**Preparation of 1-*tert*-Butylstannole Anion 16:** A diethyl ether (0.7 mL) solution of stannole dianion **3** prepared from hexaphenylstannole **4** (58 mg, 0.09 mmol) with lithium (5 mg, 0.72 mmol) was added to a diethyl ether (2 mL) solution of *tert*-butyl chloride (0.01 mL, 0.09 mmol) at room temperature. The resulting bright-red solution was degassed by freeze-pump-thaw cycles and sealed. **16:** $^1$H NMR ($Et_2O/C_6D_6$): $\delta$ = 1.25 (s, 9 H), 6.61–6.78 (m, 12 H), 6.80–6.83 (m, 4 H), 6.88–6.90 (m, 4 H) ppm. $^{13}$C NMR ($Et_2O/C_6D_6$): $\delta$ = 28.64 (s), 33.71 (q), 122.22 (d), 124.04 (d), 126.80 (d), 127.07 (d), 129.35 (d), 131.59 (d), 145.05 (s), 150.35 (s), 151.78 (s), 170.66 (s, $J_{C,Sn}$ = 113 Hz) ppm. $^{119}$Sn NMR ($Et_2O/C_6D_6$): $\delta$ = 30.4 ppm. $^7$Li NMR ($Et_2O/C_6D_6$): $\delta$ = 0.92 ppm.

**Formation of 17 by Oxidation of 1-*tert*-Butylstannole Anion 16:** A diethyl ether (4 mL) solution of stannole dianion **3** prepared from hexaphenylstannole **4** (197 mg, 0.31 mmol) with lithium (21 mg, 3.03 mmol) was added to a diethyl ether (2 mL) solution of *tert*-butyl chloride (0.04 mL, 0.34 mmol) at room temperature. After being stirred for 30 min, the resulting bright-red solution was exposed to air for a few minutes. After filtration of materials insoluble in dichloromethane, the filtrate was recrystallized from dichloromethane and methanol to give bi(1-*tert*-butyl-2,3,4,5-tetraphenyl-1-stannacyclopentadienyl) (**17**)[9] (45 mg, 0.042 mmol, 27%).

**Reaction of Stannole Dianion 3 with Bromobenzene:** A diethyl ether (7 mL) solution of stannole dianion **3** prepared from hexaphenylstannole **4** (404 mg, 0.64 mmol) and lithium (53 mg, 7.57 mmol) was added to a diethyl ether (2 mL) solution of bromobenzene (0.067 mL, 0.64 mmol) at room temperature. After being stirred for 5 h, the resulting solution was exposed to air for a few minutes. After filtration of materials insoluble in dichloromethane, a complex mixture (293 mg) was obtained.

**Preparation of 1-(2,4,6-Triisopropylphenyl)stannole Anion 19:** A diethyl ether (10 mL) solution of stannole dianion **3** prepared from hexaphenylstannole **4** (707 mg, 1.12 mmol) with lithium (77 mg, 11.1 mmol) was added to a diethyl ether (3 mL) solution of 1-bromo-2,4,6-triisopropylbenzene (317 mg, 1.12 mmol) at room temperature. After being stirred overnight, the resulting deep-red solution was degassed by freeze-pump-thaw cycles and sealed. In a glovebox, after filtration of insoluble materials, the filtrate was concentrated. The residue was washed with hexane to give 1-lithio-1-(2,4,6-triisopropylphenyl)-2,3,4,5-tetraphenylstannole (**19**). **19:** $^1$H NMR ($Et_2O/C_6D_6$): $\delta$ = 1.12–1.17 (m, 18 H), 2.66–2.80 (sept, $J_{H,H}$ = 7 Hz, 2 H), 2.88–2.98 (sept, $J_{H,H}$ = 7 Hz, 1 H), 6.55–6.61 (m, 2 H), 6.61–6.67 (m, 2 H), 6.67–6.77 (m, 8 H), 6.77–6.85 (m, 10 H) ppm. $^{13}$C NMR ($Et_2O/C_6D_6$): $\delta$ = 24.25 (q), 25.84 (q), 34.82 (d), 40.93 (d), 122.24 (d), 122.43 (d), 124.22 (d), 124.45 (d), 126.80 (d), 127.04 (d), 127.39 (d, $J_{C,Sn}$ = 14 Hz), 128.53 (d), 128.74 (d, $J_{C,Sn}$ = 14 Hz), 131.47 (d), 138.60 (d, $J_{C,Sn}$ = 47 Hz), 144.74 (s), 148.97 (s), 149.69 (s, $J_{C,Sn}$ = 35 Hz), 152.23 (s, $J_{C,Sn}$ = 15 Hz), 156.47 (s, $J_{C,Sn}$ = 150 Hz), 161.61 (s), 170.39 (s, $J_{C,Sn}$ = 90 Hz) ppm. $^{119}$Sn NMR ($Et_2O/C_6D_6$): $\delta$ = –49.6 ppm. $^7$Li NMR ($Et_2O/C_6D_6$): $\delta$ = 0.95 ppm. The elemental analysis of **19** could not be carried out because of its extremely high reactivity toward water and oxygen.

**Reaction of Stannole Anion 19 with Methyl Iodide:** A diethyl ether (4 mL) solution of stannole dianion **3** prepared from hexaphenylstannole **4** (150 mg, 0.24 mmol) and lithium (16 mg, 2.29 mmol) was added to a diethyl ether (2 mL) solution of 1-bromo-2,4,6-triisopropylbenzene (66 mg, 0.23 mmol) at room temperature. After being stirred for 4 h, the mixture was treated with methyl iodide (0.1 mL, 1.61 mol). After removal of volatile substances, materials insoluble in dichloromethane were removed by filtration. The residue was subjected to GPC to afford 1-methyl-2,3,4,5-tetraphenyl-1-(2,4,6-triisopropylphenyl)stannole (**18**) (48 mg, 0.07 mmol, 29%). **18:** M.p. 188 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 0.96 (s, $J_{H,Sn}$ = 55 Hz, 3 H), 1.05 (d, $J_{H,H}$ = 7 Hz, 12 H), 1.24 (d, $J_{H,H}$ = 7 Hz, 6 H), 2.86 (sept, $J_{H,H}$ = 7 Hz, 1 H), 2.97 (sept, $J_{H,H}$ = 7 Hz, 2 H), 6.73–6.84 (m, 4 H), 6.84–6.95 (m, 12 H), 6.95–7.05 (m, 6 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = –3.04 (q, $J_{C,Sn}$ = 323 Hz), 23.88 (q), 24.93 (q), 34.14 (d), 38.13 (d, $J_{C,Sn}$ = 33 Hz), 121.50 (d, $J_{C,Sn}$ = 49 Hz), 124.90 (d), 125.49 (d), 127.07 (d), 127.62 (d), 128.93 (d, $J_{C,Sn}$ = 20 Hz), 130.30 (d), 137.17 (s), 140.93 (s, $J_{C,Sn}$ = 63 Hz), 143.12 (s, $J_{C,Sn}$ = 45 Hz), 147.09 (s, $J_{C,Sn}$ = 406 Hz), 150.12 (s, $J_{C,Sn}$ = 10 Hz), 153.08 (s, $J_{C,Sn}$ = 84 Hz), 155.92 (s, $J_{C,Sn}$ = 43 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –66.0 ppm. $C_{44}H_{46}Sn$ (693.60): calcd. C 76.20, H 6.69; found C 76.19, H 6.71.

**Oxidation of Stannole Anion 19:** A diethyl ether (4 mL) solution of stannole dianion **3** prepared from hexaphenylstannole **4** (310 mg, 0.49 mmol) and lithium (32 mg, 4.61 mmol) was added to 1-bromo-2,4,6-triisopropylbenzene (139 mg, 0.49 mmol) at room temperature. After being stirred for 8 h, the resulting solution was exposed to air for a few minutes. After filtration of materials insoluble in diethyl ether, a complex mixture (410 mg) was obtained.

**Preparation of 1-[2,6-Bis(2,4,6-trimethylphenyl)phenyl]stannole Anion 21:** A diethyl ether (7 mL) solution of stannole dianion **3** prepared from hexaphenylstannole **4** (770 mg, 1.22 mmol) and lithium (86 mg, 12.3 mmol) was added to a diethyl ether (3 mL) solution of 1-iodo-2,6-bis(2,4,6-trimethylphenyl)benzene[23] (450 mg, 1.09 mmol) at room temperature. After being stirred for 3 d, the resulting deep-red solution was degassed by freeze-pump-thaw cycles and sealed. After removal of insoluble materials by filtration,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the filtrate was concentrated in a glovebox to give 1-[2,6-bis(2,4,6-trimethylphenyl)phenyl]-1-lithio-2,3,4,5-tetraphenylstannole (**21**). The $^1$H and $^{13}$C NMR signals due to **21** are too complicated to be assigned probably because of steric congestion. However, in the $^{13}$C NMR spectrum, the signal assignable to the α-carbon atom was observed at $\delta$ = 170.34ppm. **21:** $^{119}$Sn NMR ($Et_2O/C_6D_6$): $\delta$ = –50.2 ppm. $^7$Li NMR ($Et_2O/C_6D_6$): $\delta$ = 0.15 ppm. The elemental analysis of **21** could not be carried out because of its extremely high reactivity toward water and oxygen.

**Preparation of 1-[2,6-Bis(2,4,6-triisopropylphenyl)phenyl]stannole Anion 22:** A diethyl ether (5 mL) solution of stannole dianion **3** from hexaphenylstannole **4** (319 mg, 0.50 mmol) and lithium (35 mg, 5.07 mmol) was added to a diethyl ether (2 mL) solution of 1-iodo-2,6-bis(2,4,6-triisopropylphenyl)benzene[24] (230 mg, 0.48 mmol) at room temperature. After being stirred for 3 d, the resulting deep-red solution was degassed by freeze-pump-thaw cycles and sealed. After removal of insoluble materials by filtration, the filtrate was concentrated in a glovebox to give 1-[2,6-bis(2,4,6-triisopropylphenyl)phenyl]-1-lithio-2,3,4,5-tetraphenylstannole (**22**). The $^1$H and $^{13}$C NMR signals for **22** are too complicated to be assigned probably because of steric congestion. However, in the $^{13}$C NMR spectrum, the signal assignable to the α-carbon atom was observed at $\delta$ = 170.33ppm. **22:** $^{119}$Sn NMR ($Et_2O/C_6D_6$): $\delta$ = –47.1 ppm. $^7$Li NMR ($Et_2O/C_6D_6$): $\delta$ = 0.61 ppm. The elemental analysis of **22** could not be carried out because of its extremely high reactivity toward water and oxygen.

**Preraration of 1-Triisopropylsilylstannole Anion 23:** Chlorotriisopropylsilane (0.025 mL, 0.12 mmol) was added to a diethyl ether (1 mL) solution of stannole dianion **3** (54 mg, 0.11 mmol) at room temperature in a glovebox. After being stirred overnight, the reaction mixture was concentrated in a glovebox to give 1-lithio-2,3,4,5-tetraphenyl-1-(triisopropylsilyl)stannole (**23**). **23:** $^1$H NMR ($Et_2O/C_6D_6$): $\delta$ = 1.20–1.46 (m, 3 H), 6.61–6.64 (m, 4 H), 6.64–6.75 (m, 6 H), 6.81–6.89 (m, 10 H) ppm. The signals due to the methyl protons of the triisopropylsilyl groups are overlapped with those of the methyl protons of diethyl ether. $^{13}$C NMR ($Et_2O/C_6D_6$): $\delta$ = 15.52 (q), 20.29 (d, $J_{C,Sn}$ = 13 Hz), 124.78 (d), 125.47 (d), 127.35 (d), 127.59 (d), 130.59 (d), 130.94 (d), 142.77 (s, $J_{C,Sn}$ = 37 Hz), 145.50 (s, $J_{C,Sn}$ = 40 Hz), 155.04 (s, $J_{C,Sn}$ = 46 Hz), 156.01 (s, $J_{C,Sn}$ = 190 Hz) ppm. $^{119}$Sn NMR ($Et_2O/C_6D_6$): $\delta$ = –218.5 ($^1J_{Sn,Si}$ = 380 Hz) ppm. $^7$Li NMR ($Et_2O/C_6D_6$): $\delta$ = 0.48 ppm. The elemental analysis of **23** could not be carried out because of its extremely high reactivity toward water and oxygen.

**Reaction of the 1-Triisopropylsilylstannole Anion 23 with Methyl Iodide:** In a glovebox, a diethyl ether (3 mL) solution of stannole dianion **3** (94 mg, 0.19 mmol) and chlorotriisopropylsilane (0.041 mL, 0.19 mmol) was stirred at room temperature overnight and the resulting mixture was treated with methyl iodide (0.1 mL, 1.61 mmol). After removal of materials insoluble in diethyl ether, a complex mixture (101 mg) was obtained.

**Preparation of 1-Triphenylstannylstannole Anion 24:** Chlorotriphenylstannane (55 mg, 0.16 mmol) was added to a diethyl ether (2 mL) solution of stannole dianion **3** (70 mg, 0.14 mmol) at room temperature in a glovebox. After being stirred overnight, the reaction mixture was concentrated in a glovebox to give 1-lithio-2,3,4,5-tetraphenyl-1-(triphenylstannyl)stannole (**24**). **24:** $^1$H NMR ($Et_2O/C_6D_6$): $\delta$ = 6.55–6.80 (m, 16 H), 6.80–6.94 (m, 4 H), 6.94–7.06 (m, 9 H), 7.35–7.46 (m, 6 H) ppm. $^{13}$C NMR ($Et_2O/C_6D_6$): $\delta$ = 122.48 (d), 124.10 (d), 126.73 (d), 126.82 (d), 127.09 (d), 127.71 (d), 129.58 (d), 131.76 (d), 138.51 (d, $J_{C,Sn}$ = 37, 188 Hz), 144.83 (s), 148.85 (s), 149.70 (s), 151.99 (s), 172.03 (s, $J_{C,Sn}$ = 148 Hz) ppm. $^{119}$Sn NMR ($Et_2O/C_6D_6$): $\delta$ = –98.7 ($^1J_{Sn,Sn}$ = 3801 Hz), –240.5 ($^1J_{Sn,Sn}$ = 3801 Hz) ppm. $^7$Li NMR ($Et_2O/C_6D_6$): $\delta$ = –0.74, 0.62 ppm. The elemental analysis of **24** could not be carried out because of its extremely high reactivity toward water and oxygen.

**Reaction of 1-(Triphenylstannyl)stannole Anion 24 with Methyl Iodide:** A diethyl ether (2 mL) solution of the stannole dianion **3** (102 mg, 0.21 mmol) and chlorotriphenylstannane (80 mg, 0.21 mmol) was stirred in a glovebox at room temperature for 2 h, and the resulting mixture was treated with methyl iodide (0.1 mL, 1.61 mmol). After removal of volatile substances, insoluble inorganic salts were filtered off. The residue was subjected to GPC to afford 1-methyl-2,3,4,5-tetraphenyl1-(triphenylstannyl)-stannole (**25**) (80 mg, 0.097 mmol, 47%). **25:** M.p. 143 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 0.89 (s, $J_{H,Sn}$ = 15, 53 Hz, 3 H), 6.70–6.80 (m, 8 H), 6.88–6.97 (m, 12 H), 7.25–7.34 (m, 9 H), 7.34–7.49 (m, 6 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = –7.59 (q, $J_{C,Sn}$ = 59 Hz), 125.08 (d), 125.70 (d), 127.26 (d), 127.78 (d), 128.67 (d), 128.79 (d, $J_{C,Sn}$ = 11 Hz), 129.39 (d, $J_{C,Sn}$ = 21 Hz), 130.34 (d), 137.34 (d, $J_{C,Sn}$ = 8, 41 Hz), 139.13 (s, $J_{C,Sn}$ = 55 Hz), 140.86 (s, $J_{C,Sn}$ = 5, 58 Hz), 142.77 (s, $J_{C,Sn}$ = 47 Hz), 147.78 (s), 153.50 (s, $J_{C,Sn}$ = 21 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –87.3 (s, $^1J_{Sn,Sn}$ = 3532 Hz), –127.4 (s, $^1J_{Sn,Sn}$ = 3532 Hz) ppm. $C_{47}H_{38}Sn_2$ (840.25): calcd. C 67.18, H 4.56; found C 66.90, H 4.49.

**Reaction of the 1-(Triphenylstannyl)stannole Anion 24 with Chlorotriphenylstannane:** A diethyl ether (2 mL) solution of the stannole dianion **3** (107 mg, 0.22 mmol) and chlorotriphenylstannane (168 mg, 0.44 mmol) was stirred in a glovebox at room temperature for 30 min. The color of the reaction mixture changed from dark-red to yellow. After removal of volatile substances, insoluble inorganic salts were filtered off. The residue was subjected to GPC to afford 2,3,4,5-tetraphenyl-1,1-bis(triphenylstannyl)stannole (**26**) (100 mg, 0.085 mmol, 39%). **26:** M.p. 175–177 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 6.48–6.56 (m, 4 H), 6.66–6.75 (m, 8 H), 6.80–6.88 (m, 2 H), 6.88–7.00 (m, 6 H), 7.11–7.35 (m, 30 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 124.91 (d), 125.64 (d), 127.21 (d), 127.62 (d), 128.65 (d), 127.86 (d), 128.78 (d, $J_{C,Sn}$ = 11 Hz), 129.59 (d, $J_{C,Sn}$ = 15 Hz), 137.33 (d, $J_{C,Sn}$ = 8, 42 Hz), 139.06 (s, $J_{C,Sn}$ = 11, 54 Hz), 141.05 (s, $J_{C,Sn}$ = 50 Hz), 142.93 (s, $J_{C,Sn}$ = 45 Hz), 150.22 (s, $J_{C,Sn}$ = 12 Hz), 153.74 (s, $J_{C,Sn}$ = 19, 63 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –115.7 ($^1J_{Sn,Sn}$ = 2159 Hz, $^2J_{Sn,Sn}$ = 615 Hz), –219.8 ($^1J_{Sn,Sn}$ = 2159 Hz) ppm. The elemental analysis of **26** could not be carried out because of its instability. For the $^1$H, $^{13}$C, and $^{119}$Sn NMR spectra of **26**, see Supporting Information.

**Supporting Information** (see footnote on the first page of this article): All NMR spectroscopic data of compounds, **1**, **16**, **19**, **21**, **22**, **23**, **24**, and **26**. Experimental details for control experiment of the reduction of 1,1′-bistannole **1** with lithium to give stannole anion **1** and dianion **3**.

# Anion Separation with Metal–Organic Frameworks

**Radu Custelcean*[a] and Bruce A. Moyer*[a]**

**Keywords:** Anions / Crystal engineering / Host–guest systems / Molecular recognition

The application of metal–organic frameworks (MOFs) to anion separations with a special emphasis on anion selectivity is reviewed. The coordination frameworks are classified on the basis of the main interactions to the included anion, from weak and non-specific van der Waals forces to more specific interactions such as coordination to Lewis acid metal centers or hydrogen bonding. The importance of anion solvation phenomena to the observed anion selectivities is highlighted, and strategies for reversing the Hofmeister bias that favors large, less hydrophilic anions, and for obtaining peak selectivities based on shape recognition are delineated. Functionalization of the anion-binding sites in MOFs with strong and directional hydrogen-bonding groups that are complementary to the included anion, combined with organizational rigidity of the coordination framework, appears to be the most promising approach for achieving non-Hofmeister selectivity.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

Metal–organic frameworks (MOFs), also called coordination polymers, or coordination networks, have developed into one of the most prolific areas of research in materials chemistry.[1] The extraordinary popularity of MOFs could be explained by the ease of their synthesis based on the self-assembly of metal cations with organic linkers possessing divergent coordinating groups. Another appealing feature characteristic to this class of materials is their crystallinity, which allows for their precise structural characterization by diffraction methods, thus facilitating their rational design and the formulation of structure/property relationships. Furthermore, the ability to readily modify the linkers by employing the power of organic synthesis is another great advantage over purely inorganic materials. While the initial focus in this area was the synthesis and structural characterization, an increasing number of MOFs is now being explored for many potentially useful properties, which may very soon lead to commercial applications.[2] One of the early recognized functionalities in MOFs was their anion-exchange ability, particularly for cationic frameworks made from neutral organic linkers, which intrinsically include charge-balancing anions. Since the first reported example

*Radu Custelcean was born in 1972 in Transylvania, Romania, and studied Chemistry at Babes-Bolyai University, where he graduated with an MS degree in 1996. He then moved to Michigan State University, where he received his PhD in Chemistry under the supervision of James E. Jackson, for work on structure and reactivity of hydrogen-bonded crystals. In 2000 he joined the research group of Michael D. Ward at the University of Minnesota as a postoctoral fellow, where he worked on crystal design using hydrogen bonds. Since 2003 he has been working as a research scientist in the Chemical Separations Group at Oak Ridge National Laboratory. His main research interests are in crystal engineering of hydrogen-bonded and coordination frameworks, crystalline organic materials, and chemical separations.*

*Bruce A. Moyer received his PhD in Inorganic Chemistry in 1979 working with Thomas J. Meyer at the University of North Carolina at Chapel Hill. He then joined the staff at Oak Ridge National Laboratory, where he now leads the Chemical Separations Group. Since 2001, he has served as Co-Editor of the journal Solvent Extraction and Ion Exchange. His research interests have focused on use of molecular recognition principles in effecting selective extraction of inorganic ions and how the resulting understanding can be applied to problems in waste treatment, environmental remediation, and nuclear separations.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of anion exchange in an MOF,[3] further examples of coordination frameworks with anion-exchange properties have been studied, revealing that the environment around the bound anions can vary considerably. It occurred to us to ask whether it was possible to identify systematic structural features that could in turn be related to selectivity in anion exchange. As selectivity is essential to any chemical separation process, a detailed understanding of the factors governing anion selectivity in MOFs is of paramount importance if this class of materials is to be successfully utilized in anion-separation applications. The primary scope of this review article is therefore to provide a concise summary of the progress in this area, including recent contributions from our own research, with a special emphasis on factors relating to anion selectivity. Toward this end, we found it helpful to draw comparisons to selectivity principles applicable to anion separation in molecular separation systems, where the basis for selectivity is better understood and somewhat simpler. Accordingly, in the following section on fundamentals of anion selectivity and separation, a general strategy is proposed for obtaining selectivity by design to overcome the dominant solvation-based Hofmeister bias that otherwise favors hydrophobic, charge-diffuse anions. Specific examples of anion exchange and separations with MOFs are then presented, which are organized around the main interactions between the anions and the coordination frameworks. Finally, the current status of the field is summarized at the end of the paper, emphasizing its outstanding challenges and suggesting future research directions.

## 2. Fundamentals of Anion Separations

### Selectivity Patterns in Separations

Selectivity may be classified as monotonic, step, peak, or some combination thereof in the separation of a related group of species. Within the unified theory of separations,[4] a separation is effected by a driving force acting unequally on species having different properties. Monotonic selectivity, which has been referred to as bias,[5] simply follows a steadily increasing or decreasing trend according to some varying property within the family of interest. Step or threshold phenomena occur when a limit or discontinuity is reached. Peak selectivity follows from recognition due to complementary bonding interactions. Each of these selectivity types has its uses, and one is better than another only in the context of the economics of the intended use. Hence, inferior selectivity is often tolerated in practice except under demanding circumstances where, for example, one is faced with high concentrations of competing species, high purity requirements, or very expensive footprint costs. Given that separation problems from such arenas as pharmaceuticals, metal recycling, electronics materials, environmental cleanup, nuclear-waste treatment, or nuclear reprocessing are increasingly demanding, the need for new separation systems exhibiting peak selectivity is growing.

Toward understanding principles of anion selectivity in MOFs, we focus in this section on origins of selectivity in molecular systems. This approach presupposes that bonding interactions underlie selectivity generally, and thus, the interactions found in molecular systems should be discernible in MOFs, subject to additional lattice considerations present in the solid state. Although the growing literature on anion recognition[6] has emphasized complexation in homogeneous media, it is of greatest interest in separations to examine partitioning processes, wherein interactions in the receiving phase are played-off against the strong energy requirement of the initial step of anion dehydration. By extension, an MOF would be the receiving phase of interest in the latter part of this review. The present section will begin with the examination of solvation-based selectivity, in which the receiving phase is a fluid environment that may freely reoptimize interactions about any given extracted anion. The discussion will then turn to the effects of single-point interactions in the receiving phase and finally to the effects of multi-point interactions presented by structured host environments. In a broad sense, interactions in the receiving phase may be controlled in their degree of electrostatic or covalent character and associated degree of structural constraint. The net effect is to control the steepness and sign of monotonic selectivity or, more interestingly, to effect sharp departures giving rise to step or peak selectivity.

### Hofmeister Effects on Selectivity

Almost 12 decades ago, Franz Hofmeister noted a particular ordering of anions in the ability of salts of a common cation to precipitate egg-white globulin.[7,8] The original ordering from this work was:

Sulfate > Phosphate* > Acetate > Citrate > Tartrate > Hydrogen carbonate > Chromate ≈ Chloride > Nitrate > Chlorate

(*tabulated by Hofmeister as phosphate but considered by him to be the monohydrogen phosphate dianion)

Hofmeister's key conclusion was that the effectiveness of the salts in precipitating the egg-white globulin increases with "their water attracting capacity." Because ion hydration is so strong and dominates in many chemical phenomena, it is not surprising that the "Hofmeister order" or variations of it have been broadly observed.[9–11] Indeed, a recent conference has been devoted to Hofmeister effects.[12] These phenomena have been divided into those that deal with bulk hydration or activity coefficients (Hofmeister's water-attracting capacity) and those involved with specific ion adsorption or surface effects (binding, partitioning, electrical double-layer, Donnan, etc.).[10] Because Hofmeister effects generally operate in complex systems, where the net observable properties arise from a combination of effects, there are often exceptions to the original order, as even noted immediately by Hofmeister himself.[13] Not surprisingly, the literature gives many variants of the Hofmeister order that include other anions, reversals of positions of certain anions in the order, and even complete reversal of the entire order. However, references to the "Hofmeister order" most often mirror the order of decreasing anion hydration energy or charge density.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Remarkably, the original observations of Hofmeister provide a useful starting point in interpreting the properties of MOFs that ultimately give rise to anion selectivity in crystallization. Given that the Hofmeister order is rather ubiquitous as a selectivity pattern in separations,[5] our premise is that controlling the binding environment of the anion within the MOF leads ultimately to controlled selectivity, especially selectivity that violates the Hofmeister order. We shall approach this question further below. At the outset, however, we recognize the importance of salting-out on solubility, expecting that the first role of Hofmeister effects on MOF solubility is to determine the solution-phase activity coefficients of dissolved MOF precursor components. By changing the anion in the solution phase, one in essence performs the classical Hofmeister experiment. The Hofmeister order would thus be expected on this basis. However, to the extent that one can control the aqueous-phase composition, one has some control over the salting effect in a given experiment. For example, one may employ low salt concentrations, where specific ion effects are minor. We will not concern ourselves further with this aspect of anion selectivity.

## Solvation-Based Selectivity: Normal and Anti-Hofmeister Bias

Hofmeister effects have long been known in ion-partitioning processes, although not named as such until recently. The order of anion exchange in liquid/liquid systems typically obtained is:[5]

$$PO_4^{3-} < CO_3^{2-} < SO_4^{2-} << Cl^- < Br^- < NO_3^- < SCN^- < I^- < ClO_4^-$$

This order is preserved over many systems in which the receiving phase does not possess strong hydrogen-bond (H-bond) donors or other specific anion-binding sites, and for practical purposes, it is the Hofmeister order to which we will refer for anion partitioning. Its similarity with Hofmeister's original order[7] is evident. Many more anions can be added to this list according to criteria discussed below and in more detail elsewhere,[5] but such fine-tuning invariably produces exceptions from system to system. It may be noted that the order above is preserved in certain related anion-partitioning systems, such as anion-exchange resins[14] and liquid-membrane potentiometric sensors.[15] The literature on anion sensing by membrane electrodes is particularly abundant, explicitly recognizing the Hofmeister order as the order of potentiometric selectivity typically observed if no recognition agents are added.

In general, the Hofmeister order in liquid/liquid systems can be understood in straightforward manner as the dehydration of the anion and resolvation in the receiving phase.[5] In terms of standard Gibbs energies, we have $\Delta G_p° = \Delta G_S° - \Delta G_h°$, where subscripts p, S, and h refer to partitioning, solvation, and hydration, respectively. Table 1 gives a listing of selected $\Delta G_h°$ values and other data for a few anions of interest here,[16] presented in order of decreasing $\Delta G_h°$ and extractability.

Table 1. Ionic radii ($r_-$) and standard Gibbs energies of hydration ($\Delta G_h°$) and transfer ($\Delta G_{tr}°$) for representative anions.[a]

[a] Values of $\Delta G_{tr}°$ are given in kJ/mol relative to the tetraphenylarsonium tetraphenylborate extrathermodynamic assumption at 25 °C. Abbreviations: 1,2-DCE: 1,2-dichloroethane; $PhNO_2$: nitrobenzene; $CH_3CN$: acetonitrile; FA: formamide; MeOH: methanol; TFE: 2,2,2-trifluoroethanol. Data taken from compilations[16–18] and published results.[19]

It may be seen at once that the $\Delta G_h°$ values approximately follow Hofmeister's original order, the greater hydration corresponding to the greater protein precipitation ability. Further, the $\Delta G_h°$ values decrease with increasing charge density, as the $\Delta G_h°$ values are nearly proportional to $-Z^2/r_-$ (where $Z$ is the charge and $r_-$ is the thermochemical radius). Further, except for tetraphenylborate, $\Delta G_h°$ values are negative and large. In the present context of anion extraction, anion hydration thus resists extraction, and for anions smaller than perchlorate, the Gibbs energy of hydration is typically not fully recovered in transfer to other solvents (positive $\Delta G_{tr}°$, where transfer refers to pure solvents, as opposed to mutually saturated in the case of partitioning). Thus, transfer for these ions is not favorable and requires an additional driving force to occur (e.g., cation co-extraction, binding, or ion-pairing). However, the values of $\Delta G_{tr}°$ approximately follow the same order as the values of $\Delta G_h°$, implying that hydration and solvation roughly follow the same order. The obtained Hofmeister behavior in partitioning thus corresponds to extraction strength increasing in order of decreasing anion hydration Gibbs energy. We have referred to such behavior as "Hofmeister bias"[20] or *normal Hofmeister* selectivity. As shown below,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

it is in principle (if not in the exceptional actual example) possible to reverse Hofmeister bias in anion extraction if the solvent is capable of exceeding the solvation of the ion in water. In this case, we may expect *anti-Hofmeister* behavior. By contrast, an ordering in which certain anions are displaced from Hofmeister bias or its reverse would be referred to as *non-Hofmeister* behavior.

To illustrate the major factors underlying anion selectivity in anion transfer, Figure 1 shows several plots of $\Delta G_{tr}°$ for a series of anions vs. $1/r_-$ for a range of solvents. Over a fairly substantial range of anion radii (0.133 nm for $F^-$ to 0.421 nm for $Ph_4B^-$), it may be seen that, within some degree of scatter, extractability approximately increases with increasing anion radius for a given solvent. The scatter may be attributed in part to the nonspherical geometries for the eight nonhalide anions and overall varied nature of their properties (e.g., polarizability). As the anion radius increases, cavity formation begins to play a dominant role, because of the high cohesive energy density of water compared with organic solvents.[21] Cavity formation is an energetic cost or repulsive effect that has been related to the enthalpy of vaporization as the measure of difficulty in breaking solvent intermolecular interactions. In an extraction system with water as the starting phase, the effect is to repel the species into the receiving phase according to the molar volume of the species. Hence, as anion radii become larger than approximately perchlorate ($r_-$ = 0.240 nm), the transfer apparently becomes favorable owing to the increasing dominance of the cavity-formation term of the ion-transfer process. In general, the plots are not linear, as they bend over to varying degrees, though they are often treated as linear, when the hydrophobic (significant cavity-formation term) anions like picrate and $Ph_4B^-$ are omitted. It may be noted that acetonitrile, nitrobenzene, and 1,2-dichloroethylene have closely overlapping plots. In fact, one may find that analogous plots for other chemically diverse polar solvents fall about this band, provided that they do not have a strong H-bond donor ability ($\alpha < 0.5$, where $\alpha$ is the Kamlet–Taft solvatochromic H-bond parameter[22]). One may see that the exceptions are small-molecule solvents that are strong H-bond donors (formamide: $\alpha$ = 0.71; methanol: $\alpha$ = 0.93; 2,2,2-trifluoroethanol: $\alpha$ = 1.51). In other words, these are solvents that can efficiently replace the H-bonds lost in the dehydration part of the transfer process. The H-bond donor ability clearly plays a dominant role. In fact, in a statistical analysis of ion transfer Gibbs energies, it was noted that the solvent H-bond donor ability is the major solvent property governing the magnitude of $\Delta G_{tr}°$.[23] Remarkably, the loss of bias with increasing $\alpha$ reaches such a degree with 2,2,2-trifluoroethanol that the trend apparently reverses, fluoride ion being transferred slightly more favorably than the other halides. Thus, where anion hydration for anions smaller than perchlorate is generally not fully recovered on resolvation, in the case of the very strong H-bond donor solvents like 2,2,2-trifluoroethanol, the resolvation slightly overcompensates the loss of hydration. An example of this principle at work in favoring fluoride over the larger halides using a phenol as solvent has been reported.[24]

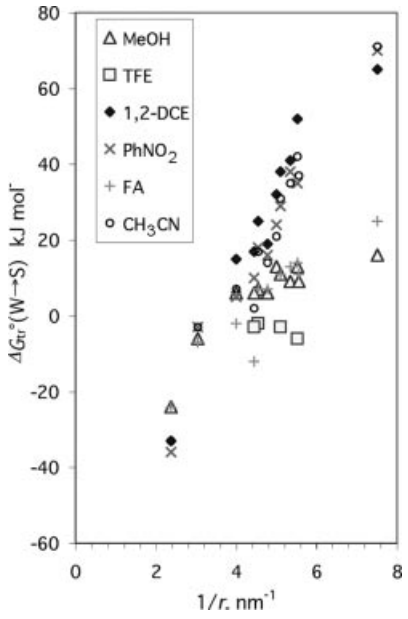

Figure 1. Standard Gibbs energies of transfer for univalent anions from water to organic solvents as a function of reciprocal anion thermochemical radius. Values of $\Delta G_{tr}°$ are given in kJ/mol relative to the tetraphenylarsonium tetraphenylborate extrathermodynamic assumption at 25 °C. Abbreviations: 1,2-DCE: 1,2-dichloroethane; $PhNO_2$: nitrobenzene; $CH_3CN$: acetonitrile; FA: formamide; MeOH: methanol; TFE: 2,2,2-trifluoroethanol. Data taken from compilations.[16–18]

To summarize monotonic anion selectivity, the process of anion transfer is strongly biased toward larger, charge-diffuse anions. This Hofmeister bias may be manipulated by varying the H-bond donor ability of the solvent and to a lesser extent by varying the size of the H-bond donor molecules, that is, the presumed number of H-bonds that the solvent can provide to a given anion based on packing considerations. The smaller the anion, the larger the effect. The trend can be reversed in principle by employing small, very strong H-bond donors as solvent molecules. For anions larger than perchlorate, cavity formation (lipophilicity) becomes dominant, and anion selectivity in this class becomes insensitive to H-bond donor ability. We will henceforth in this review interest ourselves in anions smaller than perchlorate as a class and refer to them without further distinction.

## Overcoming the Hofmeister Bias

### *A Qualitative Model*

Now that the Hofmeister bias has been seen to arise in solvation phenomena, we can begin to devise strategies to overcome it toward obtaining selectivity patterns of our own design. To organize our thinking in this regard, we have devized a qualitative model based on established foundational concepts in supramolecular chemistry[25] and bonding in coordination chemistry.[26] The model is shown

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in Figure 2. The diagram shows regions corresponding to normal-Hofmeister, anti-Hofmeister, and non-Hofmeister selectivity.

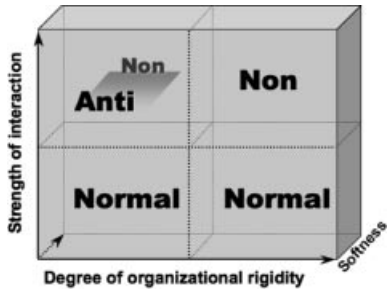

Figure 2. Selectivity in anion separation. The descriptors in the boxes refer to whether normal-Hofmeister, anti-Hofmeister, or non-Hofmeister selectivity is obtained.

It was seen above that the steepness and sign of the Hofmeister bias was controlled mainly by the strength of a primarily electrostatic interaction, H-bonding. Accordingly, as the *number* and *strength* of these individual interactions[25d] between solvent molecules and a given anion increase, normal Hofmeister bias decreases and then, in principle, reverses. Focusing for the moment only on H-bonding interactions, it is clear that the *total* strength of the interaction of the anion with its environment increases with increasing *complementarity*[25a,25c] between the arrangement of H-bonds donated by surrounding molecules and the receptor sites of the anion. However, solvent molecules are at best weakly constrained in their ability to assemble about the anion. Within their own steric constraints and thermal motion, they are free to maximize the net interaction with the anion and with themselves to come to a minimum Gibbs energy condition. If the anion is replaced with another anion, the solvent molecules will be able to move about to accommodate the new anion, again maximizing the total interaction. Thus, we have captured the concept of total interaction strength in the vertical axis in Figure 2, where H-bonding and other interactions can be manipulated subject to our own design. If the interactions are electrostatic and unconstrained, as in fluid systems, the effect is to produce either normal- or anti-Hofmeister selectivity.

To obtain non-Hofmeister selectivity, it is logical either to employ non-electrostatic interactions or to constrain the spatial arrangement of interacting groups or atoms about the anion. In any case, no strategy can succeed in this regard using only weak interactions, because of the steepness of the $Z^2/r_$ dependence. Thus, the lower regions of Figure 2 are the domain of normal Hofmeister selectivity. Most strategies for anion binding today employ H-bonding or other electrostatic interactions as the basis for recognition, and normal Hofmeister bias still tends to be commonly observed, leading us to conclude that systems so far investigated for separations often lack sufficiently strong and structurally constrained H-bond donor groups. The *affinity/selectivity* principle recently put forth[27] leads to the expectation that the greatest selectivity will occur with stronger interactions, which will magnify differences in the ability of a given host to accommodate anions of different size or structure. With a sufficiently strong total interaction with a given anion, implying strong individual interactions and with high overall complementarity, it is expected that peak selectivity for that anion will arise when the structure of the host environment is unable to rearrange to accommodate other anions. For molecular hosts, the familiar term *preorganization*[25b] embodies this concept, but this term loses meaning for self-assembled hosts that form in situ in the presence of the guests. Instead, we chose the term *organizational rigidity* for the horizontal axis in Figure 2, to capture both the concept of rigidity, meaning that the crystal lattice is unable to expand or contract, and structural uniqueness, meaning there is only one favorable way to assemble the subunits of the host framework.

The third axis in Figure 2 allows the introduction of a degree of softness or covalency into the interaction of donor groups with the anion. Given that the Hofmeister bias rests on the strength of electrostatic interactions, primarily H-bonding, then soft Lewis acid/base interactions[26] should lead to peak selectivity for soft or polarizable anions. This should be true even if the soft Lewis acid sites are not constrained in space.

In section 3 of this article, we try to make some comparisons of the above-presented model with literature observations as a way to test our thinking and to look for ways to escape the Hofmeister bias in anion separations. We believe the model is useful in describing three orthogonal concepts, that of total binding strength (embodying the concept of complementarity), organizational rigidity, and softness. However, the model is meant only to be a qualitative guide, with no fixed divisions between resultant selectivity patterns. Moreover, there are obvious limits to be encountered. For example, H-bond donor groups should not be so strong that proton-transfer processes occur, leading to considerations beyond this discussion. In addition, one does not desire to employ covalent interactions to the degree that the guest anion is chemically transformed or that the binding becomes irreversible. Host/guest chemistry and separation chemistry share the general approach of using reversible, non-covalent interactions.

### *Single-Point Interactions*

Toward ultimate shape selectivity that violates the Hofmeister bias in a separation, one must assemble groups in space that interact with an anion along defined vectors. Solid-state host assemblies like MOFs are well suited for this task, though most of the insight obtained thus far on anion recognition has emerged from studies of molecular systems in solution. From the literature on anion coordination chemistry, one can make use of H-bonding, coulombic, Lewis acid/base, van der Waals, hydrophobic, and other interactions.[28,29] Let us first examine selectivity inherent in certain single-point interactions that must ultimately be assembled in the complete host/guest supramolecular structure.

Coulombic interactions are anti-Hofmeister and will therefore influence bias. Whereas solvation involves the ide-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

alized lone ion surrounded by solvent molecules, real separation systems involve interactions with counterions. These can be incorporated into receptor design itself[25a,28,29] but otherwise must still be allowed for as one of the governing factors in the resultant selectivity obtained. Viewing extraction as a step-wise process, the first step can be taken as ion partitioning followed by other interactions, which include ion-pairing or coordination. Ion-pairing usually favors small anions for a given cation, and this interaction opposes Hofmeister bias.[5] However, for univalent ions, ion-pairing is generally a weaker influence on selectivity as compared with solvation, and thus, Hofmeister bias persists, albeit attenuated. A prime example is the use of lipophilic quaternary ammonium salts as liquid/liquid anion exchangers, and the selectivity is also seen in strong-base anion-exchange resins.[5,14] It has been seen that the size of the cation determines the steepness of the bias, smaller quaternary ammonium cations possessing smaller alkyl chains, giving larger attenuation of Hofmeister bias.

More generally, coordination of anions with Lewis acid sites allows wide latitude in obtaining desired selectivity, leading to potential departures from Hofmeister bias selectivity. Such interactions may be treated as coordination or ion-pairing phenomena as appropriate, but in general the effect on selectivity derives from the bonding interaction with the Lewis acid site. Accordingly, the hard/soft acid/base concept[26] lends itself well in manipulating selectivity. Because the origin of Hofmeister behavior is so strongly influenced by the H-bonding ability of the solvating environment and because H-bonding is largely electrostatic, it may be expected that, constraining steric or multi-point (chelating) effects being absent, hard Lewis acid sites may tend to give rise to normal- or anti-Hofmeister bias. The hard/hard interaction itself tends to be anti-Hofmeister, the question being whether this effect is sufficiently strong to overcome the Hofmeister bias of the ion-partitioning step. If the charge on the hard Lewis acid site is not high, the strength of the coordination interaction is usually insufficient to reverse the Hofmeister bias of ion partitioning but only to attenuate it. This is typically the case with extraction of alkali and alkaline earth cations by crown ethers, which has been long known to follow the normal Hofmeister bias.[5,19,20,30] Accordingly, salts with charge-diffuse anions are easier to extract, implying that such anions (like perchlorate) would exchange for more hydrophilic ones (like nitrate or chloride) associated with the organic-phase crown ether complex of the extracted metal cation. This bias has been used to advantage to extract sodium pertechnetate from nuclear waste (high in nitrate), for example.[31,32] It should be pointed out that the actual coordination of the anion to Lewis acid centers in solution in most cases is not confirmed, and it is possible that the anion interacts through a mediating water molecule or outer-sphere ion-pairing.

As the charge of the Lewis acid site increases, it is indeed found that the Hofmeister bias can be disturbed or reversed in accordance with a strong hard/hard interaction, though steric influences are typically present. Thus, an enhanced fluoride selectivity is often observed, and the selectivity may overall be non- vs. anti-Hofmeister. Examples are known in which sorbent materials containing higher-charged metals like $Fe^{III}$ and $Zr^{IV}$ prefer small, hydrophilic anions.[33,34] In liquid/liquid extraction and transport, a (salen)$Mn^{III}$-type complex and a neutral tetraaza-macrocyclic $Ni^{II}$ complex were observed to have enhanced fluoride selectivity.[35] In transport using these respective carriers, the following orders were found: $F^- > Br^- > Cl^- > NO_3^-$ and $Cl^- > F^- > NO_3^- > Br^-$, while in extraction, the $Mn^{III}$ complex gave the order $Br^- > NO_3^- > F^-$ and the $Ni^{II}$ complex detectably extracted only $F^-$. Neutral tris(β-diketonato) complexes of lanthanides transport $Cl^-$ faster than $Br^-$, $I^-$, and even $ClO_4^-$.[36]

The use of Lewis acid sites for selective anion binding has been under investigation for development of potentiometric anion sensors, providing insight into anion-binding selectivity in ion partitioning. Typical membrane electrodes employ a polymer membrane, such as poly(vinyl chloride), containing a plasticizer, solvating additives, quaternary ammonium anion exchanger, and possibly an ion receptor. Without an anion receptor, the normal Hofmeister order of electrode selectivity is obtained in accordance with a governing solvation principle.[15,37] Added Lewis acid anion receptors yield selectivity patterns violating the normal Hofmeister order. Metalloporphyrins[38] and phthalocyanates[39] yield varied responses depending on the bound metal ion. With hard metal ions like $Zr^{IV}$,[38b] $Lu^{III}$,[38c] and $Al^{III}$,[39] it is typical for the $F^-$ response to be enhanced relative to the other anions, which still tend to follow the Hofmeister order. Fluoride and thiocyanate are even selected in preference to perchlorate using (octaethylporphyrin)$Zr^{IV}$.[38b] With (octaethylporphyrin)$In^{III}$, a striking rejection of nitrate and perchlorate in favor of thiocyanate and iodide was obtained in electrodes designed for salicylate response.[38a] Other types of Lewis acid receptors have also yielded non-Hofmeister selectivity in membrane electrodes. Thiocyanate selectivity has been obtained using a (Schiff base)Cd complex[40] and triphenyltin chloride.[41] Iodide selectivity was achieved with a lipophilic $Hg^{II}$ complex.[42] A remarkable non-Hofmeister selectivity was obtained with certain organodifluorotin(IV) compounds, giving the order: $F^- > CH_3COO^- > Cl^- > I^- \approx Br^- > ClO_4^- > NO_2^- > NO_3^- > SCN^-$.[43]

### *Multipoint Recognition*

Researchers have taken an active interest in finding synthetic molecular receptors that violate Hofmeister behavior in separations by use of constrained multipoint binding interactions. Despite the considerable challenge posed by the steep bias in ion partitioning ($Z^2/r_-$ dependence),[44] the progress made so far indicates that a combination of sufficiently strong and structurally constrained binding sites on the host can succeed in this regard. Starting with less effective systems, the bidentate H-bond donors that have been examined appear to be too weak with respect to H-bond strength or rigidity to effect significant departures from Hofmeister bias. In that the anions are still largely open to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the influence of solvation, overall complementarity is low, and the affinity/selectivity principle[27] would imply only perturbation or attenuation of Hofmeister bias. These near-normal Hofmeister systems thus lie in the lower left box in the selectivity model shown in Figure 2. Examples in liquid/liquid extraction include diphenylurea[45] and *m*-diphenyldisulfonamides,[20,46] though peak selectivity for iodide has been claimed for monothiouronium receptors.[47] Receptors offering four or more H-bonds on flexible arms show greater signs of disrupting the expected Hofmeister order. However, typically the charge-diffuse anions like $ClO_4^-$, $I^-$, and $SCN^-$ are still favored, and non-Hofmeister behavior tends to take the form of enhancements for certain anions or switched preferences within the series. Even with a rigid steroidal platform supporting two or three arms, "cholapod" receptors with varied H-bond donor functionalities (imide, amide, carbamate, urea, thiourea, and sulfonamide) still basically follow near-normal Hofmeister behavior in liquid/liquid extraction.[27,48] Tris- and tetrakis(amide) receptors employing polyaza-macrocycle platforms exhibited normal Hofmeister bias in transport.[34] Evaluated in ion-selective electrodes, this group also includes iodide-selective bis(thiouronium) receptors,[47] tripodal tris(ureas) with enhanced sulfate sensitivity,[49] and bis(thiourea) receptors employing a rigid steroidal platform also with enhanced sulfate sensitivity.[50]

The greatest degree of success in achieving non-Hofmeister behavior (upper right box in Figure 2) has involved macrocyclic geometries in which H-bond donor functionalities are constrained as part of the ring structure and also systems employing Lewis acid binding sites. An elegant demonstration of the macrocyclic effect on extraction selectivity was obtained by cyclization of two urea arms on a steroid platform, whereupon the nearly normal Hofmeister behavior of the uncyclized analog was transformed in the most striking case to the non-Hofmeister ordering: $Br^- > I^- \approx Cl^- > NO_3^- > PF_6^- > CH_3COO^- \approx EtSO_3^-$.[51] The selectivity order depended upon the link used in the cyclization. Fluorinated calixpyrroles featuring strong H-bond donation and the constraints of macrocyclic geometry exhibit non-Hofmeister behavior in liquid/liquid extraction.[52] Orders observed for the octafluorocalix[4]pyrrole and the decafluorocalix[5]pyrrole differed as follows: $ClO_4^- > I^- \approx Br^- \approx Cl^- > NO_3^- > F^-$ and $ClO_4^- > I^- \approx NO_3^- > F^- > Br^- > Cl^-$, respectively. Interestingly, the selectivity order for calix[4]pyrrole is anti-Hofmeister: $HPO_4^{2-} \approx F^- \approx OH^- > Cl^- > Br^-$.[53]

Receptors containing metal cations as well as H-bond donor groups offer the potential for anion/metal interaction and greater encapsulation of the anion, and the metal complexation can also serve to organize the anion-binding groups. Only a limited number of systems have been studied in extractive separations; (salophene)uranyl receptors bearing two sulfonamide sidearms were shown to be selective carriers for $H_2PO_4^-$ vs. $Cl^-$, the latter being the anion preferred by solvation effects alone.[54] A salicylaldoxime complex of $Ni^{II}$ exhibits the normal Hofmeister $Cl^-/SO_4^{2-}$ selectivity in transport experiments in which protonation of amine-containing sidearms provides both cationic and H-bond donor sites.[55] The metal ion serves only to organize the sidearms rather than serve as an anion-coordination site. Normal Hofmeister selectivity ($I^- > Br^- > Cl^-$) was also observed in transport of alkali metal salts by macrobicyclic receptors in which the two N atoms of the crown ether diaza-18-crown-6 are bridged by isophthalamide-type bridges capable of donating two H-bonds.[56] In this case, mild cation/anion interaction and structural constraints suffice only to attenuate the normal Hofmeister order. Selective transport of $Cl^-$ over other halide ions was observed with transition-metal-containing resorcinarenes bearing bis(pyridylmethyl)amine sidearms for metal-ion binding.[57]

## 3. Anion Separation with Metal–Organic Frameworks

Conceptually, we pose the question as to whether a strategy can be devized for obtaining separation selectivity by design in MOFs by taking some lessons learned from the study of molecular systems as discussed above and as illustrated in Figure 2. Quite simply, we are led to expect that normal Hofmeister selectivity will arise from H-bonding or other interactions involving the anion in the receiving-phase (MOF) environment that are weaker than those in water. Stronger H-bonding or other interactions that could compensate for anion dehydration would lead to anti- or non-Hofmeister behavior depending on the softness of the host binding sites and the degree of organizational rigidity of the MOF. In particular, MOFs offer the potential to achieve the extreme organizational rigidity that has been so elusive in molecular hosts. Provided that the included anions interact sufficiently strongly with surrounding groups within the MOF, which requires a high degree of complementarity between the binding sites of the guest anion and the host MOF, it should therefore be possible to approach perfect peak selectivity with total exclusion of all but the target anion. This ideal condition leads to non-Hofmeister selectivity in the upper right quadrant of Figure 2. If there are multiple ways to assemble the MOF to accommodate different anions or if the unit-cell parameters are adjustable, then the resulting lower degree of organizational rigidity would lead leftward in the diagram in Figure 2 toward anti- or non-Hofmeister behavior depending on the softness of the individual binding interactions. Regarding the lower right quadrant of the diagram, a question remains as to whether a rigid MOF with little or no ability to donate H-bonds would exhibit step or threshold selectivity. This may be true, as we suspect it is for molecular systems, but among the anions below the size threshold that could fit inside the MOF cavities, the larger, poorly hydrated anions would still be preferred, which is in effect Hofmeister behavior. The size cut-off effect may also apply to less rigid frameworks, as the crystal lattice can only expand to the point that the intermolecular interactions that insure the crystal cohesion become too weak relative to the solvation of the MOF components, which would lead to crystal dis-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solution. Alternatively, if anion binding represents a significant portion of the total lattice energy, the MOF crystal may only form with those anions whose interaction energies exceed a certain threshold, which would also lead to step selectivity.

An important issue with direct implications on how one can best approach the anion separation with MOFs is the anion-exchange mechanism in this class of materials. Figure 3 depicts the two mechanisms generally expected for anion exchange in MOFs. The early studies almost universally assumed a solid-state exchange mechanism, similar to those found in ion-exchange resins or zeolites, which occurs by diffusion of the ions in and out of the crystals with preservation of the structural integrity of the coordination network. This assumption was generally based on the observation that MOFs have very low solubility in most solvents, and, in some cases, on the structural similarities between the initial and final frameworks. However, a recent study by the groups of Champness and Schröder challenged this commonly accepted view, and demonstrated without equivoque that, at least in certain one-dimensional coordination polymers, the apparent anion exchange from water is solvent-mediated, involving dissolution and recrystallization of the MOF crystals.[58,59] This process is driven by the difference in solubility between the initial and final MOF phases, and does not require substantial water solubilities. In fact, anion exchange by dissolution/recrystallization has long been known in simple inorganic salts. For example, silver chloride, which for all practical purposes is considered water-insoluble, exchanges 90% of $Cl^-$ by $I^-$ within minutes, a process that is driven by the even smaller solubility of AgI in water. This process was exploited for the recovery of radioactive iodide from fission products.[60]

Although the dissolution/recrystallization appears the most likely mechanism for anion exchange from water, we cannot completely rule out the possibility that the anion exchange may occur by a solid-state exchange mechanism in some cases, or a combination of the two mechanisms. Such a scenario, however, requires that the anion diffusion through the coordination network be fast enough to compete with the dissolution/recrystallization process. To the best of our knowledge, no solid-state anion-exchange mechanism has been unequivocally demonstrated for any MOF to date.[61]

We have recently articulated an alternative approach to anion separation that involves competitive crystallization of the coordination networks.[62] This strategy differs from the traditional anion-exchange approach with the MOFs treated as separation agents, in that the crystallization process involved in the MOF synthesis is in itself exploited as a separation tool. More specifically, the MOF is competitively crystallized from a mixture of anions, which may result in the selective inclusion of certain anions depending on their size, shape, or specific interactions with the network. Such an approach avoids the common problem of slow ion-exchange kinetics in the solid state and broadens the applicability of MOFs to one of the commercially most important and economical separation technology, namely crystallization.

Whether the anion separation is realized by ion exchange, similarly to zeolites or ion-exchange resins, or by competitive crystallization, anion selectivity in MOFs is ultimately determined by the intermolecular interactions between the anion and the crystalline MOF matrix. It is therefore instructive to classify the MOFs that have relevance to anion exchange or separation based on the nature and

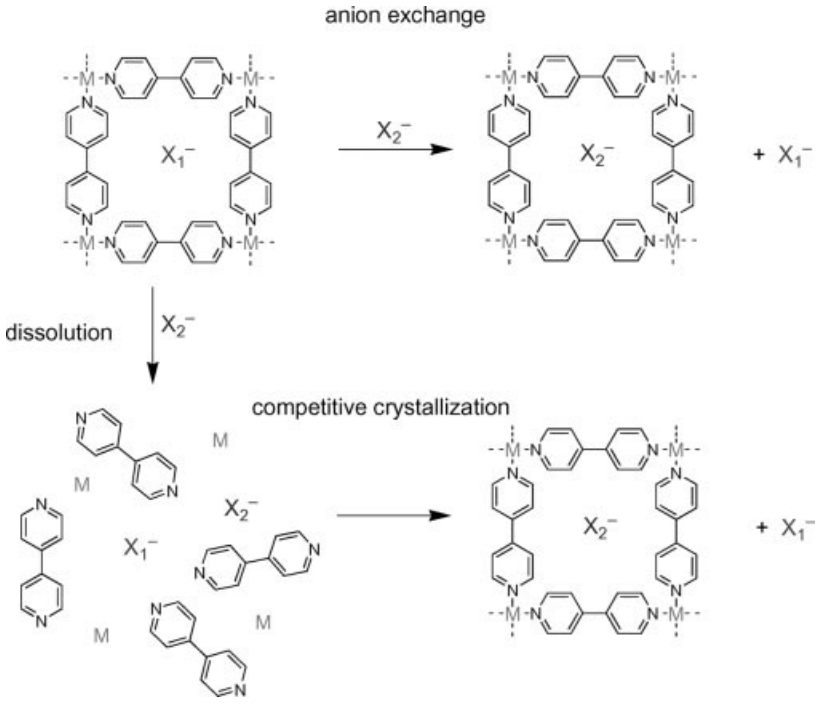

Figure 3. Generic representation of the two main mechanisms expected for anion exchange in MOFs.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

strength of anion/framework interactions, and try to correlate these with the observed anion selectivities. Figure 4 illustrates the main types of interactions involving anions inside MOF crystals. The most common situation (case a) involves van der Waals interactions between the anion and the coordination network, with long-range coulombic interactions with the cationic framework additionally present.

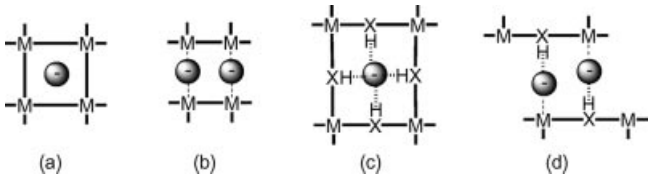

Figure 4. Typical intermolecular interactions involving anions inside MOFs. (a) van der Waals and coulombic; (b) metal coordination; (c) hydrogen bonding; (d) hydrogen bonding and metal coordination.

These interactions are typically too weak to overcome the solvation bias and thus lead to normal Hofmeister selectivity. A step (threshold) selectivity based on the anion size may nevertheless be expected, as too-large anions may not fit inside the MOF lattice and could therefore be excluded. The next case involves direct anion coordination to the metal centers in the network (case b). These Lewis acid/base interactions may partly compensate for the anion dehydration and thus attenuate the Hofmeister bias, or, if they are sufficiently strong, they may even reverse it (anti-Hofmeister selectivity). However, unless the MOF is organizationally rigid or unless the metal coordination sites are soft, peak selectivity (non-Hofmeister) is unlikely to be observed. Cases c and d involve specific hydrogen bonding or combinations of hydrogen bonding and metal coordination between the anion and the framework. These interactions may be very specific, and, as a function of their number and strength, may overcome the solvation bias resulting in

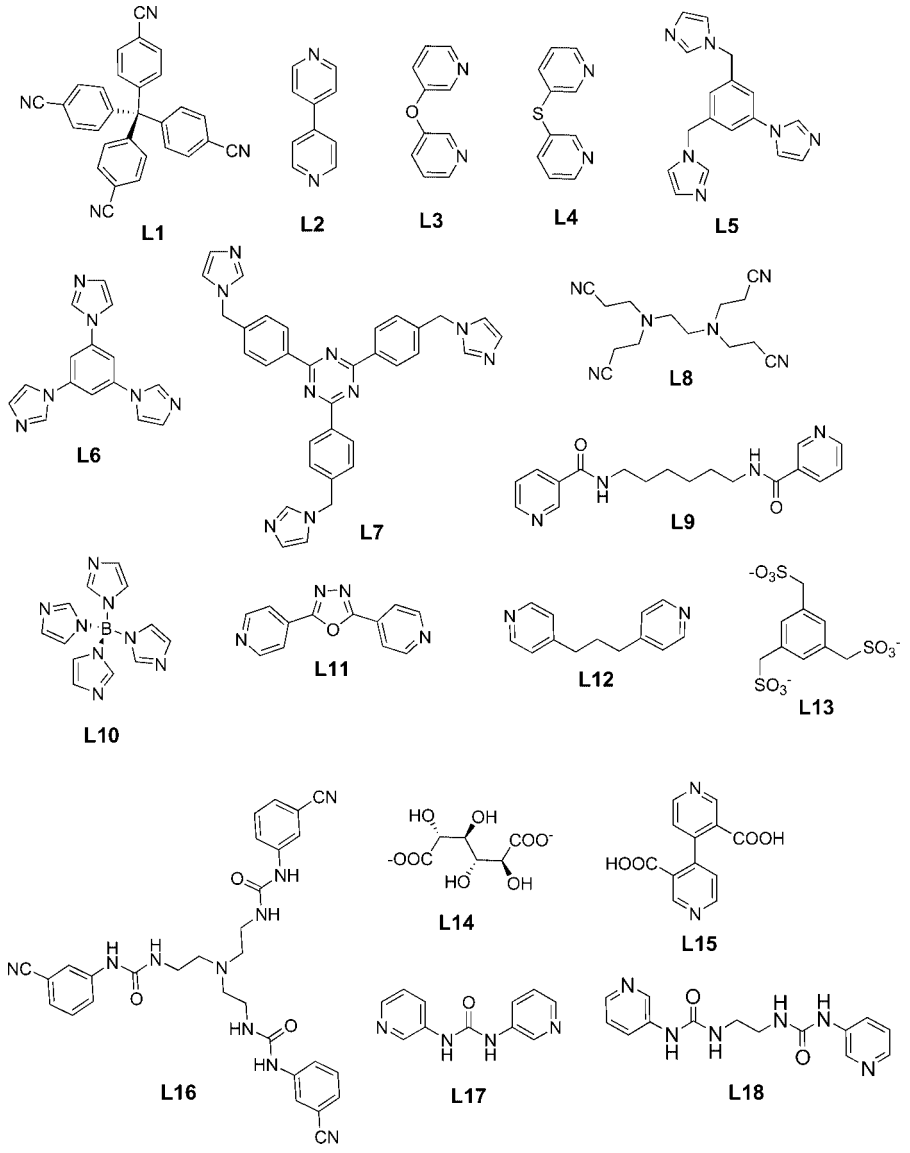

Figure 5. MOF linkers employed for anion exchange or separation.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

either anti-Hofmeister or non-Hofmeister selectivities, depending on the rigidity of the framework.

In the following pages, specific examples of each class of anion interactions will be presented in the order of increasing binding strength, starting with nonspecific van der Waals interactions and moving towards more selective metal coordination and hydrogen-bonding interactions. Figure 5 lists the organic linkers involved in the MOFs discussed in this review.

### Anion Inclusion by van der Waals and Coulombic Interactions

As most coordination solids reported in the literature are built from relatively large and nonpolar organic linkers (Figure 5), the resulting anion-binding sites are fairly hydrophobic, an environment not very different from those found in nonpolar organic solvents or ion-exchange resins. Anion inclusion selectivity in these solids is thus typically dominated by solvation effects, which results in Hofmeister bias, favoring larger, less hydrophilic anions such as $ClO_4^-$ or $PF_6^-$.

One of the first deliberately designed coordination networks, reported by Robson et al. in 1990,[3] was built from linker **L1** and $Cu^I$ cations, which resulted in a 3D coordination framework with a diamondoid topology containing large pores filled with disordered solvent and $BF_4^-$ counteranions. The $BF_4^-$ anions could be easily exchanged with $PF_6^-$, but the reversibility and selectivity of the exchange was not reported. Five years later, Yaghi et al. reported another 3D coordination framework of $Cu^I$ with **L2**, which included hydrated $NO_3^-$ as counteranion. The disordered nitrate anions were loosely bound inside the channels, and could be easily exchanged in aqueous media by either hydrophobic $BF_4^-$, or hydrophilic $SO_4^{2-}$. The anion-exchange selectivity was, however, not addressed in this study.[63] When $NiClO_4$ was used with the same linker, a different coordination framework was obtained, which displayed a 1D railroad topology that included large channels filled with additional linker molecules, water solvent, and perchlorate anions. The anions were once again disordered, indicating weak interaction with the channel walls. Removal of the water solvent from the channels further increased the mobility of the perchlorate anions, which could be easily exchanged with $PF_6^-$.[64]

An interesting series of coordination polymers was reported by Jung et al., who used linker **L3** with various silver salts AgX (X = $NO_3^-$, $BF_4^-$, $ClO_4^-$, and $PF_6^-$) to assemble 1D helical coordination frameworks that included the anions inside the cationic cylindrical channels created inside the helices (Figure 6).[65] The coordination helices showed remarkable flexibility, adjusting their helical pitch to the size of the anion, from 7.4 to 9.6 Å. The anions could be readily exchanged with each other, which can be explained by their nonspecific interactions with the hydrophobic channels, and the high flexibility of the helices. However, no anion-selectivity information was provided. When the analogous linker **L4** was used instead, similar coordination polymers with helical topology were obtained, which also displayed anion exchange abilities, with the large $ClO_4^-$ and $PF_6^-$ being preferred over the smaller $NO_3^-$ or $BF_4^-$ anions (Hofmeister selectivity).[66]

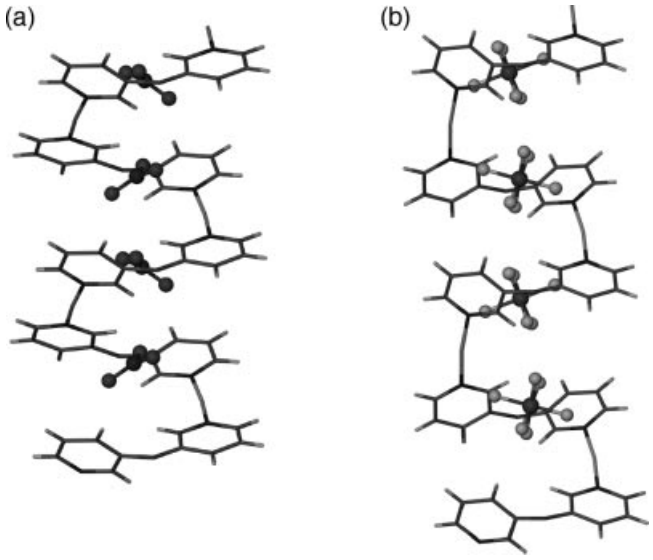

Figure 6. Crystal structures of [Ag(**L3**)]X showing helical coordination polymers (stick) with anions (ball-and-stick) included in the cylindrical channels inside helices: (a) X = $NO_3^-$; (b) X = $PF_6^-$.

A number of MOFs intercalating anions between hydrophobic 2D coordination layers have been reported. For example, Suh et al. described a series of Ag coordination polymers containing linker **L8**, and $NO_3^-$, $ClO_4^-$, and $CF_3SO_3^-$ anions, and reported their anion exchange properties.[67] The structures containing perchlorate or triflate displayed 2D coordination networks with the anions intercalated between the hydrophobic layers, while the structure containing the nitrate displayed 1D coordination chains, with the $NO_3^-$ coordinating the silver cations (Figure 7). Pairwise anion exchange experiments showed Hofmeister selectivity with $ClO_4^-$ being the most favored anion. Nitrate, on the other hand was favored over $CF_3SO_3^-$, which is a perturbation from the Hofmeister series, a fact that may be attributed to $NO_3^-$ coordination to the Lewis acid $Ag^+$.

Sun et al. reported a series of layered cationic frameworks with anion exchange properties, containing linkers **L5**–**L7** coordinating various transition metals.[68] Figure 8 illustrates a typical example involving linker **L5** and $Cd(NO_3)_2$, with the nitrate anions and solvent water molecules occupying the space between the cationic $Cd(\mathbf{L5})_2$ layers.[68b] The nitrate anions could be completely exchanged by $ClO_4^-$ with the formation of an isostructural coordination network, as found by powder X-ray diffraction and FTIR. The anion exchange was not completely reversible, as only about 50% of $ClO_4^-$ could be exchanged with $NO_3^-$, indicating Hofmeister selectivity. The $NO_2^-$ anion, on the other hand, could be reversibly exchanged with $NO_3^-$, apparently due to the more similar free energies of hydration of these two anions compared with the less hydrophilic $ClO_4^-$.

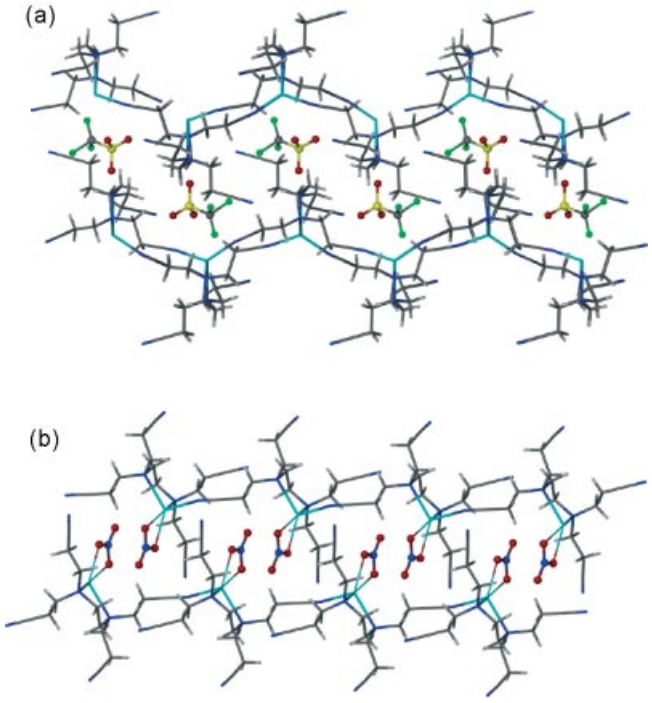

Figure 7. X-ray crystal structures of [Ag(**L8**)]X [X = $CF_3SO_3^-$ (a), $NO_3^-$ (b)], showing the intercalation of the anions between hydrophobic layers (a) or chains (b). Coordination frameworks and anions are shown as stick and ball-and-stick models, respectively.

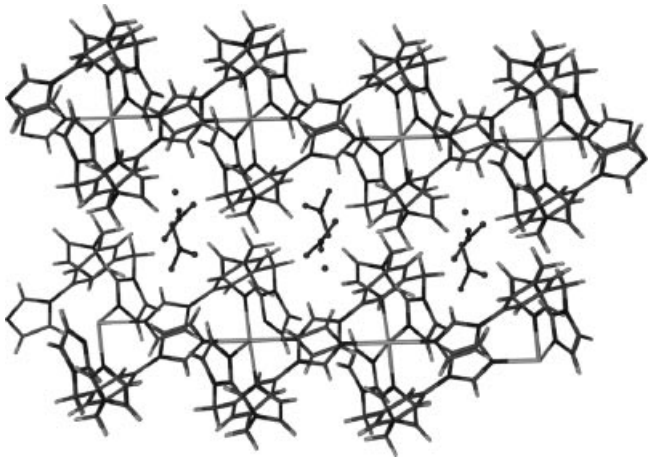

Figure 8. Crystal structure of [Cd(**L5**)$_2$]$(NO_3)_2(H_2O)$ with the nitrate and water intercalated between coordination layers. Coordination framework and anions are shown as stick and ball-and-stick models, respectively.

An interesting case of anion selectivity was found by Kitagawa et al. in a coordination polymer obtained from **L2** and $Cu^{2+}$ in the presence of an equimolar mixture of $PF_6^-$ and $ClO_4^-$ anions, which resulted in a 2D layered structure containing two types of channels, with the two anions included separately in each channel.[69] It is remarkable that despite the absence of any specific interactions between the anions and the coordination framework, the two anions were individually recognized by the two slightly different channels, which resulted in the separation of $PF_6^-$ and $ClO_4^-$, albeit only on a molecular scale (Figure 9).

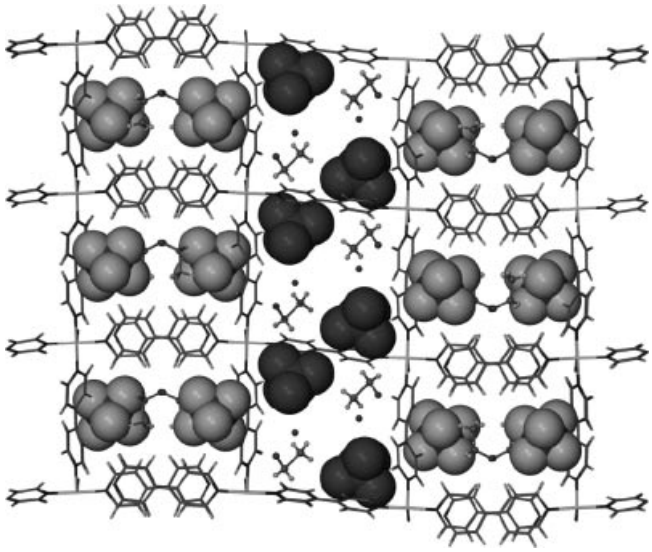

Figure 9. Crystal structure of $[Cu_2(\mathbf{L2})_5(H_2O)_4](ClO_4)_2(PF_6)_2(H_2O)_2(EtOH)_4$ showing the segregation of $ClO_4^-$ and $PF_6^-$ in alternating channels. Coordination framework, anions, and solvent are depicted as stick, space-filling, and ball-and-stick models, respectively.

### Anion Inclusion by Metal Coordination

Because most metal cations in MOFs have significant Lewis acidity, it is not uncommon for the metal nodes to serve as binding sites for the anions. Considering that these interactions may be relatively strong and directional, it can be anticipated that the presence of anion–metal coordination bonds could reverse the Hofmeister bias otherwise expected for anion exchange in hydrophobic MOFs. It should be kept in mind, however, that anion–metal coordination interactions do not operate alone in the crystal, and the ubiquitous van der Waals forces may remain in many cases the overall dominant interactions between the anion and the coordination framework, thus leading to Hofmeister selectivity. The same result should be expected if the anion is exposed to a significant degree to the water solvent present in the channels (poor complementarity).

An early example of exchange of an anion associated with a metal center in an MOF was reported by Yaghi et al.[70] Nitrate anions in [Ag(**L2**)]$(NO_3)$ interact weakly with the silver nodes in this 3D coordination network, and can be exchanged reversibly by $PF_6^-$, $MoO_4^-$, $BF_4^-$, or $SO_4^{2-}$. However, since the structures of the resulting exchanged solids have not been elucidated, and competition experiments have not been reported, it is difficult to evaluate the anion selectivity of these MOFs.

An extensive anion exchange study in a series of coordination polymers with the general formula [Ag(**L9**)]X (X = $ClO_4^-$, $NO_3^-$, $CF_3SO_3^-$) was reported by Yip et al.[71] The linker connects the silver nodes into 1D coordination

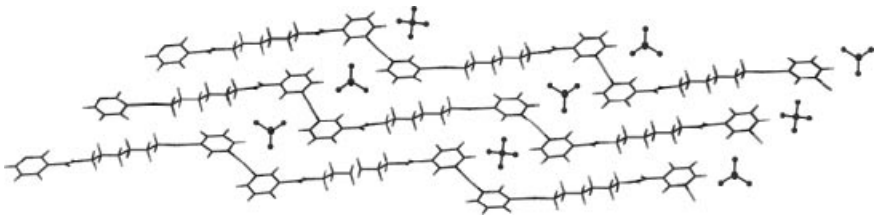

Figure 10. Crystal structure of [Ag(**L9**)]($ClO_4$) showing perchlorate anions intercalated between coordination layers and positioned within close proximity to the silver nodes. $ClO_4^-$ anions are disordered, and only one orientation is depicted for clarity. Coordination framework and anions are shown as stick and ball-and-stick models, respectively.

chains, which are further associated into layers by NH···O hydrogen bonds among the amide groups. The anions are weakly coordinated to the Ag cations and are located between the layers, with the perchlorate and nitrate anions displaying significant disorder (Figure 10). Despite the anions being coordinated to the Ag Lewis acid centers, these interactions were apparently not strong enough to completely overcome the anion solvation bias in this series of coordination polymers, as pairwise anion exchange experiments indicated the following selectivity: $ClO_4^- > NO_3^- > CF_3SO_3^-$. While the preference for perchlorate indicates Hofmeister behavior, the selectivity of $NO_3^-$ over $CF_3SO_3^-$ represents a perturbation from the Hofmeister series, which may be the result of the stronger nitrate coordination to the Ag nodes.

Crystallization of **L2** and $Cu^{2+}$ from an equimolar mixture of $NO_3^-$ and $PF_6^-$ resulted in the inclusion of both anions in a 1:3 ratio. The 2D square grids of the resulting coordination network are further linked in the third dimension by alternating $NO_3^-$ and $PF_6^-$, with two additional $PF_6^-$ anions being included inside the hydrophobic channels of the crystal (Figure 11). Attempts to co-include other anions such as $BF_4^-$ or $SO_4^{2-}$ failed, and only $PF_6^-$ was included in the presence of these two anions. Thus, the more hydrophobic $PF_6^-$ seems to be preferred by this coordination network, although the inclusion of $NO_3^-$ but not of $BF_4^-$ or $SO_4^{2-}$ indicates peak selectivity.[69]

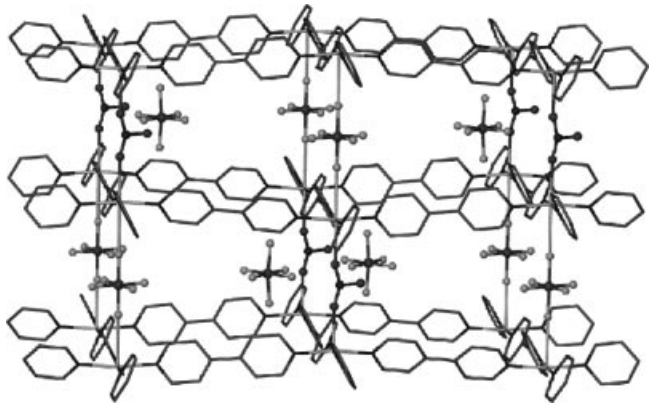

Figure 11. Crystal structure of $[Cu_2(PF_6)(NO_3)(\mathbf{L2})_4](PF_6)_2(H_2O)_2$ showing 2D $Cu^{II}$ coordination grids connected by bridging $NO_3^-$ and $PF_6^-$ anions, and the inclusion of additional $PF_6^-$ anions inside the channels. Included water solvent is not shown. Anions are depicted as ball-and-stick models and the framework as a stick model.

The anion selectivity in MOFs containing metal-binding sites can also be controlled by the match between the hardness or softness of the anion (Lewis base) and metal center (Lewis acid). For example, the 2D coordination network made from **L10** and soft $Pb^{2+}$ Lewis acid metal centers can easily exchange nitrate with the softer iodide. The nitrate anions do not coordinate the metal nodes and occupy the interlayer space together with solvating water molecules. Upon exposure to an aqueous solution containing 1 molequiv. of KI, the nitrate could be completely exchanged with iodide, with the latter coordinating the $Pb^{2+}$ Lewis acid centers (Figure 12).[72]

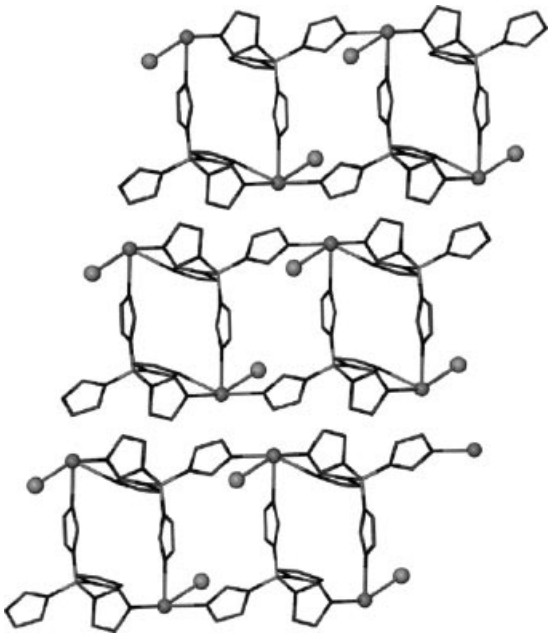

Figure 12. Crystal structure of [Pb(**L10**)]I showing a layered framework with the iodide anions coordinating the lead metal centers. The $I^-$ and $Pb^{2+}$ are depicted as balls and **L10** is shown as a stick model.

A clear example of anti-Hofmeister selectivity was observed in the anion exchange in a series of MOFs built from **L11** and $Cu^{2+}$.[73] When $PF_6^-$ and $ClO_4^-$ were used as anions, two isostructural coordination networks with interpenetrated 3D diamondoid topologies were obtained, with the non-coordinating hexafluorophosphate or perchlorate anions and water solvent molecules occupying the pores. These anions could be irreversibly exchanged with the more hydrophilic $N_3^-$ or $SO_4^{2-}$ anions, with complete reorganiza-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion of the coordination networks. Figure 13 depicts the crystal structure of the sulfate-exchanged framework, which consists of layers of $Cu^{2+}$ coordinated by $\mu_3$-bridging sulfate anions, with the organic linkers connecting the inorganic layers. Apparently, the strong and specific coordinating bonds to the copper centers resulted in the sulfate anions being preferred against the weaker Lewis bases $PF_6^-$ or $ClO_4^-$. However, since the two structures have completely different architectures (and therefore different stabilities), it is not clear to what extent the preference for sulfate can be attributed to its stronger Lewis basicity or to the inherent difference in stability between the two coordination networks.

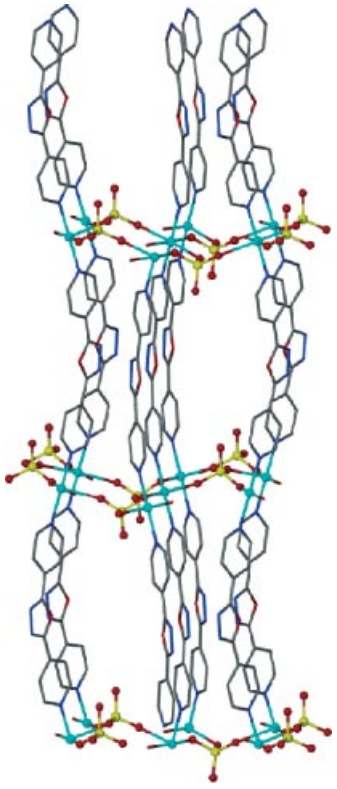

Figure 13. Structure of [Cu(**L11**)($H_2O$)($SO_4$)]($H_2O$)$_2$ showing $Cu^{II}$–$SO_4$ coordination layers connected by **L11** linkers into a 3D framework. The sulfate anions and the copper centers are depicted as ball-and-stick models and the linker is shown as a stick model. Water molecules included in the channels are not shown.

That the framework stability can decisively influence the anion exchange selectivity in MOFs was clearly demonstrated in the coordination networks [Ag(**L12**)(X)] (X = $ClO_4^-$, $PF_6^-$).[74] The two solids have similar coordination structures consisting of 1D coordination chains, with the anions weakly coordinating the silver centers. The two structures differ though in the number and strength of the inter-chain Ag–Ag interactions. The perchlorate anion was irreversibly exchanged with hexafluorophosphate, a process that was driven by the argentophilic interactions that were stronger and more numerous in the $PF_6^-$ structure. This example is a clear illustration of how other types of intermolecular forces in MOF crystals can override the anion-framework interactions, and thus control the anion selectivity.

### Anion Inclusion by Hydrogen Bonding

Among the intermolecular interactions involving anions, hydrogen bonding appears to have the greatest potential for inducing non-Hofmeister selectivity. In this regard, the ready availability of chelating hydrogen-bonding groups that can establish multiple contacts with the targeting anions, and the possibility of appending multiple such groups to organic linkers by using the power of organic synthesis, offer great prospects for the design of MOFs with shape recognition and non-Hofmeister selectivities. One of the remaining challenges associated with the utilization of hydrogen-bonding groups, though, is their tendency to self-associate, which diminishes or completely eliminates their ability to bind anions. The elaboration of functional MOFs for anion recognition and separation needs therefore to incorporate effective molecular- and crystal-design strategies that prevent such self-neutralizing "reactions" among the hydrogen-bonding groups from occurring.

The most common situation of anion hydrogen bonding in MOFs involves coordinating water as a proton donor. An example of coordination network in this category that was explored as an anion exchanger is [$Ba_2$(**L13**)($H_2O$)$_5$]Cl, reported by Shimizu et al.[75] This structure can be described as consisting of cationic barium sulfonate layers pillared by the mesitylene linkers into a 3D coordination network containing channels occupied by chloride anions (Figure 14). The $Ba^{2+}$ centers are further coordinated by water molecules, which act as hydrogen-bond donors to $Cl^-$. Most chloride anions (75–85%) could be exchanged by fluoride when the crystals were suspended in MeCN containing 1 equiv. of $F^-$. However, since the anion exchange was effected from a relatively nonpolar solvent, the inclusion of the more hydrophilic fluoride inside the polar channels of this coordination framework is not surprising, and may be considered normal Hofmeister behavior.

The microporous coordination polymer made from the hydrophilic linker **L14** and $Tb^{3+}$ was recently reported to selectively sense anions (Figure 15).[76] Despite its neutral charge, this coordination network can absorb different anions (as sodium salts) into its hydrophilic channels functionalized with free –OH groups. The anion inclusion was detected by the luminescence enhancement caused by the interactions of the anions with the network, presumably through hydrogen bonding. The response to various anions was found to follow the order: $CO_3^{2-} > CN^- > I^- > Br^- > Cl^- >> F^- \approx SO_4^{2-} \approx PO_4^{3-}$. One may easily notice that except for carbonate and cyanide the other anions conform to the Hofmeister behavior, indicating that the presence of the –OH hydrogen-bonding groups is not sufficient to reverse the solvation bias in this MOF. The strikingly different selectivity for carbonate and cyanide, which are both relatively strong bases, suggests to us a different mechanism

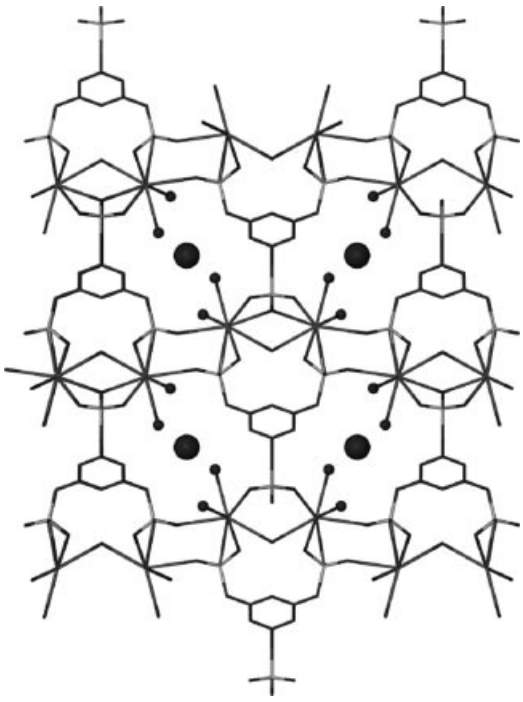

Figure 14. Structure of the $[Ba_2(\mathbf{L13})(H_2O)_5]Cl$ coordination network showing chloride anions (large balls) included in polar channels decorated with water molecules (small balls) acting as hydrogen-bond donors. The water protonscould not be located from the X-ray structure.

for their binding, possibly involving deprotonation of the OH groups. Unfortunately, no structural information about the binding of the anions (and the sodium countercation) inside the channels of this material is available, which makes the interpretation of the observed selectivity difficult.

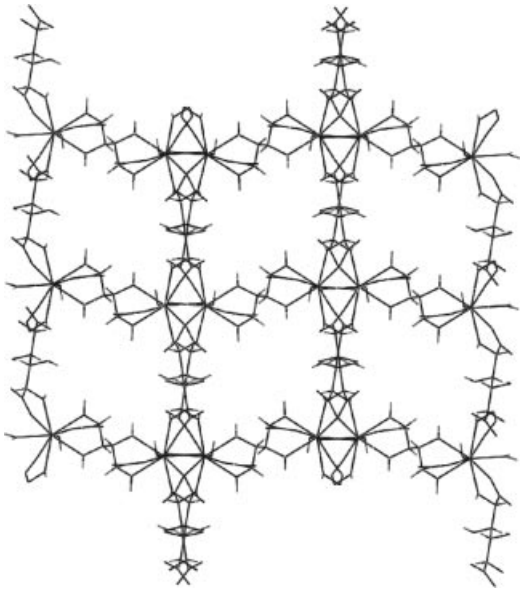

Figure 15. Crystal structure of $[Tb(\mathbf{L14})_{1.5}(H_2O)_2](H_2O)_5$, with the water included in the channels removed.

Work in our group has involved the design and synthesis of coordination frameworks functionalized with hydrogen-bonding groups for anion recognition and separation. Along this line, we synthesized a cationic square-grid coordination network assembled from $Cu^{2+}$ and linker **L15**, which contained 1D channels functionalized with free –COOH binding groups (Figure 16).[77] The availability of free carboxylic groups in a coordination network is remarkable, as these groups typically become involved in the network assembly through coordination to the metal centers or hydrogen bonding. The key factors for the formation of this functional MOF appear to be the low pH (1.6) involved in its synthesis, which kept the carboxylic groups protonated and thus unavailable for metal coordination, and the aqueous solvent, which prevented the –COOH groups from self-associating by hydrogen bonding. The carboxylic groups remained thus available to bind anionic guests included in the channels of this MOF. Competitive crystallization experiments found that this coordination network preferentially includes halides against $NO_3^-$, $SO_4^{2-}$, or $ClO_4^-$ oxo anions, with a slight preference for chloride. Single-crystal X-ray structural analysis showed the inclusion of $Cl(H_2O)_4^-$ clusters hydrogen-bonded by the carboxylic groups inside the 1D channels. The clusters assume a square-pyramidal geometry, which is the most stable structure of $Cl(H_2O)_4^-$, as predicted by theoretical calculations. The observed peak selectivity for halides can be rationalized by the good complementarity (size, symmetry, and hydrogen-bond functionality) between the channels of the MOF host and the $Cl(H_2O)_4^-$ guest. The larger oxo anions, by comparison, would have to lose most of their solvating water to fit inside the channels, which would be energetically unfavorable. On the other hand, $Br^-$ and $F^-$ are known to form water clusters that are similar in size and shape with the $Cl(H_2O)_4^-$, which may account for the reduced selectivity observed within the halide series. This system provides an example of non-Hofmeister anion selectivity in an MOF (upper-right quadrant in Figure 2), that results from the combination of high complementarity (insured by functionalization with H-bonding groups) with structural rigidity. Furthermore, this example inspires an alternative approach to anion separation with MOFs, where the coordination framework host can be designed to selectively include anion/water clusters of different sizes and geometries, which may result in selectivities that are different from those normally associated with "naked" anions.

Looking to improve anion recognition and selectivity in MOFs, we turned our attention to urea proton donors. Urea is a particularly effective anion-binding group, as it is capable of chelating the targeted anion with its two preorganized NH protons, which may result in enhanced binding strength and recognition abilities.[78] We and others have demonstrated that ureas can be easily incorporated as functional units into coordination frameworks, wherein they can specifically chelate various oxo anions.[79] Although ureas are prone to self-association into hydrogen-bonded tapes, we found that substitution with the electron-withdrawing pyridine groups, such as in linkers **L17** and **L18**, greatly

diminishes this tendency as a result of stronger intramolecular CH···O hydrogen bonds, which decreases the ability of the C=O group to engage in intermolecular hydrogen bonds (Figure 17).[79a,80]

The urea-functionalized linker **L17** forms 1D coordination polymers with $ZnCl_2$, $ZnBr_2$, $ZnI_2$, and $ZnSO_4$ from water/ethanol mixtures, with the coordination chains further linked by urea···anion hydrogen bonds and anion–Zn coordination bonds (Figure 18).[62] In direct contrast, $Zn(NO_3)_2$ and $Zn(ClO_4)_2$ do not form coordination networks under the same conditions, which prompted us to investigate the possibility of anion separation by selective crystallization of Zn(**L17**) coordination networks. Addition of an ethanolic solution of **L17** to an aqueous solution containing 1 equiv. of $Zn(NO_3)_2$ and 1 equiv. of each NaCl, NaBr, NaI, $NaClO_4$, and $Na_2SO_4$ resulted in selective crystallization of the halides as a solid solution with the composition $Zn(\mathbf{L17})(Cl)_x(Br)_y(I)_z$ ($x + y + z = 2$), and total exclusion of the oxo anions, as demonstrated by FTIR spectroscopy and X-ray diffraction. Although sulfate can form a coordination polymer under these conditions, this anion proved uncompetitive against the halides, as the formation of the $[Zn(\mathbf{L17})(SO_4)(H_2O)_3](EtOH)$ phase that would otherwise be observed is apparently inhibited by the presence of the competing anions. Furthermore, the size and charge mismatch of $SO_4^{2-}$ apparently prohibits its inclusion in the Zn(**L17**) halide phase. The composition of the precipitated solid from the competitive crystallization experiment was found to be time-dependent (Figure 19). Thus, after 30 min, the kinetically controlled crystalline product consisted of mainly the $Zn(\mathbf{L17})Cl_2$ phase, with a small amount of the $Zn(\mathbf{L17})Br_2$ phase also present. Elemental analysis indicated that chloride was the major halide found in this solid, followed by bromide and iodide, which corresponds to an anti-Hofmeister selectivity. The preference for the smaller, more densely charged $Cl^-$ against the more hydrophobic $Br^-$ and $I^-$ in the $Zn(\mathbf{L17})Cl_2$ phase can be rationalized on the basis of the strong interactions of the halides with the $Zn^{2+}$ Lewis acid centers and hydrogen bonding to the urea groups, which apparently provide a more stabilizing environment than that found in water. This solid, however, slowly redissolved, and, after 5 d, the thermodynamically more stable $Zn(\mathbf{L17})Br_2$ was the only phase observed. This phase also included chloride and iodide in a solid solution form, with the relative amounts of the halides still corresponding to an anti-Hofmeister selectivity. The relative halide content continued to change if the precipitated solid was left in the supernatant solution for up to 2 weeks, when the dominant halide in the solid became $Br^-$, followed by $Cl^-$ and $I^-$ (Figure 19). A crystal structure of the $Zn(\mathbf{L17})Br_2$ phase showed that it contained two different halide sites, with only one of them participating to hydrogen bonding with the urea groups (Figure 18), which

explains the lower discrimination among halides found in the final solid. Nevertheless, the Zn(**L17**)$Br_2$ phase is thermodynamically more stable than the Zn(**L17**)$Cl_2$ one, apparently due to its more efficient crystal packing. This observation points to another important factor in anion selectivity in MOF crystallizations, which is the overall lattice stabilities of the competing coordination networks, which ultimately dictate their solubilities.

The concomitant inclusion of different halides in the same structural frameworks simplifies the interpretation of the observed selectivity by careful examination of the coordination environments around the included anions. This was conveniently done by structural analysis of single crystals grown from 1:1 mixtures of different zinc halide salt pairs. For example, crystallization of a 1:1 mixture of $ZnCl_2$ and $ZnBr_2$ with a stoichiometric amount of **L17** resulted in concomitant formation of both the Zn(**L17**)$Br_2$ (major) and Zn(**L17**)$Cl_2$ (minor) single-crystalline phases. X-ray diffraction analysis of the major phase showed segregation of the

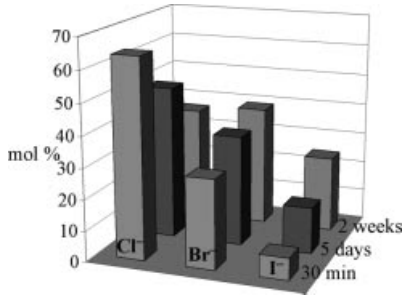

Figure 19. Halide compositions of the solids obtained from the competitive crystallizations of [Zn(**L17**)]$X_2$ coordination networks.

two halides between the two different halide sites. Thus, the site hydrogen-bonded to urea contained 66% $Cl^-$, while the non-hydrogen-bonded site contained only 40% $Cl^-$ (with the $Br^-$ occupying the remaining 34% and 60%, respectively, of the two sites), which corresponded to the $ZnCl_{1.06}Br_{0.94}$(**L17**) overall crystal composition. On the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

other hand, the two equivalent halide sites in the Zn(**L17**)-$Cl_2$ minor crystal phase are both hydrogen-bonded by NH protons from an urea group, which translated into a higher chloride content of 71% [corresponding to the $ZnCl_{1.42}Br_{0.58}$(**L17**) crystal composition]. Analogous crystallization of a 1:1 mixture of $ZnBr_2$ and $ZnI_2$ with a stoichiometric amount of **L17** resulted in exclusive formation of the $ZnBr_2$(**L17**) phase, which, however, contained both bromide and iodide in different proportions depending on the crystal site. Thus, the urea-hydrogen-bonded site contained 59% $Br^-$, whereas the non-hydrogen-bonded site contained only 33% $Br^-$, corresponding to a crystal composition of $ZnBr_{0.92}I_{1.08}$(**L17**). An even more dramatic segregation of halides was found in the mixed crystals obtained from a 1:1 mixture of $ZnCl_2$ and $ZnI_2$, which contained 85% $Cl^-$ on the hydrogen-bonded site and only 26% $Cl^-$ on the non-hydrogen-bonded site [corresponding to the $ZnCl_{1.11}I_{0.89}$(**L17**) crystal composition]. These mixed structures allowed us to formulate some simple structure/selectivity principles for halide inclusion in these coordination frameworks. Thus, in the Zn(**L17**)$Cl_2$ phase, with all halide sites equivalent and consisting of strong coordination to the $Zn^{2+}$ centers and hydrogen bonding to urea, the more densely charged and stronger base $Cl^-$ was preferred against the larger, less basic $Br^-$. In the Zn(**L17**)$Br_2$ phase, on the other hand, the more acidic site hydrogen-bonded to urea included significantly larger proportions of the more basic halide, whereas the larger, less basic halides preferred the non-hydrogen-bonded site, where van der Waals forces were dominant. All these observations strongly indicate an anti-Hofmeister selectivity within the halide series. However, it should also be noted here that the total exclusion of the oxo anions could be considered as a non-Hofmeister behavior, or peak selectivity for the halide group.

In order to achieve higher selectivity for oxo anions, we reasoned that the design of more elaborate linkers, containing multiple urea groups positioned optimally around the anion, should result in superior shape recognition and peak selectivity. Towards this end, we have been interested in the design of coordination polymers with exclusive sulfate selectivity. Molecular models suggested that sulfate ideally accommodates 6 urea groups, each binding to one of the 6 O–S–O edges of the tetrahedral $SO_4^{2-}$ in a total of 12 hydrogen bonds (Figure 20a).[78a] Linker **L16**, built from TREN, seemed ideal for this purpose, as indicated by molecular modeling, which showed that sulfate can accommodate two such TREN-based linkers. Indeed, crystal-structure analysis showed that the coordination framework obtained from **L16** and $Ag_2SO_4$ encapsulates the sulfate (Figure 20), with 6 urea groups saturating the anion by 12 hydrogen bonds (three to each O atom).[81] For comparison, proteins are known to bind sulfate by only 7 hydrogen bonds, and the highest sulfate coordination number previously observed in a synthetic host was 8.[82] Other anions of various shapes and basicities, such as $BF_4^-$, $NO_3^-$, $MeSO_3^-$, or $CH_3COO^-$ did not form a coordination polymer with **L16** under similar conditions due to their negligible interactions with this linker, as indicated by NMR spectroscopy. Instead, crystallization of the free linker through urea···urea hydrogen bonding was observed in the presence

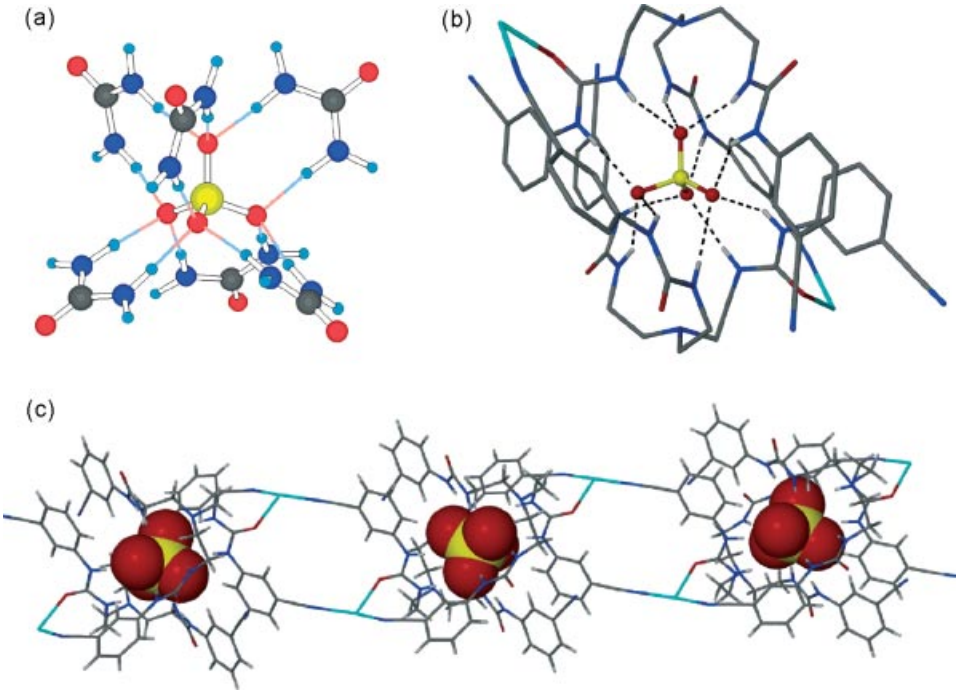

Figure 20. Encapsulation of $SO_4^{2-}$ in an urea-functionalized coordination polymer. (a) Molecular model showing optimal sulfate binding by 12 hydrogen bonds from 6 urea groups. of these anions, which indicates threshold selectivity, with only the strongly interacting sulfate anion being able to compete against linker self-association.[83]

## 4. Conclusions and Future Prospects

With their great structural diversity and ease of synthesis, MOFs are versatile materials for anion separations. However, without proper crystal structure control, this architectural variety may appear in the same time daunting to someone who wants to design an anion receptor with predictable anion selectivity. Like with any other potential applications of MOFs, further progress in crystal engineering of these materials is needed before they can be predictably used for anion separations. Towards this end, it is important to find new MOFs that preserve a common structural framework in the presence of various anions, to allow for unambiguous interpretation of the observed anion selectivity based on the interactions of the anions with the coordination frameworks. MOF functionalization with strong and specific anion-binding groups such as Lewis acid metal centers or hydrogen-bonding groups for complementary anion coordination is typically needed for selectivities that depart from the solvation bias. Like with discrete anion receptors in solution, the best peak selectivity is observed in MOFs that combine structural constraints and rigidity with a sufficient number of strong binding groups that are optimally positioned around the anion for shape recognition. To date, however, there is a very limited number of coordination frameworks that satisfy these conditions, which can be explained by the fact that most of these solids have not been specifically designed for anion recognition and separation. As a result, the vast majority of MOFs studied to date show typical solvation-controlled Hofmeister selectivities. More systematic structure/properties studies need to be done to better understand the principles governing anion selectivities inside the MOF cavities, with the ultimate goal to obtain peak selectivities for targeted anions by deliberate design. Sorely needed at this time are more quantitative studies of anion exchange and separations, including competition experiments, anion-exchange isotherms, thermodynamic and kinetic measurements, and mechanistic investigations of anion transport. Computational studies could also offer valuable information about the energetics of anion binding inside the coordination frameworks, as well as the electronic and steric requirements for optimal anion selectivity. Such fundamental inquiries may eventually reward us with new materials with unprecedented efficiencies in real-world separations.

# Structural Distortion and Magnetic Behavior in Cyanide-Bridged $Fe^{III}_2Ni^{II}_2$ Complexes

**Dongfeng Li,[a] Rodolphe Clérac,[b] Guangbin Wang,[c] Gordon T. Yee,[c] and Stephen M. Holmes*[a]**

**Keywords:** Cyanometalate / Magnetism / Single-molecule magnets / Pyrazolylborate / Magnetic relaxation

The X-ray structure, spectroscopic, and magnetic properties of a cyanide-bridged complex, $\{[(Tp^*)Fe^{III}(CN)_3]_2[Ni^{II}(bipy)_2]_2[OTf]_2\}\cdot 2H_2O$ (**2**) are described [Tp* = hydridotris(3,5-dimethylpyrazol-1-yl)borate; bipy = 2,2′-bipyridine; OTf = trifluromethanesulfonate]. Magnetic measurements indicate that **2** exhibits an $S = 3$ ground state and slow relaxation of the magnetization. Magnetostructural comparisons to the more symmetrical analog $\{[(Tp^*)Fe^{III}(CN)_3]_2[Ni^{II}(DMF)_4]_2[OTf]_2\}\cdot 2DMF$ (**1**) are also described. Surprisingly, the magnetic properties of **1** and **2** are similar despite the presence of a non-planar $\{Fe^{III}_2Ni^{II}_2(\mu\text{-}CN)_4\}$ core and severely distorted $Ni^{II}$ coordination sphere in **2**, suggesting that the $Ni^{II}$ centers play a minor role in the slow magnetization relaxation behavior of the clusters.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Single-molecule magnets (SMMs) have remained an active area of research over the last decade due to their unusual magnetic properties and potential use in molecule-based information storage devices.[1–5] The largest family of SMMs contain anisotropic metal centers linked by oxo- and carboxylate ligands, with $Mn_{12}O_{12}(O_2CMe)_{16}(OH_2)_4$ being the best characterized example. The complex exhibits superparamagnetic-like behavior owing to the large spin ground state and Ising-type anisotropy derived from the anisotropic metal centers present.[1–5]

Several polynuclear cyanide-bridged complexes that exhibit slow relaxation of the magnetization containing $[fac\text{-}LM(CN)_3]^{n-}$ units have been described over the last few years, where L = 1,4,7-trimethyltriazacyclononane, 1,1,1-tris(diphenylphosphanomethyl)ethane, tris(3,5-dimethylpyrazolyl)borate, and tris(pyrazolyl)borate.[5–15] Among these, we previously reported that $\{[(Tp^*)Fe^{III}(CN)_3Ni^{II}(DMF)_4]_2[OTf]_2\}\cdot 2DMF$ (**1**) exhibits slow relaxation of the magnetization with an apparent blocking temperature near 1.8 K [Tp* = hydridotris(3,5-dimethylpyrazol-1-yl)borate, OTf = trifluoromethanesulfonate, DMF = dimethylformamide].[7]

Recently, Rogez et al. reported that distorted six-coordinate nickel(II) complexes can exhibit very large and negative $D$ values ($D = -10.1$ cm$^{-1}$),[16] while Accorsi et al. demonstrated that anisotropy barriers in tetrairon(III) single-molecule magnets can be systematically tuned by ligand substitution; Brechin et al. has demonstrated that $[Mn^{III}]_6$ clusters can also be tuned by this strategy.[17] We rationalized that replacement of DMF ligands present in **1** for rigid, sterically demanding ancillary ligands such as 2,2′-bipryidine (bipy), would significantly distort the $Ni^{II}$ coordination sphere and afford greater single-ion anisotropy. If greater single-ion anisotropy of the $Ni^{II}$ centers translates into greater molecular anisotropy, then the energy barrier and the blocking temperature of the $\{Fe^{III}_2Ni^{II}_2\}$ complexes may also be systematically tuned. In the present Communication, we compare the structures and spectroscopic and magnetic properties of two rectangular complexes, $\{[(Tp^*)Fe^{III}(CN)_3]_2[Ni^{II}(L_n)]_2[OTf]_2\}$ ($L_n$ = 4 DMF, **1**; 2 bipy, **2**), that exhibit $S = 3$ ground states and slow relaxation of the magnetization.[7,18]

## Results and Discussion

### Synthesis and Characterization

Treatment of $\{[(Tp^*)Fe^{III}(CN)_3]_2[Ni^{II}(DMF)_4]_2[OTf]_2\}\cdot 2DMF$ (**1**)[7] with 2,2′-bipyridine (bipy) in MeCN/MeOH (v/v, 1:1) mixtures cleanly affords $\{[(Tp^*)Fe^{III}(CN)_3]_2[Ni^{II}(bipy)_2]_2[OTf]_2\}\cdot 2H_2O$ (**2**) as a red crystalline solid.[18] The infrared spectrum of **2** exhibits intense $\nu_{BH}$ and $\nu_{CN}$ stretching absorptions at 2553, 2158 and 2128 cm$^{-1}$, respectively, that are shifted to higher energies relative to those seen for $[NEt_4][(Tp^*)Fe^{III}(CN)_3]$ (2549 and

2115 $cm^{-1}$); the $\nu_{CN}$ stretches are tentatively assigned as bridging and terminal cyanides, respectively.[6–9,19–22] In comparison the energies of the $\nu_{BH}$ (2547 $cm^{-1}$) and $\nu_{CN}$ (2170, 2163, and 2120 $cm^{-1}$) stretching absorptions[7] for **1** are found at higher energies than those in **2**, suggesting that either depopulation of the 5σ cyanide orbital is less efficient, and/or more efficient π back-bonding occurs in **2**.[29]

Compound **2** crystallizes in the triclinic $P\bar{1}$ space group and is structurally related to **1**.[23] The cationic rectangular complex consists of two octahedral [*cis*-$Ni^{II}(bipy)_2]^{2+}$ centers that are linked to two adjacent $[(Tp^*)Fe^{III}(CN)_3]^-$ anions (Figure 1) through bridging cyanides. The Fe–C≡N bond angles and Fe–C and Ni–N bond lengths are comparable in **1** and **2**, respectively (Table 1). The structural details of **1** have been previously reported.[7]

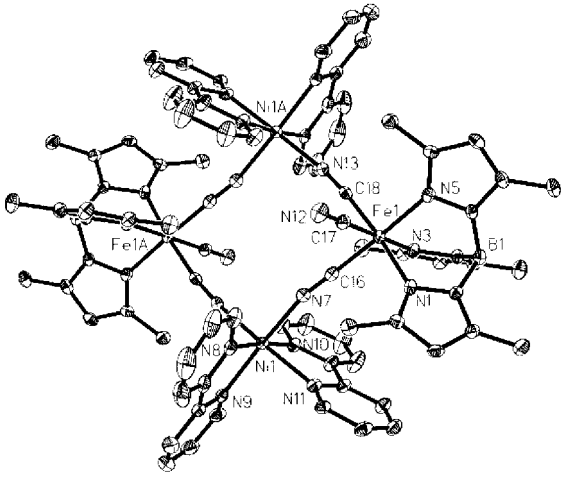

Figure 1. X-ray structure of **2**. Thermal ellipsoids are at the 50% level and all anions, lattice solvent, and hydrogen atoms are omitted for clarity.

Table 1. Selected bond lengths [Å] and angles (°) for **1** and **2**.

| | | | |
|---|---|---|---|
| Compound **1** | | | |
| Fe1–C16 | 1.928(5) | C16–Fe1–C18 | 85.4(2) |
| Fe1–C18 | 1.927(5) | N9–Ni1–N7A | 92.3(1) |
| Ni1–N9 | 2.039(4) | Ni1–N9–C18 | 176.9(4) |
| | | Fe1–C16–N7 | 177.3(4) |
| Compound **2** | | | |
| Fe1–C16 | 1.920(5) | C16–Fe1–C18 | 83.8(2) |
| Fe1–C17 | 1.932(5) | N7–Ni1–N13A | 95.1(2) |
| Ni1–N7 | 2.063(4) | Ni1–N7–C16 | 167.1(4) |
| | | Fe1–C16–N7 | 178.0(4) |

In **2**, the Ni1–N bond lengths for the *cis* cyanides are 2.042(4) (Ni1–N7) and 2.063(4) Å (Ni1–N13A), while those for the bipyridine, range from 2.074(4) (Ni1–N8) to 2.112(4) Å (Ni1–N11), respectively (Table 1). The bridging cyanide Fe1–C bond lengths, 1.916(5) and 1.920(5) Å, are nearly equivalent, while the longest distance [1.932(5) Å] is found for the terminal cyanide (Fe1–C17).[18] The bridging Fe–C≡N bond angles range from 173.4(4)° (Fe1–C18–N13) to 178.0(4)° (Fe1–C16–N7), while the terminal cyanide (Fe–C17–N12) is nearly linear [178.1(4)°]. The Ni–N≡C bond angles are significantly bent, ranging from 167.1(4)° (Ni1–N7–C16) to 171.9(3)° (Ni1–N13A–C18A), respectively; the N–Ni–N bond angles of the [*cis*-$Ni^{II}(bipy)_2(\mu\text{-}NC)_2$] fragments range from 78.5(2) to 98.8(2)°. We presume that significant steric congestion, between the Tp* and bipy ligands, afford dissimilar N7–Ni1–N13A [95.1(2) Å] and C16–Fe1–C18 [83.8(2) Å] bond angles, and a distorted nonplanar $\{Fe^{III}_2Ni^{II}_2(CN)_4\}$ framework. The intramolecular Fe1···Fe1A, Fe1···Ni1, and Ni1···Ni1A contacts are 7.628(1), 5.097(1), and 6.733(1) Å, respectively, while the closest intermolecular contacts between terminal cyanides and bipy rings are 3.297(1) Å (Figure 1).[18] In comparison the closest intercluster contacts for **1** are 4.363(3) Å.[7]

The structural distortions of **1** and **2** can be further described by the torsion angles present in each complex.[18] Looking down the Ni1(μ-CN)Fe1 axis and considering only the inner-sphere atoms coordinated to each metal center in **1** for clarity, the N7A–Ni1–Fe1–N7, O1A–Ni1–Fe1–N3, O1B–Ni1–Fe1–N5, and O1D–Ni1–Fe1–N8 torsion angles are ca. 3.6, 7.7, 11.3, and 8.4°, respectively, suggesting that **1** adopts a rather flat rectangular structure (Figure 2). In comparison, **2** exhibits a very distorted $\{Fe^{III}_2Ni^{II}_2(\mu\text{-}CN)_4\}$ core, as indicated by the nonlinear μ-CN bridges and large angular deviations from an eclipsed configuration of coordinated heteroatoms present on the Fe and Ni centers; the N11–Ni1–Fe1–N1, N8–Ni1–Fe1–N12, N13–Ni1–Fe1–N13A, and N10–Ni1–Fe1–N3 angles are 24.5, 18.4, 5.5, and 10.6°, respectively (Figure 1).[18]

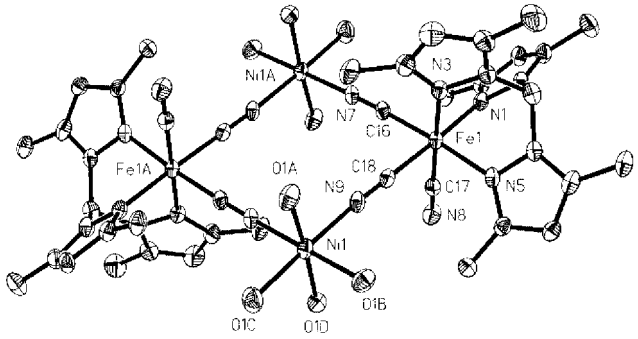

Figure 2. X-ray structure of **1**. Thermal ellipsoids are at the 50% level and all anions, lattice solvent, and hydrogen atoms are omitted for clarity.

## Magnetic Characterization

The $\chi T$ vs. $T$ data suggests that the $Fe^{III}$ ($S$ = 1/2) and $Ni^{II}$ ($S$ = 1) centers in **2** are ferromagnetically coupled (Figure 3), because the $\chi T$ product gradually increases from 3.8 $cm^3\,K\,mol^{-1}$ (300 K), reaching a maximum value of 7.7 $cm^3\,K\,mol^{-1}$ at 7 K. Below 7 K, $\chi T$ decreases towards a minimum value of 6.6 $cm^3\,K\,mol^{-1}$ at 1.83 K.[6–9,21,22] Based on the tetranuclear structure of **2**, the magnetic data has been modeled using an isotropic Heisenberg model in the weak field approximation.[24–26] The theoretical susceptibility has been deduced from application of the van Vleck equation to the Kambe method, by the following spin Ham-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

iltonian: $H = -2J\{(S_1 + S_2)\cdot(S_3 + S_4)\}$,[27,28] where $J$ is the isotropic exchange interaction between $Fe^{III}$ and $Ni^{II}$ sites and $S_i$ is the spin operator for each metal center ($S_i$ = 1, $Ni^{II}$, with $i$ = 1–2; $S_i$ = 1/2, $Fe^{III}$, with $i$ = 3–4). The best set of parameters obtained are $J/k_B$ = +9.4(3) K and $g_{iso}$ = 2.29(1) using the data above 20 K, in order to minimize anisotropy effects or intermolecular antiferromagnetic exchange interactions (Figure 3).[8,11,18,22]

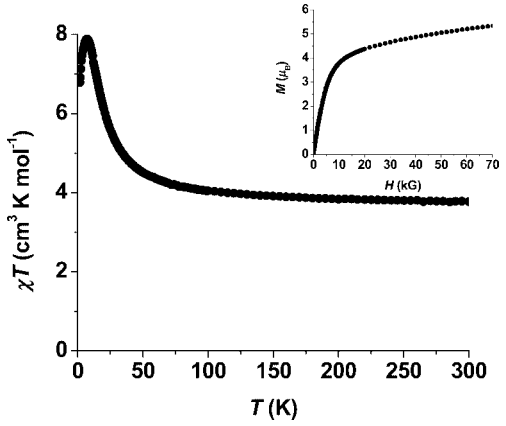

Figure 3. Temperature dependence of the $\chi T$ product for **2** at $H$ = 0.1 T. Inset: Field dependence of the magnetization at 1.8 K.

When non-zero inter complex exchange interactions ($J'$) are also taken into consideration using a mean field approximation,[24–26] the data can not be adequately reproduced between 300 and 1.8 K (Figure S2; supporting information; for supporting information see also the footnote on the first page of this paper),[18] indicating that additional factors (e.g. anisotropy, second-neighbor Fe···Fe or Ni···Ni magnetic interactions) may also be relevant. The magnitude of the magnetic Ni–Fe exchange coupling constant calculated for **2** is slightly larger than that determined for **1** [7.6 K],[8,18] being comparable to values found for other tri- and tetranuclear complexes containing $Ni^{II}$ and $[(Tp^{R,R})Fe^{III}(CN)_3]^-$ (R = H, Me) and centers.[6–9,24–26] Confirmation of an $S$ = 3 ground state is obtained in the $M$ vs. $H_{dc}$ data at 1.85 K because the magnetization is nearly saturated at 7 T, approaching a maximum value of 6 $\mu_B$ (see inset in Figure 3).[18]

The temperature dependence of the ac susceptibility for **2** was measured at several different frequencies at $H_{dc}$ = 0 Oe (Figure 4). The ac susceptibility is frequency-dependent suggesting that the **2** exhibits slow relaxation of the magnetization. From the data shown in Figure 3, the relaxation time $\tau$, can be determined from the maximum of $\chi''(T)$.[4] The relaxation time for **2** follows an Arrhenius law with an energy gap of 20.4 K and $\tau_0 = 5.4 \times 10^{-9}$ s (see inset in Figure S5 in the supporting information). As in many complexes that exhibit slow relaxation of the magnetization, it is likely that the observed energy barrier takes an effective value, resulting from a "short-cut" of the thermal barrier by quantum tunnelling of the magnetization (QTM). In zero field, the $\pm m_S$ states have the same energy and QTM between these pairs of levels is possible. When a magnetic field is applied, the $m_S < 0$ and $m_S > 0$ levels decrease and increase respectively in energy, preventing quantum tunneling between the $\pm m_S$ states.[4]

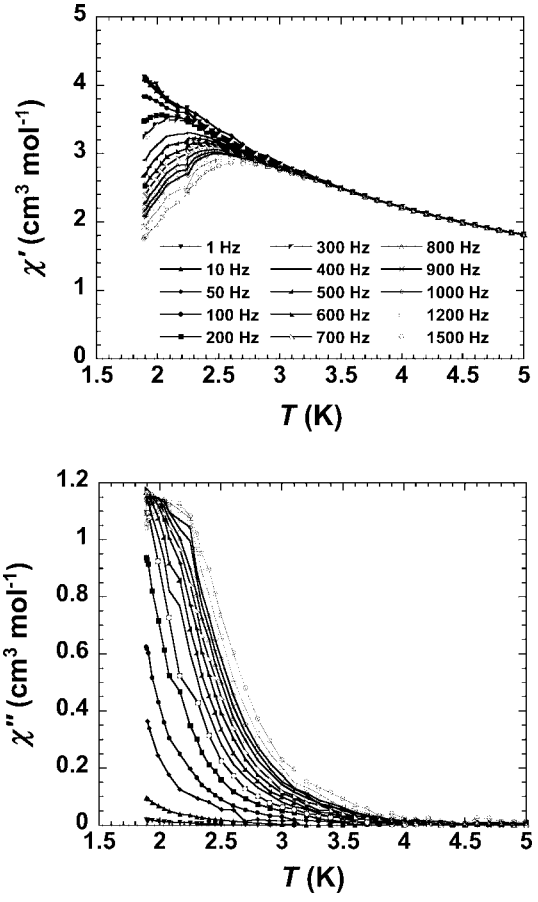

Figure 4. Temperature dependence of the real ($\chi'$, top) and imaginary ($\chi''$, bottom) components of the ac susceptibility for **2** ($H_{dc}$ = 0 Oe; $H_{ac}$ = 3 Oe) between 1 and 1500 Hz.

To further investigate the activated behavior of **2**, we performed ac susceptibility measurements under several applied dc magnetic fields (Figures 5, 6, and S3, S4 in the supporting information).[18] At 1.85 K, the characteristic frequency (maximum of the $\chi''$ vs. ν plot) decreases rapidly from 600 Hz at 0 Oe, approaches a nearly constant value of 2 Hz at 4000 Oe, and disappears when $H_{dc}$ ca. 14000 Oe, as expected when the magnetization is almost saturated (Figure 5). As shown by this result, the QTM relaxation pathway remains efficient even at 1.85 K in zero-field. As expected for a SMM that exhibits fast quantum tunneling of the magnetization (for $H_{dc}$ = 0), the application of non-zero magnetic fields increases the magnetization relaxation time (i.e. relaxation mode frequency decreases with increasing $H_{dc}$). For **2**, the relaxation time can be estimated using the ac measurements under 4000 Oe, which follow Arrhenius behavior with $\tau_0 = 8.4 \times 10^{-8}$ s and an effective energy gap of 25.7 K (Figure 6). This value allows for a rough estimation of the uniaxial anisotropy and affords $D/k_B \approx -2.9$ K.[18]

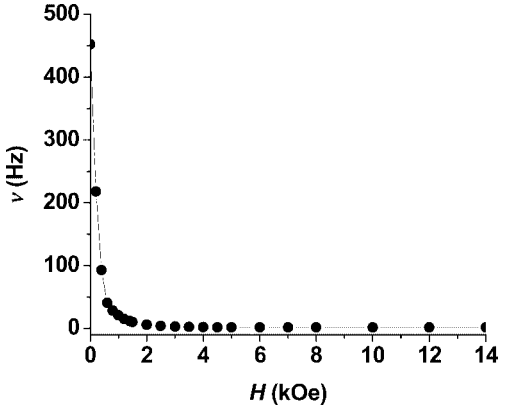

Figure 5. Field dependence of the characteristic frequency at 1.85 K.

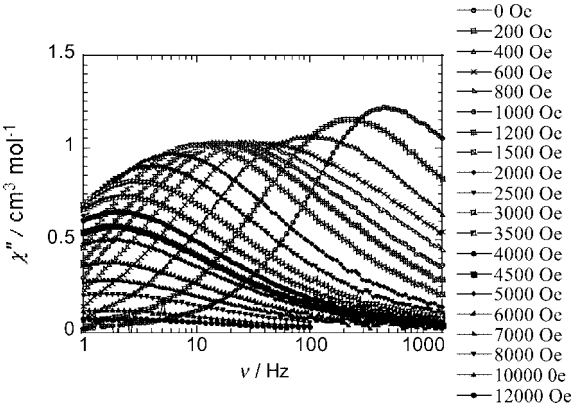

Figure 6. Frequency dependence of $\chi''$ at 1.85 K under various applied $H_{dc}$ for **2**.

To date, few systematic studies of cyanide-bridged polynuclear complexes that exhibit slow relaxation of the magnetization have been described for a given structural archetype. We previously reported that in $\{Fe^{III}_2Ni^{II}\}$ complexes bending of the M–C≡N–M′ bridges significantly impacts the superexchange efficiency ($J$) and anisotropy energy barrier ($\Delta$): nonlinear cyanide bridges usually afford smaller $J$ and $\Delta$ values.[24–26,30] We had anticipated that structural distortion of the $\{Fe^{III}_2Ni^{II}_2(\mu\text{-}CN)_4\}$ core and concomitant coordination spheres of the metal ions present would afford similar changes in exchange coupling ($J$), zero-field splitting ($D$), and effective barrier heights ($\Delta_{eff}$) of the tetranuclear complexes.

However, we were surprized to find that despite having bent Fe–C≡N–Ni units, **2** exhibits ferromagnetic superexchange interactions ($J > 0$) that are slightly larger than those in **1**.[7] Recent DFT calculations for $\{Fe^{III}_2M^{II}_2(\mu\text{-}CN)_4\}$ complexes ($M^{II}$ = Mn, Co, Ni) suggest that the total magnetic anisotropy of the ground state is largely dependent on transverse anisotropy contributions (ca. 15–36%) to the total longitudinal anisotropy, originating from the orbital contributions of the $S = 1/2$ $Fe^{II}$ centers.[31] In comparison to $Mn_{12}O_{12}(O_2CMe)_{16}(OH_2)_4$ faster quantum tunneling rates, larger $D$ parameters, and angular-momentum contributions to the magnetic ground state (ca. 4 times) are found for **1** and **2**. The ac susceptibility measurements ($H_{dc}$ = 0) indicate **1** and **2** exhibit similar behavior suggesting that both exhibit slow relaxation of the magnetization. We postulate that the single-ion anisotropy contributions of the $Ni^{II}$ centers are of minor importance in tuning the magnetic relaxation behavior of the these tetranuclear complexes.

## Conclusions

In summary, we have described the preparation, structures, and magnetic properties of two rectangular cyanide-bridged $\{Fe^{III}_2Ni^{II}_2\}$ complexes that exhibit slow relaxation of the magnetization. We propose that steric repulsion between the $[(Tp^*)Fe^{III}(CN)_3]^-$ and $[Ni^{II}(bipy)_2]^{2+}$ units affords bent cyanide bridges that are *cis* to each other affording a distorted-octahedral $Ni^{II}$ coordination environment in **2**. Surprisingly, despite severe structural distortion of the $\{Fe^{III}_2Ni^{II}_2(CN)_4\}$ core, **2** exhibits slow frequency-dependent magnetization relaxation behavior that is comparable to **1**, a more symmetrical analog. We tentatively propose that for **1** and **2** the height of the magnetization reversal barrier is largely dependent on the single-ion anisotropy contributions of the low-spin $Fe^{III}$ centers, while the $Ni^{II}$ centers appear to be of minor importance. A future report will describe how spin-orbit coupling and orbital contributions of the magnetic ions contribute to the overall magnetic anisotropy and relaxation behavior of several polynuclear cyanide-bridged complexes.[31]

## Experimental Section

**General:** All operations were conducted while dark in a vacuum or under argon using standard Schlenk and drybox techniques. Transfers of solutions containing cyanides were carried out through stainless steel cannulas. The salts $[NEt_4][(Tp^*)Fe^{III}(CN)_3]$,[7] $Ni(OTs)_2$,[32] and **1**[21] were prepared according to modified literature methods. Diethyl ether was distilled from sodium/benzophenone and sparged with argon prior to use. DMF (Baker) was dried with activated Linde 13-X molecular sieves and sparged with argon prior to use. 2,2′-Bipyridine (Aldrich) was used as received.

**Physical Methods:** The IR spectra were recorded as Nujol mulls between KBr plates with a Mattson Galaxy 5200 FTIR instrument. The dc magnetic measurements were obtained using crushed, single crystals of **2**, on a Quantum Design MPMS-XL SQUID magnetometer, operating between 1.8 and 300 K, in a 0.1 T static magnetic field. Initial ac measurements were obtained over 1.8 to 5 K ($H_{dc}$ = 0 Oe and $H_{ac}$ = 3 Oe) and between 1 and 1500 Hz; additional measurements were obtained at temperatures between 1.8 and 5 K ($H_{dc}$ = 0, 1000 and 4000 Oe; $H_{ac}$ = 3 Oe). Magnetic data were corrected for the sample holder diamagnetism, while diamagnetic contributions from the samples were estimated using Pascal's constants.[36] Microanalyses were performed by Robertson Microlit Laboratory.

**X-ray Structural Studies:** Crystals of **2** were grown from DMF/$Et_2O$ solutions of **1**[7] treated with 4 equiv. of 2,2′-bipyridine. X-ray diffraction data were collected at 90.0(2) K with a Bruker X8 Proteum rotating-anode CCD diffractometer with graphite-monochromated Cu-$K_\alpha$ ($\lambda$ = 1.54178 Å) radiation from irregular shaped crystals, mounted in Paratone-N oil on glass fibers. Initial cell parameters

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were obtained (DENZO)[33] from ten 1° frames and were refined via a least-squares scheme using all data-collection frames (SCALEPACK).[33] Lorentz/polarization corrections were applied during data reduction. The structures were solved by direct methods (SHELXS97) and completed by difference Fourier methods (SHELXL97).[34] Refinement was performed against $F^2$ by weighted full-matrix least-squares (SHELXL97)[34] and empirical absorption corrections (either SCALEPACK[33] or SADABS[34]) were applied. Hydrogen atoms were found in difference maps and subsequently placed at calculated positions using suitable riding models with isotropic displacement parameters derived from their carrier atoms. Non-hydrogen atoms were refined with anisotropic displacement parameters. Atomic scattering factors were taken from the International Tables for Crystallography vol. C.3.[35] Crystal data, relevant details of the structure determinations, and selected geometrical parameters are provided in the supporting information.[18]

**Synthesis of 2:** Treatment of $\{[(Tp^*)Fe^{III}(CN)_3]_2[Ni^{II}(DMF)_4]_2[OTf]_2\}\cdot 2DMF$ (**1**) (0.949 g, 0.50 mmol) in MeOH/$CH_3CN$ [30 mL, 1:1 (v/v) ] with 2,2′-bipyridine (0.312 g, 2.00 mmol) afforded a red solution that was layered with $Et_2O$ (20 mL) and allowed to stand for 3 d. The red needles were collected by filtration, washed with $CH_3CN$ (5 mL) and $Et_2O$ (3 × 5 mL), and dried in air overnight. Yield: 0.546 g (55.3%). $C_{78}H_{84}B_2F_6Fe_2N_{26}Ni_2O_{10}S_2$ (1974.53): calcd. C 47.40, H 4.30, N 18.43; found C 47.43, H 4.10, N 18.76. IR (Nujol): $\tilde{\nu}$ = 3460 (br., m), 2952 (vs), 2926 (vs), 2854 (vs), 2553 (m), 2158 (vs), 2128 (m), 1634 (m), 1598 (s), 1575 (m), 1567 (m), 1543 (vs), 1489 (s), 1447 (vs), 1417 (vs), 1375 (vs), 1310 (m), 1285 (vs), 1256 (vs), 1227 (vs), 1203 (vs), 1162 (vs), 1108 (m), 1062 (vs), 1031 (vs), 988 (m), 867 (m), 815 (m), 806 (m), 775 (vs), 738 (s), 722 (m), 692 (m), 641 (vs), 575 (m), 544 (w), 517 (m), 440 (m), 429 (m), 410 (m) $cm^{-1}$.

**Supporting Information** (see also the footnote on the first page of this article): Crystallographic data (CIF format) and additional magnetic data for **2**.

CCDC-634744 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Assessing Guest Selectivity within Metallacrown Host Compartments

**Choong-Sun Lim,[a] Annabel Cutland Van Noord,[a] Jeff W. Kampf,[a] and Vincent L. Pecoraro*[a]**

**Keywords:** Molecular compartment / Metallacrown / Selective recognition / Host–guest chemistry

15-MC-5 complexes associate in the solid state to form chiral compartments capable of binding guests. Using small molecular yardsticks, we are able to assess the size restrictions of these structures. Dicarboxylate guests that are too short to span the $Gd^{III}$ ions are stabilized by solvates that hydrogen bond to the uncoordinated carboxylate, while guests that are too long destroy the weakly associated structure. We also demonstrate that all that is required for guest encapsulation is unsaturation of the chain connection carboxylates rather than necessitating the presence of aromaticity.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

In 1989, we described the concept of building metallamacrocycles[1–3] using the metallacrown analogy.[4] These early analogs of crown ethers,[5,6] which have M–N–O connectivity instead of the O–C–C repeat unit of a crown ether, were often planar, containing a site for cation binding in a central cavity and a surface upon which anions could be appended.[7,8] Subsequently, chiral 15-MC-5 complexes,[9] adorned with aromatic groups, were shown to form molecular compartments[10–13] in the solid state. These compartments are reminiscient of the cryptatoclathrates described by Saalfrank.[14] Metallacrowns made exclusively with (*R*)- or (*S*)-phenylalaninehydroxamic acid form metallamacrocycles having a hydrophobic face surrounded by five benzyl groups that generate a cavity for a guest and a much less sterically encumbered hydrophilic face.[15] Previous solution studies have demonstrated that these 15-MC-5 structures are stable in solution when $Ln^{III}$ ions are present.[7,9,16] When crystals are grown from water, the phenyl groups from the two metallacrowns contact one another like two folded hands, hence we call this form the hands structure. In contrast, crystals prepared from methanol/water mixtures lead to a different "polymorph" in which the metallacrowns form helices with microporous channels rather than compartments.[17] In the hands polymorph, the hydrophobic faces of two metallacrowns associate, forming a compartment in which a guest is sequestered.[11,13] Of significant interest, aliphatic carboxylates are generally excluded from this compartment and bind solely to the hydrophilic face of the metallacrowns while, in contrast, aromatic carboxylic acids can be confined within this aromatic rich environment.[11,13] Thus, succinate or adipate have never been observed within the compartment, whereas terephthalate binds to this site preferentially.

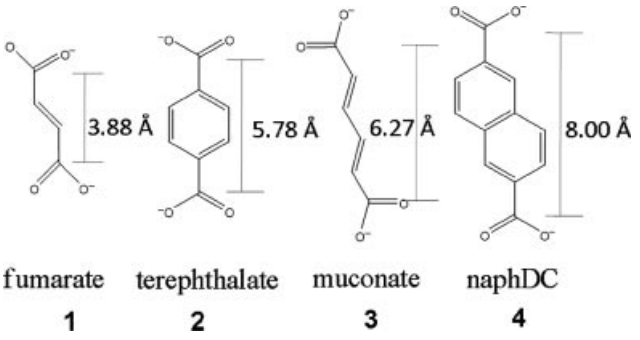
## Discussion and Results

The ability to exploit the size and chemical nature of organic dicarboxylates to discriminate guest binding is a desirable design concept. We have been interested in assessing whether an aromatic ring is an essential feature allowing access of the guest into the compartments hydrophobic cavity or whether simple unsaturation within the backbone is sufficient for cavity recognition.

Furthermore, we felt that it was prudent to use rigid molecules of varying length as molecular yardsticks that would determine to what extent the cylinder's long axis could be stretched in order to accommodate a dicarboxylate guest. In this report, we demonstrate that the presence of even one double bond allows the guest to insert within the compartment. We also show that when phenylalaninehydroxamic acid is used to form the host, there is a narrow range of acceptable lengths for guests to span the compartment.

We have chosen the well characterized $Gd(NO_3)_3$[15-$MC_{L\text{-pheHA}}$-5][11] as our host for these studies and we selected four different guest molecules (Scheme 1) to determine which physical properties of guests are required for a good fit within the compartments. Because carboxylates may bind to metals in an *endo*,*exo* or bidentate manner,[18] we have provided lengths for these molecules which are measured between the carboxylate carbon atoms rather than to the oxygen atoms. All four compounds have double bonds as well as carboxylate moieties at each end resulting in their binding to the gadolinium of each metallacrown toward the hydrophobic face.[19–22]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. Guest molecules bound to hydrophobic site of metallacrown (**3**: *trans*,*trans*-muconate, **4**: 2,6-naphthalenedicarboxylate).

By using X-ray diffraction studies, we observed that the terephthalate and *trans*,*trans*-muconate guests (with C–C bond lengths of 5.8 Å and 6.3 Å, respectively) connect two metallacrowns across the hydrophobic faces.[23] Each of the carboxylate groups bind to the $Gd^{III}$ in an *endo*,*endo*-1,3-bidentate fashion. These structures are shown in Figure 1. The Gd–Gd distances between the two metallacrowns are ca. 11.6 Å for both the muconate and terephthalate structures (Figure 2 and Table 1). Furthermore, the two metallacrowns are stacked nearly on top of one another with only a 2–5° tilt angle and are slipped to one side by only 7–10°. This observation suggests that the metallacrowns are ideally oriented, and that there are strong interactions between the phenyl groups of the two metallacrowns composing the compartment. In addition, two phenyl groups of the metallacrowns make hydrophobic contacts with the phenyl ring of the guest. Because both the terephthalate metallacrown and muconate metallacrown have similar structures, the formation of compartments is not affected by the difference in steric bulk of the two guests. *The fact that muconate is found within the hydrophobic cavity demonstrates that aromaticity is not an essential feature for guest recognition as the two double bonds of this molecule apparently are sufficient to drive it into the interior of the capsule.*

The shorter and longer dicarboxylates that were examined illustrate the length restriction for guests within the capsule. Fumarate has the shortest length (3.88 Å) between the two α-carbon atoms of the dicarboxylates. As shown in Figure 1, fumarate with a single double bond is still able to insert within the compartment; however, it is too short to span the two central Gd ions. This is even true given that fumarate adopts a monodentate, *endo* coordination mode which acts to extend the length of the molecule as compared to the bidentate geometries observed for muconate and terephthalate.

The fumarate is stabilized within the compartment by forming a hydrogen bond to a water molecule that is bound to the $Gd^{III}$ of the second metallacrown. Clearly, the compartment with bound fumarate is highly distorted. While the Gd–Gd distance shortens to 11.2 Å, the orientation of the two metallacrown rings is greatly perturbed. In particular, the $Gd^{III}$ of the top metallacrown is shifted over 6 Å with respect to the $Gd^{III}$ of the bottom metallacrown, whereas the corresponding orientation for muconate and

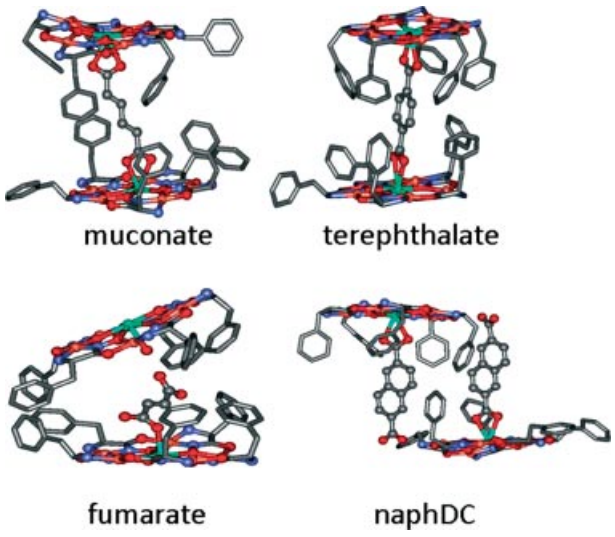


Figure 1. Structure of muconate-MC and terephthalate-MC show molecular compartments. However, fumarate-MC and 2,6-naphthalenedicarboxylate-MC do not form compartments. Guests on the hydrophilic sites of both metallacrowns of all compartments were omitted.[23]

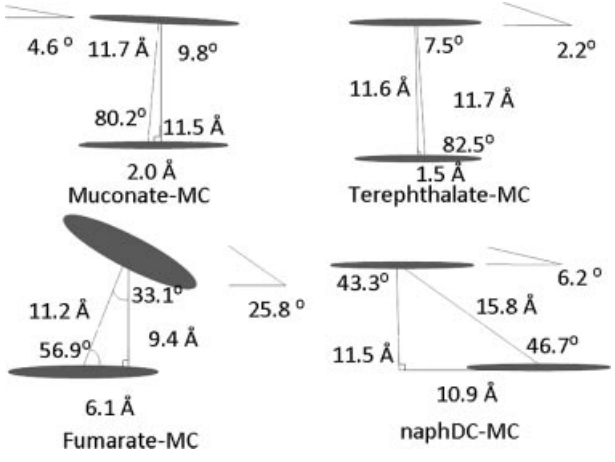

Figure 2. Diagram which shows bonding distance and angles between metallacrown and each guest compound in the crystal structure.

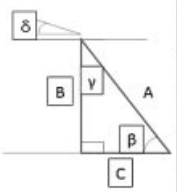
Table 1. Distances and angles of each guest to metallacrowns.



| | fumarate | Terephth-alate | Muconate | NaphDC |
|---|---|---|---|---|
| A | 11.2 Å | 11.7 Å | 11.7 Å | 15.8 Å |
| B | 9.4 Å | 11.6 Å | 11.5 Å | 11.5 Å |
| C | 6.1 Å | 1.5 Å | 2.0 Å | 10.9 Å |
| β | 56.9° | 82.5° | 80.2° | 46.7° |
| γ | 33.1° | 7.5° | 9.8° | 43.3° |
| δ | 25.8° | 2.2° | 4.6° | 6.2° |

A: distance between two centers of the planes
B: the closest distance between a center of one plane to the other plane
C: shifted distance of a metallacrown to the other one
δ: angle between two planes

terephthalate structures is 2 Å or less. This shift of the metallacrown centroids cause a marked slippage (33°) and tilting (26°) of the metallacrown rings as shown in Figure 2. All of these changes lead to a distorted and opened compartment.

While shortening the guest length causes major reorientation of the $[Gd(15\text{-}MC\text{-}5)]_2$ compartment, inclusion of naphthalenedicarboxylate as a guest, which has the longest distance (8 Å) between two α-carbon atoms, completely destroys the compartment structure. The distance between the two α-carbon atoms of naphthalenedicarboxylate is sufficient to connect the two metallacrowns. However, doing so prevents the phenyl groups of the hosts from interacting well with one another by pushing the two metallacrowns far away. The absence of the π–π interactions between these rings diminishes the stability of the compartment leading to a solid with individual naphthalenedicarboxylates bound to metallacrowns rather than forming compartments using the hands structure. Figure 1 illustrates that the naphthalenedicarboxylate binds to $Gd^{III}$ as an *endo*,*endo*-1,3-bidentate chelate; however, another metallacrown is unavailable to bind the second carboxylate group. The result is that the closest Gd–Gd distance is over 15 Å and the metallacrown rings are slid almost 11 Å with respect to one another. Interestingly, because the two metallacrowns are no longer constrained to form a compartment, the tilt angle between adjacent, noninteracting metallacrowns at 6.2° is more similar to muconate and terephthalate systems then the fumarate complex.

## Conclusion

A structural analysis of $[Gd(15\text{-}MC\text{-}5)]_2^{6+}$ compartments demonstrates that there is a narrow cylinder length that will accommodate a guest. For rigid ligands containing two carboxylates the length appears to be ca. 11.5 Å. Significantly shorter or longer guests perturb the compartment integrity and, in the case of guests that are too long, will completely disrupt the compartment from forming. These observations are useful for designing a second generation of metallacrown based compartments that will be able to bind longer guests with the ultimate objective of carrying out regio- or stereoselective transformations within the cavity of these supramolecular complexes. We conclude that longer guests such as 2,6-naphthalenedicarboxylate would be better able to fit into the hydrophobic site using extended aromatic side chains rather than the L-phenylalaninehydroxamic acid to form metallacrown compartments. In contrast, $Gd(NO_3)_3[15\text{-}MC_{L\text{-}pheHA}\text{-}5]$ complex appears perfect for guests such as muconate or terephthalate.

## Experimental Section

All reagents were purchased from Aldrich and used without further purification. $Gd(NO_3)_3[15\text{-}MC_{L\text{-}pheHA}\text{-}5]$ was prepared by the method published in ref.[11]

**Reaction of 1 with $Gd(NO_3)_3$[15-$MC_{L\text{-}pheHA}$-5]:** $Gd(NO_3)_3[15\text{-}MC_{L\text{-}pheHA}\text{-}5]$ (30 mg, 0.019 mol) and **1** (9.1 mg, 0.057 mol) reacted in water, and enough methanol was added to dissolve all products that formed yielding a water/methanol mixture of ratio 1:2. The solution was slowly evaporated to get single crystal for X-ray diffraction.

**Reaction of 2 with $Gd(NO_3)_3$[15-$MC_{L\text{-}pheHA}$-5]:** $Gd(NO_3)_3[15\text{-}MC_{L\text{-}pheHA}\text{-}5]$ (30 mg, 0.019 mol) and **2** (12 mg, 0.057 mol) reacted in water/methanol (1:2). Crystals were grown by slow evaporation.

**Reaction of 3 with $Gd(NO_3)_3$[15-$MC_{L\text{-}pheHA}$-5]:** $Gd(NO_3)_3[15\text{-}MC_{L\text{-}pheHA}\text{-}5]$ (30 mg, 0.019 mol) and **3** (8.1 mg, 0.057 mol), which had been neutralized with 1 N NaOH, reacted in water/methanol (1:2). Crystals were grown by slow evaporation.

**Reaction of 4 with $Gd(NO_3)_3$[15-$MC_{L\text{-}pheHA}$-5]:** $Gd(NO_3)_3[15\text{-}_{L\text{-}pheHA}\text{-}5]$ (30 mg, 0.019 mol) and **4** (17 mg, 0.057 mol) reacted in water/methanol (1:2). Crystals were grown by slow evaporation.

CCDC-635552 to -635554 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Structural and Theoretical Insights into Metal–Scorpionate Ligand Complexes

Matthias Schwalbe,[a] Prokopis C. Andrikopoulos,[a] David R. Armstrong,[a] John Reglinski,*[a] and Mark D. Spicer*[a]

**Keywords:** Nitric oxide / Soft scorpionates / Molybdenum / Tungsten / Molecular orbital calculations

The syntheses of the complexes $[M(Tm^{Me})(CO)_2(NO)]$ (M = Mo, W) by reaction of $NOBF_4$ with $[M(Tm^{Me})(CO)_3]^-$ are reported and their spectroscopic characterisation and crystal structures are described. The analogous Cr complex could not be prepared by this methodology. The complexes adopt the expected pseudo-octahedral geometry. Complexes $[M(L)(CO)_2(NO)]$ (M = Cr, Mo, W; L = Cp, Tp and $Tm^{Me}$) together with the hypothetical $[Mo(CO)_2(NO)]^+$ cation were subjected to DFT calculations. Geometry-optimised structures closely parallel the crystallographic determinations and indicate that the complex $[Cr(Tm^{Me})(CO)_2(NO)]$ is not inherently unstable. The DFT calculations allow the assignment of the C–O and N–O stretches in the IR spectrum and give insight into both the M–NO bonding and the metal to tripodal ligand bonding. The electron-donor strengths are confirmed to lie in the order $Tm^{Me} > Tp > Cp$. A side reaction of the B–H moiety of the $Tm^{Me}$ anion with $NO^+$ results in the isolation of the dimethylformamide adduct of (trismethimazolyl)borane, providing further evidence that the reaction pathways of the $Tm^R$ ligands are more varied and less passive than in the chemistry of the nitrogen-based scorpionates.

## Introduction

While a ligand may grow in popularity on the basis of a straightforward, high-yield preparation, and the ready synthesis of a suite of interesting complexes, its full utility can only be realised when a deeper understanding of the metal–ligand interaction is attained. Such an understanding leads in turn to an ability to predict the influence on a given metal centre, the chemistry it will support and the chemical frontiers which can be challenged by its use. Ground-breaking discoveries in chemistry, such as the first dihydrogen species, $[W(CO)_3(P\mathit{i}Pr_3)_2(H_2)]$,[1] and the unexpectedly stable alkyne complexes (e.g. $[CpMo(CO)(RC{\equiv}CR')_2]^+$)[2] are more easily rationalised in retrospect, when the various supporting ligand–metal interactions are understood.

The character of the ligand is usually described in terms of steric and electronic influences. Steric bulk can be readily altered, and demands only that the modified ligand does not preclude the formation of the principal metal–ligand bond. The result is to constrain the remaining coordination sites. Thus, with $PEt_3$, the complex $[Pt^0(PEt_3)_4]$ can be formed, while with the bulkier phosphane $PCy_3$, only three phosphanes are able to coordinate to the metal centre and $[Pt^0(PCy_3)_3]$ is formed.[3] Electronic properties are more complex, although ultimately the main concern is usually the donor strength. This can be influenced by inductive effects (basicity) and by the donor/acceptor properties of the ligand. Furthermore, terms such as hardness and softness and ligand-field strength can also be used in this context to explain aspects of ligand behaviour. However, what is clear is that these various steric and electronic factors rarely act in isolation, but rather a complex inter-relationship exists between them.

Many popular ligand systems are designed in such a way that the user can tailor both effects. Foremost amongst these ligand systems are the poly(azolyl)borate anions commonly known as the scorpionates.[4] Since their introduction in 1966 there has been a steady evolution of these systems. The introduction of steric bulk was quickly achieved, and latterly more limited attention has been given to their electronic properties.[5] We have sought to extend the scope of the scorpionate ligands by developing "soft" tripodal systems such as the hydrotris(methimazolyl)borate anion ($Tm^{Me}$)[6,7] (Scheme 1), replacing the heterocyclic nitrogen donors of hydrotris(pyrazolyl)borate anion (Tp) with thione sulfur donors. Initially, studies using these ligands produced results which were qualitatively in accordance with accepted hard and soft acid/base concepts. For example, it was found to be relatively simple to form soft scorpionate complexes of copper(I),[6,8] but much more difficult to generate the analogous copper(II) species and to this day the simple complexes of copper(II) remain elusive.[9] Furthermore, unlike the nominally hard pyrazole based ligands, our thione

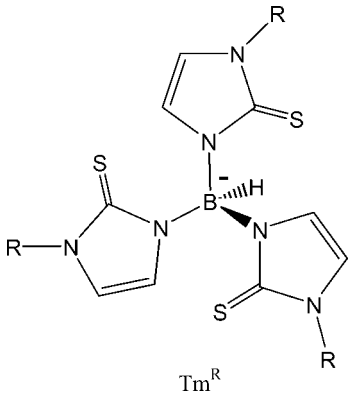
donor ligands readily form a range of stable complexes of the lower main group elements (e.g. Sb, Te and Bi).[10] In the face of these predictable observations, a number of intriguing anomalies began to appear in the behaviour of these soft scorpionates, which did not support the view that their chemistry could be explained purely on the basis of hard and soft acid/base properties.



$Tm^R$

Scheme 1.

It is of interest to compare the three 6e⁻ face capping ligands, Tm, Tp and Cp. While the relative hardness of these ligands would be expected to lie in the order Tp > Cp > $Tm^{Me}$, most quantitative results obtained placed the ligands in a different order. Thus, in the complexes [$Fe^{II}(L)_2$], there is a transition from low spin (Cp) to spin-crossover (Tp) to high spin ($Tm^{Me}$) magnetic behaviour, suggesting that the spectrochemical series for these ligands lies in the order Cp > Tp > $Tm^{Me}$.[11] This is further supported by the cobalt chemistry of these ligands,[12] in which a tetrahedral (weak field) complex [$Co^{II}(Tm^{Me})X$] is obtained with $Tm^{Me}$, while the stronger field ligands Cp and Tp both form sandwich complexes [$Co^{II}(L)_2$].

Additionally, in our study of the group 6 species ([$Mo(Tm^{Me})(CO)_2(\eta^3\text{-}C_3H_5)$] and [$W(Tm^{Me})(CO)_3I$])[13a] we observed that the carbonyl stretching frequencies of the iodo and $\eta^3$-allyl species also lie in the order Cp > Tp > $Tm^{Me}$, suggesting that Tm is in fact the strongest electron donor of the three tripodal ligands and Cp the weakest. It is notable that Tp, as the moiety which relies on σ interactions, is found in the middle of this short series and not at either of its termini. This has been further supported by other observations. For instance, the reduction potentials of the complexes $[Co^{III}(L)_2]^+$ confirm that the $Tm^{Me}$ complex is the most difficult to reduce, consistent with $Tm^{Me}$ being the strongest electron donor.[12] Furthermore, we found that we were unable to stabilise tin(II) complexes with the $Tm^{Me}$ ligand, obtaining only the tin(IV) adducts. In this situation oxidation occurred even under anaerobic conditions,[10m] thus supporting the idea that the $Tm^{Me}$ ligand is an unusually strong electron donor.

It is clear that our appreciation of the $Tm^R$ ligand system is as yet incomplete. We therefore decided to undertake DFT calculations on an appropriate series of complexes in an effort to extend our understanding of both the ligand and the metal–ligand bonding interaction. The previously studied group 6 (Mo, W) carbonyl complexes seemed ideal for this purpose. However, the unusual geometries of the [$M(Tm^{Me})(CO)_3I$] and [$M(Tm^{Me})(CO)_2(\eta^3\text{-allyl})$] complexes seemed less than ideal and since the more regular octahedral complexes [$M(L)(CO)_2(NO)$] (L = Cp, Tp) are well known and several are structurally characterised, these were chosen. Helpfully, both the CO and NO ligands report (by their C–O and N–O stretching frequencies) on the electronic properties of the complexes. We have prepared the $Tm^{Me}$ analogues, characterised them crystallographically and spectroscopically and have undertaken DFT calculations on each of the complexes. We report here the results of this study.

## Results and Discussion

Initially the study set out to produce the complete series of group 6 species, [$M(Tm^{Me})(CO)_2(NO)$] (where M = Cr, Mo or W), using established methods (Scheme 2). The molybdenum and tungsten complexes were isolated and crystallised straightforwardly, albeit in poor yield. The reactions were not optimised, and as discussed below, there is at least one other product from the reaction, which is formed via a competing reaction pathway. In contrast, we were unable to isolate the chromium complex.[14] In retrospect this result is not particularly surprising, as the early reports of the preparation of the group 6 cyclopentadienyl complexes clearly show that a unified synthetic strategy for these compounds does not exist either.[15]

### Structural Analysis

The complexes [$M(Tm^{Me})(CO)_2(NO)$] (M = Mo, W) were characterised by X-ray crystallography to reveal the expected structural motifs (Figure 1) in which the $Tm^{Me}$ ligand caps one face of the coordination polyhedron, in keeping with the known Tp and Cp analogues. The metals adopt slightly distorted octahedral coordination geometries (Table 1) and, as previously observed, the ligand bite angles (S–M–S) are on average slightly greater than 90°, while the adjacent angles range from 85.53° to 93.27° for molybdenum and 86.25° to 94.28° for tungsten. Due to the lanthanide contraction and the more efficient overlap of the tungsten d-orbitals with those on sulfur, the M–S distances in

the two complexes are similar, with the Mo–S distances in the molybdenum complex being slightly longer than the equivalent W–S distances. Consistent with the other structures obtained from the metal complexes of this ligand,[6–13] the methimazolyl rings of the $Tm^{Me}$ ligand lie at a mean angle of 33.5° to the imaginary H–B–M axis. This has the effect of reducing the symmetry of the $M(Tm^{Me})$ fragment from $C_{3v}$ to approximately $C_3$ thus minimising the steric strain in the eight-membered chelate rings.

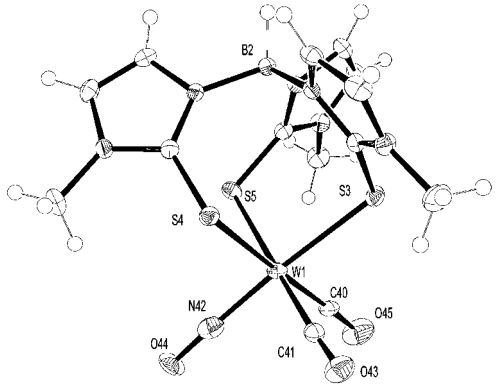

Figure 1. The X-ray crystal structure of $[W(Tm^{Me})(CO)_2(NO)]$. The molybdenum complex (not shown) is isostructural with its heavier congener. The atoms are labelled in a manner consistent with the output from the DFT studies. Thermal ellipsoids are at 50%.

Due to the difficulty in identifying the occupants of the positions associated with the carbonyl carbon atoms and nitrosyl nitrogen in the X-ray structure, the nitrosyl nitrogen was placed in accordance with the results of the DFT calculations (vide infra), i.e. *cis* to the shortest M–S bond. This problem obviates any meaningful comparison with the analogous Tp and Cp systems, which are beset by similar, but irresolvable, problems. Metrical parameters for $[W(Tp)(CO)_2NO]$ and $[W(Cp)(CO)_2NO]$ and the esds for $[Mo(Cp)(CO)_2NO]$ are not available. Values for the $[Mo(CO)_2NO]^+$ ion have been calculated in an attempt to provide information that is independent of the facial ligand.

Although the X-ray crystal structures clearly confirm the identity of the two species, ambiguity remains in that it was not possible to distinguish crystallographically between the C and N atoms of CO and NO. Consequently, the relative positions of the π acid ligands cannot be established beyond doubt. The problem of distinguishing between CO and NO is also evident in the structures of the analogous CpMo[16] and TpMo[17] complexes. Inspection of our structures revealed in each case one of the M–S distances to be shorter than the other two. Intuitively, the unique nitrosyl ligand might be expected to occupy the site *trans* to this bond with the two carbonyl ligands being placed *trans* to the two slightly longer M–S distances, reflecting the relative *trans*-effects of the M–CO and M–NO fragments.

In view of this ambiguity we were interested to apply DFT methods in an attempt to resolve the dilemma. Furthermore, calculations were expected to give insights into a number of aspects of these complexes, including (i) assignment of the CO and NO stretching frequencies in the IR spectrum, (ii) the nature of the M–NO bonding, and (iii) the nature of the metal to tripodal ligand bonds.

## DFT Molecular Orbital Calculations

Thus, we have subjected $[M(Tm^{Me})(CO)_2(NO)]$ (M = Cr, Mo, W) and their Tp and Cp analogues to DFT analysis, using the atomic coordinates retrieved from the respective X-ray crystal structures (where available) as a starting point for geometry optimisation (see Supporting Information). While calculations were performed for all nine possible complexes $[M(L)(CO)_2(NO)]$ (M = Cr, Mo, W; L = $Tm^{Me}$, Tp, Cp) only the data for molybdenum are presented in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Figure 2. Calculated structures of $[Mo(L)(CO)_2NO]$ (from left to right, L absent, i.e. $[Mo(CO)_2NO]^+$, L = Cp, Tp, and $Tm^{Me}$).

detail here, together with the $Tm^{Me}$ complexes of Cr and W. The remaining data for the chromium and tungsten species are deposited as electronic supporting information, and show remarkably similar structural features and trends (for supporting information see also the footnote on the first page of this paper). Although we have been unable to prepare the complex $[Cr(Tm^{Me})(CO)_2(NO)]$ the calculations suggest there is no inherent instability of the complex provided an appropriate synthetic route can be devised. In addition, calculations on the fragment $[Mo(CO)_2(NO)]^+$, without the face capping ligand, were performed for comparative purposes.

The three calculated structures for the molybdenum complexes $[Mo(L)(CO)_2(NO)]$ (Figure 2) are found to maintain the same gross features as the crystallographic structures presented in Figure 1 and Table 1. It is interesting that for the $Tm^{Me}$ complexes they indicate that the NO ligand should lie *cis*- to the shortest M–S bond (rather than *trans*). We have subsequently refined the X-ray data in light of this observation to give acceptable convergence and structural parameters. However, as expected there are some deviations (up to 4% difference) between the crystallographically determined and calculated bond lengths and angles in all three species. These differences are seen most markedly in the metal-coordination sphere, where calculated M–S distances are ca. 0.1 Å longer than those observed experimentally, and in the π acid ligands, where the M–C, M–N, C–O and N–O distances do not exactly correlate. These differences presumably arise from a combination of factors not least the uncertainty of placing the key atoms in the X-ray structures (NO vs. CO), the approximations in the potentials used for the heavier transition metals, and because the calculations pertain to a gas-phase species in contrast to the solid state structural data. Nevertheless, consistent trends are observed giving confidence in the validity of the results.

One interesting feature of the DFT calculations is the infrared frequencies obtained (Table 2), which clearly identify the single NO and two CO stretches observed in these species. Correction factors are often applied to band frequencies in order to obtain acceptable agreement between experiment and theory. In this case no such correction was deemed necessary, as the agreement between the observed and calculated band frequencies is good. Indeed the discrepancies are not appreciably worse than those observed between the infra-red data obtained in the liquid and solid phase. The major divergence between experiment and theory is in the relative intensities of the bands (Table 2). The calculations suggest that the intensities of the three bands should be similar, but experimentally the νNO is significantly (×2) more intense than the νCO.

The hypothetical $[M(CO)_2(NO)]^+$ fragment was generated to allow us to better inspect the influence of the facially capping ligand. The fragment itself is calculated to have an ν(NO) = 1804 $cm^{-1}$ and ν(CO) = 2006 and 2062 $cm^{-1}$, which reflects the cationic nature of the species. The effect of adding a tripodal ligand to this fragment is to

lower the calculated stretching frequencies by ca. 100 $cm^{-1}$. This is consistent with the increased electron density at the metal centre, transmitted through classical back-bonding to the NO and CO π* orbitals. The fine detail reveals the relative effects of the individual tripodal ligands. On average, the complexes with the Cp ligand have slightly higher stretching frequencies than those with Tp, while the $Tm^{Me}$ complexes consistently have the lowest stretching frequencies by some 20–30 $cm^{-1}$. This implies that $Tm^{Me}$ is the most electron-releasing of the three ligands. The trend in IR stretching frequencies is mirrored by the changes in the calculated structural parameters. The N–O and C–O distances show an increase in the order Cp < Tp < $Tm^{Me}$, while the M–C and M–N distances decrease from Cp through to $Tm^{Me}$. The Mulliken charge distributions also support this view (Table 3). In each case the negative charge on the nitrosyl oxygen is found to increase Cp < Tp < Tm for molybdenum and tungsten, respectively, indicative of the expected decrease in overall cationic character of the nitrosyl ligand. Thus the calculations, combined with the experimental vibrational spectra, confirm Tm to be the most electron-donating of the three face-capping ligands.

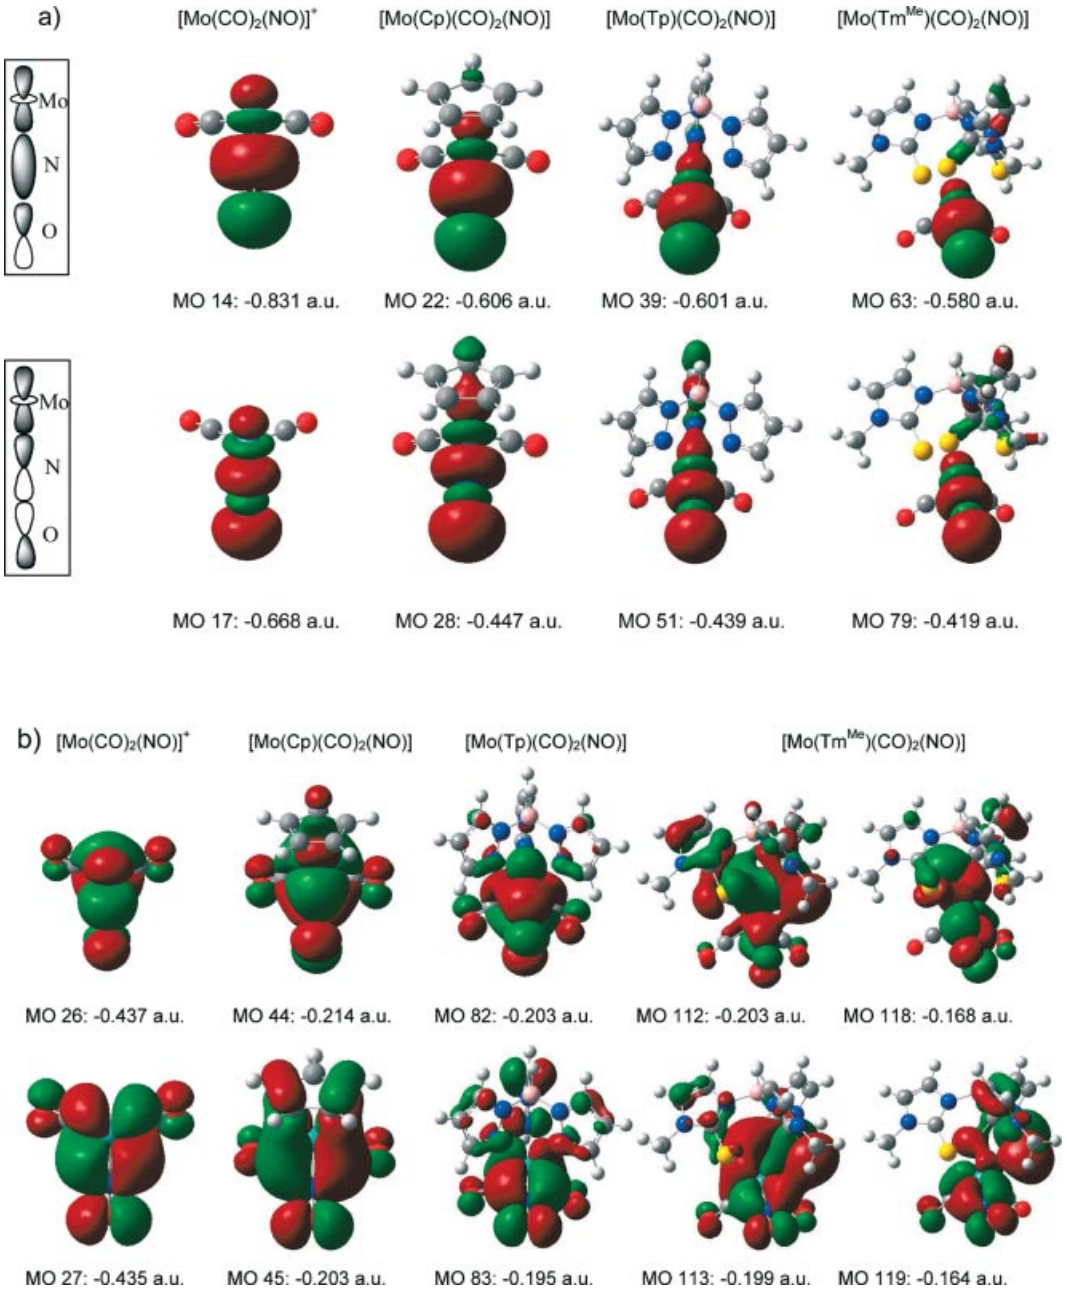

Figure 3. Calculated MOs describing a) the metal to NO σ bonding and b) the metal to NO π back-bonding in $[Mo(CO)_2(NO)]^+$, and $[Mo(L)(CO)_2(NO)]$ (L = Cp, Tp and $Tm^{Me}$). The symmetry of the $Tm^{Me}$ adducts are lower than the corresponding Tp and Cp species. Consequently the calculations reveal that $Tm^{Me}$ has two π* molecular orbitals of suitable energy for each of those identified for Tp and Cp.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Although the nitrosyl stretching frequencies of $[M(L)(CO)_2(NO)]$ (M = Mo, W; L = $Tm^{Me}$, Tp, Cp) place them within the range observed for bent nitrosyl ligands (1525–1690 $cm^{-1}$), it is evident from the DFT calculations and crystallographic studies, that the M–N–O moiety remains linear (<M–N–O 179° calcd.). The observed NO stretching frequency in $[W(Tm^{Me})(CO)_2(NO)]$ at 1614 $cm^{-1}$ is amongst the lowest values yet recorded for a linear NO ligand (1600 $cm^{-1}$).[18,19] This prompted us to examine the metal-nitrosyl bonding in more detail (Figure 3). In the absence of tripodal ligands, the description of the M–NO bonding derived from the DFT calculations confirms the accepted σ donor, π acceptor model. The NO ligand lies on the *z* axis and the $d_{z^2}$ orbital overlaps with nitrogen s and p orbitals to form the σ bond. The π component of the bonding involves interaction of $d_{xz}$ and $d_{yz}$ orbitals with the orthogonal sets of π* orbitals on NO. Furthermore, there appears to be significant overlap of the CO π* orbitals with the $d_{xy}$ orbital. The calculated ν(NO) is 1804 $cm^{-1}$, clearly in the region normally associated with linear NO ligands.

On addition of the facially capping ligands to the $[Mo(CO)_2(NO)]^+$ fragment, the bonding picture is largely maintained. However, in the cases of Cp and $Tm^{Me}$ there are significant interactions between the M–NO bonding orbitals and orbitals on the tripodal ligands. Furthermore, the loss of the plane of symmetry in the case of the $Tm^{Me}$ ligand, further complicates the picture. We have selected the major metal–ligand bonding orbitals in the $[M(CO)_2(NO)]^+$ fragment, identified the most closely corresponding orbitals in the $[M(L)(CO)_2(NO)]$ complexes and plotted their energies (Figure 4). On complexation of the face-capping ligand the species becomes electrically neutral and thus there is an increase in the orbital energies relative to the positively charged $[M(CO)_2(NO)]^+$ fragment. It must be argued that the overall effect of complexation of the ligand will be to stabilise this fragment via the bond energies associated with the formation of three extra M–S bonds. However, the rise in orbital energies reflects a destabilisation of the metal/π acid bonding. This is consistent with the weakening of C–O and N–O bonds in the accepted σ-donor π-(acceptor) bonding model. The DFT calculations also allow us an intriguing view of the key molecular orbital interactions in the three metal fragments CpM, TpM and TmM (Figure 3). Consistent with the work of Bergman et al.,[20] Joshi et al.,[21] and Nemykin & Basu,[22] the interactions between Tp and the metal seem to be predominantly directed through nitrogen-based σ donor interactions only and that the influence of the ligand on the ancillary π acid ligands is through these remote interactions. On the other hand, the CpMo fragment indicates significant, direct π overlap between the facially capping ligand and orbitals on

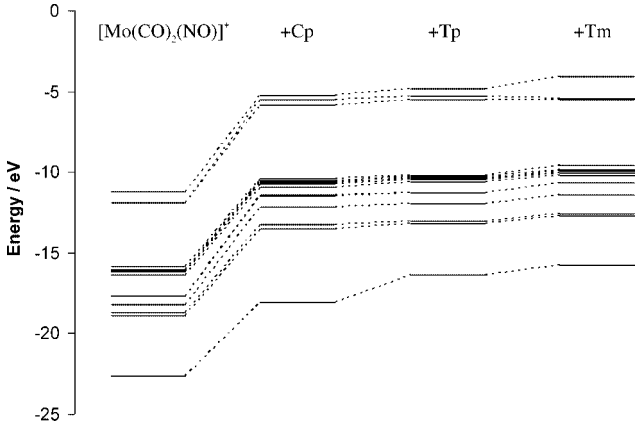

Figure 4. Perturbation of the Mo–π acid ligand bonding on addition of tripodal ligands to the $[Mo(CO)_2(NO)]^+$ fragment.

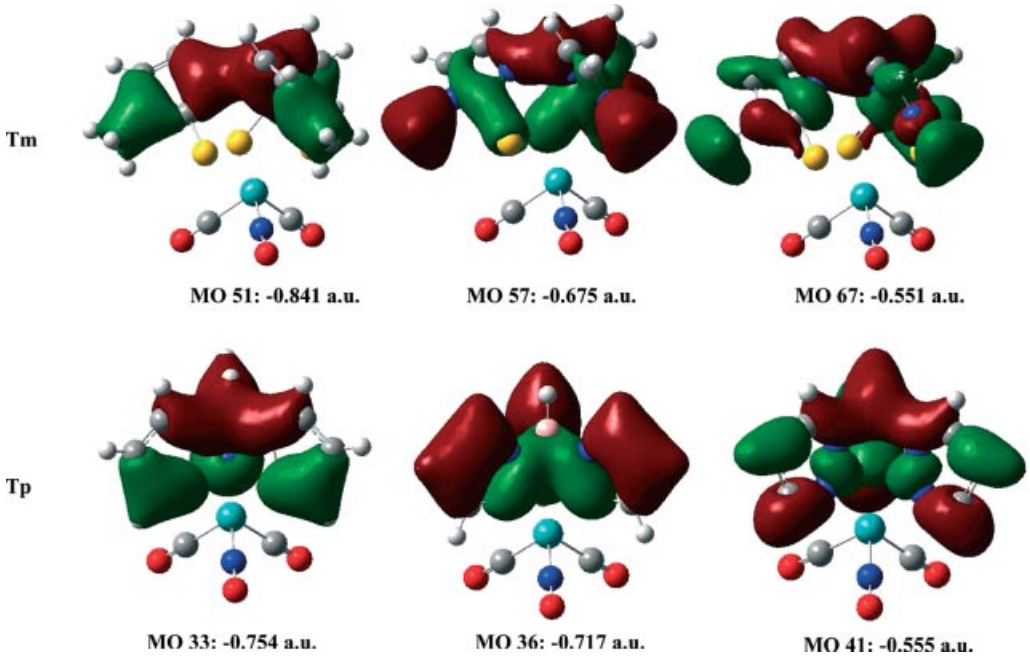

Figure 5. A selection of DFT derived orbitals depicting delocalisation through the $Tm^{Me}$ and Tp Ligands.

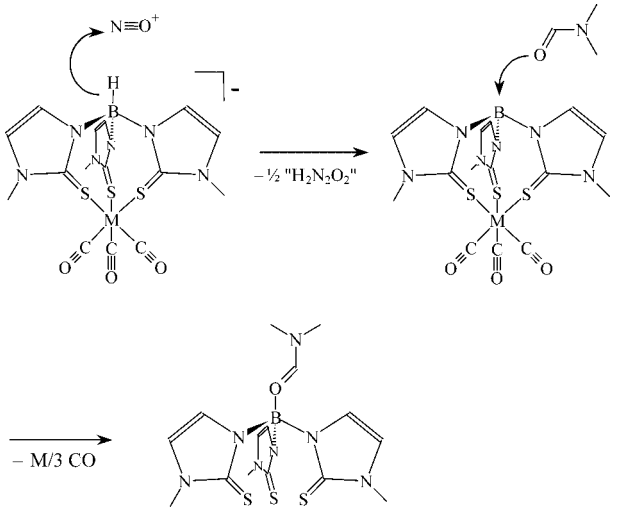
the π acid ligands (NO, CO) indicating that strong synergistic bonding operates through the metal centre. The molecular orbitals generated for Tm are more complex than both Cp and Tp, in part because of the lower symmetry and in part because there are significantly more atoms. The sulfur–metal interaction is also considerably more complex than the corresponding nitrogen–metal interaction in Tp complexes. This arises from the presence of predominantly p orbital lone pairs based on sulfur. The π interaction of the sulfur p orbitals with the metal to π acid backbonding orbitals (e.g. MO 113, Figure 3) suggests that the sulfur donor has a direct influence on the nitric oxide ligand. This observation may go some way to explaining why the M–NO fragment remains linear but has a very low stretching frequency.

The DFT calculations also give us an insight into the behaviour of the B–H and the heterocyclic moieties in Tm and Tp. As reported by Joshi et al. for Tp systems,[21] the Tm ligand also shows extensive delocalisation of the heterocyclic rings through boron (Figure 5). In effect each of these ligands has an extended π system which allows electronic communication throughout the ligand. Thus the calculations suggest that the substituents placed on the methimazolyl nitrogen (methyl in $Tm^{Me}$), and on the bridgehead boron atom, will have a significant influence on the donor properties of the ligand, perhaps greater than has hitherto been recognised.

Thus the DFT calculations confirm that the electron-donor properties ($Tm^{Me} > Tp > Cp$) of these three face-capping ligands are dominated by their bonding mode. The σ donor, π donor bonding of Tm is consistent with the lowest CO and NO stretching frequencies in these complexes, but also with the weak field behaviour observed in other systems.[11,12] Likewise, the simple σ donor Tp to metal interactions and the weak π acceptor properties of Cp are also consistent with the ordering of their properties. It is clear that the term "soft" in relation to the $Tm^R$ ligands is useful. However, this label effectively disguises the view that these ligands can be exceptionally strong electron donors.

### An Alternative Reaction Pathway

The overall yields of the reactions conducted in this work were low. This was in part due to the lack of priority in optimising them. However, it was also evident that the nitrosonium cation was not restricted to reacting at the metal centre alone. As a small oxidising agent it is also capable of reacting at the reducing borohydride group, producing a simple borane (Scheme 3), which is trapped by the DMF to produce the novel, neutral DMF adduct of tris(methimazolyl)borane (Figure 6). Although this species was only a minor by-product from the reaction containing molybdenum, it was a significant proportion of the product from the tungsten reaction. The boron-centred molecule maintains many of the structural features of the Tm anion. The three sulfur atoms revert to a position above the $BN_3$ plane, with the methimazoles adopting a $C_3$-symmetric propeller conformation around the B–O axis reminiscent of the orientation in the crystal structure of the free parent $Tm^{Me}$ anion.[7] The presence of the large DMF unit does however somewhat reduce the angle that the heterocyclic rings adopt to the main B–O axis. Oxidation of the anion and removal of the small negatively charged hydride leaves the borane with less electron density to distribute around the $B(mt)_3$ moiety, an effect which is evident in the C=S bond lengths, which are much shorter (i.e. have greater double-bond character) than those in the parent $Tm^{Me}$. If the parent $Tm^{Me}$ anion is considered to be a facially capping six electron donor analogous to Cp and Tp, then this new DMF adduct, being neutral, can be considered as an arene analogue.



Scheme 3.

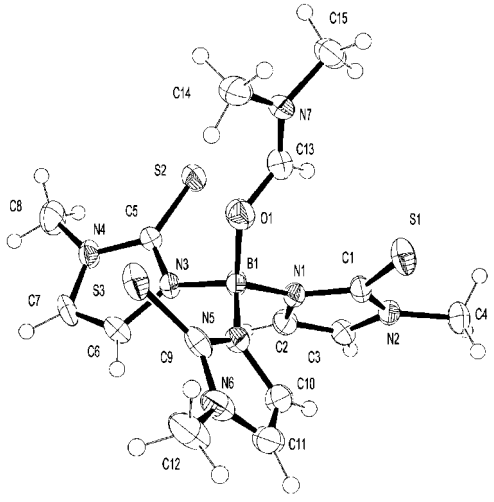


Figure 6. X-ray crystal structure of the dimethylformamide adduct of tris(methimazolyl)borane. Thermal ellipsoids are at 50%.

While the B–H moiety rarely reacts in Tp chemistry, it is not uncommon for it to do so in $Tm^R$ chemistry. Hill has identified two related products which stem from the same reaction profile, namely a cyclic species and an elegant series of metal boratranes.[23] We have observed additional species in these reactions and, because these "degradative"

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pathways are of interest in themselves, they will be discussed in greater detail in a subsequent report. In conclusion the data supports the view that $Tm^{Me}$ is a strong π donor and that its character, i.e. its softness, is tempered by the nature of the bonding in the complex. This observation sets it apart from the anionic tripodal phosphanyl borate[24] and thioalkyl borates[5,8a–8c] and as such we can expect to continue seeing greater diversity within this sub grouping of the scorpionate species.

## Experimental Section

Unless otherwise stated all experiments were carried out using standard Schlenk techniques and commercially available chemicals. Hexane, THF and diethyl ether were dried and distilled from potassium under dinitrogen. Dichloromethane was dried and distilled from calcium hydride under dinitrogen. Dimethylformamide was dried with molecular sieves (4 Å) prior to distillation at reduced pressure. NMR analysis was carried out with a Bruker AMX 400 operating at 400 MHz for proton and 100 MHz for carbon. Infrared spectra were recorded as potassium bromide discs or in solution (dichloromethane) with a Nicolet Avatar 360 FT-IR spectrometer. Sodium hydrotris(methimazolyl)borate ($NaTm^{Me}$) was prepared using published methods.[6,7]

**Preparation of [Dicarbonyl(nitrosyl)hydrotris(methimazolyl)borato]-molybdenum:** Hexacarbonylmolybdenum (0.26 g, 1.0 mmol) was dissolved in dimethylformamide (20 mL) under dinitrogen. The reaction mixture was refluxed gently for 20 h whereupon the solution became very dark in colour. The solution was cooled to room temperature and $NaTm^{Me}$ (0.40 g, 1.1 mmol) added. The solution was stirred for 24 h after which time an equimolar amount of nitrosonium tetrafluoroborate (0.12 g, 1.0 mmol) was added. The solution was stirred for a further 2 h during which time gas evolution (CO) was evident. The DMF was removed by vacuum distillation and the product extracted into THF (3 × 40 mL), filtered through celite and stored at –20 °C overnight. The solution separated into a black tar and an orange liquor. The liquors were refiltered and reduced in volume and returned to the freezer at –20 °C. Over a 48-h period a crop of red crystals formed. These were collected by aspirating the liquors from the Schlenk tube thus leaving the desired material in the flask. Crystals suitable for X-ray analysis were removed from the sample prior to drying at reduced pressure overnight. Yield: 0.08 g, 15%. $C_{14}H_{16}BMoN_7O_3S_3$ (533.26): calcd. C 31.53, H 3.02, N 18.39; found C 32.13, H 3.87, N 18.57. $^1$H NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 7.34 (dd, 2 H, –CH=), 7.30 (d, $J$ = 2.1 Hz, 1 H, CH), 7.04 (d, $J$ = 2.1 Hz, 1 H, CH), 7.02 (d, $J$ = 2.1 Hz, 1 H, CH), 6.97 (d, $J$ = 2.1 Hz, 1 H, CH), 3.61 (s, 3 H, $CH_3$), 3.56 (s, 3 H, $CH_3$), 3.50 (s, 3 H, $CH_3$) ppm. IR (KBr disc): $\tilde{\nu}$ = 2468 (weak, BH), 1995 (strong, CO), 1898 (strong, CO), 1630 (strong, NO), 736 (m, C=S), ($CH_2Cl_2$): $\tilde{\nu}$ = 2006 (strong, CO), 1915 (strong, CO), 1636 (strong, NO) cm$^{-1}$.

**Preparation of Dimethylformamido(trismethimazolyl)borane and [Dicarbonyl(nitrosyl)hydrotris(methimazolyl)borato]tungsten:** Hexacarbonyltungsten (0.70 g, 2.0 mmol) was dissolved in dimethylformamide (20 mL) under dinitrogen. The reaction mixture was refluxed gently for 20 h whereupon the solution became very dark green. The solution was cooled to room temperature and $NaTm^{Me}$ (0.75 g, 2.0 mmol) added. The solution was stirred for 48 h after which time an equimolar amount of nitrosonium tetrafluoroborate (0.24 g, 2.0 mmol) was added. The solution was stirred for a further 4 h during which time gas evolution (CO) was evident. The DMF was removed by vacuum distillation and the product extracted into THF (3 × 40 mL), filtered through celite, reduced in volume by 60% and stored at –20 °C overnight whereupon a crop of pale orange crystals formed. These were collected by aspirating the liquors from the Schlenk tube. Crystals for X-ray analysis were removed from the sample prior to drying at reduced pressure overnight. These were found to be an intriguing and significant side product. Yield: 70 mg, 8%. $C_{15}H_{22}BN_7OS_3$ (423.38): calcd. C 42.54, H 5.24, N 23.16; found C 41.22, H 3.90, N 23.46. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 8.70 (s, 1 H, –CHO), 6.68 (d, $J$ = 2.3 Hz, 3 H, CH), 6.46 (br. s, 3 H, CH), 3.59 (s, 9 H, $CH_3$), 3.32 (s, 3 H,

**X-ray Crystallography:** Crystals were coated in mineral oil and mounted on glass fibres. Data were collected at 123 K with a Nonius Kappa CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. The heavy atom positions were determined by Patterson methods and the remaining atoms located in difference electron density maps. Full matrix least-squares refinement was based on $F^2$, with all non-hydrogen atoms anisotropic. While hydrogen atoms were mostly observed in the difference maps, they were placed in calculated positions riding on the parent atoms. The structure solution and refinement used the program SHELX-97[25] and the graphical interface WinGX.[26] The structure of $B(mt)_3{\cdot}$dmf contained severely disordered solvent molecule (THF), which was compensated for by use of the SQUEEZE algorithm.[27] A summary of the crystallographic parameters is given in Table 4.

**Density Functional Theory (DFT) Molecular Orbital Calculations:** Calculations were performed using the Gaussian 98 program.[28] The molecular species were subjected to geometry optimisation at the DFT[29] level and the 6-311G** basis set[30] for the atoms C, N, O, S, B and H. For molybdenum and tungsten, the Stuttgart RSC 1997 ECP basis set, augmented by a diffuse s and p functions with a common exponent of 0.005, was used.[31] Preliminary calculations were carried out on [Mo(Cp)$(CO)_2$(NO)] using four different DFT functionals namely BLYP,[32] B3LYP, BP86,[33] and MPW1PW91.[34] The best agreement with respect to the experimental carbonyl and nitrosyl infra-red frequencies was obtained using the BLYP functionals and hence these were used for the rest of the molecules.

**Supporting Information** (see also the footnote on the first page of this article): X-ray crystallographic data in CIF format and results of DFT calculations (calculated MO orbitals).

CCDC-625101 (for [$B(mt)_3$(DMF)]), -625102 (for [Mo($Tm^{Me}$)$(CO)_2$NO]) and -625103 (for [W($Tm^{Me}$)$(CO)_2$NO]) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Protonation of Tris(iminocatecholato) Complexes of Gallium(III) and Titanium(IV)

**Markus Albrecht,*[a] Simon Burk,[a] Ralf Stoffel,[b] Arne Lüchow,[b] Roland Fröhlich,[c] Michael Kogej,[d][‡] and Christoph A. Schalley[d]**

*Dedicated to Professor Dr. H. G. Thomas on the occasion of his 70th birthday*

**Keywords:** Coordination compounds / Helicates / Protonation / Self-assembly / Computational chemistry

The coordination behaviour of the chiral tren-type tripodal ligand **3**-$H_6$ with gallium(III) and titanium(IV) ions was investigated and it was found that only mononuclear complexes are formed. In the presence of $Na^+$, one of the cations acts as a template and is bound inside the "cap" of $[Na(\mathbf{3})M]^{n-}$ (M = Ga, $n$ = 2; M = Ti, $n$ = 1). If no such cation is present, three protons are bound to the iminocatechol units in order to prevent repulsion between lone pairs at nitrogen and oxygen. To minimize the charge repulsion between the protonated imines of $[H_3(\mathbf{3})M]^{n+}$ (M = Ga, $n$ = 0; M = Ti, $n$ = 1), an enamine/chinomethine mesomeric structure becomes important. The adoption of this unusual mesomeric form by the iminocatecholates was supported by computational methods. In further investigations, we found, that the addition of protons ($H_2SO_4$) to the dinuclear (catecholimine)titanium helicate $K_4[(\mathbf{4})_3Ti_2]$ leads to protonation of the imine part of the iminocatechol. An excess of acid results in the hydrolysis of the complexes as well as of the imine units.

## Introduction

Self-assembly processes depend strongly on the geometry of molecular building blocks, which are able to form well-defined aggregates by non-covalent or coordinative interactions.[1] The outcome is often predictable, if rigid moieties are used.[2] However, with flexible units, prediction is still challenging, because many different steric, electronic, and entropic aspects need to be taken into account, which may counterbalance each other to some extent and thus make it difficult to estimate their final net effect.

