru^{III/II})$ (as exemplified by the *p*-tolyl case). However, under the basic conditions provided by TEOA, the catechol groups had probably ionized – even more likely because of the additional nitrogens – since this would have served to balance the metal charge and would have constituted a binding site for $MV^{2+}$. The catecholate oxidation would then have occurred at a less positive potential. It is therefore probable that catecholate groups served as internal quenchers of the excited states of our deprotected complexes. This is illustrated in Scheme 2, where a possible mechanism for precipitate formation is compared to "normal" photo-catalytic cycles. Just as with other $Ru^{II}$ complexes of this type, the $^3$MLCT excited state **B** can undergo "normal" non-radiative decay (path *a*). In our case, it can also undergo non-radiative decay from an internally quenched state **D** (path *b*), or "normal" reductive quenching by TEOA to **C** followed by electron transfer to $MV^{2+}$ and regenerating the ground state **A** (path *c*). Alternatively, the internally quenched state **D** can feasibly be reduced by TEOA to **C** in an "abnormal" reductive quenching (path *d*), or oxidized by $MV^{2+}$ (path *e*) in "abnormal" oxidative quenching to produce a radical product **E**. But $E(TEOA^{\cdot+/0})$ is 0.81 V vs. SCE,[27] i.e. below the catechol oxidation potential. Hence, as depicted, **D** should have been able to oxidize TEOA and path *d* should have been followed. At the same time, oxidative quenching of **D** (path *e*) might also have occurred and the cation radical product **E** should have been reduced by TEOA to regenerate **A** (path *f*). In both cases, $MV^{\cdot+}$ would have accumulated and no insoluble paramagnetic species should have formed by path *g*.

With TEOA acting as a base instead, catecholates would result. If their lower oxidation potentials indeed lie below $E(TEOA^{\cdot+/0})$, then paths *d* and *f* would be obviated and **E** would accumulate by path *e*. (The amount of $MV^{\cdot+}$ so formed could not have exceeded the amount of Ru complex initially present; it would have been too small to observe and would have quickly decayed aerobically.) The fates of the resulting radicals **E** are unknown, but deprotonation (by TEOA) and dimerization by phenolic coupling are likely outcomes, eventually resulting in the paramagnetic precipitates that were observed.

There are several possible reasons for the better photovoltaic behaviour of the N719 dye. Its MLCT band at 534 nm extends well beyond 700 nm,[28] although the ε

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

value at $\lambda_{max}$ is actually a little weaker ($1.42 \times 10^4$ M$^{-1}$ cm$^{-1}$) than with our materials. Its $\tau$ value (50 ns)[28] is also larger than that of $[Ru(\mathbf{1})_2]^{2+}$. Photovoltaic sensitizers normally have $E(Ru^{III/II})$ well below 1 V vs. SCE (0.85 V for N719 itself,[28] 0.61 V[29] for $[Ru(tpy)(SCN)_3]^0$), much less positive than in dpp complexes, so that the driving force for electron injection is much weaker with dpp complexes. Internal quenching by catechol groups could short-circuit the photoconduction process by constituting a second, "abnormal", non-radiative decay path (path *b* in Scheme 2) for the excited state, and thereby decrease the solar conversion efficiency. This would need to occur at a rate competitive with electron injection, but the literature suggests that electron injection is exceedingly fast (on sub-ps or even fs timescales)[30–32] and it occurs even with sensitizers having exceedingly short $\tau$ values.[33]

Finally, another contributing factor may have been the state of aggregation on the surface. In multilayer assemblies, the outer layers may be too distant from the surface for an efficient photo-induced transfer of an electron to the surface, and may insulate the inner layers from the $I^-/I_3^-$ of the bulk phase, preventing the photo-produced $Ru^{III}$ state from returning to the ground $Ru^{II}$ state, and thereby effectively slowing down or stopping the catalytic cycle. Rice et al. report using cholic acid derivatives to inhibit aggregation,[20] but no such treatment was applied in our experiments.

Overall, the differences in photovoltaic behaviour between the three complexes tested may be due to a combination of factors, including differences in the complexes' photophysical properties once anchored to the electrode surface, the driving force for electron injection and the state of aggregation at the surface. It may be possible to address each of these factors in new sensitizer designs.

## Experimental Section

**General:** Samples of **1** and $[Ru(\mathbf{1})_2](PF_6)_2$ were prepared according to Liegghio et al.[6]

All NMR spectra were obtained with a Bruker AMX-400 spectrometer at 300 K. Signal assignments are given using the position labels of Scheme 1. Electron-impact mass spectrometry (EI-MS) was performed by Dr. Alex Young of the University of Toronto on a Micromass 70S-250 sector instrument at 70 eV. Laser Desorption Ionization-Time of Flight mass spectra (LDI-TOF-MS) were obtained on a Voyager DE STR instrument, while electrospray mass spectra were obtained on a Sciex-TAGA 600E instrument. Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, ON, Canada.

Electronic spectroscopy was performed on a HP 8452A instrument. Stock solutions that were $5 \times 10^{-4}$ M in Ru were prepared. Aliquots (0.5 mL) were diluted with 2 mL of $CH_3CN$ in a disposable polymethacrylate cuvette (spectral range: 275–800 nm) to achieve a final concentration of $1 \times 10^{-4}$ M. Acetonitrile in a matching cuvette was used for baseline correction. The cuvettes were maintained at 25 °C by a Peltier block controlled by a HP 89090A controller. To explore the effect of deprotonation, 2 mL aliquots of the Ru stock were combined with 0–2 mL of an $8 \times 10^{-4}$ M stock solution of $Et_3N$ in $CH_3CN$, and the resulting mixture was diluted to 4 mL with $CH_3CN$. Samples were also prepared with 2.25–3 mL $Et_3N$ without further dilution, and the increased volume was taken into account. The position of the MLCT $\lambda_{max}$ was monitored and the nominal $\varepsilon$ values were computed.

Cyclic voltammetry was performed with an Obbligato Objectives Faraday MP potentiometer, using a graphite working electrode, a Pt wire counter electrode, and a Ag/AgCl *quasi*-reference electrode, which was prepared by immersing a virgin Ag wire in 1 M HCl and rinsing with $H_2O$ and absolute ethanol. Sample solutions in either $CH_3CN$ or DMF were assembled by combining 5 mL of a $5 \times 10^{-3}$ M Ru stock solution and 5 mL of a 0.1 M stock solution of tetrabutylammonium hexafluorophosphate (TBAH), then degassed

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

by bubbling with Ar for 2–3 min. For the last scan at the end of an experiment, 5 mL of a $5 \times 10^{-3}$ M ferrocene (Fc, $E°$ = 0.40 V in $CH_3CN$ containing TBAH vs. SCE)[34] stock solution was added.

For photosensitizer assessments, the equipment, sample preparation, data acquisition and data treatment were exactly as described earlier.[23]

For the photovoltaic measurements, titania films were prepared on commercial Pilkington TEC 8 conductive glass plates according to a standard procedure,[28,35] using the scalpel technique. The films were sintered and stored in a dessicator in the dark. Before impregnating the films, they were heat-treated at 450 °C for 30 min. While still hot at ca. 100 °C, they were immersed in sensitizer solutions, where they remained for grafting for 3 d. The sensitizers were dissolved in dry acetonitrile (distilled over $P_2O_5$) giving a ca. $1 \times 10^{-4}$ M solution of $[Ru(\mathbf{3})_2](PF_6)_2$ and a ca. $2 \times 10^{-4}$ M solution of $[Ru(\mathbf{1})(\mathbf{3})](PF_6)_2$, both of which were stored in the dark. A solid-state polyethylene oxide/titania/$I^-/I_3^-$ composite electrolyte[36,37] was used in the course of the experiments. The electrolyte was sandwiched between the photoelectrode and the platinized counterelectrode. Current–voltage (I–V) characteristics were obtained by connecting the cell to a variable resistor together with a micro-amperemeter in series and a voltmeter in parallel. Illumination was provided by a 300-W Xe light source (Oriel). A cut-off filter was used to exclude wavelengths less than 400 nm so as to prevent the generation of electron-hole pairs through direct $TiO_2$ bandgap excitation. Through accurate positioning of the cell assembly, all measurements were obtained under global air mass 1.5 (AM 1.5) solar irradiation conditions[38] (power density 1000 W $m^{-2}$). The experiments were repeated four times for each complex and a mean value was taken. *cis*-Bis(2,2′-bipyridyl-4,4′-dicarboxylato)bis(thiocyanato)ruthenium(II) bis(tetrabutylammonium) salt (N719 dye), purchased from Solaronix s.a., was used for comparison.

**4-(3,4-Methylenedioxyphenyl)-2,6-dipyrazinylpyridine (2):** Acetylpyrazine (0.20 g, 1.6 mmol) and piperonal (0.12 g, 0.8 mmol) were dissolved in a mixture of concentrated $NH_4OH$ (0.5 mL), 15% aq. KOH (5.2 mL), and methanol (5.7 mL), giving a canary yellow solution. The mixture turned beige over a period of 4 d at room temperature, and had formed a precipitate. This was isolated by filtration, rinsing with MeOH/$H_2O$ (1:1), then heated in hot acetone for 3 h to dissolve. The solution was cooled, then filtered. The solid was washed with acetone and ether, and then left to dry in a 70–80 °C oven, providing **2** in 75% yield (0.28 g). $^1$H NMR (400 MHz, $CDCl_3$, 300 K): $\delta$ = 9.90 (s, 1 H, *c*), 8.73 (3s, 3 H, *a*, *b* & *d*), 7.39 (d, 1 H, *e*), 7.28 (s, 1 H, *g*), 6.99 (d, 1 H, *f*), 6.09 (s, 2 H, *h*) ppm. EI–MS: *m*/*z* = 355. $C_{20}H_{13}N_5O_2$ (355.4): calcd. C 67.60, H 3.70, N 19.71; found C 67.54, H 3.75, N 19.58.

**$[Ru(\mathbf{2})_2](PF_6)_2$:** $RuCl_3 \cdot 3H_2O$ (0.10 g, 0.38 mmol) and $AgBF_4$ (0.20 g, 1.2 mmol) were heated in acetonitrile at reflux for 3 h, then filtered free of AgCl, affording a deep green solution. The solvent was then removed and replaced with fresh ethylene glycol. Ligand 2 (0.28 g, 0.76 mmol) was added, and the mixture was heated to reflux overnight, changing to a deep red colour. The Ru complex was precipitated by adding two equivalents of aqueous $NH_4PF_6$ (0.12 g, 0.76 mmol), collected by filtration, rinsed with ether and left to dry overnight in a 60–80 °C oven. Yield 0.94 g (85%). $^1$H NMR (400 MHz, $CD_3CN$, 300 K): δ = 9.76 (s, 2 H, c), 9.13 (s, 2 H, d), 8.40 (d, 2 H, b), 7.82 (d, 1 H, e), 7.78 (s, 1 H, g), 7.54 (d, 2 H, a), 7.27 (d, 1 H, f), 6.23 (s, 2 H, h) ppm. ES-MS: m/z = 406. $C_{40}H_{26}N_{10}O_4Ru^{2+}$ requires 406. $C_{40}H_{26}F_{12}N_{10}O_4P_2Ru$ (1101.7): calcd. C 43.61, H 2.38, N 12.71; found C 43.96, H 2.29, N 12.69.

**$[Ru(\mathbf{1})(\mathbf{2})](PF_6)_2$:** $RuCl_3 \cdot 3H_2O$ (0.10 g, 0.38 mmol) and ligand **2** (0.14 g, 0.38 mmol) were dissolved in acetonitrile and the mixture was left to reflux for 3 h, whence the reaction mixture became deep brown. Then, $AgBF_4$ (0.2 g, 1.2 mmol) was added, and heating continued for an additional 3 h, developing a deep green colour. This mixture was filtered free of AgCl, the filtrate was freed of solvent, then diluted with fresh ethylene glycol. Ligand **1** (0.12 g, 0.38 mmol) was then added and the mixture was heated to reflux overnight, changing to a deep red. The complex was precipitated by addition of aqueous $NH_4PF_6$ (0.12 g, 0.76 mmol), collected by filtration, and washed with diethyl ether, then left to dry overnight in a 60–80 °C oven. Yield 0.75 g (70%). $^1$H NMR (400 MHz, $CD_3CN$, 300 K): $\delta$ = 9.76 (2s, 2 H, *c* & *c**), 9.19 (s, 1 H, *d*), 9.12 (s, 1 H, *d**), 8.40 (m, 2 H, *b* & *b**), 8.17 (d, 2 H, *e**), 7.82 (d, 1 H, *e*), 7.78 (s, 1 H, *g*), 7.66 (d, 2 H, *f**), 7.55 (m, 2 H, *a* & *a**), 7.27 (d, 1 H, *f*), 6.23 (s, 1 H, *h*), 2.58 (s, 3 H, *g**) ppm. ES-MS: *m*/*z* = 391.0. $C_{40}H_{28}N_{10}O_2Ru^{2+}$ calcd. 390.9. $C_{40}H_{28}F_{12}N_{10}O_2P_2Ru$ (1071.7): calcd. C 44.83, H 2.63, N 13.07; found C 44.67, H 2.54, N 12.96.

**$[Ru(\mathbf{3})_2](PF_6)_2$:** $[Ru(\mathbf{2})_2](PF_6)_2$ (0.10 g, 0.91 mmol) was dissolved in 30–45% HBr in acetic acid (40 mL) and heated to just below reflux temperature for 3–4 d, whence the colour turned deep brown. The solvent was removed in vacuo and the residue was dissolved in a minimal amount of $CH_3CN$. The product was precipitated with 2 M aqueous $NH_4PF_6$ (30 mL), collected by filtration and washed with diethyl ether, then was left to dry overnight in a 50–60 °C oven. Yield 1.02 g (95%). $^1$H NMR (400 MHz, $CD_3CN$, 300 K): $\delta$ = 9.77 (s, 2 H, *c*), 9.13 (s, 2 H, *d*), 8.38 (d, 2 H, *b*), 7.79 (s, 2 H, *g*), 7.70 (d, 1 H, *e*), 7.54 (d, 2 H, *a*), 7.22 (d, 1 H, *f*) ppm. LDI-TOF-MS: *m*/*z* = 788.1. $C_{40}H_{28}N_{10}O_2Ru^+$ requires 788.1. $C_{38}H_{26}N_{10}O_4P_2F_{12}Ru$ (1077.7): calcd. C 43.65, H 2.51, N 13.40; found C 43.47, H 2.43, N 13.36.