During the last couple of years we and others have been investigating the coordination chemistry of tris(catechol) ligands which have been able to form supramolecular tetrahedra of the $M_4L_4$ type.[3] Starting with rigid ligand systems like **1**-$H_6$, we easily obtained the desired container molecule $[Ti_4\mathbf{1}_4]^{8-}$, which shows interesting host–guest chemistry.[4]

Ligand **2**-$H_6$ (Figure 1), on the other hand, is more flexible. Therefore, it either can form a mononuclear

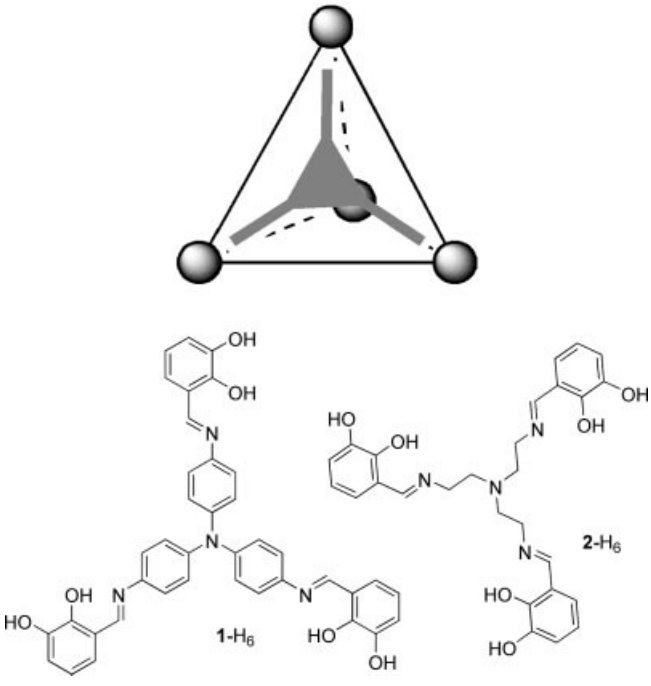

Figure 1. Schematic representation of a metallosupramolecular tetrahedon and appropriate triangular ligands.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

"[Ti(**2**)]$^{2-}$" complex or a tetrahedron [Ti$_4$**2**$_4$]$^{8-}$ depending on the templating cation which is present. The smaller sodium cation nicely fits into the cavity formed when all catecholato units coordinate to the same metal center and thus template the formation of mononuclear complexes, while the potassium ion, whose size exceeds that of this cavity, favours the formation of the tetrahedron in dmso.[5]

Although a simple tetrahedron is not chiral, the self-assembled $M_4L_4$ tetrahedra possess twisted chiral complex units as cornerstones. In order to generate chiral enantiomerically pure tetrahedra, we now investigated triangular ligands **3**-$H_6$ based on the chiral tren-type platform, developed by Moberg et al.,[6] which can be considered to be a chiral variant of **2**-$H_6$. However, coordination studies with titanium(IV) and gallium(III) cations show the bulkiness of the isopropyl substituents at the ligand to be so high that the ligand cannot adopt the appropriate extended conformation with the triangular geometry required to occupy a face of the tetrahedron. Consequently, the ligand forms only mononuclear complexes. If no appropriate template cation is present to fill the cavity, the mononuclear complex is highly basic and takes up three protons in order to compensate the repulsion between electron pairs at the imine nitrogen atom and the internal catecholato oxygen atom. Similar hydrogen bonding can be observed in the complexes of catecholamides.[7]

This protonation behaviour cannot only be observed for the tritopic ligand **3**-$H_6$, but also in the case of a titanium helicate formed from the ditopic ligand **4**-$H_4$.[8] A gallium(III) complex of the monotopic **5**-$H_2$ seems to show a similar behaviour, but protonation is accompanied by decomposition (Figure 2).[9]

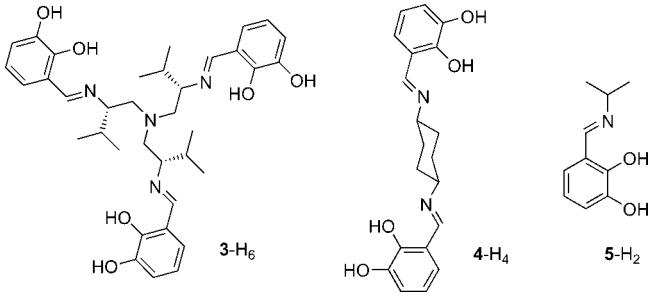

Figure 2. Ligands discussed in this study.

## Results and Discussion

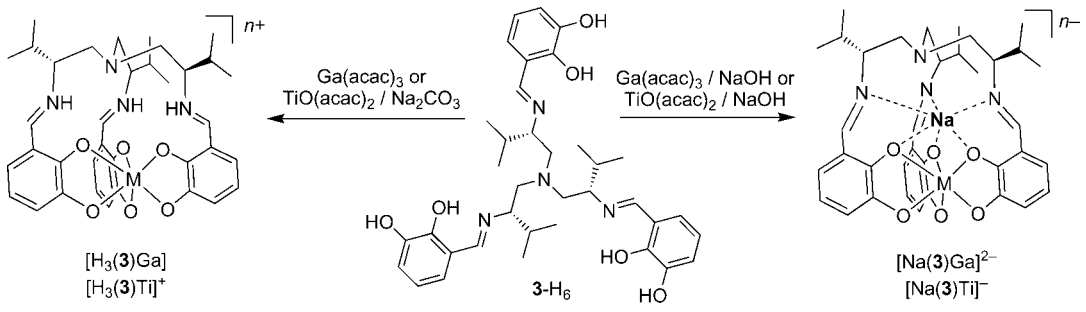
### Coordination Chemistry of Ligand 3-$H_6$ with Titanium(IV) and Gallium(III)

The chiral tritopic ligand **3**-$H_6$ was prepared by utilizing Moberg's procedure[6] for the synthesis of the tetraamine precursor followed by imine condensation with 3 equiv. of 2,3-dihydroxybenzaldehyde (Scheme 1).[10]

Reaction of ligand **3**-$H_6$ with 1 equiv. of gallium(III) acetylacetonate in the presence of 1.5 equiv. of sodium carbonate does not only yield the desired mononuclear complex $Na_2$[Na⊂{(**3**)Ga}]. Instead, the $^1$H NMR spectrum in [$D_6$]-dmso indicates the presence of two different species. One set of low-field signals at $\delta$ = 7.89 (s, $CH_{imine}$), 6.06 (d, $J$ = 7.7 Hz, $H_{cat}$), 6.02 (d, $J$ = 7.7 Hz, $H_{cat}$) and 5.91 (t, $J$ = 7.7 Hz, $H_{cat}$) ppm can be assigned to $Na_2$[Na⊂{(**3**)Ga}] by comparison with the chemical shifts observed for the already known compound Na[Na⊂{(**2**)Ti}].[5] The second set of signals for catechol protons appears at $\delta$ = 6.40 (m, 6 H) and 6.33 (m, 3 H) ppm. The most intriguing feature is the appearance of the imine CH resonance at $\delta$ = 8.62 ppm as a doublet with $J$ = 13.5 Hz and of an additional doublet of doublets at $\delta$ = 12.5 ($J$ = 13.5, 11.1 Hz) ppm. According to the coupling pattern and the far low-field shift of this signal, we assign it to a proton at the imine nitrogen atom. As shown in Figure 4, both species can also be obtained in pure form. Use of the stronger base NaOH allows the formation of $Na_2$[Na⊂{(**3**)Ga}], while in the absence of base only the protonated species is obtained.

Using titanium(IV) as the central metal ion, we obtained similar results. With NaOH, the complex Na[Na⊂{(**3**)Ti}] is formed, while use of the weaker base sodium carbonate leads to the formation of only the species showing the protonated imine signals at $\delta$ = 12.0 (m, =NH) and 9.05 (d, $J$ = 14.6 Hz, =CH) ppm.[11]

According to those results, we propose, that both gallium and both titanium compounds are mononuclear complexes of ligand **3**. According to earlier crystal structure investigations of iminocatecholato complexes,[12] conformation **I** (Figure 3) is preferred over structure **II** due to electron-pair repulsion. However, molecular models suggest conformation **I** not to be achievable for the mononuclear complexes studied here due to the restrictions imposed by the tren subunit connecting the catecholate units. Consequently, the



Scheme 1.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

parent compounds $[(\mathbf{3})Ga]^{3-}$ and $[(\mathbf{3})Ti]^{2-}$ should significantly suffer from the repulsion of the electron pairs at the imine nitrogen atoms and at the internal catecholato oxygen atoms.

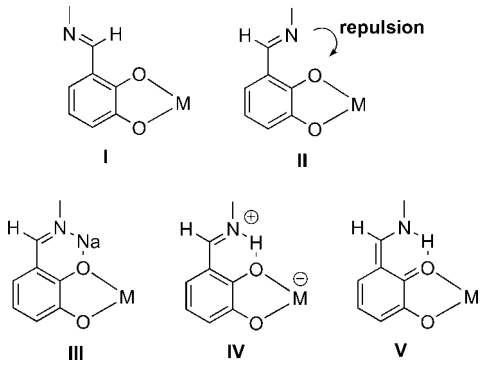


Figure 3. Different binding modes of the catecholimine ligand.

The formation of the mononuclear complexes is nevertheless possible, when the repulsion is taken care of by a cation (sodium) chelated by the imine group and the internal catecholato oxygen atom as in **III** or by protonation of the imine group, thus creating a hydrogen bond to the adjacent oxygen atom as shown in the two mesomeric structures **IV** and **V**.

According to the $^1H$ NMR spectra as shown in Figure 4 (d–f), a situation like that described by structures **IV** and **V** is present in our complexes.[13] The resonances at low field are due to the hydrogen bonds between N and O, which show a coupling with the imine CH group as well as with the CH group of the spacer. Complexes of similarly protonated salicylimines are frequently found, e.g. in the work by Binnemans et al. on mesogenic lanthanide complexes.[14] In the present case, this protonation needs to occur three times within the cavity of the complex in order to waive all three unfavorable N/O interactions in $[(\mathbf{3})M]^{n-}$ (M = Ga, $n$ = 3; M = Ti, $n$ = 2). This should lead to a high accumulation of positive charge in the triply protonated counterparts $[H_3(\mathbf{3})M]^{n+}$ (M = Ga, $n$ = 0; M = Ti, $n$ = 1), which is, however, at least to some extent compensated by the negatively charged metal complex units. In addition, the charges can be distributed over the respective aromatic system with the enaminone **V** as a "neutral" mesomeric structure.[15] These factors make the imine nitrogen atoms rather basic sites which are not fully deprotonated during complex formation with carbonate.

The gallium complex $[H_3(\mathbf{3})Ga]$ is soluble in $D_2O$. Hereby the acidic protons are exchanged by deuterium resulting in the disappearance of the corresponding signal and the appearance of a singlet for the imine proton.

The triply protonated compound $[H_3(\mathbf{3})Ga]$ is neutral and thus not directly detectable by mass spectrometry without attaching an additional – and potentially interfering – charge. The corresponding sodium complex $[Na(\mathbf{3})Ga]^{2-}$ on the other hand is a dianion, which again may cause problems due to charge repulsion in the gas phase. Therefore, we focused on the corresponding titanium(IV) species $[H_3(\mathbf{3})Ti]^+$ and $[Na(\mathbf{3})Ti]^-$ which should both be easily detected by electrospray ionization Fourier-transform ion-cy-

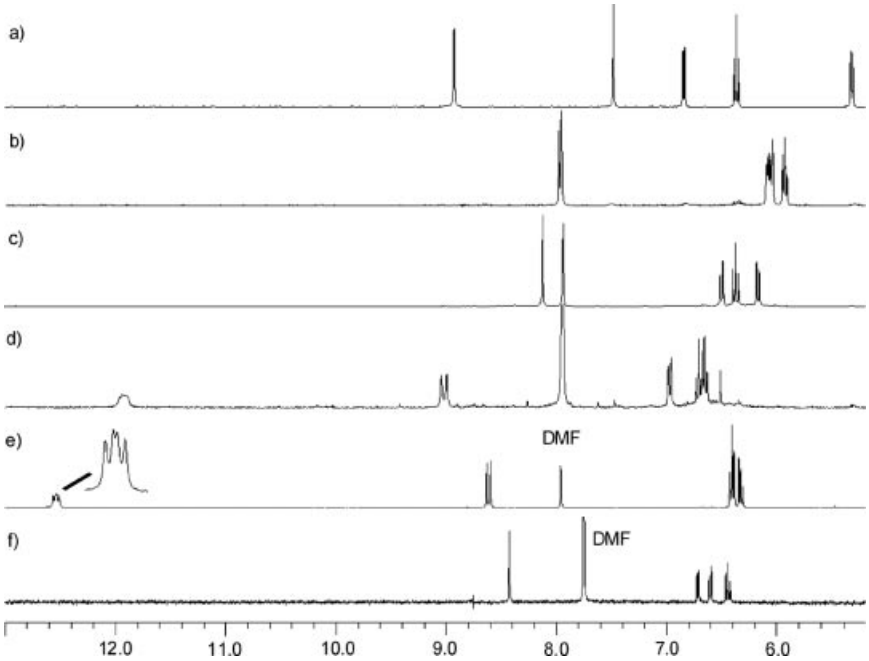

Figure 4. $^1H$ NMR spectra of the low-field region of **3**-$H_6$ (a), $Na_2[Na(\mathbf{3})Ga]$ (b), Na $[Na(\mathbf{3})Ti]$ (c), $[H_3(\mathbf{3})Ti]^+$ (d), and $[H_3(\mathbf{3})Ga]$ (e) in $[D_6]$dmso and of $[D_3(\mathbf{3})Ga]$ in $D_2O$ (f).

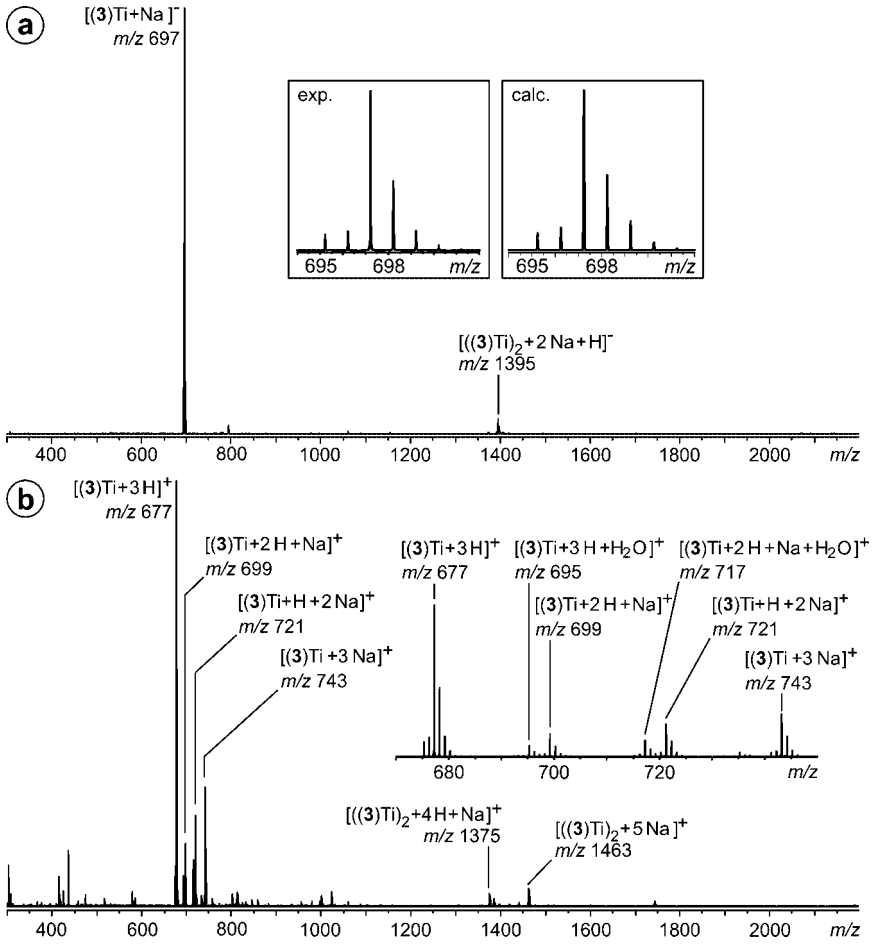

Figure 5. a) ESI FT-ICR mass spectrum of a 100 μM solution of Na[Na(**3**)Ti] in thf (negative mode). The insets show the observed and calculated isotope patterns. b) ESI FT-ICR mass spectrum of a 100 μM solution of Na[Na(**3**)Ti] in thf (positive mode). The region *m/z* = 670–750 is expanded. The water adducts and sodium/proton exchange products can be traced back to some residual water in the solvent.

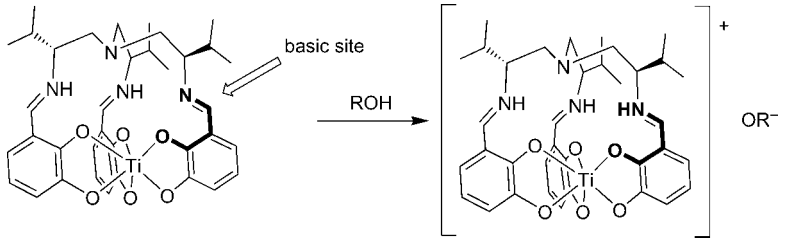
clotron-resonance (ESI FT-ICR) mass spectrometric experiments (Figure 5).[16]

In the negative mode, a 100 μM solution of Na[Na(**3**)Ti] in thf gives rise to a signal corresponding to the anion [Na(**3**)Ti]⁻ as the by far dominating peak. The only other signal is due to {[Na(**3**)Ti]$_2$H}⁻ at *m/z* = 1395, which we attribute to an unspecific proton-bonded dimer. In the positive detection mode, a more complex spectrum is obtained, which exhibits signals for ions that underwent $Na^+/H^+$ exchange reactions up to the $[H_3(\mathbf{3})Ti]^+$ cation, where all sodium ions have been replaced. Although the source of the protons can only be residual water contained in the thf used as the spray solvent, the $[H_3(\mathbf{3})Ti]^+$ cation is the most prominent ion observed in the spectrum indicating a high tendency for protonation of the imine groups.

In a neutral, doubly protonated species [H$_2$(**3**)Ti], one imine site still suffers from a repulsion between N and O electron pairs, thus leading to a highly basic position within the complex (see Scheme 2). This site is able to deprotonate slightly acidic compounds like alcohols or water. In order to study this aspect further, *negative*-mode mass spectra of Na$_2$[(**3**)Ti] in thf were recorded in the presence of differently substituted alcohols (Figure 6). Besides the signal of the expected [Na(**3**)Ti]⁻ anion, several signals for anions appear



Scheme 2.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in which the sodium cation has been replaced by a proton: $[H(\mathbf{3})Ti]^-$, $[H_2(\mathbf{3})Ti]\cdot RO^-$, $[H_2(\mathbf{3})Ti]\cdot Cl^-$, and $[H_3(\mathbf{3})Ti]^+\cdot RO^-\cdot Cl^-$ (likely, the chloride is background chloride as often found in the negative-mode mass spectra). The latter three anions correspond to doubly protonated neutral or triply protonated cationic complexes in which an appropriate number of anions provides the overall negative charge necessary for the experiment in the negative mode. It is intri-

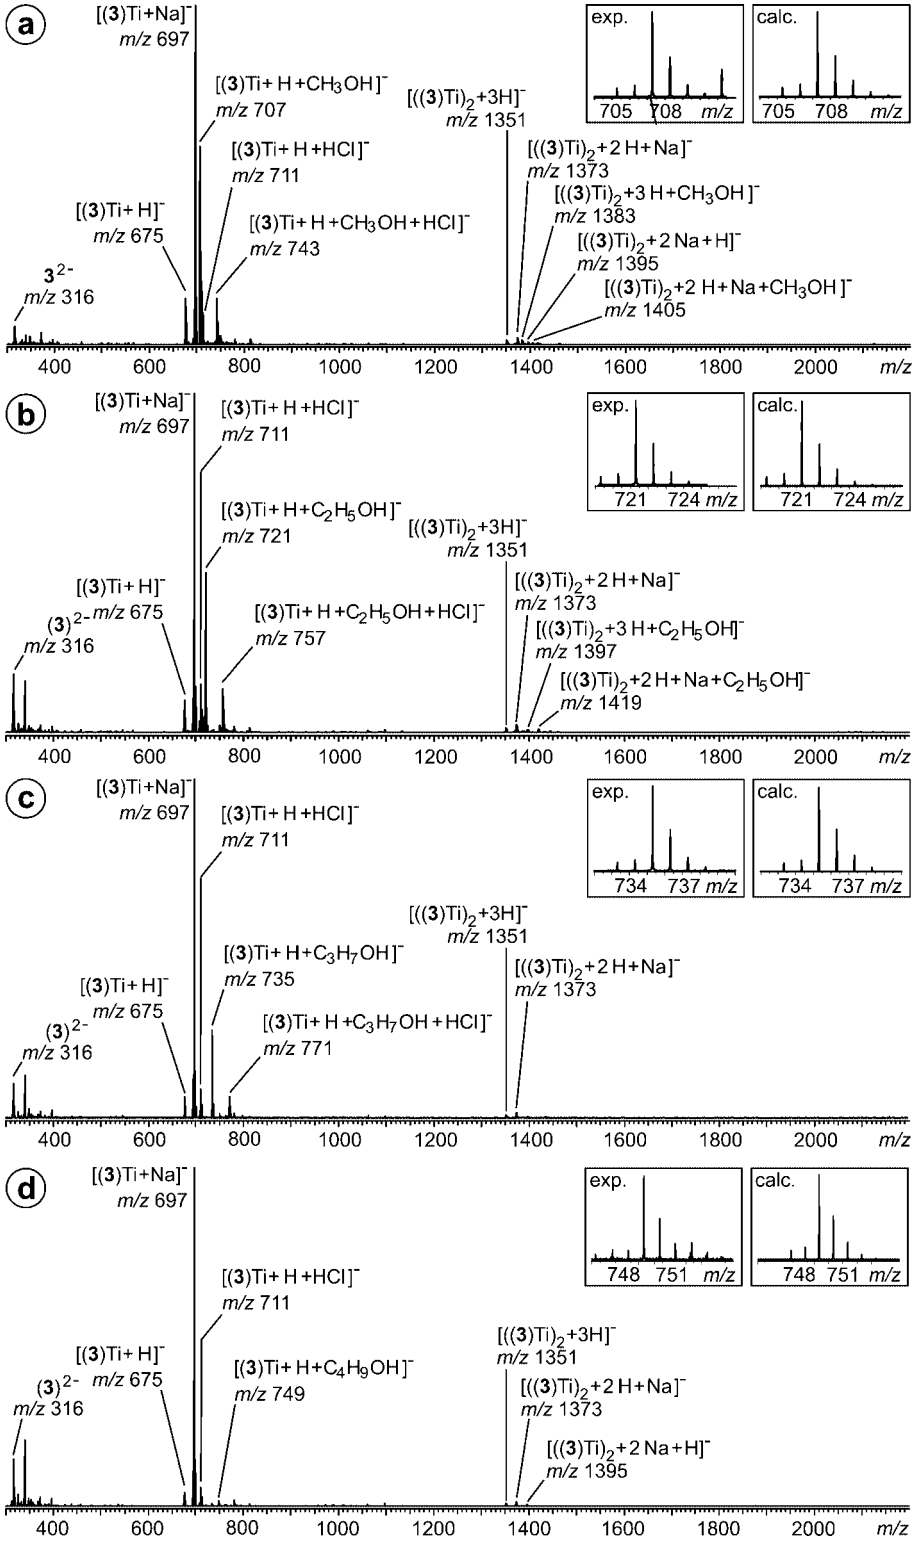


Figure 6. ESI FT-ICR mass spectrum of a 100 μM solution of $Na_2[(\mathbf{3})Ti]$ in thf (negative mode) in the presence of the same amount of different alcohols: (a) methanol, (b) ethanol, (c) 2-propanol, (d) *tert*-butyl alcohol. The observed and calculated isotopic patterns of the species with alcohol are shown. All spectra were measured under exactly the same conditions.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

guing to see that the intensity ratios among these four complexes do not change much irrespective of the nature of the alcohol, while the ratio of the sum of all protonated complexes relative to the sodiated complexes undergoes a drastic change with increasing size of the substituent R on the alcohol. This trend follows the solution acidities of the alcohols ($pK_a$ values for alcohols determined in water: MeOH: 15.49; EtOH: 15.90; *i*PrOH: 16.57; *t*BuOH: 16.84).[17] Methanol as the most acidic one in this series yields the most intense signals for the protonated complexes; *tert*-butyl alcohol as the least acidic one gives rise only to signals of very low intensities for the protonated complexes relative to the sodiated ones. The observed trend, however, does not follow the gas-phase proton affinities ($MeO^-$: 1596 kJ/mol; $EtO^-$: 1583 kJ/mol; $iPrO^-$: 1569 kJ/mol; $tBuO^-$: 1568 kJ/mol),[18] which would – in contrast to the experiment – lead to the expectation that methanol protonates the complex less easily and thus does not form complexes such as [$H_2$(**3**)Ti]·$RO^-$ with higher abundance than *tert*-butyl alcohol. Consequently, we conclude that the mass spectrometric experiments provide some insight into the solution-phase protonation equilibria.

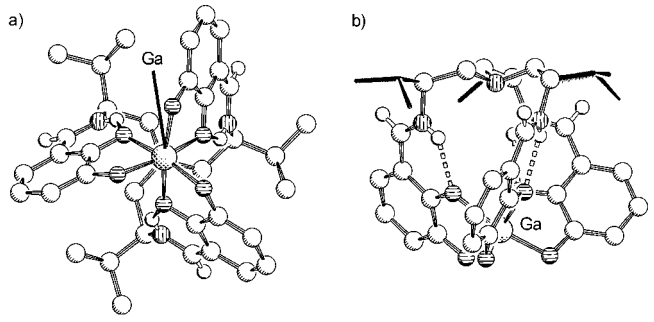

Figure 7. Molecular structure of [$H_3$(**3**)Ga] in the crystal. (a) View along the Ga–$N_{amine}$ $C_3$ axis. (b) Side view (isopropyl groups are only indicated). Hydrogen atoms other than imine CH and N–H···O are omitted for clarity.

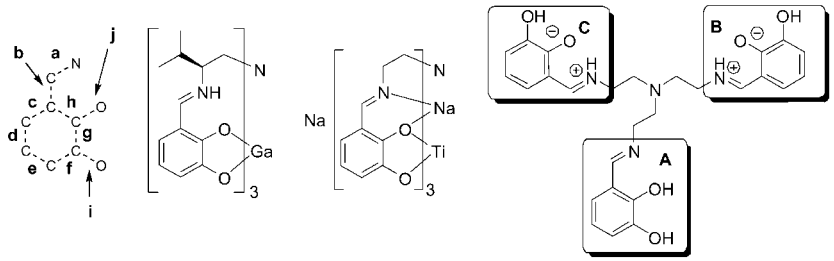
Fortunately, we were able to obtain X-ray quality crystals of [$H_3$(**3**)Ga] from dmf/diethyl ether. The structure is shown in Figure 7. The compound crystallizes in the hexagonal space group $P6_3$ (No. 173) and was refined to $R = 0.051$. The molecule is located on an axis of threefold symmetry.

Figure 7 shows the molecular structure of [$H_3$(**3**)Ga]. The chiral tripodal ligand **3** is coordinating the gallium(III) ions and induces the Δ-configuration at the tris(catecholato) complex unit. The chiral "tren analogue" spacer is forming a close-to-planar platform with the isopropyl groups located in this plane, pointing to the outside. In this way, the sterically least crowded conformation is adopted. The imine units are protonated (the proton positions could be refined) forming hydrogen bonds to the internal oxygen atoms of the catecholato unit, as it was discussed in Figure 3 (**IV**/**V**).

A deeper insight into the structural features of this compound can be given by comparing the bond lengths with those of the related compounds **2**-$H_6$[19] and Na[Na(**2**)Ti],[5] as it is done in detail in Table 1.

For the catecholimine **A** of **2**-$H_6$, the bond lengths are in the expected range. The imine bond (**a**) is a typical C=N bond with a length of 1.280 Å. The distance $C(sp^2)_{imine}$–$C(sp^2)_{aromatic}$ is 1.450 Å (**b**). Within the aromatic system typical C–C bond lengths of approximately 1.38 Å (**c**–**h**) are found and the C–$O_{catechol}$ distances are about 1.36 Å (**i**, **j**). A similar situation is observed for the complex Na[Na(**2**)-Ti]. However, in the units **B** and **C** of **2**-$H_6$, a significant alternation of bond lengths can be observed for the aromatic units (**c**–**h**), while the C–O bond lengths are different, e.g. **B**: C–OH 1.360 Å (**i**), C=O 1.299 Å (**j**). The alternation of the aromatic bond lengths is even more pronounced in [$H_3$(**3**)Ga] so that the mesomeric structure **V** in Figure 3 significantly contributes to an accurate description of this

Table 1. Comparison of the bond lengths (Å) of the iminocatechol units of [$H_3$(**3**)Ga], Na[Na(**2**)Ti] and **2**-$H_6$ in the crystal. In Na[Na(**2**)Ti], the moieties are crystallographically independent and therefore the shortest and longest values are given. In **2**-$H_6$ one "normal" iminocatechol unit is observed (**A**) while the two others (**B**, **C**) show proton transfer from the catechol OH group to the imine nitrogen atom. Data for Na[Na(**2**)Ti][5] and **2**-$H_6$[19] were taken from the literature.



| | [$H_3$(**3**)Ga] | Na[Na(**2**)Ti] | **2**-$H_6$ (**A**) | **2**-$H_6$ (**B**) | **2**-$H_6$ (**C**) |
|---|---|---|---|---|---|
| **a** | 1.298 | 1.263–1.272 | 1.280 | 1.287 | 1.295 |
| **b** | 1.425 | 1.442–1.478 | 1.450 | 1.420 | 1.424 |
| **c** | 1.426 | 1.375–1.412 | 1.398 | 1.416 | 1.411 |
| **d** | 1.358 | 1.377–1.405 | 1.377 | 1.360 | 1.365 |
| **e** | 1.408 | 1.361–1.405 | 1.390 | 1.400 | 1.402 |
| **f** | 1.383 | 1.350–1.385 | 1.375 | 1.366 | 1.365 |
| **g** | 1.439 | 1.398–1.424 | 1.393 | 1.428 | 1.428 |

complex. Here, we observe four relatively long C–C distances of 1.408–1.439 Å and two short ones with 1.358 and 1.383 Å. A remarkable difference can be also observed for the $C_{catecholate}$–O bonds. The internal one is relatively short with 1.296 Å due to its increased double-bond character, while the other one is significantly longer (1.334 Å).

### The Protonation Behaviour of $K_4[(4)_3Ti_2]$

Attempts to obtain analogous protonated helicates of iminocatecholates by reaction of either gallium(III) acetylacetonate or titanoyl(IV) acetylacetonate with ligand **4**-$H_4$ in the absence of base were not successful. Therefore, we used the preformed helicate $K_4[(4)_3Ti_2]$[8] [the corresponding dinuclear gallium(III) helicate can unfortunately not be obtained] and protonated it by stepwise addition of sulfuric acid in [$D_6$]dmso.

The $^1$H NMR resonances (Figure 8) of the catechol protons of $K_4[(4)_3Ti_2]$ (**A**) appear at $\delta$ = 6.86, 6.29, and 6.07 ppm and that of the imine group at $\delta$ = 8.58 (s) ppm. Upon addition of sulfuric acid in steps of 1 equiv. $H^+$ (0.5 equiv. $H_2SO_4$), the spectrum changes drastically. This is best monitored by the shift of the imine CH signal (Figure 9). Initially a partial protonation occurs, which leads to a dynamic species (protonation ↔ deprotonation). Upon addition of 5–8 equiv. of protons, a final spectrum is obtained which corresponds to **B** in Figure 8.

The catechol signals of **B** are observed at $\delta$ = 7.04, 6.67, and 6.57 ppm and the imine resonance is found as a doublet at $\delta$ = 7.40 ($J$ = 15.7 Hz)ppm which couples with a signal at $\delta$ = 11.95 (dd, $J$ = 15.7, 5.2 Hz) ppm. The observed spectrum is in accordance with a protonated species $[H_6(4)_3Ti_2]^{2+}$, in which the six protons are fixed in the interior of the triple-stranded helicate in the same way as dis-

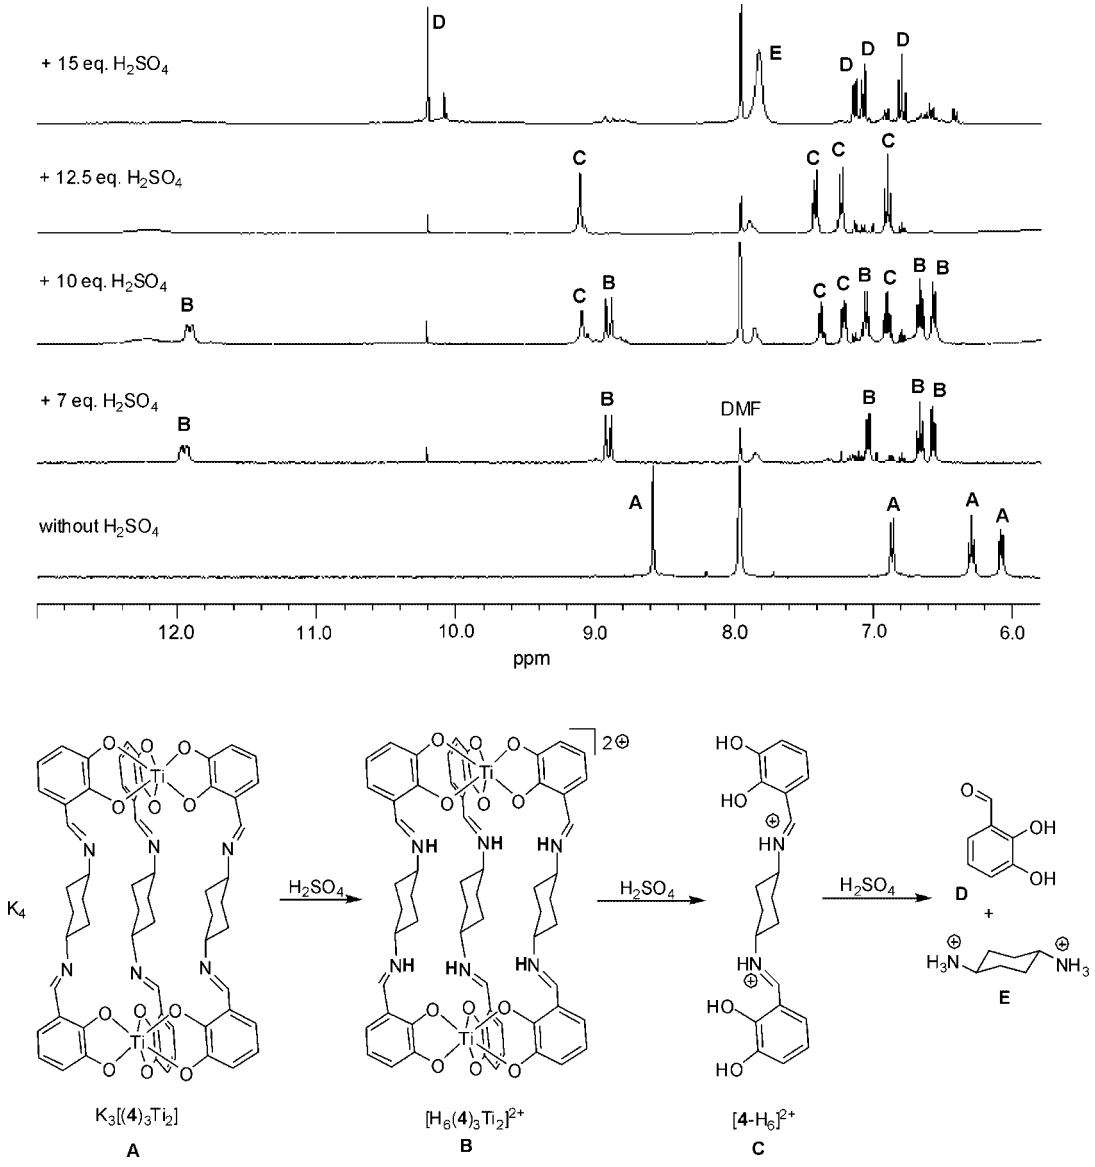

Figure 8. Change of the low-field region of the $^1$H NMR spectrum of $K_4[(4)_3Ti_2]$ in [$D_6$]dmso upon controlled addition of $H_2SO_4$ in [$D_6$]-dmso.

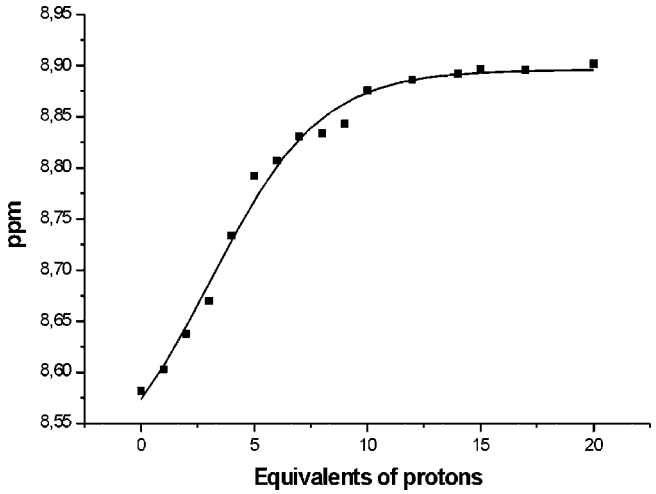

Figure 9. Change of the chemical shift of the imine CH resonance of $[(\mathbf{4})_3Ti_2]^{4-}$ in $[D_6]$dmso upon successive addition of protons ($H_2SO_4$).

cussed for the mononuclear complexes above. This compound can be observed by ESI MS at *m*/*z* = 1151.6 ($[\mathbf{4}_3Ti_2H_5]^+$), 1256.1 ($[\mathbf{4}_3Ti_2H_6SO_4Li]^+$), and 1452.5 ($[\mathbf{4}_3Ti_2H_6SO_4(H_2SO_4)_2Li]^+$).

Further addition of sulfuric acid generates a new species which – at 12.5 equiv. – becomes the major one (**C**). Here, the complex is decomposed and the free protonated ligand $[\mathbf{4}\text{-}H_6]^{2+}$ is liberated. The same spectrum is obtained by protonation of **4**-$H_4$ in $[D_6]$dmso in the absence of any metal ions. Further addition of acid leads to the hydrolysis of the imine groups by residual water in the solvent, and 2,3-dihydroxybenzaldehyde (**D**) and protonated *trans*-1,4-diaminocyclohexane (**E**) are formed.

The protonation of corresponding mononuclear complexes[20] is rather difficult, due to the lability of the complexes in the presence of protons. For $K_2[(\mathbf{5})_3Ti]$ and $K_3[(\mathbf{5})_3Ga]$, no reliable results were obtained. However, we were able to observe NMR resonances for $K_3[(\mathbf{5})_3Ga]$ with the characteristic pattern of an imine species. Unfortunately, we could not obtain pure compounds due to decomposition of the complex simultaneous to protonation.

## Computational Considerations

In order to obtain a deeper insight into the bonding behaviour of the iminocatecholates, we performed a computational study. The most simple model for the ligand we considered is the iminocatechol **6**. We calculated **6** and its enaminone tautomer **7** using the hybrid B3LYP density functional method (DFT) with the TZVP basis set[21] and the second-order Moller-Plesset perturbation theory (MP2) employing the 6-311G(d,p) basis set.[22] The imine is found to be more stable than the enaminone by 25 kJ/mol at the MP2 level of theory. The same result is obtained for the mono-deprotonated species. The X-ray data are more consistent with the enaminone structure **7** rather than with the iminocatechol **6**. The bond lengths are listed in Table 2. We analysed computationally the stability of both tautomeric forms in various metal complexes and found in those with gallium(III) ions no stable imine structure at all but only the enaminone. This can be understood in terms of a weakening of the O–H bond when the complex with the metal ion is formed. The most simple complex we considered was **8** for which the calculated bond lengths show very good agreement with the X-ray data of $[H_3(\mathbf{3})Ga]$. The largest complex we calculated on the B3LYP/TZVP level was the tren derivate $[H_3(\mathbf{2})Ga]$. The Ga atom was treated with a scalar relativistic effective core potential (ECP). For the small complexes such as **8** we employed the MDF10 ECP[23] with the corresponding cc-pVTZ-PP basis set.[24] In all complexes with three catecholato units the simpler ECP SDF28 was used with the corresponding basis set.[25] The

bond lengths of $[H_3(\mathbf{2})Ga]$ do not deviate significantly from the simpler model complex **8** demonstrating that interactions of the three catecholato units do not change the bonding in this case. Very similar results were also obtained for gallium tris(catecholate)s with three simple imine-type ligands.

A closer inspection of Table 2 reveals a deviation of the computed and measured distances for the imine group. The X-ray $C_{aromatic}$–$C_{imine}$ and $C_{imine}$–N distances are about halfway between the imine structure **6** and the enamine structure **7**. The existence of the enamine tautomer rather than the imine form has been established computationally. As a tautomeric form of the enamine the protonated imine has to be considered. With the computational methods used here we can only predict that the enamine form dominates the protonated imine by analysing the order of the molecular orbitals, but more elaborate methods would be required to assess the contribution of the second mesomer.

The results of the computational chemistry strongly support the interpretations of our experimental findings. In the (iminocatecholato)gallium complexes an enamine/quinomethine-type structure is the dominating mesomeric form.

## Conclusions

Our earlier results on the formation of the molecular tetrahedron $[(\mathbf{2})_4Ti_4]^{8-}$ from the flexible ligand **2** made us believe, that we have an easy entry for the preparation of related derivatives, to which we can attach substituents, e.g. in order to introduce chiral information. However, the conformation of ligand **2** is controlled by electronic influences: the repulsion between the free imine nitrogen and catecholato oxygen electron pairs or by the ability of this unit to chelate a metal cation. On the other hand, for ligand **3** additional steric effects become dominant (Figure 10).

For the formation of a tetrahedron vs. a mononuclear complex, two different conformations of the ligand have to be considered. The tetrahedron is formed, if the ligand can spread out to form a triangle with the catechol units located at the corners. This is possible with ligand **2**-$H_6$. In case of **3**-$H_6$ this conformation is "sterically encumbered" due to the bulky isopropyl groups (see Figure 10). The most relaxed conformation is the "cap-type" structure, in which the three catechol moieties are predisposed for tripodal binding of one metal ion. In a 1:1 complex between **3** and a metal ion [e.g. gallium(III)] repulsion between the free electron pairs occurs. This can be overcome either by addition of sodium cations as templates or by proton extraction from solvent (alcohol or water). In the latter case, a high positive charge is now accumulated in the "cap" of the compound which is compensated by adopting an enaminone/chinomethine mesomeric structure.

In dinuclear helicate-type (and mononuclear noncapped) complexes, it is possible to obtain similar protonated structures by addition of mineral acids. However, addition of an excess of acid leads to the decomposition of the complex and finally to the hydrolysis of the imine ligands.

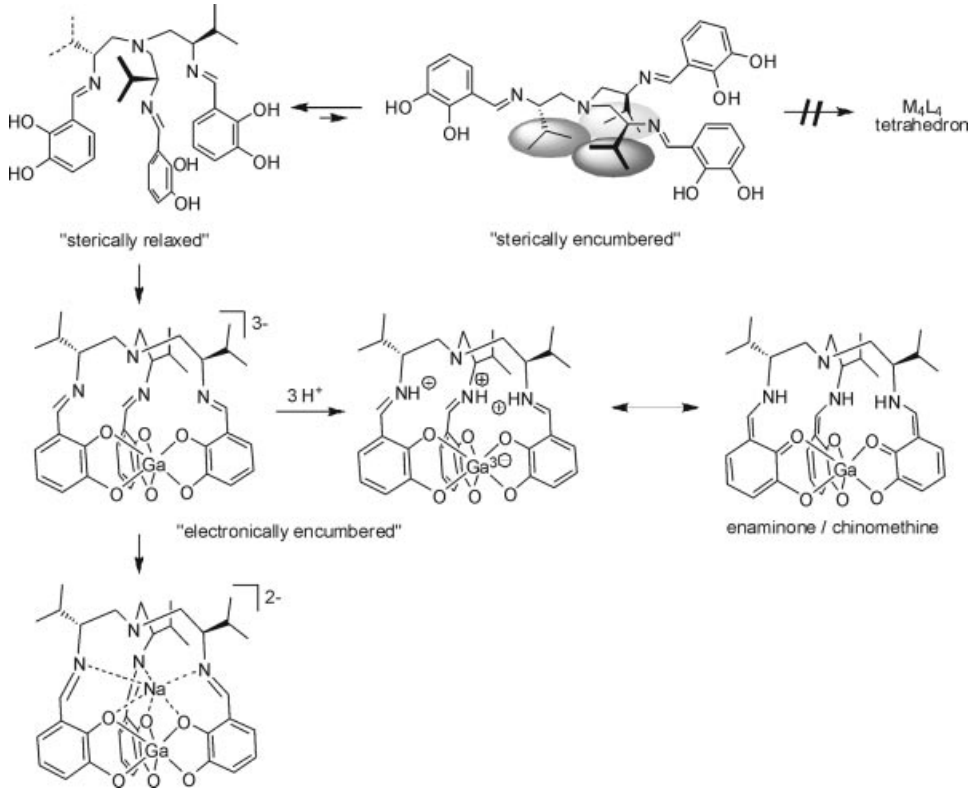

Figure 10. Stabilizing and destabilizing influences that control the sodium- or proton-templated formation of mononuclear gallium(III) complexes.

The experimental findings of this study were supported by high-level ab initio and density functional calculations on the simple mesomeric catechol structures **6** and **7**, and the complexes **8** and [$H_3$(**2**)Ga].

This study shows that subtle influences can control the outcome of a metallosupramolecular coordination study. Steric constraints at ligands, geometry of metal coordination, influence of templates, solvent effects, pH, electronic effects, steric effects are only few aspects, which have to be considered in order to rationally control the self-assembly of sophisticated supramolecular aggregates. The present study is only a small step in order to achieve this goal, but it demonstrates the power of several of the mentioned aspects to interfere in the assembly process.

## Experimental Section

**General:** NMR spectra were recorded with a Varian Mercury 300 or Inova 400 spectrometer. FT-IR spectra were recorded with a Bruker IFS spectrometer. Mass spectra were taken with a Thermo Deca XP mass spectrometer. Elemental analyses were obtained with a Heraeus CHN-O-Rapid analyser. ESI MS spectra were measured in thf using a Bruker APEX IV fourier-transform ion cyclotron resonance (FT-ICR) mass spectrometer with an Apollo electrospray ion source described in detail earlier.[26] The chiral tren derivative was prepared as described by Moberg et al.[6]

**3-$H_6$:** The (2*S*)-$N^1$,$N^1$-bis[(*S*)-2-amino-3-methylbutyl]-3-methylbutane-1,2-diamine (0.118 g, 0.43 mmol) and 2,3-dihydroxybenzaldehyde (0.185 g, 1.34 mmol, 3.1 equiv.) were dissolved in distilled methanol (10 mL), and the mixture was stirred overnight. The tris(catechol) **3**-$H_6$ precipitated as yellow solid. It was collected by filtration and was washed with cold methanol. Yield: 0.126 g (0.20 mmol, 46.4%). M.p. 259 °C. $^1$H NMR (400 MHz, [$D_6$]dmso): $\delta$ = 14.06 (s, 3 H, OH), 8.92 (s, 3 H, OH), 7.47 (s, 3 H, $CH_{aldehyde}$), 6.84 (dd, *J* = 1.4, 7.8 Hz, 3 H, $CH_{arom}$), 6.36 (t, *J* = 7.8 Hz, 3 H, $CH_{arom}$), 5.33 (dd, *J* = 1.4, 7.8 Hz, 3 H, $CH_{arom}$), 2.84 (m, 3 H, $CH_{alkyl}$), 2.70 (dd, *J* = 13.5, 8.5 Hz, 3 H, $CH_{alkyl}$), 2.57 (d, *J* = 13.5 Hz, 3 H, $CH_{alkyl}$), 1.79 (m, 3 H, $CH_{alkyl}$), 0.85 (d, *J* = 6.9 Hz, 9 H, $CH_{alkyl}$), 0.80 (d, *J* = 6.6 Hz, 9 H, $CH_{alkyl}$). IR (KBr): $\tilde{\nu}$ = 3392, 3290, 2961, 2877, 1636, 1544, 1522, 1465, 1395, 1230, 1055, 1016, 856, 780, 736, 490, 465 cm$^{-1}$. MS (EI, 70 eV): *m*/*z* = 632.3 [$M^+$], 440.2 [$C_{25}H_{35}N_3O_4^+$], 303.1 [$C_{17}H_{25}N_3O_2^+$], 318.1 [$C_{18}H_{28}N_3O_2^+$], 192.1 [$C_{11}H_{11}NO_2^+$], 123.0 [$C_7H_7O_2^+$]. $C_{36}H_{48}N_4O_6$ (632.79) calcd. # Iron(III) Tris(pyridinehydroxamate)s and Related Nickel(II) and Zinc(II) Complexes: Potential Platforms for the Design of Novel Heterodimetallic Supramolecular Assemblies

**Clodagh Mulcahy,[a][‡] Krystyna A. Krot,[a] Darren M. Griffith,[a] Kyrill Yu. Suponitsky,[b] Zoya A. Starikova,[b] and Celine J. Marmion*[a]**

**Keywords:** Iron / Hydroxamic acids / Speciation / Supramolecular chemistry / Crystal packing

The reaction of 3- and 4-pyhaH (pyhaH = pyridinehydroxamic acid) with hydrated metal salts ($Fe^{III}$, $Ni^{II}$, $Zn^{II}$) in aqueous solution affords tris(pyridinehydroxamate)s in the case of $Fe^{III}$ and bis(pyridinehydroxamate)s in the case of $Zn^{II}$ and $Ni^{II}$ in both the solid state and in solution. These metal pyridinehydroxamates that have the hydroxamato moiety coordinated in an O,O′-bidentate fashion all contain free pyridine nitrogen donor atoms that might allow them to be used as building blocks in the construction of pyridinehydroxamato-bridged supramolecular assemblies. The crystal and molecular structures of the two novel $Fe^{III}$ tris(pyridinehydroxamate) building blocks $[Fe^{III}(3\text{-pyha})_3]\cdot 5.125H_2O$ (**1a**) and $[Fe^{III}(4\text{-pyha})_3]\cdot 5.5H_2O$ (**2a**) are found to have different packing systems despite the similar nature of the two complexes. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Hydroxamic acids, which were first discovered by Lossen in the late 19th century,[1] are now firmly established as an important family of biomedical ligands with complex and well-defined chemistry and a wide variety of pharmaceutical properties.[2] While hydroxamic acid containing compounds are most notably associated with Fe transport phenomena, they are ubiquitous in biology, playing vital roles in maintaining the proper function of enzymes in electron and oxygen transport and other life-sustaining processes.[2] The versatile biological activity of hydroxamic acids is due to their strong metal-chelating ability and possibly their nitric oxide releasing properties.[3]

The powerful metal-chelating ability of hydroxamic acids has been utilised to spectacular effect in the construction of a diverse host of fascinating metal complexes. These include hydroxamates,[4] hydroximates[4] and examples in supramolecular chemistry such as metallacrowns,[5] coordination polymers[6] and tetrahedral cluster complexes.[7]

As ligands, hydroxamic acids typically coordinate in an O,O′-bidentate chelating fashion, coordinating through the carbonyl oxygen atom and the deprotonated hydroxy group to form very stable five-membered chelates. Other binding modes are possible, however, such as monodentate binding through the deprotonated nitrogen or oxygen atoms, although these modes require specially designed coordination environments to provide stabilisation.[2,8] Bidentate binding of two metal ions has also been observed in an O,μ-O′-chelating mode.[9] The complexation behaviour of hydroxamic acids can also be dramatically altered by the incorporation of ancillary coordinating groups at adjacent sites in the molecule.[10] Additional deprotonation of the hydroxamato moiety can occur by metal-induced processes, leading to the formation of hydroximato complexes featuring both mono- and bidentate coordination where both the N- and O-atoms of the hydroxamic acid are deprotonated.[11,12]

We recently reported that 2-pyridinehydroxamic acid (2-pyhaH) can coordinate to $Pt^{II}$ to form a novel dinuclear $Pt^{II}$ hydroximate complex, $[\{cis\text{-}Pt(NH_3)_2\}_2(\mu\text{-}2\text{-}pyhaH_{-1})](ClO_4)_2\cdot H_2O$, with the di(ammine)$Pt^{II}$ moieties bridged by the doubly deprotonated pyridinehydroximato ligand, with N,N′-chelation to one *cis*-$Pt(NH_3)_2$ moiety and O,O′-chelation to the other (Figure 1).[4]

We also recently utilised 3- and 4-pyridinehydroxamic acids 3- and 4-pyhaH as bridging scaffolds in the design of $Pt^{II}/M^{II}$ coordination polymers (M = Cu, Ni or Zn) because they can coordinate $Pt^{II}$ in a monodentate fashion through the pyridine nitrogen atom only, thus leaving the hydroxamic acid moiety free to coordinate to a separate metal ion (Figure 2).[6]

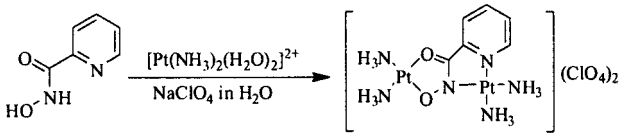

Figure 1. Coordination of 2-pyhaH to $Pt^{II}$ to form the novel dinuclear $Pt^{II}$ hydroximate [{*cis*-$Pt(NH_3)_2$}$_2$(μ-2-pyha$H_{-1}$)]$(ClO_4)_2$·$H_2O$.

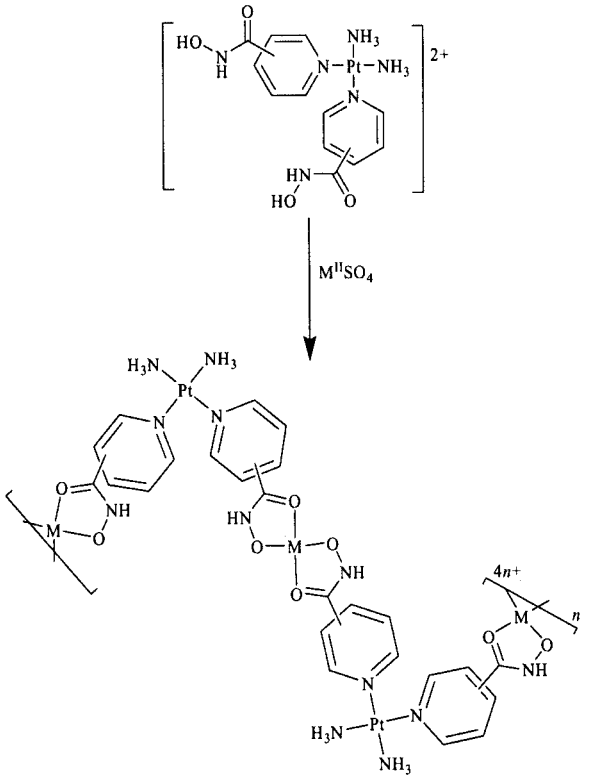

Figure 2. $Pt^{II}/M^{II}$ coordination polymers (M = Cu, Ni or Zn) constructed with 3- and 4-pyhaH as bridging scaffolds.

The present study extends this work to a new family of 3- and 4-pyridinehydroxamato complexes of $Fe^{III}$, $Ni^{II}$ and $Zn^{II}$. We report the synthesis and crystal structures of $[Fe^{III}(3\text{-pyha})_3]\cdot 5.125H_2O$ and $[Fe^{III}(4\text{-pyha})_3]\cdot 5.5H_2O$ and the synthesis and characterisation of related $Ni^{II}$ and $Zn^{II}$ complexes. We hypothesise that such metal pyridinehydroxamates, where the hydroxamato moiety is coordinated to the metal ion in an O,O′-monoanionic way, may act as platforms for the design of novel heterodimetallic supramolecular assemblies because they contain free pyridine nitrogen donor atoms that can coordinate another metal ion. The crystal and molecular structures of the two $Fe^{III}$ tris(pyridinehydroxamate) building blocks are found to have different packing systems despite the similar nature of the two complexes.

## Results and Discussion

### Syntheses of Mono- and Heteronuclear Metal Pyridinehydroxamates

Pyridinehydroxamic acids were synthesised from the corresponding methyl or ethyl esters in high yield and purity. The metal pyridinehydroxamates were generally synthesised by dissolving the hydroxamic acid in water and adding an aqueous solution of the metal salt. This method yielded tris(pyridinehydroxamate)s in the case of $Fe^{III}$ (Figure 3) and bis(pyridinehydroxamate)s in the case of $Ni^{II}$ and $Zn^{II}$ (Figure 4). Upon adjusting the pH to around 5.5, colour changes (to deep red, green and white for the $Fe^{III}$, $Ni^{II}$ and $Zn^{II}$ complexes, respectively) were observed accompanied by precipitation of the metal pyridinehydroxamates. All complexes were formed in reasonably good yields and high purity and were characterised by elemental analysis, IR spectroscopy and, where possible, UV/Vis spectroscopy. Only the $Fe^{III}$ tris(pyridinehydroxamate)s formed crystals of good enough quality for X-ray analysis.

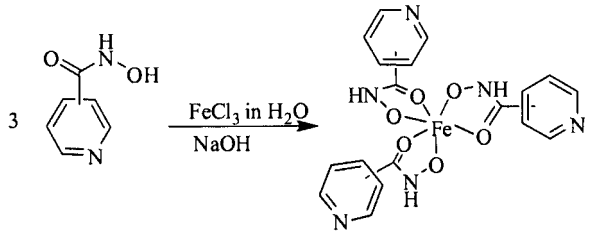

Figure 3. Synthesis of $Fe^{III}$ tris(pyridinehydroxamate)s.

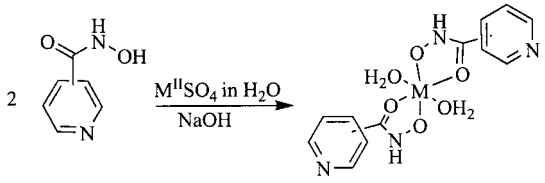

Figure 4. Synthesis of $M^{II}$ bis(pyridinehydroxamate)s (M = Ni or Zn).

IR spectroscopy proved a particularly useful technique for characterisation of the metal pyridinehydroxamates and assigning the coordination modes of the pyridinehydroxamato ligands. The IR spectra of $[Fe^{III}(3\text{-pyha})_3]\cdot 6.5H_2O$ and $[Fe^{III}(4\text{-pyha})_3]\cdot 1.5H_2O$ show a sharp and intense carbonyl stretch at 1600 and 1595 $cm^{-1}$, respectively, which are at lower wavenumbers than in the uncoordinated 3-pyhaH and 4-pyhaH ligands (1660 vs and 1643 s $cm^{-1}$ for 3-pyhaH and 1642 vs and 1608 s $cm^{-1}$ for 4-pyhaH). This indisputably confirms the involvement of the carbonyl oxygen atom in coordination of the $Fe^{III}$ metal ion and is consistent with the X-ray crystallographic results. Similarly, the IR spectra of $[Zn^{II}(3\text{-pyha})_2(H_2O)_2]$ and $[Zn^{II}(4\text{-pyha})_2(H_2O)_2]\cdot H_2O$ each display a carbonyl stretch at 1618 vs and 1613 vs $cm^{-1}$, respectively, each of which has a shoulder at 1599 and 1592 vs $cm^{-1}$, respectively. Analogous shifts in the IR stretching frequencies were observed for the $Ni^{II}$ bis(pyridinehydroxamate)s, indicative of O,O′-hydroxamato coordination. In addition, each metal complex exhibits the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

characteristic C–N and N–H stretching bands of the hydroxamato moiety in the region 1555–1520 $cm^{-1}$ and 3300–3185 $cm^{-1}$, respectively.

### Crystal Structure of 1a

Crystals of $[Fe^{III}(3\text{-pyha})_3]\cdot 5.125H_2O$ formed from the mother liquor of the reaction between 3-pyhaH and $FeCl_3\cdot 6H_2O$. They were found to be of the monoclinic space group $P2_1/c$ with eight formula units per unit cell. The structure consists of two independent molecules (**A** and **B**) of $Fe^{III}(3\text{-pyha})_3$ (an ORTEP view of **A** and **B** at the 50% probability level is depicted in Figure 5). As expected due to the well-documented high affinity of $Fe^{III}$ for hydroxamic acids,[13] the $Fe^{III}$ core is in a distorted octahedral $O_6$ environment with three 3-pyha chelating ligands coordinating through both oxygen atoms of the hydroxamato moiety to form stable five-membered chelate rings with the pyridine-hydroxamato rings almost planar (Figure 5). The deviations of the $Fe^{III}$ ions from the O–N–C–O planes are rather small (0.01–0.34 Å). The orientations of the pyridine rings with respect to the planes of the corresponding chelating ligands differ significantly for **A** and **B**, as shown by their respective N–C–C–C torsion angles (Table 1).

The range of torsion angles observed can be attributed to the influence of the hydrogen bonds formed between the pyridine nitrogen atoms and water molecules and also the stacking interactions between the pyridine rings. It should be noted that not all of the pyridine nitrogen atoms are involved in hydrogen bonding, whereas all of the pyridine rings are involved in stacking interactions. The degree of rotation of the pyridine ring relative to the hydroxamato functionality does not depend directly on the participation of the corresponding nitrogen atom in hydrogen bonding. For instance, in molecule **A** only two pyridine rings [containing the N(4A), N(6A) atoms], which are nearly coplanar to the connected hydroxamato rings (Table 1), are hydrogen-bonded to water molecules. The opposite situation is observed for molecule **B**, however, in which coplanar pyridine rings are not involved in hydrogen bonding while the other pyridine atom [N(5B)] forms a hydrogen bond with a water molecule. Thus, the conformation of the molecules in **1a** is defined by the effects of the crystal field, which is influenced by the hydrogen-bonding system as well as stacking interactions as a whole.

The $Fe^{III}(3\text{-pyha})_3$ molecules form columns parallel to the screw axis by means of N–H···O hydrogen bonds and stacking interactions. The N(2B)–H(2NB)···O(1A) bond is formed between two independent molecules **A** and **B**, while the N(1B)–H(1NB)···O(3B) hydrogen bond connects molecules of type **B** only (see Figure S1 in the Supporting Information). All other hydrogen bonds involve water molecules. Stacking interactions exist between molecules **A** and **B**, **A** and **B"**, and **B** and **B"**. The formation of columns leaves a space between molecules which is filled with molecules from the neighbouring columns to form an interpenetrated columnar structure with stacking interactions between columns and with channels parallel to the screw axis that are filled with water molecules (see Figure S2 in the Supporting Information).

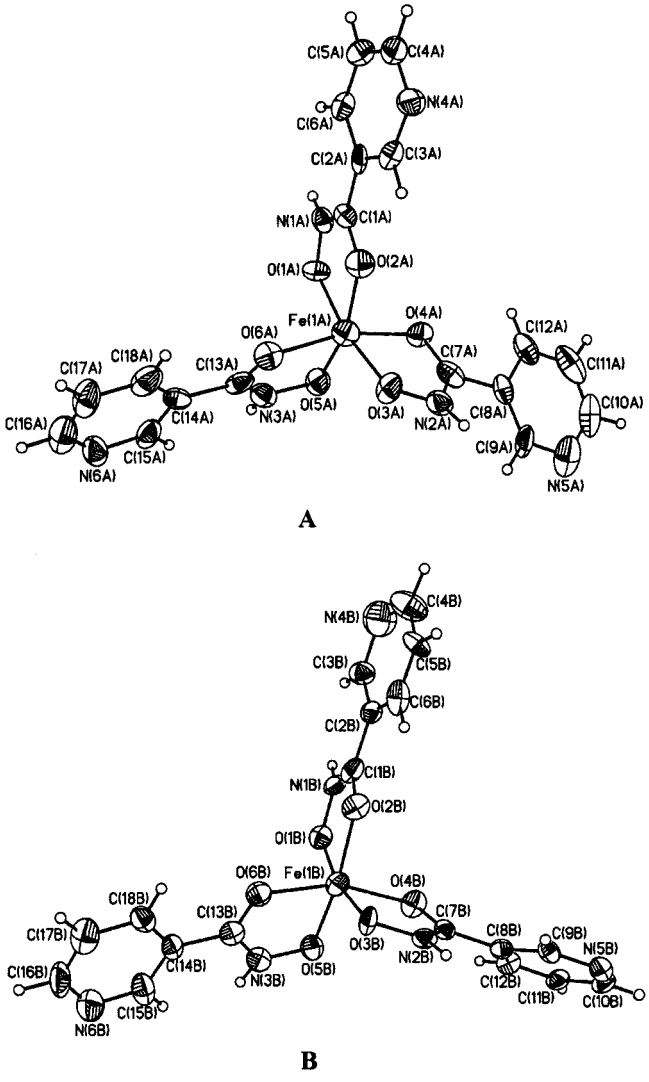

Figure 5. ORTEP drawings (50% probability) of the two independent molecules (**A** and **B**) of **1a** showing the atomic numbering scheme (water molecules of crystallisation have been omitted for clarity).

Table 1. Relative orientation of the pyridine rings and the corresponding hydroxamato rings for **1a** (**A** and **B**).

| Torsion angle [°] | A | B |
|---|---|---|
| N(1)–C(1)–C(2)–C(3) | –174.1(5) | 11.0(8) |
| N(2)–C(7)–C(8)–C(9) | 31.5(8) | –32.7(8) |
| N(3)–C(13)–C(14)–C(15) | 10.1(8) | –1.6(8) |

### Crystal Structure of 2a

$[Fe^{III}(4\text{-pyha})_3]\cdot 5.5H_2O$ crystallises in the tetragonal space group $I4_1a$ with 5.5 water molecules of crystallisation per Fe centre and sixteen formula units in the unit cell. The molecular core consists of an $Fe^{III}$ centre with three almost

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

planar 4-pyha ligands coordinating through both oxygen atoms of the pyridinehydroxamato group to form stable five-membered chelates (Figure 6). The orientations of the pyridine rings with respect to the planes of the corresponding chelating moieties are characterised by their respective N–C–C–C torsion angles (Table 2).

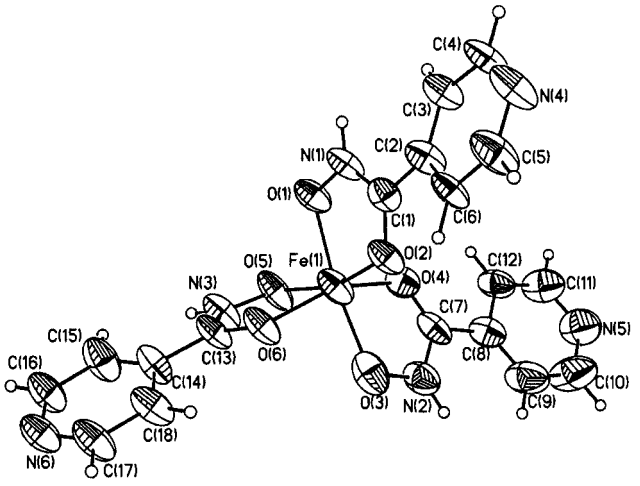

Figure 6. ORTEP view (50% probability) of **2a** showing the atomic numbering scheme (water molecules have been omitted for clarity).

Table 2. Relative orientation of the pyridine rings and corresponding hydroxamato rings in **2a**.

| Atoms | Torsion angle [°] |
|---|---|
| N(1)–C(1)–C(2)–C(3) | –24.7(14) |
| N(2)–C(7)–C(8)–C(9) | –7.5(15) |
| N(3)–C(13)–C(14)–C(15) | –17.6(15) |

The deviations of the $Fe^{III}$ metal ions from the O–N–C–O planes are rather small (0.01–0.34 Å). The crystal packing motif of **2a** is based on two N(1)–H(1N)···O(1) and N(3)–H(3N)···N(6) hydrogen bonds between tris(4-pyha)Fe molecules, which results in a layered structure. Layers parallel to the *ab* crystallographic plane can be described as being built from hydrogen-bonded tetrameric fragments (Figure 7); π-stacking interactions between pyridine rings are also present in the layers (see Figure S3 in the Supporting Information). There are two types of tetrameric fragments in the layer, both of which are formed by molecules related by a fourfold screw axis. The first is formed by N(1)–H(1N)···O(1) interactions and has a butterfly structure, while the other is assembled by means of N(3)–H(3N)···N(6) bonds and is tetrahedral.

The tetrameric fragments are characterised by a chessboard order such that tetramers of the first type are connected to each other by tetramers of the second type, with each molecule participating in both types of tetramers and having four hydrogen-bonded neighbours (Figure 7).

The space between the hydrogen-bonded layers of **2a** is filled with the molecules of neighbouring layers, which results in an interpenetrated layered structure containing channels filled with water molecules. Two types of channels are found in the crystal structure of **2a**: the first is parallel to the *b* axis and the second parallel to the *a* axis (see Figure S3 in the Supporting Information). The crystal structure of **2a** therefore represents a four-layered packing pattern.

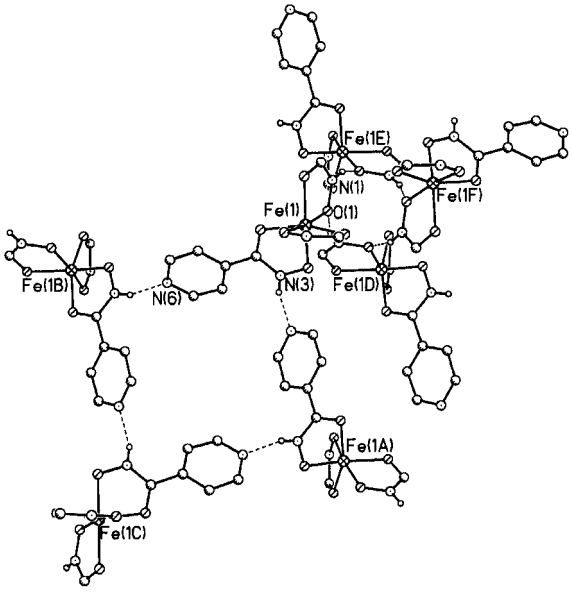

Figure 7. Two tetramers of **2a** formed by N(1)–H(1N)···O(1) and N(3)–H(3N)···N(6) hydrogen bonds (pyridine fragments not involved in hydrogen bonding have been omitted for clarity). Symmetry relations: Fe(1) [*x*, *y*, *z*], Fe(1A) [1.25 – *y*, 0.25 + *x*, 0.25 – *z*], Fe(1B) [–0.25 + *y*, 1.25 – *x*, 0.25 – *z*], Fe(1C) [1 – *x*, 1.5 – *y*, *z*], Fe(1D) [0.75 + *y*, 1.25 – *x*, 0.25 – *z*], Fe(1E) [1.25 – *y*, –0.75 + *x*, 0.25 – *z*], Fe(1F)[2 – *x*, 0.5 – *y*, *z*].

## Formation Constants and Species Distribution Curves

The protonation constants of the pyridinehydroxamic acid ligands 3-pyha ($L^1$) and 4-pyha ($L^2$) and the overall stability constants for the binary ML systems (M = $Fe^{III}$, $Ni^{II}$ or $Zn^{II}$; L = $L^1$ or $L^2$) were calculated from potentiometric data. Two protonation processes were observed for each ligand upon titration with KOH (Figure 8); one proton is released from the pyridine N-atom and a second from the hydroxamate OH group (Table 3). The $pK_{a2}$ value for 3-pyhaH, which corresponds to deprotonation of the hydroxamate OH group, is marginally higher than that for 4-pyhaH.

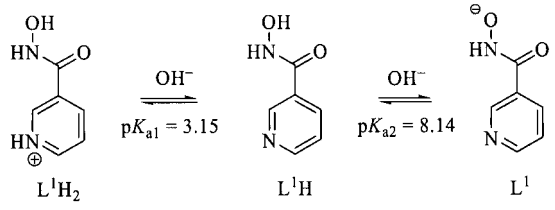

Figure 8. Protonation processes for 3-pyha$H_2$ upon titration with KOH.

| $ML^2H_{-2}$ | 11–2 | | | –13.35(0.01) |

For each system studied, the titration curves show significant shifts that are indicative of complex formation. The titration curves for the $FeL^2$ system are shown in Figure 9 as a representative example of the tris(hydroxamato) systems. $Fe^{III}$ forms ML, $ML_2$ and $ML_3$ species with both $L^1$ and $L^2$ (Figure 10) upon increasing pH, as expected, with stability constants slightly lower than those previously reported for the $Fe^{III}$ benzohydroxamate system.[14] We attribute this to the more electron-rich nature of the pyridine ring with respect to benzene.

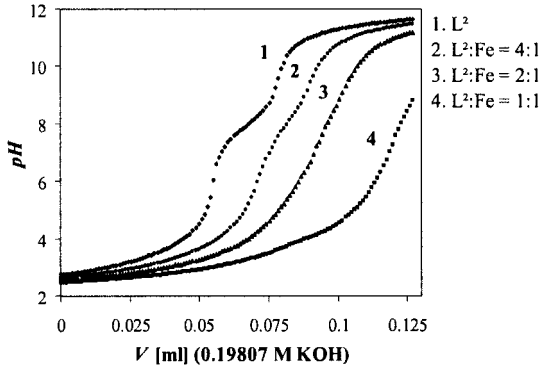

Figure 9. Titration curves for the $Fe^{III}L^2$ binary system.

The speciation studies support the presence of ML and $ML_2$ complexes for the $Ni^{II}$ and $Zn^{II}$ binary systems. The $ML_2$ complexes were also obtained in the solid state (**3**–**6**). The titration curves (Figure 11) and species distribution curves (Figure 12) for the $NiL^2$ system are shown as representative examples of the bis(hydroxamato) systems. The $M(L^1)_2$ complexes ($\log\beta \approx 8.4$) were found to be slightly more stable in solution than their $M(L^2)_2$ analogues ($\log\beta \approx 7.7$).

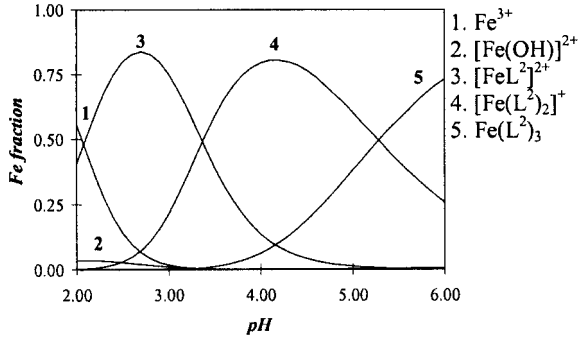

Figure 10. Distribution curves for the $Fe^{III}L^2$ system at pH = 2–6; $[Fe^{III}]$ = 1 mM; $[L^2]$ = 3 mM.

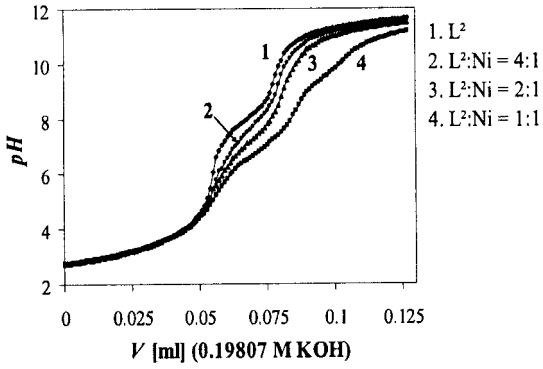

Figure 11. Titration curves for the $Ni^{II}L^2$ binary system.

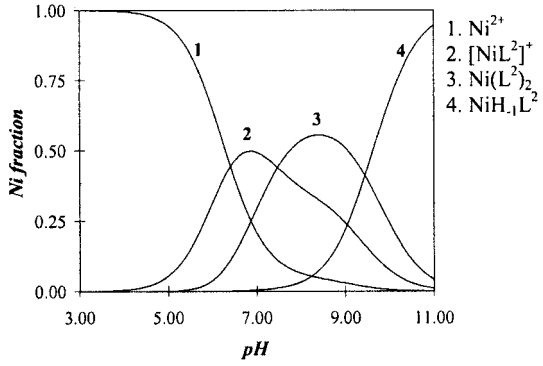

Figure 12. Distribution curves for the $Ni^{II}L^2$ system at pH = 2–6; $[Ni^{II}]$ = 1 mM; $[L^2]$ = 3 mM.

## Spectrophotometric Study

Hydroxamic acids are known to form stable complexes with $Fe^{III}$.[14] The $Fe^{III}$–hydroxamate interaction is characterised in the UV/Vis spectrum by a $\pi(\text{ligand}) \rightarrow d\pi(\text{Fe})$ ligand-to-metal charge-transfer (LMCT) band. We monitored the reaction between $Fe^{III}$ and L [L = 3-pyha ($L^1$) and 4-pyha ($L^2$)] over the pH range of 2.11–5.97 (in line with the speciation studies reported) with an $Fe^{III}$/L ratio of 1:3 by spectrophotometry. Upon increasing the pH, we observed a hypsochromic shift of the LMCT band and an increase in absorption intensity corresponding to the formation of the mono-, bis- and tris(hydroxamato) complexes of $Fe^{III}$ and also consistent with previously reported $Fe^{III}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

hydroxamate systems.[14] Precipitation was observed at pH > 5.97. The 1:1 complexes give spectra with $\lambda_{max} \approx 510$ nm, the 1:2 complexes spectra with $\lambda_{max} \approx 480$ nm and the 1:3 complexes spectra with $\lambda_{max} \approx 425$ nm. The UV/Vis spectra of the $Fe^{III}L^2$ system are shown in Figure 13 as a representative example. The spectrophotometric results complement our potentiometry data and further confirm the formation of FeL, $FeL_2$ and $FeL_3$ complexes.

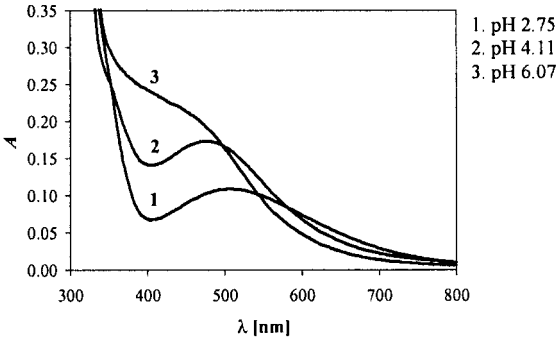

Figure 13. UV/Vis spectra of aqueous solutions of $Fe^{III}$ (0.1 mM) and $L^2$ (0.3 mM) in $KNO_3$ (0.1 mM) at pH = 2.75, 4.11 and 6.07.

## Conclusions

The affinity of hard $Ni^{II}$, $Zn^{II}$ and $Fe^{III}$ centres for hard oxygen donors facilitates the formation of a series of novel metal pyridinehydroxamates where the coordination mode is exclusively hydroxamato-O,O′ with the ligand chelating to the metal centre as a monoanionic species. The crystal and molecular structures of two $Fe^{III}$ tris(pyridinehydroxamate) building blocks have been determined and found to have different packing systems despite the similar nature of the two complexes. A comparative analysis of the crystal packing systems allows us to suggest that the different packing motifs found in **1a** and **2a** might, at least partly, be explained by the participation of the pyridine N-atom in hydrogen bonding to the pyridinehydroxamate ring in **2a**, while in **1a** hydrogen bonds are formed only between the pyridinehydroxamate rings and pyridine N-atoms are involved in hydrogen bonding with water molecules only.

These novel pyridinehydroxamato complexes of $Fe^{III}$, $Ni^{II}$ and $Zn^{II}$ lend themselves to further investigation as potential platforms for the design of novel heterodimetallic supramolecular assemblies.

## Experimental Section

**Materials and Methods:** All reagents, deuteriated solvents and metal salts were purchased from Sigma Aldrich and used without further purification. IR spectra were recorded as KBr discs with a Mattson Genesis II CSI FTIR spectrometer in the 4000–400 $cm^{-1}$ region. UV/Vis spectra were recorded with a Helios Alpha Thermo Spectronic Spectrophotometer in a quartz cell. C, H, N, Fe, Ni and Zn elemental analyses were performed at the Microanalytical Laboratories, University College Dublin, Ireland. $^1$H NMR spectra were recorded with a Bruker Advance DPX 400 FT spectrometer at the Department of Chemistry, Trinity College Dublin, Ireland. The residual undeuterated DMSO signal was used as an internal reference at $\delta = 2.505$ ppm.

**Preparation of the Ligands:** These were prepared as reported previously.[6]

**3-Pyridinehydroxamic Acid (3-pyhaH, $L^1$):** Hydroxylamine hydrochloride (5.07 g, 72 mmol) was added to sodium hydroxide (5.83 g, 146 mmol) in deionised water (37 mL) and the resulting solution was added dropwise to a solution of methyl nicotinate (5.00 g, 36 mmol) in methanol (55 mL). The solution was stirred at room temperature for 72 h, after which it was acidified to pH = 5.5 with 5% HCl. The solvent was removed in vacuo to yield a yellow solid. Methanol (60 mL) was added and sodium chloride was filtered off. The solvent was removed in vacuo to yield a light pink solid, which was recrystallised from water. Yield: 3.00 g (22 mmol, 66%). $C_6H_6N_2O_2$ (138.12): calcd. C 52.17, H 4.38, N 20.28; found C 51.98, H 4.24, N 20.14. $^1$H NMR [400 MHz, $(CD_3)_2SO$, 25 °C]: $\delta$ = 11.41 (s, 1 H, OH), 9.24 (br. s, 1 H, NH), 8.90 (d, $^4J_{H,H}$ = 2.00 Hz, 1 H, H2), 8.70 (dd, $^3J_{H,H}$ = 5.04, $^4J_{H,H}$ = 1.52 Hz, 1 H, H4), 8.10 (dt, $^3J_{H,H}$ = 8.00, $^4J_{H,H}$ = 2.00 Hz, 1 H, H6) 7.51 (dd, $^3J_{H,H}$ = 8.04, $^4J_{H,H}$ = 5.04 Hz, 1 H, H5) ppm. IR (KBr disc): $\tilde{\nu}_{max}$ = 3196 vs (hydroxamate N–H), 2802 s (hydroxamate O–H), 1660 vs and 1643 vs (hydroxamate C=O), 1594 s, 1557 s (hydroxamate C–N) $cm^{-1}$.

**4-Pyridinehydroxamic Acid (4-pyhaH, $L^2$):** This compound was prepared according to the same method as for 3-pyhaH except ethyl isonicotinate was used instead of methyl nicotinate. Yield: 55%. $C_6H_6N_2O_2$ (138.12): calcd. C 52.17, H 4.38, N 20.28; found C 51.94, H 4.29, N 20.12. $^1$H NMR [400 MHz, $(CD_3)_2SO$, 25 °C]: $\delta$ = 11.41 (s, 1 H, OH), 9.37 (br. s, 1 H, NH), 8.70 (d, $^3J_{H,H}$ = 5.6 Hz, 2 H, H2/6), 7.68 (d, $^3J_{H,H}$ = 6.0 Hz, 2 H, H3/5) ppm. IR (KBr disc): $\tilde{\nu}_{max}$ = 3186 vs. (hydroxamate N–H), 2850b (hydroxamate O–H), 1642 vs. and 1608 s (hydroxamate C=O), 1551 s, 1531 s (hydroxamate C–N) $cm^{-1}$.

**Preparation of Metal Pyridinehydroxamates**

**$[Fe^{III}(3\text{-pyha})_3]\cdot 6.5H_2O$ (1):** 3-pyhaH (150 mg, 1.086 mmol) was dissolved in tepid deionised water (5 mL) and, after allowing it to return to room temperature, an aqueous solution (5 mL) of $FeCl_3\cdot 6H_2O$ (97.8 mg, 0.362 mmol) was added. The pH was adjusted to 5.5 with 5% NaOH, which resulted in the precipitation of a red solid. This was filtered, washed with water (3 mL) and dried over $P_2O_5$. Yield: 141 mg (0.253 mmol, 70%). $C_{18}H_{28}FeN_6O_{12.5}$ (584.29): calcd. C 37.00, H 4.83, N 14.38, Fe 9.56; found C 37.00, H 2.87, N 14.00, Fe 9.22. IR (KBr disc): $\tilde{\nu}_{max}$ = 3186 vs (hydroxamato N–H), 1600 vs (hydroxamato C=O), 1549 s, 1518 s (hydroxamato C–N) $cm^{-1}$. UV/Vis ($H_2O$): $\lambda_{max}$ = 430 nm ($\varepsilon$ = 2200 $M^{-1}cm^{-1}$, LMCT). Single crystals of $[Fe^{III}(3\text{-pyha})_3]\cdot 5.125H_2O$ (**1a**) suitable for an X-ray diffraction study, were obtained from the filtrate after standing at room temperature for 2 d.

**$[Fe^{III}(4\text{-pyha})_3]\cdot 1.5H_2O$ (2):** 4-pyhaH (150 mg, 1.086 mmol) was dissolved in tepid deionised water (5 mL) and, after allowing it to return to room temperature, an aqueous solution (5 mL) of $FeCl_3\cdot 6H_2O$ (97.8 mg, 0.362 mmol) was added. The pH was adjusted to 5.5 with 5% NaOH, which resulting in the precipitation of a red solid. This was filtered, washed with water (3 mL) and dried over $P_2O_5$. Yield: 120 mg (0.243 mmol, 67%). $C_{18}H_{18}FeN_6O_{7.5}$ (494.22): calcd. C 43.74, H 3.67, Fe 11.30, N 17.00; found C 43.98, H 3.38, Fe 11.40, N 16.93. IR (KBr disc): $\tilde{\nu}_{max}$ = 3186 vs (hydroxamato N–H), 1595 vs (hydroxamato C=O), 1555 s (hydroxamato C–N) $cm^{-1}$. UV/Vis ($H_2O$): $\lambda_{max}$ = 430 nm ($\varepsilon$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

= 2800 $M^{-1}cm^{-1}$, LMCT). Single crystals of $Fe^{III}(4\text{-pyha})_3 \cdot 5.5H_2O$ (**2a**) suitable for an X-ray diffraction study were obtained from the filtrate after standing at room temperature for 2 d.

**$[Ni^{II}(3\text{-pyha})_2(H_2O)_2]$ (3):** 3-pyhaH (100 mg, 0.724 mmol) was dissolved in tepid deionised water (5 mL) and an aqueous solution (5 mL) of $NiSO_4 \cdot 6H_2O$ (95 mg, 0.362 mmol) was added. The pH was adjusted to 5.5 with 5% NaOH, which resulted in the precipitation of a green solid. This was filtered, washed with water (3 mL) and dried over $P_2O_5$. Yield: 79 mg (0.213 mmol, 59%). $C_{12}H_{14}N_4NiO_6$ (368.96): calcd. C 39.06, H 3.82, N 15.19, Ni 15.91; found C 38.69, H 3.69, N 14.70, Ni 16.50. IR (KBr disc): $\tilde{\nu}_{max}$ = 3210 vs (hydroxamato N–H), 1611 vs (hydroxamato C=O), 1524 s (hydroxamato C–N) $cm^{-1}$.

**$[Ni^{II}(4\text{-pyha})_2(H_2O)_2]$ (4):** 4-pyhaH (100 mg, 0.724 mmol) was dissolved in tepid deionised water (5 mL) and an aqueous solution (5 mL) of $NiSO_4 \cdot 6H_2O$ (95 mg, 0.362 mmol) was added. The pH was adjusted to 5.5 with 5% NaOH, which resulted in the precipitation of a green solid. This was filtered, washed with water (3 mL) and dried over $P_2O_5$. Yield: 94 mg (0.253 mmol, 70%). $C_{12}H_{14}N_4NiO_6$ (368.96): calcd. C 39.06, H 3.82, N 15.19, Ni 15.91; found C 39.12, H 3.33, N 14.80, Ni 15.83. IR (KBr disc): $\tilde{\nu}_{max}$ = 3185 vs (hydroxamato N–H), 1613 vs, 1586 vs (hydroxamato C=O), 1533 vs (hydroxamato C–N) $cm^{-1}$.

**$[Zn^{II}(3\text{-pyha})_2(H_2O)_2]$ (5):** 3-pyhaH (100 mg, 0.724 mmol) was dissolved in tepid deionised water (10 mL). $ZnSO_4 \cdot 7H_2O$ (104 mg, 0.362 mmol) was added to this solution and the pH was adjusted to 5.5 with 5% NaOH. The resultant white precipitate was filtered, washed with water (3 mL) and dried over $P_2O_5$. Yield: 61 mg (0.163 mmol, 45%). $C_{12}H_{14}N_4O_6Zn$ (375.65): calcd. C 38.37, H 3.76, N 14.91, Zn 17.41; found C 38.16, H 3.58, N 14.70, Zn 16.37. IR (KBr disc): $\tilde{\nu}_{max}$ = 3292 vs (hydroxamato N–H), 1618 vs (hydroxamato C=O), 1547 m (hydroxamato C–N) $cm^{-1}$.

**$[Zn^{II}(4\text{-pyha})_2(H_2O)_2] \cdot H_2O$ (6):** 4-pyhaH (100 mg, 0.724 mmol) was dissolved in tepid deionised water (10 mL). $ZnSO_4 \cdot 7H_2O$ (104 mg, 0.362 mmol) was added to this solution and the pH was adjusted to 6 with 5% NaOH. The resultant white precipitate was filtered, washed with water (3 mL) and dried over $P_2O_5$. Yield: 79 mg (0.199 mmol, 55%). $C_{12}H_{16}N_4O_7Zn$ (393.67): calcd. C 36.61, H 4.10, N 14.23, Zn 16.61; found C 37.06, H 3.04, N 14.28, Zn 16.56. IR (KBr disc): $\tilde{\nu}_{max}$ = 3295 vs (hydroxamato N–H), 1613 vs, 1592 vs (hydroxamato C=O), 1536 s (hydroxamato C–N) $cm^{-1}$.

**Potentiometric Studies:** Potentiometric measurements were carried out using solutions of 0.1 M $KNO_3$ ionic strength at 25 °C. A carbonate-free KOH solution (0.19807 M) standardised with potassium hydrogen phthalate[15] was used as titrant. The pH-metric studies were carried out with a Molspin pH-meter and titration controller with Thermo Russell CMAW711 combined electrode and Hamilton syringe autoburette, in the pH range of 2.5–10.5. The electrode system was calibrated daily by the method of Irving et al.[16] ($pK_w$ = 13.831) and the pH meter readings were converted into hydrogen ion concentrations. The initial volume of the samples was about 2 mL and the ligand concentration was 0.002 M in all systems. Three different metal/ligand ratios (1:1, 1:2 and 1:4) were used. The pH-metric data were used to determine $pK_a$ values and the stoichiometry of the species and to calculate their concentration stability constants. The calculations were performed with the Hyperquad 2000[17] program. Literature data were used for (hydroxido)$Fe^{III}$ complexes: $[FeH_{-1}]^{2+}$: –3.21; $[FeH_{-2}]^{+}$: –6.73; $[Fe_2H_{-2}]^{4+}$: –4.09; $[Fe_3H_{-4}]^{5+}$: –7.58.[18] The standard deviations quoted refer to random errors.

**Spectrophotometric Studies:** UV/Vis spectra for the $Fe^{III}L$ systems ($L^1$ = 3-pyha and $L^2$ = 4-pyha) were obtained with a Helios Alpha Thermo Spectronic Spectrophotometer in the region 300–800 nm. The Fe/L ratios were 1:3 ($[Fe^{III}]$ = 0.1 mM). The pH of the solutions was adjusted with KOH (0.02 M) and $HNO_3$ (0.02 M).

**Crystallographic Measurements for 1a and 2a:** X-ray crystallographic experiments were carried out with a SMART 1000 CCD diffractometer [$\lambda$(Mo-$K_\alpha$) = 0.71073 Å, graphite monochromator, $\omega$-scans] at 120(2) K. The details of the data collection and crystal structure refinements using the SAINT Plus,[19] SADABS and SHELXTL-97[20] program packages are summarised in Table 4. For both structures, hydrogen atoms attached to the nitrogen atoms and to the oxygen atoms of water molecules were located in the difference Fourier maps and were then shifted to the standard X-ray values for N–H and O–H bonds and included in the refinement using the riding approximation. All other hydrogen atoms were placed in geometrically calculated positions and refined with a riding model as well. CCDC-628980 (**1a**) and -628981 (**2a**) contain the supplementary crystallographic data for this paper. These can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.ac.uk/data_request/cif.

# Gas-Phase Structure and Vibrational Properties of Trifluoromethyl Trifluoromethanesulfonate, $CF_3SO_2OCF_3$

**María E. Tuttolomondo,[a] Pablo E. Argañaraz,[a] Eduardo L. Varetti,[b][‡] Stuart A. Hayes,[c] Derek A. Wann,[c] Heather E. Robertson,[c] David W. H. Rankin,[c] and Aida Ben Altabef*[a][‡]**

**Keywords:** Electron diffraction / IR spectroscopy / Raman spectroscopy / Structure elucidation / Ab initio calculations

Trifluoromethyl trifluoromethanesulfonate, $CF_3SO_2OCF_3$, has been synthesised and its gas-phase structure determined from electron-diffraction data. This structural study was supported by HF, MP2 and DFT (B3LYP and B1B95) calculations, which revealed a strong dependence of the theoretical structure on the polarisation of the basis set. Infrared spectra for the gas and solid and a Raman spectrum for the liquid were obtained, and the observed bands were assigned. The experimental vibrational data, along with theoretical (B3LYP) force constants, were used to define a scaled quantum mechanical force field, which enabled reproduction of the measured frequencies with a final root-mean-square deviation of 6 $cm^{-1}$.

## Introduction

The synthesis of trifluoromethyl trifluoromethanesulfonate, $CF_3SO_2OCF_3$, was first reported by Noftle and Cady[1] as a product of the thermal decomposition of $(CF_3SO_2)_2O$. Different synthetic routes were later proposed by Olah and Ohyama,[2] Kobayashi et al.[3] and Hassani et al.,[4] but no structural or vibrational studies have been reported.

Our previous studies on derivatives of trifluoromethanesulfonic acid[5–8] have been extended to $CF_3SO_2OCF_3$ in order to investigate further the characteristic conformations and force constants for such molecules. For that purpose, the substance has been synthesised and its gas-phase structure determined by electron diffraction. Additionally, infrared and Raman spectra were recorded for different physical states. These experimental measurements were complemented by quantum chemical calculations to obtain an optimised molecular structure and frequencies corresponding to the normal modes of vibration. Of particular interest is the comparison of the experimental and theoretical molecular geometric parameters and conformational isomers with the experimental results previously obtained for $CF_3SO_2OCH_3$[5] and $ClSO_2OCF_3$,[9] and with those calculated for several $CF_3SO_2X$[6] and $CF_3SO_2OX$[7,8] molecules, which shows that covalent sulfonates prefer a *gauche* conformation (Figure 1).[5]

## Results and Discussion

### Theoretical Study

A starting geometry for $CF_3SO_2OCF_3$ was obtained by using RHF theory with a 3-21G(d) basis set[10–12] followed by a 6-31G(d) basis set.[13–15] Electron correlation was then accounted for by using the MP2,[16] B3LYP[17] and B1B95[18] methods before increasing the basis set sequentially from 6-31G(d) to 6-311+G(d).[19,20] In addition, the 6-31G(3df) basis set,[21] the Dunning correlation-consistent basis sets, cc-pVDZ and cc-pVTZ[22] and Ahlrichs' TZVP[23] and TZVPP[24] basis sets were used to gauge the

effect of including further polarisation functions. The results of the geometry optimisations are available in Tables S1 and S2 in the Supporting Information. In all cases, a molecular structure with $C_1$ symmetry was predicted, as shown in Figure 1. The force field obtained at the RHF/6-31G(d) level was then used with the program SHRINK[25] to obtain estimates of the amplitudes of vibration ($u_{h1}$) and perpendicular vibrational correction terms ($k_{h1}$) used in the gas electron diffraction (GED) refinement.

Scans of the potential energy with respect to the C–S–O–C torsion were performed at the RHF/6-31G(d) and MP2/6-31G(d) levels and a third scan at the MP2/6-31G(d) level with the 6-31G(3df) basis set on sulfur (Figure 2). These reveal two symmetrically equivalent minima, corresponding to enantiomers, and O–C(5) eclipses one or other of the S=O bonds when viewed down the S–O(4) bond. As enantiomers are indistinguishable by GED, the subsequent refinement was performed with the eclipsing of the S=O(3) bond by O–C as in the calculated structures. The shallow barrier between the two equivalent conformers is ca. 5–10 kJ mol$^{-1}$, easily surmountable at the experimental temperatures. The quantum chemical calculations predict the existence of two stable, asymmetric (point group $C_1$) and structurally equivalent conformers for $CF_3SO_2OCF_3$, both with a *gauche* conformation with a C–S–O–C dihedral angle of about 110°. As shown in Table 1, this angle is relatively sensitive to changes in method and basis set and has a larger value than that calculated for $CF_3SO_2OCH_3$ (93°).[5] Similar molecules that were previously studied by us were also calculated to have *gauche* conformations, with C–S–O–C dihedral angles of 114.8° in $CF_3SO_2OCH_2CF_3$[7] and 91.5° in $CF_3SO_2OCH_2CH_3$[8] [B3LYP/6-31G(d) values in both cases].

The calculated C–O and C–F bond lengths converged reasonably well with increasing basis set size and showed fairly good agreement between different post-Hartree–Fock methods, as shown in Table 1. Bond lengths to sulfur, however, are extremely sensitive to both method and basis set. Particularly interesting was the result of adding additional polarisation functions to the basis set, which resulted in shortening of the bond lengths, the most significant is a reduction of 5.5 pm for the S–O bond [MP2/6-31G(d) to MP2/6-31G(3df)].

With reference to structural studies on $CF_3SO_2OCH_3$[5] and $ClSO_2OCF_3$,[9] the bond lengths to sulfur were overestimated by B3LYP relative to those obtained by GED and X-ray crystal values (the latter for $ClSO_2OCF_3$ only). With this in mind, the MP2/6-31G(3df) geometry appeared to be the best as both a starting point for the GED refinement and the basis for geometrical restraints.

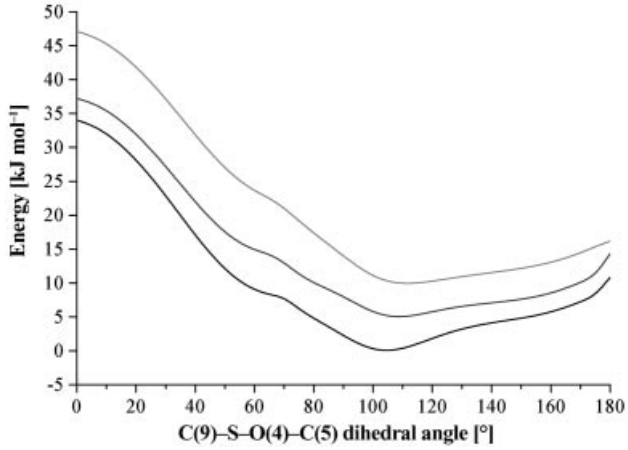

Figure 2. Torsional potential around the S–O(4) bond for $CF_3SO_2OCF_3$, stepped in 5° increments. Calculations were performed at the HF (light grey) and MP2 (dark grey) levels by using a 6-31G(d) basis set and by using MP2/6-31G(d) with 3df polarisation on sulfur (black).

## GED Model

The molecular model for the GED refinement assumed overall $C_1$ symmetry (Figure 1), as predicted by the calculations. The structure of $CF_3SO_2OCF_3$ was defined in terms of 25 independent parameters, comprising 11 bond lengths and differences, 10 bond angles and differences, one tilt angle and three torsional angles, listed in Table 2. The bonded distances S–O(4), O(4)–C(5) and S–C(9) were each defined individually ($p_7$, $p_{10}$ and $p_{11}$, respectively), whilst simple averages were taken of the six C–F bond lengths ($p_1$) and of the two S=O bond lengths ($p_8$). The difference between the average C–F distance in the $CF_3$ group bonded to O(4) (group 1) and the average C–F distance in the $CF_3$ group bonded directly to the sulfur atom (group 2) was defined ($p_2$). For $CF_3$ in group 1, the C–F(6) distance was then found by defining the difference between this distance and the average of the C–F(7) and C–F(8) bond lengths ($p_3$). The difference between the latter two bond lengths was then defined ($p_5$). Similarly, in group 2, the difference between the C–F(11) distance and an average of the other two bond lengths ($p_4$) and the difference between the C–F(12) bond length and the C–F(10) bond length ($p_6$) were defined. The

[a] Restraint values are given by the corresponding MP2/6-31G(3df) values.

The geometry around sulfur was described using three angles and two differences: the O(4)–S–C(9) angle ($p_{12}$), the average of the O(2)–S–O(4) and O(3)–S–O(4) angles ($p_{13}$) and their difference ($p_{14}$), and the average of the O(2)–S–C(9) and O(3)–S–C(9) angles ($p_{15}$) and their difference ($p_{16}$).

Fluorine atom positions in $CF_3$ in group 1 were described by using the average of the three internal F–C–F angles ($p_{19}$) and the difference between the F(7)–C–F(8) angle and the angles F(6)–C–F(7) and F(6)–C–F(8) ($p_{20}$), the latter two angles are assumed to be identical. The orientation of this $CF_3$ group with respect to sulfur was defined by using the angles S–O–C ($p_{17}$) and O–C–F(6) ($p_{18}$), and the torsional angles C–S–O–C ($p_{23}$) and S–O–C–F(6) ($p_{24}$).

$CF_3$ in group 2 was described by using a single F–C–F angle ($p_{22}$) and orientated by using a tilt angle ($p_{21}$). A positive tilt was defined as a reduction in the S–C–F(11) angle, with the zero point occurring when the three S–C–F angles are equal. This group was also allowed to rotate around the S–C bond, defined by the torsional angle O(4)–S–C–F(11) ($p_{25}$). In this case, an angle of 180° corresponds to a staggered conformation and a larger angle brings F(11) closer to O(3).

## Electron Diffraction Refinement

The GED refinement (Table 3) was carried out with the SARACEN method,[26] which allows parameters that are poorly defined by GED data alone to be restrained to calculated values with specified uncertainties, on the basis of the degree of convergence of the calculations. Distances were corrected for curvilinear perpendicular motion ($k_{h1}$) and yielded $r_{h1}$ parameters.[25] All 25 independent parameters were refined, along with two individual and eight groups of amplitudes of vibration, to produce an $R_G$ factor of 0.067 ($R_D$ = 0.029). The refined parameters are displayed in Table 2 along with the corresponding values predicted by MP2/6-31G(3df) calculations. The radial-distribution curve is shown in Figure 3, and the molecular-scattering intensity curve is provided as Supporting Information (Figure S1).

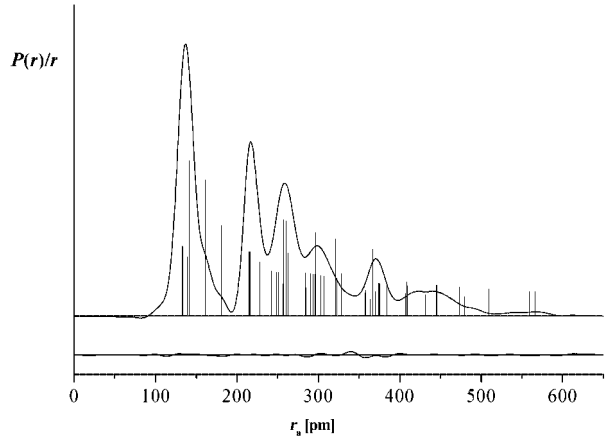

Figure 3. Experimental and difference (experimental – theoretical) radial-distribution curves, $P(r)/r$, for $CF_3SO_2OCF_3$. Before Fourier inversion, the data were multiplied by $s \times \exp[(-0.00002s^2)/(Z_S - f_S)(Z_F - f_F)]$.

Where required, restraints on geometrical parameters were derived from the MP2/6-31G(3df) calculated values. Those applied directly to independent or dependent parameters are given in Table 2, whilst restraints on the differences between independent parameters are provided in Table 3. The only group of amplitudes of vibration allowed to refine

Table 3. Restraints on differences between pairs of independent parameters (distances in pm, angles in degrees).

unrestrained was that containing the bonded distances of less than 150 pm. The remaining amplitudes for bonded atom pairs were restrained with uncertainties of 10% of their calculated values, whilst the groups of non-bonded amplitudes were restrained with uncertainties of 20%. A full list of interatomic distances and corresponding calculated and refined amplitudes of vibration are provided in Table S3 (Supporting Information), and the least-squares correlation matrix in Table S4.

### GED and Calculated Structures

Two large discrepancies can be seen between the GED and calculated structures: the S–C bond length and the torsional angles, particularly C–S–O–C. The S–C distance is 2.5 pm shorter than that predicted by MP2/6-31G(3df) calculations. However, the S–O bond length, which for similar compounds is generally poorly defined by theory, is only 0.7 pm shorter experimentally. The MP2/6-31G(3df) calculation is thus significantly more accurate for predicting these bond lengths than other methods or basis sets requiring similar computational resources. For instance, the MP2/6-311+G(d) calculation overestimates the S–O and S–C distances by 5.6 and 3.0 pm, respectively, and B3LYP/6-31G(3df) underestimates the same bond lengths by 2.0 and 6.1 pm, respectively. The B1B95/6-31G(3df) calculation predicts parameter values that are similar to those predicted by MP2, overestimating the respective S–O and S–C distances by 0.3 and 3.8 pm, respectively, relative to the GED values. MP2 and B1B95 are therefore marginally better than B3LYP at describing the geometry of $CF_3SO_2OCF_3$, and for this type of compound, B1B95 is likely be the best compromise between accuracy and computational cost. Comparison of these results with parameters for similar compounds $CF_3SO_2OCH_3$[5] and $FSO_2OSF_5$,[27] studied by GED and B3LYP/6-31G(d) calculations, shows that in these cases, despite the reasonably close agreement between different theoretical methods, the experimental S–O bonds are 5–7 pm shorter. In the case of $CF_3SO_2OCH_3$,[5] the experimentally determined S–C bond is 3.3 pm shorter. The study on $ClSO_2OCF_3$[9] also shows that B3LYP/6-311G(d) underestimates the S–O bond length by 6 to 7 pm, but the B3LYP/6-311+G(3df) calculation reduces this difference to ca. 3 pm. These GED and theoretical results are therefore consistent with the more general observation that distances between sulfur and oxygen are poorly predicted with standard methods [such as MP2/6-31G(d)], and indicate that this may be due primarily to insufficient polarisation functions in the basis set. This conclusion is also consistent with the molecular structures calculated at the MP2 level by using Dunning's cc-pVDZ and cc-pVTZ, and Ahlrichs' TZVP and TZVPP basis sets (Table S2). As was the case for the Pople 6-31G(d) basis set, the cc-pVDZ and TZVP bases contain only a single d-type Gaussian and underestimate the S–O bond length by 8.9 and 6.6 pm, respectively. In contrast, the cc-pVTZ and TZVPP bases, which both incorporate two d-type and one f-type Gaussian, underestimate the S–O bond length by just 2.4 and 2.3 pm, respectively, relative to the GED determined value of 161.5(4) pm. Similar observations can also be made for the S=O and S–C bond lengths, albeit to a lesser extent.

The C–S–O–C torsional angle was found to be 119.5(18)° by GED relative to between 105 and 112° by various theoretical methods. However, the estimated standard deviation of this value does not give a good estimate of its uncertainty, as the refinement can be performed by fixing this angle at any arbitrary value between 100 and 150° without significantly affecting the remaining parameters or the $R_G$ factor. It would, in principle, be possible to replace the rigid model adopted in the refinement by a dynamic model based on the potential function of the C–S–O–C torsion. However, it can be seen from the theoretical potential energy scan (Figure 2) that this potential energy curve is not a simple function, and several parameters would be required to model it. In such cases, the uncertainties of the extra parameters are extremely large, and so the refined values are of little physical significance. We therefore did not use such a dynamic model in this case.

### Vibrational Study

$CF_3SO_2OCF_3$ has $C_1$ symmetry, and therefore its 30 normal modes of vibration are active in the IR and Raman spectra. Representative spectra appear in Figures 4 (IR spectra of the gas and solid) and 5 (Raman spectrum of the liquid), and the frequencies for the observed spectral features are collated in Table 4.

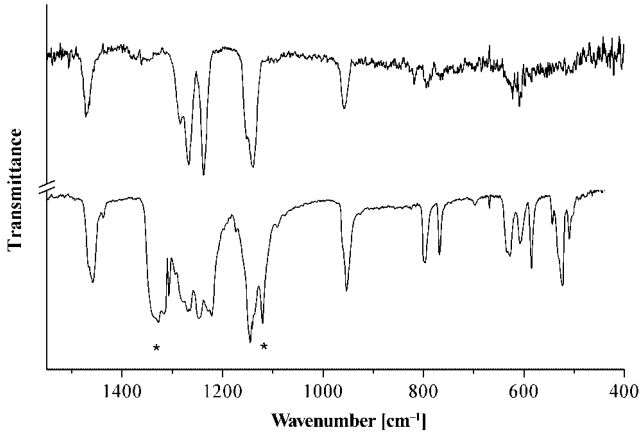

Figure 4. Infrared spectra for $CF_3SO_2OCF_3$ in the gas phase (upper trace; resolution 2 $cm^{-1}$, path length 10 cm, pressure ca. 1.0 Torr) and in the solid phase (lower trace; film on cooled KBr window, resolution 2 $cm^{-1}$). Asterisks indicate solid $SO_2$ bands.

The B3LYP calculations reproduced the normal frequencies of vibration with the following root-mean-square-deviation (RMSD) values for each basis set: 19.8 $cm^{-1}$ for 6-31G(d), 21.6 $cm^{-1}$ for 6-311G(d) and 27.1 $cm^{-1}$ for 6-311+G(d). The first and second basis sets reproduce the experimental frequencies somewhat better, and the results obtained with the 6-31G(d) basis set were used for the vibrational analysis, in order to allow direct comparison with

calculations performed previously for related molecules. The calculated frequencies of vibration appear in Table 5, together with the experimental values.

The proposed assignments of spectral features to the different modes of vibration given in Table 4 are based on the calculated frequencies and on the infrared and Raman intensities and also on comparisons with known data for related molecules.

### *$SO_2$ Group Modes*

The $SO_2$ antisymmetric and symmetric stretching modes appear in the regions 1357–1467 $cm^{-1}$ and 1140–1157 $cm^{-1}$, respectively, in the molecules $CF_3SO_2X$ (X = F, OH, $NH_2$, $CH_3$, $OCH_2CH_3$, $OCH_2CF_3$).[6–8] The intense bands observed at 1469 and 1139 $cm^{-1}$ in the spectrum of the gas can therefore immediately be assigned to these modes. The last mode, however, is a complex mix of several simple vibrations, as discussed below. The medium intensity band at 586 $cm^{-1}$ in the gas infrared spectrum is assigned to the $SO_2$ bend. This frequency is somewhat higher than usual, as this mode appears in the region 488–538 $cm^{-1}$ in the compounds listed above. The bands for the three modes corresponding to the movements of the whole $SO_2$ group appear at relatively low frequencies. The following assignments are proposed, with the corresponding frequency ranges for the molecules mentioned above in parentheses: $SO_2$ wagging, 606 $cm^{-1}$ (611–628 $cm^{-1}$); $SO_2$ rocking, 394 $cm^{-1}$ (382–463 $cm^{-1}$); $SO_2$ twisting, 300 $cm^{-1}$ (310–351 $cm^{-1}$). These assignments are also supported by the calculations.

### *Trifluoromethyl Group Modes*

Inspection of the atomic displacements for the vibrational modes calculated in the 1100–1300 $cm^{-1}$ region shows that the stretching vibrations, especially the symmetric stretches, of the two $CF_3$ groups are strongly coupled. For this reason it is not possible to discuss the assignments of bands for these two groups separately.

The two $CF_3$ symmetric modes are predicted to have large Raman intensities. One mode includes the symmetric stretches of the two $CF_3$ groups, coupled with contributions from the CS and CO stretches and the $SO_2$ symmetric stretch; the latter is out of phase in relation to the other four. The second mode mixes the same five simple vibrations, but with the $SO_2$ symmetric stretch now in phase. These two complex modes are assigned to the strong Raman bands located at 1268 and 1146 $cm^{-1}$. The 1146 $cm^{-1}$ band exhibits a shoulder at ca. 1120 $cm^{-1}$, best defined in the infrared spectrum of the solid, and is assigned to a third mode, which also mixes the two $CF_3$ symmetric stretching vibrations and the CO and CS stretches in an out-of-phase fashion, but with almost no participation of the $SO_2$ symmetric stretch. Four bands should still be assigned to the $CF_3$ antisymmetric stretching vibrations. As not enough arguments are available for precise assignments, those appearing in Table 4 and Table 5 are tentative.

Symmetric deformation modes are observed at 792 $cm^{-1}$ ($CF_3S$ group) and 695 $cm^{-1}$ ($CF_3O$ group) in the gas infrared spectra. The two antisymmetric deformation modes of the $SCF_3$ group appear at 540 and 560 $cm^{-1}$, i.e. about 10 $cm^{-1}$ higher than the calculated values. The antisymmet-

ric deformation modes of the $CF_3O$ group show a larger splitting, appearing at 508 and 627 $cm^{-1}$.

The $CF_3$ rocking modes were assigned by taking into account the theoretically predicted frequencies and with knowledge of modes in related molecules. In this way, the weak bands located at 200 and 280 $cm^{-1}$ are assigned to the rocking modes of the $CF_3S$ group, which appear at around 200 and 340 $cm^{-1}$ in $CF_3SO_2X$ molecules.[6] Higher frequencies, with values of 340 and 440 $cm^{-1}$, were reported for the $CF_3O$ rocking motions in $CF_3OX$ molecules,[28] and consequently the bands observed at 345 and 444 $cm^{-1}$ for $CF_3SO_2OCF_3$ are assigned to these modes.

### *Skeletal Modes*

The O–S stretching mode appears as a strong Raman band located at 766 $cm^{-1}$. The strong 956 $cm^{-1}$ infrared band in the gas spectrum is well predicted by calculations, in terms of both position and intensity, to be due to the C–O stretch, although the mode is best described as the out-of-phase coupling of the C–O and O–S stretches, as can be observed from the calculated atomic displacements when displayed with the program GaussView.[29]

The 320 $cm^{-1}$ mode shows a strong contribution from the C–S stretch. The CSO bend appears as the main component of the 150 $cm^{-1}$ mode, and is also strongly coupled with the COS bend in the 172 $cm^{-1}$ mode. These last two modes appear as very weak, ill-defined Raman bands.

### *Torsional Modes*

Very weak spectral features were expected for the three torsional modes and, in fact, no bands could be identified to be assigned to these modes.

## Calculation of Force Constants

The Cartesian force field for $CF_3SO_2OCF_3$, as calculated, was transformed into the set of non-redundant, natural coordinates defined in Table 6 through the B-matrix[30] obtained with a standard program. Such coordinates take into account the local symmetry around the C and S atoms and are in accordance with the proposals of Fogarasi et al.[31] The resulting force field was subsequently scaled by using the scheme proposed by Pulay et al.,[32] in which the diagonal force constants are multiplied by scale factors $k_{f,i}$, $k_{f,j}$, etc., and the corresponding interaction constants are multiplied by $(k_{f,i} \times k_{f,j})^{1/2}$. A set of initial scale factors was defined by using values recommended by Kalincsák and Pongor[33] where available and by using unity for the rest. These scale factors were subsequently adjusted by a least-squares procedure in order to obtain the best fit to the experimental frequencies.(initial and final scale factors are available in Table S5, Supporting Information). All vibrational bands were assigned the same weight in the adjustment except for those missing or showing uncertain fre-

[a] Latin letters denote changes in bonds between the atoms whose numbers appear in parentheses. Greek letters denote changes in angles defined by the atoms that are also indicated with numbers.

quencies, for which zero weights were used. No empirical correction of the theoretical geometry was used. The potential-energy distribution, which shows the relative contribution of the diagonal force constants to each vibrational mode, was subsequently calculated with the resulting scaled quantum mechanics (SQM) force field. The resulting frequencies, final RMSD value and potential-energy distribution are presented in Table 5. It can be seen that only about one half of the modes have a participation of ≥50% of one definite coordinate, whereas the other modes represent complex vibrations where several coordinates are involved.

The force-field transformation, scaling and potential-energy distribution calculations were performed with the program FCARTP.[34] The atomic displacements, given by the calculations for each vibrational mode, served as a tool to help understand qualitatively the nature of the molecular vibrations. The program GaussView was used along with the corresponding data to represent this graphically.[29]

The SQM force field (Table S6, Supporting Information) was used to calculate the internal force constants for $CF_3SO_2OCF_3$ (Table 7), and these are compared to the equivalent values for some related molecules. It can be seen that on moving from $CF_3SO_2OCF_3$ to $CF_3SO_2OCH_3$, the calculated S–O bond becomes shorter (from 168.2 to 162.2 pm), and, consequently, the corresponding force constant increases (from 3.82 to 4.96 mdyn Å$^{-1}$). In contrast, the adjacent O–C bond length increases (from 139.3 to 145.5 pm), and its force constant decreases (from 5.50 to 4.60 mdyn Å$^{-1}$). The highly electronegative $CF_3$ group seems to enhance the participation of the oxygen electronic charge in the O–C bond of $CF_3SO_2OCF_3$, strengthening that bond to the detriment of the S–O bond.

Table 7. Force constants in internal (valence) coordinates for $CF_3SO_2OCF_3$ and related molecules.

## Conclusions

$CF_3SO_2OCF_3$ was synthesised in good yields by using a published technique. A complete investigation of its gas-phase molecular structure was carried out by using electron diffraction techniques complemented by theoretical methods. The experimental and theoretical structures both show this molecule as a single *gauche* conformer having a C–S–O–C dihedral angle of 119.5(18)° determined by GED, relative to 105 to 112° calculated by quantum chemistry calculations. A comparison of the bond lengths obtained by GED and those predicted by various ab initio and DFT methods shows that $CF_3SO_2OCF_3$ is a particularly challenging case for theoretical geometry optimisation. The inclusion of multiple polarisation functions in the basis set plays a crucial role, but the choice of method is also significant. These results are consistent with what seem to be common structural characteristics of covalent sulfonates.

Infrared and Raman spectra were obtained for $CF_3SO_2OCF_3$, and bands assignable to 27 out of the expected 30 normal modes of vibration were observed. The vibrational data were used as a basis to define the symmetry (SQM force field) and internal force constants of the molecule.

### Synthesis

$CF_3SO_2OCF_3$ was synthesised by reaction between $CF_3SO_2OH$ and its anhydride, $(CF_3SO_2)_2O$, according to the method reported by Hassani et al.[4] The reactants were heated in a sealed tube for 1 h at approximately 450 K, and after the reaction had occurred, the product was purified by distillation on a vacuum line.

### Gas Electron Diffraction (GED)

Data were collected by using the Edinburgh gas electron diffraction apparatus[35] with an accelerating voltage of ca. 40 kV (ca. 6 pm electron wavelength) on Kodak Electron Image film. Nozzle-to-film distances were determined by using benzene vapour as a standard, immediately after recording the diffraction patterns for $CF_3SO_2OCF_3$. Sample and nozzle temperatures of 195 and 298 K, respectively, were used for both the short and long nozzle-to-camera distances (130.5 and 291.5 mm). The electron scattering pattern was converted into digital form by using an Epson Expression 1680 Pro flatbed scanner with a scanning program that was described elsewhere.[36] Data reduction and least-squares refinements were carried out with the ed@ed program[37] employing the scattering factors of Ross et al.[38] The scale factors, *s* limits, weighting points, correlation parameters and electron wavelengths are given in Table S7 (Supporting Information).

### Infrared and Raman Spectra

Infrared spectra for $CF_3SO_2OCF_3$ in the gas and solid phases were recorded in the 400–4000 $cm^{-1}$ range by using a Perkin–Elmer 1600 FTIR instrument. The spectrum for the solid was obtained after depositing the compound from the vacuum line onto a KBr window, maintained at about 197 K, in a variable temperature RIIC (VLT-2) cell. The Raman spectrum for the liquid at room temperature was obtained with the FRA-106 accessory mounted on a Bruker IFS66 FTIR instrument, by using 1064-nm light from a Nd/YAG laser for excitation.

## Computational Resources

The majority of the calculations described in this paper were performed with a Linux 10-processor Parallel Quantum Solutions (PQS) workstation[39] running the Gaussian 03 suite of programs.[40] The scans of the potential-energy surface and all calculations using the 6-31G(3df), cc-pVTZ, TZVP and TZVPP basis sets were performed with the resources of the EPSRC National Service for Computational Chemistry Software[41] on a cluster of 22 Linux Opteron nodes, where each Opteron server has twin 2.4 GHz Opteron 250 CPUs and 8 GB of memory connected with a high-speed, low-latency Myrinet network.

**Supporting Information** (see footnote on the first page of this article): Details of GED data analysis parameters, interatomic distances, amplitudes of vibrations, distance corrections for perpendicular motion, the least-squares correlation matrix and the molecular-scattering intensity curves used in the GED refinement are presented. Geometric molecular parameters for all ab initio and DFT calculations are also given. GED atomic coordinates and those obtained from MP2/6-31G(3df), MP2/cc-pVTZ, MP2/TZVPP, B3LYP/6-31G(3df) and B1B95/6-31G(3df) calculations are provided, as well as the force field scaling factors.

## Acknowledgments

Research grants from the following Argentine institutions are gratefully acknowledged: CONICET (Consejo Nacional de Investigaciones Científicas y Técnicas), ANPCYT (Agencia Nacional de Promoción Científica y Tecnológica) (PICT 11127), CIUNT (Consejo de Investigaciones de la Universidad Nacional de Tucumán) and UNLP (Universidad Nacional de La Plata). # Systematic Counterion Tuning of the Solid-State Structure of $[Pt(thiourea)_4]^{2+}$

**Wolfgang Schiessl,[a] Ralph Puchta,[a,b] Živadin D. Bugarčić,[a,c] Frank W. Heinemann,[a] and Rudi van Eldik*[a]**

**Keywords:** Counter ion / Conformers / Crystal engineering

Four different limiting molecular conformations are possible for the homoleptic square-planar complex tetrakis(thiourea)-platinum(II) depending on the up-down orientation of the four thiourea (TU) ligands with respect to the $PtS_4$ plane. The realization of all four possible conformers can be achieved by a systematic variation of the counter anion making use of their individual hydrogen bonding ability. In total, the molecular and crystal structures of seven tetrakis(thiourea)platinum(II) complexes were determined by X-ray diffraction. These are: $[Pt(TU)_4]Cl_2$, $[Pt(TU)_4]I_2$, $[Pt(TU)_4](CF_3SO_3)_2$, $[Pt(TU)_4](BPh_4)_2$, $[Pt(TU)_4](ClO_4)_2$, $[Pt(TU)_4]SiF_6{\cdot}0.25H_2O$ and $[Pt(TU)_4]S_2O_6$. In all cases thiourea is coordinated by the sulfur atom and the two amino groups are not involved in the complex formation. The four independent Pt–S distances do not differ significantly from each other with an average value of 2.324(3) Å. The coordination geometry around the platinum center is distorted square-planar. The orientation of the four TU groups in $[Pt(TU)_4]^{2+}$ depends on the molecular packing forces and hydrogen bonding ability of the counter anion. Hydrogen bonds of the type N–H···X (X = $Cl^-$, $I^-$, $F^-$, O and S) are observed.

## Introduction

In contrast to its inertness as a metal, platinum and its compounds have become a major field of interest with respect to their possible applications. Besides the common usage of dispersed platinum metal as catalytic material in industrial processes,[1] $Pt^{II}$ complexes are amongst the most commonly used antitumor drugs for certain types of cancer.[2] Intracellular thiols are known to play an important role in the metabolism of Pt antitumor drugs, since they are involved in trapping of the drug,[3] renal toxicity and other side-effects.[4] Thiourea (TU) is one of the best known nucleophiles for $Pt^{II}$ complexes[5,6] and is commonly used in the investigation of ligand-substitution reactions in coordination chemistry. Moreover, thiourea can very easily displace other ligands from $Pt^{II}$ complexes, including S-bonded ligands such as L-cysteine in $[Pt(terpy)(S\text{-}cys)]^+$ with a rate constant of $0.94 \pm 0.02$ $M^{-1}s^{-1}$ at 25 °C, and even much easier guanosine in $[Pt(terpy)(N7\text{-}guo)]^{2+}$ with a rate constant of $4.87 \pm 0.03$ $M^{-1}s^{-1}$.[7] The strong binding ability of S-donor nucleophiles can as well be used to reverse unwanted side-effects in chemotherapy.[8,9] It has been demonstrated that thiourea could restore the biological activity of platinated DNA.[10] Thiourea and other sulfur-containing compounds such as diethyl dithiocarbamate (DEDTC), sodium thiosulfate (STS), glutathione (GSH), *S*-2-(3-(aminopropylamino)ethylphosphorothioic acid (amifostine, WR-2721, Ethiol), methionine, cysteine, penicillamine, biotin, sodium 2-mercaptoethanesulfonate (mesna) and its oxidized S–S bridged dimer (di)mesna (BNP-7787), have been applied as rescue or protective agents, in order to reduce the toxicity of platinum antitumor complexes.[11,12,13] The protective effect of these compounds is either to prevent or to reverse the formation of Pt–S adducts in proteins.

Thiourea coordinates flexibly via the S-donor to the platinum center and the two amino groups are not involved in the complex formation.[14,15] For the proper interaction of drugs with purely organic material, the consideration of different conformations is very important, as the drugs have to fit inside the enzyme pocket.[16] Therefore, the question of conformers should also be addressed in the development of drug mimetics based on metal complexes. The $NH_2$ groups on thiourea can be utilized to form hydrogen-bonded mediated clusters together with suitable anions or other compounds, resulting in interesting structural host-guest motifs.[17] Furthermore, there is current interest in the design of selective receptors for anions,[18,19] which could interact through either electrostatic or hydrogen-bonding interactions.[20,21] The orientation of the four TU groups depends on the molecular packing forces and hydrogen bonding. In the following, these conformers are referred to as OOOO, IOOO, IIOO and IOIO with respect to the flip-flop orientation of the thiourea ligands as shown in Figure 1. Although most of these conformers have been re-

ported individually as part of studies focusing on other topics,[22,23,24] we will show in the present study that all four possible conformers of the $[Pt(TU)_4]^{2+}$ unit can be realized by systematic tuning of the molecular structure by the hydrogen-bonding ability of the inorganic counter anion exclusively, without the need of organic substances or additional solvent species as frame works.

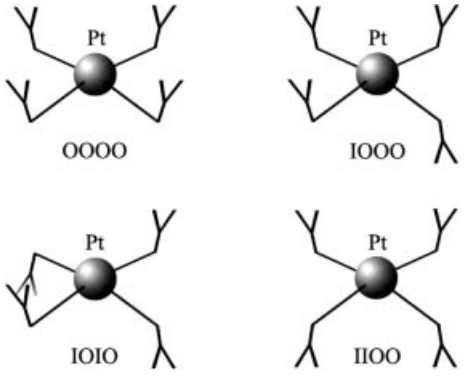

Figure 1. Schematic overview and definition of abbreviations for the four possible $[Pt(TU)_4]^{2+}$ conformers.

As part of our interest in the synthesis, structure and reactivity of coordination complexes of $Pd^{II}$ and $Pt^{II}$, we report here a systematic and detailed study of the crystal structures of $[Pt(TU)_4]X_n$, where X represents the counterions $Cl^-$, $I^-$, $CF_3SO_3^-$, $BPh_4^-$ and $ClO_4^-$ ($n$ = 2), and $S_2O_8^{2-}$ and $SiF_6^{2-}$ ($n$ = 1), in an attempt to gain information on the crystal packing, hydrogen bonding network and orientation of the four TU ligands as a function of the selected counterion.

## Results and Discussion

### Theoretical Calculations

Three of the four possible conformers were calculated applying symmetry constrains. The non-symmetrical IOOO ($C_1$), calculated without symmetry constrains, changed its conformation during the structure optimization and became the energetically most favorable IOIO. On the one hand we attribute this to the low energy barrier for rotation along the Pt–S bond, on the other hand it emphasizes the influence of the counterion. The moderate energy differences between the three conformers (IOIO 0 kcal/mol, IIOO 2 kcal/mol and OOOO 8 kcal/mol) in the gas phase[25] (see Figure 2 and Table 1) are in a range that can be exceeded by extra stabilization via hydrogen bonding. On the basis of 5 to 10 kcal/mol per hydrogen bond in the solid state,[26] already one or two hydrogen bonds should be able to overcome the calculated energy barrier between the different conformers. Since in every $[Pt(TU)_4]^{2+}$ motif 16 $H_{N-H}$ are available for possible hydrogen bond formation, the TU moieties are forced into their respective orientation.

In order to support a distinctive hydrogen network, we selected in addition to halogen anions also oxo and per-

fluoro anions, viz. $ClO_4^-$, $S_2O_6^{2-}$, $SiF_6^{2-}$ and $CF_3SO_3^-$. Whereas the halogen anions have the rotational symmetric $K_h$ point group, the oxo and perfluoro anions have different symmetry groups with corresponding subgroups. The basic idea was to utilize these symmetry elements to stabilize the suggested $[Pt(TU)_4]^{2+}$ rotamers. In order to obtain the conformational structure of $[Pt(TU)_4]^{2+}$ in the absence of a hydrogen bonding network with the anions, we used $[B(Ph)_4]^-$ as a counterion. As summarized in Table 1, the Pt–S bonds in all conformers are almost identical with 2.42 Å, the $Pt^{II}$ is ideally square-planar coordinated by the four S-donors (except in OOOO) and the C=S–$Pt^{II}$ shows equivalent angles of 111°. The distortion in the OOOO conformer can be explained in terms of only two TU ligands that have a NH-group showing a common orientation toward a neighboring thiourea sulfur (NH···S 2.48 Å), whereas the other two TU exhibit a contact toward their own S atom.

## Crystallographic Results

The molecular structures of the $[Pt(TU)_4]^{2+}$ cations in the complexes $[Pt(TU)_4]SiF_6{\cdot}0.25H_2O$, $[Pt(TU)_4]S_2O_6$, $[Pt(TU)_4](ClO_4)_2$, $[Pt(TU)_4]I_2$, $[Pt(TU)_4](BPh_4)_2$, $[Pt(TU)_4](CF_3SO_3)_2$ and $[Pt(TU)_4]Cl_2$ are shown in Figures 3, 4, 5, and 6 (see also Figures S1 to S3 in the Supporting Information). Selected bond lengths and angles for the various $[Pt(TU)]X_n$ complexes are given in Tables 2, 3, 4, 5, 6, 7, and 8.

In general, TU is coordinated to Pt via its sulfur donor in all the $[Pt(TU)_4]^{2+}$ cations. The coordination geometry around the platinum center is distorted square-planar.

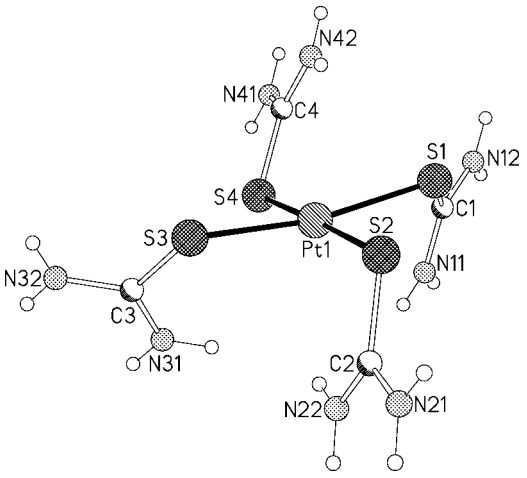

Figure 4. Molecular structure of the $[Pt(TU)_4]^{2+}$ cation of the complex $[Pt(TU)_4]S_2O_6$, (IOOO).

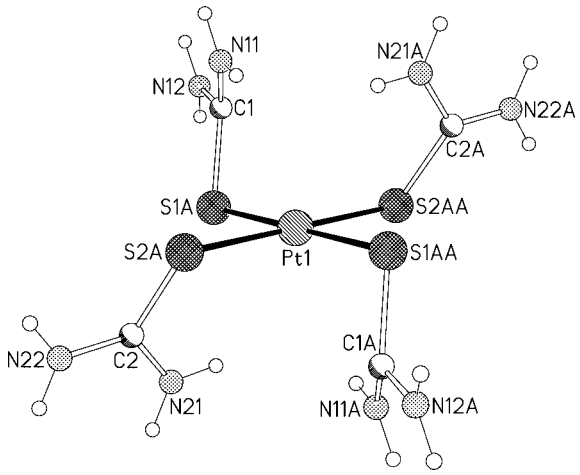

Figure 5. Molecular structure of the $[Pt(TU)_4]^{2+}$ cation of the complex $[Pt(TU)_4](ClO_4)_2$, (IIOO).

Whereas in most of the complexes the largest deviation from the optimum value of 90° for the S–Pt–S angle is less than 4.5°, significantly larger angles of 101.68(2)° in $[Pt(TU)_4](CF_3SO_3)_2$ and 98.84(2)° in $[Pt(TU)_4]Cl_2$ indicate a stronger distortion of the square planar arrangement, which is in good agreement with literature values reported for the chloride complex, viz. 98.3(02)°[14] and 98.9(1)°.[15] The central Pt atom in all investigated complexes is situated well within the $S_4$ plane; the only significant displacement of the Pt center from the square plane is observed for the complex in $[Pt(TU)_4]SiF_6$ [0.180(1) Å] and $[Pt(TU)_4]S_2O_6$ [0.091(1) Å].

The thiourea ligands are arranged in a rotor-like fashion with respect to the $PtS_4$ plane, independent of whether they point upwards or downwards. The dihedral angle between the $PtS_4$ plane and a least-squares plane calculated through the thiourea ligand unit $S=C(N_2)$ varies between 35.3(1)° and 85.2(2)°, with an overall average of 64.9°. The four Pt–S distances in each of the $[Pt(TU)_4]^{2+}$ units do not differ much from each other (see Tables 2, 3, 4, 5, 6, 7, and 8) and cover the narrow range from 2.313(2) Å (shortest distance found in $[Pt(TU)_4](ClO_4)_2$) to 2.345(1) Å (longest distance found in $[Pt(TU)_4](BPh_4)_2$). The overall average value calculated for all Pt–S bond lengths for all investigated $[Pt(TU)_4]X_n$ complexes amounts to 2.324(3) Å. This is in very good

agreement with earlier published results (2.324 Å) for $[Pt(TU)]Cl_2$,[15] and is only slightly longer than earlier published data (2.313 Å) for the same complex.[14]

Whereas the parameters for the central $PtS_4$ unit are basically the same for all investigated $[Pt(TU)_4]^{2+}$ cations, remarkable differences are observed for the orientation of the four thiourea ligands with respect to the $PtS_4$ plane that results in one of the conformations OOOO, IOOO, IIOO or IOIO.

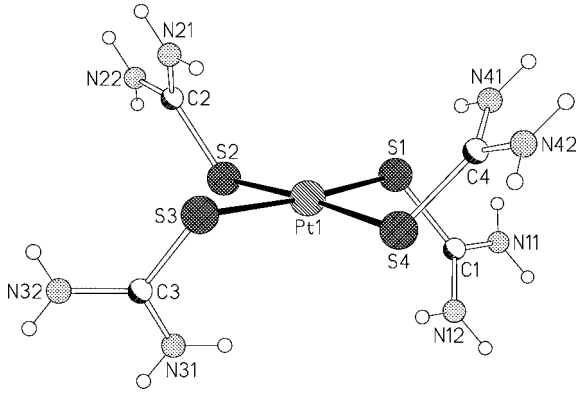

Figure 6. Molecular structure of the $[Pt(TU)_4]^{2+}$ cation of the complex $[Pt(TU)_4]Cl_2$, (IOIO).

### $[Pt(TU)_4]SiF_6 \cdot 0.25H_2O$, Conformation OOOO

Both the $[Pt(TU)_4]^{2+}$ cation and the $SiF_6^{2-}$ anion are situated on a crystallographic fourfold rotation axis ($C_4$ molecule symmetry).[27] Within the crystal the anion is situated exactly above and below the $PtS_4$ plane of the cation (Figure 7), with distances between the axial fluorine atoms (F12 and F11A) and Pt of 3.125(2) and 4.562(2) Å, respectively. The short Pt···F12 distance reflects the fact that F12 is involved in strong hydrogen bonding (Table 3) acting as a fourfold acceptor, thus forcing the OOOO conformation of the cation with the $NH_2$ groups of the thiourea ligands as hydrogen-bond donors. The hydrogen-bond acceptor function of F12 results in a significant longer Si–F bond (1.703(2) Å vs. an average of 1.683(3) Å for the other five Si–F distances). In contrast to these strong intermolecular

being the acceptor. Thus, two-dimensional double layers of cations and anions are formed with an up-side (O) face-to-face arrangement of the cations and the anions being located in between. These double layers are linked further by additional intermolecular N–H···S bridges to complete the three-dimensional hydrogen bond network (Figure 8). From the refinement results we concluded the presence of not more than 1/4 water molecule per complex unit. This only partially occupied water molecule is located at a position that allows for the formation of hydrogen bonds to four neighboring $SiF_6^{2-}$ anions depending on the orientation of the $H_2O$ (being situated in the special position *4a* of the space group leading to rotational disorder). This enables the water molecule to further interconnect the anions within layers parallel to the crystallographic *ab* plane (see Figure 8).

### $[Pt(TU)_4]S_2O_6$, Conformation IOOO

The $[Pt(TU)_4]^{2+}$ cation has $C_1$ symmetry and the $S_2O_6^{2-}$ anion is situated above the $PtS_4$ plane with three of the thiourea groups pointing upwards (Figure 9). The dithionate anion is connected to the cation by three hydrogen bonds with the O53 atom acting as acceptor resulting in a Pt–O53 distance of 3.394(3) Å. The fourth down-oriented thiourea ligand is involved in a moderate to strong intramolecular hydrogen bond (N42–H42B···S1) with a donor acceptor distance N42···S1 of 3.268(4) Å (Table 5). Other possible intramolecular hydrogen bonds may be present but are significantly weaker having either longer N···S distances (3.691(4), 4.999(4) Å] or much less favorable N–H···S angles (98.9(1)°]. Each of the eight $NH_2$ groups of the $[Pt(TU)_4]^{2+}$ cation is involved in two or three hydrogen bridges

Symmetry transformations used to generate equivalent atoms: #1 $-x+1, y-1/2, -z+3/2$; #2 $x, y-1, z$; #3 $x, -y+5/2, z+1/2$; #4 $x, -y+3/2, z+1/2$; #5 $-x, -y+2, -z+1$; #6 $x, y+1, z$; #7 $x, -y+3/2, z-1/2$; #8 $x, -y+5/2, z-1/2$

(Table 4). The remaining five O atoms of the $S_2O_6^{2-}$ anion act as acceptors for two hydrogen bonds each. Interestingly, one $S_2O_6^{2-}$ anion forms hydrogen bonds to six different cations, thus controlling the packing arrangement.

Within the crystal packing the $[Pt(TU)_4]^{2+}$ cations form zig-zag chains along the crystallographic *b* direction, the cations being connected by intermolecular N–H···S hydrogen bridges with S1, S2 and S3 acting as acceptors, while S4 is only involved in the above mentioned intramolecular H bond. The zig-zag chains form a herringbone arrangement with the $S_2O_6^{2-}$ anions occupying the resulting channels (Figure 10).

### $[Pt(TU)_4](ClO_4)_2$, Conformation IIOO

The $[Pt(TU)_4]^{2+}$ cation is situated on a crystallographic inversion center and, consequently, has $C_i$ symmetry. Similar to the observation made for the OOOO-type complex $[Pt(TU)_4]SiF_6$, the $ClO_4^-$ anions are again arranged above

and below the $PtS_4$ plane of the $[Pt(TU)_4]^{2+}$ cation, but now form a significantly tilted angle. The angle between the perpendicular axis to the $PtS_4$ plane and the O···Pt···O line amounts to 22.4(1)°, and the corresponding O13···Pt1–S angles are 74.6(1)° (S1A), 73.6(1)° (S2A), 105.4(1)° (S1AA) and 106.4(1)° (S2AA). The oxygen atoms O13 and O13A both act as acceptors for two hydrogen bridges to the up- and down-oriented thiourea ligands (Figure 11), and the distance between Pt and the two symmetry related oxygen atoms O13 and O13A is 3.352(3) Å. Though the asymmetric part of the unit cell contains two independent molecules that are both subjected to disorder with two alternative positions for each of the sulfur atoms, the same arrangement of cations and anions is observed for both. Only one significant intramolecular hydrogen bond is observed in each of the two independent cations, viz. N21–H21B···S1A and N41A–H41B···S3A (see Table 5).

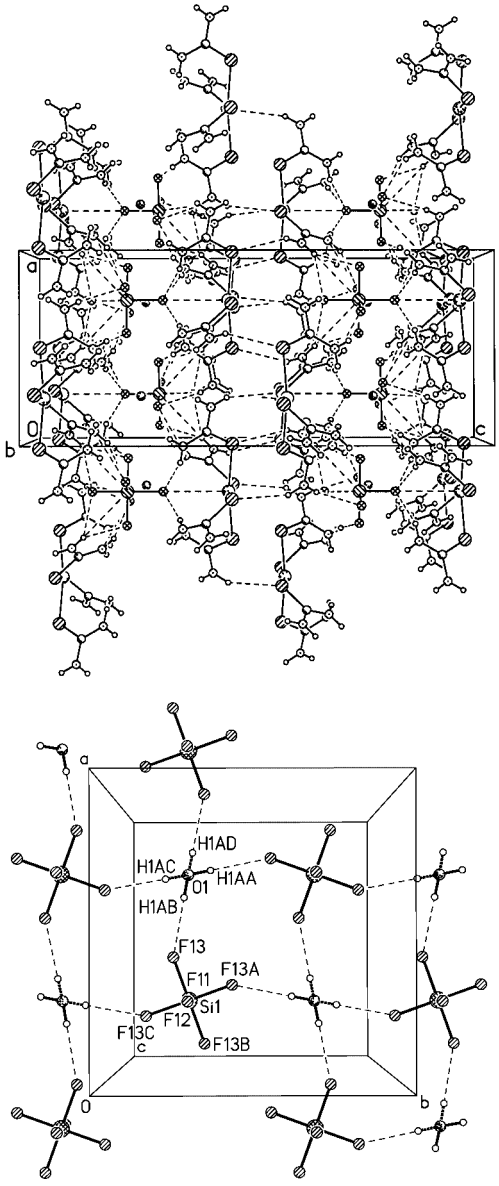

Figure 8. Crystal packing of $[Pt(TU)_4]SiF_6 \cdot 0.25H_2O$ (top) and crystal packing details of $[Pt(TU)_4]SiF_6 \cdot 0.25H_2O$ (bottom) highlighting the intermolecular hydrogen bonds between the partially occupied and disordered water molecules and the $SiF_6^{2-}$ anions parallel to the crystallographic *ab* plane (dashed solid lines between O and H atoms indicate the alternative orientation for the water molecule resulting from symmetry requirements).

The crystal packing is characterized by layers of $[Pt(TU)_4]^{2+}$ cations perpendicular to the *c* direction. Within these layers the cations are connected via intermolecular N–H···S hydrogen bridges. The space between the cation layers is occupied by the $ClO_4^-$ anions connecting the layers via intermolecular N–H···O hydrogen bridges (see Figure 12 and Table 5).

### $[Pt(TU)_4]Cl_2$, Conformation IOIO

We have re-examined the previously reported X-ray structure of $[Pt(TU)_4]Cl_2$.[14,15,22] The $[Pt(TU)_4]^{2+}$ cation in

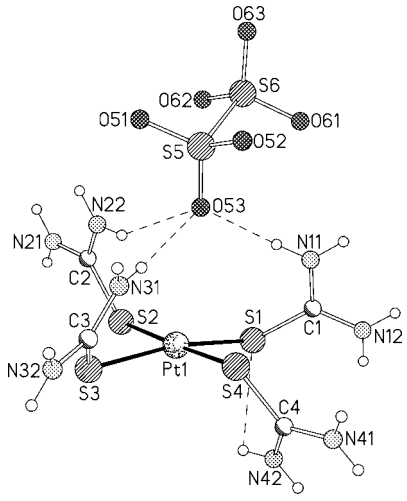

Figure 9. Conformation and H-bonding in $[Pt(TU)_4]S_2O_6$ (IOOO).

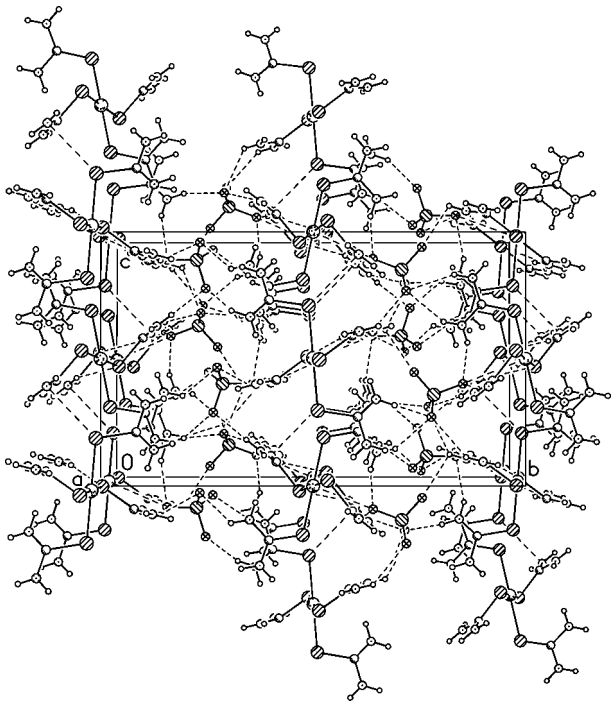

Figure 12. Crystal packing of $[Pt(TU)_4](ClO_4)_2$.

this molecular structure has only $C_1$ symmetry and shows significant deviation from the ideal square planar arrangement as is indicated by the S–Pt–S angles [largest deviation from 90° is observed for S1–Pt1–S4: 98.84(2)°]. The $Cl^-$ anions are situated above and below the $PtS_4$ plane but do not form a straight line with the Pt center any longer, the Cl1···Pt1···Cl2 angle being now 130.16(1)° instead of 180° in the $SiF_6^-$ and $ClO_4^-$ salts. Significant differences are observed for the two Pt···Cl distances [Pt1···Cl1 4.143(1) Å vs. Pt1···Cl2 3.727(1) Å]. Whereas Girling et al.[14] report five and three hydrogen bonds for the two halogen anions, respectively, our data indicate only two hydrogen bonds formed to the above the $PtS_4$ plane positioned chloride anion Cl1 and only one to the below the plane situated single Cl2. Consistent with other findings in the literature,[15] intramolecular N–H···S hydrogen bonding seems to have a stronger effect on the conformation here (see Figure 13 and Table 2). Besides comparably short H···S and N···S distances, the N–H···S angles (> 130°) become more favorable for effective hydrogen bonding.

Within the crystal the $[Pt(TU)_4]^{2+}$ cations are linked by intermolecular N–H···S hydrogen bridges and form stacks running along the crystallographic *a* axis. Each of the $Cl^-$ ions is linked to five neighbored cations by intermolecular N–H···Cl bridges and connects the cation stacks to complete the three-dimensional hydrogen bonding network of the crystal structure (see Figure 14 and Table 2).

### $[Pt(TU)_4](BPh_4)_2$, Conformation IIOO

The molecular and crystal structure of this compound is interesting since the $BPh_4^-$ anion cannot act as a hydrogen-

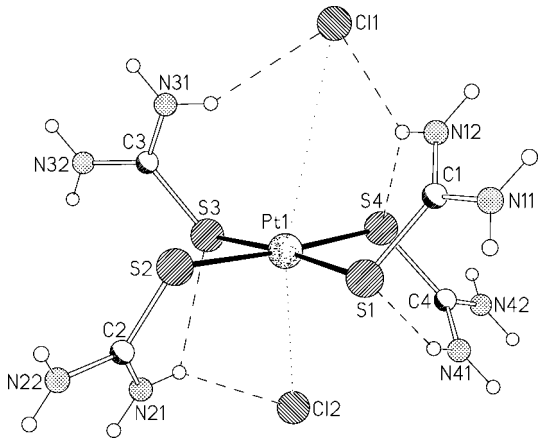

Figure 13. Conformation and H-bonding in $[Pt(TU)_4]Cl_2$.

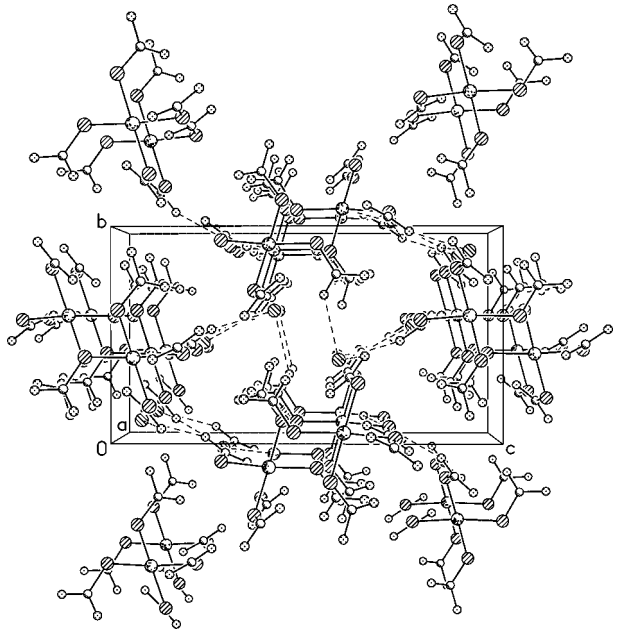

Figure 14. Crystal packing of $[Pt(TU)_4]Cl_2$.

bond acceptor. The $[Pt(TU)_4]^{2+}$ cation has crystallographically imposed $C_i$ symmetry. The rotor-like arrangement of the thiourea ligands with respect to the $PtS_4$ plane features two smaller and two larger dihedral angles of 49.1(1)° and 79.2(1)°, respectively. Surprisingly, intramolecular hydrogen bonds seem to play only a minor role. According to the parameters, only two of them can be mentioned here (Table 8). The crystalline packing can be described as hexagonal close packing of the $BPh_4^-$ anions, whereas the $[Pt(TU)_4]^{2+}$ cations occupy one half of the octahedral interstices.

### $[Pt(TU)_4]I_2$ and $[Pt(TU)_4](CF_3SO_3)_2$, Conformation IIOO

In these two crystal structures the structural motif of the arrangement of the two anions above and below the $[Pt(TU)_4]^{2+}$ moiety is repeated (see $[Pt(TU)_4](ClO_4)_2$). In the iodide compound the corresponding tilt angle between

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the perpendicular axis to the $PtS_4$ plane and the I···Pt···I line amounts to 22.5(1)°, whereas this angle is 18.4(1)° in the triflate compound (using the sulfur atoms of the two anions for the construction of the line). In both compounds again numerous intermolecular N–H···S bridges force the formation of cation layers. The anions are situated in the space between the layers and connect these by intermolecular hydrogen bonds of the N–H···I or N–H···O and N–H···F type, respectively (see Tables 6 and 7).

## Conclusions

Seven $[Pt(TU)_4]X_n$ (X = $Cl^-$, $I^-$, $CF_3SO_3^-$, $BPh_4^-$ and $ClO_4^-$ ($n$ = 2), and $S_2O_8^{2-}$ and $SiF_6^{2-}$ ($n$ = 1)) complexes were synthesized and their crystal structures were determined by X-ray diffraction. Theoretical calculations show that the possible limiting conformations for the $[Pt(TU)_4]^{2+}$ moiety have only moderate energy differences (OOOO: 7.9 kcal/mol, IIOO: 2.1 kcal/mol (relative energy differences compared to the IOIO conformer)). These energy differences can be overcome by efficient hydrogen bonding, in which each of the $NH_2$ groups of the thiourea ligand can act as hydrogen-bond donor, provided the counterions can serve as acceptors. Consequently, the realization of the four theoretically limiting conformations (OOOO, IOOO, IIOO, IOIO) was achieved by the use of different counterions. Whereas the highly symmetrical $SiF_6^{2-}$ di-anion forced the formation of the all-up conformation (OOOO) using its ability to act as acceptor for four individual equidistant N–H···F hydrogen bridges, the use of other anions resulted in less symmetrical molecular structures. The use of $S_2O_6^{2-}$, the second di-anion in the group of anions in this study leads to the formation of the IOOO conformer of the $[Pt(TU)_4]^{2+}$ cation with three practically equivalent N–H···O hydrogen bridges to one oxygen atom (O53) of the dithionate acting as acceptor, and the remaining five oxygens being involved in an extensive hydrogen bonding network connecting cations and anions. $ClO_4^-$, $CF_3SO_3^-$ and $I^-$ as mono-anions all created an analogous structural motif with one anion above and one below the $PtS_4$ plane, but with a significant tilt angle of roughly 20° between the X···Pt···X line and the perpendicular axis to the $PtS_4$ plane. The resulting arrangement of cation-anion hydrogen interactions leads to the formation of the IIOO conformer in these three crystal structures. The IIOO conformer was also realized in the complex $[Pt(TU)_4](BPh_4)_2$, but without having the possibility of forming intermolecular cation-anion hydrogen bridges. Though intramolecular hydrogen bond formation would be an alternative in the $BPh_4^-$ salt, and is indeed observed to a more or less extent in all investigated $[Pt(TU)_4]^{2+}$ cations, no significantly stronger intramolecular hydrogen bonds have been observed here. From the parameters, a more pronounced influence of intramolecular hydrogen bonding can be attributed to the complex $[Pt(TU)_4]Cl_2$ having the smallest anion and exhibiting the IOIO conformation of the $[Pt(TU)_4]^{2+}$ cation.

Due to the small energy differences between the four limiting conformers, the choice of a suitable anion in terms of size, hydrogen-bond acceptor ability and/or symmetry can force the formation of either of the OOOO, IOOO, IIOO, or IOIO conformers in the solid state.

### Quantum Chemical Methods

We performed RB3LYP[28,29,30]/LANL2DZp[31,32,33,34] hybrid density functional calculations, i.e., with pseudo-potentials on the heavy elements and the valence basis set augmented with polarization functions.[35,36] In addition, we used RB3LYP/LACV3P+**,[32,33,34,37] a basis set originally developed by Schrödinger Inc. Structures were characterized as minima by computation of vibrational frequencies. Relative energies were corrected for zero point vibrational energy. The GAUSSIAN 03 suite of programs was used.[38]

## Experimental Section

Thiourea (Merck, p.a. quality grade) and $K_2[PtCl_4]$ (Johnson Matthey) were of the highest purity commercially available and used as received.

**Tetrakis(thiourea)platinum(II) Chloride, $[Pt(TU)_4]Cl_2$:** Preparation according to a previously published method.[39] $C_4H_{16}Cl_2N_8PtS_4$ (570.46): Calcd. C 8.42, H 2.83, N 19.64, S 22.48; found: C 8.43, H 2.74, N 19.45, S 22.32.

**Tetrakis(thiourea)platinum(II) Dithionate, $[Pt(TU)_4]S_2O_6$:** An acidic aqueous solution (pH 2) of $K_2[PtCl_4]$ (0.2 mM) and thiourea (10 mM) was heated under reflux for 12 h. After formation of the tetrakis(thiourea)platinum(II) complex, the solution was concentrated by a factor of 10 and an equal aliquot of a saturated solution of $Na_2S_2O_6$ was added. Single crystals of $[Pt(TU)_4]S_2O_6$ were obtained by slow evaporation of the solution. Elemental analysis could not be performed due to a very low yield of crystals.

**Tetrakis(thiourea)platinum(II) Hexafluorosilicate, $[Pt(TU)_4]SiF_6 \cdot 0.25H_2O$:** Crystal preparation was done as described above with a saturated solution of $Na_2SiF_6$, and single crystals were obtained within minutes after the saturated counterion solution was added. $C_{16}H_{66}F_{24}N_{32}OPt_4S_{16}Si_4$ (2584.54): Calcd. C 7.44, H 2.57, N 17.34, S 19.85; found: C 7.52, H 2.59, N 17.02, S 20.00.

Crystal preparations for all the other complexes, **$[Pt(TU)_4](ClO_4)_2$**, **$[Pt(TU)_4]I_2$**, **$[Pt(TU)_4](CF_3SO_3)_2$**, and **$[Pt(TU)_4](BPh_4)_2$** were done as described above. The crystals suitable for X-ray measurements were obtained by crystallization from water and after cooling in a refrigerator.

**$[Pt(TU)_4](ClO_4)_2$:** $C_4H_{16}Cl_2N_8O_8PtS_4$ (698.46): Calcd. C 6.88, H 2.31, N 16.04, S 18.36; found: C 7.05, H 2.46, N 15.83, S 18.56.

**$[Pt(TU)_4]I_2$:** No elemental analysis due to a very low yield of crystals.

**$[Pt(TU)_4](CF_3SO_3)_2$:** $C_6H_{16}F_6N_8O_6PtS_6$ (797.68): Calcd. C 9.03, H 2.02, N 14.05, S 24.07; found: C 9.08, H 1.94, N 13.92, S 23.92.

**$[Pt(TU)_4](BPh_4)_2$:** $C_{52}H_{56}B_2N_8PtS_4$ (1138.02): Calcd. C 54.88, H 4.96, N 9.85, S 11.27; found: C 54.84, H 5.20, N 10.27, S 11.57.

**X-ray Crystal Structure Determination of $[Pt(TU)_4]Cl_2$, $[Pt(TU)_4]I_2$, $[Pt(TU)_4](CF_3SO_3)_2$, $[Pt(TU)_4](BPh_4)_2$, $[Pt(TU)_4](ClO_4)_2$, $[Pt(TU)_4]$-**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**$SiF_6$·0.25$H_2O$ and [Pt(TU)$_4$]$S_2O_6$:** X-ray intensities were collected at 100 K on a Bruker-Nonius KappaCCD diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å, graphite monochromator). Lorentz and polarization corrections were applied, absorption effects were corrected on the basis of multiple scans using SADABS[40] with the exception of [Pt(TU)$_4$]($BPh_4$)$_2$ where a numerical absorption correction was applied instead. All structures were solved by direct methods and refined using full-matrix least-squares procedures on $F^2$. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms are placed in positions calculated for optimized geometry, their isotropic displacement parameters were tied to those of their corresponding N

or C carrier atoms by a factor of 1.2. The hydrogen atom for the solvent water molecule in the crystal structure of $[Pt(TU)_4]SiF_6 \cdot 0.25H_2O$ (with the oxygen being located in position *4a* of space group *P4/ncc*, no. 130) was taken from a difference fourier syntheses and not refined. The crystal used to determine the structure of **$[Pt(TU)_4](ClO_4)_2$** proved to be a pseudomerohedral twin. The application of an appropriate twin matrix (TWIN 1 0 0 0 –1 0 0 0 –1) resulted in a significant improvement of the refinement though the twinning was present only to a minor extent [BASF = 0.050(2)].

Crystallographic data and a summary of data collection and refinement parameters for all seven complexes are given in Table 9. For structure solution, refinement and graphical representations the SHELXTL NT 6.12 program package was used.[41]

CCDC-631060 (for **$[Pt(TU)_4]Cl_2$**), -631061 (for **$[Pt(TU)_4]I_2$**), -631062 (for **$[Pt(TU)_4](CF_3SO_3)_2$**), and -631063 (for **$[Pt(TU)_4](BPh_4)_2$**), -631064 (for **$[Pt(TU)_4](ClO_4)_2$**), -631065 (for **$[Pt(TU)_4]SiF_6 \cdot 0.25H_2O$**) and -631066 (for **$[Pt(TU)_4]S_2O_6$**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Figures S1 to S3 present the molecular structure of the $[Pt(TU)_4]^{2+}$ cation in different complexes of the IIOO type.

## Acknowledgments

The authors gratefully acknowledge financial support from the Deutsche Forschungsgemeinschaft (DFG) and thank Immo Weber, Dr. Nico van Eikema Hommes and Eike Hübner for fruitful discussions, and Christina Wronna for elemental analysis. ZDB thanks Deutscher Akademischer Austauschdienst (DAAD) for a fellowship. We also thank Prof. Tim Clark, Computer Chemistry Center and the Regionales Rechenzentrum Erlangen (RRZE) for computer time.

# Mononuclear and Heterodinuclear Metal Complexes of Nonsymmetric Ditertiary Phosphanes Derived from $R_2PCH_2OH$

**Gavin M. Brown,[a] Mark R. J. Elsegood,[a] Andrew J. Lake,[a] Noelia M. Sanchez-Ballester,[a] Martin B. Smith,*[a] Thomas S. Varley,[a] and Kevin Blann*[b]**

**Keywords:** Late-transition metals / P ligands / Heterobimetallics / Coordination modes

The new nonsymmetric ditertiary phosphanes, $Ph_2PCH_2N(R)CH_2PAd$ [**3a**: R = $C_6H_5$, **3b**: R = $C_6H_4(4\text{-}CH_3)$] were prepared using a three-step sequence of condensation reactions. Hence treatment of AdP-H (AdP-H = 1,3,5,7-tetramethyl-2,4,8-trioxa-6-phosphaadamantane) with $(CH_2O)_n$ at 110 °C gave the adamantane-derived hydroxymethylphosphane **1**, which upon condensation with $C_6H_5NH_2$ or $C_6H_4(4\text{-}CH_3)NH_2$ gave the secondary aminophosphanes $HN(R)CH_2PAd$ [**2a**: R = $C_6H_5$, **2b**: R = $C_6H_4(4\text{-}CH_3)$]. Further condensation of **2a** or **2b** with $Ph_2PCH_2OH$ gave **3a** or **3b** in high yields (ca. 85 %) containing the sterically encumbered adamantane cage. The coordination capabilities of **2a**, **3a** and **3b** have been explored with various $Pd^{II}$, $Pt^{II}$, $Ru^{II}$, $Ir^{III}$ and $Au^{I}$ metal centres. Bridge cleavage of $\{Pd(\kappa^2\text{-}C,N\text{-}C_{16}H_{16}N)Br\}_2$ with 2 equiv. of **2a** gave the neutral, mononuclear complex $Pd(\kappa^2\text{-}C,N\text{-}C_{16}H_{16}N)Br$(**2a**) (**4**). Reaction of **3a/3b** with $MCl_2$(cod) (M = Pt, Pd) gave the corresponding $\kappa^2$-*P,P′*-chelate complexes *cis*-$MCl_2$(**3**) [**5a**: M = Pt, R = $C_6H_5$, **5b**: Pt, R = $C_6H_4(4\text{-}CH_3)$, **5c**: Pd, R = $C_6H_5$, **5d**: Pd, R = $C_6H_4(4\text{-}CH_3)$]. In contrast, bridge cleavage of the dimers $\{RuCl_2(\eta^6\text{-}p\text{-cym})\}_2$ or $\{IrCl_2(\eta^5\text{-}Cp^*)\}_2$ with **3a** gave the $\kappa^1$-*P*-monodentate complexes $RuCl_2(\eta^6\text{-}p\text{-cym})$(**3a**) (**6**) and $IrCl_2(\eta^5\text{-}Cp^*)$(**3a**) (**7**), respectively, in which the –PAd group is noncoordinating. Reaction of **6** or **7** with AuCl(tht) (tht = tetrahydrothiophene) gave the mixed-metal complexes $\kappa^2$-*P,P′*-μ-$RuCl_2(\eta^6\text{-}p\text{-cym})\{Ph_2PCH_2N(Ph)CH_2PAd(AuCl)\}$ (**8**) and $\kappa^2$-*P,P′*-μ-$IrCl_2(\eta^5\text{-}Cp^*)\{Ph_2PCH_2N(Ph)CH_2PAd(AuCl)\}$ (**9**). All new compounds have been fully characterised by spectroscopic and analytical methods. Furthermore, the structures of **2a**, **4**, **5a**, **5b** and **6**–**9** have been elucidated by single-crystal X-ray crystallography. The X-ray structures of **5a**, **5b** and **6**–**9** represent the first examples of crystallographically characterised nonsymmetric ditertiary phosphane complexes bearing one adamantane moiety.

## Introduction

As part of ongoing studies[1–5] in our group we have been interested in developing new tertiary and symmetric ditertiary phosphanes using Mannich-based condensation reactions. Compounds of the formula $(R_2PCH_2)_2N(R)$ and $\{(R_2PCH_2)_2N\}_2(R)$ are two such examples[6–10] which have interesting coordination properties, catalytic applications and, more recently, are important ligands for self-assembly reactions using covalent bonds or H-bonding interactions.[1,2,4,11] The tetraphenyl-substituted phosphane $(Ph_2PCH_2)_2N(R)$, closely related to the three-carbon spacer $(Ph_2PCH_2)_2CH_2$ [1,3-bis(diphenylphosphanyl)propane, dppp], has been successfully utilised in several metal-catalysed reactions.[12–14] Furthermore, a related $C_3$ backbone diphosphane structurally comparable to dppp, is the bulky electron-rich diphosphane $(AdPCH_2)_2CH_2$ (bpap) recently reported by Pringle and co-workers.[15,16] Both bpap and related diphospha-adamantane ligands have been shown to form complexes with Ru, Pd and Au metal centres.[15,16] There has also been interest in these adamantane-based phosphane ligands for their important uses in a range of catalytic metal-mediated transformations such as aminations, hydroformylation, hydrogenations, methoxycarbonylation of internal alkenes and Suzuki and Sonogashira couplings.[17–25]

Nonsymmetric ditertiary phosphanes have seldom been studied in relation to their symmetric counterparts possibly reflecting the necessity to perform multistep syntheses.[26–31] When considering possible coordination modes for nonsymmetric diphosphanes of the type $R_2PCH_2XCH_2PR'_2$ various coordination modes are plausible some of which are shown in Figure 1. Hence $\kappa^1$-*P*-monodentate coordination is possible at either $–PR_2$ or $–PR'_2$ centres (structures **I** and **II**) and μ-*PP′* bridging between similar/disparate metal centres (structures **III**–**V**; the presence of a metal–metal interaction is illustrated by a dashed line). Alternatively such mixed ligands may adopt a more classic $\kappa^2$-*PP′*-chelating mode to a single metal centre (structure **VI**). Finally, depending on the nature of the X spacer group [e.g. N-

$(CH_2)_4$] separating the two phosphorus donor atoms, $\kappa^3$-*PNP′*-tridentate coordination is possible utilising all three group-15 donor atoms (structure **VII**).[8]

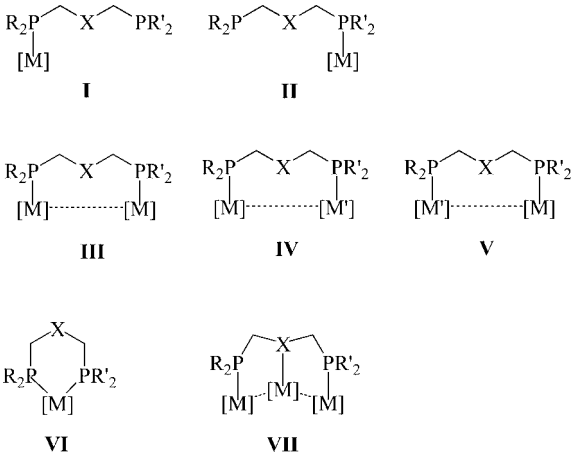

Figure 1. Schematic representation of the possible coordination modes for $R_2PCH_2XCH_2PR'_2$.

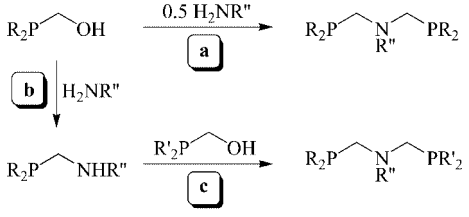
Herein we report a simple two-step condensation procedure (Scheme 1, pathway **b/c**) by which ditertiary phosphanes bearing non-equivalent groups (–$PPh_2$ and –PAd) can be obtained. In contrast, while pathway **a** generally affords symmetric diphosphanes, pathway **b** gives initially a secondary aminophosphane that can undergo further reaction with a second different hydroxymethylphosphane precursor (pathway **c**) to yield the desired nonsymmetric diphosphane. We demonstrate that these ligands exhibit diverse coordination behaviour towards a range of late transition metals, and can function in a $\kappa^1$-*P*-monodentate manner in which the –PAd fragment remains non-coordinating (structure **I**). This has allowed us to use these intermediates as "metalloligands" for the construction of heterobimetallic species as exemplified by our syntheses of complexes containing Ru/Au and Ir/Au metal centre combinations. The single-crystal X-ray structures of eight compounds are reported.

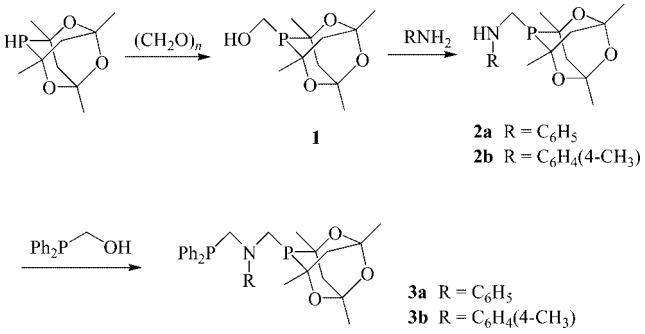


Scheme 1.

## Results and Discussion

### Ligand Syntheses

Previous studies using $Ph_2PCH_2OH$ have shown that condensation with primary amines ($RNH_2$) can be used to access either singly substituted products [of the type $Ph_2PCH_2N(H)R$] or symmetric ditertiary phosphanes [of the type $(Ph_2PCH_2)_2N(R)$] depending on the R group.[1–5] We have found that by using two consecutive Mannich based condensation reactions, nonsymmetric ditertiary phosphanes such as **3a** and **3b** can be realised. Accordingly, insertion of paraformaldehyde into the P–H bond of AdP-H (1:1 ratio) at 110 °C for 90 min affords the hydroxymethyl-functionalised phosphane **1**. Mannich condensation of **1** with $H_2NC_6H_5$ (1:1 ratio) in $CH_3OH$ at room temperature, under anaerobic conditions, gave the secondary aminophosphane **2a** as a racemic mixture of enantiomers. Similarly, **2b** could be prepared from $H_2NC_6H_4(4\text{-}CH_3)$ employing a similar method (Scheme 2). Further treatment of **2a** (or **2b**) with $Ph_2PCH_2OH$ in $CH_3OH$ at room temperature gave the desired nonsymmetric ditertiary phosphanes **3a** (or **3b**) in good yields (ca. 85%). The formulation of these compounds were confirmed by a combination of spectroscopic and analytical methods.



Scheme 2.

The $^{31}P\{^1H\}$ NMR chemical shifts for **1**, **2a** and **2b** are all similar [$\delta$(P) –31.2, –32.2 and –32.4 ppm, respectively], but differ from the starting secondary phosphane AdP-H, by ca. 20 ppm [$\delta$(P) –49.7 ppm, $CDCl_3$].[32] Furthermore, the $^{31}P\{^1H\}$ NMR chemical shifts for **1**, **2a** and **2b** differ by ca. 10 ppm with respect to the phenyl-modified phosphaadamantanes, AdP-Ph, previously reported.[19] Upon second condensation the $^{31}P$ resonance for the –PAd group is shifted upfield by ca. 10 ppm to –41.5 ppm (for **3a**) and –42.0 ppm (for **3b**). The –$PPh_2$ resonance is observed at $\delta$(P) –27.4 ppm (for **3a**) and –27.6 ppm (for **3b**), which differs by ca. 10 ppm with respect to dppp [$\delta$(P) –17.3 ppm, $CDCl_3$]. In the $^1H$ NMR spectra of **2a** and **2b** the $CH_2$ hydrogen atoms are diastereotopic as two separate doublet of doublets are observed at ca. 3.4 and 2.9 ppm. On the basis of FT-IR spectroscopy (KBr pellets), characteristic $\nu_{O-H}$ and $\nu_{N-H}$ stretches were observed at 3470 $cm^{-1}$, 3367 $cm^{-1}$ and 3319 $cm^{-1}$ for **1**, **2a** and **2b**, respectively, yet these frequencies were absent in either **3a** or **3b** as would be expected. Other characterising data are given in Table 1 and the Exp. Sect.

The X-ray structure of **2a** has been determined (Figure 2, Table 2) and confirms the presence of the phospha-adamantane cage. While a few crystallographic examples of sterically hindered phosphanes containing this cage have been reported in the literature[15–19,21,25] this structure represents

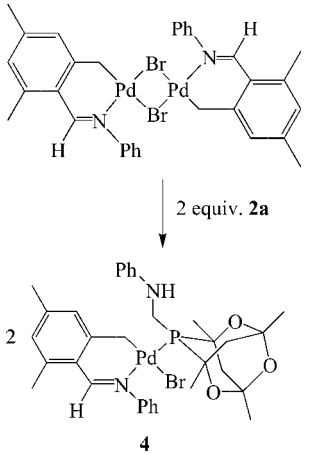
## Coordination Studies

Given the paucity of palladium complexes with adamantane-based phosphorus ligands documented in the literature[17,19,25] we prepared the palladium(II) complex **4** by bridge cleavage of the known[34] dimeric compound {Pd($\kappa^2$-*C,N*-$C_{16}H_{16}N$)Br}$_2$ with **2a** in refluxing acetone [Equation (1)]. Compound **4** displayed a singlet at $\delta$(P) 18.7 ppm in the $^{31}P\{^1H\}$ NMR spectrum (Table 1) and furthermore was characterised by single-crystal X-ray crystallography.



(1)

The X-ray structure (Figure 3, Table 2) confirmed a near square-planar arrangement about palladium with angles in the range 82.47(8)–95.42(7) Å. The Pd(1)–P(1) distance in **4** [2.2522(6) Å] is as expected. As previously observed for

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

other cyclometallated complexes of palladium the phosphane **2a** is *trans* to the imine nitrogen N(2).[35] Within the $\kappa^2$-*C*,*N*-metallated ligand an *E* configuration is adopted by the two arene groups located about the C(24)=N(2) imine double bond. The six-membered $PdC_4N$ metallacycle adopts a nonplanar conformation hinged about C(24)/C(33). The Pd deviates from the P(1)/Br(1)/N(2)/C(33) mean plane by 0.0242 Å. Within the bonded P ligand the intra-cage C–P–C angle is 94.05(10)° which is slightly enlarged with respect to **2a** [92.90(8)°] but similar in magnitude to other coordinated phospha-adamantane ligands.[16,19] The amine group forms an intramolecular hydrogen bond to the coordinated bromide ligand [N(1)···Br(1) 3.265(2) Å, H(1)···Br(1) 2.61(3) Å; N(1)–H(1)···Br(1) 137(2)°].

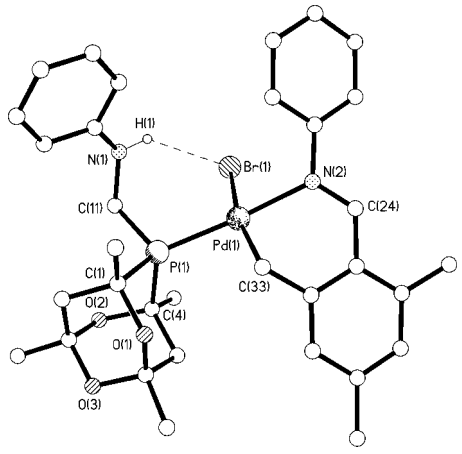


Figure 3. Molecular structure of **4**. All hydrogen atoms except on N(1) have been removed for clarity.

Reaction of **3a** (and **3b**) with $MCl_2$(cod) (M = Pt, Pd) gave the dichloro $\kappa^2$-*P*,*P*′-chelate compounds $MCl_2$(**3a**) [M = Pt **5a**; Pd **5c**] and $MCl_2$(**3b**) [M = Pt **5b**; Pd **5d**] in high yields (Scheme 3). By virtue of the different substituents on each phosphorus the $^{31}P\{^1H\}$ NMR spectra of the chelate complexes **5a**–**5d** are particularly diagnostic showing a classical AX pattern (Table 1). The $^{31}P$ chemical shifts between the two phosphorus nuclei differ by ca. 10 ppm whilst the *J*(PtP) couplings differ by ca. 250 Hz with the *J*(PtP) coupling to the –PAd group being the larger of the two. These variations can presumably be ascribed to the difference in stereoelectronic properties between the two phosphorus centres.

The X-ray structures of the nonsymmetric diphosphane platinum(II) complexes **5a** and **5b** have been determined (Figure 4, Figure 5 and Table 3). Suitable crystals of **5a** and **5b** were obtained by slow diffusion of diethyl ether into a $CDCl_3$ solution. The X-ray structures show that both **5a** and **5b** adopt a chelating coordination mode and furthermore, the coordination environment around platinum is ostensibly square-planar. In **5a** the P(2)–Pt(1)–Cl(2) [83.07(5)°] bond angle is contracted by some 10° with respect to P(1)–Pt(1)–Cl(1) [93.87(6)°] clearly reflecting the different steric effects of phenyl vs. adamantane groups. The P(1)–Pt(1)–P(2) hinge angle is 96.33(5)° which compares favourably with the previously reported angle for the symmetric, bulky diphosphane palladium(II) complex $PdCl_2$(bpap), previously reported by Pringle and coworkers.[15] The Pt–P [2.2362(16), 2.2373(14) Å] and Pt–Cl [2.3545(14), 2.3499(14) Å] bond lengths are similar and illustrate the negligible effect the different substituents on P have on these distances. The Pt is out of the mean plane [defined by the donor atoms P(1), P(2), Cl(1) and Cl(2)] by 0.0139 Å (for **5a**) and 0.0451 Å (for **5b**). The six-membered Pt–P–C–N–C–P′ rings in **5a** and **5b** adopt a conformation in which the Pt(1), P(1), P(2), C(11) and C(18) atoms are essentially flat (to within ±0.07 Å for **5a**; ±0.19 Å for **5b**) and N(1) is out of this plane by 0.74 Å (for **5a**) and 0.66 Å (for **5b**). Furthermore the N–arene torsion angles, defined by the C(11)/N(1)/C(18) and C(12)>C(17) mean planes, are 37° and 76° for **5a** and **5b** respectively. Analysis of the packing in the two crystal structures shows the orientations of the N–arene rings are determined by weak C–H(Me or Ph)···π(N–arene) interactions to neighbouring molecules.

Having established these nonsymmetric ligands successfully *P*,*P*′-chelate to platinum(II) and palladium(II) metal centres we next sought to establish whether the sterically demanding adamantane group could impose a *P*-monodentate mode of binding through the sterically less encumbered $-PPh_2$ group. This sort of *P*-monodentate behaviour, whilst known for flexible small bite angle diphosphanes such as dppm,[36] dppa [bis(phenylphosphanyl)amine][37] and others,[28] is less prevalent with dppp bearing an extended $C_3$ spacer. Gratifyingly when we reacted **3a** with $\{RuCl_2(\eta^6\text{-}p\text{-cym})\}_2$ or $\{IrCl_2(\eta^5\text{-Cp*})\}_2$ in dichloromethane we obtained the $\kappa^1$-*P*-monodentate complexes **6** and **7** in high yields. Presumably under these experimental conditions the –PAd group is too bulky to coordinate to the $RuCl_2(\eta^6\text{-}p\text{-cym})$ or $IrCl_2(\eta^5\text{-Cp*})$ fragments [vide infra for reactions with AuCl(tht)]. The $^{31}P\{^1H\}$ NMR spectra (Table 1) are particularly informative showing new downfield $\delta$(P) resonances for the coordinated $-PPh_2$ group at $\delta$(P) 23.6 ppm (for **6**) and –5.1 ppm (for **7**) whilst the pendant –PAd group is observed at $\delta$(P) ca. –39 ppm (cf. –41.5 ppm for **3a**).

The X-ray structures of the piano-stool complexes **6** and **7** have both been established by X-ray crystallography (see Figures 6 and 7, Table 3). Within the coordination sphere of **6** the Ru–P, Ru–Cl or $Ru-C_{arene}$ bond lengths are comparable to other half-sandwich compounds e. g. $RuCl_2$(*p*-cym)PTA (PTA = 1,3,5-triaza-7-phosphatricyclo[3.3.1.1]-decane), $RuCl_2$(*p*-cym)$Ph_2P(2\text{-}C_5H_4N)$ and $RuCl_2$(*p*-cym)$Ph_2PCH_2Y$ [Y = $-NHC_6H_4(2\text{-}CO_2H)$, $-NHC_6H_4(2\text{-OH})$, $-NHC_6H_4(2\text{-}CH_2OH)$].[1,38] As a consequence of $\kappa^1$-*P*-monodentate coordination the C(11)–N(1)–C(18) bond angle has marginally increased by ca. 3° for **6** (and 4° for **7**) with respect to that observed in the $\kappa^2$-*P*,*P*′-chelate complexes **5a** and **5b**. The P···P separations within **6** and **7** are 4.868 Å and 5.319 Å, respectively.

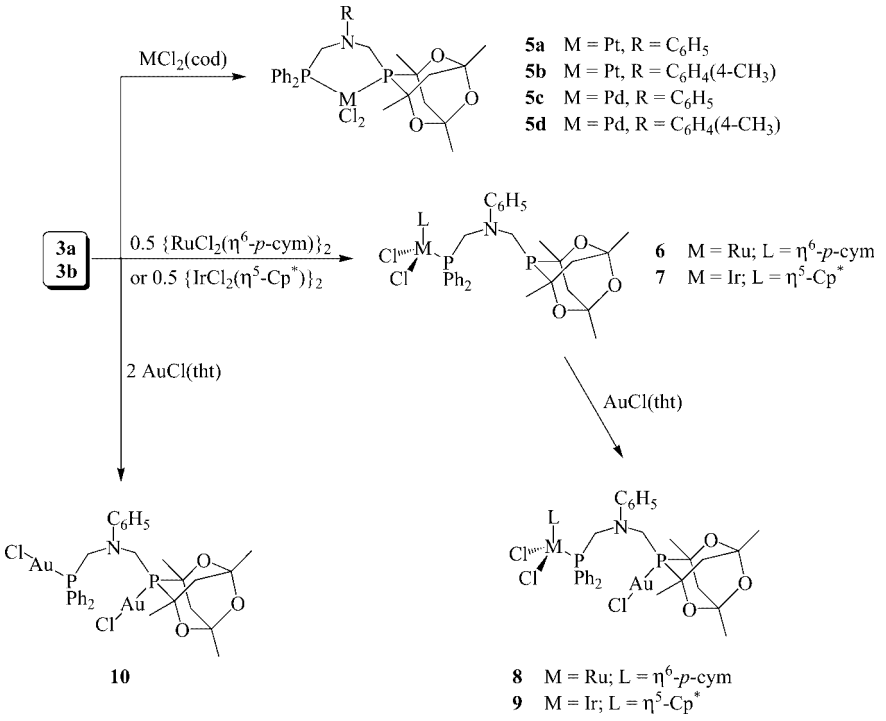

Scheme 3.

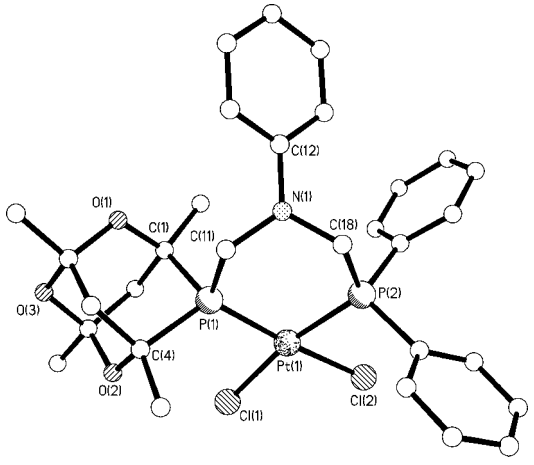

Figure 4. Molecular structure of **5a**. All hydrogen atoms and solvent have been removed for clarity.

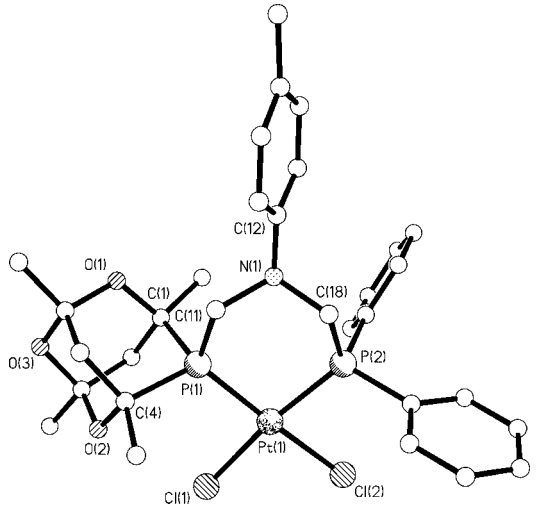

Figure 5. Molecular structure of **5b**. All hydrogen atoms and solvent have been removed for clarity.

In order to pursue the possibility of introducing a second metal centre we elected to react both **6** and **7** with 1 equiv. of AuCl(tht) in dichloromethane at room temperature. After work up the red/orange solids $\kappa^2$-*P*,*P*′-μ-$RuCl_2(\eta^6$-*p*-cym){$Ph_2PCH_2N(Ph)CH_2PAd(AuCl)$} **8** and $\kappa^2$-*P*,*P*′-μ-$IrCl_2(\eta^5$-Cp*){$Ph_2PCH_2N(Ph)CH_2PAd(AuCl)$} **9** were isolated in 93% and 77% yields respectively. The $^{31}P\{^1H\}$ NMR spectra were particularly informative showing a downfield shift for –PAd to $\delta$(P) 24.1 ppm (for **8**) and $\delta$(P) –3.2 ppm (for **9**) with respect to the noncomplexed –PAd group in **6** and **7** (Table 1). Further indication for gold(I) coordination was evident from the IR spectra which clearly showed $\nu_{AuCl}$ vibrations at 331 $cm^{-1}$ and 336 $cm^{-1}$ for **8** and **9**, respectively.