**$[Ru(\mathbf{1})(\mathbf{3})](PF_6)_2$:** The procedure used to generate $[Ru(\mathbf{3})_2](PF_6)_2$ was applied to $[Ru(\mathbf{1})(\mathbf{2})](PF_6)_2$ (0.10 g, 0.93 mmol). Yield 0.95 g (90%). $^1$H NMR (400 MHz, $CD_3CN$, 300 K): $\delta$ = 9.79 (2s, 2 H, *c* & *c**), 9.19 (2s, 2 H, *d* & *d**), 8.39 (m, 2 H, *b* & *b**), 8.17 (d, 2 H, *e**), 7.87 (s, 1 H, *g*), 7.71 (d, 1 H, *e*), 7.64 (d, 2 H, *f**), 7.53 (m, 2 H, *a* & *a**), 7.22 (d, 1 H, *f*), 2.58 (s, 3 H, *g**) ppm. LDI-TOF-MS: *m*/*z* = 768.7. $C_{39}H_{27}N_{10}O_2Ru^+$ requires 768.3. $C_{39}H_{27}N_{10}O_2P_2F_{12}Ru$ (1058.7): calcd. C 44.25, H 2.57, N 13.23; found C 44.14, H 2.51, N 13.19.

# Structural Chemistry of a New 10H Hexagonal Perovskite: $BaMn_{0.4}Fe_{0.6}O_{2.73}$

**Laura Miranda,[a] Julio Ramírez-Castellanos,[a] María Hernando,[a,b] Aurea Varela,[a] José M. González-Calbet,[a] and Marina Parras*[a]**

**Keywords:** Hexagonal perovskites / Magnetic properties / Mn polytypes / High-resolution electron microscopy

A new 10H polytype has been stabilized in the $BaMn_{1-x}Fe_xO_{3-y}$ system with the composition $BaMn_{0.4}Fe_{0.6}O_{2.73}$. The anionic composition has been established by a reduction and re-oxidation cycle in the stability range of this phase. The structural characterization was carried out by high-resolution electron microscopy (HREM), electron diffraction, and X-ray diffraction. The structure is closely related to the ideal $(hch'ch)_2$ 10H polytype with two oxygen-deficient hexagonal (h′) $BaO_{2-y}$ layers per unit formula. This framework gives rise to blocks of three octahedra sharing faces linked by corners to two corner-sharing tetrahedra.

## Introduction

The perovskite family is one of the series of oxides most widely studied in the field of solid state chemistry. The compositional flexibility of a perovskite is reflected in the ability of its structure to accommodate a large variety of cations into the oxygen framework due, in part, to the huge range of structurally related polymorphs which can be adopted. The crystal structures of perovskites, $ABO_3$, can be considered to consist of stacks of pseudo-close-packed layers $AO_3$; the smaller B cations occupy the oxygen octahedral holes between the layers. When all the $AO_3$ layers stack in a cubic close-packed structure (ABC sequence), the $[BO_6]$ octahedra form the three-dimensional, corner-sharing network of the well-known cubic perovskite of the 3C structural type. On the contrary, if all the $AO_3$ layers are in a hexagonal close-packing structure (AB sequence), the octahedra sharing faces and the one-dimensional 2H structural type (hexagonal perovskite) is obtained. In general, the hexagonal perovskites are less common than the cubic ones because of unfavorable electrostatic cation repulsion associated with the much shorter B–B distance between adjacent face-sharing octahedra.

Between hexagonal and cubic perovskites, a wide range of hexagonal polytypes has been described, whose structures arise from different cubic (c) and hexagonal (h) periodic mixed sequences of the $AO_3$ layers. These polytypes are usually referred to by the symbols $n$H or $n$R, where $n$ corresponds to the number of layers per unit cell, while H and R denote the hexagonal and rhombohedral symmetry, respectively, of the corresponding unit cell.

Many compounds with a hexagonal perovskite-type structure have been reported during the last years. The cation size, the electronic configuration of the B cations, and the oxygen stoichiometry are factors that strongly influence the stabilization of a particular polytype for a given composition. $BaMnO_3$[1] crystallizes in the 2H hexagonal type (**…**hhh**…** sequence). In this system, the introduction of anionic vacancies leads to the stabilization of a large number of anion-deficient $BaMnO_{3-y}$ hexagonal polytypes containing 100–50% hexagonal stacking.[2–5] This behavior is also observed in the $BaFeO_{3-y}$ system, which has been extensively studied in the $0 < y \leq 0.5$ compositional range.[6–10] This system is characterized by a large structural variety; in particular, three different hexagonal polytypes are stabilized for the more oxidized samples. Unlike in the Ba-Mn-O system, stoichiometric $BaFeO_3$ has not been stabilized up to now, but the closest anionic composition, $BaFeO_{2.95}$, adopts the 6H hexagonal polytype with a $(hcc)_2$ stacking arrangement containing only 33% hexagonal layers,[11] that is, much less than $BaMnO_3$. This feature can be related to the bigger size of $Fe^{IV}$ relative to that of $Mn^{IV}$, both of which are in an octahedral oxygen environment ($r_{Fe}^{IV}$ = 0.585 Å, $r_{Mn}^{IV}$ = 0.550 Å).[12] Actually, in general, an increase of the cubic layers per unit cell occurs when the $r_A/r_B$ ratio decreases, because of the increase of the cationic repulsion in the face-sharing octahedra.

Similarly, different structural modifications have been reported within more complex systems where two or more cations of different chemical nature occupy the B position of the perovskite. Taking into account the great number of polytypes that can be stabilized in the above-mentioned Ba-Mn-O and Ba-Fe-O systems, a diverse structural chemistry may be expected for the $BaMn_{1-x}Fe_xO_{3-y}$ system. This fact,

besides the current interest in the physical properties of Mn-containing perovskites, provides a significant motivation for investigating the effects of substituting Fe for Mn in $BaMnO_3$. Previous work in $BaMn_{1-x}Fe_xO_{3-y}$ involved the stabilization of a 6H polytype (hhhchc sequence) for the $0 \leq x \leq 0.3$ compositional range.[13] All the samples are oxygen-deficient. In view of the sensitivity of the structural chemistry to cation size or redox chemistry, it seems reasonable that changes in the cationic distribution of the B sites are accompanied by structural changes. Therefore, we have investigated this system and we have identified a new single phase adopting a 10H hexagonal polytype. We report in this paper the synthesis and the structural study, of $BaMn_{0.4}Fe_{0.6}O_{3-y}$, carried out by using X-ray diffraction, selected area electron diffraction (SAED), and high-resolution electron microscopy (HREM).

## Results and Discussion

### Microstructural Characterization

The initial characterization of $BaMn_{0.4}Fe_{0.6}O_{3-y}$ by X-ray diffraction suggests that it is a hexagonal single-phase material with unit cell dimensions corresponding to a 10H polytype. There are twelve stacking sequences of the $BaO_3$ layers which can result in a 10H cell. Three of them correspond to a $P6_3/mmc$ space group whereas the other nine correspond to space groups without systematic extinctions ($P\bar{6}m2$, $P\bar{3}m1$ and $P3m1$).

The SAED patterns along the most relevant zone axes [001], [010], and [1$\bar{1}$0], are shown in Figure 1a, b, and c, respectively. The diffraction spots are always sharp, and no streaking or diffuse intensity is observed. All the reflections appearing in these patterns can be indexed on the basis of a hexagonal unit cell of lattice parameters close to $a$ = 5.7, $c$ = 24.7 Å. In addition, as it can be observed in the SAED pattern in Figure 1b, the reflection conditions are compatible with a $P6_3/mmc$ space group. By tilting 30° around the $c^*$ axis (Figure 1c), all the spots due to multiple diffraction are visible. According to these results, three stacking sequences are possible for this 10H structure: $(ccccch)_2$, $(hhhcc)_2$, and $(hchch)_2$. The first one presents a much greater proportion of cubic layers than the other two; this sequence has been found in $SrMn_{0.7}Fe_{0.3}O_{2.87}$.[14] The bigger size of the barium atom allows the stabilization of polytypes with a large component of hexagonal perovskite; therefore, one of the other two sequences (containing a 60% of hexagonal layers) seems to be more probable.

Electron microscopy is a very efficient tool for determining the layer-stacking sequence along the $c$ axis. Figure 2a corresponds to the HREM along the [010] axis. In this zone, the structure is viewed parallel to the columns of close-packed Ba–O rows, and therefore the sequence of the layers is directly revealed. In fact, in the hexagonal polytypes, the image contrast along the [010] projection consists of lines of dots in which the straight segments correspond to adjacent cubic (c) layers, whereas every change of slope is associated to the presence of hexagonal (h) layers. Ac-

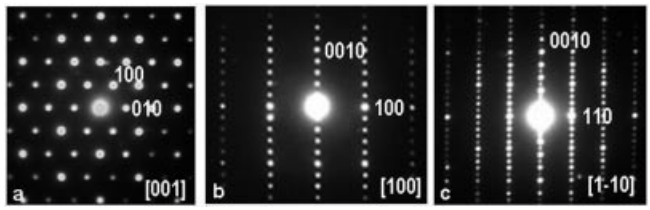

Figure 1. SAED patterns corresponding to $BaMn_{0.4}Fe_{0.6}O_{2.73}$ along (a) [001], (b) [010] and (c) [1$\bar{1}$0].

cording to this, the observed contrast of the image (see Figure 2b) can be interpreted as corresponding to a $(hchch)_2$ layer arrangement. Therefore, from the ideal atomic coordinates corresponding to this 10H sequence, an image calculation was performed. The simulated image (inset of Figure 2a) nicely fits the experimental one for $\Delta t$ = 70 Å, $\Delta f$ = –500 Å. This result shows that $BaMn_{0.6}Fe_{0.4}O_{3-y}$ either actually exhibits this hexagonal 10H structure or has a closely related structural type. In this structure (Figure 3a), blocks of three face-sharing octahedra are linked by their terminal corners to blocks of two face-sharing octahedra. It is worth mentioning that this hexagonal polytype is stable in both the Ba-Mn-O and the Ba-Fe-O systems for the compositions $BaMnO_{2.90}$[2] and $BaFeO_{2.80}$,[9,10] respectively.

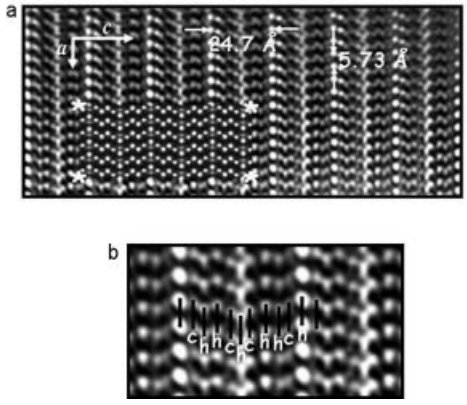

Figure 2. (a) HRTEM image of $BaMn_{0.4}Fe_{0.6}O_{2.73}$ along [010]; the calculated image is shown in the inset. ($\Delta t$ = 70 Å, $\Delta f$ = –500 Å) (b) Enlarged image showing the stacking sequence of the $BaO_3$ layers along the $c$ axis.

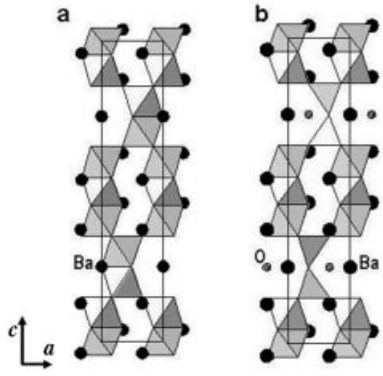

Figure 3. Structural models corresponding to: (a) the 10H-$ABO_3$ polytype; (b) 10H-$BaFeO_{2.80}$ (according to ref.[10]). Only the Ba and nonbonding O atoms are marked.

### Compositional Characterization

The cationic composition was determined by energy-dispersive X-ray spectroscopy (EDS). In order to ensure the chemical homogeneity of the sample, the analysis was performed not only on several dozens of crystallites, but also in different crystal zones. Initially, the absence of Al (from crucible material) in the crystals was confirmed by a preliminary search of all the elements present in the studied samples. Once the lack of additional elements was confirmed, the Ba/Mn/Fe ratio was obtained from the relative intensity of the Ba-$L_\alpha 1$ (4.466 eV), Mn-$K_\alpha 1$ (5.899 eV), and Fe-$K_\alpha 1$ (6.404 eV) lines in the EDS spectra. The obtained result, $Ba_{1.00(2)}Mn_{0.39(3)}Fe_{0.61(1)}O_x$, is in agreement with the nominal composition.

The sample is rather insoluble and we were unable to perform a volumetric analysis to determine the oxygen content. Therefore, in order to establish the anionic stoichiometry, we have undertaken a thermogravimetric study of the sample. First, the sample was reduced under a 300-mbar $H_2$/200-mbar He atmosphere and heated at 3 °C/min up to 700 °C (Figure 4). Under these experimental conditions, the weight loss is close to 7.1%, BaO, MnO, FeO, and Fe metal being identified by XRD as final products of the reduction. However, since the FeO/Fe ratio in the final products is not known, it is not possible to obtain the oxygen content of the studied sample from this experiment. Unfortunately, even for the most reductive conditions, a FeO/Fe mixture was always obtained. Therefore, in order to estimate the oxygen content, it was necessary to design a different reduction pathway.

In this context, the oxygen content of the above sample can be obtained by thermogravimetric analysis if its anionic compositional range is known. In fact, $BaFeO_{2.80}$[9] adopts the same 10H structural type as the anionic vacancies located in the hexagonal layers on the dimer structural units, changing its anionic composition from $BaO_3$ to $BaO_2$ (Figure 3b). The remaining two oxygen atoms rearrange in such a way that only one of them is bonded to the two Fe atoms adjacent to the layer, thus leading to a dimer of corner-sharing tetrahedra. The other oxygen is a nonbonding atom. For lower oxygen content, this nonbonding oxygen is partially removed, and this results in a hexagonal $BaO_{2-y}$ layer.[10] On the basis of the crystallochemical analysis of this phase, we propose that, in a similar way, the anionic range of the stability of the 10H-$BaMn_{0.4}Fe_{0.6}O_{3-y}$ phase varies from 2.80 to 2.60, which corresponds to the range from an h-$BaO_2$ down to an h-BaO layer from one to zero nonbonding oxygen atoms, respectively. According to this assumption, the anionic composition of $BaMn_{0.4}Fe_{0.6}O_{3-y}$ can be obtained from a reduction and re-oxidation cycle of the sample.