Upon complexation the gold(I) chloride fragment is approximately linear with respect to the coordinated –PAd moiety (see Figures 8 and 9, Table 4). The Au–Cl and Au–P bond lengths are normal and in the region previously observed for phosphane gold(I) complexes.[4,39–41] No significant changes are observed for the M–Cl and M–P (M = Ru or Ir) distances/bond angles upon gold complexation. In addition the Cl(1)–Au(1)–P(1) angles [177.18(4)° for **8**; 174.42(8)° for **9**] suggest very minimal steric congestion between the adamantane cage or neighbouring N–Ph group. Furthermore, the C(11)–N(1)–C(18) angles for **8** and **9** are 115.9(2)° and 115.5(6)°, respectively, whilst the N–arene

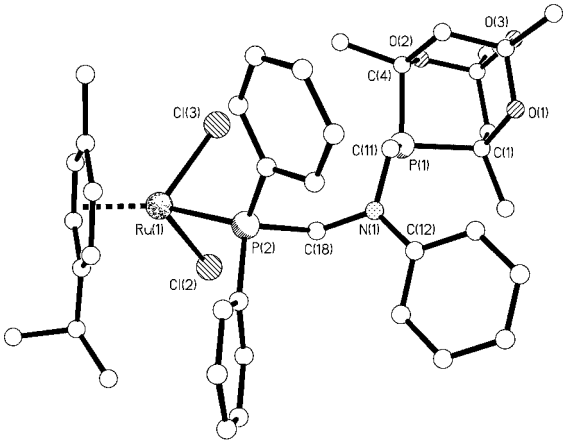

Figure 6. Molecular structure of **6**; all hydrogen atoms and solvent have been removed for clarity.

torsion angles for **6**–**9**, defined by the C(11)/N(1)/C(18) and C(12)>C(17) mean planes, are all in the range 7.6–17.3°. The P···P distances in both heterobimetallic complexes are 5.238 Å and 5.283 Å for **8** and **9**, which also dictate large Ru···Au [8.304 Å] and Ir···Au [8.481 Å] separations. The shortest intermolecular Au···Au separations are 7.628 Å and 5.987 Å, respectively, indicating the absence of any significant aurophilic interactions between neighbouring P–Au–Cl units.[42]

We next sought to demonstrate whether **3a** could bridge two identical metal centres and accordingly prepared the digold(I) compound **10** from 2 AuCl(tht) and 1 equiv. of **3a** in $CH_2Cl_2$. The ambient temperature $^{31}P\{^1H\}$ NMR spectrum of **10** in $CDCl_3$ revealed two broad resonances around $\delta$(P) 15 ppm which sharpened upon cooling to –50 °C (Figure 10). The close similarity of both phosphorus signals makes assignment of these somewhat speculative. The

downfield resonance at $\delta$(P) 14 ppm is tentatively assigned to the $-PPh_2(AuCl)$ bonded metal centre by analogy with $PhN(CH_2PPh_2AuCl)_2$ which has recently been reported.[4]

## Conclusions

In summary, we have developed a facile method for the synthesis of two nonsymmetric ditertiary phosphanes bearing one bulky substituent on phosphorus. This procedure is potentially a valuable synthetic route to highly modular nonsymmetric diphosphanes with tuneable stereoelectronic properties. Whilst $\kappa^2$-*P,P′*-chelation is observed upon complexation to square-planar metal centres we have shown the ability of one of these ligands to function as a $\kappa^1$-*P*-monodentate tertiary phosphane. Coordination to a second, different metal, affords new examples of late transition metal heterobimetallic compounds bridged by the phosphane **3a**. This clearly illustrates the importance of steric effects on phosphorus and how this can be implemented in directing variable ligating modes. Our work should be contrasted with that of others who have shown that dppp can readily act as a bridging ligand affording symmetric dinuclear complexes based on e. g. Mo,[43] Ru,[44] Ir,[45] Ni,[46] Pd[47] and Au[48] metal fragments. However, crystallographic examples where dppp bridges two different metal sites are extremely scarce.[45b] Dinuclear Rh/Au complexes[49] have recently been reported using $\kappa^3$-*PN*$_2$-bridged pyridylphosphanes whilst $\{Ph_2PCH_2\}_2PPh$ has been used to generate, amongst others, cationic Ru/Rh and Ru/Ag heteronuclear complexes.[50,51] Further studies are in progress and will be reported in due course.

## Experimental Section

**Materials:** Standard Schlenk techniques were used for the synthesis of **1**, **2a**, **2b**, **3a** and **3b** whilst all other reactions were carried out in air using previously distilled solvents unless otherwise stated. (Diphenylphosphanyl)methanol[52] and the metal complexes AuCl(tht) (tht = tetrahydrothiophene),[53] $\{RuCl_2(\eta^6\text{-}p\text{-cym})\}_2$,[54] $\{IrCl_2(\eta^5\text{-Cp*})\}_2$ (Cp* = 1,2,3,4,5-pentamethylcyclopentadienyl),[55] $MCl_2$(cod) (M = Pd, Pt)[56] and $\{Pd(\kappa^2\text{-}C,N\text{-}C_{16}H_{16}N)Br\}_2$[34] were prepared according to known procedures. All other chemicals were obtained from commercial suppliers and used directly without further purification.

**Instrumentation:** Infrared spectra were recorded as KBr pellets in the range 4000–200 $cm^{-1}$ with a Perkin–Elmer System 2000 Fourier-transform spectrometer, $^1H$ NMR spectra (400 MHz) with a Bruker DPX-400 FT spectrometer with chemical shifts ($\delta$) in ppm to high frequency of $SiMe_4$ and coupling constants ($J$) in Hz, $^{31}P\{^1H\}$ NMR spectra (162 MHz) were recorded with a Bruker DPX-400 FT spectrometer with chemical shifts ($\delta$) in ppm to high frequency of 85% $H_3PO_4$. All NMR spectra were measured in $CDCl_3$ unless otherwise stated. Elemental analyses (Perkin–Elmer 2400 CHN or Exeter Analytical, Inc. CE-440 Elemental Analyzers) were performed by the Loughborough University Analytical Service within the Department of Chemistry.

**Preparation of 1:** 1,3,5,7-Tetramethyl-2,4,8-trioxa-6-phosphaadamantane (0.649 g, 2.91 mmol) and $(CH_2O)_n$ (0.096 g, 3.20 mmol) were heated at 110 °C for 90 min affording a yellow oil which was used directly in subsequent condensation reactions. Compound **1** slowly crystallises upon standing in a freezer. Routinely the purity of **1** was shown, by $^{31}P\{^1H\}$ NMR, to be ca. 85%. $^1H$ NMR ($CDCl_3$): $\delta$ = 4.06 (m, $CH_2$), 2.45 (s, OH), 1.97–1.35 (m, Ad cage) ppm.

**Preparation of 2a:** A solution of $C_6H_5NH_2$ (5.561 g, 59.7 mmol) in methanol (HPLC grade, 35 mL) was added to a methanol (HPLC grade, 35 mL) solution of **1** (2.714 g, 9.37 mmol) by cannula. The resulting mixture was stirred for 17 h and then concentrated under reduced pressure to ca. 10 mL. The solid was collected by suction filtration and dried in vacuo. Yield: 2.455 g, 84%. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.16–6.58 (m, arom. H), 3.85 (NH), 3.43 (dd, $J$ = 12 Hz, 1.6 Hz, $CH_2$), 2.91 (dd, $J$ = 13 Hz, 3.2 Hz, $CH_2$), 1.92–1.30 (m, Ad cage) ppm. $C_{17}H_{24}NO_3P$ (321.37): calcd. C 63.54, H 7.53, N 4.36; found C 63.05, H 7.52, N 4.30. This procedure was also used for the preparation of **2b** albeit in lower yield (53%). For **2b:** $^1H$ NMR ($CDCl_3$): $\delta$ = 7.01 (d, $J$ = 8 Hz, arom. H), 6.60 (d, $J$ = 8.4 Hz, arom. H), 3.90 (NH), 3.48 (dd, $J$ = 13 Hz, 1.4 Hz, $CH_2$), 2.96 (dd, $J$ = 13.2 Hz, 3.2 Hz, $CH_2$), 2.25 ($CH_3$), 1.98–1.33 (m, Ad cage) ppm. $C_{18}H_{26}NO_3P$ (335.4): calcd. C 64.46, H 7.81, N 4.18; found C 64.37, H 7.79, N 4.26.

**Preparation of 3a:** A solution of $Ph_2PCH_2OH$ (0.245 g, 0.906 mmol) in methanol (HPLC grade, 5 mL) was added to a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

methanol (HPLC grade, 5 mL) suspension of **2** (0.327 g, 0.906 mmol) by cannula. The mixture was stirred for 24 h and the solid **3a** collected by suction filtration and dried in vacuo. Yield: 0.412 g, 87%. For **3a**, $^1$H NMR ($CDCl_3$): $\delta$ = 7.38–6.72 (m, arom. H), 4.33–4.11 (m, $CH_2$), 3.56 (d, $J$ = 14.4 Hz, $CH_2$), 3.10 (dd, $J$ = 14.4 Hz, 5.2 Hz, $CH_2$), 1.88–1.08 (m, Ad cage) ppm. This procedure was also used for the preparation of **3b** (85%). The purity of **3a** (and **3b**) were shown, by $^{31}P\{^1H\}$ NMR, to be ca. 75–80%. For **3b**, $^1$H NMR ($CDCl_3$): $\delta$ = 7.44–7.24 (m, arom. H), 6.97 (d, $J$ = 8.4 Hz, arom. H), 6.76 (d, $J$ = 8.8 Hz, arom. H), 4.26–4.13 (m, $CH_2$), 3.53 (d, $J$ = 14.4 Hz, $CH_2$), 3.10 (dd, $J$ = 14.6 Hz, 5 Hz, $CH_2$), 2.19 ($CH_3$), 1.83–1.02 (m, Ad cage) ppm. All efforts to obtain analytical samples of **3a** (and **3b**) have so far been unsuccessful.

**Preparation of 4:** A mixture of **2a** (0.071 g, 0.221 mmol) and $\{Pd(\kappa^2\text{-}C,N\text{-}C_{16}H_{16}N)Br\}_2$ (0.090 g, 0.110 mmol) in HPLC grade acetone (10 mL) were refluxed for 75 min. After cooling the solution was concentrated under reduced pressure to ca. 2–3 mL and diethyl ether (10 mL)/hexanes (10 mL) added. The solid was collected by suction filtration and dried in vacuo. Yield: 0.113 g, 70%. $^1$H NMR ($CDCl_3$): $\delta$ = 8.22 (d, $J$ = 12.4 Hz, CH=N), 7.67–6.43 (arom. H), 4.70 (NH), 4.23 (d, $J$ = 12.8 Hz, $CH_2$), 3.77–3.63 (m, $CH_2$), 2.43 and 2.24 ($CH_3$), 2.41–1.46 (m, Ad cage) ppm. $C_{33}H_{37}BrN_2O_3PPd$ (726.99): calcd. C 54.52, H 5.13, N 3.85; found C 54.09, H 5.47, N 3.77.

**Preparation of 5a: 3a** (0.119 g, 0.192 mmol) was added as a solid to a $CH_2Cl_2$ (10 mL) solution of $PtCl_2$(cod) (0.072 g, 0.192 mmol). The solution was stirred for 2.5 h and then concentrated to ca. 1–2 mL under reduced pressure. Addition of diethyl ether (20 mL) afforded a solid which was collected by suction filtration and dried in vacuo. Yield: 0.129 g, 85%. $C_{30}H_{35}Cl_2NO_3P_2Pt\cdot 0.5CH_2Cl_2$ (828.04): calcd. C 44.24, H 4.38, N 1.69; found C 43.94, H 3.89, N 2.04. A similar procedure was also used for the preparation of **5b** (92%). $^1$H NMR ($CDCl_3$): $\delta$ = 8.02–7.31 (m, arom. H), 7.04 (d, $J$ = 8.4 Hz, arom. H), 6.80 (d, $J$ = 8.8 Hz, arom. H), 4.27–4.09 (m, $CH_2$), 3.47–3.23 (m, $CH_2$), 2.23 ($CH_3$), 1.76–1.19 (m, Ad cage) ppm. $C_{31}H_{37}Cl_2NO_3P_2Pt\cdot CH_2Cl_2$ (884.53): calcd. C 43.44, H 4.44, N 1.58; found C 42.94, H 4.03, N 1.49. The dichloropalladium(II) complexes **5c** (from **3a**) and **5d** (from **3b**) were prepared in 98% and 92% yields respectively. For **5c:** $C_{30}H_{35}Cl_2NO_3P_2Pd\cdot 0.75CH_2Cl_2$ (760.61): calcd. C 48.56, H 4.84, N 1.84; found C 48.84, H 4.48, N 1.57. For **5d**, $^1$H NMR ($CDCl_3$): $\delta$ = 7.97–7.33 (m, arom. H), 7.04 (d, $J$ = 8 Hz, arom. H), 6.76 (d, $J$ = 8 Hz, arom. H), 4.11–4.03 and 3.52–3.22 (m, $CH_2$), 2.23 ($CH_3$), 1.81–1.27 (m, Ad cage) ppm. $C_{31}H_{37}Cl_2NO_3P_2Pd\cdot 2.5CH_2Cl_2$ (923.27): calcd. C 43.58, H 4.59, N 1.52; found C 43.09, H 4.24, N 1.71.

**Preparation of 6: 3a** (0.098 g, 0.151 mmol) was added as a solid to a $CH_2Cl_2$ (10 mL) solution of $\{RuCl_2(\eta^6\text{-}p\text{-cym})\}_2$ (0.046 g, 0.075 mmol). The solution was stirred for 45 min and then concentrated to ca. 1–2 mL under reduced pressure. Addition of diethyl ether (25 mL) and hexane (25 mL) afforded a red/orange solid which was collected by suction filtration and dried in vacuo. Yield: 0.078 g, 63%. $C_{40}H_{49}Cl_2NO_3P_2Ru\cdot 0.25CH_2Cl_2$ (847.03): calcd. C 57.07, H 5.89, N 1.65; found C 56.97, H 6.27, N 1.66. A similar procedure was also used for the preparation of the iridium(III) complex **7** (96%). For **7**, $^1$H NMR ($CDCl_3$): $\delta$ = 7.86–6.36 (m, arom. H), 5.26 (d, $J$ = 4 Hz, $CH_2$) and 5.08 (d, $J$ = 16 Hz, $CH_2$), 2.98 (dd, $J$ = 15.2 Hz, 4.4 Hz, $CH_2$) and 2.71 (d, $J$ = 15.2 Hz, $CH_2$), 1.79–1.11 (m, Ad cage), 1.28 (d, $J$ = 2 Hz, Cp*) ppm. $C_{40}H_{50}Cl_2IrNO_3P_2\cdot 4.5CH_2Cl_2$ (1300.26): calcd. C 41.11, H 4.57, N 1.08; found C 40.78, H 4.41, N 1.02.

**Preparation of 8:** AuCl(tht) (0.016 g, 0.050 mmol) was added as a solid to a $CH_2Cl_2$ (10 mL) solution of **6** (0.055 g, 0.050 mmol). The solution was stirred for 45 min and then concentrated to ca. 1–2 mL under reduced pressure. Addition of diethyl ether (25 mL) and hexane (25 mL) afforded a red/orange solid which was collected by suction filtration and dried in vacuo. Yield: 0.049 g, 93%. For **8**, $C_{40}H_{49}AuCl_3NO_3P_2Ru$ (1058.22): calcd. C 45.40, H 4.67, N 1.32; found C 46.26, H 4.48, N 1.06. A similar procedure was also used for the preparation of the iridium(III) complex **9** (77%). For **9**, $^1$H NMR ($CDCl_3$): $\delta$ = 7.89–6.45 (m, arom. H), 5.26 (d, $J$ = 16.8 Hz, $CH_2$) and 4.95 (d, $J$ = 16 Hz, $CH_2$), 3.56 (d, $J$ = 16 Hz, $CH_2$) and 3.30 (dd, $J$ = 15.8 Hz, 4.2 Hz, $CH_2$), 2.19–1.10 (m, Ad cage), 1.28 (d, $J$ = 2 Hz, Cp*) ppm. $C_{40}H_{50}AuCl_3IrNO_3P_2$ (1150.36): calcd. C 41.77, H 4.38, N 1.22; found C 41.69, H 4.17, N 1.20.

**Preparation of 10: 3a** (75% purity, 0.117 g, 0.164 mmol) was added as a solid to a $CH_2Cl_2$ (10 mL) solution of AuCl(tht) (0.105 g, 0.328 mmol). The solution was stirred for 45 min in the dark and then concentrated to ca. 1–2 mL under reduced pressure. Addition of diethyl ether (25 mL) and hexane (25 mL) afforded solid **10** which was collected by suction filtration and dried in vacuo. Yield: 0.135 g, 84%. $C_{30}H_{35}Au_2Cl_2NO_3P_2\cdot 0.75C_6H_{14}$ (1049.08): calcd. C 39.50, H 4.37, N 1.34; found C 39.25, H 3.76, N 1.55.

**X-ray Crystallography:** Vapour diffusion of diethyl ether into an acetone solution (for **4**) or $CDCl_3$ solutions (for **5a** or **5b**) over several days afforded suitable X-ray quality crystals. Compound **9** was obtained by slow diffusion of petroleum ether (b.p. 60–80 °C) into a $CDCl_3$ solution whereas slow diffusion of hexane into a $CH_2Cl_2$ solution gave suitable crystals of compound **6**. Compound **2a** was obtained upon allowing a $CH_3OH$ filtrate to stand for several days. Compounds **7** and **8** were obtained by slow evaporation to dryness of a $CH_2Cl_2$/petroleum ether (b.p. 60–80 °C) or $CHCl_3$/hexane solution respectively. Details for the crystal data of **2a** and **4**–**9** and a summary of data collection parameters are given in Table 5 and Table 6.

Measurements were made with either a Bruker AXS SMART 1000 CCD area-detector diffractometer[57] for **2a**, **4**, **5a**, **5b** and **8** using sealed-tube graphite-monochromated Mo-$K_\alpha$ radiation and narrow frame exposures (0.3°) in $\omega$ or a Bruker-Nonius 95 mm CCD kappa diffractometer[58,59] equipped with a rotating anode generator for **6**, **7** and **9**. Cell parameters were refined from the observed $\omega$ angles of all strong reflections in each data set. Intensities were corrected semiempirically for absorption, on the basis of symmetry-equivalent and repeated reflections. The structures were solved by direct methods (Patterson synthesis for **5a**, **5b**, **8** and **9**), and refined on $F^2$ values for all unique data by full-matrix least-squares.[60] Tables 5 and 6 give further details. All non-hydrogen atoms were refined anisotropically. For **5b** a molecule of $Et_2O$ is badly disordered over an inversion centre while in **7** there is a disordered molecule of $CH_2Cl_2$ in a general position; these were modelled by the Platon Squeeze procedure.[61] In **6** a molecule of $CH_2Cl_2$ is disordered over an inversion centre. In **8** a molecule of $CHCl_3$ was disordered with the three Cl atoms split over two sets of positions, the major sites occupied 72.1(3)%. The disorder in **6** and **8** was modelled with restraints applied to assist geometry and anisotropic displacement parameters.

CCDC-629342 to -629349 (for compounds **2a**, **4** and **5a**–**9**) contain the the complete set of X-ray crystallographic structural data. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. at the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44-1223-336-033; E-mail: deposit@ccdc.ac.uk) on request, quoting the deposition numbers.

## Acknowledgments

We thank the EPSRC, Sasol Technology (Pty) Ltd. and Loughborough University for studentships. We are grateful to Cytec Canada Inc. for the kind donation of the secondary cage phosphane used in this work and to Johnson-Matthey for their loan of precious metals. The EPSRC Mass Spectrometry Service centre at Swansea are also acknowledged. The EPSRC X-ray service at Southampton are gratefully acknowledged for the data collection for compounds **6**, **7** and **9**. Finally we thank Dr Mark Edgar for acquiring the variable-temperature NMR spectra for compound **10**.

# Tungsten Oxide and Tungsten Oxide-Titania Thin Films Prepared by Aerosol-Assisted Deposition – Use of Preformed Solid Nanoparticles

**Uzma Qureshi,[a] Christopher Blackman,[a] Geoffrey Hyett,[a] and Ivan P. Parkin*[a]**

**Keywords:** Tungsten oxide / Aerosol-assisted CVD / Thin films

Aerosol-assisted deposition (AAD) was used to deposit films of $WO_3$ from a suspension of solid nanoparticulate $WO_3$ in toluene. Titania films were deposited by the aerosol-assisted chemical vapour deposition of $[Ti(OiPr)_4]$ in the presence of $WO_3$ nanoparticles. The $WO_3$ and $TiO_2$ films exhibited photoactivity and photoinduced superhydrophilicity, further the titania films showed very unusual highly crenulated microstructures. These microstructures could not be obtained by sol-gel, atmospheric pressure chemical vapour deposition or evaporation routes. Furthermore, the microstructures could not be obtained from $[Ti(OiPr)_4]$ in the absence of nanoparticulate $WO_3$.

## Introduction

Nanoparticles are a major research interest worldwide, and a variety of different shapes and compositions can now be produced.[1,2] Many potential applications depend on formation of a nanocomposite, which serves both to immobilise the particles and render them chemically inert. In addition, the incorporation of nanoparticles into a matrix can change the properties of both the particle and the host. One area that has gained rapid attention is the growth of nanoparticles within a host film.[3–10] The presence of nanoparticles can assist in photogenerated charge separation, and this has been exploited in improved titania photocatalysts,[3,11,12] iron oxide photoanodes,[13] and tungsten oxide photochromic and electrochromic films,[14,15] all with incorporated gold nanoparticles.

Several strategies for production of nanoparticles within a host matrix have been devised including; synthesis of the semiconductor matrix followed by addition of pre-formed nanoparticles in a second step.[3,14–16] synthesis of the semiconductor matrix followed by application of metal ions in a second step; high energy ion implantation[6,17,18] and spin coating with a solution of metal ions followed by photocatalytic reduction or heat treatment[8,19] and synthesis of the semiconductor matrix and metal particles in a single step.[13,20,21] In all of these routes the nanoparticle is either used in a charged charge-stabilised or ligand-stabilised form dissolved in solution or generated in situ.[22] Furthermore, the use of a bulk nanoparticulate powder in forming thin films has not been investigated.

The physical state and composition of a precursor are critical in determining the quality of a thin film. In both physical vapour deposition (PVD) and chemical vapour deposition the precursor is transported through a vacuum or gas medium in the form of reactive atoms or molecular entities. These then undergo various surface reactions to form the desired film. The precursors are typically metal or ceramic tablets in the case of PVD, or volatile molecular entities in the case of CVD. On occasions the CVD process has been modified so that molecular precursors that are involatile or that undergo too ready a decomposition are first dissolved in an aerosol, and the aerosol is used as the transport medium to deliver the precursor to the substrate surface. Much work in this area has been pioneered by O'Brien.[23] Preformed bulk solids, suspended in a solution, have not been used in aerosol-assisted chemical vapour deposition. The use of solid particles to form thin films is however well known in a number of processes, in particular cold-spraying, plasma-spraying and thermal-spraying.[24] In these techniques either the solid particles are fired at very high kinetic energies at the surface, normally by a plasma-jet and a coating is formed by "splatting" of the solid on the surface or hybrid thermal-spraying is used in which some movement or reaction of the particles occurs on the surface.[24–26] One very new and emerging area of spraying technology is the use of suspension plasma spraying (SPS), using d.c. or R.F. plasma spray torches, in which powder particles are injected into the plasma flow using a liquid as carrier media, instead of the classical carrier gas.[26] This new approach offers unique possibilities to carry nanosized particles to manufacture finely grained coatings.

This paper details the preparation of $WO_3$ thin films from preformed commercially available solid nanoparticulate $WO_3$ using aerosol-assisted transport. These solid nanoparticles were used in a conventional CVD experiment using an aerosol as a carrier medium. Parallels to spray coating exist except that a high velocity gas stream or reactive plasma was not required. A separate set of experiments

[a] Department of Chemistry, University College London, 20 Gordon Street, London, WC1H OAJ, UK

investigated what happened when the $WO_3$ nanoparticles were added to a titanium dioxide AACVD precursor, which was then used to deposit thin films with small tungsten contents but greatly ordered titania microstructures. This work shows that solid nanoparticles can be used and transformed into an adhesive thin film provided that they can be dissolved/suspended in an appropriate carrier solvent and without the use of plasma spraying or high velocity "splatting". Furthermore, these nanoparticulates may act as templates to influence the production of highly unusual microstructures from traditional CVD precursors.

## Results and Discussion

### Preparation of $WO_3$ Thin Films by Aerosol Transport from Solid Nanoparticulate $WO_3$

Tungsten oxide thin films were prepared on glass from the aerosol-assisted deposition (AAD) of commercial nanoparticulate tungsten oxide powder. The films were uniform and pale yellow in colour. They covered the glass substrate. The films passed the Scotch tape test, were adhesive, could not be wiped off but could be scratched with both a brass and steel stylus. Interestingly all of the deposition was on the top substrate plate rather than the heated bottom plate (even with lower substrate temperatures). We have prepared tungsten oxide films by conventional atmospheric pressure chemical vapour deposition, film formation is then on the heated substrate. The films formed previously by conventional APCVD or reported here by aerosol-assisted AAD show similar properties except that by conventional CVD formation of substochiometric $WO_{3-x}$ is an issue.[18]

X-ray powder diffraction of the tungsten oxide films showed that the material was crystalline (Figure 1) with the fully stoichiometric triclinic $WO_3$ structure. This matched exactly by eye the diffraction pattern of the initial powder although perhaps some slight grain growth occurred. The indexed cell constants (from Reitveld analysis[29]) for the starting nanoparticulate powder were $a$ = 7.285(1) Å, $b$ = 7.488(1) Å, $c$ = 7.650(1) Å; $\alpha$ = 89.57(3)°, $\beta$ = 90.18(4)°, $\gamma$ = 90.81(1)° and for the thin film $a$ = 7.321(1) Å, $b$ = 7.525(1) Å, $c$ = 7.683(2) Å; $\alpha$ = 89.58(3)°, $\beta$ = 90.18(1)°, $\gamma$ = 90.78(1)°. These cell constants compare very favourably with those obtained on triclinic $WO_3$ by Woodward et. al.[20] $a$ = 7.312(1) Å, $b$ = 7.525(1) Å, $c$ = 7.689(1) Å; $\alpha$ = 88.847(3)°, $\beta$ = 90.192(4)°, $\gamma$ = 90.94(1)°. The X-ray pattern of the thin film indicates that there is no significant preferred orientation of the crystallites on the surface. This is completely different to conventional atmospheric pressure CVD and aerosol-assisted CVD approaches to tungsten oxide on glass where preferred orientation in the (020) direction predominated.[28] Average crystallite sizes as determined by XRD line broadening using the Scherrer equation (GSAS) were 199(2) Å for the starting powder as and 227(2) Å for the thin film.[29] This indicates some slight grain growth or selective deposition of the slightly larger grains within the weighted average crystallite size.

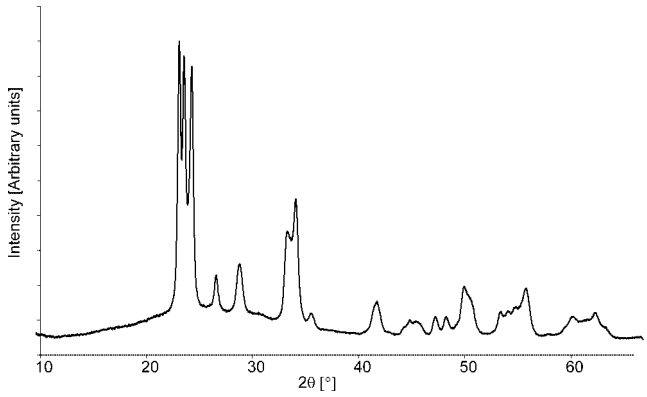

Figure 1. X-ray powder diffraction pattern of the $WO_3$ films formed at 450 °C by the aerosol-assisted deposition of nanoparticulate $WO_3$ suspended in toluene.

Scanning electron microscopy of the tungsten oxide thin films showed a dense continuous film made up of interlocking particles of approximate size 20–50 nm, Figure 2. EDX analysis showed that the films contained only tungsten and oxygen in a 1:3 ratio. The initial tungsten oxide powder was examined by TEM before the aerosol-assisted process. The powder was made up of agglomerates, however a number of small isolated $WO_3$ particles of size 15–20 nm could be seen. The Raman pattern for the as formed $WO_3$ film is identical to the starting material and is a perfect match for triclinic $WO_3$.[21]

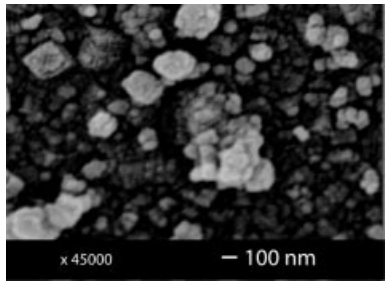

Figure 2. Scanning electron micrograph of the $WO_3$ films formed at 450 °C by the aerosol-assisted deposition of nanoparticulate $WO_3$ suspended in toluene.

The tungsten oxide films displayed two useful functional properties – they were active photocatalysts and they showed photoinduced superhydrophilicity. The contact angle for water droplets on the tungsten oxide thin films was very low – between 3–7°, indicating that the surface is very hydrophilic. This contact angle dropped further to between 0.5–2° on exposure of the surface for 0.5 h to 254-nm radiation. On keeping the samples in the dark for 24 h the contact angle increased to 7–8°, and on further irradiation decreased again to between 0.5–2°. The reversible change in contact angle with light/dark storage has been observed before for $TiO_2$ films.[31] The explanation was that in the light $Ti^{III}$ hydroxide centres are created at the surface which strongly hydrogen bond water and hence reduce the contact angle. A slower oxidative process reverts the $Ti^{III}$ to $Ti^{IV}$ with release of water and loss of the hydroxy groups. In the dark formation of $Ti^{IV}$ predominates as there is no light to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

promote $Ti^{III}$ formation, and the films become less hydrophilic. The same behaviour could be responsible for what is seen for the tungsten oxide films with formation of a hydroxylated surface in the light and its subsequent loss on oxidation in the dark. A slight colour change was noted between the films kept in the dark which were pale yellow, and those exposed to light which were slightly darker, this could indicate some $W^{V}$ centre formation. The observed water contact angles of the $WO_3$ films are lower – that is the films are more hydrophilic than $WO_3$ made by APCVD and AACVD using traditional soluble molecular precursors.[32] This change in contact angle with time was repeated over many light-dark cycles. The very low initial contact angle puts these films in the class of superhydrophilic films and gives lower measurements to that of titanium dioxide thin films formed from sol-gel or CVD. The contact angle is probably a consequence of the surface being both partially hydroxylated and hence able to hydrogen bond effectively to the water, and having high porosity engendered by having a very fine microstructural form of nanoscaled particles. The $WO_3$ films readily destroyed a stearic acid overlayer and did so with both 254 and 365 nm irradiation, rates of destruction ($1.5 \times 10^{12}$ molecules $cm^{-2}min^{-1}$ for 254 nm) were similar to previously reported CVD prepared $WO_3$ and $TiO_2$ thin films.[30,32,33]

The aerosol transport method provides a ready means of forming thin films from a solid and completely involatile precursor. The fact that the initial tungsten oxide powder was made of nanoparticles probably helped suspension into the toluene solution and facilitated transport of the nanoparticulate solid to the substrate where the aerosol evaporated; and a thin film was laid down on the upper substrate. Notably the initial nanoparticle crystallite sizes (15–20 nm) are considerably smaller than the aerosol droplets (20 μm). The films formed, however, did seem to be composed of nanoparticulates as judged by SEM, although some agglomeration was noted. There seems to have been some sintering and partial crystal growth during the aerosol-assisted transport and deposition. Notably the large agglomerates (micron sized) that were observed in the initial starting powder were not seen in the thin films. Furthermore, these agglomerates did not dissolve in the initial precursor solution and were not found in the reactor flask after the deposition. Some evidence of larger agglomerates was seen in the exhaust of the reactor. Hence in this system we believe that the initial powder gets effectively transferred in the aerosol process. The film that is formed is on the top plate of the reactor and is composed of only relatively small nanoparticulates that are interlocked together – rather than the agglomerated particles seen by TEM in the initial starting powder. The best explanation for this is the thermophoretic effect. Large particles can not diffuse through the stagnant boundary layer effectively due to a buoyancy effect where faster moving gas particles are moving away from the hot surface preventing deposition on the bottom substrate. The cooler top plate is not directly heated making it easier for the smaller particles to penetrate the boundary layer. Hence in the process a degree of nanoscale sieving has occurred. The smaller nanoparticles can be incorporated in a film whilst the larger aggregated ones are repelled and exit to the exhaust.

We have shown that solid nanoparticulate starting materials, provided they can be suspended/dissolved in an appropriate solvent, do make useful precursors for the formation of thin films. This process has not been termed CVD as such as no overriding chemical reaction seems to have occurred, the initial material and final material were very similar by XRD, save some possible grain growth. However some interaction and bonding has occurred between the underlying substrate and the particles as the film is adhesive. The new deposition method developed here is similar to suspension plasma spraying of nanoparticles,[26] but avoids the use of a plasma and a high velocity stream, and hence is much simpler to use and operate.

A comparison was made between the aerosol-assisted process described above and using a spin coating or evaporation technique using the same $WO_3$/toluene nanoparticulate suspension. The films formed by spin coating both before and after firing were nonadhesive and powdery. The SEM of the films are very similar to those formed by AAD with particles matching those seen in the AACVD experiments. However, an important difference is that these films failed the Scotch tape test, and could be wiped off with a tissue, unlike those formed in the AAD process.

### Preparation of Titania Films in the Presence of Tungsten Oxide Nanoparticles

Aerosol-assisted chemical vapour deposition of anatase titania was accomplished from $[Ti(OiPr)_4]$ dissolved in toluene at a deposition temperature of 450 °C in the presence of tungsten oxide nanoparticles. The films of $TiO_2$ formed in the presence of $WO_3$ nanoparticles were generally a very pale yellow-beige – compared to the colourless or white films formed from $[Ti(OiPr)_4]$ alone. Some "rainbow-like" interference fringes could be seen in reflection at the edges of the film due to variations in thickness. The films passed the Scotch tape test and were resistant to wiping but could be scratched with a brass scalpel. They showed minimal specular haze assessed as 2%. The films showed good transmission between 50 and 60% in the visible region. The films formed both on the heated substrate and the top plate – unlike the $WO_3$ nanoparticle experiments where the film was only on the unheated top plate. The same microstructures and analysis were seen for both top and substrate plates.

Wide-area EDAX analysis showed that the films were made up of titanium and oxygen with just a trace of tungsten present (detectable but less than 1 atom% – and so not directly quantifiable). SEM imaging showed a plate-like morphology oriented perpendicular to the substrate of dimension ca 500 nm by 10 nm and underlying plates in a seemingly "wedding cake" structure, Figure 3. This microstructure is to the best of our knowledge unique for a titania film – and was repeatable in over five separate repeat

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

experiments. Indeed each particle seemed to have the self-same highly structured shape and were arranged as if in a mosaic pattern across the surface made up of a similar repeating units. High resolution SEM or spot EDAX analysis did not find any tungsten oxide particles. Previous work on titania by AACVD and APCVD on glass and indeed deposition of $TiO_2$ from $[Ti(OiPr)_4]$ from this work has always formed a smooth continuous film or a random island-like growth.[30] Hence as all other factors were the same the presence of the tungsten nanoparticles is the most likely cause of this unique surface architecture. Side-on SEM images allowed the determination of the film thickness and hence the growth rate of the films. It was found that the film thickness was 7–10 μm depending on the film sample analysed. The growth rate was calculated to be 3.5–10 μm per hour.

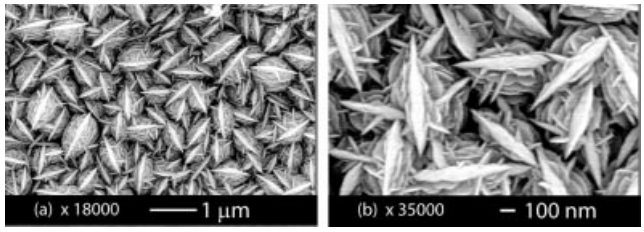

Figure 3. Scanning electron micrograph of the $TiO_2$ films formed at 450 °C by the aerosol-assisted deposition of $[Ti(OiPr)_4]$ in the presence of nanoparticulate $WO_3$: a) at 18000 times magnification; and b) at 35000 times magnification.

The thin film of $TiO_2$ deposited with $WO_3$ nanoparticles was investigated using powder X-ray diffraction, and then modelled using Rietveld refinement.[28] The pattern was found to be well modelled by the anatase phase of $TiO_2$ [$I4_1/amd$, $a$ = 3.7804(3) Å, $c$ = 9.500(2) Å], once the lattice and peak profile parameters were refined and preferred orientation taken into account (See Figure 4 and Figure 5). The preferred orientation was modelled using the March–Dollase model.[34] A good match to the recorded data was found when the 110 plane was used as the preferred plane with a March coefficient of $r$ = 0.542(2), a measure of the sample compression/elongation due to preferred orientation. As the SEM images indicate the crystallites are plate-like (rather than rod-like) then, as the value of $r$ is less than 1, we can conclude that the crystals are preferentially aligned so that the 110 plane is parallel to the deposition surface.[30]

Additional peaks were also found in the pattern for the part of the film that was 5 cm from the reactor inlet (marked with *asterisks* in Figure 5). These could be indexed as belonging to a cubic cell with lattice parameter $a$ = 5.646 Å and systematic absences consistent with face-centred symmetry. These peaks were of much lower intensity than those corresponding to $TiO_2$, suggesting that this phase is present only in small amounts. A search of the inorganic crystal structure database was conducted to identify this phase, but no reasonable match could be found.

The Raman patterns for the titania films (recorded at multiple points across the films surface) showed the expected bands for anatase with bands at 143, 396, 515 and 612 $cm^{-1}$, no evidence was seen for any tungsten oxide phase at any part of the deposited film.

The titania films were very hydrophilic as formed. Typical initial water droplet contact angles were around 5–10°, this is smaller than that found for a typical titania coating formed by CVD which gave initial water contact angles of ca 30°.[32,33] This difference in contact angle can be attributed to the microstructure seen from the SEM measurements. The films exhibited photo-induced superhydrophilicity. The films were also photocatalytically active showing ready destruction of a stearic acid over-layer with both 254 and 365 nm radiation and were comparable in photodegradation ability to previously analysed sol-gel and CVD prepared titania.[35] Using 254-nm light half of the stearic acid coating was removed in 1.2 h ($4 \times 10^{12}$ mole-

Diffraction data shown by crosses, upper continuous line is the refined model, and lower line is the difference plot. The lower set of tick marks correspond to the $TiO_2$ main phase. The higher set of tick marks are the indexed second phase (*F* cubic, $a$ = 5.646 Å), these peaks are also marked by asterisks. Pattern was obtained from the surface 5 cm away from the reactor inlet.

cules cm$^2$ min$^{-1}$ for 254 nm) compared to 2.2 h for a comparable 365-nm source.

As a comparison to the films formed by AACVD the same $WO_3$ nanoparticulate-[Ti(O*i*Pr)$_4$] precursor solution was used to make sol-gel dip-coated films (Figure 6). The reason for this study was to see whether the unusual microstructure would follow in films made from the same precursor solution – but processed in a different way. By using the sol-gel process a nonadhesive, pale yellow, powdery film resulted. This was unlike those formed by AAD that adhered well to the substrate. Furthermore, the SEM of the films showed a particulate microstructure. Hence the fine structure seen in the AAD route was not in evidence and indicates the uniqueness of that approach in controlling – influencing the underlying microstructure. This microstructure gave rise to an important functional property – a very low water contact, much lower than that seen in conventional titania films formed by APCVD, AACVD or sol-gel methods. The unusual microstructure with the crenulated surface texture is most likely responsible for this low value. The ability to have very low contact angles for water is an important criteria for self-cleaning applications for example on windows. Indeed a number of commercial products (Pilkington Activ, Saint Goban Bioclean and PPG sunclean) all make use of this phenomena. The contact angles seen in this work for the structured films are lower than those reported for the commercial products – which typically have values around 10°. One counter point is that the microstructure induces more diffuse specular reflectance (haze) of around 2% compared to commercial windows that have a value of less than 0.2%.

The role of the tungsten oxide nanoparticles in engendering the unusual microstructures has not been fully elucidated in this work. The tungsten oxide obviously plays a major role because in its absence the films of titania formed are continuous and lack the self-similarity across the surface. Tungsten has been detected in the films albeit at ca 1 atom% level. This tungsten has not been seen as individual nanoparticles and spot EDAX analysis can find no evidence of localised high tungsten concentrations. It is possible that some tungsten has been incorporated in the titania lattice in the form of a solid solution- however the Raman and XRD provide no evidence for this in terms of changes in peak position or lattice parameter. The presence of a small amount of secondary phase in the XRD pattern suggests that this could be playing a structurally directing role. The phase is present at only a percent and although few peaks are seen it does match well for a cubic cell.

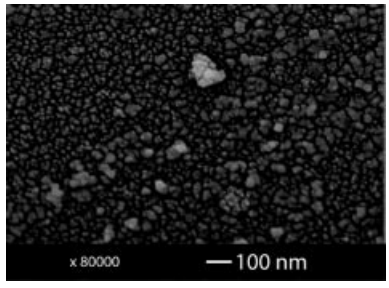

Figure 6. SEM of the $WO_3$–$TiO_2$ film formed by sol-gel dip coating followed by firing at 550 °C.

We have previously reported on the use of preformed – soluble ionic nanoparticles for the formation of composite thin films.[36] In that case gold nanoparticles were generated and then encapsulated in a titania or tungsten oxide matrix. That work is different to that reported here in that the nanoparticles were dissolved in solution rather than acting as a suspension. Further, the films generated did not have any unusual microstructures – the gold was simply embedded in the host matrix. Hence by using a commercial solid nanoparticulate powder we have shown that it is possible to make adherent thin films composed of nanoparticles, and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

that the presence of these particles can affect the surface morphology of titanium dioxide. The nanoparticles used in these experiments were unlike conventional methods that use nanoparticles – where they are charged or ligand stabilized.

## Conclusions

Aerosol-assisted deposition (AAD) was used to deposit $WO_3$ nanoparticle thin films from a solid nanoscaled precursor. This was a convenient method for applying thin films to glass as it provides reasonable growth rates (3–7 $\mu m\,h^{-1}$) and conformal coverage of the substrate. The films were adhesive and were superhydrophilic. This route shows promise for the formation of thin films of material from involatile nanoscaled solid precursor and is the antithesis of what would normally be required for thin film deposition – i.e. a molecular volatile precursor. Titania films formed in the presence of $WO_3$ nanoparticles form unique microstructures and exhibited two key functional properties, photocatalysis and photoinduced superhydrophilicity. The initial water contact angles of these films are considerably lower than that seen for $TiO_2$ films prepared in the absence of nanoparticles and is attributed to the "fractal-like" microstructure.

## Experimental Section

Solid $WO_3$ nanoparticles and titanium tetraisopropoxide were obtained from Aldrich and used as supplied (99% purity). The pale yellow $WO_3$ nanoparticles (typically 0.2 g, 0.862 mmol) were sonicated by an ultrasonic bath (2 h) to aid dispersion in toluene (40 mL). This produced a pale yellow solution with some undissolved solid. This solution was used as a precursor for aerosol-assisted transport to form $WO_3$ films on glass. A similar concentration solution of $WO_3$ in toluene was used to make $WO_3$–$TiO_2$ thin films – except in that case titanium isopropoxide (0.56 g, 1.972 mmol) was added to the initial precursor solution (W: Ti molar ratio 1:2.28). It should be noted that on leaving the nanoparticulate suspension to stand for 12 h the solution became colourless and by weight seemingly all of the initial particles came out of the solution.

Three series of AACVD experiments were conducted using the following starting solutions/suspensions:

i) A suspension of $WO_3$ nanoparticles (0.2 g, 0.862 mmol) in toluene (40 mL) to form $WO_3$ thin films.

ii) [Ti(O*i*Pr)$_4$] (0.56 g, 1.972 mmol) dissolved in toluene (40 mL) to form $TiO_2$ films.

iii) A mixture of suspended $WO_3$ nanoparticles (0.2 g 0.862 mmol) and [Ti(O*i*Pr)$_4$] (0.56 g, 1.972 mmol) dissolved in toluene (40 mL) to form highly ordered microstructures

All AACVD experiments were performed on a custom built apparatus consisting of a horizontal-bed cold-wall reactor connected to an arrangement of delivery tubing, a bubbler and a humidifier – full details of the reactor have been published previously.[27]

The CVD reactor itself consisted of a silica glass substrate and supported top plate in a cylindrical quartz tube. The cylindrical quartz tube was open at both ends with each end capped by a stainless steel plate. Nitrogen gas entered the system through a brass manifold, which generated an uniform flow of gas across the width of the reactor. The uniform flow then passed between the heated glass bottom plate and the unheated glass top plate that was 5 mm above the heated surface. Thus a channel is present for the gas to flow between. The glass substrates of dimensions $150 \times 45 \times 4$ mm were heated by a graphite block that contained a Whatman cartridge heater. The glass substrates (both top plate and heated bottom plate) were supplied by Pilkington Glass and were pre-coated with a $SiO_2$ barrier layer. This barrier layer prevented atoms within the glass diffusing into the deposited film.

A typical deposition experiment proceeded as follows. The precursor mixture was transferred to the aerosol chamber, a customised PTFE container. A flow of nitrogen (BOC, 99.99%) was passed through the apparatus at all times. The glass substrate was cleaned using a tissue soaked in water, then with a tissue soaked with propan-2-ol. The glass was allowed to dry in air prior to it being mounted in the CVD chamber. The temperature of the glass inside of the reactor was measured by Pt–Rh thermocouples. Depositions were conducted at 400, 450 and 500 °C. Once the temperature was stabilised, an aerosol was then generated using an ultrasonic humidifier, and nitrogen gas passed through the aerosol mist (2 $L\,min^{-1}$), directing the aerosol to the CVD reactor. The aerosol passed through the brass manifold and entered the reactor between the heated substrate and the glass top-plate, placed parallel to the substrate. Any waste products exited through the exhaust. The gas flow was continued until all the precursor mix had passed through the reactor, typically taking 1 to 2 hours depending on the gas flow rate, carbon reactor temperature and solvent. The coated films on glass were cooled to room temperature in situ under a flow of $N_2$, and after cooling were handled and stored in air.

**Spin Coating/ Evaporation Coating:** Films of $WO_3$ and $TiO_2$/$WO_3$ were made by spin and evaporation coating of the precursor solutions mentioned above (0.2 g of $WO_3$ and 0.56 g of [Ti(O*i*Pr)$_4$] in toluene (40 mL). These coatings were fired in a furnace at 550 °C for 1 hour in air. The purpose of these experiments was to explore the differences in microstructure, surface adhesion and durability of the coating compared to those formed by the AACVD route.

**Film Analysis:** X-ray diffraction patterns were measured with a Bruker GADS using Cu-$K_\alpha$ radiation ($K_{\alpha 1}$ = 1.5406 Å). The system had a focussed and movable *x*-*y* stage to analyse various portions of the film. The diffractometer used glancing incident radiation (1.5°). The diffraction patterns were modelled using the Reitveld method with the GSAS suite of programmes and were compared to database standards.[25] EDAX was obtained on a Philips XL30E-SEM instrument and SEM was obtained with a JEOL 6301 instrument. UV/Vis/NIR spectra were recorded in the range 190–1100 nm using a Helios double beam instrument. Reflectance and transmission spectra were recorded between 300 and 1200 nm by a Zeiss miniature spectrometer. Reflectance measurements were standardised relative to a rhodium mirror and transmission relative to air. Raman spectra were acquired with a Renishaw Raman System 1000 using a helium-neon laser of wavelength 632.8 nm. The Raman system was calibrated against the emission lines of neon.

The photocatalytic properties of the samples were assessed by the destruction of an overlayer of a test organic stearic acid on a $3 \times 3$ cm portion of coated glass. This coated glass had been irradiated at 254 nm for 1 h prior to measurement. The stearic acid was applied by dropping 7.5 μL of a 0.4-mmol solution of stearic acid in methanol onto the glass surface which was spun at 1500 revolutions a minute during the dropping procedure. The infrared spectra

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the stearic-acid overlayer was measured over the range 2950–2800 $cm^{-1}$. The glass coated with stearic acid was irradiated with 365-nm radiation provided by BDH germicidal lamps (2 × 8 W). The IR spectra of the stearic acid was measured after 30 min intervals for up to 2 h and the areas of the bands that attributed to the C–H stretches were quantified.

The advancing water contact angles were determined by measuring the width of a known volume of water (1 μL) with a travelling microscope and then entering the spread into a simple trigonometric program.

# Luminescent and Electronic Properties of Stilbenoid NCN-Pincer $Pt^{II}$ Compounds

**Guido D. Batema,[a] Koen T. L. van de Westelaken,[a] Javier Guerra,[a] Martin Lutz,[b] Anthony L. Spek,[b] Cornelis A. van Walree,[a] Celso de Mello Donegá,[c] Andries Meijerink,[c] Gerard P. M. van Klink,[a] and Gerard van Koten*[a]**

**Keywords:** Donor–acceptor systems / Luminescence / N-ligands / Platinum

A series of novel 4,4′-disubstituted organic–organometallic stilbenes were synthesized, that is, the 4′-substituted stilbenoid–NCN-pincer platinum(II) complexes [PtCl(NCN–R-4)] (NCN–R-4 = $[C_6H_2(CH_2NMe_2)_2$-2,6-R-4$]^-$ in which R = $C_2H_2C_6H_4$-R′-4′ with R′ = $NMe_2$, OMe, $SiMe_3$, H, I, CN, $NO_2$) (**1**–**7**). In these compounds the PtCl grouping can be considered to be present as a donor substituent. Their synthesis involved a Horner–Wadsworth–Emmons reaction of [PtCl(NCN–CHO-4)] (**9**) with the appropriate phosphonate ester derivatives (**8a**–**g**). Under these reaction conditions, the C–Pt bond in aldehyde **9** was not affected, and the platinated stilbene products were obtained in 53–90 % yield. The solid-state structures of complexes **1**, **2** and **5**–**7** were determined by single-crystal X-ray diffraction, which revealed interesting bent conformations for **2**, **5** and **7**. Linear correlations were found between both the $^{13}C\{^1H\}$ (C *ipso* to Pt) and the $^{195}Pt\{^1H\}$ NMR chemical shift and the Hammett $\sigma_p$ value of the R′ substituent; therefore, these NMR shifts can be used as a qualitative probe for the electronic properties of the delocalized π-system to which it is connected. The platinum–stilbene complexes were investigated for charge-transfer properties in solvents of different polarity. The luminescent properties, shown by donor–acceptor complexes **1**, **6** and **7**, were investigated by fluorescence spectroscopy, and the complexes showed positive solvatochromism, which indicates dipolar character of the excited state. The excited state lifetimes, which were in the picosecond range, and the quantum yields (ranging from 0.002 to 0.2) were also determined for these complexes. It was established that the presence of the transition metal favours nonradiative decay from the excited state to the ground state.

## Introduction

Conjugated molecules are regarded with high interest for their optoelectronic properties[1] in, for instance, materials with nonlinear optical (NLO)[2] behaviour and for applications in optoelectronic devices such as light-emitting diodes.[3] The properties of these molecules depend on the nature and length of the conjugation path and on the functional groups present in the system. By connecting donor and acceptor groups through a π-electron bridge, intramolecular electron transfer can be achieved. A well-known example of such a push–pull conjugated system is *trans* 4-dimethylamino-4′-nitrostilbene (DANS),[4] a member of the *trans* 4,4′-disubstituted stilbene family (Scheme 1), which has been studied predominantly for its special photophysical and NLO properties.[5–8]

Currently, conjugated systems containing transition metals attract much attention,[9–13] especially because the optoelectronic properties of these systems can be affected by changing the metal ion, the coordinating anions and ligands or by changing the nature of the connecting conjugated system. Interesting examples of metal–organic conjugated molecules studied for their NLO properties are the ferrocene-functionalized donor–acceptor complexes reported by McCleverty and coworkers.[14–17] In our group, bis(pincer–metal)acetylene complexes[18–21] and heterometallic terpyridine–pincer-based complexes[22] were studied in which the communication between two metals by a conjugated ligand bridge was investigated.

We already showed the feasibility of remotely influencing the electron density on the metal centre of the [MX(NCN–R-4)] pincer system (M = Ni, Pd or Pt; X = Cl, Br or I) by altering the *para* substituent R [R = $NO_2$, C(O)Me, COOH,

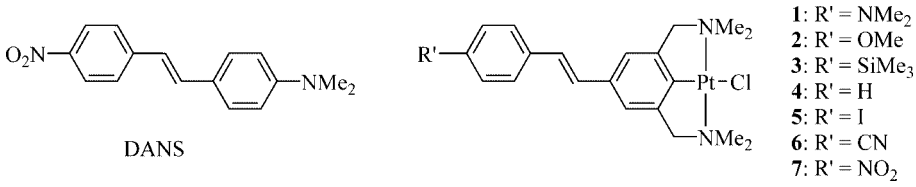


Scheme 1.

CHO, $SO_3H$, $PO(OEt)_2$, PO(OH)(OEt), $PO(OH)_2$, I, Cl, H, $CH_2OH$, OMe, SMe or $NH_2$].[23,24] In this series, a linear correlation was found between the ease of oxidation of the nickel centre and the electron-donating properties of the *para* substituent [redox potential $E_{p,a}$ ($Ni^{II}/Ni^{III}$) versus $\sigma_p$]. Correlations were also found between NMR chemical shifts [$^{13}C\{^1H\}$ and $^{195}Pt\{^1H\}$] of the complexes and the Hammett substituent parameter $\sigma_p$ (for M = Ni: $\delta = {}^{13}C_{ipso}$ versus $\sigma_p$; for M = Pt: $\delta = {}^{195}Pt$ versus $\sigma_p$). Conversely, in the same study, for the carboxylic acid functionalized platinum compound [PtI(NCN–COOH-4)], the Hammett $\sigma_p$ value of the platinum iodide moiety was determined to amount to –1.18 in methanol and –0.72 in water/methanol (1:1). The value and the negative sign of this Hammett substituent constant implied that the *para* platinum iodide group can be considered as an electron-donating substituent comparable in strength to a dimethylamino group [$NMe_2$; $\sigma_p$ = –0.83; the tabulated $\sigma_m$ value of the $CH_2N(Me)_2$ group is 0.00].[25] Consequently, it should be possible to introduce the aryl NCN metal system as the donor group into a donor–acceptor system, like in DANS, that is, to replace the *N*,*N*-dimethylaminobenzene moiety with the NCN–PtCl moiety (Scheme 1). Moreover, recent studies showed that certain $Pt^{II}$–pincer systems have interesting photochemical properties;[26–28] for example, Connick and coworkers studied luminescent NCN–$Pt^{II}$ pincer complexes based on 1,3-bis(piperidylmethyl)benzene.[29–31] Kanbara and coworkers applied a thioamide-based SCS–$Pt^{II}$ pincer complex in a light-emitting diode exhibiting red-coloured electroluminescence.[32]

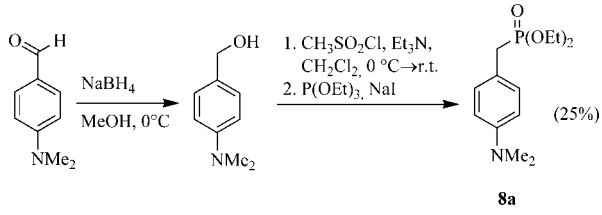
In the present study we set out to prepare a series of stilbenoid platinum compounds [PtCl{NCN($C_2H_2C_6H_4$-R′-4′)-4}] (**1**–**7**) in which the donor site (the PtCl grouping) is kept constant and the nature of the R′ group is varied (R′ = $NMe_2$, OMe, $SiMe_3$, H, I, CN, $NO_2$). By introducing different substituents at the 4′-position of the stilbenoid–pincer backbone, the donor–acceptor properties of the stilbenoid platinum system could be studied.

An important synthetic objective of the present study was to explore methods for the construction of the stilbene moiety by using a suitable *para*-substituted pincer molecule with the NCN–Pt arrangement already in place. A pronounced influence of the *para* substituent on the (photo)-physical properties of the stilbenoid platinum complexes has been found and will be discussed with the help of the results from solid-state structures, $^{13}C\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectroscopic analysis, UV/Vis and emission spectroscopy.

## Results and Discussion

### Synthesis

A series of substituted benzyl phosphonates[33–38] **8b**–**g** was prepared by a Michaelis–Arbuzov reaction between triethyl phosphite and the appropriate *para*-substituted benzylic bromide, which were either commercially available or could be prepared in a single step by a recently improved[39] radical bromination reaction of the available toluene derivative. Phosphonate ester **8a** was synthesized by reduction of 4-dimethylaminobenzaldehyde with sodium borohydride to form 4-dimethylaminobenzyl alcohol,[40] which was then in situ reacted with methanesulfonyl chloride and subsequently converted into the phosphonate ester by an Arbuzov reaction[41] (Scheme 2).



Scheme 2.

Stilbenoid NCN-pincer platinum(II) compounds **1**–**7** were obtained as *trans* compounds in moderate-to-good yield by a Horner–Wadsworth–Emmons condensation reaction of [PtCl(NCN–CHO-4)] (**9**) and the appropriate phosphonate ester **8** in the presence of potassium *tert*-butoxide (Scheme 3).[42–44] Upon hydrolysis of the reaction mixture, the pure *trans* isomers of **1**–**7** precipitated out of the solution and were isolated by filtration as air-stable solids. The solids were fully characterized by $^1H$, $^{13}C\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectroscopy, elemental analysis, mass spectrometry, and compounds **1**, **2**, **5**, **6** and **7** were also characterized by single-crystal X-ray structure determination. In this study, only the *trans* isomers of **1**–**7** were obtained in a pure form and further studied. From the filtrate, a *trans*–*cis* mixture (determined by $^1H$ NMR spectroscopy) was obtained of which the *cis* isomer was always present as the minor component. In the solid state, the compounds do not undergo *trans*–*cis* isomerization upon exposure to daylight in contrast to the compounds in solution, which do undergo this *trans*–*cis* isomerization.[5,6] Noteworthy, the Pt–C bond of **9** remains intact throughout the complete reaction under the applied reaction conditions and no visible formation of zero-valent platinum was ob-

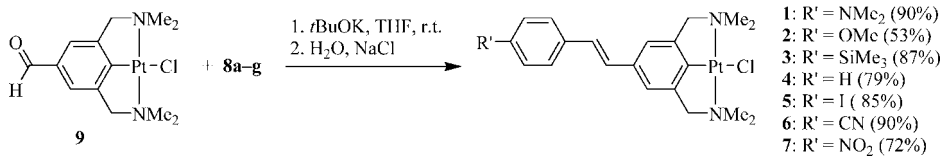

Scheme 3.

served in the olefination reaction induced by the presence of the strong base.

## Crystal Structures

Crystals suitable for single-crystal X-ray structure determination of **1** (Figure 1), **2**, **5**, **6** and **7** (Figure 2) were obtained by slow evaporation of deuterated dichloromethane solutions, which were initially prepared and used for the NMR studies.

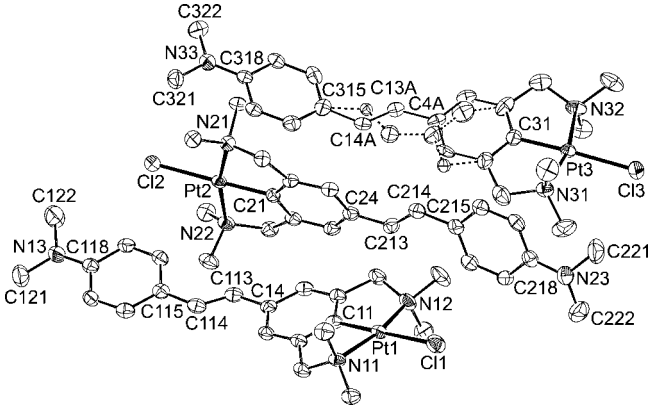

Figure 1. Displacement ellipsoid plot (50% probability level) of the three independent molecules in the crystal structure of **1** (viewed along the crystallographic *b* axis). Hydrogen atoms and partially occupied $CH_2Cl_2$ molecules are omitted for clarity. The minor conformation (19% occupancy) of disordered residue 3 is drawn in dashed lines.

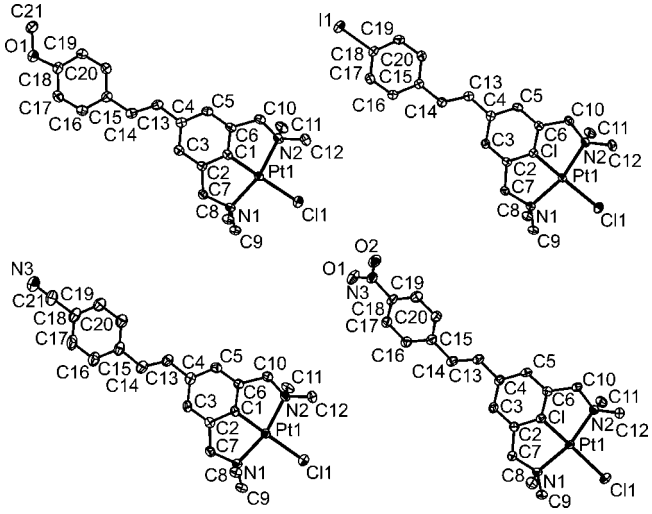

Figure 2. Displacement ellipsoid plot (50% probability level) of complexes **2** (top left), **5** (top right), **6** (bottom left) and **7** (bottom right). Hydrogen atoms have been omitted for clarity.

Compound **1** crystallizes with three independent molecules in the asymmetric unit of which one is disordered about the central double bond (Figure 1). This type of disorder is rather common in *trans*-stilbene and *trans*-azobenzene derivatives.[45] The two ordered molecules have very similar bond lengths and angles (Table 1) but differ in the conformation of the 4-dimethylaminostyryl fragment (Figure S1, Supporting Information). The overall shape of the molecules is bent; the $C_{ipso}$ carbon atoms are 0.448(4) and 0.270(4) Å (for residues 1 and 2, respectively), beneath the least-squares plane of the central double bond (C4–C13–C14–C15). For the corresponding *para* carbon atoms C18, the distances are 0.099(4) and 0.311(4) Å for residues 1 and 2, respectively. In the crystal, the molecules of the metal complex are stacked on top of each other in an antiparallel fashion. These stacks run in the crystallographic [1,0,1] direction (Figure 1). Intermolecular π-stacking interactions could not be observed in this crystal structure.

Despite the different *para* substituents, compounds **2**, **5** and **6** are isostructural in the solid state. They have similar bond lengths and bond angles (Table 2) and also nearly identical conformations and crystal packings. Small differences are observed for intermolecular interactions involving the *para* substituents. Molecular plots of **2**, **5** and **6** are displayed in Figure 2; likewise in the crystal structure of **1**, the molecules have an overall bent shape (Figure 3). Again, the C1 $C_{ipso}$ atom and the C18 aryl carbon atom are beneath the plane of the central double bond with values of 0.382(2), 0.363(3) and 0.343(3) for C1 and 0.307(3), 0.307(4) and 0.101(4) for C18. Also, the crystal structures of **2**, **5** and **6** do not express intermolecular π-stacking interactions. There are only weak intermolecular C–H···π and C–H···Cl interactions, and in some crystals C–H···O (compound **2**) and C–H···N (compound **6**) hydrogen bonds are present. The latter certainly do not determine the packing mode because hydrogen bond interactions in **5** are missing.

All molecules are arranged in the crystallographic *b*-direction in an approximately perpendicular orientation with respect to each other (Figure 4). In the crystallographic *a* direction, layers of polar Pt–Cl units alternate with hydrophobic organic layers.

The molecular geometry of **7** in the crystal is very similar to that of compounds **1**, **2**, **5** and **6** (Table 2). The nitro group in the *para* position is slightly rotated out of the plane with an O2–N3–C18–C17 torsion angle of 165.4(3)°. There is also a slight rotation of the *para* nitrophenyl moiety with respect to the central double bond, expressed in a C13–C14–C15–C16 torsion angle of 167.8(3)°. In contrast to compounds **1**, **2**, **5** and **6**, the shape of **7** is not bent; the C1 $C_{ipso}$ atom and the C18 phenyl carbon are essentially in

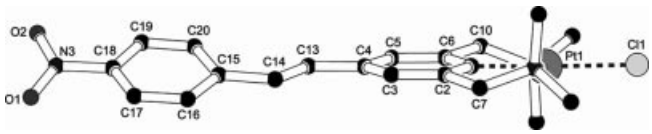

Figure 5. Side view of **7** in the crystal that shows the extended overall shape. Hydrogen atoms are omitted for clarity.

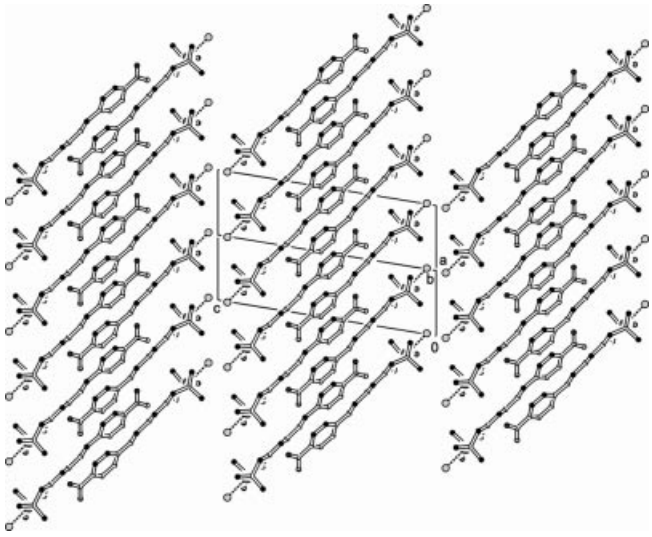

Figure 6. Packing of **7** in the crystal. Hydrogen atoms are omitted for clarity. Projection along the crystallographic [1,–1,0] direction.

defined by C1–N1–Pt1–N2–Cl1. For the two five-membered metallacycles, which are slightly puckered, torsion angles for the Pt1–N1–C7–C2 and Pt1–N2–C10–C6 bonds ranging from 25 to 32° were found. The platinum to $C_{ipso}$ (Pt–C) distances of **1**, **2** and **5**–**7** are in the range of 1.915 to 1.934 Å, as expected.[47]

For the stilbenoid backbone of **1**, **2** and **5**–**7**, similar geometric features were found compared to other reported transition-metal-containing stilbenoid fragments.[9,50,51]

A comparison of the torsion angles between the *trans* bonded 4-styrenyl grouping and the aromatic NCN ring show these fragments to be slightly rotated about the olefinic C–C double bond with torsion angles ranging from 171.8 to 176.2°. For **1** (residues 1 and 3), **2** and **6**, torsion angles between the two aromatic planes (as defined in Tables 1 and 2) of about 9–15° were found. Notable larger torsion angles (ranging from 21° to 26°) were found in **7**, **1** (residue 2) and **5**. As a result of the resonance stabilization energy in conjugated systems, it is expected for stilbenes that the phenyl rings and the ethylene bridge have a nearly coplanar geometry.[52–55] In practice, torsion angles around 0–5° are commonly found in the solid-state structures,[56–58] although a small part of the reported stilbenoid molecules show larger torsion angles ranging from 20 to 27°.[59–61] Such deviations from coplanarity can be explained by a combination of alkenyl-H–*ortho*-H repulsion and by crystal packing forces.

A smaller deviation (1.0–2.7°) from the planar geometry is found for the dihedral angles between the planes formed by the *para* R′ substituent (connected to C18) and its aromatic ring (defined by C15–C16–C17–C18–C19–C20), except for **7** (R′ = $NO_2$), of which the nitro group deviates almost 15° from coplanarity (Table 2, Figure 5). This deviation is commonly found for an aromatic nitro group.[62]

The alternation of bond length $\delta r$ in the phenyl rings provides information about the presence of possible quinoid character in these rings, which reflects ground-state charge-transfer character.[63,64] In benzene, the $\delta r$ value equals 0, whereas values between 0.08 and 0.10 are found in a fully quinoid ring. In the analyses of **2**, **5**, **6** and **7**, for the R′-substituted phenyl ring, $\delta r$ values between 0.003 and 0.016 are found;[65] for the metal-substituted ring, values of $\delta r$ range from 0.015 to 0.019. This indicates that in both substituted rings a slight degree of quinoid character is present. This supports the idea that the metal-containing group acts as an electroactive substituent. The electron donating $NMe_2$ substituent present in **1**, however, seems to induce more quinoid character in the R′ phenyl ring because a value of $\delta r$ = 0.025 in residue 1 and 2 is found. The larger contribution into the quinoid character induced by the $NMe_2$ group was also reported by others.[66] The effect of the $NMe_2$ group seems to oppose that of the metal substituent in **1** because a smaller alternation in the bond length ($\delta r$ = 0.009 and 0.013 for residue 1 and 2, respectively) occurs here relative to that of **2**, **5**, **6** and **7**.

## NMR Spectroscopy

Solutions of **1**–**7** in $CD_2Cl_2$ (0.01 M) were studied by $^1H$, $^{13}C\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectroscopy. In the $^1H$ NMR spectra, resonances for the $(CH_3)_2N$ and the $ArCH_2N$ protons of the $CH_2NMe_2$ substituents were observed at $\delta$ = 3.04–3.05 ppm and at $\delta$ = 4.02–4.08 ppm, respectively, and showed characteristic satellites resulting from platinum coupling [$^3J$(H,Pt) ≈ 37 and 46 Hz, respectively]. For compounds **1**, **2** and **4**–**7**, characteristic resonances of the vinylic protons were observed at $\delta$ = 6.8–7.2 ppm with large coupling constants [$^3J$(H,H) = 16 Hz] indicative of a *trans* configuration. For **3**, the chemical shift difference between the vinylic protons was so small that the coupling was not resolved in the higher order pattern.

In the $^{13}C\{^1H\}$ NMR spectra of some of the compounds, a two [$^2J$(C,Pt) = 62–67 Hz] or three bond coupling [$^3J$(C,Pt) = 35–37 Hz] of platinum to carbon was observed. A linear correlation was found ($R^2$ = 0.9842) when the $^{13}C\{^1H\}$ NMR chemical shift of the $C_{ipso}$ (to platinum; Table 3) of **1**–**7** was plotted against the Hammett $\sigma_p$ parameter of the *para* R′ substituents (Figure 7), which suggests that the effect on the electronic character of the conjugated molecule induced by the different *para* substituents can be experienced within the complete system. A previous correlation study on *para*-substituted stilbenoid ferrocene analogues showed a similar substituent effect[67] when the $^{13}C\{^1H\}$ NMR chemical shift of the ferrocenyl carbons was plotted against the Hammett $\sigma_p$ parameter.

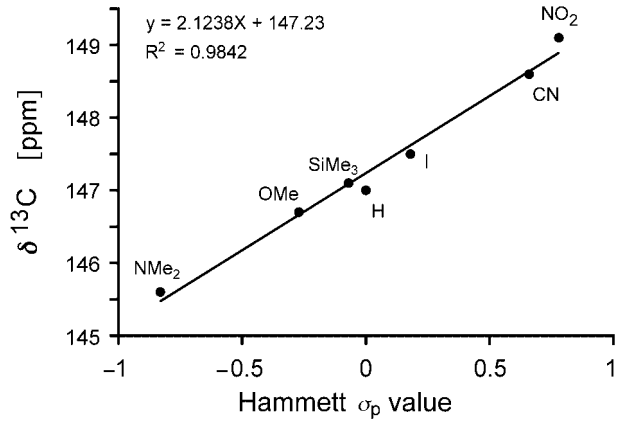

Figure 7. Hammett correlation of the $^{13}C\{^1H\}$ $C_{ipso}$ NMR chemical shift of **1**–**7**.

The electron density at the metal centre of complexes **1**–**7** was probed with $^{195}Pt\{^1H\}$ NMR spectroscopy. The sensitivity of the $^{195}Pt$ nucleus towards changes in, for instance, the geometry and the oxidation state of the metal centre or changes in the electronic nature of the surrounding ligands, is reflected in the $^{195}Pt\{^1H\}$ NMR chemical shift.[68] For **1**–**7**, that is, upon going through the series from an electron-donating ($NMe_2$) to an electron-accepting ($NO_2$) *para* substituent, the $^{195}Pt\{^1H\}$ NMR chemical shift moves to a higher frequency, which points to a less-shielded platinum nucleus (Table 3). A plot of the $^{195}Pt\{^1H\}$ NMR chemical shift against the Hammett $\sigma_p$ parameter resulted in a good linear correlation ($R^2$ = 0.9604, Figure 8). The results show the power of the $^{195}Pt\{^1H\}$ NMR chemical shift as a qualitative probe for the electronic character of the molecule (including $C_{ipso}$) to which the metal is connected. The slope of the line provides information about the efficiency of communication between the substituent and the metal centre, and therefore, it was compared with the slope of a similar graph from an earlier study in which the $^{195}Pt\{^1H\}$ NMR shift of *para*-functionalized phenyl pincers [PtCl(NCN–R-4)] was correlated with the Hammett $\sigma_p$ parameter.[23] Indeed, the slope of 25 in the present study found for the stilbenoid NCN-pincer platinum compounds is less steep relative to the 171 found for the [PtCl(NCN–R-4)] compounds earlier. This smaller number is in agreement with the larger size of the π system in **1**–**7**, over which the effect of the 4-R′ group to the 4-PtCl grouping is spread out.

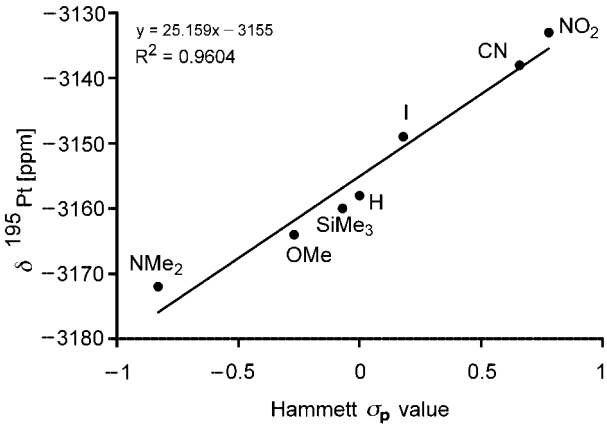

Figure 8. Hammett correlation of the $^{195}Pt\{^1H\}$ NMR chemical shift of **1**–**7**.

As pointed out above, the compounds in solution do undergo *trans–cis* isomerization when exposed to light.[6] Irradiation of a $CD_2Cl_2$ solution of **7** ($9.5\times10^{-3}$ M, $\lambda_{ex}$ = 365 nm) for 2 h resulted in a *trans–cis* mixture. After 1 h, the photostationary state of the isomerization reaction was reached, and a *trans–cis* ratio of exactly 1:1 was observed. In the $^1H$ NMR spectrum, the formation of the *cis* isomer could be observed by the appearance of new peaks for all the protons (Figure 9). The doublets at $\delta$ = 6.65 ppm and $\delta$ = 6.53 ppm are assigned to the *cis* protons of the ethylene bridge which have a characteristic *cis* coupling constant, $^3J$(H,H) = 12 Hz. Recently, this in-solution *trans–cis* isomerization process was also observed by others in a study of cyclometallated $Pt^{II}$ complexes containing substituted 4-styryl-2-phenylpyridine ligands.[69]

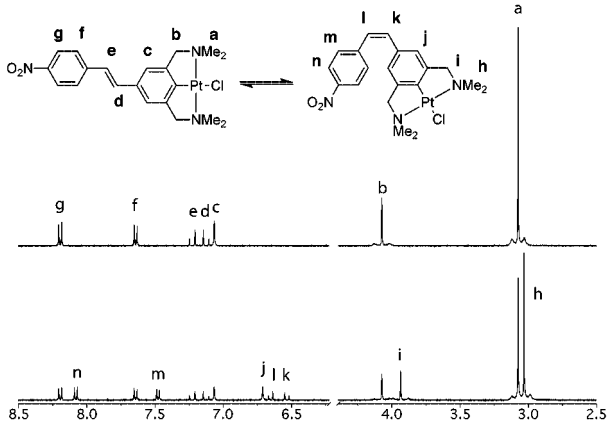

Figure 9. $^1H$ NMR spectra of **7**, before (top; only *trans*) and after (bottom; *trans–cis* mixture) UV irradiation (400 MHz, $CD_2Cl_2$, $9.5\times10^{-3}$ M; $\lambda_{ex}$ = 365 nm, 1 h).

## UV/Vis Spectroscopy

The complexes are well soluble in dichloromethane, but their solubility decreases in solvents like diethyl ether,

whereas they are insoluble in cyclohexane. As a result of this restricted solubility, the absorption coefficients of the complexes were only determined in dichloromethane. The absorption spectra for **1**–**7** (Figure 10, Table 4) show a weak band between 244 and 298 nm (not observed for **1**) that originates from the excitation of the singlet ground state ($S_0$) to a higher excited state (e.g. $S_0 \rightarrow S_2$).[1] A more intense lower energy band ($S_0$–$S_1$) is observed in the range of 341 to 415 nm. The position of this band shifts to lower energy with increasing acceptor strength, that is by going from **4** (R′ = H) to **7** (R′ = $NO_2$). Therefore, in the presence of an acceptor functionality, this transition involves intramolecular charge transfer (ICT) in which the NCN–PtCl fragment, as anticipated, behaves as a donor functionality. The observed bathochromic shift is in agreement with calculated charge-transfer properties of 4,4′-substituted donor–acceptor stilbenes,[70] where an increase in the donor–acceptor strength causes the HOMO–LUMO distance of the molecule to decrease, which results in an absorption at lower wavelength. A change in the donor properties of R′ by going through the series from **4** to **1** only slightly affects the absorption maximum ($\lambda_{max}$) of the compounds.

For comparison of **1**–**7** with organic 4,4′-substituted donor–acceptor stilbene analogues, DANS was used as a reference system. In Figure 10 it can be seen that the absorption maxima of **7** and DANS are slightly shifted with respect to each other, which reflects the different nature of the PtCl grouping versus the $NMe_2$ group. Moreover, the absorption measurements of complexes **1**–**7** in different solvents showed no distinct solvent polarity dependence (Table 4), as was reported previously for the organic stilbene analogues,[71,72] which points to a nonpolar ground state of the stilbenoid NCN–Pt compounds.

A qualitative screening of the luminescence of solutions of **1**–**7** in dichloromethane by use of a standard laboratory UV-lamp ($\lambda$ = 365 nm) revealed that, surprisingly, both the 4-donor–4′-donor complex **1** and complexes **6** and **7** with a strong donor–acceptor combination are luminescent. Therefore, these complexes were further studied for their photophysical properties by determination of the fluorescence maxima ($\lambda_{fl}$), quantum yields ($\Phi_{fl}$) and excited state lifetimes ($\tau_{fl}$). From this data, the radiative ($k_r$) and nonradiative ($k_{nr}$) decay constants were calculated. Complexes **2**–**4** showed no luminescence, and complex **5** showed only very weak luminescence, which was too weak to be studied in more detail.

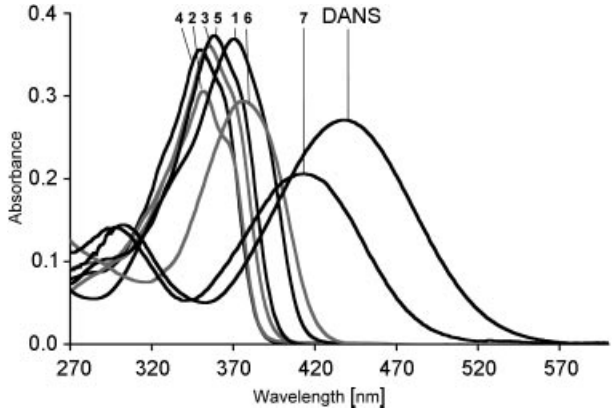

Figure 10. UV/Vis spectra of **1**–**7** in $CH_2Cl_2$. Most intense band, from left to right: R′ = H (**4**), OMe (**2**), $SiMe_3$ (**3**), I (**5**), $NMe_2$ (**1**), CN (**6**), $NO_2$ (**7**) and DANS.

For complexes **1**, **6** and **7**, the emission spectra and excited state lifetimes were recorded in solvents of different polarity (Tables 5 and 6). For all compounds, a bathochromic shift in the emission maximum with an increase in solvent polarity was observed, as is displayed for **6** in Figure 11. The occurrence of this positive solvatochromism, which is the most extensive for **7**, reflects the formation of a charge-separated or dipolar-excited state.

donor–acceptor systems can be approximated by using the Lippert equation [Equation (1)][74]

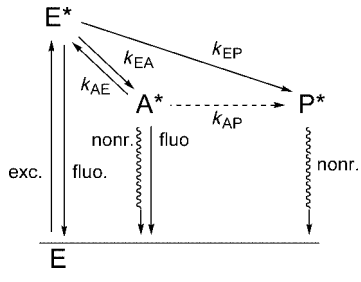
$$\nu_{abs} - \nu_{fl} = \frac{2\Delta\mu^2}{hc\rho^3}\Delta f + \text{constant}$$

$$\Delta f = \frac{\varepsilon - 1}{2\varepsilon + 1} - \frac{n^2 - 1}{2n^2 + 1} \quad (1)$$

where $h$ is Planck's constant and $c$ is the speed of light. The $\rho$ (Onsager cavity radius) of the molecule can be estimated by numerous methods,[75,76] and in this study the radii of molecules **6** and **7** were estimated from their solid-state structures (estimated to be 4.36 and 4.39 Å, respectively).[77,78]

From the slopes derived from the Lippert plot of **6** and **7** (the values in dichloromethane were excluded from the trend line, Figure 12), $\Delta\mu$ was estimated to be 11 and 13 D, respectively. This implies that in these systems, excited state charge separation is present but to a lesser extent than that found for related 4,4′-substituted stilbenes.[79] The larger dipole moment found for **7** is a result of the stronger electron accepting nitro group.

The excited state behaviour of 4,4′-substituted organic stilbenes has been studied intensively.[8,80–86] For the excited state of the molecule, a three-state kinetic scheme is suggested (Scheme 4).[86] The ground state molecule (E) can be excited into the emissive state E* (planar geometry) in which the molecule is suggested to have biradicaloid character. Emissive relaxation to the ground state from E* is accompanied by two competing relaxation pathways. One proceeds through the nonemissive "phantom-singlet state" (P*), in which the molecule assumes a twisted conformation (double bond twist, including the *trans–cis* isomerization process),[6] also referred to as the photochemical funnel toward the ground state. The alternative follows a pathway which involves rotation about a bond between the aromatic moiety and the central double bond and ends up in a twisted intramolecular charge transfer state A* (TICT state), which is considered to be responsible for the main



Scheme 4. The three-state kinetic scheme proposed for the relaxation of 4,4′-substituted organic stilbenes after excitation.

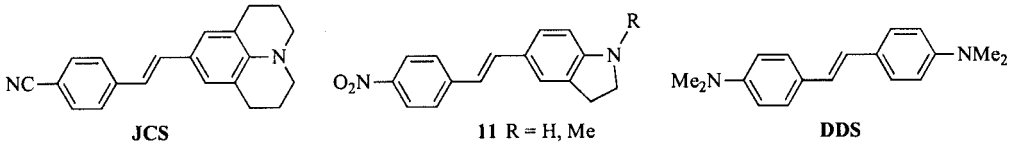

Figure 13. Donor–acceptor stilbenes **JCS** and **11**, donor–donor stilbene **DDS**.

part of the emission. The photophysics of the molecule are dependent on the relative energy of the three different energy states, which are influenced by the solvent polarity and by the donor–acceptor strength of the substituents.

For 4,4′-substituted organic stilbenes in which the donor substituent is an alkylamino group, the TICT state can be reached by a single bond twist about the single bond between the alkylamino group and the aromatic ring or by a twist about the single bond between the anilino group and the double bond. To exclude the alkylamino TICT state, other groups developed and studied the more rigid amino substituted donor–acceptor stilbenes **JCS**[84] and **11**[72] (Figure 13). In our study, the excited state behaviour of **6** and **7** will be compared with that of **JCS** and **11**, respectively, with regard to the NCN–PtCl fragment of **6** and **7** as the rigid donor fragment. So far, we were not able to find a rigid reference system for **1** in the literature; therefore, it was compared with **DDS**[82] (Figure 13), which contains two $NMe_2$ groups.

The fluorescence quantum yields of **1** range from 0.002 to 0.017, and they are remarkably low relative to the values found for **DDS** (ranging from 0.39 to 0.57). Presumably, the presence of the NCN–PtCl fragment favours nonradiative decay by accelerating intersystem crossing. The fluorescence quantum yields of **1** slightly increase with increasing solvent polarity (Table 5), which is probably due to stabilization of the A* state with increasing solvent polarity.[82,87] The fluorescence lifetimes of **1** at room temperature, which were derived from a biexponential decay curve (Table 5; only the slower components of the decay curves are reported here, ranging from 289 to 537 ps), decrease with increasing solvent polarity and are shorter than the value found for **DDS** (900 ps in ethanol at 300 K). It must be noted that the nonradiative decay rates [$k_{nr} = (1 - \Phi_{fl})/\tau_{fl}$] increase with increasing solvent polarity. In more polar solvents, the low-lying A* state is increasingly populated, and the smaller energetic distance to the ground state favours nonradiative decay.

For **6**, an increase in the quantum yield and the lifetime is observed when the polarity of the solvent increases, which can be explained by the dipolar character of the states involved. Both E* and A* are highly polar, with an increased dipole moment for A*; P* has weak or nonpolar properties.[83] Therefore, an increase in the solvent polarity stabilizes E* and A*, and to a much lesser extent P*. As a result, the nonradiative decay, which is governed by the access to P*, becomes less important. For **6**, indeed a decrease in $k_{nr}$ with increasing solvent polarity is found. This is in agreement with what was found for **JCS**,[83,84] for which the yield of the nonradiative decay also decreases with increasing solvent polarity.

For **7**, a reverse dependency of the fluorescence lifetime and quantum yield on the solvent polarity was found. Roughly, an increase in the fluorescence quantum yield and the fluorescence lifetime was observed when the solvent polarity decreases. The remarkable change in the photophysical properties accompanying the change of a cyano group to a nitro group was studied intensively,[72] and the change is also found for **11**. As a consequence of its larger dipole moment, an increase in the solvent polarity results in a decreased energy level of the A* state of **7**. The lower energy minimizes the distance from A* to the ground state and causes radiationless decay from A* to compete with fluorescence. As a result from the energetically low-lying A* state, the P* level plays no significant role, and therefore, relaxation proceeds primarily by way of the A* state.

## Conclusions

A useful and efficient synthetic route towards electronically tunable organometallic stilbenes based on a series of stilbenoid NCN–$Pt^{II}$ pincers is reported. The *trans* configuration of the complexes is maintained in the solid state, but in solution they undergo *trans–cis* isomerization upon exposure to light. The physical data reported for compounds **1**–**7** reflect that a substituent effect can be experienced within the complete delocalized π-system. The linear correlation found between the $^{13}C\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR chemical shifts and the Hammett $\sigma_p$ value indicates that the metal is sensitive to the change in the electronic properties of the delocalized π-system. In this way the metal centre can communicate with a substituent that is situated quite a distance from itself. Therefore, we can regard the platinum centre as a probe by using the $^{195}Pt\{^1H\}$ NMR chemical shift data as a readout for the electronic properties of a conjugated system that is connected to it. The UV/Vis and fluorescence study show that the NCN–PtCl fragment can be qualitatively regarded as an electron-donating group. From the low quantum yields and fast decay rates, it can be concluded that the presence of the platinum centre favours nonradiative decay when compared with the organic stilbene analogues.

## Experimental Section

**General**: All reactions involving air- or moisture-sensitive reagents were performed by using standard Schlenk techniques unless stated otherwise. Light-sensitive compounds and solutions were protected from the light with the use of aluminium foil. Pentane, THF and $Et_2O$ were distilled from Na/benzophenone, $CH_2Cl_2$ was distilled

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

from $CaH_2$ and triethylamine was distilled from KOH prior to use. The platinum precursor $[Pt(p\text{-tol})_2(SEt_2)]_2$,[88,89] [PtBr(NCN–CHO-4)],[90] trimethyl(*p*-tolyl)silane[91] and the respective *para*-substituted diethyl benzylphosphonates **8b**–**g** were prepared according to published procedures of which the benzylic bromination step was performed according to the published procedure of Amijs and coworkers.[39] All other reagents were commercially available and used without further purification. $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded at 25 °C with a Bruker AC 300 NMR or Varian Inova 300 or Varian 400 spectrometers, chemical shifts are reported relative to residual solvent resonances. $^{195}Pt\{^1H\}$ NMR spectra were recorded with a Varian Inova 300 MHz NMR spectrometer, referenced to external $Na_2PtCl_6$ (1 M in $D_2O$, $\delta$ = 0 ppm).[92] Elemental analyses were performed by Kolbe, Mikroanalytisches Laboratorium (Mülheim a.d. Ruhr, Germany). ES-MS spectra were obtained from the Biomolecular Mass Spectrometry Group at the Utrecht University. Infrared spectra were recorded with a Perkin–Elmer Spectrum 1 FTIR spectrometer. UV spectra were collected with Cary 1 or Cary 5 spectrophotometers in spectrophotomeric-grade solvents. Fluorescence emission spectra were obtained with a Spex Fluorolog instrument, equipped with a Spex 1680 double excitation monochromator, a Spex 1681 emission monochromator and a Spex 1911F detector. Fluorescence spectra were corrected for the detector spectral response with the aid of a correction file provided by the manufacturer. Fluorescence quantum yields were determined relative to 9,10-diphenylanthracene ($\Phi_{fl}$ = 0.90, excitation wavelength 370 nm).[93] Solvents used for fluorescence measurements were of spectrophotometric grade (Acros). Lifetime measurements were performed with the use of a Pico Quant PDL 800-B laser as the excitation source ($\lambda_{exc}$ = 406 nm, 55 ps pulse width, 2.5–40 MHz repetition rate). The luminescence was collected through a focusing lens, filtered through a crossed polarizer and a combination of suitable optical cut-off filters, dispersed by a 0.1 m monochromator (1350 lines mm$^{-1}$ grating, blazed at 500 nm) and detected by a fast Hamamatsu photomultiplier tube (PMT) (H5738P-01). The PMT signal was amplified by an inverting preamplifier (PAM-102-T – PicoQuant) and used as the start input for a Time Harp 200 multichannel computer card, which was synchronized with the laser pulse by the stop input. The decay curves were obtained by time-correlated single photon counting (TCPCS) by time-to-amplitude conversion (TAC). The ratio of stop to start pulses was kept low (below 0.04) to assure good statistics. The instrument response function (IRF) was measured by using a dilute suspension of silica particles (LUDOX) as the scattering medium and the same experimental conditions used for the fluorescence decay measurements. The raw data was deconvoluted from the IRF and analyzed by fluorescence decay analysis software (Fluofit 3.3). The instrumental resolution was 30 ps (10% of the IRF FWHM).

**Diethyl 4-Dimethylaminobenzylphosphonate (8a):** At 0 °C, methanesulfonyl chloride (0.54 mL, 6.98 mmol) was added dropwise to a solution of 4-dimethylaminobenzyl alcohol (1.0 g, 6.61 mmol) and triethylamine (1.12 mL) in dichloromethane (20 mL). After complete addition, the solution was warmed to room temperature for 1 h. Next, all volatiles were evaporated, and triethylphosphite (4 mL) and NaI (400 mg, 2.67 mmol) were added to the oily residue. The mixture was heated at 110 °C for 2.5 h after which the excess triethylphosphite was distilled off in vacuo. At room temperature, water (10 mL) and ethyl acetate (20 mL) were subsequently added to the residue. The organic layer was separated, washed with saturated $NaHCO_3$ (5 mL) and NaCl solution (5 mL), and dried using $Na_2SO_4$. After evaporation and Kügelrohr distillation, an oily product (0.9 g) was obtained. Further purification of the product could be achieved by column chromatography [neutral $Al_2O_3$, hexane/ethyl acetate (9:1), then gradient elution increasing to pure ethyl acetate] and **8a** (455 mg, 1.68 mmol, 25%) was isolated as an oil. $^1H$ NMR (300 MHz, $C_6D_6$): $\delta$ = 7.29 [dd, $^3J$(H,H) = 8.9 Hz, $^4J$(H,H) = 2.5 Hz, 2 H, ArH], 6.57 [d, $^3J$(H,H) = 8.5 Hz, 2 H, ArH], 3.89 (m, 4 H, $OCH_2$), 3.02 [d, $^2J$(H,P) = 20.9 Hz, 2 H, $CH_2P$], 2.49 [s, 6 H, $N(CH_3)_2$], 0.97 [t, $^3J$(H,H) = 7.1 Hz, 6 H, $CH_3$] ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $C_6D_6$): $\delta$ = 149.8, 130.8 [d, $J$(C,P) = 6.5 Hz], 119.7 [d, $J$(C,P) = 9.3 Hz], 113.0, 61.7 [d, $J$(C,P) = 6.5 Hz], 40.2, 33.1 [d, $J$(C,P) = 139.5 Hz, $CH_2P$], 16.5 [d, $J$(C,P) = 5.4 Hz] ppm. IR (ATR): $\tilde{\nu}$ = 2980, 2906, 2801, 1736, 1615, 1567, 1521, 1479, 1445, 1391, 1348, 1243, 1201, 1191, 1163, 1097, 1052, 1022, 945, 847, 822, 774, 731, 717, 689 cm$^{-1}$. MS (ES+, $CH_2Cl_2$): $m/z$ = 272.15 $[M + H]^+$. $C_{13}H_{22}NO_3P$ (271.30): calcd. C 57.55, H 8.17, N 5.16; found C 57.42, H 8.24, N 5.09.

**[PtCl(NCN–CHO-4)] (9):** [PtBr(NCN–CHO-4)] (1.19 g, 2.40 mmol) in wet acetone (10 mL) was treated with $AgBF_4$ (0.49 g, 2.52 mmol) for 1 h, and the formed precipitate was filtered through Celite. To the filtrate, a solution of NaCl (1.4 g, 23 mmol) in demineralized water (2 mL) was added, and the mixture was stirred for 1.5 h after which all the volatiles were removed in vacuo. After the addition of demineralized water (15 mL) and $CH_2Cl_2$ (15 mL), the mixture was filtered through Celite. The residue was extracted with dichloromethane (3 × 15 mL) after which the organic fraction of the filtrate was separated. The organic fraction was dried with $MgSO_4$, filtered and concentrated in vacuo to yield the crude product as a solid. Purification by column chromatography ($CH_2Cl_2$/MeOH, 9:1, $SiO_2$) yielded **9** (0.86 g, 1.91 mmol, 80%) as a light yellow solid. $^1H$ NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 9.82 (s, 1 H, CHO), 7.32 (s, 2 H, ArH), 4.08 [s, $^3J$(H,Pt) = 46.2 Hz, 4 H, $CH_2$], 3.05 [s, $^3J$(H,Pt) = 38.2 Hz, 12 H, $CH_3$] ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CD_2Cl_2$): $\delta$ = 192.0 (CHO), 157.5 ($C_{ipso}$ to Pt), 144.7 ($C_{ortho}$ to Pt), 133.4, 121.4 [$^3J$(C,Pt) = 35.6 Hz; $C_{meta}$ to Pt], 77.3 [$^2J$(C,Pt) = 61.0 Hz; $NCH_2$], 54.5 [$N(CH_3)_2$] ppm. $^{195}Pt\{^1H\}$ NMR (64 MHz, $CD_2Cl_2$): $\delta$ = –3068 ppm. IR (ATR): $\tilde{\nu}$ = 3017, 2980, 2929, 1674 (C=O), 1398, 737 cm$^{-1}$. MS (ES+, $CH_3CN$): $m/z$ = 455.14 $[M - Cl + CH_3CN]^+$, 414.10 $[M - Cl]^+$. $C_{13}H_{19}ClN_2OPt$ (449.84): calcd. C 34.71, H 4.26, N 6.23; found C 34.80, H 4.19, N 6.17.

**General Procedure for the Preparation of Stilbenoid Pincer Compounds 1–7:** In a dry Schlenk tube, *para*-aldehyde substituted pincer platinum derivative **9** and the appropriate phosphonate ester **8** were dissolved in dry degassed THF (10–15 mL). While stirring, *t*BuOK (2.5 equiv.) was added to the reaction mixture, under a nitrogen outflow, which directly caused a strong colour change of the reaction mixture. Upon completion of the reaction, monitored by TLC, the mixture was quenched at 0 °C by the addition of ice and an aqueous NaCl solution (to prevent halogen abstraction on the Pt centre). The formed precipitate was isolated by filtration through a glass filter. The residue was dissolved in dichloromethane, dried with $MgSO_4$, filtered and evaporated to leave the crude product. The crude product was purified by precipitation out of a small amount of dichloromethane by the addition of pentane.

**[PtCl{NCN($C_2H_2C_6H_4$-$NMe_2$-4′)-4}] (1):** Diethyl 4-dimethylaminobenzylphosphonate (**8a**; 100 mg, 0.369 mmol), **9** (150 mg, 0.334 mmol). Product isolated as a pale yellow powder (171 mg, 0.302 mmol, 90%). $^1H$ NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 7.37 [d, $^3J$(H,H) = 8.8 Hz, 2 H, ArH], 6.97 [d, $^3J$(H,H) = 16.2 Hz, 1 H, *trans* CH=CH], 6.96 (s, 2 H, ArH), 6.81 [d, $^3J$(H,H) = 16.8 Hz, 1 H, *trans* CH=CH], 6.70 [d, $^3J$(H,H) = 8.8 Hz, 2 H, ArH], 4.02 [s, $^3J$(H,Pt) = 46.2 Hz, 4 H, $CH_2$], 3.04 [s, $^3J$(H,Pt) = 37.9 Hz, 12 H, $CH_3$], 2.96 (s, 6 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CD_2Cl_2$): $\delta$ = 150.4 [Ar*C*N$(CH_3)_2$], 145.6 ($C_{ipso}$ to Pt), 144.2, 134.0, 127.4, 126.5, 126.2, 125.8, 117.6 [$^3J$(C,Pt) = 34.9 Hz; $C_{meta}$ to Pt], 112.8,

**X-ray Crystal Structure Determinations:** X-ray intensities were measured with a Nonius KappaCCD diffractometer with rotating anode and graphite monochromator ($\lambda$ = 0.71073 Å) at a temperature of 150 K. The structures were solved with automated Patterson methods[94] and refined with SHELXL-97[95] against $F^2$ of all reflections. The initial atomic coordinates of **2** were taken from isostructural compound **6**. Geometry calculations and checking for higher symmetry were performed with the PLATON[96] program. In structure **1**, the $CH_2Cl_2$ solvent molecule was refined with a partial occupation. One of the metal complexes was disordered about the central double bond. In **1** and **7**, hydrogen atoms were introduced in geometrically optimized positions and refined with a riding model. In **2**, **5** and **6**, all hydrogen atoms were located in the difference Fourier map and refined with a riding model. Further crystallographic details are given in Table 7. CCDC-626890 (compound **1**), -626891 (compound **2**), -626892 (compound **5**), -626893 (compound **6**) and -626894 (compound **7**) contain the supplemen-

# Preparation and Characterization of Dinuclear $Ni^{II}$ Amine-Thiophenolate Complexes Coligated by $EO_4^-$ (E = Cl, Re) and $EO_4^{2-}$ Oxoanions (E = S, Cr, Mo, W)

**Vasile Lozan[a] and Berthold Kersting*[a]**

**Keywords:** Dinuclear complexes / Macrocyclic ligands / Oxoanions

The ability of dinuclear nickel(II) complexes of the type $[(L^{Me})Ni^{II}_2(L')]$ to coordinate tetrahedral main group and transition metal oxoanions ($L' = EO_4^-$, $EO_4^{2-}$) has been examined ($(L^{Me})^{2-}$ is the deprotonated form of the 24-membered macrocyclic hexaaza-dithiophenolate ligand $H_2L^{Me}$). The following complexes have been synthesized: $[(L^{Me})Ni_2(ClO_4)][ClO_4]$ (**2**$[ClO_4]$), $[(L^{Me})Ni_2(ReO_4)][ReO_4]$ (**3**$[ReO_4]$), $[(L^{Me})Ni_2(SO_4)]$ (**4**), $[(L^{Me})Ni_2(CrO_4)]$ (**5**), $[(L^{Me})Ni_2(MoO_4)]$ (**6**), and $[(L^{Me})Ni_2(WO_4)]$ (**7**). Complexes **2**$[ClO_4]$, **3**$[ReO_4]$, **4**, **5**, and **7** have been characterized by X-ray crystallography. The complexes are isostructural, with the $EO_4^-$ and $EO_4^{2-}$ groups bonded in a $\mu_{1,3}$-bridging mode to generate dioctahedral $N_3Ni(\mu\text{-}S)_2(\mu_{1,3}\text{-}EO_4)NiN_3$ core structures. The doubly charged $EO_4^{2-}$ groups interact more strongly with the $[(L^{Me})Ni_2]^{2+}$ fragment than the $EO_4^-$ groups as reflected by the Ni–O distances which are significantly longer in **2** and **3** than in **4**–**7**. The nickel(II) ions in **4** and **6** are weakly ferromagnetically coupled ($J$ = 24.8 and 3.75 $cm^{-1}$, respectively) and the magnitude of the coupling appears to correlate with the Ni–S–Ni angle.

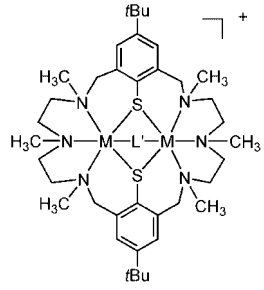
## Introduction

The macrocyclic hexaaza-dithiophenolate macrocycle $H_2L^{Me}$ is an effective dinucleating ligand that supports the formation of bioctahedral complexes of the type $[(L^{Me})M_2(L')]^+$ with numerous transition metals such as Mn, Fe, Co, Ni, Zn,[1] and Cd (Scheme 1).[2] These complexes have a rich coordination chemistry since the $[(L^{Me})M_2]^{2+}$ fragments are able to coordinate a large variety of coligands L′. These include $Cl^-$,[3] $OH^-$,[4] $NO_2^-$, $NO_3^-$, $N_3^-$,[5] $BH_4^-$,[6] various carboxylates,[7–9] $N_2H_4$, pyrazolate, and pyridazine,[5] and some biologically relevant molecules such as $HCO_3^-$, $(p\text{-}NO_2C_6H_4O)_2PO_2^-$, and proline.[10]

In earlier work, we have also described the synthesis of a few $[(L^{Me})M_2(L')]^+$ complexes bearing tetrahedral main group and transition metal oxoanions. The X-ray crystal structures of the complexes $[(L^{Me})Co^{II}_2(MoO_4)]$[11] and $[(L^{Me})Ni^{II}_2(O_2P(OH)_2)]^+$ have been reported.[7] In view of the biological, technological and environmental importance of these anions,[12,13] we considered it worthwhile to prepare further complexes of this type to gain more insight into the binding of the oxoanions by the $[(L^{Me})M_2]^{2+}$ fragments. Here we describe the synthesis and characterization of a series of novel dinickel complexes bearing $ClO_4^-$, $ReO_4^-$, $SO_4^{2-}$, $CrO_4^{2-}$, $MoO_4^{2-}$, and $WO_4^{2-}$ ligands and explore their structural features.



$[(L^{Me})M^{II}_2(L')]^+$

## Results and Discussion

### Synthesis of Complexes

The complexes were prepared as indicated in Scheme 2. The perchlorato (**2**) and perrhenato (**3**) complexes were found to be inaccessible by direct reactions of the chloro complex **1** and the respective $EO_4^-$ ligand. In order to achieve their coordination, a $Cl^-$ abstraction was necessary. When **1**$[ClO_4]$ was dissolved in $CH_3CN$ and one equiv. of $Pb(ClO_4)_2$ was added, a dark green solution of **2** formed

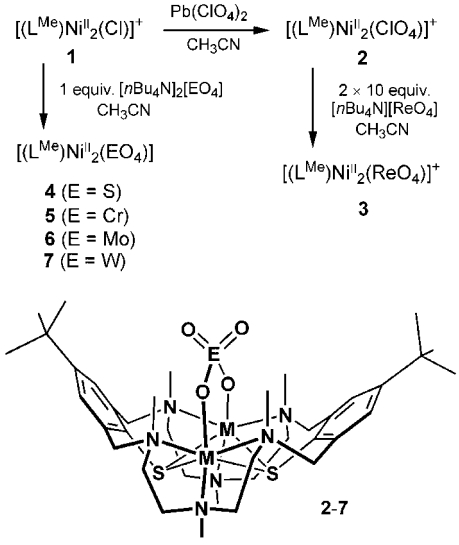
immediately, from which the previously reported perchlorate salt **2**[$ClO_4$] could be isolated as a dark-green, air-stable solid.[6] The $ClO_4^-$ in **2** is extreme labile and proved to be a suitable precursor for the synthesis of other $[(L^{Me})Ni_2(L')]^+$ complexes. Upon treatment of **2** with a large excess of [$n$Bu$_4$N][$ReO_4$] in acetonitrile, both the $ClO_4^-$ ligand and the $ClO_4^-$ counterion can be substituted for $ReO_4^-$ to give **3**[$ReO_4$], as indicated by elemental analyses and IR spectroscopy. Attempts to exchange the $ClO_4^-$ ion by a $MnO_4^-$ ion did not meet with any success. Treatment of **2**[$ClO_4$] with [$n$Bu$_4$N][$MnO_4$] resulted in the formation of an insoluble brown solid, from which no products could be isolated.



Scheme 2. Synthesis of complexes **2**–**7** from precursor **1**.

Although the $Cl^-$ complex **1** proved to be less labile than the $ClO_4^-$ complex **2**, substitution reactions succeeded with the $EO_4^{2-}$ ions (E = S, Cr, Mo, W); the driving force behind these syntheses presumably being the low solubility of the resulting neutral complexes. Thus, when solutions of $[(L^{Me})Ni^{II}_2(Cl)]^+$ **1** in acetonitrile were treated with equimolar amounts of the respective [$n$Bu$_4$N]$_2$[$EO_4$] salt at room temperature, pale green (**4**, **6**, **7**) or yellow (**5**) $[(L^{Me})Ni_2(EO_4)]$ complexes were formed within 4–12 h in good yields (69–88%). In contrast to **2**[$ClO_4$] and **3**[$ReO_4$], these neutral complexes were found to be sufficiently soluble in $CH_2Cl_2$, acetone, DMF, THF, but virtually insoluble in $CH_3CN$ and MeOH. All complexes were characterized by elemental analysis and standard spectroscopic methods. The crystal structures of **2**[$BPh_4$]·1.5$Me_2CO$·0.5MeOH, **3**[$ReO_4$]·$H_2O$, **4**·2$H_2O$·MeCN, **5**, and **7**·2$H_2O$·MeCN were also determined by X-ray diffraction.

## Spectroscopic Characterization

Infrared data for the complexes and their assignments are listed in Table 1. In addition to the bands arising from the $[(L^{Me})Ni_2]^{2+}$ fragments, all the complexes show strong IR bands for the $[EO_4]^{2-}$ and $[EO_4]^-$ groups. For the sulfato complex **4** two such bands are observed, as in other $SO_4^{2-}$ complexes,[14] at 1120 and 620 $cm^{-1}$; these are assigned to the antisymmetric stretching ($\nu_3$) and bending ($\nu_4$) modes of the sulfate ion. In view of the lowering of the symmetry by coordination to the $[(L^{Me})Ni_2]^{2+}$ fragment, a splitting of the $\nu_3$ mode of the $[EO_4]^{2-}$ ion is expected.[15] For **4** and **5**, this splitting is not resolved. In the case of the molybdato and wolframato complexes **6** and **7**, however, a split $\nu_3$ band is clearly discernible. Each of these compounds reveals two nearly equally intense absorptions in the 800 to 850 $cm^{-1}$ range, typical for coordinated $[MoO_4]^{2-}$,[14] and $[WO_4]^{2-}$ groups.[16] The IR spectra of **2**[$ClO_4$] and **3**[$ReO_4$] both reveal two broad but unsplit bands reflecting the presence of coordinating and non-coordinating $EO_4^-$ species. The observed wavenumbers are not markedly different from those of the free ions.[17–19]

The electronic spectra of the compounds were registered in acetonitrile or dichloromethane solution. Selected data are reported in Table 1. The intense absorptions below 500 nm can be attributed to π-π* transitions within the aromatic rings of the supporting ligand or to $RS^-\rightarrow Ni^{II}$ charge-transfer bands. Above 500 nm, each compound displays two weak absorption bands, typical of six-coordinate nickel(II) complexes.[20,21] Both the $\nu_1$ and the $\nu_2$ transitions are broad and unsymmetrical, indicative of the presence of a significant distortion from octahedral symmetry. The

slight differences in the position of the *d-d* transitions show that each complex retains its integrity in solution. The solid state magnetic moments for **4** and **6** are also consistent with an octahedral structure (see below).

### X-ray Crystallography

From a solution of the perchlorate salt of **2** in acetone/methanol to which $NaBPh_4$ had been added, pale green crystals of **2**$[BPh_4]\cdot 1.5Me_2CO\cdot 0.5MeOH$ suitable for X-ray crystallographic analysis were obtained after slow evaporation. The structure consists of dinuclear nickel complexes, tetraphenylborate anions, and acetone and methanol molecules of solvent of crystallization. There are no intermolecular interactions between these components in the solid state. Figure 1 presents an ORTEP view of the cation **2**. Selected bond lengths and angles are given in Table 2 and Table 3. The cation is isostructural with the other nickel complexes, with the perchlorate being coordinated in a bidentate bridging mode and the supporting ligand adopting a bowl-shaped $C_{2v}$ symmetric conformation typical for $[(L^{Me})M^{II}_2(L')]$ complexes coligated by $\mu_{1,3}$-bridging oxyanions.[22] The lability of the perchlorato complex is reflected in the long Ni–O bonds at 2.144(6) Å. In fact, this is the longest Ni–O distance reported for dinuclear $[(L^{Me})Ni_2(L')]^+$ complexes. Note, that the elongation of the Ni–O bonds in **2** is compensated for by an increase of the Ni–N and Ni–S distances. Overall, these structural parameters indicate that the monocharged perchlorate ion binds more weakly to the dinuclear $[(L^{Me})Ni_2]^{2+}$ fragment in **2** than does the doubly charged sulfato ligand in **4**.

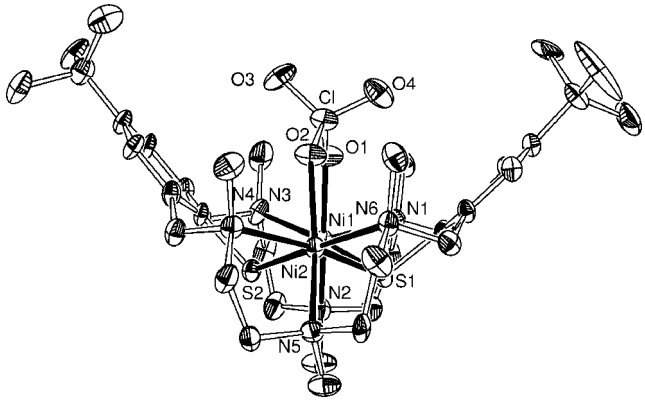

Figure 1. Structure of the cation **2** in crystals of **2**$[BPh_4]\cdot 1.5Me_2CO\cdot 0.5MeOH$. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms are omitted for reasons of clarity.

Pale green crystals of the perrhenato complex **3**$[ReO_4]\cdot H_2O$ suitable for X-ray diffraction analysis were obtained by slow evaporation of an acetonitrile/ethanol solution. The crystal structure consists of the dinuclear perrhenate complex **3**, perrhenate anions and water solvate molecules. As can be seen from Figure 2, complex **3** is isostructural with **2**. Within the $[(L^{Me})Ni_2]^{2+}$ fragments in **2** and **3**, the Ni–S and Ni–N bond lengths are very similar, with the largest difference outside experimental error being ca. 0.1 Å in the Ni–N(6) bonds. The coordination of the larger perrhenate group also results in a slight opening up of the Ni–S–Ni angles to 94.95(7)° thereby causing a larger Ni···Ni separation of 3.630(1) Å. The Ni–O distances are slightly shorter than in **2**, but still larger than those in **4** and **7**. In contrast to **2**, the terminal oxygen atoms of the two $ReO_4^-$ groups are involved in hydrogen bonding interactions with the water molecule of solvent of crystallization. These hydrogen bonds may be classified as moderate based on the bond

lengths of ca. 2.8 Å [O(4)···O(9) 2.822 Å, O(6)···O(9) 2.842 Å]. Similar hydrogen-bonding interactions are also observed in **4** and **7**.

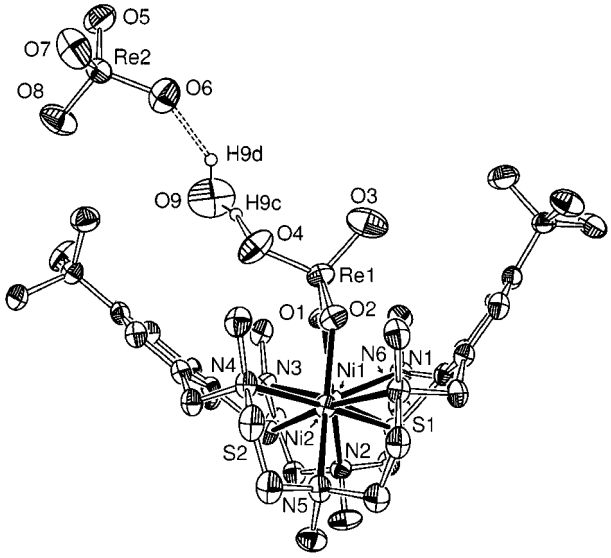

Figure 2. ORTEP plot of the structure of **3**. The hydrogen bonding interactions between the water molecule and the perrhenate groups are shown (dashed lines). Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms, except H(9c) and H(9d), are omitted for reasons of clarity.

Pale green crystals of the sulfato complex **4**·2$H_2O$·MeCN were grown by slow evaporation of a mixed (1:1) ethanol/acetonitrile solution of **4**. Figure 3 provides an ORTEP view of the structure of the neutral complex. As in **3**, there is a short O···O distance between the sulfato oxygen atom O(4) and a water molecule [*d*(O(4)···O(5) 2.671 Å] indicative of a hydrogen-bonding interaction. Complex **4** is the first example of a [($L^{Me}$)$Ni_2$(L′)] complex bearing a doubly charged coligand. A comparison of structure **2** with structure **4** allows the effects of $ClO_4^-$ vs. $SO_4^{2-}$ coordination in otherwise identical [($L^{Me}$)$Ni_2$]$^{2+}$ fragments to be evaluated. The only significant differences among these complexes are in the average Ni–O bond lengths, with the sulfato complex having significantly shorter Ni–O bonds than the perchlorato complex, most likely as a consequence of an increased electrostatic interaction. In this regard, it is also interesting to note that the terminal S=O bonds are slightly shorter than the bridging S–O bonds [e.g., 1.454(3) vs. 1.487(3) Å]. A similar behaviour has been noted previously for [($L^{Me}$)-$Co^{II}_2$($MoO_4$)].[11]

Slow evaporation of a $CH_2Cl_2$ solution of the chromato complex **5** gave orange crystals that were analyzed by X-ray crystallography. Although, the structure determination is of low quality and not as good as desired for publication,[23] it can serve to confirm the formulation and the atom connectivity of the neutral $CrO_4^{2-}$ complex. The structure is depicted in Figure 4, but not discussed further.

The wolframato complex **7** is isomorphous with **4**, with very similar unit cell parameters and molecular dimensions. The molecular structure is illustrated in Figure 5, and salient bond lengths and angles are given in Table 2 and

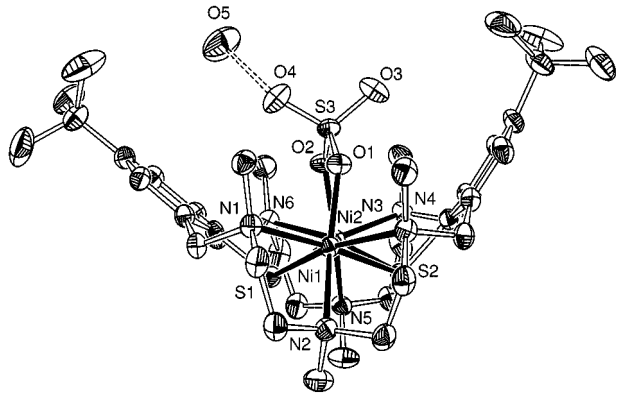

Figure 3. ORTEP plot of the neutral complex **4**. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms are omitted for reasons of clarity. The dashed line indicates the hydrogen bond between the sulfato oxygen atom O(4) and the water molecule O(5).

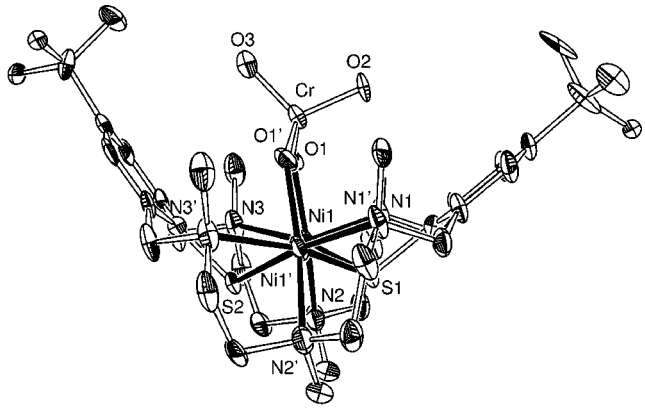

Figure 4. Structure of the neutral complex **5** with thermal ellipsoids drawn at the 50% probability level. Hydrogen atoms are omitted for reasons of clarity. Only one orientation of the disordered *t*Bu groups is displayed. Selected bond lengths [Å] and angles [°]: Ni–O(1) 2.001, Cr–O(1) 1.671, Cr–O(2) 1.639, Cr–O(3) 1.644; Ni(1)–S(1)–Ni(1′) 94.3, Ni(1)–S(2)–Ni(1′) 89.3. Symmetry code used to generate equivalent atoms: *x*, 0.5–*y*, *z* (′).

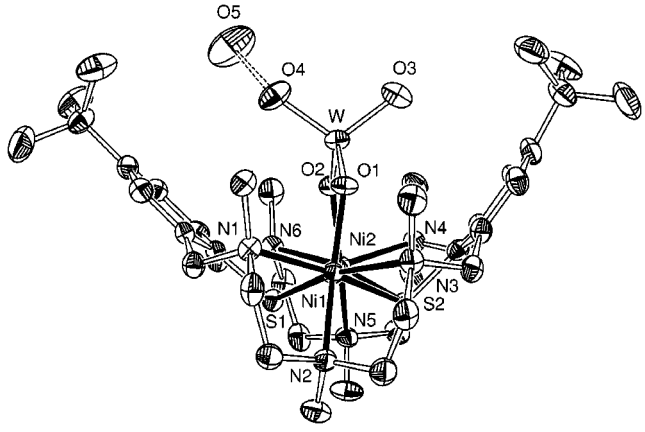

Figure 5. ORTEP plot of complex **7**. Thermal ellipsoids are drawn at 50% probability. Hydrogen atoms have been omitted for reasons of clarity. The dashed line indicates the hydrogen bond between the wolframato oxygen atom O(4) and the water molecule O(5).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 3. The average Ni–O bond length of 2.000(4) Å resembles that in **4**, again much shorter than in **2** and **3**. In agreement with the splitting of the $v_3$ band in the IR, the coordination about the tungsten atom is not perfectly tetrahedral. The W–O bonds vary between 1.749(4) Å and 1.778(4) Å and the O–W–O bond angles range from 106.5(2) to 111.9(2)°. The Ni···Ni separation is 3.655(1) Å in **7** and is 3.506(1) in **4**. As a consequence, the Ni–S–Ni bond angle in the wolframato complex **7** (93.61(6)°] is wider than in **4** (90.00(4)°].

### Magnetic Properties of Complexes 4 and 6

Temperature-dependent magnetic susceptibility measurements for complexes **4** and **6** were carried out to see whether magnetic exchange interactions are present in these complexes. The temperature dependent susceptibility data for powdered samples of the two complexes have been measured between 4.0 and 289 K by using a Faraday balance in an applied external magnetic field of 1.1 T. Figure 6 displays the temperature dependence of the effective moment ($\mu_{eff}$ per dinuclear complex) for complex **4**. The effective magnetic moment increases from 4.58 $\mu_B$ at 295 K to a maximum value of 5.10 $\mu_B$ at 25 K, and then decreases rapidly to 4.94 $\mu_B$ at 4.4 K. This behaviour indicates an intramolecular ferromagnetic exchange interaction between the two $Ni^{II}$ ions that leads to an S = 2 ground state of complex **4**. The decrease in $\mu_B$ below 22 K is presumably due to zero-field splitting of $Ni^{II}$.

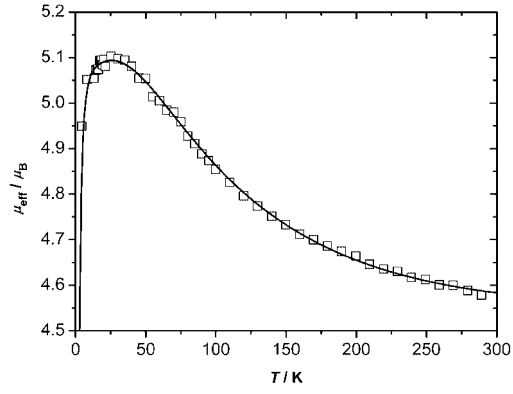

Figure 6. Temperature dependence of $\mu_{eff}$ for **4** (per dinuclear complex). The full line represents the best theoretical fit to eq. (1). Experimental and calculated values are provided as supporting information.

The temperature dependence of the magnetic moment for the wolframato complex **6** is similar to that of the sulfato complex **4** (Figure 7). The effective magnetic moment per dinuclear complex also increases from 4.33 $\mu_B$ at 295 K to a maximum of 5.08 $\mu_B$ at 10 K and then decreases again with decreasing temperature. The fact that the maximum occurs at lower temperatures than in **4** is indicative of a weaker ferromagnetic exchange interaction between the two $Ni^{II}$ ions in **6**.

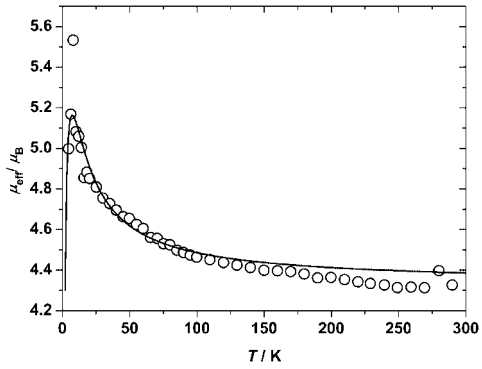

Figure 7. Temperature dependence of $\mu_{eff}$ for the molybdato complex **6** (per dinuclear complex). The full line represents the best theoretical fit to eq. (1). Experimental and calculated values are provided as supporting information.

To determine the magnitude of the exchange interactions, the temperature dependence of the magnetic data were simulated using the appropriate spin-Hamiltonian (1) including the isotropic HDVV exchange, the single-ion zero-field splitting and the single-ion Zeeman interaction by using a full-matrix diagonalization approach.[22,24] For complex **4** an excellent fit was obtained with $J$ = +24.8 $cm^{-1}$, $g$ = 2.08, and $|D|$ = 2.56 $cm^{-1}$. The experimental data for complex **6** were also analyzed in terms of the spin-Hamiltonian in eq. (1) The best fit gave $J$ = +3.75 $cm^{-1}$, $g$ = 2.17, and $|D|$ = 3.27 $cm^{-1}$. Although the experimental data could not be reproduced in every detail in this case, it is clear that the exchange interaction between the two $Ni^{II}$ ions in **6** is also ferromagnetic in nature and that this interaction is significantly weaker than in **4**.

$$H = -2JS_1S_2 + \sum_{i=1}^{2}[D_i(\hat{S}_{zi}^2 - \tfrac{1}{3}S_i(S_i+1)) + g_i\mu_B S_i B] \qquad (1)$$

It has been noted previously, that there exists a relationship between the sign and magnitude of the coupling parameter and the Ni–S–Ni angle in bioctahedral dinickel complexes supported by $(L^{Me})^{2-}$.[5,22] The coupling is antiferromagnetic in nature if the Ni–S–Ni angle deviates by more than about ±10° from 90°. For angles within the 90 ± 10° range a ferromagnetic interaction is observed. Moreover, the closer the Ni–S–Ni angles is at 90° the higher will be the magnitude of the ferromagnetic exchange interaction. Our observations of ferromagnetic exchange interactions in **4** and **6**, for which the Ni–S–Ni angles are in the 90 ± 10° range,[25] are in good agreement with the reported trend.

## Conclusions

The ability of the $[(L^{Me})Ni_2]^{2+}$ fragment to bind tetrahedral oxoanions of various main-group and transition elements has been demonstrated with the synthesis of a series of cationic ($n$ = 1) and neutral complexes ($n$ = 0) of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

type $[(L^{Me})Ni_2(EO_4)]^{n+}$, namely $[(L^{Me})Ni_2(ClO_4)]^+$ (**2**), $[(L^{Me})Ni_2(ReO_4)]^+$ (**3**), $[(L^{Me})Ni_2(SO_4)]$ (**4**), $[(L^{Me})Ni_2(CrO_4)]$ (**5**), $[(L^{Me})Ni_2(MoO_4)]$ (**6**), and $[(L^{Me})Ni_2(WO_4)]$ (**7**). All complexes were readily prepared and fully characterized by elemental analysis, IR and UV/Vis spectroscopy. The single-crystal X-ray structure determinations of **2**[$BPh_4$], **3**[$ReO_4$], **4**, **5**, and **7** showed the oxoanions to be coordinated in a $\mu_{1,3}$-bridging mode. Analysis of the structural parameters indicate that the monocharged $EO_4^-$ ions bind more weakly to the dinuclear $[(L^{Me})Ni_2]^{2+}$ fragment in **2** and **3** than the doubly charged $EO_4^{2-}$ groups in **4**–**7**. This was further confirmed by the lability of the $ClO_4^-$ ion in **2**, which renders this complex to be a suitable starting material for other $[(L^{Me})Ni_2(L')]^+$ complexes. The binding and solubility differences of the cationic and neutral $[(L^{Me})Ni_2(EO_4)]$ complexes suggests a possible use of the $[(L^{Me})Ni_2]^{2+}$ fragment in the selective recognition or separation of tetrahedral oxoanions. Studies on these and related topics are in progress in our laboratory.

## Experimental Section

All preparations were carried out under argon. Reagent grade solvents were used throughout. $[(L^{Me})Ni^{II}_2Cl]ClO_4$ (**1**) was prepared as described previously.[3] $[nBu_4N]_2[CrO_4]$ and $[nBu_4N]_2[MoO_4]$ were prepared from $[nBu_4N]OH$ and $CrO_3$ or $MoO_3{\cdot}2H_2O$,[26] respectively, using the procedure reported for $[nBu_4N]_2[WO_4]$.[27] All other reagents were obtained from standard commercial sources and used without further purifications. Melting points were determined in open glass capillaries and are uncorrected. Infrared spectra were recorded on a Bruker VECTOR 22 FT-IR spectrometer. The electronic absorption spectra were measured on a Jasco V-570 UV/Vis/NIR spectrometer. Elemental analyses were carried out with a VARIO EL elemental analyzer. Temperature-dependent (295–2 K) magnetic susceptibility measurements were carried out on Faraday balance (Manics DSM10 magnetometer) over the temperature range 4–295 K in an external magnetic field of 1.1 T. The observed susceptibility data were corrected for the underlying diamagnetism by the use of tabulated Pascal's constants.

***Caution!*** *Perchlorate salts of transition metal complexes are hazardous and may explode. Only small quantities should be prepared and handled with great care.*

**$[(L^{Me})Ni^{II}_2(\mu\text{-}ClO_4)][ClO_4]$ (2[$ClO_4$]):** To a solution of $[(L^{Me})Ni^{II}_2Cl][ClO_4]$ (**1**[$ClO_4$]) (184 mg, 0.200 mmol) in MeCN (50 mL) was added solid $Pb(ClO_4)_2$ (44.7 mg, 0.110 mmol). The reaction mixture was stirred for 2 h before $PbCl_2$ was removed by filtration. To the dark green filtrate was added a solution of $LiClO_4{\cdot}3H_2O$ (321 mg, 2.00 mol) in EtOH (100 mL). The solution was concentrated in vacuo to afford a dark green precipitate which was isolated by filtration and dried in air. Yield: 148 mg (75%). M.p. 308–309 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3443 (s br), 3045 (w), 3024 (w), 2992 (w), 2958 (s), 2900 (w), 2866 (s), 2815 (w), 1489 (w), 1462 (s), 1426 (w), 1395 (m), 1377 (w), 1363 (m), 1345 (vw), 1326 (w), 1310 (m), 1293 (w), 1262 (m), 1236 (m), 1200 (w), 1170 (m), 1156 (s), 1113 [vs, $\nu_3(ClO_4^-)$], 1097 [vs, $\nu_3(ClO_4^-)$], 1019 (m), 1000 (w), 981 (w), 911 (m), 932 (m), 895 (w), 882 (m), 824 (s), 818 (s), 808 (w), 754 (w), 624 [s, $\nu_4(ClO_4^-)$], 603 (w), 564 (w), 544 (w), 533 (w), 494 (w), 418 (w) $cm^{-1}$. UV/Vis (MeCN): $\lambda$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 578 (129), 1066 (86) nm. $C_{38}H_{64}Cl_2N_6Ni_2O_8S_2{\cdot}EtOH{\cdot}H_2O$ (985.37 + 64.08): calcd. C 45.78, H 6.92, N 8.01, S 6.11; found C 46.06, H 6.82, N 8.06, S. 6.00.

**$[(L^{Me})Ni^{II}_2(ReO_4)][ReO_4]$ (3[$ReO_4$]):** To a solution of $[(L^{Me})Ni_2(ClO_4)][ClO_4]$ (98 mg, 0.100 mmol) in acetonitrile (30 mL) was added an acetonitrile solution (20 mL) of $[nBu_4N][ReO_4]$ (493 mg, 1.00 mmol). The mixture was stirred for 12 h and concentrated in vacuo to give a yellow solid, which was filtered, washed with ethanol and dried in air. To remove traces of perchlorate impurities this material was treated again with a ten-fold molar excess of $[nBu_4N][ReO_4]$ as described above. Recrystallization from a mixed ethanol/acetonitrile solvent system then gave the title compound in analytically pure form. Yield: 107 mg (81%). M.p. > 365 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3560 (m), 3465 (m), 2961 (s), 2867 (s), 2248 [w, $\nu$(CN)], 1869 (w), 1637 (w), 1597 (w), 1461 (s), 1423 (w), 1394 (m), 1362 (m), 1306 (m), 1262 (m), 1231 (m), 1200 (w), 1168 (w), 1152 (m), 1132 (w), 1102 (w), 1074 (s), 1063 (s), 1041 (s), 998 (w), 977 (w), 963 (w), 931 [s, $\nu_3(ReO_4^-)$], 909 [s, $\nu_3(ReO_4^-)$], 824 (s), 807 (m), 751 (m), 666 (w), 630 (m), 602 (w), 564 (w), 539 (w), 531 (w), 493 (w), 467 (w), 434 (w), 416 (w) $cm^{-1}$. **Crystallography:** Crystals of **2**[$BPh_4$]·1.5($Me_2CO$)·0.5$H_2O$ were obtained from an acetone solution of **2**[$ClO_4$] to which a solution of $NaBPh_4$ in methanol had been added. Single-crystals of **5** were grown by recrystallization from $CH_2Cl_2$. All other compounds crystallized upon slow evaporation from 1:1 acetonitrile/ethanol solutions. Crystal data and refinement details are listed in Table 4. The intensity data were collected on a Bruker Smart CCD diffractometer. Graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) was used throughout. The data were processed with SAINT[28] and corrected for absorption using SADABS.[29] The structures were solved by direct methods (SHELXS)[30] and refined by full-matrix least-squares on $F^2$ using SHELXTL (version 5.1).[31] All non-hydrogen atoms were refined with anisotropic displacement parameters, except the C and O atoms of the disordered MeOH molecule in **2**.

Some of the solvate molecules in **2**, **4** and **7** were found to be severely disordered and/or partially occupied. The MeOH molecule in **2** lies near an inversion center such that only half a molecule lies in the asymmetric unit. The occupancy factor of one acetone molecule was also reduced to 0.5, and the C and O atoms were refined with equivalent anisotropic thermal parameters. In addition, one *tert*-butyl group was found to be disordered over two positions. A split atom model with restrained C–C and C···C distances was applied by using appropriate SADI instructions. In the isomorphous complexes **4** and **7**, one water molecule was found to be disordered over two sites with occupation factors of ca. 0.7 and 0.3. The C and N atoms of the acetonitrile molecule in **7** reveal high displacement parameters indicative of disorder. It was not possible to resolve this disorder, and geometric constraints using DFIX instructions were required to keep the structure of the solvate molecule reasonable. The MeCN molecule in **4**·2$H_2O$·MeCN could not be located from Fourier maps. The coordinates of the atoms were taken from the structure of **7** and the acetonitrile molecule was allowed to ride on the oxygen atom O(6b) by using an AFIX 3 instruction. The hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters, e.g., $U_{iso}$(H) = 1.2 × $U_{iso}$(parent) or $U_{iso}$(H) = 1.5 × $U_{iso}$(C) for methyl groups. The hydrogen atoms of the water molecule in **3** were calculated assuming a O–H distance of 0.96 Å and an ideal tetrahedral geometry. For **4** and **7**, water and acetonitrile hydrogen atoms were not included in the refinement. Graphics were obtained with ORTEP 3 for Windows.[32]

CCDC-631192 to -631195 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Derivation of the magnetic susceptibility expression for **4** and **6** and magnetic susceptibility data for **4** and **5** as a function of the temperature.

# Synthesis and Structural Characterisation of Diorganotin(IV) and Diphenyllead(IV) Complexes of Pyrimidine-2-thionate Derivatives

**Antonio Rodríguez,[a] Antonio Sousa-Pedrares,[a] J. Arturo García-Vázquez,*[a] Jaime Romero,[a] Antonio Sousa,[a] and Umberto Russo[b]**

**Keywords:** Tin / Lead / N,S ligands / NMR spectroscopy / Moessbauer spectroscopy

The reaction between the ligands 4-(trifluoromethyl)pyrimidine-2-thione (4-$CF_3$pymSH) and 6-methyl-4-(trifluoromethyl)pyrimidine-2-thione (6-Me-4-$CF_3$pymSH) and the corresponding diorganotin(IV) dichloride [$R_2SnCl_2$] (R = Me, *t*Bu or Ph) or diphenyllead(IV) dichloride in the presence of triethylamine yields the diorganotin(IV) complexes [$R_2$Sn(4-$CF_3$pymS)$_2$] and [$R_2$Sn(6-Me-4-$CF_3$pymS)$_2$] or diorganolead-(IV) complexes [$Ph_2$Pb(4-$CF_3$pymS)$_2$] and [$Ph_2$Pb(6-Me-4-$CF_3$pymS)$_2$], respectively. The compounds have been characterised by microanalysis, mass spectrometry and by IR and Mössbauer spectroscopy and, in the case of the compound that was sufficiently soluble, by $^1$H, $^{13}$C, $^{119}$Sn and $^{207}$Pb NMR spectroscopy. The compounds [$Me_2$Sn(4-$CF_3$pymS)$_2$] (**1**), [$Ph_2$Sn(4-$CF_3$pymS)$_2$] (**2**), [$Ph_2$Sn(6-Me-4-$CF_3$pymS)$_2$] (**5**), [*t*$Bu_2$Sn(6-Me-4-$CF_3$pymS)$_2$] (**6**), [$Ph_2$Pb(4-$CF_3$pymS)$_2$] (**7**) and [$Ph_2$Pb(6-Me-4-$CF_3$pymS)$_2$] (**8**) have also been characterised by X-ray diffraction. The X-ray crystal structures show that the metal centre in all these complexes is in a distorted octahedral environment with bonds to two carbon atoms from the aryl or alkyl substituents and to sulfur and heterocyclic nitrogen atoms from the pyrimidine derivative, which acts a ($\kappa^2$-N,S) chelating ligand.

## Introduction

The chemistry of metal complexes of heterocyclic thione ligands is receiving increasing attention, largely because of the potential relevance of such compounds as models of active sites in metalloenzymes and also their ability to adopt geometries of variable nuclearity and great structural complexity, which is a result of the tendency of thiolate ligands to bridge metal centres to yield oligomeric or polymeric species.[1–8]

However, in comparison with the coordination chemistry of transition metals, the chemistry of main group metals with sulfur ligands remains much less developed.[9–13] In many cases, the interaction of toxic main group metals with biological systems frequently involves bonding of the metal to the sulfhydryl groups present in enzymes. Hence, an insight into the chemistry of main group thiolate compounds is important in terms of understanding the aforementioned interaction and for the design of detoxifying agents.[14,15] This interest has led us to study organotin and organolead compounds that, in a biological medium, react with thiol groups in relevant molecules to yield products that are characterised by metal–thiolate interactions, which are of interest in the design of sequestering agents; indeed, several papers have been dedicated to the design of specific complexing agents.[15,16] In addition, organotin complexes have been studied more recently in terms of their pharmacological and antitumour activity.[17–22]

As a continuation of our studies into the coordination chemistry of sterically hindered heterocyclic thiones,[23] we report here the synthesis and characterisation of diorganotin(IV) and diphenyllead(IV) complexes with 4-(trifluoromethyl)pyrimidine-2-thione and 6-methyl-4-(trifluoromethyl)-pyrimidine-2-thione ligands, the structures of which are shown in Scheme 1. These ligands, besides having solubilising and bulky groups, belong to one of the most versatile types of sulfur ligand in terms of coordination modes. For example, they can act (a) as a neutral monodentate ligand coordinated through the sulfur atom,[24] through one of the nitrogen atoms,[25] and as a bridging ligand through sulfur[26] or as an N,S-chelating ligand,[27,28] or (b) as an anionic ligand, in which case they can be monodentate through the sulfur atom,[29] an N,S-chelating ligand[30–32] or

a binuclear bridging ligand through nitrogen and sulfur,[33] or sulfur only,[34] and as a binuclear triply bridging ligand through sulfur and one of the nitrogen atoms,[31,35] or the two nitrogen and sulfur atoms,[36,37] and as a trinuclear triply bridging system.[38]

Moreover, these ligands were chosen because they are unsymmetrical ambidentate systems and can therefore give rise to linkage isomerism when they are coordinated in some of the aforementioned ways.

## Results and Discussion

A series of diorganotin(IV) and diphenyllead(IV) complexes of general formulae $[R_2Sn(RpymS)_2]$ and $[Ph_2Pb(RpymS)_2]$ were synthesised in reasonable yields (47–74%) from the appropriate diorganotin(IV) dichloride $[R_2SnCl_2]$ (R = Me, Ph, *t*Bu) or diphenyllead(IV) dichloride ($Ph_2PbCl_2$) and the corresponding pyrimidine-2-thione derivative in methanol in the presence of triethylamine, according to Scheme 2.

The complexes reported here are air-stable as solids and do not show a tendency to decompose or oxidise. In addition, they have quite high solubility in the reaction medium, so the resulting solutions were concentrated in order to obtain the corresponding solids. Crystals of $[Ph_2Sn(4\text{-}CF_3pymS)_2]$ (**2**), $[Ph_2Sn(6\text{-Me-}4\text{-}CF_3pymS)_2]$ (**5**), $[Ph_2Pb(4\text{-}CF_3pymS)_2]$ (**7**) and $[Ph_2Pb(6\text{-Me-}4\text{-}CF_3pymS)_2]$ (**8**) suitable for X-ray studies were obtained by slow evaporation of the mother liquor at room temperature; $[Me_2Sn(4\text{-}CF_3pymS)_2]$ (**1**) and $[tBu_2Sn(6\text{-Me-}4\text{-}CF_3pymS)_2]$ (**6**) were obtained by recrystallisation of the initial product from ethanol.

one of the nitrogen atoms. Therefore, this pyrimidinethionate derivative is an example of an unsymmetrical ambidentate ligand whose N,S-bidentate coordination to the tin atom could generate linkage isomerism depending on which nitrogen atom is involved. In the case under discussion, the ligand uses the nitrogen atom with less hindrance (i.e., that in position 1), which is the nitrogen atom farthest from the trifluoromethyl substituent in the pyrimidine ring. This suggests that the nitrogen atom involved in the coordination in **1** and **2** is determined by the steric hindrance introduced by the trifluoromethyl group. In the case of the 6-methyl-4-(trifluoromethyl)pyrimidine-2-thionate ligand, the presence of the $CF_3$ group in the 4-position produces greater steric hindrance than the methyl group in the 6-position and, once again, the heterocyclic ligand in $[Ph_2Sn(6\text{-Me-}4\text{-}CF_3pymS)_2]$ (**5**) and $[tBu_2Sn(6\text{-Me-}4\text{-}CF_3pymS)_2]$ (**6**) adopts the same coordination mode as the 4-(trifluoromethyl)pyrimidine-2-thionate ligand in **1** and **2**. Naturally, other factors, such as crystal packing and inter- and/or intramolecular interactions, can also play a role in the coordination mode of the 4-(trifluoromethyl)pyrimidine-2-thionate ligand.

These complexes can be considered to be examples of a hexacoordinate bischelate diorganotin(IV) complex in which the environment around the tin atom is highly distorted octahedral. The C–Sn–C bond angle [123.0(2)° for **1**, 125.67(13)° for **2**, 126.76(12)° for **5** and 131.6(2)° for **6**] is intermediate between the ideal value for the *cis* isomer (90°) and the *trans* isomer (180°), a similar situation to that found in the majority of this type of compounds (122–155°), which suggests that the geometry of **1**, **2**, **5** and **6** can be described as a distorted trapezoidal bipyramid[39] in which the equatorial plane is formed by the sulfur and nitrogen atoms (the longest vertices of the trapezium consist of the two nitrogen atoms and the shortest contain the sulfur atoms) and the axial positions are occupied by the two methyl groups. Another possibility is to consider the compound as a bicapped tetrahedron[40,41] defined by the carbon and sulfur atoms, with four tetrahedral angles close to the ideal value [105.14(6)–113.87(11)°] and two C–Sn–C [123.0(2)–131.6(2)°] and S–Sn–S [84.12(5)–89.31(3)°] angles distorted by the influence of the capping atoms.

The Sn–S bond lengths [2.4599(7)–2.4886(12) Å] are slightly longer than the sum of the covalent radii of these elements (2.42 Å). These values are similar to those found in other hexacoordinate diorganotin(IV) compounds with anionic heterocyclic thionate N,S-chelate ligands, which have values in the range 2.4476(10)–2.503(2) Å.[22,42–46] Examples of such complexes include $[Me_2Sn(pyS)_2]$ [2.487(2) Å],[42] $[Ph_2Sn(4,6\text{-}Me_2\text{-}2\text{-}pymS)_2]$ [2.4476(10)],[44] $[(cyclo\text{-}C_6H_{11})_2Sn(pyS)_2]$ [2.503(2) Å][45] and $[Ph_2Sn(pyS)_2]$ [2.485(1) Å].[46] The Sn–C bond lengths [2.108(4)–2.216(4) Å] are similar to those found in the complexes $[R_2Sn(chelate)_2]$ discussed above, which have values in the range 2.046(14)–2.25(1) Å. The Sn–N bond lengths [2.770(3)–2.978(4) Å] are shorter than the sum of the van der Waals radii of these elements (3.75 Å)[47] but are rather longer than those found in other complexes containing Sn–N bonds {e.g., 2.271(9) and 2.256(9) Å in $[Cl_2Sn(pyS)_2]$}.[48] However, the values obtained for **1**, **2**, **5** and **6** are in the range found in the aforementioned $[R_2Sn(chelate)_2]$ complexes [2.639(6)–3.083(3) Å].

Both heterocyclic ligands in complexes **1**, **2** and **6** are essentially planar, with the sulfur atoms lying practically in the plane of the pyrimidine ring to which they are bonded. On the other hand, the tin atom lies out of these planes by 0.265(6) Å for **1** and 0.171(8) Å for **6** and practically in the plane of the pyrimidine ring in **2** [0.064(4) Å]. Each of the pyrimidine rings in compound **5** is also planar. However, whereas the sulfur and tin atoms are in the plane of the pyrimidine ring to which they are bound [deviation of 0.002 Å for S(1) and 0.028 Å for Sn] for one of these ligands, for the other ligand S(2) (0.094 Å) and Sn (0.228 Å) lie out of the plane of the pyrimidine ring. Moreover, the interplanar angle between the pyrimidine rings in **2** is only 0.23°. Consequently, **2** has an arrangement similar to that found in the complex dimethylbis(pyridine-2-thionato)tin(IV)[42] but is very different to that in the complexes dichloridobis(pyridine-2-thionato)tin(IV),[48] in which the planes of the two ligand molecules are almost perpendicular, and in **1**, **5** and **6**, where the thionate ligands form a dihedral angle [20.2(2)°, 6.89° and 9.09°, respectively] intermediate between those found in the aforementioned complexes.

The S–C [1.734(3)–1.753(4) Å] bond lengths in **1**, **2**, **5** and **6** are intermediate between the values observed in the free ligands 4,6-dimethylpyrimidine-2-thione[28] and 4,6-dimethyl-1-phenylpyrimidine-2-thione[27] [1.692(2) and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.686(4) Å, respectively], which exist in the thione form in the solid state, and the values of 1.781(2) and 1.782(3) Å found in bis(pyrimidyl)-2,2′-disulfide[49] and bis(4,6-dimethylpyrimidyl)-2,2′-disulfide,[50] which possess a simple C–S bond; this suggests that the ligand is coordinated in a form that is closer to the pyrimidine-2-thionate than to the thione form.

### Molecular Structures of $[Ph_2Pb(4\text{-}CF_3pymS)_2]$ (7) and $[Ph_2Pb(6\text{-}Me\text{-}4\text{-}CF_3pymS)_2]$ (8)

The molecular structures of **7** and **8** are shown in Figure 5 and Figure 6, respectively, together with the atom labelling scheme adopted. Crystallographic data and selected bond lengths and angles are given in the Experimental Section and Tables 5 and 6, respectively.

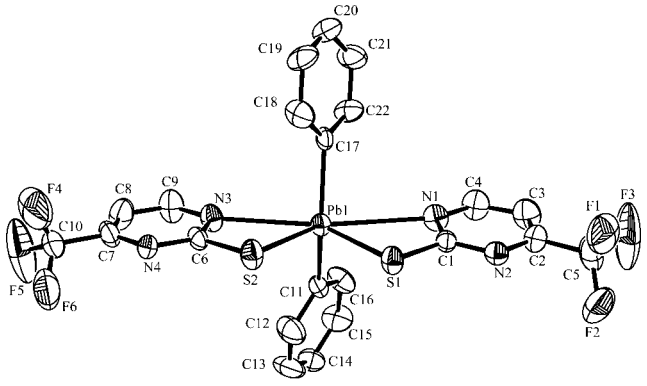

Figure 5. Crystal structure of $[Ph_2Pb(4\text{-}CF_3pymS)_2]$ (**7**) (50% probability displacement ellipsoids).

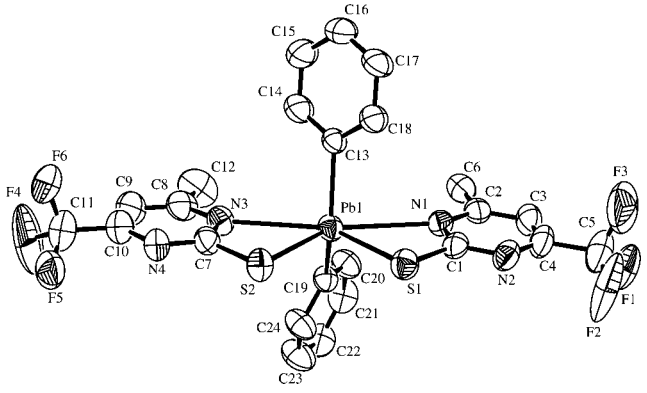

Figure 6. Crystal structure of $[Ph_2Pb(6\text{-}Me\text{-}4\text{-}CF_3pymS)_2]$ (**8**) (50% probability displacement ellipsoids).

The structures determined for these complexes are, as far as we know, the first examples of lead(IV) complexes containing heterocyclic thione ligands, such as pyridine-2-thione or pyrimidine-2-thione. The only previously reported structures containing lead and this type of ligand are the mononuclear complex $[Pb(3\text{-}CF_3pyS)_2]$[9] and trinuclear complex $[Pb_3(3\text{-}Me_3SipyS)_6]$.[51] In both cases the lead atom is in the oxidation state (II). This situation precludes a direct comparison involving the structural parameters of the compounds reported here.

Table 5. Selected bond lengths [Å] and angles [°] for $[Ph_2Pb(4\text{-}CF_3pymS)_2]$ (**7**).

[a] Symmetry codes: #1: $-x + 2$, $-y$, $-z + 2$; #2: $x + 0.5$, $-y + 0.5$, $z + 0.5$.

The complexes $[Ph_2Pb(4\text{-}CF_3pymS)_2]$ (**7**) and $[Ph_2Pb(6\text{-}Me\text{-}4\text{-}CF_3pymS)_2]$ (**8**) consist of neutral monomeric molecules in which the lead atoms are coordinated by two monoanionic thionate ligands and two phenyl groups. The thionate ligands are coordinated to the lead through their sulfur atoms and, more weakly, to one of the nitrogen atoms of each ligand, in such a way that each thionate ligand acts a bidentate chelate system ($\kappa^2$-N,S). In this way, the coordination number for the lead atom is six and the environment around this metal atom can be described as being similar to the analogous tin(IV) complexes **2** and **5**,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

i.e., a skewed trapezoidal bipyramid or a bicapped tetrahedron. The C–Pd–C bond angles are 142.8(4) Å for **7** and 134.59(19) Å for **8**, which are larger than those found in the diorganotin(IV) complexes previously described. In addition, in **7** and **8** the heterocyclic ligands adopt, for the same reasons, the same coordination mode as in the tin complexes mentioned previously.

The Pb–S bond lengths, 2.577(3) and 2.582(3) Å for **7** and 2.5722(14) and 2.5723(15) Å for **8**, are close to those found in diorganolead(II) tetracoordinate with thiolate ligands; 2.489(6) Å in $[Ph_3PbSMe]$[52] or 2.523(5) and 2.580(4) Å in $[(Ph_3Pb)_2(dmit)]$,[53] where $H_2dmit$ is 4,5-dimercapto-1,3-dithio-2-thione. However, the values found in **7** and **8** are lower than those found in the hexacoordinate thiolate $\{Ph_2Pb[S_2P(OCH_2Ph)_2]_2\}$,[54] 2.679(6) and 2.957(6) Å. The Pb–N bond lengths, 2.824(9) and 2.986(10) Å for **7** and 2.865(5) and 2.909(4) Å for **8**, are much longer than the sum of the corresponding covalent radii for lead (1.600 Å) and nitrogen (0.700 Å) and also longer than those found in other hexacoordinate diorganolead(IV) complexes containing a Pb–N bond; for example, 2.498(7) and 2.461(7) Å in $[Ph_2PbCl_2(imidazole)_2]$.[55] The fact that these distances are shorter than the sum of the van der Waals radii (3.82 Å) suggests that the Pb···N bonds in complexes **7** and **8** are significantly weaker than a normal intermolecular Pb–N bond, a situation similar to that observed in organotin complexes discussed above.

The phenyl and pyrimidine rings are planar [maximum deviation 0.010(3) Å]. The interplanar angle between the pyrimidine rings is only 4.75° in **7** and 3.76(3)° in **8** whereas the rings of the phenyl groups have interplanar angles of 19.63(8)° and 76.04(2)°, respectively. In compound **7**, the sulfur and lead atoms lie approximately in the plane of the pyrimidine ring to which they are bound. However, in **8** the sulfur atoms are approximately in the plane of the pyrimidine rings to which they are bound; 0.038(6) Å for S(1) and 0.067(7) Å for S(2). The lead atom is also practically in the plane of the pyrimidine to which S(1) is bonded [0.055(8) Å] but is out of the plane of the pyrimidine ring to which S(2) is attached [0.296(9) Å].

The average length of the S–C bond, 1.731(11) Å, is similar to that found in other complexes with pyrimidine-2-thionate derivatives, a fact that suggests that this ligand is coordinated in a form that is closer to the thionate than the thione.

## Crystal Packing and Intermolecular Interactions in 1, 2 and 5–8

The crystal packing in compounds **1**, **2** and **5**–**8** is mainly dictated by C–H···X hydrogen-bonding interactions between different C–H groups and the sulfur and nitrogen atoms of the pyrimidine-2-thionate ligands that are not coordinated, as well as interactions involving the $CF_3$ groups (see Tables 1–6).[56,57]

The way in which these C–H···X interactions propagate in space enables the crystal structures of these compounds to be classified into three groups: (1) interactions that propagate in a direction that gives rise to chains that interact weakly with one another; (2) bidimensional interactions that give rise to layers that interact weakly with one another; (3) interactions that are similar in intensity in all three dimensions.

### *Compounds with Crystal Packing in Chains*

The crystal packing arrangements in $[Ph_2Sn(4\text{-}CF_3pymS)_2]$ (**2**), $[tBu_2Sn(6\text{-}Me\text{-}4\text{-}CF_3pymS)_2]$ (**6**) and $[Ph_2Pb(4\text{-}CF_3pymS)_2]$ (**7**) can be described as chains parallel to the crystallographic *b* axis. The pyrimidine rings and the metal atoms are located approximately in the same plane throughout each of the chains. This arrangement is the result of weak C–H···X interactions that propagate along this direction. In **2** and **7**, this arrangement consists of two C–H···S[58,59] interactions between two C–H groups from the phenyl rings and the same sulfur atom of one of the pyrimidine-2-thionate ligands (**7**; see Figure 7) or with a sulfur atom of a different pyrimidine-2-thionate ligand (**2**). This situation is reflected in the angle between the planes of the phenyl rings, which is 19.63(80)° for **7** and 58.96(10)° for **2**. At the same time, and in the same direction, C–H···N[60,61] interactions are established between the uncoordinated nitrogen atom and the symmetry equivalent C–H *para* to this nitrogen (see Figure 7).

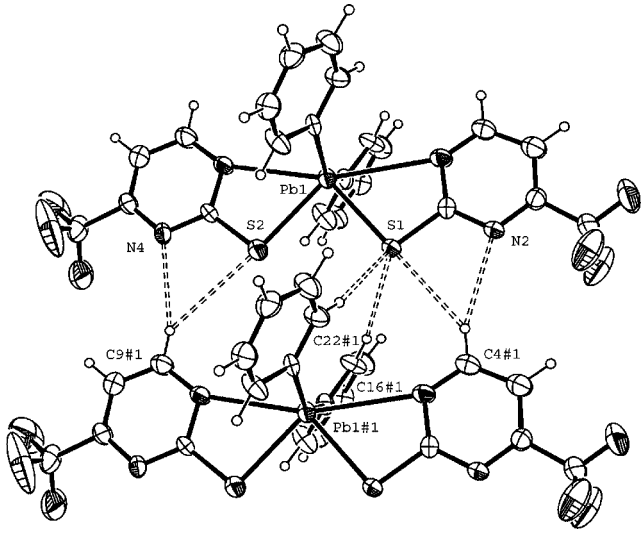

Figure 7. The crystal packing in **7**. Dashed lines show the C–H···S and the C–H···N interactions.

The crystal network of $[tBu_2Sn(6\text{-}Me\text{-}4\text{-}CF_3pymS)_2]$ (**6**) contains the same type of chain along the crystallographic *b* axis, with weak C–H···N and C–H···S interactions similar to those in the two previous cases, although in this case the C–H donor is the methyl group *para* to the uncoordinated nitrogen atom.

In all three cases each of the chains is involved in weak interactions with neighbouring chains in such a way that the planes of the pyrimidine rings along the chain are parallel to one another in the resulting crystal packing. These inter-chain interactions can be classified into two types:

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

those that involve the phenyl (complexes **2** and **7**) or *tert*-butyl (complex **6**), which are established with other chains located above and below the plane of the pyrimidine-2-thionate ligands, and those that involve $CF_3$ groups.[56,57] These $CF_3$ groups are located near to other trifluoromethyl groups in all three cases, a situation that is usual for this type of group.

### *Compounds with Crystal Packing in Layers*

The only compound reported here that shows this type of packing is $[Me_2Sn(4\text{-}CF_3pymS)_2]$ (**1**). Each pyrimidine-2-thionate ligand in this compound establishes two C–H···S interactions between the thionate groups and the C–H groups *para* to the sulfur atoms, as shown in Figure 8. The propagation of these interactions gives rise to layers of molecules parallel to the crystallographic AB plane. Within these layers the $CF_3$ groups are located very close to other $CF_3$ groups in such a way that F···F interactions are also formed within each layer; these interactions are not shown in Figure 8.

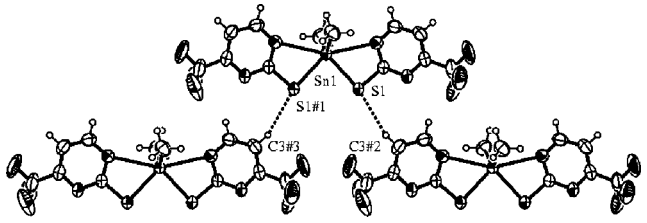

Figure 8. The crystal packing in **1**. Dashed lines show the C–H···S interactions.

The layers that are parallel to the AB planes interact weakly with one another through C–H···S[58,59] interactions between the methyl groups above and below the layers and the sulfur atoms of the pyrimidine-2-thionate ligands in neighbouring layers.

### *Compounds with Three-Dimensional Crystal Packing*

The compounds $[Ph_2Sn(6\text{-Me-}4\text{-}CF_3pymS)_2]$ (**5**) and $[Ph_2Pb(6\text{-Me-}4\text{-}CF_3pymS)_2]$ (**8**) are isomorphous and have identical crystal packing arrangements as a result of interactions of similar strength in three directions in space. The interactions responsible for the packing in these compounds are also C–H···S[58,59] interactions, and each of the thionate groups in the complex is involved in interactions with different C–H groups of other neighbouring complex molecules, as shown in Figure 9.

The S(1) sulfur atom establishes one of these interactions with a C–H group of one of the phenyl rings, while the S(2) sulfur establishes an interaction with a methyl group of a pyrimidine-2-thionate ligand of a neighbouring complex.

There is another type of interaction in addition to the C–H···S interactions, which involves π-π stacking between the phenyl ring not involved in C–H···S interactions and a symmetry equivalent centre of the pyrimidine ring connected to sulfur S(1). This interaction, which is relatively weak, is of the "parallel displaced" type and the centroids of the two rings are separated by 3.920 Å from tin and 3.843 Å from lead. As in the previously discussed complexes, the $CF_3$ groups are located very close to other $CF_3$ groups in such a way that F···F interactions are established.[56,57]

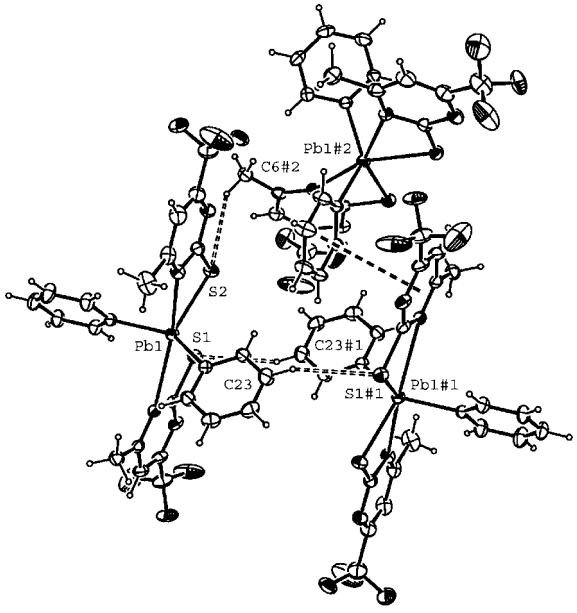

Figure 9. The crystal packing in **8**. Dashed lines show the C–H···S and the π-π stacking interactions.

## Spectroscopic Studies

### *IR Spectroscopy*

The IR spectra of the complexes (see the Experimental Section) show that the ν(N–H) bands of the free pyrimidine-2-thione ligands, which appear between 3200–3050 $cm^{-1}$, are absent from the thionate complexes. This indicates that deprotonation of the thionate group has occurred and therefore that the pyrimidine-2-thione is coordinated in the thionate form. This conclusion is supported by the shift to lower wavenumbers (1580–1550 $cm^{-1}$ in the complexes) of the strong bands due to ν(C=C) and ν(C=N), which appear at 1650–1550 $cm^{-1}$ in the free ligands. The spectra of the complexes also show bands due to the ring breathing vibration in the regions 1110–990 $cm^{-1}$ and 750–620 $cm^{-1}$, which are at higher wavenumbers than the corresponding bands in the free ligands. These shifts provide evidence for coordination of the ligands through the nitrogen atom.[62] The spectra of the methyl and *tert*-butyl derivatives also show additional medium intensity bands at 3100–2900 $cm^{-1}$, which correspond to the vibrations of the methyl groups.

### *NMR Spectra*

The main change in the $^1H$ NMR spectra of the thionate complexes brought about by complexation is the disappearance of the broad signal due to the N–H proton; this confirms that the ligand is in the deprotonated thionate form in the complexes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The $^1$H NMR spectra of the complexes show, in addition to the signals corresponding to the protons on the heterocyclic thionate ligand, signals due to the methyl, *tert*-butyl and phenyl groups of the organometallic fragments. The spectra of the dimethyltin(IV) derivatives also contain a signal at high field ($\delta$ = 1.1 ppm), which is attributed to the protons on the methyl groups of the $Me_2Sn$ fragment. These signals are accompanied by satellite peaks due to coupling of the proton with $^{119}$Sn and $^{117}$Sn nuclei. The $^2J_{^1H,^{119}Sn}$ and $^2J_{^1H,^{117}Sn}$ coupling constants are 74 and 72 Hz, respectively, and these values are similar to those found in other compounds containing the $Me_2Sn$ fragment.[22,63] These $^2J$ coupling constant values can be used to estimate the Me–Sn–Me angle.[64] The values calculated for these angles are 123.9° and 121.8° for **1** and **4**, respectively, and are very similar to one another and also to that found in the solid state for **1** by X-ray diffraction. This suggests that the structures of both compounds in solution are the same as that determined in the solid state for compound **1**.

The $^1$H NMR spectra of the $tBu_2Sn$ derivatives each contain a singlet at around $\delta$ = 1.50 ppm due to the *tert*-butyl protons. Once more, the corresponding satellite peaks can be observed. The $^3J_{^1H,^{119}Sn}$ and $^3J_{^1H,^{117}Sn}$ coupling constants in these cases are 52 and 50 Hz, respectively. The $^1$H NMR spectra of the $Ph_2Sn$ and $Ph_2Pb$ derivatives contain peaks attributable to the aromatic protons. Two groups of signals can be observed. The first is at $\delta$ = 7.8 ppm and is due to the protons *ortho* to the Sn atom. The second group appears at $\delta$ = 7.4 ppm and it is attributable to the other ring protons. The signals in the first group, in the case of the $Ph_2Sn$ derivatives, show satellite signals due to $^1$H-$^{119}$Sn coupling. In these cases, the $^3J_{^1H,^{119}Sn}$ values are close to 75 Hz.

The $^{13}$C NMR spectrum of the free ligand 6-Me-4-$CF_3$pymSH contains twice the expected number of signals for C(2), C(6), $CF_3$ and $CH_3$ as the free ligand exists in two tautomeric forms. This doubling in the number of signals is not observed in the $^{13}$C NMR spectra of the metal complexes. This situation provides evidence that the ligand is coordinated to the metal only in the thionate form in solution. The $^{13}$C NMR spectra of the other complexes that were sufficiently soluble in $CDCl_3$ show, in addition to the expected signals for the thionate ligand, signals attributable to the methyl group ($\delta$ = 6.5–5.5 ppm), phenyl group ($\delta$ = 122–140 ppm) and quaternary and primary carbon atoms from the *t*Bu groups ($\delta$ = 30–40 ppm) in the organometallic fragment.

The $^{119}$Sn NMR spectra of these complexes were recorded at room temperature in $CDCl_3$ using $SnMe_4$ as an external standard. The $^{119}$Sn chemical shifts seem to depend more on the nature of the alkyl or aryl groups bonded to the tin atom than on the pyrimidine ligand. Indeed, it appears that these groups do not have a significant effect on the shielding or deshielding of the tin nucleus. Whereas the $^{119}$Sn chemical shift for the diphenyltin(IV) derivatives appears at $\delta$ = –201.0 ppm for **2** and $\delta$ = –179.3 ppm for **5**, the compounds containing alkyl groups show less negative $^{119}$Sn chemical shifts. For example, the $Me_2Sn$ derivatives exhibit signals at $\delta$ = –70.3 ppm for **1** and $\delta$ = –86.4 ppm for **4**. These values are within the range reported for other complexes of diphenyl- or dimethyltin(IV) with pyrimidine or pyrimidine-2-thionate ligands with the same coordination number.[22,47,65] In the spectra of the $tBu_2Sn$ derivatives, the values of the $^{119}$Sn chemical shift are $\delta$ = –32.1 ppm for **3** and $\delta$ = –4.8 ppm for **6**. These seem to indicate that the complexes have a lower coordination number (tetracoordination) in $CDCl_3$ solution than in the solid state.[66] This change can be explained in terms of the breakdown of Sn–N interactions in solution, with these bonds in **6** (obtained from X-ray crystallography) being longer than the others presented in this work.

The $^{207}$Pb NMR spectra of diphenyllead(IV) complexes were recorded at room temperature in $CDCl_3$ using $PbMe_4$ as an external standard. The $^{207}$Pb chemical shift seems to be particularly sensitive to the electronic environment and is therefore an excellent tool for the study of changes in coordination number.[67] The $^{207}$Pb spectra contain a single peak at around $\delta$ = –199.0 ppm for **7** and $\delta$ = –206.7 ppm for **8**. These values suggest that both complexes of diphenyllead(IV) have the same coordination number in $CDCl_3$ solution (probably hexacoordinate as in the solid state).

### *Mass Spectra*

The tin and lead complexes were also characterised by mass spectrometry using the positive ion FAB technique in 3-nitrobenzyl alcohol (NBA) as matrix. The FAB spectra of dimethyl- and di-*tert*-butyltin with 4-$CF_3$pymS and dimethyltin with 6-Me-4-$CF_3$pymS show the molecular ion peak with the appropriate isotope distribution (*m*/*z* 508, 592 and 536, respectively). In these cases, peaks were also observed due to the fragments produced by the loss of one thionate ligand (*m*/*z* 328, 412 and 342, respectively) or one of these ligands and the two alkyl groups. The spectra of the other tin complexes do not show the molecular ion peaks but do show peaks associated with loss of one phenyl group [*m*/*z* 555 for $PhSn(4\text{-}CF_3pymS)_2$ and 582 for $PhSn(6\text{-}Me\text{-}4\text{-}CF_3pymS)_2$] or one thionate ligand [*m*/*z* 453 for $Ph_2Sn(4\text{-}CF_3pymS)$, 467 for $Ph_2Sn(6\text{-}Me\text{-}4\text{-}CF_3pymS)$ and 427 for $tBu_2Sn(4\text{-}CF_3pymS)_2$].

The FAB mass spectrum of $[Ph_2Pb(4\text{-}CF_3pymS)_2]$ shows the molecular ion peak at *m*/*z* = 720. In this compound, and also in the other lead compound, peaks corresponding to fragments of the parent ions due to loss of different groups from the compounds are observed. For example, peaks are observed at *m*/*z* 540 for **7** and 555 for **8** and these are associated with $Ph_2Pb(RpymS)$ formed by loss of one thionate ligand. Peaks due to the fragments produced by the loss of two phenyl groups and one thionate ligand (*m*/*z* 386 when R = $CF_3$ and 400 when R = 6-Me-4-$CF_3$) are also seen.

### *Mössbauer Spectra*

As expected from their chemical formulae, the Mössbauer spectra of the reported compounds show only a single, slightly asymmetric, quadrupole split doublet (Table 7).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The linewidths are narrow enough to rule out any doublet overlap, which implies the existence of just a single tin site in each complex. The isomer shift values are rather surprising as they are grouped around two values, both of which are typical for $SnR_2$ derivatives (1.49 and 1.87 mm s$^{-1}$), in an unexpected way. In fact, the inductive effects of the organic groups would lead to increasing values in the order Ph >> Me > Bu, and so the only explanation must lie in different geometrical distortions or in varying Sn–N bond lengths. A closer analysis of Tables 2, 3, 4, and 5 shows that the average Sn–N bond length for compounds **1**, **2**, and **5**, which have the lowest isomer shift values, is 2.817 ± 0.039 Å, clearly shorter than that of compound **6** [2.978(4) Å]. This value, even though significantly shorter than the sum of the van der Waals radii of these atoms (3.75 Å), indicates that the two Sn–N bonds are rather weak and so the coordination geometry around the tin centre has a considerable fourfold character. This increases the s-electron density at the tin nucleus and so leads to a larger isomer shift. Moreover, the presence of a methyl group in the ligand does not affect the electron density on the tin atom, as expected. The quadrupole splitting values are also very close to each other and quite low, close to values typical for *cis*-$SnR_2$ derivatives (1.7–2.2 mm s$^{-1}$).

Table 7. Mössbauer parameters collected at 80 K. The $\delta$ values are quoted relative to $SnO_2$ at room temperature.

| | $\delta$ [mm s$^{-1}$] | $\Delta E_Q$ [mm s$^{-1}$] | $\Gamma$ [mm s$^{-1}$] | $\Gamma_2/\Gamma_1$ |
|---|---|---|---|---|
| [$Me_2Sn(4\text{-}CF_3pymS)_2$] (**1**) | 1.49 | 2.46 | 0.87 | 0.91 |
| [$Ph_2Sn(4\text{-}CF_3pymS)_2$] (**2**) | 1.49 | 2.68 | 0.87 | 0.97 |
| [$tBu_2Sn(4\text{-}CF_3pymS)_2$] (**3**) | 1.87 | 2.74 | 0.86 | 0.96 |
| [$Ph_2Sn(6\text{-}Me\text{-}4\text{-}CF_3pymS)_2$] (**5**) | 1.49 | 2.54 | 0.85 | 1.03 |
| [$tBu_2Sn(6\text{-}Me\text{-}4\text{-}CF_3pymS)_2$] (**6**) | 1.87 | 2.70 | 0.92 | 0.93 |

Point charge calculations performed by ignoring the influence of the pymS ligand on the electron density around the tin atoms, but taking into account only the experimental C–Sn–C bond angles, afforded values that were too high (2.83–3.14 mm s$^{-1}$) and strongly dependent on the input values. In fact, the C–Sn–C bond angles [123.0–131.6°] are intermediate between the ideal values for the *cis* (90°) and for the *trans* isomer (180°), a situation similar to that found in the majority of this type of compounds (122–155°). The coordination geometry for these compounds can, in fact, be described as a distorted trapezoidal bipyramid[39] in which the equatorial plane is formed by the sulfur and nitrogen atoms, or as a bicapped tetrahedron. These results point to the inability of the point charge method to reproduce the Mössbauer quadrupole splitting in the case of severely distorted structures.

## Conclusions

The work described here involves the synthesis and structural characterisation of a series of compounds obtained by the reaction of the appropriate diorganotin(IV) and diphenyllead(IV) dichlorides with 4-(trifluoromethyl)pyrimidine-2-thione and 6-methyl-4-(trifluoromethyl)pyrimidine-2-thione in methanol in the presence of triethylamine.

The structures of the diorganotin(IV) and diphenyllead(IV) compounds have been investigated and the coordination polyhedron of the metal atom can be described either as a distorted skew-trapezoid or a bicapped tetrahedron, with the heterocyclic thionate acting in a bidentate ($\kappa^2$-N,S) manner. In these arrangements the ligands are unsymmetrical ambidentate and therefore the N,S-bidentate coordination to the metallic atom could generate linkage isomerism through one of the two nitrogen atoms. Only one coordination mode is found in these complexes and this involves the sulfur atom and the less hindered nitrogen atom, which is farthest from the group with the highest level of steric hindrance in the heterocyclic rings; in both cases this is the trifluoromethyl group. Furthermore, it is worth noting that the R groups (methyl, *tert*-butyl or phenyl) of the $R_2M$ moiety do not markedly influence the structure of the complex.

## Experimental Section

**General:** 4-(Trifluoromethyl)pyrimidine-2-thione, 1,1,1-trifluoro-2,4-pentanedione, thiourea, triethylamine, dimethyltin(IV) dichloride, diphenyltin(IV) dichloride, bis(*tert*-butyl)tin dichloride and diphenyllead(IV) dichloride were obtained commercially and used as supplied.

Elemental analysis was performed with a Carlo–Erba EA microanalyser. IR spectra were recorded as KBr mulls with a Bruker IFS-66V spectrophotometer. $^1$H and $^{13}$C NMR spectra were recorded with a Bruker AMX 300 MHz instrument using $CDCl_3$ or [$D_6$]DMSO as solvent. Chemical shifts are quoted relative to TMS as the internal standard. $^{119}$Sn and $^{207}$Pb NMR spectra were recorded with a Bruker AMX500 spectrometer in $CHCl_3$ as solvent using $SnMe_4$ and $PbMe_4$ as an external standard, respectively. The Mössbauer spectra were recorded at $T$ = 80 K in a constant acceleration apparatus and are referenced to $SnO_2$. The mass spectra (FAB) were recorded with a Micromass Autospec spectrometer, with 3-nitrobenzyl alcohol as the matrix material.

**Synthesis of 6-Me-4-$CF_3$pymSH:** This compound was obtained by direct reaction between thiourea (2.428 g, 32 mmol) and 1,1,1-trifluoro-2,4-pentanedione (5 g, 32 mmol) in ethanol in the presence of concentrated hydrochloric acid (1 mL) as a catalyst. The mixture was heated under reflux for 2 h and the resulting dusty yellow solid was filtered off. $C_6H_5F_3N_2S$: calcd. C 37.11, H 2.60, N 14.43, S 16.51; found C 36.39, H 2.60, N 14.26, S 16.38. IR (KBr): $\tilde{\nu}$ = 3100–3200 cm$^{-1}$ m, br, 1615 vs, 1590 vs, 1440 m, 1350 vs, 1320 w, 1200 s, br, 1130 m, 1100 m, 1030 w, 970 s, 920 m, 860 w, 850 m, 705 w, 660 w, 595 w, 570 w, 530 m, 510 w, 470 m, 450 m, 370 w. $^1$H NMR ([$D_6$]DMSO): $\delta$ = 14.40 (s, 1 H, NH), 7.19 (s, 1 H, H-5), 2.39 (s, 3 H, $CH_3$) ppm. $^{13}$C NMR ([$D_6$]DMSO): $\delta$ = 181.00 and 172.13 (s, C-2), 155.86 and 153.72 (q, $^2J_{^{13}C,^{19}F}$ = 35 Hz, C-4), 104.89 (s, C-5), 163.61 (s, C-6), 119.27 and 119.67 (q, $^1J_{^{13}C,^{19}F}$ = 275 Hz, $CF_3$), 23.45 and 18.46 (s, $CH_3$). MS (FAB): *m*/*z* (%) 194 (27) [6-Me-4-$CF_3$pymSH].

**Synthesis of [$Me_2Sn(4\text{-}CF_3pymS)_2$] (1):** Triethylamine (0.128 mL, 0.700 mmol) was added by syringe to a solution of 4-$CF_3$pymSH (0.150 g, 0.832 mmol) in methanol (50 mL) and the resulting solution was stirred for 1 h at room temperature. A solution of dimethyltin dichloride (0.091 g, 0.414 mmol) in methanol (15 mL) was then added and the mixture was heated under reflux for about

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2.5 h. The solution was filtered and slow evaporation of the solvent gave rise to a cream-coloured solid, which was recrystallised from ethanol to give yellow crystals suitable for X-ray studies. Yield: 0.099 g (47%). $C_{12}H_{10}F_6N_4S_2Sn$ (507.04): calcd. C 28.43, H 1.99, N 11.05, S 12.65; found C 28.44, H 1.65, N 11.03, S 12.71. IR (KBr): $\tilde{\nu}$ = 3050 $cm^{-1}$ w, 1550 s, 1420 m, 1340 vs, 1325 vs, 1200 s, 1160 vs, br, 1110 s, 980 w, 840 sh, 830 s, 780 m, 730 m, 665 m, 555 w, 520 w, 460 w, 355 w, 320 w. $^1$H NMR ($CDCl_3$): $\delta$ = 8.7 (d, $^3J_{H,H}$ = 4.9 Hz, 1 H, H-6), 7.3 (d, $^3J_{H,H}$ = 4.9 Hz, 1 H, H-5), 1.1 (s, 3 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 175 (s, $C^2$), 160 (s, $C^6$), 150 (q, $C^4$), 120 (q, $C^7$), 115 (s, $C^5$), 5.4 ppm (s, Me). $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –70.29 ppm. MS (FAB): *m*/*z* (%) 508 (12) [$Me_2Sn$(4-$CF_3$pymS)$_2$], 328 (100) [$Me_2Sn$(4-$CF_3$pymS)].

**Synthesis of [$Ph_2Sn$(4-$CF_3$pymS)$_2$] (2):** The same procedure as for **1** was used for the synthesis of the diphenyltin derivative. A solution of $Ph_2SnCl_2$ (0.142 g, 0.413 mmol), 4-$CF_3$pymSH (0.150 g, 0.832 mmol) and $NEt_3$ (0.128 mL, 0.700 mmol) in methanol (40 mL) was heated under reflux for 3 h. This solution was concentrated to give single crystals suitable for X-ray studies. Yield: 0.193 g (74%). $C_{22}H_{14}F_6N_4S_2Sn$ (631.18): calcd. C 41.86, H 2.24, N 8.88, S 10.16; found C 42.31, H 2.30, N 8.21, S 10.12. IR (KBr): $\tilde{\nu}$ = 3040 $cm^{-1}$ w, 1550 vs, 1470 m, 1420 s, 1330 vs, br, 1200 s, 1140 m, 1110 m, 1060 w, 1015 w, 990 w, 975 w, 960 vw, 910 w, 830 s, 780 vw, 720 s, 690 m, 665 s, 460 w, 440 m, 355 m, 320 m. $^1$H NMR ($CDCl_3$): $\delta$ = 8.38 (d, $^3J_{H,H}$ = 5.1 Hz, 1 H, H-6), 7.8 (br, phenyl H) and 7.4 (br, phenyl H), 7.08 (d, $^3J_{H,H}$ = 5.1 Hz, 1 H, H-5) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 129–135 ppm (aromatic carbons). NO other signals could be detected due to the poor solubility of this complex. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –201 ppm. MS (FAB): *m*/*z* (%) 554.8 (12) [PhSn(4-$CF_3$pymS)$_2$], 452.9, (54) [$Ph_2Sn$(4-$CF_3$pymS)], 298.8 (7) [Sn(4-$CF_3$pymS)].

**Synthesis of [*t*$Bu_2$Sn(4-$CF_3$pymS)$_2$] (3):** A solution of *t*$Bu_2SnCl_2$ (0.126 g, 0.414 mmol) in methanol was added to a solution of 4-$CF_3$pymSH (0.150 g, 0.832 mmol) and $NEt_3$ (0.128 mL, 0.421 mmol) in methanol (30 mL) and the reaction mixture was stirred and heated under reflux for 3 h. The resulting solution was slowly evaporated at room temperature to give colourless crystals suitable for X-ray studies. Yield: 0.175 g (74%). $C_{18}H_{22}F_6N_4S_2Sn$ (591.20): calcd. C 36.57, H 3.75, N 9.48, S 10.85; found C 36.74, H 3.14, N 9.50, S 10.96. IR (KBr): $\tilde{\nu}$ = 3050 $cm^{-1}$ w, 2980 w, 2940 w, 2840 m, 1550 s, 1460 m, 1450 m, 1425 m, 1340 w, 1330 vs,br, 1205 s, 1190 m, 1150 m, 1140 m, 1110 m, 1080 vw, 1010 w, 975 w, 935 w, 830 m, 730 m, 665 m, 460 vw, 350 w, 315 w. $^1$H NMR ($CDCl_3$): $\delta$ = 8.8 (d, $^3J_{H,H}$ = 4.9 Hz, 1 H, H-6), 7.4 (d, $^3J_{H,H}$ = 4.9 Hz, 1 H, H-5), 1.50 (s, 9 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 170 (s, $C^2$), 160 (s, $C^6$), 155 (q, $C^4$), 120 (q, $C^7$), 95 (s, $C^5$), 29.7, 30.0 and 31.6 ppm (*t*Bu). $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –32.16 ppm. MS (FAB): *m*/*z* (%) 592 (14) [*t*$Bu_2$Sn(4-$CF_3$pymS)$_2$], 534 (12) [*t*$Bu_2$Sn(4-$CF_3$pymS)$_2$ – 3F], 412 (76) [*t*$Bu_2$Sn(4-$CF_3$pymS)], 298 (100) [Sn(4-$CF_3$pymS)].

**Synthesis of [$Me_2$Sn(6-Me-4-$CF_3$pymS)$_2$] (4):** A solution of $Me_2SnCl_2$ (0.100 g, 0.220 mmol) was added to a solution of (6-Me-4-$CF_3$pymSH) (0.030 g, 0.157 mmol) and $NEt_3$ (0.073 g, 0.233 mmol) in methanol (40 mL) with constant stirring at room temperature. This mixture was heated under reflux for 2.5 h. The solution was the concentrated to give single crystals that were not suitable for X-ray studies. Yield: 0.132 g (54%). $C_{14}H_{14}F_6N_4S_2Sn$ (535.09): calcd. C 31.43, H 2.64, N 10.47, S 11.98; found C 31.52, H 2.52, N 10.51, S 11.72. IR (KBr): $\tilde{\nu}$ = 3080 $cm^{-1}$ w, 3060 w, 1575 m, 1540 s, 1530 vw, 1390 vs, 1365 m, 1310 w, 1265 vs, 1255 m, 1220 w, 1190 w, 1165 w, 1140 m, 1110 m, 1030 w, 990 w, 980 w, 920 m, 875 w, 855 s, 790 m, br, 710 s, 550 m, 515 w, 480 w, 460 w. $^1$H NMR ($CDCl_3$): $\delta$ = 7.14 (s, 1 H, H-5), 2.55 (s, 3 H, H-8), 1.08 (s, 3 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 176.6 (s, $C^2$), 155 (q, $C^4$), 110.6 (s, $C^5$), 171 (s, $C^6$), 120 (q, $C^7$) 24.84 (s, $C^8$), 5.79 ppm (s, Me). $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –86.4 ppm. MS (FAB): *m*/*z* (%) 536 (19) [$Me_2$Sn(6-Me-4-$CF_3$pymS)$_2$], 342 (100) [$Me_2$Sn(6-Me-4-$CF_3$pymS)].

**Synthesis of [$Ph_2$Sn(6-Me-4-$CF_3$pymS)$_2$] (5):** A solution containing diphenyltin dichloride (0.150 g, 0.436 mmol), 6-methyl-4-(trifluoromethyl)pyrimidine-2-thione (0.140 g, 0.721 mmol) and triethylamine (0.110 g, 0.400 mmol) in methanol (30 mL) was heated under reflux for 3 h. It was then evaporated to give white, needle-like crystals that were suitable for X-ray studies. Yield: 0.139 g (52%). $C_{24}H_{18}F_6N_4S_2Sn$ (659.23): calcd. C 43.73, H 2.75, N 8.50, S 9.73; found C 43.12, H 2.49, N 8.38, S 9.62. IR (KBr): $\tilde{\nu}$ = 3080 $cm^{-1}$ w, 1575 s, 1530 s, 1470 w, 1440 w, 1425 m, 1385 s, 1360 m, 1305 vw, 1265 vs, 1250 w, 1220 m, 1190 m, 1170 m, 1135 s, 1110 m, 1070 vw, 995 w, 980 vw, 920 w, 845 s, 730 m, 710 s, 690 m, 545 w, 460 w, 440 m. $^1$H NMR ($CDCl_3$): $\delta$ = 7.85 (m, *ortho*-phenyl), 7.3 (m, phenyl) 7.15 (s, 1 H, H-5), 2.5 (s, 3 H, H-8) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 173.3 (s, $C^2$), 156.0 (q, $C^4$), 141.5–122.4 (phenyl carbons), 112.2 (s, $C^5$), 170.0 (s, $C^6$), 120 (q, $C^7$), 24.13 ppm (s, $C^8$). $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –179.3 ppm. MS (FAB): *m*/*z* (%) 582 (12) [PhSn(6-Me-4-$CF_3$pymS)$_2$], 467 (52) [$Ph_2$Sn(6-Me-4-$CF_3$pymS)], 312 (15) [Sn(4-Me-6-$CF_3$pymS)].

**Synthesis of [*t*$Bu_2$Sn(6-Me-4-$CF_3$pymS)$_2$] (6):** The same procedure as for **4** was used for the synthesis of the di-*tert*-butyltin derivative. A solution of 6-Me-4-$CF_3$pymSH (0.150 g, 0.772 mmol) in methanol (50 mL) was added to a solution containing di-*tert*-butyltin dichloride (0.140 g, 0.461 mmol) and $NEt_3$ (0.110 g, 0.700 mmol) in methanol (15 mL) and the mixture was stirred and heated under reflux for 4 h. It was then filtered and evaporated to give a white crystalline solid (0.136 g, 57%). Crystallisation from ethanol gave single crystals that were suitable for X-ray studies. $C_{20}H_{26}F_6N_4S_2Sn$ (619.26): calcd. C 38.79, H 4.23, N 9.05, S 10.35; found C 38.76, H 4.11, N 8.98, S 10.08. IR (KBr): $\tilde{\nu}$ = 3060 $cm^{-1}$ w, 2980 m, 2940 w, 2840 m, 1570 s, 1530 s, 1450 m, 1430 w, 1390 vs, 1355 w, 1305 m, 1260 vs, br, 1220 m, 1175 m, 1150 vs, br, 1100 w, 1010 w, 970 m, 920 m, 840 s, 800 vw, 780 vw, 655 s, 575 w, 550 m, 480 vw, 450 w. $^1$H NMR ($CDCl_3$): $\delta$ = 7.13 (s, 1 H, H-5), 2.56 (s, 3 H, H-8), 1.49 (s, 9 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 176 (s, $C^2$), 170.2 (s, $C^6$), 112.07 (s, $C^5$), 25.02 (s, $C^8$), 46 [s, $C(CH_3)_3$], 31.82 ppm [s, $C(CH_3)_3$]. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –4.78 ppm. MS (FAB): *m*/*z* (%) 506.9 (13) [Sn(6-Me-4-$CF_3$pymS)$_2$], 427.0 (72) [*t*$Bu_2$Sn(6-Me-4-$CF_3$pymS)], 312.9 (100) [Sn(6-Me-4-$CF_3$pymS)].

**Synthesis of [$Ph_2$Pb(4-$CF_3$pymS)$_2$] (7):** A solution of 4-$CF_3$pymSH (0.150 g, 0.832 mmol) and $NEt_3$ (0.126 g, 0.700 mmol) in methanol (50 mL) was added to a stirred suspension of diphenyllead dichloride (0.179 g, 0.414 mmol) in methanol (15 mL). The reaction mixture was heated under reflux for 4 h and the yellow solid was filtered off, washed with diethyl ether and dried under vacuum. The mother liquor yielded crystals suitable for X-ray studies (0.112 g, 56%). $C_{22}H_{14}F_6N_4PbS_2$ (719.68): calcd. C 36.72, H 1.96, N 7.78, S 8.91; found C 36.70, H 2.03, N 7.78, S 8.90. IR (KBr): $\tilde{\nu}$ = 3040 $cm^{-1}$ w, 1555 s, 1465 w, 1430 w, 1415 m, 1340 s, 1330 s, 1205 s, 1170 w, 1140 m, 1115 m, 1010 w, 990 m, 975 w, 835 m, 730 m, 720 m, 680 vw, 670 m, 440 m. $^1$H NMR ($CDCl_3$): $\delta$ = 8.54 (d, $^3J_{H,H}$ = 5.0 Hz, 1 H, H-6), 8.14–7.29 (phenyl H), 7.15 ppm (d, $^3J_{H,H}$ = 5.0 Hz, 1 H, H-5). $^{13}$C NMR ($CDCl_3$): $\delta$ = 135–130 ppm (phenyl C). $^{207}$Pb NMR ($CDCl_3$): $\delta$ = –199.0 ppm. MS (FAB): *m*/*z* (%) 720 (6) [$Ph_2$Pb(4-$CF_3$pymS)$_2$], 540 (100) [$Ph_2$Pb(4-$CF_3$pymS)], 386 (40) [Pb(4-$CF_3$pymS)], 284 (28) [PhPb].

**Synthesis of [$Ph_2$Pb(6-Me-4-$CF_3$pymS)$_2$] (8):** A similar procedure to that described above was followed, starting from a suspension

of $Ph_2PbCl_2$ (166 mg) in methanol, and a mixture of 6-Me-4-$CF_3$pymSH (150 mg, mmol) and $NEt_3$ (110 mL, mmol) in methanol (50 mL). Concentration of the mother liquor in air at room temperature gave crystals of [$Ph_2Pb$(6-Me-4-$CF_3$pymS)$_2$] suitable for X-ray studies (0.175 g, 61%). $C_{24}H_{18}F_6N_4S_2Pb$ (747.74): calcd. C 38.55, H 2.43, N 7.49, S 8.58; found C 38.84, H 2.64, N 7.28, S 8.51. IR (KBr): $\tilde{\nu}$ = 1570 $cm^{-1}$ m, 1560 m, 1535 w, 1465 w, 1425 w, 1385 vs, 1360 w, 1305 vw, 1260 vs, br, 1220 m, 1190 w, 1170 w, 1130 m, 1110 w, 1010 w, 990 m, 915 w, 840 m, 720 m, 710 m, 680 vw, 540 w, 425 w. $^1$H NMR ($CDCl_3$): $\delta$ = 8.14–7.30 (m, phenyl H), 7.00 (s, 1 H, H-5), 2.32 (s, 3 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 135–130 (phenyl C), 25 ppm (s, C$^8$). $^{207}$Pb NMR ($CDCl_3$): $\delta$ = –206.7 ppm. MS (FAB): *m*/*z* (%) 555.0 (100) [$Ph_2Pb$(6-Me-4-$CF_3$pymS)], 400.4 (45) [Pb(6-Me-4-$CF_3$pymS)], 285 (37) [PhPb], 207 (11) [Pb].

***Caution:*** *Lead is a highly toxic cumulative poison. Compounds should be handled carefully.*

**Crystal Structure Determinations:** X-ray data for compounds **1**, **2** and **5**–**8** were collected on a Bruker Smart CCD 1000 diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The data were collected at $T$ = 293 K for all structures.

Table 8. Summary of crystal data and structure refinement for ligands and tin and lead compounds.

| Compound | [$Me_2Sn$(4-$CF_3$pymS)$_2$] (**1**) | [$Ph_2Sn$(4-$CF_3$pymS)$_2$] (**2**) | [$Ph_2Sn$(6-Me-4-$CF_3$ pymS)$_2$] (**5**) |

The $\omega$-scan technique was employed to measure intensities for all crystals. Decomposition of the crystals did not occur during data collection. The intensities of all data sets were corrected for Lorentz and polarisation effects. Absorption corrections were carried out using SADABS.[68] All the structures were solved by direct methods and refined[69] by full-matrix least-squares based on $F^2$. For all the complexes, hydrogen atoms were also included in idealised positions and refined with isotropic displacement parameters. The $CF_3$ groups of compounds **1**, **2**, **5** and **8** were found to be disordered over two positions with occupancies 73:27 and 52:48 for the groups on C(5) and C(10) in compound **8**, 60:40 for the $CF_3$ group in compound **1**, 50:50 for the $CF_3$ group in **2**, and 55:45 and 62:38 for the groups on C(5) and C(10) in compound **5**.

Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from the International Tables for X-ray Crystallography.[70] The crystal data and summary of data collection and structure refinement for these compounds are given in Table 8. ORTEP 3 drawings,[71] along with the numbering schemes used, are provided in the text.

CCDC-622379 to -622384 (for **1**, **2** and **5**–**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry*. Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** the synthesis of the mixed-metal Dawson sandwich complexes $[MCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ by the addition of the transition metal cation $M^{2+}$ to the "lacunary" sandwich complex $[NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{17-}$. This "lacunary" species is a good precursor for the preparation mixed-metal sandwich complexes, with promising interesting catalytic, electocatalytic and magnetic properties. Details of the synthesis and the structural characterization in solution are discussed in the article by L. Ruhlmann and R. Touvenot on p. 1493 ff.

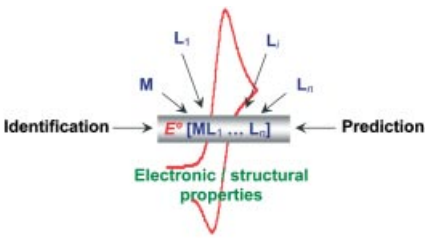
Characterization of Coordination Compounds by Electrochemical Parameters

**Keywords:** Electrochemistry / Redox potential / Additivity models / Ligand parameters / Ligand effects



Attention is drawn to the interest shown in the redox potential and derived electrochemical parameters that are used for the caracterization and identification of coordination compounds.

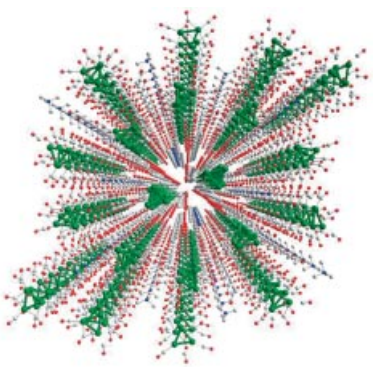
## SHORT COMMUNICATIONS

### Molecular Wires

**C. Femoni, F. Kaswalder, M. C. Iapalucci, G. Longoni,* S. Zacchini ..... 1483–1486**

Infinite Molecular $\{[Pt_{3n}(CO)_{6n}]^{2-}\}_\infty$ Conductor Wires by Self-Assembly of $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 5–8) Cluster Dianions Formally Resembling CO-Sheathed Three-Platinum Cables

**Keywords:** Carbonyl ligands / Cluster compounds / Platinum / Structure elucidation / Conducting materials



Self-assembly of $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 5–8) cluster dianions into infinite semicontinuous or continuous $\{[Pt_{3n}(CO)_{3n}(\mu\text{-}CO)_{3n}]^{2-}\}_\infty$ conductor wires is obtained upon crystallization. Pellets of these salts exhibit conductor behavior that roughly depends on the interdianion gap along the wires.

5. Final Comments

## 1. Introduction

Coordination compounds are usually characterized by common IR and multi-nuclear NMR spectroscopic methods, elemental analysis and, whenever possible, by single-crystal X-ray diffraction. In contrast, electrochemical methods, although being increasingly applied in the last few years (mainly cyclic voltammetry) to measure the redox potential, induce chemical reactions by electron transfer and study the mechanisms of redox processes,[1–4] have not yet found a common application as a characterization or identification tool for such compounds. This is somewhat surprising in view of the useful information associated with the redox potential of a compound.

The main aim of this Microreview is to draw the attention of the coordination and organometallic chemists to the fact that the redox potential of a complex can provide a relevant structural and electronic meaning, allowing for the quantification of the metal and ligand electron acceptor/donor properties, which can then be applied as an important characterization parameter, the use of which has still been neglected. For such a purpose, the review focuses on the seminal works of Pickett and Lever who have proposed useful models for the redox potential/structure relationships in metal complexes, and on the developments thereof, which have been introduced namely by the current author and his research group.

Since the redox potentials of metal complexes have been correlated over the years to a variety of other properties[5–7] that are also dependent on the electronic/structural features of the complexes, one could expect the possibility of using the redox potential to quantify the electron donor/acceptor properties of the ligands and their coordination metal

*Armando J. L. Pombeiro, Full Professor (since 1989) at the Instituto Superior Técnico, was born in Porto in 1949 and obtained his D.Phil. degree at the University of Sussex (1976) under the supervision of Professors R. L. Richards and J. Chatt. His main research interests are in the fields of activation, by transition-metal centres, of small molecules (with biological, environmental, pharmacological or industrial significance, such as alkanes, nitriles or oximes), metal-mediated synthesis, catalysis (namely functionalization of alkanes under mild conditions), and molecular electrochemistry of coordination compounds (redox potential-structure relationships, electron-transfer-induced reactions, electrosynthesis, electrocatalysis, mechanisms of redox processes). He has published one book (and edited two more) and ca. 380 original papers, review articles, book contributions and patents. He is a full member of the Academy of Sciences of Lisbon, Vice-President of its Class of Sciences and former Secretary-General. He is the Academy representative at the International Council for Science (ICSU) and the European Academies Science Advisory Council (EASAC). He is a former member of the Higher Council for Science, Technology and Innovation, of international Evaluation Commissions of Portuguese and foreign Universities, and of NATO ASI Advisory Panels. He is a cofounder of the Portuguese Electrochemical Society (former President) and of the Iberoamerican Electrochemical Society.*

centres. This would provide an important characterization method for the complexes based on their redox potentials, but would require the establishment of defined relationships between the redox potential and such electronic properties of all the particular ligands and metal sites that constitute the coordination entity under study. To keep matters simple additive effects on the redox potential have been sought.

Following preliminary additivity recognitions,[8,9] within a series of closely related 18-electron first-row transition-metal complexes of the general type $[M(CO)_{6-x}L_x]^{y+}$, which undergo a single-electron reversible oxidation centred at the metal atom, the main systematic approaches have been proposed by Pickett et al.,[10–12] Lever[13–16] and Bursten.[17–19]

The Bursten model is based on a direct linear correlation (with a negative slope) between the HOMO energy and the oxidation potential ($E_{1/2}$) of octahedral $d^6$ metal complexes of the type $[ML_nL'_{6-n}]$ (L = stronger π-acceptor than L′). This potential (viz. HOMO energy) is determined in an additive way by the effects ($B$) of all the $n$L and $(6 - n)$L′ ligands and by the effects ($C$) of the ligands, $x$L and $(4 - x)$L′, that π-interact with the metal dπ orbital comprised in the HOMO of the complex {[Equation (1)] in which $A^0$ depends on the metal atom, in particular its oxidation state, and trivially on the solvent and reference electrode}.

$$E_{1/2} = A^{o} + nB^{L} + (6-n)B^{L'} + xC^{L} + (4-x)C^{L'} \quad (1)$$

In spite of the immediate significance of this model, in terms of the redox potential/redox orbital energy relationship, its basic expression (1) (although it can adopt a simpler form) is considerably complex, requires the differentiation of the ligands in terms of their π-acceptance ability and still remains relatively unexplored. Moreover, it can be correlated to the other models (namely the Pickett one[20]), which are easier to apply and will not be considered further.

It is worth mentioning that, for comparative purposes, the redox potentials have to have a common reference, which often requires a conversion.[21,22] In Pickett's model the potentials have typically been quoted relative to the saturated calomel electrode (SCE), whereas in the Lever one they have been referenced to the normal hydrogen electrode (NHE).

## 2. Partial Additivity Models – Pickett's and Derived Models

In these models, some of the ligands (and therefore their effects) are included in the overall metal centre $\{M_s\}$ to which the other ligand(s) $L_n$ is (are) bonded in the $[M_sL_n]$ complex and therefore the additive effects on the redox potential are assumed only for the $\{M_s\}$ and the $n$L ligand(s). In the extreme case, as in Pickett's model, $n = 1$, i.e. only one ligand is distinct from the binding metal site in the $[M_sL]$ complex, corresponding to a minimum additivity requirement. Extensions of this model to other cases, with a separation of more than one ligand ($n > 1$) from $\{M_s\}$ (a higher additivity assumption), have been proposed by the current author.

### 2.1. General

The linear relationships observed by Pickett et al. between the oxidation potentials ($E^{ox}_{1/2}$) of the members of a series of 18-electron octahedral-type complexes $[M_sL]$ (bearing a variable L ligand at a 16-electron $M_s$ metal centre) and the oxidation potentials of the homologous complexes $[Cr(CO)_5L]$ [with the $\{Cr(CO)_5\}$ site and the common L ligand] can be expressed by the basic Equation (2). Herein, $E_s$ is the oxidation potential of the carbonyl complex $[M_s(CO)]$ [Equation (3)], a measure of the *electron richness* of the metal centre (the higher this property, the lower $E_s$), the slope $\beta$ is the *polarizability* of the metal site (a measure of the sensitivity of the HOMO energy to a variation of the ligand L) and the *ligand $P_L$ parameter* [given by Equation (4)] is the shift in the oxidation potential resulting from the replacement of one CO group in $[Cr(CO)_6]$ by one L ligand.[10]

$$E^{ox}_{1/2}[M_sL] = E_s + \beta P_L \quad (2)$$

$$E_s\{M_s\} = E^{ox}_{1/2}[M_s(CO)] \quad (3)$$

$$P_L(L) = E^{ox}_{1/2}[Cr(CO)_5L] - E^{ox}_{1/2}[Cr(CO)_6] \quad (4)$$

Expression (2) allows (i) the estimate of $E_s$ and $\beta$ of the metal centre from the plot of the oxidation potential of a series of complexes $[M_sL]$ vs. $P_L$, or (ii) the estimate of $P_L$ for the ligand L if $E_s$ and $\beta$ are known for a certain $\{M_s\}$ centre, as well as the oxidation potential of the particular complex $[M_sL]$ with this metal site and the ligand L, or (iii) the estimate of either $E_s$ or $\beta$, when the other parameters and the oxidation potential of an $[M_sL]$ complex is known, or (iv) the prediction of the oxidation potential of any $[M_sL]$ complex provided the corresponding $E_s$, $\beta$ and $P_L$ parameters are known.

The above Pickett's approach has been adapted or extended to complexes of types other than $[M_sL]$ as follows.

Extension of the additivity to 18-electron complexes $[M_sL_n]$ ($n = 2, 3$; $n = 1$ was the original case) leads to Equations (5), (6) and (7),[5,23] with the $P_{nL}$ ligand parameter rep-

$$E^{ox}_{1/2}[M_sL_n] = E_s + \beta P_{nL} \quad (5)$$

$$E_s = E^{ox}_{1/2}[M_s(CO)_n] \quad (6)$$

$$P_{nL} = E^{ox}_{1/2}[Cr(CO)_{6-n}L_n] - E^{ox}_{1/2}[Cr(CO)_6] \quad (7)$$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

resenting the shift of the oxidation potential upon replacement of *n*CO ligands in $[Cr(CO)_6]$ by *n*L ligands. It is the sum of the *n* individual $P_L$ values [Equation (8)] when the L ligands have independent effects on the oxidation potential.[5,23] The metal centre $\{M_s\}$ is then a 14-electron ($n$ = 2) or a 12-electron ($n$ = 3) site.

$$P_{nL} = n\,P_L \tag{8}$$

For the mixed-ligand complexes $[M_sLL']$, the oxidation potential was shown[24] to be the average of those of the corresponding $[M_sL_2]$ and $[M_sL'_2]$ [Equation (9)] when the metal sites $\{M_sL\}$ and $\{M_sL'\}$ exhibit analogous values of polarizability ($\beta$).

$$E^{ox}_{1/2}[M_sLL'] = 1/2\,\{E^{ox}_{1/2}[M_sL_2] + E^{ox}_{1/2}[M_sL'_2]\} \tag{9}$$

Moreover, the oxidation potential of the complexes $[M_sL_2]$ was demonstrated[25] to be given by Equation (10), showing that the potential of any member of the series can be predicted provided one knows the oxidation potential of the dicarbonyl complex $[M_s(CO)_2]$, the $E_s$ and $\beta$ values of an auxiliary $\{M_sL'\}$ site with the auxiliary L′ ligand and the $P_L$ values of both L and L′. The knowledge of these auxiliary parameters also allows for the estimate of the electron richness and polarizability of the $\{M_sL\}$ centre [Equations (11) and (12)].[25]

These expressions, (9)–(12), with an evident predictive value, have been successfully applied to the series of isocyanido and carbonyl complexes of rhenium(I), *trans*-$[ReLL'(dppe)_2]^+$ (L, L′ = CNR, CO; dppe = $Ph_2PCH_2CH_2PPh_2$) and *trans*-$[ReL_2(dppe)_2]^+$ (L = CNR, CO),[24–25] and of nitrile and carbonyl complexes of iron(II), *trans*-$[FeL_2(depe)_2]^{2+}$ (L = NCR, CO; depe = $Et_2PCH_2CH_2PEt_2$).[26] The $E_s$ and $\beta$ values of the corresponding *trans*-$\{ReL(dppe)_2\}^+$ and *trans*-$\{FeL(depe)_2\}^{2+}$ metal sites have also been estimated (see below).[24–26]

An extension of the model to open-shell 17- and 16-electron complexes has also been carried out.[27,28] The general expressions (2)–(4) can be kept but now the metal site $\{M_s\}$ is a 15- or a 14-electron centre, respectively. The approach has been applied to the 17-electron complexes *cis*-$[ReCl(L)(dppe)_2]^+$ (L = NCR, CO) and *trans*-$[FeBr(L)(depe)_2]^{2+}$, with a 15-electron $Re^{II}$ or $Fe^{III}$ centre,[27] and to the square-planar 16-electron $Rh^I$ complexes $[Rh(O\cap O)(CO)L]$ [O∩O = $MeC(O)CHC(O)Me^-$ (acac), $PhC(O)CHC(O)Me^-$ (bac)].[28]

$$E_s\{M_sL\} = \left[1 - \frac{P_L(L)}{P_L(L')}\right]E^{ox}_{1/2}[M_s(CO)_2] + \frac{P_L(L)}{P_L(L')}E_s\{M_sL'\} \tag{11}$$

$$\beta\{M_sL\} = \frac{\left[1 - \frac{P_L(L)}{P_L(L')}\right]E_s\{M_sL'\} - \left[1 - \frac{P_L(L)}{P_L(L')}\right]E^{ox}_{1/2}[M_s(CO)_2] + \beta\{M_sL'\}P_L(L)}{P_L(L')} \tag{12}$$

### 2.2. $P_L$ Ligand Parameter

The $P_L$ ligand parameter can be obtained from expression (4) if the oxidation potential of the corresponding $[Cr(CO)_5L]$ complex is known, or otherwise by using the general Equation (2) if one knows the oxidation potential of a particular $[M_sL]$ complex with that ligand binding a metal centre $\{M_s\}$ with known $E_s$ and $\beta$ values. It can also be derived from the Lever $E_L$ parameter (see below). $P_L$ values are already known for a wide variety of ligands[5,10,24–56] and lists have been collected[36,56] with particular emphasis on the estimate of the values for carbynes, carbenes, vinylidenes, allenylidenes and alkynyls.[36] Representative examples are given in Table 1, which also includes those reported recently.

The $P_L$ ligand parameter reflects both σ- and π-effects in an overall manner and is considered as a *measure* of the net electron-donor minus the electron-acceptor ability of the ligand L, since the higher this property the less stabilized will be the HOMO for $[Cr(CO)_5L]$ and hence the lower oxidation potential of this complex and the lower the $P_L$ parameter [Equation (4)]. Although the oxidation potential of a compound depends on the energetics of both the compound and its oxidized form, a linear correlation of the oxidation potential with the HOMO energy (see above) is expected for a series of closely related complexes such as $[Cr(CO)_5L]$ with a variable L.

The strongest net π-electron acceptors exhibit the highest $P_L$ values (≥0), namely $NO^+$ (+1.40 V)[10] > carbynes (+0.24 to +0.21 V)[29] > $\eta^2$-vinyl (+0.22 V)[31] > benzoyl isocyanide (+0.20 V)[30] > $PF_3$ (+0.14 V)[32] > aminocarbyne ($=CNH_2^+$) (+0.09 V)[31] > CO (0 V).

Dinitrogen and the phosphaalkyne P≡C*t*Bu, coordinated in the $\eta^1$-mode, have $P_L$ values (–0.07[10] and –0.04[33] V, respectively) close to that of CO (0 V), but this is accounted for by the limited σ-donor and π-acceptor abilities of the former ligands. Similar $P_L$ values can be displayed by both a weak π-acceptor/weak σ-donor ligand and a strong π-acceptor/strong σ-donor one, since $P_L$ is determined by the net π-electron acceptor minus σ-donor character of the ligand.

$$E^{ox}_{1/2}[M_sL_2] = \left[1 - \frac{P_L(L)}{P_L(L')}\right]^2 E^{ox}_{1/2}[M_s(CO)_2] + \left[\frac{2P_L(L)}{P_L(L')} - \frac{P_L^2(L)}{P_L^2(L')}\right]E_s\{M_sL'\} + \frac{P_L^2(L)}{P_L(L')}\beta\{M_sL'\} \tag{10}$$

[a] Ordered generally from higher to lower $P_L$ and/or $E_L$ values; for multidentate ligands the values refer to each ligating arm. [b] At an electron-rich metal centre such as *trans*-$\{MX(dppe)_2\}$ (M = Re, Tc; X = Cl, H). [c] At an electron-poor metal centre such as $\{Cr(CO)_5\}$. [d] The $P_L$ values of –1.0 and –0.74 V have been estimated at the $\{Cr(CO)_5\}$ and *trans*-$\{FeH(dppe)_2\}^+$ centres, respectively. [e] Carboxylate arm.

Isocyanides show $P_L$ values that are spread over a wide range, from +0.2 to –0.4 V (Table 1): benzoyl isocyanide[30] > bent isocyanides[24,25,34,35] > ferricinium isocyanides[38,39] > phosphonium isocyanides[41] ≥ linear isocyanides.[24,25,34,43]

Metallo-cyanide adducts and other cyano adducts are quite sensitive to the Lewis acid but are always stronger net electron acceptors than cyanide: $CNBF_3^-$[30] ≥ $CN–NiCl_2(Pcy_3)^-$[40] > $CN–VCl_3(thf)_2^-$[30] > $CN–BPh_3^-$[46] > $CN–PdCl_2(PPh_3)^-$[40] > $CN^-$.[10,30]

Carbenes and related ligands are spread over an even wider window of $P_L$ values (from 0 to –1.7 V): vinylidenes C=CHR[29,36] ≥ allenylidenes $C{=}C{=}CR_2$[36,42] > bithiophene-carbenes[44] ≥ oxocarbenes C(OR)Y[36] > thiocarbenes C(SR)Y[36] > aminocarbenes C(NRR′) Y,[5,36] ferrocenyl-oxocarbenes[36] ≥ phosphoylide-aminocarbenes[41] > ferrocenyl-aminocarbenes[36] > anionic oxycarbenes $C(O^-)Y$.[36]

Organonitriles ($P_L$ from –0.23 to –0.58 V)[10,27] behave as weaker π-acceptors than analogous isocyanides, whereas cyanamides $N{\equiv}C–NR_2$ (with the electron-donor amino group)[26,47–49] and related species, such as cyanoguanidine $N{\equiv}C–NC(NH_2)_2$,[50] and hydrogen dicyanamide N≡CNHCN,[50] are quite strong net electron-donor neutral ligands, being comparable to $NCS^-$[10] or $CF_3COO^-$.[10]

The strongest net electron-donors are the following, with $P_L$ values below –1.0 V: aryls, alkyls and $NO^-$,[36] $OH^-$,[10] anionic oxycarbenes $[=C(O^-)Y]$,[36] hydrogen cyanamide ($NCNH^-$),[49] $F^-$,[54] $N_3^-$,[10] $H^-$,[10] alkynyls ($C{\equiv}CR^-$),[5,36,42,52,53] monodeprotonated cyanoguanidine $[NCNC(NH)NH_2^-]$,[50] acyl- or aroylcyanamide $[NCNC(O)R^-]$,[51] $Cl^-$,[10] $Br^-$,[10] $NCO^-$,[10] $I^-$,[10] dicyanamide ($NCNCN^-$).[50]

A *modification of a ligand* naturally leads to a change of $P_L$. Hence, protonation is expected to result in an increase of $P_L$ due the promotion of the net electron acceptance (or hampering of the net electron donation), as shown in the following cases (see Table 1): protonation of vinylidenes C=CHR to carbynes $CCH_2R^+$ ($\Delta P_L$ = 0.5 V),[29,36] of a bent isocyanide $C{\equiv}NR$ to an aminocarbyne $C{=}NR_2^+$ (R = H) ($\Delta P_L$ = 0.2 V),[31,36] of phosphoylide-aminocarbenes (protonation at the ylide carbon atom) ($\Delta P_L$ = 0.3 V)[41] and of indole derivatives (protonation at N) ($\Delta P_L$ = 0.5 V).[41]

Oxidation of a metallo-ligand has the same type of effect if there is electronic communication between the two metal atoms, as observed for the ferrocene–isocyanide $C{\equiv}N–Fc$[38,39] and fumaronitrile–iron $N{\equiv}CCH{=}CHC{\equiv}N-\{FeH(dppe)_2\}^+$[37] systems ($\Delta P_L \approx 0.2$ V).

Linkage isomerization with an ambidentate ligand can result in a high $P_L$ variation, as in the case of dimethyl sulfoxide (DMSO) ($\Delta P_L \approx 1.1$ V upon changing from O- to S-binding).[57]

A further important matter concerns the possibility, in some cases, of $P_L$ *dependence on the metal centre*, which was not accounted for by the initial Pickett's model. Although such a behaviour poses difficulties to the application of this model, the recognition of the failure of Equation (2) in particular cases enables us to propose corrections to the $P_L$ values for such cases. This has been recognized for isocyanides,[24,25,34,35] nitriles,[27] cyanamides[26,47–49] and cyanide.[30] A high electron richness of the metal centre and a strong electron release from the *trans* ligand promote the net π-electron acceptance (or hamper the net electron donation) of the ligand under study, resulting in a positive correction (up to 0.34 V) for its usual $P_L$ value.

Hence, in such cases, $P_L$ also conveys information on the electronic properties of the metal centre and, for isocyanides, is also diagnostic of their bent or linear geometry. For *trans*-$\{ReCl(dppe)_2\}$ ($E_s$ = 0.68 V) or for $\{Cr(CO)_5\}$ ($E_s$ = 1.50 V), the former with a much higher electron richness, isocyanides are bent (stronger π-acceptors, higher $P_L$ values

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

by ca. 0.26 V) or linear (weaker π-acceptors), respectively. For *trans*-{TcH(dppe)$_2$}, with a higher electron richness ($E_s$ = 0.34 V), an even greater correction (+0.34 V)[35] is required.

### 2.3. $E_s$ and $\beta$ Metal-Site Parameters

The electron richness ($E_s$) of a metal centre {M$_s$} is given, by definition [Equation (3)], as the oxidation potential of its carbonyl complex [M$_s$(CO)]. It can also be obtained, as well as the polarizability ($\beta$), from the plot of $E^{ox}_{1/2}$[M$_s$L] vs. $P_L$(L) [Equation (2)], comprising as many points as possible. Less direct methods can be applied, namely by considering an auxiliary site {M′$_s$} with known $E_s$ and $\beta$ values, and comparing the oxidation potentials of [M$_s$L] with those of homologues of the related series [M′$_s$L] [from the intercept and the slope of Equation (13), $E_s$ and $\beta$ can be estimated for {M$_s$}]. Other cases have been indicated above [Equations (11) and (12)].

$$E^{ox}[M_sL] - E^{ox}[M'_sL] = (E_s\{M_s\} - E_s\{M'_s\}) + (\beta\{M_s\} - \beta\{M'_s\})\,P_L(L) \quad (13)$$

$E_s$ and $\beta$ values are known[10,24–28,34,35,41,43,56,58–61] for the following {M$_s$} centres, ordered, within each group, according to decreasing $E_s$ values: (a) 16-electron square-pyramidal ones: {FeL(depe)$_2$}$^{2+}$ (L = CO, NCR),[26] {W(≡CR)(CO)$_2$(dppe)}$^+$,[43] {M(CO)$_5$} (M = Cr, Mo, W),[41] {ReL(dppe)$_2$}$^+$ (L = CO, N$_2$, CNR),[5,24,25] {FeX(LL)$_2$}$^+$ (X = Br, H; LL = depe, dppe),[27,10] {Mo(NO)(dppe)$_2$}$^+$,[10] {Mn(CO)(dppm)$_2$}$^+$,[58] {ReX(dppe)$_2$} (X = CN, NCS, Cl, NCO, N$_3$),[34,59,60] *cis*-{ReCl(dppe)$_2$},[27] {TcH(dppe)$_2$},[35] {MoL(dppe)$_2$} (L = CO, N$_2$, NCPh),[10] {Mo(N$_3$)(dppe)$_2$}$^-$;[10] (b) 16-electron half-sandwich ones: {Mo($\eta^7$-C$_7$H$_7$)(LL)}$^+$ (LL = dppe, *t*Bu$_2$-diazabutadiene, bipyridine);[56,61] (c) 15-electron ones: {FeBr(depe)$_2$}$^{2+}$,[27] *cis*-{ReCl(dppe)$_2$}$^+$;[27] (d) 14-electron T-shaped one: {Rh(acac)(CO)}.[28]

The electron richness is unfavoured (increase of $E_s$) by the presence, within {M$_s$}, of ligands (e.g. carbyne or CO) with a strong π-acceptance (high $P_L$), by the increase of charge and by the metal oxidation state. Thus, the least electron-rich sites are the dicationic Fe$^{II}$ centres {FeL(depe)$_2$}$^{2+}$ (L = CO, NCR) ($E_s$ = 2.3–1.7 V vs. SCE),[26] the dicationic Fe$^{III}$ site {FeBr(depe)$_2$}$^{2+}$ ($E_s$ = 1.98 V vs. SCE)[27] and the cationic carbyne-carbonyl centres {W(≡CR)(CO)$_2$(dppe)}$^+$ ($E_s$ = 1.7–1.6 V vs. SCE),[43] followed by the pentacarbonyls {M(CO)$_5$} (M = Cr, Mo, W) ($E_s$ = 1.50 V vs. SCE).[41]

At the other extreme, as the most electron-rich centre, lies the anionic Mo$^0$ site {Mo(N$_3$)(dppe)$_2$}$^-$ ($E_s$ = –1.00 V vs. SCE)[10] with the strong electron-donor azide ligand, followed by the neutral {MoL(dppe)$_2$} (L = NCPh, N$_2$, CO) sites, all with negative $E_s$ values.

Interestingly, the polarizability ($\beta$) of the metal centre also tends to decrease (as does the electron richness) with the increase of the net π-electron acceptor ability of a ligand (increase of $P_L$) comprised in {M$_s$}, as observed for a series of related centres such as *trans*-{M(L)(dppe)$_2$}$^+$ (M = Tc,[35] L = H; M = Re;[5,24,25,34,59,60] L = Cl$^-$, CN$^-$, CNR, CO). In accord, {Mo(NO)(dppe)$_2$}$^+$ and {W(≡CR)(CO)$_2$(dppe)$_2$}, with the very strong π-acceptors NO$^+$ and carbyne/CO ligands, are the centres with the lowest $\beta$ values (0.51[10] and 0.61–0.73,[43] respectively). The delocalization of the HOMO towards the strong π-acceptor ligands in {M$_s$}, as shown by MO calculations in the W–carbyne case,[43] leads to an attenuation effect (energy "buffering", low $\beta$) on the changes of the HOMO energy upon change of another ligand (L) bound to the centre in the complex [M$_s$L].

## 3. Full Additivity Lever's Model

### 3.1. General

In this model, the additivity is extended to all the ligands, and the redox potential of a complex with the M$^{n+1/n}$ redox couple is given by Equation (14) in V vs. NHE, where $S_M$ (slope) and $I_M$ (intercept) depend on the metal and redox couple, the spin state and the stereochemistry, and $E_L$ is an additive ligand parameter that was obtained through a statistical analysis on the known redox potentials of the high number of complexes with the Ru$^{III/II}$ redox couple.[13–16]

$$E_{1/2}[M^{n+1/n}] = S_M(\Sigma E_L) + I_M \quad / \text{V vs. NHE} \quad (14)$$

On account of its wide scope of application, simple use and availability of data, Lever's model became the most popular one and has been reviewed.[13–16] However, its high generality is concomitant with the risk of failure for particular cases, and for strong π-acceptor ligands, e.g. CO, carbynes and isocyanides. Equation (14) requires the use of empirical terms that reflect additional HOMO stabilization effects. Corrections have also been introduced[13] to account for isomeric effects.

The attenuation of the CO ligand additivity effect, also in agreement with electronic spectroscopic and X-ray data, has been recognized[62] for the Os$^{IV/III}$ and Os$^{III/II}$ redox potentials in a series of hexacoordinate mixed halide/carbonyl and halide/carbonyl/nitrile complexes, i.e. the shift of the redox potential upon the first replacement of a halide or a nitrile by a CO ligand is much more pronounced (ca. two to three times) than the shift resulting from the second replacement. Similar nonlinear trends are exhibited by related (isocyanido)Os complexes,[62] although a roughly constant potential shift is observed per each halide replacement by nitrile either in the Os series[62] or in the Ru analogues.[63]

Hence, the mutual influence of the strong π-accepting CO or isocyanido ligands, in such series, leads to an attenuation of the corresponding ligand additivity effects.

The deviation from linearity [Equation (14)] for a wide range of $\Sigma E_L$, as observed for the Re$^{I/II}$ redox system,[14] can be overcome by the consideration of either different

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

expressions along the $\Sigma E_L$ scale or of a curved relationship, the latter is supported by some studies on a series of $Re^{I}$–vinylidene or –nitrile[27] complexes.

Although typically applied only to hexacoordinate complexes, the model has been recently extended by the current author to square-planar tetracoordinate[28,64] and pentacoordinate[28] $Rh^{I/II}$ complexes; the former has also been studied by others[65] although with a smaller number of compounds. Extensions to particular Ru clusters,[66–68] sandwich and half-sandwich complexes,[15,16,69] and to reduction processes centred at ligands[15,16] have also been proposed.

### 3.2. $E_L$ Ligand Parameter and Associated Ones

The ligand $E_L$ parameter depends on the reference electrode (it has been referenced to the NHE), in contrast with the $P_L$ parameter, but both are related by the experimentally observed Equation (15), which, however, fails for strong π-acceptor ligands (see above) when the Lever Equation (14) also requires corrections. Hence, for such ligands, Equation (15) has to be used cautiously for the estimate of the value of one of the parameters from that of the other one. Recognized examples of failure of Equation (15) include, apart from CO, carbynes and bent isocyanides, as well as a number of metallo-cyanide and other cyano adducts e.g. C≡N–A$^-$ [A = $BF_3$,[30] $BPh_3$,[30] $ML_{n-1}$ (M = $V^{III}$, $Re^{V}$, $Ni^{II}$, $Pd^{II}$)[30,40]]. Nevertheless, Equation (15) is valid for allenylidenes and alkynyls.[28,36,42]

$$P_L = 1.17\,E_L - 0.86 \quad (15)$$

$E_L$ values are already known for a wide variety of ligands,[13–16,28–30,36,41,57,64,70–75] including an extensive list of recently estimated values by the current author[36] for many carbyne, carbene, vinylidene, allenylidene and alkynyl ligands. Examples are given in Table 1.

$S_M$ and $I_M$ values (listed in refs.[13–16,36,56]) have already been proposed for the following $M^{n+1/n}$ redox couples: M = Nb ($n$ = 3, 4),[13] Ta ($n$ = 4),[13] Cr ($n$ = 0, 2),[13] Mo ($n$ = 0, 1),[13] Tc ($n$ = 1–3),[14] Re ($n$ = 1–3),[14] Fe ($n$ = 2, 3),[13,26,27] Ru ($n$ = 2, 3),[13,71] Os ($n$ = 2)[13] and Rh ($n$ = 1).[28,64] Normally, the redox centres are six-coordinate, with the exception of the four- and five-coordinate $Rh^{II/I}$,[28,64] and in particular the five-coordinate $Fe^{III/II}$[13] and $Mn^{II/III}$[13] cases. The parameters usually have been obtained in organic media, but different values are observed in water where solvation effects and the complex charge can play a relevant role, as observed for $Cr^{III/II}$,[13] $Fe^{III/II}$,[13] $Ru^{III/II}$ (2+/1+),[13] $Ru^{III/II}$ (1–/2–)[71,75] and $Os^{III/II}$[13] systems. The charge effect has been studied[75] particularly for the $Ru^{III/II}$ system.

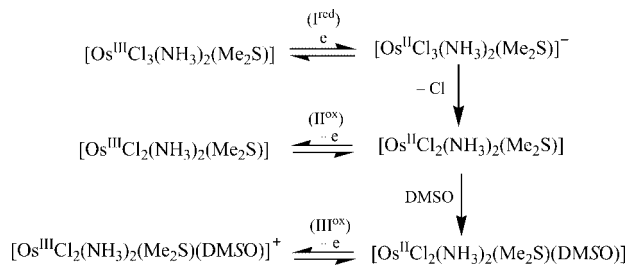
Moreover, particular sets of $S_M$ and $I_M$ values, different from the general ones but that better fit an expression of the type (14), have been proposed[26,27] for certain series of complexes.

## 4. Identification of Coordination Compounds

The relationships discussed above [in particular (2) and (14)] between the redox potential of a complex and the electrochemical ligand and metal centre parameters can be used not only to estimate (from the measured redox potential) these parameters that characterize the components of the complex, as discussed above, but also conversely to predict the redox potential of any complex, provided the values of those parameters are known. This latter approach has been much less explored but its significance towards the identification of coordination compounds is rather valuable. It can assist in the identification not only of isolated complexes but also of those generated in situ in a reaction process. This can be conveniently done by cyclic voltammetry, an expedient and rapid method to search for redox waves and measure their potentials, provided these lie within the available solvent/electrolyte potential range and the species have a sufficient lifetime for the wave detection. The redox waves should also be reversible, at least partially, since irreversible processes can lead to considerable shifts in the redox potential.

The identification of the new species generated upon an electron-transfer induced chemical reaction greatly contributes to the understanding of the redox process whose mechanism, in some cases, has been established by digital simulation of the cyclic voltammograms. This is illustrated by the following cases investigated in the author's laboratory.

The trichloro-$Os^{III}$ complex *mer*-$[OsCl_3(NH_3)_2(Me_2S)]$ undergoes, by cyclic voltamemtry in DMSO, a single-electron partially reversible reduction wave ($I^{red}$, Figure 1), which involves heterolytic Os–Cl bond rupture with loss of $Cl^-$ followed by its replacement by DMSO to afford the *S*-coordinated complex $[Os^{II}Cl_2(NH_3)(Me_2S)(DMSO)]$ (Scheme 1).[57] This product as well as an intermediate species that was postulated as the pentacoordinate complex $[OsCl_2(NH_3)_2(Me_2S)]$ were detected by their oxidation waves ($II^{ox}$ and $III^{ox}$, respectively, Figure 1) upon scan reversal following the reduction wave ($I^{red}$) of the starting complex.[57] The identification of the product was based on the very close agreement between the measured value of its oxidation potential ($III^{ox}$) and the predicted one by applying Lever's Equation (14).[57]



Scheme 1.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

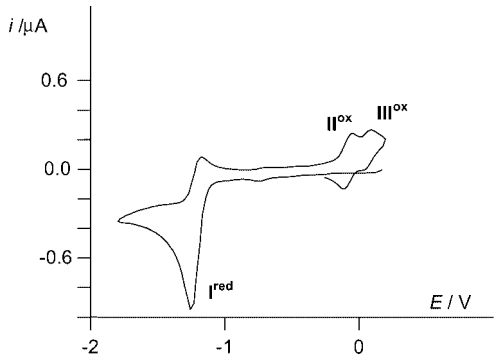


Figure 1. Cyclic voltammogram of *mer*-$[OsCl_3(NH_3)_2(Me_2S)]$ in DMSO with 0.2 M $[Bu_4N][BF_4]$ at a Pt electrode (scan rate: 0.2 $V s^{-1}$).[57]

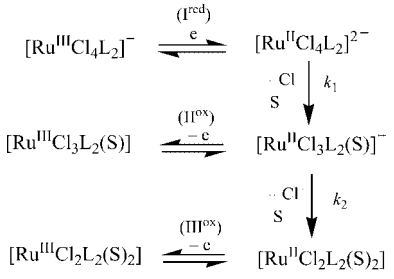
Other recent examples concern various series of chlorido/azole–ruthenium(III) complexes with antitumor activity, such as $[RuCl_4L_2]^-$[71,75] (L = imidazole, benzimidazole, triazole, pyrazole, indazole or a substituted derivative), $[RuCl_3L_3]$[75] or $[RuCl_2L_4]^+$.[75] They exhibit a single electron reduction (wave $I^{red}$) to the corresponding $Ru^{II}$ complexes, which then readily undergo sequential dechlorination steps upon solvolysis [S = dimethylformamide (DMF) or DMSO] (Scheme 2 for $[RuCl_4L_2]^-$).



Scheme 2.

The partially dechlorinated/solvated $Ru^{II}$ products, such as $[RuCl_3L_2(S)]^-$ and $[RuCl_2L_2(S)_2]$ derived from $[RuCl_4L_2]^-$, were detected in situ by the appearance of their $Ru^{II}/Ru^{III}$ oxidation waves ($II^{ox}$ and $III^{ox}$, respectively) and identified by the similarity of the corresponding measured oxidation potential values with those predicted by using Lever's Equation (14). A similar behaviour was observed for the other series of azole complexes.

The mechanisms of the processes were investigated in detail by digital simulation of cyclic voltammetry,[71,75] allowing us to estimate the kinetic rate constant of solvolysis upon reduction ($k_1$ and $k_2$), which interestingly were shown to correlate with the redox potential[71,75] (thus, with the azole $E_L$ parameter) and with the anti-tumor activity.[76,77]

## 5. Final Comments

The redox potential of a coordination compound bears rich structural/electronic information, which has started to be explored, in a systematic way, by ligand and metal parameterizations that constitute the bases of simple additive models. The electron donor/acceptor properties of the ligands and binding metal centres can thus be quantified through the values of associated electrochemical parameters, which, conversely, once known, can be used to predict the redox potentials of their complexes.

The latter approach (the estimate of the redox potential) can provide an important contribution towards the identification of unknown complexes by comparing the predicted and the experimentally measured values of the redox potential. The complexes, products or intermediates in reactions, can thus be identified in situ, without the need for their isolation from the solution, lowering the risks of their loss upon further reaction or decomposition.

Another important perspective concerns the possibility of correlating not only the redox potential but also, in a more perceivable way, the above electrochemical ligand (and/or metal site) parameters, with a variety of other properties of the complexes that are also determined by electronic and structural features,[5,6,15,16,69,78] such as ligand IR stretching frequencies,[74] energy of MLCT bands,[16] Hammett's σ-substituent constants and related ones,[69,79,80] Tolman's electronic parameter[81] or metal–metal interaction in ligand-bridged dinuclear complexes. Some of those correlations can allow the estimate of $E_L$ or $P_L$ for further ligands.

Ligand coordination[10,11,34,57] and chemical reactivity[10,37,82–85] criteria have also been proposed in a few cases. A different type of relationship, between the azole $E_L$ ligand parameter and the anticancer activity, has recently been recognized[76,77] for some ruthenium complexes.

However, one should be aware of the model's limitation, associated with the additivity assumption that does not take into account interactions and synergisms. Pickett's model, in its initial form, bears the minimum additivity (only the effect of a single ligand is separated from all the others, taken as a whole) and is expected to be more accurate for particular sets of complexes but has the lowest generality, while Lever's model assumes a full additivity and is more general but has a higher risk of failure in particular cases. These include isomeric effects that require the consideration of corrective terms in Lever's equation,[14] whereas they can be handled by Pickett's model by considering distinct ($E_s$, $\beta$) sets of values for the different isomers.[27,34] The isomeric dependence of the redox potential is particularly relevant in accounting for the type of mechanism of electron-transfer-induced isomerizations in coordination compounds.[86–89]

Another frequent limitation results from the small number of available data (in some cases limited to a single complex) used to estimate the ligand or metal parameters. Many more complexes have to be studied and the values of these parameters averaged.

Although extensions of the initial models have already been proposed, they have still to be further applied to other types of complexes with different metals and ligands, electron counts, geometries, etc. The results so far achieved, as illustrated above, are promising and the field hopefully will attract wider attention.

# Infinite Molecular $\{[Pt_{3n}(CO)_{6n}]^{2-}\}_\infty$ Conductor Wires by Self-Assembly of $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 5–8) Cluster Dianions Formally Resembling CO-Sheathed Three-Platinum Cables

**Cristina Femoni,[a] Francesco Kaswalder,[a] Maria Carmela Iapalucci,[a] Giuliano Longoni,*[a] and Stefano Zacchini[a]**

*Dedicated to Prof. Larry F. Dahl*

**Keywords:** Carbonyl ligands / Cluster compounds / Platinum / Structure elucidation / Conducting materials

Miscellaneous tetrasubstituted ammonium salts of $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 5–8) clusters, obtained by the stoichiometric oxidation of the corresponding $[Pt_9(CO)_{18}]^{2-}$ salts with tropylium tetrafluoroborate, self-assemble into infinite semicontinuous or continuous $\{[Pt_{3n}(CO)_{3n}(\mu\text{-}CO)_{3n}]^{2-}\}_\infty$ conductor wires upon crystallization. Pellets of these salts exhibit conductor behavior that roughly depends on the interdianion gap along the wires.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

One dimensional molecular metal wires[1,2] and one- and two-dimensional superclusters that are assembled through M–M bonds[3,4] are interesting as low-dimensional molecular materials, and they may find applications in molecular electronics and nanolithography.[5–7] According to EHMO calculations, the LUMO of a $Pt_3(CO)_3(\mu\text{-}CO)_3$ triangular moiety involves the combination of cyclopropenyl-like in-phase Pt $p_z$ atomic orbitals.[8,9] For an infinite stack of neutral $Pt_3(CO)_3(\mu\text{-}CO)_3$ or dianionic $[Pt_3(CO)_3(\mu\text{-}CO)_3]^{2-}$ moieties, the σMO band, which is generated along the $C_3$ axis by the cyclopropenyl-like MOs, should be empty or completely filled, respectively. Therefore, such a stack should not be stable. However, in the case where the stack is generated by the assembly of $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n > 1$) cluster dianions, the above MO band would only be $1/n$ filled; therefore, the stack could be feasible and may behave as a conducting molecular wire.

The first hint of a possible strategy that might favor self-assembly of $[Pt_{3n}(CO)_{6n}]^{2-}$ clusters was suggested by the recent structural characterization of the $[NBu_4]_2[Pt_{12}(CO)_{24}]$ and $[NBu_4]_2[Pt_{24}(CO)_{48}]$ salts.[10,11] In fact, the $[NBu_4]_2[Pt_{12}(CO)_{24}]$ salt is based on zero-dimensional packing of separated $[NBu_4]^+$ and $[Pt_{12}(CO)_{24}]^{2-}$ ions, as it was for the previously characterized $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 2, 3, 5) dianions in their $[PPh_4]^+$ or $[AsPh_4]^+$ salts.[12] Conversely, the $[NBu_4]_2[Pt_{24}(CO)_{48}]$ salt displays a 2D packing motif based on layers of parallel 1D infinite stacks of $Pt_3(CO)_6$ units intercalated by layers of $[NBu_4]^+$ cations. It was shown by Pauling that the $r^-/r^+$ ratio ($r$ = ionic radius) directs the choice of the ionic lattice of salts of monoatomic ions. In view of the cylindrical shape of the $[Pt_{3n}(CO)_{6n}]^{2-}$ dianions, it appeared more appropriate to substitute $r^-$ with the length of the dianion (L), and consequently, to replace $r^+$ by the diameter of the cation (D), and to use the L/D ratio as a rough guideline to achieve self-assembly of the dianions. In particular, it was speculated that a high L/D ratio would imply a great difference between the sizes of the dianion and the cation and a decreased repulsion between the dianions; the constant 2– charge would be delocalized over an increasing number of $Pt_3(CO)_6$ units. Furthermore, in the case of self-assembly of continuous $[Pt_{3n}(CO)_{6n}]^{2-}$ stacks, L would also determine the amount of filling of the σMO band that develops along the $C_3$ axis.

We have, therefore, reinvestigated the synthesis and structures of miscellaneous $[NR_4]_2[Pt_{3n}(CO)_{6n}]$ salts to assess the effect of the L/D ratio on self-assembly. We report here some significant structural results, as well as preliminary resistivity measurements of the above salts, which point out that stacking of $[Pt_{3n}(CO)_{6n}]^{2-}$ dianions leads to conducting molecular wires.

The investigated salts are collected in Table 1. All $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 4, 5, 6, and 8) salts have been prepared by the stoichiometric oxidation of the corresponding $[Pt_6(CO)_{12}]^{2-}$ salt[13] with tropylium tetrafluoroborate and crystallized from THF/toluene or acetone/2-propanol mixtures. The formulas of miscellaneous salts were established

by single-crystal X-ray diffraction studies, whereas the purities of the crystalline batches were ascertained by elemental analysis, ESI-MS, and IR spectroscopy.[14]

Table 1. Dependence of resistivity from crystal packing and interanionic gap.

| Compound | L/D[a] | Packing | Gap[b] | Resistivity [Ω cm] | Ref. |
|---|---|---|---|---|---|
| $[NBu_4]_2[Pt_{12}(CO)_{24}]$ | 1.0 | 0D | – | $>10^8$ | [10] |
| $[NMe_4]_2[Pt_{12}(CO)_{24}]$ | 2.5 | 0D | – | $>10^8$ | |
| $[NEt_4]_2[Pt_{15}(CO)_{30}]$ | 2.0 | 3D | 3.50 | $2.10^5$ | |
| $[NMe_4]_2[Pt_{18}(CO)_{36}]\cdot 2Me_2CO$ | 3.8 | 1D | 3.09 | $6.10^2$ | |
| $[NEt_4]_2[Pt_{24}(CO)_{48}]$ | 3.3 | 2D | 3.07 | $1.10^2$ | |
| $[NBu_4]_2[Pt_{24}(CO)_{48}]$ | 2.0 | 2D | 3.21 | $2.10^3$ | [11] |

[a] L = (distance between the centroids of the outer $Pt_3$ triangles) + [2 × (van der Waals radius of Pt)]; D = [2 × (average distance between the N and H atoms of the outer $-CH_3$ moiety)] + [2 × (van der Waals radius of H)]. [b] The gap between $[Pt_{3n}(CO)_{6n}]^{2-}$ dianions along the stack is given in Å.

The unit cell of $[NMe_4]_2[Pt_{12}(CO)_{24}]$, in spite of a L/D ratio (2.5) greater than that of $[NBu_4]_2[Pt_{24}(CO)_{48}]$ (see Table 1), contains separated $[Pt_{12}(CO)_{24}]^{2-}$ dianions and $[NMe_4]^+$ cations. As shown in Figure 1, distinct $[Pt_{12}(CO)_{24}]^{2-}$ dianions separated by $[NMe_4]^+$ cations, which hinder the formation of columnar stacks, can be clearly identified. In contrast to the previously characterized $[NBu_4]_2[Pt_{12}(CO)_{24}]$ salt,[10] the cation is also perfectly ordered. The intramolecular parameters of the $[Pt_{12}(CO)_{24}]^{2-}$ dianion are very similar in both salts.

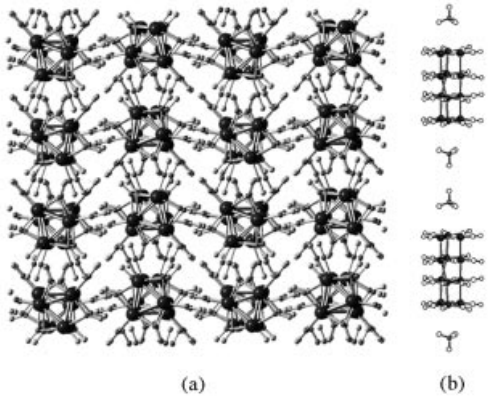

Figure 1. The packing of the $[NMe_4]_2[Pt_{12}(CO)_{24}]$ salt: (a) stacking of $[Pt_{12}(CO)_{24}]^{2-}$ dianions, (b) a portion of one stack that points out the presence of $[NMe_4]^+$ cations separating the $[Pt_{12}(CO)_{24}]^{2-}$ dianions.

The $[NEt_4]_2[Pt_{15}(CO)_{30}]$ salt exhibits incipient columnar self-assembly of $[Pt_{15}(CO)_{30}]^{2-}$ dianions, though it features a smaller L/D ratio (ca. 2) than $[NMe_4]_2[Pt_{12}(CO)_{24}]$. A similar feature was anticipated by the $[EtV^{+\cdot}]_2[EtV^{2+}][Pt_{15}(CO)_{30}]_2$ salt.[17] As shown in Figure 2a, the $[NEt_4]_2[Pt_{15}(CO)_{30}]$ salt displays a 3D packing of quasicontinuous stacks of $Pt_3(CO)_3(\mu\text{-}CO)_3$ units oriented along the four diagonals of the cubic unit cell. The infinite stacks are built from distinct $[Pt_{15}(CO)_{30}]^{2-}$ dianions that are separated by interdianion distances of 3.45–3.54 Å, which are significantly longer than the intraion–intertriangular distances, which are comprised in the 3.06 to 3.15 Å range.

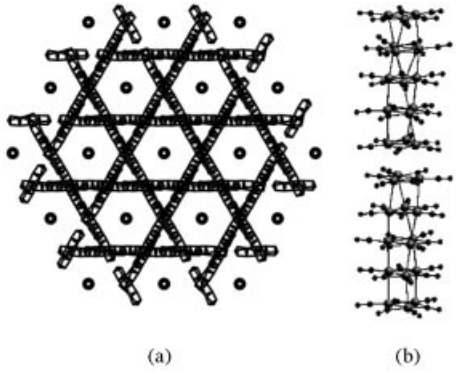

Figure 2. The packing of the $[NEt_4]_2[Pt_{15}(CO)_{30}]$ salt: (a) stacking of $[Pt_{15}(CO)_{30}]^{2-}$ dianions according to the four diagonals of the cubic unit cell (cations and carbonyl groups have been omitted for the sake of clarity), (b) a portion of the $[Pt_{15}(CO)_{30}]^{2-}$ stacks that point out the presence of a gap between the dianions.

Rewardingly, an increase in the L/D ratio beyond 3 enables the formation of continuous stacks of $Pt_3(CO)_3(\mu\text{-}CO)_3$ units, as shown by the structures of $[NMe_4]_2[Pt_{18}(CO)_{36}]\cdot 2Me_2CO$ and $[NEt_4]_2[Pt_{24}(CO)_{48}]$, respectively shown in Figures 3 and 4. They consist of 1D and 2D packing of continuous stacks of $Pt_3(CO)_3(\mu\text{-}CO)_3$ units, in which the individual $[Pt_{18}(CO)_{36}]^{2-}$ and $[Pt_{24}(CO)_{48}]^{2-}$ dianions are no longer distinguishable. Indeed, the $Pt_3(CO)_3(\mu\text{-}CO)_3$ stacks of $[NMe_4]_2[Pt_{18}(CO)_{36}]\cdot 2Me_2CO$ exhibit a constant interlayer periodicity of 3.08 Å, whereas those of $[NEt_4]_2[Pt_{24}(CO)_{48}]$ display alternating interlayer distances of 3.067 and 3.071 Å.

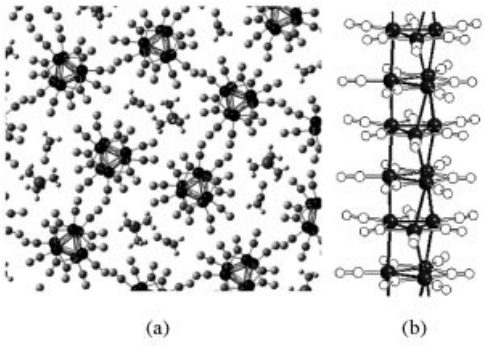

Figure 3. The packing of the $[NMe_4]_2[Pt_{18}(CO)_{36}]\cdot 2Me_2CO$ salt: (a) 1D packing of infinite columnar stacks of $[Pt_{18}(CO)_{36}]^{2-}$ dianions, (b) a portion of the stack that corresponds to a $[Pt_{18}(CO)_{36}]^{2-}$ dianion.

From the above results, it seems reasonable to conclude that L/D ratios > 3 favor self-assembly of $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n \geq 6$) dianions into infinite continuous wires because squeezing these elongated dianions together does not trigger repulsive forces that are too high. Because repulsive forces are expected to increase rapidly for $n \leq 6$, L/D ratios comprised in the 2 to 3 range are less discriminating and may lead to zero-dimensional packing or quasicontinuous wires that are dependent on the length of the dianion. Notably, the formation of infinite $[Pt_{3n}(CO)_{6n}]^{2-}$ continuous wires should be disfavored by Peierls distortions.[18,19] Their effectiveness in

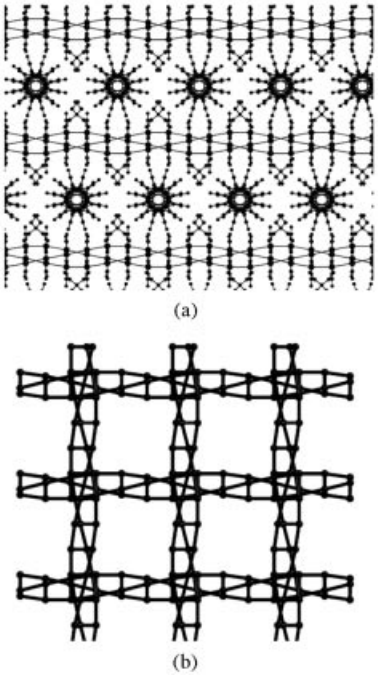

Figure 4. Two different views of the packing of the $[NEt_4]_2[Pt_{24}(CO)_{48}]$ salt: (a) 2D packing of infinite columnar stacks of $[Pt_{24}(CO)_{48}]^{2-}$ dianions according to two directions of the Cartesian axes, which gives rise to two orthogonal layers of parallel stacks, (b) continuity of the stack of $[Pt_{24}(CO)_{48}]^{2-}$ dianions (in this view carbonyl groups and cations are omitted for clarity).

partitioning the stack might be contrasted by the loss of density at the highest L/D ratios.

As shown in Table 1, the resemblance of the infinite $Pt_3(CO)_3(\mu\text{-}CO)_3$ stacks found in $[NMe_4]_2[Pt_{18}(CO)_{36}]\cdot 2Me_2CO$ and $[NEt_4]_2[Pt_{24}(CO)_{48}]$ to CO-insulated platinum cables is not only morphological but also functional. Resistivity measurements were carried out under a nitrogen atmosphere at room temperature with a four-point probe on pressed pellets (ca. $13 \times 1$ mm) of powdered samples. Whereas the zero-dimensional salts expectedly display the resistivity of an insulator material ($>10^8\ \Omega$cm), the salts that are based on quasicontinuous or continuous stacks exhibit resistivity in the $10^5$ to $10^2\ \Omega$cm range. Perhaps, it is significant that the lowest resistivity values are shown by those salts containing continuous columnar stacks of $Pt_3(CO)_3(\mu\text{-}CO)_3$ moieties. Although the resistivity of the above samples was measured on pellets of polycrystalline materials, the lowest observed values are already comparable to those exhibited by single crystals of other mixed-valence molecular chains featuring much shorter M–M bonds, such as $K_2[Pt(CN)_4]Cl_{0.32}\cdot 2.62H_2O$ and $[Rh(MeCN)_4(BF_4)_{1.5}]_x$.[20,21] It seems, therefore, of interest to carry out further physical characterizations (particularly variable temperature resistivity on single-crystals, solid-state $^{195}Pt$ NMR spectroscopic analysis, and magnetic measurements) to better assess the nature of these conductor molecular materials.

A clear effect of the support on self-assembly was observed by STM imaging of HOPG impregnated with water/2-propanol solutions of $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 4–6) dianions, which pointed out the preferential formation of nanowires over other morphologies.[22] As inferred from TEM images, well-defined Pt morphologies, including Pt nanowires, were also obtained by preparing $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 2–4) dianions in the micropores of zeolites, followed by thermal decomposition.[23]

The present work demonstrates that self-assembly of $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 6, 8) into infinite wires readily occurs by crystallization from solution and affords macroscopic crystals that, in favorable cases,[24] enable full elucidation of the wire structure by single-crystal X-ray diffraction studies. In view of the above observations, salts of the $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 6, 8) dianion with L/D > 3 seem the most promising materials for patterning surfaces with conductor molecular CO-sheathed Pt nano- and microcables, as well as Pt metal nanowires by suitable treatment of the former.

matized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Owing to rapid crystal decay at room temperature because of solvent loss, the data had to be collected at 100 K. Furthermore, the structure was recognized to be pseudomerohedrally twinned and a suitable set of BASF/TWIN parameters was used in the refinement, according to the procedure described in SHELX-97: [15] twin law [010 100 00–1]. Final $R$ value was 0.1025 and $wR$ = 0.2521 for 6583 independent reflections having $I > 2\sigma(I)$. *Crystal data for* $[NEt_4]_2[Pt_{24}(CO)_{48}]$*:* Tetragonal, space group $I\bar{4}2d$, $a$ = 12.2675(4) Å, $c$ = 34.251(3) Å, $U$ = 5154.5(5) Å$^3$, $Z$ = 2, $D_c$ = 4.051 g/cm$^3$, $T$ = 298 K, graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), final $R$ value was 0.0197 and $wR$ = 0.0446 for 2535 independent reflections having $I > 2\sigma(I)$. Data were corrected for Lorentz-polarization and absorption effects (empirical absorption SADABS[16]). The structures were solved by direct methods and refined with full-matrix least-squares (SHELX-97[15]). CCDC-626053 to -626056 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. IR and ESI-MS are unambiguously diagnostic of the purity of the $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 4, 5, 6) dianions, as a consequence of the varying ratio of number-of-charges/number-of-CO and sufficient stability of those ions in ESI conditions. Given that the $Pt_3(CO)_6$ units are constantly held together by only two electrons, species with $n > 6$ are hardly distinguishable both by IR and ESI-MS because of the leveling of the number-of-charges/number-of-CO ratio and fragmentation under ESI conditions. An almost Gaussian distribution of oligomers with $n \leq 6$ and $n \geq 6$ is observed,[10] even if the presence of oligomers with $n < 6$ in the injected solution is excluded by IR. Therefore, the purity of the $[NEt_4]_2[Pt_{24}(CO)_{48}]$ and $[NBu_4]_2[Pt_{24}(CO)_{48}]$ batches could only be assessed by a combination of IR and elemental analysis.

# New Aspects for Modeling Supramolecular Interactions in Vanadium Haloperoxidases: β-Cyclodextrin Inclusion Compounds of *cis*-Dioxovanadium(V) Complexes

**Ines Lippold,[a] Helmar Görls,[a] and Winfried Plass*[a]**

**Keywords:** Cyclodextrins / Host–guest systems / Inclusion compounds / Vanadium / X-ray diffraction

The reaction of potassium vanadate and the hydrazone ligand derived from Schiff base condensation of salicylaldehyde and biphenyl-4-carboxylic acid hydrazide ($H_2$salhybiph) in the presence of β-cyclodextrin (β-CD) in water yields the 1:1 inclusion compound K[$VO_2$(salhybiph)@β-CD]. The characterization in solution confirmed the integrity of the inclusion compound in different polar solvents such as DMSO and water. The inclusion compound crystallizes with additional water molecules in the triclinic space group *P*1. The supramolecular aggregation of the inclusion compound in the solid state is established through hydrogen bonding interactions between adjacent β-CD hosts and the π–π stacking ability of the ligand side chain of the guest complexes.

## Introduction

Vanadium haloperoxidases (V-HPO) are enzymes that catalyze the oxidation of halides to the corresponding hypohalous acids. These oxidized intermediates then readily halogenate organic substrates or convert hydrogen peroxide to singlet oxygen.[1] In addition, these enzymes can also catalyze the oxidation of organic sulfides to sulfoxides.[2] The active site of this class of enzymes consists of a vanadate moiety with a proposed trigonal bipyramidal geometry covalently bound to a histidine residue and held within the protein by strong hydrogen-bonding interactions with several amino acid residues.[3] Furthermore, this active site architecture is also found for certain acid phosphatases,[4] but with subtle distinctions concerning the relative positions of the amino acid residues.[5] The catalytic activity of V-HPO enzymes is proposed to be driven by this hydrogen-bonding network.[6] Therefore, V-HPO model systems need to be designed that provide a polar protic surrounding in order to offer the possibility for such relevant hydrogen-bonding interactions. Examples for such vanadium complexes derived from *N*-salicylidene hydrazides with a hydroxy substituted side chain have recently been reported.[7,8]

An alternative method to provide such an environment for the complex moieties can be through their interaction with appropriate host molecules, which would generate host–guest assemblies. Cyclodextrins (CDs) represent hosts with hydrophobic cavities and hydrophilic outer walls and generate inclusion complexes with various apolar groups that are included partially or completely in the cavity.[9] CDs are well known to form a variety of hydrogen bonds because of their free OH-groups. Parts of the guest protruding out of the CD ring opening could take part in this hydrogen bonding system. CDs and their substituted derivatives could be considered artificial enzymes as a result of their ability to react as catalysts for several asymmetric reactions, such as oxidation reactions, hydrolyses, and racemate separation.[10] Moreover, CDs are known to bind organometallic complexes containing aromatic constituents and such encapsulated complexes often exhibit markedly different physical and chemical properties.[11] Nevertheless, only very few examples of such inclusion complexes reported in the literature have been successfully characterized by single-crystal X-ray diffraction.[12]

We have recently reported the application of the *N*-salicylidene hydrazide ligand system for generating vanadium(V) complexes with a variety of functional groups attached to the ligand core.[7,8,13,14] Extending this approach, we report herein the synthesis and structure of a *cis*-dioxovanadium(V) complex containing an appropriate apolar biphenyl group in the ligand side chain, and its inclusion compound with β-CD.

## Results and Discussion

The *N*-salicylidene hydrazide ligand with apolar side chain used in this study is derived from Schiff base condensation of salicylaldehyde and biphenyl-4-carboxylic acid hydrazide ($H_2$salhybiph; Figure 1). Reaction of potassium

vanadate with the $H_2$salhybiph ligand in a methanol/acetone solution leads to the potassium salt of the corresponding *cis*-dioxovanadium(V) complex K[$VO_2$(salhybiph)]. The addition of acetone to the reaction solution is required owing to the very poor solubility of the $H_2$salhybiph ligand system in methanol. After a reaction time of 2 d, K[$VO_2$-(salhybiph)] can be isolated as a yellow crystalline solid material. Notably, the analogous reaction for ammonium vanadate affords the neutral *cis*-dioxovanadium(V) complex [$VO_2$(Hsalhybiph)] as the isolated product in a much lower yield. This is due to the fact that the ligand system under study is prone to variable protonation states at the amide group, which along with the presence of the protolytically active ammonium ions allows the generation of various complex species.[13] Therefore, the potassium vanadate route seems to be more promising for the generation of the relevant inclusion compounds.

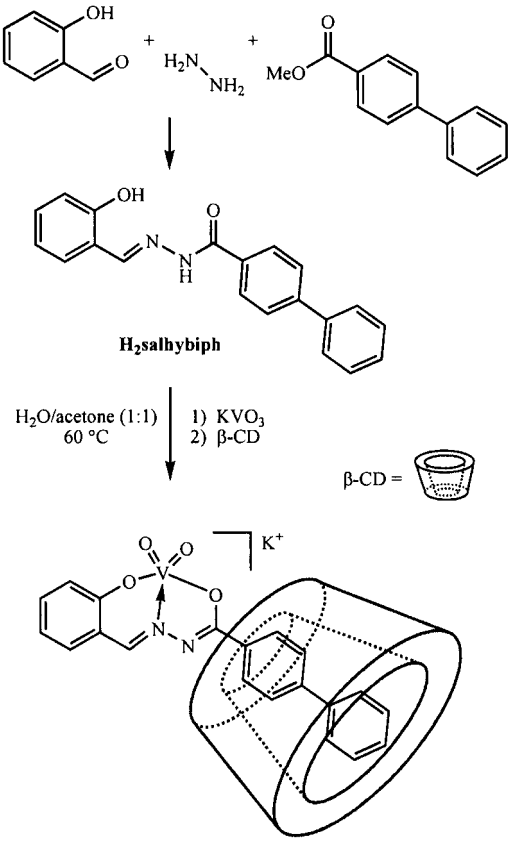

Figure 1. Synthesis of the inclusion compound K[$VO_2$(salhybiph)@β-CD].

The inclusion compound K[$VO_2$(salhybiph)@β-CD] was synthesized by a one-pot reaction of potassium vanadate with the $H_2$salhybiph ligand and β-CD in a water/acetone solution (Figure 1). The presence of β-CD results in a considerably shorter reaction time of about 2 h, and the reaction can be visually followed by the dissolution of the ligand. The 1:1 inclusion compound K[$VO_2$(salhybiph)@β-CD] can be isolated as yellow crystals, which have been fully characterized in solution and in the solid state.

The solution structure of the inclusion compound K[$VO_2$(salhybiph)@β-CD] can be unambiguously established by $^1$H NMR spectroscopy. Proton diffusion-ordered NMR spectroscopy (DOSY) clearly proves the integrity of the inclusion compound in solution, as only one species can be detected. The NOESY NMR spectra exhibit cross-peaks between the proton signals of the biphenyl side chain of the vanadium complex and those of the β-CD host (Figure 2). In particular for the 3-H and 5-H protons of the β-CD that extend into the β-CD host cavity, strong interactions with the aromatic protons of the biphenyl side chain of the guest are observed. The absence of cross-peaks between the 5-H protons of the β-CD and the Hbp7 and Hbp8 protons of the biphenyl group of the guest complex strongly suggests that the guest penetrates into the β-CD cavity from the primary hydroxy side. This is confirmed by the intense cross-peaks that are observed between the 6-H protons of the β-CD host and the Hbp2 and Hbp3 protons of the biphenyl side chain of the guest complex. Moreover, the lack of cross-peaks between the aromatic protons of the salicylidene moiety and the β-CD host proves that this part of the guest complex is distant from the β-CD. This also corroborates the presence of a 1:1 inclusion compound with a clear

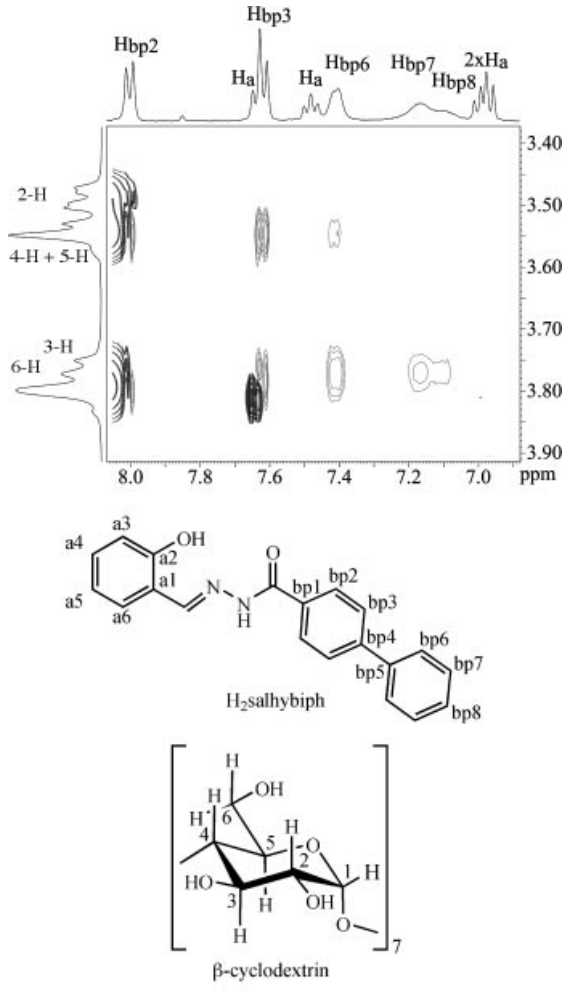

Figure 2. NOESY spectrum of K[$VO_2$(salhybiph)@β-CD] in $D_2O$ and labeling schemes for host and guest.

preference for the interaction of the biphenyl side chain with the β-CD host cavity.

For the solid state characterization of the inclusion compound K[$VO_2$(salhybiph)@β-CD], crystals suitable for X-ray analysis were grown by slowly cooling a hot aqueous solution of the inclusion compound. For different batches, a considerable variation in the water content was found. Thermogravimetric analysis (TGA) of these materials reveals a weight loss of about 6.5% (16.6%) in the temperature range form room temperature up to 140 °C, assigned to the removal of water molecules in the interstices between the inclusion compounds. In agreement with the elemental analysis, this indicates anywhere between 6.5 and 18 water molecules of crystallization per host–guest unit in the solid state. Above 200 °C, the inclusion compound starts to decompose. This temperature is somewhat lower than that observed for plain β-CD hydrate which starts to decompose at around 270 °C.[15] This difference can be attributed to the promoting effect of the metal complex host on the decomposition of the β-CD, and this provides further evidence for significant host–guest interaction in the inclusion compound. The final residual masses at 750 °C of 8.8 and 7.1% observed for different batches correspond very well to the values calculated for the formation of potassium orthovanadate, $KVO_3$ (8.1 and 7.3%, respectively; cf. Experimental Section).[16]

Crystallographic investigation shows that this inclusion compound crystallizes in the triclinic space group *P*1. The asymmetric unit contains two inclusion compounds together with the solvent water molecules, with the latter as well as the potassium cations disordered over several crystallographic positions. The molecular structure of the inclusion compound is shown in Figure 3. As expected from the solution NMR spectra, the *cis*-dioxovanadium(V) complex intrudes only partially into the β-CD cavity. Only the biphenyl side chain is located within the hydrophobic cavity of the host, whereas the remaining polar part of the complex is situated outside the primary hydroxy side of the β-CD host.

The vanadium atom of the guest complex exhibits an almost ideal square pyramidal environment with the coordinated $H_2$salhybiph ligand in its dianionic form, which is characterized by $\tau$ values lower than 0.10 ($\tau$ = 0 for ideal tetragonal pyramid; $\tau$ = 1 for ideal trigonal bipyramid). The basal plane of the square pyramid is given by atoms N*i*1, O*i*3, and O*i*4 (*i* = 1, 2) of the ligand and the oxo group O*i*2; the apical position is occupied by the oxo group O*i*1. Relative to the mean plane given by the donor atoms of the chelate ligand system, the vanadium atom is displaced towards the apical oxo group O*i*1 by about 40 pm, whereas the oxo group O*i*2 is slightly tilted towards the opposite side of the ligand plane with a deviation by about 15 pm from that plane. The structural parameters are consistent with those observed for other vanadium(V) complexes containing similar *N*-salicylidene hydrazide ligands, in particular the V=O (O*i*1 and O*i*2) as well as the V–N (N*i*1) and V–O (O*i*3 and O*i*4) bond lengths are within the expected range for such *cis*-dioxovanadium(V) complexes.[8,13]

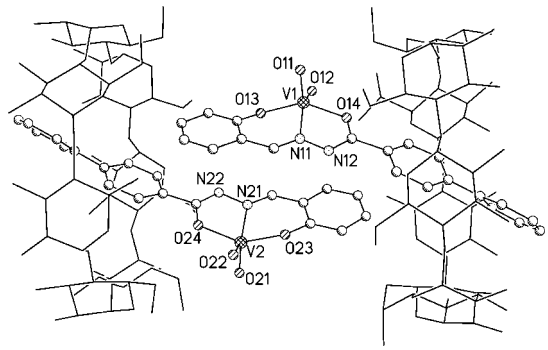

Figure 3. Representation of the molecular structure of the inclusion compound K[$VO_2$(salhybiph)@β-CD] that shows the two independent host–guest assemblies in the asymmetric unit. Selected bond lengths [pm] and angles [°]: V1–O11 159.6(9), V1–O12 159.8(8), V1–O13 189.3(7), V1–O14 196.7(6), V1–N11 215.5(7), N11–N12 139.3(9), O14–C18 127.8(10), N12–C18 129.7(11), O11–V1–O12 106.0(7), O11–V1–O13 102.4(4), O11–V1–O14 104.0(4), O12–V1–O13 98.5(4), O12–V1–O14 94.0(4), O13–V1–O14 146.3(3), O11–V1–N11 99.8(5), O12–V1–N11 153.4(5), O13–V1–N11 82.2(3), O14–V1–N11 73.0(3).

In the solid state, the inclusion compound K[$VO_2$-(salhybiph)@β-CD] forms head-to-head dimers with the secondary hydroxy sides of both β-CD hosts linked by hydrogen bonds as depicted in Figure 4. This arrangement leads to a π–π interaction of the biphenyl side chains of the corresponding guest molecules at a distance of 363 pm. The *cis*-dioxovanadium moieties of the guest molecules protrude from their hosts on the primary hydroxy group side and thereby generate a gap with a distance of about 910 pm between the adjacent head-to-head dimers. The protruding complex fragments of the adjacent dimers possess a staggered arrangement with a nearly coplanar orientation of their ligand planes (defined by N*i*1, O*i*3, and O*i*4 with *i* = 1, 2), which are about 340 pm apart. The overall packing of the head-to-head dimers can be described as a so-called "channel-type" arrangement[17] which is built from host guest dimers that are stringed together. These channels are oriented along the [001] direction and linked through hydrogen bonds between primary hydroxy groups (C-6) of neighboring β-CDs as depicted in Figure 5.

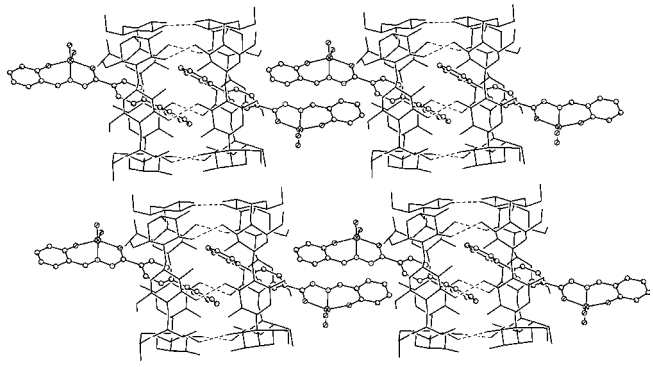

Figure 4. Packing of the inclusion compound K[$VO_2$(salhybiph)@β-CD] viewed approximately perpendicular to the [001] direction of the β-CD channel alignment. Hydrogen bonds between neighboring β-CDs are drawn as broken lines.

## Conclusions

We present the first supramolecular inclusion compound of a *cis*-dioxovanadium(V) complex with cyclodextrins. To facilitate this, a new vanadium complex derived from *N*-salicylidene hydrazide containing a hydrophobic biphenyl side chain matching the β-CD host cavity was synthesized. The integrity of the isolated inclusion compound K[$VO_2$-(salhybiph)@β-CD] in solution was confirmed by NMR spectroscopy. The solid-state structure reveals a channel-type packing of the head-to-head β-CD dimers which is cross-linked through hydrogen bonds and intercalated potassium cations. Through modification of the CD-host, it should be possible to utilize this concept for the generation of novel systems in oxidation catalysis, including the potential influence of the sugar backbone on chiral induction of vanadium-catalyzed oxidation reactions.

## Experimental Section

**General Remarks:** The synthesis of the ligand biphenyl-4-carboxylic acid salicylidene hydrazide ($H_2$salhybiph) and its neutral *cis*-dioxovanadium(V) complex [$VO_2$(Hsalhybiph)] is described in the Supporting Information. $^1$H, $^{13}$C and $^{51}$V as well as NOESY and DOSY NMR spectra were recorded with a 400 MHz Bruker AVANCE spectrometer. For notation used in the assignment of the atoms, see Figure 2. The chemical shift values for the $^{51}$V NMR spectra are reported relative to $VOCl_3$ as an external standard. Elemental analyses (C, H, N) were carried out with a Leco CHNS-932 elemental analyzer. Mass spectra were measured with a MAT95XL Finnigan instrument utilizing electron spray ionization and observation in the negative mode. IR spectra were recorded with a Bruker IFS55/Equinox spectrometer on samples prepared as KBr pellets. Thermogravimetric analysis (TGA) for powdered samples was performed with a Netzsch STA409PC Luxx apparatus under a constant flow of air ranging from room temperature up to 1000 °C with a heating rate of 5 °C/min. Atomic absorption spectrometry (AAS) was performed with an AA-6800 from Shimadzu.

**K[$VO_2$(salhybiph)]:** A suspension of biphenyl-4-carboxylic acid salicylidene hydrazide (0.200 g, 0.63 mmol) in an acetone/methanol mixture (30:5, 35 mL) was heated to 60 °C. After the addition of $KVO_3$ (0.087 g, 0.63 mmol), the suspension turned yellow–orange, and after 2 d of continuous stirring a clear solution was obtained. Upon removal of the solvent, the crude product was redissolved in hot methanol (30 mL), filtered, and kept for crystallization. Yield: 0.170 g (62%). $^1$H NMR (400 MHz, [$D_6$]DMSO): $\delta$ = 6.78 (t, $J$ = 7.3 Hz, 1 H, $H_{a5}$), 6.80 (d, $J$ = 8.4 Hz, 1 H, $H_{a3}$), 7.35 (t, $J$ = 7.8 Hz, 1 H, $H_{a4}$), 7.39 (tt, $J$ = 7.4 and 2.1 Hz, 1 H, $H_{bp8}$), 7.48 (t, $J$ = 7.5 Hz, 2 H, $H_{bp7}$), 7.57 (d, $J$ = 6.8 Hz, 1 H, $H_{a6}$), 7.52 (d, $J$ = 8.2 Hz, 2 H, $H_{bp3}$), 7.75 (t, $J$ = 8.9 Hz, 2 H, $H_{bp6}$), 8.10 (d, $J$ = 8.3 Hz, 2 H, $H_{bp2}$), 9.00 (s, 1 H, CH=N) ppm. $^{13}$C NMR (100 MHz, [$D_6$]DMSO): $\delta$ = 116.65 ($HC_{a5}$), 119.45, 119.86 ($HC_{a3}$ and $C_{a1}$), 126.34, 126.65 ($HC_{bp3}$ and $HC_{bp6}$), 127.78 ($HC_{bp8}$), 128.29 ($HC_{bp2}$), 128.93 ($HC_{bp7}$), 131.85 ($C_{bp1}$), 132.47 ($HC_{a6}$), 133.03 ($HC_{a4}$), 139.33 ($C_{bp4}$), 141.91 ($C_{bp5}$), 155.51 (C=N), 164.59 ($C_{a2}$), 169.48 (C=O) ppm. $^{51}$V NMR (105 MHz, [$D_6$]DMSO): $\delta$ = –532 ($\nu_{1/2}$ = 1122 Hz) ppm. IR (KBr): $\tilde{\nu}$ = 3447 (s), 3055 (w), 3028 (w), 2929 (w), 1615 (vs), 1550 (m), 1513 (m), 1476 (w), 1446 (m), 1383 (w), 1344 (s), 1278 (m), 1204 (w), 1157 (w), 950 (s), 904 (s), 875 (s), 760 (m), 740 (s), 696 (m) cm$^{-1}$. MS (ESI–, MeOH): $m/z$ (%) = 397 (100) [$VO_2$(salhybiph)]$^-$.$C_{20}H_{14}KN_2O_4V$ (436.38): calcd. C 55.05, H 3.23, N 6.42; found C 55.05, H 3.25, N 6.28.

**K[$VO_2$(salhybiph)@β-Cyclodextrin]·$x$$H_2O$:** Biphenyl-4-carboxylic acid salicylidene hydrazide (0.100 g, 0.32 mmol) was suspended in a solution of β-cyclodextrin (0.359 g, 0.32 mmol) in water (15 mL) at 60 °C. Acetone (15 mL) was added for better solubility of the ligand. Upon addition of $KVO_3$ (0.044 g, 0.32 mmol), the suspension turned yellow and, after stirring for 2 h at 60 °C, became a clear solution. The hot solution was filtered, and acetone was removed under reduced pressure. The solution was heated to 70 °C, allowed to slowly cool to room temperature, and the product precipitated as pale yellow cubic crystals. The water content of the isolated crystalline material varies considerably for different synthetic batches. Yield: 0.29 g (50%). Batch 1: $C_{62}H_{84}KN_2O_{39}V$·6.5$H_2O$ (1697.47): calcd. C 44.10, H 5.79, N 1.67; found C 44.04, H 5.94, N 1.39. TGA: Weight loss up to 140 °C of 6.5% (calcd. 6.9%), residual mass at 750 °C of 8.8% (calcd. 8.1% for $KVO_3$). Batch 2: $C_{62}H_{84}KN_2O_{39}V$·18$H_2O$ (1895.64): calcd. C 39.28, H 6.38, N 1.48, K 2.06; found C 39.79, H 6.39, N 1.21, K 1.2–2.3. TGA: Weight loss up to 140 °C of 16.6% (calcd. 17.1%), residual mass at 750 °C of 7.1% (calcd. 7.3% for $KVO_3$). $^1$H NMR (400 MHz, [$D_6$]DMSO): $\delta$ = 3.25–3.40 (m, 2 H, 2-H and 4-H), 3.50–3.70 (m, 4 H, 3-H, 5-H, and 6-H), 4.44 (t, $J$ = 5.5 Hz, 1 H, C6-OH), 4.82 (d, $J$ = 3.3 Hz, 1 H, 1-H), 5.66 (d, $J$ = 2.2 Hz, 1 H, C3-OH), 5.71 (d, $J$ = 6.9 Hz, 1 H, C2-OH), 6.77 (t, $J$ = 7.2 Hz, 1 H, $H_{a5}$), 6.78 (d, $J$ = 7.4 Hz, 1 H, $H_{a3}$), 7.34 (dt, $J$ = 7.7 and 2.0 Hz, 1 H, $H_{a4}$), 7.38 (tt, $J$ = 7.5 Hz and 1.2 Hz, 1 H, $H_{bp8}$), 7.48 (t, $J$ = 7.6 Hz, 2 H, $H_{bp7}$), 7.56 (dd, $J$ = 8.1 and 1.8 Hz, 1 H, $H_{a6}$), 7.75 (t, $J$ = 8.2 Hz, 4 H, $H_{bp3}$ and $H_{bp6}$), 8.08 (d, $J$ = 8.4 Hz, 2 H, $H_{bp2}$), 8.98 (s, 1 H, CH = N) ppm. $^1$H NMR (400 MHz, $D_2O$): $\delta$ = 3.43 (dd, $J$ = 9.9 Hz and 3.4 Hz, 1 H, 2-H), 3.45–3.50 (m, 2 H, 4-H and 5-H), 3.70–3.80 (m, 3 H, 3-H and 6-H), 4.90 (d, $J$ = 3.5 Hz, 1 H, 1-H), 6.91 (d, $J$ = 8.4 Hz, 1 H, $H_{a3}$), 6.94 (t, $J$ = 7.6 Hz, 1 H, $H_{a5}$), 7.04 (br. s, 1 H, $H_{bp8}$), 7.11 (s, 2 H, $H_{bp7}$), 7.35 (d, $J$ = 6.2 Hz, 2 H, $H_{bp6}$), 7.42 (t, $J$ = 8.0 Hz, 1 H, $H_{a4}$), 7.57 (t, $J$ = 8.0 Hz, 2 H, $H_{bp3}$), 7.57 (t, $J$ = 8.0 Hz, 1 H, $H_{a6}$), 7.95 (d, $J$ = 8.0 Hz, 2 H, $H_{bp2}$), 8.89 (s, 1 H, CH=N) ppm.$^{13}$C NMR (100 MHz, [$D_6$]DMSO): $\delta$ = 59.92 (C-6), 72.04 (C-5), 72.41 (C-2), 73.05 (C-3), 81.54 (C-4), 101.93 (C-1), 116.70 ($HC_{a5}$), 119.51, 119.92 ($HC_{a3}$ and $C_{a1}$),

126.43, 126.72 ($HC_{bp3}$ and $HC_{bp6}$), 127.85 ($HC_{bp8}$), 128.33 ($HC_{bp2}$), 129.00 ($HC_{bp7}$), 131.78 ($C_{bp1}$), 132.51 ($HC_{a6}$), 133.11 ($HC_{a4}$), 139.43 ($C_{bp4}$), 141.94 ($C_{bp5}$), 155.60 (C=N), 164.69 ($C_{a2}$), 169.51 (C=O) ppm. $^{51}$V NMR (105 MHz, [D$_6$]DMSO): $\delta$ = –532 ppm ($\nu_{1/2}$ = 1067 Hz). $^{51}$V NMR (105 MHz, $D_2O$): $\delta$ = –533 ppm. IR (KBr): $\tilde{\nu}$ = 3392 (vs), 2929 (m), 1612 (m), 1550 (w), 1509 (w), 1490 (w), 1448 (w), 1388 (w), 1156 (m), 1079 (m), 1028 (s), 945 (m), 906 (m), 759 (w) cm$^{-1}$. MS (ESI–, MeOH): *m*/*z* (%) = 2667 (8) {[$VO_2$(salhybiph)] +2β-CD}$^-$, 1532 (42) {[$VO_2$(salhybiph)] + β-CD}$^-$, 1134 (30) [β-CD – H]$^+$, 397 (100) [$VO_2$(salhybiph)]$^-$.

**X-ray Crystallographic Study of K[$VO_2$(salhybiph)@β-Cyclodextrin]·*x*$H_2O$:** Crystals suitable for X-ray analysis were grown by slow cooling of a hot water solution of the inclusion compound. $C_{62}H_{84}KN_2O_{39}V(\cdot 8H_2O)$, $M_r$ = 1715.48 g mol$^{-1}$, triclinic, space group *P*1, *a* = 1535.37(5), *b* = 1545.54(7), *c* = 2146.64(8) pm, *α* = 94.710(2), β = 98.484(2), *γ* = 102.994(2)°, *V* = 4873.9(3) × 10$^6$ pm$^3$, *Z* = 2, $\mu$(Mo-$K_\alpha$) = 0.229 mm$^{-1}$, 32730 reflections measured with a Nonius KappaCCD diffractometer at 183(2) K in the 2.49 to 27.50° *Θ* range. The structure was solved by direct methods and subsequently refined against $F^2$ with the SHELXL-97 program,[18] which converged at $R_1$ = 0.1126 for 20029 observed reflections with $I > 2\sigma(I)$ and $wR_2$ = 0.3385 for all unique reflections with a goodness-of-fit on $F^2$ of 1.165. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms bonded to carbon atoms were introduced in theoretical positions but not refined. As known from the analytical data of different batches the content of water molecules is varying. For the measured crystals an overall content of eight water molecules could be assigned. The potassium cations and the water molecules were found to be disordered over several crystallographic positions and refined with partial occupancy factors. The discrimination between potassium and water sites is made on the basis of the potential coordination numbers and hydrogen bonding interactions. For the water molecules, no attached hydrogen atoms were considered. Additional disorder was found for one of the included anionic vanadium complexes (V2) which was refined with a relative ratio of about 1:2. The largest positive and negative residual Fourier peaks after the refinement were equal to 0.82 and –0.51, respectively. CCDC-629924 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Experimental details for the synthesis of the $H_2$salhybiph ligand and the [$VO_2$H(salhybiph)] complex.

# Mixed-Metal Dawson Sandwich Complexes: Synthesis, Spectroscopic Characterization and Electrochemical Behaviour of $Na_{16}[M^{II}Co_3(H_2O)_2(P_2W_{15}O_{56})_2]$ (M = Mn, Co, Ni, Zn and Cd)

**Laurent Ruhlmann,*[a] Claire Costa-Coquelard,[a] Jacqueline Canny,[b] and René Thouvenot*[b]**

**Keywords:** Dawson complexes / Paramagnetic $^{31}P$ NMR spectroscopy / Electrochemistry

Mixed-metal Dawson sandwich complexes $[MCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ (represented as $\{MCo_3P_4W_{30}\}$) have been synthesized by the reaction of $M^{2+}$ (where M = Mn, Co, Ni, Zn and Cd) with the "lacunary" sandwich complex αβ-$[NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{17-}$ (represented as $\{NaCo_3P_4W_{30}\}$): $[NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{17-} + M^{2+} \rightarrow [MCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{16-} + Na^+$. The $\{MCo_3P_4W_{30}\}$ species were characterized by IR spectroscopy, elemental analysis and $^{31}P$ solution NMR spectroscopy. The electrochemical behaviour of these mixed-metal sandwich complexes was investigated in aqueous solution and compared with that of ββ-$[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ (represented as ββ-$\{Co_4P_4W_{30}\}$) and $\{NaCo_3P_4W_{30}\}$.

## Introduction

Polyoxometalates (POMs) and their transition-metal-substituted derivatives are metal–oxygen anionic clusters with applications in fields as diverse as magnetochemistry, medicine and catalysis.[1–4]

All investigations centred around this large and growing class of clusters required previous knowledge of their precise composition and structure; therefore, the continuing development of rational methods for the systematic modification of POM systems remains very important.

It is well known that the reaction of the trivacant Dawson anion α-$[P_2W_{15}O_{56}]^{12-}$ with transition-metal cations yields sandwich complexes $[M_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ ($M^{2+}$ = $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Zn^{2+}$ and $Cd^{2+}$), in which a sheet of four M atoms (two internal and two external) is sandwiched between two $\{P_2W_{15}\}$ subunits.[5] For all Dawson, tetranuclear, sandwich complexes characterized by X-ray diffraction, the "classical" ββ configuration is observed with β connectivities between both trivacant $\{P_2W_{15}\}$ units and the central $M_4$ tetrad[5c,5e,5f,5h] (Figure 1a). This type of arrangement leads to a molecular anion with $C_{2h}$ symmetry in which the two $\{P_2W_{15}\}$ moieties are equivalent.

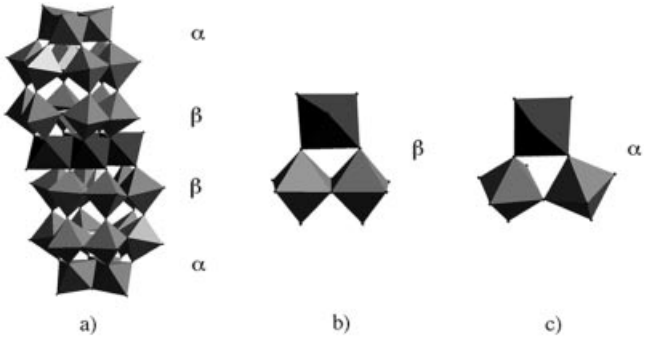

Figure 1. Polyhedral representation of the (a) αββα-$\{M_4P_4W_{30}\}$ sandwich structure, and of the (b) β and (c) α junctions.

The β junction implies a connection between one internal $MO_6$ octahedron and one dimeric $W_2O_{10}$ unit (Figure 1b), whereas for the α junction, this internal $MO_6$ octahedron is connected to two dimeric $W_2O_{10}$ units (Figure 1c).[6]

In the case of cobalt complexes, we previously reported that the synthesis in neutral solution leads to a mixture of symmetrical and unsymmetrical complexes as shown by $^{31}P$ NMR spectroscopy.[7a] One reasonable hypothesis for the structure of the dissymmetrical $\{Co_4P_4W_{30}\}$ species is that it presents both types of junction, α and β, between the two $\{P_2W_{15}\}$ units and the central $Co_4$ sheet.

Dinuclear and trinuclear sandwich complexes $[Na_2M_2(H_2O)_2(P_2W_{15}O_{56})_2]^{n-}$ and $[NaM_3(H_2O)_2(P_2W_{15}O_{56})_2]^{m-}$ ($M^{2+}$ = $Co^{2+}$, $n$ = 18, $m$ = 17 and $M^{3+}$ = $Fe^{3+}$, $n$ = 16, $m$ = 14) have also been obtained.[7b,7c,8,9]

For the diiron species $[Na_2(H_2O)_2Fe_2(P_2W_{15}O_{56})_2]^{16-}$, the junctions between the trivacant moieties $\{P_2W_{15}\}$ and the metallic sheet are both of the α-type (Figure 2), whereas in the case of the trimetallic complexes ($M^{2+/3+}$ = $Co^{2+}$ or $Fe^{3+}$), the structures may be considered as resulting from the fusion of one α-$\{M_3P_2W_{15}\}$ and one "lacunary" β-$\{M_2P_2W_{15}\}$ unit, and the lacuna is occupied by a $Na^+$ cation.[8–10]

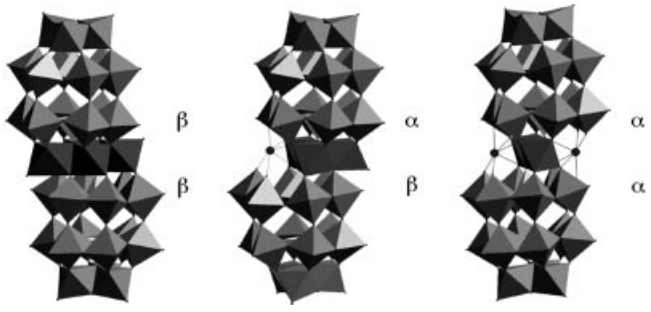

Figure 2. Polyhedral representations of the crystallographically resolved Dawson sandwich structures: ββ-$\{M_4P_4W_{30}\}$ (left), αβ-$\{NaM_3P_4W_{30}\}$ (middle) and αα-$\{Na_2M_2P_4W_{30}\}$ (right). For the "lacunary" structures, the aqua ligands are omitted for clarity.

As the $Na^+$ cations are weakly bonded, the di- and trimetallic complexes may act as divacant and monovacant "lacunary" species, respectively, and mixed-metal sandwich complexes can be obtained by addition of a transition-metal cation $M^{n+}$. Indeed, the reaction of $M^{2+}$ (M = Mn, Co, Ni, Zn) with $\{Na_2Fe_2P_4W_{30}\}$ leads to "saturated" sandwich complexes $[M^{II}_2(H_2O)_2Fe^{III}_2(P_2W_{15}O_{56})_2]^{14-}$ (abbreviated as $\{M_2Fe_2P_4W_{30}\}$).[7b,11,12] In each case, replacement of the two $Na^+$ cations by two $M^{2+}$ metallic cations induces conformational changes that lead to a β connectivity for both $\{P_2W_{15}\}$–$M_2Fe_2$ junctions.

The tricobalt species $[NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{17-}$ (abbreviated as $\{NaCo_3P_4W_{30}\}$)[8] reported recently also appears to be a suitable starting species for the synthesis of mixed-metal sandwich complexes (Figure 3).

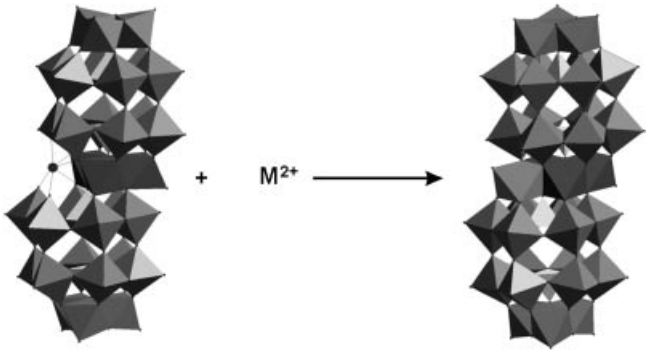

Figure 3. Principle of the synthesis of the mixed-metal Dawson sandwich complexes $\{MCo_3P_4W_{30}\}$.

Such complexes can be used in catalytic reactions as inorganic analogues of metalloporphyrins, and both the redox and the catalytic properties of these complexes can be modulated by the nature of the addendum atom M.[13]

We report here the synthesis and characterization (by IR and $^{31}P$ NMR spectroscopy and elemental analysis) of a new family of these mixed-metal sandwich complexes $[MCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ (abbreviated as $\{MCo_3P_4W_{30}\}$) where $M^{2+}$ = $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Zn^{2+}$ and $Cd^{2+}$. We also present the electrochemical behaviour of $\{MCo_3P_4W_{30}\}$ and compare it with that of the tetracobalt complex and the trinuclear precursor $\{NaCo_3P_4W_{30}\}$.[8]

## Results and Discussion

### Synthesis

The tricobalt sandwich complex is formally an unsaturated species. As shown by $^{31}P$ NMR spectroscopy, addition of a slight excess of $Co^{2+}$ to the aqueous solution of $\{NaCo_3P_4W_{30}\}$ leads to the immediate and quantitative formation of one dissymmetrical $\{Co_4P_4W_{30}\}$ complex (Figure 4, middle)[8] according to the global reaction [Equation (1)]:

$$[NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{17-} + Co^{2+} \rightarrow \text{dissym-}[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-} + Na^+ \quad (1)$$

The pH of the solution (initially around 6.5) does not change markedly by addition of $Co^{2+}$. At this pH, the dissymmetrical complex appears very stable, whereas at low pH (ca. 3) it evolves into the symmetrical ββ-$\{Co_4P_4W_{30}\}$ form (Figure 4, bottom).[15] As reported by Coronado and co-workers,[10] the lacunary $\{NaCo_3P_4W_{30}\}$ species presents an αβ connectivity; the rapid addition of $Co^{2+}$ to form the saturated compound likely leads primarily to the αβ-$\{Co_4P_4W_{30}\}$ isomer, which is stable in neutral medium. In acidic medium, however, it isomerizes slowly and irreversibly into ββ-$\{Co_4P_4W_{30}\}$ by formal π/3-rotation of the $\{P_2W_{15}\}$ unit of the α-$\{Co_3P_2W_{15}\}$ moiety leading to β-$\{Co_3P_2W_{15}\}$. The whole process is described as follows [Equation (2)] and [Equation (3)]:

$$\alpha\beta\text{-}[NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{17-} + Co^{2+} \xrightarrow{\text{rapid, pH ca. 6.5}} \alpha\beta\text{-}[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-} + Na^+ \quad (2)$$

$$\alpha\beta\text{-}[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-} \xrightarrow{\text{slow, pH ca. 3}} \beta\beta\text{-}[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-} \quad (3)$$

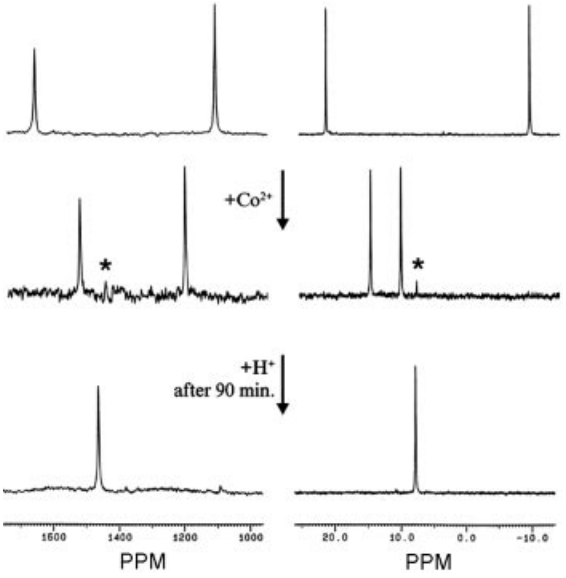

Figure 4. Formation of $\{CoCo_3P_4W_{30}\}$ by addition of $Co^{2+}$ to $\{NaCo_3P_4W_{30}\}$ followed by 121.5 MHz $^{31}P$ NMR spectroscopy. Top: initial spectrum of $\{NaCo_3P_4W_{30}\}$, middle: immediately after addition of 2 equiv. $Co^{2+}$ per $\{NaCo_3P_4W_{30}\}$, bottom: after lowering the pH by addition of 2 equiv. $H_3O^+$. Experimental conditions: $c$ = 0.02 mol L$^{-1}$ in $D_2O/H_2O$ (1:1), $T$ = 300 K.

To obtain analytically pure αβ-$Na_{16}[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]$ it is necessary to use a fourfold excess of $Co^{2+}$ in order to displace the $Na^+$ cation from the central $Na\text{-}Co_3O_{14}(H_2O)_2$ cluster. Actually, by using less than four equivalents of $Co^{2+}$, a mixture of αβ-$\{Co_4P_4W_{30}\}$ and αβ-$\{NaCo_3P_4W_{30}\}$ is always obtained. The crystallisation of $\{MCo_3P_4W_{30}\}$ further requires the addition of NaCl in order to lower the solubility by ionic strength and common cation effects.

The mixed-metal tricobalt sandwich complexes $\{MCo_3P_4W_{30}\}$ (M = $Mn^{2+}$, $Ni^{2+}$, $Zn^{2+}$ and $Cd^{2+}$) are prepared similarly by addition of a fourfold excess of $M^{2+}$ to $\{NaCo_3P_4W_{30}\}$ in 1 mol L$^{-1}$ NaCl. $^{31}P$ NMR spectroscopy shows that the addition reaction is quite selective as no other compound can be detected except for trace amounts of the $\{NaCo_3P_4W_{30}\}$ precursor.

This method, namely simple addition of a transition-metal ion to the "lacunary" tricobalt compound, then leads to a clean reaction without any substitution in the POM subunits. This furnishes a coherent series of new mixed-metal sandwich complexes.

## IR Characterization

The IR spectra of $\{MCo_3P_4W_{30}\}$ ($M^{2+}$ = $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Zn^{2+}$ and $Cd^{2+}$) are shown in Figure S1 (see Supporting Information) and are compared to that of the precursor compound αβ-$\{NaCo_3P_4W_{30}\}$ and to that of ββ-$\{Co_4P_4W_{30}\}$.

In addition to numerous W–O and W–O–W bands at relatively low wavenumbers (<1000 cm$^{-1}$),[16] the IR spectra of phosphorus-centred polyoxotungstates present well-separated P–O stretching vibrations between 1200 and 1000 cm$^{-1}$.[17]

In our previous papers, we have discussed in detail the pattern of the $PO_4$ stretching region for various ββ-$\{M_4P_4W_{30}\}$ sandwich complexes; it shows two bands at around 1080 (strong) and 1010 cm$^{-1}$ (weak) that are assigned to the unperturbed $PW_9$ moiety and one band at ca. 1055 cm$^{-1}$ (medium) that is attributed to the perturbed $PW_6$ subunit.[7a,8] For the tricobalt precursor αβ-$\{NaCo_3P_4W_{30}\}$, the latter signal is split into two bands, at 1044 cm$^{-1}$ and 1035 cm$^{-1}$, according to the non-equivalence of the two $PW_6$ subunits ($PW_6Co_3$ and $PW_6Co_2Na$).[8,10]

The mixed-tricobalt species $\{MCo_3P_4W_{30}\}$ can be formed from the trimetallic species by replacing the "external" $Na^+$ ion by one transition metal (Figure 3). Unlike those for $\{CdCo_3P_4W_{30}\}$, the two bands for the $PW_6$ subunits in $\{NaCo_3P_4W_{30}\}$ coalesce into one band at ca. 1050 cm$^{-1}$, which shows that the two saturated subunits $PW_6Co_3$ and $PW_6Co_2M$ are nearly equivalent. Such a behaviour was already observed for lacunary and monosubstituted Keggin tungstophosphates, where addition of the transition-metal cation to the lacunary species induces a marked decrease in the splitting of the P–O stretching vibrations.[17a]

Whereas the size of the first row transition-metal cations $Mn^{2+}$ ($r$ = 0.83 Å), $Ni^{2+}$($r$ = 0.69 Å) and $Zn^{2+}$ ($r$ = 0.74 Å) are comparable to that of $Co^{2+}$ ($r$ = 0.74 Å), the cadmium cation is significantly larger ($r$ = 0.95 Å) and it does not fit exactly into the lacuna and therefore does not interact as strongly as the other cations with the oxygen atom of $PO_4$. This accounts for the observation of two bands at around 1045 cm$^{-1}$ ($PW_6Co_3$) and 1035 cm$^{-1}$ (shoulder, $PW_6Co_2Cd$) for $\{CdCo_3P_4W_{30}\}$. Nevertheless, the overall IR spectra of all $\{MCo_3P_4W_{30}\}$ are similar to that of $\{Co_4P_4W_{30}\}$, which indicates a structural similarity throughout the whole series.

## $^{31}P$ NMR Characterization

$^{31}P$ NMR spectroscopy is particularly suitable to check the polyoxometalate purity and to obtain some structural information, i.e. overall symmetry of the species and relative positions of the substituting elements.[12]

The $^{31}P$ NMR spectra of $\{MCo_3P_4W_{30}\}$ ($M^{2+}$ = $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Zn^{2+}$ and $Cd^{2+}$) are reported in Figure 5 and all data are given in Table 1. Paramagnetic Dawson species always exhibit two markedly different types of $^{31}P$ resonances: the P atoms labelled P(1) in the $PW_6$ subunits close to the paramagnetic centres give rise to broad and strongly shifted (generally towards high frequency) signals, and those labelled P(2) in the $PW_9$ subunits far from the paramagnetic centres give rise to relatively sharp lines at a chemical shift close to that of diamagnetic metallophosphates (between +20 and –20 ppm).[18]

As in the case for $\{NaCo_3P_4W_{30}\}$, the $^{31}P$ NMR spectra of all $\{MCo_3P_4W_{30}\}$ present two relatively narrow lines ($\Delta\nu_{1/2}$: 10–30 Hz) of equal intensity, which are assigned to

[a] Unbuffered 0.02 mol $L^{-1}$ solutions in $D_2O/H_2O$ (1:1) at 300 K. [b] P(1) and P(2) in the $PW_6$ and $PW_9$ subunits, respectively. [c] In ppm with respect to 85% $H_3PO_4$. [d] In Hz.

the two non-equivalent P(2) atoms, and two broad signals attributed to the P(1) atoms (Figure 5). This confirms that the two $\{P_2W_{15}\}$ moieties remain non-equivalent in the $\{MCo_3P_4W_{30}\}$ complexes (Figure 3).

By examination of the data reported in Table 1, we notice that, for all first-row transition-metal species, one P(1) signal is always observed from about +1150 to +1200 ppm. By plotting its $^{31}P$ chemical shift with respect to the atomic number of $M^{2+}$, we observe a moderate and quasilinear variation, whereas the second P(1) signal shifts considerably (Figure 6a). We can tentatively assign the latter signal to the P(1) atom of the $PW_6Co_2M$ subunit that is closer to the addendum $M^{2+}$ cation ($d_{P(1)-M}$: ca. 3.3 Å) rather than to the P(1) atom of the $PW_6Co_3$ subunit ($d_{P(1)-M}$: ca. 4.6 Å). On the contrary, the P(2) chemical shifts are not very sensitive to the nature of $M^{2+}$ with the exception of $Co^{2+}$. Two P(2) signals are observed at around +0.4 to +0.6 ppm and +17.9 to +18.4 ppm, which agrees with phosphorus atoms in the $PW_9$ subunits far from the paramagnetic centres ($d_{P(2)-M} > 7$ Å) and consequently less affected (Figure 6b). It is somewhat puzzling that both the P(2) chemical shifts

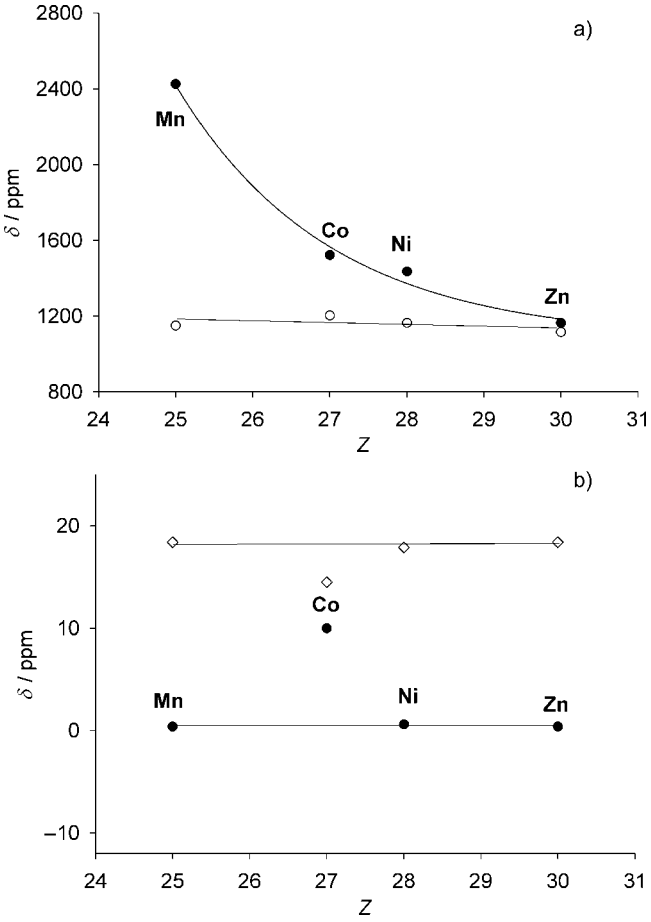

Figure 6. Plot of the variation of a) $\delta_{P(1)}$ and b) $\delta_{P(2)}$ of $\{MCo_3P_4W_{30}\}$ ($M^{2+}$ = $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$ and $Zn^{2+}$) with respect to the atomic number of M. (For the complete series including $Cd^{2+}$ see Figure S3 of the Supporting Information).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for αβ-$\{Co_4P_4W_{30}\}$ do not fall on the line, which may suggest that the $\{MCo_3P_4W_{30}\}$ (M ≠ Co) species present another conformation with ββ connectivities. This question cannot be answered until an X-ray structure determination has been performed.

We notice that the Mn compound presents the largest shift amongst the P(1) signals (+2425 ppm); this $^{31}P$ resonance is also the broadest one (2.4 kHz, Figure 5, top).

## Electrochemistry

### *General Electrochemical Behaviour*

The electrochemical behaviour of complexes $\{NaCo_3P_4W_{30}\}$ and $\{MCo_3P_4W_{30}\}$ was studied in aqueous solution (pH 3.5) by cyclic voltammetry (CV). All electrochemical data are gathered in Table 2, and typical cyclic voltammograms are presented in Figure 7 and Figure 8.

These complexes exhibit three successive reduction processes involving the W centres. For these three couples, the cathodic (and anodic) peak currents are almost proportional to the square root of the scan rate up to 100 mV s$^{-1}$, which indicates that the reduction (and oxidation) processes are both diffusion-controlled.

The voltammograms of $\{ZnCo_3P_4W_{30}\}$, $\{NiCo_3P_4W_{30}\}$ and αβ-$\{Co_4P_4W_{30}\}$ are very similar to that of ββ-$\{Co_4P_4W_{30}\}$ (Figure 7 top and Figure S2), however, with slightly different potentials (Table 2).

In the case of $\{CdCo_3P_4W_{30}\}$, the third reduction process presents a typical pattern that is characteristic of adsorption of metallic Cd at the electrode (Figure 7, bottom). In the forward scan, at –0.859 V, $Cd^{2+}$ is also reduced along with the W centres; this results in the deposition of metallic Cd. In the reverse scan, $Cd^0$ is reoxidized to $Cd^{2+}$, which re-enters the sandwich anion; this gives rise to the intense and symmetrical anodic redissolution peak. The whole reduction and the first reoxidation processes of $\{CdCo_3P_4W_{30}\}$ can be expressed according to Equations (4), (5), (6), (7) and (8).

For all species, controlled-potential coulometry at –0.55 V shows that the solution turns deep blue and consumes between 2.1 and 2.2 electrons per sandwich complex;

$$[CdCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{16-} + 2e^- \leftrightarrows [CdCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{18-} \quad (4)$$

$$[CdCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{18-} + 2e^- \leftrightarrows [CdCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{20-} \quad (5)$$

$$[CdCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{20-} + 4e^- + Na^+ \rightarrow [NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{23-} + Cd^0 \quad (6)$$

$$Cd^0 \rightarrow Cd^{2+} + 2e^- \quad (7)$$

$$[NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{23-} + Cd^{2+} \rightarrow [CdCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{20-} + 2e^- + Na^+ \quad (8)$$

at –0.70 V, the number of exchanged electrons is between 4.1 and 4.3. This shows that both the first and the second processes involve two electrons.

In addition to the cathodic waves as discussed above, the manganese species $\{MnCo_3P_4W_{30}\}$ is also electroactive at a positive potential: an anodic peak at +1.027 V and the associated cathodic peak at +0.719 V correspond to the oxidation and reduction of the Mn centre (Figure 8).[7a,12,19]

Controlled-potential coulometry at +1.10 V results in the passage of 2.2 electrons per complex, whereas subsequent reduction at +0.60 V consumes only 1.1 electron. This suggests that the $Mn^{II}$ is oxidized directly to $Mn^{IV}$, but in the reverse process $Mn^{IV}$ is reduced to $Mn^{III}$; further reduction to recover $Mn^{II}$ in $\{MnCo_3P_4W_{30}\}$ likely leads to a broad peak hardly detectable even after several repetitive scans.

Similar behaviours were previously reported for α$_2$-$[Mn^{II}P_2W_{17}O_{61}]^{8-}$, $[ZnW_{11}MnO_{39}]^{8-}$ and $[Mn_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ (abbreviated as $\{Mn_4P_4W_{30}\}$); in the last case, the four Mn centres are simultaneously oxidized in a eight-electron process, and the two successive reduction processes $Mn^{IV}$ to $Mn^{III}$ and $Mn^{III}$ to $Mn^{II}$ both consume four electrons.[7a,19]

In that case, the curve-crossing at about 1 V is probably due to the deposition, at the electrode, of the species generated during the oxidation process (Figure 8, dotted line).

Table 2. Electrochemical data of the Dawson sandwich complexes obtained from cyclic voltammetry (scan rate = 20 mV s$^{-1}$) in 0.5 mol L$^{-1}$ $Na_2SO_4$ + $H_2SO_4$ (pH 3.5). All redox potentials $E°'$, approximated by $(E_p^a + E_p^c)/2$ for the reversible steps, are given in V vs. SCE.

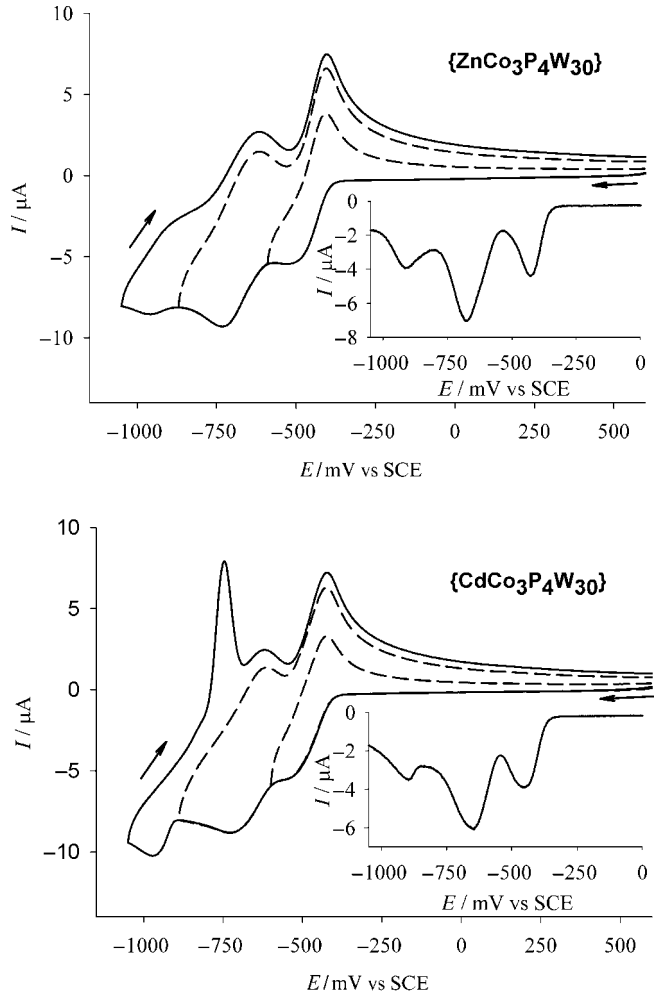

Figure 7. Cyclic voltammograms of $\{ZnCo_3P_4W_{30}\}$ (top) and $\{CdCo_3P_4W_{30}\}$ (bottom) in 0.5 mol L$^{-1}$ $Na_2SO_4$ + $H_2SO_4$ at pH 3.5 with different negative potential limits: –0.60 V, –0.89 V and –1.05 V. Scan rate = 20 mV s$^{-1}$, $c$ = 0.5 mmol L$^{-1}$. Inset: Differential pulse voltammetry at a scan rate of 25 mV s$^{-1}$.

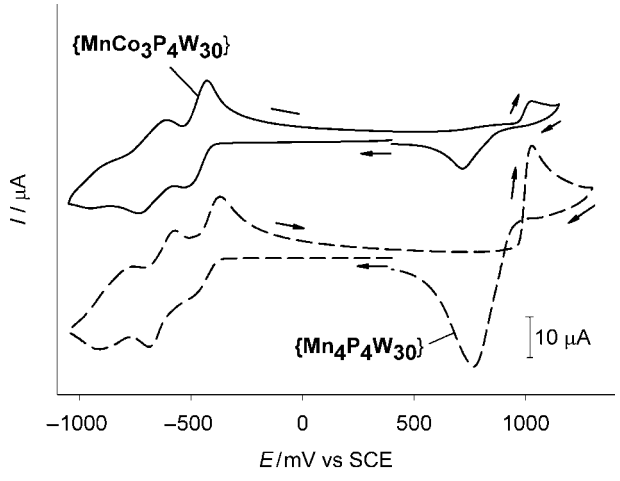

Figure 8. Cyclic voltammograms of $\{MnCo_3P_4W_{30}\}$ (full line) and $\{Mn_4P_4W_{30}\}$ (dotted line) in 0.5 mol L$^{-1}$ $Na_2SO_4$ + $H_2SO_4$ at pH 3.5. Scan rate = 20 mV s$^{-1}$, $c$ = 0.5 mmol L$^{-1}$.

## Summary and Concluding Remarks

In this work, we report for the first time the preparation and characterization of mixed-metal–tricobalt sandwich complexes $[MCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ ($\{MCo_3P_4W_{30}\}$; $M^{2+}$ = $Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Zn^{2+}$ and $Cd^{2+}$).

As in the case for $\{NaCo_3P_4W_{30}\}$, the $^{31}$P NMR spectrum of each $\{MCo_3P_4W_{30}\}$ complex presents two relatively narrow lines of equal intensity assigned to the two non-equivalent P(2) atoms and two broad signals attributed to the P(1) atoms, which indicates that the two $\{P_2W_{15}\}$ moieties remain non-equivalent in the $\{MCo_3P_4W_{30}\}$ complexes. Moreover, by plotting $\delta_{P(1)}$ with respect to the atomic number of M, we notice that one of the two P(1) signals presents a moderate and quasilinear shift with respect to the atomic number, whereas the second P(1) signal changes considerably. This large variation leads us to tentatively assign this signal to the P(1) atom of the $PW_6Co_2M$ subunit that is closer to the addendum $M^{2+}$ cation.

On the contrary, the P(2) signals are not very sensitive to the nature of $M^{2+}$ (with the exception of $Co^{2+}$), which is in agreement with the fact that these phosphorus atoms are in the $PW_9$ subunits far from $M^{2+}$.

The electrochemical behaviours of $\{MCo_3P_4W_{30}\}$ were investigated systematically, with reference to that of αβ-$\{NaCo_3P_4W_{30}\}$ or ββ-$\{Co_4P_4W_{30}\}$. All these compounds exhibit three reversible W-centred reduction processes with slightly different peak potentials, which suggests that the anions have similar structures.

Different electrochemical behaviours can be distinguished: with $Co^{2+}$, $Ni^{2+}$ and $Zn^{2+}$, the metallic centres are not electroactive, whereas with $Mn^{2+}$ and $Cd^{2+}$, redox reactions originating from the metals are observed.

The $Mn^{2+}$ complex presents one oxidation process, corresponding to the $Mn^{II}/Mn^{IV}$ couple, followed, in the reverse scan, by the reduction of $Mn^{IV}$ to $Mn^{III}$. Further reduction to recover $Mn^{II}$ complex is hardly detectable.

The "lacunary" sandwich complex $\{NaCo_3P_4W_{30}\}$ appears to be a good precursor to prepare new classes of mixed-metal polytungstates in which the nature of the metal can be varied considerably. This opens the route to the preparation of mixed-metal sandwich complexes with interesting catalytic and magnetic properties.

## Experimental Section

**General Comment:** Most common laboratory chemicals were of reagent grade purchased from commercial sources, and were used without further purification.

**Preparation of Compounds:** The trinuclear complex αβ-$[NaCo_3(H_2O)_2(P_2W_{15}O_{56})_2]^{17-}$ $\{NaCo_3P_4W_{30}\}$ was prepared as described previously.[8]

For all subsequent compounds, the purity was checked by $^{31}$P NMR spectroscopy: except for $\{CoCo_3P_4W_{30}\}$, no spurious signal could be detected from the noise for all compounds, which shows that the purity is at least 97%.

**αβ-$Na_{16}[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]\cdot 51H_2O$:** $\{NaCo_3P_4W_{30}\}$ (1.00 g, 0.110 mmol) was dissolved in 10 mL of water. By addition of

$Co(NO_3)_2{\cdot}6H_2O$ (128.0 mg, 0.440 mmol) while stirring vigorously, the solution immediately turned from dark red to brown. The resulting neutral solution (pH ca. 6.5) was stirred for 2 h, after which NaCl (0.60 g) was added. The solution was concentrated in air in an open vessel, and a greenish brown precipitate appeared after ca. 1 d. The precipitate was collected on a sintered glass frit (porosity 4) after 2 d and dried in air (yield 0.43 g, 43%). $^{31}P$ NMR spectroscopy shows that this sample is contaminated by less than 5% of the symmetrical ββ isomer. $Co_4Na_{16}P_4W_{30}O_{112}{\cdot}53H_2O$ (8989.7): calcd. Co 2.62, P 1.38, W 61.35, $H_2O$ 10.62; found Co 2.60, P 1.38, W 61.21, $H_2O$ 10.62. $^{31}P$ NMR: ($D_2O/H_2O$, 1:1): $\delta$ = +10.0 ($\Delta\nu_{1/2}$ = 14 Hz), +14.5 ($\Delta\nu_{1/2}$ = 13 Hz), +1203 ($\Delta\nu_{1/2}$ = 440 Hz), +1522 ppm ($\Delta\nu_{1/2}$ = 540 Hz).

**$Na_{16}[MnCo_3(H_2O)_2(P_2W_{15}O_{56})_2]{\cdot}51H_2O$.:** This complex was prepared following the same procedure as that for αβ-$\{Co_4P_4W_{30}\}$ by using $MnCl_2{\cdot}6H_2O$ (102.9 mg, 0.440 mmol) instead of $Co(NO_3)_2{\cdot}6H_2O$. The greenish-orange precipitate was collected on a sintered glass frit (porosity 4) after 2 d (yield 0.72 g, 73%). $MnCo_3Na_{16}P_4W_{30}O_{112}{\cdot}53H_2O$ (8985.7): calcd. Co 1.97, Mn 0.61, P 1.38, W 61.38, $H_2O$ 10.63; found Co 1.95, Mn 0.63, P 1.37, W 61.29, $H_2O$ 10.63. $^{31}P$ NMR: ($D_2O/H_2O$, 1:1), $\delta$ = +0.4 ($\Delta\nu_{1/2}$ = 17 Hz), +18.4 ($\Delta\nu_{1/2}$ = 21 Hz), +1150 ($\Delta\nu_{1/2}$ = 470 Hz), +2425 ppm ($\Delta\nu_{1/2}$ = 2.4 kHz).

**$Na_{16}[NiCo_3(H_2O)_2(P_2W_{15}O_{56})_2]{\cdot}49H_2O$:** This complex was prepared following the same procedure as that for αβ-$\{Co_4P_4W_{30}\}$ by using $NiCl_2{\cdot}6H_2O$ (104.4 mg, 0.440 mmol) instead of $Co(NO_3)_2{\cdot}6H_2O$. The yellow-brown precipitate was collected on a sintered glass frit (porosity 4) after 2 d (yield 0.68 g, 69%). $NiCo_3Na_{16}P_4W_{30}O_{112}{\cdot}51H_2O$ (8989.5): calcd. Co 1.97, Ni 0.66, P 1.38, W 61.60, $H_2O$ 10.26; found Co 1.99, Ni 0.63, P 1.39, W 61.70, $H_2O$ 10.26. $^{31}P$ NMR: ($D_2O/H_2O$, 1:1): $\delta$ = +0.6 ($\Delta\nu_{1/2}$ = 31 Hz), +17.9 ($\Delta\nu_{1/2}$ = 31 Hz), +1164 ($\Delta\nu_{1/2}$ = 450 Hz), +1435 ($\Delta\nu_{1/2}$ = 630 Hz).

**$Na_{16}[ZnCo_3(H_2O)_2(P_2W_{15}O_{56})_2]{\cdot}49H_2O$:** This complex was prepared following the same procedure as that for αβ-$\{Co_4P_4W_{30}\}$ by using $ZnCl_2{\cdot}6H_2O$ (107.5 mg, 0.440 mmol) instead of $Co(NO_3)_2{\cdot}6H_2O$. The grey-brown precipitate was collected on a sintered glass frit (porosity 4) after 2 d (yield 0.84 g, 85%). $ZnCo_3Na_{16}P_4W_{30}O_{112}{\cdot}51H_2O$ (8996.1): calcd. Co 1.97, P 1.38, W 61.56, Zn 0.73, $H_2O$ 10.25; found Co 1.96, P 1.35, W 61.91, Zn 0.76, $H_2O$ 10.25. $^{31}P$ NMR: ($D_2O/H_2O$, 1:1): $\delta$ = +0.4 ($\Delta\nu_{1/2}$ = 10 Hz), +18.4 ppm ($\Delta\nu_{1/2}$ = 10 Hz), +1116 ppm ($\Delta\nu_{1/2}$ = 365 Hz), +1163 ($\Delta\nu_{1/2}$ = 550 Hz).

**$Na_{16}[CdCo_3(H_2O)_2(P_2W_{15}O_{56})_2]{\cdot}47H_2O$:** This complex was prepared following the same procedure as that for αβ-$\{Co_4P_4W_{30}\}$ by using $CdCl_2{\cdot}6H_2O$ (128.0 mg, 0.440 mmol) instead of $Co(NO_3)_2{\cdot}6H_2O$. The grey-brown precipitate was collected on a sintered glass frit (porosity 4) after 2 d (yield 0.70 g, 71%). $CdCo_3Na_{16}P_4W_{30}O_{112}{\cdot}49H_2O$ (9043.2): calcd. Cd 1.25, Co 1.97, P 1.38, W 61.48, $H_2O$ 9.84; found Cd 1.22, Co 1.94, P 1.39, W 61.24, $H_2O$ 9.84. $^{31}P$ NMR: ($D_2O/H_2O$, 1:1): $\delta$ = –3.2 ($\Delta\nu_{1/2}$ = 8 Hz), +19.2 ($\Delta\nu_{1/2}$ = 8 Hz), +1075 ($\Delta\nu_{1/2}$ = 250 Hz), +1283 ppm ($\Delta\nu_{1/2}$ = 430 Hz).

**NMR and IR Spectroscopic Measurements:** $^{31}P$ NMR spectra were recorded in 5-mm o.d. tubes on a Bruker AC 300 or a Bruker AvanceII 300 spectrometer operating at 121.5 MHz. The NMR spectra were obtained at 300 K with 0.02 M solutions in $D_2O/H_2O$ (1:1) and were referenced to external 85% $H_3PO_4$ (IUPAC convention) by the substitution method. The $^{31}P$ chemical shifts are pH dependent and some small differences may be observed between the synthetic solution and those obtained after redissolving the solid samples. IR spectra were recorded on a Bio-Rad FTS 165 FTIR spectrophotometer on KBr pellets.

**Electrochemical Experiments:** Water, used for all electrochemical measurements, was obtained by passing through a Milli-$RO_4$ unit and subsequently through a Millipore Q water purification set. $H_2SO_4$ solutions and solid $Na_2SO_4$ were commercial products (Prolabo). The electrolyte was made up from 0.5 M $Na_2SO_4$ aqueous solution, and its pH was precisely adjusted to 3.5 by addition of 0.5 M ($H_2SO_4$ + $Na_2SO_4$) aqueous solution. The solutions were deaerated thoroughly for at least 30 min by bubbling argon (Ar-U from Air Liquide) through the solution and kept under argon atmosphere during the whole experiment.

The source, mounting and polishing of the glassy carbon electrode (GC, Tokai, Japan) have been described previously.[14] The glassy carbon samples had a diameter of 3 mm. The electrochemical apparatus EG&G 273A was driven by a personal computer. Potentials are quoted against a saturated calomel electrode (SCE). The counter electrode was a platinum gauze with a large surface area. All experiments were carried out at room temperature. Controlled potential coulometry experiments were conducted under continuous bubbling and stirring, and a large surface glassy carbon plate ($s$ = 6 $cm^2$) was used.

**Analyses:** Elemental analyses were performed by the Service Central d'Analyse du CNRS, Vernaison (France). The water content was determined by thermogravimetric analysis.

**Supporting Information** (see footnote on the first page of this article): The IR spectra of $\{MCo_3P_4W_{30}\}$ (Figure S1), cyclic voltammograms of ββ-$\{Co_4P_4W_{30}\}$ and αβ-$\{Co_4P_4W_{30}\}$ at pH 3.5 (Figure S2) and plot of the variation of $\delta_{P(1)}$ and $\delta_{P(2)}$ of $\{MCo_3P_4W_{30}\}$, including that of M = $Cd^{2+}$ (Figure S3).

[15] The X-ray structure of ββ-$Na_{16}[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]\cdot 51H_2O$ has been reported in detail recently. The anion $[Co_4(H_2O)_2(P_2W_{15}O_{56})_2]^{16-}$ contains a sheet of four $Co^{II}$ ions forming an oxo–aqua metallic core $Co_4O_{14}(H_2O)_2$, which is sandwiched between two trivacant α-$[P_2W_{15}O_{56}]^{12-}$ ({$P_2W_{15}$}) subunits, with two β connectivities. The crystal structure confirms the $C_{2h}$ symmetry of the whole polyanion, which is in agreement with $^{31}P$ NMR spectroscopy. S. Liu, D. G. Kurth, B. Bredenkőtter, D. Volkmer, *J. Am. Chem. # New Anions of Pentacoordinate Phosphorus Containing Fluorine and Trifluoromethyl Groups

**Natalya V. Pavlenko,[a] Lesya A. Babadzhanova,[a] Igor I. Gerus,[b] Yurii L. Yagupolskii,*[a] Wieland Tyrra,[c] and Dieter Naumann[c]**

*Dedicated to Professor Karl Otto Christe on the occasion of his 70th birthday*

**Keywords:** Phosphorus / Fluorides / Silanes / Pentacoordinate anions

The unique pseudo-trigonal-bipyramidal $CF_3PF_3O^-$ and $(CF_3)_2PF_2O^-$ anions were obtained and characterised for the first time. They were formed by the reactions of $(PhO)_3P(O)$, $Me_3SiCF_3$ and the fluoride ion sources $[Me_4N]F$ and CsF, respectively, in glyme. These anions represent the stable transition states postulated for nucleophilic substitution at a tetrahedral phosphorus atom. The salt $Cs[(CF_3)_2PF_2O]$ (**7**) is stable at room temperature for a month, while $[Me_4N][CF_3PF_3O]$ (**1**) dismutates into $[Me_4N][CF_3PF(O)O]$ (**2**) and $[Me_4N][CF_3PF_5]$ (**3**) above 0 °C.

## Introduction

The importance of fluorinated compounds is rapidly increasing in many fields of modern agrochemistry, pharmaceutical industry and material sciences.[1] During the past several decades numerous methods were developed for the direct introduction of fluorinated substituents, in particular trifluoromethyl groups, into different types of molecules. Among a wide variety of reagents for $CF_3$ group introduction, commercially available trimethyl(trifluoromethyl)-silane had become the reagent of choice.[2] However, only a few phosphorus-containing electrophiles have been used for nucleophilic trifluoromethylation with $Me_3SiCF_3$.[3]

It has been shown that it is possible to convert $P^V$–F compounds into the corresponding $P^V$–$CF_3$ derivatives by reactions of $Me_3SiCF_3$ in the presence of catalytic amounts of $F^-$ sources.[3] In order to avoid the use of toxic phosphorous oxofluorides as starting materials and taking into account two examples of successful trifluoromethylation of aryl esters of $P^{III}$-acids by $Me_3SiCF_3$[3c] and by Ruppert's method,[4] we investigated the reactions of triphenylphosphate and $Me_3SiCF_3$ in the presence of fluoride sources. It should be noted in advance that the results differ from each other depending on the initiator, $[Me_4N]F$ or CsF, and will therefore be described separately.

## Results and Discussion

### Reactions of $(PhO)_3P(O)$ with $Me_3SiCF_3$ and $[Me_4N]F$

The reactions of $(PhO)_3P(O)$ with $Me_3SiCF_3$ and $[Me_4N]F$ yielded complex product mixtures. The composition strongly depended on the stoichiometry of the starting materials, the solvent and the temperature. The conditions for obtaining tetramethylammonium trifluoro(trifluoromethyl)phosphoranolate (**1**) as the major phosphorus-containing compound were 4 equiv. $[Me_4N]F$, 1 equiv. $Me_3SiCF_3$ and 1 equiv. $(PhO)_3P(O)$, with dme as the solvent and a temperature of –40 °C (Scheme 1).

Salt **1** contains a unique anion that represents the stable transition state usually postulated in the course of nucleophilic substitution at a tetrahedral phosphorus atom.[5] Compound **1** is stable for a reasonable time, both in solution and in the solid state at temperatures equal to or below 0 °C. It presents one more example of hypervalent compounds whose stability is significantly increased by the introduction of perfluoroalkyl groups.

The formation of the trifluoro(trifluoromethyl)phosphoranolate anion and its structure were established by NMR spectroscopic and mass spectrometric data. NMR spectra recorded at 20 °C are of first order and imply that the anion appears to be rigid at this temperature (Figure 1, Table 1).

The anion exhibits two signals in the $^{19}F$ NMR spectrum for the fluorine atoms attached to the phosphorus centre with an integrative ratio of 1:2. The low-field doublet of triplets ($\delta$ = –46.9 ppm) corresponds to the fluorine atom in the axial position ($^1J_{F_{ax}-P}$ = 812 Hz, $^2J_{F_{ax}-F_{eq}}$ = 82 Hz),

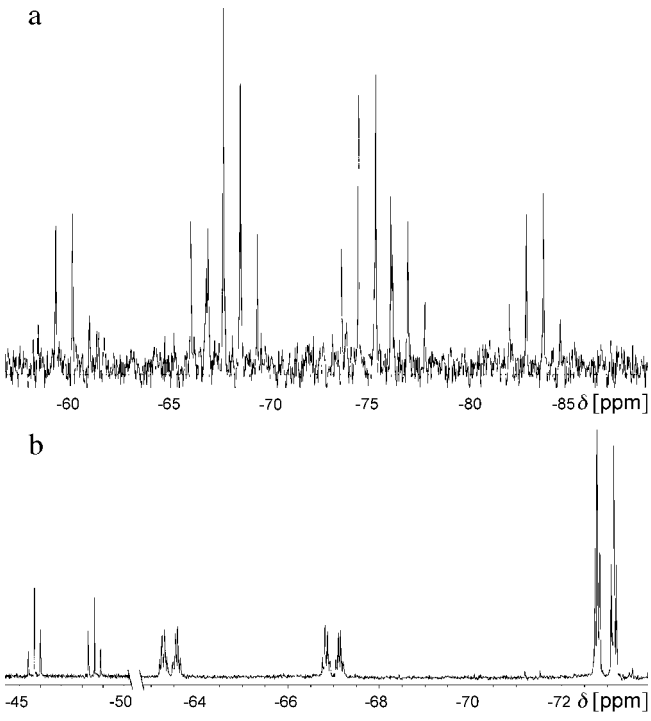

Figure 1. NMR spectra of $[Me_4N][CF_3PF_3O]$ (**1**) recorded in $CD_3CN$: (a) $^{31}P$ spectrum (121.42 MHz) and (b) $^{19}F$ spectrum (282.41 MHz).

and the doublet of doublets of quartets ($\delta$ = –65.2 ppm) is assigned to two equatorial fluorine atoms ($^1J_{F_{eq}-P}$ = 1010 Hz, $^2J_{F_{eq}-F_{ax}}$ = 82 Hz, $^3J_{F_{eq}-CF_3}$ = 15 Hz). The signal of the $CF_3$ group is found at $\delta$ = –73.0 ppm and appears as a doublet of triplets ($^2J_{CF_3-P}$ = 100 Hz, $^3J_{CF_3-F_{eq}}$ = 15 Hz). The chemical shift ($\delta < -70$ ppm) of the $CF_3$ group suggests axial position in comparison with NMR spectroscopic data of related compounds.[7] The triplet of doublets of quartets ($\delta$ = –71.3 ppm) in the $^{31}P$ NMR spectrum falls into the shift range of pentacoordinate phosphorus[7,8] and proves additionally that the anion contains two different types of fluorine atoms and one $CF_3$ group. Thus the anion of salt **1** has the structure of a trigonal bipyramid with one fluorine atom and the trifluoromethyl group in axial positions and two fluorine atoms and the oxygen atom in the equatorial plane. The $^1H$ NMR spectrum shows only the signal of the tetramethylammonium cation at $\delta$ = 2.95 ppm.

Salt **1** undergoes slow dismutation at temperatures above 0 °C, forming stable tetracoordinate and hexacoordinate (compounds **2** and **3**, respectively) phosphorus species (Scheme 2). Therefore, NMR spectra could be run at ambient temperature.

Dismutation of salt **1** presumably proceeds with initial formation of the (trifluoromethyl)phosphonyl difluoride (**A**) by fluoride elimination; **A** reacts with the anion **1** to form the second intermediate, the dimeric anion **B**. The

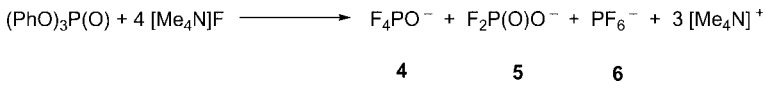


Scheme 4.

fluoride anion liberated in the first reaction step then attacks the hexacoordinate phosphorus atom of intermediate **B** to give salts **2** and **3** as the final reaction products. Both salts were separated by fractional crystallisation and characterised by NMR spectroscopic methods and elemental analyses.

It is explicitly noteworthy that the result of the reaction between $(PhO)_3P(O)$, $Me_3SiCF_3$ and $[Me_4N]F$ provides a new method to obtain two important perfluoroalkyl-containing phosphorus anions, that is, fluoro(trifluoromethyl)-phosphonate (in salt **2**) and hard-to-prepare $\lambda^6$-pentafluoro(trifluoromethyl)phosphate (in salt **3**).[9] The doubtless advantages of this method are the good availability of the starting materials, the mild reaction conditions and the high yields of the target products.

An equimolar mixture of salts **2** and **3** was also obtained by fluorination of (trifluoromethyl)phosphonyl dichloride with $[Me_4N]F$ (Scheme 3).

However, in this case we were unable to isolate salt **1**. It was only detected in the NMR spectra of the mixture together with salts **2** and **3**. This may be explained by the initial formation of (trifluoromethyl)phosphonyl difluoride (**A**) which adds $[Me_4N]F$ to form salt **1**. Similarly the dismutation process starts as outlined earlier, analogous to the elusive tetrafluorophosphate dismutation presented by Christe et al.[8] The latter anion was obtained by $F^-$ addition to $P(O)F_3$, and its composition was elucidated by NMR experiments performed at –140 °C. In one of our experiments, triphenylphosphate was treated with 4 equiv. $[Me_4N]F$ in dme at –40 °C. All phosphorus-containing products were insoluble in dme at this temperature as well as at 20 °C. The $^{19}F$- and $^{31}P$ NMR spectra analysis ([$D_6$]-dmso, room temperature) showed that the reaction mixture contained tetrafluorophosphoranolate (**4**) as the major product and its dismutation products **5** and **6** as minor ones (Scheme 4).

NMR investigations of 1:1 mixtures of $(PhO)_3P(O)$ and $[Me_4N]F$ at –70 °C gave no evidence for the key ion $[(PhO)_3PFO]^-$ but allowed the detection of $(PhO)_2P(O)F$ {$\delta_F$ (dme/[$D_8$]thf, v/v = 50:50, –40 °C) = –78.7 ppm, $^1J_{F–P}$ = 996 Hz; $\delta_P$ (dme/[$D_8$]thf, v/v = 50:50, –40 °C) = –17.0 ppm, $^1J_{F–P}$ = 996 Hz}[10] and its consecutive products **5**, $[(PhO)_2P(O)O]^-$ and $[PhOPF(O)O]^-$.[11,12]

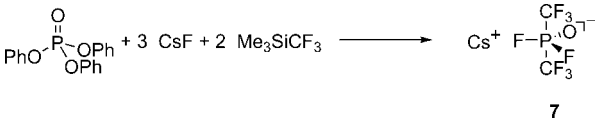
The characteristic NMR spectroscopic data for the compounds **4**, **5** (Table 1) and **6** are in full agreement with the data given by Christe et al.[8] The main advantage of the $[F_4PO]^-$ anion synthesis starting from triphenylphosphate is the relative stability of this anion in the solid state as well as in dmso solution at 20 °C. This result supports the suggestion that the presence of excess $P(O)F_3$ used in the known procedure significantly accelerates the dismutation process.[8]

### Reactions of $(PhO)_3P(O)$ with $Me_3SiCF_3$ and CsF

To our great surprise we were unable to obtain the Cs analogue of salt **1** under the same reaction conditions using CsF instead of $[Me_4N]F$. The product of this reaction was the pentacoordinate phosphorus anion difluorobis(trifluoromethyl)phosphoranolate, $[(CF_3)_2PF_2O]^-$, while reasonable

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

amounts of the starting material triphenylphosphate remained unchanged. Variation of the stoichiometry to 3 equiv. CsF, 2 equiv. $Me_3SiCF_3$ and 1 equiv. $(PhO)_3P(O)$ led to a nearly pure solution of cesium difluorobis(trifluoromethyl)phosphoranolate (**7**) (Scheme 5).



Scheme 5.

By comparison to the known structure[13] and NMR spectroscopic data[7] of the closely related $(CF_3)_2PF_3$ and the easily interpretable $^{19}F$- and $^{31}P$ NMR spectra of salt **7** on a first order basis (Figure 2, Table 1), we propose both $CF_3$ groups reside in axial positions, while the two fluorine atoms and the oxygen atom are located in the equatorial plane of a trigonal bipyramid.

The triplet of septets in the range of pentacoordinate phosphorus ($\delta$ = –64.9 ppm) in the $^{31}P$ NMR spectrum gives evidence that anion **7** contains two magnetically equivalent fluorine atoms and two equivalent $CF_3$ groups. The $^{19}F$ NMR spectrum exhibits the signal of two fluorine atoms bonded to the phosphorus atom as a doublet of septets centred at $\delta$ = –75.0 ppm. Correspondingly, the signals of the trifluoromethyl groups are split into doublets of triplets centred at $\delta$ = –74.3 ppm with $^2J_{CF_3-P}$ = 113 Hz and $^3J_{CF_3-F_{eq}}$ = 16 Hz. The high-field shifts of both signals, compared with values found for compounds with opposite arrangement of the $CF_3$ groups and the fluorine atoms,[7] as well as the value of $^1J_{F-P}$ = 1080 Hz, indicate that the fluorine atoms are located in the equatorial plane of the trigonal bipyramid.

Salt **7** is stable in dme or $CH_3CN$ solutions, as well as in the solid state for months at 20 °C, but it is extremely sensitive to moisture. Also, storing the solid especially in glassware causes decomposition into bis(trifluoromethyl)phosphinic (**8**)[6,14] and (trifluoromethyl)phosphonic (**10**)[6,15] acids (Scheme 6).

The degradation of **7** can be explained on the assumption of the intermediate formation of bis(trifluoromethyl)phosphinyl fluoride (**C**) which is hydrolysed either by replacement of the fluorine atom or the trifluoromethyl group by hydroxy groups. In the latter case, NMR spectroscopic evidence was found for fluoro(trifluoromethyl)phosphonic acid (**9**) [$\delta_F$ ($CD_3CN$) = –71.8 ppm (d, $^1J_{F-P}$ = 980 Hz), –72.7 ppm (d, $^2J_{F-P}$ = 102 Hz); $\delta_P$ ($CD_3CN$) = –8.8 ppm (dq, $^1J_{F-P}$ = 980 Hz, $^2J_{F-P}$ = 102 Hz)] which is rapidly hydrolysed to acid **10**.

In order to obtain the Cs analogue of salt **1**, we performed the reaction of (trifluoromethyl)phosphonyl dichloride with CsF (Scheme 7).

The instability of **11** prevented its detection in NMR spectra of the reaction mixture. Only an equimolar mixture of the dismutation products, fluoro(trifluoromethyl)phosphonate **12** and $\lambda^6$-pentafluoro(trifluoromethyl)phosphate **13** was obtained. The salts were separated by fractional crystallisation, and both compounds were characterised. It is noteworthy that salts with the anion $CF_3PF_5^-$ were reported at the end of the 1960s,[9] but the NMR spectroscopic characterisation had remained insufficient until now. The $^{19}F$- and $^{31}P$ NMR spectroscopic data for salt **13** are shown in Figure 3 (cf. Table 1).

The $^{19}F$ NMR spectrum of the Cs salt **13** is of higher order; the calculated spectrum[16] for an $A_3B_4CX$ spin system matched well with the measured spectrum. While the

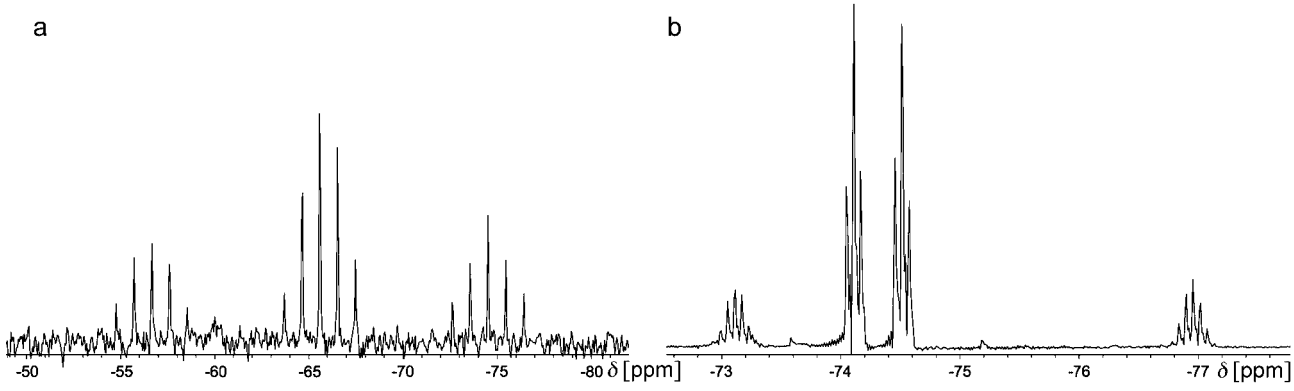


Figure 2. NMR spectra of $Cs[(CF_3)_2PF_2O]$ (**7**) recorded in $CD_3CN$ at 20 °C: (a) $^{31}P$ spectrum (121.42 MHz) and (b) $^{19}F$ spectrum (282.41 MHz).

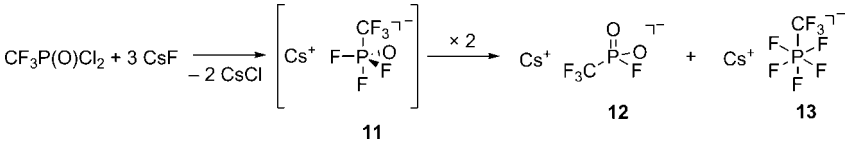

Scheme 7.

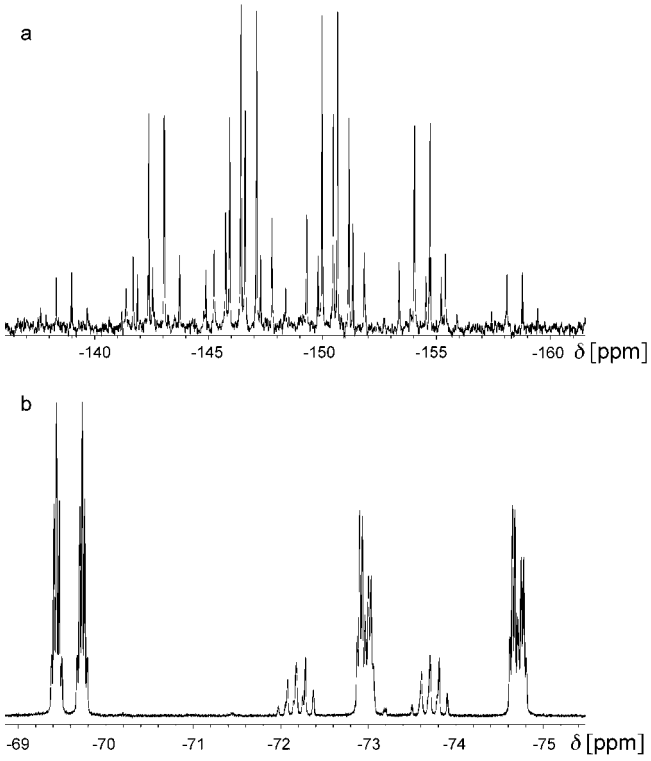

Figure 3. NMR spectra of $Cs[CF_3PF_5]$ (**13**) recorded in $D_2O$ at 20 °C: (a) $^{31}P$ spectrum (202.45 MHz) and (b) $^{19}F$ spectrum (470.54 MHz).

signals for the fluorine atoms directly bonded to phosphorus appear as doublets of complex multiplets ($\delta_{F_{ax}}$ = –72.9 ppm, $\delta_{F_{eq}}$ = –73.9 ppm), the signal of the $CF_3$ group ($\delta$ = –69.5 ppm) can be interpreted as a "first order" doublet ($^2J_{CF_3-P}$ = 140 Hz) of quintets ($^3J_{CF_3-F_{eq}}$ = 13 Hz) of doublets ($^3J_{CF_3-F_{ax}}$ = 2.5 Hz). The doublet of quintets of quartets in the $^{31}P$ NMR spectrum unambiguously confirms the predicted octahedral structure of the anion.

## Conclusions

Some general conclusions can be made thus far. Tetracoordinate triphenylphosphate is converted into the highly fluorinated pentacoordinate phosphorus derivatives **1** or **7** in the reaction with $Me_3SiCF_3$ and sources of fluoride. We assume that the nucleophilic substitution at the tetrahedral phosphorus atom follows the addition-elimination process[5] and, as far as $F^-$ is in excess relative to the second nucleophile "$CF_3^-$", the first step of the reaction is the addition of $F^-$ to the P=O bond of triphenylphosphate to give intermediate **D** (Scheme 8) followed by spontaneous $PhO^-$ elimination to give $(PhO)_2P(O)F$.[10] The ease of adding fluoride to tris(pentafluoroethyl)phosphane oxide[17] and phosphoryl trifluoride[8] further supports this assumption. Upon the substitution of the next PhO group, the highly reactive "$CF_3^-$" nucleophile can compete with the fluoride anion, as is shown in the proposed reaction mechanism (Scheme 8).

One of the facts that supports this scheme is that the intermediate of type **G** (mixed with salt **1**) was observed in the NMR spectra of the reaction mixture with the reagent ratio $(PhO)_3P(O)/Me_3SiCF_3/[Me_4N]F$ = 1:2:1. This intermediate is tetramethylammonium phenyl difluoro(trifluoromethyl)phosphonate (**14**) (Figure 4).

The NMR spectroscopic data (Table 1) allow us to propose the mentioned structure of this unstable anion.

We have characterised three compounds among the possible final structures of type **H**, namely the tetramethylammonium salt of the tetrafluorophosphoranolate ion (**4**), salt **1** with one trifluoromethyl group and salt **7** with two trifluoromethyl groups attached to the phosphorus atom. The stability of anions of type **H** increases significantly in the series $POF_4^- < CF_3POF_3^- < (CF_3)_2POF_2^-$, but their solubility in organic solvents changes in the reverse order. The solvent plays a key role in the investigated reactions; dme is the best choice allowing selective reactions, whereas mix-

Figure 4. Tetramethylammonium phenyl difluoro(trifluoromethyl)-phosphonate (**14**).

tures are formed in thf, and no reaction is observed in ether or propionitrile. The distinct difference in the results depending on whether $[Me_4N]F$ or CsF is used as a fluoride source is probably a result of their different solubility in dme. The less soluble CsF provides a lower concentration of fluoride in solution, and consequently the possibility of the substrate reacting with the competitive nucleophile "$CF_3^-$" is favoured. The result is the formation of salt **7** containing two trifluoromethyl groups. It is noteworthy that we have never observed an anion with three $CF_3$ groups bonded to the phosphorus atom even when using a high excess of trimethyl(trifluoromethyl)silane relative to the fluoride source.

## Experimental Section

**General:** All reactions were carried out under argon, using Schlenk type glassware with rigorous exclusion of traces of moisture and air. The solvents were purified by standard methods and were condensed in vacuo prior to use. $Me_3SiCF_3$ was purchased from ABCR. $[Me_4N]F$[18] and $CF_3P(O)Cl_2$[19] were synthesised according to literature procedures. $[Me_4N]F$ and CsF were carefully dried in vacuo directly before use. Room temp. $^1$H-, $^{19}$F-, $^{31}$P- and $^{13}$C NMR spectra were recorded with either a Varian VXR-300 or a Bruker Avance II 300 spectrometer and in one case (salt **13**) with a Bruker Avance DRX 500 spectrometer. Low-temperature NMR experiments were performed with a Bruker AC 200 spectrometer. Chemical shifts are given in ppm relative to $Me_4Si$ as internal and $CCl_3F$ and 85% $H_3PO_4$ as external standards. The NMR spectroscopic data are compiled in Table 1. Negative ESI mass spectra were recorded with a Finnigan MAT 900 apparatus with a flow rate of 2 μL/min. Intensities are referenced to the most intense peak of a group.

**Tetramethylammonium Trifluoro(trifluoromethyl)phosphoranolate (1):** To a solution of triphenylphosphate (0.60 g, 1.84 mmol) and trimethyl(trifluoromethyl)silane (0.32 g, 2.25 mmol) in dimethoxyethane (dme) (10 mL) at –40 °C was added $[Me_4N]F$ (0.69 g, 7.42 mmol) in small portions over a period of 15 min, and the resulting mixture was stirred for 2 h at this temperature and was then warmed slowly (≈ 4 h) to 0 °C. Stirring was continued at this temperature for 30 min, and the white precipitate was immediately filtered. The solvent was removed in vacuo, and the residue was suspended in diethyl ether (≈ 5 mL) at 0 °C, filtered and dried in vacuo at this temperature to give salt **1**. Yield: 0.38 g (82%). $^1$H NMR ($CD_3CN$): $\delta$ = 2.95 (s, $NCH_3$) ppm. Negative ESI-MS (MeCN): *m*/*z* (%) = 151 (20) $[CF_3(F)P(O)O]^-$, 173 (100) $[CF_3PF_3O]^-$, 223 (68) $[(CF_3)_2PF_2O]^-$, 225 (45) $[CF_3P(O)(OPh)O]^-$. *Note*: Care has to be taken that the operations are performed as quickly as possible to avoid decomposition.

**The Dismutation Reaction of Compound 1:** The solution of **1** (0.38 g, 1.54 mmol) in MeCN (10 mL) was kept at room temp. until $^{31}$P NMR spectra showed complete disappearance of a multiplet at $\delta$ = –71 ppm (≈ 8 h). The solvent was removed in vacuo, and the residue was extracted with hot dme (3 × 10 mL). The solvent was reduced to about 10 mL. After storage of the resultant solution at –17 °C overnight, colourless crystals unsuitable for XRD measurements of **2** were obtained. Yield: 0.13 g (78%). M.p. 110–113 °C (dec.). $^1$H NMR ($D_2O$): $\delta$ = 2.93 (s, $NCH_3$) ppm. $C_5H_{12}F_4NO_2P$ (225.15): calcd. C 26.67, H 5.37, N 6.22; found C 26.35, H 5.72, N 6.13. The residue after extraction was recrystallised from MeCN to give salt **3**. Yield: 0.18 g (86%). M.p. 263–266 °C (dec.). $^1$H NMR ($D_2O$): $\delta$ = 2.89 (s, $NCH_3$) ppm. $C_5H_{12}F_8NP$ (269.15): calcd. C 22.31, H 4.49, N 5.20; found C 22.15, H 4.53, N 5.13.

**Fluorination of (Trifluoromethyl)phosphonyl Dichloride with Tetramethylammonium Fluoride:** To a solution of $CF_3P(O)Cl_2$ (0.50 g, 2.67 mmol) in dme (10 mL) at –40 °C was added $[Me_4N]F$ (0.77 g, 8.27 mmol) in small portions over a period of 15 min. The resulting mixture was stirred for 2 h at this temperature and was then warmed slowly (≈ 4 h) to 0 °C. Stirring was continued at this temperature for 30 min, and the precipitate was filtered off. $^{19}$F- and $^{31}$P NMR spectra of the resultant filtrate showed the presence of compounds **1**, **2** and **3** in a ratio of approximately 2:4:3. The solution was kept at room temp. overnight to complete the dismutation of compound **1**. The solvent was removed in vacuo. The reaction mixture was worked up in the same manner as described earlier. After purification, compounds **2** and **3** were obtained in yields of 72% (0.22 g) and 53% (0.19 g), respectively. Some part of the less soluble salt **3** precipitated together with $[Me_4N]Cl$. Extraction of the primary precipitate with hot MeCN yielded more compound **3** (0.10 g) giving a total yield of compound **3** of 0.29 g (81%).

**Cesium Difluorobis(trifluoromethyl)phosphoranolate (7):** To a solution of triphenylphosphate (0.60 g, 1.84 mmol) and trimethyl(trifluoromethyl)silane (0.55 g, 3.87 mmol) in dme (10 mL) at –40 °C was added CsF (0.84 g, 5.53 mmol) in small portions over a period of 15 min. The resulting mixture was stirred for 2 h at this temperature and was then warmed slowly to room temp. Stirring was continued overnight, the precipitated solid was filtered off, and the solvent was removed in vacuo. The residue was washed with benzene (3 × 5 mL), filtered and dried in vacuo to give salt **7**. Yield: 0.31 g (48%). M.p. 73–75 °C (dec.). Because of the extreme moisture sensitivity of compound **7**, we were unable to obtain satisfactory elemental analytical data. Negative ESI-MS (MeCN): *m*/*z* (%) = 223 (100) $[(CF_3)_2PF_2O]^-$.

**Fluorination of (Trifluoromethyl)phosphonyl Dichloride with Cesium Fluoride:** To a solution of $CF_3P(O)Cl_2$ (0.40 g, 2.14 mmol) in dme (10 mL) at –40 °C was added CsF (0.99 g, 6.52 mmol) in small portions over a period of 15 min. The mixture was stirred for 2 h at this temperature and was then warmed to room temp. Stirring was continued overnight, the solvent was removed in vacuo, and the residue was extracted with hot MeCN (50 mL). After storing the solution at –17 °C, the precipitate was filtered off and recrystallised from a 10:1 (v/v) dioxane/water mixture to yield the pure salt **13** as colourless crystals unsuitable for XRD measurements. Yield: 0.31 g (87%). $CCsF_8P$ (327.89): calcd. C 3.66, P 9.45; found C 3.57, P. 9.52. $^{19}$F- and $^{31}$P NMR spectra of the resultant filtrate showed the presence of salt **12** (Table 1) as the major product (>70%). This compound was not fully characterised because of its high sensitivity to moisture.

# Ruthenium Complex Fragments as Constituents of Trinuclear Photoactive Supramolecular Assemblies Based on Hydrogen Bond Association

**Kathi Halbauer,[a] Angela Göbel,[a] Anke Sterzik,[a] Helmar Görls,[a] Sven Rau,[a] and Wolfgang Imhof*[a]**

**Keywords:** Supramolecular Photochemistry / Bibenzimidazole ligands / Hydrogen bonds / Ruthenium

The reaction of the octahedral complexes *cis*- or *trans*-$[Ru(C{\equiv}N\text{-}tBu)_4(CN)_2]$, ($Ru(CN)_2$), with the photochemically active [bis(bipyridyl)bibenzimidazole-ruthenium(II)], ($RubiH_2$), component via hydrogen bond association results in the formation of supramolecular aggregates with modified photophysical properties. The first structural characterization of a supramolecular adduct is reported, in which the N–H functions of the ruthenium bound bibenzimidazole ligand via hydrogen bonds serve as an interface directly toward a cyanide ligand acting as a bridge to another transition metal. In addition, the maximum stoichiometry of the supramolecular associates is estimated by NMR titration experiments and association constants of the hydrogen bonded adducts are determined by the decay of the emission intensity during the titration experiments.

## Introduction

One of the most challenging goals in chemistry is the conversion of sunlight into electrical, chemical or even mechanical energy. In order to achieve this goal a detailed understanding of suitable chromophore–quencher complexes is a crucial prerequisite for the construction of e.g. photovoltaic cells. Chromophore systems based on transition metals have been widely investigated for polypyridyl complexes[1] or on the basis of porphyrin complexes[2] closely resembling the natural chlorophyll chromophore used in photosynthetic organisms. In general, these efforts may be subdivided into systems in which the chromophore and the quencher are linked via strong interactions like covalent bonds or coordinative bonds on one side and aggregates that are interconnected via weak interactions like hydrogen bonds, hydrophobic interactions or π-stacking effects on the other side.[3]

The construction of multicentred supramolecular assemblies using complementary hydrogen-bond donor and acceptor sites is very appealing due to its synthetic advantages and intrinsic modular approach. In most examples that have been described in the literature up to now metal hybrid assemblies or organic assemblies have been investigated and hydrogen bonds between carboxylic acids (which by definition are self-complementary), nucleobases or protonated cyclam units were used to construct supramolecular assemblies of two different coordination complexes.[3] Campagna as well as Ward and co-workers have shown that $Ru^{II}$ complexes may act as quencher components if they are assembled to suitable chromophore systems via hydrogen bonds realized by cyanide ligands.[3a,3c] Nevertheless, it has to be pointed out that the syntheses of bipy, terpy or porphyrin ligands with pendant nucleobase or cyclam units still are complex multi-step procedures and the distance between the photochemically active metal center and the additional coordination complex subunit is quite large.

We herein report the synthesis and characterisation of supramolecular assemblies between different $Ru^{II}$ complexes where it is possible to control not only the photophysical properties of the chromophore but also the geometry and nuclearity of the aggregates formed. The control over the geometry can be exercised by variation of the H-bond acceptor utilised whereas the nuclearity can be influenced by simple stoichiometry.

## Results and Discussion

Recently, some of us reported the synthesis of complexes of the type $[Ru(bipy^*)_2(biH_2)]^{2+}$ ($biH_2$ = 5,5′,6,6′-tetramethyl-2,2′-bibenzimidazole, bipy* = 4,4′-di-*tert*-butyl-2,2′-bipyridine) which show photophysical properties that are comparable to those of the well-known $[Ru(bipy)_3]^{2+}$ compounds.[4] One of the most important features of the $biH_2$ ligand is the fact that the N–H functions are very efficient hydrogen-bond donor sites leading to the coordination of anions or solvent molecules in almost all structurally

characterized derivatives.[5] It has already been demonstrated that a hydrogen-bonded adduct of this ruthenium complex together with an osmium compound containing a carboxylated bipy ligand exhibits an effective energy transfer from Ru to Os upon irradiation.[3c] So we decided to combine a $[Ru(bipy^*)_2(biH_2)]^{2+}$ complex with compounds of the type $[Ru(C{\equiv}N\text{-}t\text{Bu})_4(CN)_2]$, which are easily accessible as a 1:1 mixture of the *cis*- and *trans*-isomers from the reaction of $Ru_3(CO)_{12}$ with *tert*-butyl isocyanide in the presence of of carbon monoxide ($p$ = 10 atm).[6]

Scheme 1 shows two possible 2:1 adducts of $[Ru(bipy^*)_2(biH_2)]^{2+}$ and $[Ru(C{\equiv}N\text{-}t\text{Bu})_4(CN)_2]$ in *cis*- and *trans*-conformation. The assumption of 2:1 adducts under stoichiometric conditions seems to be reasonable from a thermodynamic point of view because it provides the formation of a maximum number of hydrogen bonds. This assumption is additionally confirmed by NMR titration experiments which show that the signal representing the protons in 4,4′-position of the $biH_2$ ligand is significantly influenced by the stepwise addition of *cis*-$[Ru(C{\equiv}N\text{-}t\text{Bu})_4(CN)_2]$ (Figure 1). Compared to solutions of pure $RubiH_2$ the addition of *cis*-$Ru(CN)_2$ leads to a downfield shift of the corresponding signal. The effect is much less pronounced if the *trans*-isomer of the cyano complex is used presumably due to less steric interaction with the protons in 4,4′-position of the bibenzimidazole ligand in this case. In Figure 2 the product ($m_f \times \Delta\delta$) is plotted against the molar fraction itself. It can be seen that up to a $m_f$ value of app. 0.66 representing a ratio $Ru(CN)_2$:$RubiH_2$ = 2:1 an increase of ($m_f \times \Delta\delta$) is observed whereas for higher $m_f$ values a decrease of ($m_f \times \Delta\delta$) becomes evident. From this behaviour we can conclude that the maximum stoichiometry of hydrogen bonded associates consisting of $Ru(CN)_2$ and $RubiH_2$ in solution is 2:1.[7] Similar NMR titration experiments have also been used to determine the association constants of hydrogen bonded adducts.[3e,8] Nevertheless, this approach is only successful for associates of a 1:1 composition meaning that for the estimation of association constants of the aggregates that are present in our solutions we had to employ another method.

The fact that hydrogen bonds are readily formed in solution and that the so formed associates are quite stable is verified by the IR spectra of the corresponding mixtures which show a shift in the stretching frequencies of the cyanide and isocyanide ligands (cf. Experimental Part). For all molar fractions higher than 0.33 ($Ru(CN)_2$:$RubiH_2$ = 1:2) no bands corresponding to the free cyano complexes are visible in the IR spectra. So e.g. for mixtures of *trans*-$[Ru(C{\equiv}N\text{-}t\text{Bu})_4(CN)_2]$ and $[Ru(bipy^*)_2(biH_2)]^{2+}$ in a 1:2 ratio, the corresponding bands are observed at 2164 and 2101 $cm^{-1}$ compared to 2150 and 2108 $cm^{-1}$ for pure *trans*-$[Ru(C{\equiv}N\text{-}t\text{Bu})_4(CN)_2]$.[6] In the ESI-MS spectra of both compounds, peaks corresponding to the cationic 1:1 supramolecular assemblies $\{[Ru(bipy^*)_2(biH_2)][Ru(C{\equiv}N\text{-}t\text{Bu})_4(CN)_2]\}(PF_6)$ are observed (cf. Experimental Part).

Recrystallization of a mixture of $[Ru(bipy^*)_2(biH_2)](PF_6)_2$ and *trans*-$[Ru(C{\equiv}N\text{-}t\text{Bu})_4(CN)_2]$ in a 2:1 ratio from dichloromethane yielded crystals suitable for X-ray diffraction.[9] The supramolecular structure of the hydrogen-

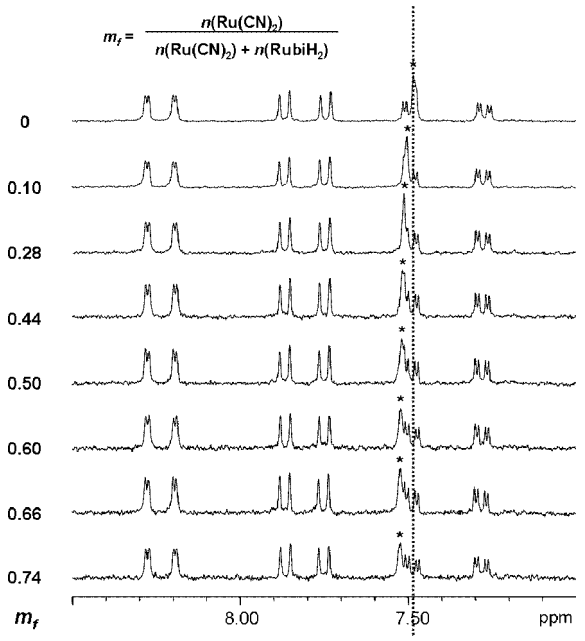

Figure 1. Section of the $^1$H-NMR spectra of [Ru(bipy*)$_2$(biH$_2$)](PF$_6$)$_2$ and [*cis*-Ru(C≡N-*t*Bu)$_4$(CN)$_2$] at various molar fractions ($m_f$ = $n$(Ru(CN)$_2$)/[$n$(Ru(CN)$_2$) + $n$(RubiH$_2$)]; signal of the 4,4′-position marked with an asterisk).

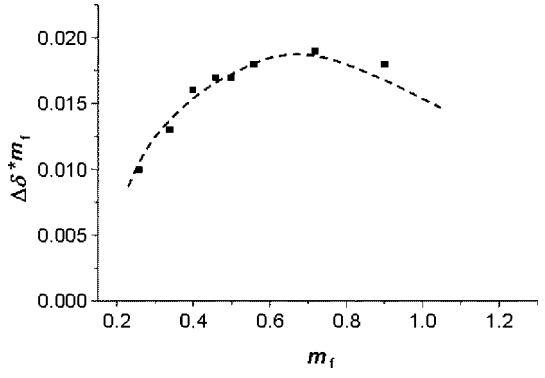

Figure 2. ($\Delta\delta^* \times m_f$) vs. $m_f$ plot showing the maximum stoichiometry of hydrogen bonded adducts in solution to be of the composition Ru(CN)$_2$:RubiH$_2$ = 2:1 ($m_f$ = 0.66).

bonded adduct is depicted in Figure 3. It is obvious that indeed a 2:1 assembly has been formed. All ruthenium atoms show a virtually perfect octahedral coordination sphere and bond lengths and angles of the ligands are as expected (Table 1). The observed monoclinic space group $P2_1/c$ shows Ru2 to be situated at the crystallographic center of inversion. Both N–H functions of the bibenzimidazole ligand are engaged in hydrogen bonds. N2–H2 acts as a hydrogen-bond donor site towards the cyanide nitrogen atom N9 with an N–N distance of 278(2) pm and a N2–H2···N9 bond angle of 166(1) deg. The second N–H group N4–H4 shows a hydrogen bond towards a water molecule (N4–O1w 282(2) pm, N4–H4···O1w 159(1) deg). The distance of 301(2) pm between O1w and N9 is indicative of another weak hydrogen bond between a proton of the water molecule and the cyanide nitrogen atom. The hydrogen bond lengths and angles fit very well to numerous examples of weak hydrogen bonding described in the literature.[10] Figure 3 also shows a view of the hydrogen-bonded adduct down the plane of the bibenzimidazole ligands. All carbon and hydrogen atoms of the bipy*, biH$_2$ (except C1 and C8) and *tert*-butyl groups have been omitted. The angle between the bibenzimidazole plane and the Ru2(CN)$_2$ plane measures to 131(2) deg.

It should be pointed out that from the same recrystallization another crystal has been investigated by means of X-ray crystallography (cf. Supporting Information). Although the quality of this crystal was inferior compared to the structure determination shown in Figure 3, the structural motif in this crystal structure unequivocally reveals a hydrogen bond network with the cyanide ligands being situated symmetrically between the two N–H groups of the bibenzimidazole ligands like it is depicted in Scheme 1. These different supramolecular assemblies clearly demonstrate that polar solvents compete for the hydrogen-bond donor sites with the cyanide ligands.

To the best of our knowledge these compounds are the first structurally characterized adducts of a photochemically active [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ complex in which the N–H functions are connected via hydrogen bonds directly to a cyanide ligand acting as a bridge to another transition metal. We therefore explored the influence of the binding of the cyano compound to the photochemically active ruthenium bibenzimidazole complex on the photophysical properties of the latter. Solutions of pure [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ typically exhibit a strong emission at app. 650 nm. Figure 4 illustrates the emission spectra of mixtures of [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ and *trans*-[Ru(C≡N-*t*Bu)$_4$(CN)$_2$] depending on the molar fraction of the cyano complex. It clearly demonstrates that there is a decay in emission intensity with increasing amount of *trans*-[Ru(C≡N-*t*Bu)$_4$(CN)$_2$] until the emission is almost completely quenched. In addition, the emission is shifted to app. 675 nm. Since the formation of hydrogen bonds may be understood in terms of an acid base reaction this bathochromic shift corresponds to observations reported in the literature, that deprotonation of the N–H functions in [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ complexes leads to quenching or at least a strong bathochromic shift of the emission band.[11] The emission intensities of solutions of the same concentrations of [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ are considerably higher than those of mixtures of [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ and *trans*-[Ru(C≡N-*t*Bu)$_4$(CN)$_2$]. The corresponding plot for *cis*-[Ru(C≡N-*t*Bu)$_4$(CN)$_2$], which may be found in the Supporting Information, is virtually identical. We therefore conclude that in both cases 1:1 and 2:1 adducts are readily formed in the quite diluted solutions that are used for the spectroscopic investigations ($c$(*cis*/*trans*-[Ru(C≡N-*t*Bu)$_4$(CN)$_2$]) + $c$([Ru(bipy*)$_2$(biH$_2$)]$^{2+}$) = $2.573 \times 10^{-6}$ mol L$^{-1}$). In addition, a dilution experiment of a 2:1 mixture of *trans*-[Ru(C≡N-*t*Bu)$_4$(CN)$_2$] and [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ shows that the emission intensities for the mixtures are significantly lower than the emission intensity of [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ alone in a blank experiment down

to a concentration of app. $5 \times 10^{-7}$ mol $L^{-1}$ demonstrating the stability of the hydrogen bonded adducts.

One major question arising in the investigation of the supramolecular adducts described herein is the question concerning the association constants of these associates. In the literature either NMR titration experiments or Stern–Volmer plots have frequently been employed in similar cases. Nevertheless, these approaches have almost exclusively been applied to 1:1 adducts. From NMR experiments (vide supra) and from the fact that a distinct decrase of the emission intensity is observed up to a $m_f = 0.66$ (and a much less pronounced decrase for higher concentrations of $Ru(CN)_2$) we conclude that in solution adducts of the general formula $\{(RubiH_2)(Ru(CN)_2)_2\}$ are formed. We therefore have to address the question of the equilibrium constant of the following reaction

$$\{(RubiH_2)(Ru(CN)_2)_2\} \rightleftharpoons RubiH_2 + 2\ Ru(CN)_2$$

with the mass-action law

$$K_D = \frac{c(RubiH_2) \cdot c(Ru(CN)_2)^2}{c\{(RubiH_2)(Ru(CN)_2)_2\}}$$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

providing us with the dissociation constant $K_D$. From the mass-action law we can conclude

$$\log\left(\frac{c(\mathrm{RubiH_2})}{c\{(\mathrm{RubiH_2})(\mathrm{Ru(CN)_2})_2\}}\right) = -2\log(c(\mathrm{Ru(CN)_2})) - \mathrm{p}K_D$$

Applying a methodology that has been used to elucidate the p$K_a$ values of bibenzimidazole ligands in ruthenium complexes from absorption intensities depending on the amount of base present in the solution[12] we are now able to calculate the p$K_D$ value from the emission intensity of pure $RubiH_2$ ($I$($RubiH_2$)), the emission intensities of mixtures with an excess of *cis*/*trans*-$Ru(CN)_2$ ($I$\{($RubiH_2$)($Ru(CN)_2$)$_2$\}) and the emission intensity of the mixtures with different concentrations of *cis*/*trans*-$Ru(CN)_2$ ($I$(M)).

$$\log\left(\frac{I\{(\mathrm{RubiH_2})(\mathrm{Ru(CN)_2})_2\} - I(\mathrm{M})}{I(\mathrm{M}) - I(\mathrm{RubiH_2})}\right) = -2\log(c(\mathrm{Ru(CN)_2})) - \mathrm{p}K_D$$

This means that a plot of the logarithmic term on the left side of the equation vs. –2 log($c$($Ru(CN)_2$)) should give a linear function with the axis intercept representing the p$K_D$ value of the corresponding supramolecular adduct. In Figure 5 a plot of the emission intensity vs. log($c$(*trans*-$Ru(CN)_2$)) showing a sigmoidal shape typical for titration curves and another plot of the logarithmic term of the latter equation vs. –2 log($c$(*trans*-$Ru(CN)_2$)) of linear shape are depicted. The titration of $RubiH_2$ with *cis*-$Ru(CN)_2$ leads to very similar plots although the sigmoidal shape of the titration curve is less pronounced (cf. Supporting Information). From the linear functions we can estimate a p$K_D$ value for \{($Ru(biH_2)$(*cis*-$Ru(CN)_2$)$_2$\} of 7.1 and for

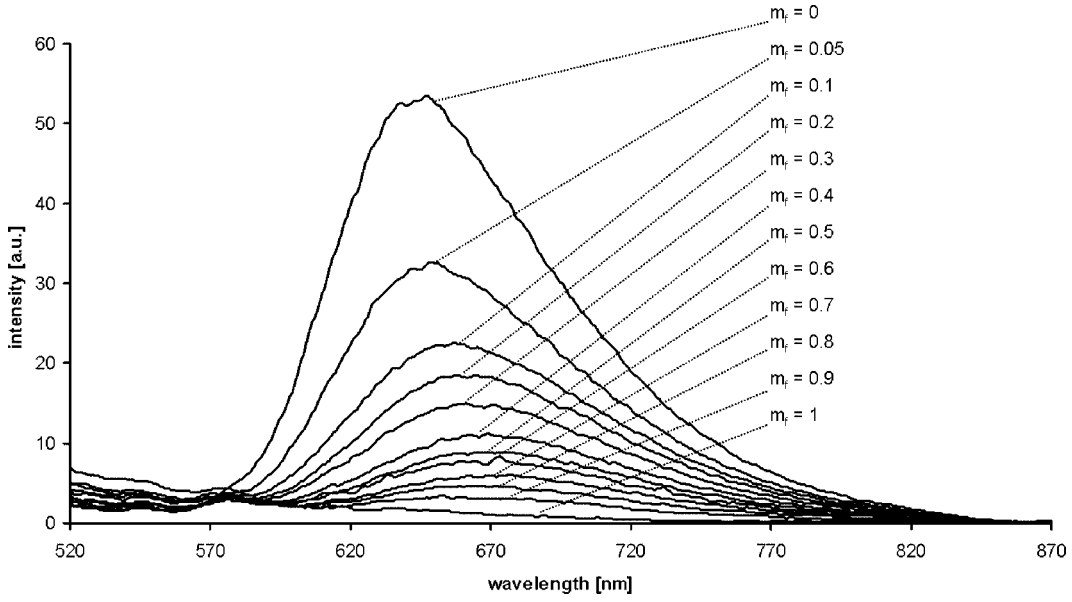

Figure 4. Emission spectra of the mixtures of [$Ru(bipy^*)_2(biH_2)$]($PF_6$)$_2$ and [*trans*-$Ru(C{\equiv}N\text{-}tBu)_4(CN)_2$] at various molar fractions.

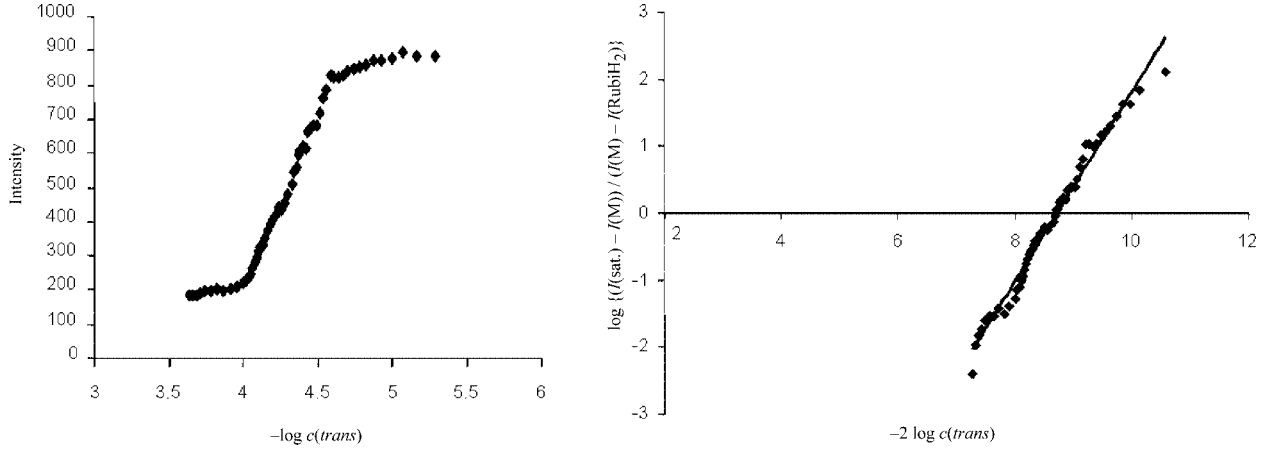

Figure 5. Emission intensity vs. log $c$(*trans*-$Ru(CN)_2$) plot (left) and log \{($I$(sat.) – $I$(M))/($I$(M) – ($I$($RubiH_2$)\} vs. –2 log $c$(*trans*-$Ru(CN)_2$).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

{(Ru(biH$_2$)(*trans*-Ru(CN)$_2$)$_2$} a p$K_D$ value of 12.3. The adduct of *trans*-Ru(CN)$_2$ thus is much more stable compared to the *cis* analogue which makes sense in terms of less steric interactions with the bibenzimidazole ligand leading to the much better pronounced saturation behaviour and titration curves.

The deactivation of the excited state of the [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ component may in principle be achieved by either electron or energy transfer from the [Ru(bipy*)$_2$(biH$_2$)]$^{2+}$ fragment to the cyano complex fragment. Taking into account the results described in the literature in connection with related systems[3] as well as cyclovoltammetric investigations of the cyano compounds showing that both isomers may be neither reduced nor oxidised makes the former possibility quite unlikely.

## Experimental Section

All procedures were carried out in anhydrous, freshly distilled solvents. Infrared spectra were recorded on a Perkin–Elmer FT-IR System 2000 using 0.2 mm KBr cuvettes. NMR spectra were recorded on a Bruker DRX400 spectrometer ($^1$H: 400.13 MHz, $^{13}$C: 100.62 MHz, $CDCl_3$ as internal standard). Mass spectra were recorded on a Finnigan MAT SSQ 710 instrument. Elemental analyses were carried out at the laboratory of the Institute of Organic Chemistry and Macromolecular Chemistry, Friedrich-Schiller-Universität, Jena, Germany.

**X-ray Crystallographic Studies:** The structure determinations were carried out on a Enraf Nonius Kappa CCD diffractometer, the crystals being mounted in a stream of cold nitrogen, crystal detector distance 29 mm using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz and polarization effects but not for absorption. The structures were dissolved by direct methods and refined by full-matrix least-squares techniques against $F^2$ using the programs SHELXS86 and SHELXL97.[13] All hydrogen atoms were constrained in idealized positions during the final stages of the refinement. The isotropic replacement parameters of all hydrogen atoms were fixed to 1.5 times the value of the corresponding carbon or nitrogen atom. The molecular illustrations were drawn using the program XP.[14]

CCDC-600734 and -600735 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The Magnetic Structure of $Mn_2GeSe_4$

**Holger Mikus,[a] Hans-Jörg Deiseroth,*[a] Krassimir Aleksandrov,[a] Clemens Ritter,[b] and Reinhard K. Kremer[c]**

**Keywords:** Olivine / Magnetic structure / Manganese / Germanium / Selenium / Antiferromagnetism

The magnetic structure of the olivine type $Mn_2GeSe_4$ is investigated by powder neutron diffraction between 2 K and ambient temperature. Based on a number of "magnetic reflections" occurring below $T_c$ = 66 K a model for the magnetic structure of the $Mn^{2+}$ ions ($d^5$) is derived by structure refinements based on the FULLPROF program system. Most important result is an antiferromagnetic arrangement of the $Mn^{2+}$ moments in successive layers along [001] ("easy direction"). This ordering evolves gradually with decreasing temperature as can be seen from the temperature dependence of the resultant magnetization of the two magnetic sublattices. The magnetization direction of one of the magnetic sublattices shows a weak tendency at low temperatures to deviate from the easy direction [001] towards [100]. The magnetic structure proposed for the title compound is comparable with the ones found for other magnetic thio- and seleno-olivines although a comprehensive picture for the magnetic properties of this group of solids is still lacking. The explanation for the "weak ferromagnetism" below $T_c$ = 66 K with a saturation magnetization of about 0.5 $\mu_B$ per $Mn^{2+}$ ion in a field of 7 T (2 K) as derived from earlier susceptibility measurements remains still speculative. It may result from local non-zero components that do not show up in the overall magnetic structure.