Let us go back now to the reduction curve in Figure 4. In inset (a), a slight change in the slope is visible at 375 °C, corresponding to a weight loss close to 0.9%, that could indicate the existence of a stable phase with lower oxygen content. Therefore, in order to stabilize this reduced phase, we have carried out a partial reduction of the starting material under a 100-mbar $H_2$/400-mbar He atmosphere by heating at 2 °C/min up to 280 °C for 12 h to ensure oxygen homogeneity in the final product. This reduction process is represented in Figure 5. The lost weight between the starting and the final points amounts to 0.88%. In addition, the X-ray data shows that the reduced phase maintains the basic structural features of the 10H phase. Taking into account the above considerations, if we assume that the stabilized phase corresponds to the lowest limit of the 10H anionic stability range, i.e., $BaMn_{0.4}Fe_{0.6}O_{2.60}$, $BaMn_{0.4}Fe_{0.6}O_{2.73}$ should be the composition of the starting material.

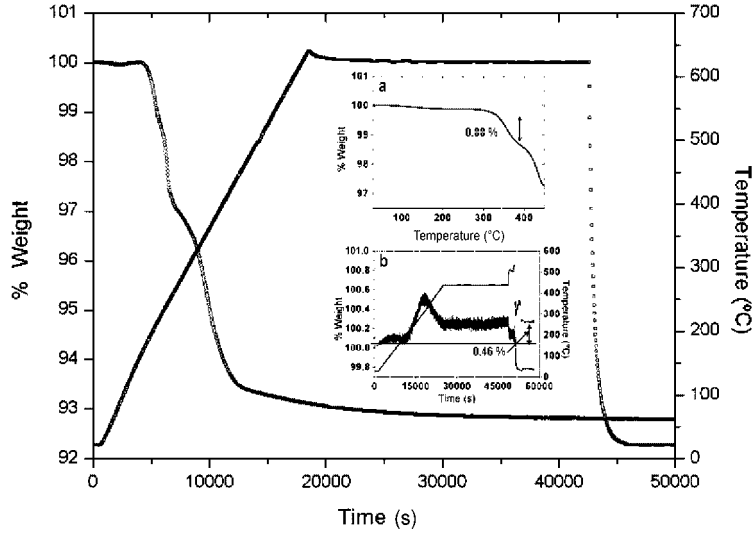

Figure 4. Thermogravimetric analysis of $BaMn_{0.4}Fe_{0.6}O_{3-y}$. The experiment was carried out in a 300-mbar $H_2$/200-mbar He atmosphere. Inset (a): The temperature dependence of the weight loss. Inset (b): Thermogravimetric curve corresponding to the oxidation of $BaMn_{0.4}Fe_{0.6}O_{3-y}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

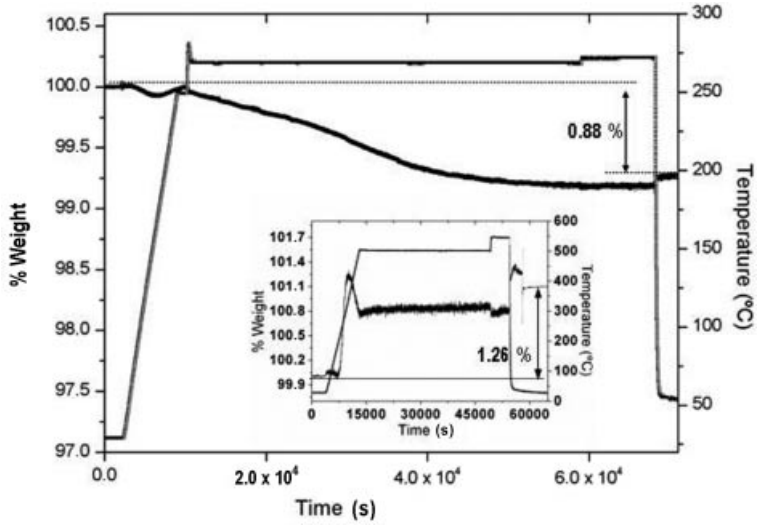

Figure 5. Thermogravimetric curve corresponding to the reduction process (100-mbar $H_2$/400-mbar He; 2 °C/min up to 270 °C) from the starting material, $BaMn_{0.4}Fe_{0.6}O_{3-y}$, up to a composition of $BaMn_{0.4}Fe_{0.6}O_{2.60}$. The re-oxidation process is shown in the inset.

On the other hand, the starting material was also heated at 2 °C/min up to 400 °C under 1 atm $O_2$ in a CAHN electrobalance. As shown in inset (b) of Figure 4, the weight of the sample increases slightly with temperature up to a gain of 0.46%. The low stability of the equipment (CAHN electrobalance) used for data collection when working at a static gas pressure of 1 atm gives rise to high data dispersion, which is reflected in the thickness of the oxidation line. However, this experimental aspect does not influence the reliability of the determined oxygen content since both initial and final weight are measured at 0.5-mbar He in a static atmosphere. The XRD pattern of the final product shows that the oxidized sample also maintains the 10H structure of the starting phase. Taking into account the above considerations, this process should be associated to the oxidation from the starting material up to the most oxidized 10H sample, i.e., according to previous results, to the reaction: $BaMn_{0.4}Fe_{0.6}O_{2.73} + O_2 \rightarrow BaMn_{0.4}Fe_{0.6}O_{2.80}$. For this process, the theoretical weight gain corresponds to 0.47%, which nicely fits with the experimental one of 0.46%.

Finally, we have completed this cycle by the re-oxidation of the reduced $BaMn_{0.4}Fe_{0.6}O_{2.60}$ sample (see inset of Figure 5). In this process, the sample weight increases up to 1.26%, in agreement with the $BaMn_{0.4}Fe_{0.6}O_{2.60} + O_2 \rightarrow BaMn_{0.4}Fe_{0.6}O_{2.80}$ reaction (theoretical value: 1.36%). This result supports the previous ones; therefore, from this thermogravimetric study, the anionic stoichiometry of the studied sample is $BaMn_{0.4}Fe_{0.6}O_{2.73}$.

### Structural Refinement

According to the above results, $BaMn_{0.4}Fe_{0.6}O_{2.73}$ adopts a structure based on a 10H-$(hch'ch)_2$ sequence. A structural study by X-ray profile refinement has been performed by taking as starting model the structural parameters of the hexagonal 10H-$BaFeO_{2.80-y}$ in the space group $P6_3/mmc$.[9]

Because of their similar scattering factors, Mn and Fe are indistinguishable by XRD; therefore, both metals were randomly distributed over the two crystallographically different octahedral sites, the tetrahedral one is fully occupied by Fe, since neither $Mn^{III}$ nor $Mn^{IV}$ are stable in this oxygen coordination. In addition, the determined anionic stoichiometry indicates the presence of oxygen vacancies in the structure, which, according to the above considerations, have been located into the hexagonal h′-$BaO_2$ up to a $BaO_{1.65}$ anionic composition; the nonbonding oxygen position (2c) being 65% occupied. This structural feature will be confirmed by neutron diffraction.

The refinement was stable, and it was possible to refine the positions of the oxygen atoms and the isotropic temperature factor for each type of atom (Ba, Mn/Fe, O). Figure 6 shows the graphical results of the fitting of the experimental X-ray diffraction pattern and the difference between observed and calculated data. The final structural parameters are given in Table 1; Table 2 shows selected interatomic distances.

A schematic representation of the structure is depicted in Figure 7. The octahedron at the center of the trimer, $M_3O_6$, is regular with six identical M–O bonds of length 1.918 Å. This value is in excellent agreement with Mn–O bond lengths observed for $Mn^{IV}$ in the same environment as 2H-$BaMnO_3$ (1.9044 Å),[15] and it is also close to that found in 10H-$BaFeO_{2.8-y}$ for $Fe^{III}$ in octahedral coordination ($d_{average}$ = 2.01 Å).[9,10] In contrast, the $M1O_6$ octahedron is quite distorted, with three long and three short M–O bonds (see Table 2), indicating that metals in this position are displaced from the center toward the oxygen atoms in the cubic layer (O1), i.e., to the neighboring tetrahedra sharing a corner, and hence away from the shared face. As a consequence, with respect to the ideal structure, the M3···M1 distance increases, reducing the electrostatic repulsion between cations in adjacent face-sharing polyhedra. This feature is shown by other polytypes with structural

octahedral trimers like 9R-$BaIr_xMn_{1-x}O_3$.[16] In addition, these M–O octahedral bond lengths [$d_{average}(M2O_6)$ = 1.97 Å] agree with those of the Ba-Mn/Fe-O polytypes, for instance, in 6H-$BaMn_{0.767}Fe_{0.233}O_{2.87}$ the Mn/Fe–O bond lengths range from 1.94 to 2.14 Å, whereas the Fe–O bond lengths in 10H-$BaFeO_{2.8-y}$[9,10] range from 1.94 to 1.859 Å; both are in octahedral coordination.

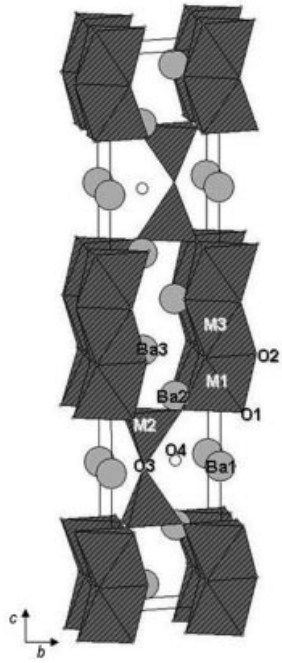

Figure 7. Structural model corresponding to $BaMn_{0.4}Fe_{0.6}O_{2.73}$.

The $Fe2O_4$ tetrahedra are quite distorted with three long Fe2–O1 bonds (1.860 Å) and one short Fe2–O3 bond (1.71 Å). These values are close to those observed in the 10H-$BaFeO_{2.8-y}$[9,10] (1.83 and 1.76 Å, respectively). Finally, as in $BaFeO_{2.8-y}$, the long Fe2–O4 distance obtained (3.672 Å) is not within the bonding distance of the M2 cation.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As we have already mentioned, from the XRD data we are unable to discern between the two metals; however, we can propose a tentative cationic distribution over the different sites. In this sense, it is well known that the presence of Mn stabilizes strings of various face-sharing octahedra in such a way that $Mn^{IV}$ shows a strong preference for occupying the central one of these units. Therefore, we can assume that Mn should be located mainly in the center of the trimers. This fact is well in accordance with the high symmetry of this M3 site. The units of tetrahedra sharing corners involve only Fe (probably in the III oxidation state); therefore, according to the Mn/Fe experimental cationic ratio of 0.4:0.6, Mn/Fe should occupy the outer octahedra of the trimer units in a ratio close to 50:50. If Mn is stabilized as $Mn^{IV}$, the oxidation state of the Fe remaining in this polyhedron should be close to 3.3; this fact indicates the presence of $Fe^{IV}$ in this polyhedron, whose high-spin configuration should be stabilized by the large distortion of the M1 site. The large contrast between the scattering lengths of Mn and Fe makes neutron scattering a particularly sensitive tool in this case. Therefore, in order to confirm these crystallochemical considerations, a neutron diffraction study is in progress.

We would like to emphasize that, from single-crystal XRD analysis, an orthorhombic deformation is found in 10H-$BaFeO_{2.80}$ (*Cmcm* space group).[10] This lower symmetry seems to be caused by a displacement of barium and oxygen atoms in the $BaO_2$ layers from hexagonal special positions, changing the symmetry from hexagonal to orthorhombic. We have also performed the refinement of the 10H-$BaMn_{0.4}Fe_{0.6}O_{2.73}$ structure by using the orthorhombic description reported for the 10H-$BaFeO_{2.8}$ polytype. However, even though a similar displacement of the barium into the $BaO_2$ layers seems occur, we are unable to draw any meaningful conclusion in relation to this symmetry change, since it is not possible to obtain accurate atomic positions of the oxygen atoms from powder X-ray diffraction analysis.

### Magnetic Properties

The magnetic properties of 10H-$BaMn_{0.4}Fe_{0.6}O_{2.73}$ have also been explored. Figure 8 shows the temperature dependence of the magnetic susceptibility as measured in a field of 1000 Oe. A very slight divergence between the zero-field-cooled (ZFC) and field-cooled (FC) data opens up below 150 K. Besides, low values, close to $2.4 \times 10^{-3}$ emu/mol, and weak temperature dependence of the magnetic susceptibility are observed above 100 K. These features suggest the presence of strong interactions between magnetic cations in this temperature range; the negative temperature intercept shown in the inverse magnetic susceptibility plot can indicate that these interactions are antiferromagnetic. Analogous behavior has been evidenced in other Mn polytypes, as in 4H-$SrMnO_{3-x}$[17] where only short-range antiferromagnetic coupling between the $Mn^{4+}$ cations in the $Mn_2O_9$ face-sharing octahedra is detected. In a similar way, it can be considered that short-range antiferromagnetic coupling takes place between the $Mn^{4+}$ cations in the $Mn_3O_9$ structural units in $BaMn_{0.4}Fe_{0.6}O_{2.73}$. However, long-range interactions do not occur, since it is no indication of 3D magnetic order in the susceptibility data at low temperatures. Because of these short-range interactions, we cannot obtain the oxidation state of Mn/Fe cations from the magnetic susceptibility curve. Nevertheless, according to the anionic stoichiometry of the sample and on the basis of crystallochemical considerations, the following formulation $Ba[(Mn_{0.2}^{IV})(Fe_{0.14}^{III}Fe_{0.06}^{IV})]_{Oh1}[Mn_{0.2}^{IV}]_{Oh3}[Fe_{0.4}^{III}]_{td}O_{2.73}$ can be proposed for the investigated sample.

## Experimental Section

The black polycrystalline sample of $BaMn_{0.4}Fe_{0.6}O_{3-y}$ was prepared from a well-ground stoichiometric mixture of $BaCO_3$ (Aldrich, 99.98%), $MnCO_3$ (Aldrich, 99%), and $Fe_2O_3$ (Aldrich, 99.98%). The mixture was heated in an $Al_2O_3$ crucible at 900 °C in air for 48 h. Then, the sample was treated at 1200 °C for one

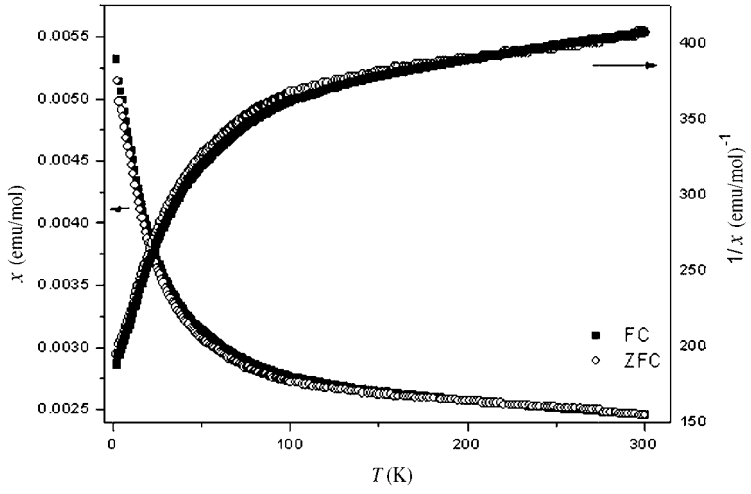

Figure 8. Temperature dependence of the magnetic susceptibility under an applied magnetic field of 1000 Oe.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

day and then quenched to room temperature. This process was repeated four times with intermediate grinding in order to ensure homogeneity.

The average cationic composition was determined by Inductively Coupled Plasma (ICP) analysis, whereas the local composition was analyzed by EDS with an INCA analyzer system attached to a JEOL 3000 FEG electron microscope. The overall oxygen content was determined by thermogravimetric analysis with a thermobalance based on a CAHN D-200 electrobalance, which allows the determination of variations of the oxygen content within $\pm 1 \times 10^{-3}$ on a sample of about 100 mg when working under an atmosphere of 500 mbar gas.

Powder XRD patterns were collected by using Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å) at room temperature with a PHILIPS X′PERT PRO MPD diffractometer equipped with a germanium monochromator. Diffraction data were analyzed by the Rietveld method[18] using the Fullprof program.[19]

SAED and HREM were performed with a JEOL 3000 FEG electron microscope fitted with a double-tilting goniometer stage ($\pm$ 22°, $\pm$ 22°). Simulated HREM images were calculated by the multislice method with the MacTempas software package.

# Main Group Lewis Acid/Base-Stabilised Phosphanylboranes

**Ariane Adolf,[a] Manfred Zabel,[a] and Manfred Scheer*[a]**

*Dedicated to Professor Michael Binnewies on the occasion of his 60th birthday*

**Keywords:** Boron / Phosphorus / Hydrides / Lewis acids / Lewis bases

The parent compounds of phosphanylboranes of the type $(LA)H_2P–BH_2(LB)$ (LA = Lewis acid, LB = Lewis base) stabilised by Lewis acid/Lewis base have been synthesised by using perfluorinated main-group Lewis acids. The Lewis acid–phosphane adducts $(C_6F_5)_3BPH_3$, $(C_6F_5)_3BPPhH_2$ and $(C_6F_5)_3GaPPhH_2$ (**3**) were used as starting materials, which upon lithiation with *n*BuLi react with the chlorinated Lewis base borane adduct $ClBH_2NMe_3$. The LA/LB stabilised phosphanylboranes $(C_6F_5)_3BPH_2BH_2NMe_3$ (**1**), $(C_6F_5)_3BPPhHBH_2NMe_3$ (**4**) and $(C_6F_5)_3GaPPhHBH_2NMe_3$ (**5**), were obtained via salt elimination reactions. $(C_6F_5)_3GaPH_2BH_2NMe_3$ (**2**) was not accessible using this method due to the unavailability of an efficient synthetic route to $(C_6F_5)_3GaPH_3$. The synthesis of **2** could be achieved quantitatively via reaction of $PH_2BH_2NMe_3$ with $(C_6F_5)_3Ga{\cdot}Et_2O$. All products were comprehensively characterised by spectroscopic methods and X-ray crystallography. Additionally, the intermediate products $(C_6F_5)_3BPH_2Li$ and $(C_6F_5)_3GaPPhH_2$ (**3**) were spectroscopically characterised.

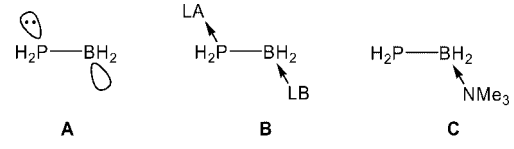
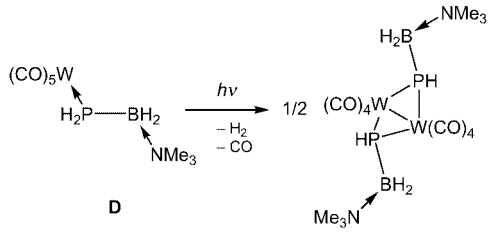
## Introduction

Phosphanylboranes $(R_2P–BR'_2)_n$ have attracted much attention since the beginning of the 90's.[1] However, attempts to isolate the parent compound of this class $(H_2P–BH_2)$ (**A**) (Scheme 1) have been futile, and only theoretical investigations on **A** have been performed.[2] Oligophosphanylboranes with the general formula $(HRP–BH_2)_n$ can be synthesised via dehydrocoupling reactions at elevated temperatures[3] or catalysed by either $Rh^I$ complexes (R = Ph)[4] or $B(C_6F_5)_3$ (R = H).[5] Experimentally accessible monomeric phosphanylboranes are mostly stabilised by sterically demanding substituents to avoid intermolecular oligomerisation.[1] Our approach to the parent compounds of phosphanylboranes was to stabilise them by the coordination of Lewis acids and Lewis bases as type **B** compounds. By this way the lone pair of the pnicogen is occupied by a Lewis acid (LA) and the Group 13 element is coordinated by a Lewis base (LB) (**B**).[6] Recently we were able to synthesise the first phosphanylborane **C**, which is stabilised only by a Lewis base.[7]

The Lewis acid stabilised phosphanylboranes that we synthesised carry transition metal carbonyls as the Lewis acid.[6] In contrast, less is known about main group Lewis acid stabilised group 13/15 compounds.[5,7,8] A disadvantage of transition metal carbonyls as Lewis acids is their influence on the reactivity of the phosphanylboranes [Equation (1)]. For example, photolysis of compound **D** leads to a dimer with elimination of CO and $H_2$.[6] Furthermore, the reaction of **D** with iodine leads to oxidation of the tungsten atom with concomitant loss of CO and not, as expected, to halogenation of the phosphorus atom.[9]



Scheme 1.



(1)

In order to circumvent the problem of CO elimination reactions, we decided to use main group Lewis acids for the synthesis of LA/LB stabilised phosphanylboranes.

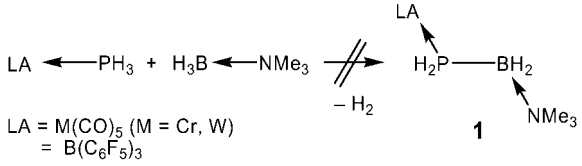
Herein we report on the synthesis and characterisation of hydrogen substituted LA/LB stabilised phosphanylboranes with $B(C_6F_5)_3$ and $Ga(C_6F_5)_3$ as main group Lewis acids.[10] Furthermore, the synthesis of the LA/LB stabilised phosphanylboranes is described which are substituted with a phenyl group at the phosphorus atom.



(2)

## Results and Discussion

### Synthesis and Spectroscopic Characterisation of the Lewis Acid/Base-Stabilised Phosphanylboranes

For the synthesis of the type **B** compounds containing transition metal carbonyls as the LA, the salt elimination method was chosen as a general synthetic route since the $H_2$ elimination had failed. The same behaviour was found for the main group LA containing compounds [Equation (2)].

Thus, for the synthesis of the LA/LB stabilised phosphanylborane **1** [Equation (3)] $(C_6F_5)_3BPH_3$ was metallated in toluene with *n*BuLi. The $^{31}P$ NMR spectrum of the in situ generated $[(C_6F_5)_3BPH_2Li]$ in $[D_8]$THF exhibits a multiplet of triplets at $\delta$ = –165.1 ppm (Figure 1). The strongly upfield shifted resonance of the phosphorus nucleus of $[(C_6F_5)_3BPH_2Li]$ can be attributed to the formation of a negatively charged phosphanido complex. The $^1J_{P,H}$ value of 180 Hz of $[(C_6F_5)_3BPH_2Li]$ is comparable with the coupling constant in $BH_3PH_2Li$ ($^1J_{P,H}$ = 175).[11] By treating $[(C_6F_5)_3BPH_2Li]$ with $ClBH_2NMe_3$, $(C_6F_5)_3BPH_2BH_2NMe_3$ (**1**) is formed [Equation (3)].

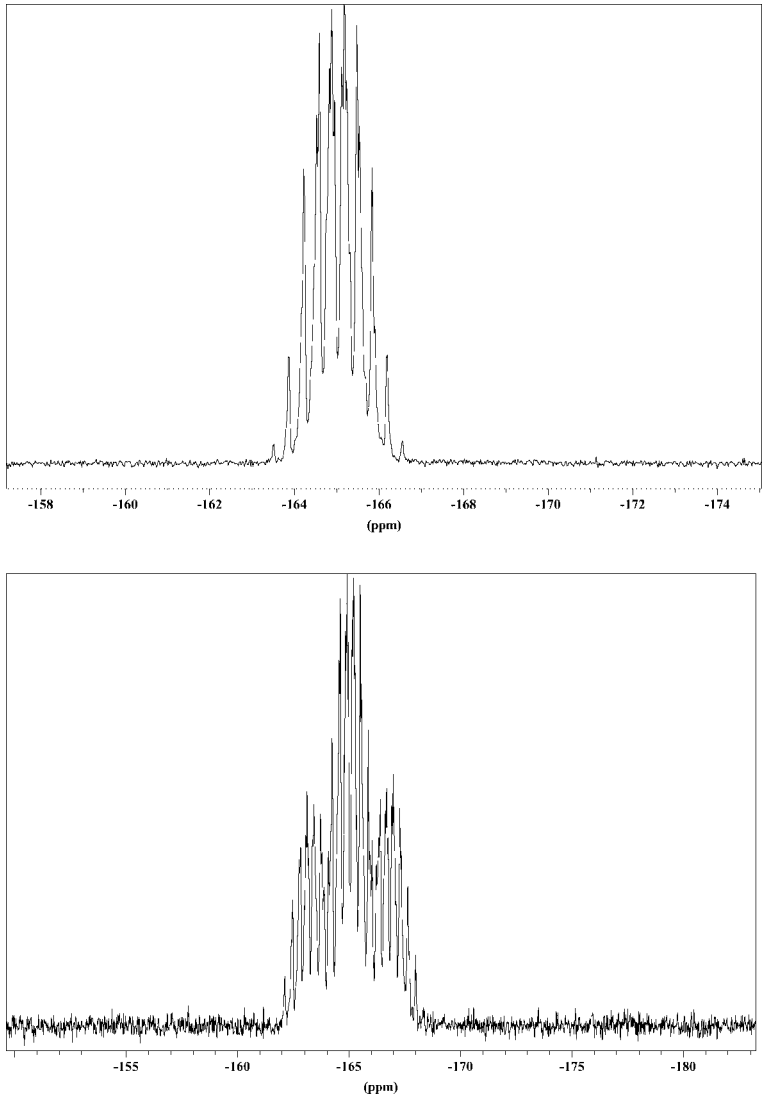


Figure 1. $^{31}P\{^1H\}$ (top) and $^{31}P$ NMR spectra (bottom) of $[(C_6F_5)_3BPH_2Li]$.

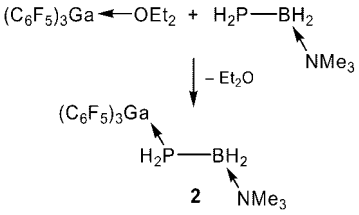
(3)

Since $(C_6F_5)_3GaPH_3$ could not be synthesised in sufficient amounts, the LiCl-elimination route is unsuitable.[12] An elegant way to obtain $(C_6F_5)_3GaPH_2BH_2NMe_3$ (**2**) in quantitative yields is the reaction of $(C_6F_5)_3Ga{\cdot}OEt_2$[13] with $PH_2BH_2NMe_3$ **C** in toluene according to Equation (4).



(4)

Furthermore, the synthesis of the LA/LB stabilised phosphanylboranes bearing a phenyl substituent at the P atom was of interest. This additional stabilisation could be helpful in subsequent investigations concerning the abstraction of the Lewis base.

Since $(C_6F_5)_3BPPhH_2$[5] was already described in the literature, the unknown Ga analogue $(C_6F_5)_3GaPPhH_2$ (**3**) was synthesised in almost quantitative yield by adding $PPhH_2$ to a solution of $(C_6F_5)_3Ga{\cdot}OEt_2$ in toluene [Equation (5)].

(5)

The $^1H$ NMR spectrum of **3** shows a doublet at $\delta$ = 4.53 ppm ($^1J_{P,H}$ = 369 Hz) attributable to the $PH_2$ protons. The phenyl protons are detected as multiplets between 6.65 and 6.85 ppm. The $^{31}P\{^1H\}$ NMR spectrum reveals a resonance at $\delta$ = –81.4 ppm which is detected as a triplet ($^1J_{P,H}$ = 369 Hz).

$(C_6F_5)_3GaPPhH_2$ (**3**) crystallises as colourless prisms in the triclinic space group $P\bar{1}$. The Ga–P bond length (2.477(1) Å] is within the normal range for Ga–P single bonds, which may vary from 2.256(3) Å to 2.462(3) Å.[1b,14] A π-stacking interaction between the phenyl ring at the P atom and one of the perfluorinated phenyl rings of $(C_6F_5)_3Ga$ is observed (Figure 2) with a distance of 3.851(1) Å between the ring centres, which is longer than the interlayer distance in graphite (3.354 Å). The angle between the planes of these two phenyl rings was determined to be 24.04°. These results are in good agreement with known aryl–perfluoroaryl π-interactions, where the distances and angles between the aromatic rings are in the range of 3.3 to 3.8 Å and 20°, respectively.[15–17]

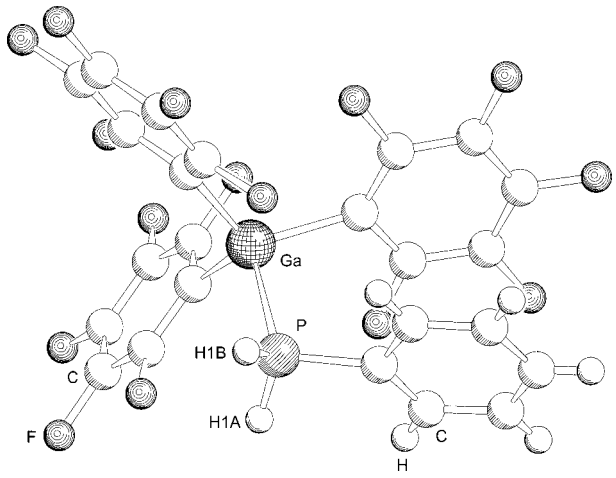


Figure 2. Molecular structure of $(C_6F_5)_3GaPPhH_2$ (**3**) in the crystal.