## Introduction

$Mn_2GeSe_4$ is one of the rare ternary selenides that crystallizes in the olivine structure type with Se atoms forming a hexagonal close packing. The $Mn^{2+}$ ions ($3d^5$) occupy half of the octahedral and the $Ge^{4+}$ one eighth of the tetrahedral holes. Crystal structure and temperature dependence of the magnetic susceptibility for $Mn_2GeSe_4$ were recently determined[1]. Above 150 K the susceptibility shows a clear paramagnetic field independent Curie–Weiss behaviour with an extrapolated Curie temperature $\Theta$ = –240(5) K indicating predominant antiferromagnetic exchange interactions between the $Mn^{2+}$ ions. Below 150 down to 66 K significant deviations from an ideal Curie–Weiss behaviour are observed until below $T_c$ = 66 K the susceptibility increases and becomes clearly field dependent. Consequently $1/\chi$ drops sharply for the low field data which we ascribe to a weak ferromagnetic component that is saturated in the high field measurement.

In this paper we present the results of elastic neutron scattering measurements on powder samples obtained at the ILL Grenoble using the instruments D2B and D20. The model for the magnetic structure of $Mn_2GeSe_4$ at different temperatures is based on Rietveld refinements and discussed on the background of earlier susceptibility and magnetisation measurements. A particular problem of a detailed comparison between the susceptibility measurement and the magnetic structure as obtained by neutron diffraction is that the latter one is measured under *zero* field conditions whereas the magnetization measurements require a *non-zero* field. So a *weak* magnetization detected by a susceptibility measurement may not necessarily be reflected by the magnetic structure.

## Results and Discussion

### General

A few investigations concerning magnetic properties (susceptibility, magnetic structure) of sulfur and selenium containing olivines which are closely related to the title compound, have been carried out in the past. They were initiated by the surprising observation of a *sharp* local $1/\chi$ minimum between 83 and 85 K for $Mn_2SiS_4$[2,3,4] accompanied by the occurrence of "weak ferromagnetism". This effect might be related to "metamagnetism" occurring in certain antiferromagnetic compounds under special conditions as a function of an external field (see, for example, ref.[5]). Indeed below 85 K $Mn_2SiS_4$ is antiferromagnetic with a change of the easy direction from [010] to [100] between 83 and 85 K. Above 85 K the compound is paramag-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

netic. In particular the *sharp* local $1/\chi$ minimum is unique among the chalcogen containing olivines investigated so far. A further example is $Mn_2SiSe_4$ which is comparable to $Mn_2SiS_4$ in its *general* susceptibility behaviour, but is characterized by a *broad* local $1/\chi$ minimum between 66 and 30 K[6,7]. The $Mn^{2+}$ ions in $Mn_2SiSe_4$ show an antiferromagnetic ordering (easy direction: [001]). A complex behaviour with respect to the temperature dependence of susceptibility and magnetization was discussed on the basis of several measurements in two independent publications for the olivine type $Fe_2GeS_4$ ($T_N$ = 144 K)[3,8]. This compound shows an antiferromagnetic ordering below 144 K (easy direction [010]) followed by a change of the easy direction to [001] at lower temperatures. The susceptibility behaviour of $Mn_2GeS_4$ is unknown but its antiferromagnetic structure was determined at 4.2 K[9] (easy direction [010]).

## The Olivine Structure

Some important aspects of the well known olivine structure[10] with respect to an understanding of the magnetic structure of $Mn_2GeSe_4$ are summarized subsequently. Olivine and spinel are frequent competitors for solids with the general chemical composition $A_2BX_4$. The olivine structure is preferred if relatively large cations (A = $Mn^{2+}$) occupy the octahedral and relatively small cations (B = $Ge^{4+}$) the tetrahedral holes. The opposite is true for spinel (further details see, for example, ref.[11,12]).

Concerning the magnetic structure it is important to mention that the $MnSe_6$ octahedra are arranged in layers perpendicular to [001] at $z \approx 0$ and $z \approx 0.5$. *Inside* the layers the octahedra share *common edges* and form zig-zag chains which are separated by $GeSe_4$ tetrahedra. Between successive layers along [001] the $AX_6$ octahedra share *corners* only (Figure 1). A section of the resulting three dimensional arrangement of the $Mn^{2+}$ ions in layers perpendicular to [001] referring to the just mentioned zig-zag arrangement of $MnSe_6$ octahedra is shown in Figure 2. It can be seen that the $Mn^{2+}$ ions form isolated triangular strands along [010]. In the (110) plane the strands are separated by $GeSe_4$ tetrahedra (not shown in Figures 1 and 2). Interatomic distances between $Mn^{2+}$ ions inside the strands are around 400 pm between adjacent strands they are greater than 479 pm in all directions.

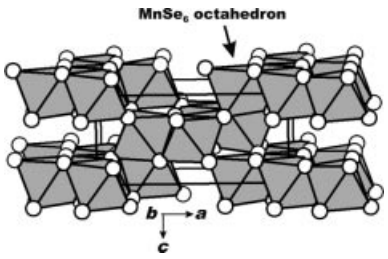

Figure 1. Section of the $Mn_2GeSe_4$ structure emphasizing the arrangement of the $MnSe_6$ octahedra. The $GeSe_4$ tetrahedra are omitted for clarity.

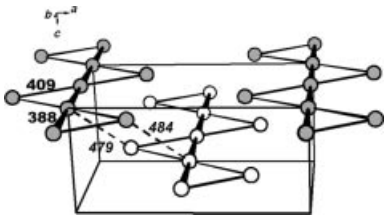

Figure 2. Perspective drawing of the arrangement of $Mn^{2+}$ ions (approximately along [010]) in $Mn_2GeSe_4$ with shortest interatomic distances *d*(Mn–Mn) inside and between the strands.

## Magnetic Structure and Magnetization

Figure 3 shows a Rietveld plot (3 K) and Figure 4 neutron scattering diagrams (D2B, low 2Theta section) for three different temperatures (3, 63 and 196 K). Upon cooling below 66 K five significant magnetic reflections with increasing intensity can be indexed as 100, 110, 300, 310 and 120. The Miller indices of these magnetic reflections can be assigned on the basis of the chemical unit cell, but apparently violate the a-glide plane in *Pnma*. They are similar to those ones found in the 1.4 K measurement for $Mn_2SiSe_4$[6,7] but are different from the ones found for $Fe_2GeS_4$[8] at 85 and 4.2 K.

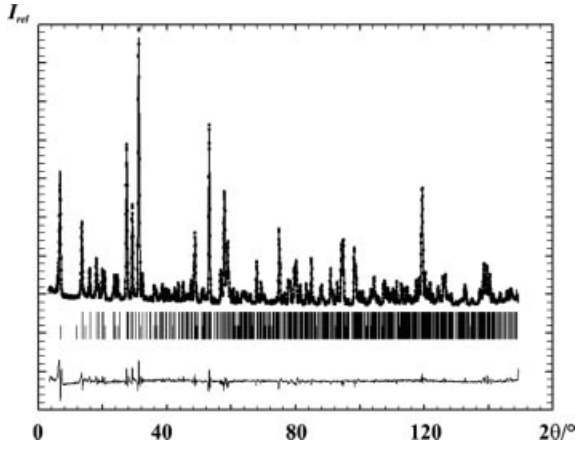

Figure 3. A Rietveld plot of a neutron scattering measurement of $Mn_2GeSe_4$ at 3 K.

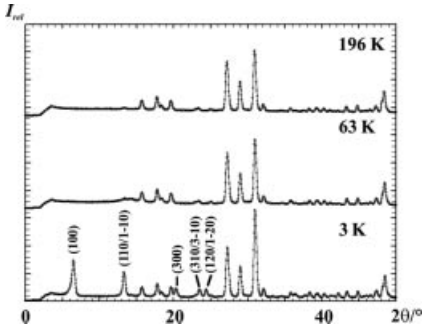

Figure 4. Neutron scattering diagrams for $Mn_2GeSe_4$ at 196, 63 and 3 K. The magnetic reflections are marked by their Miller indices.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As in the case of $Mn_2SiSe_4$, [001] reflections are basically absent (see however discussion below). This indicates an antiferromagnetic arrangement of $Mn^{2+}$ ions in the layers at $z \approx 0$ and $z \approx 0.5$ with the magnetic vector aligned along [001] ("easy direction") similar to the magnetic structure of $Mn_2SiSe_4$ (see above). In accordance with $Mn_2SiSe_4$ we assumed for our initial Rietveld refinements (3 K data obtained with the D2B instrument) a model based on an ordered magnetic phase characterized by a $C_z(4a) - C_z(4b)$ coupling. 4a and 4b are the Wyckoff positions for the two crystallographically different $Mn^{2+}$ ions and $C_z$ refers to Bertauts notation[13] for this type of coupling in space group *Pnma*. Relevant refinement data for different temperatures based on the magnetic reflections are given in Table 1. Further details are discussed in ref.[14]

Table 1. Reliability factors for the chemical ($R_B$) and the magnetic structure (magnetic $R$) of $Mn_2GeSe_4$ between 10 and 65 K as obtained by Rietveld refinements with neutron powder data at different temperatures.

[a] $R_B = [\sum_h |I_{obs,h} - I_{calc,h}|]/[\sum_h |I_{obs,h}|]$. [b] The magnetic $R$ is defined as $R_B$ but it is applied to magnetic intensities.

As a result of these initial calculations it can be stated that the magnetic structures of $Mn_2SiSe_4$ and the title compound (Figure 5, a) are similar, except a possible transverse component of one of the magnetic sublattices (see below). In most of the other chalcogeno-olivines investigated up to now such a transverse component of at least one magnetic sublattice is superimposed to the general antiferromagnetic order. Such transverse components evolve either continuously with decreasing temperature or they occur in an intermediate temperature range. A good example is the just mentioned $Mn_2SiSe_4$ where a transverse component was discussed but could not be verified significantly by the magnetic structure.[6,7] Indeed a closer inspection of details of the magnetic scattering diagrams of the title compound in combination with Rietveld refinements based on the D2B data showed a weak indication for a transverse component of *one* of the two magnetic sublattices (Figure 5, b). In particular the very weak and somewhat diffuse scattering intensity at the 2Theta position where the magnetic 001 reflection occurs (marked by an arrow in Figure 4) is a (weak) indicator for a possible deviation from the [001] direction. There is low significance but an apparent tendency from our refinement calculations that this deviation is associated to those $Mn^{2+}$ ions which belong to the Wyckoff position 4(a). A final proof based on the existing data is, however, not possible presently.

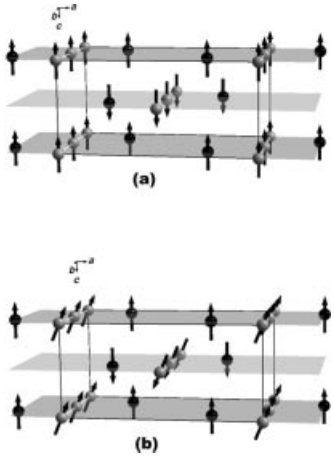

Figure 5. (a) The magnetic structure of $Mn_2GeSe_4$ as obtained by *initial* Rietveld refinements based on 3 K neutron scattering data. Mn atoms belonging to Wyckoff position 4(a): light gray balls, Wyckoff position 4(b): black balls. (b) Possible magnetic structure below 66 K including a deviation of the $Mn^{2+}$ in Wyckoff position 4(a) from the easy direction [001] towards [100] (qualitative representation of the unknown inclination angle).

It is further interesting to look at the magnetization per $Mn^{2+}$ ion for the two magnetic sublattices (Figure 6), derived from the evaluation of the D20 neutron data. One can see clearly that the successive ordering with decreasing temperature evolves with different velocities for the two sublattices, although both end up with a resultant magnetization per $Mn^{2+}$ ion of 4.25 $\mu_B$. This value corresponds to the one found for $Mn_2SiSe_4$ (4.5 $\mu_B$ see ref.[6,7]) and is in good agreement with the assumed $d^5$ configuration for $Mn^{2+}$.

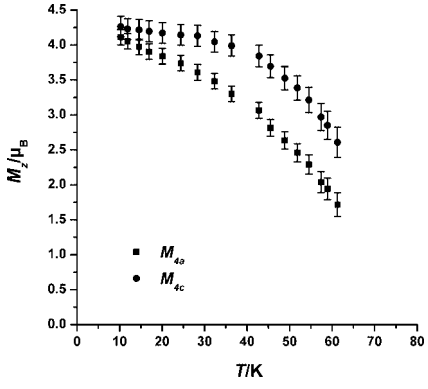

Figure 6. The resultant magnetization for the two magnetic sublattices as derived from the refinements of powder neutron diffraction diagrams between 10 and 60 K.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Neither the deviation alone nor the antiferromagnetic basis structure, however, account for the very weak resultant ferromagnetic magnetization ($< 0.05\ \mu_B$ per $Mn^{2+}$ ion) of the title compound even in low fields at low temperatures. As Figure 7 shows this weak magnetization, which may result from non-compensating local components in the overall antiferromagnetic sample, saturates even in an external field of 7 T to about 0.5 $\mu_B$ per $Mn^{2+}$ ion only.

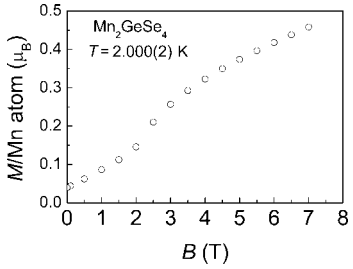

Figure 7. The resultant overall magnetization per $Mn^{2+}$ at 2 K in an external field between 0 and 7 T.

One cannot expect from neutron powder diffraction data to reflect the origin of such a weak resultant magnetization in the magnetic structure. Speculations about magnetically non compensated grain boundaries and domain size effects as possible origins can be found in the literature (e.g., ref.[6,7]). Moreover we note the slight anomaly in the *M* vs. *B* curve (Figure 7) between 2 and 4 T which is not discussed in this paper but seems to be an indication for more subtle magnetic properties of the title compound.

## Experimental Section

Powder samples of $Mn_2GeSe_4$ were obtained by the experimental procedure described in ref.[1] The neutron diffraction measurements were carried out with the D2B and D20 powder diffractometer at the ILL in Grenoble with samples contained in cylindrical vanadium containers and loaded into a standard helium flow cryostat. Data were collected at the temperatures 3 K, 63 K, 196 K (D2B) and with the instrument D20 in the temperature range 10 K $< T <$ 75 K using different $\Delta T$ steps. The wavelength was 1.594 Å. Data sets cover a range in $2\Theta$ up to 160° and have an angular resolution of 0.05°. The Rietveld method (Fullprof package[15,16]) was used to refine at first the chemical structure at room temperature. In subsequent refinement cycles based on low temperature data various refinement strategies were used. In these calculations the magnetic moment vectors of all eight $Mn^{2+}$ ions in the Wyckoff positions 4(a) and 4(c) were refined either independently or partly fixed by constraints. The room-temperature data served as basis for the positional parameters of the chemical structure. In addition to the magnetic moment vectors only thermal parameters and lattice constants were refined with low-temperature data.

# Synthesis, Characterization, and Catalytic Activity of Some Neodymium(III), Ytterbium(II), and Europium(II) Complexes with Pyrrolidinyl- and Piperidinyl-Functionalized Indenyl Ligands

**Shuangliu Zhou,[a] Shaowu Wang,*[a,b] Enhong Sheng,[a] Lijun Zhang,[a] Zeyan Yu,[a] Xiaobing Xi,[a] Guodong Chen,[a] Wei Luo,[a] and Yan Li[a]**

**Keywords:** Homolysis / Catalysts / Polymerization / Lanthanoids

A series of organolanthanide complexes with pyrrolidinyl- and piperidinyl- functionalized indenyl ligands were synthesized by reaction of $[(Me_3Si)_2N]_3Ln^{III}(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu, Nd) with the corresponding indene compounds. Treatment of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(THF)_3$ with 2 equiv. of $C_9H_6$-1-R-3-$CH_2SiMe_2NC_4H_8$ (R = H, $CH_3$) in refluxing toluene produced the corresponding organoytterbium(II) complexes with formula $[\eta^m{:}\eta^1\text{-}C_9H_5\text{-}1\text{-}R\text{-}3\text{-}CH_2SiMe_2NC_4H_8]_2Yb^{II}$ [$m$ = 5, R = H (**2**); $m$ = 3, R = $CH_3$ (**3**)] in 49 and 58 % yield, respectively. Treatment of $[(Me_3Si)_2N]_3Ln^{III}(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu, Nd) with 2 equiv. of $C_9H_7CH_2SiMe_2NC_5H_{10}$ (**1**) in toluene at moderately high temperatures afforded, after workup, the corresponding organolanthanide complexes with formula $[\eta^5{:}\eta^1\text{-}C_9H_6CH_2SiMe_2NC_5H_{10}]_2Yb^{II}$ (**4**), $[\eta^5{:}\eta^1\text{-}C_9H_6CH_2SiMe_2NC_5H_{10}]_2Eu^{II}$ (**5**), and $[C_9H_6CH_2SiMe_2NC_5H_{10}]_3Nd^{III}\cdot THF$ (**6**) in 37, 71, and 29 % yield, respectively. All the compounds were fully characterized by spectroscopic methods and elemental analyses. The structures of complexes **2**, **3**, **5**, and **6** were additionally determined by single-crystal X-ray analyses. The catalytic properties of all the organolanthanide complexes on the ring-opening polymerization of ε-caprolactone have been studied. The effects of temperature, solvent, and coordination on the catalytic activities of the complexes were examined.

## Introduction

Over the past few decades, great progress has been made in the chemistry of divalent organolanthanide complexes. Divalent organolanthanide complexes exhibited a particularly rich reaction chemistry based on their strong reductive properties.[1] A variety of complexes have been synthesized and used in organic synthesis and polymer chemistry.[2] Generally, divalent organolanthanide complexes were synthesized by metathesis reaction of alkaline metal salts of a ligand with $LnI_2$ or by reductive reaction of lanthanide(III) halides with metallic atoms.[3]

Lanthanide complexes have received much interest for their potential application as homogeneous catalysts or catalyst precursors for various useful transformations such as olefin polymerization,[4] hydroamination of olefins and alkynes,[5] hydrophosphination of olefins and alkynes,[6] Tishchenko reactions,[7] ring-opening polymerization of ε-caprolactone and δ-valerolactone,[8] and insertion reactions.[9] Recently, our group has reported that the tetracoordinate lanthanide amides $[(Me_3Si)_2N]_3Ln^{III}(\mu\text{-}Cl)Li(THF)_3$ can work as efficient catalysts for the aldol-condensation reaction,[10] or initiators for the Cannizzaro-type disproportionation of aromatic aldehydes to amides and alcohols.[11]

At the same time, we have also demonstrated that the interactions of indene compounds having nitrogen-containing substituents or oxygen-containing substituents with the lanthanide(III) amides $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu) produced organolanthanide(II) complexes.[12] The formation pathway of the organolanthanide(II) complexes is proposed to proceed through a tandem silylamine elimination[13]/homolysis of the Ln–N bonds, thus it provides a new methodology for the preparation of the lanthanide(II) complexes. Especially, the reaction of heterocyclic-functionalized indene compound $C_9H_7CH_2SiMe_2NC_4H_8$ with the europium(III) amide $[(Me_3Si)_2N]_3Eu(\mu\text{-}Cl)Li(THF)_3$ has led to the isolation and characterization of the unexpected novel triple-decker tetranuclear europium(II) complex with the linked indenyl ligands,[12e] and a novel ytterbium(II) complex having the indenyl ligand bonded to the metal through a benzo ring with an $\eta^4$ hapticity has been isolated and characterized by treatment of the *N*-piperidinylethyl functionalized indene compound with the ytterbium(III) amide $[(Me_3Si)_2N]_3Yb(\mu\text{-}Cl)Li(THF)_3$,[12d] indicating the ligands' effects on the reactivity patterns and coordination modes. In order to further study the reduction potentials of the lanthanides and the ligands' effect on reactivity patterns and the bonding modes between the ligands

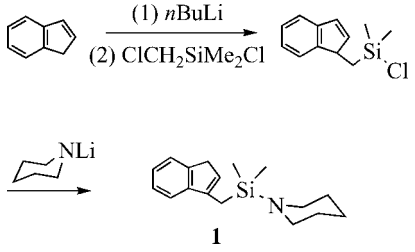
and the lanthanide metals, we have studied the reactions of $C_9H_6$-1-R-3-$CH_2SiMe_2NC_4H_8$ (R = H, Me), and $C_9H_7CH_2SiMe_2NC_5H_{10}$ with the lanthanide(III) amides $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu, Nd).

In this paper, we will report the interactions of $C_9H_6$-1-R-3-$CH_2SiMe_2NC_4H_8$ (R = H, Me), and $C_9H_7CH_2SiMe_2NC_5H_{10}$ with the lanthanide(III) amides $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu, Nd) leading to preparation and characterization of a series of new organolanthanide(II) complexes and an organoneodymium(III) complex. The catalytic activities of these complexes as single-component ε-caprolactone polymerization catalysts were also examined.

## Results and Discussion

### Synthesis and Characterization of $C_9H_7CH_2SiMe_2NC_5H_{10}$ (1)

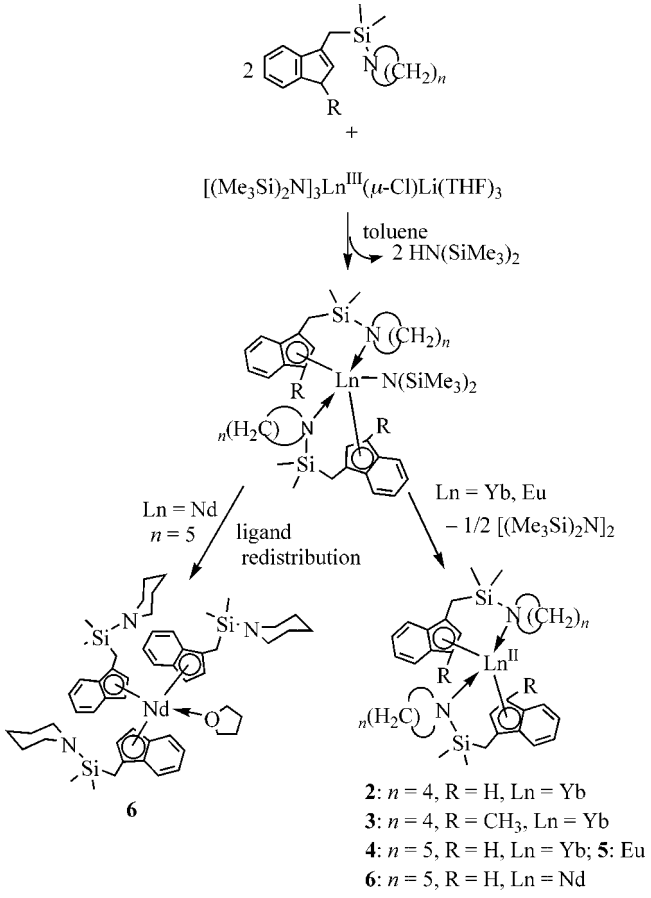
Interaction of $C_9H_7Li$ with 1 equiv. of $ClSiMe_2CH_2Cl$, followed by treatment with 1 equiv. of lithium piperidinide $C_5H_{10}NLi$, gave piperidinyl-functionalized indene compound $C_9H_7CH_2SiMe_2NC_5H_{10}$ (**1**) in good yield (Scheme 1). The compound was fully characterized by spectroscopic methods and elemental analysis. The nucleophilic substitution reaction of $C_9H_7Li$ with $ClSiMe_2CH_2Cl$ occurs at the C–Cl bond, not at the Si–Cl bond on the basis of the NMR analyses of the reaction products. Similar results were observed in the reaction of $C_5Me_4HLi$ or $Ph_2PLi$ with $ClSiMe_2CH_2Cl$, giving the corresponding product $C_5HMe_4CH_2SiMe_2Cl$[14] or $Ph_2PCH_2SiMe_2Cl$,[15] indicating the electronic and steric effects on the reactivity of the C–Cl and Si–Cl bonds.



Scheme 1.

### Synthesis and Characterization of Organolanthanide Complexes with Pyrrolidinyl- and Piperidinyl-Functionalized Indenyl Ligands

Treatment of the lanthanide(III) amides $[(Me_3Si)_2N]_3Ln^{III}(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu) with 2 equiv. of $C_9H_6$-1-R-3-$CH_2SiMe_2NC_4H_8$ (R = H, $CH_3$) and $C_9H_7CH_2SiMe_2NC_5H_{10}$ in toluene produced the lanthanide(II) complexes with formula $[\eta^m\text{:}\eta^1\text{-}C_9H_5\text{-}1\text{-}R\text{-}3\text{-}CH_2SiMe_2NC_4H_8]_2Yb^{II}$ [*m* = 5, R = H (**2**); *m* = 3, R = $CH_3$(**3**)] and $[\eta^5\text{:}\eta^1\text{-}C_9H_6CH_2SiMe_2NC_5H_{10}]_2Ln^{II}$ [Ln = Yb(**4**); Ln = Eu(**5**)] (Scheme 2). The complexes **2**, **3**, **4**, and **5** are sensitive to air and moisture, they are soluble in polar solvents such as THF, DME, and pyridine, and slightly soluble in toluene, but insoluble in *n*-hexane. All the complexes were fully characterized by spectroscopic methods and elemental analyses. The structures of the complexes **2**, **3**, and **5** were determined by single-crystal X-ray analyses. X-ray analyses showed that the complexes **2**, **3**, and **5** were a monomeric structure, not a triple-decker sandwich tetranuclear structure analogous to the complex[12e] from the reaction of $[(Me_3Si)_2N]_3Eu^{III}(\mu\text{-}Cl)Li(THF)_3$ with $C_9H_7CH_2SiMe_2NC_4H_8$, probably due to different reduction potentials of lanthanide ions, and the ligands' steric and electronic effects.



Scheme 2.

Estimated $Ln^{3+}/Ln^{2+}$ reduction potentials are as follows:[16] $E°(Eu^{3+}/Eu^{2+})$ = –0.35 V, $E°(Yb^{3+}/Yb^{2+})$ = –1.15 V, $E°(Nd^{3+}/Nd^{2+})$ = –2.62 V. This suggested that europium(III) and ytterbium(III) could be more easily reduced to europium(II) and ytterbium(II) than other lanthanide(III) metal ions. To probe reduction potential effects on the reactivity, the reaction of $[(Me_3Si)_2N]_3Nd^{III}(\mu\text{-}Cl)Li(THF)_3$ with $C_9H_7CH_2SiMe_2NC_5H_{10}$ (**1**) was studied.

The reaction of $[(Me_3Si)_2N]_3Nd^{III}(\mu\text{-}Cl)Li(THF)_3$ with 2 equiv. of $C_9H_7CH_2SiMe_2NC_5H_{10}$ (**1**) in refluxing toluene produced, after recrystallization from *n*-hexane, a neodymium(III) complex $[C_9H_6CH_2SiMe_2NC_5H_{10}]_3Nd^{III}\cdot THF$ (**6**) (Scheme 2). The complex is sensitive to air and moisture. It is soluble in THF, DME, toluene, and pyridine, and slightly

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

soluble in *n*-hexane. The complex was fully characterized by spectroscopic methods and elemental analysis. Its structure was determined by single-crystal X-ray analysis. X-ray analysis showed that complex **6** is a trivalent neodymium(III) complex composed of three indenyl ligands π-bonded with the central metal and one coordinated tetrahydrofuran. Homolysis of the Nd–N bond was not observed probably due to the reduction potential of the $Nd^{3+}/Nd^{2+}$ and steric effects.

We have proved that the interactions of indene compounds without donor-substituted groups on the indene ring with lanthanide(III) amides $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu) produced lanthanide(III) amides $(Ind')_2LnN(SiMe_3)_2$ (Ind′ = indenyl- or ethylene-bridged indenyl ligands), while the interactions of the heteroatom side-arm functionalized indene compounds with $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu) produced lanthanide(II) complexes; the formation pathway of the lanthanide(II) complexes has been proposed via a tandem silylamine elimination/homolysis of the Ln–N bond (Ln = Yb, Eu) based on the experimental results.[12] Thus, the formation of the above europium(II) and ytterbium(II) complexes is proposed to go through a tandem silylamine elimination/homolysis of the Ln–N (Ln = Yb, Eu) bonds, but the formation of neodymium(III) complex **6** may go through a silylamine elimination, followed by a ligand redistribution reaction (Scheme 2).

### Molecular Structures of Complexes 2, 3, 5, and 6

X-ray analyses revealed that the central metal ions of the complexes **2** (Figure 1), **3** (Figure 2), and **5** (Figure 3) exist in a +2 oxidation state. The results further confirmed that the formation of these organolanthanide(II) complexes involves a one-electron reductive elimination process. The selected bond lengths and angles are listed in Table 1. It can be seen that the lanthanide contraction is clearly reflected by the average Ln–C and Ln–N distances.

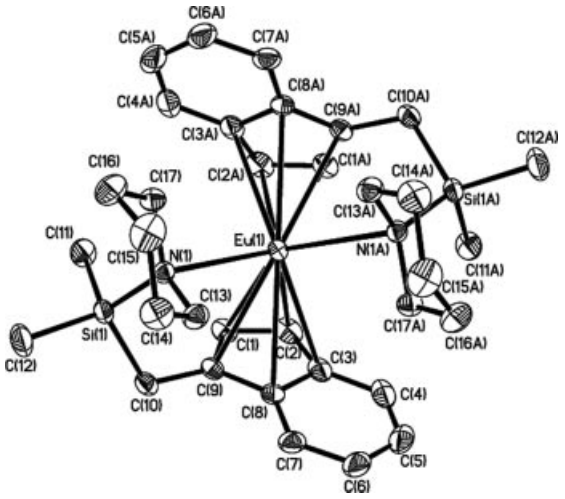

Figure 3. Molecular structure of $[\eta^5{:}\eta^1\text{-}C_9H_6CH_2SiMe_2NC_5H_{10}]_2\text{-}Eu^{II}$ (**5**). Hydrogen atoms are omitted for clarity.

From Table 1, we can see that the Yb–C bond lengths in complex **2** range from 2.649(9) to 2.930(8) Å, with an average of 2.786(9) Å, which is comparable to the average Yb–C distances of 2.806(12) and 2.778(14) Å found in the corresponding indenyl ytterbium(II) complexes $[\eta^5{:}\eta^1\text{-}Me_2Si(Me_2NCH_2CH_2C_9H_5)(NHtBu)]_2Yb^{II}$,[12a] $[\eta^5{:}\eta^1\text{-}(Me_2NCH_2CH_2C_9H_5SiMe_3)]_2Yb^{II}$.[12a] This average Yb–C distance of 2.786(9) Å found in **2** is longer than the corresponding values of 2.722(10) Å found in $[\eta^5{:}\eta^1\text{-}(Me_2NCH_2CH_2C_9H_6)]_2Yb^{II}$,[12a] 2.723(14) Å found in $[\eta^5{:}\eta^1\text{-}(2\text{-}C_5H_4NCH_2)C_9H_6]_2Yb^{II}$,[12f] 2.737(4) Å found in $[\eta^5{:}\eta^1\text{-}(MeOCH_2CH_2C_5H_4)]_2Yb^{II}(THF)$,[17] and 2.75 Å found in $[Me_3Si(C_5H_4)]_2Yb(THF)_2$.[18] The above differences in the average Yb–C distances of different ytterbium(II) complexes may be due to steric effects and ionic radii differences.

The Yb to C(11) and C(12), which are shared by both C5 and C6 rings, distances of 2.944(4) and 2.929(4) Å in complex **3** are significantly longer than those of others [ranging from 2.714(4) to 2.811(4) Å], suggesting that the Yb atom tends to bond with indenyl ligands in an $\eta^3$-mode. The average Yb–C distance of 2.838(4) Å found in **3** is obviously longer than the corresponding value of 2.786(9) Å found in **2**. This distance is also longer than those of 2.818(3) Å in $[\eta^5\text{-}Me_2Si(C_9H_6)(C_2B_{10}H_{11})]Yb(THF)[(\mu\text{-}\eta^5){:}\sigma\text{-}Me_2Si(C_9H_6)(C_2B_{10}H_{10})]Na(THF)_3$,[19] 2.814(7) Å in $[\eta^5{:}\eta^1{:}\sigma\text{-}Me_2Si(C_9H_5CH_2CH_2OMe)(C_2B_{10}H_{10})]Yb(DME)\text{-}(THF)$,[20] 2.806(12) Å in $[\eta^5{:}\eta^1\text{-}Me_2Si(Me_2NCH_2CH_2\text{-}C_9H_5)(NHtBu)]_2Yb^{II}$,[12a] 2.778(14) Å found in $[\eta^5{:}\eta^1\text{-}(Me_2NCH_2CH_2C_9H_5SiMe_3)]_2Yb^{II}$,[12a] and 2.732(18) Å in $[\eta^5{:}\eta^1\text{-}(C_4H_7OCH_2C_9H_5SiMe_3)]_2Ln^{II}$,[12g] indicating steric and electronic effects.

The average Yb–N bond length of 2.645(8) Å in **2** is compared with the average Yb–N distances of 2.634(4) Å in **3**, 2.673(11) Å in $[\eta^5{:}\eta^1\text{-}Me_2Si(Me_2NCH_2CH_2C_9H_5)(NHtBu)]_2\text{-}Yb^{II}$,[12a] and 2.650(12) Å in $[\eta^5{:}\eta^1\text{-}(Me_2NCH_2CH_2C_9H_5Si\text{-}Me_3)]_2Yb^{II}$,[12a] but longer than those of 2.561(7) Å in $[\eta^5{:}\eta^1\text{-}(2\text{-}C_5H_4NCH_2)C_9H_6]_2Yb^{II}$,[12f] and 2.588(7) Å in $[\eta^5{:}\eta^1\text{-}(Me_2NCH_2CH_2C_9H_6)]_2Yb^{II}$,[12a] respectively. The above difference in the average Yb–N distances in different ytterbium(II) complexes may be due to steric effects and

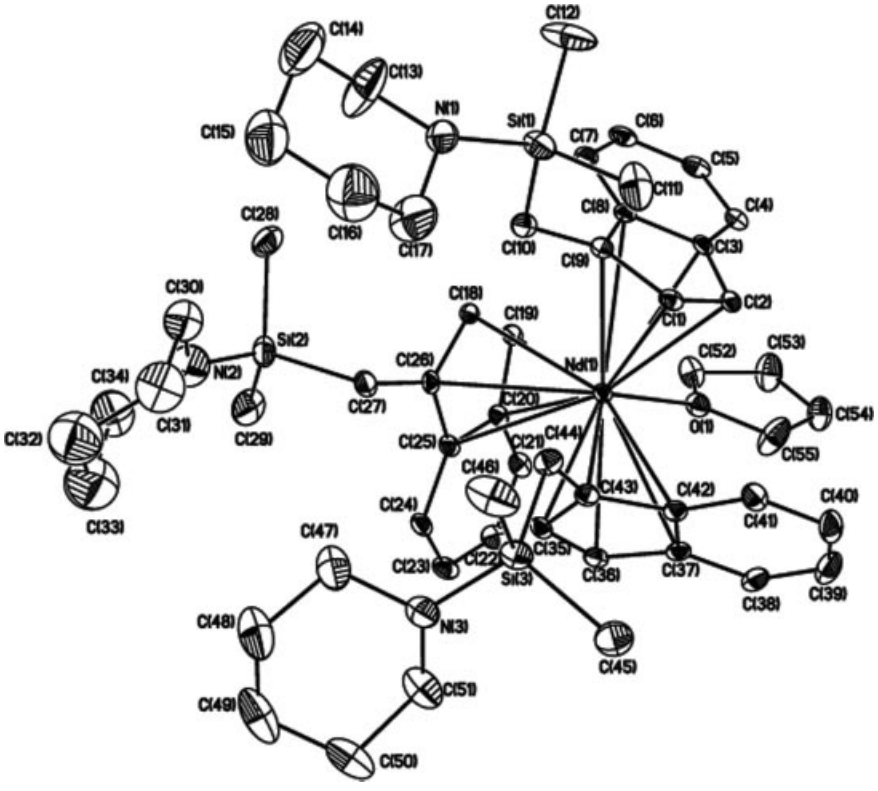

Figure 4. Molecular structure of $[C_9H_6CH_2SiMe_2NC_5H_{10}]_3Nd^{III}\cdot THF$ (**6**). Hydrogen atoms are omitted for clarity.

the hybridization state of nitrogen atoms. The N–Yb–N angle of 106.6(2)° in **2** is comparable to the corresponding angle of 106.50(16)° in **3**, but larger than the corresponding angles of 95.1(4), 92.8(5), and 103.7(2)° found in $[\eta^5{:}\eta^1$-$Me_2Si(Me_2NCH_2CH_2C_9H_5)(NHtBu)]_2Yb^{II}$,[12a] $[\eta^5{:}\eta^1$-$(Me_2NCH_2CH_2C_9H_5SiMe_3)]_2Yb^{II}$,[12a] and $[\eta^5{:}\eta^1$-$(Me_2NCH_2CH_2C_9H_6)]_2Yb^{II}$,[12a] respectively, suggesting steric and electronic effects.

The average Eu–C bond length of 2.885(3) Å in complex **5** is comparable to the average Eu–C bond lengths of 2.883(11), 2.873(10), and 2.841(7) Å found in the corresponding indenyl europium(II) complexes $[\eta^5{:}\eta^1$-$Me_2Si(Me_2NCH_2CH_2C_9H_5)(NHtBu)]_2Eu^{II}$,[12c] $[\eta^5{:}\eta^1$-$(Me_2NCH_2CH_2C_9H_5SiMe_3)]_2Eu^{II}$,[12c] and $[\eta^5{:}\eta^1$-$(Me_2NCH_2CH_2C_9H_6)]_2Eu^{II}$,[12c] but shorter than that of 2.911(18) Å in $[\eta^5{:}\eta^1$-$C_9H_5$-1-Me-3-$CH_2SiMe_2NC_4H_8]_2Eu^{II}$.[12e] The above differences in the average Eu–C bond lengths of different europium(II) complexes may be due to steric effects.

The average Eu–N bond length of 2.794(2) Å in **5** is longer than those of 2.753(16), 2.748(9), 2.744(8), and 2.711(6) Å found in $[\eta^5{:}\eta^1$-$C_9H_5$-1-Me-3-$CH_2SiMe_2NC_4H_8]_2Eu^{II}$,[12e] $[\eta^5{:}\eta^1$-$Me_2Si(Me_2NCH_2CH_2C_9H_5)(NHtBu)]_2Eu^{II}$,[12c] $[\eta^5{:}\eta^1$-$(Me_2NCH_2CH_2C_9H_5SiMe_3)]_2Eu^{II}$,[12c] and $[\eta^5{:}\eta^1$-$(Me_2NCH_2CH_2C_9H_6)]_2Eu^{II}$,[12c] respectively, suggesting steric effects. The N–Eu–N angle of 109.99(8)° in **2** is close to the corresponding angle of 110.19(15)° in $[\eta^5{:}\eta^1$-$C_9H_5$-1-Me-3-$CH_2SiMe_2NC_4H_8]_2Eu^{II}$,[12e] but larger than those of 96.1(3), 92.9(3), and 104.7(2)° found in $[\eta^5{:}\eta^1$-$Me_2Si(Me_2NCH_2CH_2C_9H_5)(NHtBu)]_2Eu^{II}$,[12c] $[\eta^5{:}\eta^1$-$(Me_2NCH_2CH_2C_9H_5SiMe_3)]_2Eu^{II}$,[12c] and $[\eta^5{:}\eta^1$-$(Me_2NCH_2CH_2C_9H_6)]_2Eu^{II}$,[12c] respectively, indicating steric and electronic effects.

X-ray analysis reveals that the central metal ion of complex **6** (Figure 4) exists in a +3 oxidation state, and the central metal in complex **6** is coordinated by three indenyl ligands tending to $\eta^3$ bonding modes based on the determined Nd–C distances, and by an oxygen atom of the tetrahydrofuran in $\eta^1$-mode.

The average value of the Nd–C distances of 2.845(5) Å found in **6** is longer than the average Nd–C distances of 2.83(3) Å found in $(C_9H_7)_3Nd{\cdot}THF$,[21] 2.836(9) Å found in $[Na(C_4H_8O)_6][Nd(\eta^5$-$C_9H_7)_3(\mu$-C1)$Nd(\eta^5$-$C_9H_7)_3]$,[22] but shorter than the average Nd–C distance of 2.91(5) Å found in $(C_5Me_5)_3Nd$,[23] indicating steric effects on the coordination and bonding.

### Ring-Opening Polymerization of ε-Caprolactone

The complexes as single-component catalysts in ε-caprolactone polymerization were examined. It was found that all of the complexes exhibited good catalytic activities for ring-opening polymerization of ε-caprolactone in toluene, THF, and DME (Table 2). From Table 2, we can see that the complexes with piperidinyl-functionalized indenyl ligands exhibited higher catalytic activities in temperature ranges of 60 to –30 °C than those of the complexes with pyrrolidinyl-functionalized indenyl ligands, indicating the ligands' effects on catalytic activities of the complexes. From Table 2, we can also see that the catalyst **3** showed a higher catalytic activity than that of the catalyst **2** especially at relatively high temperatures, probably due to different bonding modes between the ligands and the central metals.

Examination of the solvents effects on the catalytic activities of the catalysts **2**–**6** indicated that the catalytic activities of the catalysts have good activity in toluene, THF, or DME. Simultaneously, we found that the molecular weights of the polymers obtained in toluene were higher than those obtained in THF and DME, indicating the solvents' effects on the chain propagation process. It was also found that the molecular weight distributions of the polymers obtained in toluene were slightly broader than those obtained in THF and DME.

The results of the temperature effects on the catalytic activities of the complexes **2**–**6** are listed in Table 2. In the table, we can see that the complexes **4**–**6** showed high catalytic activities in temperature ranges of 60 to –30 °C, but the complexes **2**, and **3** showed the highest catalytic activities at 0 °C. It was also found that the molecular weights of the polymers generally increase as the polymerization temperatures decrease, indicating that a chain propagation process is favored at relatively low temperatures.

The proposed mechanism of the ε-CL polymerization catalyzed by the lanthanide(II) complexes is that the lanthanide(II) complexes are oxidized by the lactone at the first stage, which forms an alkoxyl lanthanide(III) species.[24] Then, the chain propagation process was performed through a coordination-insertion process (Scheme 3).[25] However, the possible mechanism of the polymerization catalyzed by the neodymium(III) complex is through a coordination–insertion process.[25]

## Conclusions

In summary, a series of organolanthanide(II) complexes and an organolanthanide(III) complex with pyrrolidinyl- and piperidinyl-functionalized indenyl ligands were synthesized by the reactions of $C_9H_6$-1-R-3-$CH_2SiMe_2NC_4H_8$ (R = H, Me) or $C_9H_7CH_2SiMe_2NC_5H_{10}$ with the lanthanide(III) amides $[(Me_3Si)_2N]_3Ln(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb, Eu, Nd). This work demonstrated that the reduction potentials of $Ln^{3+}/Ln^{2+}$ and the ligands have an influence on the reactivity patterns. The formation pathway of the lanthanide(II) complexes and the neodymium(III) complex was proposed on the basis of our previous experimental results. Structural analyses of the complexes indicated that substituents on the ligands have an influence on the bonding modes between the ligands and the central metals. The results of the catalytic activities of the newly prepared complexes indicated that the temperatures, solvents, ligands, and the bonding modes between the ligands and the central metals have an influence on the catalytic activities of the catalysts, the molecular weights, and the molecular weight distributions of the polymers.

## Experimental Section

**General Remarks:** All syntheses and manipulations of air- and moisture-sensitive materials were performed under dry argon and an oxygen-free atmosphere using standard Schlenk techniques or in a glovebox. All solvents were refluxed and distilled from either finely divided $LiAlH_4$ or sodium benzophenone ketyl under argon prior to use unless otherwise noted. $CDCl_3$ was dried with activated 4-Å molecular sieves. ε-Caprolactone (ε-CL) was dried with finely divided $CaH_2$ and distilled before use. $ClCH_2SiMe_2Cl$ was bought from Aldrich Chemicals and distilled before use. $C_9H_6$-1-R-3-$CH_2SiMe_2NC_4H_8$ (R = H, $CH_3$)[12e] and $[(Me_3Si)_2N]_3Ln^{III}(\mu\text{-}Cl)Li(THF)_3$ (Ln = Yb,[12a] Eu,[26] Nd[26]) were prepared according to literature methods. Elemental analyses data were obtained with a Perkin–Elmer 2400 Series II elemental analyzer. IR spectra were recorded with a Perkin–Elmer 983(G) spectrometer (CsI crystal plate, Nujol mulls). $^1H$ NMR and $^{13}C$ NMR spectra for analyses of compounds were recorded with a Bruker AV-300 NMR spectrometer in $C_5D_5N$ ([$D_5$]pyridine) for lanthanide complexes and in $CDCl_3$ for organic compounds. Gel permeation chromatography (GPC) analyses of polymer samples were carried out at 30 °C using THF as an eluent with a Waters-2414 instrument and calibrated using monodispersed polystyrene standards at a flow rate of 1.0 mL min$^{-1}$.

**Preparation of $C_9H_7CH_2SiMe_2NC_5H_{10}$ (1):** To a solution of indene (10.0 mL, 85.2 mmol) in THF (80.0 mL) was slowly added a 1.57-M *n*BuLi solution (54.0 mL, 85.2 mmol) at 0 °C. The reaction mixture was stirred for 12 h at room temperature, and was then cooled to 0 °C. To the reaction mixture was added fresh $ClSiMe_2CH_2Cl$ (11.3 mL, 85.2 mmol) in one portion. The reaction mixture was stirred for 12 h at room temperature. The solvents were pumped off under reduced pressure. The residue was extract with diethyl ether (2 × 20.0 mL), the extractions were combined, and solvent was pumped off under vacuum. Distillation of the resulting liquid gives the product $C_9H_7CH_2SiMe_2Cl$ as a colorless oil (14.9 g, 79% yield). B.p. 88–90 °C/0.02 Torr. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.52 (m, 2 H), 7.27 (m, 2 H), 7.01 (d, $J$ = 4.52 Hz, 1 H), 6.68 (dd, $J$ = 4.52, 6.99 Hz, 1 H), 3.78 (d, $J$ = 6.99 Hz, 1 H), 2.80 (s, 2 H), 0.06 (s, 6 H) ppm. $^{13}C$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 144.2, 144.1, 134.4, 129.8, 125.2, 123.9, 122.6, 121.2, 43.7, 24.9, –5.8 ppm. $C_{12}H_{15}ClSi$ (222.79): calcd. C 64.69, H 6.79; found C 64.51, H 7.02. To a freshly prepared THF (50 mL) solution of lithium piperidinide $C_5H_{10}NLi$ (3.37 g, 36.6 mmol) was added slowly the above prepared indene compound $C_9H_7CH_2SiMe_2Cl$ (8.14 g, 36.6 mmol) at 0 °C. The reaction mixture was then stirred for 12 h at 50 °C. The solvent was pumped off under reduced pressure. The residue was extracted with diethyl ether (2 × 20.0 mL), the extractions were combined, and the solvents were pumped off under vacuum. Distillation of the residue gave **1** as a colorless oil (8.03 g, 81% yield). B.p. 118–121 °C/0.02 Torr. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.49–7.20 (m, 4 H), 6.09 (s, 1 H), 3.39 (d, $J$ = 7.53, 2 H), 2.87 (m, 4 H), 2.09 (s, 2 H), 1.58 (m, 4 H), 1.42 (m, 4 H), 0.09 (s, 6 H) ppm. $^{13}C$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 146.4, 144.4, 141.6, 126.1, 125.8, 124.3, 123.5, 119.4, 47.3, 46.6, 37.8, 27.9, 27.0, 25.6, 17.4, –2.1 ppm. IR (Nujol mulls): $\tilde{\nu}$ = 2953 (s), 2923 (s), 2853 (s), 1601 (w), 1573 (w), 1460 (m), 1376 (m), 1252 (m), 1170 (w), 1060 (m), 962 (m), 838 (m), 765 (s), 718 (m), 413 (w) cm$^{-1}$. $C_{17}H_{25}NSi$ (271.47): calcd. C 75.21, H 9.28, N 5.16; found C 75.06, H 9.24, N 4.80.

**Preparation of $[\eta^5{:}\eta^1\text{-}(C_9H_6CH_2SiMe_2NC_4H_8)]_2Yb^{II}$ (2):** To a toluene (10.0 mL) solution of $C_9H_7CH_2SiMe_2NC_4H_8$ (0.617 g, 2.40 mmol) was added a toluene (50.0 mL) solution of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(THF)_3$ (1.096 g, 1.20 mmol) at room temperature. After the reaction mixture was stirred at room temperature for 6 h, the mixture was then refluxed for 12 h, the solution gradually changed from yellow to green to red. The solvent was evaporated under reduced pressure. The residue was washed with *n*-hexane (10.0 mL). The resulting solid was extracted with toluene (2 × 15.0 mL). The extractions were combined and concentrated to about 15.0 mL. The red crystals were obtained by cooling the concentrated solution at 0 °C for several days (0.403 g, 49% yield). M.p. 169–170 °C. $^1H$ NMR (300 MHz, $C_5D_5N$, 25 °C): $\delta$ = 7.55 (m, 4 H), 7.18 (m, 4 H), 6.96 (m, 2 H), 6.03 (m, 2 H) ($C_9H_6$), 2.11 (s, 4 H) ($CH_2$), 2.85 (m, 8 H), 1.52 (m, 8 H) ($C_4H_8N$), 0.10 (s, 12 H) [$Si(CH_3)_2$] ppm. IR (Nujol mulls): $\tilde{\nu}$ = 2925 (s), 2855 (s), 2333 (w), 1714 (m), 1604 (m), 1546 (m), 1461 (m), 1377 (s), 1249 (m), 1194 (w), 1006 (m), 829 (m), 755 (m), 721 (m), 467 (w) cm$^{-1}$. $C_{32}H_{44}N_2Si_2Yb$ (685.02): calcd. C 56.03, H 6.47, N 4.08; found C 55.79, H 6.45, N 3.92.

**Preparation of $[\eta^3{:}\eta^1\text{-}C_9H_5\text{-}1\text{-}CH_3\text{-}3\text{-}CH_2SiMe_2NC_4H_8]_2Yb^{II}$(3):** This compound was prepared as red crystals in 58% yield from the reaction of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-}Cl)Li(THF)_3$ (1.096 g, 1.20 mmol) with $C_9H_6$-1-$CH_3$-3-$CH_2SiMe_2NC_4H_8$ (0.650 g, 2.40 mmol) by using procedures similar to those used for the preparation of **2**. M.p. 178–181 °C. $^1H$ NMR (300 MHz, $C_5D_5N$, 25 °C): $\delta$ = 7.36 (m, 8 H), 5.93 (s, 2 H) ($C_9H_6$), 2.82 (m, 8 H) ($C_4H_8N$), 2.03 (s, 4 H) ($CH_2$), 1.49 (m, 8 H) ($C_4H_8N$), 1.18 (m, 6 H) ($CH_3$), 0.06 (s, 12 H) [$Si(CH_3)_2$] ppm. IR (Nujol mulls): $\tilde{\nu}$ = 2961 (s), 2869 (m), 1603 (m), 1559 (m), 1540 (s), 1457 (m), 1354 (w), 1256 (m), 1153 (w),

1019 (m), 877 (m), 751 (m), 668 (m), 419 (w) $cm^{-1}$. $C_{34}H_{48}N_2Si_2Yb$ (713.97): calcd. C 57.20, H 6.78, N 3.92; found C 57.42, H 6.67, N 4.44.

**Preparation of $[\eta^5:\eta^1\text{-}C_9H_6CH_2SiMe_2NC_5H_{10}]_2Yb^{II}$ (4):** This compound was prepared as a red powder in 37% yield from the reaction of $[(Me_3Si)_2N]_3Yb^{III}(\mu\text{-Cl})Li(THF)_3$ (1.278 g, 1.40 mmol) with $C_9H_7CH_2SiMe_2NC_5H_{10}$ (**1**) (0.759 g, 2.80 mmol) in refluxing toluene by using procedures similar to those used for the preparation of **2**. M.p. 153–155 °C. $^1H$ NMR (300 MHz, $C_5D_5N$, 25 °C): $\delta$ = 7.38 (m, 8 H), 6.08 (d, 4 H) ($C_9H_6$), 2.69 (m, 8 H) ($C_5H_{10}N$), 2.03 (s, 4 H) ($CH_2$), 1.38 (m, 8 H) ($C_5H_{10}N$), 1.24 (m, 4 H) ($C_5H_{10}N$), 0.03 (m, 12 H) [$Si(CH_3)_2$] ppm. $C_{34}H_{48}N_2Si_2Yb$ (713.97): calcd. C 57.20, H 6.78, N; 3.92; found C 57.13, H 6.54, N 4.55.

**Preparation of $[\eta^5:\eta^1\text{-}C_9H_6CH_2SiMe_2NC_5H_{10}]_2Eu^{II}$ (5):** This compound was prepared as yellow crystals in 71% yield from the reaction of $[(Me_3Si)_2N]_3Eu^{III}(\mu\text{-Cl})Li(THF)_3$ (1.247 g, 1.40 mmol) with $C_9H_7CH_2SiMe_2NC_5H_{10}$ (**1**) (0.759 g, 2.80 mmol) in toluene at 60 °C by using procedures similar to those used for the preparation of **2**. NMR ($C_5D_5N$) spectra of the compound were not informative due to lack of locking signals for the paramagnetic property of the europium(II) complex. M.p. 132–133 °C. IR (Nujol mulls): $\tilde{\nu}$ = 3064 (w), 2931 (s), 2852 (m), 1540 (m), 1507 (m), 1490 (m), 1459 (m), 1448 (m), 1249 (s), 1059 (m), 962 (m), 833 (s), 766 (s), 719 (m), 668 (m) $cm^{-1}$. $C_{34}H_{48}EuN_2Si_2$ (692.89): calcd. 58.94, H 6.98, N 4.04; found C 58.77, H 7.32, N 3.83.

**Preparation of $[C_9H_6CH_2SiMe_2NC_5H_{10}]_3Nd^{III}\cdot THF$ (6):** To a toluene (10.0 mL) solution of $C_9H_7CH_2SiMe_2NC_5H_{10}$ (**1**) (0.759 g, 2.80 mmol) was added a toluene (50.0 mL) solution of $[(Me_3Si)_2N]_3Nd^{III}(\mu\text{-Cl})Li(THF)_3$ (1.238 g, 1.40 mmol) at room temperature. After the reaction mixture was stirred at room temperature for 6 h, the mixture was then refluxed for 12 h. The solvent was evaporated under reduced pressure. The residue was extracted with *n*-hexane (2 × 15.0 mL). The extractions were combined and concentrated to about 20.0 mL. The green crystals were obtained by cooling the concentrated solution at 0 °C for several days [0.417 g, 29% yield based on $[(Me_3Si)_2N]_3Nd^{III}(\mu\text{-Cl})Li(THF)_3$]. NMR ($C_5D_5N$) spectra of the compound were not informative due to lack of locking signals for the paramagnetic property of the neodymium(III) complex. M.p. 146–148 °C. IR (Nujol mulls): $\tilde{\nu}$ = 2933 (m), 1601 (m), 1520 (m), 1445 (m), 1398 (m), 1292 (m), 1251 (s), 1203 (w), 1030 (m), 962 (m), 870 (s), 853 (s), 766 (s), 720 (m), 668 (w) $cm^{-1}$. $C_{51}H_{72}N_3NdSi_3$ (955.63): calcd. C 64.10, H 7.59, N 4.40; found C 64.25, H 7.16, N 5.07.

**X-ray Crystallography:** Suitable crystals of complexes **2**, **3**, **5**, and **6** were each mounted in a sealed capillary. Diffraction was performed with a Siemens SMART CCD-area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å); temperature 293(2) K; $\phi$ and $\omega$ scan technique; SADABS effects and empirical absorption were applied in the data corrections. All structures were solved by direct methods (SHELXTL-97),[27] completed by subsequent difference Fourier syntheses, and refined by full-matrix least-squares calculations based on $F^2$ (SHELXTL-97).[27] See Table 3 for crystallographic data.

CCDC-627924 (for **2**), -627925 (for **3**), -627923 (for **5**), and -627922 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**ε-Caprolactone Polymerization:** ε-CL polymerization reactions were performed in a 50-mL Schlenk flask, placed in an external temperature-controlled bath, on a Schlenk line or in a glovebox. In a typical procedure, the catalyst (20–50 mg) was loaded into the Schlenk flask and the solvent was added. The ε-CL was added through a gastight syringe after the external bath temperature was stabilized. The polymer product was precipitated into hydrochloric acid (0.1 M, 50.0 mL), washed with hydrochloric acid (0.1 M), and then dried to a constant weight in a vacuum oven at 50 °C. The molecular weights of the polymers were analyzed by GPC techniques.

# Small Group IIa–VIa Clusters and Related Systems: A Theoretical Study of Physical Properties, Reactivity, and Electronic Spectra

**Martin Srnec*[a] and Rudolf Zahradník[b]**

**Keywords:** Ab initio calculations / Cluster compounds / Structural elucidation

In the monomeric form, the title systems assume unexpected optical properties, and as oligomers they can serve as candidates for molecular devices. In bulk they are attractive in the area of material science. A broad set of quantum chemical methods ranging from density functional theory by the Hartree–Fock method and the Møller–Plesset perturbation theory to the coupled-cluster method, in connection with nonrelativistic Dunning's basis sets as well as with relativistic SDD basis sets were used. Electronic spectra were analyzed by means of time-dependent DFT, with the symmetry-adapted cluster configuration interaction and with the internally contracted multireference configuration interaction. The Douglas–Kroll–Hess quasirelativistic Hamiltonian served as a basis for the estimation of the role of relativistic effects. All the diatomics representing 25 elements of a matrix formed by the combination of group IIa (Be, ..., Ba) with group VIa (O, ..., Po) atoms were characterized by calculated bond length, valence vibration, dipole moment, and the Hartree–Fock frontier orbital energies. Calculated characteristics were confronted with experimental data. The geometry of the oligomers (from dimers through hexamers) was investigated systematically, and the nature of the located stationary points on the respective potential energy surfaces was established. Special attention was paid to the four lightest elements of the group IIa–VIa matrix, i.e. BeO, BeS, MgO, and MgS. As for electronic spectra, the systems of the first column (BeO, ..., BaO), the first row (BeO, ..., BePo), and the systems of the main diagonal (BeO, ..., BaPo) were calculated in the form of monomers and dimers. Analogous calculations were performed for a few group Ia–VIIa, IIIa–Va, IVa–IVa, and IIb–VIa systems. The group IIa–VIa and IIb–VIa diatomics exhibit electronic transitions in the visible region of the spectrum, and the longest wavelength bands are located in the near-infrared region. MgO represents an extreme with the first band appearing at about 3500 $cm^{-1}$, which strictly speaking makes the use of the Born–Oppenheimer approximation questionable. Whenever experimental transitions are available, the agreement between the calculated and observed band positions is good. Passing from monomers to oligomers is always associated with a significant hypsochromic shift in the first transition.

## Introduction

Contemporary electronics, material science, molecular engines, an urgent desire to build computers on the basis of appropriate molecules and macromolecules, and a general tendency to miniaturize prompted us to search for species and materials with the desired properties. These compounds require special physical, chemical, and mechanical characteristics.

For years conjugated organic systems have attracted attention on the basis of the above-mentioned aims and also in connection with the investigation of structure–color relationships. Special interest has been paid to intensively colored species[1a,2] and to systems possessing the longest wavelength transition in the near-infrared region.[1b] Such systems exhibit a very narrow gap between the highest occupied and the lowest unoccupied molecular orbitals (HOMO and LUMO, respectively).

Inorganic systems were, except for various transition-metal complexes, on the periphery of interest. This changed after the discovery of interesting facets (including semiconductivity) of some solids derived, for example, from group IIb–VIa binary compounds, such as, ZnO, ZnS, CdO, and CdS.[3a–3c] Species that are derived from group IIa–VIa elements have received much less attention than the group IIb–VIa compounds. It was shown recently that monomeric forms of group IIa–VIa binary species and small oligomers thereof absorb in the visible and near-infrared regions.[4] Passing from monomers to oligomers of increasing size manifests itself by a hypsochromic shift, which is opposite to that which is known for conjugated organic species.

The group IIa–VIa combination of atoms can be extended to other isoelectronic pairs: groups Ia–VIIa, IIIa–Va, and IVa–IVa. When considering the five elements com-

prising the individual groups of the periodic table, 25 species are derived for each of these combinations. The lightest species consists of LiF, BeO, BN, and $C_2$. These prototypes are followed by 24 molecules; the total number of nonidentical group IVa–IVa combinations amounts to $n(n-1)/2$ (where $n$ is the number of elements in the group), five of them being homonuclear, the remaining, heteronuclear.

In all these instances, 1–10 nm clusters of these parent species represent systems in which the properties are tunable by their size and/or by passing from one element to another element belonging to the same group.

With the group IIa–VIa systems, mostly species containing beryllium and magnesium were investigated. The majority of studies on beryllium compounds, probably because of their toxicity,[5–23] is more theoretical than experimental. Magnesium compounds, mainly MgO, were studied in the context of group IIa–VIa compounds most frequently.[24–50] The number of studies of binary systems containing heavier group IIa metals (Ca, Sr, Ba) is smaller.[24,51–56] Widely investigated were group IIb–VIa systems because of their practical importance. However, only papers having some relevance to systems dealt with in this work are cited.[3a–3c,57–74]

Species of these classes attract attention as nanoparticle[56,62,63,66,68,71,75] materials for quantum dots,[56,58,59] as clusters[24,25,31,43,52,57,59,64a,64b,69] and semiconductors,[3c,57,60,74] and as materials used in the preparation of nanotubes and nanowires.[50,52] The transition between clusters and bulk was investigated.[76] The band structure[7] of BeO and MgO surfaces[26,44a,44b] (and their infrared spectra[37]), as well as doped MgO,[26] were also subjects of scrutiny. Trends in the series BeO through BaO[10] and BeS through BeTe[15,19,23] were described. BeS[6,9,12,17] and MgS[25,33,40] represent materials worth mentioning. Not only closed-shell parent systems, but also radical–ions[13,14,27a,29,35,36] derived from them were subjects of studies, sometimes by means of photoelectron spectroscopy.[27a,38] The electron affinity of BeO is so high that complexes with rare gases were described.[8]

In addition to the currently widely used Hartree–Fock, Møller–Plesset, and coupled-cluster methods (vide infra), density functional theory[10,11,22,34,49,53,73] and empirical potentials[24,46,51] served to describe large systems, clusters in particular. A full configuration interaction (CI) was used to study[5] the electronic structure of BeO.

Electronic spectra investigations[16,27b,27c,34,48,56] involved mainly MgO (size-dependency of the MgO clusters[42]). In ref.[54] spectra of CaO, SrO, and BaO were analyzed. A correlation was found to exist between the energy of the Khon–Sham orbitals and the excitation energies.[77] Infrared spectra of MgO[37] and BeO complexes with noble gases[21,22] are available.

Calculations of dissociation energies (e.g. for MgO,[28] $MgO^+$, and $SrO^+$ in ref.[28]), as well as heats of formation (BeO, MgO, CaO),[20] still represent a rather demanding task.

In this paper, we utilize various quantum chemical methods to determine the structural and electronic characteristics of monomeric through hexameric group IIa–VIa species (group IIa: Be through Ba; group VIa: O through Po) and to determine how these characteristics vary with different elements, cluster size, and geometrical structure. We focus on the following features: (1) Screening structural and physical properties of all 25 group IIa–VIa monomers. (2) Detailing the study of the properties of the four lightest MX monomers (M = Be, Mg; X = O, S). (3) Testing relativistic effects on the properties of a representative molecule, CaSe. (4) Characterizing geometries of oligomeric isomers. (5) Characterizing electronic spectra for the most stable isomers. (6) Evaluating trends of physical characteristics in a series of oligomers.

## Computational Details

Quantum chemical methods were used for the computation of the structural and physical properties of selected group IIa–VIa diatomics MX, their oligomers $M_iX_i$ (from dimers to hexamers, $i$ = 2,.., 6), and for some related systems by using the Gaussian 03 program package.[78]

In the first part concerning diatomics, attention was focused on screening the bond lengths, the harmonic valence vibrations, the electric dipole moments, and frontier orbital energies. The following computational schemes were used: density functional theory (DFT) with the B3LYP exchange-correlation functional, the Hartree–Fock method (HF), and the second-order Møller–Plesset perturbation theory (MP2). Calculations were performed for all the matrix elements (diatomics) of the group IIa–VIa matrix. Relativistic pseudopotentials were used throughout the calculations so as to describe relativistic effects, which increase with $Z^4$ and $Z^2$ ($Z$ – proton number) for inner and outer electrons, respectively. The SDD basis sets[79a] are appropriate for this purpose and are available in the Gaussian 03 standard library. Analysis of the wavefunctions was carried out by means of the CASSCF method[79b] by using the MOLPRO 02 program.[79c]

The second part relates to the four lightest members of the group IIa–VIa matrix. These diatomics were extensively characterized by means of the DFT method using nonrelativistic Dunning's basis sets[80a–80c] (cc-pVXZ from double-zeta to quintuple-zeta) and the calculated characteristics were almost always extrapolated to the complete basis set (CBS) limit according to the (quasi)linear dependency between the physical characteristics and the reciprocals of the total number of basis set functions.[81] Unless otherwise stated, the geometry optimization of the oligomers was always performed at the B3LYP/cc-pVTZ level. The positions of the first electronic valence (the longest wavelength) bands of these species were estimated by means of the time-dependent density functional method (TD–B3LYP). These results were then compared with the experimental data (if available) and with the results of two more robust methods, namely, the symmetry-adapted cluster configuration interaction (SAC–CI),[82] including single and double excitations, and the internally contracted multireference config-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

uration interaction (icMRCI),[83a,83b] also with single and double excitations. Specification of the reference configuration space related to icMRCI calculations will be mentioned with concrete instances. The electronic transitions were fitted with equal-weighted Gauss/Lorentz curves with half-maximum widths of 1000 $cm^{-1}$; the Frank–Condon factors were not considered.

In the third part, we were interested in the trends of some structural and spectral features along the horizontal (the first row), the vertical (the first column), and the main diagonal directions of the group IIa–VIa matrix (Figure 1). The second-order Douglas–Kroll–Hess (DKH)[84a–84c] scalar quasirelativistic Hamiltonian was explored in the local spin density basis set DZVP[85] and the large-core SDD pseudopotential technique (vide supra), both within the B3LYP procedure. The DKH method neglects the two-electron relativistic corrections and also spin-orbit coupling. This method is based on the free-particle Foldy–Wouthuysen (FW)[84d] transformation, which separates the electronic and positronic solutions of the Dirac equation by the unitary transformation of the Dirac–Coulomb–Breit Hamiltonian. The approximate scheme of the DKH method applies the free-particle FW transformation to the molecular bare-nucleus Hamiltonian and, moreover, also applies additional transformations to remove off-diagonal Hamiltonian elements, which results in variational stability.

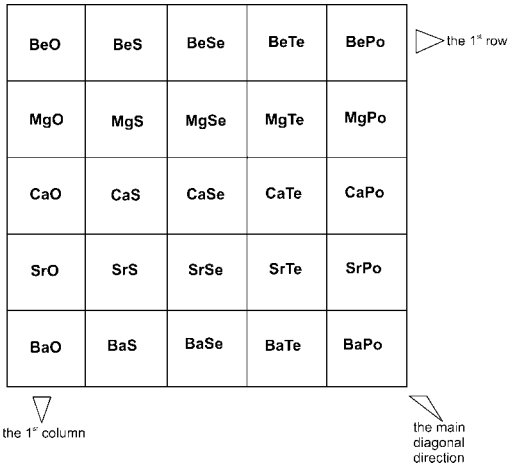

Figure 1. Diatomics formed by a combination of atoms of groups IIa and VIa. Three main directions are indicated.

The adiabatic and vertical ionization potentials ($I_a$ and $I_v$, respectively) and the adiabatic and vertical electron affinities ($A_a$ and $A_v$, respectively) are defined as follows [Equations (1), (2), (3), and (4)]:

$$I_a = E_{M_iX_i^{+-}}\left(M_iX_i^{+-}\right) - E_{M_iX_i}\left(M_iX_i\right) + \frac{1}{2}h\sum_j^{3N-6}\left[\nu_j\left(M_iX_i^{++}\right) - \nu_j\left(M_iX_i\right)\right] \quad (1)$$

$$I_v = E_{M_iX_i^{+-}}\left(M_iX_i\right) - E_{M_iX_i}\left(M_iX_i\right) \quad (2)$$

$$A_a = E_{M_iX_i^{--}}\left(M_iX_i^{--}\right) - E_{M_iX_i}\left(M_iX_i\right) + \frac{1}{2}h\sum_j^{3N-6}\left[\nu_j\left(M_iX_i^{--}\right) - \nu_j\left(M_iX_i\right)\right] \quad (3)$$

$$A_v = E_{M_iX_i^{--}}\left(M_iX_i\right) - E_{M_iX_i}\left(M_iX_i\right) \quad (4)$$

where the lower index and the index in parentheses specify chemical species and the structure, which was optimized, respectively. The adiabatic forms include the zero-point energy (ZPE) corrections; $\nu_j$ stands for the $j$th vibrational mode. The energy of the open-shell species was calculated by unrestricted methods.

The energy of formation of the oligomers was calculated by means of the following expression [Equation (5)]:

$$\Delta E = (iE_M + iE_x - E_{M_iX_i})/i \quad (5)$$

Equation (5) permits the estimation of the relative stability of the isomers. The basis set superposition error (BSSE) was calculated by using the function counterpoise method[86] and included throughout. It necessarily tends to zero when approaching complete basis sets.

The Mulliken population analysis was used for semiquantitative estimates of partial charges at the atoms.

## Results and Discussion

### Monomers: Screening of Structural and Selected Physical Properties

The ground state of all the studied species is a singlet state. The only uncertainty is related to BaPo. Again, a singlet represents the ground state with the SDD basis set (S–T split amounts to 3.6 kcal $mol^{-1}$ with B3LYP). With the ECP-CRENBL[87] basis set, however, the opposite is true (T–S split is equal to 13.5 kcal $mol^{-1}$ with B3LYP). The semiquantitative estimates of the S–T splittings for all group IIa–VIa species are available on request from the authors.

Bond lengths, valence vibrations, dipole moments, and frontier orbital energies for 25 group IIa–VIa diatomics are summarized in Figure 2. The bond length dependencies (A, B) are monotonic and reflect the empirical statement that passing from the first-row element to its nearest neighbor manifests itself roughly with the same degree of change relative to that found by passing between the second and the fifth period. The B3LYP, HF, and MP2 bond length courses overlap significantly. Average deviations between calculated and observed[88] bond lengths for the species of the first matrix column amount to 29 (B3LYP/SDD), 24 (HF/SDD), and 70 pm (MP2/SDD).

Dependences C and D in Figure 2 have to do with harmonic wavenumbers ($\tilde{\nu}$), which decrease monotonically in the columns and rows of the matrix. By contrast, force constants of magnesium chalcogenides exert minima. This agrees well with the remarkable reactivity of MgO.[31] Again, the features of the species that include first-row ele-

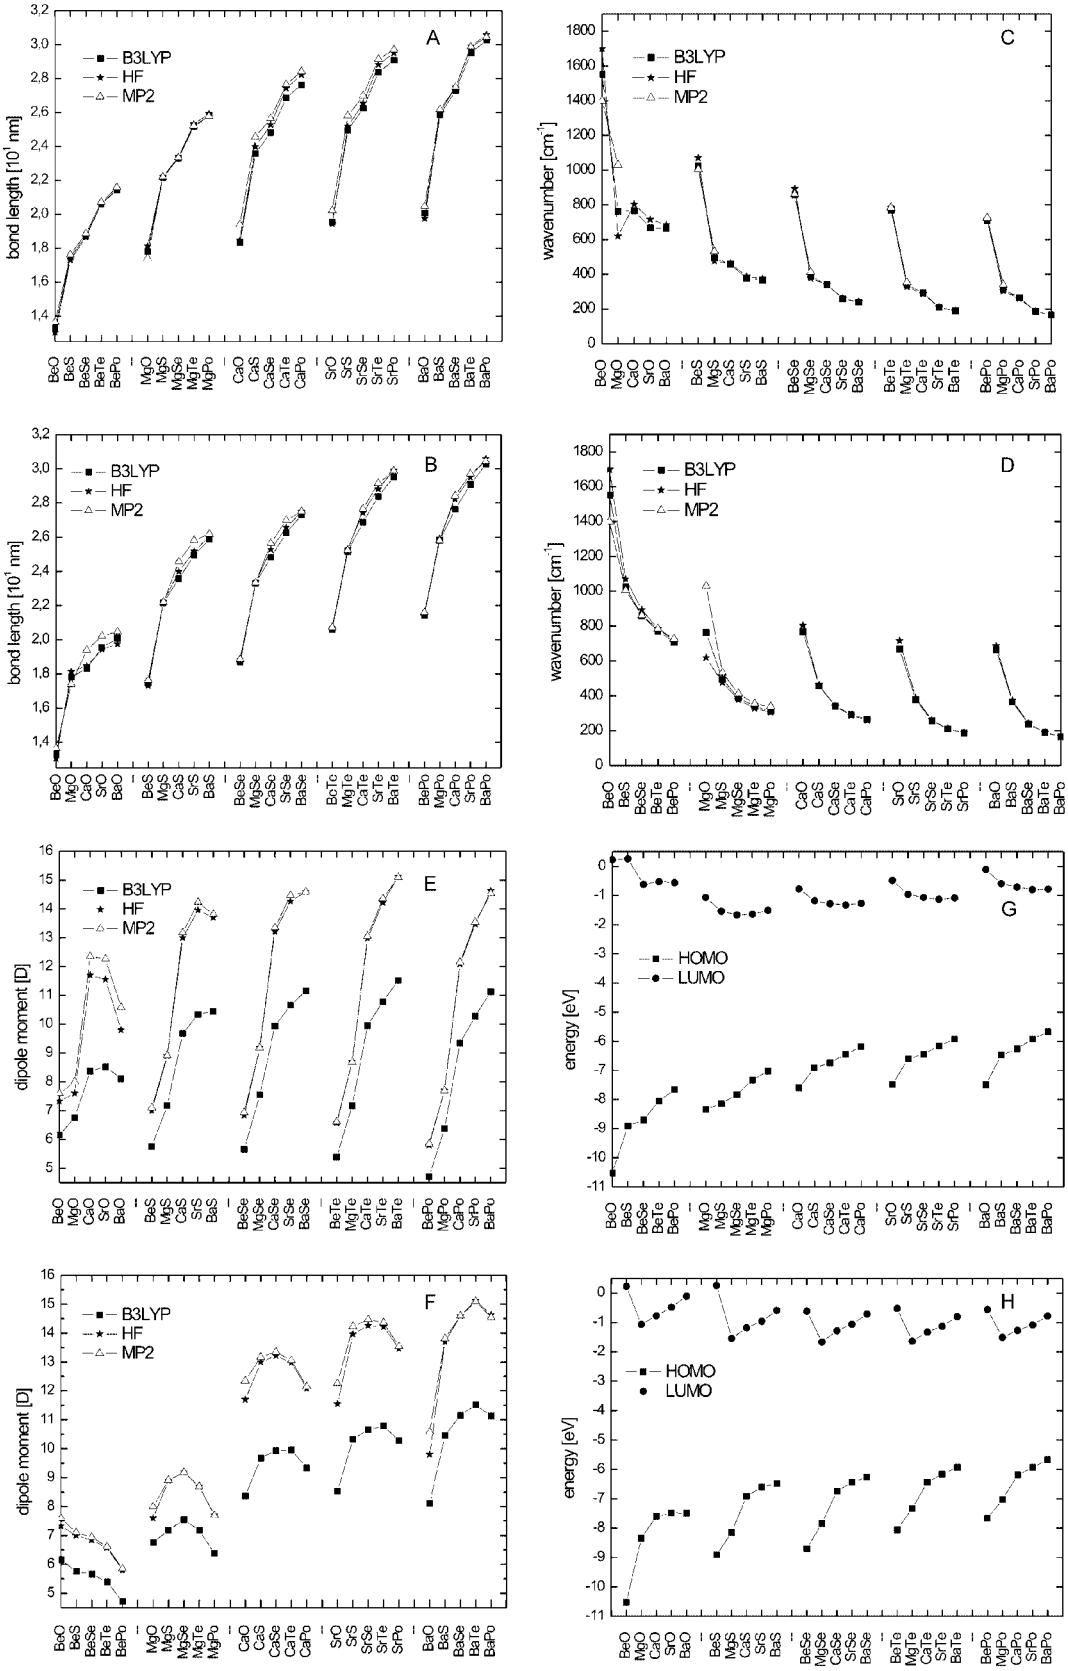

Figure 2. Trends of bond lengths, $\ell$(A, B), wavenumbers of valence vibrations, $\tilde{\nu}$(C, D), electric dipole moments, $\mu$(E, F), and energies of frontier orbitals, $E$(G, H) for 25 group IIa–VIa diatomics: oxides, sulfides, selenides, tellurides, polonides of beryllium, magnesium, calcium, strontium, and barium, respectively. Computational methods and units used are indicated in the graphs. The DFT (B3LYP), HF, and MP2 methods were used with pseudopotential SDD basis sets. HF frontier orbital energies correspond, except for signs, to Koopmans' ionization potential and electron affinity.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ments are shifted from the data for the rest of the systems. This is particularly obvious for BeO. There is a fair agreement between B3LYP/SDD and experimental wavenumbers for species of the first matrix column. The largest deviation was observed for MgO (16%), whereas for BaO it amounted to only 0.6%.

The dipole moments (Figure 2, E and F) indicate significantly the ionic nature of all the systems. There is a rather dramatic difference between the B3LYP and the HF and MP2 values (always with the SDD basis sets). Reasonable agreement between B3LYP and highly accurate theoretical values for BeO (6.16 and 6.15–6.25 D,[18] respectively) and BeS (5.76 and 5.19 D,[17] respectively) suggest the superiority of the B3LYP estimates with respect to the two other procedures. This confirms our previous experience.[81] In contrast to dependencies for species in columns, the dependencies in the rows exerts (except for beryllium chalcogenides) well-developed maxima for selenides or tellurides. On the whole, the B3LYP dipole moments assume values between 5 and 11 D.

The HF frontier orbital energies (Figure 2, G and H) represent, within the framework of the Koopmans' theorem, the first vertical ionization potential (HOMO) and the first vertical electron affinity (LUMO). The ionization potentials decrease and the electron affinities increase in the rows of the matrix. Dependencies for electron affinities

Table 1. Calculated bond lengths ($R_e$), dipole moments ($\mu$), wavenumber of valence vibrations ($\tilde{\nu}$), vertical ionization potential ($I_v$), vertical electron affinity ($A_v$), and formation enthalpy corresponding to the process $MX(^1\Sigma^+) = M(^1S) + X(^1D)$ for BeO, BeS, MgO, and MgS. The B3LYP and MP2 methods were obtained for Dunnig's basis sets (n; cc-pVXZ with X = D, T, Q, 5). Only in a few cases were very sophisticated calculated values used as a benchmark instead of experimental values.

along the columns exert clear minima for the Mg-containing species.

The differences between the calculated (HF, Koopmans' theorem) and observed[89] ionization potentials for the species in the first column ($\Delta I = I_{calcd.} - I_{exp.}$) amount to 0.42, –0.43, –0.80, –0.88, and –0.89 eV. Notably, CI vectors in the CASSCF approach suggest an admixture of 7 to 10% of excited configurations in the ground states.

### The BeO, BeS, MgO, and MgS Systems

The results of DFT and MP2 calculations for bond length, dipole moment, valence vibration, vertical ionization potential and electron affinity, and heat of formation for the title diatomics are presented in Table 1. The bond lengths and valence vibrations can be obtained for the set of diatomics under study with satisfactory precision.

The MP2 CBS bond lengths, when compared to experimental values, exhibit an average deviation of 0.7 pm. The B3LYP CBS values underestimate the experiment by 1.1 pm. The average deviation of wavenumbers is smallest for the B3LYP procedure and amounts in the CBS limit to 36 $cm^{-1}$.

Vertical ionization potentials and electron affinities were obtained from Equations (2) and (4). The overall agreement is satisfactory, which also applies to HF data (not included in Table 1) with the use of Koopmans' theorem.

Figure 3. Localized stationary points on the B3LYP/cc-pVDZ energy hypersurfaces of $Be_2O_2$, $Be_2S_2$, $Mg_2O_2$, and $Mg_2S_2$. Each of them is described by symmetry point group and electronic ground state. White and grey balls correspond to metal (Be, Mg) and chalcogen (O, S) atoms, respectively. In the presented table, basic information about the isomers found is collected in the following way: A – nature of stationary point (GM – global minimum, LM – local minimum, S*n* – saddle point of *n*th order); B – multireference wavefunction character of isomer [percentage ratio of the two most dominant wavefunctions; analysis with CASSCF(4,6)]; C – relative energies of dimer isomers (in $kJ\,mol^{-1}$).

### Calcium Selenide: Testing System for Relativistic Contribution Estimate

This system consisting of the fourth row elements was used for estimating the role of relativistic effects. The comparison was made with nonrelativistic B3LYP/cc-pVTZ and quasirelativistic DKH-B3LYP/cc-pVTZ methods. The latter method includes those components of relativistic corrections which can be considered essential. The calculations were performed for the monomer ($^1A_{1g}$) and the dimer ($^1B_{3u}$) and concerned molecular geometry, heat of formation, the first adiabatic ionization potential and electron affinity, wavenumbers of vibrational modes, and excitation energies for the longest wavelength electronic transition. The results are transparent: except for the heats of formation, the changes are not significant. In the case of the (negative) heats of formation, the relativistic values are about 20% bigger than the nonrelativistic ones.

### Structure of Oligomers $M_iX_i$ (M = Be, Mg; X = O, S; *i* = 2–6)

*Dimers:* Stationary points on the respective potential energy surfaces have been obtained by the energy minimization of numerous initial structures selected on the basis of chemical intuition and fantasy. The nature of the located stationary points was ascertained by means of the eigenvalue signs of the respective Hessians. This made it possible to distinguish global and local minima and the first- and higher-order saddle points. Except for minima, only the first-order saddle points are of chemical relevance, and they represent activated complexes of the Eyring absolute rate theory. The structures investigated with the dimers and detailed information on the nature of the located stationary points is presented in Figure 3. For the sake of simplicity, we concluded that the rhombic structure with acute angles at chalcogens represented a global minimum not only with $Be_2O_2$, $Be_2S_2$, $Mg_2O_2$, and $Mg_2S_2$ but in general also with analogue dimers. We observe that the opposite is true with group IIIa–Va dimers: acute angles are associated with the metal atoms.[90] Moreover, all these species represent single-reference systems. Figure 3 shows that a local minimum is only a little higher in energy than the global minimum. However, in the case of $Mg_2O_2$, structure *b* is about 36 kJ mol$^{-1}$ above the global minimum, and with $Mg_2S_2$, structre *c* is 23 kJ mol$^{-1}$ above the global minimum.

Passing from monomers to dimers is accompanied by a lengthening of the M–X bond by 16, 18, 12, and 17 pm for $Be_2O_2$, $Be_2S_2$, $Mg_2O_2$, and $Mg_2S_2$, respectively (B3LYP/cc-pVDZ). The softer nature of these bonds is indicated by the $b_{1u}$ harmonic normal vibrational modes of the dimers.

*Trimers:* Despite great effort, it seems that the only significant minimum on the PES of these systems are hexagons possessing the $D_{3h}$ structure. They are products of strong electrostatic (head–tail) interactions of three building units. It is tempting to try to ascribe the stability of the $D_{3h}$ structures to a kind of aromaticity. Although there is a significant formal similarity between the systems under study and moieties such as benzene and cyclic $C_6$ ($D_{3h}$), the great difference in the electronegativity of the atoms that form building units (e.g. Be and O) reduces delocalization considerably. Again, the angles at the chalcogen atoms of the trimers are smaller than those at metal atoms. The structure of the group IIIa–Va and group IIb–VIa species is analogous.[69,90] Chemical intuition has strong support in molecular dynamics. We have been able to show by a simulated annealing procedure[91] the superiority of the $D_{3h}$ structure for the four dimers which were thoroughly studied. Heavier trimers from the group IIIa–Va matrix prefer[90] a three-dimensional structure, which was ascribed to the low-lying d orbitals and energy diminution due to higher coordination numbers. We might add that linear trimers represent saddle points of the higher order. The bond lengths in trimers are equal 146.7, 190.9, 184.0, and 229.9 pm for the BeO, BeS, MgO, and MgS bonds, respectively. This means that all the bonds are about 3 pm shorter than the analogous bonds in the dimers.

*Tetramers:* We have been able to localize three stationary points with all four building units under study (Figure 4). The BeO tetramer is the most stable in a planar octagonal form ($D_{4h}$). $Mg_4O_4$ and $Mg_4S_4$ assume a heterocubic structure ($T_d$); with $Be_4S_4$ the situation is somewhat more involved. A minimum of $D_{2d}$ symmetry passes through an extremely low-lying transition state of $D_{4h}$ symmetry into an equivalent $D_{2d}$ system. The B3LYP/cc-pVTZ barrier

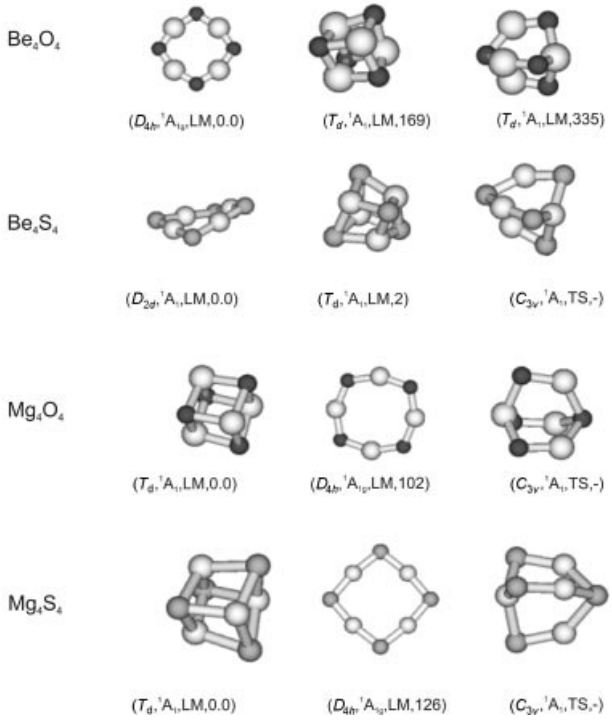

Figure 4. Localized stationary points on the B3LYP/cc-pVDZ energy hypersurfaces of $Be_4O_4$, $Be_4S_4$, $Mg_4O_4$, and $Mg_4S_4$. Symmetry group, electronic state, nature of the stationary point, and relative energy (kJ mol$^{-1}$) with respect to the most stable isomer are in parentheses. Dark spheres stand for chalcogen. Local minima (LM) and transition states (TS).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

amounts to 0.5 kJ mol$^{-1}$ and can be neglected at room temperature. The $A_1$ ground state is not degenerate and therefore the deviation from coplanarity cannot be attributed to the Jahn–Teller effect. However, pseudo Jahn–Teller distortion is applicable, which is supported by arguments in ref.[60] The HOMO ($b_{1u}$) and LUMO ($a_{1g}$) orbitals in the $D_{2d}$ geometry are transformed into $a_1$ orbitals, which are capable of mixing. The mixing is probably not very pronounced because of the large energy gap between these orbitals estimated on the basis of the first electronic transition (3.9 eV; TD-B3LYP/cc-pVDZ). At this level, the energy difference between the $D_{2d}$ and $T_d$ structures is so small that the order of isomers can be changed when passing to a higher level of theory.

The $Be_4O_4$, $Mg_4O_4$, and $Mg_4S_4$ clusters with $D_{4h}$ symmetry and $Be_4S_4$ with $D_{2d}$ symmetry have bond lengths equal to 145.3, 182.6, 228.6 and 190.1 pm, respectively (B3LYP/cc-pVDZ), which correspond roughly to the values of the bond lengths in the trimers. The contraction of bond lengths with respect to those of dimers could indicate heteroaromatic behavior of the rings. The bond lengths in the most stable isomers of $Mg_4O_4$ and $Mg_4S_4$ (both with $T_d$ symmetry) are 195.7 and 243.0 pm, which is in agreement with the expected increase in bond lengths when passing to bulk: $(MgO)_\infty$, 210.6 and $(MgS)_\infty$, 260.0 pm.

*Pentamers:* Localized stationary points are summarized in Figure 5. Only $Be_5O_5$ assumes a planar monocyclic structure (decagon) with $D_{5h}$ symmetry. Another isomer has a naphthalene-like structure with $C_{2v}$ symmetry. The other three pentamers are most stable in a nonplanar structure ($C_s$). Monocyclic structures with $Be_5S_5$ are nonplanar ($C_s$), whereas with $Mg_5O_5$ they are planar ($D_{5h}$). The $D_{5h}$ structure of $Mg_5S_5$ is a second-order saddle point. The addition of one electron to the monocyclic nonplanar $C_s$ structure of $Be_5S_5$ causes planarization of the ring ($D_{5h}$) accompanied by reduction of the Be–Be distance. Ladder structures have been localized with pentamers except $Be_5O_5$, but they have little chemical relevance.

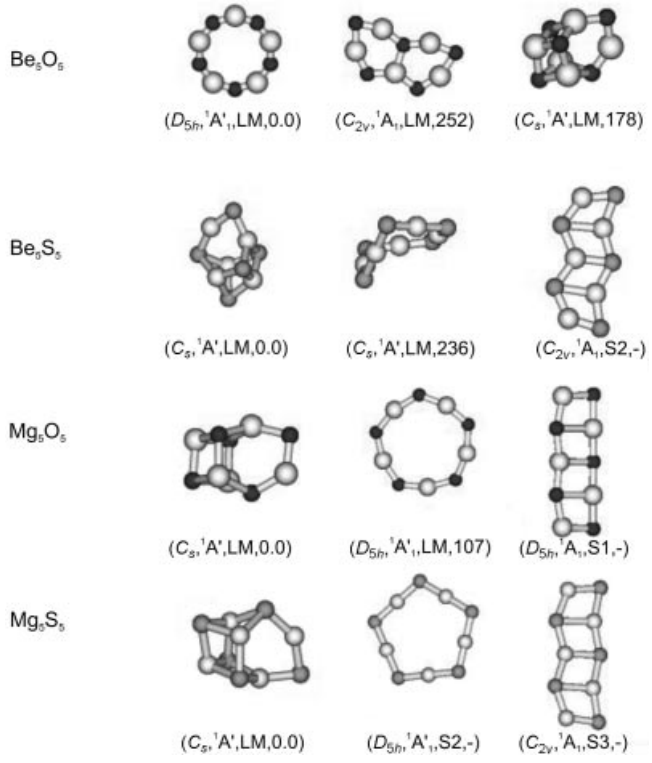

Figure 5. Localized stationary points on the B3LYP/cc-pVDZ energy hypersurfaces of $Be_5O_5$, $Be_5S_5$, $Mg_5O_5$, and $Mg_5S_5$. Symmetry group, electronic state, nature of the stationary point, and relative energy (kJ mol$^{-1}$) with respect to the most stable isomer are in parentheses. Dark spheres stand for chalcogen. Local minima (LM) and saddle points of the *n*th order (S*n*).

*Hexamers:* Ten local minima are among 16-localized stationary points for the four systems under study (Figure 6). With all hexamers, the most stable forms have $D_{3d}$ structure, which consists of six-membered cycles in a stacking arrangement. This form represents a building unit of wurzite crystals, which concerns beryllium oxide and sulfide. Magnesium compounds crystallize frequently into a cubic structure, which, at the level of hexamers, is represented by the $D_{2h}$ structure. It can be considered a kind of "sandwich" consisting of three stable rhombic units. Only $Mg_6O_6$ and $Mg_6S_6$ represent local minima; the beryllium containing systems of the $D_{2h}$ structure are saddle points.

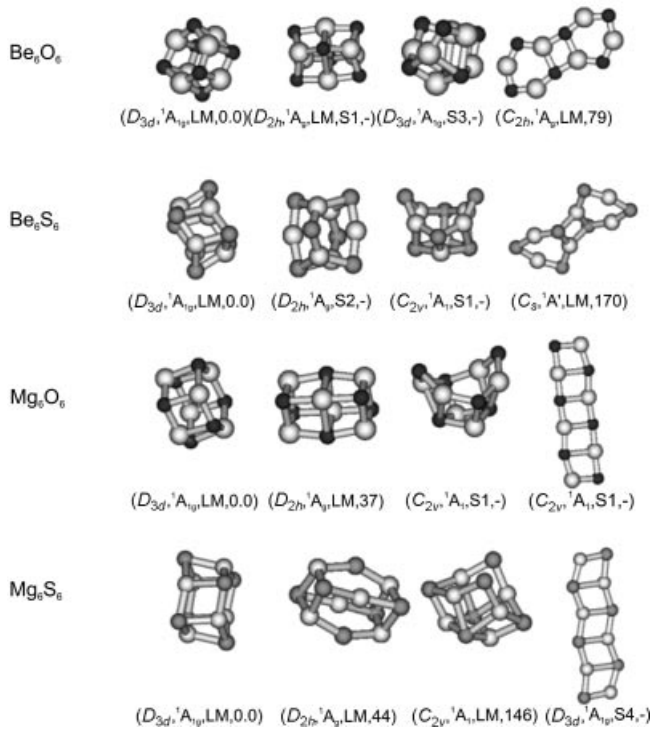

Figure 6. Localized stationary points on the B3LYP/cc-pVDZ energy hypersurfaces of $Be_6O_6$, $Be_6S_6$, $Mg_6O_6$, and $Mg_6S_6$. Symmetry group, electronic state, nature of the stationary point, and relative energy (kJ mol$^{-1}$) with respect to the most stable isomer are in parentheses. Dark spheres stand for chalcogen. Local minima (LM) and saddle points of the *n*th order (S*n*).

Bowl-like $C_{2v}$ structures consisting of tetragons, in contrast to $Zn_6S_6$ and $Zn_6Se_6$ clusters,[60] are not stable species; they are just saddle points. $Mg_6S_6$ assumes a special posi-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion by being a local minimum. This might be tentatively ascribed to the d orbitals of S and Mg, which stabilize systems with atoms having high coordination numbers.

The $Be_6O_6$ system exists with a local minimum ($C_{2h}$) consisting of two hexagons and one (connecting) rhombic motif. Therefore, there is a formal resemblance between this system and diphenylene in the benzenoid hydrocarbon series. With reference to $Be_6S_6$, this $C_{2h}$ structure converges to a nonplanar system with $C_s$ structure, whereas $Mg_6O_6$ and $Mg_6S_6$ pass into a ladder structure of a saddle-point nature.

Time consumption connected with the B3LYP/cc-pVDZ geometry optimization of hexamers can be reduced considerably by using the PM3 preoptimization.[92]

## Electronic Spectra

We believe we have shown convincingly[4] that for BeO, BeS, MgO, and MgS the longest wavelength transitions calculated by TD-B3LYP/cc-pVDZ and SAC-CI(SD)/cc-pVDZ mutually agree satisfactorily. The same is true when

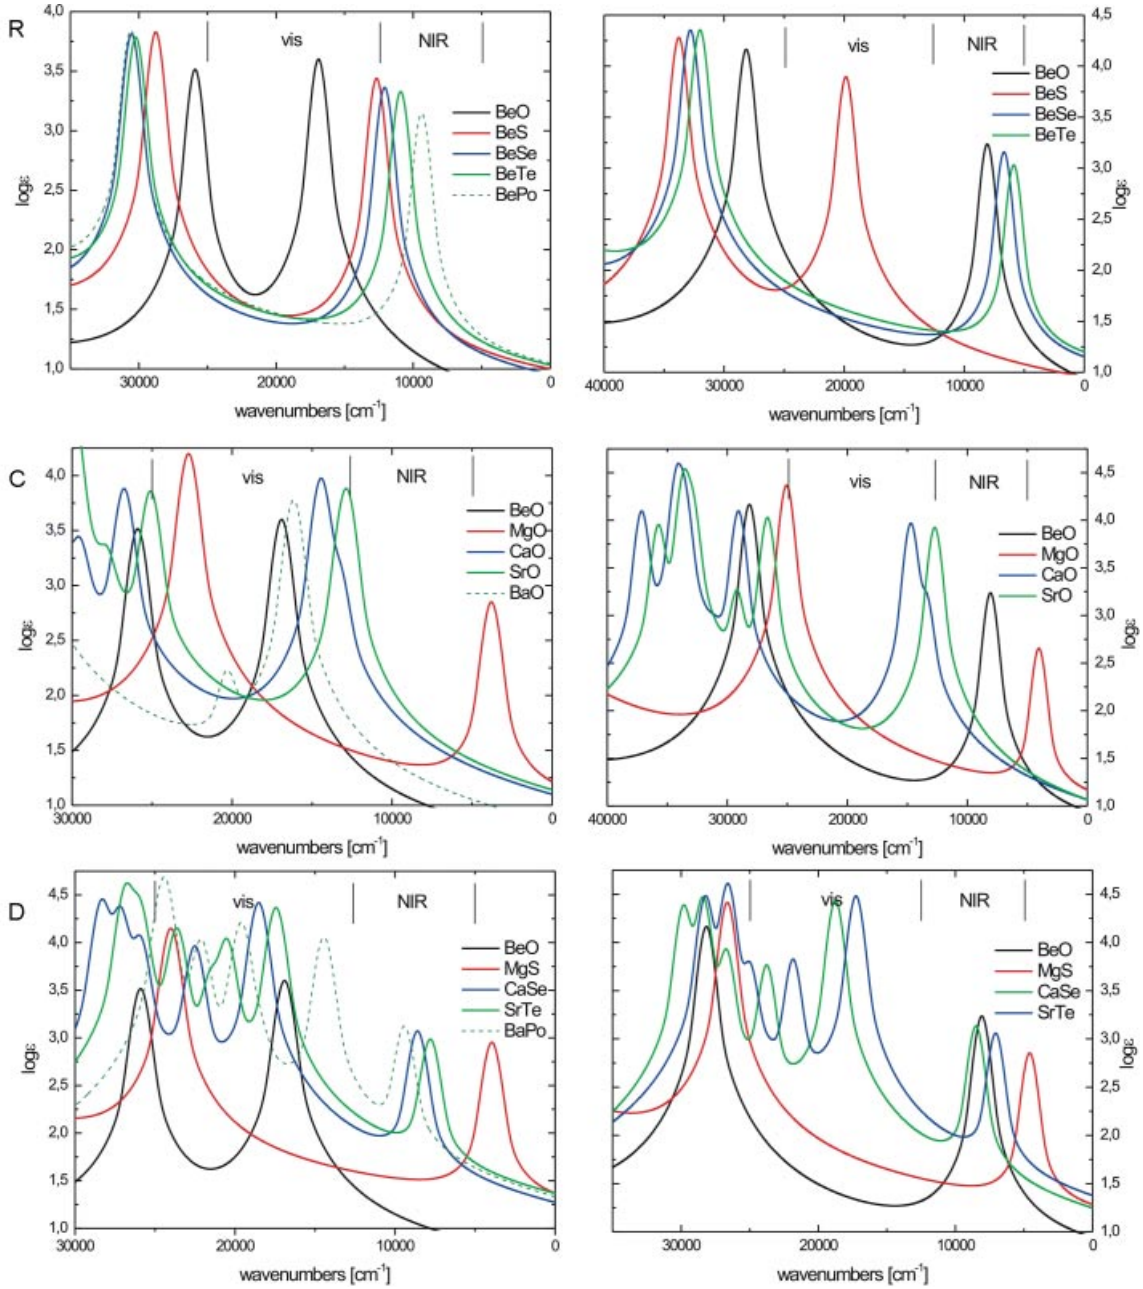

Figure 7. Computed electronic spectra of the group IIa–VIa diatomics at the TD-B3LYP/SDD (the left column) and DKH-B3LYP/VDZP (the right column) level. Three directions in the group IIa–VIa matrix are considered (the first column, C; the first row, R; the main diagonal, D). The regions of visible (vis) and near-infrared regions (NIR) are indicated.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

comparing calculated and observed[4] band positions in the near-infrared and visible regions of the spectrum. An analogous statement is valid for dimers of the above-mentioned diatomics, except that there are no experimental data available. In all instances, passing from monomer to dimer is accompanied by a very large hypsochromic shift. Moreover, it has been shown with the monomers that the use of the icMRCI procedure produces similar results. Although passing from DZ to TZ brings about an improvement in all three methods relative to the experimental values, the TD-B3LYP/cc-pVDZ method is well-suited and a relatively economic procedure for good semiquantitative predictions.

The order of transitions with oxides forming the first column (BeO, ..., BaO) remains unchanged ($X^1\Sigma^+ \rightarrow A^1\Pi$, $X^1\Sigma^+ \rightarrow B^1\Sigma^+$, $X^1\Sigma^+ \rightarrow B^1\Pi$, and $X^1\Sigma^+ \rightarrow C^1\Sigma^+$) between BeO and CaO. For SrO, the two first transitions are approximately equal in energy, and with BaO, the first band connected with the $\Sigma^+ \rightarrow \Sigma^+$ transition is observed.

Instead of calculating the electronic spectroscopic data for all matrix elements and the dimers thereof, we dealt with systems of the first column (BeO, ..., BaO), of the first row (BeO, ..., BePo), and with systems formed from the main diagonal (BeO, ..., BaPo) (cf. Figure 1). The respective theoretical absorption curves are depicted in Figure 7 for di-

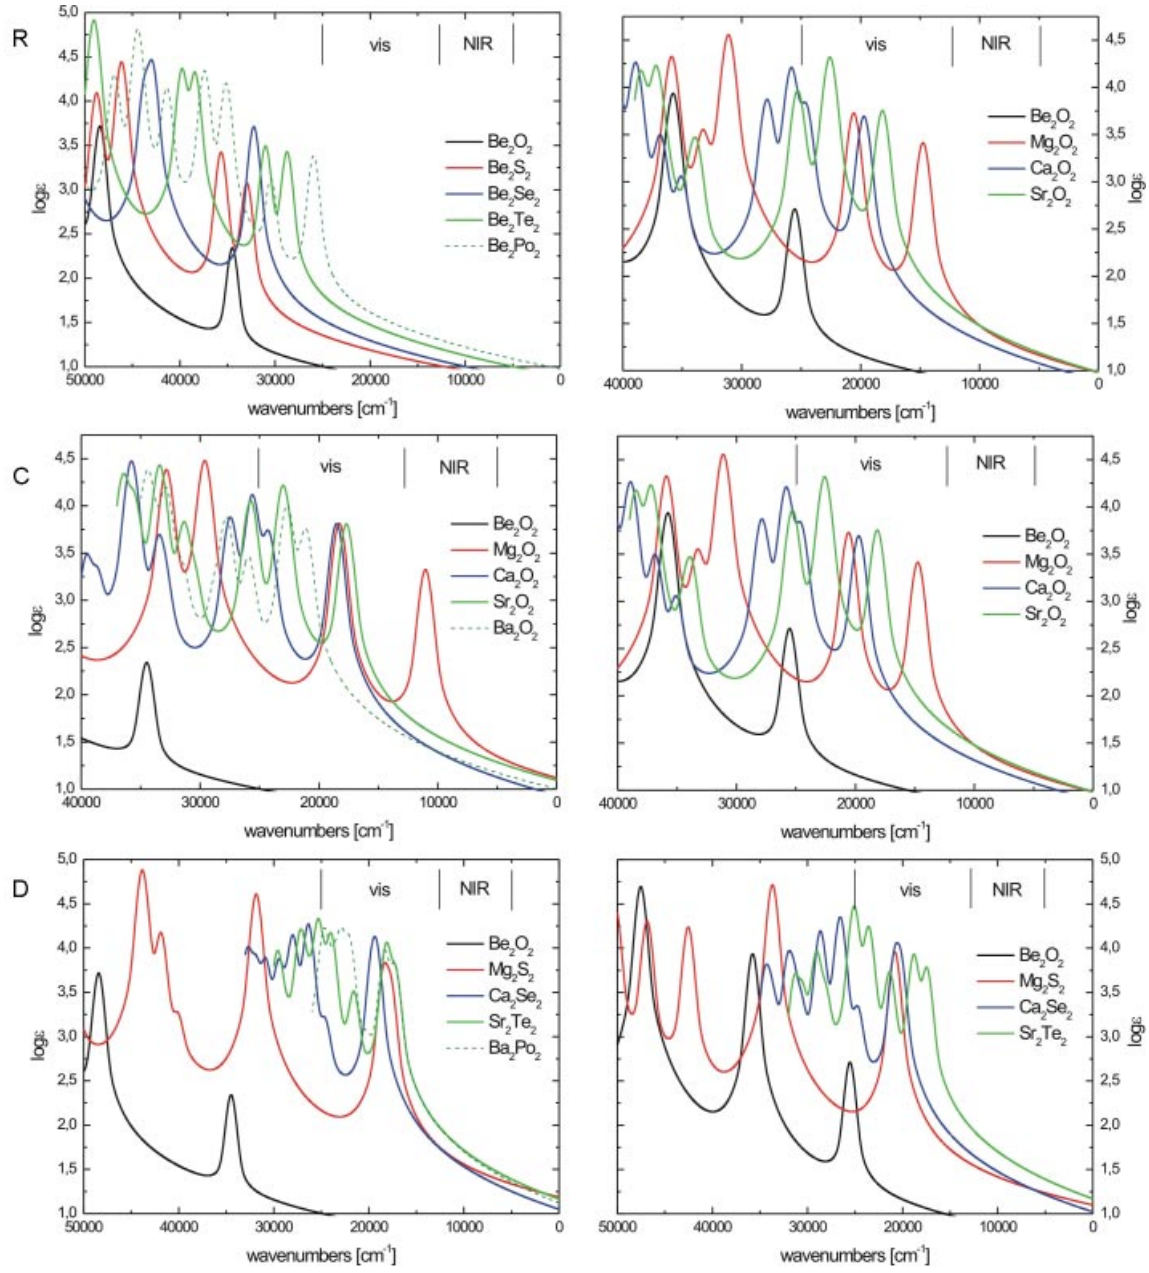

Figure 8. Computed electronic spectra of dimers of the group IIa–VIa diatomics at the TD-B3LYP/SDD (the left column) and DKH-B3LYP/VDZP (the right column) level. Three directions in the group IIa–VIa matrix are considered (the first column, C; the first row, R; the main diagonal, D). The regions of visible (vis) and near-infrared regions (NIR) are indicated.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atomics and in Figure 8 for their dimers. On the basis of comparison between calculated and observed band positions for all group IIa oxides and BeS and MgS, it is possible to say that the curves in Figures 7 and 8 offer a realistic picture of the electronic spectra. The first absorption band is either in the near-infrared region (in the majority of cases) or in the visible region. The overall picture is quite similar for both theoretical levels used, but the DKH procedure seems to be more reliable. However, the only real failure of the pseudopotential basis set (SDD) is for BeO and its dimer.

Calculated electronic spectra for the most stable pairs of isomers of the dimers, tetramers, and hexamers of MgO suggest the possibility to use this type of spectroscopy for structure elucidation (Supporting Information, see Figure S1).

### Trends in Physical Characteristics in Series of Oligomers

A summarizing note on the geometry of clusters will be augmented by remarks on ionization potentials and elec-

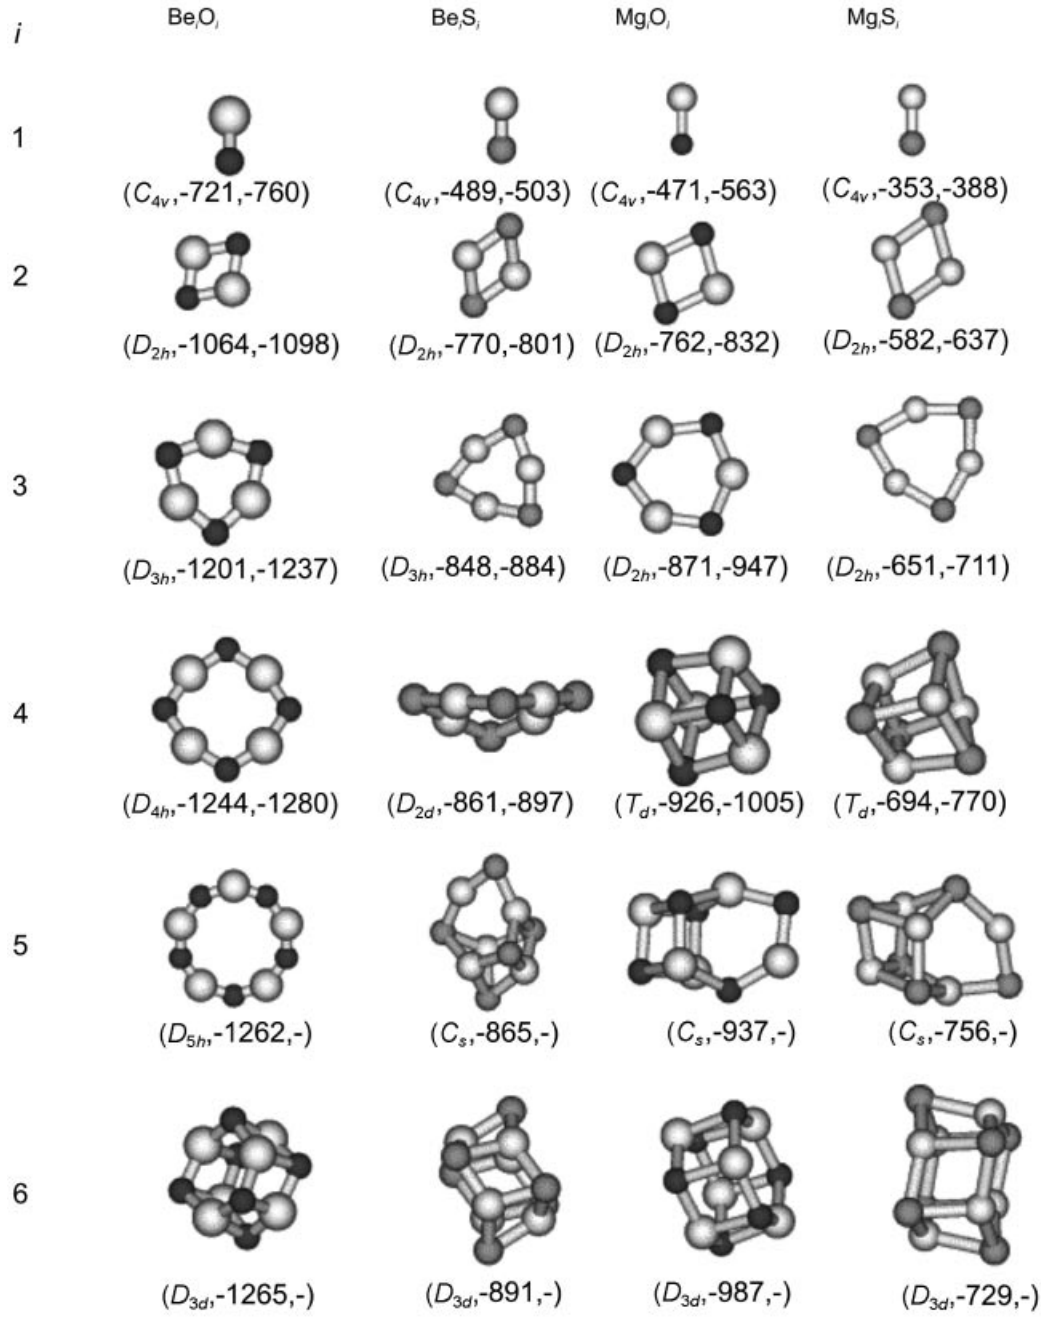

Figure 9. Structure of global minima of $(MX)_i$ on the respective energy hypersurface. Symmetry group and calculated energy of formation, $\Delta E$ (B3LYP/cc-pVTZ and MP2/cc-pVTZ) per MX unit (kJ mol$^{-1}$). Basis set superposition error is included. Dark spheres mean chalcogen.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tron affinities. Assumed global minima are summed up in Figure 9. Notably, higher oligomers consist of rhombic and hexagonal motifs. Specific energies of formation of oligomers, that is energies per monomer unit, are defined by Equation (5). The two sets of formation energies (DFT and MP2) are available up to tetramer and differ by about 5%. It is hardly possible to say which of the methods should be preferred. Obviously, however, it is desirable to have for small oligomers such a comparison available and, for more extensive systems, the DFT procedure represents the only, remarkably reliable, chance. Increasing specific formation energy suggests the increasing stability of larger oligomers and also their decreasing reactivity. It is known from the literature[3c,69] that attempts to obtain cohesion energy of a crystal by extrapolating the formation energy of small clusters are not successful. Internal energy of BeO and MgO crystals are 1180 and 995 kJ mol$^{-1}$.[93]

Ionization potentials, $I$, and electron affinities, $A$, are valuable characteristics in several respects. The BeO clusters are used as representatives. Adiabatic and vertical values are defined by Equations (1)–(4). In opposition to the formation energies, the plots of $I$ and $A$ against the cluster size are not smooth (Figure 10). Relative maxima with ionization potentials correspond to $i$ = 3 and 5, whereas minima are at $i$ = 2, 4, and 6. This suggests that there is stabilization of cycles with 6 and 10 atoms; minima on the plot are connected with 4, 8, and 12 atoms in the ring. It is at least formally an analogy to the aromatic and nonaromatic cyclic, conjugated hydrocarbons. The same was observed in the BN series, that is aromaticity with $(BN)_3$ and $(BN)_5$.[94] the adiabatic and vertical values differ very little, which indicates an absence of dramatic geometry changes after removal or addition of an electron. The trends are the same for both methods used.

In Table S1 (Supporting Information), we summarize the values of the partial charges at the metal atoms for the oligomers depicted in Figure 9. We wish to underline two points: (1) The ionic character increases with cluster size, which correlates to a hypsochromic shift in the electronic spectra (vide infra). The partial charges are also significantly influenced by the coordination environment and that is apparent in the series of $Be_iO_i$, $i$ = 1–6. Only the $Be_6O_6$ system has a different coordination number of atoms and is not consistent with the smooth trend for $i$ = 1–5. (2) The MgO molecule exerts significant covalency; the growth of ionic character for the MgO clusters with increasing $i$ is most dramatic among species included in Figure 9.

The dependence of the positions on the longest wavelength bands for oxides and sulfides of beryllium and magnesium is shown in Figure 11. The only structurally homogeneous series for $i$ = 1–5 is BeO: the first band of the cyclic structures exhibits a dramatic hypsochromic shift from about 10 000 ($i$ = 1) to 60 000 cm$^{-1}$ ($i$ = 5). The bathochromic shift when passing from pentamer to hexamer is, no doubt, due to structural changes, namely to the transition to a three-dimensional structure ($D_{3d}$). The courses for the remaining three systems support the plausibility of this assumption because a change from hypsochromicity to bathochromicity manifests itself by passing from trimer to tetramer, which coincides with passing from planarity to three-dimensional structures.

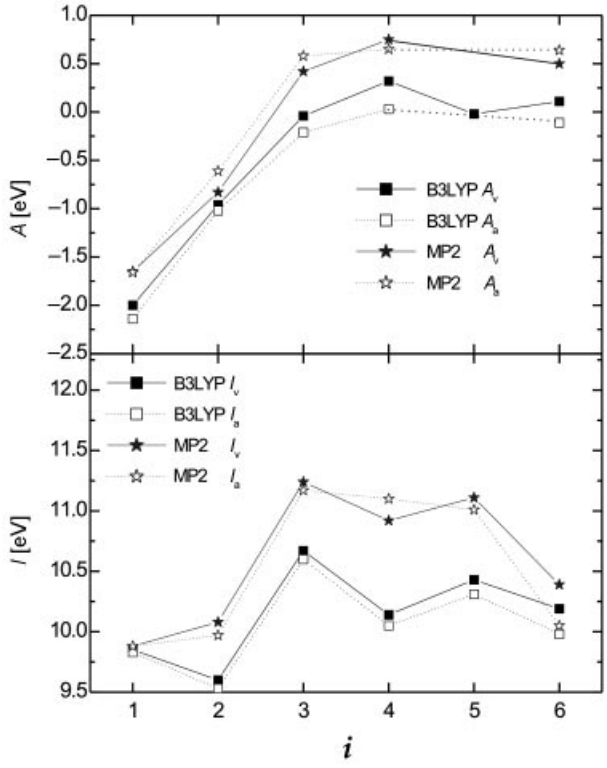

Figure 10. Vertical and adiabatic ionization potentials and electron affinities plotted against the size of the most stable $(BeO)_i$ oligomers (eV). In adiabatic values zero-point energy is included [cf. Equations (1)–(4)]. B3LYP/cc-pVDZ (squares: full-vertical, empty-adiabatic), MP2/cc-pVDZ (stars: full-vertical, empty-adiabatic) calculations.

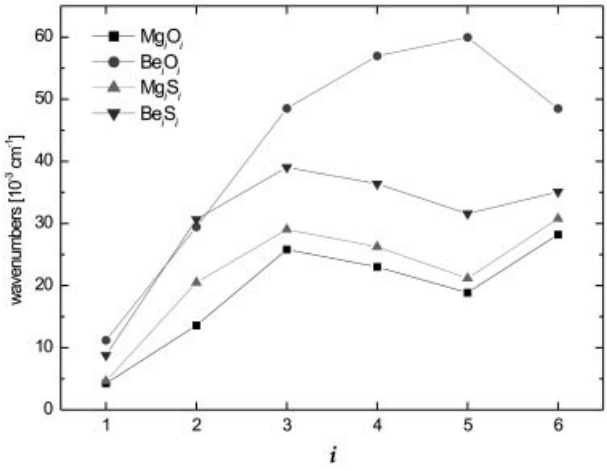

Figure 11. The shift in the position of the longest wavelength absorption band in the electronic spectra in four series of systems ranging from monomer up to hexamer. The calculations have been performed at the TD-B3LYP/cc-pVTZ level.

A remarkably close correlation exists between TD DFT excitation energies (for transitions which dominate the HOMO–LUMO excitation) and differences of Khon–Sham

eigenvalues, which result from the solution of Kohn–Sham equations with the B3LYP functional. Recently, such correlations were observed and analyzed.[70,77] This finding is valuable because it makes estimates of the first-band position on the basis of a calculation possible, which, for extensive systems, are significantly more economic than complete TD DFT calculations.

Finally, let us briefly comment on the first and second excitation energies in the isoelectronic series of diatomics related to the second row of the periodic table. The wavenumbers [$cm^{-1}$] are as follows: LiF: 40530, 45600; BeO: 9410, 21250; BN: 27880, –; and $C_2$: 720, –. These values were obtained at the TD-B3LYP/cc-pVTZ level (LiF, BeO) or taken from ref.[95] (BN, $C_2$). Except for group IIa–VIa species, in all instances the passing from monomers (diatomics) to dimers is associated with a bathochromic shift.

The related group IIb–VIa diatomics MX (M = Zn, Cd, Hg; X = O, S) exert the first two bands in similar regions as the group IIa–VIa species. Whereas the first peak (TD-B3LYP/cc-pVTZ [$cm^{-1}$]) is located in the near-infrared or infrared region (ZnO: 5570; ZnS: 5040; CdO: 2810; CdS: 2810; HgO: 3350; HgS: 1960) with very low intensity, the second one, which is more intensive by about two orders of magnitude, is shifted to the near-UV region (ZnO: 31470; ZnS: 32290; CdO: 28400; CdS: 28730; HgO: 32560; HgS: 32635).

## Conclusions

Although the group IIa–VIa system in bulk does not attract the attention of many chemists, which is (partly) due to a big gap between valence and conduction bands and their chemical inertness, the opposite is true for group IIa–VIa diatomics and clusters thereof. We found that the diatomics unexpectedly exert the first absorption band in the near-infrared or visible regions and this band is progressively shifted toward shorter wavelengths with growing cluster size.

The structural variety of group IIa–VIa species is significantly limited by strong ionic interaction of metal–chalcogen poles. Therefore, the most stable structures of larger clusters could be considered as a combination of a few, rhombic and hexagonal, patterns.

We feel strongly that catalytic properties of bulk surfaces could be enhanced by deposing cluster-like structures. In this work, we tried to demonstrate how electronic characteristics are tunable by varying the metal and chalcogen, cluster size, and isomerization. We hope that the group IIa–VIa species can be valuable for new molecular devices similar to the group IIb–VIa species.

# Study of the Defects in Sintered $SnO_2$ by High-Resolution Transmission Electron Microscopy and Cathodoluminescence

David Maestre,[a] Julio Ramírez-Castellanos,[b] Pedro Hidalgo,[a] Ana Cremades,[a] José M. González-Calbet,[b] and Javier Piqueras*[a]

**Keywords:** Semiconductors / Luminescence / Microstructure / Resistivity

The defect structure of sintered $SnO_2$ was investigated by high-resolution transmission electron microscopy (HRTEM), cathodoluminescence (CL), and electrical measurements. HRTEM shows the presence of the SnO phase in the sintered samples as well as twinning, stacking faults, and disordered intergrowths. The sintered samples annealed under an oxygen atmosphere show changes in the defect structure and in the CL spectra. In particular, the intensity of a CL band at 1.94 eV, related to oxygen vacancies, decreased as the electrical resistivity increased. The results are discussed by considering the presence of stoichiometric defects such as oxygen vacancies and Sn interstitials in the final structure and their evolution during the annealing process under an oxygen atmosphere.

## Introduction

$SnO_2$ is a semiconducting oxide of interest for technological applications such as gas sensors, transparent electrical contacts, or optoelectronics.[1–3] It is commonly accepted that its electrical conductivity is related to its nonstoichiometry, which is due to a large concentration of oxygen vacancies that act as shallow donors close to the conduction band.[4] However, this vacancy model seems to raise a few fundamental questions with regard to the general understanding of the phenomenon of transparent conductivity. Some theoretical results[5] point to an important role of the interstitial Sn atoms, which present unusual stability owing to the multivalence of tin, under different chemical potential conditions in $SnO_2$.

In this work, the defect structure of sintered $SnO_2$ ceramic samples and its correlation with optical and electrical properties were investigated. In particular, the role of oxygen vacancies and of tin interstitials in the luminescence and electrical resistivity of the sintered samples was analyzed. Samples prepared under different thermal treatments were characterized by the cathodoluminescence (CL) mode in a scanning electron microscope (SEM), x-ray diffraction (XRD), high-resolution transmission electron microscopy (HRTEM), and electrical resistivity measurements.

## Results

The sintered samples have irregular-shaped grains with different sizes and porosities as a function of the annealing temperature. We have previously reported[6] that the cathodoluminescence spectra of $SnO_2$-sintered samples show three main contributions centered around 1.94, 2.25, and 2.58 eV, whose relative intensities depend on the sintering treatment. The 1.94 eV emission has been related to the presence of oxygen vacancies[6,7] which act as shallow donors in $SnO_2$.

Figure 1 shows CL spectra recorded at 80 K on samples sintered in air for 10 h at 1200 °C, and subsequently treated under an oxygen atmosphere at 600 and 900 °C. As a reference, the spectrum of the sample sintered in air for 10 h at 1200 °C, is also represented. No significant changes in the spectrum can be appreciated after the treatment under an oxygen atmosphere at 600 °C. However, thermal treatments at higher temperatures (900 °C) produce a decrease in the total CL signal, but mainly of the 1.94 eV emission intensity. Figure 2 shows CL spectra of samples sintered in air for 10 h at 1500 °C, with and without subsequent treatment in an oxygen atmosphere. The 2.25 eV emission is dominant in the three spectra, whereas the 1.94 eV emission has almost disappeared. A decrease in the CL intensity is also observed as the temperature of the oxygen annealing is increased.

In order to investigate the changes that these treatments produce in the oxide microstructure and composition of $SnO_2$, analysis by means of XRD and HRTEM were carried out. XRD of the samples sintered at 1200 °C and 1500 °C show a crystalline structure of rutile type, with a tetragonal unit cell and parameters $a$ = 0.4738 nm and $c$ =

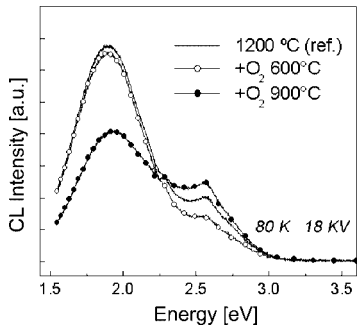

Figure 1. CL spectra of samples sintered in air at 1200 °C, some of which were subsequently treated under an oxygen atmosphere at 600 or 900 °C.

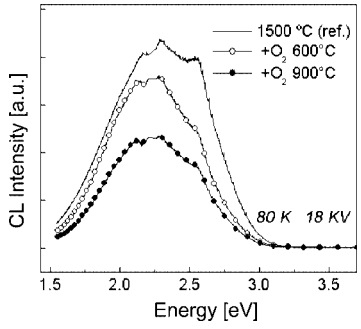

Figure 2. CL spectra of samples sintered in air at 1500 °C for 10 h, and samples further annealed under an atmosphere of oxygen at 600 and 900 °C.

0.3187 nm, and $P4_2/mnm$ space group. SAED and HRTEM studies show the presence of different defects, including twinning, stacking faults, disordered intergrowths, domains, and amorphization.

Figure 3a shows the fast Fourier transform (FFT) pattern along the [001] zone axis of the sample sintered at 1200 °C, which can be indexed on the basis of the rutile crystal structure. The corresponding HRTEM image (Figure 3b) shows a very well-ordered material with interplanar distances of 0.47 nm.

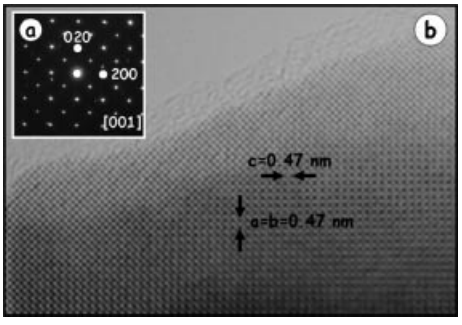

Figure 3. FFT pattern along the [001] axis (a), and HRTEM image (b) of a sample sintered in air at 1200 °C for 10 h.

In contrast, Figure 4a shows the FFT pattern along the [111] zone axis of the same sample, which can also be indexed on the basis of the rutile crystal structure. However, the splitting of the main diffraction spots (marked by arrows) suggests the existence of twining. In the corresponding HRTEM image (Figure 4b), twin planes along (011) are observed. These straight twin boundaries are coherent and consist of Sn atoms shared by the two neighboring components of the twin.[8] Huang et al.[9] reported that the Sn sublattice is mirror symmetric to the coherent twin boundary (CTB), whereas the oxygen atoms forming octahedral cages around the Sn atoms are not mirror symmetric to the CTB.

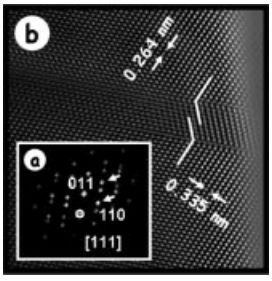

Figure 4. FFT pattern along the [111] zone axis (a) of a sample sintered in air at 1200 °C for 10 h and the corresponding HRTEM image (b), showing twin planes along (011).

Figure 5 corresponds to a different area of the same sample. The inset (Figure 5a) shows the corresponding FFT pattern along the [111] zone axis, which shows both splitting and streaking of the diffraction spots; this is indicative of high structural disorder, as it can be seen in the corresponding HRTEM micrograph (Figure 5b) where recurrent twinning and disorder intergrowths are observed. HRTEM characterization also shows that after annealing under an oxygen atmosphere at 900 °C, the density of defects decreases.

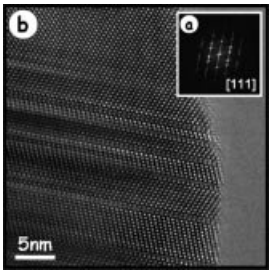

Figure 5. FFT pattern along the [111] axis (a) and HRTEM image showing structural disorder and recurrent twinnings (b) corresponding to a different area of the sample observed in Figures 3 and 4.

Alternatively, Figure 6a shows the SAED pattern of the sample treated at 1500 °C in air for 10 h. The diffuse rings indicate the presence of an amorphous phase. Moreover, the intensity and discrete spots in this FFT pattern (Figure 6b) suggest the presence of randomly oriented grains of very small dimensions. Figure 6c reveals a complex microstructure, where crystallized domains (dashed circle) in an amorphous matrix are observed. Therefore, in some crystals of this sample, interplanar distances of 0.48 nm were measured (Figure 7a), which corresponds to the *c* axis of the SnO phase. The inset (Figure 7b) shows the corresponding

FFT pattern. Notably, further thermal treatment at 900 °C under an oxygen atmosphere led to better recrystallization of the sample.

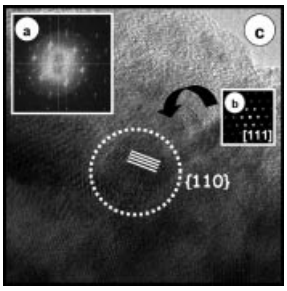

Figure 6. SAED (a) and FFT pattern (b) of a sample sintered in air at 1500 °C for 10 h. HRTEM image (c) reveals the presence of crystallized domains in an amorphous matrix.

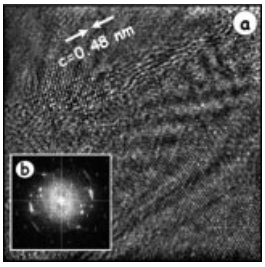

Figure 7. HRTEM image (a) of a sample sintered in air at 1500 °C for 10 h. The inset shows the corresponding FFT pattern.

As the presence of oxygen vacancies acting as donors determines the electrical properties of $SnO_2$, resistivity measurements were carried out. Results are presented in Table 1 and Figure 8.

Table 1. Evolution of the samples resistivity as a function of the sintering temperature and post annealing under an oxygen atmosphere at 900 °C.

| Temperature [°C] | Resistivity [Ω cm] | + $O_2$ (900 °C) |
|---|---|---|
| 1000 | $(0.9 \pm 0.2)\ 10^3$ | $(3.1 \pm 0.5)\ 10^4$ |
| 1100 | $(3.5 \pm 0.7)\ 10^3$ | |
| 1200 | $(2.3 \pm 0.4)\ 10^4$ | $(1.2 \pm 0.2)\ 10^4$ |
| 1300 | $(9.0 \pm 1.5)\ 10^5$ | |

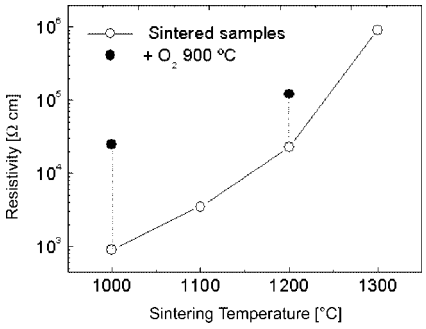

Figure 8. Resistivity of samples as a function of the sintering temperature and further annealing under an oxygen atmosphere at 900 °C.

The results show a rise in the resistivity as the temperature used during the sintering treatments was increased. Note that the *y* axis in Figure 8 is logarithmic-scaled, which denotes a faster increase in the resistivity at higher sintering temperatures. Moreover, the annealing process, which is performed under an oxygen atmosphere heated at 900 °C, also causes an increase in the resistivity, as shown in Figure 8. The samples sintered at temperatures above 1300 °C present a resistivity higher than $10^8\ \Omega$cm, but exact values could not be obtained with the experimental setup used.

## Discussion

The influence of oxygen vacancies ($V_O$) on the electrical conduction, structure, or luminescence properties of $SnO_2$ has been often considered, whereas the influence of Sn interstitials ($Sn_i$) is usually ignored. Different authors[4,10] have pointed out that oxygen vacancies are mainly responsible for several optical and electrical properties of $SnO_2$, and they act as shallow donor levels below the conduction band. Both donor defects, $V_O$ and $Sn_i$, can donate electrons to the conduction band without increasing the optical interband absorption, which explains the coexistence of conductivity and transparency in this material. Themlin et al.,[11] from their synchrotron results on the $SnO_2$ (110) surface, concluded the existence of states sensitive to oxygen chemisorption, situated 1.4 eV above the valence band top. These levels, related to the $Sn^{2+}$ cation and associated with the presence of oxygen vacancies, are compatible with the transitions leading to the 1.94 eV emission observed in the present work. Also, our previous studies[6] showed the connection between this emission and the oxygen vacancies. The fact that treatment of the sample under an oxygen atmosphere heated at 900 °C causes the intensity of the 1.94 eV band to decrease, also indicates an annealing-induced decrease in the vacancy concentration as a result of thermally activated oxygen diffusion. In the samples sintered at 1500 °C without additional treatments, the 1.94 eV CL emission hardly appears; therefore, subsequent oxygen treatments cannot affect this emission intensity as much as in the samples sintered at 1200 °C. The kinetics of the oxygen–$SnO_2$ reaction, as well as the oxygen diffusion mechanism, were previously investigated. Kamp et al.[12] concluded that at temperatures below 800 °C, only surface reactions like adsorption occurs, which is the diffusion process that is activated at higher temperatures. These processes would be related to a change in the oxidation state of the adsorbed oxygen at 450 °C,[13] which turns $O_2^-$ into $O^-$ (the latter being more reactive). Themlin et al.[11] observed that an increase in the temperature to 630 °C initiates the bulk-oxygen diffusion process. Our CL results (Figure 1) show a decrease in the 1.94 eV emission, related to the oxygen vacancies, that occurs during the treatment of the sample under an oxygen atmosphere heated at 900 °C, which agrees with these observations. Sintering at high temperatures, up to 1500 °C, results in the progressive disappearance of the oxygen vacancies' concentration, as suggested not only by

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the decrease in the 1.94 eV emission, but also for the charge effects appearing during the observations in SEM. The resistivity increase that is produced at higher sintering temperatures and during oxygen treatments, shown in Figure 8, agrees with a decrease in the vacancy concentration detected by the evolution of the 1.94 eV band. Indeed, perfectly stoichiometric samples are highly resistive.[14] Paria et al.[15] obtained similar resistivity results on sintered $SnO_2$ to those presented here. The crystallinity improvement produced by the oxygen treatments agrees with the well-ordered appearance observed in the HRTEM images. Conversely, sintering treatments can also increase the presence of defects (as shown in Figures 5 and 7), which reduces the carriers mobility, and the conductivity as well. Previous work confirms the decrease in the conductivity as the pressure and the oxygen content in the reactive atmosphere is increased.[16]

SAED and HRTEM analyses show that planar defects, such as recurrent twinning, stacking faults, and vacancies, are present in these samples. In addition, at high temperatures, the material seems to consist of both a polycrystalline $SnO_2$ phase and an amorphous SnO phase.[17] Moreover, the decomposition of $SnO_2$ into SnO, according to the reaction $SnO_2 \rightarrow SnO + V_O^-$, at high temperatures, has to be considered. These processes begin with the formation of intermediate phases, such as $Sn_3O_4$, SnO, and even metallic Sn, by internal oxygen disproportionate allocation, depending on the temperature and atmosphere conditions, as described by Cahen et al.[18] Many crystal defects, including twinning, crystallographic shear planes (CSP), stacking faults, and oxygen vacancies, are formed during these processes. In our case, the partial SnO formation was observed when the $SnO_2$ material was treated at high temperatures in air. Because both compounds are structurally related, it is reasonable to think that they can easily exist in the same crystal, as observed in samples treated at 1500 °C in air (Figure 7). In the $SnO_2$ rutile structure, each Sn atom has six oxygen neighbors, which form a distorted octahedral. The distance between the Sn and O atoms within one octahedron is 0.21 nm. In SnO, each Sn atom has four oxygen neighbors, but all of them are located on the same side of the Sn atoms, as shown by the pyramid consisting of one Sn atom and four O atoms in the SnO unit cell. The Sn–O bonds have a length of 0.222 nm. Accordingly, the $SnO_2$ phase can be easily transformed into the SnO phase by removing the O atoms from $SnO_2$ and by slightly adjusting the position of the Sn atoms. The formation of $Sn_i$ requires the rearrangement of its atomic environment by ionic relaxations resembling the local structure of SnO, which can also explain the observed SnO phase.

The sintered samples that were treated under an oxygen atmosphere were found mainly to consist of the $SnO_2$ phase. This shows that the SnO phase formed by the reduction of $SnO_2$ at high temperature is unstable under oxidation conditions and will be transformed into the $SnO_2$ rutile phase through an oxidation process. During this process, a decrease in the $V_O$ and $Sn_i$ concentration takes place along with an increase in resistivity.

## Conclusions

Sintering $SnO_2$ in air at high temperatures results in a high density of defects, as observed by SAED and HRTEM, as well as in the presence of the SnO phase which can be explained by $Sn_i$ formation. The sintering treatments modify the CL signal, mainly the 1.94 eV emission, which disappears at temperatures greater than 1500 °C. This emission, which has been associated with the presence of oxygen vacancies, is decreased during post sintering treatments under an oxygen atmosphere. This process governed by oxygen diffusion, was detected after treatments at 900 °C. The decrease in the $V_O$ concentration is associated with a large increase in resistivity. Annealing under an oxygen atmosphere at high temperatures improves the crystallinity of the samples and leads to the formation of a pure $SnO_2$ rutile phase.

## Experimental Section

The starting material used was commercial $SnO_2$ powder (Aldrich Chemical Company Inc., 99.9% purity). The powder, consisting of particles and aggregates of rounded particles with sizes of about 200 nm, was compacted under a compressive load of 2 tons to form disc-shaped samples that were about 7 mm in diameter and 2 mm thick. The samples were sintered in air for 10 h at temperatures between 1000 °C and 1500 °C and some of them were subsequently annealed for 2 h under an oxygen atmosphere at 600 °C and 900 °C.

The samples were observed in the secondary electron (SE) and cathodoluminescence (CL) modes with a Hitachi S-2500 or a Leica 440 SEM, at accelerating voltages ranging from 10 to 30 kV at a temperature of 80 K. The CL spectra were recorded either with the photomultiplier tube attached to an Oriel 78215 computer-controlled monochromator or with a CCD camera with a built-in spectrograph (Hamamatsu PMA-11). Resistivity measurements were performed by means of the Van der Pauw technique, in air and at room temperature. Structural information of the samples was obtained by X-ray diffraction (XRD) performed with a Philips diffractometer and high resolution transmission energy microscopy (HRTEM) with a JEOL 300 FEG electron microscope.

# Correlation between the Stoichiometry and the Bistability of Electronic States in Valence-Tautomeric $Rb_xMn[Fe(CN)_6]_y \cdot zH_2O$ Complexes

**Saioa Cobo,[a] Raquel Fernández,[a] Lionel Salmon,[a] Gábor Molnár,[a] and Azzedine Bousseksou*[a]**

**Keywords:** Prussian blue analogues / Magnetic properties / Phase transitions / Raman spectroscopy

A series of Prussian blue analogues, $Rb_xMn[Fe(CN)_6]_y \cdot zH_2O$ with different stoichiometries have been synthesized. Elemental analyses reveal a quasilinear decrease in *x* and *y* when *z* increases. Some of these samples present a first-order phase transition between the $Mn^{II}$–$Fe^{III}$ and $Mn^{III}$–$Fe^{II}$ electronic states with large thermal hysteresis loops observed in the magnetic susceptibility. The phase-transition temperatures correlate with the stoichiometry, but quantitative predictions cannot be made because of the disordered nature of the compounds. Contrary to previous literature reports, calorimetric and Raman spectroscopic measurements reveal that the charge-transfer phase transition is accompanied by a significant entropy change, $\Delta S = 48–59\ J\,K^{-1}\,mol^{-1}$, of mainly vibrational origin. In addition to the thermal phase transition, Raman spectra also show that below ca. 120 K a photoinduced $Mn^{III}$–$Fe^{II}$ to $Mn^{II}$–$Fe^{III}$ conversion occurs in certain stoichiometries.

## Introduction

The bistability of electronic states in transition-metal complexes represents an important field of research in coordination chemistry. The bistability in these compounds generally arises from strong electron-lattice couplings. Typical examples are spin crossover phenomena,[1,2] and valence-tautomerism.[3] In this latter class, valence-tautomeric Prussian blue analogues of transition metals with general formula $A_xM^{II}[M'^{III}(CN)_6]_y \cdot nH_2O$ (where A is an alkali metal cation, and M and M′ are divalent or trivalent transition-metal cations) have attracted considerable interest because of their remarkable magnetic properties, such as high Curie temperatures[4,5] or photomagnetic phenomena.[6–8] In some of these complexes, a first-order thermal phase transition was observed and associated with metal-to-metal electron transfer.[9,10] The compound $Rb_xMn[Fe(CN)_6]_y \cdot zH_2O$ shown in Figure 1 (noncoordinated water molecules and rubidium atoms are not represented) is one of the most studied members of this family.[10,11] It exhibits switching phenomena between the high-temperature (HT) $Fe^{III}$($S$ = 1/2)–CN–$Mn^{II}$($S$ = 5/2) and the low-temperature (LT) $Fe^{II}$($S$ = 0)–CN–$Mn^{III}$($S$ = 2) states that can be induced by changing the sample temperature or pressure as well as by light irradiation.[10–18] The two phases display markedly different magnetic, optical, and electric properties.

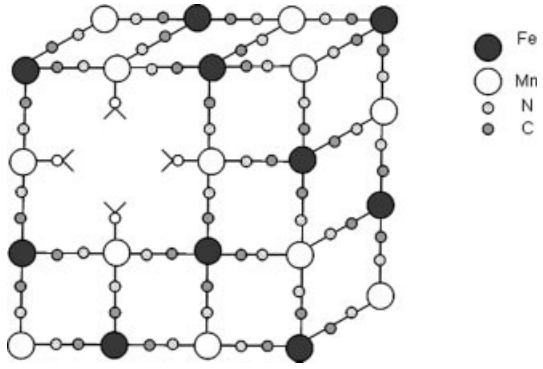

Figure 1. Schematic structure of $Rb_xMn[Fe(CN)_6]_y \cdot zH_2O$ with a $Fe(CN)_6^{3-}$ vacancy. (Noncoordinated water molecules and rubidium atoms are not represented.)

Even if $Rb_xMn[Fe(CN)_6]_y \cdot zH_2O$ has been the object of many investigations, several questions remain to be clarified. Notably, the control of the phase-transition temperature is an important issue because these compounds present very large thermal hysteresis loops (up to 138 K).[18] Such a large bistability domain is an appealing property for the application of these materials in various devices (e.g. memories). In preliminary results, Ohkoshi et al.[17] found a correlation between the hysteresis width and the stoichiometry of these compounds, but further measurements performed by the same group[18] and others[11] appear to escape this correlation. Another important question concerns the origin of the thermal phase transition. This question has been investigated extensively in the case of spin-crossover complexes and it is now generally accepted that thermal spin

crossover is an entropy-driven phenomenon and coupling between the electronic states and the phonon system plays a fundamental role.[19] Data on Prussian blue analogues are considerably less extensive.[20] However, it seems a reasonable assumption to attribute a similar importance to the vibrations because the most prominent structural changes in both cases are the metal–ligand bond length. Therefore, it is very surprising that the transition entropy for the title compound was found hardly of the order of the electronic entropy change.[10,21] This paper has been written in order to discuss these questions. In this aim, we have synthesized nine samples of different stoichiometry and characterized them by using Raman spectroscopy, elemental analysis, and magnetic and calorimetric measurements.

## Results and Discussion

### Stoichiometry and Magnetic Properties

Elemental analysis reveals significant differences between the different $Rb_xMn[Fe(CN)_6]_y{\cdot}zH_2O$ samples. For each compound, a chemical formula, taking into account the chemical arrangement of the system, the weight percentage of each element, and the electroneutrality, is proposed (Table 1). Figure 2 shows the $Rb^+$ ($x$) and $H_2O$ ($z$) content of each sample and those reported in refs.[11,17] as a function of the iron proportion. Clearly, independent of the synthetic method, a quasilinear correlation exists between these quantities, which can be understood as follows. In each case, the system contains a certain amount of $[Fe(CN)_6]^{3-}$ vacancies (Figure 1). The formation of these vacancies leads to a lower $Rb^+$ proportion ($x$) in order to maintain the charge neutrality. Indeed, the regression analysis shows that for each missing $[Fe(CN)_6]^{3-}$ unit, ca. three $Rb^+$ ions are removed from the crystal lattice. Moreover, the $H_2O$ content ($z$) increases because the water molecules complete the coordination around the $Mn^{II}$ ions at the place of the missing $[Fe(CN)_6]^{3-}$ entities and we can safely state that the non-stoichiometric crystal lattice contains a relatively large amount of noncoordinated water molecules as well. However, according to Figure 2b, the formation of one $[Fe(CN)_6]^{3-}$ vacancy leads to the uptake of ca. 22 water molecules; 6 of which would complete the coordination sphere of the $Mn^{II}$ ions at the place of the missing N atoms, and the remaining water molecules become encapsulated in the remaining cavities. Let us also note that the reproducibility of the synthesis (samples **7**–**9**) is relatively poor owing mainly to the extreme insolubility and the disordered nature of the sample.

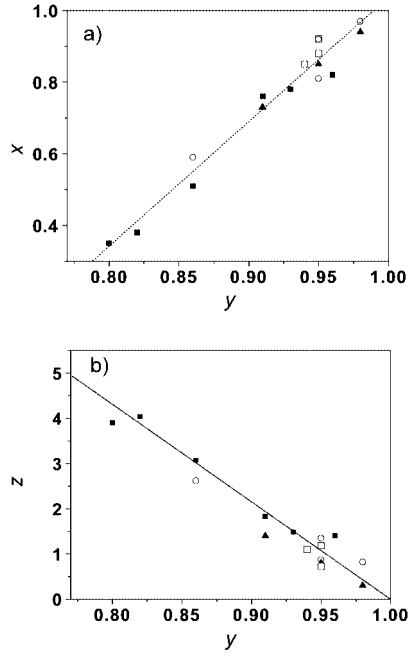

Figure 2. $Rb^+$ content (a) and $H_2O$ content (b) as a function of Fe content in $Rb_xMn[Fe(CN)_6]_y{\cdot}zH_2O$. (Full squares: samples **1**–**6**, open squares: samples **7**–**9**, open circles: data from ref.,[11] full triangles: data from ref.[17]) Straight lines represent linear fits on the data.

Figure 3 shows the product of molar magnetic susceptibility and the temperature for samples **1**–**9** as a function of temperature. One of the interesting points of the $\chi_M T$–$T$ plots is that the values for compounds **1**–**3** are around 5.0 $cm^3 mol^{-1}$ K for the whole range of temperatures, which indicates that the ground state consists mainly of the $Fe^{III}{}_{LS}$–CN–$Mn^{II}{}_{HS}$ configuration (HT phase). In contrast, the $\chi_M T$ value for compounds **4**–**6** and **7**–**9** varies significantly with the temperature and reveals a HT→LT phase transition with a large hysteresis loop. We can explain these results by using the arguments proposed for the first time in ref.[11] In the idealized formula Rb:Mn:Fe = 1:1:1 for $Rb_xMn[Fe(CN)_6]_y \cdot zH_2O$, the ground state is the $Fe^{II}{}_{LS}$–CN–$Mn^{III}{}_{HS}$ configuration, which remains stable up to ca. 300 K. Above this temperature, the $Fe^{III}{}_{LS}$–CN–$Mn^{II}{}_{HS}$ configuration becomes the thermodynamically stable phase because of its higher entropy (vide infra). On the contrary, in a nonidealized formula with vacant $Fe(CN)_6$ sites, oxygen atoms of the water molecule coordinate to the Mn ions instead of the nitrogen atoms of the cyanide, and the average environment of the manganese ions changes to $Mn^{III}(O_2H)_x(NC)_{6-x}$. As a result, the ligand field strength of the $Mn^{III}$ ions becomes weaker and consequently the redox potential of the $Mn^{III}/Mn^{II}$ couple increases leading finally to the oxidation of the $Fe^{II}$ ion. If the water content is sufficiently high, the redox potential increases to such an extent that the $Fe^{III}{}_{LS}$–CN–$Mn^{II}{}_{HS}$ form becomes stable at very low temperatures.

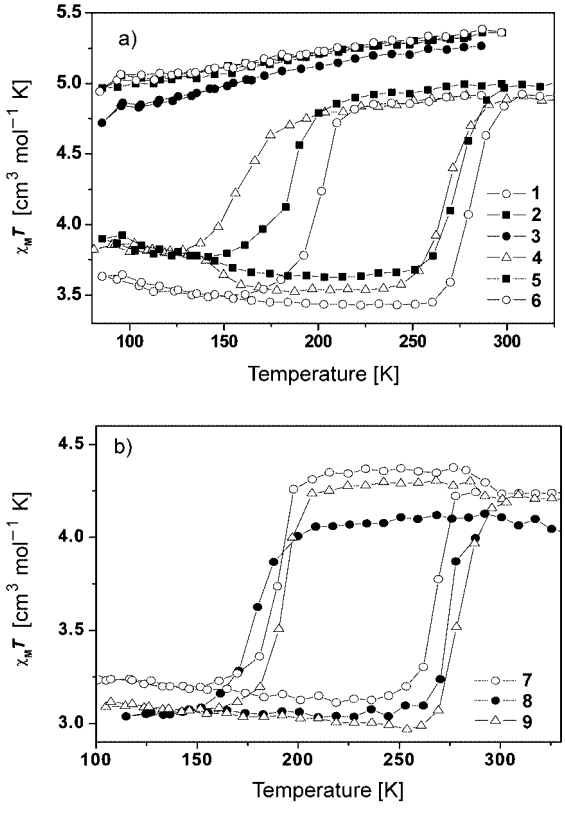

Figure 3. $\chi_M T$ versus $T$ curves for samples **1**–**6** (a) and **7**–**9** (b). (Data points are connected to guide the eye.)

The $\chi_M T$–$T$ curve for compound **4** decreases abruptly from 4.7 $cm^3 mol^{-1}$ K to 3.6 $cm^3 mol^{-1}$ K below 184 K upon cooling and, conversely, as the sample was warmed in the LT phase, the $\chi_M T$ value increased around 272 K and reached the HT value. The width of the thermal hysteresis loop (112 K) is defined by $T_{1/2}\downarrow$ = 160 K and $T_{1/2}\uparrow$ = 272 K. The $\chi_M T$–$T$ plots for sample **6** showed $\Delta T$ = 81 K, $T_{1/2}\downarrow$ = 201 K, $T_{1/2}\uparrow$ = 282 K, and for sample **5** $\Delta T$ = 87 K, $T_{1/2}\downarrow$ = 184 K, $T_{1/2}\uparrow$ = 271 K. This series of compounds agrees with Ohkoshi's proposition,[17] that is, the $\Delta T$ value increases as the Fe/Mn ratio decreases. To prove the reproducibility of the synthesis, and Ohkoshi's findings, we have synthesized three more compounds, **7**–**9**. Figure 4 shows the $\Delta T$, $T_{1/2}\downarrow$, and $T_{1/2}\uparrow$ values for each sample and for those reported in refs.[11,17] as a function of the $Rb^+$ proportion (although the relevant parameter is the Fe content, we have chosen to plot them as a function of the Rb content because [Fe] and [Rb] are proportional and the sample-to-sample changes in [Rb] are higher). This figure appears to indeed reveal some general trends. When decreasing the value of $x$ (i.e. the Rb content) from 0.97 to 0.73, the phase transition shifts from 301 K (240 K) to

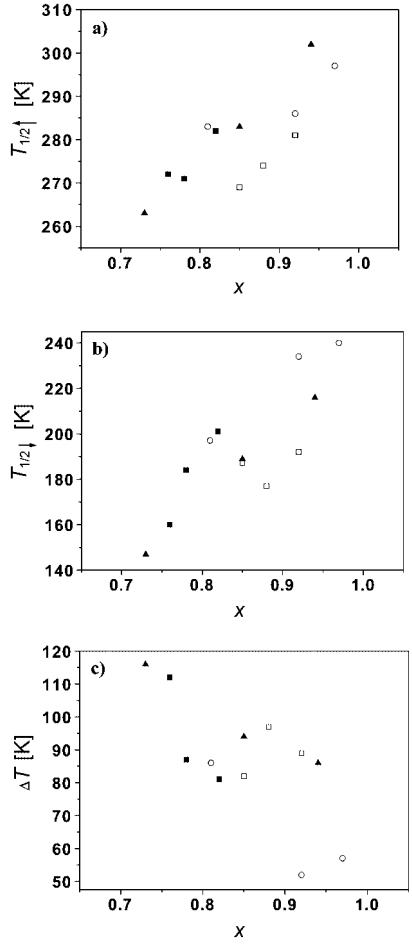

Figure 4. Phase transition temperatures in the heating (a) and cooling (b) modes and hysteresis width (c) as a function of the Rb content in $Rb_xMn[Fe(CN)_6]_y \cdot zH_2O$. (Full squares: samples **1**–**6**, open squares: samples **7**–**9**, open circles: data from ref.,[11] full triangles: data from ref.[17])

263 K (147 K) in the heating (cooling) cycles, and accordingly the hysteresis width increases. It is interesting to note that the increase in the hysteresis width is due to the fact that $T_{1/2}\downarrow$ changes more than $T_{1/2}\uparrow$. In fact, according to the Ising-like model developed in ref.,[22] the hysteresis loop width is proportional to $J/T_c$, where $J$ is a phenomenological parameter for the cooperativity and $T_c$ is the transition temperature. Because $T_c \cong (T_{1/2}\downarrow + T_{1/2}\uparrow)/2$, this inverse proportional relationship explains the increase in the hysteresis width when $T_{1/2}\downarrow$ decreases.

Nonetheless, the data are rather scattered and one can observe differences as much as 20–30 K for samples having the same composition. Let us also note that the sample reported in ref.,[18] which contains also an important amount of the reduced form, $Fe^{II}$–CN–$Mn^{II}$ escapes even the loose correlation seen in Figure 4. In summary, however, we find that the general tendency is the shift in the phase transition to lower temperatures with increasing deviations from the idealized (Rb:Mn:Fe = 1:1:1) stoichiometry. As explained above, this observation can be understood as a result of the weakening ligand field on the manganese ions and associated change of the redox properties. We believe that the fact that the correlation is rather vague is a result of the disordered nature of these compounds containing various types of defects in arbitrary distribution.

### Entropy Change on Phase Transition

As already mentioned, the valence-tautomeric thermal phase transition is entropy driven. The entropy change can be represented as the sum of electronic, vibrational, configurational, rotational, and translational terms. The two latter are excluded from consideration in the solid state. Moreover, in the absence of orientational disorder the configurational term can also be neglected. The electronic term may contain spin and orbital contributions. Assuming the idealized cubic symmetry of the Prussian blue structure, the LT phase [$Mn^{III}(^5E_g$)–$Fe^{II}(^1A_{1g})$] has a 2(orbital) × 5(spin) = 10-fold degeneracy, whereas the degeneracy of the HT phase [$Mn^{II}(^6A_{1g}$)–$Fe^{III}(^2T_{2g})$] is 3(orbital) × 12(spin) = 36-fold. This would lead to an electronic entropy change of $\Delta S_{el} = R\ln(36/10) = 10.6\ J\,K^{-1}\,mol^{-1}$. However, the orbital degeneracy of the $Mn^{III}$ ion is removed by the Jahn–Teller effect[10] and it is reasonable to assume also that in the non-stoichiometric disordered structures, the local symmetry around the iron atoms are not perfectly octahedral either, and therefore, the orbital moment of the $Fe^{III}$ ion is quenched, which leads to the $^5B_{1g}$ and $^2B_{2g}$ terms for $Mn^{III}$ and $Fe^{III}$, respectively. Then, one obtains the spin-only value of $\Delta S_{el} = R\ln(12/5) = 7.3\ J\,K^{-1}\,mol^{-1}$. This value is indeed quite close to the experimentally observed value of $6\ J\,K^{-1}\,mol^{-1}$.[10] However, it is well-known that the weakening of the metal–ligand bonds results in a strong increase in the vibrational partition functions.[23] In the case of $Rb_xMn[Fe(CN)_6]_y{\cdot}zH_2O$, the formation of the LT phase is accompanied by a discontinuous lattice contraction of ca. 10% and a reduction in the average Fe–Mn distance from 5.27 Å to 5.10 Å! Such a huge change in the bond lengths must lead to observable differences in the vibrational entropy. For this reason, we have carried out DSC measurements. Figure 5 shows the DSC curves of sample **7**, which exhibits singularities around 170 K and 280 K in the cooling and heating modes, respectively. These peaks clearly correspond to the charge-transfer phase transition. The enthalpy variation associated with the phase transition is $\Delta H = 11\ kJ\,mol^{-1}$. Then, assuming that $T_c \cong (T_{1/2}\downarrow + T_{1/2}\uparrow)/2 = 230$ K (calculated from the more accurate magnetic data), one obtains $\Delta S = \Delta H/T_c = 48\ J\,K^{-1}\,mol^{-1}$. Fairly similar results ($\Delta H = 13.6\ kJ\,mol^{-1}$, $\Delta S = 59\ J\,K^{-1}\,mol^{-1}$) were obtained for sample **6** as well, whereas sample **2**, which remains in the HT phase in the whole temperature range, showed no singularity in the calorimetric data. These results are therefore in significant disagreement with the results of other groups,[10,11] but seem to be more realistic for us taking into account the electronic and structural changes discussed above.

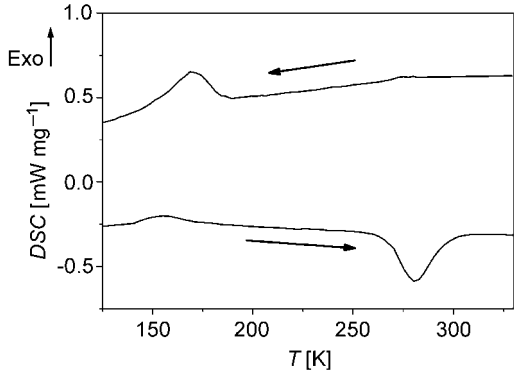

Figure 5. DSC curves of sample **7** in the heating and cooling cycles.

The calorimetric data strongly suggest that the phase transition is associated with a significant change in the vibrational entropy (ca. 40–50 $J\,K^{-1}\,mol^{-1}$), which should be obviously reflected by the vibrational spectra of the compound. Representative Raman spectra of **7** are shown in Figure 6. In agreement with previous IR spectroscopic data on this complex,[12] the CN stretching modes can be chosen to follow the electron transfer. In the HT phase, two intense Raman modes were observed around 2159 and 2170 $cm^{-1}$ and assigned to the stretching modes of the CN moiety bridged between $Fe^{III}$ and $Mn^{II}$. It should be also noted that the completely reduced form $Fe^{II}$–CN–$Mn^{II}$ of the compound was not observed in the Raman spectra. When decreasing the temperature, the spectra change drastically and at 120 K, two Raman modes are observed at ca. 2096 and 2114 $cm^{-1}$, which can be assigned to the stretching modes of the CN ligand linked to the $Fe^{II}$ and $Mn^{III}$ in the LT phase. The phase transition appears to be incomplete at low temperatures. CN stretching modes thus provide very useful diagnostic features concerning the electronic configuration of the system, but their contribution to the vibrational entropy is negligible as only the frequencies below ca. 600 $cm^{-1}$ can give significant contributions.[23] Low frequency Raman spectra in the two phases are shown in Fig-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ure 6b. Without isotope-substitution data, the assignment of these modes is not feasible, but we note that, according to literature data,[24] frequencies around 550, 450, and 200 $cm^{-1}$ in Prussian blue analogues can be attributed to $\nu$(FeC), $\delta$(FeCN), and $\delta$(CFeC) modes, respectively. Indeed, a number of modes appear around these frequencies. Although the former do not seem to be very sensitive to the actual electronic configuration, huge changes are observed at lower frequencies (180–320 $cm^{-1}$), which thus tend to support the large vibrational entropy changes revealed by the calorimetry data.

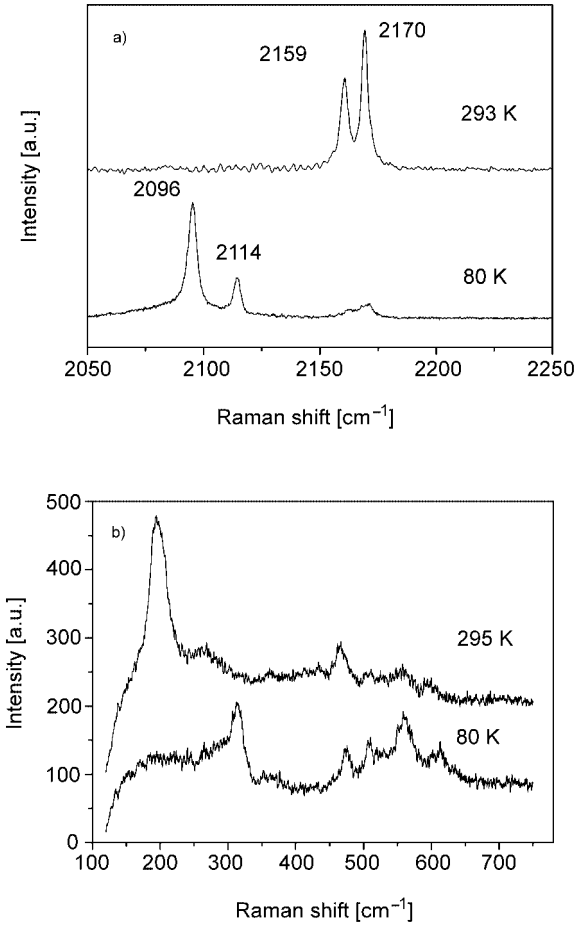

Figure 6. Raman spectra of sample **7** in the $\nu_{CN}$ (a) and low-frequency (b) regions at selected temperatures (cooling mode).

### Additional Raman Spectroscopic Data

During the Raman spectroscopic study, other interesting phenomena were uncovered as well. As the temperature is decreased below ca. 120 K in certain samples, the LT phase starts to transform back to the HT phase and at 80 K the Raman spectrum becomes fairly similar to the 293 K spectrum (Figure 7). In agreement with the observations made by Moritomo et al.,[16] this LT→HT transformation at low temperatures is clearly a photoinduced effect due to the laser light used to excite Raman scattering. However, this photoinduced effect was only observed in samples **4**–**6** and **8**, but no effect was detected at all in samples **7** and **9** (Figure 6). Note also that samples **1**–**3** cannot display such phenomenon as they remain in the HT phase down to 80 K. It was established by Escax et al.[7,8] that defects play an important role in the photoconversion efficiency in Co–Fe Prussian blue analogues. In fact, vacancies provide certain flexibility to the lattice and thus allow an easier relaxation of the lattice strain induced by the volume expansion during light irradiation. However, in our case it seems difficult to find a clear link between the occurrence of the photoinduced transformation and the sample stoichiometries (see Table 1). A detailed investigation of the temperature dependence of the photoconversion efficiency and the stability of the metastable phases down to liquid helium temperatures will be necessary to determine the pertinent parameters governing this phenomenon.

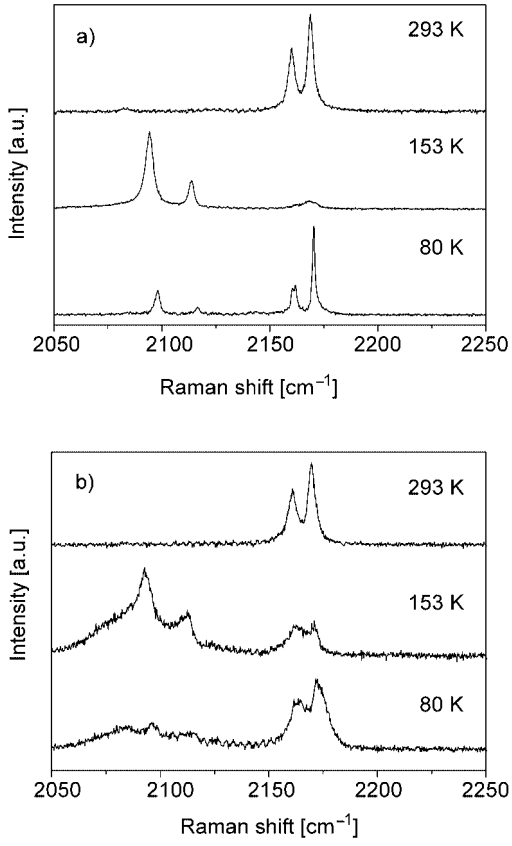

Figure 7. Raman spectra of sample **8** (a) and sample **5** (b) in the $\nu_{CN}$ frequency region at selected temperatures (cooling mode).

Figure 7 also shows that in sample **5** the Raman frequencies at low temperatures become extremely broad and unresolved. Such broadening of Raman modes can be expected as the degree of disorder increases as a result of the broader distribution in the bond lengths and the bond angles. Furthermore, as the disordered phase loses symmetry the associated selection rules may also change and one can also expect mode splittings and the appearance of modes, which are otherwise forbidden by the selection rules in the higher symmetry (i.e. more stoichiometric) forms. While in the LT phase the frequencies become badly re-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solved, the broadening of the modes in the HT phase can be used for diagnostic purposes as suggested by Vertelman et al.[11] In agreement with these authors, we observed that complexes exhibiting a conversion between the two valence-tautomeric forms show considerably narrower Raman linewidths in the CN-stretching region than complexes which do not present this phase transition (Figure 8).

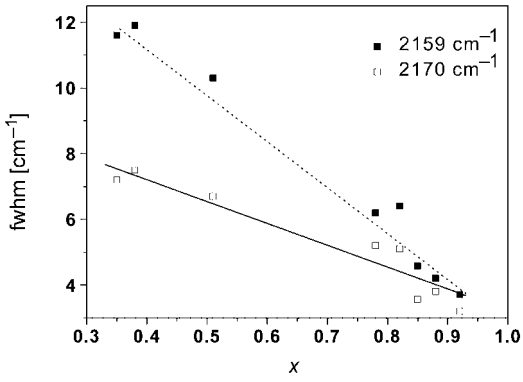

Figure 8. Full width at half maximum of selected Raman modes in $Rb_xMn[Fe(CN)_6]_y{\cdot}zH_2O$ at 298 K as a function of the Rb content. (Straight lines represent linear fits on the data.)

## Conclusions

We have synthesized a series of nonstoichiometric $Rb_xMn[Fe(CN)_6]_y{\cdot}zH_2O$ compounds, some of which display charge-transfer phase-transition phenomena as a function of their composition. We have found, independently of the reaction conditions, a fairly good quantitative correlation between the Rb, Fe, and $H_2O$ proportions, which can be explained by simple arguments based on the chemical arrangement of the system. The general tendency between the phase transition temperature and the sample stoichiometry, initially proposed by Ohkoshi et al.,[17] was confirmed. However, the quantitative correlation they propose was not observed probably because of the inherent disorder in these systems. Contrary to two independent reports,[10,21] we found that the phase transition is accompanied by an important change in the entropy of mainly vibrational origin, which is reflected in the huge changes observed in low frequency Raman spectra. Further work should address the question of the properties of the light-induced metastable phase, which was observed in the Raman spectra.

## Experimental Section

**Syntheses:** A solution of $MnCl_2{\cdot}4H_2O$ (Aldrich) in Millipore $H_2O$ (3 $cm^3$) was slowly mixed with a solution of $K_3Fe(CN)_6$ (Aldrich) and RbCl (Aldrich) in Millipore $H_2O$ (3 $cm^3$). All solutions were stirred mechanically and kept at a temperature of 50 °C during the addition procedure. A brown powder precipitate was filtered, washed with Millipore $H_2O$ and dried in air at room temperature. Nine different syntheses were realized (Table 2), six to observe the effect of concentrations (samples **1**–**6**) and three more to observe the reproducibility of the synthesis (samples **7**–**9**).

Table 2. Concentration of reactants used for the synthesis of different samples.

| Sample | $MnCl_2{\cdot}4H_2O$ [mol $dm^{-3}$] | RbCl [mol $dm^{-3}$] | $K_3Fe(CN)_6$ [mol $dm^{-3}$] |
|---|---|---|---|
| **1** | 0.11 | 0.48 | 0.1 |
| **2** | 0.14 | 1.01 | 0.1 |
| **3** | 0.1 | 2.03 | 0.1 |
| **4** | 0.06 | 1 | 0.1 |
| **5** | 0.11 | 1 | 0.1 |
| **6** | 0.07 | 1.02 | 0.1 |
| **7** | 0.11 | 1 | 0.1 |
| **8** | 0.11 | 1 | 0.1 |
| **9** | 0.06 | 1 | 0.1 |

**Microanalyses:** Analysis for C, H, and N were performed after combustion at 850 °C by using IR detection and gravimetry by means of a Perkin–Elmer 2400 series II device. Fe, Mn, Rb, and K concentration were determined with ICP–AES (Inductively Coupled Plasma Atomic Emission Spectroscopy) after acid digestion in $H_2SO_4/HNO_3$. Standard deviations of the measured metal concentrations were typically around 2 rel.%. The O and H atoms were assumed to be the only other elements present in the samples and the $H_2O$ content was obtained by difference to 100%. (The K concentration was found to be negligible.)

**Spectroscopy:** Raman spectra were collected between 300 K and 80 K with a LabRAM-HR (Jobin Yvon) Raman microspectrometer and a Linkam THMS-600 cryostage. The 632.8 nm line of a He–Ne laser was used as the excitation source and a spectral resolution of ca. 1 $cm^{-1}$ was obtained.

**Magnetic Studies:** Magnetic susceptibility measurements were carried out between 350–80 K by using a homemade Faraday-type magnetometer equipped with a continuous-flow Oxford Instruments cryostat. Measurements were done isothermally by steps of 10 K in 5 different magnetic fields between 4500 and 15000 Oe. Calibration of magnetic susceptibility was performed by using the reference compound $HgCo(SCN)_4$. Data were corrected for diamagnetic contributions.

**Differential Scanning Calorimetry (DSC):** DSC analysis was carried out with a Netsch DSC 204 instrument under helium purging gas (20 $cm^3\,min^{-1}$) at a scan rate of 10 $K\,min^{-1}$ both in heating and cooling modes. Temperature and enthalpy ($\Delta H$) were calibrated by using the melting transition of standard materials (Hg, In, Sn). The uncertainty in the transition enthalpy ($\Delta H_{HL}$) and entropy ($\Delta S_{HL}$) is estimated at ca. 10% because of the subtraction of the unknown baseline and uncertainties in the residual (i.e. nontransformed) fractions.

## Acknowledgments

S. Seyrac and J.-F. Meunier (LCC-CNRS) are acknowledged for CHN, DSC, and magnetic measurements. The ICP-AES analysis was made by the Service Central d'Analyse du CNRS (Vernaison).

# Synthesis, Characterization and Redox Behaviour of Mono- and Dicarbonyl Phosphane Rhenium(I) Complexes Bearing N-, N,N- and N,O-Type Ligands

**Alexander M. Kirillov,[a] Matti Haukka,[b] M. Fátima C. Guedes da Silva,[a] and Armando J. L. Pombeiro*[a]**

**Keywords:** Carbonyl ligands / Electrochemistry / N ligands / Rhenium

New mono- and dicarbonyl phosphane $Re^{I}$ complexes $[ReCl(L)_2(CO)(PPh_3)_2]$ {L = 3,5-$Me_2$-Hpz (**3**), quin (**4**)} and $[Re(L)_n(CO)_2(PPh_3)_2][BPh_4]_m$ {L = pz/Hpz, $n$ = 2, $m$ = 0 (**2**); L = 4,7-$Ph_2$-phen, $n$ = 1, $m$ = 1 (**5**); L = 2-Me-dipic, $n$ = 1, $m$ = 0 (**6**)} were prepared by reaction of the dinitrogen $Re^{I}$ precursor $[ReCl(N_2)(CO)_2(PPh_3)_2]$ (**1**), in refluxing methanol or methanol/benzene mixture, with 3,5-dimethylpyrazole (3,5-$Me_2$-Hpz), quinoline (quin), pyrazole (Hpz), 4,7-diphenyl-1,10-phenanthroline (4,7-$Ph_2$-phen) and dipicolinic acid ($H_2$dipic), respectively, with esterification of the latter in **6** to afford the 2-methoxycarbonyl-6-pyridinecarboxylate (2-Me-dipic) moiety. Complexes **2**–**6** were characterized by IR spectroscopy, $^{1}$H-, $^{31}$P{$^{1}$H}- and $^{13}$C{$^{1}$H} NMR spectroscopy, FAB-MS, cyclic voltammetry, elemental analyses and single-crystal X-ray diffraction (for **2**, **5** and **6**) analyses which indicate mutually *trans* triphenylphosphane ligands. The redox behaviour of the obtained complexes in solution was studied, and the Lever electrochemical ligand parameter $E_L$ was determined, for the first time, for 4,7-$Ph_2$-phen. Compounds **2**–**6** represent the first examples of *mono*- and *dicarbonyl* Re complexes bearing these types of ligands.

## Introduction

Dinitrogen complexes of rhenium are an important class of compounds within the low-oxidation-state coordination chemistry of this metal, particularly because of their significance in the field of nitrogen fixation and as versatile synthons for a variety of new rhenium derivatives.[1,2] The lability of the coordinated $N_2$ in Re complexes allows its displacement by a variety of small molecules (e.g., CO, $H_2$, $CS_2$, NO, nitriles, oximes, alkynes, azides, cyanates, etc.) and various P-, N-, O-, S- or mixed-donor ligands.[1,3] In this respect, the bis(diphosphane) complex *trans*-$[ReCl(N_2)(dppe)_2]$ {dppe = 1,2-bis(diphenylphosphanyl)-ethane} is the most studied member within the whole family of Re dinitrogen complexes.[1b,1e,1g,3a,3e,4] A few studies have been performed on the monophosphane analogues $[ReCl(N_2)(L)_4]$ (L = $PMe_2Ph$ or $PMePh_2$),[1b,5a,5b] whereas the reactivity of the related mixed $N_2$/CO complex $[ReCl(N_2)(CO)_2(PPh_3)_2]$ (**1**) appears to have been investigated only in a couple of cases; one instance involved its reactions with some amino acids conjugated with 2-aminothiazole (L) to afford monocarbonyl $Re^{II}$ complexes of the general formula $[ReCl(L)(CO)(PPh_3)_2]$.[5c] The other case led to the $Re^{I}$ dinitrogen compound $[Re(pic)(N_2)(CO)(PPh_3)_2]$ (pic = picolinate) by reaction of **1** with picolinic acid (Hpic),[6a] thus initially extending to the low $Re^{I}$ oxidation state (and to picolinate) our interest in higher-oxidation-state rhenium complexes with N- or O-ligands, namely some benzoyldiazenido-$Re^{III}$[6b] and oxo-$Re^{V}$[6c] compounds which were shown to act as catalysts for the peroxidative oxidation[6b] or carboxylation[6c] of alkanes. To further explore the use of **1** as a convenient precursor for the synthesis of new $Re^{I}$ compounds with N-, N,N- or N,O-ligands, we studied its reactions with various N-heterocycle species, that is, pyrazole, 3,5-dimethylpyrazole, quinoline, 4,7-diphenyl-1,10-phenanthroline and dipicolinic acid (Scheme 1), and we prepared and characterized a series of derived mono- and dicarbonyl complexes. Although heterocycle ligands of such types are rather simple and commonly used in coordination chemistry, their complexes with the monocarbonyl {Re(CO)} or dicarbonyl {$Re(CO)_2$} core are still very rare.[7] This contrasts with the tricarbonyl {$Re(CO)_3$} core, whose coordination chemistry was extensively developed over the last two decades,[8] with application in nuclear-medical research, in the preparation of photoluminescent materials, in catalysis and in supramolecular chemistry.[7a,9]

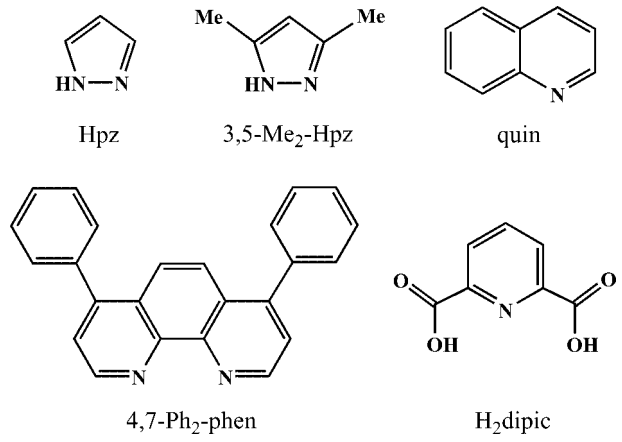

Scheme 1.

In particular, despite the fact that a number of *tricarbonyl* Re complexes with these ligands were already known,[10] to the best of our knowledge, there were no examples of *mono*- and *dicarbonyl* Re complexes comprising pyrazole, 3,5-dimethylpyrazole or quinoline ligands, as well as any phenanthroline or dipicolinate derivatives. The redox properties of the synthesized complexes were also investigated by cyclic voltammetry, and the value of the electrochemical Lever ligand parameter $E_L$[11] was estimated, for the first time, for the 4,7-$Ph_2$-phen ligand.

## Results and Discussion

### Synthesis and Spectroscopic Characterization

The reactions of the dinitrogen rhenium(I) complex $[ReCl(N_2)(CO)_2(PPh_3)_2]$ (**1**) with the N-heterocycle ligands of Scheme 1 in refluxing methanol or a methanol/benzene mixture led to the displacement of the $N_2/Cl^-$ ligands, or of the $N_2$ and one CO ligand in **1** (Scheme 2), thus allowing the formation of the new mono- and dicarbonyl rhenium(I) complexes $[ReCl(L)_2(CO)(PPh_3)_2]$ {L = 3,5-$Me_2$-Hpz (**3**), quin (**4**)} and $[Re(L)_n(CO)_2(PPh_3)_2][BPh_4]_m$ {L = pz/Hpz, $n$ = 2, $m$ = 0 (**2**); L = 4,7-$Ph_2$-phen, $n$ = 1, $m$ = 1 (**5**); L = 2-Me-dipic (2-methoxycarbonyl-6-pyridinecarboxylate), $n$ = 1, $m$ = 0 (**6**)}, which were isolated as air-stable crystalline solids in 78–44% yields. Hence, the reaction of **1** with pyrazole (Hpz, Scheme 2, reaction 1) gave the pale-yellow dicarbonyl complex $[Re(pz)(Hpz)(CO)_2(PPh_3)_2]$ (**2**) with one pyrazolate ($pz^-$) ligand and one pyrazole (Hpz) ligand, formed upon $N_2$ and HCl elimination, while the use of 3,5-dimethylpyrazole (3,5-$Me_2$-Hpz, reaction 2) led to the displacement of $N_2$ and one CO ligand, yielding the yellow monocarbonyl dipyrazole compound $[ReCl(3,5\text{-}Me_2\text{-}Hpz)_2(CO)(PPh_3)_2]$ (**3**). The related deep-purple monocarbonyl complex $[ReCl(quin)_2(CO)(PPh_3)_2]$ (**4**) was obtained by treatment of the starting material **1** with an excess of quinoline (quin, Scheme 2, reaction 3). The reactions of 4,7-diphenyl-1,10-phenanthroline (4,7-$Ph_2$-phen) and dipicolinic (2,6-pyridinedicarboxylic) acid ($H_2$dipic) with **1** (reactions 4, 5) led to the deep-red ionic Re compound $[Re(4,7\text{-}Ph_2\text{-}phen)(CO)_2(PPh_3)_2][BPh_4]$ (**5**) (upon addition of $Na[BPh_4]$) and the orange neutral complex $[Re(2\text{-}Me\text{-}dipic)(CO)_2(PPh_3)_2]$ (**6**), respectively. The complexes **2**–**6** were characterized by IR spectroscopy, FAB-MS, $^1$H-, $^{31}P\{^1H\}$- and $^{13}C\{^1H\}$ NMR spectroscopy, cyclic voltammetry, elemental analyses and single-crystal X-ray diffraction (for **2**, **5** and **6**) structural analyses.

Complex **2** bears both one Hpz ligand and its anionic conjugate base ($pz^-$). However, the $^1$H- and $^{13}C\{^1H\}$ NMR spectra show their magnetic equivalence as accounting for a single set of resonances attributable to proton or carbon atoms of both ligands. In the $^1$H NMR spectrum of **2**, the broad 1 H intensity N*H* signal at $\delta$ = 11.26 ppm is assigned to N–*H*···N, although the upfield shift relative to uncoordinated pyrazole [$\delta$(N*H*) = 13.60 ppm, $CCl_4$ (0.5 M)][12] cannot be directly related to the effects of the hydrogen bond and/or of a dynamic proton exchange since in other cases[10a] they led to lowfield shifts. The solid-state IR spectrum of **2** exhibits an intense ν(NH) band with a maximum at 3317 $cm^{-1}$, whose broad character is indicative of hydrogen bonding.

In contrast, both 3,5-$Me_2$-Hpz ligands are neutral in complex **3**. Its $^1$H NMR spectrum shows a 2 H intensity N*H* signal at $\delta$ = 11.06 ppm, which is also shifted upfield relative to free 3,5-dimethylpyrazole [$\delta$(N*H*) = 12.29 ppm, $CDCl_3$ (1.0 M)],[12] while the IR spectrum of this compound exhibits a ν(NH) band at 3222 $cm^{-1}$.

In complex **6** the dipicolinate ligand (2-Me-dipic) is bidentate, exhibiting N,O-coordination and one free arm whose esterification to give a methyl acetate moiety occurred during the synthesis in methanol solution, conceivably being promoted by the $Re^I$ centre since the methyl ester was not detected in a blank experiment upon refluxing dipicolinic acid in methanol for several hours in the absence of a metal complex. The same type of esterification was previously observed[6c] by us in the course of the synthesis of $Re^V$ complexes such as $[ReOCl_2(2\text{-}Me\text{-}dipic)(PPh_3)]$ and $[ReOCl\{(OCH_2CH_2)N(CH_2COO)(CH_2COOCH_3)\}(PPh_3)]$ derived from dipicolinic and *N*-(2-hydroxyethyl)iminodiacetic acids, respectively. The presence of the methyl ester group in **6** is corroborated by the detection of the corresponding $CH_3$ resonances in the $^1$H- ($\delta$ = 4.19 ppm) and $^{13}C\{^1H\}$ ($\delta$ = 53.91 ppm) NMR spectra. Moreover, the IR spectrum of **6** shows strong bands at 1740 and 1435 $cm^{-1}$ associated with $\nu_{as}$ and $\nu_s$ vibrations, respectively, of the COOMe fragment.

The $^{13}C\{^1H\}$ NMR spectra of the dicarbonyl complexes exhibit two *C*O signals, lying in the $\delta$ range of ca. 203–189 ppm for complexes **2** and **6**, whereas in **5** they are significantly shifted upfield to $\delta$ = 166.74 and 166.04 ppm. In the monocarbonyl complex **3** the corresponding *C*O resonance is observed at $\delta$ = 197.80 ppm. The $^{31}P\{^1H\}$ NMR spectra of all complexes **2**–**6** indicate the stereochemically favoured *trans* phosphane coordination in view of the single resonance detected in the $\delta$ range of ca. 32–20 ppm (relative to external $H_3PO_4$), which is shifted downfield from that ($\delta$ = –5.47 ppm) of free triphenylphosphane. These signals and all other NMR resonances of complexes **2**–**6** are unexcep-

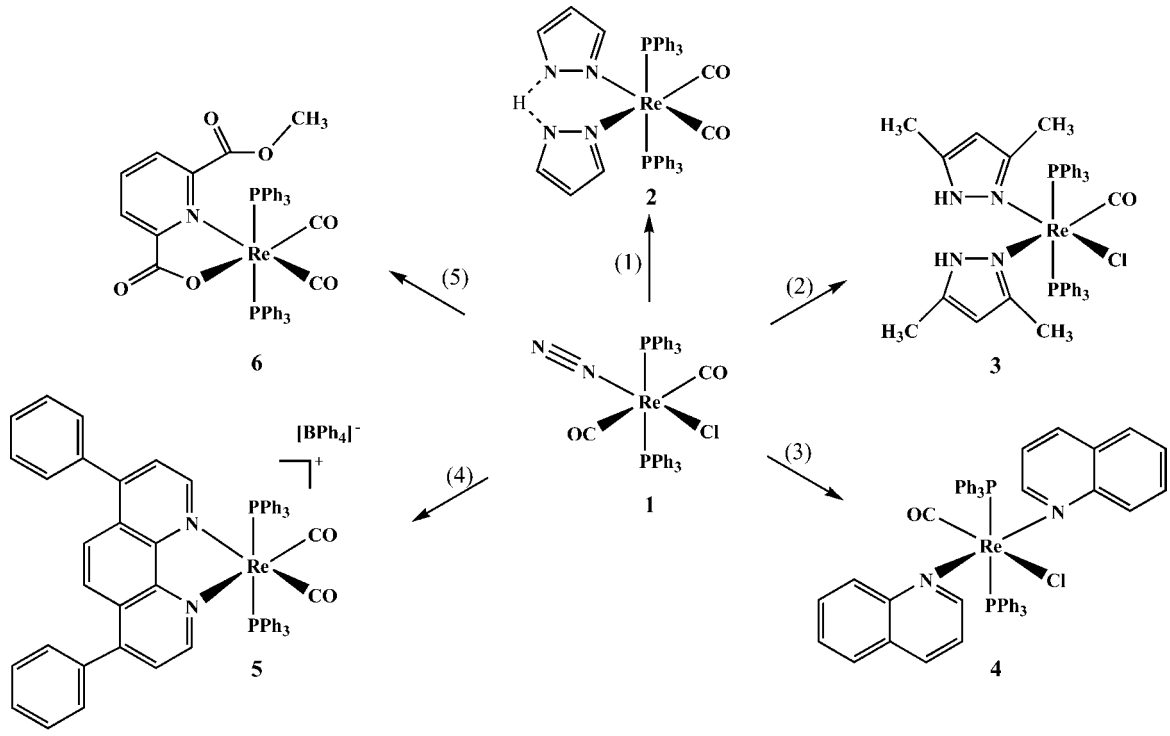

Scheme 2. (1): + Hpz – $N_2$ – HCl; (2): + 3,5-$Me_2$-Hpz – $N_2$ – CO; (3): + quin – $N_2$ – CO; (4): + 4,7-$Ph_2$-phen + Na[$BPh_4$] – $N_2$ – NaCl; (5): + $H_2$dipic – $N_2$ – HCl.

tional and comparable to those found in related rhenium complexes.[6,10a,10e–g,13]

The IR spectra of the dicarbonyl complexes **2**, **5** and **6** exhibit two strong ν(CO) bands in the 1929–1924 and 1853–1841 $cm^{-1}$ ranges, similar to those of the starting material **1** (1921 and 1844 $cm^{-1}$) and other dicarbonyl $Re^{I}$ complexes containing the *cis*-{$Re(CO)_2$} moiety, for example, [$Re(L)(CO)_2(PPh_3)_2$] {L = MeCOO or EtCOO;[14a] $OC(NH_2)S$, OC(NHPh)S or $OC(NHC_6H_4Me\text{-}4)S$}[14b] and [$Re(L)(CO)_2$(bipy)] {bipy = 2,2′-bipyridine, L = diethyl-2-(*N*-*p*-tolylimino)-3-(hydroxymethylene)butane-1,2-dicarboxylate}.[14c] An additional ν(CO) band is detected at 2032 $cm^{-1}$ in the spectrum of **2**, as observed with other rhenium carbonyl complexes comprising pyrazole moieties.[14d] Two strong ν(CO) bands at 1922 and 1839 $cm^{-1}$ are also shown by **3**, whereas in complex **4** the ν(CO) band is detected at 1778 $cm^{-1}$, being considerably shifted to a lower-energy region more typical for a bridging carbonyl group.[14e] Nevertheless, we believe that compound **4** is mononuclear and bears a terminal carbonyl ligand *trans* to the ligated $Cl^-$, as formulated in Scheme 2. This is in agreement with (i) an X-ray single-crystal diffraction analysis of **4** which indicates its basic and mononuclear structure, with the *trans*-CO/Cl arrangement, although with a too-high error to be reported, as well as with (ii) a FAB-MS(+) analysis which clearly detects the molecular ion [$ReCl(quin)_2(CO)(PPh_3)_2$]$^+$ as the heaviest observed fragment (see later). A low IR ν(CO) value (ca. 1800 $cm^{-1}$)[4e] was also found for the $Re^{I}$ monocarbonyl complex *trans*-[$ReCl(CO)(dppe)_2$] with the strong electron-donor chloro ligand which promotes the electron release from $d_\pi$ orbitals of the metal to the π*(CO) orbitals, as it also conceivably occurs in complex **4**. This is also assisted by the limited π-electron acceptance of the two quinoline ligands in comparison with the CO and $N_2$ ligands in compound **1**. The IR spectra of complexes **3**–**6** also show a set of bands due to the $\nu_{as}$ and $\nu_s$ vibrations of CH groups in the typical 3060–3050 and 3000–2925 $cm^{-1}$ ranges, respectively. The characteristic ν(PPh) bands due to the $PPh_3$ ligands are observed at 747–743 and 697–695 $cm^{-1}$.