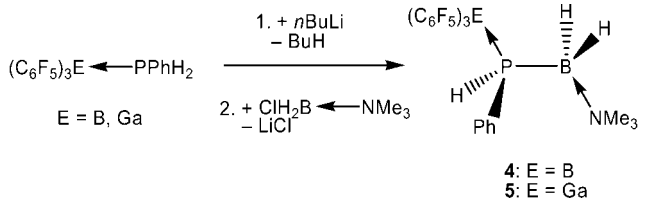
Metalation of $(C_6F_5)_3GaPPhH_2$ **3** as well as of $(C_6F_5)_3BPPhH_2$ with *n*BuLi leads to $[(C_6F_5)_3EPPhHLi]$ which were then treated with $ClBH_2NMe_3$ to yield colourless crystals of $(C_6F_5)_3BPPhHBH_2NMe_3$ (**4**) and $(C_6F_5)_3GaPPhHBH_2NMe_3$ (**5**), respectively [Equation (6)].



(6)

Only in the mass spectrum of **5** is the molecular ion peak detected. In the case of **1**, **4** and **5** the highest peak is that of the Lewis acid $[E(C_6F_5)_3]^+$. Furthermore, in the mass spectrum of **2** a peak corresponding to $[PH_2BH_2NMe_3]^+$ was found. The IR spectra of the compounds **1**, **2**, **4** and **5** reveal absorptions in the range of 2410 $cm^{-1}$ to 2460 $cm^{-1}$ for the B–H stretching modes and the P–H stretching frequencies appear between 2320 $cm^{-1}$ and 2440 $cm^{-1}$. The $^{19}F$ NMR spectra of the products show the three separated resonances for *ortho*-, *meta*- and *para*-fluorine atoms. The *ortho* and the *meta* resonances of **1** are slightly upfield shifted compared to the corresponding resonances of free $(C_6F_5)_3B$.[18] The *para*-fluorine resonance of **1**, in which the boron atom of the Lewis acid is in a tetrahedral environment, is shifted downfield by about 10 ppm relative to that of free $(C_6F_5)_3B$ in which the boron atom possesses a trigonal planar geometry.

In the $^1H$ NMR spectrum of **1** a singlet is detected at $\delta$ = 2.11 ppm for the trimethylamine group, and a doublet at $\delta$ = 4.0 ppm ($^1J_{P,H}$ = 345 Hz) arising from the $PH_2$ protons. The $^{31}P\{^1H\}$ NMR spectrum of **1** shows a broadened singlet at $\delta$ = –109.8 ppm, while the proton-coupled spectrum reveals a broad triplet ($^1J_{P,H}$ = 345 Hz). Also, the $^{11}B\{^1H\}$ NMR spectrum shows a broad resonance at $\delta$ = –0.4 ppm

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for the $BH_2$ moiety, which splits into a broad triplet with a boron–hydrogen coupling constant of $^1J_{B,H}$ = 133 Hz when the spectrum is measured with proton coupling. In comparison with the trigonal planar surrounded boron atom of free $B(C_6F_5)_3$, which can be detected in its $^{11}B$ NMR spectrum at $\delta$ = 59.6 ppm, the resonance of the boron atom of the LA in compound **1**, which is in a tetrahedral environment, is shifted strongly upfield and appears at $\delta$ = –18.3 ppm as a broad singlet.

The chemical shift for the methyl protons of the Lewis base of **2** is detected at $\delta$ = 1.48 ppm in the $^1H$ NMR spectrum and the $PH_2$ protons show a broad doublet at $\delta$ = 2.85 ppm ($^1J_{P,H}$ = 318 Hz). The $^{31}P$ NMR spectrum of **2** shows a broad triplet at $\delta$ = –161.1 ppm ($^1J_{P,H}$ = 321.8 Hz) and a broad singlet in the case of the $^{31}P\{^1H\}$ NMR spectrum. In the $^{11}B\{^1H\}$ NMR spectrum the resonance for the boron nucleus is detected at $\delta$ = –10.81 ppm as a broad singlet, with no discernible fine structure. Acquisition of the proton-coupled spectrum only leads to broadening of this signal.

The $^1H$ NMR spectrum of **4** shows a singlet at $\delta$ = 1.33 ppm which can be assigned to the $NMe_3$ group, a resonance for the P–H proton, which splits into a doublet at $\delta$ = 5.44 ppm ($^1J_{P,H}$ = 353 Hz), and multiplets for the aromatic protons between 6.8 and 7.0 ppm. The $^{31}P\{^1H\}$ NMR spectrum shows a resonance at $\delta$ = –51.5 ppm, which is detected in the $^{31}P$ NMR as a doublet ($^1J_{P,H}$ = 352 Hz). The boron atom of the Lewis acid $(C_6F_5)_3B$ can be detected in the $^{11}B$ NMR and $^{11}B\{^1H\}$ NMR spectra ($\delta$ = –14.7 ppm) as can that of the $BH_2$ group ($\delta$ = –10.8 ppm). The latter signal is only revealed as a broad singlet, displaying no splitting into a triplet when a proton-coupled spectrum of **4** is recorded.

The $^1H$ NMR spectrum of **5** shows a broadened doublet at $\delta$ = 4.53 ppm arising from the PH unit ($^1J_{P,H}$ = 328 Hz). The $NMe_3$ resonance is detected at $\delta$ = 1.34 ppm and the protons of the phenyl group are split into a multiplet between 6.8 and 6.9 ppm. The $^{31}P\{^1H\}$NMR spectrum of **5** shows a resonance at $\delta$ = –77.9 ppm, which is detected as a triplet ($^1J_{P,H}$ = 328 Hz) in the $^{31}P$ NMR spectrum. The $^{11}B\{^1H\}$ NMR spectrum shows a broad signal at $\delta$ = –9.7 ppm, which reveals slightly broadening in the proton-coupled spectrum.

## X-ray Structural Characterisation of the Lewis Acid/Base-Stabilised Phosphanylboranes

The compounds **1**–**5** crystallise as colourless prisms from a mixture of toluene and *n*-hexane. The structures were confirmed by X-ray diffraction studies (Table 2). Selected bond lengths and angles of the compounds **1**, **2**, **4** and **5** are listed in Table 1.

**1**, **2**, **4** and **5** show the same HRP–$BH_2$ structural motif [**1**, **2**: R = H (Figure 3); **4**, **5**: R = Ph (Figure 4)] in the solid state. This moiety is coordinated to the Lewis acid (**1**, **4**: $B(C_6F_5)_3$; **2**, **5**: $Ga(C_6F_5)_3$) by the lone pair of the phosphorus atom, so that the phosphorus is surrounded by four substituents. The boron atom is in a tetrahedral environment due to coordination of the Lewis base $NMe_3$. The Lewis acid (**1**, **4**: $B(C_6F_5)_3$; **2**, **5**: $Ga(C_6F_5)_3$) and the Lewis base $NMe_3$ adopt a *trans* arrangement and the substituents around the P–B bond are arranged in a slightly staggered geometry. The compounds **1** and **2** are isostructural and crystallise in the centrosymmetric space group $P\bar{1}$ revealing

Table 1. Selected bond lengths [Å] and angles [°] of the phosphanylboranes **1**, **2**, **4** and **5**.

the same staggered geometry around the P–B core as both enantiomers show which are present in the solid state (Figure 5, a).

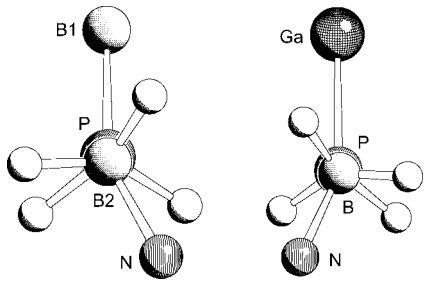

Figure 5. Staggered conformation around the B–P bonds in **1** (left, E = B) and **2** (right, E = Ga).

Besides the LA and LB, **1** and **2** are only substituted by hydrogen atoms. The P–B bond distances of **1** [(1.989(4) Å] and **2** [(1.992(2) Å] agree well with usual P–B single-bond distances, which range from 1.90 Å to 2.0 Å.[1] A comparison with the P–B bond length in $[W(CO)_5PH_2BH_2NMe_3]$ **D** [(1.955(2) Å] shows that compounds **1** and **2** possess slightly longer P–B bond distances. The P–B bond distance in the calculated LA and LB free compound **A** is with 1.90 Å[2b] (1.905 Å[2c]) slightly shortened due to a small P–B π-bond contribution in **A**, which is absent in the LA/LB stabilised molecules **1** and **2**. Whereas the P–B–N angles of **1** [(112.2(2)°] and **2** [(113.36(14)°] are very similar, the LA–P–B angles differ significantly [**1**: 122.98(13)°; **2**: 116.55(8)°], revealing the different valence radii of the boron and gallium atoms in the LA.

Compounds **4** and **5**, which possess a phenyl substituent at the phosphorus atom, show similar structures, although they do not crystallise in the same space group. The values of their P–B bond distances do not differ much. Their P–B–N angles are very similar [**4**: 116.05(16); **5**: 115.06(16)°], as are their LA–P–B angles [**4**: 111.02(10)°; **5**: 114.17(9)°]. The substituents around the P–B core in **4** and **5** adopt a staggered geometry (Figure 6).

Whereas the Ga containing LA substituted compound **5** shows some π-stacking interaction between one of the perfluorinated phenyl rings of the LA and the phenyl substituent at the phosphorus atom (Figure 7), no π-stacking interaction is noticeable in **4**. The center-to-center distance of the phenyl rings in **5** is 4.082 Å, which is longer than the distance between the fluoroaryl and the aryl groups in **3** (3.851 Å). The angle formed by the two planes of the staggered phenyl rings is 29°.

In comparison with the bond distance of the B–P core of the phosphanylboranes the boron containing LA–P bond distances in **1** and **4** are slightly elongated [**1**: 2.076(3) Å; **4**: 2.046(3) Å]. The Ga–P bond distance in compound **5** [2.424(1) Å] shows nearly the same length as that that is found in the starting material **3** [2.477(1) Å], and is in the normal range for a Ga–P single bond, which varies between 2.256(3) Å and 2.462(3) Å.[1b,14] The value of the Ga–P bond length of compound **2** [2.393(1) Å] also lies within this range.

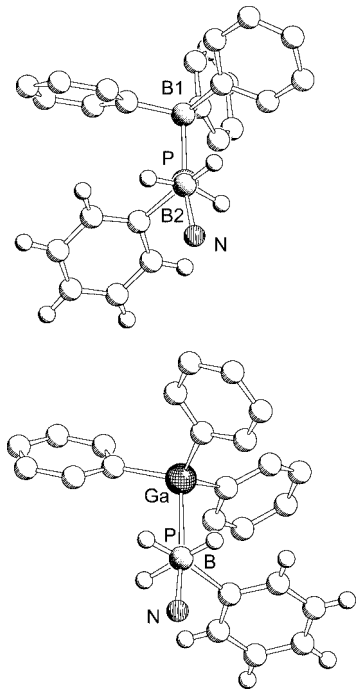

Figure 6. Staggered geometries of **4** (top, E = B) and **5** (bottom, E = Ga). F atoms and Me groups are omitted for clarity.

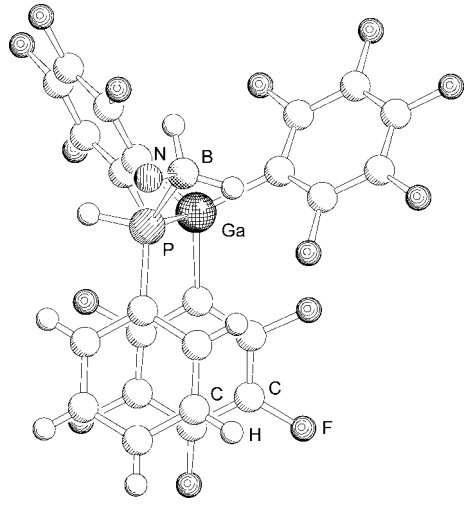

Figure 7. π-stacking interaction in **5**.

In 2003 Denis et al. reported on the dehydrocoupling between $(C_6F_5)_3BPH_2R$ (R = H or Ph) and $BH_3/SMe_2$ to form $(C_6F_5)_3BPH_2BH_2SMe_2$ and $(C_6F_5)_3BPH(Ph)$-$BH_2SMe_2$.[5] They described a subsequent polymerization at 20 °C in the case of the phenyl-substituted derivative and at 110 °C for 3 h in the case of the hydrogen substituted derivative, which led to the formation of the polymers $[PHRBH_2]_n$ (R = H or Ph) and $(C_6F_5)_3BSMe_2$, as confirmed by NMR studies. In contrast the $NMe_3$-substituted LA/LB-stabilised phosphanylboranes **1**, **2**, **4**, and **5**, which we report herein, show a very high thermal stability up to 150 °C, without any signs of decomposition or dehydrocoupling to form polymerisation products.

## Conclusions

The results reported herein have shown that we were able to use perfluorinated main group Lewis acids to prepare LA/LB-stabilised phosphanylboranes. The parent compound $H_2P–BH_2$ can be stabilised with $NMe_3$ as the Lewis base and $B(C_6F_5)_3$ (**1**) or $Ga(C_6F_5)_3$ (**2**) as the main group Lewis acid. Furthermore the synthesis of the phenyl-substituted LA/LB stabilised phosphanylboranes **4** and **5** was achieved. In the solid state, the substituents in all products show a staggered geometry around the central P–B core. In the Ga containing compounds **3** and **5**, π-stacking interactions between one of the perfluorinated phenyl rings of the LA and the phenyl substituent at the phosphorus atom contribute to their stability. These compounds do not show any tendency to polymerise in contrast to previously reported $SMe_2$-substituted compounds.[5] Furthermore we expect that removal of the Lewis base from the synthesised compounds will yield stable derivatives stabilised only by a Lewis acid. These investigations are in progress.

## Experimental Section

**General Techniques:** All manipulations were performed under an atmosphere of dry nitrogen using standard Glovebox and Schlenk techniques. Solvents were purified and degassed by standard procedures. The compounds $B(C_6F_5)_3$,[13] $(C_6F_5)_3GaOEt_2$,[13] $(C_6F_5)_3BPH_3$,[19] $(C_6F_5)_3BPPhH_2$,[5] $PH_2BH_2NMe_3$,[7] $ClBH_2NMe_3$[20] and $PPhH_2$[21] were prepared according to the literature procedures. *n*BuLi (Fluka, 1.6 molar solution in *n*-hexane) was used as received.

The NMR spectra were recorded on either a Bruker 300 or Avance 400 spectrometer with $\delta$ referenced to external $SiMe_4$ ($^1H$), $H_3PO_4$ ($^{31}P$), $BF_3–Et_2O$ ($^{11}B$) and $CFCl_3$ ($^{19}F$). IR spectra were measured on a DIGILAB (FTS 800) FT-IR spectrometer. All mass spectra were recorded on a Finnigan MAT 95 (FD) or a Finnigan MAT SSQ 710 A (EI, 70 eV) instrument.

**Synthesis of $(C_6F_5)_3BPH_2BH_2NMe_3$ (1):** To a solution of $(C_6F_5)_3BPH_3$ (170 mg, 0.31 mmol) in toluene (20 mL), *n*BuLi (0.19 mL, 0.31 mmol) is added dropwise at 0 °C. After stirring the solution at room temperature for 3 h, the formation of $(C_6F_5)_3BPH_2Li$ is confirmed by $^{31}P$ NMR ([D$_8$]THF, 101.256 MHz, $\delta$ = –165.14, mt, $^1J_{P,H}$ = 180 Hz, $PH_2$). $ClBH_2NMe_3$ (33 mg, 0.31 mmol) is then added and the mixture is stirred at room temperature for 18 h. The LiCl precipitate is filtered through a plug of Celite and the resulting solution is concentrated to 2 mL in vacuo. Colourless crystals of **1** are obtained as prisms by slow diffusion of *n*-hexane into this solution of **1** at room temperature. Yield 163 mg (85%). $^1H$ NMR ($C_6D_6$, 25 °C, 250 MHz): $\delta$ = 2.11 (s, 9 H, $N(CH_3)_3$), 4.0 (dm, $^1J_{P,H}$ = 345 Hz, 2 H, $PH_2$) ppm. $^{31}P$ NMR ($C_6D_6$, 25 °C, 101.3 MHz): $\delta$ = –109.66 (br. t, $^1J_{P,H}$ = 345 Hz, $PH_2$) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = –109.81 (br. s, $PH_2$) ppm. $^{11}B$ NMR ($C_6D_6$, 25 °C, 96.3 MHz): $\delta$ = –0.42 (br. t, $^1J_{B,H}$ = 133 Hz, $BH_2$), –18.27 (br. s, $B(C_6F_5)_3$) ppm. $^{11}B\{^1H\}$ NMR: $\delta$ = –0.4 (br. s, $BH_2$), –18.27 (br. s, $B(C_6F_5)_3$) ppm. $^{19}F$ NMR ($C_6D_6$, 25 °C, 282.4 MHz): $\delta$ = –130.8 (br. s, 6 F, *o*-F), –157.52 (t, $^3J_{F,F}$ = 20.8 Hz, 3 F, *p*-F), –164.03 (m, 6 F, *m*-F) ppm. EI-MS (70eV, 180 °C): *m*/*z* (%) = 512 (100) $[(C_6F_5)_3B]^+$, 168 (52) $[C_6F_5H]^+$, 58 (64) $[NMe_3–H]^+$. Raman (Solid): $\tilde{\nu}$ = 3027 (s, CH), 2973 (s, CH), 2956 (s, CH), 2871 (s, CH), 2471 (br. m, BH), 2433 (s, PH), 2394 (vs, PH), 1647 (s, CF), 1377 (m), 975 (br. m), 850 (s), 595 (m), 581 (s), 490 (s), 472 (m), 448 (s), 394 (s) cm$^{-1}$. IR (KBr): $\tilde{\nu}$ = 3026 (s, CH), 2962 (s, CH), 2925 (m, CH), 2853 (w, CH), 2463 (s, BH), 2433 (s, BH), 2394 (w, PH), 2324 (vw, PH), 1647 (vs, CF), 1601 (w), 1518 (vs), 1464 (vs), 1376 (s), 1281 (s), 1130 (s), 1110 (vs), 1085 (s), 1071 (w, sh), 982 (s), 966 (s), 868 (m), 826 (m), 784 (s), 772 (s), 736 (m), 709 (m), 674 (s), 670 (s, sh), 624 (m), 575 (m), 472 (br. m) cm$^{-1}$. $C_{21}H_{13}B_2F_{15}NP$ (616.9): calcd. C 40.88, H 2.12, N 2.27; found C 41.25, H 2.38, N 2.28.

**Synthesis of $(C_6F_5)_3GaPH_2BH_2NMe_3$ (2):** $(C_6F_5)_3GaOEt_2$ (356 mg, 0.552 mmol) is added to a solution of $PH_2BH_2NMe_3$ (0.058 mg, 0.552 mmol) in toluene (25 mL). After stirring for 18 h, the solution is concentrated to ca. 4 mL in vacuo. Colourless crystals of **2** are obtained by slow diffusion of *n*-hexane into this solution at room temperature. Yield 401 mg (97%). $^1H$ NMR ($C_6D_6$, 25 °C, 300 MHz): $\delta$ = 1.48 (s, 9 H, $N(CH_3)_3$), 2.85 (br. d, $^1J_{P,H}$ = 318 Hz, 2 H, $PH_2$) ppm. $^{31}P$ NMR ($C_6D_6$, 25 °C, 121.5 MHz): $\delta$ = –161.13 (br. t, $^1J_{P,H}$ = 321.8 Hz, $PH_2$) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = –161.14 (s, $PH_2$) ppm. $^{11}B$ NMR ($C_6D_6$, 25 °C, 128.4 MHz): $\delta$ = –10.94 (br. s, $BH_2$) ppm. $^{11}B\{^1H\}$ NMR: $\delta$ = –10.81 (br. s, $BH_2$) ppm. $^{19}F$ NMR ($C_6D_6$, 25 °C, 282.4 MHz): $\delta$ = –122.7 (d, $^3J_{F,F}$ = 18.5 Hz, 6 F, *o*-F), –154.4 (t, $^3J_{F,F}$ = 19.6 Hz, 3 F, *p*-F), –161.9 (m, 6 F, *m*-F) ppm. EI-MS (70 eV): *m*/*z* (%) = 570 (21) $[[(C_6F_5)_3Ga]^+]$, 403 (43) $[[(C_6F_5)_2Ga]^+]$, 168 (100) $[[C_6F_5H]^+]$, 105 (12) $[[PH_2BH_2NMe_3]^+]$. IR (KBr): $\tilde{\nu}$ = 3026 (s, CH), 2961 (s, CH), 2925 (m, CH), 2853 (br. m, CH), 2454 (s, BH), 2424 (s, BH), 2374 (br. m, PH), 2318 (m, PH), 1643 (vs, CF), 1613 (w), 1556 (w, sh), 1511 (vs), 1467 (vs), 1445 (m, sh), 1411 (m), 1363 (s), 1268 (s), 1243 (m), 1160 (s), 1126 (s), 1066 (vs), 1015 (m), 960 (vs), 863 (s), 798 (m), 756 (m), 740 (w), 720 (w), 700 (m), 608 (m), 490 (m) cm$^{-1}$. $C_{21}H_{13}BF_{15}GaNP$ (675.8): calcd. C 37.32, H 1.94, N 2.07; found C 37.21, H 2.01, N 2.02.

**Synthesis of $(C_6F_5)_3GaPPhH_2$ (3):** $PhPH_2$ (0.852 mL, 0.853 g, 7.75 mmol) is added slowly to a solution of $(C_6F_5)_3GaOEt_2$ (5 g, 7.75 mmol) in toluene (70 mL) at 0 °C. After stirring the solution for 18 h at room temperature the solvent is removed in vacuo and the residue is washed with *n*-hexane (3 × 20 mL) leaving $(C_6F_5)_3GaPPhH_2$ as a white powder. Single crystals of **3** can be obtained by recrystallisation from a mixture of toluene and *n*-hexane as colourless prisms. Yield 5.06 g (91%). $^1H$ NMR ($C_6D_6$, 25 °C, 400 MHz): $\delta$ = 4.53 (d, $^1J_{P,H}$ = 369 Hz, 2 H, $PH_2$), 6.65–6.85 (m, 5 H, Ph) ppm. $^{31}P$ NMR ($C_6D_6$, 25 °C, 162 MHz): $\delta$ = –81.44 (t, $^1J_{P,H}$ = 369 Hz, $PH_2$) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = –81.44 (s, $PH_2$) ppm. $^{19}F$ NMR ($C_6D_6$, 25 °C, 376.5 MHz): $\delta$ = –122.89 (d, $^3J_{F,F}$ = 17 Hz, 6 F, *o*-F), –151.73 (t, $^3J_{F,F}$ = 20 Hz, 3 F, *p*-F), –160.46 (m, 6 F, *m*-F) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$, 25 °C, 75.5 MHz): $\delta$ = 129.19 (d, $^3J_{C,P}$ = 9 Hz, *m*-C ($C_6H_5$)), 130.74 (s, *p*-C ($C_6H_5$)), 133.79 (d, $^2J_{C,P}$ = 12 Hz, *o*-C ($C_6H_5$)), 137.42 (br. d, $^1J_{C,F}$ = 250 Hz, *p*-C, $Ga(C_6F_5)_3$), 142.06 (br. d, $^1J_{C,F}$ = 254 Hz, *m*-C, $Ga(C_6F_5)_3$), 148.97 (br. d, $^1J_{C,F}$ = 235 Hz, *o*-C, $Ga(C_6F_5)_3$) ppm. EI-MS (70 eV, toluene): *m*/*z* (%) = 570 (15) $[Ga(C_6F_5)_3]^+$, 168 (100) $[C_6F_5H]^+$. IR (KBr): $\tilde{\nu}$ = 3067 (m, CH), 2968 (w, CH), 2916 (w, CH), 2880 (w, CH), 2405 (m, PH), 2323 (m, PH), 1639 (s, CF), 1613 (w), 1576 (w), 1555 (w, sh), 1510 (vs), 1468 (vs), 1443 (s, sh), 1365 (s), 1271 (s), 1221 (m), 1127 (m), 1086 (s, sh), 1068 (vs), 1024 (m), 999 (m), 962 (vs), 844 (s), 799 (m), 738 (s), 719 (w), 691 (m), 611 (m), 582 (w), 491 (m), 460 (w), 412 (m) cm$^{-1}$. $C_{24}H_7F_{15}GaP$ (681): calcd. C 42.33, H 1.04; found C 42.17, H 1.12.

**Synthesis of $(C_6F_5)_3BPPhHBH_2NMe_3$ (4):** To a solution of $(C_6F_5)_3BPPhH_2$ (298 mg, 0.479 mmol) in toluene (25 mL), *n*BuLi (0.3 mL, 0.48 mmol) is added slowly at 0 °C. After stirring the solution at room temperature for 1 h, $ClBH_2NMe_3$ (51 mg, 0.475 mmol) is added and the solution is stirred overnight at room

diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods with the program SHELXS-97,[23a] and full-matrix least-squares refinement on $F^2$ in SHELXL-97[23b] was performed with anisotropic displacements for non-H atoms. Hydrogen atoms at the carbon atoms were located in idealised positions and refined isotropically according to the riding model. The hydrogen atoms at the phosphorus and boron atoms could be localised by residual electron density and freely refined. CCDC-630846 (for **1**), -630849 (for **2**), -630847 (for **3**), -630850 (for **4**), and -630848 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Aiding Factors in the Formation of Azaplatinacyclobutane Rings – X-ray and Crystal Structure of [Pt{CH(Ph)$CH_2$$NEt_2$-κC,κN}(*N*,*N*,*N*′,*N*′-tetramethylethylenediamine)]$^+$ and of Its Open-Chain Precursor

**Giuseppe Lorusso,[a] Carmen R. Barone,[a] Nicola G. Di Masi,[a] Concetta Pacifico,[a] Luciana Maresca,*[a] and Giovanni Natile[a]**

**Keywords:** Chelates / Metallacycles / N ligands / Nucleophilic addition / Platinum

The addition products **2** of a secondary amine to a coordinated olefin, in the cationic complexes [PtCl(η$^2$-$CH_2$=CHR)(tmeda)]$^+$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine; R = Me, **1a**; Ph, **1b**, H, **1c**), undergo in basic medium an intramolecular nucleophilic substitution with elimination of the chlorido ligand and formation of an azaplatinacyclobutane ring **3**. The ring-closing process occurs notwithstanding the absence of a labilizing ligand *trans* to the leaving chlorido ligand and of bulky substituents on the amino–ethanide chain. If the addition product **2** is a mixture of Markovnikov and anti-Markovnikov isomers, the ring-closing reaction is faster for the anti-Markovnikov form, and this leads to an increase of the relative amount of the anti-Markovnikov isomer in the cyclized species **3**. The difference in the rate of formation of the azaplatinacyclobutane ring between the two isomers has been interpreted on the basis of a more favorable stereochemistry in the case of the anti-Markovnikov form. The X-ray crystal structures of [Pt{CH(Ph)$CH_2$$NEt_2$-κC,κN}(tmeda)]$^+$ (**3bn**) and of its open-chain precursor, [PtCl{CH(Ph)$CH_2$$NHEt_2$}(tmeda)]$^+$ (**2bn**) fully support this hypothesis.