The positive FAB-MS spectra of compounds **3**–**6** exhibit the molecular ions $[M]^+$ with the expected isotopic patterns at *m*/*z* values of 966, 1032, 1099 and 947, respectively, while the protonated molecular ion $[M + H]^+$ is detected at *m*/*z* = 903 in the spectrum of **2**. Fragmentation pathways involve the stepwise loss of CO, Cl and $PPh_3$ ligands as well as of N-, N,N- or N,O-moieties. A comparative analysis of peak intensities concerned with typical fragmentations suggests that in complexes **3**–**6** the elimination of one $PPh_3$ ligand is a favourable process, in agreement with the detection of very intense signals assigned to the [M – $PPh_3$] (in **3**, **4**), [M – $PPh_3$ – 2CO] (in **5**) and [M – $PPh_3$ – CO] (in **6**) fragments. In contrast, the release of one or two pyrazole ligands is more favourable in **2** since a set of intense peaks attributed to the [M – pz], [M – pz – CO], [M – pz – Hpz] and [M – pz – Hpz – CO] fragments is observed. The presence of the $[BPh_4]^-$ counterion in **5** is clearly confirmed by the negative FAB-MS spectrum (the intense signal of the $[M]^-$ molecular ion at *m*/*z* = 319 with the expected isotopic pattern) and by the IR spectrum. Also, elemental analyses

of all compounds are consistent with the proposed formulations (Scheme 2) which are further confirmed by single-crystal X-ray diffraction studies (for **2**, **5** and **6**).

### X-ray Crystal Structures

The molecular structures of complexes **2**, **5** and **6** are shown in Figures 1, 2 and 3, respectively, and selected bond lengths and angles are given in Table 1. All compounds crystallize in the monoclinic crystal system (space group $P2_1/n$) and exhibit a distorted octahedral coordination environment about rhenium filled by the N-, N,N- or N,O-ligand(s), two triphenylphosphane groups and two carbonyl groups.

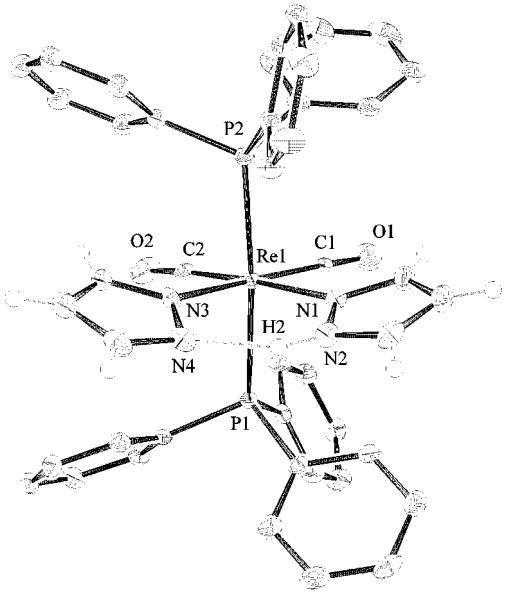

Figure 1. An ORTEP representation of **2** with ellipsoids shown at the 50% probability level. Phenyl hydrogen atoms are omitted for clarity.

The molecular structure of **2** (Figure 1) shows the $pz^-$ and Hpz ligands *trans* to the carbonyl groups. The Re1–C1 and Re1–C2 bond lengths of 1.920(4) and 1.893(4) Å, respectively, are common for rhenium carbonyl complexes,[10a,10d–g,15] while the carbonyl C1–O1 and C2–O2 distances of 1.141(5) and 1.162(5) Å, respectively, are comparable to the C≡O bond of ca. 1.128 Å[16] in molecular carbon monoxide. The binding of the Hpz/$pz^-$ ligands to rhenium is characterized by a slight difference between the Re1–N1 [2.219(3) Å] and Re1–N3 [2.176(3) Å] bond lengths which agree with those reported for other rhenium carbonyl complexes comprising pyrazole or hydrotris(pyrazolyl)-borate $[HB(pz)_3]^-$ derivatives, for example, $[Re(pz)(Hpz)_2(CO)_3]$,[10a] $[Re\{HB(pz)_3\}(CO)_2L]$ (L = THF or $PPh_3$)[15b] and $[\{Re(B(Hpz)_3)(CO)_2\}_2(N_2)]$.[17] Although only one NH proton is crystallographically localized at one of the pyrazole moieties of **2**, its assignment to the N2 atom is rather formal and in reality it may be split between N2 and N4. This agrees with the observation of a rather short N2–H2···N4 intramolecular hydrogen bond with N2···N4 distance of 2.627(5) Å [N2–H2 0.94(4) Å and H2···N4 1.74(5) Å; N2–H2···N4 156(4)°], which connects two pyrazole groups forming the Re1–N1–N2···N4–N3 ring with the N1–Re1–N3 angle of 89.22(12)°. Related features of the NH protons assignment and splitting, and the hydrogen-bonding interactions within the Hpz and $pz^-$ fragments were observed in some Re, Ru, Co, Pd, Pt and Zn complexes.[10a] The triphenylphosphane groups are bound almost linearly, and the Re–P distances range from 2.4251(10) to 2.4453(10) Å being comparable to those of compounds **5** and **6** and in accordance with those reported for other carbonyl rhenium complexes with *trans* $PPh_3$ ligands.[14a,18]

| C2–Re1–O3 | – | – | 176.63(18) |
| N1–Re1–N2 | – | 75.73(14) | – |
| N1–Re1–N3 | 89.22(12) | – | – |
| N1–Re1–O3 | – | – | 74.51(16) |
| C1–Re1–P1 | 90.65(11) | 89.78(14) | 89.19(14) |
| C2–Re1–P1 | 84.02(12) | 90.66(17) | 90.87(16) |
| C1–Re1–P2 | 91.66(11) | 88.90(14) | 89.18(14) |
| C2–Re1–P2 | 91.69(12) | 91.74(17) | 91.35(16) |
| N1–Re1–P1 | 92.24(9) | 89.94(10) | 90.37(11) |
| N1–Re1–P2 | 92.07(9) | 90.90(10) | 90.95(11) |
| P1–Re1–P2 | 175.26(3) | 177.36(4) | 177.13(5) |
| Re1–C1–O1 | 176.6(3) | 179.2(6) | 176.9(5) |
| Re1–C2–O2 | 175.8(4) | 178.2(8) | 176.1(5) |

The major deviation from the octahedral geometry in **2** concerns the C2–Re1–P1 angle of 84.02(12)°; the other bond angles are relatively close to the idealized 90° and 180°.

Compound **5** is the first structurally characterized example with the 4,7-diphenyl-1,10-phenanthroline ligand within the large family of phenanthroline Re complexes. Its molecular structure comprises the $[Re(4,7\text{-}Ph_2\text{-}phen)(CO)_2(PPh_3)_2]^+$ cation and the $[BPh_4]^-$ anion, with the separation between rhenium and boron centres being ca. 8.91 Å. The cationic part also contains two phosphane ligands in *trans* position, whereas the equatorial sites are occupied by the bidentate phenanthroline ligand and the two carbonyl groups (Figure 2). The octahedral environment around rhenium is more distorted than that of complex **2**, exhibiting a major deviation from an idealized geometry with a minimal N1–Re1–N2 angle of 75.73(14)°. The Re1–C1 and Re1–C2 bonds of 2.004(6) and 2.042(7) Å, respectively, are lengthened by ca. 0.10–0.15 Å relative to the corresponding distances in **2** and other complexes with a phenanthroline moiety.[10d–g,15a] Such an elongation of the Re–C distances is concomitant with the shortening of the C1–O1 and C2–O2 bonds to 0.977(6) and 0.860(6) Å, respectively; the latter distance is unusually short and this is not reflected in ν(CO) which is comparable to the other complexes. The phenanthroline molecule is bound to the metal forming a N1–C13–C14–N2–Re1 chelate ring, and the Re1–N1 and Re1–N2 bonds of 2.162(4) and 2.147(4) Å, respectively, lie in the range of ca. 2.14–2.22 Å reported for other phenanthroline Re complexes.[10d–g,15a]

The structure of **6** (Figure 3), with a chelating methyldipicolinate ligand, is similar to that of **2** comprising the pyrazolate/pyrazole ligands in the equatorial sites. In the monoesterificated dipicolinate ligand, the nitrogen N1 is *trans* to the C1–O1 carbonyl group and the carboxylate oxygen O3 is *trans* to the C2–O2 ligand, forming a Re1–N1–C3–C4–O3 chelate ring with a N1–Re1–O3 bite angle of 74.51(16)° which is the most deviated angle from the idealized 90° around the distorted octahedral geometry of the Re1 centre. The bond lengths within the dipicolinate moiety in **6** are analogous to those of $[ReBr\{C_5H_3N(COOEt)(COOMe)\}(CO)_3]$[10i] and $[ReOCl_2(2\text{-Me-dipic})]$,[6c] although the latter contains a rather short Re–$O_{dipic}$ bond [2.037(2) Å] relative to the corresponding Re1–O3 distance of 2.176(4) Å in **6**. The Re1–C1 [1.918(6) Å] and Re1–C2 [1.887(7) Å] bonds as well as the C1–O1 [1.126(6) Å] and C2–O2 [1.167(7) Å] distances in **6** are standard and very close to those of **2** (Table 1) and other carbonyl rhenium complexes.[10a,10d–g,15] In the structure of **6**·EtOH, O–H···O hydrogen-bonding interactions are observed between the dipicolinate oxygen O4 and the hydroxy group of the ethanol crystallization molecule [O99···O4 2.671(8) Å], as well as between two ethanol molecules from adjacent units [O99···O99 2.869(2) Å].

## Electrochemical Studies

Complexes **2**, **3**, **5** and **6** exhibit, by cyclic voltammetry at a Pt electrode in 0.2 M $[nBu_4N][BF_4]/CH_2Cl_2$ solution, a first single-electron reversible (or quasireversible) (for **2** and **5**) or irreversible (for **3** and **6**) oxidation at ${}^{I}E_{1/2}{}^{ox}$ = 0.67 (**2**) and 1.22 (**5**) V or ${}^{I}E_{p}{}^{ox}$ = 0.75 (**3**) and 0.87 (**6**) V vs. SCE (Table 2, Figure 4 for **5**), assigned to the $Re^{I} \rightarrow Re^{II}$ oxidation, followed by a second reversible (for **2** and **3**) or irreversible (for **6**) oxidation at close potentials (1.00 to 1.15 V vs. SCE), most likely caused by the $Re^{II} \rightarrow Re^{III}$ oxidation. A third irreversible oxidation wave is also observed for compounds **2**, **3** and **6** at a higher potential (ca. 1.34–1.43 V vs. SCE). Complex **4** could not be studied by cyclic voltammetry because of its instability in the solvent/electrolyte medium.

For the quasireversible waves, increasing the scan rate from 0.2 to 0.5 or 1.0 $V s^{-1}$ usually led to an enhancement of the degree of reversibility. The oxidation potentials of the neutral complexes **2**, **3** and **6** are lower than the corresponding potentials for the starting compound **1** (${}^{I}E_{1/2}{}^{ox}$ = 0.94, ${}^{II}E_{p}{}^{ox}$ = 1.79 V vs. SCE, measured[6a] under identical experimental conditions). This confirms the stronger electron-donor character of the N- and N,O-ligands in **2**, **3** and **6** relative to ligated $Cl^-$ + $N_2$ or $N_2$ + CO in **1**, in agreement with the π-electron-acceptor character of $N_2$ and CO. The highest oxidation potential is observed for $[Re(4,7\text{-}Ph_2\text{-}phen)(CO)_2(PPh_3)_2]^+$ in **5** (${}^{I}E_{1/2}{}^{ox}$ = 1.22 V vs. SCE) on account of its positive charge.

In addition, compounds **5** and **6** show (Table 2, Figure 4 for **5**) one reversible reduction wave at an unusually high potential (${}^{I}E_{1/2}{}^{red}$ = –0.01 and –0.18 V vs. SCE, respec-

Table 2. Cyclic voltammetric data for the $Re^{I}$ complexes.[a]

| | ${}^{I}E_{1/2}^{ox}$ (${}^{I}E_{p}^{ox}$) | ${}^{II}E_{1/2}^{ox}$ (${}^{II}E_{p}^{ox}$) | (${}^{III}E_{p}^{ox}$) | ${}^{I}E_{1/2}^{red}$ | ${}^{II}E_{1/2}^{red}$ |
|---|---|---|---|---|---|
| **1**[b] | 0.94 | (1.79) | – | – | – |
| **2**[c] | 0.67 | 1.00 | (1.41) | – | – |
| **3**[d] | (0.75)[e] | 1.00 | (1.34) | – | – |
| **5**[f] | 1.22 | – | – | –0.01 | –1.21 |
| **6** | (0.87) | (1.15)[e] | (1.43) | –0.18 | –0.57 |

[a] Values given in V ± 0.02 vs. SCE ($CH_2Cl_2$/[$n$Bu$_4$N][$BF_4$], $v$ = 0.2 V s$^{-1}$, for further details see Exp. Sect.); $E_{1/2}$ corresponds to half-wave potential of reversible or quasireversible wave; peak potentials ($E_p$) for irreversible waves are given in brackets. [b] Included for comparison from ref.[6a] [c] Two new reduction waves at $E_p^{red}$ = –0.30 V and $E_{1/2}^{red}$ = –0.79 V (not observed in initial oxidation and reduction scans) appeared over time, conceivably caused by decomposition products. [d] Two new reduction waves at $E_{1/2}^{red}$ = –0.21 V and $E_{1/2}^{red}$ = –0.70 V (not observed in initial oxidation and reduction scans) appeared over time, conceivably caused by decomposition products. [e] This wave becomes quasireversible at higher scan rates ($v$ = 0.5 or 1.0 V s$^{-1}$). [f] An additional wave was observed at $E_p^{ox}$ = 0.97 V as a result of the oxidation of the counterion [$BPh_4$]$^-$.

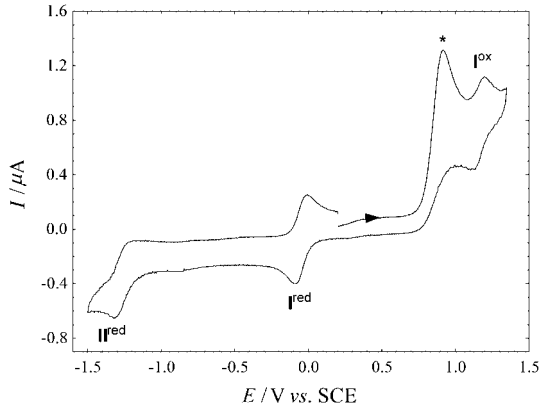

Figure 4. Cyclic voltammogram of [Re(4,7-$Ph_2$-phen)(CO)$_2$($PPh_3$)$_2$]-[$BPh_4$] (**5**) ($8.5 \times 10^{-4}$ mol L$^{-1}$), in 0.2 M [$n$Bu$_4$N][$BF_4$]/$CH_2Cl_2$, at a Pt working electrode and at a scan rate of 0.2 V s$^{-1}$; * wave due to the oxidation of the counterion [$BPh_4$]$^-$.

tively), followed by a second quasireversible reduction wave at ${}^{II}E_{1/2}^{red}$ = –1.21 (**5**) and –0.57 (**6**) V vs. SCE. The evidence for considering the wave at $E_{1/2}$ = –0.01 V vs. SCE in compound **5** as a reduction wave is apparent from its position in the $I$ (current) scale in the cyclic voltammogram (Figure S1 in the Supporting Information). Further proof is provided by controlled potential electrolysis (CPE) at a potential slightly lower than that of $I^{red}$ (i.e., at –0.30 V), which led to a colour change of solution (i.e., from deep brown to clear green), while neither alteration in colour was detected nor charge was measured upon attempted CPE at a potential above that of the same wave.

According to literature data for other $Re^{I}$ compounds with aromatic N-heterocycle ligands[7b,19–22] (e.g., [{ReCl(CO)$_3$}$_2$(ddpq)] {ddpq = 6,7-dimethyl-2,3-bis(2-pyridyl)quinoxaline}, [Re(bpa)(bqu)(CO)$_3$]$^+$ {bpa = 1,2-bis(4-pyridyl)ethane, bqu = 2,2′-biquinoline}, [Re(bpy)(4,4′-bpy)(CO)$_3$]$^+$ {bpy = 2,2′-bipyridine, 4,4′-bpy = 4,4′-bipyridine}, etc.),[19,20] the waves (one or two) observed at less negative potentials (i.e., from –0.2 to –1.1 V vs. SCE) are expected to correspond to N,N(N,O)-ligand-centred reductions, whereas the waves at more negative potentials can be assigned to the $Re^{I} \rightarrow Re^{0}$ reduction. Although our measured less-negative potentials are considerably higher than most of those in the literature, they are comparable to, for example, $E_{1/2}^{red}$ = –0.24 V vs. SCE reported for a ligand-centred process in [{Re(CO)$_3$(CH$_3$CN)}$_2$(ppz)]$^{2+}$ (ppz = 4′,7′-phenanthrolino-5′,6′:5,6-pyrazine).[20] However, one should mention that the free 4,7-$Ph_2$-phen species does not show any waves in the window from –2.0 to +2.0 V vs. SCE.

The possible ligand-centred character of the $I^{red}$ wave (Figure 4) is also supported by the UV/Vis spectrum of **5** recorded in $CH_2Cl_2$ solution, which reveals the presence of a rather broad and intense ($\varepsilon \approx 9200$ L mol$^{-1}$ cm$^{-1}$) band with a maximum at ca. 400 nm, most likely related to a metal-to-ligand charge-transfer (MLCT) process and in agreement with reported data for $Re^{I}$ systems with polypyridyl ligands.[7b,20–22] For example, MLCT bands with a rather close absorption maximum and intensity have been observed for [Re(bpy)(py)(CO)$_2${P(OEt)$_3$}][$PF_6$][7b] (bpy = 2,2′-bipyridine, py = pyridine) ($\lambda_{max}$ = 397 nm), [Re(bpy)(CO)$_2$($PPh_3$)$_2$][$PF_6$][7b] ($\lambda_{max}$ = 401 nm), [Re{(CF$_3$)$_2$-bpy}(CO)$_2${P(OEt)$_3$}$_2$][$PF_6$][7b] {(CF$_3$)$_2$bpy = 4,4′-bis(trifluoromethyl)bipyridine} ($\lambda_{max}$ = 404 nm) and [ReCl(bppz)-(CO)$_3$][20] {bppz = 2,3-bis(2-pyridyl)pyrazine} ($\lambda_{max}$ = 417 nm).

The measured first oxidation potential (upon conversion to the NHE scale) for the rhenium(I) complex [Re(4,7-$Ph_2$-phen)(CO)$_2$($PPh_3$)$_2$]$^+$ in **5** (${}^{I}E_{1/2}^{ox}$ = 1.22 V vs. SCE, i.e., 1.22 + 0.245[11] = 1.47 V vs. NHE) was applied to calculate the electrochemical Lever $E_L$ parameter[11,23] for the 4,7-$Ph_2$-phen ligand according to the Lever's equation (1), valid for octahedral complexes, where $\sum E_L$ is the sum of the $E_L$ values for all the ligands, and $S_M$ and $I_M$ are standard parameters dependent on the metal redox couple, spin state and stereochemistry.[11]

$$E = S_M(\sum E_L) + I_M, \text{ V vs. NHE} \quad (1)$$

Thus, applying the corresponding $S_M$ = 0.76 and $I_M$ = –0.95 V vs. NHE values for the $Re^{II/I}$ couple[11b] and the $E_L$ values for the CO and $PPh_3$ ligands ($E_L$ = 0.99 and 0.39 V vs. NHE, respectively),[11a,23] we have estimated, for the first time, the value of the electrochemical Lever ligand parameter, $E_L$ = 0.21 V vs. NHE, for each binding arm of the 4,7-$Ph_2$-phen ligand. This value is comparable to those previously established[11a,23] for monodentate 1,10-phenanthroline ($E_L$ = 0.26 V vs. NHE) and 4,7-dimethyl-1,10-phenanthroline ($E_L$ = 0.23 V vs. NHE) ligands.

## Conclusions

This study shows that the mixed dinitrogen-dicarbonyl complex [ReCl(N$_2$)(CO)$_2$($PPh_3$)$_2$] (**1**) constitutes a convenient starting material for the synthesis of new low-oxidation-state Re complexes bearing N-, N,N- or N,O-ligands with unsaturated N-heterocycle groups coordinated to {Re(CO)} or {Re(CO)$_2$} centres. It is thus possible to open

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a suitable entry to mono- and dicarbonyl Re complexes with such types of ligands, allowing the extension to the $\{Re(CO)_n\}$ ($n$ = 1 or 2) centres of the rich coordination chemistry that is being developed for complexes with the tricarbonyl $\{Re(CO)_3\}$ site[8] which has found applications in various fields such as nuclear medicine, pharmacology, photoluminescent materials, supramolecular chemistry and catalysis.[7a,9]

It is also necessary to mention that the axial bisphosphane *trans*-$\{Re(PPh_3)_2\}^+$ core in complex **1** remains during the substitution reactions which involve only the equatorial $N_2$/CO/$Cl^-$ ligands. The observed behaviour can be accounted for by a combination of various factors, namely the usual lability of the dinitrogen ligand (a rather weak σ-electron donor),[24] the labilization of the chloro ligand upon loss of $N_2$ (a π-electron acceptor that, when *trans* to $Cl^-$, enhances the electron release from the latter to the metal), the strong *trans* influence of the effective π-acceptor CO ligands in *trans* position (with their resulting mutual labilization), the protic-acid character of the new ligand precursor and the chelating effect of a possible bidentate new ligand.

Hence, on reactions of **1** with acidic N-heterocycle ligands (pyrazole or dipicolinic acid, reactions 1 and 5, respectively), $N_2$ and $Cl^-$ are the replaced ligands (the substitution of the latter being assisted by protonation), whereas the reactions of **1** with nonacidic and nonchelating N-heterocycle ligands (3,5-dimethylpyrazole and quinoline, reactions 2 and 3, respectively) occur by displacement of $N_2$ and one CO ligand. Chelation of the new ligand(s) leads to CO *trans*-to-*cis* isomerization with the formation of *cis*-dicarbonyl products (reactions 1, 4 and 5) from the *trans*-dicarbonyl starting complex **1**. However, *cis*- to *trans*-Cl/CO isomerization can occur (reaction 3) with a nonchelating bulky ligand, resulting in a particularly favourable π-donor/π-acceptor interaction between the former ligands (compound **4**).

The synthetic significance of those observations, namely in terms of selectivity, deserves further exploration, by taking advantage of the versatile structural/electronic features of the mixed $N_2$/CO complex **1** as demonstrated in this study.

## Experimental Section

### General Materials and Procedures

All synthetic work was performed under dinitrogen using standard Schlenk techniques. The solvents were dried and degassed by standard methods. Potassium perrhenate (Merck), triphenylphosphane (Aldrich), benzoylhydrazine (Aldrich), carbon monoxide (Air Products), pyrazole (Aldrich), 3,5-dimethylpyrazole (Aldrich), quinoline (Merck), 4,7-diphenyl-1,10-phenanthroline (Aldrich), sodium tetraphenylborate (Aldrich) and 2,6-pyridinedicarboxylic acid (Aldrich) were obtained from commercial sources and used as received. $[ReCl(N_2)(CO)_2(PPh_3)_2]$ (**1**) was prepared by a published method.[1g]

C, H and N elemental analyses were carried out by the Microanalytical Service of the Instituto Superior Técnico. The FAB mass spectra were obtained with a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (*m*-NBA) matrices of the samples with 8 keV (ca. 1.18 $10^{15}$ J) Xe atoms. Mass calibration for data system acquisition was achieved using CsI. Infrared spectra (4000–400 $cm^{-1}$) were recorded with a Jasco FT/IR-430 instrument in KBr pellets. $^1H$-, $^{31}P\{^1H\}$- and $^{13}C\{^1H\}$ NMR spectra were measured with a Varian UNITY 300 spectrometer at ambient temp. The $^{31}P$ chemical shifts are relative to external 85% $H_3PO_4$ aqueous solution. UV/Vis spectra were recorded with a Jasco model 7800 UV/Vis spectrophotometer.

The electrochemical experiments were carried out with an EG&G PAR 273A potentiostat/galvanostat connected to a personal computer through a GPIB interface. Cyclic voltammetry (CV) studies were undertaken in a two-compartment three-electrode cell, at platinum-wire working electrode (d = 0.5 mm) and counter electrodes, in 0.2 M $[nBu_4N][BF_4]/CH_2Cl_2$ solution. A Luggin capillary connected to a silver-wire pseudoreference electrode was used to control the working electrode potential. Controlled potential electrolysis (CPE) experiments were carried out in electrolyte solutions with the mentioned composition, in a two-compartment three-electrode cell with platinum-gauze working electrode and counter electrodes in compartments separated by a glass frit; a Luggin capillary, probing the working electrode, was connected to a silver-wire pseudoreference electrode. The CPE experiments were monitored regularly by cyclic voltammetry, thus assuring that no significant potential drift occurred along the electrolyses. The oxidation potentials of the complexes were measured by CV in the presence of ferrocene as the internal standard, and the redox potential values are quoted relative to the SCE by using the $[Fe(\eta^5\text{-}C_5H_5)_2]^{0/+}$ ($E_{1/2}^{ox}$ = 0.525 V vs. SCE) redox couple in 0.2 M $CH_2Cl_2$/$[Bu_4N][BF_4]$ solution.[25] The obtained potentials vs. SCE can be converted into the NHE scale by addition of 0.245 V.[11]

**$[Re(pz)(Hpz)(CO)_2(PPh_3)_2]$ (2):** A mixture of **1** (50 mg, 0.060 mmol) and pyrazole (41 mg, 0.60 mmol) was refluxed in MeOH (20 mL) for 2 d to produce a brown suspension. It was filtered off, washed with MeOH (3 × 10 mL), $C_6H_6$ (3 × 5 mL) and $Et_2O$ (3 × 10 mL) and dried in vacuo to yield complex **2** as a pale-yellow microcrystalline solid. Yield: 78% (42 mg), based on **1**. Further purification of **2** can be achieved by recrystallization from a $CH_2Cl_2/C_6H_6$/EtOH mixture. $C_{44}H_{36}N_4O_2P_2Re$ (901.9): calcd. C 58.59, H 4.13, N 6.21; found C 58.27, H 4.21, N 5.89. FAB-MS(+): $m/z$ = 903 $[M + H]^+$, 835 $[M – pz]^+$, 807 $[M – pz – CO]^+$, 778 $[M – Hpz – 2CO]^+$, 767 $[M – pz – Hpz]^+$, 739 $[M – pz – Hpz – CO]^+$, 709 $[Re(PPh_3)_2 – 2H]^+$, 613 $[M – PPh_3 – CO + H]^+$, 449 $[RePPh_3]^+$. IR (KBr): $\tilde{\nu}$ = 3317 (s br) ν(NH), 3148 (w) $\nu_{as}$(CH) and 3055 (w) $\nu_s$(CH), 2032 (m), 1924 (s) and 1841 (s) ν(CO), 743 (s) and 697 (s) ν(PPh) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 11.26 (s br, 1 H, N*H*), 7.81 [m, 2 H, pz*H*(3/5)], 7.68–7.50 (m, 12 H, $PPh_3$), 7.45–7.30 (m, 18 H, $PPh_3$), 6.81 [d, $J$ = 2.0 Hz, 2 H, pz*H*(3/5)], 5.88 [t, $J$ = 2.1 Hz, 2 H, pz*H*(4)] ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 202.86 and 202.04 (*C*O), 142.15 (pz*C*), 134.75–134.30 (m, $PPh_3$), 133.91 (pz*C*), 129.77 (d, $J_{CP}$ = 9.4 Hz, $PPh_3$), 128.70–128.35 (m, $PPh_3$), 107.61 (pz*C*) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 20.75 (s) ppm. X-ray-quality crystals of **2** were grown by slow evaporation at 5 °C of a $CH_2Cl_2/C_6H_6$/EtOH solution of **2**.

**$[ReCl(3,5\text{-}Me_2\text{-}Hpz)_2(CO)(PPh_3)_2]$ (3):** A mixture of **1** (50 mg, 0.060 mmol) and 3,5-dimethylpyrazole (58 mg, 0.60 mmol) was refluxed in MeOH (20 mL) for 2.5 d to produce a brown-yellow cloudy solution. The solid was filtered off, washed with MeOH (3 × 10 mL) and $Et_2O$ (3 × 10 mL) and dried in vacuo to yield complex **3** as a yellow microcrystalline solid. Further purification of **3** can be achieved by recrystallization from a $C_6H_6$/EtOH(MeOH)

IR (KBr): $\tilde{\nu}$ = 3222 (s) ν(NH), 3059 (w) $\nu_{as}$(CH), 3002 (w) and 2925 (w) $\nu_s$(CH), 1922 (s) and 1839 (s) ν(CO), 1571 (m) ν(C=N), 746 (m) and 695 (s) ν(PPh) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 11.06 (s, 2 H, N*H*), 7.65–7.10 (m, 30 H, $PPh_3$), 5.34 (s, 2 H, pz*H*), 1.76–1.56 (m, 12 H, pz$CH_3$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 197.80 (*C*O), 152.44 and 139.74 (pz*C*), 134.90–134.20 (m, $PPh_3$), 129.82 (s, $PPh_3$), 128.60–128.30 (m, $PPh_3$), 107.76 (pz*C*), 15.95 and 11.44 (pz$CH_3$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 21.04 (s) ppm.

**$[ReCl(quin)_2(CO)(PPh_3)_2]$ (4):** Complex **1** (50 mg, 0.060 mmol) was refluxed in a quinoline (0.50 mL) and methanol (20 mL) mixture for 15 h to produce a deep-brown cloudy solution. The solid was filtered off, washed with MeOH (5 × 10 mL) and $Et_2O$ (3 × 10 mL) and dried in vacuo to yield complex **4** as a deep-purple microcrystalline solid. Yield: 70% (43 mg), based on **1**. $C_{55}H_{44}ClN_2OP_2Re$ (1032.6): calcd. C 63.98, H 4.30, N 2.71; found C 63.66, H 4.63, N 2.72. FAB-MS(+): *m*/*z* = 1032 $[M]^+$, 770 $[M - PPh_3]^+$, 641 $[M - PPh_3 - quin]^+$, 613 $[M - PPh_3 - quin - CO]^+$, 484 $[M - PPh_3 - 2quin - CO]^+$. IR (KBr): $\tilde{\nu}$ = 3051 (m) $\nu_{as}$(CH), 3000 (w) $\nu_s$(CH), 1778 (s) ν(CO), 745 (s) and 695 (s) (PPh) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.71–7.40, 7.33–7.12 and 7.06–6.92 (m, 10 H + 18 H + 16 H, $PPh_3$ + quin*H*) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 30.79 (s) ppm. No reliable $^{13}C\{^1H\}$ NMR spectrum could be accumulated because of the gradual decomposition of **4** in $CDCl_3$ or [$D_6$]acetone. Single crystals were grown by slow evaporation at 5 °C of a $CH_2Cl_2$/$Me_2CO$(EtOH) solution of **4**. The proposed formulation of **4** with the *trans*-CO/Cl arrangement was also confirmed by a single-crystal X-ray diffraction analysis, but with a rather high error due to a heavy disorder.

**$[Re(4,7\text{-}Ph_2\text{-}phen)(CO)_2(PPh_3)_2][BPh_4]$ (5):** A mixture of **1** (50 mg, 0.060 mmol) and 4,7-diphenyl-1,10-phenanthroline (60 mg, 0.18 mmol) was refluxed in a MeOH (10 mL) and $C_6H_6$ (20 mL) mixture overnight. The resulting deep-green clear solution was concentrated under reduced pressure to give a green oil which was dissolved in EtOH (15 mL) and treated with an ethanol solution (30 mL) of $Na[BPh_4]$ (205 mg, 0.60 mmol). The obtained deep-green suspension was almost completely dissolved upon addition of acetone (30 mL). The resulting green clear solution was filtered and left to evaporate in air in a beaker at ambient temp. Deep-red crystals formed in a few days from that green solution. They were isolated by filtration, washed gently with $Et_2O$, collected and dried in vacuo to yield compound **5**. Yield: 64% (54 mg), based on **1**. $C_{86}H_{66}BN_2O_2P_2Re$ (1418.4): calcd. C 72.82, H 4.69, N 1.97; found C 72.47, H 4.86, N 2.25. FAB-MS(–): *m*/*z* = 319 $[BPh_4]^-$. IR (KBr): $\tilde{\nu}$ = 3054 (m br) $\nu_{as}$(CH), 2999 (w) and 2983 (w) $\nu_s$(CH), 1927 (s) and 1852 (s) ν(CO), 744 (s) and 697 (s) (PPh) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.90–6.40 (m, 66 H, $PPh_3$ + $BPh_4$ + phen*H*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 166.04 and 164.74 (*C*=O), 140.15 (m), 137.08, 133.24 (m), 130.97, 130.18 (d, $J_{CP}$ = 6.0 Hz), 129.32 (m), 126.62 (m), 126.09 (m) and 122.17 ($PPh_3$ + $BPh_4$ + phen*C*) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 22.51 (s) ppm. X-ray-quality crystals of **5**·0.5$CH_2Cl_2$ were grown by slow evaporation of an EtOH/$Me_2CO$/$CH_2Cl_2$ solution of **5**.

**$[Re(2\text{-}Me\text{-}dipic)(CO)_2(PPh_3)_2]$ (6):** To a solution of **1** (50 mg, 0.060 mmol) in MeOH (20 mL) and $C_6H_6$ (10 mL) was added an excess of 2,6-pyridinedicarboxylic acid (108 mg, 0.60 mmol), and the reaction mixture was refluxed for 1 d. The resulting deep-orange clear solution was concentrated under reduced pressure to give an orange oil which was treated with MeOH (15 mL). The solid that separated out from the resulting solution was filtered off and discarded. The filtrate was evaporated under reduced pressure giving an orange oily solid to which $Et_2O$ (30 mL) was added to form an orange precipitate. It was filtered off, washed with $Et_2O$ (3 × 10 mL) and dissolved on a filter in $Me_2CO$ (5 mL) to form a deep-orange solution which was taken to dryness under reduced pressure yielding an orange oil. Further addition of $Et_2O$ (30 mL) led to the formation of a solid which was filtered off, washed with $Et_2O$ (3 × 10 mL) and dried in vacuo to give complex **6** as an orange microcrystalline material. Yield: 44% (25 mg), based on **1**. $C_{46}H_{36}NO_6P_2Re$ (946.9): calcd. C 58.35, H 3.83, N 1.48; found C 58.03, H 3.49, N 1.84. FAB-MS(+): *m*/*z* = 947 $[M]^+$, 919 $[M - CO]^+$, 767 $[M - \{2\text{-}Me\text{-}dipic\}]^+$, 739 $[M - \{2\text{-}Me\text{-}dipic\} - CO]^+$, 657 $[M - PPh_3 - CO]^+$, 642 $[M - PPh_3 - CO - Me]^+$, 629 $[M - PPh_3 - 2CO]^+$, 614 $[M - PPh_3 - 2CO - Me]^+$, 505 $[M - PPh_3 - \{2\text{-}Me\text{-}dipic\}]^+$, 447 $[RePPh_3 - 2H]^+$. IR (KBr): $\tilde{\nu}$ = 3058 (m) $\nu_{as}$(CH), 2954 (w) $\nu_s$(CH), 1929 (s) and 1853 (s) ν(CO), 1740 (s) $\nu_{as}$(COOMe), 1692 (s) $\nu_{as}$(COO), 1482 (m) $\nu_s$(COO), 1435 (s) $\nu_s$(COOMe), 747 (s) and 696 (s) ν(PPh) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.59 (t, *J* = 7.9 Hz, 1 H, py*H*), 8.49 (t, *J* = 7.8 Hz, 1 H, py*H*), 8.30 (m, 1 H, py*H*), 7.91–7.32 (m, 30 H, $PPh_3$), 4.19 (s, 3 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 208.54 and 189.24 (*C*O), 166.31 (*C*OO), 153.53 (*C*OOMe), 140.27, 139.08, 132.37, 131.62 and 127.65 (py*C*), 134.83 (d, $J_{CP}$ = 9.3 Hz), 134.42–134.26 (m), 130.25 and 129.63–128.30 (m, $PPh_3$), 53.91 ($CH_3$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 31.96 (s) ppm. X-ray-quality crystals of **6**·EtOH were grown by slow evaporation at 5 °C of an EtOH/$Me_2CO$ or EtOH/$C_6H_6$ solution of **6**.

**X-ray Crystal Structure Determinations:** The X-ray diffraction data of **2**, **5** and **6** were collected with a Nonius Kappa CCD diffractometer using Mo-$K_\alpha$ radiation. The Denzo-Scalepack[26] program package was used for cell refinements and data reductions. All structures were solved by direct methods using the SHELXS-97,[27] SIR97[28] or SIR2002[29] programs with the WinGX[30] graphical user interface. An empirical absorption correction was applied to all data ($T_{max}/T_{min}$: 0.6242/0.5545, 0.8965/0.5149, 0.5172/0.7256 for **2**, **5** and **6**, respectively) using SORTAV[31] or XPREP in SHELXTL v.6.14–1[32] program. Structural refinements were carried out with SHELXL-97.[33] In **2** the NH hydrogen atom was located from the difference Fourier map and refined isotropically. In **5** one of the phenyl groups in 4,7-$Ph_2$-phen is disordered over two sites with occupancies 0.72 and 0.28. In these groups the aromatic rings were refined with fixed C–C distances of 1.39 Å. Moreover, the disordered $CH_2Cl_2$ solvent molecule was modelled by placing the two chlorines over three sites with equal occupancies. The solvent was partially lost from the structure, and all in all only half a molecule of $CH_2Cl_2$ was introduced into the structure. Because of the disorder, $CH_2Cl_2$ was refined only isotropically and the hydrogen atoms were omitted. In **6** the carbon atoms of the EtOH molecule are disordered over two sites with occupancies 0.55 and 0.45. The OH hydrogen atom of EtOH was located from the difference Fourier map but not refined ($U_{iso}$ = 0.12). Other hydro-

# Zinc, Cadmium and Mercury Dithiocarboxylates: Synthesis, Characterization, Structure and Their Transformation to Metal Sulfide Nanoparticles

**Gotluru Kedarnath,[a] Vimal K. Jain,*[a] Shamik Ghoshal,[a] Gautam K. Dey,[b] Carol A. Ellis,[c] and Edward R. T. Tiekink*[c]**

**Keywords:** Zinc / Cadmium / Mercury / Dithiocarboxylates / Nanoparticles

Reactions of $M(OAc)_2{\cdot}nH_2O$ and $M(OAc)_2$(tmeda) with dithiocarboxylic acids gave $[M(S_2CTol)_2]_n$ (**1**) (M = Zn or Cd; Tol = $C_6H_4Me$-4) and $[M(S_2CAr)_2(tmeda)]$ (**3**) (M = Zn, Cd, Hg; Ar = Ph or Tol), respectively, in high yields as deep-colored crystalline solids. The former are soluble in pyridine to give pyridine adducts $[M(S_2CTol)_2(py)]$ (**2**). These complexes were characterized by elemental analysis, UV/Vis and NMR ($^1H$, $^{13}C$) spectroscopy. The absorptions in the electronic spectra have been assigned to ligand-to-ligand charge-transfer transitions. The crystal and molecular structures of the monomeric species $[Zn(S_2CTol)_2(py)]$ (**2**), $[Zn(S_2CPh)_2(tmeda)]$ (**3a**), $[Zn(S_2CTol)_2(tmeda)]$ (**3b**) and $[Cd(S_2CTol)_2(tmeda)]$ (**3d**) have been established by X-ray crystallography. In $[Zn(S_2CTol)_2(py)]$, chelating dithiocarboxylate ligands and pyridine define a coordination geometry intermediate between square pyramidal and trigonal bipyramidal. In each of **3a** and **3b**, tetrahedral $N_2S_2$ coordination geometries are found as the dithiocarboxylate ligands are effectively monodentate; evidence for the greater coordination potential is found for $^-S_2CTol$ over $^-S_2CPh$. Chelating dithiocarboxylate ligands in $[Cd(S_2CTol)_2(tmeda)]$ (**3d**) lead to an octahedral geometry. Thermal behavior has been studied by thermogravimetric analysis. The $[M(S_2CAr)_2(tmeda)]$ complexes underwent a three-step decomposition. Pyrolysis in the temperature range 300–500 °C and solvothermal decomposition in ethylenediamine and hexadecylamine (HDA) gave metal sulfide nanoparticles. The MS (M = Zn, Cd, Hg) nanoparticles were characterized by XRD, EDAX, absorption/emission spectroscopy and electron microscopy (TEM). Solvothermal decomposition gave hexagonal phases of nanoparticles whereas heating in a furnace gave cubic ZnS and HgS, and hexagonal CdS.

## Introduction

During the past two decades considerable effort has been made to prepare high-quality monodispersed surface-passivated nanoparticles of II–VI semiconductors.[1] Owing to their quantum-confinement effect, semiconductor nanoparticles exhibit remarkable size- and shape-dependent optical properties which have led to their use in opto-electronic devices[2–6] and biological imaging.[7,8] Although a wide range of synthetic routes have been developed to prepare II–VI semiconductor nanoparticles,[8–11] decomposition of single-source molecular precursors in a suitable solvent has proved quite successful for isolation of high-quality nanoparticles within a narrow size distribution. The area has been dominated by ZnE and CdE (E = S, Se, Te) nanoparticles with limited investigations on HgE. Metal organochalcogenolates, $[M(EPh)_2(tmeda)]$ (M = Zn or Cd; E = S, Se or Te),[12] thiocarboxylates $[M(SCOR)_2L_2]$ (M = Zn or Cd; L = tmeda, 2-lutidene; R = Me, *t*Bu)[13] and $[Cd(SCOPh)_2(2,2'\text{-bipyridine})]$,[14] selenocarboxylates, $[M(SeCOAr)_2(tmeda)]$ (M = Zn or Cd),[15] xanthates $[M(S_2COR)_2]$ (M = Zn or Cd; R = Et, *i*Pr),[16,17] dithiocarbamates $[M(S_2NRR')_2]$ (M = Zn or Cd)[18,19] and dithiophosphinates $[M(S_2P\textit{i}Bu_2)_2]$ (M = Zn, Cd)[20] have been employed for the preparation of ME (M = Zn, Cd; E = S, Se, Te) nanoparticles/thin films.

Chemistry of the zinc-triad 1,1-dithiolates has been of considerable interest due to their numerous applications (e.g., lubricating oil in combustion engine, vulcanization of rubber, floating agents in metallurgy) and diverse structural features.[21–24] Subtle changes in organic substituents on the dithiolate group or in an auxiliary ligand often result in different structural motifs. Thus, molecules with zero- (discrete mono- and bi-nuclear complexes), one-, two- and three-dimensional structural motifs have been isolated and structurally characterized.[24] The 1,1-dithiolate chemistry of the zinc-triad has been dominated by ligands of the type **A**–**D** with relatively little attention to dithiocarboxylates (**E**), Scheme 1.[25–27] With the above in mind, it was consid-

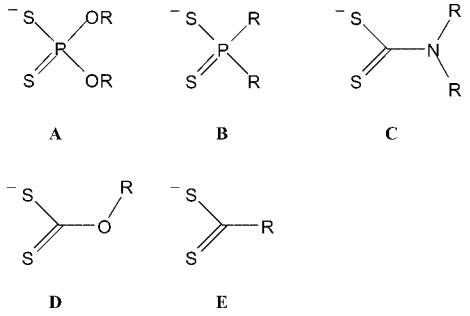
ered worthwhile to explore the dithiocarboxylate chemistry of zinc, cadmium and mercury with the aim of isolating new structural motifs and also to develop a new family of promising single-source molecular precursors for the synthesis of MS nanoparticles. Results of this work are described herein.



Scheme 1.

## Results and Discussion

Treatment of $M(OAc)_2 \cdot 2H_2O$ with *p*-tolyldithiocarboxylic acid in methanol gave sparingly soluble orange complexes of composition $[M(S_2Ctol)_2]$ (**1**) [M = Zn (**1a**) or Cd (**1b**)]. The complexes dissolved readily in pyridine solution, with concomitant formation of the corresponding pyridine adducts $[Zn(S_2CTol)_2(py)]$ (**2**). The reaction of $[M(OAc)_2$-(tmeda)] with dithiocarboxylic acid in benzene afforded deep-colored complexes of the general formula, $[M(S_2COAr)_2(tmeda)]$ (**3**) [Equation (1)].

$$[M(OAc)_2(tmeda)] + 2\ ArCS_2H \rightarrow [M(S_2CAr)_2(tmeda)] + 2\ AcOH\ldots \quad (1)$$

| Hg | Tol | **3f** |

The electronic spectra of these complexes in dichloromethane solution displayed two (Ar = Ph) and three (Ar = Tol) absorption bands and are assigned for transitions in thiocarbonyl group. The electronic spectra of metal dithiocarboxylates have been reported to display characteristic absorption maxima in the region 250–550 nm attributable to π–π* and n–π* transitions.[28] The $^1H$ NMR spectra exhibited characteristic peaks due to tmeda and dithiolate ligand protons. The absence of singlets ascribed to the SH proton in the spectra indicate deprotonation of the acid. The $NMe_2$ and $NCH_2$ protons resonances appeared as singlets in the ranges 2.39–2.65 and 2.57–2.73 ppm, respectively. The resonance due to 2,6-protons of the aryl ring are deshielded with reference to the free ligand. The $^{13}C\{^1H\}$ NMR spectra showed singlets for $NMe_2$ and $NCH_2$ carbon atoms of tmeda at ca. 46.0 ppm and ca. 56.5 ppm, respectively. The resonance due to thiocarbonyl carbon (C=S) is deshielded (<20 ppm) on complexation, deshielding being greater in cadmium complexes than the corresponding zinc derivatives.

### Structural Characteristics

The molecular structure of $[Zn(S_2CTol)_2(py)]$ (**2**) is represented in Figure 1 (a). The molecule is disposed about a crystallographic twofold axis which bisects the pyridine molecule and contains the zinc atom. The zinc atom is five-coordinate within a $NS_4$ donor set defined by two asymmetrically chelating dithiocarboxylate ligands and the pyridine-N atom. The Zn–S1 and Zn–S2 bond lengths are 2.3499(9) and 2.6046(11) Å, respectively and this asymmetry is reflected in the associated C–S distances so that S1–C1 is significantly longer than S2–C2, i.e., 1.716(3) and 1.679(3) Å,

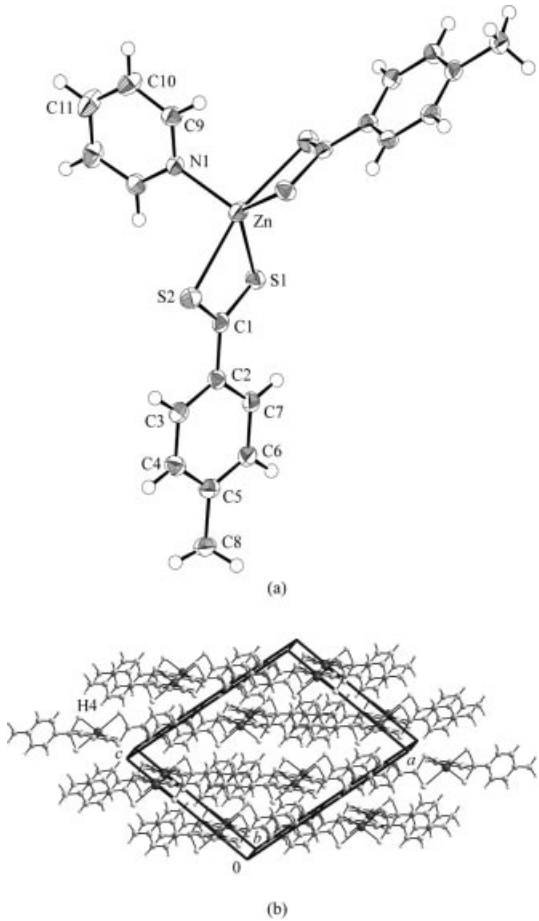

Figure 1. (a) Molecular structure and (b) unit cell contents for $[Zn(S_2CTol)_2(py)]$ (**2**).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

respectively; the Zn–N1 distance is 2.046(3) Å. The dihedral angle between the two $ZnS_2C$ chelate rings is 53.96(7)° and each of these is effectively orthogonal to the pyridine ring, dihedral angle = 79.87(10)°. The range of angles subtended at the zinc atom extends from 72.04(2)°, for the S1–Zn–S2 chelate angle to 164.55(4)°, for S2–Zn–S2$^{i}$; symmetry operation *i*: *–x*, *y*, 1/2 – *z*. The coordination geometry is intermediate between square pyramidal ($\tau$ = 0) and trigonal bipyramidal ($\tau$ = 1) as exemplified in the value of $\tau$ of 0.61.[29] The closely related structure of [Zn($S_2CC_6H_2$-4-OH-3,5-$t$Bu$_2$)$_2$(py)][26] also features an intermediate geometry but one more inclined towards a square-pyramidal geometry as judged by the $\tau$ value of 0.43. The 1,1-dithiolate ligand is not strictly planar, there being a twist about the C1–C2 bond in **2** as seen in the value of –162.7(2)° for the S1/C1/C2/C3 torsion angle. In the crystal structure, Figure 1 (b), molecules pack in layers along (101). The primary contacts within layers are π···π interactions of 3.7202(19) Å between interdigitated C2–C7 rings (symmetry operation: 1/2 – *x*, 1/2 – *y*, *–z*). The interactions between successive layers are of the type C–H···π. Thus, the C4–H···ring centroid (pyridine) distance is 2.88 Å with an angle of 153° subtended at the H4 atom (symmetry operation: 1/2 + *x*, 1/2 + *y*, *z*).

A formal decrease in the coordination number of zinc is found in the structure of [Zn($S_2$CTol)$_2$(tmeda)] (**3b**). The molecule, Figure 2 (a), has twofold symmetry, with the axis bisecting the tmeda ligand and containing zinc atom. The zinc atom is four-coordinate with the $N_2S_2$ coordination geometry defined by chelating tmeda and monodentate dithiocarboxylate ligands. The respective Zn–S1 and Zn–S2 distances are 2.3238(7) and 3.0860(9) Å, and these distances are significantly shorter and longer than the equivalent distances in the pyridine analog, respectively. The asymmetric mode of coordination is reflected in the respective S1–C1 and S2–C1 bond lengths of 1.705(3) and 1.667(3) Å; the Zn–N1 distance is 2.170(2) Å. The range of angles subtended at the tetrahedrally coordinated zinc atom is 84.11(11)°, for the N1–Zn–N1$^{i}$ chelate angle, to 132.46(5)° for S1–Zn–S1$^{i}$; symmetry operation *i*: *–1 – x*, *–y*, *z*. The wider angle is certainly due to the close approach of the S2 atoms. A small twist is apparent between the $S_2C$ and aromatic ring as seen in the S1/C1/C2/C3 torsion angle of 174.88(18)°. In the crystal structure, Figure 2 (b), the molecules form chains along the *c* axis stabilized by $C_{methyl}$–H···π interactions so that the C8–H···ring centroid of C2–C7 distance is 2.88 Å and angle at H of 130° for symmetry operation: –1/2 – *x*, *y*, –1/2 + *z*.

The influence of substituting the $^{-}S_2$CTol ligand by $^{-}S_2$CPh was investigated by examining the crystal and molecular structure of [Zn($S_2$CPh)$_2$(tmeda)] (**3a**). The molecule, Figure 3 (a), has twofold symmetry as described for **3b** but the structures are not isomorphous. To a first approximation, the coordination geometry for both structures is the same. Thus, the zinc atom exists is a distorted tetrahedral geometry defined by a $N_2S_2$ donor set. The Zn–S1 and Zn–S2 distances of 2.3079(12) and 3.2736(14) Å are respectively, shorter and longer than the comparable distances in **3b**. This is reflected in the S1–C1 and S2–C1 distances of

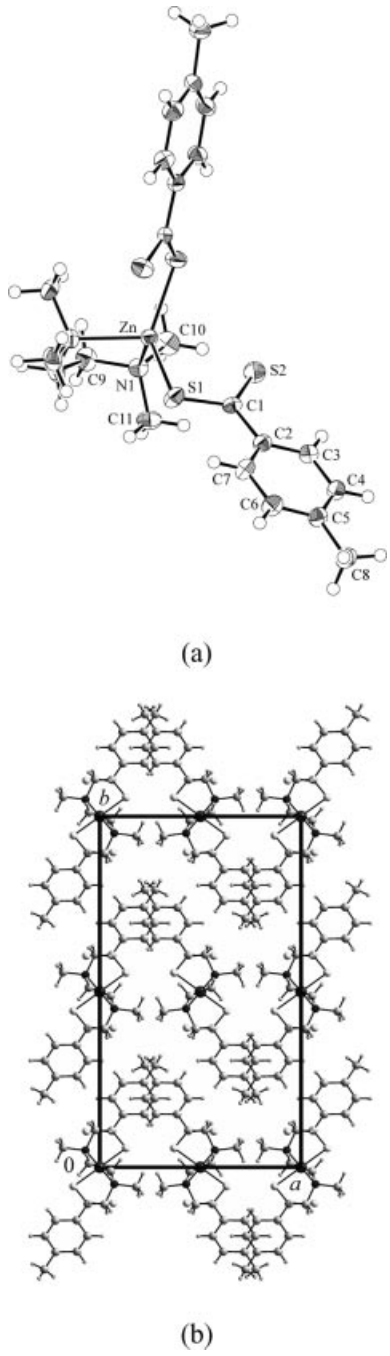

Figure 2. (a) Molecular structure and (b) unit cell contents for [Zn($S_2$CTol)$_2$(tmeda)] (**3b**).

1.725(5) and 1.653(5) Å. The difference in mode of coordination of the two 1,1-dithiolate ligands can be conveniently realized by considering the Δ(Zn–S) and the associated Δ(C–S) values, with greater values been correlated with greater asymmetry. Thus, in **3b** these compute to 0.76 and 0.04 Å, respectively, which are smaller than the values found for **4a** of 0.97 and 0.07 Å, respectively. Further, the Zn–N1 distance of 2.127(4) Å is shorter in the present structure. These results correlate in the expected fashion with the electron-donating ability of the methyl group in the $^{-}S_2$CTol ligand that makes this a comparatively better

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chelating agent. However, it is noted that there is a significant twist about the C1–C2 bond of the $^{-}S_2CTol$ ligand as seen in the value of 142.8(4)° for the S1/C1/C2/C3 torsion angle, and so the negative inductive effect exerted by the methyl group is not the reason for the different coordinating abilities. By contrast to the previously described crystal structures, in the absence of π···π and C–H···π interactions, C–H···S interactions dominate the crystal packing in **3a**. Thus, in addition to a variety of intramolecular C–H···S interactions, three intermolecular C–H···S interactions may be discerned in the stabilization of the crystal structure. A view of the unit-cell contents is shown in Figure 3 (b). Here, two C–H···S interactions are highlighted and show adjacent C–H atoms of an aromatic ring bridging S1 and S2 atoms of different ligands but of the same molecule. The parameters associated with interaction "(a)" are C6–H···S1$^{i}$ of 3.10 Å with an angle of 164° subtended at the H6 atom, and "(b)" C5–H···S2$^{ii}$ of 3.06 Å and angle 125°; symmetry operations *i*: *–x*, 1 – *y*, 1 – *z* and *ii*: *x*, 1 – *y*, –1/2 + *z*. Orthogonal C8–H···S2$^{iii}$ interactions, i.e., involving methylene-H atoms, of 3.02 Å and angle 173°, link translationally related molecules along the *b*-direction into chains; symmetry operation *iii*: *x*, 1 + *y*, *z*.

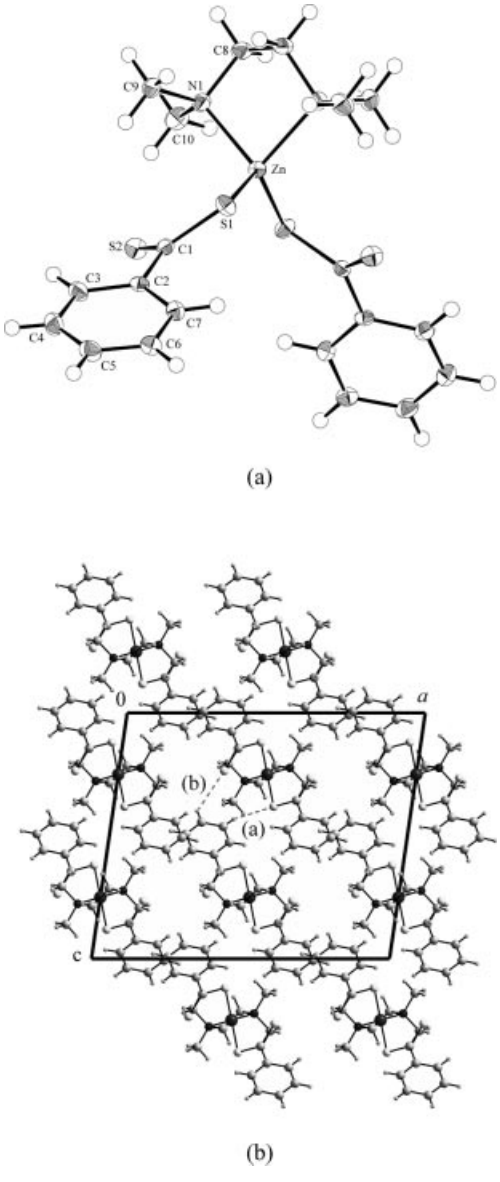

Figure 3. (a) Molecular structure and (b) unit cell contents for [Zn($S_2CPh$)$_2$(tmeda)] (**3a**).

The remaining structure to be described is that of [Cd($S_2CTol$)$_2$(tmeda)] (**3d**), shown in Figure 4. This structure is isomorphous with the zinc analog described above, but the coordination geometry is different. Here, owing to the greater propensity of the larger cadmium atom to increase its coordination number, the coordination geometry is based on a distorted octahedron within a $N_2S_4$ donor set. The dithiocarboxylate ligand forms nearly symmetric Cd–S bonds of 2.6508(8) and 2.7336(9) Å, Δ(Cd–S) is only 0.08 Å; the Cd–N1 bond length is 2.416(2) Å. Distortions from the ideal octahedral geometry may be traced to the acute chelate angles of 66.18(2)°, for S1–Cd–S2, and 76.15(12)°, for N1–Cd–N1$^{i}$; symmetry operation *i*: *–x*, *–y*, *z*. The $CS_2$ and aromatic portions of the 1,1-dithiolate ligand are effectively co-planar as evidenced by the S1/C1/C2/C3 torsion angle of –174.3(2)°. The crystal packing is as described above for **3d** with a C8–H···ring centroid of C2–C7 distance is 2.94 Å and angle at H of 131° for symmetry operation: –1/2 – *x*, *y*, 1/2 + *z*.

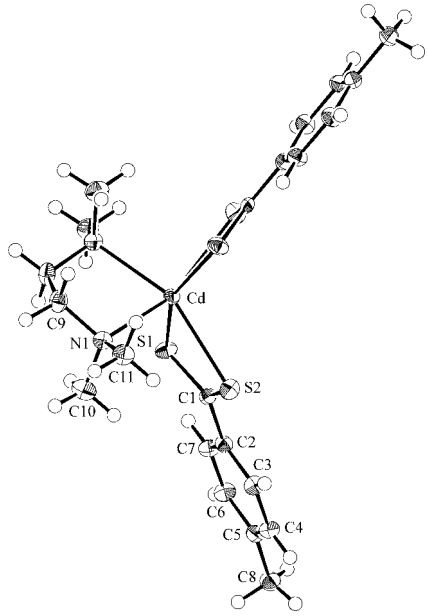

Figure 4. Molecular structure of [Cd($S_2CTol$)$_2$(tmeda)] (**3d**).

## Thermal Studies

TG analyses were carried out to study the thermal behavior and suitability of these complexes for the preparation of metal sulfides. These complexes underwent a three-step decomposition, exemplified for [Zn($S_2CPh$)$_2$(tmeda)] (**3a**) in Figure S1 (see Supporting Information), with the formation of metal sulfides as inferred from the weight loss (e.g. **3a**, calculated weight loss: 80.0% and observed weight loss:

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

76.5%) and confirmed from the XRD patterns of the residues. The onset temperatures are **3a**, 194 °C; **3b**, 178 °C; **3c**, 175 °C; **3d**, 180 °C. The TG curves of the zinc complexes showed slightly separated steps while for the cadmium and mercury derivatives they were poorly resolved indicating instability of the intermediate species. The first step, based on percentage of weight loss (e.g. **3a**, calcd. weight loss for tmeda: 23.8% and obsd. weight loss for first step: 23.8%) has been attributed to the elimination of tmeda. The second and third steps can be characterized for decomposition of dithiocarboxylate groups.

Pyrolysis of $[M(S_2CAr)_2(tmeda)]$ (Ar = Ph, Tol) was carried out at 350 °C under flowing nitrogen for 2 h. In each case metal sulfides (MS; M = Zn, Cd, Hg) were formed as confirmed by their XRD patterns (see Figure 5 and Figures S2–S3 in the Supporting Information) and EDAX analysis (Ar = Ph) (ZnS: calcd 67.1, S 32.9; found Zn 60.2, S 39.8. CdS: calcd Cd 77.8, S 22.2; found Cd 74.3, S 25.7. HgS: calcd. Hg 86.2, S 13.8; found Hg 84.2, S 15.8). The XRD patterns of ZnS and HgS were consistent with the formation of cubic phase of the material,[30,31] whereas CdS was isolated in the hexagonal phase.[32] The pyrolysis of $[Cd(S_2CPh)_2(tmeda)]$ (**3c**), carried out at 300, 400 and 500 °C, also gave hexagonal CdS with the average particle sizes of 18, 36 and 43 nm, respectively, from the Scherrer equation.[33] This indicates that particle size increases with increasing decomposition temperature at a given time. The absorption spectrum of CdS nanoparticles (obtained at 300 °C) showed a broad peak at 505 nm. The emission profile displayed a band at 521 nm, which may be due to surface traps (Figure 6). The particles are of 15 nm in size as estimated from the Brus expression.[34]

Solvothermal decomposition of $[M(S_2CPh)_2(tmeda)]$ (M = Zn, Cd, Hg) was examined in different coordinating solvents, such as ethylenediamine and HDA, to assess their suitability as precursors for the preparation of MS nanoparticles. Pyrolysis of $[M(S_2CPh)_2(tmeda)]$ in refluxing ethylenediamine gave hexagonal phases of MS (from XRD) nanoparticles which were isolated as cream (ZnS), yellow-orange (CdS) and orange (HgS) powders by centrifugation (Figure S4 in the Supporting Information). The particle sizes, estimated from the Scherrer formula,[33] are 34 (ZnS), 29 (CdS) and 103 (HgS) nm. The mercury complex can be pyrolyzed in ethylenediamine at a temperature as low as 57 °C with the formation of hexagonal HgS, having an average particle size (diameter) of 21 nm. The absorption spectra of CdS and HgS nanoparticles (obtained at 122 °C in ethylenediamine) displayed peaks at 480 and 401 nm, respectively. Emission profile (Figure 7) of these CdS nanoparticles exhibited a band at 518 nm (bulk CdS bandgap is 515 nm), which may be due to surface traps.

Nanoparticles prepared under different conditions are known to give different phases and sizes due to different nucleation mechanisms.[35] It is likely that in the present circumstances different nanoparticles are obtained owing to different mechanisms of formation and temperatures. Thus, when the precursor is heated without solvent, initially tmeda is released (as inferred from TG curve) followed by decomposition of the complex, whereas in a coordinating solvent, the coordinating ligand helps in passivating the surface of the particles resulting in different phases.

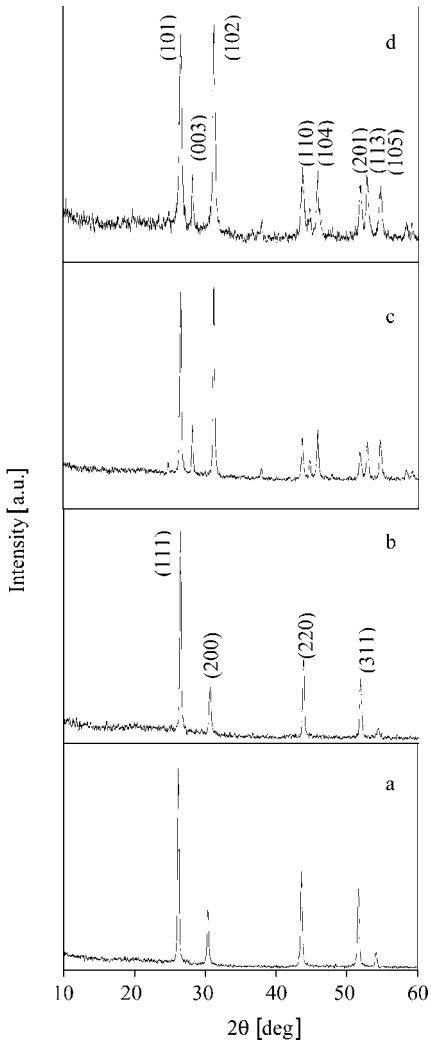

Figure 5. XRD patterns of the HgS nanoparticles prepared under different conditions from $[Hg(SC_2Ph)_2(tmeda)]$; a) heated in a furnace at 250 °C, b) heated in a furnace at 350 °C, c) thermolysis in ethylenediamine at 125 °C and d) thermolysis in HDA at 125 °C.

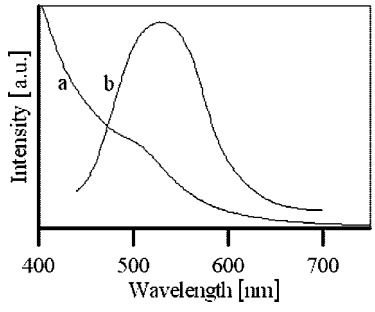

Figure 6. a) Absorption and b) emission spectra of CdS nanoparticles obtained by the pyrolysis of $[Cd(S_2CPh)_2(tmeda)]$ in a furnace at 300 °C under flowing nitrogen.

Pyrolysis of $[Cd(S_2CPh)_2(tmeda)]$ (**3c**) and $[Hg(S_2CPh)_2(tmeda)]$ (**3e**) was also carried out in HDA either at different

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

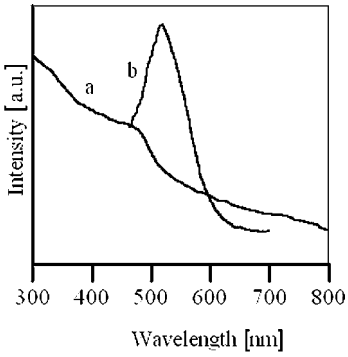

Figure 7. a) Absorption and b) emission spectra of CdS nanoparticles obtained by pyrolysis of $[Cd(S_2CPh)_2(tmeda)]$ in ethylenediamine at 122 °C.

temperatures and/or different concentrations of the precursor. Thermolysis of **3c** in HDA at 188, 188, and 225 °C having precursor/solvent mol ratio of 1:34, 1:55, and 1:55, respectively gave yellow-orange nanoparticles of hexagonal CdS with particle sizes 17, 26, and 34 nm, respectively. Their absorption spectra (Figure 8) in toluene showed exciton peaks at 466, 473 and 503 nm, respectively, which are blue shifted from bulk CdS (515 nm). The emission spectra of the samples prepared at 188 °C of precursor: solvent mol ratio of 1:34 and 1:55 exhibited a broad emission at 523 and 546 nm, respectively. Both absorption and emission maxima are red-shifted with increasing size of the CdS nanoparticles. Pyrolysis of **3e** in HDA (precursor/HDA mol ratio = 1:70) at 125 °C afforded the hexagonal phase of HgS,[36] whereas at 160 °C it gave cubic HgS with particle size of 26 nm and 34 nm (from the Scherrer formula[33]), respectively.

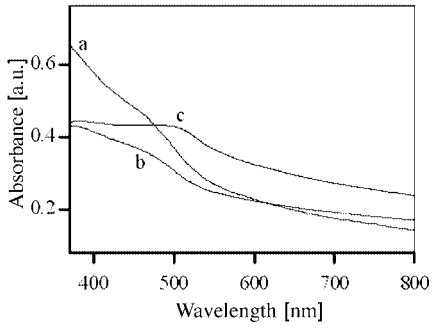

Figure 8. Absorption spectra of CdS nanoparticles obtained by the pyrolysis of $[Cd(S_2CPh)_2(tmeda)]$ with precursor: coordinating solvent mole ratio a) 1:34 (188 °C), b) 1:55 (188 °C) and c) 1:55 (225 °C).

Thermolysis of **3c** in HDA at 188, 188 and 225 °C having precursor/solvent mol ratio of 1:34, 1:55 and 1:55, respectively, gave nanoparticles of hexagonal CdS with different particle sizes. At fixed precursor/solvent mol ratio and duration, particle size increases with increase of temperature. This may be due to the growth of particles that accelerates with increasing temperature.[37] Thermolysis at a fixed duration and temperature with different precursor/solvent mol ratio 1:34 (particle size is 17 nm) and 1:55 (particle size is 26 nm) also gave different particle sizes which may be due to Ostwald ripenening.[38]

### Electron Microscopy

The Selected Area Electron Diffraction (SAED) patterns of MS nanoparticles (Figure 9; Figures S5–S6 in the Supporting Information) obtained by pyrolysis of $[M(S_2CPh)_2(tmeda)]$ in a furnace at 350 °C for M = Zn, and in ethylenediamine for M = Cd (122 °C) and Hg (57 °C) revealed the formation of crystalline material. The diffraction rings in the SAED pattern of ZnS corresponds to the lattice planes (111), (220) and (311) which are assigned for the cubic phase. Concentric rings in the SAED patterns of MS (M = Cd or Hg) have been attributed to the lattice planes (100), (002), (101), (102), (110), (103) and (112) (CdS); (101), (102), (110), (104) and (105) (HgS), respectively, of the hexagonal phases of MS. The phases determined from the SAED and XRD patterns are in agreement. The TEM image of MS showed that ZnS nanoparticles [Figure S5 (Supporting Information)] are spherical in shape with an average diameter of 10 nm, while those of CdS (Figure 9) and HgS (Figure S6, Supporting Information) are nearly spherical with the average size of 20 and 25 nm, respectively. However, in the case of CdS, the presence of a small amount of nanorods of 20–60 nm in length and diameter of 12–20 nm

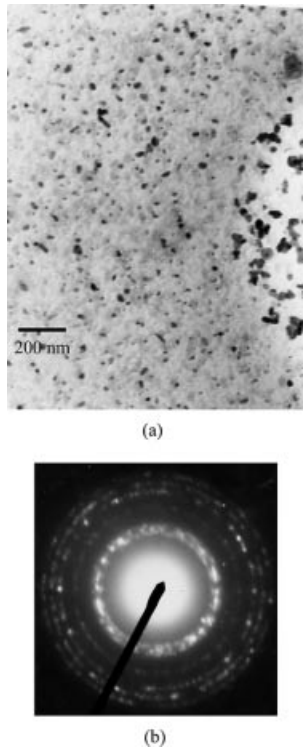

Figure 9. a) TEM image and b) SAED pattern of CdS nanoparticles obtained by pyrolysis of $[Cd(S_2CPh)_2(tmeda)]$ in ethylenediamine at 122 °C. In b) the inner ring is assigned to planes (100), (002) and (101), with the remaining rings from inner to outer corresponding to planes (102), (110), (103) and (112), respectively.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was also observed. Co-formation of nanoparticles of different morphology is known and optimization of reaction conditions can lead to the preferential deposition of one form over another.[39] The particle sizes of ZnS and HgS nanoparticles obtained from TEM images are in agreement with the sizes estimated from XRD pattern using the Scherrer formula,[33] whereas the sizes evaluated by these techniques differs for CdS nanoparticles. This inconsistency could be due to the deviation from spherical morphology of the CdS particles.[40]

## Conclusions

Zinc, cadmium and mercury dithiocarboxylate complexes are conveniently prepared in high yields and are stable at room temperature for several months. The homoleptic derivatives are associated in the solid state and are sparingly soluble in non-coordinating solvents. The complexes with neutral donor ligands (e.g., py or tmeda) are discrete monomers. These complexes undergo facile decomposition both in the solid state (furnace heating) and in solution (solvothermal) to yield metal sulfide nanoparticles. The solvothermal decomposition affords nanoparticles at moderately low temperatures which can be as low as 57 °C for the preparation of HgS. Different phases (cubic/hexagonal) can be obtained under different experimental conditions. Thus, owing to the synthetic ease and facile conversion into phase pure metal sulfide nanoparticles, these complexes prove to be reliable precursors for the generation of MS, M = Zn, Cd and Hg.

## Experimental Section

**General:** Elemental analyses were carried out by Radio Chemistry Division of B.A.R.C. $^1$H and $^{13}$C{$^1$H} NMR spectra were recorded with a Bruker DPX-300 NMR spectrometer operating at 300 and 75.47 MHz, respectively. Chemical shifts are relative to internal chloroform resonances at $\delta$ = 7.26 ppm for $^1$H and $\delta$ = 77.0 ppm for $^{13}$C{$^1$H}. UV/Vis absorption spectra were recorded with a Chemito Spectrascan UV 2600 double beam UV/Vis spectrophotometer. Fluorescence spectra were recorded using a Hitachi F-4500 FL spectrofluorometer.

Thermogravimetric analyses (TGA) were carried out with a Nitzsch STA PC-Luxx TG-DTA instrument, which was calibrated with $CaC_2O_4{\cdot}H_2O$. TG curves were recorded at a heating rate of 5 °C min$^{-1}$ under a flow of nitrogen. Solvents were dried and distilled before use under nitrogen. HPLC-grade toluene was used in all experiments involving HDA as a capping agent while methanol was used in case of ethylenediamine as the capping agent. Dimethylformamide was used in pyrolysis experiments for optical studies. X-ray powder diffraction patterns were measured using Cu-$K_\alpha$ radiation with a Philips PW1820 powder diffractometer. EDAX were carried out with a Tescan Vega 2300T/40 instrument. A JEOL-2000FX transmission electron microscope operating at accelerating voltages up to 200 kV was used for TEM studies. The samples for TEM and SAED were prepared by placing a drop of sample dispersed in acetone on a carbon-coated copper grid.

**Materials:** Zinc, cadmium and mercury acetates, *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmeda), hexadecylamine (HDA) and ethylenediamine (en), solvents were obtained from commercial sources. [M(OAc)$_2$(tmeda)] (M = Zn, Cd and Hg) were prepared by refluxing metal acetates with an excess of tmeda in dichloromethane under an inert atmosphere for 2 h. Dithiocarboxylic acids, $RCS_2H$ (R = Ph, *p*-Tol) [NMR in $CDCl_3$ for R = Ph, $^1$H NMR: $\delta$ = 6.40 (br. s, SH), 7.39 (br., 2 H, 3,5-H), 7.57 (br., 1 H, 4-H), 8.07 (br., *J* = 8.2 Hz, 2 H, 2,6-H) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 126.7 (C-3,5), 128.2 (C-4), 133.0 (C-2,6), 143.5 (C-1), 225.2 ($CS_2$) ppm. $^1$H NMR for R = *p*-Tol: $\delta$ = 2.38 (s, *Me*-tol), 4.71 (s, SH), 7.19 (d, *J* = 8.3 Hz, 2 H, 3,5-H), 7.98 (d, *J* = 8.2 Hz, 2 H, 2,6-H) ($C_6H_4$) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 21.5 (Me), 126.9 (C-2,6), 129.0 (C-3,5), 141.1 (C-4), 144.2 (C-1), 224.6 ($CS_2$) ppm] were prepared by the reaction of RMgBr with $CS_2$ in diethyl ether as described in the literature method.[41]

**Preparation of [Zn(S$_2$CTol)$_2$] (1a):** A methanolic solution of $Zn(OAc)_2{\cdot}2H_2O$ (390 mg, 1.78 mmol) was added to a benzene solution (20 mL) of $HS_2CTol$ (600 mg, 3.56 mmol), with vigorous stirring which continued for 2 h under nitrogen. The solvents were evaporated under vacuum to afford an orange residue (660 mg, 93%), m.p. 175 °C. $C_{16}H_{14}S_4Zn$ (399.94): calcd. C 48.0, H 3.5, S 32.1; found C 47.5, H 3.4, S 32.6. UV/Vis ($CH_2Cl_2$): $\lambda$ = 334, 350 and 392 nm. $^1$H NMR ($CDCl_3$): $\delta$ = 2.43 (s, C*H*$_3$C$_6$H$_4$CS$_2$), 7.22 (d, 7.5 Hz, $C_6H_4$), 8.28 (d, 7.5 Hz, $C_6H_4$) ppm. A portion of the residue was recrystallized as red crystals from dichloromethane containing few drops of pyridine. The $^1$H NMR spectrum of these crystals, [Zn(S$_2$CTol)$_2$(py)] (**2**), showed resonances due to coordinated pyridine: $^1$H NMR: $\delta$ = 2.73 (s, C*H*$_3$C$_6$H$_4$CS$_2$), 7.15 (d, *J* = 7.7 Hz, $C_6H_4$), 7.70 (d, *J* = 7 Hz, $C_6H_4$), 7.31 (br.), 8.38 (br.), 8.64 (br., py); this formulation was confirmed by an X-ray crystallographic study for red crystals grown by the slow evaporation of a dichloromethane solution of the compound.

**Preparation of [Cd(S$_2$CTol)$_2$] (1b):** This was prepared in a manner similar to the zinc complex in 92% yield as a red-orange crystalline solid; m.p. 160 °C. $C_{16}H_{14}CdS_4$ (446.96): calcd. C 43.0, H 3.2, S 28.7; found C 43.0, H 3.1, S 29.4. UV/Vis ($CH_2Cl_2$): $\lambda$ = 321, 345, 360 nm. $^1$H NMR ($CDCl_3$): $\delta$ = 2.37 (s, C*H*$_3$C$_6$H$_4$CS$_2$), 7.12 (br., *C*$_6$*H*$_4$), 8.30 (br., $C_6H_4$) ppm.

**Preparation of [Zn(S$_2$CTol)$_2$(tmeda)] (3b):** Solid [Zn(OAc)$_2$(tmeda)] (590 mg, 1.97 mmol) was added to a benzene solution (20 mL) of $HS_2CTol$ (660 mg, 3.92 mmol), with vigorous stirring, which continued for 2 h under nitrogen. The solvent was removed under vacuum to yield an orange residue which was recrystallzed from dichloromethane/toluene (1:3) mixture to give red crystals (930 mg, 91% yield), m.p. 173 °C. $C_{22}H_{30}N_2S_4Zn$ (516.14): calcd. C 51.2, H 5.9, N 5.4, S 24.9; found C 51.3, H 5.9, N 5.4, S 25.0. UV/Vis ($CH_2Cl_2$): $\lambda$ = 307, 326, 366 nm. $^1$H NMR ($CDCl_3$): $\delta$ = 2.35 (s, C*H*$_3$C$_6$H$_4$CS$_2$), 2.62 (s, $NMe_2$), 2.70 (s, $NCH_2$), 7.10 (d, *J* = 7.4 Hz, $C_6H_4$), 8.36 (d, *J* = 7.3 Hz, $C_6H_4$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 21.4 (*C*H$_3$-C$_6$H$_4$CS$_2$), 46.2 ($NMe_2$), 56.9 ($NCH_2$), 127.2, 128.1, 128.7, 142.7 ($C_6H_4$), 245.0 (C=S) ppm. Red crystals for X-ray diffraction were grown by the slow evaporation of a dichloromethane/toluene (3:1) solution of the compound.

**Preparation of [Zn(S$_2$CPh)$_2$(tmeda)] (3a):** This was prepared in a manner similar to [Zn(S$_2$CTol)$_2$(tmeda)] and recrystallized from dichloromethane/toluene as dark-red crystals in 92% yield, m.p. 152 °C (dec). $C_{20}H_{26}N_2S_4Zn$ (488.08): calcd. C 49.2, H 5.4, N 5.7, S 26.3; found C 49.5, H 5.4, N 5.9, S 25.7. UV/Vis ($CH_2Cl_2$): $\lambda$ = 302, 366 nm. $^1$H NMR ($CDCl_3$): $\delta$ = 2.65 (s, $NMe_2$), 2.73 (s, $NCH_2$), 7.30 (t, *J* = 7.7 Hz), 7.47 (t, *J* = 7.2 Hz), 8.44 (d, *J* = 7.4 Hz, Ph) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 46.1 ($NMe_2$), 56.7 ($NCH_2$), 126.9, 127.3, 131.7, 145.4 (Ph), 245.9 (C=S) ppm. Red crystals for X-ray crystallography were grown by the slow evapora-

tion of a dichloromethane/toluene (3:1) solution of the compound.

**Preparation of [Cd($S_2$CPh)$_2$(tmeda)] (3c):** This complex was prepared in a similar fashion to its zinc analog and recrystallized from dichloromethane/hexane or dichloromethane/toluene mixture as orange crystals in 90% yield; m.p. 164 °C (dec). $C_{20}H_{26}CdN_2S_4$ (535.11): calcd. C 44.9, H 4.9, N 5.2, S 24.0; found C 45.4, H 4.8, N 4.8, S 24.5. UV/Vis ($CH_2Cl_2$): $\lambda$ = 304, 368 nm. $^1$H NMR ($CDCl_3$): $\delta$ = 2.60 (s, $NMe_2$), 2.69 (s, $NCH_2$), 7.32 (t, $J$ = 7.8 Hz), 7.48 (t, $J$ = 7.3 Hz), 8.47 (d, $J$ = 7.7 Hz) (Ph) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 46.0 ($NMe_2$), 56.7 ($NCH_2$), 127.3, 128.2, 131.9, 145.4 (Ph), 249.0 (s, C=S) ppm. Red crystals for X-ray diffraction were grown by the slow evaporation of a chloroform/toluene (3:1) solution of the compound.

**Preparation of [Cd($S_2$CTol)$_2$(tmeda)] (3d):** This was prepared similarly to [Zn($S_2$CTol)$_2$(tmeda)] and recrystallized from dichloromethane/toluene in 90% yield as orange crystals; m.p. 176 °C. $C_{22}H_{30}CdN_2S_4$ (563.16): calcd. C 46.9, H 5.4, N 5.0, S 22.8; found C 47.3, H 5.4, N 5.1, S 23.0. UV/Vis ($CH_2Cl_2$): $\lambda$ = 316, 328, 376 nm. $^1$H NMR ($CDCl_3$): $\delta$ = 2.37 (s, C$H_3$C$_6$H$_4$CS$_2$), 2.57 (s, $NMe_2$), 2.66 (s, $NCH_2$), 7.10 (d, $J$ = 7.8 Hz, $C_6H_4$), 8.39 (d, $J$ = 7.8 Hz, $C_6H_4$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 21.4 (*C*H$_3$-C$_6$H$_4$CS$_2$), 46.0 ($NMe_2$), 57.0 ($NCH_2$), 127.7, 128.1, 142.9, 143.4 (Ph), 248.4 (C=S) ppm.

**Preparation of [Hg($S_2$CPh)$_2$(tmeda)] (3e):** The complex was obtained as a brown solid similarly to the previous mercury complex in 90% yield; m.p. 78 °C (dec). $C_{20}H_{26}HgN_2S_4$ (623.29): calcd. C 38.5, H 4.2, N 4.5, S 20.6; found C 37.9, H 3.7, N 4.3, S 21.2. UV/Vis ($CH_2Cl_2$): $\lambda$ = 298 (sh), 310 nm. $^1$H NMR ($CDCl_3$): $\delta$ = 2.43 (s, $NMe_2$), 2.66 (s, $NCH_2$), 7.38 (t, $J$ = 7 Hz), 7.56 (t, $J$ = 7.2 Hz), 8.19 (br., Ph) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 45.2 ($NMe_2$), 56.2 ($NCH_2$), 126.9, 127.9, 132.7, 144.3 (Ph) ppm; the resonance due to C=S was not resolved.

**Preparation of [Hg($S_2$CTol)$_2$(tmeda)] (3f):** This was prepared similarly to its zinc, cadmium analogs as a brown solid in 91%; m.p. 112 °C. $C_{22}H_{30}HgN_2S_4$ (651.34): calcd. C 40.6, H 4.6, N 4.3, S 19.7; found C 40.1, H 4.1, N 4.0, S 20.3. UV/Vis ($CH_2Cl_2$): $\lambda$ = 315, 335, 361 nm. $^1$H NMR ($CDCl_3$): $\delta$ = 2.39 (s, $NMe_2$), 2.38 (s, C$H_3$C$_6$H$_4$CS$_2$), 2.57 (s, $NCH_2$), 7.16 (d, $J$ = 7.7 Hz, $C_6H_4$), 8.15 (br., $C_6H_4$) ppm.

**X-ray Crystallography:** Intensity data for [Zn($S_2$CTol)$_2$(py)], [Zn($S_2$CTol)$_2$(tmeda)], [Zn($S_2$CPh)$_2$(tmeda)] and [Cd($S_2$CTol)$_2$-(tmeda)] were measured with a Rigaku AFC12/Saturn724 CCD fitted with Mo-$K_\alpha$ radiation so that $\theta$ = 27.5°. The structures were solved by heavy-atom methods[42] and refinement was on $F^2$ [43] using data that had been corrected for absorption effects with an empirical procedure,[44] with non-hydrogen atoms modeled with anisotropic displacement parameters, with hydrogen atoms in their calculated positions, and using a weighting scheme of the form $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. The absolute configuration of [M($S_2$CTol)$_2$(tmeda)], M = Zn and Cd, was determined on the basis of differences in Friedel pairs included in the data sets and confirmed by the near-zero value of the Flack parameter in each case, i.e. 0.006(12) and –0.01(3), respectively.[45] A residual electron density peak of 2.02 e Å$^{-3}$ was noted in the final difference map for [Zn($S_2$CPh)$_2$(tmeda)], this was located between the Zn and S1 atoms. A residual of 1.05 e Å$^{-3}$ was located 0.02 Å from the Cd atom in [Cd($S_2$CTol)$_2$(tmeda)]. Molecular structures shown in Figures 1, 2, 3, and 4 were drawn at the 50% probability level using ORTEP.[46] The DIAMOND program[47] was used for the remaining crystallographic figures. Data manipulation and analyses were performed with teXsan[48] and PLATON.[49] Crystallographic data and refinement details are given in Table 1.

**Preparation of Metal Sulfide Nanoparticles**

**(a) Pyrolysis in a Furnace:** A weighed quantity of a sample (ca. 200 mg) in a quartz boat, was pyrolyzed at 350 °C (unless otherwise stated) in a furnace under flowing nitrogen for 2 h. After cooling, the residue in the quartz boat was again weighed and characterized by XRD and in some cases by UV/Vis spectroscopy. The pyrolysis of **3c** was carried out at three different temperatures, 300, 400 and 500 °C and the dark-red residual powder was characterized by XRD.

Table 1. Crystallographic parameters and refinement details for [Zn($S_2$CTol)$_2$(py)], [Zn($S_2$CTol)$_2$(tmeda)], [Zn($S_2$CPh)$_2$(tmeda)] and [Cd($S_2$CTol)$_2$(tmeda)].

**(b) Preparation of MS (M = Zn, Cd, Hg) Nanoparticles in Coordinating Solvents:** All experiments were performed similarly. A typical experiment is described below:

In a three-necked flask fitted with a thermometer, HDA (hexadecylamine) (5 g) was degassed at 120 °C under argon for 1 h with continuous stirring. The temperature was slowly raised to 225 °C and stabilized at this temperature. To this, a solution of **3c** (200 mg, 0.37 mmol) in dichloromethane (3 mL) was injected rapidly. The temperature dropped to 195 °C and was slowly raised to 225 °C and maintained at this temperature for 10 min. This hot solution was maintained at 225 °C for 20 min and was cooled to 70 °C and methanol was added to precipitate yellow CdS nanoparticles. The yellow flocculate was given a thorough washing with methanol followed by centrifuging and drying under vacuum.

Similarly, experiments were carried out at different temperatures and at different concentrations of precursor and coordinating solvent. Metal sulfide nanoparticles prepared in ethylenediamine were isolated by centrifuging rather than precipitating with methanol. The particles thus separated were thoroughly washed with methanol and dried. In case of experiments performed in ethylenediamine, a sudden surge in temperature to 135–140 °C was observed when the precursor (zinc, cadmium and mercury) was injected at 115 °C into ethylenediamine.

**Supporting Information** (see also the footnote on the first page of this article): XRD slides of nanoparticles of different colors, SAED patterns and TEM images of ZnS, HgS nanoparticles.

## Acknowledgments

We thank Drs. T. Mukherjee and S. K. Kulshreshtha for encouragement of this work. The authors are grateful to Dr. S. K. Gupta and his group for EDAX measurements and Dr. V. K. Manchanda and his group for providing microanalysis of these complexes.

# Nickel(II)-Carbene Intermediates in Reactions of Geminal Dihaloalkanes with Nickel(0) Reagents and the Corresponding Carbene Capture as the Phosphonium Ylide[‡]

**John J. Eisch,*[a] Yun Qian,[a] and Arnold L. Rheingold[b]**

**Keywords:** Nickel(0) reagents / Nickel(II)-carbenes / Phosphonium ylides / α-Elimination / Carbon-carbon bond formation

In a previous study of geminal bond cleavages of substrates of the type $R_2CE_2$ [$E_2 = X_2$, O, S, Li($SO_2$Ph)] by nickel(0) reagents [$L_nNi$, $L_n$ = $(Cod)_2$, $(Et_4P)_4$], leading to $R_2C{=}CR_2$ as products, the tentative hypothesis had been proposed that such reactions likely proceed via nickel(0)-carbene intermediates (J. J. Eisch, Y. Qian, M. Singh, *J. Organomet. Chem.* **1996**, *512*, 207). Because such proposed nickel(0)-carbenes do not satisfactorily account for reactions encountered with such α-eliminations, a detailed reexamination of the reaction of these nickel(0) reagents with geminal dihalides has been undertaken. For example, two reactions of such presumed nickel(0)-carbenes remained anomalous: (1) the failure of 5,5-dibromotetraphenylcyclopentadiene to form its expected dimer, octaphenylphenylfulvalene and instead the formation of triethylphosphonium tetraphenylcyclopentadienide in its reaction with $(Et_3P)_4Ni$; and (2) the presumed capture of intermediate $R_2C{=}Ni^0$ in presence of the trapping agent (benzaldehyde or benzophenone). As to the first anomaly, a detailed study has shown that no trace of octaphenylfulvalene was formed. As to the second anomaly, the $R_2C$ fragment could be trapped by the carbonyl reagents only in reactions involving $(Et_3P)_4Ni$, but not in reactions with $(Cod)_2Ni$. This finding compels one to conclude that the carbonyl reagent is capturing the Wittig reagent, $R_2C{=}PEt_3$, and not $R_2C{=}Ni^0$. Based upon all present data, the mechanism of such C=C bond dimerizations is best explicable in terms of nickel(II)-carbenes. The triethylphosphonium tetraphenylcyclopentadienide formed here has by single-crystal X-ray structure determination, complemented by $^{13}C$ NMR spectroscopic data, been found to have the zwitterionic structure $Ph_4Cp^-$–$^+PEt_3$ as its paramount resonance contributor.

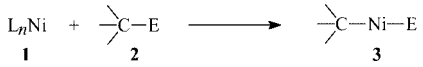
## Introduction

The oxidative addition of nickel(0) complexes ($L_nNi$, **1**) into σ-covalent bonds between carbon and a wide variety of heteroatoms or even another carbon [**2**; E = X, O (of epoxide ring or allylic ether), N, C, S, P, Al][2,3] produces organonickel intermediates (**3**) pivotal in olefin isomerization,[3] olefin and diolefin oligomerization,[3] desulfurization of aromatic sulfur heterocycles,[4] epoxide deoxygenation[5] and the Kumada carbon–carbon cross coupling[6] [Equation (1)].



**1** **2** **3** (1)

A recent study of nickel(0)-induced α-eliminations from geminal disubstituted alkanes **4** leading directly to carbon–carbon π-bond coupling also appears to involve such oxidative addition by nickel(0) to produce **5**[7] (Scheme 1). However, in this situation adduct **5** could lead to C=C bond coupling via two distinctly different routes: (1) **5** could itself undergo an α-elimination yielding a nickel(II)-carbene complex (**6**); or (2) alternatively, **5** could undergo a second oxidative addition with **1** to produce dinickelaalkane **7**, which upon elimination of NiAB (**8**) would yield nickel(0)-carbene complex **9**. Then via a dimerization-elimination of nickel(II)-carbene **6** (path 1) or by a coupling process through nickel(0)-carbene **9** and **4** (path 2) the olefin dimer **10** would result. This previous global investigation of α-eliminations of geminally disubstituted hydrocarbons by nickel(0) rea-

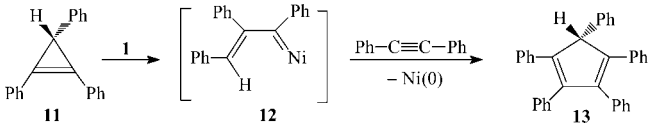
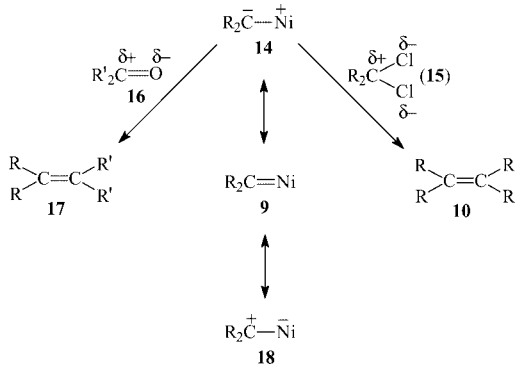
gents has embraced in its survey dihalo, sulfonyl lithio, ketonic, thioketonic and even cyclopropene reagents.[7]

Since the ring-opening and alkyne-insertion reactions of 1,2,3-triphenylcyclopropene (**11**) with nickel(0) complexes to produce intermediate **12** seemed to be explicable only in terms of path 2 (Scheme 2; Diels–Alder capture of **12** by diphenylacetylene and subsequent $Ni^0$-elimination to yield **13**), we made the preliminary hypothesis that all such geminal disubstituted derivatives would similarly involve nickel(0)-carbene intermediates.



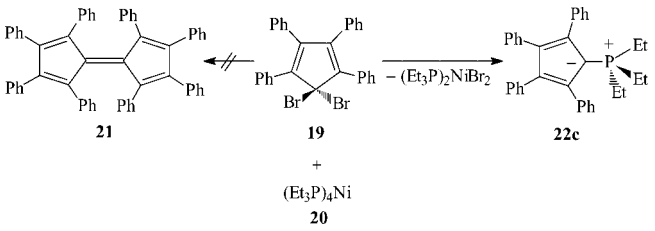
Scheme 2.

But in extending path 2 to the reactions of $L_nNi$ (**1**) with geminal dichlorides, for example, one would have to invoke the unlikely polarization **14** to explain the coupling with $R_2CCl_2$ (**15**) to form olefin dimer **10** or the purported capture of **9** as **17** with an aldehyde or ketone $R_2C{=}O$ (**16**), benzaldehyde or benzophenone for **9** in ref.[7] (Scheme 3). On the contrary, with late transition metal or Fischer carbenes, the carbene center is known to exhibit *electrophilic* (**18**), rather than nucleophilic (**14**) character. Accordingly, resonance structure **14** would be only a minor contributor to the actual π-electron distribution in **9**.



Scheme 3.

Because of these incongruities between the experimental observations made in the reactions of geminal dihalides (e.g. **15**) with nickel(0) reagents **1** and the postulated role of nickel(0)-carbenes (Scheme 1; path 2: **4** → **5** → **7** → **9** → **10**), we have reinvestigated these reactions in a more searching manner. We have tried to detect and identify all possible by-products and side products. Most of all, we have striven to explain the anomalous course of the attempted carbon–carbon π-bond coupling of 5,5-dibromotetraphenylcyclopentadiene (**19**) by tetrakis(triethylphosphane)nickel(0), $(Et_3P)_4Ni$ (**20**). Instead of dimerizing to octaphenylfulvalene (**21**), the corresponding phosphonium ylide or Wittig reagent **22c** was formed in high yield[7] (Scheme 4). Any acceptable reaction mechanism, in our opinion, would have to explain how such Wittig reagents could readily arise in the course of such couplings. We will show that only the intermediacy of nickel(II)-carbene complexes (Scheme 1; path 1: **4** → **5** → **6** → **10**) can readily lead to Wittig reagents in situ.



Scheme 4.

## Results and Discussion

### Anomalous Reaction of 5,5-Dibromotetraphenylcyclopentadiene (19) with $(Et_3P)_4Ni$ (20)

The reaction mixture of a 1:3 molar ratio of **19** and **20** in THF at room temp. was freed of volatiles and the resulting residue was extracted with warm cyclohexane. The extract deposited 70% of triethylphosphonium tetraphenylcyclopentadienide (**22c**).[8a] From the concentrated and cooled cyclohexane filtrate were obtained 80% of the expected $(Et_3P)_2NiBr_2$. Finally, treating the last filtrate with deoxygenated 6 N aqueous HCl led upon hydrolytic workup to the isolation of 1,2,3,4-tetraphenylcyclopentadiene (**23**, 24%) as the only detectable organic product with no sign of fulvalene **21**. The hydrocarbon **23** can be considered as the expected reductive cleavage product of phosphonium ylide **22c** by **20** and acid, shown in Scheme 5, a reaction having ample precedent.[8b] From this detailed analysis of the reaction products, we therefore conclude that the formation of phosphonium ylide in Scheme 3 has proceeded essentially to completion without the generation of any **21**. The failure of any fulvalene like **21** to form in such a reaction cannot be ascribed to any inherent instability of these substituted fulvalenes. Both 1,2,3,4-tetraphenylfulvalene (m.p. 202 °C)[9a] and octaphenylfulvalene [**21**, m.p. 170 °C (dec.)][9b] have been prepared as brilliant orange-red solids and have been found to be indefinitely stable below 100 °C.

### The Stability and Structure of Triethylphosphonium Tetraphenylcyclopentadienide (22c)

Although the phosphonium ylide **22c** has all the structural features of a typical Wittig reagent, it is stable to air and moisture when stored at room temperature and does not react with either benzaldehyde or benzophenone in warm cyclohexane to give a fulvene, the expected Wittig methylenation reaction product. But the corresponding triphenylphosphonium cyclopentadienide has also been shown by Ramirez and Levy not to react with cyclohexanone even at elevated temperatures.[10] In both instances, the delocalization of the anionic charge and Hückel aromaticity of such a cyclopentadienyl ring could be viewed as the cause for the inertness of such Wittig reagents.

The single-crystal X-ray structure determination of phosphonium ylide **22c** (Figure 1 and Tables 1 and 2) sheds light on the extent of delocalization of the negative charge in the cyclopentadienyl moiety of **22c**, namely the relative importance of resonance structures **22a**, **22b** and **22c**, as well as the relative importance of the neutral phosphorane resonance structure **22d**, often invoked with Wittig reagents. It should be noted that this XRD structure of **22c** is not the first trisubstituted phosphonium cyclopentadienide whose structure has been determined in the crystalline state. The crystal structure of triphenylphosphonium cyclopentadienide (**24**) has been determined by X-ray crystallography and the question of the degree of ylide-ylene character in the cyclopentadienyl carbon–phosphorus bond carefully addressed.[11a] This prior work has been most valuable in our present attempt to evaluate the relative contributions of resonance structures **22a**–**22d**.

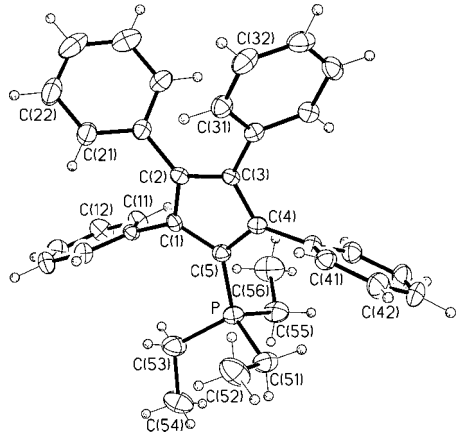

Figure 1. ORTEP projection of triethylphosphonium tetraphenylcyclopentadienide (**22c**) with ellipsoids at the 30% probability level.

In Table 1 are listed the experimentally determined C(5)–P and C–C bond lengths of greatest relevance in evaluating the relative contributions of resonance structures **22a**–**22d**. The observed C–C bond lengths within the cyclopentadienyl ring, as shown in **22d**, can be profitably compared with those of the cyclopentadienyl anion.[12] Of analogous use is a comparison of C(5)–P bond length in **22a**–**d** with that of the similar phosphonium ylide **24** and that of naphthalene derivative **25**.[13a]

Table 1. Selected bond lengths and angles of triethylphosphonium tetraphenylcyclopentadienide (**22c**).

| Bond lengths [Å] | | | |
|---|---|---|---|
| P–C(5) | 1.756(5) | C(1)–C(16) | 1.492(6) |

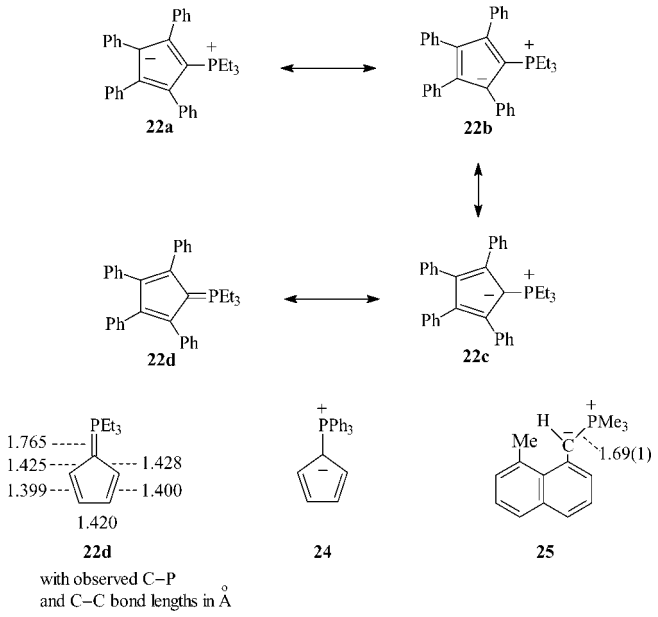
In the first place, the clearly alternating C–C bond lengths of the cyclopentadienyl ring (1.40 ± 0.02 Å) of **22a**–**d** indicate that resonance structures **22a** and **22b** make relatively lesser contributions to the π-electron distribution. In the cyclopentadienyl anion of KCp(18-crown-6), however, the ring C–C bond lengths range from 1.37 to 1.41 Å with a mean of 1.40 Å. The distances in **22a**–**d** might be considered the same within experimental error, if their bond length alternation did not so nicely parallel the C–C bonding in resonance structures **22c** or **22d**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



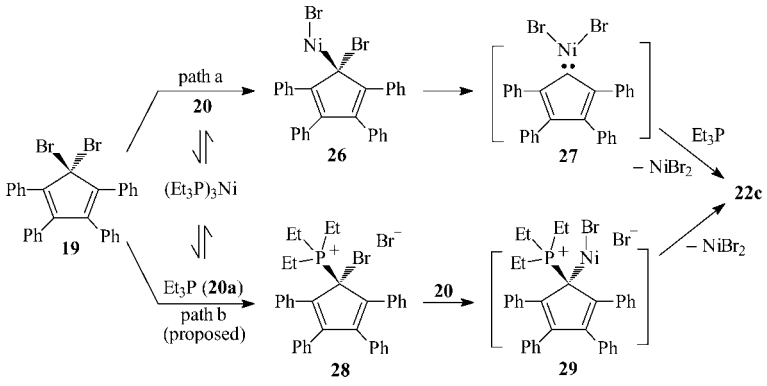
The question of ionic or double character of the carbene–carbon bonding with phosphorus can reasonably be judged on the basis of the carbene C–P bond in **25**, one of the few open-chain phosphoranes with alkyl substituents, whose XRD structures have been measured. At 1.69 Å the C–P bond in **25** should have more C=P bond character than that in **22a**–**d**, 0.08 Å longer. Another indication of lessened C=P bonding in **22a**–**d** results from comparing the bond lengths of the C–P bonds of the three ethyl groups attached to phosphorus, 1.81 Å, with the carbene C(5)–P bond, 1.77 Å. A change in the C($sp^3$) hybridization of the ethyl in **22** to the C($sp^2$) hybridization of the phenyl in $Ph_4P^+$ (1.81 → 1.79 Å) suggests that the $sp^2$-hybridized carbene-carbon–phosphorus bond length would be 1.79 Å for an ordinary single C–P bond. This length is so close to the observed 1.77 Å as to indicate that there is markedly less phosphorane character in **22**, as suggested by **22c** than there is in **25** (C–P bond of 1.69 Å) or even in **24** (C–P bond of 1.72 Å). Therefore, the carbon–phosphorus linkage is best represented by the single resonance structure **22c**. The greater zwitterionic character in the carbene-carbon–phosphorus bond of **22c**, compared with that of **24**, can be attributed to the following electronic stabilization: (1) the presence of electron-donating ethyl groups on P, instead of phenyl groups, stabilizing the cationic P-center; and (2) the presence of π-electron-withdrawing phenyl groups on the cyclopentadienyl ring, instead of hydrogens, stabilizing the anionic C-center. Assigning a reliable percentage of ylene-ylide character to the C–P bond, however, seems to be beset with great uncertainty.[11b]

The $^{13}C$ NMR spectrum of **22c** provides confirmation of the higher charge density of carbon C(5) over that of centers C(1) or C(4).[13b] The doublet centered at $\delta$ = 124.85 ppm displays the largest $^{13}C$-$^{31}P$ coupling (60 Hz) whereas the doublets at $\delta$ = 127.10 ppm and 127.80 ppm are split by 25 Hz and 18 Hz, respectively. As expected, the doublet with the largest splitting must be assigned to C(5), which is closest to the phosphorus. Since C(5) is the closest to phosphorus and its signal is the most shielded, it would thus have a higher electron density than those of C(1) and C(4).

### Possible Mechanistic Routes to Triethylphosphonium Tetraphenylcyclopentadienide (22c)

Two quite divergent pathways leading from 5,5-dibromotetraphenylcyclopentadiene (**19**) and $(Et_3P)_4Ni$ (**20**) to **22c** can be envisioned, the one an integral part of the nickel(II)-carbene pathway proposed here for the coupling of geminal dihalides to yield dimeric olefins via intermediates analogous to **26** and **27** (cf. infra) (path a; Scheme 6) and the other involving an initially formed quarternary phosphonium salt (**28**), followed by oxidative addition of $Ni^0$ from **20** to produce **29** and concluded by elimination of $NiBr_2$ (path b).[14] Clearly, the latter route would involve no nickel-carbene complex as such.

As will be discussed below, there is ample precedent for the coupling of geminal dihalides by $Ni^0$ reagents, either $(Et_3P)_4Ni$ (**20**) or $(Cod)_2Ni$ (**34**), via intermediates like **26** and **27**, when steric factors do not prevent their coupling. Thus, the feasibility of path a is evident. On the other hand, path b requires as its first step the slow quaternization of $Et_3P$ (**20a**) by **19** to form **28**, a process known to require a combination of higher temperatures, peroxides and/or ultraviolet radiation to be initiated and widely considered to involve free-radical chain reactions.[15a,15b] By contrast, it



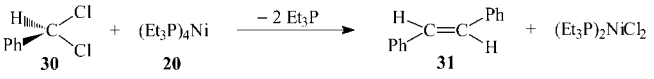
Scheme 6.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

should be noted that the reaction of **19** with **20** proceeds readily at room temperature in oxygen- and peroxide-free THF with no special illumination. Furthermore, the reaction of putative intermediate **28** with **20** to yield the necessary **29** is obviously fraught with steric hindrance. Finally and decisively, the attempted interaction of **19** with **20a** in THF, with the conditions under which **19** and **20** react completely (18 h at 25 °C), failed altogether. Since this proposed first step of path b has been attempted in this study without success, path b can be dismissed as a viable alternative to path a.

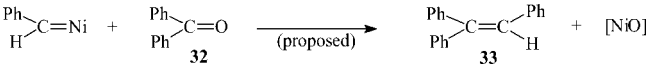
### Reactions of α,α-Dichlorotoluene (30) with Nickel(0) Reagents

In our previous report we observed that a 1:2 mixture of α,α-dichlorotoluene (**30**) and $(Et_3P)_4Ni$ (**20**) reacted in THF at 25 °C to give 98% of *trans*-stilbene (**31**) [Equation (2)].[16]



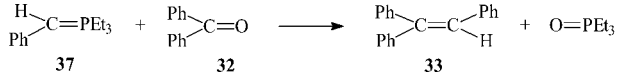
(2)

In a parallel reaction conducted at 0 °C, the 1:2 mixture of **30** and **20** was allowed to react in the presence of 1 equiv. of benzophenone (**32**). Hydrolytic workup led to the isolation of 40% of **31** and 47% of triphenylethylene (**33**). The formation of **33** was at first thought to have originated from a Wittig-like reaction of the nickel(0)-carbene, PhCH=Ni, with **32** through the elimination of NiO [Equation (3)].



(3)

But the present findings, employing $(Cod)_2Ni$ (**34**) with **30**, tend to rule out this interpretation. Certainly, a 1:2 mixture of **30** and **34** reacted equally smoothly in THF at 25 °C to produce a high yield of *trans*-stilbene (96%). But the corresponding attempted trapping experiment involving a 1:2:1 mixture of **30**, **34** and **32** again led only to a high conversion to *trans*-stilbene (94%) with no detectable amount of the trapping product **33**. If the nickel(0)-carbene, PhCH=Ni, were the source of **33**, it should also have been present in this mixture and therefore have been trapped. Since no such trapping product was detected, we suggest an alternative and mechanically more reasonable source of **33**. We now propose, instead, that a nickel(II)-carbene (**36**) is generated in these coupling reactions and that coupling occurs through the reaction between **36** and oxidative-addition product **35**. The matched polarities of carbon–nickel bond of **35** and the Fischer-carbene-carbon–nickel(II) bond of **36** should foster rapid C–C bond formation to yield **31**. Only in the C–C couplings employing reagent **20** would the triethylphosphane be present to undergo a competitive reaction with the electrophilic carbon of nickel(II)-carbene **36**, leading to the displacement of nickel(II) chloride as its $Et_3P$ complex and the generation of phosphane ylide **37** (Scheme 7). The reaction of benzophenone (**32**) with this Wittig reagent, rather than the dubious reaction with the previously suggested nickel(0)-carbene, is therefore concluded to be the actual source of the triphenylethylene (**33**) [Equation (4)].

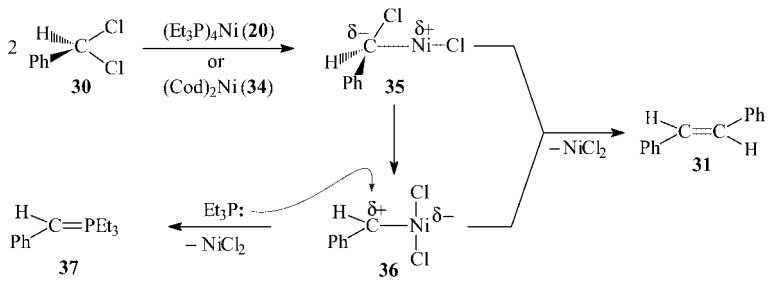


(4)

The observation of phosphonium ylide **22c** as the ultimate Wittig-like reagent from dibromo compound **19** and nickel reagent **20**, as well as the aforementioned detection of **37** in the reaction of geminal dichloro compound **30** with **20**, show that phosphonium ylides can occur as intermediates in such C–C bond-coupling reactions. That they are necessary intermediates, however, seems most unlikely.[17]

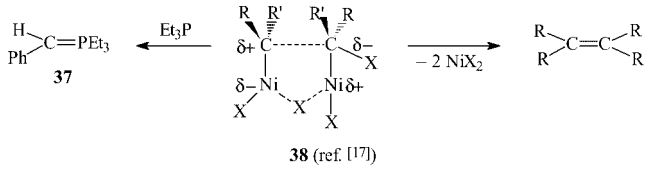
### Generalized Mechanism for the Nickel(0)-Promoted Coupling of Geminal Disubstituted Hydrocarbons

The foregoing coupling mechanism, having nickel(II)-carbenes as key intermediates, can be rationally applied to the other geminal dihalohydrocarbons already studied, namely dibromomethane, dichlorodiphenylmethane and 5,5-dibromo-1,2,3,4-tetraphenylcyclopentadiene (**19**) (Scheme 8).



Scheme 7.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

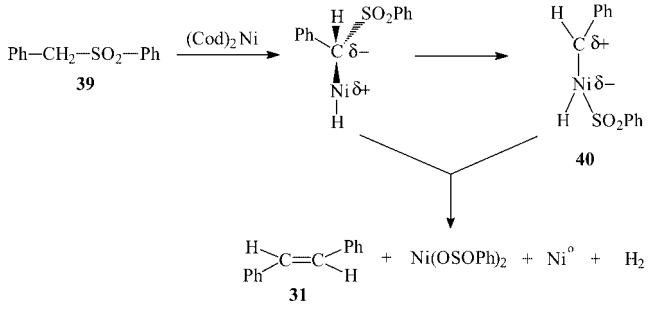


Scheme 8.

Considering **38** as an appropriate activated complex,[18] it is clear that when R and R′ are space-filling groups as in the reaction of 5,5-dibromotetraphenylcyclopentadiene (**19**) (R and R′ combined as a 1,4-tetraphenylbutadienylene group), then C–C bond formation will be relatively slow and the $Et_3P$ attack will form the Wittig reagent selectively. With R and R′ as phenyl groups, C–C bonding is still possible but backside attack at the pseudo-tertiary carbene-carbon by $Et_3P$ should be slow. This view is in agreement with our previous finding that the reaction of $(Et_3P)_4Ni$ with dichlorodiphenylmethane in the presence of benzaldehyde leads to 95% of tetraphenylethylene with no sign of triphenylethylene, the expected Wittig reaction product expected to arise from benzaldehyde and $Ph_2C{=}PEt_3$.[19]

Finally, with R = Ph and R′ = H, as was presented in Scheme 5, C–C bond formation would occur along the internuclear line in **38** with the phenyl groups *trans* to each other for steric reasons. In this case, the carbene-carbon is pseudo-secondary and hence more accessible to backside attack by $Et_3P$ and thus the formation of the corresponding Wittig reagent. With R and R′ as H in dihalomethanes, the frontside C–C coupling in **38** and the backside attack by $Et_3P$ should be of comparable facility and therefore C–C coupling and Wittig-reagent formation both are possible and in fact observed.

The coupling mechanism operative with other geminal disubstituted hydrocarbon derivatives, such as thioketones and α-lithioorganic sulfones, is also most likely one involving analogous nickel(II)-carbene intermediates.[20] Even the behavior of benzylic sulfones toward nickel(0) reagents indicates the possible intermediacy of nickel(II)-carbene complexes. Benzyl phenyl sulfone (**39**), for example, reacted with $(Cod)_2Ni$ in toluene at 25 °C over an extended period to give the deposition of nickel metal. Hydrolytic workup gave a 40% yield of *trans*-stilbene (**31**) with no trace of bibenzyl (Scheme 9). The absence of bibenzyl is consistent with the absence of reductive cleavage of the C–S bond. The formation of *trans*-stilbene can be readily explained through the oxidative addition process depicted in Scheme 9, which would lead to a nickel(II)-carbene (**40**) and thus to C–C bond coupling analogous to that in Scheme 7.



Scheme 9.

## Conclusions

The bond cleavages of geminal dihalides of the type $R_2CX_2$ by nickel(0) reagents is best depicted as leading to dimers $R_2C{=}CR_2$ via nickel(II)-carbenes by the following sequence of reactions: (1) oxidative addition of $Ni^0$ to produce $XR_2C–Ni–X$;to provide the nickel(II)-carbene, $R_2C^+–{}^-NiX_2$; (3) C=C bond formation between $XR_2C^{\delta-}–{}^{\delta+}NiX_2$ and $R_2C^+–{}^-NiX_2$ because of opposite polarities. If step 3 is too slow in the reactions involving $(Et_3P)_4Ni$, then any free $Et_3P$ can displace the $NiX_2$ from $R_2C^+–{}^-NiX_2$ and capture the $R_2C$ ligand as the Wittig reagent, $R_2C{=}PEt_3$. Such a Wittig reagent, rather than the previously assumed nickel(0)-carbene, $R_2C{=}Ni^0$, is responsible for the formation of $R_2C{=}CR'R''$ when $R'R''C{=}O$ is added to such reaction mixtures.

Triethylphosphonium tetraphenylcyclopentadienide (**22c**), the Wittig reagent obtained in high yield from the unsuccessful attempt to couple 5,5-dibromotetraphenylcyclopentadiene to produce octaphenylfulvalene (cf. supra: slow step 3), was subjected to X-ray crystallographic structure determination. Such structural data, together with its $^{13}C$ NMR chemical shifts and $^{13}C$-$^{31}P$ coupling constants, are clearly consistent with the electronic structure **22c**, where the ring C(5)–P bond is essentially a zwitterionic single C–P bond and the negative charge of the *pseudo*-cyclopentadiene anion greatest on C(5).

## Experimental Section

**General Procedures and Techniques:** All reactions were carried out under a positive pressure of anhydrous, oxygen-free argon. All solvents employed with organometallic compounds were dried and distilled from a sodium metal/benzophenone ketyl mixture prior to use. The preparation and purification of oxygen- and moisture-sensitive reagents were carried out under argon with the use of Schlenk techniques.[21] The IR spectra were recorded with a Perkin–Elmer instrument, model 457 and samples were measured either as mineral oil mulls or as KBr films. The NMR spectra ($^1H$ and $^{13}C$) were recorded with a Bruker spectrometer, model AM-360 and tetramethylsilane (TMS) was used as the internal standard. The chemical shifts reported are expressed on the $\delta$-scale and in parts per million (ppm) from the reference TMS signal. The gas-chromatographic analyses were carried out with a Hewlett–Packard instrument, model 5880, provided with a 6 ft OV-101 packed column or with a Hewlett–Packard instrument, model 5890, having a 30 m SE-30 capillary column, respectively. Melting points were determined with a Thomas-Hoover Unimelt capillary melting point apparatus and are uncorrected. The $(Cod)_2Ni$ was prepared according to a procedure adapted from those of Semmelhack[22] and of Schunn.[23] The yield of product has been improved to 95% by purifying the starting materials with extreme care.

The $(Et_3P)_4Ni$ was prepared according to the method of Cundy[24] and the (Cod)(Bpy)Ni by the procedure of Dinjus et al.[25] The α,α-dichlorotoluene, dichlorodiphenylmethane and dibromomethane

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were purchased at 98+% of purity and their purity further checked by gas chromatography.

The 5,5-dibromotetraphenylcyclopentadiende (**19**) was prepared for the first time by the following procedure developed in this laboratory. A solution of 3.76 g (10.0 mmol) of 1,2,3,4-tetraphenylcyclopentadiene (**23**) in 80 mL of $CCl_4$ was treated with 3.65 g (20.5 mmol) of *N*-bromosuccinimide (99%) and the suspension heated at reflux until all suspended solid had risen to the surface (90 min). During the heating, a small illuminated UV lamp was focused on the reaction flask. The hot solution was then filtered from the succinimide and the filtrate freed of solvent in a rotary evaporator. The pale yellow solid residue of 5.1 g was essentially pure **19** because the peak at $\delta = 4.0$ ppm in the $^1$H NMR spectrum of the starting diene was absent. Recrystallization from 95% ethanol yielded 4.4 g (83%) of pure **19**, m.p. 154–155 °C. $C_{29}H_{20}Br_2$ (528.30): C 65.31, H 3.78; found C 65.69, H 3.82.

The sample of octaphenylfulvalene (**21**) was prepared by the following route. A suspension of 1.50 g (2.80 mmol) of **19**, prepared in the foregoing method, and 5.0 g (76 mmol) of zinc dust in 50 mL of benzene was treated with a crystal of iodine as an activator and was then stirred under reflux for 6 h. The resulting deep red suspension was filtered hot. The filtrate was freed of solvent in a rotary evaporator to leave a deep red gummy residue. Stirring this residue with hot portions of a 1:1 (v/v) mixture of benzene/95% ethanol gave a deep red extract. Concentration and cooling of the extract gave 710 mg (69%) of brilliant orange-red solid (**21**), which had multiplets of proton signals between $\delta = 7.0$ ppm and 7.4 ppm in the $^1$H NMR spectrum and whose mass spectrum at 70eV had a parent peak at $m/z = 736$, characteristic of fulvalene **21**. No peaks were present indicative of any **19** or any other bromine-containing component (with isotopic $^{79}$Br and $^{81}$Br components). This sample melted at 170 °C with decomposition, despite several recrystallizations from 95% ethanol/toluene. $C_{58}H_{40}$ (736.77): calcd. C 94.54, H 5.46; found C 94.10, H 5.16.

**X-ray Crystallographic Study of Triethylphosphonium Tetraphenylcyclopentadienide (22). Crystal Mounting and Data Collection:** Data were collected at room temperature with a Siemens P4 diffractometer equipped with a scintillation counter. An orange crystal was mounted on a glass fiber with epoxy cement and a unit cell determined from the angular settings of 25 centered reflections. Systematic absences in the diffraction data indicated either the monoclinic space groups $P2_1$ or $P2_1/m$. *E* statistics initially indicated the noncentrosymmetric alternative, and the structure that was developed in this setting proved to be incompatible with mirror-plane symmetry. All non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were treated as idealized contributions. The correctness of the reported hand was affirmed by the value of the refined Flack parameter: 0.04(17). All software used was contained in the SHELXTL and data collection libraries of programs provided by the Siemens Corporation (Madison, WI). The pertinent crystal data and structure refinement are presented in Table 2. CCDC-628202 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Preparation of Triethylphosphonium Tetraphenylcyclopentadienide (22c) from 5,5-Dibromotetraphenylcyclopentadiene (19) and $(Et_3P)_4$-Ni (20):** A solution of 1.94 g (3.66 mmol) of **19** in 60 mL of THF was treated with 640 mg (1.20 mmol) of **20** at 25 °C. The dark red solution was stirred for 18 h and then the THF was removed under reduced pressure. The dark residue was extracted with warm cyclohexane (6 10-mL portions of deoxygenated solvent). The hot extracts were filtered, concentrated to 2/3 of volume and chilled to deposit 1.24 g of amber-colored **22c** (70%). Recrystallization from cyclohexane yielded pale orange **22c**, m.p. 200–202 °C, which was submitted to X-ray single-crystal determination (Table 2). $^1$H NMR ($C_6D_6$): $\delta = 0.41$–0.50 (m, 9 H), 1.02–1.21 (m, 6 H), 6.82–7.59 (m, 304) ppm. $^{13}$C NMR ($C_6D_6$): $\delta = 15.98$ (d), 20.17 (3), 124.85 (d), 127.10 (d), 127.80 (m, high intensity), 132.45 (d) ppm. The $J_{C,P}$ values of the doublets at $\delta = 124.85$, 127.10 and 127.80 ppm are 60, 25 and 18 Hz, respectively.

The original cyclohexane filtrate from which **22c** had crystallized was concentrated to dryness under reduced pressure and the residue dissolved in dry, deoxygenated $C_6H_6$. The $^1$H NMR spectrum of this solution displayed only very broad absorptions, characteristic of the presence of paramagnetic components. Hence, the entire $C_6D_6$ solution was treated with deoxygenated 6 N aqueous HCl. Hydrolytic workup yielded 107 mg of a reddish solid, whose $^1$H NMR spectrum showed it to be largely **23** (m.p. 180–181 °C, 24%, $^1$H NMR peak at $\delta = 4.0$ ppm).

The deep red reaction residue remaining after the cyclohexane extraction of the reaction mixture was redissolved in THF and cooled to –78 °C. Long dark red needles of $(Et_3P)_2NiBr_2$ were formed (440 mg, 80%).[26] The $^1$H NMR spectrum showed no aromatic proton absorptions.

**Attempted Reaction of 5,5-Dibromotetraphenylcyclopentadiene (19) with Triethylphosphane (20a). Test of the First Proposed Step, 19 + 20 → 28, of Path b in Scheme 6:** A solution of 3.88 g (7.32 mmol) of **19** and 0.87 g (7.4 mmol) of **20a** dissolved in 120 mL of anhydrous, deoxygenated THF was allowed to stand under an argon atmosphere for 18 h at 25 ± 5 °C in a Schlenk flask sheathed in aluminum foil, so as to exclude light. During this time, the initially pale yellow solution did not change color nor did any solid precipitate. All volatiles were then removed under reduced pressure at 25 °C and the resulting residue was shown to be essentially pure **19** by $^1$H and $^{13}$C NMR spectroscopic analysis.

**Reaction of $(Cod)_2Ni$ (34) with α,α-Dichlorotoluene (30):** In our previous report on the reactions of geminal dihaloalkanes with nickel(0) reagents[7] the experimental details for the individual reactions of α,α-dichlorotoluene, dichlorodiphenylmethane and dibromomethane with $(Et_3P)_4Ni$ or for the reaction of dichlorodiphenylmethane with $(Cod)_2Ni$ have already been published. The following experiment is described here for the first time.

A solution of $(Cod)_2Ni$ (**34**, 1.35 g, 4.90 mmol) and α,α-dichlorotoluene (**30**, 0.40 g, 2.40 mmol) in 20 mL of THF was stirred for 2 h at 25 °C. Quenching with deoxygenated 6 N HCl under argon. Usual workup (diethyl ether extraction, neutralization with solid $NaHCO_3$, solvent removal and flash chromatography) permitted the isolation of only *trans*-stilbene (**31**) (225 mg, 96%).

**Reactions of $(Cod)_2Ni$ (34) with α,α-Dichlorotoluene (30) in the Presence of Benzophenone (28):** A reaction run almost identical to the foregoing was conducted, except that 1 equiv. of benzophenone (**32**) was present. The analogous workup of the reaction mixture and flash chromatography led only to *trans*-stilbene (94%), with 90% of the benzophenone recovered.

**Reaction of $(Cod)_2Ni$ (34) with Benzyl Phenyl Sulfone (39):** A solution of **34** (1.24 g, 4.50 mmol) and **39** (1.05 g, 4.50 mmol) in 60 mL of dry, deoxygenated toluene became black upon mixing the components. The black mixture was stirred at 25 °C for 4 h and then at reflux for 3 h, during which latter period a nickel mirror appeared on the flask wall. Hydrolysis of the mixture with deoxygenated, aqueous 6 N HCl led to gas evolution. Separation and drying of the toluene layer, removal of solvent and flash

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chromatography led to the isolation of *trans*-stilbene (0.81 g, 39%) and recovered **39**. No sign of bibenzyl was seen in the $^1$H NMR spectrum of the crude reaction product.

## Acknowledgments

This research has received the financial support of Akzo Corporate Research America Inc. and the Boulder Scientific Company, Mead, Colorado. Furthermore, through an Alexander von Humboldt Senior Scientist Award, the corresponding author was able to spend his sabbatical leave during the academic year of 2005–2006 in the Institute of Inorganic Chemistry of the Munich Technical University, Germany. There, in the research group of Wolfgang A. Herrmann, he received much insight into the chemistry of nitrogenr heterocyclic carbene complexes of transition metal salts. Finally, the authors are grateful for valuable orienting experiments with nickel(0) and zirconium(II) carbenoid reactions to former coworkers, Drs. Adetenu Adeosun, Tomasz Dluzniewski, Somnath Dutta and Xin Ma.

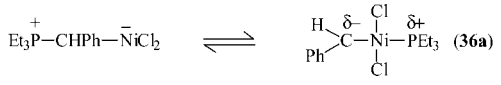
On the Allred-Rochow scale phosphorus at 2.06 is electron-releasing relative to carbon at 2.50 and thus magnetically shielding towards carbon.
[14] A referee has been helpful in suggesting the possibility of path b as an alternative possibility for producing **22c** from **19** and **20** without the intermediacy of a nickel(II)-carbene. In addition, the same referee suggested the key experiment for deciding on the viability of path b as a competing mechanism, namely whether or not **19** and **20a** would react with each other at 25 °C.

Soc.* **1957**, *79*, 5829–5830. b) Although this report appeared 50 years ago, it has not been repudiated since and in fact is treated as reliable in a classic monograph on organophosphorus reactions: R. F. Hudson, *Structure and Mechanism in Organo-Phosphorus Chemistry*, Academic Press, New York, **1965**, pp. 297–299.
[16] When the THF solution of the final reaction mixture was concentrated to half its volume and then cooled to 0 °C, dark red crystals of bis(triethylphosphane)nickel(II) chloride were deposited, mp. 113–115 °C (68%); D. T. Doughty, G. Gordon, R. P. Stewart Jr, *J. Am. Chem. Soc.* **1979**, *101*, 2645–2648.
[17] A referee has proposed that in such coupling reactions of geminal dihalides with $(Et_3P)_4Ni$ (**20**) perhaps metal carbenes are not involved at all, that maybe they are just phosphonium ylide adducts, $R_3P^+–CR_2–^-NiCl_2$ and, as Milstein and co-workers have shown, that ylides could be converted to metal-carbenes by late transition metal compounds (M. Gandelman, K. M. Naing, B. Rybtchinski, E. Poverenov, Y. Ben-David, N. Ashkenazi, R. M. Gauvin, D. Milstein, *J. Am. Chem. Soc.* **2005**, *127*, 15265–15272). Admittedly, our work has shown that phosphonium ylide **22c** is readily formed from dibromo compound **19** and $(Et_3P)_4Ni$ (**20**) and that **30** and **20** produce Wittig reagent **37** in solution, which is capable of being captured in a Wittig reaction with benzophenone. Despite the presence of **37** in such reactions, such phosphonium ylides or their complexes with $NiCl_2$ cannot be essential intermediates in these coupling reactions, because **30** can be converted into olefin dimer **31** in over 90% yield either by $(Et_3P)_4Ni$ or by $(Cod)_2Ni$. Obviously, the latter nickel(0) complex could not involve any phosphonium ylide. In fact, any phosphonium ylide generated with **30** may be in ready equilibrium with the crucial carbene intermediate **36a** (**36** with coordinated $Et_3P$):



**(36a)**

[18] The likelihood of a bridging halide between the nickel centers in the proposed activated complex **38** is supported by the known dimeric structure of η$^4$-tetraphenylcyclobutadiene–nickel(II) bromide where the two units of the monomer are held together by two Ni···Br···Ni bridges.
[19] The failure to detect triphenylethylene in this trapping experiment with benzaldehyde can stem from either of two causes: (1) the supposed ylide, $Ph_2C{=}PEt_2$, is too slow to react with PhCHO, before it reacts thus: $Ph_2C{=}PEt_3 + Ph_2C(Cl)NiCl \rightarrow Ph_2C{=}CPh_2 + (Et_3P)_2NiCl_2$; or (2) in analogy with Scheme 7, $Et_3P$ is unable, for steric reasons, to react with $Ph_2C–NiCl_2$ (**36**) before coupling occurs via **38**.
[20] The α-elimination of lithium benzenesulfinate from Ph–CHLi–$SO_2$Ph cannot be effected by heating this dry salt under argon at 90–120 °C for 5 h. No trace of either *cis*- or *trans*-stilbene could be detected upon hydrolytic workup and 90% of the starting sulfone was recovered. By contrast, irradiation of Ph–CHLi–$SO_2$Ph in THF under argon in a quartz tube in a Rayonet rotating reactor (model 100), equipped with lamptubes of 254 nm wavelength for 24 h and subsequent hydrolysis yielded upon liquid chromatography on silica gel with a hexane eluent: (a) a 1:1.3 mixture of *cis*- and *trans*-stilbenes (33%); and (b) *cis*- and *trans*-1,2,3-triphenylcyclopropanes (25%), besides recovered Ph–$CH_2$–$SO_2$–Ph. The cyclopropanes were identified by their C-H proton singlets at $\delta$ = 2.82 (*cis*) and 2.73 (*trans*) ppm ($CDCl_3$) and the mass spectrum of the mixture: MS (70eV): *m/z* = 270 [M], 179, 178, 152, 89, 77 (Y. Qian, Masters Thesis, SUNY-Binghamton, **1992**, p. 57; Y. Qian, Research Notebook No. 1, May 22, **1991**, p. 36). More to the point of this study, however, is the finding that 1–10 mol-% of Ni(acac)$_2$ can cause the catalytic elimination of LiOSOPh from Ph–CHLi–$SO_2$Ph in THF from 0 °C to reflux, leading to variable proportions of solely *trans*-stilbene and *trans*-1,2,3-triphenylcyclopropane, as attested to by their IR, $^1$H NMR and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mass spectra on pure samples separated by column chromatography (silica gel/hexane). In two separate further experiments, one with 1,1-diphenylethylene and the other with diphenylacetylene, the benzylidene fragment from Ph–CHLi–$SO_2$Ph was trapped as 1,1,2-triphenylcyclopropane and 1,2,3-triphenylcyclopropene, respectively (ref.[7]; Y. Qian, Doctoral Dissertation, SUNY-Binghamton, **1996**, pp. 117–118; Y. Qian, Research Notebook No. 1, October 19, **1991**, p. 66). The detailed mechanisms of these carbenoid oligomerizations are under further investigation.

# The Ditertiary-Phosphane-Bridged Heteronuclear Cluster $RuOs_3(\mu\text{-}H)_2(CO)_9(\mu\text{-}CO)_2(\mu\text{-}dppm)$: Synthesis and Reactivity with Alkynes

**Yong Leng Kelvin Tan[a] and Weng Kee Leong*[a]**

**Keywords:** Heterometallic complexes / Ruthenium / Osmium / Ditertiary phosphanes / Alkynes

A high-yielding alternative synthesis of the dppm-bridged heteronuclear cluster $RuOs_3(\mu\text{-}H)_2(CO)_9(\mu\text{-}CO)_2(\mu\text{-}dppm)$ (**1**) [dppm = bis(diphenylphosphanyl)methane] has been developed. Thermolysis of **1** resulted in dephenylation of both phosphane groups to afford the butterfly cluster $RuOs_3(CO)_{12}(\mu_4,\kappa^2\text{:}\kappa^2\text{-}PhPCH_2PPh)$ (**2**). The reaction of **1** with selected alkynes afforded the products $RuOs_3(\mu\text{-}H)(CO)_8(\mu\text{-}CO)(\mu_3,\kappa^2\text{:}\kappa^1\text{-}PhPCH_2PPh_2)(\mu_3,\eta^1\text{:}\eta^2\text{:}\eta^1\text{-}L)$ (**3**) (L = alkyne) in which the alkyne is aligned parallel to an Os–Os bond (// Os-Os isomer). The clusters incorporating internal alkynes underwent isomerization to the //Ru-Os isomer by alkyne and hydride migration. Several other cluster products of these reactions were also identified, including $RuOs_3(\mu\text{-}H)(CO)_8(\mu\text{-}CO)(\mu_3,\kappa^2\text{:}\kappa^1\text{-}PhPCH_2PPh_2)(\mu_3,\eta^1\text{:}\eta^2\text{:}\eta^1\text{-}t\text{Bu}C_2CHO)$ (**6**) in which the methyl group of the alkyne has been oxidized to an aldehyde.

## 1. Introduction

Ditertiary phosphane ligands continue to play an important role in the chemistry of transition-metal clusters because they have the ability to maintain the integrity of the metal framework during chemical reactions, preventing cluster fragmentation and enhancing the catalytic activity of the ditertiary-phosphane-stabilized cluster. Several tri- and tetranuclear ruthenium clusters containing ditertiary phosphane ligands have been studied for their catalytic potential in alkene hydrogenation and isomerization reactions.[1] For these studies, the presence of the phosphane ligand ensured that cluster nuclearity was maintained even under severe reaction conditions. These clusters were found to exhibit greater thermal stability and lower tendency towards decomposition at higher pressure, clearly pointing to the cluster-stabilizing properties of the ditertiary phosphane ligand. In contrast, the catalytic potential of heteronuclear clusters incorporating ditertiary phosphane ligands remains relatively unexplored. The combination of different transition metals within the same framework in heteronuclear clusters may induce novel forms of substrate activation, thus giving rise to interesting chemistry. We have been investigating the chemistry of the hetero group 8 tetranuclear cluster $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ and its derivatives.[2] In the course of our investigations, we have found that the cluster fragments at elevated temperatures. Our efforts to incorporate the dppm ligand onto the cluster by TMNO (trimethylamine-*N*-oxide) activation have led to the isolation of $RuOs_3(\mu\text{-}H)_2(CO)_9(\mu\text{-}CO)_2(\mu\text{-}dppm)$ (**1**) in moderate yield (57%), together with other products.[3] We were interested in further exploring the reactivity and catalytic potential of **1**. In this paper, we would like to report an alternative, high-yield, synthetic route to **1** and our investigations into its reactions with a number of representative alkynes.

## 2. Results and Discussion

### 2.1. Synthesis and Thermal Stability of $RuOs_3(\mu\text{-}H)_2(CO)_9(\mu\text{-}CO)_2(\mu\text{-}dppm)$ (1)

The mononuclear ruthenium complex $Ru(CO)_4(\kappa^1\text{-}dppm)$, which can be prepared in situ by treating dppm with $Ru(CO)_4(C_2H_4)$,[4] has been shown to be a versatile building block for increasing cluster nuclearity. The pendant arm of the ditertiary phosphane can aid the joining of the mononuclear complex to the target cluster; subsequently, metal–metal interactions can be facilitated between the two units held in close proximity to each other.[5] Thus the addition of $Os_3(\mu\text{-}H)_2(CO)_{10}$ to a hexane solution of $Ru(CO)_4(\kappa^1\text{-}dppm)$ resulted in an instantaneous color change to light yellow. Subsequent workup afforded **1** in 82% yield; the minor side products obtained were $Ru_3(CO)_{12}$ and $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ (Scheme 1).

Thermolysis of **1** in refluxing hexane afforded the novel butterfly cluster $RuOs_3(CO)_{12}(\mu_4,\kappa^2\text{:}\kappa^2\text{-}PhPCH_2PPh)$ (**2**) and the trinuclear cluster $Os_3(\mu\text{-}H)_2(CO)_8(\mu\text{-}dppm)$ in 69% and 15% yields, respectively. The unsaturated, 46-electron hydrido osmium cluster $Os_3(\mu\text{-}H)_2(CO)_8(\mu\text{-}dppm)$ has previously been obtained by the treatment of either $Os_3(\mu\text{-}H)(CO)_8[Ph_2PCH_2PPh(C_6H_4)]$ or $Os_3(\mu\text{-}H)_2(CO)_7(\mu\text{-}dppm)(\mu_3\text{-}CN_2)$ with hydrogen gas at elevated tempera-

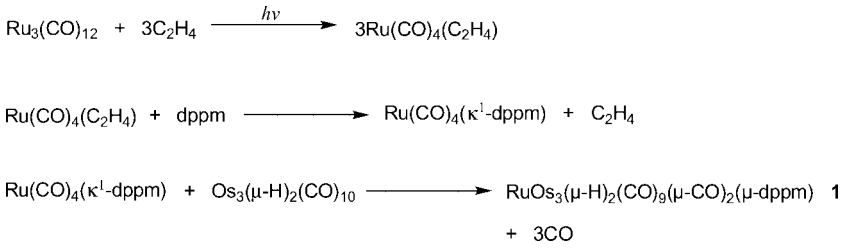

Scheme 1.

tures.[6] The novel cluster **2** has been completely characterized by spectroscopic, elemental and single-crystal X-ray crystallographic analyses; an ORTEP plot showing the atomic numbering scheme and selected bond parameters are given in Figure 1.

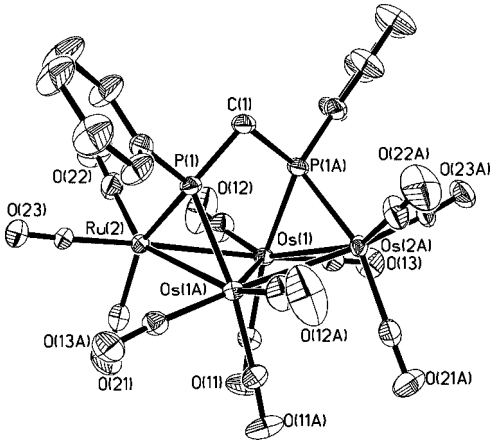

Figure 1. ORTEP diagram (50% probability thermal ellipsoids, organic hydrogen atoms omitted). Selected bond lengths [Å] and angles [°] for **2**: Os(1)–Os(1A) = 2.9067(6), Os(1)–Ru(2) = 2.9289(6), Os(1A)–Ru(2) = 2.8236(6), P(1)–Os(1A) = 2.3591(14), P(1)–Ru(2) = 2.3228(15); Ru(2)–Os(1)–Os(1A) = 61.456(16), Os(1)–Os(1A)–Ru(2) = 57.875(12), Os(1A)–Ru(2)–Os(1) = 60.669(13), Ru(2)–P(1)–Os(1A) = 74.18(4). There is Ru/Os disorder (1:1) over Ru(2) and Os(2A).

The cluster valence electron count for cluster **2** is 62, which is in accord with that predicted by the effective atomic number (EAN) rule for a tetranuclear cluster with five metal–metal bonds.[7] The dihedral angle between the two wings of the butterfly core of **2** is 150.9°. Dephenylation at each phosphane of the ligand has led to phosphanido bridges across two metal–metal bonds. The phenyl groups were probably lost as benzenes with the cluster-bound hydrides.[1c,8] There is a total of twelve carbonyl groups on the cluster, compared to eleven in cluster **1**, the additional carbonyl ligand presumably coming from other decomposition products of the reaction.

The spectroscopic data obtained confirms that the solid-state structure of **2** is retained in solution. The $^{31}P\{^1H\}$ NMR spectrum comprised two sets of doublets at $\delta$ = 77.40 and –22.34 ppm. A downfield shift of the phosphorus signals relative to those observed for **1**, in addition to the large $^2J_{PP}$ of 116.4 Hz, supported the presence of two bridging phosphanido moieties.[9] On the basis of previous observations that a phosphanido bridge across an Os–Os bond resonates at a higher field than one across a Ru–Os edge,[2b,10] the higher-field phosphorus resonance has been assigned to the phosphanido bridging the Os–Os bond.

### 2.2. Reaction of 1 with Alkynes

The reaction of **1** with the alkynes diphenylacetylene, 2-pentyne, 4,4-dimethyl-2-pentyne, phenylacetylene, or *tert*-butylacetylene, at elevated temperatures, afforded up to two products, **3** and **4**, each with the general formula $RuOs_3(\mu\text{-}H)(CO)_8(\mu\text{-}CO)(\mu_3,\kappa^2\text{:}\kappa^1\text{-}PhPCH_2PPh_2)(\mu_3,\eta^1\text{:}\eta^2\text{:}\eta^1\text{-}L)$ [L = PhCCPh (**a**), $C_2H_5CCCH_3$ (**b**), *t*BuCCCH$_3$ (**c**) for **3** and **4**; PhCCH (**d**), *t*BuCCH (**e**) for **3** (products **4d** and **4c** were not obtained)], as well as some other minor products in some cases (Scheme 2).

Clusters **3** and **4** are isomers differing in whether the $\mu_3,\eta^1\text{:}\eta^2\text{:}\eta^1$-bonded alkyne is parallel to an Os–Os edge (// Os-Os isomer, **3**), or to an Ru–Os edge (// Ru-Os isomer, **4**). Clusters **3** and **4** are also of interest because, in general, tetranuclear clusters tend to form butterfly clusters on reaction with alkynes, i.e., cleavage of a metal–metal bond is common.[11] Thus there are rarely examples in which the tetrahedral core is retained.[2g,12] In the formation of these clusters, dephenylation of one of the phosphane groups of the dppm ligand has occurred. Clusters **3** and **4** have been characterized spectroscopically and analytically, and for **3a**–**e** and **4a**–**b**, by single-crystal X-ray crystallographic studies as well; the ORTEP plots for **3b** and **4b** are shown in Figure 2 and Figure 3, respectively.

### 2.3. Structural Discussion on 3 and 4

Selected bond parameters and a common atomic numbering scheme for clusters **3a**–**e** are given in Table 1.

The metal core in clusters **3** adopts a closed tetrahedral geometry, with a valence electron count of 60, as predicted by the EAN rule.[7] The five-electron donor $PhPCH_2PPh_2$ phosphanido-phosphane ligand caps the Os(1)–Os(2)–Ru(4) triangular metal face of the tetrahedron, the phosphanido group adopting an asymmetrical bridging mode in which the Os(2)–P(2) bond is significantly shorter than the Ru(4)–P(2) bond. C–C bond elongation of the coordinated alkynes is observed, with lengths ranging from 1.366(14) to 1.426(12) Å, which are in the ranges of carbon–carbon $sp^2$–$sp^2$ double and single bonds (1.32 and 1.48 Å, respectively).[13] In principle, for such unsymmetrical alkynes, there is the possibility of alkyne isomerism, i.e., the forma-

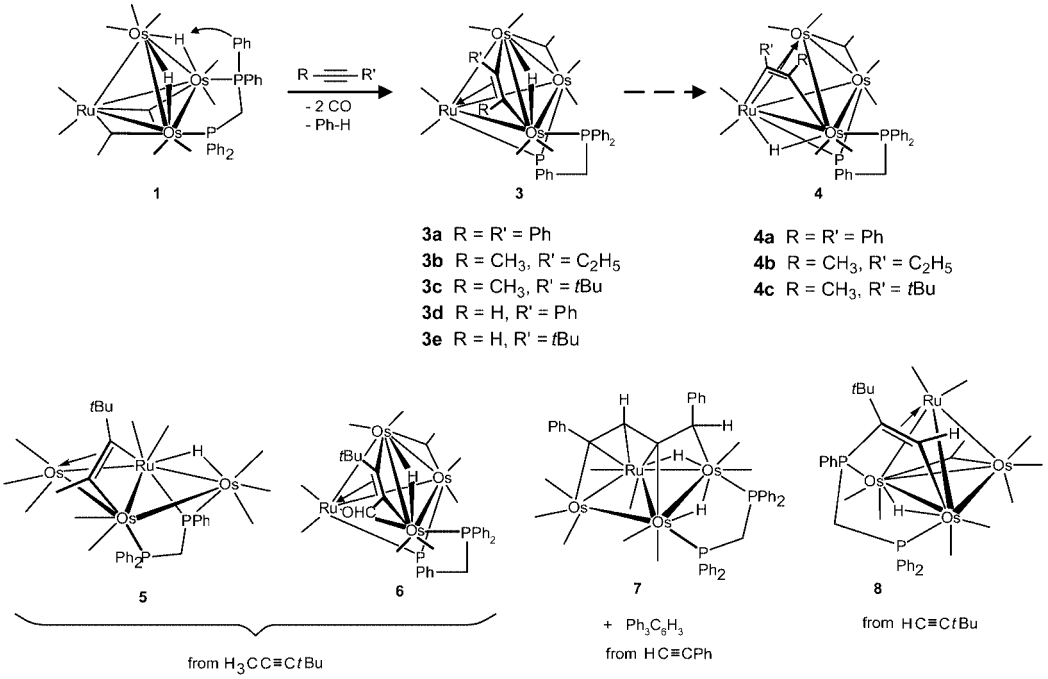

Scheme 2.

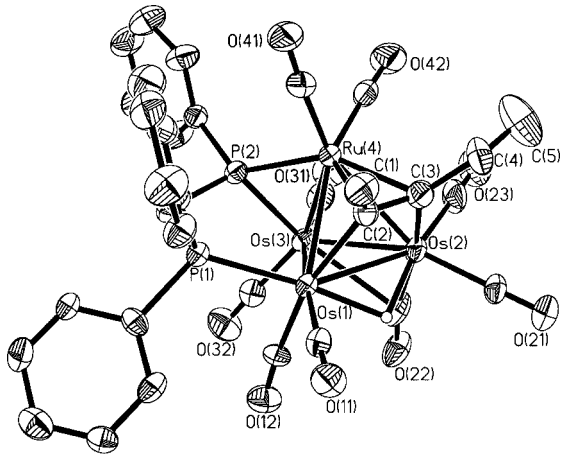

Figure 2. ORTEP diagram (50% probability thermal ellipsoids, organic hydrogen atoms omitted) for **3b**.

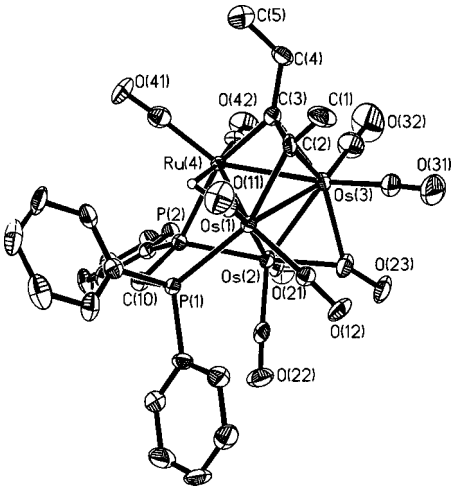

Figure 3. ORTEP diagram (50% probability thermal ellipsoids, organic hydrogen atoms omitted) for **4b**.

tion of isomers which differ in the orientation of the substituents on the alkyne with respect to the phosphanido bridge.[14] The stereoselectivity in **3** may be rationalized by the steric interaction between the phosphane ligand and the bulkier substituent on the alkyne moiety.

The metal–metal bond lengths for **3** show some fairly clear trends. The longest metal–metal contact in the tetrahedral core is in the triangular metal face capped by the phosphanido-phosphane moiety; the lengthening of the Os(1)–Os(2) vector is likely to have resulted from the need to accommodate the steric demands imposed by the phosphanido-phosphane ligand. In comparison to the corresponding distances in $RuOs_3(\mu\text{-}PPh_2)(\mu\text{-}H)_3(CO)_{11}$, $RuOs_3(\mu\text{-}PPh_2)_2(\mu\text{-}H)_2(CO)_{10}$, $RuOs_3(\mu\text{-}PPh_2)_2(\mu\text{-}H)_4(CO)_9$, and $RuOs_3(\mu\text{-}PPh_2)(\mu\text{-}H)_3(CO)_{10}(PPh_3)$,[2b] the phosphanido-bridged Os(2)–Ru(4) bond in **3** (average 2.788 Å) is shorter. One interesting feature is that the Os(1)–Os(3) bond does not display the usual lengthening associated with a hydride-bridged metal–metal vector. This may be ascribed to the presence of the alkyne ligand, which also spans the same edge, therefore countering the normal lengthening effect. The shortest metal–metal separation in the cluster [Os(2)–Os(3)] is associated with the bridging carbonyl group.

A similar tabulation for **4a** and **4b** is given in Table 2; attempts to grow suitable crystals of **4c** proved unsuccessful. There are two crystallographically independent molecules

[a] Disorder of ruthenium over Os(2) and Ru(4).

in the asymmetric unit of **4a**; their bond parameters are fairly similar. The crystals of both **4a** and **4b** exhibited disorder of the ruthenium atom about two alternative sites in the metal framework. This disorder was solved with ruthenium occupancies of about 0.08 and 0.92 at M(3) and M(4), respectively, for **4a**, and 0.07 and 0.93 at M(3) and M(4), respectively, for **4b**. As in **3**, the phosphanido-phosphane bridged Os(1)–Os(2) edge is the longest metal–metal bond in the tetrahedral core, while the carbonyl-bridged Os(2)–Os(3) bond is the shortest.

The NMR spectra of both **4a** and **4b** indicated the presence of two isomers in an approximately 11:1 ratio in solution. The hydride resonances for each of these isomers appear as doublets of doublets of doublets; the coupling constants have been confirmed by selective decoupling experiments. The splitting pattern and values of the coupling constants provided further evidence that the hydride bridges the same metal–metal edge as the phosphanido-phosphane ligand and is found in a *cisoid* position relative to the two phosphorus atoms. Both the $^{31}P\{^1H\}$ and the $^1H$ NMR spectra of **4c** indicated that three isomers are present in an approximately 8:1:1 ratio in solution. $^{31}P\{^1H\}$-$^{31}P\{^1H\}$ COSY and $^{31}P\{^1H\}$-$^1H$ HMBC experiments were carried out to aid the elucidation of the P-P and P-H correlations, while the coupling constants were confirmed by $^1H\{^{31}P\}$ selective decoupling experiments. A 2D $^1H$ EXSY experiment performed at ambient temperature indicated no chemical exchange between the three isomers of **4c**. The proposed solution-state structures and tentative NMR assignments for **4a**–**c** are shown in Figure 4, and at least for **4a** and **4b**, are consistent with the disorder observed in the solid state.[2c–2f]

The hydride resonances for **4** were shifted upfield relative to those for the corresponding isomer **3**. This may be ascribed to an increase in electron density at the hydride for **4**, since the hydride spans the Os(1)–Ru(4) edge, which contains the bridging phosphanido-phosphane ligand and is thus expected to be the most electron-rich metal–metal bond.[15] The two phosphorus resonances for **4a**–**c** are also shifted downfield relative to **3a**–**c**. More notably, the values of the $^2J_{PP}$ coupling constants for **4a**–**c** are almost twice those found for **3a**–**c**, although the P–C–P bond angle in the two isomers do not differ significantly.

conditions. Clusters **3** and **4** are the kinetic and thermodynamic products, respectively. It has been noticed that, in several heterometallic clusters, the coordinated alkynes are apparently oriented such that the π-bond is directed towards the less electron-rich metal.[16] Likewise, in ditertiary-phosphane-substituted triosmium clusters incorporating hydride ligands, the hydride is observed to occupy the most electron-rich metal–metal bond in the cluster.[15] In **4**, the Os(1) and Ru(4) metal atoms are electron-rich as a result of σ-donation from the ligating phosphanidophosphane moiety, which probably is the driving force for the reorientation of the alkyne and hydride over the Os(1)–Os(3)–Ru(4) edge.

The isomerization of **3a**–**c** to **4a**–**c** involves a flipping of the alkyne ligand about the Os(1)–Os(3)–Ru(4) face, coupled with hydride migration from the Os(1)–Os(3) to the Os(1)–Ru(4) edge. It is envisaged that this dynamic process occurs via an intermediate in which the alkyne is coordinated in a $\mu_3,\eta^2{:}\eta^2$ perpendicular fashion (Scheme 3). Such a process has been previously proposed to account for the observed rotation of parallel-coordinated alkynes on a triosmium cluster.[17] More recently, a reversed scheme termed *switchback motion* has been suggested to explain the fluxional behavior of the triruthenium cluster $[\{Cp^*Ru(\mu\text{-}H)\}_3(\mu_3,\eta^2{:}\eta^2\text{-}C_5H_6)]$.[18] We have monitored the isomerization of **3c** to **4c** by $^1H$ NMR spectroscopy and found that it is a very slow process at ambient temperature. After five months at ambient temperature, the mixture was heated in refluxing hexane for 4 h in order to obtain the equilibrium concentrations. The final spectrum recorded after thermolysis of the mixture gave $K_{eqm} = [\mathbf{4c}]_{eqm}/[\mathbf{3c}]_{eqm} = 10.9$ and $\Delta G = -RT \ln K_{eqm} = -5.92\ kJ\,mol^{-1}$. The half-life for the isomerization was estimated to be ca. 77 d.

### 2.5. Other Products

A number of other novel clusters were also isolated from these reactions with alkynes, viz. $RuOs_3(\mu\text{-H})(CO)_{10}(\mu_3,\kappa^2{:}\kappa^1\text{-}PhPCH_2PPh_2)(\mu_3,\eta^1{:}\eta^2{:}\eta^1\text{-}t\text{BuC}_2CH_3)$ (**5**) and $RuOs_3(\mu\text{-H})(CO)_8(\mu\text{-CO})(\mu_3,\kappa^2{:}\kappa^1\text{-}PhPCH_2PPh_2)(\mu_3,\eta^1{:}\eta^2{:}\eta^1\text{-}t\text{BuC}_2CHO)$ (**6**) from 4,4-dimethyl-2-pentyne, $RuOs_3(\mu\text{-H})_2(CO)_9(\mu\text{-}Ph_2PCH_2PPh_2)(\mu_4,\eta^1{:}\eta^2{:}\eta^2{:}\eta^1\text{-}PhCCHCCHPh)$ (**7**) from phenylacetylene, and $RuOs_3(\mu\text{-H})(CO)_9(\mu\text{-CO})[\mu_3,\eta^1{:}\eta^2{:}\kappa^1{:}\kappa^1\text{-}(HC{=}Ct\text{Bu})PhPCH_2PPh_2]$ (**8**) from *tert*-butylacetylene. The characterization of all these clusters is complete, including single-crystal X-ray diffraction studies. The ORTEP plots and selected bond parameters for **5**–**8** are given in Figure 5, Figure 6, Figure 7, and Figure 8.

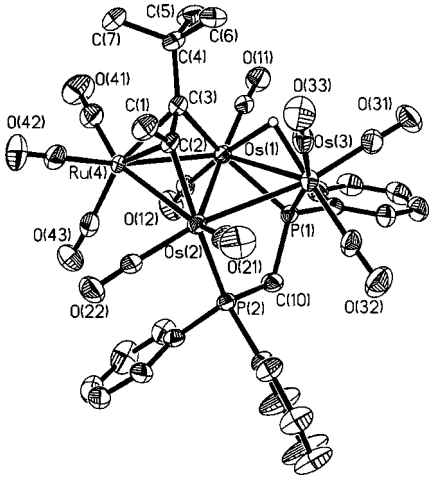

Figure 5. ORTEP diagram (50% probability thermal ellipsoids, organic hydrogen atoms omitted). Selected bond lengths [Å] and angles [°] for **5**: Os(1)–Os(2) = 2.7947(4), Os(1)–Os(3) = 2.8787(4), Os(1)–Ru(4) = 2.7535(5), Os(2)–Os(3) = 2.9403(4), Os(2)–Ru(4) = 2.7854(4), Os(1)–P(1) = 2.3010(16), Os(3)–P(1) = 2.3364(17), Os(2)–P(2) = 2.3965(17), Os(1)–C(3) = 2.204(7), Os(2)–C(2) = 2.089(6), Ru(4)–C(2) = 2.262(7), Ru(4)–C(3) = 2.181(7); Os(1)–P(1)–Os(3) = 76.74(4).

The molecular structure of **5** shows disorder of the heavy atoms, which was solved with ruthenium occupancies of 0.33 and 0.67 at M(1) and M(4), respectively. Cluster **5** comprises an open butterfly-shaped tetranuclear metal core, the two wings of the butterfly cluster having a dihedral angle of 157.6° between them. A metal-bound hydride bridges the Os(1)–Os(3) vector. The position of this hydride was located by a low-angle difference map and verified by XHYDEX calculations.[19] One triangular wing of the but-

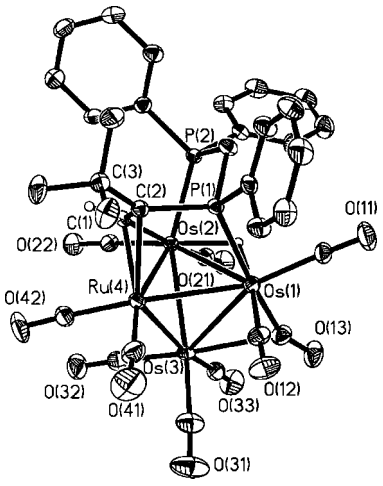

Figure 8. ORTEP diagram (50% probability thermal ellipsoids, organic hydrogen atoms omitted). Selected bond lengths [Å] and angles [°] for **8**: Os(1)–Os(2) = 2.9290(2), Os(1)–Os(3) = 2.8684(2), Os(1)–Ru(4) = 2.8484(3), Os(2)–Os(3) = 2.8319(2), Os(2)–Ru(4) = 2.7656(3), Os(3)–Ru(4) = 2.6588(3), Os(1)–P(1) = 2.3726(10), Os(2)–P(2) = 2.3382(10), Os(2)–C(1) = 2.149(4), P(1)–C(2) = 1.805(4), C(1)–C(2) = 1.407(5), Os(1)–C(13) = 1.984(5), Os(3)–C(13) = 2.478(5); Os(1)–C(13)–Os(3) = 79.16(16).

terfly cluster is capped by the dephenylated dppm ligand, while the other wing is capped by the alkyne moiety, and these ligands are orientated on opposite sides of the plane defined by the four metal atoms.

The $^{31}P\{^1H\}$ and $^1H$ NMR spectra of **5** showed that there were two isomers in solution. The NMR resonances have been assigned with the aid of $^1H\{^{31}P\}$ selective decoupling and $^{31}P\{^1H\}$-$^1H$ HMBC experimental data, and also on the basis of earlier observations that $^{31}P$ chemical shifts for a phosphanido bridges across Ru–Os edges are found downfield relative to those across Os–Os bonds.[2b,10] The proposed solution-state structures and their tentative NMR assignments are displayed in Figure 9, and are in agreement with the disorder in the solid-state structure. Thermolysis of **5** afforded **3c** and **4c** in 49% and 46% yields (with respect to the amount of **5** that reacted), respectively, indicating that **5** may be a precursor to **3c**. The formation of **3c** from **5** should be a multistep process, involving the elimination of one CO ligand, migration of hydride and CO ligands, metal–carbon bond cleavage and formation, and metal–metal bond formation, but the sequence of these processes remains unknown.

The crystal of **6** also exhibited disorder of the metal framework, which was solved with ruthenium occupancies of about 0.42 and 0.58 at M(3) and M(4), respectively. Cluster **6** is structurally very similar to **3c**, and it contains almost the same ligand set. The main structural difference is the replacement of the methyl substituent on the coordinated alkyne moiety by an aldehyde functional group. Both the $^1H$ and $^{31}P\{^1H\}$ NMR spectra of **6** displayed two sets of signals integrating to give a 7:1 ratio, indicating the presence of two isomers in solution. The proposed solution-state structures for the two isomers of **6**, which are in agreement with the disorder observed in the solid-state crystal

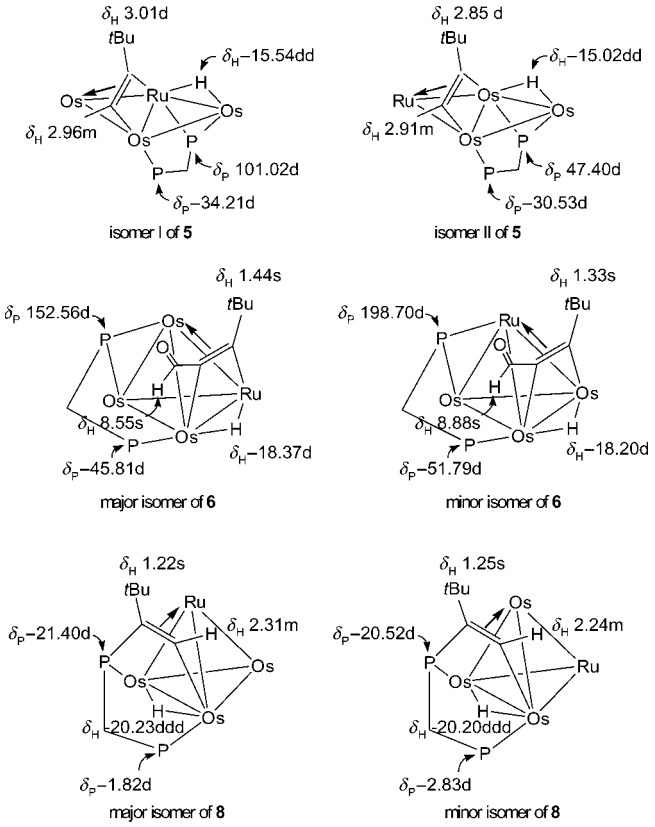

Figure 9. Proposed solution-state structures and tentative NMR assignments for **5**, **6**, and **8** (carbonyl and phenyl groups omitted).

structure, are shown in Figure 9 together with the tentative NMR assignments.

We have carried out a number of experiments to understand how the aldehyde group in **6** could have been formed. Monitoring the reaction of **1** with 4,4-dimethyl-2-pentyne in degassed $[D_{12}]$cyclohexane by $^1H$ NMR spectroscopy indicated that formation of the aldehyde occurred during the reaction. Carrying out the reaction in the presence of air resulted in a slightly higher yield of **6** (15% vs. 12% in the degassed sample). Cluster **6** was formed even when the reaction was carried out under anhydrous conditions; similarly, the yield of **6** did not increase upon addition of water to the system. Thermolysis of **3c**, **4c**, or **5** in air did not result in the formation of **6**. Oxidation of the methyl group to form the aldehyde prior to alkyne coordination to the metal cluster is unlikely, as previously reported reactions between clusters and unsaturated aldehydes or ketones gave products in which the oxygen atom of the organic carbonyl ligand is coordinated to the metal core.[20] Presumably the alkyne is oxidized in the presence of **1** to afford **6**, while **3c**, **4c**, and **5** appear not to be involved in this process, although the oxidant remains unknown.

Cluster **7** is another butterfly-shaped tetranuclear cluster, with a dihedral angle of 166.4° between the wing planes. The Os(1)–Os(2) edge is bridged by the dppm ligand, and the metal–phosphorus bond lengths do not differ significantly from those found for the parent cluster **1**. The XHYDEX program indicated that hydride ligands bridged

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

both Os(1)–Os(2) and Os(1)–Ru(4); this is supported by the observation that these vectors are long [3.0121(4) and 2.9363(6) Å, respectively]. In **7**, two phenylacetylenes have coupled head-to-head, and the resulting four-carbon ligand is coordinated to all four metal atoms, with an $\eta^3$-allylic interaction to Ru(4);[21] there is no evidence of another isomer displaying head-to-tail coupling, although both types of products have been reported for ruthenium and osmium clusters.[22] The organic moiety formally donates six electrons, resulting in a cluster electron count of 62 for **7**, in accordance with the effective atomic number (EAN) rule.[7] Carbon–carbon bond lengths within the organic ligand range from 1.425(10) to 1.464(9) Å, which are in the ranges of carbon–carbon $sp^2$–$sp^2$ double and single bonds (1.32 and 1.48 Å, respectively),[13] suggesting some electron delocalization over the entire carbon chain. Dimerization of the two alkyne units also resulted in a hydrogen atom shift, which has been postulated to precede the C–C coupling step.[23] The spectroscopic data for **7** clearly points to the retention of the solid-state structure in solution.

Cluster **8** retains the tetrahedral metal framework of the parent cluster **1**; the long Os(1)–Os(2) edge [2.9290(2) Å] is bridged by both a hydride and a dephenylated dppm moiety. A salient structural feature in **8** is the formation of a phosphorus–carbon bond between the dephenylated phosphane P(1) and the C(2) carbon of the vinyl organic fragment [P(1)–C(2) = 1.805(4) Å], resulting in the capping of the Os(1)–Os(2)–Ru(4) triangular face of the metal tetrahedron by the novel ligand (HC=C*t*Bu)$PhPCH_2PPh_2$ in a $\mu_3,\eta^1{:}\eta^2{:}\kappa^1{:}\kappa^1$ manner. Reports of P–C coupling between two separate ligands are rare in cluster chemistry, few examples are known.[24] This ligand donates a total of seven electrons to the cluster, and **8** is formally a 60-electron species in accordance with the observed tetrahedral metal core. The crystal of **8** also exhibited disorder of the metal framework, which was solved with ruthenium occupancies of about 0.11 and 0.89 at M(3) and M(4), respectively.

The NMR spectra of **8** showed that there are two isomers present in an approximate 9:1 ratio in solution. $^1H\{^{31}P\}$ as well as $^1H\{^1H\}$ selective decoupling experiments have been utilized to aid the assignment of the signals. The proposed solution-state structures for the isomers of **8** and their tentative NMR assignments are given in Figure 9; the structures, as well as their relative proportions, are in agreement with those expected from the disorder found in the solid state. On prolonged standing in solution, **8** was found to slowly convert to **3e**; this process could be speeded up by thermolysis. Thus, **8** is a precursor to **3e**, but this conversion has to be a multistep process.

In addition to **3d** and **7**, the reaction with phenylacetylene afforded, as characterized by mass spectrometry and $^1H$ NMR spectroscopy, a mixture of 1,3,5- and 1,2,4-triphenylbenzene.[25] Gas chromatography-mass spectrometry (GC-MS) analysis indicated that these cyclotrimerized products were present in a 1:2 ratio. We have found that **3d** catalyzed the cyclotrimerization of phenylacetylene; the cluster was recoverable quantitatively and no intermediates could be isolated. A number of organometallic compounds are known to catalyze the [2+2+2]-cyclotrimerization of alkynes,[26] but few cluster catalysts are known.[27] Thus far, attempts at optimization showed that **3d** is at best a modest catalyst, with TON $< 2$ for a catalyst loading of 1 mol-%. In contrast, **7** failed to react with phenylacetylene under similar conditions, suggesting that it is not directly involved in the catalytic step. Furthermore, **7** was not obtained in the reaction of **3d** with phenylacetylene, indicating that it is not a side product of the catalytic reaction. No cyclotrimerization product was obtained from the reaction of **2** with the other alkynes reported here, and **3d** also failed to catalyze the cyclotrimerization of diphenylacetylene (an internal alkyne) or *tert*-butylacetylene (a terminal alkyne).

## 3. Concluding Remarks

In this study, we have found that **1** reacts with both terminal and internal alkynes to afford initially cluster **3** in which the alkyne is bonded in a $\mu_3,\eta^1{:}\eta^2{:}\eta^1$ fashion and the alkyne C≡C bond is parallel to an Os–Os edge; the tetrahedral core of the cluster is retained. The binding of the alkyne appears to be highly stereoselective, since for unsymmetrical alkynes, the bulkier substituent is oriented away from the dephenylated dppm moiety. In the case of internal alkynes, **3** isomerized slowly to form **4**. This isomerization process involved migration of both the alkyne and hydride across a triangular metal face to bridge the most electron-rich metal–metal bond of the cluster, which is that bridged by the dephenylated dppm; the stereoselectivity appears to be similar to that in **3**. Cluster **3d** was also found to be a modest catalyst for the cyclotrimerization of phenylacetylene.

These results point to stereoselective binding of alkynes in such heterometallic clusters, and indicate that the ditertiary phosphane ligand can play an important role in the high stereoselectivity exhibited as well as in keeping the cluster framework intact. Hence, such clusters may play a useful role in the stereocontrol of reactions with alkynes and provide a possible direction for future work.

## 4. Experimental Section

**4.1. General Procedures:** All reactions and manipulations were carried out under nitrogen by using standard Schlenk techniques. Solvents were purified, dried, distilled, and stored under nitrogen prior to use. The products were separated by thin layer chromatography (TLC), by using plates coated with silica gel 60 F254 of 0.25 or 0.5 mm thickness and extracted with dichloromethane. Routine NMR spectra were acquired with a Bruker ACF300 NMR spectrometer, while decoupling and 2D NMR spectra were obtained with a Bruker Avance DRX500 or Bruker AMX500 machine. The solvent used was deuterated chloroform unless otherwise stated. Chemical shifts reported are referenced to that for the residual proton of the solvent for $^1H$, and to 85% aqueous $H_3PO_4$ (external standard) for $^{31}P\{^1H\}$. Mass spectra were obtained with a Finnigan MAT95XL-T spectrometer in an *m*-nitrobenzyl alcohol matrix. Microanalyses were carried out by the microanalytical laboratory at the National University of Singapore. GC-MS analysis was car-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ried out with an Agilent GC 6890 with Mass Selective Detector MS 5973, using a 300 mm × 0.25 mm × 0.25 μm HP-1 MS column. The cluster $Os_3(\mu\text{-}H)_2(CO)_{10}$ was prepared according to the literature method.[28] $Ru_3(CO)_{12}$ was purchased from Oxkem Ltd; all other reagents were from commercial sources and were used as supplied.

**4.2. Synthesis of $RuOs_3(\mu\text{-}H)_2(CO)_9(\mu\text{-}CO)_2(\mu\text{-}dppm)$ (1):** $Ru_3(CO)_{12}$ (8.0 mg, 0.013 mmol) was placed with hexane (20 mL) into a 100-mL round-bottomed flask fitted with a Teflon valve. After three freeze-pump-thaw cycles, ethene gas at ca. 20 psi was introduced at ambient temperature. The mixture was then irradiated with a 60W Phillips reflector lamp, while being cooled in an ice-water bath, until the solution became colorless (ca. 2 h). $Ru(CO)_4(C_2H_4)$ was formed in quantitative yield, as characterized by infrared spectroscopy. A stoichiometric equivalent of dppm was added to the solution which was still kept in the ice-water bath. Formation of $Ru(CO)_4(\kappa^1\text{-dppm})$ was established by its infrared spectroscopic data. Addition of $Os_3(\mu\text{-}H)_2(CO)_{10}$ (30.1 mg, 0.036 mmol) resulted in an immediate color change to light yellow. The mixture was stirred under a nitrogen atmosphere for 1.5 h. Removal of the solvent and volatiles in vacuo and column chromatographic separation of the residue, with hexane and dichloromethane as eluants, yielded three bands. [Yields are calculated with respect to $Os_3(\mu\text{-}H)_2(CO)_{10}$ used.] The first two bands were identified from their infrared spectra as $Ru_3(CO)_{12}$ (1.2 mg, 0.002 mmol) and $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ (5.6 mg, 15%), respectively. The third band was identified from its infrared spectrum as $RuOs_3(\mu\text{-}H)_2(CO)_9(\mu\text{-}CO)_2(\mu\text{-}dppm)$ (**1**) (40.3 mg, 82%).

**4.3. Thermolysis of 1:** To a Schlenk tube containing **1** (16.9 mg, 0.012 mmol) was added hexane (30 mL), and the reaction mixture was stirred and heated under reflux for 4 h. The solvent was removed under reduced pressure, and the residue obtained was redissolved in a minimum of dichloromethane and chromatographed on TLC plates. Elution with hexane/dichloromethane (4:1, v/v) yielded two bands. Band 1 ($R_f$ = 0.49) gave dark red crystals of $RuOs_3(CO)_{12}(\mu_4,\kappa^2\text{:}\kappa^2\text{-}PhPCH_2PPh)$ (**2**). Yield: 10.4 mg, 69%. Band 2 ($R_f$ = 0.19) gave dark red crystals of $Os_3(\mu\text{-}H)_2(CO)_8(\mu\text{-dppm})$. Yield: 2.1 mg, 15%. IR ($CH_2Cl_2$) $\nu$(CO) : $\tilde{\nu}$ = 2068 (s), 2005 (vs), 1983 (vs, br), 1955 (w), 1943 (w) $cm^{-1}$. $^{31}P\{^1H\}$ NMR: $\delta$ = –0.02 (s) ppm. $^1H$ NMR: $\delta$ = 7.35 (m, 20 H, Ph), 4.19 (t, $^2J_{PH}$ = 10.5 Hz, 2 H, $CH_2$), –10.26 (t, $^2J_{PH}$ = 9.9 Hz, 2 H, Os*H*Os) ppm. MS (FAB): *m*/*z* calcd. for $[M]^+$ 1181; found 1181. X-ray data: Orthorhombic, *Pbca*, *a* = 16.2438(4) Å, *b* = 16.8441(5) Å, *c* = 25.3499(7) Å, *V* = 6936.0(3) $Å^3$. Data are in agreement with literature values.[6a]

**4.4. Reactions of 1 with Alkynes:** In a typical reaction, to a Schlenk tube containing **1** and hexane (30 mL) was added the alkyne, and the reaction mixture was stirred and heated under reflux for 6 h. The solvent was removed under reduced pressure, and the residue obtained was redissolved in a minimum of dichloromethane and chromatographed on TLC plates with hexane/dichloromethane (3:2, v/v) as the mobile phase. The reaction conditions and yields are summarized in Table 3, and spectroscopic and analytical data for all new products are given in Table 4 and Table 5.

**4.5. Thermolysis of 3:** In a typical reaction, to a Schlenk tube containing **3a** (20.2 mg, 14 μmol) was added hexane (30 mL), and the

**4.6. Thermolysis of 5:** To a Schlenk tube containing **5** (10.3 mg, 0.008 mmol) was added hexane (30 mL), and the reaction mixture was stirred and heated under reflux for 4 h. Subsequent treatment as above afforded unreacted **5** (3.5 mg), **4c** (2.5 mg, 23%), and **3c** (3.7 mg, 34%).

**4.7. Reaction of 1 with 4,4-Dimethyl-2-pentyne in Air:** To a 100-mL two-necked, round-bottomed flask containing **1** (12.1 mg, 0.009 mmol) and hexane (30 mL) was added $t$BuCCCH$_3$ (0.1 mL). Air was bubbled into the mixture by means of a compressor pump and the reaction mixture was stirred and heated under reflux for 6 h. Subsequent treatment as above afforded **5** (1.8 mg, 15%), **4c** (2.9 mg, 24%), **3c** (3.5 mg, 29%) and **6** (1.8 mg, 15%).

**4.8. Thermolysis of 3c, 4c, or 5 in Air:** To a 100-mL two-necked, round-bottomed flask containing **3c** (7.1 mg, 0.005 mmol), **4c** (5.2 mg, 0.004 mmol), or **5** (8.4 mg, 0.006 mmol) was added hexane (30 mL). Air was bubbled into the mixture by means of a compressor pump and the reaction mixture was stirred and heated under reflux for 6 h. Subsequent treatment as above revealed the presence of all three clusters for the thermolysis of **5**. Clusters **3c** and **4c** were obtained from the reaction of **3c**, while only the unreacted starting cluster was observed when **4c** was heated.

**4.9. Reaction of 1 with Phenylacetylene:** To a Schlenk tube containing **1** (9.9 mg, 0.007 mmol) and hexane (30 mL) was added phenylacetylene (0.1 mL), and the reaction mixture was stirred and heated under reflux for 12 h. Subsequent treatment as above afforded triphenylbenzene (1.0 mg), **3d** (3.3 mg, 36%) and **7** (4.9 mg, 46%).

**4.10. Thermolysis of 8:** To a Schlenk tube containing **8** (8.4 mg, 0.006 mmol) was added hexane (30 mL), and the reaction mixture was stirred and heated under reflux for 4 h. Subsequent treatment as above afforded unreacted **8** (3.8 mg) and **3e** (4.3 mg, 54%).

**4.11. Cyclotrimerization Reactions of Phenylacetylene:** In a typical reaction, the cluster **3d** and PhCCH were placed in a Carius tube containing hexane (10 mL), degassed by three freeze-pump-thaw cycles, and heated.

**4.12. Reaction of 3d with Diphenylacetylene and *tert*-Butylacetylene:** To a Schlenk tube containing **3d** (5.2 mg, 0.004 mmol) and hexane (30 mL) was added PhCCPh (6.1 mg, 0.030 mmol) or $t$BuCCH (0.1 mL), and the reaction mixture was stirred and heated under reflux for 12 h. Subsequent treatment as above revealed the presence of unreacted **3d** only.

**4.13 X-ray Crystal Structure Determinations**

Crystals were mounted on quartz fibers. X-ray data were collected with a Bruker AXS APEX system, by using Mo-$K_\alpha$ radiation, with the SMART suite of programs.[29] Data were processed and corrected for Lorentz and polarization effects with SAINT,[30] and for absorption effects with SADABS.[31] Structural solution and refinement were carried out with the SHELXTL suite of programs.[32] Crystal and refinement data are summarized in Table 6, Table 7, and Table 8.

The structures were solved by direct methods to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. The hydrides were generally placed by potential energy calculations with the program XHYDEX,[19] given fixed isotropic thermal parameters, and refined riding on an osmium atom to which they are attached. Organic hydrogen atoms were generally placed in calculated positions and refined with a riding model. All non-hydrogen atoms were generally given anisotropic displacement parameters in the final model.

Cluster **2** sits across a $C_2$ symmetry axis, which passes through the methylene carbon of the dppm ligand and the midpoint of the

hinge metal–metal bond. Cluster **3b** was refined as a racemic twin. There were two molecules in the asymmetric unit for **4a**. Disorder of the heavy atom positions were found for **2**, **3e**, **4a**, **4b**, **5**, **6**, and **8**. Solvent molecules were found in the crystals of **3a** (half molecule of $CH_2Cl_2$), **3c** (half molecule of hexane), and **6** (half molecule of $CH_2Cl_2$).

CCDC-628206–CCDC-628217 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Details on the treatment of disorder, metal hydride placement and refinement, and of solvent molecules in the X-ray crystallographic studies; $^{31}P\{^1H\}$-$^1H$ HMBC spectra for **4c**, **5**, and **7**; $^{31}P\{^1H\}$-$^{31}P\{^1H\}$ COSY spectrum for **4c**; the isomerization of **3c** and **4c** (percentages against time, as obtained from $^1H$ NMR spectra); cyclotrimerization reactions of **3d** with phenylacetylene.

# The Binuclear Cyclopentadienylvanadium Carbonyls $(\eta^5\text{-}C_5H_5)_2V_2(CO)_7$ and $(\eta^5\text{-}C_5H_5)_2V_2(CO)_6$: Comparison with Homoleptic Chromium Carbonyls

**Xiuhui Zhang,[a] Qian-shu Li,*[a] Yaoming Xie,[b] R. Bruce King,*[b] and Henry F. Schaefer III[b]**

**Keywords:** Binuclear cyclopentadienylvanadium carbonyls / Density functional theory

The cyclopentadienylvanadium carbonyls $CpV(CO)_n$ ($n$ = 4, 3, 2, 1), $Cp_2V_2(CO)_7$, and $Cp_2V_2(CO)_6$ have been studied by density functional theory using the B3LYP and BP86 functionals. The optimized structure of $CpV(CO)_4$ is close to that found experimentally by X-ray and electron diffraction methods. For the coordinately unsaturated $CpV(CO)_n$ ($n$ = 3, 2, 1) the computed ν(CO) frequencies by BP86 are related to those found in low-temperature matrix isolation experiments but show some significant differences for $n$ = 3 and 2 in band spacings suggesting some matrix effects on the geometries. An optimized structure for $Cp_2V_2(CO)_7$ is found with one symmetrical bridging carbonyl group and a V–V distance of 3.306 Å (BP86) suggesting a single bond. Energetically competitive structures for $Cp_2V_2(CO)_6$ include a doubly symmetrically bridged singlet structure with only two-electron donor carbonyl groups, a triplet doubly semibridged structure, and a singlet structure with one four-electron donor bridging carbonyl group. Thermodynamic considerations rationalize why neither $Cp_2V_2(CO)_7$ nor $Cp_2V_2(CO)_6$ have yet been synthesized. Thus $Cp_2V_2(CO)_7$ is predicted to be unstable with respect to dissociation into $CpV(CO)_4$ + $CpV(CO)_3$. Furthermore, the dissociation energy of the lowest lying singlet isomer from $Cp_2V_2(CO)_6$ to $Cp_2V_2(CO)_5$ is only 10.8 kcal/mol (BP86) consistent with the formation of $Cp_2V_2(CO)_5$ rather than $Cp_2V_2(CO)_6$ upon decomposition of the presumed $CpV(CO)_3H_2$ dihydride generated by acidification of the dianion $CpV(CO)_3^{2-}$.

## 1. Introduction

Cyclopentadienylvanadium tetracarbonyl, $CpV(CO)_4$ ($Cp = \eta^5\text{-}C_5H_5$), which was originally synthesized in 1958 by E. O. Fischer,[1] can be regarded as an analogue of the long known $Fe(CO)_5$ or $Cr(CO)_6$ or the unknown $Ti(CO)_7$ depending on whether the $\eta^5\text{-}C_5H_5$ ring replaces one, two, or three carbonyl groups, respectively, in the corresponding homoleptic metal carbonyl. Photolysis of $Fe(CO)_5$ has been known[2] since 1927 to give $Fe_2(CO)_9$ (Figure 1), with the formal Fe–Fe single bond required to give each iron atom the favored 18-electron configuration.[3] However, no evidence has been found for any binuclear $Cr_2(CO)_n$ derivatives from the photolysis or thermolysis of $Cr(CO)_6$ including $Cr_2(CO)_{11}$ with a Cr–Cr single bond required to give each chromium atom the favored 18-electron configuration. This latter observation has been rationalized by our theoretical studies indicating even the lowest energy isomer of $Cr_2(CO)_{11}$ to be thermodynamically unstable with respect to mononuclear $Cr(CO)_6$ and $Cr(CO)_5$ fragments.[4] By comparison, laboratory photolysis of $CpV(CO)_4$ goes directly to $Cp_2V_2(CO)_5$ with the formal V≡V triple bond required to give both vanadium atoms the favored 18-electron configuration[5–8] (Figure 1) without any evidence for $Cp_2V_2(CO)_7$ and $Cp_2V_2(CO)_6$ intermediates expected to have formal V–V single and V = V double bonds, respectively, by the 18-electron rule.[3] We now present computational studies on these intermediate $Cp_2V_2(CO)_7$ and $Cp_2V_2(CO)_6$ molcules in order to predict structures and to understand why they have not been found in the photolysis of $CpV(CO)_4$ or other reactions of cyclopentadienylvanadium carbonyl derivatives.

## 2. Theoretical Methods

Electron correlation effects were considered by employing density functional theory (DFT) methods, which have evolved as a practical and effective computational tool, especially for organometallic compounds.[9–17] Two DFT methods were used in this study. The first functional is the hybrid B3LYP method, which is the hybrid HF/DFT method using the combination of the three-parameter Becke functional (B3) with the Lee–Yang–Parr (LYP) generalized gradient correlation functional.[18,19] The other DFT method used in this paper is BP86, which combines Becke's 1988 exchange functional (B) with Perdew's 1986 gradient corrected correlation functional method (P86).[20,21] It has been noted elsewhere that the BP86 method may be somewhat more reliable than B3LYP for the type of organometallic systems considered in this paper.[22–24]

All calculations were performed using the double-ζ plus polarization (DZP) basis sets. The DZP basis sets used for carbon and oxygen add one set of pure spherical harmonic d functions with orbital exponents $\alpha_d(C) = 0.75$ and $\alpha_d(O) = 0.85$ to the standard Huzinaga-Dunning contracted DZ sets[25,26] and are designated (9s5p1d/4s2p1d). For hydrogen, a set of p polarization functions $\alpha_p(H) = 0.75$ was added to the Huzinaga-Dunning DZ set. The loosely contracted DZP basis set for vanadium is the Wachters primitive set[27] augmented by two sets of p functions and a set of d functions, contracted following Hood, Pitzer and Schaefer,[28] designated (14s11p6d/10s8p3d).

The geometries of all structures were fully optimized using the DZP B3LYP and DZP BP86 methods, and the vibrational frequencies were determined by evaluating analytically the second derivatives of the energy with respect to the nuclear coordinates. The corresponding infrared intensities were also evaluated analytically. All of the computations were carried out with the Gaussian 03 program,[29] exercising the fine grid option (75 radial shells, 302 angular points) for evaluating integrals numerically, while the tight ($10^{-8}$ hartree) designation is the default for the self-consistent field (SCF) convergence.

The low-magnitude imaginary vibrational frequencies are suspect because of significant limitations in the numerical integration procedures used in the DFT computations. Ziegler et al.[30] have suggested that all imaginary vibrational frequencies with magnitudes less than 100 $cm^{-1}$ may be suspect, owing to the possibility of numerical errors arising from the use of standard integration grids. Therefore, we do not always follow such low imaginary vibrational frequencies unless they appear to be chemically meaningful.

## 3. Results

### 3.1 Mononuclear Cyclopentadienylvanadium Carbonyl Derivatives

Figure 2 and Table 1 depict and describe the optimized structures for $CpV(CO)_n$ ($n$ = 4, 3, 2, 1). Among these compounds $CpV(CO)_4$ is a stable 18-electron metal complex[1] whereas the coordinately unsaturated derivatives $CpV(CO)_n$ ($n$ = 3, 2, 1) have been generated by the photolysis of $CpV(CO)_4$ in frozen gas matrices (argon, methane) at 12 K.[31]

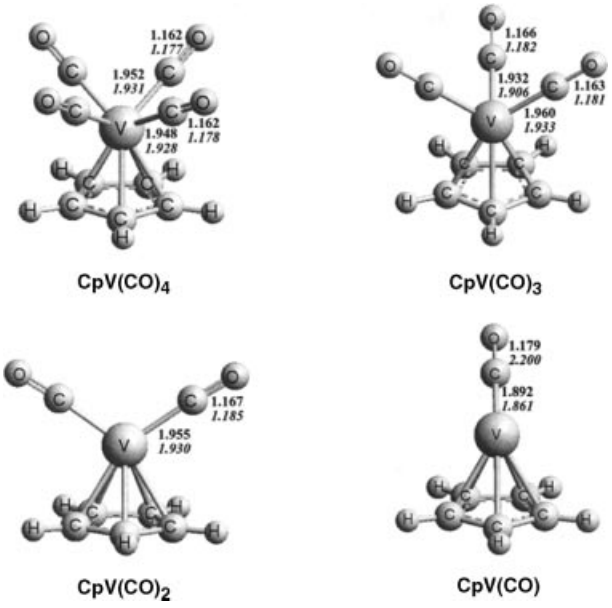

Figure 2. The optimized structures of $CpV(CO)_n$ ($n$ = 4, 3, 2, 1).

The optimized structure for $CpV(CO)_4$ is close to those found experimentally by X-ray[32] and electron diffraction[33] for crystalline and gas-phase $CpV(CO)_4$, respectively, with the latter perhaps being more accurate since the X-ray diffraction study is a rather old one predating automatic diffractometers. Thus the theoretical V–CO and C–O distances from our DFT studies are 1.948/1.952 Å (B3LYP) or 1.928/1.931 Å (BP86) and 1.162 Å (B3LYP) or 1.178 Å (BP86), respectively. This compares with 1.88/1.94 Å and 1.18/1.12 Å found by X-ray diffraction and 1.963 Å and 1.135 Å found by electron diffraction.

Table 1. The total energies ($E$, Hartree) for $CpV(CO)_n$ ($n$ = 4, 3, 2, 1). The number of imaginary vibrational frequencies (Nimg) for each structure is also listed.

| Singlet | | $CpV(CO)_4$ ($C_s$) | $CpV(CO)_3$ ($C_s$) | $CpV(CO)_2$ ($C_s$) | CpV(CO) ($C_s$) |
|---|---|---|---|---|---|
| B3LYP | $E$ | –1591.065026 | –1477.674671 | –1364.278723 | –1250.877952 |
| | Nimg | 1 (15$i$)[a] | 0 | 0 | 0 |
| BP86 | $E$ | –1591.244927 | –1477.841138 | –1364.430801 | –1251.019000 |
| | Nimg | 1 (17$i$)[a] | 0 | 0 | 0 |

[a] These imaginary frequencies were reduced to 0$i$ (B3LYP) or 2$i$ (BP86) by using the larger (120, 974) integration grid.

Table 2. Infrared-active ν(CO) vibrational frequencies ($cm^{-1}$) predicted for the mono-nuclear molecules: $CpV(CO)_n$ ($n$ = 4, 3, 2, 1) (infrared intensities in parentheses are given in km/mol).

| | B3LYP | BP86 | Experimental[a] |
|---|---|---|---|
| $CpV(CO)_4$ | 2008 (1539), 2008 (1544), 2019 (7), 2085 (624) | 1928 (1290), 1928 (1293), 1934 (4),[b] 2004 (497) | 1931, 1952,[b] 2030 |
| $CpV(CO)_3$ | 1983 (714), 1985 (1701), 2062 (718) | 1892 (1406), 1896 (536), 1967 (581) | 1857, 1887, 1953 |
| $CpV(CO)_2$ | 1954 (1964), 2028 (741) | 1854 (1634), 1924 (561) | 1894, 1992 |
| CpV(CO) | 1929 (1370) | 1823 (1039) | 1830 |

[a] Data taken from the literature (R. B. Hitam, A. J. Rest, *Organometallics* **1989**, *8*, 1598) for the ν(CO) frequencies in methane matrices at 12 K averaging out reported matrix splitting. [b] The infrared "inactive" $b_1$ ν(CO) frequency for $CpV(CO)_4$.

The infrared ν(CO) frequencies computed for $CpV(CO)_n$ ($n$ = 4, 3, 2, 1) are listed in Table 2 along with the experimental ν(CO) frequencies reported in methane matrices.[31]

The BP86 calculated frequencies for $CpV(CO)_4$ and CpV(CO) agree very well with the experimental frequencies. However, there are significant differences between the ν(CO) frequencies calculated by the usually more reliable BP86 method and those found in matrices for $CpV(CO)_3$ and $CpV(CO)_2$. In particular, although the positions of the calculated ν(CO) frequencies are reasonably close to those found experimentally, the calculated frequency separations are significantly different from those found experimentally. Thus for $CpV(CO)_2$ the two theoretical ν(CO) frequencies (Table 2) are separated by 74 $cm^{-1}$ (B3LYP) or 70 $cm^{-1}$ (BP86), whereas the experimental ν(CO) frequencies assigned to the matrix studies are separated by 98 $cm^{-1}$. The nature of the matrix experiments may be responsible for this discrepancy since the initial geometries generated by loss of a CO ligand may not fully relax to the optimized geometries at the low temperatures involved.

### 3.2 The Binuclear Derivatives $Cp_2V_2(CO)_n$ ($n$ = 7, 6)

#### *3.2.1 $Cp_2V_2(CO)_7$*

Only one optimized structure was found for $Cp_2V_2(CO)_7$ with a V–V distance short enough to imply any significant interaction between the $CpV(CO)_4$ and $CpV(CO)_3$ fragments. This structure (**7S-1** in Figure 3 and Table 3) has $C_2$ symmetry with one symmetrical bridging CO group and six terminal CO groups. The bridging CO group has V–C distances of 2.214 Å (B3LYP) or 2.185 Å (BP86) and leads to a predicted ν(CO) frequency (Table 4) of 1759 $cm^{-1}$ (BP86). The V–C distances to the terminal CO groups are in the range 1.933–1.988 Å (B3LYP) or 1.918–1.972 Å (BP86). The V–V distance of 3.382 Å (B3LYP) or 3.306 Å (BP86) is in agreement with the single bond required to give both vanadium atoms the favored 18-electron configuration.

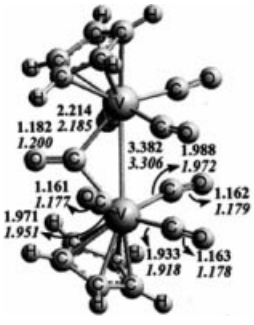

Figure 3. Optimized structure of $Cp_2V_2(CO)_7$ (**7S-1**).

Table 3. The total energy ($E$, Hartree), number of imaginary vibrational frequencies, (Nimg), and V–V distances for $Cp_2V_2(CO)_7$ (**7S-1**) by B3LYP and BP86.

| Singlet | | $Cp_2V_2(CO)_7$ ($C_2$) (**7S-1**) |
|---|---|---|
| B3LYP | $E$ | –3068.725630 |
| | V–V | 3.382 Å |
| | Nimg | 1 (19$i$) |
| BP86 | $E$ | –3069.086435 |
| | V–V | 3.306 Å |
| | Nimg | 1 (18$i$) |

This structure for $Cp_2V_2(CO)_7$ exhibits a very small imaginary vibrational frequency at 19$i$ $cm^{-1}$ (B3LYP) or 18$i$ $cm^{-1}$ (BP86). Following the corresponding normal mode causes $Cp_2V_2(CO)_7$ to dissociate into $CpV(CO)_4$ + $CpV(CO)_3$ fragments with an energy minimum at a clearly non-bonding vanadium-vanadium distance of 5.307 Å (B3LYP) or 5.283 Å (BP86). In addition, energy calculations indicate that the dissociation [Equation (1)]

$$Cp_2V_2(CO)_7 \rightarrow CpV(CO)_4 + CpV(CO)_3 \quad (1)$$

is either exothermic by 8.8 kcal/mol (B3LYP) or only very slightly endothermic by 0.2 kcal/mol (BP86). All of these observations indicate that $Cp_2V_2(CO)_7$ is unstable with respect to dissociation into $CpV(CO)_4$ + $CpV(CO)_3$ [Equation (1)] and thus unlikely to be prepared as an isolable molecule.

#### *3.2.2 $Cp_2V_2(CO)_6$*

Five low-lying stationary points are found for $Cp_2V_2(CO)_6$ (Figure 4 and Table 4 and Table 5). The B3LYP and BP86 methods disagree with respect to the relative energies of these isomers as well as key features of the optimized lowest energy triplet structure **6T-1**.

The global minimum for $Cp_2V_2(CO)_6$ using the BP86 method is a $C_{2v}$ singlet **6S-1** (Figure 4) with two symmetrical bridging carbonyl groups having equal V–C distances of

2.093 Å (B3LYP) or 2.098 Å (BP86) and exhibiting ν(CO) frequencies in the normal range for such bridging carbonyl groups, namely 1767 and 1733 $cm^{-1}$ (BP86, Table 4). For the four terminal carbonyls in **6S-1**, the V–C distances are 1.953 Å (B3LYP) or 1.937 Å (BP86). The V–V distance in **6S-1** is 2.852 Å (B3LYP) or 2.847 Å (BP86), which is the shortest vanadium-vanadium distance found in any of the $Cp_2V_2(CO)_6$ isomers and consistent with the V=V double bond required to give each vanadium atom in $Cp_2V_2(CO)_6$ the favored 18-electron configuration[3] when all of the CO groups are the usual two-electron donors. The dissociation energy of $Cp_2V_2(CO)_6$ (**6S-1**) to 2 $CpV(CO)_3$ is 31.5 kcal/mol (BP86) indicating that $Cp_2V_2(CO)_6$, unlike $Cp_2V_2(CO)_7$, is stable with respect to dissociation.

The two methods disagree on the structure of the lowest lying triplet **6T-1** of $Cp_2V_2(CO)_6$ (Figure 4). The BP86 method predicts **6T-1** to be a structure with two semibridging CO groups having V–C distances of 1.975 Å and 2.379 Å and exhibiting ν(CO) frequencies in the usual bridging range at 1799 and 1810 cm.$^{-1}$ (Table 4). The V–V bond length of 2.936 Å in **6T-1** can be interpreted as a single bond somewhat shortened by the presence of the two semibridging CO groups thereby giving both metal atoms the 17-electron configurations expected for a binuclear triplet. Using the B3LYP method gives a significantly different structure for **6T-1** with two much more unsymmetrical semibridging CO groups having V–C distances of 1.961 Å and 2.768 Å. The latter V–C distance indicates very weak interactions so that these highly unsymmetrical bridging CO groups are essentially undistinguishable from terminal CO groups consistent with their V–C–O angles close to 180°. Thus these two semibridging CO groups give ν(CO) frequencies in the terminal CO range. The V–V distance of 3.104 Å in **6T-1** found by B3LYP is nearly 0.2 Å longer than that found by BP86. This can be rationalized by the fact that the semibridging CO groups in **6T-1** found by B3LYP are so highly unsymmetrical that they function effectively as terminal CO groups and thus do not shorten the V–V distance. By either method isomer **6T-1** for $Cp_2V_2(CO)_6$ is found to have relatively little spin contamination ($<S^2>$ = 2.05 and 2.01 for B3LYP and BP86, respectively).

A triplet stationary point for $Cp_2V_2(CO)_6$ similar to **6S-1** is **6T-2**, which lies 12.3 kcal/mol above **6T-1** (B3LYP) or 5.2 kcal/mol above **6S-1** (BP86). The apparent spin contamination in **6T-2** is quite small ($<S^2>$ = 2.07 and 2.02 for B3LYP and BP86, respectively). Structure **6T-2** has one substantial imaginary vibrational frequency, namely, 304*i* $cm^{-1}$ (B3LYP) or 371*i* $cm^{-1}$ (BP86). Following the corresponding normal mode leads to structure **6T-1**. For the bridging carbonyls, the V–C distances in **6T-2** are 2.149 Å (B3LYP) or 2.126 Å (BP86) and their ν(CO) frequencies are the normal values of 1798 and 1778 $cm^{-1}$. The V–C distances to the terminal carbonyls are 1.968 Å (B3LYP) or 1.934 Å (BP86). The V–V distance in **6T-2** is 3.057 Å (B3LYP) or 2.882 Å (BP86) consistent with the single bond required to give each vanadium the 17-electron configuration for a binuclear triplet with only two-electron donor CO groups.

The next singlet structure **6S-2** for $Cp_2V_2(CO)_6$ lies 6.0 kcal/mol above **6S-1** (BP86) or 4.0 kcal/mol above **6T-1** (B3LYP). This structure has one semibridging CO group with V–C distances of 1.888 Å (B3LYP) or 1.880 Å (BP86) and 2.400 Å (B3LYP) or 2.319 Å (BP86). The V–C–O bond angle is almost linear. One of these semibridging CO group has a relatively short V–O distance of 2.279 Å (B3LYP) or 2.351 Å (BP86) indicating that it is a $\eta^2$-μ-CO group donating four electrons using both a σ-bond and a π-bond. This four-electron donor CO group is responsible for the very low bridging ν(CO) frequency of 1678 $cm^{-1}$ (Table 4). The V–V distance in **6S-2** is 3.379 Å (B3LYP) or 3.150 Å (BP86). This is longer than that in **6T-1** by ca. 0.3 Å (B3LYP) or ca. 0.2 Å (BP86) but consistent with the single bond needed to give both vanadium atoms in **6S-2** the favored 18-electron configuration in a structure with one four-electron donor bridging CO group.

The last isomer **6S-3** of $Cp_2V_2(CO)_6$ is a $C_s$ unbridged structure lying above **6T-1** by 13.1 kcal/mol (B3LYP) or above **6S-1** by 14.4 kcal/mol (BP86). Structure **6S-3** has all real vibrational frequencies. For the six carbonyls, the V–C distances are in the range of 1.929–1.976 Å (B3LYP) or 1.909–1.962 Å (BP86). The V–C–O bond angles are almost linear. The V–V distance in **6S-3** is 3.251 Å (B3LYP) or 3.023 Å (BP86), which is longer than that of **6T-1** by ca. 0.1 Å.

### 3.3 Dissociation Energies

Table 6 summarizes the calculated dissociation energies for the successive removal of carbonyl groups from the lowest lying singlet isomers of $Cp_2V_2(CO)_7$ and $Cp_2V_2(CO)_6$, namely isomers **7S-1** (Figure 2) and **6S-1** (Figure 3) for $Cp_2V_2(CO)_7$ and $Cp_2V_2(CO)_6$, respectively, as well as the calculated lowest energy singlet isomers of $Cp_2V_2(CO)_5$ and $Cp_2V_2(CO)_4$. Note that the dissociation energy for decarbonylation of $Cp_2V_2(CO)_5$ to $Cp_2V_2(CO)_4$ is considerably larger than that for decarbonylation of $Cp_2V_2(CO)_7$ to $Cp_2V_2(CO)_6$ or for $Cp_2V_2(CO)_6$ to $Cp_2V_2(CO)_5$. This thermodynamic factor may be one reason why the photochemical decarbonylation[6] of $CpV(CO)_4$ goes all the way to $Cp_2V_2(CO)_5$ without stopping at $Cp_2V_2(CO)_7$ or $Cp_2V_2(CO)_6$. In addition, $Cp_2V_2(CO)_5$ was first synthesized[5] by acidification of the anion $CpV(CO)_3^{2-}$, with the expected carbonyl dihydride $CpV(CO)_3H_2$ decomposing according to the following Equation (2).

$$2\ CpV(CO)_3H_2 \rightarrow Cp_2V_2(CO)_5 + 2\ H_2 + CO \quad (2)$$

Table 6. Dissociation energies (kcal/mol) for the successive removal of carbonyl groups from the lowest lying singlet isomers of $Cp_2V_2(CO)_n$ ($n$ = 7, 6, 5, 4).

| | B3LYP | BP86 |
|---|---|---|
| $Cp_2V_2(CO)_7 \rightarrow Cp_2V_2(CO)_6 + CO$ | 17.5 | 16.8 |
| $Cp_2V_2(CO)_6 \rightarrow Cp_2V_2(CO)_5 + CO$ | 1.2 | 10.8 |
| $Cp_2V_2(CO)_5 \rightarrow Cp_2V_2(CO)_4 + CO$ | 29.5 | 34.7 |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The fact that $Cp_2V_2(CO)_5$, rather than the expected dimer $Cp_2V_2(CO)_6$, is produced in this reaction relates to our calculation of a low dissociation energy of one CO group from $Cp_2V_2(CO)_6$ to give $Cp_2V_2(CO)_5$ (Table 6).

## 4. Discussion

A cyclopentadienyl ring is electronically equivalent to three carbonyl groups[34] but, because of its compact nature, sterically equivalent to only two carbonyl groups. Using the latter relationship the binuclear cyclopentadienylvanadium carbonyls studied in this work can be compared with the corresponding homoleptic chromium carbonyls studied previously[4,35] by replacing two carbonyl groups in the chromium derivatives with a single cyclopentadienyl ring in the vanadium derivatives. In this way $Cp_2V_2(CO)_7$ is an analogue of $Cr_2(CO)_{11}$ and thus was found to be unstable with respect to dissociation into $CpV(CO)_4$ + $CpV(CO)_3$ just as $Cr_2(CO)_{11}$ was found earlier[4] to be unstable with respect to dissociation into $Cr(CO)_6$ + $Cr(CO)_5$. The monobridged structure for $Cp_2V_2(CO)_7$, namely $Cp_2V_2(CO)_6(\mu\text{-CO})$, found in this work (Figure 2) is analogous to a monobridged structure $Cr_2(CO)_{10}(\mu\text{-CO})$ found for $Cr_2(CO)_{11}$ in the previous work.[4]

The other binuclear cyclopentadienylvanadium carbonyl derivative discussed in this paper, namely $Cp_2V_2(CO)_6$, is an analogue of $Cr_2(CO)_{10}$.[35] Both $Cp_2V_2(CO)_6$ and $Cr_2(CO)_{10}$ are predicted to be thermodynamically stable with respect to dissociation into the corresponding mononuclear fragments, namely $CpV(CO)_3$ and $Cr(CO)_5$, respectively. For $Cp_2V_2(CO)_6$ the global minimum using the BP86 functional, namely **6S-1**, is a doubly bridged structure with a V=V distance of 2.85 Å suggesting the double bond required to give both vanadium atoms the favored 18-electron configuration. Similar Cr=Cr distances are found in the lowest lying $Cr_2(CO)_{10}$ isomers, which are also doubly bridged singlets.[35] Using the B3LYP functional for $Cp_2V_2(CO)_6$ leads to a different global minimum, namely an essentially unbridged triplet **6T-1** with a predicted V–V single-bond length of 3.10 Å. This triplet structure, with 17-electron configurations for the vanadium atoms, is closely related to the structure of the experimentally known singlet $Cp_2Cr_2(CO)_6$ determined by X-ray crystallography[36] to have no bridging CO groups and a Cr–Cr single bond length of 3.28 Å consistent with 18-electron configurations for the chromium atoms. The triplet structure for $Cr_2(CO)_{10}$ corresponding to this triplet structure for $Cp_2V_2(CO)_6$ lies 12.7 kcal/mol (B3LYP) or 13.2 kcal/mol (BP86) above its singlet global minimum.[35] The singlet structure **6S-2** for $Cp_2V_2(CO)_6$, with one four-electron donor bridging carbonyl group and a V–V distance of 3.150 Å (BP86) suggesting a single bond, has no counterpart in the singlet structures[35] predicted for $Cr_2(CO)_{10}$ in previous research.

# Solvothermal Synthesis, Crystal Structure, and Thermal Stability of Three-Layered Thioantimonate(III) Complexes: $[Ni(C_3H_{10}N_2)_3]Sb_4S_7$, $[C_4H_{14}N_2]Sb_8S_{13}\cdot H_2O$, and $[C_6H_{18}N_2]Sb_{10}S_{16}\cdot H_2O$

**Meng Zhang,[a,b] Tian Lu Sheng,[a] Xi He Huang,[a] Rui Biao Fu,[a] Xin Wang,[a] Sheng Min Hu,[a] Sheng Chang Xiang,[a] and Xin Tao Wu*[a]**

**Keywords:** Thioantimonates / Solvothermal synthesis / Cations / Layered compounds

Three new thioantimonate(III) complexes $[Ni(1,2\text{-PDA})_3]Sb_4S_7$ (**1**) (1,2-PDA = 1,2-propanediamine), $[dmenH_2^{2+}]Sb_8S_{13}\cdot H_2O$ (**2**) (dmen = *N*,*N*-dimethylethylenediamine), and $[deenH_2^{2+}]Sb_{10}S_{16}\cdot H_2O$ (**3**) (deen = *N*,*N*-diethylethylenediamine), prepared under solvothermal conditions, have been characterized by single-crystal X-ray diffraction, elemental analysis, and DTA-TG measurements. In compound **1**, a rectangle-like $Sb_{16}S_{16}$ heterоring whose dimensions are about $8.1 \times 14.7$ Å is observed, this is the largest reported pore in layered thioantimonates to date. Further condensation of the $Sb_{16}S_{16}$ heterorings resulted in an unprecedented framework of the five-atom thick $Sb_xS_y^{n-}$ layer. In **2**, a new member of $Sb_nS_n$ ($n$ = 2, 3, 4, 8, 16, 30, 31, 32) heterocycles $Sb_{15}S_{15}$ heterоring has been obtained as the first example. In compound **3**, the most particular feature is that when the secondary Sb–S bonds are considered the Sb2 atom becomes sevenfold coordinated.

## Introduction

The design and synthesis of chalcogenidometalates have received considerable attention[1–3] during the past decades. To design and synthesize more compounds with various configurations, it is very important to understand which factors affect the structures of chalcogenidometalates. We have in some extent studied how the structures of the sulfur-containing transition-metal polymers are influenced by the size and charge of the cations.[1,2] By using different cations such as $[Nd(DMF)_8]^{3+}$ and $[La(DMF)_8]^{3+}$, we have successfully synthesized and characterized a large number of complexes with different structure.[4] Now we further spread our interest to the study of thioantimonates.

Dozens of open-framework thioantimonates, in which transition-metal complex cations[5–18,25] and organic amine cations[19–24] serve as charge balancing ions, have been prepared in recent years, and the synthesis of these compounds is generally completed in the presence of organic amines as structure-directing agents.[10,20,26,27,34] The organic species used are often aliphatic amines, polyamines, and alicyclic amines.[21–32] The solvothermal method was proven to be very successful in the synthesis of these compounds. Although the size and charge of cations obviously have important effects on the final structure of the anions,[17,19,23,27,32] a clear relationship between them has not been observed.[12,13] Therefore, more examples of such compounds need to be prepared for further understanding.

In this work, $[Ni(1,2\text{-PDA})_3]Sb_4S_7$ (**1**) is the first example of a thioantimonate(III) in which a 1,2-propanediamine complex of a transition metal serves as the counterion. As a result of the use of two N-substituted polyamines, *N*,*N*-dimethylethylenediamine and *N*,*N*-diethylethylenediamine, we successfully prepared two additional thioantimonate(III) complexes: $[C_4H_{14}N_2]Sb_8S_{13}\cdot H_2O$ (**2**) and $[C_6H_{18}N_2]Sb_{10}S_{16}\cdot H_2O$ (**3**).

## Results and Discussion

The structure of compound **1** is composed of isolated $[Ni(1,2\text{-PDA})_3]^{2+}$ cations and $^2_\infty[Sb_4S_7]^{2-}$ anions. The $Ni^{2+}$ ion is sixfold coordinated by six nitrogen atoms of bichelate 1,2-PDA ligands, which forms a distorted octahedron (Figure 1), as is suggested by the octahedral axial $N\text{–}Ni\text{–}N_{trans}$ angles between 171.6(4)° and 172.4(4)°. The Ni–N distances between 2.091(9) and 2.135(9) Å (Table 1) are comparable with those reported in the literature.[33,34] The $^2_\infty[Sb_4S_7]^{2-}$ anion consists of two $SbS_3$ trigonal pyramids and two $SbS_4$ units. The Sb–S distances in $SbS_3$ pyramids vary from 2.373(3) to 2.561(2) Å with S–Sb–S angles between 90.89(7)° and 98.19(9)° (Table 1). For $SbS_4$ units, both Sb

atoms have two short and two longer distances to neighboring S atoms with longer Sb–S separations in the *trans* position, the Sb–S bond lengths and S–Sb–S angles range, respectively, from 2.429(2) to 2.744(3) Å and from 81.29(8)° to 169.84(8)° (Table 1). These values are normal and comparable to other thioantimonate(III) complexes.[13,35,36] The interconnection of primary building units (PBUs) $Sb1S_4$, $Sb2S_3$, $Sb3S_3$, and $Sb4S_4$ results in an $Sb_4S_{10}$ chain (Figure 2). Through sharing S1 and S2 atoms, four chains of this condense to an $Sb_{16}S_{16}$ ring whose dimensions are about $8.1 \times 14.7$ Å (measured from coordinate to coordinate); this is the largest pore in layered thioantiomonates by far.[10,12,13,20] Further condensation of $Sb_{16}S_{16}$ rings through common S7 and S7b atoms leads to the two-dimensional layered $[Sb_4S_7]^{2-}$ anion, which is the first "five-atom"-thick layer; an overwhelming number of thioantimonate(III) complexes that have two-atom-thick layers are often found.[12] The layers lie in the (100) plane, and they are stacked onto each other along the *a* axis to form tunnels also in this direction (Figure 3). The cations are located between the layers.

The structure of compound **2** consists of double-protonated dmen cations and $^2_\infty[Sb_8S_{13}]^{2-}$ anions, seven $SbS_3$ trigonal pyramids, and one $SbS_4$ unit as the PBUs condense to form the $[Sb_8S_{13}]^{2-}$ anion through sharing common corners and edges (Figure 4). The Sb–S separations of the $SbS_3$ pyramids vary from 2.396(2) to 2.567(2) Å with the S–Sb–S angles between 85.69(4)° and 98.23(4)°. In the $Sb6S_4$ unit, the Sb6 atom has two short [2.447(2) and 2.532(2) Å] and two relatively longer distances [2.747(2) and 2.728(2) Å], the longer distances being in the *trans* position [170.00(4)°]

(Table 2). All these values are normal in thioantimonate(III) complexes.[19,22,23] Further interconnection of the $[Sb_8S_{13}]^{2-}$ anions yields undulated layers extending in the (001) plane, in which the $Sb_{15}S_{15}$ heterorings are for the first time observed (shadowed area in Figure 5). There exist nearly circular pores with dimensions of about $7.9 \times 8.4$ Å (measured from coordinate to coordinate) in these heterorings. The layers are stacked onto each other to build channels along the *c* axis, in which the organic cations and the water molecules are accommodated (Figure 5). Compound **3** is composed of double-protonated deen cations and $^2_\infty[Sb_{10}S_{16}]^{2-}$ anions. The $[Sb_{10}S_{16}]^{2-}$ anions are formed by the interconnection of nine $SbS_3$ trigonal pyramids and one $SbS_4$ unit by common corners and edges (Figure 6). In the $SbS_3$ pyramids, Sb–S distances vary from 2.404(3) to 2.595(3) Å and S–Sb–S angles are between 87.58(10)° and 98.70(10)°; in the $Sb6S_4$ moieties there are three short [2.460(3), 2.506(3), Sb6–S9: 2.585(3) Å] and one extraordinarily long Sb–S bonds [Sb6–S15a: 2.929(3) Å] with the S9–Sb6–S15a angle being 169.61(10)° (Table 3). All of these values are in the typical range.[21,22,27] Further condensation of the $[Sb_{10}S_{16}]^{2-}$ anions resulted in the two-dimensional layers extending in the (001) plane, which could be thought

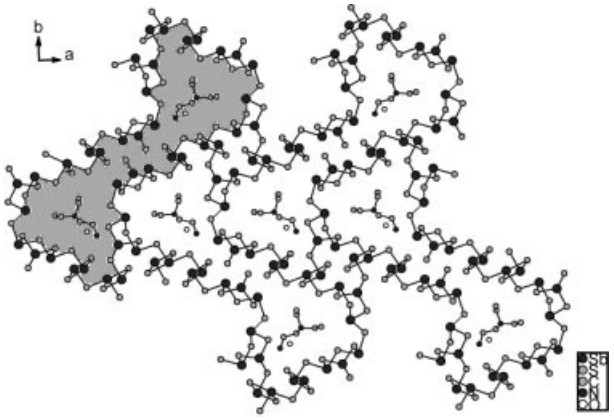

Figure 7. $[Sb_{10}S_{16}]^{2-}$ layer consists of $Sb_{30}S_{30}$ rings (shaded area) in $[C_6H_{18}N_2]Sb_{10}S_{16}\cdot H_2O$ (**3**). Organic cations and water molecules are held in tunnels. Hydrogen atoms are omitted for clarity.

to be composed of the "double-ellipsoidal"[20] $Sb_{30}S_{30}$ rings in two perpendicular directions (Figure 7). The dimensions of the ellipsoidal pores in the $Sb_{30}S_{30}$ rings are about $8.8 \times 10.1$ Å (measured from coordinate to coordinate). The layers are stacked onto each other in the [001] direction, which forms channels where the cations and water molecules are located (Figure 7).

In all three title compounds, relatively short H···S distances are observed. The short H···S separations in compound $[Ni(C_3H_{10}N_2)_3]Sb_4S_7$ scatter from 2.51 to 2.69 Å with N–H···S angles ranging from 157.5° to 177.9° (Table 4). In $[C_4H_{14}N_2]Sb_8S_{13}\cdot H_2O$, four short H···S contacts from 2.53 to 2.82 Å are found with N–H···S (or O–H···S) angles between 136.1° and 163.8° (Table 4). Several short H···S separations (2.46 to 2.60 Å) in $[C_6H_{18}N_2]$-$Sb_{10}S_{16}\cdot H_2O$ are also observed, and the N–H···S (or O–H···S) angles are in the range of 140.6 to 164.2° (Table 4). All the values indicate that weak hydrogen bonding interconnections exist between the cations and the $Sb_xS_y^{n-}$ anions.

When the secondary Sb–S bonds (sum of van der Waals' radii: $Sb_{vdw} + S_{vdw} \approx 3.85$ Å[37]) are taken into account, most Sb atoms in the three title compounds enhance their coordination numbers. In compound **1**, the Sb3 and Sb4 atoms are fivefold coordinated to form ψ-$SbS_5$ octahedra, and the Sb2 atom is surrounded by four S atoms to yield ψ-SbS4 trigonal bipyramids (Table 5). In compound **2**, the Sb1 and Sb7 atoms enhance their coordination numbers to five and the Sb2, Sb3, Sb4, Sb5, Sb6, and Sb8 atoms become sixfold coordinated (Table 5). In compound **3**, the Sb1 atom, the Sb7 and Sb8 atoms, and the Sb3, Sb4, Sb5, Sb6, Sb9, and Sb10 atoms are surrounded by four, five, and six S atoms, respectively. The most distinct character is that the Sb2 atom becomes seven-coordinate (Figure 8) with the Sb–S bond lengths varying from 3.1909(31) to 3.7607(34) Å and the S–Sb–S angles being in the range of 59.91(8)° to111.29(8)° [67.98(7) to113.14(6)° for other Sb atoms] (Table 5). To the best of our knowledge, compound **3** is the first thioantimonate in which there exists seven-coordinate Sb atoms with Sb–S distances under 3.8 Å.

In the three title compounds, the sequence of the cationic size is $[Ni(C_3H_{10}N_2)_3]^{2+}$ (in **1**) > $[C_6H_{18}N_2]^{2+}\cdot H_2O$ (in **3**) > $[C_4H_{14}N_2]^{2+}\cdot H_2O$ (in **2**), correspondingly the dimensions of pores in compounds are **1** ($8.1 \times 14.7$ Å) > **3** ($8.8 \times 10.1$ Å) > **2** ($7.9 \times 8.4$ Å), the cations and the water molecules are

located above or under the pores. So it is obvious that the cations play an important role in the formation of $Sb_xS_y^{n-}$ structures.

### Thermal Investigations

Compound **1** decomposes in a two-step manner which is accompanied by two signals in the DTA curve ($T_p$ = 192 and 286 °C; Figure S1) and the extrapolated onset temperature $T_e$ was 175 °C. The experimental total mass loss was 24.4%, which corresponds to the emission of organic amine ($-\Delta m_{theo}$ = 22.4%). For **2**, the mechanism of decomposition is more complicated and two obvious steps can be identified. In the first step, the extrapolated onset temperature $T_e$ was 140 °C and $T_p$ was 150 °C (Figure S2). The weight loss was 1.2%, which is in good agreement with the expected value for the removal of water molecules ($-\Delta m_{theo}$ = 1.0%). On further heating, another endothermic event occurred with the DTA signal at $T_p$ = 274 °C, the mass loss was 8.4% which can be attributed to the complete emission of organic ligands ($-\Delta m_{theo}$ = 6.0%). In the TG curve of **3** a smooth decrease from 63 °C to 223 °C is observed with a weight change of 1.1% (Figure S3), as corresponds to the removal of water molecules ($-\Delta m_{theo}$ = 1.0%). On further heating, a sharp weight loss of 7.6% occurred, which was accompanied by the endothermic event at $T_e$ = 247 °C and $T_p$ = 260 °C in the DTA curve. The experimental value is in good agreement with that determined for the emission of the organic component ($-\Delta m_{theo}$ = 6.3%). During the heating process, besides the removal of organic amine and water molecules, some $H_2S$ molecules were formed and emitted.[13,27] This may explain the discrepancy between the experimental and theoretic values.

## Experimental Section

**1**: Yellow crystals of $[Ni(1,2\text{-PDA})_3]Sb_4S_7$ (**1**) were obtained from Ni (0.0586 g, 1 mmol) or $NiCl_2{\cdot}6H_2O$ (0.273 g, 1 mmol), Sb (0.1217 g, 1 mmol), and S (0.1280 g, 4 mmol) in a water solution of 1,2-PDA (60%, 5 mL) under solvothermal conditions. The mixture was heated at 140 °C for 6 d in Teflon-lined steel autoclaves with an inner volume of 25 mL and then cooled to room temperature over 5 h. After the reaction mixture was filtered, the residual solid product was washed with alcohol. The yellow crystals were obtained in 30% yield (according to Sb), and they are stable in air and alcohol, but have good dissolvability in water. $C_9H_{30}N_6NiSb_4S_7$ (992.52): calcd. C 10.8, H 3.02, N 8.46; found C 10.54, H 3.23, N 8.95.

**2**: Red crystals of $[dmenH_2^{2+}]Sb_8S_{13}{\cdot}H_2O$ (**2**) were prepared from the reaction of Zn (0.0915 g, 1.4 mmol), Sb (0.1217 g, 1 mmol), and S (0.1280 g, 4 mmol) in an aqueous solution of dmen (50%, 5 mL). The mixture was heated at 140 °C for 6 d in Teflon-lined steel autoclaves and then cooled to room temperature. The reacted mixture was filtered and washed with water and alcohol to give 30% yield of crystalline **2** (based on Sb). The product is stable in air, water, and ethanol. In the absence of Zn in the reaction mixture, a decreased yield was observed. $C_4H_{16}N_2Sb_8S_{13}O$ (1498.97): calcd. C 3.20, H 1.06, N 1.87; found C 3.55, H 1.36, N 1.67.

**3**: The procedure for the synthesis of $[deenH_2^{2+}]Sb_{10}S_{16}{\cdot}H_2O$ (**3**) is the same as that of **2**. Zn (0.0729 g, 1.1 mmol), Sb (0.1217 g, 1 mmol), S (0.0712 g, 2.2 mmol), aqueous solution of deen (50%, 5 mL). Yield: 35%. In the absence of Zn in the reaction mixture, a decreased yield was observed. $C_6H_{20}N_2Sb_{10}S_{16}O$ (1866.70): calcd. C 3.86, H 1.07, N 1.50; found C 3.82, H 1.35, N 1.23.

**Structure Determination:** Intensities were collected at 293(2) K with a Simens SMART-CCD diffractometer (for **1**), at 294(2) K with a Rigaku SATURN70 CCD diffractometer (for **2**), and at 293(2) K with a Rigaku Mercury CCD diffractometer (for **3**) by using graphite-monochromated Mo-$K_a$ radiation [$\lambda$ = 0.71073 Å]. Data for all three compounds were corrected for Lorentz, polarization, and absorption effects. The structures were solved and refined by full-matrix least-squares techniques on $F^2$ by using SHELXL-97,[38] all non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated geometrically and allowed to ride on their parent atoms with fixed isotropic displacement parameters. The crystallographic data are summarized in Table 6.

CCDC-626004 (for **1**), -626005 (for **2**), and -626006 (for **3**) contain the supplementary crystallographic data for this paper. These data

can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Thermoanalytical Measurements:** Thermoanalytical measurements were performed with a DTA-TG device STA 449C from Netzsch. All measurements were performed under a nitrogen atmosphere (flow-rate: 20 mL min$^{-1}$) with $Al_2O_3$ crucibles. The heating rates are 10 K min$^{-1}$.

**X-ray Powder Diffractometry:** The X-ray powder diffraction patterns were acquired with a DMAX-2500 diffractometer by using Cu $K_a$ radiation at ambient environment.

**Supporting Information** (see footnote on the first page of this article): DTA-TG figures of the title compounds and X-ray powder patterns of crystals **2** and **3**.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** a crown-based lateral macrobicycle designed by our research group as a potential ligand for $Pb^{II}$ complexation. Lead is recognized worldwide as a serious environmental pollutant, and although it is a natural component of soil, water and vegetation, anthropogenic emissions have contributed to the dramatic increase in its level in the environment. The removal of lead from the environment and biological systems is the aim of many research groups. In particular, we are interested in the design of $Pb^{II}$-complexing agents based on crown frameworks. In this picture, the complexed $Pb^{II}$ ion has been replaced by our beautiful but polluted blue planet. The cover picture symbolizes the need for innovative ideas to solve the problem of environmental lead pollution – one solution includes the design of selective complexing agents. Details are discussed in the article by A. de Blas, T. Rodríguez-Blas et al. on p. 1635 ff.

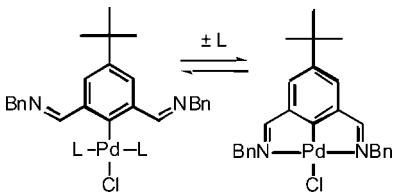
## SHORT COMMUNICATIONS

### Ligand Indexing

**M. Minakawa, K. Takenaka, Y. Uozumi* ..... 1629–1631**

Pd Pincer Complex as a Probe To Index the Coordination Ability of Various Ligands

**Keywords:** Pincer complexes / Coordination / Palladium / Phosphane ligands / Mondentate ligands



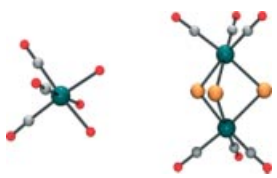
The coordination constants of 27 monodentate ligands (L) with a pincer palladium complex to form complexes of the type $ArPd(L)_2Cl$ were determined by *1*H NMR spectroscopy. This allowed the coordination ability of a wide variety of ligands, including P-, N-, and As-coordinating ligands, to be indexed.

### Bioorganometallic Re Complexes

**R. S. Herrick,* C. J. Ziegler,* A. Çetin, B. R. Franklin ..... 1632–1634**

Structure of the Triaquatricarbonylrhenium(I) Cation and Its Conjugate Base

**Keywords:** Aqua ligands / Carbonyl ligands / Hydrolysis / Rhenium



The crystal structure of the $Re(CO)_3(H_2O)_3^+$ cation has been determined, once with the $Re_2(CO)_9(\mu_3\text{-}Br)_3^-$ anion and once co-crystallized with the conjugate base, $Re(CO)_3(OH)(H_2O)_2$, with a $PF_6^-$ anion. The unexpected stability of the hydroxo compound may be due to disordering of the hydroxo and aqua ligands.

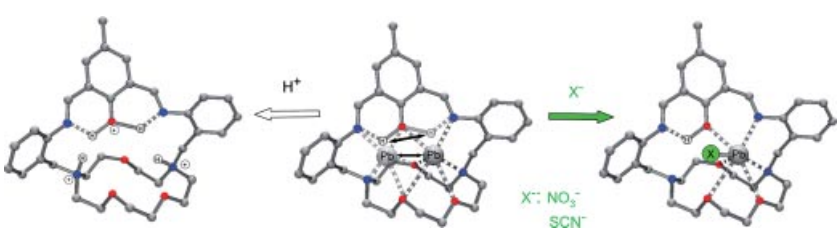
## FULL PAPERS

### Lead(II) Coordination

**D. Esteban-Gómez, C. Platas-Iglesias, F. Avecilla, A. de Blas,* T. Rodríguez-Blas* ..... 1635–1643**

Effect of Protonation and Interaction with Anions on a Lead(II) Complex with a Lateral Macrobicycle Containing a Phenol Schiff-Base Spacer

**Keywords:** Lead / Macrocycles / N,O ligands / Density functional calculations



The macrobicyclic receptor derived from 1,10-diaza-15-crown-5 incorporating a phenol Schiff-base spacer forms stable complexes with lead(II). In $[Pb(L^4)(ClO_4)](ClO_4)\cdot CH_3CN$ the $Pb^{II}$ ion is asymmetrically placed at the one end of the macrobicyclic cavity inducing chirality in the corresponding complex. The effect of the protonation on the complex at room temperature has been studied, finding that protonation causes demetallation of the complex without receptor destruction i.e. the receptor is recovered in its protonated form. Likewise, since in solution the $Pb^{II}$ ion is coordinatively unsaturated in the complex, the interaction of the $Pb^{II}$ complex with anions such as $NO_3^-$ and $SCN^-$ has been evaluated by using spectrophotometric titrations in acetonitrile.

[$Cu^{II}_4$] Clusters From the Self-Assembly of Two Imidazolidinyl 2-Phenolate-Bridged [$Cu^{II}_2$] Units: The Role of the Chloride Bridge

**Keywords:** Template synthesis / Self-assembly / Cluster compounds / Copper / Magnetic properties

The new cluster $[Cu_4(\mu_4\text{-}Cl)L_2]ClO_4{\cdot}12H_2O$ is obtained by self-assembly of two $[Cu_2L]^+$ cations around the spherical $Cl^-$ anion and shows an unprecedented single atom nucleating exogenous symmetric bridging mode. This anion-centred cluster formation is responsible for $Cl^-$ entrapment during metal coordination in a $\mu_4$ fashion.

# Pd Pincer Complex as a Probe To Index the Coordination Ability of Various Ligands

**Maki Minakawa,[a] Kazuhiro Takenaka,[a] and Yasuhiro Uozumi*[a]**

**Keywords:** Pincer complexes / Coordination / Palladium / Phosphane ligands / Mondentate ligands

An NCN pincer palladium complex was developed as a probe molecule to index the coordination ability of various monodentate ligands. Coordination constants of 27 monodentate ligands (L) with a pincer palladium complex to form complexes of the type $ArPd(L)_2Cl$ were determined by $^1H$ NMR spectroscopy. This allowed the coordination ability of a wide variety of ligands, including P-coordinating ligands (phosphane, phosphite), as well as As-coordinating $AsPh_3$, and N-coordinating pyridine, to be indexed. The differential between the highest/lowest coordination constants was $10^{12}$. The relative coordination ability is described in a logarithmic manner, $\log(K_{eq(L)}/K_{eq(PPh_3)})$, with respect to the value of $PPh_3$ to exhibit high linearity in the Hammett plot.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Transition-metal–ligand complexes have emerged as versatile and functional molecules in the domain of chemistry. Vast arrays of functional metal complexes have been developed in which ligands undergo drastic change and/or fine-tuning of their chemical and physical properties. Transition-metal-catalyzed organic transformations are the most commonly employed reactions where the choice of ligands is essential in controlling the catalytic reaction pathway. Coordination ability is one of the most fundamental and important properties of ligands and, therefore, quite a few studies have appeared that index the ligand coordination ability. However, to the best of our knowledge, no direct or precise method has appeared that allows the determination of the relative strength/weakness of the coordination ability of $PPh_3$ to palladium, for example, versus $AsPh_3$, pyridine, $PCy_3$, etc. Clearly, although pioneering strides have been made, additional studies on the ordering of the coordination abilities of ligands are warranted.

Because the coordination ability is controlled by both the electronic and steric properties of the ligand, this renders quantitative description difficult. Indeed, although the two controlling factors (electronic and steric) have been defined,[1,2] all of the well-developed research on the determination of the coordination ability of various ligands has been limited to isolated reports.[3] If a practical probe for the direct and exact observation of the coordination–dissociation equilibria of a wide range of ligands were developed, a scale of the coordination ability of various ligands would be achieved. This would provide fundamental and useful information for catalytic as well as organic, inorganic, organometallic, and materials research fields. We would like to propose pincer palladium complex **1** as a novel probe to titrate the coordination ability of various nonchelating igands to palladium to form palladium complexes $ArPd(L)_2X$. Many of these complexes are recognized as key intermediates in various palladium-catalyzed processes (e.g. cross-couplings, the Heck reaction, carbonylation, etc.).

## Results and Discussion

We have previously prepared various NCN pincer palladium complexes[4] by the ligand introduction route [Scheme 1, Equation (1)].[5] From our detailed studies on the pincer complexation process, we found that intermediate complex **2** was in equilibrium with pincer complex **1**. The coordination–dissociation behavior of the $PPh_3$ ligand of intermediate complex **2** was observed by $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy, and the coordination constant $K_{eq(PPh_3)}$ was unambiguously determined by the $^1H$ NMR spectroscopic measurement of the intramolecular $CH$=N$CH_2$Ph ligand groups [*Ha* and/or *Hb* indicated in Scheme 1, Equation (2)]. These observations led us to the conclusion that complex **1** would be a good probe to index the coordination abilities of various ligands. By using probe complex **1**, a wide range of coordination constants (the difference between the highest and lowest constants is $10^{12}$) were determined with high accuracy by $^1H$ NMR spectroscopic measurements, which allowed the relative coordination ability of 27 different ligands to be indexed.

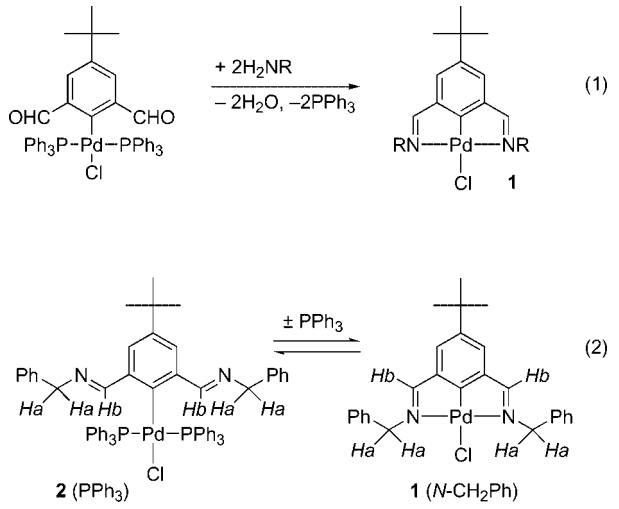

Scheme 1. Preparation and substitution equilibrium of the pincer complex: (1) ligand introduction route to pincer complexation; (2) ligand substitution equilibrium.

A typical procedure for the equilibria study by NMR spectroscopy for $PPh_3$ is as follows: Complex **1** was dissolved in $CD_2Cl_2$ (12.7 mM) at 298 K and $PPh_3$ (2 mol equiv. to **1**) was added under a nitrogen atmosphere. The resulting mixture was analyzed by $^1H$ NMR spectroscopy, where the resonances of *Ha* for complexes **2** (phosphane complex) and **1** (pincer complex) were observed at $\delta$ = 4.50 and 5.01 ppm, respectively, to provide $K_{eq(PPh_3)} = 2.06 \times 10^5$ M$^{-2}$ in $CD_2Cl_2$ (298 K). The coordination constants of 27 ligands obtained by similar NMR spectroscopic experiments are shown in Table 1. Ligands, whose coordination constants could not be determined by the present method because their coordination ability was either too strong or too weak, are also listed in Table 1 to demonstrate the scope and limitation of this system. The coordination constants of $Ph_2P(C_6H_4$-2-Me), $Ph_2P(C_6F_5)$, $P[C_6H_3$-3,5-$(CF_3)_2]_3$, $P$(2-furyl)$_3$, $P(OPh)_3$, pyridine, and $AsPh_3$ were so small that the VT-NMR spectroscopic studies were performed at lower temperatures to observe both peaks of **1** and **2** (Table 1, Entries 22–28), and their $K_{eq(L)}$ values at 298 K were estimated by a van't Hoff plot (see Supporting Information). The relative coordination ability (RCA) is described in a logarithmic manner, $\log(K_{eq(L)}/K_{eq(PPh_3)})$, with respect to the value of $PPh_3$.

Several representative and/or typical features obtained by this indexation include: (1) The coordination ability of ligands having the same cone angle was strictly determined by their electronic character (vide infra). (2) The coordination constant of $AsPh_3$ is $10^{10}$ smaller than that of $PPh_3$. (3) $P(OPh)_3$ exhibits a $10^7$ smaller value than that of its carbon analogue $P(CH_2Ph)_3$. (4) The order of the coordination ability of phosphane ligands bearing six-membered ring substituents is $PCy_3 > PPh_3 > PPh_2Cy > PPhCy_2$.[6] (5) The coordination ability is significantly affected by the steric bulkiness of the ligand [e.g. $PPh_3$ versus $PPh_2$Tol-*o* (Table 1, Entries 9 and 22)]. These features would be difficult to predict without direct observation of the $K_{eq}$ values.

Table 1. Coordination constants of various ligands.[a]

**1** + 2L ⇌ **2** (L)

| Entry | Ligand | $K_{eq(L)}$ [M$^{-2}$][b] | RCA[c] |

[a] All titrations were performed by $^1H$ NMR spectroscopic measurements at 298 K. [b] Average of two or three measurements. [c] RCA = $\log(K_{eq(L)}/K_{eq(PPh_3)})$. [d] $K_{eq}$ value was estimated by the van't Hoff plot obtained by VT-NMR spectroscopic experiments (see Supporting Information).

Figure 1 is the Hammett plot for the RCA values of various triarylphosphanes to quantify the electronic effect of the P substituents. Triarylphosphanes with *para* and *meta* monosubstituted aromatic groups having cone angles of 145 ° show excellent proportionality for the σ values[7] of the aromatic groups. Thus, the RCA value decreased proportionally as the σ value of the aromatics increased and the RCA–σ relationship exhibits high linearity (Figure 1, black solid line: $R^2$ = 0.9925), which demonstrates the high accuracy of the RCA values measured by the present method. This observation should make the prediction of the RCA value of various triarylphosphane ligands having *para* or *meta* monosubstitution possible by inter-/extrapolation (dotted line), even if the RCA value is out of the measurement range with highly electron-rich or -deficient substituents. The RCA values of triarylphosphane ligands of the 147 ° cone angle were slightly smaller than those of the plot for the ligands of the 145 ° cone angle. Thus, $P(C_6H_3$-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

3,5-$Me_2$)$_3$ and P[$C_6H_3$-3,5-($CF_3$)$_2$]$_3$ exhibited RCA values of –0.249 and –6.23, respectively (Table 1, Entries 12 and 24). More sterically demanding ligands gave lower RCA values (Table 1, Entries 20, 22, and 23).

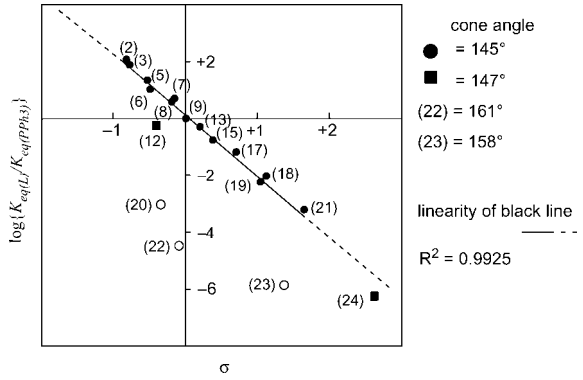

Figure 1. Hammett plot for the RCA values: $\log(K_{eq(L)}/K_{eq(PPh_3)})$ versus Taft's σ value of aromatic substituents of the triarylphosphane ligands. The numbers in parentheses correspond to the entry numbers in Table 1.

## Conclusions

We have developed pincer palladium complex **1** as a novel probe for the determination of the coordination ability of various ligands to form $ArPd(L)_2Cl$, with the relative coordination abilities of 27 ligands being determined easily by $^1$H NMR spectroscopic experiments. A two-dimensional analysis using probe complexes of different steric demands (with the use of various NR groups), as well as the application of the indexation protocol to ligands bearing other coordination sites, e.g. carbene, S, Sb, etc., are currently underway and will be reported in due course.

## Experimental Section

**General Equilibria Studies by NMR Spectroscopy:** Complex **1** and a ligand (2 equiv.) were dissolved in [$D_2$]dichloroethane. The equilibrium constant, $K_{eq}$, was determined by the integration of the resonances: the resonance integration ratio **1/2** = $x$:$y$; $K_{eq}$ = $(1/4)[\{y(x + y)^2\}/x^3][\mathbf{1}]_0^2$ ($M^{-2}$). All NMR spectroscopic data (charts, chemical shifts, integration data, etc) are provided in the Supporting Information.

**Supporting Information** (see footnote on the first page of this article): $^1$H NMR spectroscopic data with their measurement conditions for Table 1, Entries 2–28.

# Structure of the Triaquatricarbonylrhenium(I) Cation and Its Conjugate Base

**Richard S. Herrick,*[a] Christopher J. Ziegler,*[b] Anıl Çetin,[b] and Brenton R. Franklin[a]**

**Keywords:** Aqua ligands / Carbonyl ligands / Hydrolysis / Rhenium

The crystal structure of the $Re(CO)_3(H_2O)_3^+$ cation has been determined from crystals obtained by evaporation of an aqueous solution of $[Re(CO)_3(H_2O)_3]Br$. The bromide ion is incorporated in the $Re_2(CO)_9(\mu_3\text{-}Br)_3^-$ anion. A second structure was obtained by removal of bromide as AgBr and precipitation of the $Re(CO)_3(H_2O)_3^+$ cation with $PF_6^-$. In the latter structure the conjugate base, $Re(CO)_3(OH)(H_2O)_2$ is co-crystallized in the structure. Each structure along with the previously known cubane $[Re(CO)_3(\mu_3\text{-}OH)]_4\cdot 4H_2O$ was obtained multiple times during crystallization studies. The use of other anions to generate crystalline products was unsuccessful.

## Introduction

The discoveries of the $Re(CO)_3(H_2O)_3^+$ cation **1**$^+$ and its technetium congener[1,2] sparked intense interest in recent years for their potential as reagents in aqueous organometallic chemistry. One focal point is the search for viable $d^6$ $M(CO)_3L^+$ (M = $^{186/188}$Re, $^{99m}$Tc) compounds for use as therapeutic and imaging agents, respectively, in nuclear medicine.[3,4] Kinetic and thermodynamic details of water exchange and ligand substitution for these aquacarbonyl ions have been reported[5,6] and many syntheses utilizing these important synthons have been published.[7–11] Several crystal structures have been solved that formally result from the deprotonation of **1**$^+$ in aqueous solution and subsequent aggregation.[12] Although the preparation and isolation of [**1**]Br have been described[13] and attempts to grow crystals of this cation have been reported,[12] its structure has not appeared. There are, in fact, only a limited number of elucidated structures of aquacarbonyl complexes in the chemical literature, and only four structures with exclusively water and carbon monoxide as ligands.[14–17] We have discovered that crystals containing **1**$^+$ are surprisingly easy to prepare. We now report the first crystal structures of salts of **1**$^+$ and the formal appearance of its conjugate base, $Re(CO)_3(OH)(H_2O)_2$ **2** in a crystal structure.[18]

## Results and Discussion

Our initial attempt at growing crystals containing **1**$^+$ consisted of dissolving [**1**]Br in distilled water in air and allowing the water to evaporate. Crystals in two separate morphologies were obtained along with some non-crystalline material. The majority of the product was in the form of small colorless rods, with a smaller fraction of large colorless, crystalline blocks. X-ray crystallographic analysis of the blocks showed the presence of the known cubane structure $[Re(CO)_3(\mu_3\text{-}OH)]_4\cdot 4H_2O$ (**3**)[13] which had not previously been crystallized from aqueous solution. Crystallographic characterization of the rods showed the presence of the desired cation in the salt [**1**][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$.[19]

Figure 1 shows the structure of [**1**][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$. The cation has the expected octahedral geometry with a facial disposition of both carbon monoxide and water ligands. The identity of the anion was unexpected, but it is supposed that the bromide ion competes as a ligand with water molecules when the solvent evaporates as shown in Equation (1). The dimeric anion $Re_2(CO)_6(\mu_2\text{-}Br)_3^-$ has

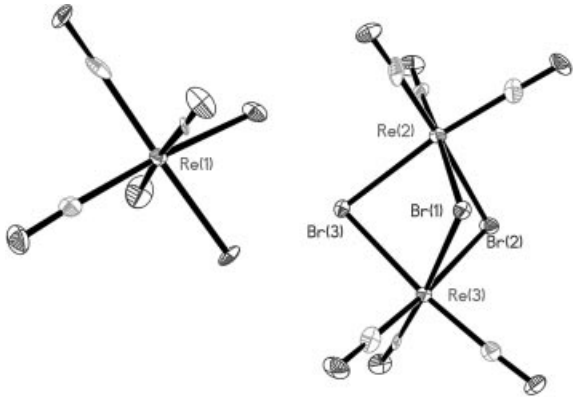

Figure 1. Structure of [**1**][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$ with 50% thermal ellipsoids. Solvent water and hydrogen atoms have been omitted.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

been seen before and has the expected $D_{3h}$ geometry.[20,21] The IR spectrum of [**1**][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$ shows two sets of tricarbonyl bands as predicted.

$$3\ \mathbf{1}^+ + 3\ Br^- \rightarrow [\mathbf{1}][Re_2(CO)_6(\mu_2\text{-}Br)_3]\cdot 6H_2O \quad (1)$$

We were interested in seeing if $\mathbf{1}^+$ could be crystallized with other anions in the hope of increasing the yield of the cation by preventing formation of the $Re_2(CO)_6(\mu_2\text{-}Br)_3^-$ anion and minimizing formation of **3**. A variety of bromide-free crystallization experiments were set up with different non-coordinating anions, $PF_6^-$, $CF_3SO_2^-$ or $NO_3^-$, at various pH values adjusted by the appropriate acid. Only the $PF_6^-$ trials produced crystals. Crystals grown with $PF_6^-$ as the counterion at acidic pH (ca. 1.5–4) produced primarily a single crystalline form of product. These needles were analyzed and can be formally represented as **2**·[**1**][$PF_6$]·$H_2O$,[22] corresponding to the co-crystallization of **2** with [**1**][$PF_6$]. In distilled water, pH = 5.6, with the $PF_6^-$ anion, crystals of **3** formed along with **2**·[**1**][$PF_6$]·$H_2O$. Figure 2 shows the structure of **2**·[**1**][$PF_6$]·$H_2O$.

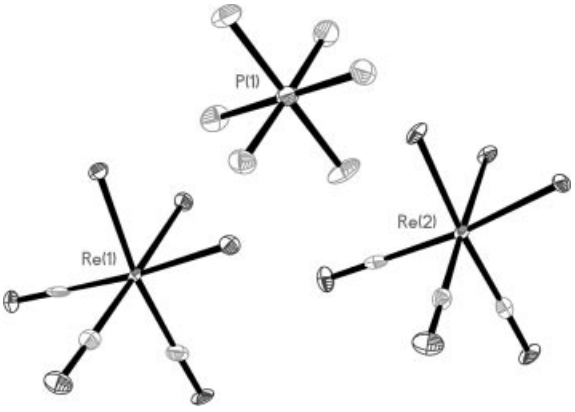

Figure 2. Structure of **2**·[**1**][$PF_6$]·$H_2O$ with 50% thermal ellipsoids. See text for explanation of the assignments of $\mathbf{1}^+$ and **2**. Solvent water and hydrogen atoms have been omitted.

Because the hydrogen atoms were not observed directly by the difference map, the assignments of $\mathbf{1}^+$ and **2** are problematic. Table 1 lists the average distances for the structures. Each monomeric rhenium species in the two structures shows a slight elongation of the octahedral geometry along the $C_3$ axis as observed for $Ru(CO)_3(H_2O)_3^{2+}$.[15] The average Re–C distance of $\mathbf{1}^+$ in [**1**][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$ is 0.03 Å longer than it is in either rhenium unit in **2**·[**1**][$PF_6$]·$H_2O$. This difference may be due in part to a decrease in hydrogen bonding in **2**·[**1**][$PF_6$]·$H_2O$ vs. [**1**][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$. The average Re–O distance in $\mathbf{1}^+$ in the first structure and in Re(1) in **2**·[**1**][$PF_6$]·$H_2O$ are nearly identical. The corresponding value for Re(2) in **2**·[**1**][$PF_6$]·$H_2O$ is about 0.02 Å shorter. At issue is whether the differences in these two average Re–O bond lengths are meaningful with regard to protonation state.

Table 1. Comparison of selected average bond lengths and angles[a] for compounds reported.

| | $\mathbf{1}^+$[b] | Re(1)[c] | Re(2)[d] | **4**[e] |
|---|---|---|---|---|
| Re–C [Å] | 1.912(12) | 1.887(8) | 1.887(14) | 1.908(4) |
| Re–O [Å] | 2.201(14) | 2.195(10) | 2.178(10) | 2.132(3) |
| C–Re–O [°] | 96.1(8) | 96.2(21) | 96.8(14) | – |

[a] Errors cover the range of observed values. [b] Average values for the cation from [**1**][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$. [c] Average values associated with Re(1) in **2**·[**1**][$PF_6$]·$H_2O$. [d] Average values associated with Re(2) in **2**·[**1**][$PF_6$]·$H_2O$. [e] From ref.[23].

The sixteen structurally characterized $Re^I$ compounds that have a CO *trans* to a water ligand, including $Re(CO)_5(H_2O)^+$,[17] were analyzed to compare bond lengths. In these compounds the Re–C bond lengths span the range 1.80–1.92 Å, while the Re–O distances vary from 2.17–2.26 Å. There is only one characterized rhenium compound, Re(dmbpy)$(CO)_3$(OH) **4** (dmbpy = 4,4′-dimethyl-2,2′-bipyridine), with a terminal hydroxide *trans* to a carbon monoxide ligand.[23] In this compound, the Re–C(*trans*) bond length measures 1.908(4) Å and the Re–O bond length is 2.132(3) Å.[24] From the structural data for **2**·[**1**][$PF_6$]·$H_2O$ the evidence is not conclusive as to whether the hydroxide is disordered over the three possible positions [making Re(1) the center of $\mathbf{1}^+$ and Re(2) the center of **2**] or over the six possible positions of the two rhenium species (meaning that the identity of $\mathbf{1}^+$ and **2** is ambiguous). However, the IR spectrum of crystals of **2**·[**1**][$PF_6$]·$H_2O$ shows a single tricarbonyl pattern suggesting that rapid proton exchange involving water ligands on both tricarbonyl species is likely.

Previous compounds crystallized from aqueous solutions of $\mathbf{1}^+$ include [$NEt_4$][$Re_2(CO)_6(\mu_2\text{-}OH)_3$] (**5**) and [$NEt_4$]-[$Re_3(CO)_9(\mu_2\text{-}OH)_3(\mu_3\text{-}OH)$] (**6**).[1] Both of these were separately prepared by addition of a stoichiometric amount of NaOH and allowing the solutions to stand. The structure of the tetranuclear cluster associated with **3** has been reported previously with other solvates but typically it was prepared from wet organic solvents and not from water directly.[12,13] Compound **2** has also been observed in solution previously, but was proposed to be an intermediate which promptly produced dimers, trimers and tetramers.[12] In all of our crystallization trials the only rhenium-containing crystalline products we observed were [**1**][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$, **2**·[**1**][$PF_6$]·$H_2O$ and **3**. Each was observed multiple times indicating that despite expectations $\mathbf{1}^+$ is a stable crystallizable species.

## Conclusions

This work has shown that it is possible to crystallize the rhenium(I)triaquatricarbonyl cation under specific conditions and with specific anions. Work is in progress to crystallize other Group 7 aqua carbonyl complexes.

## Experimental Section

**[1][$Re_2(CO)_6(\mu_2\text{-}Br)_3$]·$6H_2O$:** [**1**]Br[13] (50 mg) was dissolved in distilled water (3 mL). Slow evaporation gave a solid that consisted of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

large colorless blocks of **3**, small colorless rods of [**1**][$Re_2(CO)_6(\mu_2$-$Br)_3$]·$6H_2O$ and a non-crystalline solid. The rods were the major component of the solid. IR of separated crystals: $\tilde{\nu}$ = 2021, 2028, 1920, 1888 $cm^{-1}$.

**2·[1][$PF_6$]·$H_2O$:** 100 mg (0.22 mmol) of [**1**]Br was dissolved in 3 mL of distilled water. Addition of 55 mg (0.22 mmol) of $AgPF_6$, produced copious precipitation which was removed by centrifugation. The solution was allowed to evaporate. Large colorless blocks of **3**, rods consisting of **2**·[**1**][$PF_6$]·$H_2O$ and non-crystalline material were found. IR of separated crystals: $\tilde{\nu}$ = 2036, 1905 $cm^{-1}$.

Other attempts to grow crystals: Aqueous solutions of [**1**][$PF_6$] were created with pH values between 1.5 and 4. The solutions were allowed to slowly evaporate. In each case crystals of **2**·[**1**][$PF_6$]·$H_2O$ were obtained along with non-crystalline material. **3** was also observed in one trial due to incomplete precipitation of bromide.

# Effect of Protonation and Interaction with Anions on a Lead(II) Complex with a Lateral Macrobicycle Containing a Phenol Schiff-Base Spacer

**David Esteban-Gómez,[a] Carlos Platas-Iglesias,[a] Fernando Avecilla,[a] Andrés de Blas,*[a] and Teresa Rodríguez-Blas*[a]**

**Keywords:** Lead / Macrocycles / N,O ligands / Density functional calculations

The macrobicycle receptor **L⁴**, derived from 1,10-diaza-15-crown-5 incorporating a phenol Schiff-base spacer, forms stable complexes with lead(II). In $[Pb(L^4)(ClO_4)](ClO_4)\cdot CH_3CN$ (**1**), the lead(II) ion is asymmetrically placed at the one end of the macrobicyclic cavity, because of the intramolecular hydrogen bonding interaction that occurs between an imine nitrogen atom and the phenol group. This asymmetric position of the metal ion inside the macrobicyclic cavity induces chirality in this system. Variable temperature $^1H$ NMR spectroscopic experiments indicate that the asymmetric coordination of the metal ion inside the macrocyclic cavity is maintained in acetonitrile solution, but a translocation of the $Pb^{II}$ ion from one end of the macrobicyclic cavity to the second one occurs. This dynamic behaviour, which corresponds to the interconversion between the two possible enantiomeric forms of the complex, is fast on the NMR timescale at 320 K but slow at low temperatures, and we have estimated an activation barrier of $\Delta G^{\ddagger} = 68 \pm 2$ kJ mol$^{-1}$. We have also studied the effect of the protonation on **1** by NMR and UV/Vis spectroscopy in $CH_3CN$ solutions at room temperature, finding that diprotonation causes demetallation of the complex without receptor destruction, recovering **L⁴** in its protonated form. On the other hand, the interaction of compound **1** with anions such as $NO_3^-$ and $SCN^-$ has been evaluated by using spectrophotometric titrations in acetonitrile solution, finding log *K* values of 5.83(1) for $NO_3^-$ and 6.27(2) for $SCN^-$. The $[Pb(L^4)]^{2+}$, $[Pb(L^4)(NO_3)]^+$, $[Pb(L^4)(NCS)]^+$ and $[Pb(L^4)(SCN)]^+$ systems were characterized by means of density functional theory calculations (DFT) performed by using the B3LYP model, and the coordination geometry as well as the role of the $Pb^{II}$ lone pair has been investigated and discussed.

## Introduction

Lead is regarded as a serious environmental pollutant.[1] Considered as a cheap and convenient material to convey water to the consumers' tap, lead has been widely used for municipal service pipes, household plumbing, joints and solders. Other major uses also include electric storage batteries, paint pigments, gasoline additives or ammunition.[2] The awareness of its environmental and health effects has led the authorities to ban some of these uses in most of the developed countries, which has contributed to a decrease in the lead level in the environment. Even so, this level is still a high risk for health, and lead continues to be one of the ten most common pollutants. In fact, the concentration in drinking water, diets and ambient air is significant in some areas.[2–5]

The removal of toxic heavy metal contaminants from aqueous waste streams is currently one of the most important environmental issues under investigation. Precipitation, activated carbon absorption, bioremediation, reverse osmosis, electrolysis, cementation, irradiation, zeolite absorption, evaporation, membrane processes or ion flotation are some of the treatment methods used for heavy metal-containing waste remediation.[6] Solvent extraction and treatment with cation exchange resins are also important, especially when selective extractions are required and/or low concentrations of the target metal ion are present. Solvent extraction occurs when a metal ion associates with an organic complexant to form a species that is transferred from the aqueous to the organic phase in a two-phase system, whereas cation exchange resins are formed by a polymeric skeleton functionalized with a complexant agent capable of binding to the desired metal ion; therefore, these two methods require the presence of a selective complexant agent. The efficient use of $Pb^{II}$ complexant agents capable of acting as extracting agents requires that the following conditions are met: (i) fast binding of the metal ion by the complexant agent; (ii) selective ion complexation; (iii) sufficiently high binding strength for the metal ion to be extracted; (iv) high stability against hydrolysis, and (v) reversible complexation allowing for the total recovery of the metal without significant extracting agent destruction.[7] The search for novel

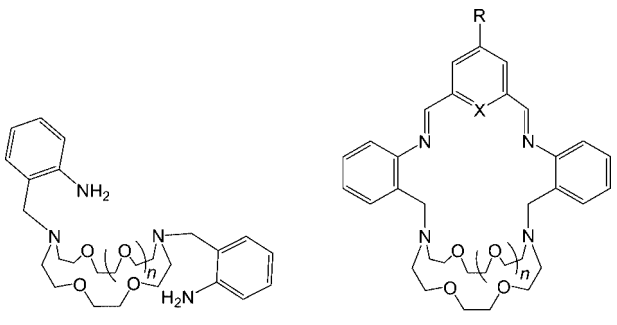
highly selective complexant agents for $Pb^{II}$ requires a great knowledge of the chemical behaviour of this cation, which has caused a resurgence of interest in its chemistry.[8–12] In recent years many reports concerning coordination chemistry of $Pb^{II}$ with a great variety of receptors have been published. The $Pb^{II}$ cation exhibits a rich and interesting coordination chemistry: it binds to a broad range of donor groups, assumes a wide range of coordination numbers and geometries and can exhibit the so-called "inert-pair effect".

Because of the highly favoured complexation, thanks to the chelate and macrocyclic effects, chelate and macrocyclic ligands have been widely used for metal extractions. Particularly, crown ethers have been recognized as a very effective class of compounds to achieve selective separation of heavy metal ions from aqueous solutions. Separation processes based on crown ether complexes of $Pb^{II}$ have been reported and are often quite selective.[13] In particular, we are interested in the design of selective complexant agents for $Pb^{II}$ based on crown frameworks. In a recent work[14] we have found that the macrobicyclic receptor **L⁵** (see Scheme 1), derived from 4,13-diaza-18-crown-6, incorporating a pyridinyl Schiff-base spacer, allows reversible and fast complexation of $Pb^{II}$. This, together with the inertia of the receptor towards hydrolysis, opens very interesting perspectives for the use of this receptor as a new lead(II) extracting agent.[15] As a continuation of this work we discuss the potential of the related receptor **L⁴** as a complexant agent for this metal ion. Likewise, the effect that the presence of different counterions and the protonation of the receptor has on the $Pb^{II}$ coordination environment have also been investigated. Receptors **L⁴** and **L⁵** derive structurally from the bibracchial lariat ethers **L¹** and **L²**, respectively, and belong to the group defined as (Schiff base) lateral macrobicycles.[16] Although both Schiff-base macrocycles and cryptands have been proposed as excellent platforms for the complexation of a wide variety of metal ions,[17,18] no example of a Schiff-base lateral macrobicycle was reported until 1999[19] when we prepared the macrobicycles **L³**–**L⁶** (see Scheme 1). Subsequent studies have demonstrated that these systems possess very promising coordinating properties.[20–22]



$Pb(L^4)(ClO_4)_2 \cdot 0.5\,H_2O$ (**1**) $[H_3L^4](ClO_4)_3 \cdot 3\,CH_3CN$ (**2**)

Scheme 1.

## Results and Discussion

Reaction between the barium complex $[Ba(L^4)](ClO_4)_2$ and $Pb(ClO_4)_2 \cdot 6H_2O$ yields the $Pb^{II}$ compound of formula $Pb(L^4)(ClO_4)_2 \cdot 0.5H_2O$ (**1**). The absence of peaks corresponding to species containing the $[Ba(L^4)]^+$ fragment in the FAB-mass spectrum coupled with the presence of an intense peak from $[Pb(L^4)(ClO_4)]^+$ confirmed that the macrobicycle **L⁴** remains intact and that transmetallation has occurred.

Slow diffusion of diethyl ether into a solution of **1** in acetonitrile gave X-ray quality crystals of this compound. Crystals comprise the cation $[Pb(L^4)(ClO_4)]^+$, a well-separated perchlorate group and an acetonitrile molecule. Figure 1 illustrates the structure of the complex cation, while selected bond lengths and angles of the coordination sphere are compiled in Table 1. The $Pb^{II}$ ion is set into the macrobicyclic cavity, bound to six of the eight heteroatoms of the receptor **L⁴** and two oxygen atoms of a perchlorate group. The interaction between the $Pb^{II}$ ion and this perchlorate group is very weak, as indicated by the $Pb–O_{perchlorate}$ distances, Pb–O(11) 2.838(5) and Pb–O(9) 3.000(7). Very often these weak interactions have been described as "semicoordination",[23] and it is usually attributed to crystal packing forces in the solid state.

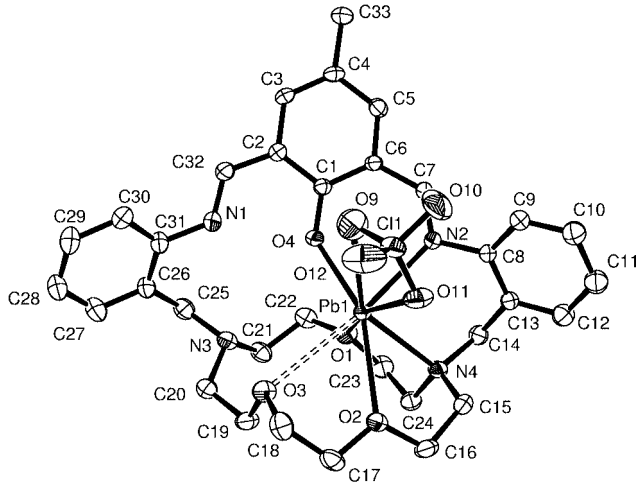


Figure 1. X-ray crystal structure of the cation in compound **1** with atom labelling; hydrogen atoms are omitted for simplicity; the ORTEP plot is drawn at the 30% probability level.

As shown in Figure 1, in $[Pb(L^4)(ClO_4)]^+$ the $Pb^{II}$ ion is asymmetrically placed at one end of the macrobicyclic cavity, coordinated to one imine nitrogen atom, N(2), one pivotal nitrogen atom, N(4), the phenol oxygen atom, O(4), and the three oxygen atoms of the crown moiety, O(1), O(2) and O(3). The $Pb^{II}$ ion is clearly closer to O(1) than to O(2) and O(3), and the considerably long Pb–O(3) and Pb–O(2) distances [3.117(5) and 2.844(4) Å, respectively] suggest that the interaction of $Pb^{II}$ with these oxygen donor atoms is

weak. The other two heteroatoms of the macrobicyclic receptor, the imine and pivotal nitrogen atoms N(1) and N(3), do not belong to the metal ion coordination environment, as evidenced by the observed Pb–N(1) and Pb–N(3) distances of 4.4515(4) and 4.0474(3) Å, respectively. Moreover, the X-ray data suggest that the imine nitrogen atom N(1) and the phenol donor O(4) are involved in an intramolecular hydrogen bonding interaction [N(1)···H(1N), 0.84(7) Å; N(1)···O(4) 2.598(7) Å, O(4)···H(1N) 1.95(8) Å, N(1)–H(1N)–O(4) 133(7)°]. These distances also indicate that proton transfer from the phenol group to the imine atom N(1) has occurred. This proton transfer has also been observed in the related complexes $[Ba(L^4)(ClO_4)(CH_3CN)]^+$[24] and $[Pb(L^6)]^{2+}$,[21] where the guest metal ion is also asymmetrically located in the macrobicyclic cavity. A remarkable characteristic of the complex is the presence of chirality induced by the asymmetric position of the metal ion inside the macrobicyclic cavity. Inspection of the crystal data reveals that in **1** both enantiomers cocrystallize in equal amounts (racemate).

The fold of $\mathbf{L^4}$ around the $Pb^{II}$ ion allows the five donors of the crown moiety, [O(1), O(2), O(3), N(3) and N(4)], to be essentially coplanar (mean deviation from plane 0.0762 Å), with the metal ion located 1.6955 Å above this plane. The coordination polyhedron may be described as a distorted monocapped pentagonal bipyramid (Figure 2). The torsion angles C(1)–C(6)–C(7)–N(2) [–6.8(10)°] and C(1)–C(2)–C(32)–N(1) [–5.1(10)°] indicate that both imine groups are slightly rotated from coplanarity with the phenol ring. This planarity loss is related to the structure of the receptor and the coordinative requirements of the metal ion guest that force the receptor to fold increasing the stress of its structure. The lateral aromatic rings of $\mathbf{L^4}$ in **1** are in different planes and intersect at 47.08°, a value substantially different from that found in the analogous barium complex $[Ba(L^4)(ClO_4)(CH_3CN)]^+$ (57.62°).[24] Likewise, the phenol ring forms a dihedral angle of 43.48° with the plane containing the benzyl ring attached to the pivotal nitrogen atom N(4), and an angle of 48.65° with the plane containing the other aromatic ring. The former is 23.9° larger than that found in $[Ba(L^4)(ClO_4)(CH_3CN)]^+$, whereas the latter is 16.3° smaller.[24] These results highlight the ability of $\mathbf{L^4}$ to adapt its conformation to the steric and electronic requirements of the metal ion.

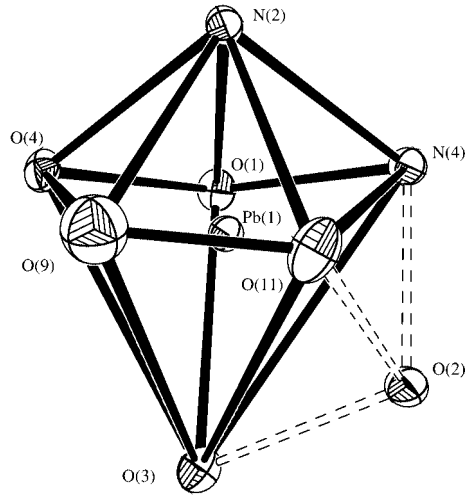

Figure 2. Coordination polyhedron around the metal ion in $[Pb(L^4)(ClO_4)]^+$.

The conductivity measurement for an ca. $10^{-3}$ M solution of **1** in acetonitrile at 20 °C ($\Lambda_M$ = 255 $cm^2\,\Omega^{-1}\,mol^{-1}$) reveals that this compound behaves as a 2:1 electrolyte in this solvent,[25] indicating that the perchlorate anions are not coordinated to the metal ion in the acetonitrile solution. This is expected when taking into account the weak interaction of a perchlorate anion with the metal ion observed in the solid state. The $^1H$ NMR spectrum of **1** recorded in $CD_3CN$ solution at 320 K is consistent with the presence of a single complex species in solution with an effective $C_s$ symmetry (Figure 3). Upon decreasing the temperature the signals corresponding to the imine and aromatic protons gradually broaden and finally split into two different signals, reflecting intramolecular conformational exchange processes (Figure 3). The spectrum recorded at 248 K shows two resonances at $\delta$ = 8.79 and 8.75 ppm attributable to the protons of the imine units, and two signals at $\delta$ = 7.90 and 7.78 ppm with a $^4J$ = 2.4 Hz from the aromatic protons of the phenol group. This is consistent with the presence of a single species in solution with $C_1$ symmetry, in agreement with the X-ray crystal structure described above. Indeed, in the solid state the $Pb^{II}$ ion is placed at one end of the macrobicyclic cavity, which results in a complex with $C_1$ symmetry. Thus, the dynamic bevaviour of compound **1** in acetonitrile solution can be attributed to a translocation of the $Pb^{II}$ ion from one end of the macrobicyclic cavity to the other. This dynamic process is fast on the NMR timescale at high temperature, thus resulting in a spectrum corresponding to a species with an effective $C_s$ symmetry in solution. From the coalescence temperature of signals corresponding to the aromatic protons of the phenol unit, which occurs at 309 K, we can estimate an activation barrier of $\Delta G^{\ddagger} = 68 \pm 2$ kJ $mol^{-1}$ for this intramolecular dy-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

namic process. As discussed above, the presence of the $Pb^{II}$ ion at one end of the macrocyclic cavity in **1** induces chirality in the complex. Thus, the dynamic process observed for this compound in solution corresponds to the interconversion between the two possible enantiomeric forms of the complex.

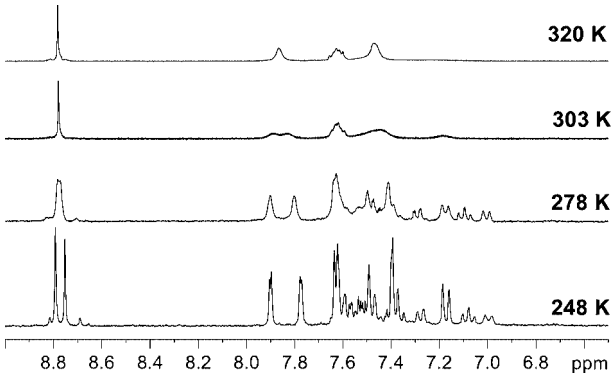

Figure 3. Part of the 300-MHz $^1$H-NMR spectra of compound **1** recorded in $CD_3CN$ at different temperatures.

The $[Pb(L^4)]^{2+}$ system was characterized by means of DFT calculations at the B3LYP level. On the basis of our previous experience for these calculations we used the standard 6-31G(d) basis set for the ligand atoms, while the LanL2DZ valence and effective core-potential functions were used for Pb.[26] The calculated structure for this complex (Figure 4) resembles the X-ray crystal structure of **1**, with the calculated bond lengths of the metal coordination environment in reasonable agreement with those obtained experimentally (Table 2). The experimental and calculated bond lengths differ by less than 0.08 Å, except the Pb–O(3) distance, which differs by ca. 0.18 Å from the experimental value. However, this is not surprising since the experimental value of the Pb–O(3) distance [3.117(5) Å] indicates a weak interaction between the metal ion and O(3). Shimoni-Livny et al.[27] have investigated a close relation between the role of a lone pair of $Pb^{II}$ and the coordination geometry for a large number of $Pb^{II}$ complexes. They have found two general structural categories of $Pb^{II}$ compounds: holodirected and hemidirected, which are distinguished by the disposition of ligands around the metal ion. In the hemidirected form there is a void in the liganding attributable to the stereochemical activity of the $Pb^{II}$ lone pair that is not found in holodirected geometry. The calculated Pb–O(1) bond length [2.479 Å] is clearly shorter than distances between the metal ion and the remaining oxygen atoms of the crown moiety. This, together with the presence of an identifiable void in the disposition of the donor atoms of the ligand around the metal ion, suggests that the $Pb^{II}$ lone pair is stereochemically active in $[Pb(L^4)]^{2+}$. The analysis of the natural bond orbitals (NBO) in $[Pb(L^4)]^{2+}$ shows that the $Pb^{II}$ lone pair orbital is predominantly 6s, but polarized by some 6p contribution: s[98.02%]p[1.98%]. Similar p contributions (>1%) have been calculated for hemidirected $Pb^{II}$ complexes with related ligands, which clearly confirm that the $Pb^{II}$ lone pair is stereochemically active in $[Pb(L^4)]^{2+}$.[26] However, we notice that in the X-ray crystal structure the Pb–O(1) bond length is slightly longer than the calculated one, which suggests that the presence of a weakly coordinating perchlorate anion around the $Pb^{II}$ ion decreases the stereochemical activity of the $Pb^{II}$ lone pair.

## Interaction with Anions

Since in solution the $Pb^{II}$ ion is coordinatively unsaturated in **1**, we have studied the interaction of this compound with anions such as $NO_3^-$ and $SCN^-$ by using spectrophotometric titrations in acetonitrile solution. The UV/Vis spectrum of **1** (Figure 5) displays a band centred at 456 nm typical of the C=N chromophores.[28,29] Upon addition of $NO_3^-$ or $SCN^-$ anions this band undergoes a blue shift to ca. 423 nm as its intensity decreases. Nonlinear least-squares analyses of the titration profiles (absorbance versus equivalents of anion added, see insets of Figure 5) clearly indicated the formation of 1:1 complexes in every case, and allowed us to estimate the association constants defined as [Equation (1)].

$$[Pb(L^4)]^{2+} + X^- \rightleftarrows [Pb(L^4)(X)]^+, \text{ where } X^- = NO_3^- \text{ or } SCN^- \quad (1)$$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

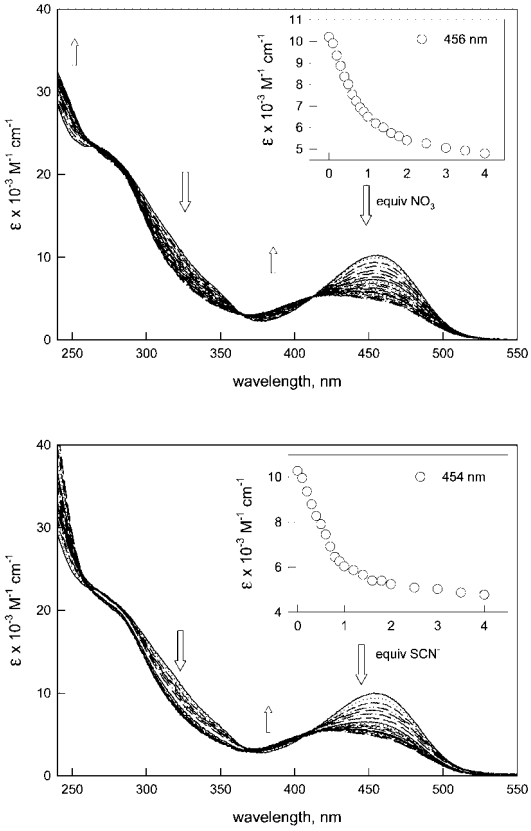

Figure 5. UV/Vis spectra taken over the course of the titration of a $10^{-5}$ M solution of compound **1** with a standard solution of tetrabutylammonium nitrate (top) or thiocyanate (bottom). The insets show titration profiles at selected wavelengths.

The analysis of the experimental data provides log *K* values of 5.83(1) ($X^- = NO_3^-$) and 6.27(2) ($X^- = SCN^-$). These results clearly confirm that the metal ion is coordinatively unsaturated in the $Pb^{II}$ complex of $\mathbf{L^4}$, and indicate that the $SCN^-$ ligand binds more strongly to $[Pb(L^4)]^{2+}$ than $NO_3^-$.

DFT calculations performed on the $[Pb(L^4)(NO_3)]^+$ system (see Supporting Information) indicate that the coordination of the nitrate anion has an important effect on the bond lengths of the metal coordination environment, which increase by ca. 0.06–0.36 Å with respect to those calculated for $[Pb(L^4)]^{2+}$ (Table 2). The $NO_3^-$ ligand coordinates in a nearly symmetrical bidentate fashion [Pb–O 2.429 and 2.479 Å]. In order to understand if the coordination of the thiocyanate ligand occurs through the nitrogen atom or through the sulfur one we have also carried out DFT calculations on the $[Pb(L^4)(NCS)]^+$ and $[Pb(L^4)(SCN)]^+$ systems. $Pb^{II}$ is classified as "intermediate" in the Pearson HSAB classification,[30] and thus it is not particularly surprising that both *N*-bonded and *S*-bonded $Pb^{II}$ complexes of thiocyanate exist.[31] The optimized geometries for both compounds are given in the Supporting Information. Our calculations predict that the *N*-bonded thiocyanate ligand results in a more stable structure, where the in vacuo relative energy of the $[Pb(L^4)(SCN)]^+$ system with respect to the $[Pb(L^4)(NCS)]^+$ is 5.47 kcal mol$^{-1}$. This is in agreement with the X-ray structure of the $Pb^{II}$ thiocyanate complex with the related macrobicycle $\mathbf{L^3}$, which shows that the thiocyanate ligand is *N*-bonded.[22] This is probably because the steric hindrance around the metal ion, caused by the coordination of the macrobicyclic receptor, favours the coordination of the $SCN^-$ ligands through the N donor atom.[32] On the other hand, the analysis of the NBOs in $[Pb(L^4)(NO_3)]^+$ indicates that the 6p contribution decreases upon coordination of the nitrate anion: s[98.57%]p[1.43%]. As a consequence the coordination geometry in $[Pb(L^4)(NO_3)]^+$ is less hemidirected than in $[Pb(L^4)]^{2+}$, and the Pb–O(1) bond length increases (Table 3). Replacing the nitrate anion by a *N*-bonded thiocyanate ligand results in a somewhat lower polarization of the Pb 6s lone pair, as follows from the NBOs analysis: s[98.72%]p[1.28%]. Furthermore, the presence of a *S*-bonded thiocyanate ligand causes a further decrease of the polarization of the Pb 6s lone pair: s[99.28%]p[0.72%]. Thus, the polarization of the Pb lone pair decreases when hard donor atoms such as O atoms of the nitrate group are replaced by softer donor atoms such as the N or S donor atoms of a thiocyanate ligand. These results are in agreement with previous observations that indicated that the coordination of soft-donor atoms favours holodirected ligand geometries in $Pb^{II}$ complexes.[26,27]

## Protonation Studies

The protonation of $Pb(L^4)(ClO_4)_2 \cdot 0.5H_2O$ (**1**) has been followed by NMR and UV/Vis spectroscopy in $CH_3CN$ solutions at room temperature. Upon addition of trifluoroacetic acid to a solution of **1** in $CD_3CN$ a new set of signals is observed in the $^1$H NMR spectra whose chemical shifts do not vary with the amount of trifluoroacetic acid added,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thereby confirming the formation of a single protonated species in acetonitrile solution. Upon addition of two equivalents of acid the signals of compound **1** nearly disappear, in agreement with the formation of the diprotonated species $[H_2L^4]^{2+}$ (see Figure 6). The two protonations probably occur on the pivotal nitrogen atoms, as previously observed for $[H_2L^5]^{2+}$.[33] The $^1H$ and $^{13}C$ NMR spectra of $[H_2L^4]^{2+}$ could be fully assigned on the basis of two-dimensional COSY, HSQC and HMBC experiments at 298 K (Table 3, see Figure 6 for labelling). The $^{13}C$ NMR spectrum shows 18 signals for the 33 carbon nuclei of the ligand, indicating an effective $C_s$ symmetry of $[H_2L^4]^{2+}$ in acetonitrile solution. The methylene protons H13/H13′ yield an AB spin pattern ($^2J_{13,13'}$ = 13.8 Hz) in the $^1H$ NMR spectrum, while the protons of the crown moiety give AA′BB′ spin patterns (Figure 6). This is indicative of a relatively rigid structure of $[H_2L^4]^{2+}$ in solution, probably because of the presence of intramolecular hydrogen bonding interactions between the protonated pivotal nitrogen atoms and oxygen atoms of the crown moiety.

Figure 7 shows a family of UV/Vis spectra recorded during the course of a titration of a $10^{-4}$ M solution of **1** with trifluoroacetic acid in $CH_3CN$ solution. Upon addition of trifluoroacetic acid the band at 456 nm experiences a blue shift to 364 nm. The presence of two sharp isosbestic points at 394 and 335 nm indicates that only two species co-exist at the equilibrium, while the profile shown in the inset of Figure 7 indicates the formation of a diprotonated species in solution upon addition of trifluoroacetic acid. Data can be interpreted on the basis of equilibrium (2).

$$[Pb(L^4)]^{2+} + 2\ H^{+} \rightleftarrows [(H_2L^4)]^{2+} + Pb^{2+},\ \beta_{12} \qquad (2)$$

A nonlinear least-squares treatment of the titration profile provides $\log\beta_{12}$ = 9.14(1). These results confirm that addition of acid to a solution of **1** causes the demetallation of the complex together with the formation of the diprotonated form of the ligand, as previously observed for $[Pb(L^5)]^{2+}$.[14] However, in the latter case the demetallation process has been shown to occur in two steps, with the formation of an intermediate monoprotonated complex species $[Pb(HL^5)]^{3+}$. By contrast, the demetallation of $[Pb(L^4)]^{2+}$ appears to occur in a single step, as described by Equation (2).

Addition of a large excess of $CF_3COOH$ to a solution of $[H_2L^4]^{2+}$ provokes further changes in the UV/Vis spectrum (Figure 7); the band from the imine group at 364 nm shows a red shift towards 495 nm. This result suggests that a third protonation process occurs in the presence of a large excess of acid. Slow evaporation of a solution of **1** in the presence of 10 equiv. of $CF_3COOH$ allowed us to obtain single crystals of $[H_3L^4](ClO_4)_3{\cdot}3CH_3CN$ (**2**) suitable for single-crystal X-ray diffraction studies, which confirms the formation of the triprotonated form of the macrobicycle under these conditions. Crystals of **2** contain the cation $[H_3L^4]^{3+}$, three perchlorate anions and acetonitrile molecules. Figure 8 shows the structure of the cation in **2**. Bond lengths and angles do not show significant deviations from the expected values. The conformation of the macrobicycle in **2** is conditioned by the presence of intramolecular hydrogen bonding interactions (Table 4) involving each pivotal nitrogen atom with two oxygen atoms of the crown moiety and both imine nitrogen atoms with the oxygen atom of the phenol group. This type of interaction seems to be responsible for the relatively rigid structure found in solution for the related diprotonated receptor $[H_2L^4]^{2+}$ described above.

## Conclusions

The Schiff-base lateral macrobicycle **L$^4$**, derived from 1,10-diaza-15-crown-5 incorporating a phenol Schiff-base spacer, forms stable complexes with $Pb^{II}$. The X-ray crystal structure of $[Pb(L^4)(ClO_4)](ClO_4)\cdot CH_3CN$ (**1**) shows that the lead(II) ion is asymmetrically placed at the one end of the macrobicyclic cavity, because of the intramolecular hydrogen bonding interaction that occurs between an imine nitrogen atom and the phenol group. This asymmetric position of the metal ion inside the macrobicyclic cavity induces chirality in this system. The asymmetric coordination of the metal ion inside the macrocyclic cavity found in the solid state is also maintained in acetonitrile solution, but a translocation of the $Pb^{II}$ ion from one end of the macrobicyclic cavity to the other occurs. This dynamic behaviour, which actually corresponds to the interconversion between the two possible enantiomeric forms of the complex, is fast on the NMR timescale at 320 K but slow at low temperatures, and we have estimated an activation barrier of $\Delta G^{\ddagger} = 68 \pm 2$ kJ mol$^{-1}$.

Both the solid state and solution structure of $[Pb(L^4)]^{2+}$ indicate that the complex is coordinatively unsaturated so that interactions with anions such as $NO_3^-$ and $SCN^-$ are possible. Spectrophotometric titrations in acetonitrile solution indicate that the $SCN^-$ ligand binds more strongly to $[Pb(L^4)]^{2+}$ than $NO_3^-$, which follows from the values of the binding constants obtained: [$\log K = 5.83(1)$ and 6.27(2) for $NO_3^-$ and $SCN^-$, respectively]. The coordination geometry as well as the role of a lone pair of $Pb^{II}$ of the systems $[Pb(L^4)]^{2+}$, $[Pb(L^4)(NO_3)]^+$, $[Pb(L^4)(NCS)]^+$ and $[Pb(L^4)(SCN)]^+$ have been investigated by means of DFT calculations. The analysis of the natural bond orbitals (NBO) in $[Pb(L^4)]^{2+}$ shows that the $Pb^{II}$ lone pair is stereochemically active in $[Pb(L^4)]^{2+}$. The 6p contribution decreases upon coordination of the nitrate anion, and so the coordination geometry in $[Pb(L^4)(NO_3)]^+$ is less hemidirected than in $[Pb(L^4)]^{2+}$. Replacing the nitrate anion by a *N*-bonded thiocyanate ligand results in a lower polarization of the Pb 6s lone pair, which further decreases when the $SCN^-$ ligand is *S*-bonded. Finally, we have found that protonation of **1** with trifluoroacetic acid in acetonitrile solution causes demetallation of the complex without receptor destruction, with receptor **L$^4$** recovered in its protonated form. This opens interesting perspectives for the use of this receptor as a potential lead(II) extracting agent.

## Experimental Section

**Materials and Synthesis:** $[Ba(L^4)](ClO_4)_2$ was prepared as described previously by us.[19] All other chemicals were purchased from commercial sources and used without further purification. Solvents were of reagent grade purified by the usual methods. Caution! Although we have experienced no difficulties with the perchlorate salts, these should be regarded as potentially explosive and handled with care.[34]

**$Pb(L^4)(ClO_4)_2·0.5H_2O$ (1):** A solution of $Pb(ClO_4)_2·6H_2O$ (0.0131 g, 0.025 mmol) in absolute ethanol (5 mL) was added while stirring to a solution of $[Ba(L^4)](ClO_4)_2$ (0.0224 g, 0.025 mmol) in the same solvent (20 mL). The reaction mixture was stirred and refluxed for 48 h. After the reaction was complete the resultant yellow solution was allowed to stand for a few days and an orange precipitate was formed, which was collected by filtration and air dried (0.016 g, 66%). $C_{33}H_{40}Cl_2N_4O_{12}Pb·0.5H_2O$ (971.2): calcd. C 40.7, H 4.2, N 5.7; found C 40.3, H 4.2, N 5.5. MS (FAB): $m/z$ = 863 $[Pb(L^4)(ClO_4)]^+$. IR (KBr): $\tilde{\nu}$ = $(C{=}N)_{imine}$ 1633, $\nu(OH)_{phenol}$ 3470, $\nu_{as}$(Cl–O) 1092, $\delta_{as}$(O–Cl–O) 623 $cm^{-1}$. X-ray quality crystals of formula $[Pb(L^4)(ClO_4)](ClO_4)·CH_3CN$ were grown by slow diffusion of diethyl ether into a solution of **1** in acetonitrile.

**Physical Methods:** Elemental analyses were carried out with a Carlo–Erba 1108 elemental analyzer. FAB mass spectra were recorded using a FISONS QUATRO mass spectrometer with a Cs ion-gun and 3-nitrobenzyl alcohol as the matrix. IR spectra were recorded, as KBr discs or nujol mulls, using a Bruker Vector 22 spectrophotometer. Conductivity measurements were carried out with a Crison Micro CM 2201 conductivimeter using ca. $10^{-3}$ M solutions of the complex in acetonitrile. $^1H$ and $^{13}C$ NMR spectra were run at 25 °C with Bruker Avance 300-MHz or Bruker WM-500 spectrometers. Chemical shifts are reported in $\delta$ values. Spectral assignments were based in part on two-dimensional COSY, HMQC and HMBC experiments. Electronic spectra in the UV/Vis range were recorded at 20 °C with a Perkin–Elmer Lambda 900 UV/Vis spectrophotometer using 1.0 cm quartz cells. Spectrophotometric titrations were performed at 25 °C on $10^{-5}$ or $10^{-4}$ M solutions of compound **1** in acetonitrile (polarographic grade). Typically, aliquots of a fresh standard solution of the titrant salt ($10^{-3}$ or $10^{-2}$ M) were added and the UV/Vis spectra of the samples were recorded. All spectrophotometric titration curves were fitted with the HYPERQUAD program.[35]

**X-ray Crystallography:** Crystal data and details on data collection and refinement are summarized in Table 5. Three dimensional X-ray data for $[Pb(L^4)(ClO_4)](ClO_4)·CH_3CN$ (**1**) and $[H_3L^4](ClO_4)_3·3CH_3CN$ (**2**) were collected with a Bruker Smart 1000 CCD diffractometer. Data were corrected for Lorentz and polarization effects and for absorption by semi-empirical methods. Complex scattering factors were taken from the program package SHELXTL[36] for **1**, and SHELX97[37] for **2**. Both structures were solved by direct methods and refined by full-matrix least-squares on $F^2$. Refinement converged with anisotropic displacement parameters for all non-hydrogen atoms. The hydrogen atoms were included in calculated positions and refined by using a riding model, except for the hydrogen atom H(1N) in **1**, and H(1N), H(2N), H(3N) and H(4N) in **2**, which were first located in a difference electron-density map and then left to freely refine. The crystal of **1** presents a disorder on the ionic perchlorate and 162 restraints had to be imposed. This disorder has been solved and two atomic sites for each oxygen atom have been observed. The site occupancy factor was 0.491 for the four oxygen atoms, O(5A), O(6A), O(7A) and O(8A). The crystal of **2** also presents disorder on one of the acetonitrile solvent molecules [site occupancy factor: 0.526 for N(7A), C(38A) and C(31A)]. CCDC-624582 and -624583 contain the supplementary crystallographic data for the structures included in this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via http://www.ccdc.cam.ac.uk/datarequest/cif.

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = \{\Sigma[w(|F_o|^2 - |F_c|^2)^2]/\Sigma[w(F_o^4)]\}^{1/2}$.

**Computational Methods:** The $[Pb(L^4)]^{2+}$, $[Pb(L^4)(NO_3)]^+$, $[Pb(L^4)(NCS)]^+$ and $[Pb(L^4)(SCN)]^+$ systems were fully optimized by using the B3LYP density functional model.[38,39] In these calculations we have used the standard 6-31G(d) basis set for the ligand atoms, while the LanL2DZ valence and effective core potential functions were used for Pb.[40] The stationary points found on the potential energy surfaces as a result of the geometry optimizations have been tested to represent energy minima rather than saddle points via frequency analysis. The relative free energy of the $[Pb(L^4)(NCS)]^+$ and $[Pb(L^4)(SCN)]^+$ complexes was calculated in vacuo at the same computational level, and it includes nonpotential energy (NPE) contributions (that is, zero point energy and thermal terms) obtained by frequency analysis. The wave functions of some of the lead complexes were analyzed by natural bond orbital analyses, involving natural atomic orbital (NAO) populations and natural bond orbitals (NBO).[41,42] All DFT calculations were performed by using the Gaussian 03 program package (Revision C.01).[43]

**Supporting Information** (see also the footnote on the first page of this article): Figure S1 showing B3LYP-optimized structures of the $[Pb(L^4)(NO_3)]^+$, $[Pb(L^4)(NCS)]^+$ and $[Pb(L^4)(SCN)]^+$ systems, and in-vacuo-optimized Cartesian coordinates [Å] for the $[Pb(L^4)]^{2+}$, $[Pb(L^4)(NO_3)]^+$, $[Pb(L^4)(NCS)]^+$ and $[Pb(L^4)(SCN)]^+$ systems.

# [$Cu^{II}_4$] Clusters From the Self-Assembly of Two Imidazolidinyl 2-Phenolate-Bridged [$Cu^{II}_2$] Units: The Role of the Chloride Bridge

**Alok Ranjan Paital,[a] Chang Seop Hong,[b] Hyoung Chan Kim,[c] and Debashis Ray*[a]**

**Keywords:** Template synthesis / Self-assembly / Cluster compounds / Copper / Magnetic properties

A new family of tetracopper clusters [$Cu_4(\mu_4$-X)$L_2$]$ClO_4$·$nH_2O$ (**1a**–**c**) [X = Cl, Br, I; $n$ = 12, 2, 2; $H_3L$ = 2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine] have been synthesised and characterised. The X-ray crystal structure of **1a** reveals that the template action of the spherical $Cl^-$ anion ($\mu_4$-$Cl^-$), which features a unique rectangular planar bridging mode, is responsible for the self-assembly of two $[Cu_2L]^+$ units in complex **1a**. In this family of complexes the spherical halides serve as templates to assemble the dimeric unit into tetrameric complexes, which gives an insight into the role of the halide bridge in tetranuclear complex formation. The capacity of this bridge to mediate magnetic coupling has been examined by bulk magnetic measurements for complex **1a**.

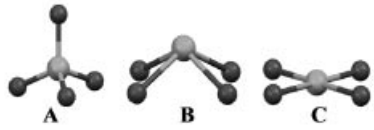
## Introduction

Cluster-like metal-organic assemblies can be obtained from cation-[1] and anion-templated[2] syntheses, and several recent reports have demonstrated that anions can be successfully employed as a template for the formation of a wide range of organic[3] and metal-organic[4] assemblies. The anionic species in these syntheses plays a templating role by using its directing properties and determines the geometry and connectivity of the final structure. The spherically symmetrical $Cl^-$ ion has recently been shown to direct the self-assembly of four trimethylphosphane-stabilised diphenylstibenium ions.[5] Anion-templated synthesis is expected to yield novel structures with properties of chemical significance. Single-atom-nucleated paramagnetic $M_4$ assemblies can generate interesting structures depending upon the number and nature of the coordination bonds they form in space.[6] The size, charge and nature of the nucleating atom also control the geometry and stability of the cluster. The $\mu_4$-$Cl^-$ coordination mode is rare for $Cu_4$ clusters of polydentate ligands and can have either tetrahedral (A)[7] or square-pyramidal (B)[2b,2c,8] geometries (Scheme 1). In these two coordination modes, the {$Cu^{II}_4(\mu_4$-Cl)} core is further supported by either phosphate or halide auxiliary bridges. The presence of auxiliary bridging ligands helps the nucleation around the chloride anion in a particular mode of binding.



Scheme 1. Left: tetrahedral $\mu_4$-Cl (ref.[7]); middle: pyramidal $\mu_4$-Cl (ref.[2b]); right: part of complex **1a**; grey: Cl; black: Cu. Structures generated with the Mercury X-ray crystallography software package (version 1.4).

On the other hand the rectangular planar structure (C), which has $C_{2h}$ symmetry and long M–Cl bonds, is not known in the literature for complexes of polydentate ligands. Recently, we have shown that the spherical $O^{2-}$ anion can function as a nucleating group that allows isolation of the tetrahedral {$Cu^{II}_4(\mu_4$-O)} core of two different non-bridging hexadentate ligands.[9] No analogous $\mu_4$-Cl-templated tetranuclear complex of a 3d element is known with similar Schiff-base ligand systems. Currently, efforts are be-

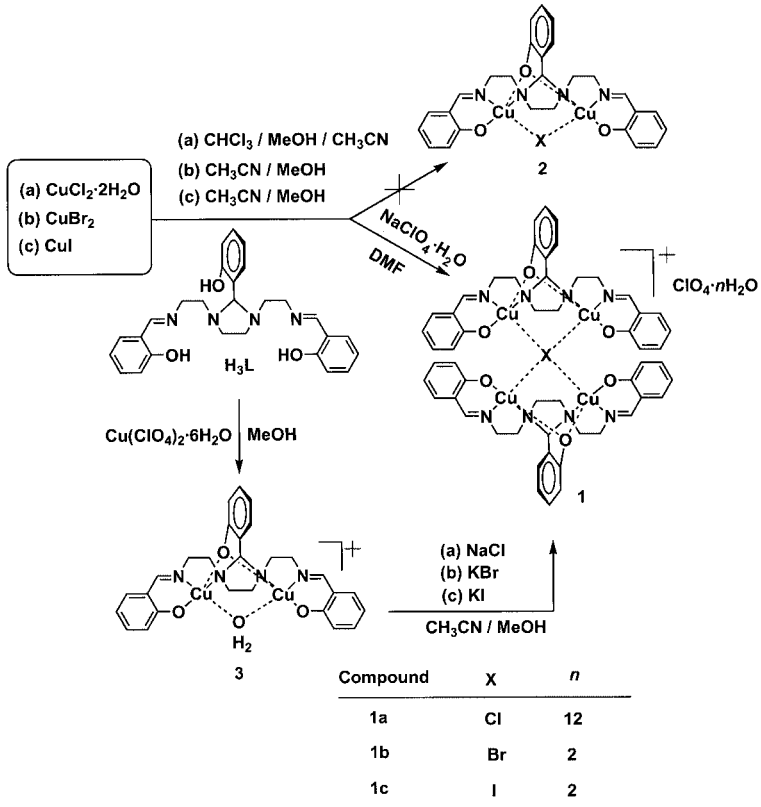

Scheme 2.

ing made to rationalize the role of the $Cu_4$ cluster based catalytic site, which has never before been found in biology, for the reduction of $N_2O$ to $N_2$.[10] The ligand $H_3L$ [2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine] has recently been shown to undergo the cation (sodium)-centred assembly of two $[Cu_2L]^+$ units upon octahedral coordination of $Na^+$ to the terminal phenolate oxygen atoms of two ligands[11] (Figure 1, left).

Here, we report the preferential formation of a rectangular {$Cu^{II}_4(\mu_4\text{-Cl})$} core in **1a**, where two $Cu_2$ units assemble around the meridian of the spherical chloride anion (Figure 1, right). The centrosymmetric geometry reduces the ligand's steric crowding. The anion (chloride)-centred assembly of two $[Cu_2L]^+$ units is responsible for its entrapment in the final complex and coordination in a $\mu_4$ mode (**1**) instead of bridging (**2**) or terminal monodentate (**6** in Scheme 3) coordination in dinuclear complex formation (Scheme 2).

## Results and Discussion

### Syntheses and Spectroscopic Characterisation

The μ-bis(tetradentate) ligand $H_3L$ [2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine] was prepared according to a literature procedure,[12] and a general procedure was followed for the synthesis of complexes **1a**–**c**. The reaction of $H_3L$ in a $CH_2Cl_2$/MeOH (1:1) solvent mixture with an $CH_3CN$/MeOH (1:1) solution of $CuCl_2·2H_2O$ in air followed by addition of $N(C_2H_5)_3$ (1:2:3 molar ratio) at room temperature afforded a green precipitate of $[Cu_4(\mu_4\text{-Cl})L_2]Cl·2H_2O$. Addition of a saturated solution of $NaClO_4·H_2O$ in MeOH to the above precipitate in dmf produced a green solution, which yielded green crystalline **1a** upon slow evaporation in air for six days. The elemental analysis and solution electrical conductivity data in dmf are consistent with the formula $[Cu_4(\mu_4\text{-Cl})L_2]ClO_4·12H_2O$ (**1a**); the yield was found to be 80%. Complexes $[Cu_4(\mu_4\text{-Br})L_2]ClO_4·2H_2O$ (**1b**) and $[Cu_4(\mu_4\text{-I})L_2]ClO_4·2H_2O$ (**1c**) were synthesised in a similar manner but with $CuBr_2$ and CuI, respectively, in $CH_3CN$/MeOH (1:1). During the synthesis of **1c** the light-yellow colour of the reaction mixture changed to green after 10 min.

All the compounds are insoluble in water and separate immediately from the reaction mixture. Elemental analysis, metal estimation, solution electrical conductivity and FT-IR and UV/Vis studies confirmed the formation of **1a**–**c**. Based on tetranuclear formulations, the molar conductivity values ($\Lambda_M$) in dmf are 90, 95 and 92 $\Omega^{-1}cm^2mol^{-1}$ (28 °C) for **1a**, **1b** and **1c**, respectively. These values correspond to the 1:1 electrolyte behaviours of **1a**–**c** in dmf and indicate the stability of the $Cu_4$ clusters in solution.[13] In the strong donor solvent dmf solvolysis of the clusters to $[Cu_2(dmf)_2L]X$ (X = Cl, Br and I) is not observed. The sharp peaks in the IR spectra of complexes **1a**–**c** at 1633, 1636 and 1632 $cm^{-1}$, respectively, are characteristic of the C=N functionality of the ligand and the broad/medium bands at

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

3388, 3427 and 3392 $cm^{-1}$, respectively, are observed for $\nu(OH)_{H_2O}$ of the lattice water molecules. Compounds **1a–c** show broad electronic absorption bands at 660 ($\varepsilon$ = 440), 620 ($\varepsilon$ = 510) and 635 nm ($\varepsilon$ = 745 $M^{-1}cm^{-1}$), respectively, for the d–d transitions. In dmf solution the $L \rightarrow Cu^{II}$ charge-transfer (CT) transitions are observed around 377 ($\varepsilon$ = 7810, 15425 and 16305 $M^{-1}cm^{-1}$). The intra-ligand CT transitions are seen around 280 nm ($\varepsilon$ = 20150, 21800 and 22425 $M^{-1}cm^{-1}$). Similarly, peaks at 1627 and 3388 $cm^{-1}$ in the IR spectrum of complex **3** are characteristic of the C=N functionality of the ligand and the $\nu(OH)_{H_2O}$ stretch of the water molecules. Compound **3** shows a broad electronic absorption band at 640 nm ($\varepsilon$ = 440 $M^{-1}cm^{-1}$) for the d–d transition and bands at 402 ($\varepsilon$ = 2770 $M^{-1}cm^{-1}$) and 273 nm ($\varepsilon$ = 22041 $M^{-1}cm^{-1}$) are observed for the charge-transfer transitions.

The nature of the final reaction product is greatly influenced by the ligand, solvent system and sequence of addition of the reactants. For example, under similar reaction conditions $H_3L$ and a substituted analogue of $H_3L$ ($H_3$mhbai in ref.[14])[15] react differently with $NaN_3$ to give the cation- and anion-centred tetranuclear copper complexes $[NaCu_4L_2(N_3)_2]ClO_4 \cdot H_2O$[11] and $[Cu_4L_2(N_3)]Cl \cdot 16H_2O$,[15] respectively. Following several synthetic trials with $NaN_3$, we failed to obtain same products ($\mu_2$-$N_3^-$ or $\mu_4$-$N_3^-$) for either of these two ligands in varying solvent systems and reaction conditions. Thus, the ligands play the deciding role for final product formation and act independently of the nature of the solvent and sequence of addition of reagents. It is an inherent property of the ligand systems that they show different self-assembly behaviours for cluster formation. Likewise, for ligand $H_3L$ reported in this paper, the dinuclear complex **2** was not obtained (Scheme 3) when a methanolic solution of the ligand was added to $CuCl_2 \cdot 2H_2O$ in MeOH/$H_2O$ (2:1) in a 1:2 molar ratio.

Complexes **1a–c** can also be obtained by an indirect route via the exogenous aqua-bridged dinuclear complex $[Cu_2L(H_2O)]ClO_4 \cdot 2H_2O$ (**3**). Complex **3** is obtained from the reaction of $Cu(ClO_4)_2 \cdot 6H_2O$ with $H_3L$ in the presence of $Et_3N$ in MeOH in a 2:1:3 molar ratio (Scheme 3). Complex **3** reacts further with NaCl, KBr or KI in a 2:1 molar ratio to give complexes **1a–c** (Scheme 2). In a two-step reaction, complex **3** initially reacts with $N_3^-$ to form the dicopper species **4** in solution. The basal-apical mode of azide coordination and face-to-face orientation of two such species provides a cavity to accommodate a $Na^+$ ion and give tetrameric complex **5**.[11] In this work, we have shown that the larger halide anions prefer metal coordination in an apical-apical mode to produce **1a–c**. The $\mu_4$-X centred $Cu_4$ complexes **1a–c**, which have four Cu–X apical bonds, also react with $NaN_3$ in MeOH/$CH_3CN$ (1:1) to produce **5**, which contains two apical and two basal Cu–N(azide) bonds. These reactions also demonstrate the successful replacement of halide groups with weaker apical-apical coordination by strong azide coordination in a basal-apical mode. So far, we have been unable to synthesise complexes **6** and **7** by varying the solvents and reaction conditions (Scheme 3).

### X-ray Structure of $[Cu_4(\mu_4\text{-}Cl)L_2]ClO_4\cdot 12H_2O$ (1a)

Single crystals of **1a** suitable for X-ray diffraction were obtained by slow evaporation of a dmf solution of the compound. It consists of a tetracopper cluster cation $[Cu_4(\mu_4\text{-}Cl)L_2]^+$ along with a disordered $ClO_4^-$ anion and twelve water molecules. An ORTEP view of $[Cu_4(\mu_4\text{-}Cl)L_2]^+$ is shown in Figure 2, and selected bond lengths and bond angles are listed in Table 1.

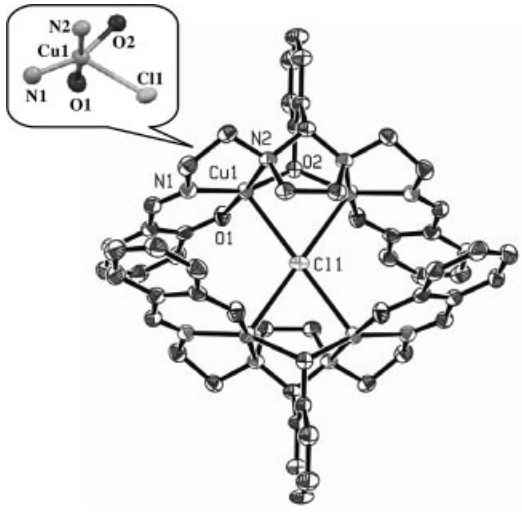

Figure 2. ORTEP representation of $[Cu_4(\mu_4\text{-}Cl)L_2]^+$ (**1a**) with ellipsoids at the 40% probability level. Hydrogen atoms have been omitted for clarity. Only independent non-carbon atoms are labelled.

Table 1. Selected bond lengths [Å] and bond angles [°] in complex **1a**.

| Bond lengths [Å] | |
|---|---|
| Cu1–O1 | 1.906(3) |
| Cu1–N1 | 1.935(3) |
| Cu1–N2 | 2.070(3) |
| Cu1–O2 | 1.971(2) |
| Cu1–Cl1 | 2.776(5) |
| **Bond angles [°]** | |
| O1–Cu1–N1 | 93.50(14) |
| N1–Cu1–N2 | 83.94(14) |
| N2–Cu1–O2 | 91.16(13) |
| O1–Cu1–O2 | 89.92(13) |
| N1–Cu1–O2 | 157.70(14) |
| O1–Cu1–N2 | 175.66(12) |
| Cu1–O2–Cu1 | 110.63(17) |
| Cu1–Cl1–Cu1 | 71.44(13) |

A rectangular arrangement of four crystallographically equivalent $Cu^{II}$ ions as two pairs of metal ions is seen in $[Cu_4(\mu_4\text{-}Cl)L_2]^+$. The cationic tetramer has crystallographic 2/*m* symmetry, with the central Cl atom at the 2/*m* centre. The metal ions within each $[Cu_2]$ pair are bridged and chelated by one $\mu\text{-}L^{3-}$ ligand. These dinuclear units are in turn linked exclusively by one unsupported $Cl^-$ ligand in a $\mu_4$-bridging mode. The polydentate ligand $L^{3-}$ within each dinuclear unit bridges the metal ions through one imidazolidine and one phenoxide moiety while further coordinating the copper ions through two terminal phenoxide and imine groups. The four copper atoms are placed at the vertices of a regular rectangle, with the chloride ligand lying at the centre of the rectangle. Each $[Cu_2]$ pair, spanning the short axis of the $[Cu_4Cl]$ rectangle is also bridged by one end of the $\mu_4\text{-}Cl^-$ ligand. The $Cl^-$ ligand fills the fifth apical coordination site of each copper. Within the $[Cu_2L]^+$ units, the bridging $Cl^-$ ions show an apical-apical coordination mode, which is different from the apical-basal binding mode of the azide ions in $[NaCu_4L_2(N_3)_2]ClO_4$.[11] At the same time, this mode of bridging also forces the imidazolidinyl phenolate oxygens to exhibit a complementary basal-apical coordination. This apical-basal and basal-apical combination is responsible for the formation of an interdimer cavity that nicely accommodates $Na^+$ ion in **5**. Contrary to this, the apical-apical halide bridging within $[Cu_2L]^+$ in **1a**–**c** retains the basal-basal coordination mode of the imidazolidinyl phenolate oxygens (Scheme 4). The four $Cu^{II}$ ions in **1a** are pentacoordinate and feature a distorted square-pyramidal $N_2O_2Cl$ environment ($\tau$ = 0.30).[16] The polyhedra around copper share the chlorine atom Cl(1) as a common apical vertex and the ligand phenolate oxygen atoms O(2) and O(2)$^{\#}$ as the shared basal donors. The sum of the angles around the oxygen atom of the central phenolate bridge is 330.61° in all basal coordinations and shows a pyramidal distortion arising from a folding of the ligand around the imidazolidine backbone, while the chlorine

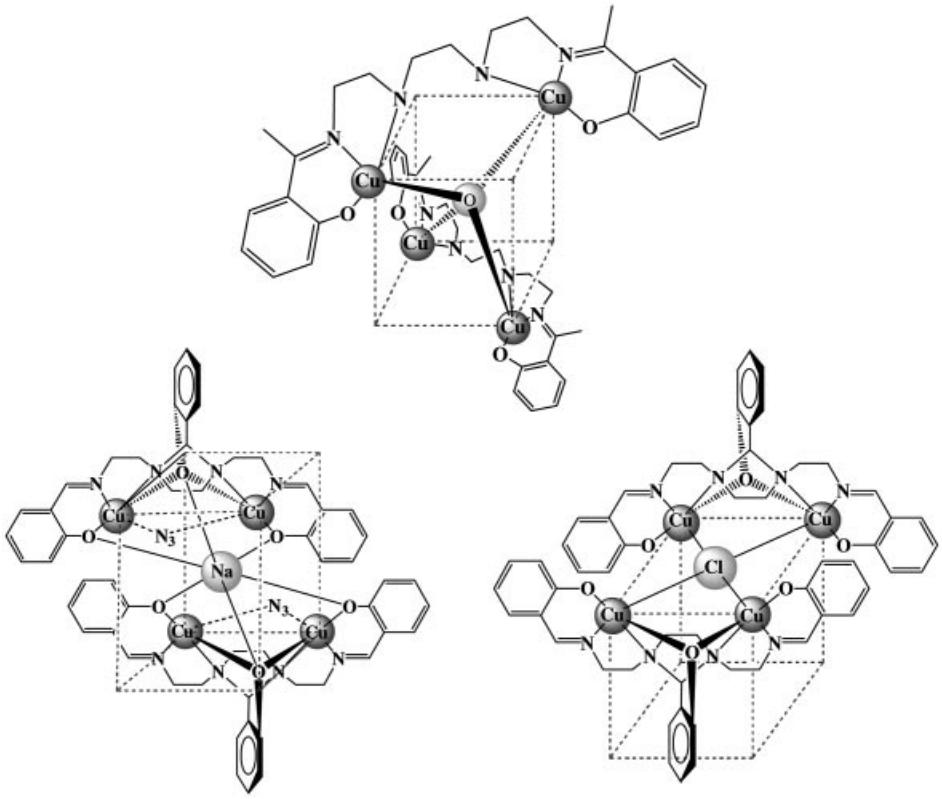

Figure 3. Three single atom nucleating self-assemblies with different polyhedral geometries: a tetrahedral $\mu_4$-$O^{2-}$-directed self-assembly (top, ref.[9]), an octahedral $Na^+$-templated self-assembly (bottom left, ref.[11]) and a planar $\mu_4$-$Cl^-$-templated self-assembly (bottom right, **1a**).

atom for apical coordination to $Cu^{II}$ presents a perfect planar geometry (sum of angles is 360°). The angle between the basal planes of the pyramids is 139.78°, thereby highlighting the non-coplanarity induced by the folded ligand system.

Each copper centre lies 0.220 Å above the mean $N_2O_2$ basal plane and is shifted towards $Cl^-$. To the best of our knowledge, this is the first $\mu_4$-chloride copper cluster of any multidentate ligand. The conformation of the $\mu_4$-$Cl^-$ moiety in **1a** is different from the two previously reported cases with respect to its symmetry (Scheme 1).[2b,7] The Cu···Cu distances within the [$Cu_4$] rectangle of **1a** are 3.241(8) Å within each [$Cu_2$] pair and 4.507(6) Å when spanned by only the $\mu_4$-$Cl^-$ ligand. The first distance is longer and the second distance is shorter than the values (3.040 and 6.009 Å, respectively) for a $Na^+$-templated tetramer of the same ligand with a rectangular disposition of the $Cu^{II}$ ions.[11] These differences are due to basal-apical coordination of the imidazolidinyl phenolic oxygen in the case of [$NaCu_4$] compared to basal-basal coordination in the present case. In the case of the [$NaCu_4$][11] cluster, the azide apical-basal coordinations provide space for $Na^+$, which controls the positions of the phenolate donors, whereas in the [$Cu_4Cl$] cluster the chloride ion with four apical bonds controls the $Cu^{II}$ positions in the cluster (Figure 3).

The Cu(1)–Cl(1) bond is inclined towards O(2), as indicated by the O(2)–Cu(1)–Cl(1) angle of 84.01° (inset of Figure 2). The C=N and C–O distances of the salicylaldimine fragments are 1.280(5) and 1.316(5) Å, respectively, consistent with the coordination of the deprotonated form of the salicylaldimine functionalities.[11] The single chloride anion binds all four Cu ions sitting at the corners of the rectangle with an average Cu···Cl distance of 2.775(5) Å, which is slightly longer than complexes containing tetrahedral and pyramidal $\mu_4$-Cl.[2b,2f,7] The C–C distance within the imid-

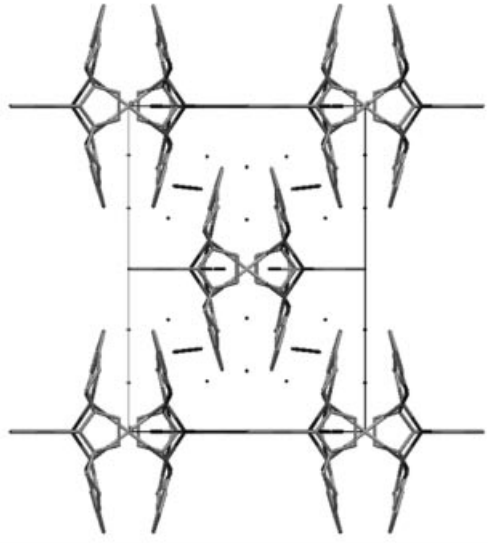

Figure 4. Packing diagram of **1a** along the crystallographic *c* axis.

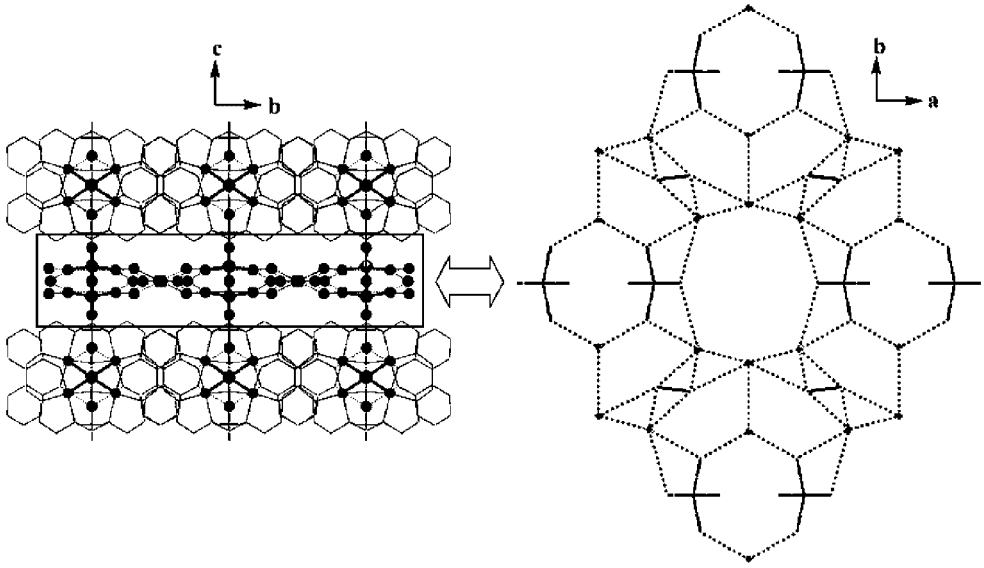

Figure 5. Packing diagram of **1a** along the crystallographic *a* axis (left) and the water–anion net inside the channel viewed along the crystallographic *c* axis (right).

azolidine ring is longer [1.527(8) Å] than the distance in the ethylenediamine backbone [1.46(2) Å].[9] The Cu–$N_{imine}$ [1.935(3) Å] and Cu–$N_{amine}$ [2.070(3) Å] distances are clearly different. The terminal Cu–$O_{phenolate}$ distance [1.906(3) Å] is shorter than the distance involving the central bridging phenolate arm [1.971(2) Å], and the intradimer Cu–Cl–Cu angle [71.44(2)°] is much smaller than the Cu–O–Cu angle [88.2(3)°] in a previously reported $Cu_2$ complex of the same ligand.[17] The $Cl^-$ ligand serves as a template and assembles two $Cu_2$ units in an inverted configuration, which reduces the steric crowding of the central imidazolidinyl phenolate parts of the ligands. Convex molecules of **1a** pack nicely along the crystallographic *c* axis (Figure 4).

The crystal packing diagram along the *a* axis clearly shows the formation of a novel water-anion net within the intercluster space (Figure 5). This net forms hydrogen bonds with the terminal phenolate oxygens (O1) that are held tight in the intercluster space. The presence of these water molecules is crucial for cluster stability and crystal growth.

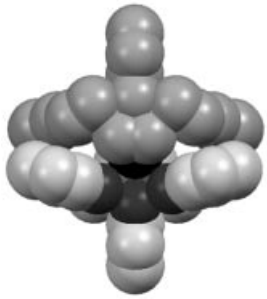

Figure 6. Two inverted crown $[Cu_2L]^+$ motifs sandwiching the chloride anion in a space filling model (ligand carbon atoms are shown in light grey and grey; black: oxygen; deep black: chlorine).

A space filling view of **1a** shows that two $Cu_2$ units sit over each other in an inverted fashion and the spherical chloride anion is trapped inside the complex (Figure 6).

### Magnetochemistry of $[Cu^{II}_4(\mu_4\text{-}Cl)L_2]ClO_4\cdot 12H_2O$ (1a)

To determine the effect of a planar $\mu_4$-Cl-bridging mode on the magnetic exchange within the cluster, bulk magnetisation measurements were carried out under a constant magnetic field of 5000 G between 1.8 and 300 K. The magnetic susceptibility data, corrected for the diamagnetic contribution of the complex and the sample holder, and TIP (temperature-independent paramagnetism) of 0.0016 $cm^3$ $mol^{-1}$, are shown in Figure 7.

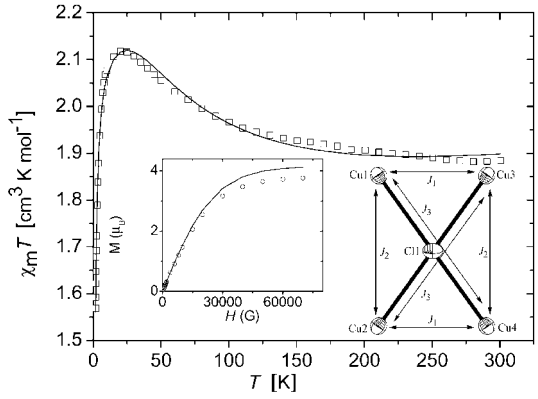

Figure 7. Plot of $\chi_m T$ vs. $T$ in a magnetic field of 5000 G. The solid lines represent the best fit. The left inset shows the field-dependence of the magnetisation at $T$ = 1.8 K. The solid line denotes the Brillouin curve calculated from two independent $S$ = 1 spin system. The right inset shows the $Cu_4Cl$ topology of the complex.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

At 300 K, the $\chi_m T$ value of 1.88 $cm^3 K mol^{-1}$ is slightly higher than the expected value for four uncoupled copper(II) ions. $\chi_m T$ increases on lowering the temperature, reaching a maximum of 2.12 $cm^3 K mol^{-1}$ at 20 K and then decreasing rapidly. The initial rise in $\chi_m T$ on cooling implies the existence of dominant ferromagnetic interactions within the cluster. Based on the structural parameters, there are three possible magnetic exchange pathways, as illustrated in the inset of Figure 7. One is through the phenoxide bridge and the Cu–*N*–C–*N*–Cu route ($J_1$), in which the main magnetic contribution would arise from the former because of the longer pathway of the latter; the other two occur via the central Cl atom ($J_2$ and $J_3$). The magnetic data were properly fitted using the isotropic exchange Hamiltonian $H = -2J_1(S_1 \cdot S_3 + S_2 \cdot S_4) - 2J_2(S_1 \cdot S_2 + S_3 \cdot S_4) - 2J_3(S_1 \cdot S_4 + S_2 \cdot S_3)$.[18] A best fit gives magnetic parameters of $g = 2.08$, $J_1 = 33.4$, $J_2 = -0.25$ and $J_3 = -0.25$ $cm^{-1}$. These magnetic results are reliable as the bond length between Cu and the apical Cl atom is significantly longer (2.775 Å) than the $Cu–O_{phenoxide}$ distance (1.980 Å). It is reasonable to suppose that the magnetic exchange coupling for $J_1$ is strong whereas $J_2$ and $J_3$ are very weak. The ferromagnetic nature through the $J_1$ pathway can arise from the counter complementary effect between the phenoxide ligand and an NCN link from the Schiff base.[19] Accurate values of $J_2$ and $J_3$ could not be determined, although overall weak antiferromagnetic interactions through pathways $J_2$ and $J_3$ are still evident. The $\mu_4$-Cl bridge mediates the magnetic coupling ineffectively because of the longer metal–chloride distance. This can be compared with the $\mu_4$-O unit, which can transmit a stronger antiferromagnetic interaction.[9] The magnetic strength through the $J_1$ pathway is stronger than in the [$NaCu_4$] cluster ($J = 5.43$ $cm^{-1}$)[11] and the tetranuclear carbonate complex ($2J = 39.44$ $cm^{-1}$).[20] From a magnetostructural point of view the magnetic orbital $d_{x^2-y^2}$ lies in the basal plane.[21] The pronounced exchange coupling ($J_1$) through the phenoxide route, compared with the [$NaCu_4$], can be understood by taking into account that the phenoxide ligand bridges two adjacent Cu centres in basal positions. This leads to effective overlap of the magnetic orbitals residing on the two Cu ions. In contrast, the apical-basal bridging mode of the phenoxide that operates in the [$NaCu_4$] cluster gives rise to a weaker overlap.[11] The field dependence of the magnetisation is plotted in the inset of Figure 7. The experimental data lie below the theoretical values derived from two uncoupled $S = 1$ spin systems. This result indicates that there are weak antiferromagnetic interactions between two pairs with an $S = 1$ ground state created by the intradimer ferromagnetic couplings at 1.8 K, which is consistent with the $\chi_m T$ vs. $T$ plot.

### Electrochemistry of $[Cu^{II}_4(\mu_4\text{-}Cl)L_2]ClO_4 \cdot 12H_2O$ (1a)

The electron-transfer behaviour of $[Cu^{II}_4(\mu_4\text{-}Cl)L_2]ClO_4 \cdot 12H_2O$ (**1a**) in dmf was studied by cyclic voltammetry at room temperature. A glassy-carbon working electrode with tetrabutylammonium perchlorate (TBAP) as supporting electrolyte at 298 K was used. The cyclic voltammogram was recorded in the potential range between –1.0 and +1.0 V vs. an Ag/AgCl reference electrode at a scan rate of 100 mV $s^{-1}$. Complexes **1b** and **1c** do not display any characteristic cyclic voltammetric response within the above-mentioned potential window, and only the $\mu_4$-chlorido-bridged complex **1a** exhibits a quasi-reversible ($i_{pc}/i_{pa} = 0.8$) response at $E_{1/2} = 0.515$ V ($\Delta Ep = 156$ mV; Figure 8). The formal potential value for the copper(II) to copper(III) oxidation is similar to other complexes containing phenoxido donor ligands.[22] No characteristic voltammetric wave was observed on the negative side (vs. Ag/AgCl) of the potential window. The observed quasi-reversible peak is assigned to a one-electron transfer process [Equation (1)] for a metal-centred oxidation. The present electrochemical redox reaction in dmf is consistent with a quasi-reversible one-electron transfer process.[23]

$$[Cu^{III}Cu^{II}_3(\mu_4\text{-}Cl)L_2]^{2+}\ (\mathbf{1a^{2+}}) + e^- \leftrightarrow [Cu^{II}_4(\mu_4\text{-}Cl)L_2]^{+}\ (\mathbf{1a^{+}}) \quad (1)$$

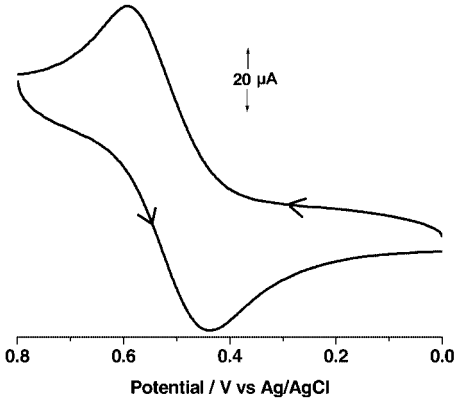

Figure 8. Cyclic voltammogram (scan rate 100 mV $s^{-1}$) of $10^{-3}$ M solutions of **1a** in dimethylformamide at a glassy-carbon electrode ($T = 298$ K).

The quasi-reversible nature of the voltammogram indicates the formation of a copper(III) centre within the cluster that is still coordinated to the $\mu_4$-$Cl^-$. The absence of any voltammetric response in the analogous bromido- and iodido-bridged complexes **1b** and **1c** indicates that the trivalent state is only stable in solution when coordinated to chloride. At 298 K the oxidized species is only stable on the voltammetric timescale.

## Concluding Remarks

We have shown that entrapment of a chloride ion by four copper ions is possible by isolating a {$Cu_4(\mu_4$-Cl)} core within a tetranuclear cluster. Two [$Cu_2$] units can be assembled around the spherical chloride ion, which serves as an anion template to give a rectangular planar geometry. The new supramolecular chlorido complex is formed in a discrete centrosymmetrical structure. The in-plane single atom nucleating coordination mode of $Cl^-$ is the first example of its kind and exclusively binds four copper(II) centres without any auxiliary bridging units. The templating role of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Cl^-$ has been demonstrated with the help of the reaction of $[Cu_2L(H_2O)]ClO_4{\cdot}2H_2O$ (**3**) with NaCl. In **1a**, a weak antiferromagnetic interaction is observed between two [$Cu^{II}_2$] units with an $S = 1$ ground state that is created by an intradimer ferromagnetic coupling mediated by the basal-basal bridging mode of the phenoxido groups.

## Experimental Section

**Materials and Physical Measurements:** Triethylenetetramine was obtained from S.D. Fine Chem. (India) and 2-hydroxybenzaldehyde from SRL (India). Cupric perchlorate hexahydrate was prepared by treating copper(II) carbonate with $HClO_4$ in a 1:1 ratio and crystallised after concentration in a water bath. All other chemicals and solvents were reagent-grade materials and were used as received without further purification. The elemental analyses (C, H, N) were performed with a Perkin–Elmer model 240 C elemental analyzer. IR spectra were recorded with a Perkin–Elmer 883 spectrophotometer. The solution electrical conductivity and electronic spectra were obtained with a Unitech type U131C digital conductivity meter with a solute concentration of about $10^{-3}$ M and a Shimadzu UV 3100 UV/Vis/NIR spectrophotometer, respectively. The room-temperature magnetic susceptibilities in the solid state were measured using a home built Gouy balance fitted with a Polytronic d.c. power supply. The experimental magnetic susceptibilities were corrected for the diamagnetic response using Pascal's constants. Magnetic measurements were carried out on polycrystalline samples (ca. 30 mg) using a Quantum Design MPMS-7 SQUID magnetometer operating at a constant magnetic field of 5000 G between 1.8 and 300 K. The experimental magnetic moment was corrected for the diamagnetic contribution from the sample holder and the diamagnetic response from the sample, which was evaluated from Pascal's constants. Electrochemical measurements were made using a PAR model 173 potentiostat/galvanostat, 175 universal programmer, 178 electrometer, and 377-cell system. A glassy carbon working electrode, a platinum-wire auxiliary electrode, and an Ag/AgCl reference electrode were used in a three-electrode configuration. A digital series 2000 Omni Graphic recorder was used to trace the voltammograms. Electrochemical measurements were performed under nitrogen in dry dmf.

All experimental procedures were performed in air at room temperature. The ligand $H_3L$ [2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine) was prepared according to a literature procedure.[12]

**Synthesis of Complexes:** Two methods were followed for the synthesis and isolation of tetranuclear complexes **1a**–**c**. Method **1** is a direct method where the complexes were synthesised from the ligand and the corresponding copper salts. Method **2** is an indirect synthetic pathway from complex **3**. Details are given below for the representative cases.

**$[Cu^{II}_2(\mu\text{-}H_2O)L]{\cdot}ClO_4{\cdot}2H_2O$ (3):** A methanolic solution of triethylamine (0.55 mL, 4 mmol) was added to a solution of the ligand (0.50 g, 1.09 mmol) in 15 mL of dichloromethane followed by a methanolic solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (0.80 g, 2.18 mmol) and the mixture was stirred at ambient temperature for one hour. The solvent was then evaporated in air, and the deep green precipitate obtained was filtered and washed with water, ethanol and finally dried in vacuo over $P_4O_{10}$. Yield: 0.60 g (75%). $C_{27}H_{33}ClCu_2N_4O_{10}$ (736.12): calcd. C 44.05, H 4.51, Cu 17.26, N 7.61; found C 43.82, H 4.94, Cu 16.90, N 7.37. IR (KBr disk): $\tilde{\nu}$ = 3388 $cm^{-1}$ br, 2936 m, 1627 s, 1595 s, 1537 s, 1447 s, 1312 s, 1094 s, 914 s, 722 s. Molar conductance (MeCN solution): $\Lambda_M$ = 130 $\Omega^{-1}cm^2mol^{-1}$. UV/Vis (dmf): $\lambda_{max}$ ($\varepsilon$) = 640 nm (290 $M^{-1}cm^{-1}$), 402 (2770), 273 (22041).

**$[Cu_4(\mu_4\text{-}Cl)L_2]ClO_4{\cdot}12H_2O$ (1a)**

**Method 1:** A solution of $H_3L$ (0.5 g, 1.09 mmol) in $CH_2Cl_2$/MeOH (1:1) (15 mL) was added to a solution of $CuCl_2{\cdot}2H_2O$ (0.371 g, 2.18 mmol) in $CH_3CN$/MeOH (1:1; 20 mL) then $Et_3N$ (0.5 mL, 3.58 mmol) was added dropwise. The mixture was stirred for 1 h and $[Cu_4(\mu_4\text{-}Cl)L_2]Cl$ precipitated as a green solid in about 80% yield. This solid was isolated, washed with cold methanol, and dried under vacuum over $P_4O_{10}$. It was then dissolved in dmf and a stoichiometric amount of $NaClO_4$ was added. Single crystals suitable for X-ray analysis were obtained from the above mixture after 6 d. $C_{54}H_{78}Cl_2Cu_4N_8O_{22}$ (1516.3): calcd. C 42.77, H 5.18, Cu 16.76, N 7.39; found C 42.48, H 5.46, Cu 16.42, N 6.98. Molar conductance (dmf): $\Lambda_M$ = 90 $\Omega^{-1}cm^2mol^{-1}$. UV/Vis spectrum (dmf): $\lambda_{max}$ ($\varepsilon$) = 660 nm (440 $M^{-1}cm^{-1}$), 377 (7810), 280 (20150). Selected IR bands (KBr) $\tilde{\nu}$ = 3388 $cm^{-1}$ vs, 1633 vs, 1445 m, 1304 m, 1120 w, 1091 m, 770 w, 667 m.

***Caution!*** *Perchlorates are potentially explosive and should be handled only in very small quantities.*

**Method 2:** A methanolic solution of NaCl (0.016 g, 0.27 mmol) was added dropwise to an acetonitrile solution (50 mL) of complex **3** (0.4 g, 0.54 mmol) and stirring was continued for 1 h to give a greenish crystalline product. This solid was isolated, washed with cold methanol/water and dried under vacuum over $P_4O_{10}$. Analytical and spectroscopic data indicated the formation of complex **1a**.

**$[Cu_4(\mu_4\text{-}Br)L_2]ClO_4{\cdot}2H_2O$ (1b)**

**Method 1:** A solution of $H_3L$ (0.5 g, 1.09 mmol) in methanol (15 mL) was added to an acetonitrile solution (30 mL) of $CuBr_2$ (0.486 g, 2.18 mmol) and then $Et_3N$ (0.5 mL, 3.58 mmol) was added dropwise. The mixture was stirred for 1 h, whereupon the complex precipitated as a green solid (ca. 74% yield). This solid was isolated, washed with cold methanol, and dried under vacuum over $P_4O_{10}$. It was then dissolved in dmf and a stoichiometric amount of $NaClO_4$ was added. After one week the resulting crystals of **1b** were isolated and dried under vacuum over $P_4O_{10}$. $C_{54}H_{58}BrClCu_4N_8O_{12}$ (1380.6): calcd. C 46.97, H 4.23, Cu 16.76, N 8.11; found C 46.88, H 4.44, Cu 16.62, N 7.86. Molar conductance (dmf): $\Lambda_M$ = 95 $\Omega^{-1}cm^2mol^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$) = 620 nm (510 $M^{-1}cm^{-1}$), 377 (15426), 280 (21800). Selected IR data (KBr): $\tilde{\nu}$ = 3427 $cm^{-1}$ vs, 1636 vs, 1458 s, 1307 m, 1130 m, 1088 s, 762 s.

**Method 2:** A methanolic solution of KBr (0.032 g, 0.27 mmol), was added dropwise to an acetonitrile solution (30 mL) of complex **3** (0.4 g, 0.54 mmol) and stirring was continued for 1 h to give a greenish crystalline product. This solid was isolated, washed with cold methanol/water and dried under vacuum over $P_4O_{10}$. All analytical and spectroscopic data indicated formation of complex **1b**. All attempts to obtain crystals of **1b** suitable for an X-ray structure determination were unsuccessful.

**$[Cu_4(\mu_4\text{-}I)L_2]ClO_4{\cdot}2H_2O$ (1c)**

**Method 1:** A solution of $H_3L$ (0.5 g, 1.09 mmol) in methanol (15 mL) was added to an acetonitrile solution (50 mL) of CuI (0.415 g, 2.18 mmol) and then $Et_3N$ (0.5 mL, 3.58 mmol) was added dropwise. The mixture was stirred for 1 h, and the complex precipitated as a green solid (ca. 69% yield). This solid was isolated, washed with cold methanol, and dried under vacuum over $P_4O_{10}$. It was then dissolved in dmf and a stoichiometric amount of $NaClO_4$ was added. After one week crystals of **1c** were isolated and dried under vacuum over $P_4O_{10}$. $C_{54}H_{58}ClCu_4IN_8O_{12}$ (1427.6):

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

calcd. C 45.43, H 4.09, Cu 17.80, N 7.84; found C 45.28, H 4.34, Cu 17.70, N 7.52. Molar conductance (dmf): $\Lambda_M$ = 92 $\Omega^{-1}cm^2mol^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$) 635 nm (747 $M^{-1}cm^{-1}$), 377 (16305), 280 (22426). Selected IR bands (KBr): $\tilde{\nu}$ = 3392 $cm^{-1}$ vs, 1632 vs, 1536 m, 1448 s, 1311 m, 1196 m, 1090 s, 766 s.

**Method 2:** A methanolic solution of KI (0.044 g, 0.27 mmol) was added dropwise to an acetonitrile solution (50 mL) of complex **3** (0.4 g, 0.54 mmol) and stirring was continued for 2 h to give a greenish crystalline solid. This solid was isolated, washed with cold methanol/water and dried under vacuum over $P_4O_{10}$. All analytical and spectroscopic data indicated formation of complex **1c**. All attempts to obtain crystals of **1c** suitable for X-ray structure determination were unsuccessful.

**$[NaCu_4L_2(N_3)_2]ClO_4\cdot H_2O$ (5)**

**Method 1:** A methanolic solution of $Cu(ClO_4)_2\cdot 6H_2O$ (0.80 g, 2.18 mmol) was added to a dichloromethane solution (10 mL) of the ligand (0.50 g, 1.09 mmol) and then a methanolic solution of $NaN_3$ (0.07 g, 1.09 mmol) was added dropwise whilst stirring at ambient temperature in air. After 15 min, a dilute methanolic solution of $Et_3N$ (0.45 mL ,3.27 mmol) was added and the reaction mixture was stirred for 1 h more. The complex precipitated as a green solid (ca. 85% yield), which was isolated, washed with water, and dried under vacuum over $P_4O_{10}$. Single crystals suitable for X-ray analysis were obtained from MeOH/MeCN (1:1) after five days. $C_{54}H_{56}ClCu_4N_{14}NaO_{11}$ (1389.8): calcd. C 46.66, H 4.06, Cu 18.28, N 14.10; found C 46.64, H 4.25, Cu 18.50, N 13.88. Molar conductance (dmf): $\Lambda_M$ = 73 $\Omega^{-1}cm^2mol^{-1}$. UV/Vis (dmf): $\lambda_{max}$ ($\varepsilon$) = 650 nm (150 $M^{-1}cm^{-1}$), 398 (2660), 271 (16062). IR (KBr disk): $\tilde{\nu}$ = 3425 $cm^{-1}$ br, 2926 m, 2076 s, 1633 s, 1595 s, 1537 s, 1447 s, 1312 s, 1274 s, 1081 s, 747 s, 625 s.

***Caution!*** *Azide derivatives are potentially explosive and should be handled only in very small quantities.*

**Method 2:** A methanolic solution of $NaN_3$ (0.035 g, 0.54 mmol) was added dropwise to an acetonitrile solution (50 mL) of complex **3** (0.4 g, 0.54 mmol) and stirring was continued for 2 h to give a greenish crystalline product, which was isolated, washed with cold methanol/water and dried under vacuum over $P_4O_{10}$. All analytical and spectroscopic data indicated the formation of complex **5**.

**Method 3:** A methanolic solution of $NaN_3$ (0.025 g, 0.395 mmol) was added dropwise to an acetonitrile solution (50 mL) of complex **1a** (0.3 g, 0.197 mmol) and stirring was continued for 1 h to give a greenish crystalline product, which was isolated, washed with cold methanol/water and dried under vacuum over $P_4O_{10}$. All analytical and spectroscopic data indicated the formation of complex **5**.

**X-ray Crystallographic Study of $[Cu_4(\mu_4\text{-}Cl)L_2]ClO_4\cdot 12H_2O$ (1a):** Green block-shaped single crystals of $[Cu_4(\mu_4\text{-}Cl)L_2]ClO_4\cdot 12H_2O$ suitable for X-ray analysis were grown by the slow evaporation of a dmf solution of the complex. The intensity data for the complex were collected on a CAD-4 single-crystal X-ray diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) by the ω-scan method for a single crystal with dimensions 0.14 × 0.12 × 0.11 $mm^3$. Precise unit cell dimensions were determined by least-squares refinement of 25 strong reflections having $2\theta$ values between 1.57 and 24.97 °. Data were collected at 298 K. A total of 3127 reflections were recorded with Miller indices $h_{min}$ = 0, $h_{max}$ = 16, $k_{min}$ = 0, $k_{max}$ = 22 and $l_{min}$ = –15, $l_{max}$ = 15. In the final cycles of full-matrix least-squares refinement on $F^2$ all non-hydrogen atoms were assigned anisotropic thermal parameters and refinement converged at $R$ = 0.0473. The residual electron density was in the range +0.491 to –0.541 e $Å^{-3}$. The structure was solved with the SHELX-97 programme system[24] and refined using full-matrix least-squares with all non-hydrogen atoms treated anisotropically and hydrogens included at calculated positions as riding on their carrier atoms. H-atoms on water molecules could not be located. The $ClO_4^-$ anion and some solvent water molecules were found to be disordered. Further information concerning X-ray data collection and structure refinement of the compound is summarised in Table 2.

# Supramolecular Helical Architectures Dictated by Folded and Extended Conformations of the Amino Acid in Ternary $Cu^{II}$/Diamine/Racemic Amino Acid Complexes

**Palani Sivagnana Subramanian,*[a] Eringathodi Suresh,[a] and Luigi Casella*[b]**

**Keywords:** Helicates / Self-assembly / Copper / Chiroptical properties / Amino acids

The ternary $Cu^{II}$ complexes [Cu(D,L-phe)(bpy)]·($ClO_4$) (**1**), [Cu(D,L-phe)(phen)($H_2O$)]·$ClO_4$·$H_2O$ (**2**), and [Cu(L-phe)(bpy)($H_2O$)]·$ClO_4$·$H_2O$ (**3**) (bpy = 2,2′-bipyridine, phen = 1,10-phenanthroline) adopt helical structures in the crystal state, as determined by an X-ray structural analysis. The supramolecular helical assembly of these complexes was also investigated by single-crystal X-ray crystallography. The complexes derived from racemic amino acids (**1** and **2**) undergo spontaneous resolution in the solid state to form separate helical chains of the ternary complex that carry a single enantiomer of the amino acid. In the case of complex **1**, the two helical chains resulting from the L- and D-phe complexes bear opposite chirality, which means that the bulk crystalline sample is racemic. In contrast, the two helical chains generated by L- and D-phe complexes in **2** have the same twist and pack together in a right-handed assembly. The (*P*)/(*M*) handedness of the helical chains is dictated by the conformational chirality (λ/δ) of the chelate rings of the D/L-amino acids.

## Introduction

Compounds that are achiral in nature but gain chiroptical properties upon formation of supramolecular helical architectures have received a great deal of interest in recent years.[1] A number of ternary $Cu^{II}$/diamine (DA) complexes with optically active D- and L-amino acids (AA), where the latter residues can be present in folded and extended conformations, are known, and their optical properties in solution have been studied extensively.[2–4] Many of the investigations on such [$Cu^{II}$(DA)(AA)][5–9] complexes reported so far have focused mainly on structure/reactivity correlations and conformational studies; no correlation between their structural architecture and solid-state optical properties has been reported. Inorganic metallohelicates[10] are known to have interesting chiroptical properties. Intensive efforts to amplify the chiroptical properties obtained by supramolecular helicity by introducing various chiral residues or molecules such as chiral spacers,[11,12] amino acids,[13,14] and chiragens[14] into the helical skeleton have been made by a number of researchers, including Raymond et al.[15] and Albrecht et al.[16] Recent articles by Kuroda et al.,[1a,17] however, have explored the chiroptical properties exhibited by achiral complexes. The self-assembled, single-stranded supramolecular architecture of ternary [$Cu^{II}$(DA)(AA)] complexes obtained from a simple one-pot reaction that contain the amino acid in their helical skeleton inspired us to investigate their optical behavior. In the structure of the complexes [Cu(D,L-phe)(bpy)]·$ClO_4$ (**1**), [Cu(D,L-phe)(phen)($H_2O$)]·$ClO_4$·$H_2O$ (**2**), and [Cu(L-phe)(bpy)($H_2O$)]·$ClO_4$·$H_2O$ (**3**) that we describe here (bpy = 2,2′-bipyridyl; phen = 1,10-phenanthroline), the difference in the orientation of the phenylalanine side chain results in folded and extended conformations of the amino acid chelate ring that lead to noncovalently propagated supramolecular helical architectures. Folded and extended forms of ternary aromatic amino acid complexes have been reported by many researchers,[2,5,7–9] and here we show how these conformations can influence the helicity of the polymeric structure of the ternary complexes. Complexes **1** and **2**, which contain racemic phenylalanine, undergo spontaneous resolution in the crystalline state and their different supramolecular helical structures result in interesting differences in chiroptical properties in the solid state. The potential sources of optical activity in the ternary complexes **1**–**3** are discussed in terms of the Δ/Λ configuration of the $Cu^{II}$ chromophoric units, the supramolecular helicity (*P*)/(*M*), and the λ/δ conformational chirality of the nonplanar D/L-amino acid chelate rings.

## Results and Discussion

### Crystal Structures and Molecular Association

ORTEP diagrams of complexes **1**–**3** with the atom numbering schemes are given in Figure 1. A summary of the crystallographic data is given in the Experimental Section and selected bond lengths and angles for **1**–**3** are given in Table 1. The $Cu^{II}$ ions in complexes **1**–**3** possess a distorted square-pyramidal geometry where the base of the square pyramid is constituted by the pyridyl nitrogen atoms of the heterocyclic diamines and the $NH_2$ and $CO_2$ groups of the amino acids (L-, D-phe). The fifth axial ligand is different and consists of a carboxylate oxygen atom in **1** and a water molecule in **2** and **3**. The long $Cu^{II}$–carboxylate oxygen bonds [Cu1–O4 2.274(2), Cu2–O2 2.261(2) Å] formed by O2 and O4 of phenylalanine in **1** define a folded single-stranded helical, cationic polymeric chain along the *a* axis. The carboxylate oxygen atom O2 coordinated to Cu(2) possesses an additional weak short contact with one of the two bipyridyl nitrogen atoms (O2–N4 2.910 Å) that may have some significance for the helical arrangement. The helical chain is constructed from –Cu1–OCO–Cu2– bonds with $Cu^{II}$ centers sitting alternatively at distances of 5.883 and 5.864 Å. The aromatic rings of the amino acids C13 to C18 and C32 to C37 adopt only a folded conformation in complex **1** and are oriented almost parallel to the bpy rings, with a slight deviation of 2.74 and 6.99°, respectively, from the mean plane, which facilitates strong intra- and intermolecular stacking interactions (Figure 2A).

[a] Symmetry operation for atom #1 = $x-1$, $y$, $z$.

Complex **2** differs from **1** and **3** by crystallizing with two independent molecules in the asymmetric unit; one contains the D isomer of the amino acid in the folded form only (henceforth referred to as **2a**), while the other contains only the L-amino acid in an extended form (henceforth referred to as **2b**). Similar folded and extended conformations have already been reported in analogous ternary copper(II) complexes such as [Cu(L-trypO)(phen)]$^+$,[18] [Cu(L-phe)(phen)Cl]·3$H_2O$,[8] [Cu(L-*o*-Me-phe)(phen)($H_2O$)]$ClO_4$,[5c] [Cu(L-$NH_2$Phe)(bpy)]·$NO_3$·$H_2O$,[8] and [Cu(L-tyr)(phen)($H_2O$)]·$ClO_4$·1.5$H_2O$,[8] etc. We have also recently reported a folded conformation of L-phe in the ternary complex [Cu(L-phe)(bpy)($H_2O$)]·$ClO_4$.[9] The coordination around $Cu^{II}$ remains almost the same for both **2a** and **2b**, although the phenylalanine side chain varies somewhat in its orientation. The apical coordination of the $Cu^{II}$ square pyramid is fulfilled by long bonds with water molecules [Cu1–O1w 2.285 (**2a**), Cu2–O2w 2.351 Å (**2b**)] in both cases, while the square base resembles that present in complexes **1** and **3**.

Similar to complex **1**, the phenyl ring of D-phe in **2a** is almost parallel to the phenanthroline ring (tilt angle of 5.29°) and forms a folded isomer. However, the phenyl moiety of L-phe in **2b** is inclined towards the perpendicular of the phenanthroline ring (tilt angle of 71.96°) to yield an extended isomer. The folded and extended isomers **2a** and **2b**, respectively, in Figure 2 are packed with the phenyl ring of the amino acid pair pointing in opposite directions and give effective π···π stacking interactions, as shown in Figure 2D. The offset inter- and intramolecular π···π stacking interactions between the phenyl rings of the bpy/phen ligands and the aromatic rings of the amino acids in complexes **1** and **2** are depicted in Figure 2; the stacking distances are given in the figure caption. The weak π···π interactions clearly play a significant role: the aromatic ring of the folded phenylalanine causes the intramolecular π···π stacking interaction and that of the extended form facilitates the intermolecular π···π stacking interaction, as indicated by the double-headed arrows in Figure 2. Further, the phenanthroline units of the folded and extended forms generate interhelical π···π stacking through the centroids [$Cg_3$(ext)···$Cg_2$(fold) 3.539 Å] of their aromatic rings.

### Supramolecular Helical Association and Chirality

The stereochemical descriptors (*P*) or (*M*) can be assigned to the helical assemblies in **1**–**3** depending on the clockwise or anticlockwise bias of the helical strand, respectively. It is noteworthy that the supramolecular packing in complexes **1**–**3** generates a one-dimensional inner-sphere helical arrangement running through the metal centers by a combination of weak inter- and intramolecular π···π stacking and hydrogen-bonding interactions, as shown in Figure 2. An imaginary helical axis drawn between the metal centers along the *a* axis is shown in Figure 3. In all cases the bipyridyl ligand and the phenyl ring of the amino acid that projects outwards revolve around the helical axis with good intra- and intermolecular π···π stacking interactions. The intramolecular helical structure running through the Cu1–OCO–Cu2 strands in complex **1** contains only folded phenylalanine isomers. As expected, therefore, the arrangement of the two polymeric helical chains containing the D- and L-amino acids in this complex occurs through the formation of alternately packed (*P*) and (*M*) helices, as shown in Figure 3A.

The coordinated O1w and O2w molecules of the folded and extended conformers in complex **2** propagate the hydrogen-bonded helical architecture through Cu1–O1w···O2CO1–Cu1 and Cu2–O2w···O4CO3–Cu2 bonds, respectively, diagonal to the *ac* plane. The O1w and O2 (carboxylate oxygen) atoms of the adjacent molecular units of the folded form are interconnected by hydrogen bonds (O1w···O2 2.747 Å) to form a single-stranded helical chain. Similarly, the O2w and O4 (carboxylate oxygen) atoms (O2w···O4 2.857 Å) of the extended form are interlinked

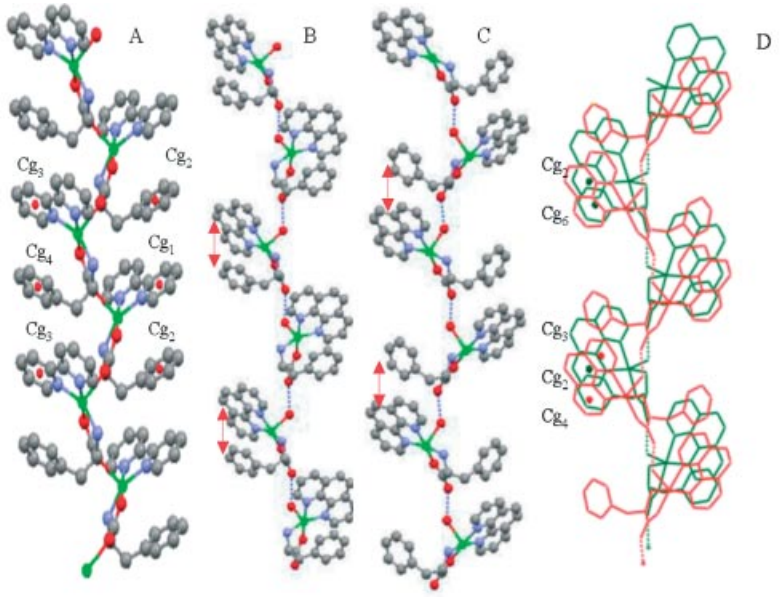

Figure 2. Stacking interactions of the phenyl rings in complexes **1** and **2** along the *a* axis. The double-headed arrows indicate the inter- and intramolecular stacking interactions. A: complex **1** [inter: Cg(1)···Cg(2) 4.158 Å; intra: Cg(1)···Cg(2) 4.154 Å; inter: Cg(3)···Cg(4) 4.264 Å; intra: Cg(3)···Cg(4) 4.044 Å]; B: complex **2** (only folded form); C: complex **2** (only extended form); D: merged packing of **2a** and **2b** [intra: Cg(2)···Cg(6) 3.882 Å; inter: Cg(3)···Cg(2) 3.539 Å]. Color scheme: red = carboxylate oxygen; green = Cu(II).

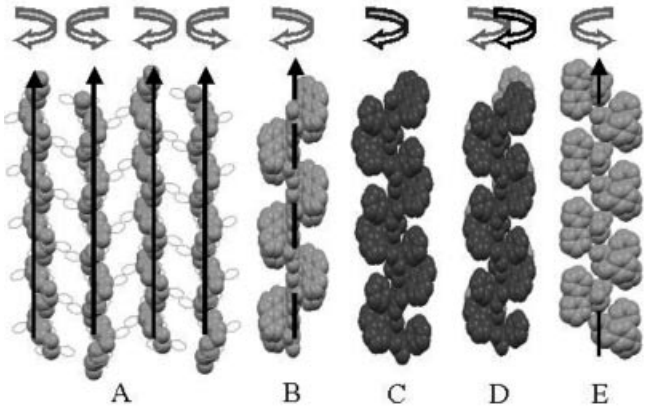

Figure 3. Space-filling model of the single-stranded supramolecular helical arrangements formed by Cu–OCO–Cu connectivity (light gray = folded; dark gray = extended). A: **1**; B: **2a**, C:**2b**; D: addition of both **2a** and **2b**; E: **3**.

through hydrogen bonding to create another helical chain. An alternate arrangement of O–H···O interactions with the lattice water molecule O3w and N–H···O bonds brings the adjacent folded and extended helical chains into close proximity to create a sheet-like architecture that restores the helical superstructure of the complex. The combined effect of various O–H···O and N–H···O interactions involving O3w–O2 (2.742 Å), O3w···O2w (2.745 Å), and N(3)H···O4 (3.024 Å) and π···π stacking interactions brings the $Cu^{II}$ centers into closer contact (5.928 Å). The hydrogen-bonded helical superstructure formed by both the folded and extended isomers can be designated as (*P*) because of the clockwise sense of its molecular rotation, as shown in Figure 3D. The folded and extended forms are shown separately in Figures 3B and C to better visualize their similar helical chirality.

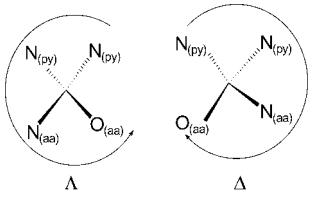
Supramolecular helices usually pack in a racemic fashion,[19] and reports on homochiral helicates are rare. Supramolecular packing of **1**, for instance, occurs with the usual racemic pattern comprising both the (*P*) and (*M*) alternate helical chains, while in the crystal structure of complex **2** packing of two (*P*) helices occurs stereospecifically to give a homochiral superstructure, as shown in Figures 3B–D. In complex **3**, the free carboxylate oxygen atom (O2) involved in N···H···O interactions [N(3)–H···O2 3.027 Å] forms a single-stranded inner-sphere helical chain through the Cu1–N3···O2CO1–Cu1 bonds along the *bc* plane, as shown in Figure 3E.

## Chiroptical Properties

In order to understand the correlation between the supramolecular helical architecture and the chiroptical properties, CD spectra for complexes **1**–**3** were recorded both in solution and on ground crystals. In general, the optical activity could be derived from the (*P*)/(*M*) helical chain chiral descriptors, the geometrical Δ/Λ descriptors of the chiral metal centers (Scheme 1), and the λ/δ conformational chirality[20] of the nonplanar L/D-amino acid chelate rings. For systems **1**–**3**, therefore, an attempt to correlate their chiroptical properties can be made. Chirality at the metal centers can be derived by taking into account the non-coplanar arrangement of the donor atoms at the base of the square pyramid in the structures of the $Cu^{II}$ centers; the descriptors[21] Δ and Λ are thus assigned depending upon the clockwise (Δ isomer) and anticlockwise (Λ isomer) operation of the chromophore $O_{(aa)} \rightarrow N_{(aa)} \rightarrow N_{(py)}$

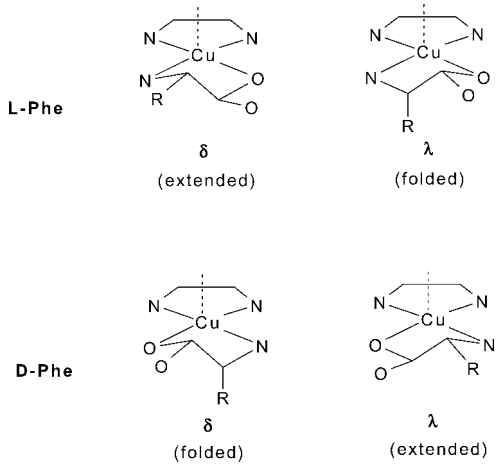
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

→ $N_{(py)}$ around the $Cu^{II}$ center, as shown in Scheme 1. In complex **1**, the (*P*) sense of the helix is associated with ΔΔΔΔ... configurations at the metal centers, while the (*M*) sense involves ΛΛΛΛ... configurations at the Cu atoms. The amino acids in complex **2** exist in folded (**2a**) and extended (**2b**) forms, both of which selectively assemble into (*P*) helical chains, although the configuration at the metal centers is ΛΔΛΔ... in the skeleton of the two helices. Furthermore, as complexes **1** and **2** possess very similar chemical compositions, the difference in their spatial arrangement caused by the folded and extended isomer and the extra space provided by the phenanthroline ligand may be the reason for its homochiral nature.



Scheme 1. Geometrical descriptors.

As regards the conformation of the amino acid chelate rings, it should be noted that the folded isomer has λ chirality for the L-phe and δ chirality for the D-phe residues, and that the opposite chirality occurs for the corresponding extended isomers (Scheme 2). The amino acids in the helical chains of complexes **1** and **3** adopt the folded conformation (λ for L-phe and δ for D-phe), although both the folded D-phe residue in **2a** and the extended L-phe residue in **2b** bear the same δ chirality.



Scheme 2. Conformations of the amino acid chelate rings.

Complex **1** assembles in alternating (*P*) and (*M*) helices through Cu1–OCO–Cu2 chains, therefore both the contributions to the overall chirality by the conformation of the amino acid chelate rings and the configuration at the $Cu^{II}$ centers perfectly cancel each other out in the enantiomeric (*P*) and (*M*) helices. In contrast, the two supramolecular helical chains built up by the D- and L-phe complexes in complex **2** bear the same (*P*) chirality. This shows that the chirality of the helical chain is dictated by the conformational chirality of the amino acid chelate ring rather than the absolute (L/D) configuration of the amino acid, with a λ conformation inducing an (*M*) helix and a δ conformation a (*P*) helix. The self-assembly process generating the helical chains is thus enantioselectively dictated by the folded or extended disposition assumed by the side-chain of the phe residues.

As expected, the CD spectra of complexes **1** and **2** in solution are flat as the polymeric structure is destroyed; the solid-state CD spectrum of complex **1** is also essentially flat, taking into account the low resolution of the experiment, whereas crystals of complex **2** appear to exhibit optical activity in the solid state, with weak but clearly detectable CD activity with a positive sign between 500 and 600 nm. The dominant CD activity for complex **3** has a negative sign and remains unchanged both in the solid state ($\lambda_{max} \approx$ 620 nm) and in solution [CD data in methanol: $\lambda_{max} \approx 565$ ($\Delta\varepsilon = -0.44\ M^{-1}\,cm^{-1}$) and 725 nm (+0.10)], thus clearly indicating that no significant change occurs in the chiral arrangement of the complex. The CD activity observed for complexes **2** and **3** in the $Cu^{II}$ d-d bands therefore reflects the opposite chirality of the amino acid chelate rings and of the corresponding helical chains associated with the two complexes in the crystalline state.

## Conclusion

We have described the formation of a series of single-stranded helical coordination polymers that contain both covalent and hydrogen bonds as a construction element. The two separate helical chains of the ternary complex carrying L- and D-phe residues in complex **1** bear opposite chirality, which means that the crystalline sample as a whole is racemic. In contrast, the two helical chains generated by the L- and D-phe complexes in **2** have the same (*P*) chirality and together form two right-handed helical assemblies. In principle, a supramolecular arrangement involving two helical chains with (*M*) chirality, built from the folded (L) and extended (D) forms of the racemic amino acid, is possible for this complex, but is probably not observed in the crystalline state due to the less favorable packing. Further studies on chiral amplification to monitor the crystallization process of metal complexes containing optically pure and racemic amino acids are currently under way in our laboratory.

## Experimental Section

**Materials:** L-Phenylalanine, D,L-phenylalanine, 2,2′-bipyridyl, and 1,10-phenanthroline were purchased from Sigma–Aldrich and used as received. All the other reagents and solvents were commercially available and used without further purification. Microanalysis of the complexes was performed with a Perkin–Elmer PE 2400 series II CHNS/O elemental analyzer. FT-IR spectra for KBr pellets (1% w/w) were recorded with a Schimadzu FT-COM 1 spectrophotometer. The CD spectra were measured for KBr pellets or methanol solutions of the complexes with a JASCO J710 dichrograph; a smoothing program from JASCO (version 1.53.00) was used to reduce the noise of the solid-state spectra.

### Preparation of the Complexes

**[Cu(D,L-phe)(bpy)]·ClO$_4$ (1):** A mixture of D,L-phenylalanine (0.82 g, 10 mmol) and NaOH (0.20 g, 10 mmol) in distilled water (50 mL) was added to an aqueous solution (25 mL) of $CuSO_4{\cdot}5H_2O$ (1.25 g, 10 mmol) and stirred for 30 min. The solution was stirred at 50 °C for another 2 h until a pale-blue precipitate had formed. An ethanolic solution (20 mL) of bipyridyl (0.78 g) was then added dropwise and the pale-blue precipitate was observed to dissolve to form a clear blue solution. At the end of the reaction, $NaClO_4{\cdot}H_2O$ (0.7 g, 10 mmol), dissolved in distilled water (20 mL), was added. $C_{19}H_{18}ClCuN_3O_6$ (483.36): calcd. C 47.30, H 3.73, N 8.71; found C 47.35, H 3.76, N 8.63. IR: $\tilde{\nu}$ = 3450–2910, 1631, 1593 (s), 1444, 1386 (m), 1320 (m), 1131, 1103, 1057 (br., s), 763, 618 (m) cm$^{-1}$.

**[Cu(D,L-phe)(phen)(H$_2$O)]·ClO$_4$·H$_2$O (2):** This complex was synthesized according to the above procedure but with phenanthroline (0.94 g, 10 mmol) in place of bipyridyl. $C_{21}H_{21}ClCuN_3O_{7.5}$ (530.40): calcd. C 47.19, H 3.96, N 7.86; found C 47.42, H 4.54, N 7.27. IR: $\tilde{\nu}$ = 3519–2940 (br., s), 1609, 1589 ($\nu_{COO}$, s), 1520 (m), 1429, 1399 (m), 1149, 1100, 1085 ($\nu_{ClO_4}$, br, s), 851 (m), 622 (m) cm$^{-1}$.

**[Cu(L-phe)(bpy)(H$_2$O)]·ClO$_4$·H$_2$O (3):** Synthesized and characterized according to the reported procedure.[9]

**Crystal Structure Determination:** Data collection for **1**–**3** was performed with a Bruker Apex CCD diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 100(2) K. Absorption corrections were applied with the multi-scan program SADABS.[22a] Further details are given in Table 2. The structures were solved by direct methods and all non-hydrogen atoms were refined anisotropically by least-squares on $F^2$ using the program SHELXTL.[22b] Hydrogen atoms were generated with a riding model. CCDC-281899 (**1**), -281900 (**2**), and -281901 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Table summarizing hydrogen-bonding network for complexes **1** and **2**.

## Acknowledgments

P. S. and E. S. are grateful to Dr. P. K. Ghosh, Director of the Central Salt and Marine Chemicals Research Institute, for his keen interest and encouragement, and Dr. A. Granata for recording the CD spectra.

# Helical Transition-Metal Complexes of Constrained 2,2′-Bidipyrrins

**Martin Bröring,*[a] Stephan Link,[a] Carsten D. Brandt,[a] and Esther Cónsul Tejero[a]**

**Keywords:** 2,2′-Bidipyrrins / Helicates / Constrained ligands / Porphyrinoids / Coordination modes

Nickel(II), palladium(II), zinc(II) and copper(II) complexes of new constrained 2,2′-bidipyrrin ligands ($H_2$BDP) with a peripheral eight-membered ring were prepared and examined with respect to coordination modes and conformation. $Ni^{II}$ and $Pd^{II}$ ions form mononuclear complexes with a distorted square-planar $N_4$ coordination, which was determined for the palladium derivative by single-crystal X-ray diffraction. $Zn^{II}$ ions lead to the formation of dinuclear $M_2L_2$ helicates, and for $Cu^{II}$ ions both coordination modes are realized. X-ray crystallographic analyses reveal short M···M distances for the dinuclear helicates of $Cu^{II}$ and $Zn^{II}$ bidipyrrins and individually distinct packing patterns for both in the solid state.

## Introduction

For a long time the coordination chemistry of open-chain tetrapyrroles was limited to bioinspired studies on the metal-binding capabilities of biliverdin-IXα (BV) and closely related model ligands.[1] Naturally occurring heme degradation processes[2] and the unexpected lability of Fe–BV complexes[3] have been the major driving forces for this research, and many questions have remained unanswered until today. Open-chain tetrapyrroles with a non-natural backbone, on the other hand, have been prepared mainly as precursors for different template-directed macrocyclizations to porphyrinoids.[4] Signs of a stand-alone coordination chemistry of such ligands hardly appeared in the literature prior to 1990.[5]

The interest in open-chain tetrapyrroles as multifunctional chelate ligands started in 1996 with Mizutani's work on the chiral recognition of amino acids by helical Zn–BV derivatives.[6] In 1998 two groups reported, independently, that open-chain oligopyrroles are useful templates for the construction of supramolecular coordination assemblies,[7] including earlier findings on similar dinuclear species.[8] A very elegant approach along this line was reported by Thompson et al., who introduced chiral carboxylic ester side chains in order to investigate stereoselective helix formation triggered by metal insertion.[9] The first bioinorganic use of linear tetrapyrroles besides heme degradation studies was reported in 2001.[10] It could be demonstrated that a dimeric manganese(III) complex of BV-IXα-dimethyl ester catalyzes the decomposition of hyperoxide, and that therefore this complex should be addressed as a functional SOD model. However, reports on investigations of possible medical applications have not yet appeared.

A tetrapyrrolic system with a particularly simple architecture is found in the non-natural 2,2′-bidipyrrin,[7b,11] which is constituted of two directly linked dipyrrin units, and which can in principle rotate around this central pyrrole–pyrrole link. 2,2′-Bidipyrrins have been shown in recent years to support a multitude of different coordination modes (Figure 1).[12] Because of the robustness of methyl-terminated 2,2′-bidipyrrins and their straightforward preparation in large amounts, these ligands would be an ideal candidate for a reference system of the natural BV-IXa and especially of the hitherto almost elusive iron complexes thereof.[13] Unfortunately, however, and similar to other natural and non-natural open-chain tetrapyrroles, 2,2′-bidipyrrins do not form sufficiently stable iron chelates.

2,2′-Bidipyrrins typically reside in an *anti* conformation in the solid state and in solution,[11b,11c,14] and we expected that, enforcing a *syn*- (or *syn-gauche*-) conformation as shown on the right in Figure 2, the formation of 1:1 chelate complexes of type **A** with kinetically labile ions should be favoured. We report here on the synthesis of such conformationally restricted 2,2′-bidipyrrins **1** and **2** and their coordination behaviour to 3d transition metals.

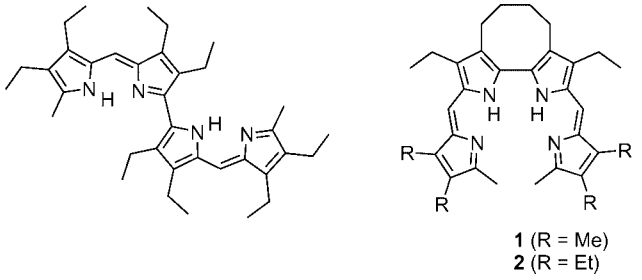

Figure 2. Conformational preferences of unrestrained and restrained 2,2′-bidipyrrins.

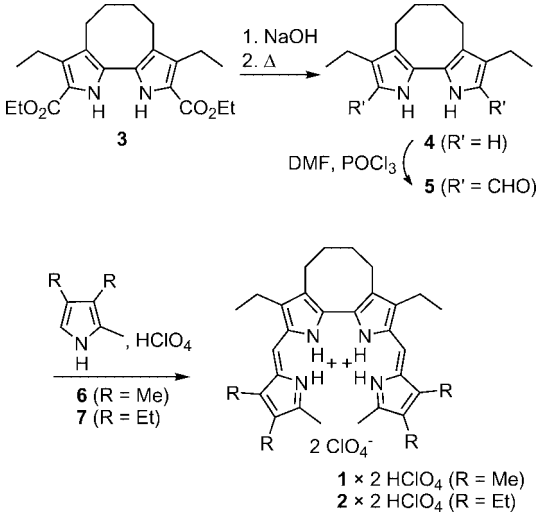
## Results and Discussion

The synthesis of the new 2,2′-bidipyrrin ligands **1** and **2** is illustrated in Scheme 1. We have chosen an eight-membered ring as an intermediately severe constraint for our purpose. A bis(indole)-based $N_4$ ligand with an identical restraint was prepared and studied before in the field of anion sensing,[15] and a maximum bis(indole) torsion angle of 65° was estimated for this compound. This estimate fits well for our intention to produce a 2,2′-bidipyrrin with a restriction to the *syn*- and/or *syn-gauche* conformation.



Scheme 1. Preparation of restrained 2,2′-bidipyrrins **1** and **2** as bis(hydroperchlorate) salts.

The new ligands **1** and **2** were obtained analogously to simpler 2,2′-bidipyrrins recently described.[11c,11d] Dialdehyde **5** was prepared from the recently communicated diester **3**[16] by a saponification-decarboxylation-formylation sequence. The electron-rich bipyrrole **4** proved to be extremely sensitive to light and air, and was therefore used directly in the Vilsmeyer formylation to yield **5** as a yellow powder in an overall yield of 72%. The acid-promoted double condensation of **5** with 2 equiv. of a 5-unsubstituted pyrrole (either **6** or **7**) was carried out at 60 °C in methanol solution. Perchloric acid was found to be the agent of choice, as the protonated products **1**·2 $HClO_4$ and **2**·2 $HClO_4$ directly crystallize from the hot reaction mixture. The yields of 50 and 48%, however, are significantly lower compared to the almost quantitative formation of nonhindered 2,2′-bidipyrrins.

The formation of the desired tetrapyrroles **1** and **2** is indicated mass spectrometrically by the signals for the $[M + 1]^+$ ions at *m*/*z* 481 and 537, respectively. Combustion analyses in combination with thermogravimetric investigations point to the presence of hydrates, that is [**1**·2$HClO_4$·$H_2O$] and [**2**·2$HClO_4$·3$H_2O$]. Further characterization was performed by $^1H$ and $^{13}C$ NMR spectroscopy. Proton NMR spectra of [**1**·2$HClO_4$·$H_2O$] and [**2**·2$HClO_4$·3$H_2O$] show broad singlets for two types of NH protons at 12.23 and 11.47 (**1**) or 11.17 and 10.55 ppm (**2**) in addition to a sharp resonance line for the *meso* H atoms at 7.06 (**1**) or 7.25 ppm (**2**). The singlet for the terminal methyl groups is found at 2.76 (**1**) and 2.73 ppm (**2**), and the $C_4$-bridge leads to broadened multiplets for the benzylic and homobenzylic methylene protons at $\delta$ = 2.7 and 1.8 ppm, respectively (Figure 3).

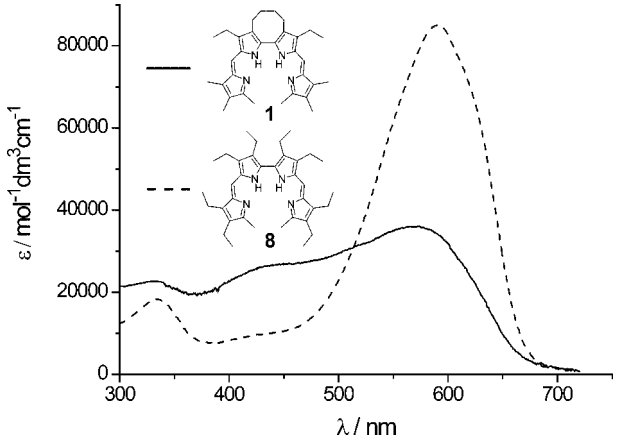


Figure 3. UV/Vis spectra ($CH_2Cl_2$) of free base **1** and octaethyldimethyl-2,2′-bidipyrrin **8**.[11d]

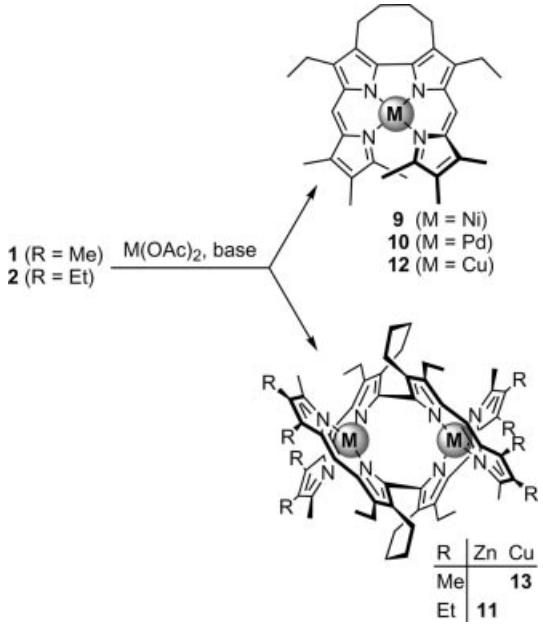
While the data discussed above give no direct hint to a special conformation of the new tetrapyrroles, the restricted rotation of **1** and **2** is well documented in the optical spectra. Figure 3 shows the UV/Vis absorption spectra of restrained **1** and of the unrestrained 2,2′-bidipyrrin **8**.[11d] Compared to octaethyldimethyl-2,2′-bidipyrrin **8** the optical transitions of **1** are significantly broader and largely equal in intensity, but very similar with respect to the absorption maxima. A possible interpretation of this spectral pattern is that the presence of the eight-membered ring in **1** prevents a single minimum conformation for the tetrapyrrole in solution. Instead, a number of energetically similar *syn-gauche* conformations exist and slowly interconvert into

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

each other. The observed line-broadening for the $C_4$-bridge methylene proton signals in the $^1H$ NMR spectra of **1** and **2** as well as the relatively high solubility of the new tetrapyrroles provide additional support for this thesis. An attempt to investigate this issue further by variable temperature NMR spectroscopy on **1** failed, however, because of severely overlapping resonances in the aliphatic region.