## Introduction

A number of azametallacyclobutanes have been reported in the literature; in some cases they have been isolated and fully characterized, while in other cases they have only been detected in solution, or proposed as key intermediates in catalytic processes concerned with the hydroamination of olefins and allenes.[1–8]

The reaction sequence leading to their formation is very much dependent upon the nature of the metal involved. In the case of early transition metals, the azametallacyclobutanes are generated by [2+2] cycloaddition of an olefin to a metalla-imido moiety (M=NR).[1] The reaction is generally reversible, and in the specific case of [$Cp_2$(THF)Zr(=*N*-*t*Bu)] reacting with norbornene, the formed azazirconacyclobutane was also structurally characterized.[1b]

A different and more complex reaction pathway was proposed for the formation of an azatungstacyclobutane. The allenyl precursor, $Cp(CO)_3W$–CH=C=$CH_2$, underwent methylamine addition both at a carbonyl ligand (which was transformed into a carbamoyl group) and at the β-carbon atom of the allenyl ligand (across the terminal double bond), accompanied by a regiospecific coupling of the amido group with the α-carbon atom of the allenyl ligand and the coordination of the amine to the tungsten metal center.[2]

Also in the case of late transition metals, several procedures have been reported to lead to the formation of azametallacyclobutanes. For instance, in the iridium-catalyzed hydroamination of norbornene, reported by Calabrese et al., a very reactive 14-electron iridium complex first undergoes oxidative addition with aniline followed by [2+2] cycloaddition of the formed metalla-amido moiety to norbornene to form an azairidacyclobutane complex.[3] An azairidacyclobutane is also formed by a ring-closing reaction (with elimination of HCl) of an iridium 2-aminoethanide complex obtained by the photolysis of an iridium hydride species in the presence of *tert*-butylamine.[4]

More recently, Puddephatt has reported a platinum(IV) complex containing an azaplatinacyclobutane ring obtained through oxidative addition of a protonated tethered imine group present on a platinum(II)-coordinated amine (the azaplatinacyclobutane ring resulting from the coordination of the imine carbon and the nitrogen atom of a 2-pyridyl substituent present on the imine carbon atom to the platinum atom).[5]

More often, 2-aminoethanide species are formed through nucleophilic addition of an amine to a coordinated olefin followed by a ring-closing process.[6–8] By this procedure stable azaplatinacyclobutane complexes have been prepared since the early 1980's. Their isolation was strictly dependent

upon the nature of the ancillary ligands and the presence of substituents on the metal-coordinated olefin and on the attacking amine.[6,7] Starting from a complex such as *cis*-[$PtCl_2(L)(\eta^2$-alkene/allene)], the addition to the olefin of a secondary amine leads to a zwitterionic species (formal negative charge on the platinum atom and positive charge on the nitrogen ammonium group), which can eliminate HCl and form an azaplatinacyclobutane ring. The reaction occurs readily when L is a *trans*-labilizer (phosphorus or sulfur donor ligand).[6,7] When L is a N-donor ligand, the ring-closing reaction is observed only in the case of olefins bearing substituents on the α and/or β carbon atoms.[7] Azaplatinacyclobutanes formed in the case of L = triphenylphosphane have also been characterized by X-ray crystallography.[6]

We have recently reconsidered the amination reaction of platinum-coordinated olefins in some cationic complexes and observed a facile ring closing of the 2-ammonium ethanide species obtained therefrom, with the ready formation of azaplatinacyclobutane rings. The results, hereafter described, have allowed us to gain new insights into factors governing this reaction (for a preliminary account see ref.[10]).

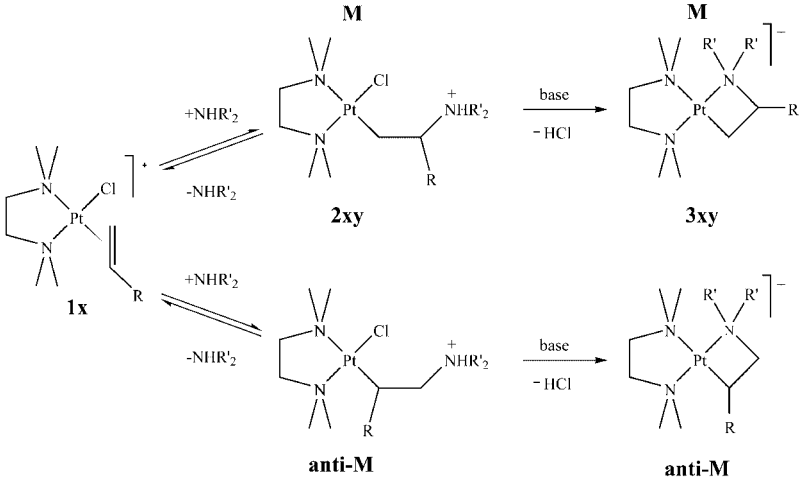
## Results and Discussion

The cationic complexes [$PtCl(\eta^2$-olefin)(tmeda)]$^+$ (**1**)[9] (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine; olefin = alkyl or aryl-substituted ethene such as propene, **1a**, or styrene, **1b**) react quickly and smoothly with secondary amines (such as dimethylamine, **m**, and diethylamine, **n**) to give the corresponding $\eta^1$-2-ammonium ethanide species **2** (see Scheme 1). Species of type **2** exist as equilibrium mixtures of Markovnikov (**M**) and anti-Markovnikov (**anti-M**) forms; the interconversion process most likely requires the detachment and re-addition of the amine as illustrated in Scheme 1. The thermodynamically determined isomeric ratio is largely in favor of the Markovnikov form in the case of **2an** and in favor of the anti-Markovnikov isomer in the case of **2bm**,**n**.[10]

Under basic conditions, the product of amination (**2** in Scheme 1) undergoes deprotonation followed by displacement of the *cis* chlorido ligand by the amine nitrogen atom and formation of an azaplatinacyclobutane species (**3** in Scheme 1). We have found that the **M/anti-M** ratio decreases on going from the linear addition product to the ring-closed species. Therefore, the linear addition product **2an**, containing at equilibrium a **M/anti-M** ratio of 95:5, yields, upon ring-closing, compound **3an**, in which the **M/anti-M** ratio decreases to 75:25. Similarly, the linear addition product **2bm**, in which at equilibrium the **M/anti-M** ratio was 30:70, gives, after the ring-closing process, compound **3bm**, in which the anti-Markovnikov isomer is the exclusive form. This behavior can be explained with a greater propensity of the linear anti-Markovnikov addition product to undergo the ring-closing reaction.

The cyclization reaction of **2an** and **2bm** (leading to **3an** and **3bm**, respectively), performed in an NMR tube under basic conditions, did show the formation of trace amounts of byproducts that were probably due to the reaction of species **1a** and **1b**, which are intermediates in the Markovnikov/anti-Markovnikov isomerization of **2a** and **2b**, with the base.[11] However, by operating on millimolar quantities and after work-up procedures, the species of type **3** were obtained in almost pure form (> 95%).

The structures of species **3** could be unequivocally determined by NMR techniques (1D and 2D $^1H$, $^1H/^{13}C$, APT). The Markovnikov and anti-Markovnikov isomers could be easily distinguished through the different patterns of connectivities in the metallacyclobutane ring. The separation of the Markovnikov and anti-Markovnikov isomers of **3an** (**3bm**,**n** are essentially formed as the **anti-M** isomer)[13] has not been attempted at this stage of the work.



**x** = **a** (R = $CH_3$), **b** (R = $C_6H_5$), **c** (R = H); **y** = **m** (R' = $CH_3$), **n** (R' = $CH_2CH_3$)

**M** = Markovnikov; **anti-M** = anti-Markovnikov

Some significant differences can be observed between the NMR parameters of the open-chain species **2** and the ring-closed species **3**. In particular, Cα is more shielded in **3** than in **2** while Cβ is more shielded in **2** than in **3** [for the pairs of compounds: **M-2an/M-3an**, **anti-M-2bm/anti-M-3bm**, and **anti-M-2bn/anti-M-3bn**; $\Delta\delta$(Cα) and $\Delta\delta$(Cβ) values are –17.8 and +6.3, –22.7 and +15.6, and –22.1 and +13.7 ppm, respectively]. Similarly to the carbon atom, the protons on the β carbon are also considerably less shielded in the cyclized species **3** than in the linear addition product **2** ($\Delta\delta$ in the range 0.6–1.9 ppm). The deshielding of the β protons was taken by Green et al. as an indicator for the occurrence of the ring-closing process[7] (although in that work the reaction stereochemistry and the possible formation of Markovnikov and anti-Markovnikov isomers were not discussed in detail). Another highly distinctive NMR feature of species **3** is the value of $^{3}J_{Pt,H}$ for the β protons, which can nearly reach 100 Hz, well above the observed values for the corresponding coupling in the linear compounds. It is worth noting that in the **anti-M** isomer, where there are two β protons, these protons are diastereotopic with a dispersion which can be as large as 1 ppm. Moreover, only for one of these protons (that at lower field), the $^{3}J_{Pt,H}$ is very high (78, 99, and 95 Hz for **anti-M-3an**, **anti-M-3bm**, and **anti-M-3bn**, respectively), while for the other proton (that at higher field) the $^{3}J_{Pt,H}$ is much smaller and ill-defined. Finally we have found that, on going form **2** to **3**, the resonance of the $^{195}$Pt nucleus shifts downfield by more than 300 ppm ($\Delta\delta$ = +354.4 and +415.7 ppm for **M-2an/M-3an** and **anti-M-2bn/anti-M-3bn**, respectively).

Crystals suitable for X-ray analysis were obtained for the **anti-M** isomers of **2bn** and **3bn**. The structures of **2bn** and **3bn**, together with the numbering scheme, are depicted in Figure 1 (bond lengths and angles are in Table 1). In both cases, the coordination around the platinum atom is roughly square planar, considering the four metal-linked atoms: the tmeda nitrogen atoms, the carbon, and the chlorine (**2bn**) or the nitrogen atom of the four-membered chelate (**3bn**). The maximum deviation from the mean plane through the four donor atoms applies to N1 in **2bn** and to C8 in **3bn** [–0.019(6) and –0.026(4) Å, respectively]; moreover, the displacement exhibited by the platinum atom is 0.0141(2) and –0.0214(1) Å for **2bn** and **3bn**, respectively. Bond lengths for Pt–C8, Pt–N1, and Pt–N2 fall in the usual range. A significant difference (0.09 and 0.12 Å, for **2bn** and **3bn**, respectively) is found between the two Pt–N bonds pertaining to the tmeda ligand, as a result of the stronger *trans* influence of the carbon atom with respect to the chlorine or nitrogen donor atoms. The penta-atomic ring, resulting from chelation of the tmeda ligand to the platinum atom, is puckered with displacements of the C1 and C2 carbon atoms on opposite sides of the plane defined by Pt, N1, and N2 [–0.44(1) and 0.24(1) Å for **2bn** and 0.398(6) and –0.310(6) Å for **3bn**].[14] In **2bn**, the C9–C8–C7–N3 torsion angle of –172.5(4)° indicates an antiperiplanar disposition of the phenyl and amine substituents on the ethanide chain. This brings the amine group in a synclinal disposition with respect to the platinum atom with a Pt–C8–C7–N3 torsion angle of –45.9(5)°. The proximity of the amine group to the chlorido ligand sets the nitrogen in a suitable position to undergo chlorido substitution and ring-closing reaction.

Table 1. Selected bond lengths [Å] and angles [°] for **2bn** and **3bn**.

| | **2bn** | **3bn** |
|---|---|---|
| Pt–C8 | 2.062(4) | 2.053(4) |
| Pt–N1 | 2.081(6) | 2.084(3) |
| Pt–N2 | 2.174(4) | 2.209(3) |
| Pt–N3 | | 2.085(3) |
| Pt–Cl1 | 2.312(2) | |
| N3–C7 | | 1.516(5) |
| C7–C8 | | 1.522(6) |
| C8–Pt–N1 | 91.5(2) | 100.3(2) |
| C8–Pt–N3 | | 70.4(2) |
| N1–Pt–N2 | 85.2(2) | 83.3(2) |
| N3–Pt–N2 | | 106.0(2) |
| N3–C7–C8 | | 103.5(3) |
| C8–Pt–Cl1 | 93.1(1) | |
| N2–Pt–Cl1 | 90.1(2) | |
| C7–C8–Pt | | 93.1(2) |

In **3bn**, the cyclobutane metallacycle is rather strained and "quasi" planar; as a consequence, the substituents on adjacent atoms of the aminoethanide chain are placed in eclipsed positions. Notwithstanding the large deviation from theoretical values of bond angles, bond lengths within the four-member metallacycle are rather normal and in agreement with values found in the analogous

[Pt($CH_2CH_2NMe_2$-κC,κN)Cl($PPh_3$)] complex, in which, however, the ethanide chain had no substituents and the Pt–N bond was *ca*. 0.04 Å longer because of the *trans* influence of phosphane.[6] The steric interaction between substituents on *cis* ligands [particularly C9···C3 = 3.426(8) and C6···C15 = 3.548(8) Å] can fully explain the pyramidal distortion of the platinum coordination center. Moreover, it can be noted that, in both compounds (**2bn** and **3bn**), the phenyl ring angle centered on the *ipso* carbon is smaller than all the others [C10–C9–C14 = 117.3(5)° and 117.3(4)° for **2bn** and **3bn**, respectively]. The distortion of benzene rings has been the object of careful studies by Domenicano et al., who have rationalized the deviations from a regular geometry in terms of electronegativity, resonance, and steric effects of the substituent. An angle that is less than 120° is indicative of the accumulation of negative charge on the *ipso* carbon induced by an electron-donor substituent (electron-withdrawing substituents produce the opposite effect).[15] Therefore, the platinum-bonded carbon atom behaves like an electron donor towards the *ipso* carbon atom of the phenyl ring, and the electronic characteristics of this carbon atom are rather similar for the two compounds.

Azaplatinacyclobutanes, analogous to those here described,[6,7] were already reported in the literature; however, all of them were characterized by the presence of a labilizing ligand *trans* to the ligand displaced in the ring-closing process (usually a chlorido), and/or by having substituents on the ethanide chain (the Thorpe–Ingold effect of these substituents promoting the chelate ring formation).[12] However, the ring-closing reaction readily occurs in our systems notwithstanding the absence of a labilizing ligand *trans* to the leaving chlorido ligand. Moreover, although compounds **2an** and **2bm**,**n** contain a substituent (a methyl and a phenyl, respectively) on the ethanide chain, we could prove that compound [PtCl($\eta^1$-$CH_2CH_2NHEt_2$)(tmeda)]($ClO_4$), **2cn**, which has no substituents on the ethanide chain, can also easily undergo a ring-closing process. In particular, **2cn** in chloroform solution, treated with a slight excess of $NHEt_2$, affords a new complex species that is characterized, with respect to the NMR parameters of **2cn**, by a considerable downfield shift of the $^{195}$Pt resonance ($\Delta\delta$ = +440 ppm), a shielding of the C and H atoms in the α position ($\Delta\delta$ = –20 and –0.6 ppm, respectively), and a deshielding of the C and H atoms in the β position ($\Delta\delta$ = +10 and +1.3 ppm, respectively). All these features are characteristic of a ring-closed species. Moreover, the ESI mass spectrum of the reaction solution did show, besides a peak at 447.9, due to residual **2cn**, another intense peak at 411.5 corresponding to the elimination of HCl from **2cn** (the absence of chlorine was also confirmed by the peak isotopic pattern).

The cyclized species **3** of this work are closely related to the metallacycles proposed by Hartwig for the rhodium-catalyzed **anti-M** amination of vinylarenes.[16] Our findings prove that the formation of such intermediates is very likely, and the greater propensity of the **anti-M** isomer to undergo a ring-closing reaction may be the reason for the **anti-M** selectivity observed in the Hartwig reaction.

It can also be noted that, in spite of its strained structure, compound **3** appears to have considerable stability. To account for such stability, the concept of geometrical rigidity (steric constraints disfavor the reorganization of the metal orbital, which is necessary for a reaction pattern to take place) can be invoked. The same concept has been proposed by Zetterberg for justifying the lack of β-hydrogen elimination in azapalladacyclobutane species.[8c]

## Conclusions

In the systems under consideration, neither the *trans*-labilization of the ligand to be displaced by the entering nitrogen, nor the presence of substituents on the ethanide chain (which facilitates cyclization by the Thorpe–Ingold effect) are necessary for the ring-closing reaction to take place. The main difference between our substrates and those previously investigated[6,7] is the absence of a formal negative charge on the aminoethanide compound undergoing cyclization (deprotonated **2**). Therefore, a greater electrophilicity of the metal center (which is deprived of formal negative charge) could be the aiding factor promoting the ring-closing process.

Another outcome of the present investigation is the greater propensity of the anti-Markovnikov isomer of **2**, as compared with the Markovnikov one, to undergo ring-closing reaction. The **anti-M** isomer of **2** differs from the **M** isomer in that it has the two substituents (the methyl or phenyl group and the amine) on different carbon atoms of the ethanide chain. Steric repulsion between the two substituents will set them in an antiperiplanar conformation. As a consequence, the amine group is brought in a synclinal conformation with respect to the platinum atom and therefore in a suitable position to undergo chlorido substitution and ring-closing. This aiding effect is not present in the Markovnikov isomer, for which the hydrocarbon and the amine substituents are on the same carbon atom of the ethanide chain. The X-ray structure of compound **2bn** has fully confirmed this prevision. The phenyl ring and the amine substituents on the ethanide chain are in antiperiplanar disposition, which brings the amine group in a synclinal position with respect to the platinum atom and close to the chlorido ligand, which can therefore be easily displaced.

## Experimental Section

**General Methods:** All reagent-grade chemicals were purchased from Aldrich and used without purification. Elemental analyses were performed by using an Elemental Analyzer 1106 Carlo Erba instrument. $^1$H NMR spectra were recorded with a DPX300 Advance Bruker instrument equipped with a probe for inverse detection and with *z* gradient for gradient-accelerated spectroscopy. $^1$H and $^{13}$C spectra were referenced to TMS; the residual proton signal of the solvent was used as internal standard. For $^{195}$Pt spectra $K_2PtCl_4$ was used as external standard (–1643.00 ppm). $^1$H/$^{13}$C inversely detected gradient-sensitivity-enhanced heterocorrelated 2D NMR spectra for normal coupling (INVIEAGSSI) were acquired by

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

using standard Bruker automation programs and pulse sequences. APT spectra were recorded on a 300-MHz Mercury Varian instrument equipped with *z* gradient. All spectra were acquired in $CDCl_3$ and at 298 K. ESI mass spectra were obtained through a direct injection (10 μL/min) of micromolar methanol solutions of all the compounds into an Agilent 1100 Series LC-MSD Trap System VL instrument.

**Synthesis**

Alkene complexes [PtCl($\eta^2$-$CH_2$=CHX)(tmeda)]($ClO_4$) (X = $CH_3$, **1a**. $C_6H_5$, **1b**) were prepared by ethene exchange on the cationic complex [PtCl($\eta^2$-$C_2H_4$)(tmeda)]($ClO_4$) (**1c**) by following a reported procedure.[17]

Amine addition compounds **2xy** were prepared by reaction of the alkene complex **1** (0.4 mmol), suspended in dichloromethane (8 mL), with a slight excess of the amine ($NHMe_2$, **m**; $NHEt_2$, **n**; 1.2-fold the stoichiometric amount). After stirring for 3 h at room temperature, complete dissolution of the solid was observed. The solution was filtered, the solvent evaporated under reduced pressure, and the oily residue, after trituration with diethyl ether, afforded a white solid which was identified as the amine addition product. The isolated yield, referred to platinum, was ca. 95% for all the compounds.

Azaplatinacyclobutane complexes **3xy** were prepared by treatment of a dichloromethane solution of the amine addition product **2xy** (0.2 mmol in 0.4 mL solvent) with a water solution of KOH (1.2 times the stoichiometric amount in 0.4 mL solvent). The mixture was kept under vigorous stirring for 48 h at room temperature. The organic phase was then removed, washed twice with water (1 mL), dried with $Na_2SO_4$, and submitted to solvent evaporation under vacuum. The oily residue, triturated with diethyl ether, afforded a white solid, which was separated by filtration of the solvent and dried. It was identified as the azaplatinacyclobutane complex. The isolated yield, referred to platinum, was ca. 90% for all compounds.

**3an($ClO_4$):** $C_{13}H_{32}ClN_3O_4Pt$ (524.94): calcd. C 29.74, H 6.14, N 8.00; found C 29.44, H 6.03, N 7.92. ### X-ray Crystallography

X-ray data were collected for the crystals **2bn**(ClO$_4$) and **3bn**(ClO$_4$) with a Bruker AXS X8 APEX CCD system equipped with a four-circle Kappa goniometer and a 4-K CCD detector (Mo-$K_\alpha$ radiation). The crystal-to-detector distance was 40 mm. The SAINT-IRIX package was employed for data reduction and unit-cell refinement.[18] All reflections were indexed, integrated, and corrected for Lorentz, polarization, and absorption effects by using the program SADABS.[19]

For compound **2bn**(ClO$_4$), which was crystallized from CHCl$_3$/pentane, a total of 33622 reflections ($\Theta_{max}$ = 37.00°) were collected. The number of independent reflections was 11082. The unit-cell dimensions were calculated from all reflections. The structure was solved by direct methods in the *Cc* space group. The model was refined by full-matrix least-squares methods. Anisotropic thermal parameters were applied for all non-hydrogen atoms. H atoms were located in difference maps, and were included in the full-matrix least-squares cycles with isotropic thermal parameters ($U$) fixed at 1.2 and 1.5 (for methyl group) times the values of $U$ of the corresponding carbon atoms. The perchlorate counterion is disordered. The final difference-Fourier map showed electron-density peaks (up to 1.839 e Å$^{-3}$) lying near the Pt atoms.

For compound **3bn**(ClO$_4$), also crystallized from CHCl$_3$/pentane, a total of 25934 reflections ($\Theta_{max}$ = 41.00°) were collected. The number of independent reflections was 12990. The unit-cell dimensions were calculated from all reflections. The structure was solved by direct methods in the $P2_1/c$ space group. The model was refined by full-matrix least-squares methods. Anisotropic thermal parameters were applied for all non-hydrogen atoms. H atoms were located in difference maps, and the parameters were freely refined. The final difference-Fourier map showed electron-density peaks (up to 3.432 e Å$^{-3}$) lying near the Pt atoms.

The crystallographic data are listed in Table 2. All calculations and molecular graphics were carried out by using the SIR2004,[20] SHELXL97,[21] PARST97,[22] WinGX,[23] or ORTEP-3 for Windows packages.[24] CCDC-624564 (**2bn**) and CCDC-269917 (**3bn**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 2. Crystal data and structure refinement parameters for **2bn**(ClO$_4$) and **3bn**(ClO$_4$).

| | **2bn**(ClO$_4$) | **3bn**(ClO$_4$) |
|---|---|---|
| Empirical formula | $C_{18}H_{35}Cl_2N_3O_4Pt$ | $C_{18}H_{34}ClN_3O_4Pt$ |
| Formula weight | 623.48 | 587.02 |
| Crystal system | monoclinic | monoclinic |
| Space group | *Cc* | $P2_1/c$ |

# The Aromatization of $C_5$ Rings on a Heteronuclear Cluster

Yong Leng Kelvin Tan[a] and Weng Kee Leong*[a]

**Keywords:** Heterometallic complexes / Ruthenium / Osmium / Carbocyclic rings / Cyclopentadienyl ligands

The reaction of the heteronuclear cluster $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ with saturated and unsaturated $C_5$ rings led to the aromatization of the rings to afford the clusters $RuOs_3(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_2(\eta^5\text{-}C_5R_4R')$. However, the reaction with cyclopentene gave the cluster $RuOs_3(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}C_5H_7)$ via C–H activation of an $sp^2$ carbon instead. Thermolysis of two of the products, $RuOs_3(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_2(\eta^5\text{-}Cp')$ and $RuOs_3(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_2(\eta^5\text{-}C_5H_4SiMe_3)$, led to their isomerization to butterfly clusters.

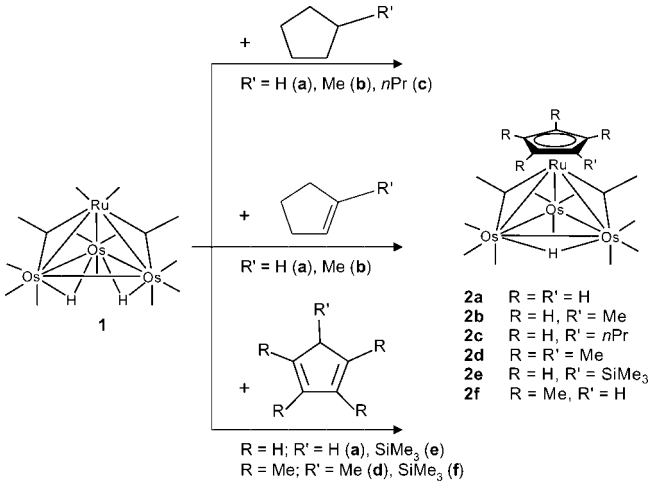
## Introduction

Carbocyclic ligands such as cyclopentadienyls are ubiquitous in organometallic chemistry, and many of their compounds are important as catalysts. Furthermore, these ligands have an important role in many catalytic processes, and establishing the nature of the ligand–metal interaction is important to an understanding of the catalytic reaction.[1] Transition-metal clusters incorporating unsaturated organic molecules can serve as useful models for comprehending these processes due to the similarities between ligand–cluster and absorbate–surface interactions. This has resulted in a well-developed chemistry of this class of compounds, and several reviews have been published.[2] In contrast to the extensive reports on the reactivity of homonuclear clusters with carbocyclic ligands, few examples exist for heteronuclear clusters. The synergistic effect of having different adjacent metals in heteronuclear clusters may offer higher activity, greater selectivity, and better stability than their homonuclear counterparts. We had earlier developed a high-yield synthetic route to the hetero group 8 tetranuclear cluster $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ (**1**) and have initiated a series of investigations into the chemistry of **1** and its derivatives.[3,4] It is with an exploration of the reactivity of a heteronuclear cluster with $C_5$ carbocyclic rings in mind that we would like to report here the results of our investigations into the reaction of **1** with a number of representative saturated and unsaturated $C_5$ rings, particularly in relation to their binding and transformation on the cluster.

## Results and Discussion

With the notable exception of cyclopentene, we have found that the reaction of **1** with a variety of cyclopentanes, cyclopentenes, and cyclopentadienes at 120 °C afforded tetrahedral clusters of the general formula $RuOs_3(\mu\text{-}H)(CO)_9(\mu\text{-}CO)_2(\eta^5\text{-}C_5R_4R')$ (**2**) in moderate to high yields; this is depicted in Scheme 1. Although aromatization of cyclohexene and cyclohexadiene on tetraosmium clusters are known,[5] this appears to be the first time that aromatization of $C_5$ rings, including even saturated ones, on clusters have been observed. All the clusters **2** have been characterized completely and, with the exception of **2c**, also by single-crystal X-ray crystallography. The synthesis of **2a** by the ionic coupling of $[Ru(C_5H_5)(MeCN)_3]^+$ with $[Os_3H(CO)_{11}]^-$ and its X-ray crystal structure have also been previously reported;[6] we are reporting our results here to minimize instrumental variations for purposes of comparison.



Scheme 1.

The ORTEP diagrams for **2d** and **2e** are shown in Figure 1, and a common atomic numbering scheme and selected bond parameters for the clusters **2** are given in Table 1. The clusters consist of a tetrahedral arrangement

of metal atoms; the three osmium atoms form the triangular basal plane and are capped by a ruthenium atom at the apex. The tetrahedral metal core with six metal–metal bonds is consistent with the valence electron count of 60 for the molecules. The longest metal–metal edge found in all of the clusters is bridged by a hydride ligand;[7] the Os(1)–Os(2) bond length ranges from 2.9413(6) to 3.0056(10) Å; the other metal–metal bond lengths in the clusters range from 2.7709(7) to 2.9060(12) Å. There are two asymmetric bridging carbonyl groups which span the Os(1)–Ru(4) and Os(2)–Ru(4) edges; the bond to the ruthenium atom [average 1.97(2) Å] is shorter than that to the osmium atom [average 2.26(4) Å]. Bridging carbonyl groups are better π-acceptors than terminal CO groups, and their presence helps to disperse the additional electron density contributed by the electron-rich Ru(η$^5$-cyclopentadienyl) fragment.[8]

The organic moiety in **2** is coordinated to the cluster at the apical ruthenium atom via the conventional η$^5$-cyclopentadienyl bonding mode. It is noted that cyclopentadienyl ligand substitution occurs overwhelmingly at the ruthenium vertex, in line with previous reports of group 15 derivatives of cluster **1**.[3] There is no evidence for the presence of an isomer with the carbocyclic ligand ligating an osmium ver-

tex. This preference for substitution at a ruthenium vertex is electronic; it cannot be statistical since that would lead to a 3:1 preference for substitution at an osmium vertex.

As has been observed for $Os_4(\mu\text{-H})(CO)_9(\mu\text{-CO})_2(\eta^5\text{-Cp*})$, one of the methyl carbon atoms in **2d** [C(103) in the ORTEP diagram] is displaced out of the plane of the central carbon ring of the pentacyclopentadienyl ligand by 18°. The displacement of the other methyl carbon atoms from the carbon ring plane for this cluster averages 7°. This bending of the methyl carbon atom has been ascribed to the steric interaction of the methyl group with the nearest carbonyl groups.[9] The presence of bridging carbonyl ligands results in a reduction of the distance as well as an increase in the nonbonding interaction between the oxygen atom of the CO ligand and any bulky substituents on the cyclopentadienyl ring, giving rise to bridging carbonyl-substituted cyclopentadienyl ring repulsion. This can be seen in **2e**, where the bulky trimethylsilyl group is placed directly above and between the two bridging carbonyl ligands to minimize steric strain, while the cyclopentadienyl ring is tilted at an angle of 36° with respect to the triosmium basal plane.