Metal coordination was studied using divalent metal acetates and excess base (sodium acetate, ammonia or sodium methoxide) in methanolic solution. Only zinc(II), copper(II), nickel(II) and palladium(II) yielded isolable complexes with **1** or **2** while no binding was observed for iron(II), manganese(II) and vanadyl(IV), and only decomposition products were detected after treatment with cobalt(II) acetate. The successful attempts are summarized in Scheme 2.



Scheme 2. Formation of nickel(II), palladium(II), zinc(II) and copper(II) chelates **9**–**13** from rotationally restricted 2,2′-bidipyrrins **1** and **2**.

The formation of nickel and palladium chelates **9** and **10** is easily monitored by an immediate colour change from dark green to brownish green and red, respectively, upon addition of metal acetate and sodium acetate to a solution of **1**. Isolation can be effected in good yields after chromatographic workup and recrystallization. As expected, the new complexes are of type **A** with a distorted square-planar arrangement of the *N* donors and therefore analogous to known nonbridged nickel- and palladium-2,2′-bidipyrrins of, for example, **8**.[12c,12d] Results from high-resolution mass spectrometry, NMR spectroscopy and UV/Vis measurements further support the assignments. In particular, the small high-field shift for the terminal methyl proton resonances at 2.44 (**9**) and 2.57 ppm (**10**) is a good indication for the strain, which is typically present at this position in helical dimethyl-2,2′-bidipyrrins of type **A**. In addition, the resonances of the *meso* protons are also detected high-field shifted at 6.24 (**9**) and 6.40 ppm (**10**). Unlike for the protonated **1** and **2**, the signals for the methylene protons of the $C_4$ bridge show sharp absorptions and indicate a rigid conformation of the eight-membered ring. The optical spectra of the nickel and palladium chelates **9** and **10** show two major absorptions at 430/530 or 430/520 nm, respectively, and are almost indistinguishable from those of their unrestrained analogues with ligand **8** (Figure 4).[12c,12d]

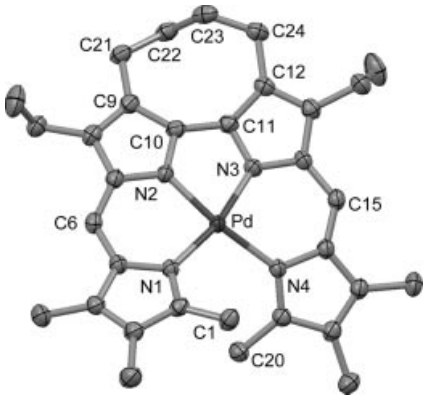


Figure 4. Molecular structure of **10**. Ellipsoids are set at 50% probability (hydrogen atoms omitted for clarity).

A detailed picture of the coordination and the degree of molecular distortion was derived from X-ray crystallographic work performed on the palladium derivative **10**. Suitable crystals were obtained by slow evaporation of a solution of **10** in dichloromethane/*n*-hexane. The compound crystallizes monoclinically in the space group $P2_1/n$ and forms green metallic plates. The molecular structure of **10** is given in Figure 4. Table 1 summarizes selected angles and distances.

The palladium(II) ion is coordinated to the four nitrogen donors of the 2,2′-bidipyrrin in a distorted square-planar fashion with Pd–N distances of 1.963(2)–2.071(2) Å. The *in-plane* distortion is mainly due to the presence of the bipyrrolic subunit, which allows an N2–Pd–N3 angle of only 78.32(9)°. More interestingly, the *out-of-plane* distortion caused by the close proximity of the terminal methyl groups C1 and C20 can be analyzed using different torsion angles. Values relevant for comparison are the torsion angles N2–C9–C10–N3, C8–C9–C10–C11 and C2–C10–C11–C19, which are found to be 11.8(3), 27.3(6) and 21.4(1)°, respectively, in **10**. These angles are reduced by 4.7, 7.3 and 6.3° with respect to the unconstrained $Pd^{II}$ chelate from ligand **8** and, in combination with the shorter C1–C20 distance of 3.217(4) Å (3.473 Å for Pd-**8**), a slight planarization of **10** becomes visible. The differences between the solid-state structures of **10** and the literature precedent, however, are quite small. In both cases the distances between the terminal methyl groups clearly undercut the sum of the *van der Waals* distances and prove the strained situation at these positions. The annelated eight-membered ring of **10** itself resides in a twist conformation, and no disorder is found in the crystal at this position (Figure 5).

The preparation of the zinc chelate **11** is straightforward. The action of sodium methoxide and excess zinc acetate on

[a] Unified numbering scheme used for all compounds, see Figure 5. [b] I and II correspond to crystallographically distinct helicates, a and b determine the respective BDP in each dimer. [c] Out-of-plane distance of the metal ion from the N1–N2–C6 or N3–N4–C15 plane.

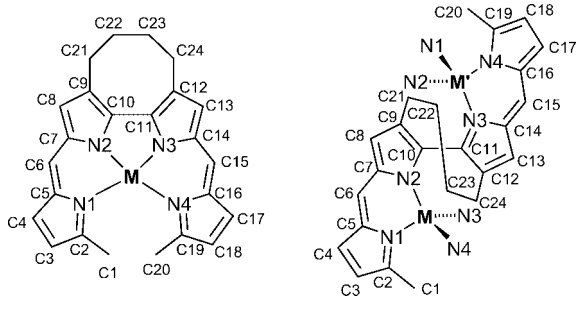

Figure 5. Unified numbering scheme used for the complexes and/or single-strand fragments of **10**, **11** and **13** in Figures 4, 6, 7, 9 and 10, and in Table 1.

ligand **2** in methanolic solution results in an immediate colour change from dark to light green. Because of the high solubility of the product **11** in most organic solvents the new complex can conveniently be isolated from this mixture by repeated pentane extraction, and forms green plates after crystallization. The results from mass spectrometry clearly point to the formation of a dinuclear zinc complex of type **C** with a complicated isotope pattern around *m*/*z* 1200. Proton NMR shows the formation of a symmetric compound, in which the terminal methyl proton signal is strongly shifted to high field with respect to **2** and can be observed as a singlet at $\delta$ = 1.66 ppm. The signal for the *meso* protons, however, appears at $\delta$ = 6.95 ppm without any significant shift (Figure 6).

For further characterization an X-ray crystallographic analysis was performed on **11**. Suitable green plates were obtained by slow evaporation of a solution of **11** in dichloromethane/*n*-hexane (1:3). Complex **11** crystallizes in the triclinic space group $P\bar{1}$. Two independent molecules I and II and their respective enantiomers are found in the unit cell. Multiple disorder was found for the orientation of nine ethyl substituents, which had to be refined with restraints. In addition, three of the four $C_4$ bridges are found to be strongly disordered and were refined assuming two conformations with occupancy factors for the atoms of concern of 0.5. Only data of molecule I will be discussed. Data for molecule II, however, are presented in Table 1 for comparison. The molecular structure of **11-I** is depicted in Figure 6. For the numbering scheme, see Figure 5.

The molecular structure of **11** shows a dinuclear double-stranded helicate with the zinc ions embedded in four N donor centres with a distorted tetrahedral geometry. Each zinc ion is coordinated to two N donor atoms of each 2,2′-

Ellipsoids are set at 40% probability.

bidipyrrin ligand. To allow the binding of two zinc centres to the same ligand the tetrapyrrole has to rotate around the central pyrrole–pyrrole bond C10–C11. The torsion at this position is, however, restricted to 41.3(6)/39.9(5) and 52.4(8)/51.0(7)° [N2–C10–C11–N3 and C9–C10–C11–C12 for the two strands of molecule I, respectively] by the annelated-eight membered ring, so that the ligand resides in the *syn-gauche* conformation with compressed $ZnN_4$ units. In the literature precedent of a nonrestrained dinuclear bidipyrrinato-helicate of zinc[7b] respective torsion angles are as large as 112.3 and 108.8° and indicate an *anti-gauche* conformation of the tetrapyrrole. The compression of the tetrahedral binding environment of the zinc ions in **11** can best be viewed by the dihedral angles between N1–Zn–N2 and N3–Zn–N4 planes, which should be 90° for a tetrahedron but range from 75.8 to 80.9° for **11**. The unrestrained analogue, on the other hand, shows an enlarged dihedral angle of 102.0°. The Zn–N distances of **11** [1.974(3)–2.030(4) Å] and the literature precedent (1.982–1.996 Å) do not differ much, but the zinc···zinc distance of **11** shrinks dramatically from 4.891 Å to 3.443 Å as a result of the backbone constraint. It should be noticed that the eight-membered rings do not form a single low-energy conformer but are found to reside either in a twist or boat conformation.[17]

The helicates of **11** arrange in pillars, which propagate along the crystallographic *b* axis (Figure 7). Next neighbours within these pillars are always of a different structure (i.e., molecule I next to molecule II and vice versa), and are alternately 10.116 and 10.149 Å apart from each other. With respect to the stereochemistry of the helicates, it is remarkable that only one enantiomeric form is contained in each chain, thus forming chiral *M*- or *P*-helical pillars. Heli-

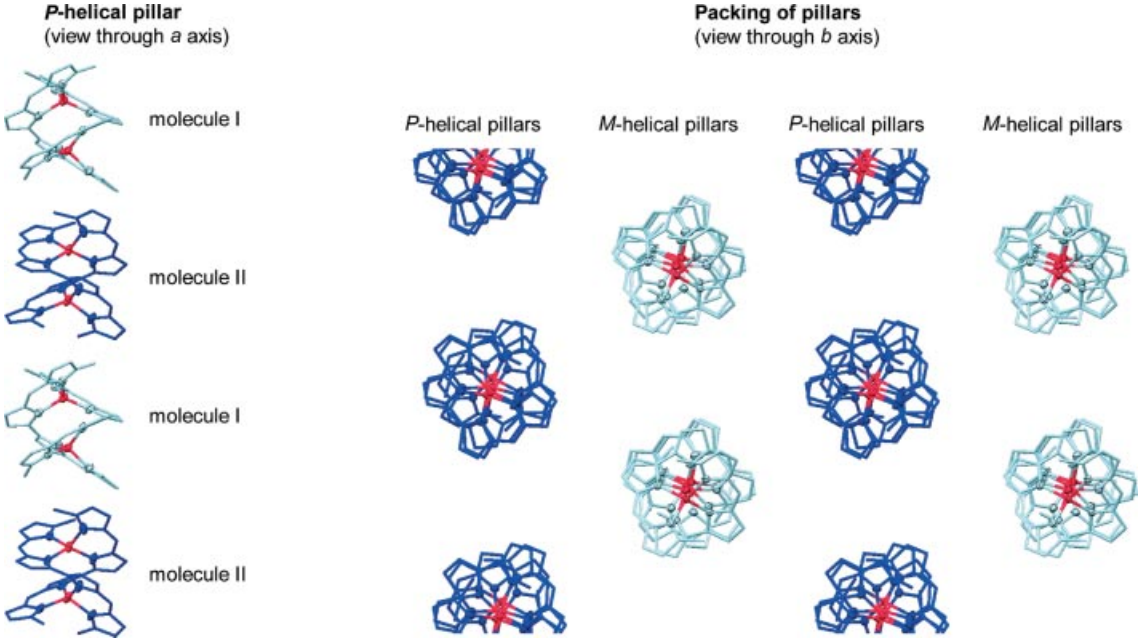

Figure 7. Packing of **11** in the crystal. Left side: *P*-helical pillar formed by the alternating arrangement of *P*-helical isomers of molecules I (bright) and II (dark). Right side: view along the pillars propagating in the crystallographic *b* axis (*P*-helices dark, *M*-helices bright). The ellipsoids are set at 40% probability. Alkyl side chains and hydrogen atoms removed for clarity.

cal pillars with both senses are then densely packed in the crystal as shown on the right in Figure 7.

Copper complexes of 2,2′-bidipyrrins usually form either in the type **A** or the type **C** structure, depending on the reaction conditions.[11f,12c] In this case, the outcome of the reaction of **1** and copper acetate depends critically on the choice of the added base. If concentrated ammonia is added to a mixture of **1** and excess copper(II) acetate in methanol, only the immediate formation of a brownish-red monomeric species **12** of type **A** is observed. Using sodium methoxide results in a mixture of **12** and some green dimeric species **13** of type **C**, which becomes the major component if only sodium acetate is added to absorb the released protons. In either case, however, the separation and isolation of **12** and **13** is quite simple because of their large differences in solubility. Monomeric **12** tends to crystallize almost quantitatively from methanolic solutions (up to 65% yield), while **13** is soluble even in cold pentane and can thus be conveniently extracted from the reaction mixtures and isolated in up to 54% yield. The compositions of both compounds were confirmed by combustion analysis and mass spectrometry.

EPR spectroscopy shows the expected signal for **12** in dichloromethane solution at ambient temperature with $g_{iso}$ = 2.096 and a quartet with $A_{Cu}$ = 82.1 G. This spectrum is identical to the one described before for the copper chelate of the unrestrained ligand **8**.[12c] Complex **13**, on the other hand, is EPR-silent under these conditions. As no well-resolved $^1$H NMR spectrum was observed, we conclude that the $Cu^{II}$ atoms of **13** are weakly antiferromagnetically coupled. The UV/Vis spectra of **12** and **13** are shown in Figure 8. Both are clearly governed by the π–π* transitions of their 2,2′-bidipyrrin ligands, which obviously change with different conformations.

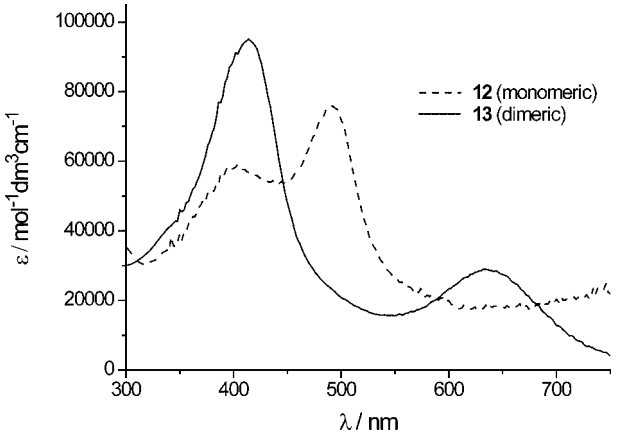

Figure 8. UV/Vis spectra ($CH_2Cl_2$, 293 K) of monomeric and dimeric copper(II) chelates **12** and **13**.

An X-ray crystallographic analysis shows that **13** resides in the assumed bishelical structure. The complex crystallized by slow evaporation of a solution of **13** in dichloromethane/pentane as a solvate **13**·$^1/_3C_5H_{12}$ in the orthorhombic system, space group *Pbcn*. Two independent molecules I and II and their respective enantiomers are found in the unit cell. Crystallographically molecule II as well as the solvent are situated on inversion centres, which explains the formula of the solvate. The eight-membered rings of molecule I and the solvent are disordered. Because of the severity of the disorder the solvent molecule was treated with the SQUEEZE command in Platon. The disorder of the eight-membered rings of molecule I is very severe, and the most disordered methylene groups had to be refined in two positions with occupancy factors of 0.5 (C22, C23) and 0.8422/0.1578 (C53, C54) and with additional restraints. Only the molecular parameters of molecule II (Figure 9) will be discussed further. Data for both molecules are presented in Table 1.

As for the zinc complex **11** shown above, the copper atoms of **13** are coordinated to both tetrapyrrole strands, which reside in a *syn-gauche* conformation with N2–C10–C11–N3 and C9–C10–C11–C12 torsion angles of 41.1(10) and 53.4(13)°, respectively, in order to accommodate two transition-metal ions. The copper $N_4$ coordination is again that of a compressed tetrahedron, which shows Cu–N bond lengths of 1.939(6)–1.999(6) Å and angles between the N1–Cu–N2 and N3–Cu–N4 planes of 65.18°, even smaller than those seen in **11**. The two copper(II) ions are located only 3.0123(13) Å apart from each other, so that a noticeable antiferromagnetic exchange interaction can be expected. This finding is in agreement with the EPR-silent character of **13**.

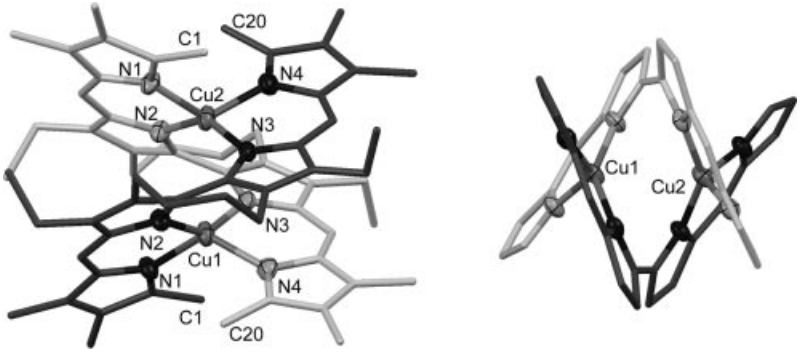

Figure 9. Molecular structure of **13**. Left side: *P* enantiomer of molecule II (carbon atoms as capped sticks and hydrogen atoms omitted for clarity); right side: view of the coordination environments of the copper ions (alkyl substituents and hydrogen atoms removed). Ellipsoids are set at 40% probability.

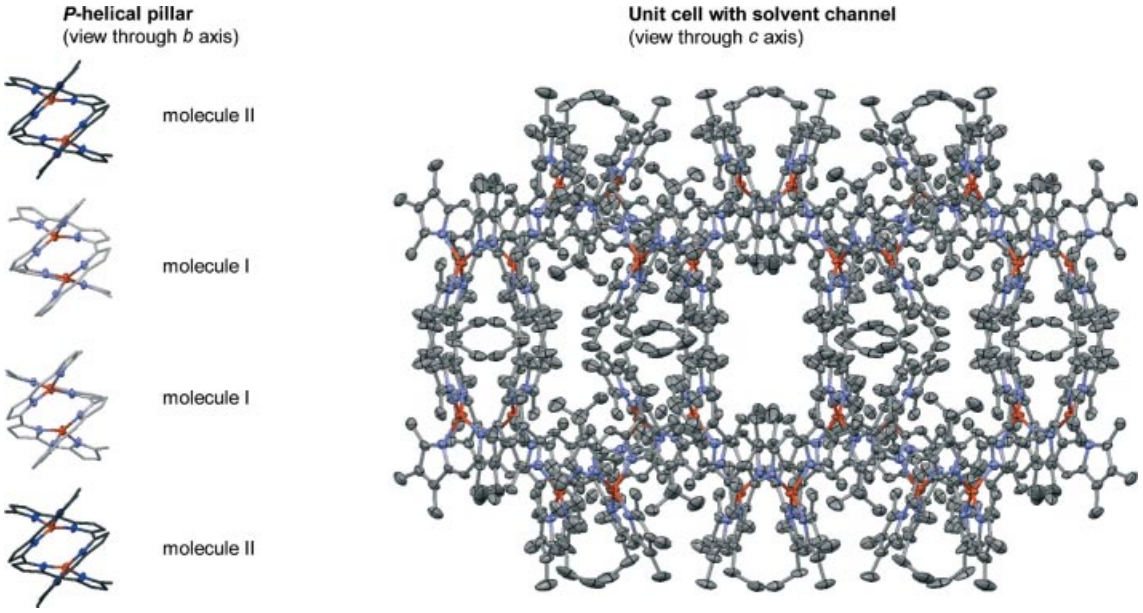

Figure 10. Packing of **13** in the crystal. Left side: *P*-helical pillar formed by *P*-helical isomers of molecule I (bright) and II (dark). Alkyl side chains and hydrogen atoms are removed for clarity. Right side: View down the solvent channel along the crystallographic *c* axis of the unit cell of **13** (solvent removed). The ellipsoids are set at 40% probability. Hydrogen atoms were removed for clarity.

The similarity between the solid-state structures of **11** and **13** comprises even the formation of enantiopure helical pillars from 1D strands of individual molecules, which are found along the crystallographic *a* axis in the crystal of **13**. The molecules are arranged in alternating distances of 9.628 and 11.124 Å (Figure 10). The obvious deviations of the packing pattern, however, originate from the differing sequences of molecules I and II within these strands, which are I – II – I – II for **11** but I – I – II – I – I – II for **13**. This nonalternating mode of the latter opens inner channels along the *c* axis (right in Figure 10), which are filled with disordered solvent molecules in order to stabilize the crystal lattice.

## Conclusions

In summary, we have prepared the first examples of conformationally restricted 2,2′-bidipyrrins **1** and **2** and described syntheses, spectroscopic properties and structural investigations for several transition-metal complexes of type **A** and type **C**. Concerning the coordination modes and binding abilities for different transition-metal ions, the constrained 2,2′-bidipyrrins **1** and **2** are amazingly similar to the unconstrained ones like **8**, although conformative differences in the molecular fine-tune have been shown by the crystallographic analyses. The aim of stabilizing labile ions in the 2,2′-bidipyrrin environment could not be achieved by this approach. However, structural information on dinuclear copper chelates of tetrapyrrolic ligands was obtained for the first time, and the unexpected finding of enantiopure 1D helical pillars for dinuclear complexes with short M···M distances points to further investigations into the use of such restricted ligands for anisotropic materials, metal-organic frameworks (MOFs) and the like.

## Experimental Section

**General:** All reagents and solvents were purchased from commercial sources and used as received. Bipyrrole diester **3**,[16] trimethylpyrrole **6**[18] and diethylmethylpyrrole **7**[19] were prepared as previously reported. NMR spectra were obtained with a Bruker AMX 400 spectrometer in the solvents indicated below. EPR spectra were measured with a Bruker ESP 300 instrument at X-band. Mass spectra were recorded with a Finnigan 90 MAT or a Micromass AutoSpec instrument. *m*/*z* values are given for the most abundant isotopes only. UV/Vis spectra were measured with a Hitachi U-3200 in the range 300–800 nm. Melting points were determined by DTA with a Thermoanalyzer DuPont 9000. For X-ray crystallographic measurements a Bruker Smart Apex with D8 goniometer was used.

CCDC-271753 to -271755 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.request/cif.

**Synthesis of 3,3′-(1,4-Butanediyl)-4,4′-diethyl-2,2′-bipyrrole-5,5′-dicarbaldehyde (5):** The bipyrrole diester **3** (6.95 g, 18.0 mmol) and sodium hydroxide (1.45 g, 36.0 mmol) were mixed with ethylene glycol (120 mL) and heated to reflux with good stirring and under strict exclusion of dioxygen and light for 2 h. Upon cooling in ice, a yellow, light-sensitive solid started to form. Degassed ice water (90 mL) was added dropwise at this temperature, and the solid was filtered, washed with additional water, and dried in the dark in high vacuo. The material was then dissolved in DMF (100 mL) with exclusion of air and moisture and cooled to 0 °C. At this temperature phosphoryl chloride (3.80 mL, 41.0 mmol) was added dropwise. Ten minutes after the addition, cooling was stopped and the mixture stirred at ambient temperature for another 2 h. The mixture was poured into water (400 mL) in an open flask, and a solution of sodium hydroxide in water (30%) was added, until a solid formed. This solid was filtered, washed carefully with water and dried in high vacuo to yield the title compound as a yellow powder. Yield 3.86 g (82%). M.p. 130 °C. $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.22 (t, 6 H, $J$ = 7.3 Hz, $CH_3CH_2$pyr), 1.81 (br. s, 4 H,

C$H_2$CH$_2$pyr), 2.75–2.70 (m, 8 H, CH$_2$C$H_2$pyr and CH$_3$C$H_2$pyr), 9.65 (br. s, 2 H, CHO), 11.56 (br. s, 2 H, NH) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 17.0, 17.1, 21.9, 26.5, 124.4, 129.3, 130.0, 138.9, 177.4 ppm. HRMS (ESI) calcd. for $C_{18}H_{22}N_2O_2$: 298.1681; obsd. 298.1672, $\Delta$ = 0.9 mmu. $C_{18}H_{22}N_2O_2$ (298.38): calcd. C 72.46, H 7.43, N 9.39; found C 72.39, H 7.26, N 9.45.

**Synthesis of 3,3′-(1,4-Butanediyl)-4,4′-diethyl-8,8′,9,9′,10,10′-hexamethyl-2,2′-bidipyrrin (1) as Bis(hydroperchlorate):** A suspension of **5** (100 mg, 0.33 mmol) and 2,3,4-trimethylpyrrole (**6**) (80 mg, 0.74 mmol) in methanol (5 mL) was heated to 60 °C. At this temperature perchloric acid (1 mL of a 70% solution in water) was added at once and heating was discontinued. The colour of the mixture changed immediately to dark green. The product crystallized upon cooling in ice as a dark solid, which was filtered, washed with small portions of ice-cold methanol, and dried in vacuo to yield a green solid. Yield 123 mg (50%). M.p. 151 °C (dec.). $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.19 (t, 6 H, $J$ = 7.3 Hz, C$H_3$CH$_2$pyr), 1.80 (m, 4 H, C$H_2$CH$_2$pyr), 2.00, 2.25 (2×s, 12 H, 2×C$H_3$pyr), 2.58–2.73 (m, 8 H, CH$_2$C$H_2$pyr and CH$_3$C$H_2$pyr), 2.76 (s, 6 H, *term*-CH$_3$), 7.06 (s, 2 H, *meso*-H), 11.47 (br. s, 2 H, NH), 12.23 (br. s, 2 H, NH) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 9.2, 10.4, 14.0, 16.2, 18.2, 22.6, 26.1, 118.9, 127.7, 128.9, 129.6, 131.7, 137.1, 143.5, 144.9, 161.7 ppm. MS (FAB): 481 [M – ($HCl_2O_8$)]$^+$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 330 (23000), 435 (27000), 565 (36000) nm. $C_{32}H_{42}Cl_2N_4O_8 \cdot 3H_2O$ (735.649): calcd. C 52.25, H 6.58, N 7.62; found C 52.39, H 6.56, N 7.85.

**Synthesis of 3,3′-(1,4-Butanediyl)-4,4′,8,8′,9,9′-hexaethyl-10,10′-dimethyl-2,2′-bidipyrrin (2) as Bis(hydroperchlorate):** Complex **2** was prepared from **3** (100 mg, 0.33 mmol) and 3,4-diethyl-2-methylpyrrole (**7**) (100 mg, 0.74 mmol) as described above for **1** and yielded a brown-violet powder. Yield 128 mg (48%). M.p. 236 °C (dec.). $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 1.17, 1.25, 1.27 (6×t, 18 H, $J$ = 7.3 Hz, C$H_3$CH$_2$pyr), 1.86 (m, 4 H, C$H_2$CH$_2$pyr), 2.54 (q, 4 H, $J$ = 7.3 Hz, CH$_3$C$H_2$pyr), 2.68–2.82 (m, 12 H, CH$_2$C$H_2$pyr and CH$_3$C$H_2$pyr), 2.73 (s, 6 H, *term*-CH$_3$), 7.25 (s, 2 H, *meso*-H), 10.55 (br. s, 2 H, NH), 11.17 (br. s, 2 H, NH) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 13.7, 14.4, 15.9, 16.6, 17.0, 17.4, 18.4, 22.6, 26.2, 119.2, 129.3, 130.4, 131.3, 133.8, 137.2, 145.8, 150.4, 162.5 ppm. MS (FAB): 537 [M – ($HCl_2O_8$)]$^+$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 330 (24000), 430 (27000), 565 (37000) nm. $C_{36}H_{50}Cl_2N_4O_8 \cdot H_2O$ (755.725): calcd. C 57.22, H 6.94, N 7.41; found C 57.35, H 6.66, N 7.42.

**Synthesis of 3,3′-(1,4-Butanediyl)-4,4′-diethyl-8,8′,9,9′,10,10′-hexamethyl-2,2′-bidipyrrinatonickel(II) (9):** A solution of nickel acetate tetrahydrate (50 mg, 0.20 mmol) in methanol (3 mL) was added to a suspension of **1** (100 mg, 0.15 mmol) and sodium acetate (100 mg, 1.21 mmol) in methanol (10 mL) and the resulting mixture was stirred for 30 min at ambient temperature. The solvent was removed in vacuo, and the residue was purified by silica chromatography with dichloromethane/*n*-hexane (1:1). The greenish-brown fraction was collected and the solvent was removed to yield **9** as a violet solid. Yield 44 mg (54%). M.p. 239 °C. $^1$H NMR (400 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.10 (t, 6 H, $J$ = 7.3 Hz, C$H_3$CH$_2$pyr), 1.39 (s, 6 H, CH$_3$pyr), 1.58–1.54 (m, 2 H, C$H_2$CH$_2$pyr), 1.66 (s, 6 H, CH$_3$pyr), 1.85–1.75 (m, 2 H, C$H_2$CH$_2$pyr), 2.20–2.52 (m, 8 H, CH$_2$C$H_2$pyr and CH$_3$C$H_2$pyr), 2.44 (s, 6 H, *term*-CH$_3$), 6.24 (s, 2 H, *meso*-H) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $C_6D_6$, 25 °C): $\delta$ = 9.3, 9.7, 16.3, 17.9, 18.4, 25.2, 26.6, 120.2, 125.1, 126.2, 133.8, 138.8, 140.8, 141.9, 152.1, 168.4 ppm. HRMS (ESI) calcd. for $C_{32}H_{38}N_4Ni$: 536.24498; obsd. 536.24629, $\Delta$ = 1.31 mmu. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 350 (20000), 430 (81000), 530 (18000), 610sh (12000) nm. $C_{32}H_{38}N_4Ni$ (537.364): calcd. C 71.52, H 7.13, N 10.43; found C 71.13, H 6.96, N 10.09.

**Synthesis of 3,3′-(1,4-Butanediyl)-4,4′-diethyl-8,8′,9,9′,10,10′-hexamethyl-2,2′-bidipyrrinatopalladium(II) (10):** A solution of palladium acetate (59 mg, 0.26 mmol) in methanol (5 mL) was added to a suspension of **1** (180 mg, 0.26 mmol) and sodium acetate (100 mg, 1.21 mmol) in methanol (10 mL) and the resulting mixture was stirred for 30 min at ambient temperature. The solvent was removed in vacuo, and the residue was purified by radial chromatography on silica with dichloromethane/*n*-hexane (1:1). The deep red fraction was collected, the solvent was removed and the residue was recrystallized from dichloromethane/*n*-hexane (1:2) to yield **10** as brownish-red crystals. Yield 94.0 mg (62%). M.p. 202 °C. $^1$H NMR (400 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.12 (t, 6 H, $J$ = 7.3 Hz, C$H_3$CH$_2$pyr), 1.52 (s, 6 H, C$H_3$pyr), 1.71–1.75 (m, 2 H, C$H_2$CH$_2$pyr), 1.77 (s, 6 H, C$H_3$pyr), 1.81–1.86 (m, 2 H, C$H_2$CH$_2$pyr), 2.35–2.41 (m, 6 H, CH$_2$C$H_2$pyr and CH$_3$C$H_2$pyr), 2.54–2.61 (m, 2 H, CH$_2$C$H_2$pyr), 2.57 (s, 6 H, *term*-CH$_3$), 6.40 (s, 2 H, *meso*-H) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $C_6D_6$, 25 °C): $\delta$ = 9.6, 9.9, 16.8, 17.0, 18.1, 22.7, 27.6, 120.6, 124.8, 126.8, 132.4, 138.1, 138.2, 142.0, 151.6, 165.4 ppm. HRMS (ESI) calcd. for $C_{32}H_{38}N_4Pd$: 584.21311; obsd. 584.21205, $\Delta$ = 1.06 mmu. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 430 (82000), 520 (32000), 770 (11000) nm. $C_{32}H_{38}N_4Pd$ (585.09): calcd. C 65.69, H 6.55, N 9.58; found C 65.42, H 6.41, N 9.37.

**Crystallographic Data for 10:** $C_{32}H_{38}N_4Pd$, green plates obtained by slow concentration of a $CH_2Cl_2$/*n*-hexane solution, crystal size: 0.40 × 0.40 × 0.30 mm, monoclinic, space group $P2_1/n$, $a$ = 8.8497(10), $b$ = 24.160(3), $c$ = 12.8685(14) Å, $\beta$ = 98.421(2)°, $V$ = 2721.7(5) Å$^3$, $\rho_{calcd.}$ = 1.428 g cm$^{-3}$, $Z$ = 4, $2\theta_{max}$ = 50°, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, scan mode: $\omega$-scans, $T$ = 193(2) K, 31431 measured, 4798 independent reflections, 4620 reflections observed for $I > 2\sigma(I)$, $\mu$ = 0.710 mm$^{-1}$, solved by Patterson method, refined with full-matrix least-squares on $F^2$ [20], 342 parameters, H atoms refined with isotropic temperature factors. $R$ = 0.0340, $wR$ = 0.0821, residual electron density $\rho$ = 0.730/–0.313 e Å$^{-3}$.

**Bis[3,3′-(1,4-butanediyl)-4,4′,8,8′,9,9′-hexaethyl-10,10′-dimethyl-2,2′-bidipyrrinatozinc(II)] (11):** A suspension of **2**·2HClO$_4$ (85.0 mg, 0.11 mmol) and sodium methoxide (54 mg, 1.0 mmol) in methanol (5 mL) is stirred for 5 min. Zinc acetate hydrate (39 mg, 0.18 mmol) is then added at once, and the solution turns to dark green. After 30 min at ambient temperature the solvent is removed in vacuo, and the dark residue is extracted into pentane. The product is purified by alumina chromatography (basic alumina I) with dichloromethane/*n*-hexane (1:1), and the intense green main fraction is collected. Crystallization from dichloromethane/*n*-hexane (1:3) yields **11** as bronze-coloured plates. Yield 55.0 mg (84%). $^1$H NMR (400 MHz, $C_6D_6$, 25 °C): $\delta$ = 0.96 (t, 12 H, $J$ = 7.4 Hz, C$H_3$CH$_2$pyr), 1.22 (t, 12 H, $J$ = 7.4 Hz, C$H_3$CH$_2$pyr), 1.24 (t, 12 H, $J$ = 7.3 Hz, C$H_3$CH$_2$pyr), 1.32–1.40 (m, 16 H, C$H_2$CH$_2$pyr and CH$_2$C$H_2$pyr), 1.66 (s, 12 H, *term*-CH$_3$), 2.10–2.31 (m, 8 H, CH$_3$C$H_2$pyr), 2.51–2.61 (m, 16 H, CH$_3$C$H_2$pyr), 6.95 (s, 4 H, *meso*-H) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $C_6D_6$, 25 °C): $\delta$ = 14.3, 14.4, 15.7, 17.9, 18.5, 23.0 29.8, 30.1, 32.3, 120.3, 130.0, 137.8, 141.2, 143.5, 150.9, 159.7 ppm; the signals four two C(sp$^2$) atoms are probably hidden underneath the solvent signal. HRMS (ESI) calcd. for $C_{72}H_{92}N_8Zn_2$: 1196.60275; obsd. 1196.60215, $\Delta$ = 0.60 mmu. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 360 (52000), 475 (138000), 620 (48000) nm. $C_{72}H_{92}N_8Zn_2$ (1200.33): calcd. C 72.04, H 7.73, N 9.34; found C 71.72, H 7.39, N 9.05.

**Crystallographic Data for 11:** $C_{72}H_{92}N_8Zn_2$, green plates obtained by slow concentration of a $CH_2Cl_2$/*n*-hexane solution, crystal size:

$0.20 \times 0.18 \times 0.17$ mm, triclinic, space group $P\bar{1}$, $a$ = 14.0038(16), $b$ = 20.206(2), $c$ = 24.556(3) Å, $\alpha$ = 72.719(2), $\beta$ = 84.446(2), $\gamma$ = 78.961(2)°, $V$ = 6505.9(13) Å$^3$, $\rho_{calcd.}$ = 1.225 g cm$^{-3}$, $Z$ = 4, $2\theta_{max}$ = 56.532°, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, scan mode: $\omega$-scans, $T$ = 153(2) K, 45469 measured, 22898 independent reflections, 17802 reflections observed for $I > 2\sigma(I)$, $\mu$ = 0.785 mm$^{-1}$, solved by Patterson method, refined with full-matrix least-squares on $F^2$ [20], 1638 parameters and 107 restraints, H atoms refined with isotropic temperature factors. $R$ = 0.0607, $wR$ = 0.1783, residual electron density $\rho$ = 0.969/–0.641 e Å$^{-3}$.

**3,3′-(1,4-Butanediyl)-4,4′-diethyl-8,8′,9,9′,10,10′-hexamethyl-2,2′-bidipyrrinatocopper(II) (12):** A suspension of **1**·2HClO$_4$ (50 mg, 0.07 mmol) in methanol (4 mL) was treated with a solution of copper acetate hydrate (20.0 mg, 0.10 mmol) in ammonia (1 mL of a conc. solution in water) at once. The colour immediately changed from dark green to brown. After 5 min the precipitated product was filtered off and washed with methanol. The solid was extracted with dichloromethane, again filtered, and the solution evaporated in vacuo to leave the title compound as a brown solid. Yield 25.0 mg (65%). M.p. 150 °C. EPR (293 K, $CH_2Cl_2$): $g_{iso}$ = 2.096, $A_{Cu}$ = 82.1 G. MS (FAB): 541 ($M^+$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 405 (57000), 495 (76000) nm. $C_{32}H_{38}CuN_4$ (542.217): calcd. C 70.88, H 7.06, N 10.33; found C 70.88, H 7.20, N 10.51.

**Bis[3,3′-(1,4-butanediyl)-4,4′-diethyl-8,8′,9,9′,10,10′-hexamethyl-2,2′-bidipyrrinatocopper(II)] (13):** A suspension of **1**·2HClO$_4$ (50 mg, 0.07 mmol) and sodium acetate (40.0 mg, 0.48 mmol) in methanol (4 mL) was treated with a solution of copper acetate hydrate (20.0 mg, 0.10 mmol). The mixture turned brown, then dark green after 1 min of stirring. After 1 h at ambient temperature the solvent was removed in vacuo and the residue was extracted with pentane. Evaporation of the solvent yielded the title compound as a dark green powder. Yield 20.0 mg (54%). M.p. 108 °C (dec.). HRMS (ESI) calcd. for $C_{64}H_{76}Cu_2N_8$: 1082.47846; obsd. 1082.47874, $\Delta$ = 0.28 mmu. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 410 (94000), 630 (29000) nm. $C_{64}H_{76}Cu_2N_8$ (1084.434): calcd. C 70.88, H 7.06, N 10.33; found C 70.55, H 6.87, N 10.01.

**Crystallographic Data for 13:** $C_{64}H_{76}N_8Cu_2$, red cubes obtained by slow concentration of a $CH_2Cl_2$/pentane solution, crystal size: $0.27 \times 0.17 \times 0.15$ mm, orthorhombic, space group *Pbcn*, $a$ = 30.3691(19), $b$ = 25.1323(16), $c$ = 22.6084(14) Å, $V$ = 17255.8(19) Å$^3$, $\rho_{calcd.}$ = 1.251 g cm$^{-3}$, $Z$ = 8, $2\theta_{max}$ = 56.488°, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, scan mode: $\omega$-scans, $T$ = 173(2) K, 243067 measured, 15182 independent reflections, 12807 reflections observed for $I > 2\sigma(I)$, $\mu$ = 0.786 mm$^{-1}$, solved by direct methods, refined with full-matrix least-squares on $F^2$ [20], 1061 parameters and 74 restraints, H atoms refined with isotropic temperature factors. $R$ = 0.1130, $wR$ = 0.2517, residual electron density $\rho$ = 1.111/–0.642 e Å$^{-3}$.

# *m*-Terphenylaluminum and -gallium Compounds: Synthesis and Conversion into Low-Coordinate Organogallium Cations

**Jackie D. Young,[a] Masood A. Khan,[a] Douglas R. Powell,[a] and Rudolf J. Wehmschulte*[b]**

**Keywords:** Aluminum / Cations / Gallium / Lewis acids / Low coordination

The reaction of two or 3 equiv. of *m*-terphenyllithium with $MCl_3$ or $AlH_3{\cdot}NMe_3$ (M = Al, Ga) affords the bis(terphenyl)-aluminum and -gallium chloride compounds [{2,6-(4-*t*$BuC_6H_4)_2C_6H_3$}$_2$GaCl] (**1**), [{2,6-(3,5-$Me_2C_6H_3)_2C_6H_3$}$_2$GaCl] (**2**), [{2,6-(4-*t*$BuC_6H_4)_2C_6H_3$}$_3$Ga] (**3**), [(2,6-$Mes_2C_6H_3)_2$AlCl] (**5**), and [(2,6-$Mes_2C_6H_3)_2$AlH] (**7**; Mes = 2,4,6-$Me_3C_6H_2$). While the gallium compounds can be obtained at room temperature, heating is required for the aluminum derivatives. The dibutyl compounds [(2,6-$Mes_2C_6H_3$)$GaBu_2$] (**8**) and [(2,6-$Dipp_2C_6H_3$)$GaBu_2$] (**9**; Dipp = 2,6-*i*$Pr_2C_6H_3$) have also been synthesized by the reaction of *m*-terphenyllithium with $ClGaBu_2$. A metathesis reaction of **2** with Li[Al{$OCH(CF_3)_2$}$_4$] gives the ionic species [(2,6-$Mes_2C_6H_3)_2$Ga]$^+$[Li{Al-[$OCH(CF_3)_2$]$_4$}$_2$]$^-$ (**11**). The cationic butyl(terphenyl)gallium compounds [(2,6-$Mes_2C_6H_3$)GaBu]$^+$ ([**13**]$^+$) and [(2,6-$Dipp_2C_6H_3$)GaBu]$^+$ ([**14**]$^+$) have been prepared by butanide abstraction with the trityl salts of the weakly coordinating anions $[B(C_6F_5)_4]^-$, $[CHB_{11}Br_6Me_5]^-$, and $[CHB_{11}Cl_{11}]^-$. These ionic species are stable at room temperature for days or weeks, although their combinations with the borate anion $[B(C_6F_5)_4]^-$ suffer from $C_6F_5$ migration, which is slow at room temperature and faster at elevated temperatures. The compound [**14**]$^+[CHB_{11}Cl_{11}]^-$ is stable at 70 °C for at least 23 h. Addition of 1-octene to a solution of [**14**]$^+[CHB_{11}Cl_{11}]^-$ in $C_6D_6$ results in olefin exchange and formation of the octyl species [(2,6-$Dipp_2C_6H_3$)Ga(octyl)]$^+$ ([**17**]$^+$), and a slow alkylation of the solvent to afford various octylbenzenes. Hydrolysis of **8** and [**13**]$^+[CHB_{11}Br_6Me_5]^-$ gives the compounds [{(2,6-$Mes_2C_6H_3$)GaBu(μ-OH)}$_2$] (**10**) and [$(BuGa)_4$(μ-$OH)_6$]$^{2+}[CHB_{11}Br_6Me_5]^-_2$ (**16**). All compounds have been characterized by $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy and mass spectrometry, and compounds **3**, **5**, **7**, **10**, and **16**·4.5$C_6H_6$ have also been characterized by single-crystal X-ray crystallography.

## Introduction

The enormous progress in the development of weakly coordinating anions during the past 10–15 years has invigorated the research of previously inaccessible, often highly reactive, cationic species.[1–4] Some recent examples in main group chemistry include a three-coordinate stannylium cation [$(Trip)_3Sn$]$^+$ (Trip = 2,4,6-*i*$Pr_3C_6H_2$),[5] two-coordinate gallium and aluminum cations [(2,6-$Mes_2C_6H_3)_2M$]$^+$ (M = Ga,[6] Al;[7] Mes = 2,4,6-$Me_3C_6H_2$), monosubstituted group 14 cations [Cp*Si]$^+$[8] and [(2,6-$Trip_2C_6H_3$)Pb]$^+$,[9] or the interesting phosphorus-based cations $[P_2X_5]^+$ and $[P_5X_2]^+$.[10] On the more applied side, there have been several studies of the potential of low-coordinate cationic organoaluminum compounds as catalysts for olefin oligomerization and polymerization.[11–14] Three-coordinate species have been obtained using monoanionic bidentate ligands,[15,16] and quasi-two-coordination has been achieved by employing two large *m*-terphenyl substituents at a single cationic aluminum center.[7] In an effort to increase the reactivity of the cationic species, we have begun to investigate methods to achieve two-coordination that do not rely on excessive steric protection, which tends to decrease and change reactivity patterns. Based on the observed close secondary Al···C contacts in [(2,6-$Mes_2C_6H_3)_2$Al]$^+$ involving the *ipso*- and *ortho*-carbon atoms of the flanking mesityl groups,[7] we speculate that a single *m*-terphenyl substituent in conjunction with the least-coordinating anions should be sufficient for the stabilization of a low-coordinate cationic center. The bulky substituents are expected to prevent close anion···cation contacts such as those observed in [$Et_2Al$]-[$CB_{11}H_6X_6$] (X = Cl, Br)[13] and to stabilize the electron-poor center through secondary M···C contacts. Ideally, the internal stabilization would be sufficiently labile to allow facile cation···substrate interactions (Scheme 1).

Here, we report the synthesis of a series of terphenylaluminum and -gallium precursor molecules and the conversion of a selection of these into cationic species.

## Results and Discussion

A series of mono- and diterphenylgallium halides and alkyl derivatives has been prepared from standard organo-

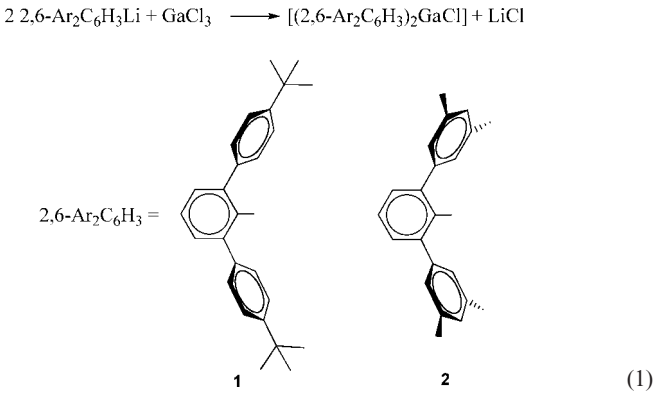
M = Al, Ga; R = alkyl; L = Lewis base, olefin

Scheme 1.

metallic procedures.[17] Selected examples have been converted into cationic species either by salt elimination or alkanide abstraction. Most of the latter reactions were performed on a small (ca. 50 μmol) scale, and the products were characterized by multinuclear NMR spectroscopy and mass spectrometry.

### Diterphenylgallium Compounds

The diterphenylgallium chloride species [{2,6-(4-$t$BuC$_6$H$_4$)$_2$C$_6$H$_3$}$_2$GaCl] (**1**) and [{2,6-(3,5-Me$_2$C$_6$H$_3$)$_2$-C$_6$H$_3$}$_2$GaCl] (**2**) were obtained in moderate yields by the metathesis reaction of 2 equiv. of the coresponding terphenyllithium compound with $GaCl_3$ at room temperature in hexane solution according to Equation (1). Compounds **1** and **2** were isolated as colorless microcrystalline solids that are readily soluble in aromatic solvents or $CH_2Cl_2$ but practically insoluble in hexanes. The synthesis of **1** under slightly different conditions and its X-ray crystal structure have been reported independently.[18] Crystals of **1** obtained from toluene solution are essentially identical to those crystallized from $Et_2O$ solution described by Robinson et al. after taking low-temperature effects in the present data set into consideration.[18]



(1)

### Triterphenylgallium

The very crowded compound [{2,6-(4-$t$BuC$_6$H$_4$)$_2$-C$_6$H$_3$}$_3$Ga] (**3**) was initially obtained in small amounts during an attempt to prepare the methyl derivative [{2,6-(4-$t$BuC$_6$H$_4$)$_2$C$_6$H$_3$}$_2$GaMe] by methylation of **1** with methyllithium. Ligand migration in arylgallium compounds is not uncommon and has been described previously.[17] The systematic reaction involving 3 equiv. of 2,6-(4-$t$BuC$_6$H$_4$)$_2$-C$_6$H$_3$Li gave **3** in 34% yield as a colorless, high-melting (m.p. 281 °C), crystalline solid. Its structure (Figure 1) features a slightly distorted trigonal-planar gallium center [Σ(C–Ga–C) = 359.3°] that is efficiently protected by three *m*-terphenyl substituents. The Ga–C bond lengths [1.989(2)–2.010(2) Å] fall within the upper range observed previously for diterphenylgallanes.[18–21] The slightly elongated Ga(1)–C(16) bond [2.010(2) Å] and the corresponding widening of the C(38)–Ga(1)–C(68) angle to 122.57(10)° may be attributed to the steric demands of the *m*-terphenyl substituents. The substituents are arranged in the typical propeller fashion,[18,22,23] and the planes of the central arene rings are rotated out of the $GaC_3$ plane by 39° [C(38) ring], 47° [C(16) ring], and 64° [C(68) ring]. Some minor distortions are found for the C(38) substituent. The central C(38) ring is bent away from the normal linear arrangement by 18.6°, as judged from the angle between the Ga(1)–C(38) and C(38)–C(41) vectors. Similarly, there is a 6.6° angle between the C(39)–C(43) and C(43)–C(46) vectors of the flanking C(43) ring. The shortest C···C contacts between neighboring arene rings are 3.22 Å for C(38)···C(18) and 3.24 Å for C(16)···C(70). Overall, the structure of **3** bears close resemblance to that of the indium analogue [{2,6-(4-$t$BuC$_6$H$_4$)$_2$C$_6$H$_3$}$_3$In].[18]

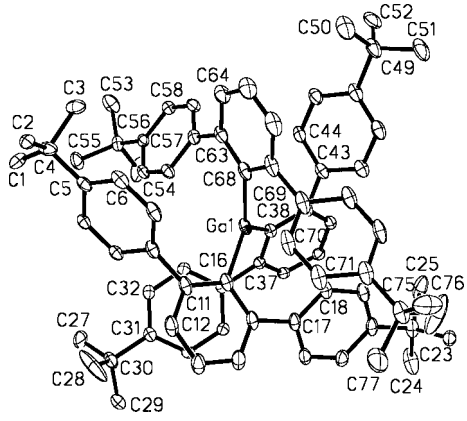


Figure 1. Thermal ellipsoid plot (50% probability ellipsoids) showing the molecular structure of **3**. Hydrogen atoms have been omitted for clarity.

### Diterphenylaluminum Compounds

Whereas the synthesis of the di- and triterphenylgallium compounds **1**–**3** as well as the more crowded species [(2,6-Mes$_2$C$_6$H$_3$)$_2$GaCl][24] (**4**) proceeds at room temperature, the preparation of the aluminum analogue [(2,6-Mes$_2$C$_6$H$_3$)$_2$-AlCl] (**5**) was complicated by the formation of a stable intermediate tentatively characterized as the alanate [(2,6-Mes$_2$C$_6$H$_3$)AlCl$_3$]Li. A closely related compound has been previously observed in the reaction of 2,6-Mes$_2$C$_6$H$_3$Li with $AlBr_3$.[25] The reaction of 2 equiv. of 2,6-Mes$_2$C$_6$H$_3$-

Li with $AlCl_3$ at room temperature for 20 h resulted in the formation of a new *m*-terphenyl compound (the alanate) and unreacted 2,6-$Mes_2C_6H_3Li$ in an approximately 1:1 ratio according to $^1H$ NMR spectroscopy. The introduction of the second terphenyl substituent requires refluxing in benzene solution. Inadvertent Al–C bond hydrolysis during reflux reduced the yield significantly, and it was difficult to isolate pure **5**. Its crystal structure (Figure 2) is isostructural with that of the gallium congener,[24] but features a significantly shorter Al–Cl bond with a value of 2.1098(12) Å [2.177(5) Å for **4**], which indicates the higher Lewis acidity of aluminum. The Al–C bond lengths, with average values of 1.978 Å, are identical with the Ga–C distances observed for **4**. The shorter Al–Cl distance results in a slight decrease of the C–M–C angle from 153.5(5)° in **4** to 147.52(13)°. Evidence for the steric crowding brought about by two large *m*-terphenyl substituents is apparent in some distortions. For example, as in **3**, the central rings of the substituents are bent away from the ideal linear alignment by 16.2° [C(15) ring] and 12.9° [C(39) ring]. Furthermore, the flanking mesityl groups are pushed out of the plane of the C(15) ring by 12.8° [C(9) mesityl] and 10.4° [C(16) mesityl].

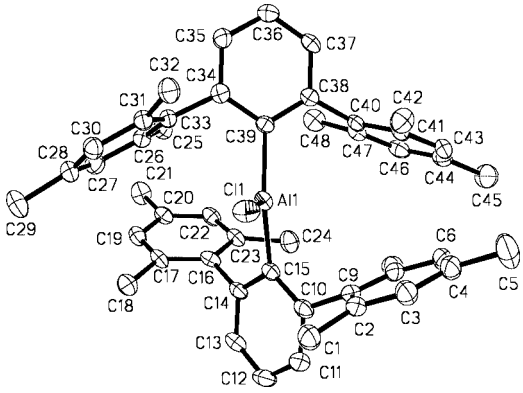

Figure 2. Thermal ellipsoid plot (50% probability ellipsoids) showing the molecular structure of **5**. Hydrogen atoms have been omitted for clarity.

The hydride derivative [(2,6-$Mes_2C_6H_3)_2GaH$] (**6**) has been prepared by the reaction of the chloride **4** with LiHBEt$_3$.[21] Because **5** could only be isolated in moderate yields, a different route was selected for the preparation of the aluminum hydride [(2,6-$Mes_2C_6H_3)_2AlH$] (**7**). Thus, reaction of 2,6-$Mes_2C_6H_3Li$ with [(2,6-$Mes_2C_6H_3)AlH_2$]·$OEt_2$[26] [Equation (2)] at 70 °C for 30 min afforded **7** in moderate to good yields in the form of well-shaped colorless crystals.[7]

$$2,6\text{-}Mes_2C_6H_3Li + [(2,6\text{-}Mes_2C_6H_3)AlH_2]\cdot OEt_2 \longrightarrow [(2,6\text{-}Mes_2C_6H_3)_2AlH] + LiH \quad (2)$$

**7**

Compound **7** is only the second example of an aluminum hydride that is three-coordinate in the solid state.[27] Similar to [Mes*$_2$AlH][27] (Mes* = 2,4,6-$tBu_3C_6H_2$), the monomeric character of **7** is also due to steric protection, as can clearly be seen in the crystal structure (Figure 3). The overall structural features are similar to those of **5** and **6**, although the distortions are less pronounced than in the structure of **5**. The Al–H distance is 1.436(18) Å and the Al–C distances average 1.990 Å. As was found for the corresponding gallium compounds **4** and **6**, the C–Al–C angle in **7**, with a value of 137.62(5)°, is also significantly smaller than in the chloride **5** [147.52(13)°, see above]. The terphenyl substituents display a staggered arrangement with respect to each other to minimize steric repulsion. The angles between the Al(1)–C(15) and C(15)–C(12) vectors and the Al(1)–C(39) and C(39)–C(36) vectors are 11.7° and 12.8°, respectively, and there are only minor distortions within the terphenyl substituents, thus indicating less steric crowding than for **5**.

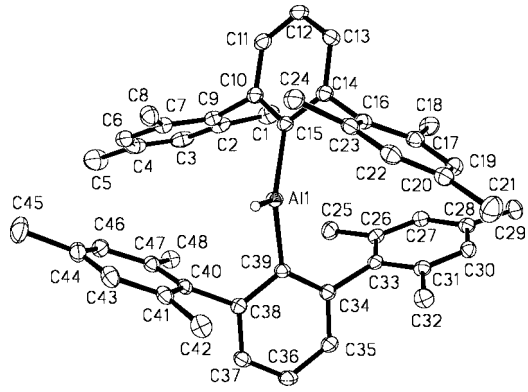

Figure 3. Thermal ellipsoid plot (50% probability ellipsoids) showing the molecular structure of **7**. Hydrogen atoms, with the exception of the hydrogen atom bound to the aluminum atom, have been omitted for clarity.

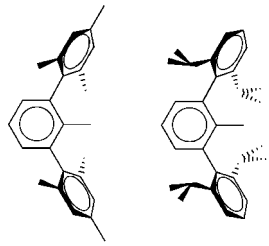
### Dibutylgallium Compounds

The dibutyl(terphenyl)gallanes [(2,6-$Mes_2C_6H_3)GaBu_2$] (**8**) and [(2,6-$Dipp_2C_6H_3)GaBu_2$] (**9**) (Dipp = 2,6-*i*$Pr_2C_6H_3$) were synthesized by the reaction of terphLi with $ClGaBu_2$ [Equation (3)].

$$2,6\text{-}Ar_2C_6H_3Li + ClGaBu_2 \longrightarrow [(2,6\text{-}Ar_2C_6H_3)GaBu_2] + LiCl \quad (3)$$

2,6-$Ar_2C_6H_3$ =



**8** **9**

The presence of the flexible *n*-butyl groups apparently prevents the formation of crystals of sufficient quality for X-ray diffraction. In fact, **8** could only be obtained as fine colorless needles, and **9** was initially isolated as a colorless oil, which eventually solidified after a month at room temperature. Despite several attempts, compounds **8** and **9**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

could not be obtained analytically pure. Both compounds are readily soluble in aliphatic and aromatic solvents. Their composition was confirmed by $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy as well as the isolation of a hydrolysis product of **8**, namely $[\{(2,6\text{-}Mes_2C_6H_3)GaBu(\mu\text{-}OH)\}_2]$ (**10**). The latter compound was isolated during an attempt to grow X-ray quality crystals by slow concentration of a 1-octene solution of **8** inside a dry box. Its structure (Figure 4) closely resembles those of the related dimeric hydroxy-bridged compounds $[\{(2,6\text{-}Mes_2C_6H_3)GaMe(\mu\text{-}OH)\}_2]$ and $[\{(2,6\text{-}Mes_2C_6H_3)GaCl(\mu\text{-}OH)\}_2]$.[21] The terphenyl substituents in the centrosymmetric molecule are positioned in a mutual *trans* orientation. The Ga–O bond lengths are essentially identical [1.947(5) and 1.952(5) Å] and are close to those found in the above-mentioned methyl derivatives and chlorides.[21]

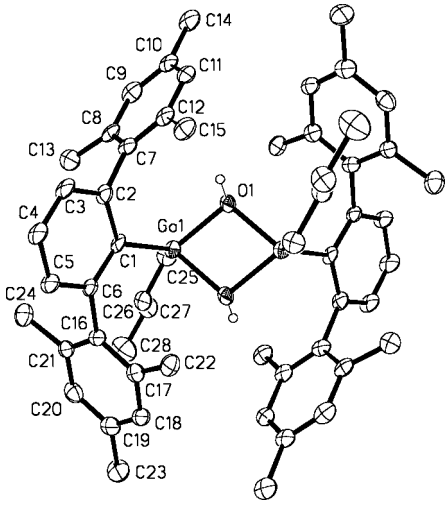


Figure 4. Thermal ellipsoid plot (50% probability ellipsoids) showing the molecular structure of **10**. Hydrogen atoms, with the exception of those bound to oxygen atoms, have been omitted for clarity.

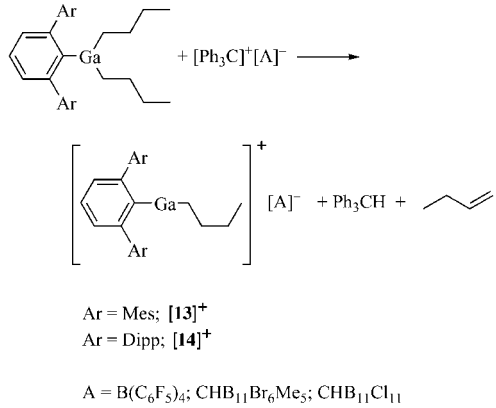
## Cation Formation

We have shown previously that the two-coordinate cationic species $[(2,6\text{-}Mes_2C_6H_3)_2Ga]^+$ and $[(2,6\text{-}Mes_2C_6H_3)_2Al]^+$ can be prepared by chloride abstraction[6] with the lithium alanate $Li[Al\{OCH(CF_3)_2\}_4]$ or by alkanide or hydride abstraction with the trityl salt $[Ph_3C]^+[B(C_6F_5)_4]^-$.[7,21] Chloride abstraction with 2 equiv. of $Li[Al\{OCH(CF_3)_2\}_4]$ also converted the sterically less encumbered diterphenylgallium chloride **2** cleanly into the cationic species $[(2,6\text{-}Ar_2C_6H_3)_2Ga]^+[Li(Al\{OCH(CF_3)_2\}_4)_2]^-$ (**11**; Ar = 3,5-$Me_2C_6H_3$). Interestingly, the analogous reaction with compound **1** to afford **12** (Ar = 4-*t*Bu$C_6H_4$) did not proceed. Monitoring of the reaction in $C_6D_5Cl$ by $^1H$ NMR spectroscopy showed broadening of some of the aromatic signals ($\delta$ = 7.4–7.0 ppm), but no further reaction was observed even after prolonged heating at 70 °C. Although attempts to isolate crystals of **11** have not yet been successful, the stoichiometry of the products is supported by the presence of the methine hydrogen signal of the anion in a relative intensity corresponding to eight hydrogen atoms in the $^1H$ NMR spectra. In addition, mass spectrometric analysis of the solution showed the presence of the cation $[\{2,6\text{-}(3,5\text{-}Me_2C_6H_3)_2C_6H_3\}_2Ga]^+$. Chlorobenzene solutions of **11** remain unchanged at room temperature for days, which suggests a surprising stability of this cationic species considering that the related electron-deficient diterphenylboranes $(2,6\text{-}Ar_2C_6H_3)_2BH$ undergo C–H activation below room temperature to give 9-borafluorenes and $H_2$.[28]

Conversion of the dibutyl(terphenyl)gallanes **8** and **9** into the cationic species $[(2,6\text{-}Mes_2C_6H_3)GaBu]^+$ ([**13**]$^+$) and $[(2,6\text{-}Dipp_2C_6H_3)GaBu]^+$ ([**14**]$^+$), was accomplished by treatment with the trityl salts $[CPh_3]^+[A]^-$ [A = $B(C_6F_5)_4$,[29] $CHB_{11}Br_6Me_5$,[30] $CHB_{11}Cl_{11}$[31]] according to Equation (4).



(4)

These reactions were performed in NMR tubes sealed with J. Young valves or in small Schlenk flasks. The progress of the reactions was monitored by recording the signals due to C*H*$Ph_3$ and C*H*$_2$C*H*$CH_2CH_3$ in the $^1H$ NMR spectrum. The reactions are relatively fast: they are complete within a few hours when both reactants are soluble in the chosen solvent. Otherwise, the reaction rate is dependent on the solubility of the trityl salt, with $[CPh_3]^+[CHB_{11}Cl_{11}]^-$ being the least soluble. Despite the small scale, all reactions are readily reproducible. It has not been possible to isolate any of the products in pure or crystalline form so far due to their tendency to form oils. Nevertheless, the identities of the products have been established by multinuclear NMR spectroscopy and ESI mass spectrometry. The best general strategy for obtaining the highest-purity samples involves performing the reaction in benzene solution followed by phase separation and washing of the dense phase containing the product with benzene. All ionic products are soluble in chlorobenzene, bromobenzene, or their mixtures with benzene. Only [**13**]$^+[CHB_{11}Br_6Me_5]^-$ is readily soluble in benzene. The other combinations of [**13**]$^+$[A]$^-$ and [**14**]$^+$[A]$^-$ form dense liquid phases, so-called liquid clathrates.[32] The solubility of [**13**]$^+[CHB_{11}Cl_{11}]^-$ lies between these extremes: a liquid clathrate separates at high concentrations (ca. 0.08 M) which can be redissolved upon dilution with $C_6D_6$. Clathrate formation has been observed previously in our laboratory for the compounds $[(2,6\text{-}Mes_2C_6H_3)_2M]^+$-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[B(C_6F_5)_4]^-$ (M = Al, Ga), which exist as separate ions.[7,21] Hence, we propose clathrate formation as supporting evidence for anion/cation separation in $[\mathbf{13}]^+[A]^-$ and $[\mathbf{14}]^+[A]^-$. Additional evidence is found in the $^{19}F$ NMR chemical shifts of $[\mathbf{13}]^+[B(C_6F_5)_4]^-$ and $[\mathbf{14}]^+[B(C_6F_5)_4]^-$, which are close to the values reported for the "free" anion.[16] However, a weak cation···$XC_6H_5$ (solvent) contact (X = Cl, Br) cannot be ruled out. Such interactions have been described for [(*i*Pr$_2$-ATI)MR][$B(C_6F_5)_4$](ClPh) (M = Al, Ga, In; *i*Pr$_2$-ATI = *N*,*N*′-diisopropylaminotroponiminate).[33]

The $^1H$ NMR spectrum of a $C_6D_6$ solution of $[\mathbf{13}]^+[CHB_{11}Br_6Me_5]^-$ shows two sets of signals for the *o*- and *o*′′-methyl groups and the *m*- and *m*′′-hydrogen atoms of the flanking mesityl groups of the *m*-terphenyl ligand due to a loss of symmetry. This, together with the fact that $[\mathbf{13}]^+[CHB_{11}Br_6Me_5]^-$ is soluble in benzene, may be viewed as good evidence for its existence as a tight ion-pair with close Ga···Br contacts similar to those observed for $[Et_2Al]^+[CB_{11}H_6X_6]^-$ (X = Cl, Br).[13] In keeping with an intermediate behavior, the $^1H$ NMR spectrum of $[\mathbf{13}]^+[CHB_{11}Cl_{11}]^-$ in $C_6D_6$ solution does not display an analogous broadening.

All ionic compounds described here are stable in solution at room temperature for days if not weeks. The $[B(C_6F_5)_4]^-$ salts are susceptible to $C_6F_5$ migration at elevated temperatures, a common occurrence for this anion in combination with strong Lewis acids.[34] For example, heating of a solution of $[\mathbf{14}]^+[B(C_6F_5)_4]^-$ at 60 °C for 16 h results in the clean formation of a 1:1 mixture of [(2,6-Dipp$_2$C$_6$H$_3$)GaBu($C_6F_5$)] (**15**) and $B(C_6F_5)_3$. These compounds were identified by $^1H$ and $^{19}F$ NMR spectroscopy, the latter by comparison with an authentic sample and published data[35] and the former by the similarity of its $^{19}F$ NMR signals with those of the related (pentafluorophenyl)aluminum species [$Me_nAl(C_6F_5)_{3-n}$].[34] On the other hand, no change of the NMR spectra of the carborane salt $[\mathbf{14}]^+[CHB_{11}Cl_{11}]^-$ was observed after heating at 68–70 °C for 23 h, thereby indicating a surprisingly high stability of this compound.

The difficulty of obtaining pure samples of any of the new ionic compounds may be illustrated by the fact that repeated attempts to crystallize $[\mathbf{13}]^+[CHB_{11}Br_6Me_5]^-$ only afforded a few crystals of the hydrolysis product $[(BuGa)_4(\mu\text{-}OH)_6]^{2+}[CHB_{11}Br_6Me_5]^-_2$ (**16**), whose structure consists of layers of $[(BuGa)_4(\mu\text{-}OH)_6]^{2+}$ dications and $[CHB_{11}Br_6Me_5]^-$ anions separated by benzene molecules. The cations and anions are well separated, but are kept in contact through hydrogen bonding between the hydroxy hydrogen atoms of the cations and bromine atoms of the anions. These contacts can be as close as 2.44 Å for H(3)···Br(3A). The dications are cage molecules with a distorted adamantane $Ga_4O_6$ framework (Figure 5). The neutral analogue $[\{(Me_3Si)_3Ga\}_4(\mu\text{-}OH)_4(\mu\text{-}O)_2]$ has been reported previously.[36] The metric parameters of both compounds are comparable, with average Ga–O and Ga–C bond lengths of 1.897(6) and 1.933(1) Å and O–Ga–O and Ga–O–Ga angles of 96.9(1.8)° and 130.8(1.0)° in **16** (Table 3) vs. 1.895 and 1.998 Å and 100.46 and 125.42°, respectively, in $[\{(Me_3Si)_3Ga\}_4(\mu\text{-}OH)_4(\mu\text{-}O)_2]$.

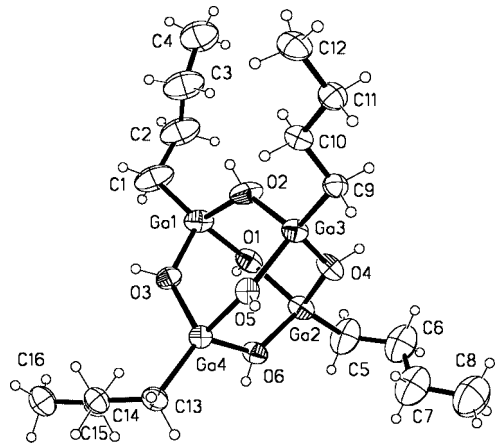


Figure 5. Thermal ellipsoid plot (30% probability ellipsoids) showing the molecular structure of the dication in **16**.

### Reaction of $[\mathbf{14}]^+$ with 1-Octene

One of the goals of the preparation of low-coordinate aluminum and gallium cations was the investigation of their interactions with olefins. The NMR spectra obtained during the monitoring of the syntheses of the various cation/anion combinations $[\mathbf{13}]^+[A]^-$ and $[\mathbf{14}]^+[A]^-$ indicated a rather slow reaction with 1-butene. Since $[\mathbf{14}]^+[CHB_{11}Cl_{11}]^-$ is thermally stable, its interaction with 1-octene was investigated more closely. Approximately 1.2 equiv. of 1-octene was added to a solution of $[\mathbf{14}]^+[CHB_{11}Cl_{11}]^-$ in a 6:1 mixture of $C_6D_6$ and $C_6D_5Cl$, and the progress of the reaction was monitored by $^1H$ NMR spectroscopy. About 15 min after the 1-octene addition, the $^1H$ NMR spectrum showed a broadening of the α-C$H_2$ signal, and signals of free 1-octene and 1-butene in an approximately 2:1 ratio were discernible. After 48 h at room temperature, the olefinic signals had almost completely disappeared, and an additional 2.4 equiv. of 1-octene was added after a reaction time of 54 h. This time, only a small amount of free 1-butene was generated, and most of the signals due to the butyl compound $[\mathbf{14}]^+$ were replaced by similar signals that were slightly shifted from their previous positions. Two more additions of 1-octene were undertaken after the olefin had been almost completely consumed. After a total reaction time of 21 d at room temperature, no more olefin signals were present, and the spectrum was dominated by octyl signals, although a slightly broadened multiplet at $\delta$ = 0.21 ppm indicated the presence of a Ga-C$H_2$ group. Analysis of the mixture by ESI mass spectrometry and GC-MS showed the presence of the octyl species [(2,6-Dipp$_2$C$_6$H$_3$)Ga(octyl)]$^+$ ($[\mathbf{17}]^+$) and various octylbenzenes. These preliminary results suggest a facile olefin/alkyl exchange followed by octene isomerization and benzene alkylation. Scheme 2 shows a proposed reaction mechanism. Further work in this area is in progress.

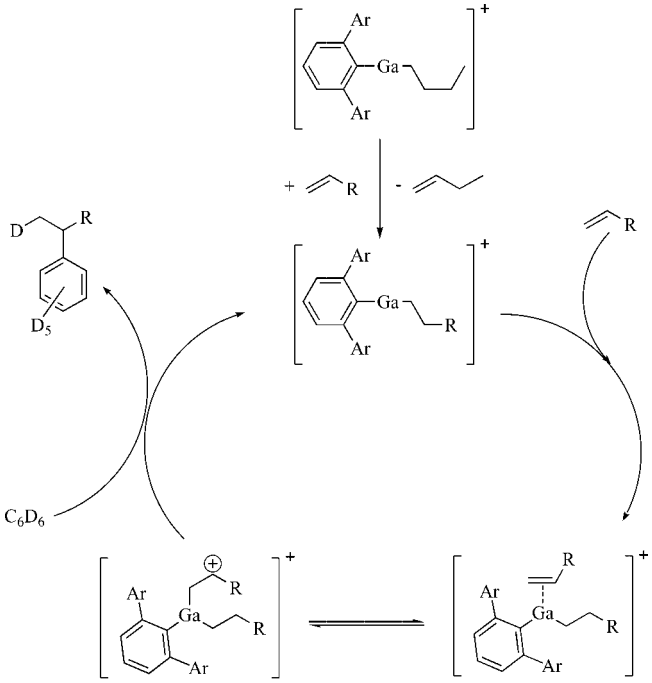

Scheme 2.

## Conclusion

Diterphenylaluminum and -gallium compounds have been prepared by the treatment of 2 equiv. of terphenyllithium with $MCl_3$ or $H_3Al{\cdot}NMe_3$; the synthesis of the aluminum species requires more forcing conditions. Dibutyl(terphenyl)gallanes have also been obtained by treating terphenyllithium with $ClGaBu_2$. The best method for the preparation of cationic gallium species $[(terph)GaR]^+$ is treatment with trityl salts of weakly coordinating anions, although chloride abstraction with a fluorinated lithium tetraalkoxidoalanate can also be used for selected gallium chloride precursors. The ionic compounds are at least moderately stable in aromatic solvents at room temperature, with the compound $[\mathbf{14}]^+[CHB_{11}Cl_{11}]^-$ being thermally stable up to 70 °C. All ionic compounds, with the exception of $[\mathbf{13}]^+[CHB_{11}Br_6Me_5]^-$, form clathrates in benzene solution, which suggests the presence of only weak ion-pairing or even "free" ions. A preliminary study on the interaction of $[\mathbf{14}]^+[CHB_{11}Cl_{11}]^-$ with 1-octene has found facile alkyl/olefin exchange at the cationic gallium center and slow octene isomerization and benzene alkylation.

## Experimental Section

**General Procedures:** All work was performed under anaerobic and anhydrous conditions by using either modified Schlenk techniques or an Innovative Technologies or Vacuum Atmospheres drybox. Solvents were freshly distilled under $N_2$ from sodium, potassium, sodium/potassium alloy, or calcium hydride and degassed twice prior to use, or they were dispensed from an MBraun Solvent Purification System. $AlCl_3$, $GaCl_3$, *n*-butyllithium (1.6 M in hexanes), and MeLi (1.6 M in $Et_2O$) were obtained from commercial suppliers. Compounds 2,6-(4-*t*Bu$C_6H_4$)$_2C_6H_3$Br,[37] 2,6-(4-*t*Bu$C_6H_4$)$_2$-$C_6H_3$Li,[38] 2,6-(3,5-$Me_2C_6H_3$)$_2C_6H_3$Li,[28] [(2,6-$Mes_2C_6H_3$)$_2$AlH] (**7**),[7] $ClGaBu_2$,[39] 2,6-$Mes_2C_6H_3$Li,[40] 2,6-$Dipp_2C_6H_3$Li,[41] and $[Ph_3C][B(C_6F_5)_4]$[29] were synthesized according to literature methods. The carborane compounds $[Ph_3C][CHB_{11}Br_6Me_5]$ and $[Ph_3C][CHB_{11}Cl_{11}]$ were supplied by Prof. Christopher A. Reed and Dr. Kee-Chan Kim from the University of California, Riverside. NMR spectra were recorded with a Varian Mercury 300 MHz, a Varian Unity Plus 400 MHz, a Bruker AMX 360, or a Bruker Avance 400 MHz spectrometer. $^1$H NMR chemical shift values were determined relative to the residual protons in $C_6D_6$ or $CDCl_3$ as internal reference ($\delta$ = 7.15 or 7.26 ppm). $^{13}$C NMR spectra were referenced to the solvent signal ($\delta$ = 128.0 or 77.0 ppm). $^{19}$F NMR spectra were referenced to an external solution of $C_6H_5CF_3$ in $C_6D_6$ ($\delta$ = –63.72 ppm). IR spectra were recorded in the range 4000–400 $cm^{-1}$ with a Nicolet Nexus 470 FTIR spectrometer. Electron impact mass spectra were recorded with a Finnigan MAT Polaris spectrometer and electrospray mass spectra with a Micromass Q-ToF or a JEOL AccuTOF DART spectrometer. Melting points were determined in Pyrex capillary tubes sealed under nitrogen with a Mel-Temp apparatus and are uncorrected. Elemental analyses were performed by Desert Analytics in Tucson, AZ.

**[{(4-*t*Bu$C_6H_4$)$_2C_6H_3$}$_2$GaCl] (1):** A solution of (4-*t*Bu$C_6H_4$)$_2$-$C_6H_3$Br (1.00 g, 2.4 mmol) in hexanes (60 mL) was treated with a hexane solution of *n*-butyllithium (0.97 mL, 2.78 M) at –78 °C. The reaction mixture was warmed to room temperature and stirred overnight. The volatile material was removed from the cloudy suspension under reduced pressure. $GaCl_3$ (0.21 g, 1.2 mmol) was added to a suspension of the resulting colorless to beige solid in hexanes (50 mL) at –78 °C. Warming to room temperature and stirring overnight afforded a suspension of **1** and LiCl. Decanting of the mother liquor, washing with hexanes and extraction with benzene gave **1** as a fine colorless solid after removal of the solvent in vacuo. Yield: 0.54 g (57%). Crystals suitable for X-ray diffraction were grown from a concentrated toluene solution at –24 °C. M.p. 202–208 °C. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.32 (d, $J$ = 7.5 Hz, *m*-H, 4 H), 7.28 (s, 4-*t*Bu$C_6H_4$, 16 H), 7.19 (t, $J$ = 7.5 Hz, *p*-H, 2 H), 1.16 (s, C$H_3$, 36 H) ppm. $^{13}$C{$^1$H} NMR (90.567 MHz, $C_6D_6$, 25 °C): $\delta$ = 150.89, 149.51, 147.05 (*i*-C), 142.96; 129.75 (*p*-C), 128.65 [*o*-C(4-*t*Bu$C_6H_4$)], 127.93 (*m*-C), 126.30 [*p*-C(4-*t*Bu$C_6H_4$)], 34.45 [$C(CH_3)_3$], 31.29 [C($CH_3$)$_3$] ppm. MS (DART, $C_6D_6$ solution): calcd. for [$M^+$ – Cl] 751.3794, found 751.3595.

**[{(3,5-$Me_2C_6H_3$)$_2C_6H_3$}$_2$GaCl] (2):** $GaCl_3$ (0.39 g, 2.2 mmol) was added through an addition funnel for solids to a suspension of 2,6-(3,5-$Me_2C_6H_3$)$_2C_6H_3$Li (1.37 g, 4.7 mmol) in hexanes at –78 °C. After 15 min, the reaction mixture was allowed to slowly warm to room temperature to give a cream-colored suspension and a dark grey solid on the bottom of the flask. After 3 d at room temperature, the dark solid was consumed. The insoluble material (1.09 g), which is a mixture of **2** and LiCl, was collected on a glass frit. Redissolution in $CH_2Cl_2$ (20 mL), followed by separation of LiCl by decantation, concentration of the clear yellow solution to ca. 2 mL and cooling at 4 °C for 2 d afforded a fine crystalline solid (0.2 g). A second batch (0.05 g) was obtained from the concentrated mother liquor at 4 °C after 3 d. Yield: 0.25 g (17%). M.p. softens at 178 °C, melts at 188–192 °C. $^1$H NMR (400 MHz $C_6D_6$, 25 °C): $\delta$ = 7.43 (d, $J$ = 7.6 Hz, *m*-H, 4 H), 7.31(s, $J$ = 7.6 Hz, *p*-H, 2 H), 7.00 [s, *o*-H(3,5-$Me_2C_6H_3$), 8 H], 6.66 [s, *p*-H(3,5-$Me_2C_6H_3$), 4 H], 1.93 (s, C$H_3$, 24 H) ppm. $^{13}$C{$^1$H} NMR (100.13 MHz, $C_6D_6$, 25 °C): $\delta$ = 149.00, 148.22, 145.82, 139.26, 129.82, 129.80, 128.31, 126.85, 21.14 ($CH_3$) ppm.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**[{(4-*t*BuC$_6$H$_4$)$_2$C$_6$H$_3$}$_3$Ga] (3):** $GaCl_3$ (0.18 g, 1.0 mmol) was added to a suspension of 4-(*t*BuC$_6$H$_4$)$_2$C$_6$H$_3$Li (1.07 g, 3.1 mmol) in hexanes (50 mL) at –78 °C through an addition funnel for solids. The mixture was warmed to room temperature and stirred for 20 h. The resulting fine, colorless precipitate was separated by filtration, and the product was obtained by crystallization of the colorless supernatant liquid at –24 °C for several days. Yield: 0.64 g (58%). Crystals suitable for X-ray diffraction were grown from a concentrated toluene solution at –24 °C. M.p. 281–283 °C. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.19 [d, $J$ = 8.4 Hz, 12 H, *o*- or *p*-(4-*t*BuC$_6$H$_4$)], 6.97 [d, $J$ = 8.1 Hz, 12 H, *o*- or *p*-(4-*t*BuC$_6$H$_4$)], 6.97 (s, 9 H, *m*- and *p*-H), 1.22 (s, 54 H, C*H*$_3$) ppm. $^{13}$C{$^1$H} NMR (75.45 MHz, $C_6D_6$, 25 °C): $\delta$ = 151.06 (*i*-C), 148.86, 148.60, 142.71, 129.80 [*o*-(4-*t*BuC$_6$H$_4$)], 127.93 (*m*- or *p*-C), 124.85 [*p*-(4-*t*BuC$_6$H$_4$)], 34.49 [*C*(CH$_3$)$_3$], 31.53 [C(*C*H$_3$)$_3$] ppm. $C_{78}H_{87}Ga$ (1094.3): calcd. C 85.61, H 8.01; found C 84.35, H 8.21.

**[(2,6-Mes$_2$C$_6$H$_3$)$_2$AlCl] (5):** $AlCl_3$ (0.25 g, 1.9 mmol) was added to a solution of 2,6-Mes$_2$C$_6$H$_3$Li (1.28 g, 4.0 mmol) in benzene (10 mL) through an addition funnel for solids with cooling in an ice bath. After warming to room temperature, the mixture was stirred for 14 h and heated to reflux for another 2 h. After cooling to room temperature, the clear yellow solution was decanted off the fine colorless precipitate, and the volatile material was distilled off under reduced pressure to give a pale-yellow foamy solid. Addition of hexanes (5–6 mL) afforded the precipitation of **5** as a fine pale-yellow powder (0.32 g) which was found to be contaminated with 22% 2,6-Mes$_2$C$_6$H$_4$. Crystals of a quality suitable for X-ray diffraction were obtained by crystallization from a saturated toluene solution at –20 °C for 7 d, although an analytically pure bulk sample could not be isolated. $^1$H NMR (400 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.05 (t, $J$ = 7.6 Hz, 2 H, *p*-H), 6.85 [s, 8 H, *m*-H(Mes)], 6.63 (d, $J$ = 7.6 Hz, 4 H, *m*-H), 2.25 (s, 12 H, *p*-C*H*$_3$), 1.83 (s, 24 H, *o*-C*H*$_3$) ppm. $^{13}$C{$^1$H} NMR (100.61 MHz, $C_6D_6$, 25 °C): $\delta$ = 150.68, 143.73 (*i*-C), 141.78, 137.58 [*o*-C(Mes)], 136.99, 130.21 (*p*-C), 129.13 [*m*-C(Mes)], 128.43 (*m*-C), 21.91 (*o*-*C*H$_3$), 21.29 (*p*-*C*H$_3$) ppm. MS (DART, solid): calcd. for [M + H$^+$] 689.3495, found 689.3583.

**[(2,6-Mes$_2$C$_6$H$_3$)GaBu$_2$] (8):** A suspension of a 9:1 mixture of 2,6-Mes$_2$C$_6$H$_3$Li/2,6-Mes$_2$C$_6$H$_4$ (2.27 g, 6.4 mmol 2,6-Mes$_2$C$_6$H$_3$Li) in hexanes (30 mL) was added slowly to a solution of $ClGaBu_2$ (1.40 g, 6.4 mmol) in hexanes (20 mL) at –78 °C. The mixture was kept at –78 °C for 30 min, then warmed to room temperature and stirred overnight. The pale-yellow solution was decanted off the fine colorless precipitate, concentrated to 5 mL, and cooled to –40 °C for 2 d. As no crystals had formed, the solution was further concentrated to about 1 mL and cooled to –40 °C for 5 d to afford fine, colorless needles (1.21 g). A second batch was obtained from the concentrated mother liquor after cooling at –40 °C for 4 d (0.81 g). Yield: 2.02 g (58%). The needles were contaminated with approximately 13% 2,6-Mes$_2$C$_6$H$_4$. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.31 (t, $J$ = 7.5 Hz, 1 H, *p*-H), 7.02 (d, $J$ = 7.5 Hz, 2 H, *m*-H), 6.81 [s, 4 H, *m*-H(Mes)], 2.16 (s, 12 H, *o*-Me), 2.13 (s, 6 H, *p*-Me), 1.23 (m, 4 H, β-C*H*$_2$), 1.04 (m, 4 H, γ-C*H*$_2$), 0.83 (t, $J$ = 6.9 Hz, 6 H, δ-C*H*$_3$), 0.54 ("t", $J$ = 7.8 Hz, 4 H, α-C*H*$_2$) ppm. $^{13}$C{$^1$H} NMR (75.45 MHz, $C_6D_6$, 25 °C): $\delta$ = 155.61, 147.00, 140.98, 137.01, 136.17, 128.88 [*m*-C(Mes)], 128.45 (*p*-C), 126.04 (*m*-C), 28.32 (β- or γ-*C*H$_2$), 28.13 (β- or γ-*C*H$_2$), 21.11 (*o*-*C*H$_3$), 21.05 (*p*-*C*H$_3$), 19.33 (α-*C*H$_2$), 14.24 (δ-*C*H$_3$) ppm.

**[(2,6-Dipp$_2$C$_6$H$_3$)GaBu$_2$] (9):** A suspension of 2,6-Dipp$_2$C$_6$H$_3$Li (2.51 g, 6.2 mmol) in hexanes (30 mL) was added slowly to a solution of $ClGaBu_2$ (1.30 g, 5.9 mmol) in hexanes (20 mL) at –78 °C. The mixture was kept at –78 °C for 30 min, warmed to room temperature and stirred overnight. The cloudy, pale-yellow solution was filtered through a sintered glass frit, and the pale-yellow filtrate was concentrated to 5 mL and cooled to –40 °C for 4 d. As no crystals had formed, the volatile material was removed under reduced pressure to give crude **9** as a pale-yellow oil, which solidified after a month at room temperature. The main impurity was identified as the arene 2,6-Dipp$_2$C$_6$H$_3$I in amounts of approximately 5%. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.25 (m, 5 H), 7.16 (m, 4 H), 3.09 [sept, $J$ = 6.9 Hz, 4 H, C*H*(CH$_3$)$_2$], 1.27 [d, $J$ = 6.9 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.14 (m, 8 H, β-, γ-CH$_2$), 1.07 [d, $J$ = 6.9 Hz, 12 H, CH(C*H*$_3$)$_2$], 0.84 (t, $J$ = 7.2 Hz, 6 H, δ-CH$_3$), 0.45 (m, 4 H, α-CH$_2$) ppm. $^{13}$C{$^1$H} NMR (75.45 MHz, $C_6D_6$, 25 °C): $\delta$ = 156.31, 147.10, 145.64, 141.89, 128.72, 127.80, 126.98, 123.36, 30.54 [*C*H(CH$_3$)$_2$], 28.24 (β- or γ-*C*H$_2$), 27.46 (β- or γ-*C*H$_2$), 26.22 [CH(*C*H$_3$)$_2$], 22.66 [CH(*C*H$_3$)$_2$], 19.93 (α-*C*H$_2$), 14.00 (δ-*C*H$_3$) ppm.

**[{(2,6-Mes$_2$C$_6$H$_3$)GaBu(μ-OH)}$_2$] (10):** A solution of crude **8** (30 mg) in $C_6D_6$ (1 mL) was placed in a small vial inside a glovebox, and the solvent was allowed to slowly evaporate through the partially tightened lid over a period of two weeks to afford a pale-yellow glass. Redissolution in 1-octene (1 mL) and subsequent slow concentration over a period of six weeks gave fine colorless needles of **10** of sufficient quality for X-ray diffraction. $^1$H NMR (400 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.21 (t, $J$ = 7.2 Hz, 2 H, *p*-H), 6.91 (d, $J$ = 7.2 Hz, 4 H, *m*-H), 6.87 [s, 8 H, *m*-H(Mes)], 2.35 (s, 12 H, *p*-Me), 2.08 (s, 24 H, *o*-Me), 1.21 (m, 4 H, β-, γ-C*H*$_2$), 0.88 (t, $J$ = 6.8 Hz, 6 H, δ-C*H*$_3$), 0.13 ("t", $J$ = 8.1 Hz, 4 H, α-C*H*$_2$), 0.09 (s, 2 H, O*H*) ppm. $^{13}$C{$^1$H} NMR (100.75 MHz, $C_6D_6$, 25 °C): $\delta$ = 148.30, 141.76, 136.38, 136.14, 128.59, 128.42, 126.95, 28.38 (β-or γ-*C*H$_2$), 28.24 (β-or γ-*C*H$_2$), 21.51 (*p*-*C*H$_3$), 21.32 (*o*-*C*H$_3$), 15.82 (α-*C*H$_2$), 14.00 (δ-*C*H$_3$) ppm. FTIR (thin film between CsI plates): $\tilde{\nu}$ = 3642 [m, ν(OH)] cm$^{-1}$.

**[{2,6-(3,5-Me$_2$C$_6$H$_3$)$_2$C$_6$H$_3$}$_2$Ga]$^+$[Li(Al{OCH(CF$_3$)$_2$}$_4$)$_2$]$^-$ (11):** A solution of **2** (32 mg, 47 μmol) in $C_6D_5Cl$ (1.0 mL) was added to finely powdered LiAl[OCH(CF$_3$)$_2$]$_4$ (70 mg, 0.1 mmol) in an NMR tube fitted with a J. Young valve. The NMR tube was shaken for 1 min and then rotated for 16 h around its long axis using a standard overhead stirrer lying on its side. The fine colorless precipitate was allowed to settle, and the clear colorless supernatant liquid containing essentially pure **11** was pipetted off. $^1$H NMR (400 MHz, $C_6D_5Cl$, 25 °C): $\delta$ = 7.58 (t, $J$ = 8.0 Hz, 2 H, *p*-H), 7.53 (d, $J$ = 8.0 Hz, 4 H, *m*-H), 6.72 [s, 4 H, *p*-H of xylyl], 6.40 [s, 8 H, *o*-H of xylyl], 4.84 [sept, $J_{H,F}$ = 5.4 Hz, 8 H, C*H*(CF$_3$)$_2$], 1.95 (s, 24 H, C*H*$_3$) ppm. $^{13}$C{$^1$H} NMR (100.61 MHz, $C_6D_5Cl$, 25 °C): $\delta$ = 148.23, 146.74, 144.42, 131.51, 125.68, 122.34 (q, $^1J_{C,F}$ = 285 Hz, *C*F$_3$), 121.14, 70.86 [sept, $^2J_{C,F}$ = 33 Hz, *C*H(CF$_3$)$_2$], 20.67 (*C*H$_3$) ppm. MS (DART, $C_6D_5Cl$ solution): calcd. 639.2542, found 639.2497; (neg. ion): calcd. for [Al{OCH(CF$_3$)$_2$}$_4$]$^-$ 694.9542, found 694.9511.

**[(2,6-Mes$_2$C$_6$H$_3$)GaBu]$^+$[B(C$_6$F$_5$)$_4$]$^-$ {[13]$^+$[B(C$_6$F$_5$)$_4$]$^-$}:** An NMR tube equipped with a J. Young valve was charged with **8** (27 mg, 50 μmol), [Ph$_3$C][B(C$_6$F$_5$)$_4$] (43 mg, 47 μmol), and $C_6D_6$ (0.7 mL), and the resulting mixture was shaken for 1 min to give a pale-yellow solution above a dense red layer (ca. 0.1 mL). The mixture was rotated at room temperature for 5 h to afford a dense, dark orange-yellow layer (0.1 mL) and a pale-yellow top layer. The top layer was pipetted off, and the bottom layer was washed with $C_6D_6$ (2 × 0.25 mL) and then dissolved in $C_6D_5Br$ (0.35 mL) to give a yellow solution. The solution contained mainly [**13**]$^+$[B(C$_6$F$_5$)$_4$]$^-$, which was contaminated with 15% of an unknown 2,6-Mes$_2$C$_6$H$_3$-containing species. $^1$H NMR [400.13 MHz, $C_6D_6$/$C_6D_5Br$ (1:3), 25 °C]: $\delta$ = 7.48 (t, $J$ = 7.6 Hz, 1 H, *p*-H), 7.10 (d, $J$ = 7.6 Hz, 2 H, *m*-H), 6.88 [s, 4 H, *m*-H(Mes)], 2.22 (s, 6 H, *p*-C*H*$_3$), 1.96 (s, 12

**[(2,6-$Mes_2C_6H_3$)GaBu]$^+$[$CHB_{11}Cl_{11}$]$^-$ {[13]$^+$[$CHB_{11}Cl_{11}$]$^-$}:** An NMR tube equipped with a J. Young valve was charged with **8** (24 mg, 45 μmol), [$Ph_3C$][$CHB_{11}Cl_{11}$]·0.8$C_7H_8$ (33 mg, 39 μmol) and $C_6D_6$ (0.6 mL), and the resulting mixture was shaken for 1 min to give a pale-yellow solution above a fine yellow solid. The mixture was rotated at room temperature for 26 h to afford a dense orange-yellow layer (0.06 mL) and a yellow top layer. In order to ensure complete consumption of the trityl salt, an additional 5 mg of **8** was added, and the tube was rotated for another 4 h. This resulted in a significant fading of the color of both layers. The top layer was pipetted off, and the bottom layer (ca. 0.03 mL) was dissolved in $C_6D_6$ (0.6 mL). The NMR spectra are in agreement with the formation of [**13**]$^+$[$CHB_{11}Cl_{11}$]$^-$, which still contained around 22% $Ph_3CH$. No further purification was attempted. The NMR spectroscopic data are given for [**13**]$^+$[$CHB_{11}Cl_{11}$]$^-$. $^1H$ NMR (400.13 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.15 (obscured by $C_6D_5H$, *p*-H), 6.85 (d, $J$ = 7.6 Hz, 2 H, *m*-H), 6.79 [s, 4 H, *m*-H(Mes)], 2.08 (s, 12 H, *o*-C$H_3$), 2.05 (s, 6 H, *p*-C$H_3$), 1.24 (m, 2 H, β-C$H_2$), 1.12 (br. s, 2 H, α-C$H_2$), 0.97 (sext, $J$ = 7.2 Hz, 2 H, γ-C$H_2$), 0.71 (t, $J$ = 7.2 H, 3 Hz, δ-C$H_3$) ppm. $^{13}C\{^1H\}$ NMR (100.61 MHz, $C_6D_6$, 25 °C): $\delta$ = 147.48, 139.39, 138.53, 136.50 [*o*-C(Mes)], 131.98, 130.16 [*m*-C(Mes)], 48.03 (br., *C*H$B_{11}Cl_{11}$), 26.76 (γ-*C*$H_2$), 26.47 (β-*C*$H_2$), 21.55 (*o*-*C*$H_3$), 20.92 (*p*-*C*$H_3$), 13.51 (δ-*C*$H_3$) ppm.

**[(2,6-$Mes_2C_6H_3$)GaBu]$^+$[$CHB_{11}Br_6Me_5$]$^-$ {[13]$^+$[$CHB_{11}Br_6Me_5$]$^-$}:** A small tube equipped with a Teflon valve was charged with **8** (28 mg, 52 μmol), [$Ph_3C$][$CHB_{11}Br_6Me_5$]·2.3$C_7H_8$ (60 mg, 52 μmol), and $C_6D_6$ (1.5 mL), and the resulting mixture was rotated at room temperature for 16 h to afford a clear, orange solution. The volatile material was distilled off in vacuo, and the resulting orange-red oil was dissolved in hexanes (1 mL). The slightly cloudy solution was cooled to –20 °C for 2 h to precipitate $Ph_3CH$. The yellow-orange supernatant liquid was pipetted off, and the solvent was allowed to evaporate slowly inside a drybox. The resulting yellow glass was investigated by $^1H$ NMR spectroscopy, and the spectra were found to be in agreement with the formulation [**13**]$^+$[$CHB_{11}Br_6Me_5$]$^-$. Small amounts of 2,6-$Mes_2C_6H_4$, $Ph_3CH$ and *n*-hexane were also present. $^1H$ NMR (400 MHz, $C_6D_6$, 25 °C): $\delta$ = 6.95 (br. s, $w_{1/2}$ = 6.9 Hz, 2 H, *m*-H of Mes), 6.73 (br. s, $w_{1/2}$ = 7.6 Hz, 2 H, *m*-H of Mes), 2.49 (br. s, $w_{1/2}$ = 6.4 Hz, 6 H, *o*-C$H_3$), 2.06 (s, 6 H, *p*-C$H_3$), 1.94 (br. s, $w_{1/2}$ = 6.4 Hz, 6 H, *o*-C$H_3$), 1.50 (m, 4 H, α-, β-C$H_2$), 1.21 [m, 2 H, γ-C*H* (obscured by hexane C$H_2$)], 0.80 (t, $J$ = 7.5 Hz, 3 H, δ-C$H_3$), 0.25 (s, 15 H, B-C$H_3$) ppm. Further attempts at purification were unsuccessful and eventually led to the formation of **16** (vide infra).

**[(2,6-$Dipp_2C_6H_3$)GaBu)]$^+$[$B(C_6F_5)_4$]$^-$ {[14]$^+$[$B(C_6F_5)_4$]$^-$}:** A solution of **9** (39 mg, 67 μmol) in $C_6D_6$ (0.8 mL) was added to [$Ph_3C$][$B(C_6F_5)_4$] (62 mg, 67 μmol) in an NMR tube equipped with a J. Young valve at room temperature. The mixture was shaken, and a dense red liquid phase separated after standing for a few minutes. After 2 h at room temperature, only a small amount of $Ph_3CH$ could be detected by $^1H$ NMR spectroscopy. The sample was rotated slightly off axis for 18 h, after which time the $^1H$ NMR spectrum showed the consumption of **9**. The yellow upper phase was pipetted off, and the dense red oily phase was washed with $C_6D_6$ (0.6 mL and 1.2 mL). The remaining red oily liquid was dissolved in a mixture of $C_6D_6/C_6D_5Cl$ (4.5:1.5). $^1H$ NMR (300 MHz, $C_6D_6/C_6D_5Cl$ (4.5:1.5), 25 °C): $\delta$ = 7.26 (t, $J$ = 6.9 Hz, 1 H, *p*-H), 7.24 (t, $J$ = 7.8 Hz, 2 H, *p*-H of Dipp), 7.14 (d, $J$ = 6.9 Hz, 2 H, *m*-H), 7.07 (d, $J$ = 7.8 Hz, 4 H, *m*-H of Dipp), 2.52 [sept, $J$ = 6.8 Hz, 4 H, C*H*$(CH_3)_2$], 0.95, [d, $J$ = 6.8 Hz, 12 H, CH(C$H_3$)$_2$], 0.92, [d, $J$ = 6.8 Hz, 12 H, CH(C$H_3$)$_2$], 0.41 (br. s, 7 H, β-, γ-C$H_2$, δ-C$H_3$), 0.04 ("t", $J$ = 6.8 Hz, 2 H, α-C$H_2$) ppm. $^{13}C\{^1H\}$ NMR (75.45 MHz, $C_6D_6/C_6D_5Cl$ (4.5:1.5), 25 °C): $\delta$ = 149.1 (br. d, $^1J_{C,F}$ = 238 Hz), 147.83, 145.81, 133.54 (*p*-C), 138.8 (br. d, $^1J_{C,F}$ = 249 Hz, *p*-*C*F), 138.05, 137.0 (br. d, $^1J_{C,F}$ = 249 Hz), 131.77 [*m*-C(Dipp)], 129.22 (*m*-C), 125.63 [*m*-C(Dipp)], 30.95 [*C*H$(CH_3)_2$], 27.44 (β- or γ-*C*$H_2$), 25.38 (β- or γ-*C*$H_2$), 24.95 [CH(*C*$H_3$)$_2$], 23.43 [CH(*C*$H_3$)$_2$], 21.58 (α-*C*$H_2$), 13.28 (δ-*C*$H_3$) ppm. $^{19}F$ NMR (284.34 MHz, $C_6D_6/C_6D_5Cl$ (4.5:1.5), 25 °C): $\delta$ = –133.12 (br. d, $J$ = 7.7 Hz, 8 F, *o*-F), –163.93 (t, $J$ = 20.8 Hz, 4 F, *p*-F), –167.72 ppm (br. t, $J$ = 18.9 Hz, 8 F, *m*-F).

**[(2,6-$Dipp_2C_6H_3$)GaBu]$^+$[$CHB_{11}Cl_{11}$]$^-$ {[14]$^+$[$CHB_{11}Cl_{11}$]$^-$}:** An NMR tube equipped with a J. Young valve was charged with **9** (36 mg, 62 μmol, 30% excess) and [$Ph_3C$][$CHB_{11}Cl_{11}$]·0.8$C_7H_8$ (40 mg, 47 μmol), and $C_6D_6$ (0.75 mL) was added. The sample was rotated horizontally slightly off axis at room temperaturefor 5 d during which time a dense orange liquid layer formed (ca. 0.1 mL). The pale-yellow upper layer was pipetted off, and the lower layer was washed twice with $C_6D_6$ (0.5 and 0.3 mL). $C_6D_5Cl$ (0.45 mL) was added to the remaining liquid to give a clear yellow orange solution of [**14**]$^+$[$CHB_{11}Cl_{11}$]$^-$. $^1H$ NMR (400.13 MHz, $C_6D_5Cl/C_6D_6$ (3:1), 25 °C): $\delta$ = 7.55 (t, $J$ = 7.6 Hz, 1 H, *p*-H), 7.48 (t, $J$ = 7.8 Hz, 2 H, *p*-H of Dipp), 7.39 (d, $J$ = 7.6 Hz, 2 H, *m*-H), 7.27 (d, $J$ = 7.8 Hz, 4 H, *m*-H of Dipp), 2.86 (br. s, 1 H, C*H*$B_{11}Cl_{11}$), 2.66 [sept, $J$ = 6.8 Hz, 4 H, C*H*$(CH_3)_2$], 1.11 [d, $J$ = 6.8 Hz, 12 H, CH(C$H_3$)$_2$], 1.07 [d, $J$ = 6.8 Hz, 12 H, CH(C$H_3$)$_2$], 0.69 (quint, $J$ = 6.8 Hz, 2 H, β-C$H_2$), 0.55 (t, $J$ = 7.6 Hz, 2 H, α-C$H_2$), 0.49 (br. s, 5 H, γ-C$H_2$, δ-C$H_3$) ppm. $^{13}C\{^1H\}$ NMR [100.61 MHz, $C_6D_5Cl/C_6D_6$ (3:1); signals referenced to $\delta$ = 133.69 ppm for *i*-C($C_6D_5Cl$), 25 °C]: $\delta$ = 149.14 (*i*-C), 147.27 [*o*-C(Dipp)], 145.40, 137.79, 133.46 (*p*-C), 131.58, 128.51, 125.49 [*m*-C(Dipp)], 46.76 (br., *C*H$B_{11}Cl_{11}$), 30.52 [*C*H$(CH_3)_2$], 24.60 [CH(*C*$H_3$)$_2$], 23.46 [CH(*C*$H_3$)$_2$], 13.20 (δ-*C*$H_3$) ppm. MS (ESI, acetonitrile solution): calcd. for [$C_{34}H_{46}Ga^+$] 523.286, found 523.3; calcd. for [$M^+$ + $CH_3CN$] 564.312, found 564.4.

**Thermal Stability of [14]$^+$[$B(C_6F_5)_4$]$^-$:** A solution of [**14**]$^+$[$B(C_6F_5)_4$]$^-$ (ca. 5 μmol) in $C_6D_6/C_6D_5Cl$ (ca. 12:1 ratio, 0.6 mL) in an NMR tube equipped with a J. Young valve was heated at 60 °C for 16 h. During that time, the phase separation disappeared and a pale-yellow solution was obtained. The NMR spectroscopic data are in accordance with the presence of two compounds, namely [(2,6-$Dipp_2C_6H_3$)GaBu($C_6F_5$)] (**15**)[34] and $B(C_6F_5)_3$.[35] $^1H$ NMR (300 MHz, $C_6D_6/C_6D_5Cl$ (12:1), 25 °C): $\delta$ = 7.26 (br. s, 3 H, *m*-, *p*-H), 7.00 [d, $J$ = 7.5 Hz, 4 H, *m*-H of Dipp], 2.99 [sept, $J$ = 6.8 Hz, 4 H, C*H*$(CH_3)_2$], 1.15, [d, $J$ = 6.8 Hz, 12 H, CH(C$H_3$)$_2$], 0.99, [d, $J$ = 6.8 Hz, 12 H, CH(C$H_3$)$_2$], 0.68 ("t", $J$ = 6.0 Hz, 3 H, δ-C$H_3$), 0.45 ("t", $J$ = 8.0 Hz, 2 H, α-C$H_2$) ppm. $^{19}F$ NMR [284.34 MHz, $C_6D_6/C_6D_5Cl$ (12:1), 25 °C]: **15**: $\delta$ = –121.90 (m, *o*-F), –155.18 (t, $J$ = 19.9 Hz, *p*-F), –162.18 (m, *m*-F) ppm; $B(C_6F_5)_3$: $\delta$ = –129.89 (m, *o*-F), –142.86 (m, *p*-F), –161.18 (m, *m*-F) ppm.

**[$(BuGa)_4(\mu\text{-}OH)_6$]$^{2+}$[$CHB_{11}Br_6Me_5$]$^-_2$ (16):** The solution of [**13**]$^+$[$CHB_{11}Br_6Me_5$]$^-$ that was used to measure the $^1H$ NMR spectrum

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was transferred to a small vial inside the glove box, and the solvent was allowed to slowly evaporate. The resulting colorless crystals were analyzed by X-ray diffraction as $Ph_3CH{\cdot}C_6H_6$[42] and **16**·4.5$C_6D_6$.

**Reaction of [14]$^+$[$CHB_{11}Cl_{11}$]$^-$ with 1-Octene:** A solution of [**14**]$^+$[$CHB_{11}Cl_{11}$]$^-$ (11 mg, 12 μmol) in a 6:1 mixture of $C_6D_6$/$C_6D_5Cl$ (0.6 mL) was treated with 1-octene (14 μmol, 2.4 μL) at room temperature. The reaction was monitored by $^1$H NMR spectroscopy. After most of the free olefin had been consumed, additional olefin was added at various intervals starting after 54 h (5 μL), then after an additional 8 d (5 μL), and finally after further 4 d (10 μL). The last olefin added had been consumed at room temperature after 7 d. Two drops of the reaction mixture were used for ESI mass spectrometry. The rest was poured into a vial in air, the solvent was allowed to evaporate, and the remaining oil was investigated by GC/MS. MS (ESI, acetonitrile solution): calcd. for $C_{38}H_{54}Ga$ [M$^+$] 579.35; found 579.6; calcd. for $C_{40}H_{57}GaN$ [M$^+$ + MeCN] 620.37; found 620.6. GC/MS: $t_R$ = 11.62 min (16%), calcd. for $C_{14}H_{16}D_6$ (4-octylbenzene) 196.21, found 196.1; 11.73 min (25%), calcd. for $C_{14}H_{16}D_6$ (3-octylbenzene) 196.21, found 196.1; 11.97 min (59%), calcd. for $C_{14}H_{16}D_6$ (2-octylbenzene) 196.21, found 196.1. Assignments were made based on the fragmentation patterns.

**X-ray Crystallography:** Crystals of **1**, **3**, and **5** were obtained by crystallization from concentrated toluene solutions at –24 °C, crystals of **7** were obtained from a concentrated benzene solution at 3–4 °C, and crystals of **10** and **16** at room temperature from a 1-octene or benzene solution of **8** or [**13**]$^+$[$CHB_{11}Br_6Me_5$]$^-$, respectively, by slow evaporation of the solvents inside a drybox. Crystals of **1**, **3**, **5**, and **7** were removed from the Schlenk tube under a stream of $N_2$ and immediately covered with a layer of hydrocarbon oil, and crystals of **10** and **16** were covered with a layer of hydrocarbon oil inside a drybox. A suitable crystal was selected, attached to a glass fiber, and immediately placed in the low-temperature nitrogen stream. Crystals of **16** experienced a phase transition around 170 K, and the data were collected at 178 K. The data were collected with a Bruker Apex diffractometer using Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation. Absorption corrections using a multi-scan method from equivalent reflections were applied for **1**, **3**, **5**, **7**, and **10**; a semi-empirical method was used for **16**.[43] The structures were solved by direct methods using the SHELXTL program suite (version 6.1[44]) and refined by full-matrix least squares on $F^2$ including all reflections. All non-hydrogen atoms were refined anisotropically, and all hydrogen atoms were included in the refinement with idealized parameters. The OH hydrogen atoms in compounds **10** and **16** were not observed, but were placed into calculated positions using riding and distance restraints, respectively. The X-ray crystal structure of **1** at room temperature was reported recently.[18] Its parameters are very similar to the ones given here with the exception of a slightly larger unit cell. The structure of **16** displayed some serious disorder problems. The structure includes one dication, two monoanions, and four and one half benzene molecules. One of the solvent molecules was severely disordered and was best modeled using the Squeeze program.[45] Three of the *n*-butyl groups on the cation were disordered and each was modeled in two orientations. The occupancies of atoms C(1)–C(4), C(5)–C(8), and C(13)–C(16) refined to 0.689(12) and 0.311(12), 0.627(11) and 0.373(11), and 0.797(9) and 0.203(9) for the unprimed and primed atoms, respectively. Restraints were placed on the positional and displacement parameters of the disordered atoms and the solvent atoms as well as the positional parameters of the hydrogen atoms bonded to the oxygen atoms and the hydrogen atoms on C(1A) and C(1B). Some details of the crystal data and refinement are given in Table 1, and selected bond lengths and angles are listed in

Table 1. Crystal data and structural refinement details for **1**, **3**, **5**, **7**, **10**, and **16**·4.5$C_6H_6$.

## Acknowledgments

Financial support for this work from the University of Oklahoma, the Florida Institute of Technology, and the donors of the Petroleum Research Fund, administered by the American Chemical Society, is gratefully acknowledged. We also thank Prof. Christopher A. Reed and Dr. Kee-Chan Kim from the University of California, Riverside, for valuable discussions and the donation of the carborane trityl salts used in this study. We are also grateful to Dr. Li Zhang for the ESI mass spectra collected at the University of Oklahoma and to Prof. Nasri Nesnas for the DART mass spectra collected at the Florida Institute of Technology. We are furthermore grateful to the National Science Foundation for the purchase of the Bruker Avance 400 NMR spectrometer (CHE 03422510).

# Copper(II)–Purine Complexes Encapsulated in NaY Zeolite

Natércia Nunes,[a] Raquel Amaro,[a] Filomena Costa,[a] Elisabetta Rombi,[b] M. Alice Carvalho,[a] Isabel C. Neves,*[a] and António M. Fonseca[a]

**Keywords:** N ligands / Copper / NaY / Encapsulation / Host–guest chemistry / Oxidation

Y-encapsulated $Cu^{II}$–purine complexes were synthesized, characterized and studied in the catalytic oxidation of cyclohexene. Encapsulation was achieved by ion-exchanging the complex from aqueous solutions containing both the purine ligand, 9-methyl-6-(methylamino)purine, and copper, in different pH, with a purine/$Cu^{II}$ molar ratio of 5:1. The resulting materials were characterized by surface analysis (XPS, SEM and XRD), chemical analysis, spectroscopic methods (EPR, FTIR and UV/Vis) and thermal analysis (TGA), which indicated that the $Cu^{II}$–purine complexes were effectively encapsulated in NaY, most probably inside the supercages, without any modification of the morphology and structure of the zeolite. Different $Cu^{II}$–purine complexes were formed, depending on the pH during synthesis. The coordination geometry of Y-encapsulated $Cu^{II}$–purine complexes was obtained with preferentially 1:2 and 1:3 Cu/L stoichiometry: complexes **A** and **B** (1:2) and complex **C** (1:3). Complex **A** was formed at pH ≥ 7, and complexes **B** and **C** (Scheme 2) were formed at pH = 5.4. Oxidation of cyclohexene with *t*BuOOH (TBHP) as the oxygen source, gave 2-cyclohexene-1-one, 2-cyclohexene-1-ol, cyclohexene oxide and 3-*tert*-butylcyclohexenyl peroxide.

## Introduction

During the last two decades the preparation and catalytic activity of transition-metal complexes encapsulated in zeolite structures have been extensively investigated because of their industrial significance. The use of metal complexes immobilized into solid supports as heterogeneous catalysts has become very important for ecofriendly industrial processes. These new catalysts can be easily separated from the reaction mixture and which also improves the recycling of the expensive catalyst.[1,2]

Encapsulation of transition-metal complexes with redox properties, in zeolites or other molecular sieves, is a theme of current research because of their potential use as heterogeneous redox catalysts. The peculiar adsorptive properties of Y zeolites originate from the positively charged exchangeable ions, which are located inside the 3D pore structure of the solid to balance the negative charge on the framework Al atoms and which can be coordinated by different functionalized ligands.[3]

The oxyfunctionalization of inexpensive hydrocarbons to produce more valuable organic compounds, such as alcohols, aldehydes and ketones, requires the selective oxidation of strong C–H bonds.[4,5] In this field, homogeneous catalysis is not suitable for applications on a large scale, because of low conversions, catalyst deactivation, the cost of the complexes and lack of recycling methods.

Y-encapsulated $Cu^{II}$–histidine complexes showed good catalytic activity in the oxidation of alcohols and alkenes in the presence of hydrogen peroxide at ambient temperatures.[6–10] Alkene oxidation led to different products, depending on the structure of both the substrate and the oxidant.[11] Heterogenized copper(II)–amino-acid complexes $[Cu(AA)_n]^{m+}$ were obtained by Weckhuysen et al.[6] by encapsulation in Y zeolites through ion exchange from aqueous solutions containing both the amino acid (AA) and copper(II), with an AA/$Cu^{II}$ ratio of 5:1. Copper(II) was chosen as the transition-metal ion because it forms the most stable coordination complexes, which typically consist of four nearby donor atoms approximately arranged in a plane around the transition-metal ion.[6–8]

The present work deals with the multistep preparation, characterization and catalytic studies of new heterogeneous materials, namely $Cu^{II}$–purine complexes encapsulated in Y zeolites. The preparation procedure includes (i) the synthesis of purine ligands and (ii) the ion-exchange procedure for encapsulating the metal complex in the NaY zeolite. The obtained samples were fully characterized by chemical analysis, spectroscopic methods (EPR, FTIR and UV/Vis), powder X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM) and thermal analysis (TGA). The cyclohexene oxidation reaction was performed in liquid phase, at 30 °C, by using *tert*-butyl hydroperoxide (*t*BuOOH) as the oxygen source.

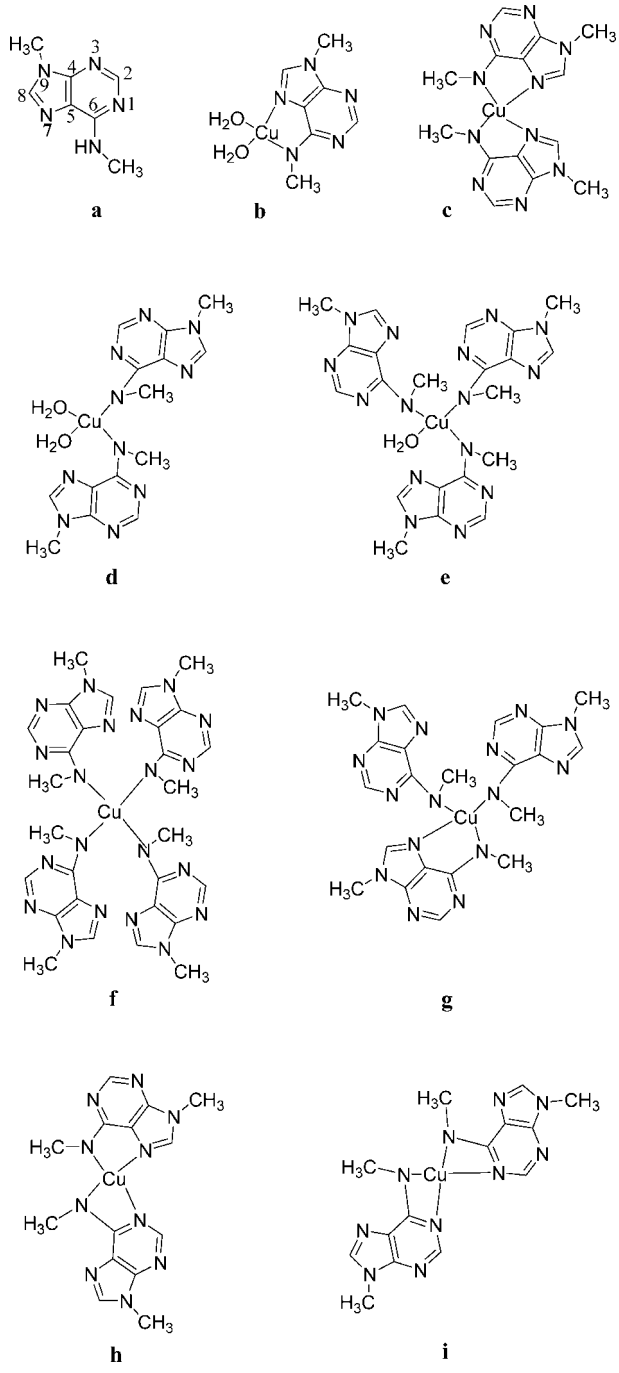
## Results and Discussion

### The 9-Methyl-6-(methylamino)purine Ligand

The biomonomer under investigation, 9-methyl-6-(methylamino)purine, a potentially polydentate ligand, can offer only nitrogen atoms as donor atoms. It was suggested that the most basic centre in purine resides in the pyrimidine ring, especially at $N^1$. However, protonation can also occur at $N^7$ and $N^9$.[12]



Scheme 1. Molecular structures of the used ligand and possible models of purine coordination in copper complexes: **a**: 9-methyl-6-(methylamino)purine; **b**: $N_{am}N^7O_wO_w$; **c**: $N_{am}(1)N^7(1)N_{am}(2)N^7(2)$; **d**: $N_{am}(1)N_{am}(2)O_wO_w$; **e**: $N_{am}(1)N_{am}(2)N_{am}(3)O_w$; **f**: $N_{am}(1)$-$N_{am}(2)N_{am}(3)N_{am}(4)$; **g**: $N_{am}(1)N_{am}(2)N_{am}(3)N^7(3)$; **h**: $N_{am}(1)$-$N^7(1)N_{am}(2)N^1(2)$; and **i**: $N_{am}(1)N^1(1)N_{am}(2)N^1(2)$ coordination. The axial ligands are omitted in these representations.

Since $N^9$ is substituted in the 9-methyl-6-(methylamino)-purine ligand, the coordination of the ligand with the copper ion can occur at $N^1$ and $N^7$ on the purine ring and at the *N*-amino nitrogen ($N_{am}$), which is bonded to $C^6$ carbon of the six-membered ring. Accordingly, different models of purine coordination in copper complexes can be derived (Scheme 1).

As shown in Scheme 1, the purine ligand can coordinate with the copper ion to generate complexes with four- and five-membered chelating rings; however, the latter ones lead to minor ring tension and to less steric hindrance, being thus preferred.

The purine ligand was characterized by spectroscopic methods. The electronic absorption spectrum of the purine ligand for pH = 7.0 and 10.0 exhibits three slight bands at $\lambda_{max}$(EtOH) = 305, 320 and 335 nm, which can be assigned to ligand n-π* transitions, and a high intense broad band at $\lambda_{max}$(EtOH) = 269 nm due to π-π* transitions.[13,14] A similar spectrum was obtained for pH = 5.4, however, a small shift to higher transition energies due to $N^1$ nitrogen protonation was observed.

The FTIR spectrum of the ligand in KBr is dominated by the characteristic bands of the purine ring ($\tilde{\nu}_{max}$ = 1617–1300 $cm^{-1}$) and by bands of the methylamino group on the 6-position of the ring ($\tilde{\nu}_{max}$ = 3273 and 1679 $cm^{-1}$). The strong and medium bands appearing between $\tilde{\nu}_{max}$ = 1617 and 1300 $cm^{-1}$ can be attributed to skeletal vibrations of the purine ring, while the methylamino group is indicated by the typical free N–H stretching vibrations at $\tilde{\nu}_{max}$ = 3273 $cm^{-1}$ and by the N–H bending vibration at $\tilde{\nu}_{max}$ = 1679 $cm^{-1}$.[13]

### Ion-Exchange Encapsulation Process of $Cu^{II}$–Purine Complexes

As it is commonly known, NaY zeolite is a microporous aluminosilicate based on sodalite cages joined by O bridges between the hexagonal faces. Eight such sodalite cages are linked together, forming a large central cavity or supercage, with a diameter of 12.5 Å. The supercages share a 12-membered ring with an open diameter of 7.4 Å. Thus, $Cu^{II}$–purine complexes can be ion-exchanged and encapsulated into the zeolite cavities.[15] In earlier studies, we showed that the methodologies used for the encapsulation/immobilization of the metal complexes in zeolites[16] and clays[17] are largely determined by the supports.

In this work, the modified zeolites with the entrapped metal complex were prepared by ion exchange in aqueous solutions, using an excess of the purine ligand (purine/$Cu^{II}$ molar ratio = 5:1). Chemical analysis (ICP-AES), and FTIR and UV/Vis spectroscopic analyses were performed at different stages of the preparation procedure in order to better characterize the prepared materials. In particular, the residual solutions obtained from the encapsulation process

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were analyzed before and after Soxhlet extraction. The results are summarized in Table 1.

Table 1. Chemical analysis of the residual solutions after the ion-exchange procedure for the preparation of the $[Cu^{II}L]_nY$ samples.

| Sample | $Cu^{II}$ [a] [mmol] | $Cu^{II}$ [b] [mmol] | $Cu^{II}$ [c] [mmol] | $Cu^{II}$ [d] [mmol] |
|---|---|---|---|---|
| $[Cu^{II}L]_{5.4}Y$ | $3.52\times10^{-2}$ | $1.65\times10^{-5}$ | $3.518\times10^{-2}$ | – |
| $[Cu^{II}L]_7Y$ | $3.52\times10^{-2}$ | $3.15\times10^{-5}$ | $3.517\times10^{-2}$ | $3.38\times10^{-2}$ |
| $[Cu^{II}L]_{10}Y$ | $3.52\times10^{-2}$ | $1.57\times10^{-5}$ | $3.518\times10^{-2}$ | – |

[a] Initial copper amount in the ion-exchange solution. [b] Residual copper amount. [c] Copper loading on NaY. [d] Copper loading on NaY after the treatment with $NaNO_3$.

It appears that the residual $Cu^{II}$ content was very low, indicating that about 99% of the copper initially present was retained inside the zeolite. This finding was also confirmed by the disappearance of the brown-green colour of the starting solution after six hours under ion exchange with the zeolite.

For the sample of $[Cu^{II}L]_7Y$ submitted to the treatment with $NaNO_3$, the amount of uncomplexed copper ions in solution was equal to $1.40\times10^{-3}$ mmol, implying a copper loading on NaY of $3.38\times10^{-2}$ mmol. The small decrease observed in the loaded amount of $Cu^{II}$, on the $[Cu^{II}L]_7Y$ sample after the $NaNO_3$ treatment, seems to indicate that almost all the adsorbed metal (96%) reacted with the purine ligand and the resulting complex became entrapped inside the zeolite.

### *$[Cu^{II}L]_nY$ before Soxhlet Extraction*

To obtain information about the adsorption of the purine ligand on zeolite, the residual solutions of the ion-exchange procedure were further analyzed by UV/Vis and FTIR spectroscopy. The presence of the purine ligand in the residual solutions is shown by the appearance of the band at $\lambda_{max}$(EtOH) = 269 nm in the UV/Vis spectra, thus indicating that the excess ligand in the initial solutions, not adsorbed by zeolite, was removed by filtration. The IR measurements also reveal the presence of bands due to the ligand, thus confirming the UV/Vis spectra results.

### *$[Cu^{II}L]_nY$ after Soxhlet Extraction*

Zeolites with the hosted metal complex, which were a brown-green colour, were extracted with ethanol to remove both the residual metal complex physically adsorbed on the external surface and the uncomplexed ligand. The resulting samples retained their initial colour after extraction. FTIR and UV/Vis spectroscopic analyses were performed on the extracting solvent; typical absorption bands of the purine ligand and complexes were present in the obtained spectra. These results confirmed that Soxhlet extraction was able to remove the entire adsorbed complex on the external surface and the uncomplexed ligand. This finding might indicate that the adsorbed ligand is fully coordinated with copper ions and that the encapsulated complex can not exit the zeolite.

### Characterization of the Modified Zeolite

The final $[Cu^{II}L]_nY$ samples obtained after the ion-exchange encapsulation process were characterized by surface analysis (XRD, SEM and XPS), spectroscopic methods (FTIR and EPR), chemical analysis (CA) and thermal analysis (TGA).

Powder X-ray diffraction patterns of the $[Cu^{II}L]_nY$ samples and the parent NaY are very similar. The unit-cell parameters were calculated from the (5 3 3), (6 4 2) and (5 5 5) reflection peak positions which were determined using the (1 1 1) reflection of the quartz ($2\theta$ = 26.64187) as an internal standard by ASTM D 3942–80. No variation was observed in the zeolite lattice parameters after the encapsulation process. This result shows that no significant structural changes in the zeolite framework occur (i.e., crystallinity of NaY is preserved) during the encapsulation process and that the zeolite structure is retained upon metal-complex encapsulation. Peaks due to the neat complex were not detected, probably because of its very low percentage loading.

$[Cu^{II}L]_nY$ samples obtained after the ion-exchange encapsulation process were analyzed by SEM. Analysis of the SEM micrographs of the parent and modified samples indicates that there were no changes in the NaY morphology and structure upon complex encapsulation (Figure 1). Furthermore, the SEM results confirm that Soxhlet extraction is a suitable method for removing all the uncomplexed ligand and the residual metal complex physically adsorbed on the external surface of zeolite.

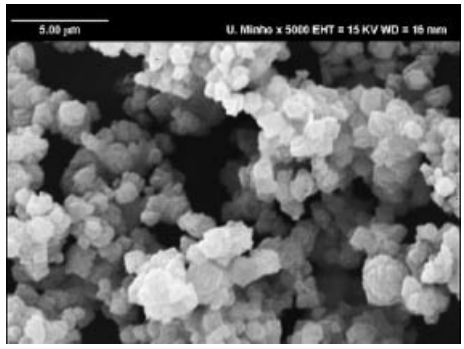


Figure 1. Scanning electron micrograph of $[Cu^{II}L]_{10}Y$ after Soxhlet extraction.

The infrared spectra of the parent NaY (**A**), $[Cu^{II}L]_7Y$ (**B**) and purine ligand (**C**) are presented in Figure 2. As the FTIR spectroscopic patterns of the $[Cu^{II}L]_nY$ samples prepared at different pH values were very similar, the sample $[Cu^{II}L]_7Y$ was chosen as a representative example.

The spectra of the parent zeolite and $[Cu^{II}L]_7Y$ are dominated by the strong bands attributable to the zeolite structure. No shift or broadening of the zeolite vibration bands are observed upon inclusion of the complex, which provides further evidence that the zeolite structure remains unchanged after the encapsulation procedure. In the $[Cu^{II}L]_7Y$ spectrum, the presence of the encapsulated organic complexes can be detected by small bands at $\tilde{\nu}_{max}$ = 1503, 1465 and 1395 $cm^{-1}$, typical of the purine ring, which appear shifted relative to those of the free ligand. The absence of N–H stretching vibration at $\tilde{\nu}_{max}$ = 3273 $cm^{-1}$ is evidence of the copper-ion coordination with the purine

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

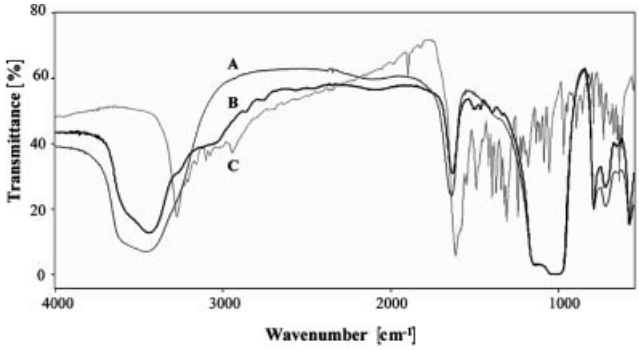

Figure 2. FTIR spectra of (A) NaY, (B) $[Cu^{II}L]_7Y$ and (C) purine ligand.

ligand and of the absence of free ligand within the zeolitic matrix. The obtained FTIR spectroscopic data indicate that the metal complex has been encapsulated in the Y zeolite and also suggest the presence of host–guest interactions with the zeolite structure.

Chemical analyses were also carried out on the solid $[Cu^{II}L]_nY$ samples. The obtained results, together with the molar Si/Al ratio and the estimated number of copper ions per unit cell, are presented in Table 2.

Table 2. Chemical analysis of the solid $[Cu^{II}L]_nY$ samples.

| | Elemental analysis [wt.-%] | | | | | | Cu/C | Cu/N |
|---|---|---|---|---|---|---|---|---|
| | Si/Al | $Cu^{II}$ [a] | $Cu^{II}$/UC | C | H | N | (w/w) | (w/w) |
| NaY | 2.88 | – | – | – | – | – | – | – |
| $[Cu^{II}L]_{5.4}Y$ | 2.95 | 0.43 | 1.10 | 1.70 | 3.20 | 1.50 | 0.25 | 0.28 |
| $[Cu^{II}L]_7Y$ | 2.98 | 0.32[b] | 0.76[b] | 1.00 | 3.00 | 0.90 | 0.32 | 0.35 |
| $[Cu^{II}L]_{10}Y$ | 2.93 | 0.41 | 0.96 | 1.30 | 2.90 | 1.10 | 0.32 | 0.37 |

[a] Copper loading on NaY. [b] Copper loading after the $NaNO_3$ treatment on NaY.

Table 2 shows that the maximum of one metal ion per unit cell is obtained on the $[Cu^{II}L]_{5.4}Y$ sample. It can also be calculated that the $(AlO_4)^-$ charges in the modified samples are not fully compensated by $Cu^{2+}$ and $Na^+$ ions. Most likely, protons balance the remaining charges through the following reaction taking place in aqueous solution:

$$\text{purine(aq)} + Cu^{2+}(aq) + H^+(aq) + Na^+(Z) \rightarrow Cu[\text{purine}]_n(Z) + Na^+(aq) + H^+(Z)$$

Charge compensation by co-exchange of protons led to some residual acidity in the zeolite, even in the samples for which NaOH was used to adjust the pH value during the preparation procedure. This residual acidity could have an effect on the catalytic behaviour of the samples in the cyclohexene oxidation reaction.[8]

The molar Si/Al ratio in $[Cu^{II}L]_nY$ samples did not change substantially upon $Cu^{II}$ complex exchange, indicating that dealumination does not occur during the encapsulation procedure. The comparisons of the molar Si/Al ratios for NaY and the modified samples confirm that the preparation method used in this work does not modify the zeolite structure, in agreement with XRD and FTIR results.

The success of the encapsulation of $Cu^{II}$–purine complexes in NaY was confirmed by the analytical data of carbon and nitrogen obtained by elemental analysis and by the copper loading obtained by ICP-AES (Table 2). The results suggest the presence of different structures of $Cu^{II}$–purine complexes with preferential Cu/ligand stoichiometry of 1:2 and 1:3.

For the 9-methyl-6-(methylamino)purine ligand, with a cation $pK_a$ value equal to 4.2,[18] the ratio of ligand·$H^+$/ligand observed at different pH syntheses is $5 \times 10^{-2}$ for pH = 5.4, $1.3 \times 10^{-3}$ for pH = 7.0 and $1.3 \times 10^{-7}$ for pH = 10.0. In acidic media, the purine ring can be protonated at $N^1$ (the more basic centre in the purine ring). This protonation hinders the coordination of the purine-ring nitrogen atoms ($N^1$ and $N^7$) with the copper ion; the formation of complexes such as **g** and **h** (Scheme 1) may be then favoured. In neutral medium, complex **h** is mainly present with two purine ligands that coordinate through the nitrogen atoms (NNNN) around the copper ion.[19,20] In more basic solutions, the nitrogen atoms of the purine ring are activated to coordinate with the copper ion, and complex **c** may be formed.

The XPS technique, which allows an analysis of the inner structure and cavity contents up to a depth of about 50 Å,[21] can provide information about the presence and distribution of $Cu^{II}$–purine complexes through the surface layer of NaY as well as on the oxidation state of the metal. All samples revealed the presence of oxygen, silicon and aluminium in their XPS resolution spectra. In the $[Cu^{II}L]_nY$ samples, the presence of the copper and nitrogen from the metal complexes was detected. In the Cu $2p_{3/2}$ and N 1s region, bands typical of the $Cu^{II}$ complexes, scarcely intense because of their low loading (as confirmed by XRD analyses), were identified. Table 3 presents the surface atomic content of sodium, silicon, aluminium and copper, obtained from the area of the relevant bands in the XPS spectrum for $[Cu^{II}L]_nY$ samples.

Table 3. Areas under the XPS Al 2p, Si 2p, Na 1s, C 1s, N 1s and Cu 2p bands for the samples.

| | XPS [atom-%] | | | | |
|---|---|---|---|---|---|
| | Si | Al | Na | $Cu^{II}$ | Si/Al |
| NaY | 23.8 | 7.4 | 11.4 | – | 3.10 |
| $[Cu^{II}]Y$ | 23.5 | 7.6 | 8.5 | 0.30 | 2.98 |
| $[Cu^{II}L]_{5.4}Y$ | 25.1 | 5.6 | 3.3 | 0.10 | 4.32 |
| $[Cu^{II}L]_7Y$ | 22.4 | 7.1 | 7.0 | 0.50 | 3.03 |
| $[Cu^{II}L]_{10}Y$ | 22.1 | 7.3 | 8.6 | 0.40 | 2.92 |

The increase in the Si/Al ratio in the modified $[Cu^{II}L]_{5.4}Y$ sample suggests that a certain dealumination takes place at the surface of the material during the encapsulation process in this case.

For $[Cu^{II}L]_7Y$ and $[Cu^{II}L]_{10}Y$ samples, the amount of Cu from XPS is very similar to the bulk copper content (Table 2). Probably, the $Cu^{II}$–purine complexes are homogeneously distributed throughout the NaY structure. However, for $[Cu^{II}L]_{5.4}Y$ the metal complexes diffuse through NaY and are preferentially located within the inner cavities.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

A medium binding-energy value of 932.2 eV for Cu $2p_{3/2}$ is obtained from the XPS spectra of $[Cu^{II}L]_nY$ samples, which confirms that the metal is in a +2 oxidation state, in agreement with the copper coordination sphere of the free complex. The same oxidation state is observed for the $[Cu^{II}]Y$ sample. All samples exhibit N 1s as a band centred at 400 eV, due to the contribution of the amine nitrogen atom of the 9-methyl-6-(methylamino)purine ligand. This result shows that the host matrix environment does not affect the valence state of the metal atom of the complexes.

Powder EPR spectra of all $[Cu^{II}L]_nY$ samples obtained at room temperature are typical of magnetically diluted samples, implying that the $Cu^{II}$–purine complexes are dispersed within the supercages of NaY, which acts as a diamagnetic matrix. The corresponding $g_{\|}$ and $A_{\|}$ values, summarized in Table 4, are axial type and exhibit well-resolved hyperfine couplings with copper ($^{63}Cu/^{65}Cu$, $I = 3/2$) in the region of low magnetic fields.[9,10]

Table 4. EPR data of the solid $[Cu^{II}L]_nY$ samples.

| Sample | $g_{\|}$ | $g_{\perp}$ | $A_{\|}$ / $10^{-4}$ cm$^{-1}$ |
|---|---|---|---|
| $[Cu^{II}L]_{5.4}Y$ | 2.490 | 2.045 | 150 |
| $[Cu^{II}L]_{7}Y$ | 2.309 | 2.049 | 180 |
| $[Cu^{II}L]_{10}Y$ | 2.302 | 2.047 | 175 |

EPR spectra of the samples prepared at pH = 7.0 and pH = 10.0 (Figure 3) show $g$ and $A$ values typical of planar coordination of nitrogen and/or oxygen in the first coordination sphere around $Cu^{II}$.[8,9,16,19] In contrast, the EPR spectrum of the $[Cu^{II}L]_{5.4}Y$ sample is complex, probably because of the presence of more than one complex species. The increase in $A_{\|}$ and the decrease in $g_{\|}$ values (see Table 4) suggest an NNNN coordination around the $Cu^{2+}$ ion.[20,22–24]

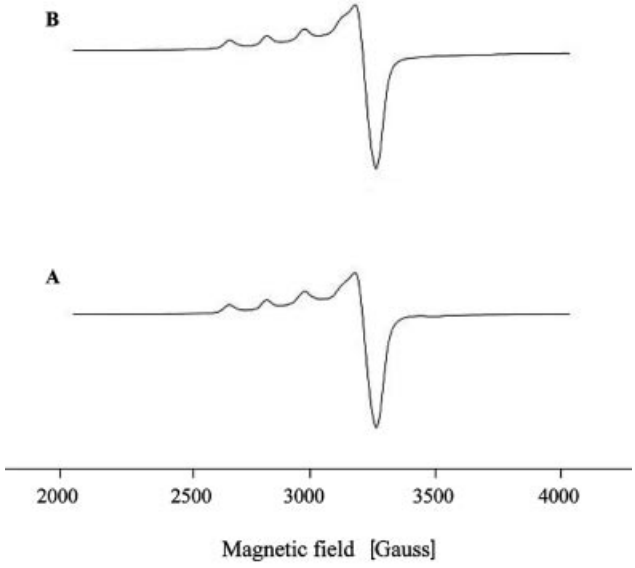

Figure 3. EPR spectra of (A) $[Cu^{II}L]_7Y$ and (B) $[Cu^{II}L]_{10}Y$.

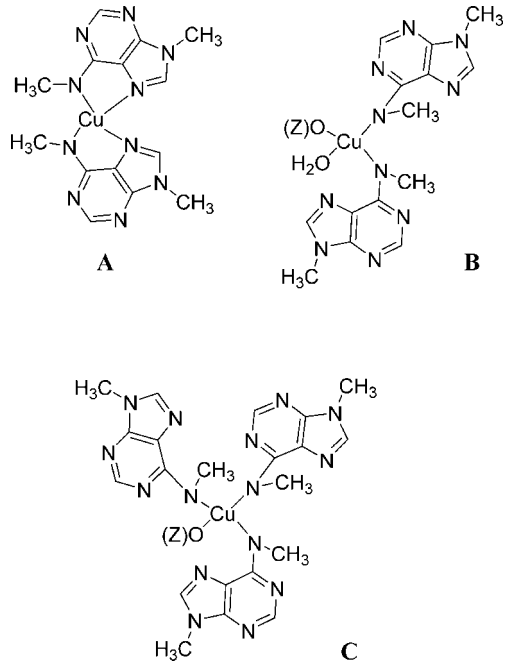
In agreement with Weckhuysen et al. who reported two different coordination modes of the $Cu^{II}$–histidine complexes encapsulated in NaY zeolite,[6–10,20] three different $Cu^{II}$–purine complexes are proposed for inside the zeolitic supercage: (i) complexes **A** and **B** with a 1:2 Cu/L stoichiometry and (ii) complex **C** with a 1:3 Cu/L stoichiometry. As shown in Scheme 2, $Cu^{II}$ is coordinated with the 9-methyl-6-(methylamino)purine ligands in complex **A** by means of two $N_{am}N^7$ chelating groups [with an $N_{am}(1)N^7(1)$-$N_{am}(2)N^7(2)$ coordination, where the numbers in brackets refer to the 9-methyl-6-(methylamino)purine molecule], while complex **B** is characterized by an $N_{am}(1)N_{am}(2)O_wO_z$ coordination, in which $O_w$ and $O_z$ symbolize a water and a zeolite framework oxygen, respectively. An $N_{am}(1)N_{am}(2)$-$N_{am}(3)O_z$ coordination is finally observed for complex **C**.



Scheme 2. Structures of copper(II)–purine complexes in Y zeolite: complex **A** with $N_{am}(1)N^7(1)N_{am}(2)N^7(2)$ coordination; complex **B** with $N_{am}(1)N_{am}(2)O_zO_w$ coordination; complex **C** with $N_{am}(1)$-$N_{am}(2)N_{am}(3)O_z$ coordination.

Although complex **A** is the dominant configuration for all samples, the relative amount of the different structures depends on the preparation conditions of the samples. It seems that the pH value during the synthesis determines the mode of coordination of the $Cu^{II}$ ion with the purine ligand; higher values (pH = 7.0 and 10.0) foster the formation of complex **A**, which accounts for 80% in both cases, while at lower pH (5.4) an increase in the amount of complexes **B** and **C** was observed.

Complementary studies performed by using thermal analysis (TGA) contributed to a better understanding of the different configurations of the encapsulated metal (depending on the pH value during the synthesis) on the thermal properties of the samples. The TGA curve of NaY shows a weight loss at 120 °C which can be attributed to the removal of intrazeolite water. After encapsulation of $Cu^{II}$–purine complexes, two major stages of weight loss can be found in a broad temperature range (i.e., 110–490 °C). The first stage occurs above 110 °C with comparable weight

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

losses for the three $[Cu^{II}L]_nY$ samples, and it is most likely caused by intrazeolite water desorption and by desorption of water associated with the encapsulated complexes. However, differences were observed at higher temperatures in the second stage of the TGA curves, which corresponds to the decomposition of the encapsulated complexes, both in the onset temperature of the decomposition process and in the weight-loss extent. Results are summarized in Table 5.

Table 5. Thermogravimetric analysis results of the solid $[Cu^{II}L]_nY$ samples.

| Sample | $T_1$[a] [°C] | $T_2$[b] [°C] | Weight loss[c] [%] |
|---|---|---|---|
| NaY | 120 | – | – |
| $[Cu^{II}L]_{5.4}Y$ | 110 | 350 | 5.4 |
| $[Cu^{II}L]_7Y$ | 110 | 420 | 3.2 |
| $[Cu^{II}L]_{10}Y$ | 110 | 480 | 3.7 |

[a] Temperature of water desorption obtained from DTG curve. [b] Temperature of complex decomposition obtained from DTG curve. [c] Weight loss due to complex decomposition obtained from DTG curve.

Differences in weight losses and onset temperatures of the complex decomposition are most probably related to (i) different coordination configurations of the $Cu^{II}$ ion with the 9-methyl-6-(methylamino)purine ligand which leads to three $Cu^{II}$–purine complexes, in agreement with chemical analysis and EPR results, and (ii) predominance of one of these $Cu^{II}$–purine complexes for high pH syntheses.

### Catalytic Behaviour of the Modified Zeolite

The effect of $Cu^{II}$–purine complexes encapsulated in NaY zeolite on the oxidation of cyclohexene with *t*BuOOH (TBHP) in decane was studied, and the results are shown in Table 6.

Table 6. Catalytic performance of the $[Cu^{II}L]_nY$ samples in cyclohexene oxidation.[a]

| Catalyst | Conversion[a] | Selectivity [%] | | |
|---|---|---|---|---|
| | [%] | Ketone[b] | Alcohol[c] | Oxide[d] |
| – | 40.3 | 62.7 | 37.3 | 0.0 |
| NaY | 40.8 | 59.0 | 41.0 | 0.0 |
| $[Cu^{II}]Y$ | 46.4 | 65.9 | 34.1 | 0.0 |
| $[Cu^{II}L]_{5.4}Y$ | 47.6 | 49.3 | 42.4 | 8.3 |
| $[Cu^{II}L]_7Y$ | 55.8 | 48.4 | 37.0 | 14.6 |
| $[Cu^{II}L]_{10}Y$ | 65.9 | 48.9 | 41.3 | 9.8 |

[a] In decane, 30 °C, TBHP/cyclohexene molar ratio = 5:3. [b] 2-Cyclohexene-1-one. [c] 2-Cyclohexene-1-ol. [d] Cyclohexene oxide.

Cyclohexene conversion and product selectivity were compared at 24 hours on-stream. Blank runs were performed to check the contribution of the radical mechanism; it was found that it accounted for about 40% of cyclohexene conversion. Only allylic oxidation occurred with the formation of 2-cyclohexene-1-one, 2-cyclohexene-1-ol and 3-*tert*-butylcyclohexenyl peroxide, as also reported in ref.,[25] while the formation of cyclohexene oxide was not observed. The NaY sample showed a quite similar behaviour.

When sodium was ion-exchanged with copper in NaY ($[Cu^{II}]Y$), a slight increase was observed both in conversion and in 2-cyclohexene-1-one selectivity. The increase in conversion from 46.4% to 65.9%, which is found by comparing the $[Cu^{II}]Y$ and $[Cu^{II}L]_{10}Y$ samples, indicates that in the presence of the purine ligand the catalytic activity is increased by a factor of 1.42. From the results in Table 6, it is evident that 2-cyclohexene-1-one is selectively formed in the presence of all catalysts. However, cyclohexene oxide is formed only on the $[Cu^{II}L]_nY$ catalysts, when $Cu^{II}$ is coordinated to the purine ligands. The selectivity value towards the epoxide seems to have a slight maximum for the $[Cu^{II}L]_7Y$ sample, while conversion increases continuously with the pH value used during the catalyst preparation. The 2-cyclohexene-1-ol selectivity also shows an increase for all the $[Cu^{II}L]_nY$ catalysts with respect to the $[Cu^{II}]Y$ sample. Further, in agreement with the findings of other authors,[7,25] the presence of 1,2-cyclohexanediol was not observed.

The formation of the allylic oxidation products, 2-cyclohexene-1-one and 2-cyclohexene-1-ol, suggests the preferential attack of the activated C–H bond over the C=C bond. Furthermore, the formation of 3-*tert*-butylcyclohexenyl peroxide is an indication of the occurrence of radical reactions.[25–28] TBHP as the oxidant promotes the allylic oxidation pathway and the extent of epoxidation is reduced. The effect of molecular oxygen in the cyclohexene epoxidation reaction with *t*BuOOH has also been reported.[29,30] It was found that when molecular oxygen acts as an oxidant in the reaction, 2-cyclohexene-1-one and 2-cyclohexene-1-ol are mainly formed.

## Conclusions

In light of the obtained results, it can be concluded that $Cu^{II}$–purine complexes coordinated with a 9-methyl-6-(methylamino)purine ligand can be encapsulated in NaY zeolite by an ion-exchange adsorption process, without structural modification or loss of crystallinity of the zeolite framework. Depending on the pH of the exchange solution, three different structures for the $Cu^{II}$–purine complexes have been proposed in the Y zeolite supercage: (i) complex **A** is located in the centre of the supercage, for which all equatorial coordination sites are provided by the purine molecules; (ii) complex **B** is coordinated to two purine molecules, for which the other two ligands are supplied by the zeolite and a water molecule; and (iii) complex **C** is coordinated to three purine ligands and to one framework oxygen atom from the zeolite.

$[Cu^{II}L]_nY$ catalysts are active in the cyclohexene oxidation reaction with TBHP. The product distribution is mainly consistent with the allylic oxidation to 2-cyclohexene-1-one and 2-cyclohexene-1-ol.

## Experimental Section

**Materials:** NaY zeolite (Si/Al = 2.88) was supplied by Grace GmbH. Chemicals for the purine ligand synthesis, the encapsulation procedure [EtOH, NaOH, HCl, $Cu(NO_3)_2{\cdot}3H_2O$ and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$NaNO_3$] and the oxidation reaction (cyclohexene, decane, *t*BuOOH [70% solution in water]) were purchased from Aldrich. All used materials were reagent grade.

**Sample Preparation:** The 9-methyl-6-(methylamino)purine ligand was synthesized as described in detail elsewhere.[31] Zeolite-encapsulated $Cu^{II}$–purine complexes were prepared according to the following experimental procedure: aqueous solutions of $Cu(NO_3)_2 \cdot 3H_2O$ (8.5 mg, $3.52 \times 10^{-2}$ mmol) and the 9-methyl-6-(methylamino)purine ligand (29.0 mg, $1.76 \times 10^{-1}$ mmol) in distilled water (100 $cm^3$) (purine/$Cu^{II}$ = 5:1; this molar ratio ensures that the purine ligand is not the limiting reactant during the encapsulation process) were added to NaY (0.5 g; previously calcined at 500 °C during 8 h under a dry air stream) at different pH (5.4, 7.0 and 10.0). Aqueous solutions of NaOH and/or HCl (0.1 mol $dm^{-3}$) were used to adjust the pH value, which was continuously monitored. The resulting mixtures were stirred at room temp. for 24 h, until the brown-green aqueous solutions became colourless, indicating that the complex was adsorbed by the zeolite. Then the suspension was filtered off, and the solid was washed with distilled water and dried at 60 °C for 8 h. The excess or uncoordinated ligand, as well as the residual metal complex physically adsorbed on the external surface, was removed by Soxhlet extraction with ethanol for 6 h. Finally, the samples were dried in an oven at 100 °C, under vacuum, for 12 h. The obtained samples are denoted as $[Cu^{II}L]_nY$, where L represents the 9-methyl-6-(methylamino)purine ligand and *n* is the pH value. A $[Cu^{II}]Y$ sample, with the same amount of copper as $[Cu^{II}L]_nY$, was also prepared for comparison. A portion of the $[Cu^{II}L]_7Y$ sample was further treated, for 6 h at room temp., with an aqueous solution of $NaNO_3$ (0.1 mol $dm^{-3}$) in order to remove the remaining uncomplexed copper ions from the zeolite; it was subsequently filtered off, washed with hot distilled water and finally dried at 60 °C for 12 h.

**Characterization:** Elemental chemical analyses (Si, Al, Na and Cu) were performed by inductively coupled plasma atomic emission spectrometry (ICP-AES) using a Philips ICP PU 7000 Spectrometer. The decomposition of solid samples was carried out by alkaline fusion; the method involves the use of lithium metaborate as the fluxing agent, which grants thermal stabilization of elements during the fusion stage at 1050 °C.[15] Chemical analysis of C, H and N were carried out with a Leco CHNS-932 analyzer. X-ray photoelectron spectroscopy analyses were obtained at the C. A. C. T. I. (Vigo University, Spain) with a VG Scientific ESCALAB 250iXL spectrometer using monochromatic Al-$K_\alpha$ radiation (1486.92 eV). Powder EPR spectra were obtained with a Bruker EMX spectrometer working at the X-band microwave frequencies (ca. 9.5 GHz) at room temp. Phase analysis was performed by XRD using a Philips PW1710 diffractometer. Scans were taken at room temp. in a $2\theta$ range between 4 and 80°, using Cu-$K_\alpha$ radiation. The SEM micrographs were collected with a LEICA Cambridge S360 Scanning Microscope equipped with an EDS system. To avoid the surface charging, samples were coated with gold in vacuo, by using a Fisons Instruments SC502 sputter coater, before being observed. Room temp. FTIR spectra of ligand and sample materials were obtained from powdered samples on KBr pellets, using a Bomem MB104 spectrometer in the range 4000–500 $cm^{-1}$ by averaging 20 scans at a maximum resolution of 4 $cm^{-1}$. The electronic UV/Vis absorption spectra of the purine ligand and residual solutions were collected in the range 600–200 nm with a Shimadzu UV/2501PC spectrophotometer using quartz cells at room temp. Thermogravimetric analyses (TGA) of the samples were carried out using a TGA 50 Shimadzu instrument under a high-purity helium flow (50 $cm^3 min^{-1}$). All samples were characterized between 25 and 600 °C with a heating rate of 6 °C $min^{-1}$.

**Catalytic Runs**

Experimental runs lasting 24 h were performed in a magnetically agitated batch reactor, equipped with an external water jacket and with a refrigerant, each connected with a cryothermostat in order to control the reaction and condensation temperatures, respectively. Prior to the catalytic tests, samples were activated in an oven at 250 °C for 2 h. The reaction conditions were $T$ = 30 °C, catalyst: 30 mg, cyclohexene: 100 μL, *t*BuOOH (5.5 mol $dm^{-3}$ in decane): 945 μL, oxidant/substrate molar ratio = 5:3 and solvent: decane.

Chromatographic analyses of the reaction mixture, sampled at 1-h intervals, were carried out using a GC HP 6890 (equipped with a capillary column SUPELCO Petrocol DH and a FID) and allowed qualitative and quantitative determination of (by the internal standard method) the reactant, cyclohexene and the following reaction products: cyclohexene oxide, 2-cyclohexene-1-one, 2-cyclohexene-1-ol and 1,2-cyclohexanediol. Other products were also observed (but not quantified) and identified by GC-MS: 3-*tert*-butylcyclohexenyl peroxide and very small amounts of 2,3-epoxycyclohexanone and 2,3-epoxycyclohexanol, together with those derived from the thermal decomposition of the *t*BuOOH.

## Acknowledgments

Dr. C. S. Rodriguez (C. A. C. T. I., Vigo University, Spain) is gratefully acknowledged for performing and interpreting the XPS analyses. Acknowledgments are also due to Dr. C. L. Remesar (GIQIMO, Santiago de Compostela University, Spain) for the EPR measurements. We thank Dr. A. S. Azevedo for collecting the powder diffraction data and Dr. C. Ribeiro for performing chemical analyses (Departamento de Ciências da Terra of Universidade do Minho). This work was supported by the Centro de Química (University of Minho, Portugal) and by Fundação para a Ciência e Tecnologia (FCT Portugal), under programme POCTI-SFA-3-686.

# Supramolecular Chemistry and Anion Binding in Palladium(II) and Silver(I) Complexes Containing *N*,*N*′-Dipyridylxanthene-4,5-dicarboxamide Ligands

**Nancy L. S. Yue,[a] Michael C. Jennings,[a] and Richard J. Puddephatt*[a]**

**Keywords:** Supramolecular / Polymers / Silver / Palladium

Two new ligands, 2,7-di-*tert*-butyl-9,9-dimethyl-*N*,*N*′-di(3-pyridyl)- (**1**) and -*N*,*N*′-bis[(3-pyridyl)methyl]xanthene-4,5-dicarboxamide (**2**), and their complexes with palladium(II) and silver(I) are reported. Intramolecular hydrogen bonding orients the ligands so as to favour formation of macrocyclic complexes, and the structures of $[Pd_2X_4(\mu\text{-}\mathbf{1})_2]$ (**3a**), X = Cl; (**3b**) X = Br, and $[Ag_2(\mu\text{-}\mathbf{2})_2](CF_3SO_3)_2$ (**5a**) are reported. Intermolecular hydrogen bonding can also occur and can lead to supramolecular self-assembly to give sheet **3a** or ribbon **5a** structures, or serve to bind anions or solvent molecules.

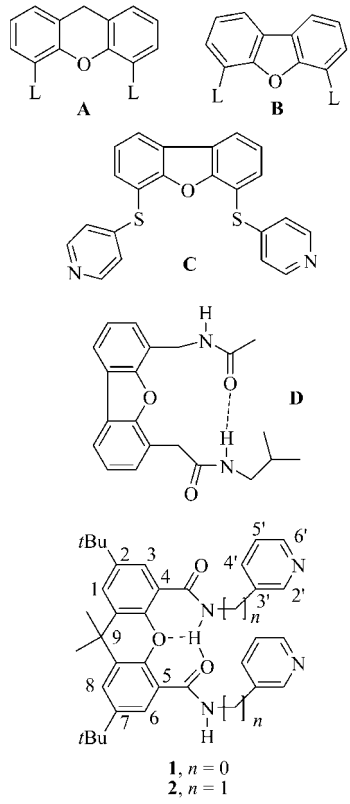
## Introduction

In the field of host–guest chemistry, there is increasing interest in the use of hybrid organic–inorganic receptors, which can be synthesized easily by the techniques of self-assembly, and in which both the organic and inorganic components can have useful functions in binding different types of guest molecules or ions.[1–5] If the organic component contains hydrogen-bonding functionality, such as an amide group, this can be used to control the ligand conformation through intraligand hydrogen bonding, and hence to determine the primary structure of the complex (for example, chelate complex, macrocycle or polymer).[6,7] In addition, the hydrogen-bonding component may control secondary or tertiary structure through further interligand hydrogen bonding, and it may be used to enhance host–guest interactions.[1–15] Thus, the combination of dynamic coordination chemistry and hydrogen bonding has proved to be particularly useful for the self-assembly of functional molecular materials.

Ligands based on the xanthene or dibenzofuran skeletons have been widely used in catalysis, because the wide bite angles that are typical with ligands of type **A** or **B** (Scheme 1) can lead to unusual reactivity.[16–23] However, they have been used less frequently in studies of self-assembly or host–guest chemistry,[24–26] though interesting ligands such as **C** (Scheme 1) have been designed.[25] In addition, xanthene skeletons with additional amide functions incorporated, such as **D** (Scheme 1), have been used as mimics for β turns in protein analogs, using intramolecular hydrogen bonds to control the β-turn orientation.[27,28] Following our interest in the self-assembly of host molecules,[29–38] this article reports silver(I) and palladium(II) complexes derived from the *N*,*N*′-di(3-pyridyl)- or *N*,*N*′-bis[(3-pyridyl)methyl]xanthene-4,5-dicarboxamide ligands **1** and **2** (Scheme 1). The ligand is designed to give easy self-



Scheme 1. The *N*,*N*′-dipyridyl-substituted xanthenedicarboxamide ligands **1** and **2**, and some related compounds containing the xanthene or dibenzofuran scaffold unit. The labelling system is defined for ligands **1** and **2**.

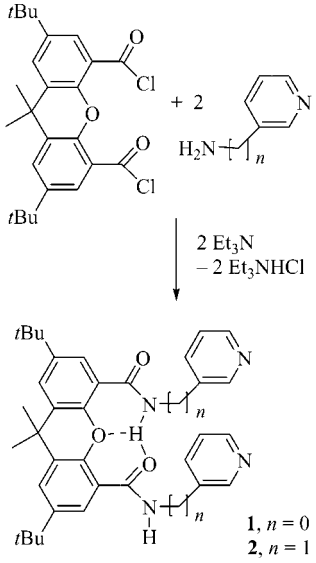
assembly of metallacyclic complexes by dynamic coordination using the pyridine groups as donors. In addition, the amide groups can be used both to orient the donor groups through intramolecular NH···O=C hydrogen bonding and to control either intermolecular assembly or host-guest chemistry through the second NH, C=O group functionality.[27–38]

## Results and Discussion

### Properties of the Ligands 1 and 2

The ligands were prepared according to Equation (1).



(1)

The ligand **2** was sufficiently soluble in $CD_2Cl_2$ to allow a study by variable-temperature NMR (Figure 1). It has previously been shown that in xanthenecarboxamide derivatives hydrogen-bonded NH proton signals appear in the region $\delta$ = 7–9 ppm and exhibit a large temperature dependence [$\Delta\delta/\Delta T < -10$ ppb/K], while free N–*H* signals appear at $\delta \approx 6$ ppm and exhibit a small temperature dependence [$\Delta\delta/\Delta T \approx -1$ ppb/K].[27,28] The resonance for the NH protons of ligand **2** occurs at $\delta$ = 8.18 ppm at 299 K and gives a value of $\Delta\delta/\Delta T = -12$ ppb/K. Only a single set of aromatic resonances was observed, indicating effective twofold symmetry (Figure 1). These data indicate that there is an easy equilibrium between the conformers **2a**, **2b** and **2c** in solution, with the equilibrium favoring the hydrogen-bonded forms (Scheme 2). The ligand **1** was insufficiently soluble in $CD_2Cl_2$ to allow a similar NMR study, but it is likely that a similar equilibrium is present. In the $^1$H NMR spectrum of **1** in $CD_2Cl_2/CD_3OD$, the NH proton exchanged rapidly with the methanol proton and so was not observed.

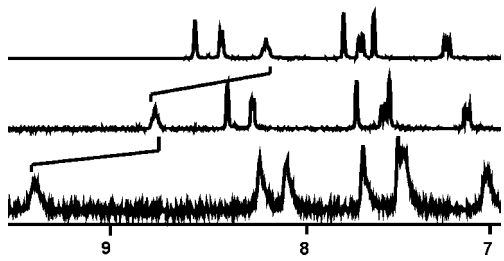


Figure 1. Variable-temperature $^1$H NMR spectra (400 MHz, top, 299 K; center, 233 K; bottom, 193 K) of ligand **2** in $CD_2Cl_2$. The bars indicate the movement of the resonance for the NH protons.

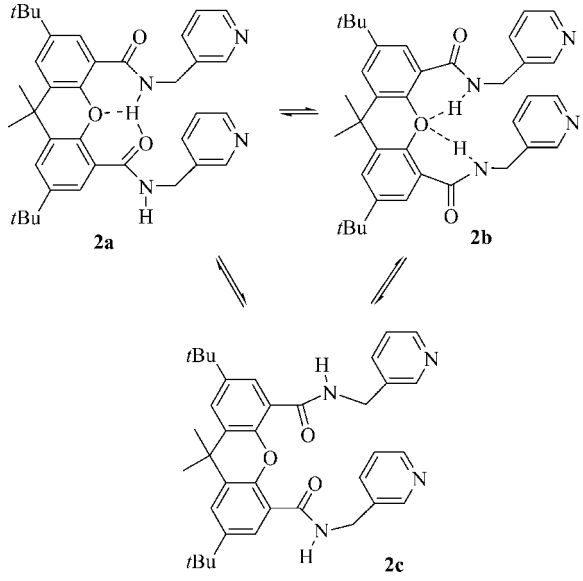


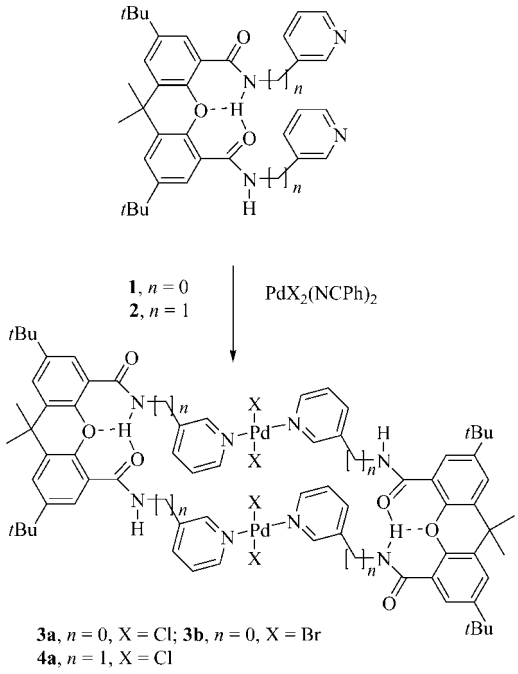
Scheme 2. Probable conformers of ligand **2** arising from rotation of the amide groups.

### Palladium(II) Complexes

Reaction of equimolar amounts of ligand **1** and $[PdX_2(NCPh)_2]$ gave the corresponding macrocyclic complexes $[Pd_2X_4(\mu\text{-}\mathbf{1})_2]$ (**3a**), X = Cl; (**3b**), X = Br (Scheme 3). Complex **3a** was essentially insoluble in common organic solvents, but **3b** was sufficiently soluble in [$D_7$]DMF to give a $^1$H NMR spectrum. The spectrum indicated effective twofold symmetry, because only a single set of resonances for the ligand **1** was observed. The amide NH resonance for **3b** was observed at $\delta$ = 10.75 ppm.

Single crystals of **3a** and **3b** were grown by slow diffusion of a solution of ligand **1** in acetonitrile/methanol into a solution of $[PdX_2(NCPh)_2]$, X = Cl or Br, in dichloromethane, under which conditions each complex crystallized as the acetonitrile solvate $[Pd_2X_4(\mu\text{-}\mathbf{1})_2]\cdot 4MeCN$. The molecular structures are shown in Figure 2. The complexes exist as macrocycles, with each palladium(II) center having the *trans*-$PdCl_2N_2$ square-planar coordination. There is a crystallographically imposed inversion center in both **3a** and **3b** (Figure 2). All amide groups are in the usual *trans* conformation. Each ligand has one NH and one C=O group directed inwards, with a transannular NH···O=C hydrogen bond between them, and one NH and C=O group directed

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Synthesis of macrocyclic palladium(II) complexes.

outwards. The inward NH group is also hydrogen-bonded to the xanthene oxygen atom (Figure 2). In complex **3b**, the outward NH group is hydrogen-bonded to an acetonitrile solvate molecule (Figure 2), but in **3a** the hydrogen bonding of the outward NH group is more complex, as described below. The other main difference in molecular structures of **3a** and **3b** is related to the conformations of the 3-pyridyl groups. In complex **3a** both pyridyl donors are roughly *syn* to the amide carbonyl group [dihedral angles C(8)N(7)C(3)C(2) –19.7°, C(34)N(36)C(37)C(38) –19.8°], but in complex **3b** one of the pyridyl groups is roughly *syn* and the other roughly *anti* to the amide carbonyl group [dihedral angles C(8)N(7)C(3)C(2) –34.7°, C(34)N(36)C(37)C(38) –136.9°]. The above torsion angles and the illustrations in Figure 2 also illustrate how the 3-pyridyl groups are distorted out of the plane of the amide units to a greater extent in **3b** compared to **3a**. As a result of the conformational difference, the palladium atoms are closer and the macrocycle more rectangular in shape in **3b** compared to **3a** [Pd···PdA 5.67 Å in **3a**; Pd···PdA 4.26 Å in **3b**].

In complex **3a** the acetonitrile molecules of solvation are not involved in hydrogen bonding with the outward NH group. Instead this NH group forms an intermolecular hydrogen bond to a chloride ligand of a neighboring molecule (Figure 3a). Each macrocycle **3a** is involved in four such hydrogen-bonding interactions through the two outward-directed NH groups and two of the four chloride ligands (Figure 3b). The overall result is that the macrocycles are assembled into sheets as shown in part b of Figure 3. This intermolecular hydrogen bonding is evidently strong enough to make complex **3a** much less soluble than **3b**. The outward-directed carbonyl group is not involved in hydrogen bonding in either complex **3a** or **3b**, and so it appears that the strength of intermolecular hydrogen bonding of the

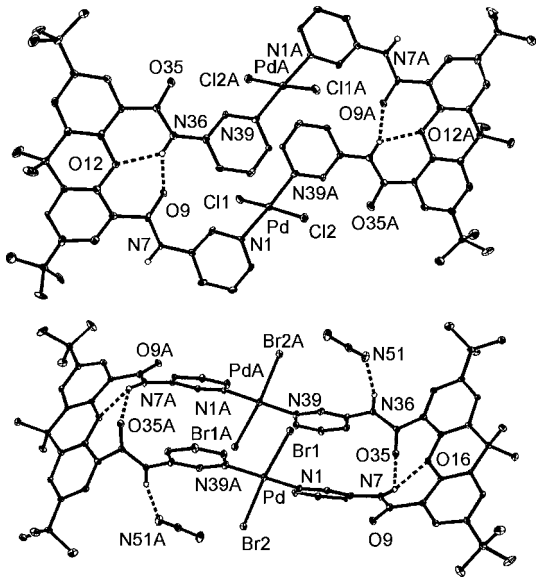


Figure 2. Molecular structures of complexes **3a** and **3b**. Selected distances: **3a**; Pd–Cl(1) 2.320(2); Pd–Cl(2) 2.293(2); Pd–N(1) 2.040(6); Pd–N(39A) 1.997(6) Å. **3b**; Pd–N(1) 1.999(7); Pd–N(39A) 2.016(7); Pd–Br(2) 2.419(1); Pd–Br(1) 2.442(1) Å. Hydrogen bond lengths: **3a**; N(36)···O(12) 2.706(8); N(36)···O(9) 2.843(7) Å. **3b**; N(7)···O(16) 2.641; N(7)···O(35) 3.081; N(36)···N(51) 3.02(1) Å.

outward NH group follows the series NH···ClPd (observed in **3a**) > NH···NCMe (observed in **3b**) > NH···BrPd, NH···O=C (not observed).

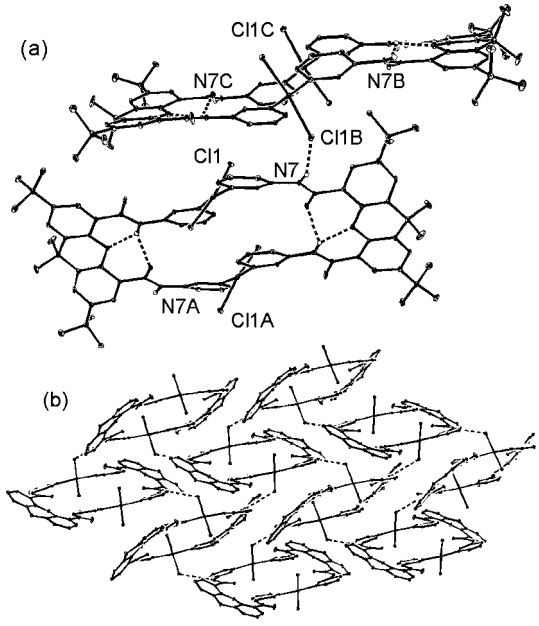

Figure 3. The self-assembly of the macrocyclic complexes **3a**: (a) an intermolecular NH···Cl interaction with distance N(7)···Cl(1B) 3.585(7) Å; (b) the sheet structure arising from the self-assembly process.

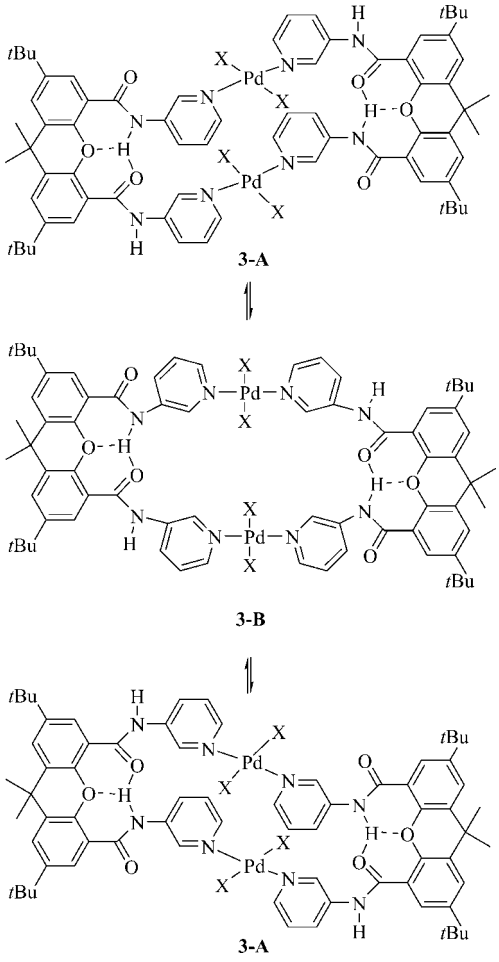
The apparent twofold symmetry of complex **3b** in solution, as determined by its $^1$H NMR spectrum, requires easy rotation of the pyridylamido units and it is likely that the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

conformers **3-A** (as seen in the solid-state structure of **3a**) and **3-B** (as seen in **3b**) are two of several that may be involved in the fluxionality (Scheme 4).



Scheme 4. Proposed mechanism of fluxionality of complex **3b** (X = Br).

The reaction of ligand **2** with $[PdCl_2(NCPh)_2]$ was more complex. The product analysed as "$PdCl_2$(**2**)", but the $^1$H NMR spectrum indicated the presence of two isomers in a roughly 3:2 ratio, each having twofold symmetry (see Exp. Sect.). Single crystals for X-ray structure determination could not be obtained. The ESI-MS gave the highest mass peak envelope centered at *m*/*z* = 1499, corresponding to $[Pd_2Cl_3(\mu\text{-}\mathbf{2})_2]^+$, as expected for loss of one chloride ligand from **4a**. Hence, it is likely that one of the isomers present is **4a** but the nature of the other isomer is not known.

### Silver(I) Complexes

The reactions of ligand **1** with silver(I) salts gave insoluble complexes which could not be characterized, but the similar reaction with the more flexible ligand **2** gave the more soluble complexes $[Ag_2(\mu\text{-}\mathbf{2})]_2(X)_2$, **5a**, X = $CF_3SO_3$; **5b**, X = $CF_3CO_2$; **5c**, X = $NO_3$; **5d**, X = $BF_4$; **5e**, X = $PF_6$. Complex **5a** was not easily soluble in dichloromethane but it was sufficiently soluble in a $CD_2Cl_2$/$CD_3OD$ mixture to give a $^1$H NMR spectrum. The $^1$H NMR spectrum in the temperature range 299–193 K indicated effective twofold symmetry of the ligand units **2**, presumably due to easy rotation of the pyridylamido units. In contrast to the case of complex **4a**, only one isomer was present (Figure 4). The resonance for the NH protons of complex **5a** occurs at $\delta$ = 9.17 ppm at 299 K and gives a value of $\Delta\delta/\Delta T$ = –3 ppb/K.

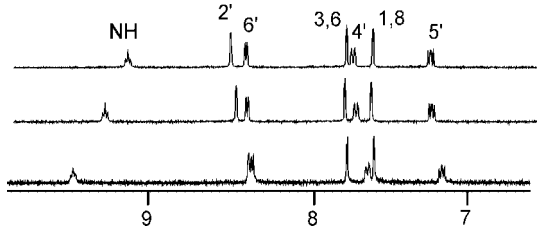


Figure 4. $^1$H NMR spectrum (400 MHz) of complex **5a** in $CD_2Cl_2$/$CD_3OD$ at (top) 299 K; (center) 273 K; (bottom) 243 K.

The structure of complex **5a** is shown in Figure 5. The complex exists in the form of a macrocycle with distorted linear silver(I) coordination [N(1)–Ag–N(41A) 168.9(3)°]. The distortion from linearity allows the silver(I) centers to form a transannular argentophilic interaction [Ag–Ag(A) 3.134(1) Å]. The conformation of the amido groups is similar to those observed in **3a** and **3b**, in which the inward NH group hydrogen bonds to both the xanthene oxygen atom and the inward directed carbonyl oxygen atom (Figure 5). The outward directed NH groups hydrogen bond to triflate anions.

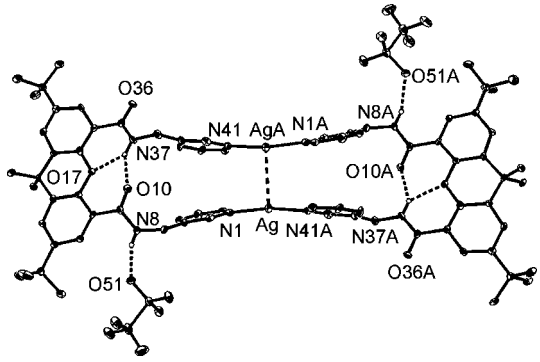

Figure 5. Structure of the silver(I) complex **5a**. Selected parameters: Ag–N(1) 2.130(7), Ag–N(41A) 2.148(7), Ag–Ag(A) 3.134(1) Å; N(1)–Ag–N(41A) 168.9(3)°. Hydrogen bonding distances: N(8)···O(51) 2.92(1), N(37)···O(10) 2.83(1), N(37)···O(17) 2.71(1) Å.

The complex **5a** undergoes further self-assembly in the solid state to give a ribbon structure, as shown in Figure 6. Each triflate ion is hydrogen-bonded to an outward-directed NH group through one of its oxygen atoms (O51), as shown in Figure 5, but each triflate also bridges between the two silver(I) centers of a neighboring macrocycle through a second oxygen atom (O52), as shown in Figure 6. Each macrocycle then interacts with four bridging triflate ions through secondary Ag···O or NH···O interactions, as shown in Figure 6, and a ribbon structure is formed.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

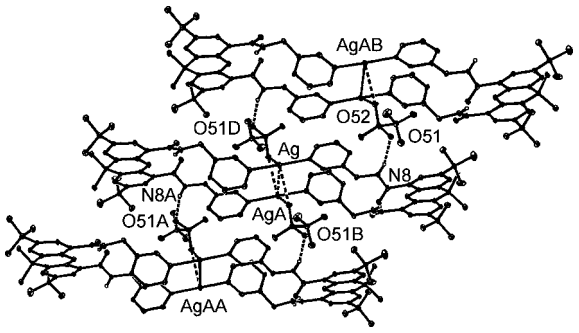

Figure 6. The ribbon structure formed by self-assembly of **5a**, showing how each macrocycle binds to two neighboring macrocycles through four bridging triflate ions. Selected distances: Ag···O(52B) and AgA···O(52D) 2.77(1), Ag···O(52D) and AgA···O(52B) 2.83(1) Å.

The interactions of complexes **5a**–**5e** with anions in dilute acetonitrile solution were studied by ESI-MS. The highest mass peaks for complexes **5a**–**5e** were observed in envelopes centered at *m*/*z* = 1546, 1511, 1458, 1483, and 1541, corresponding to $[^{107}Ag_2(\mathbf{2})_2X]^+$, with X = $O_3SCF_3$, $O_2CCF_3$, $NO_3$, $BF_4$, and $PF_6$, respectively. A dilute solution of complex **5a** ($0.5 \times 10^{-3}$ M) in acetonitrile was treated with increasing amounts of $Bu_4N^+X^-$ (X = $NO_3$, $HSO_4$, $ClO_4$, $BF_4$ and $PF_6$) to give 1:0.6, 1:0.8, 1:1.0, 1:1.2 and 1:1.4 molar ratios. By monitoring the decrease in intensity of the envelope of peaks for $[Ag_2(\mathbf{2})_2(O_3SCF_3)]^+$ at *m*/*z* = 1545, accompanied by the increase in intensity of the peaks for $[Ag_2(\mathbf{2})_2X]^+$, it is possible to estimate the relative binding abilities of the anions $X^-$. Typical spectra are shown in Figure 7. The anion binding follows the sequence $NO_3^- > HSO_4^- > CF_3SO_3^- > ClO_4^- > BF_4^-, PF_6^-$. This is consistent either with the series of p$K_a$ values of the corresponding acids [approximate p$K_a$ for $HNO_3$ –1; $H_2SO_4$ –3; $HClO_4$ –10; $CF_3SO_3H$ –13] or with the coordinating ability of the anions.[39] Hence it is not obvious if the anions mainly associate with the cation $[Ag_2(\mu\text{-}\mathbf{2})_2]^{2+}$ primarily by coordination to silver(I) or by hydrogen bonding to one of the outward-directed NH groups.

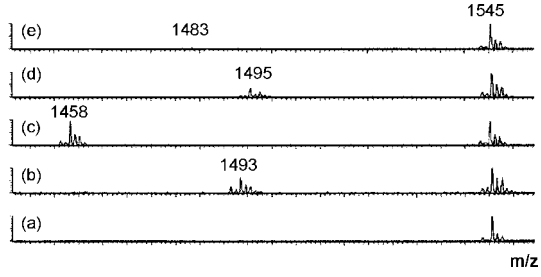

Figure 7. ESI-MS for complex **5a** in acetonitrile either alone (a) or in the presence of 1.4 equiv. of $Bu_4NX$: (b) X = $HSO_4$; (c) X = $NO_3$; (d) X = $ClO_4$; (e) X = $BF_4$.

## Conclusions

The intramolecular hydrogen bonding observed for ligands **1** and **2** serves to favor a U-shaped molecule [Scheme 1, Equation (1)] and this in turn favors formation of macrocyclic complexes with palladium(II) and silver(I). In the case of the ligand **1** only macrocyclic complexes **3a** and **3b** are formed with palladium(II) halides (Scheme 3, Figure 2) but, in the case of the more flexible ligand **2** a second isomer is formed. Examination by molecular mechanics indicates that either a monomer with chelating ligand **2** or a *cis*,*cis* dimer with bridging ligands **2** are possible for this second isomer. With silver(I), the ligand **2** forms a macrocyclic complex $[Ag_2(\mu\text{-}\mathbf{2})_2]^{2+}$ and, in the triflate salt, the anions form secondary bonds to both silver(I) and to an NH group of the ligand.

An interesting feature of the macrocyclic complexes is that there are two outward-directed NH groups available to take part in hydrogen bonding (Scheme 2). In the palladium(II) complexes **3a** and **3b**, these NH groups form hydrogen bonds to either solvent molecules (**3b**) or to chloride ligands of neighboring macrocycles (**3a**) (Figure 2 and Figure 3). In complex **3a**, this intermolecular hydrogen bonding leads to supramolecular self-assembly of a sheet structure (Figure 3). In the silver(I) complex **5a**, the outward-directed NH groups form hydrogen bonds to triflate anions (Figure 5). The triflate anions then use a second oxygen atom to form a weak coordinate bond to the two silver(I) centers of a neighboring macrocycle. The overall result is then the formation of a supramolecular "ribbon of macrocycles" structure (Figure 6). The ESI-MS of **5a** in acetonitrile solution indicates that at least partial association between the cations $[Ag_2(\mu\text{-}\mathbf{2})_2]^{2+}$ and triflate anions occurs giving the major ion $[Ag_2(\mu\text{-}\mathbf{2})_2(CF_3SO_3)]^+$. As expected, anion exchange occurs easily with other anions $X^-$ such as $HSO_4^-$, $NO_3^-$, $ClO_4^-$, $BF_4^-$ and $PF_6^-$ to give the corresponding ions $[Ag_2(\mu\text{-}\mathbf{2})_2(X)]^+$ (Figure 7). In all of the complexes, there is easy exchange in solution between the inward and outward directed NH groups, and this occurs by easy rotation of the 3-pyridylamide units (Scheme 4).

Overall, this first study of coordination complexes of ligands with amide group substituents on the xanthene scaffold indicates the promise that exists for both supramolecular self-assembly and host-guest chemistry through various forms of hydrogen bonding with the outward-directed NH groups.

## Experimental Section

NMR spectra were recorded with a Varian Inova 400 MHz spectrometer. For atom labeling see Scheme 1.

**2,7-Di-*tert*-butyl-9,9-dimethyl-*N*,*N*′-di(3-pyridyl)xanthene-4,5-dicarboxamide (1):** A solution of 3-aminopyridine (0.21 g, 2.23 mmol) in dichloromethane (20 mL) was added to a solution of 2,7-di-*tert*-butyl-9,9-dimethylxanthene-4,5-dicarbonyl dichloride (0.50 g, 1.12 mmol) and triethylamine (0.34 g, 3.35 mmol) in dry dichloromethane (50 mL). The reaction mixture was stirred overnight under nitrogen, then the solvent was evaporated under vacuum, and the residue was washed with water and acetone to give the product as a white solid. Yield: 0.33 g (52%). $^1$H NMR ($CD_2Cl_2$/$CD_3OD$): $\delta$ = 8.59 (s, 2 H, 2′-H), 8.19 (d, $J_{HH}$ = 5 Hz, 2 H, 6′-H), 7.98 (d, $J_{HH}$ = 7 Hz, 2 H, 4′-H), 7.78 (s, 2 H, 3-H, 6-H), 7.66 (s, 2 H, 1-H, 8-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

H), 7.11 (dd, $J_{HH}$ = 5 Hz, 7 Hz, 2 H, 5′-H), 1.70 (s, 6 H, $CH_3$), 1.36 (s, 18 H, *t*Bu) ppm. $C_{35}H_{38}N_4O_3$ (562.71): calcd. C 74.71, H 6.81, N 9.96; found C 74.41, H 6.42, N 10.44.

**2,7-Di-*tert*-butyl-9,9-dimethyl-*N*,*N*′-bis[(3-pyridyl)methyl]xanthene-4,5-dicarboxamide (2):** This compound was prepared according to the procedure described above for **1**. 3-(Aminomethyl)pyridine was used instead of 3-aminopyridine. Yield: 35%. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 8.57 (s, 2 H, 2′-H), 8.44 (d, $J_{HH}$ = 5 Hz, 2 H, 6′-H), 8.19 (t, $J_{HH}$ = 5 Hz, 2 H, CONH), 7.77 (s, 2 H, 3-H, 6-H), 7.69 (d, $J_{HH}$ = 8 Hz, 2 H, 4′-H), 7.60 (s, 2 H, 1-H, 8-H), 7.21 (dd, $J_{HH}$ = 5 Hz, 8 Hz, 2 H, 5′-H), 4.51 (d, $J_{HH}$ = 5 Hz, 4 H, $CH_2$), 1.68 (s, 6 H, $CH_3$), 1.33 (s, 18 H, *t*Bu) ppm. $^{13}$C NMR: $\delta$ = 167.6 (C=O), 148.9, 148.3, 146.8, 146.2, 136.5, 135.9, 130.6, 127.0, 126.1, 124.4, 121.7, 41.52 ($CH_2$), 35.1 ($CH_3$), 33.0 ($CH_3$), 51.5 (*t*Bu) ppm. $C_{37}H_{42}N_4O_3$ (590.76): calcd. C 75.23, H 7.17, N 9.48; found C 75.28, H 7.20, N 9.09.

**[Pd$_2$Cl$_4$(μ-1)$_2$] (3a):** A solution of the ligand **1** (0.0154 g, 0.026 mmol) in $CH_2Cl_2$ (10 mL) was added to a solution of [$PdCl_2$(NCPh)$_2$] (0.010 g, 0.026 mmol) in $CH_2Cl_2$ (10 mL) was added. The solution was stirred overnight, then pentane (40 mL) was added, and the yellow solid product which precipitated was collected by filtration and dried under vacuum. Yield: 0.013 g. The product was insufficiently soluble to give an NMR spectrum. $C_{70}H_{76}Cl_4N_8O_6Pd_2$ (1480.03): calcd. C 56.81, H 5.18, N 7.57; found C 56.64, H 5.00, N 7.47.

**[Pd$_2$Br$_4$(μ-1)$_2$] (3b):** A solution of the ligand **1** (0.036 g; 0.064 mmol) in dichloromethane (10 mL) was added to a solution [$PdBr_2$(NCPh)$_2$] (0.030 g, 0.064 mmol) in a mixture of acetonitrile (5 mL) and dichloromethane (5 mL). The solution was stirred overnight, then pentane (40 mL) was added, and the yellow solid product was collected by filtration and dried under vacuum. Yield: 0.043 g. $^1$H NMR ([D$_7$]DMF): $\delta$ = 10.75 (s, 4 H, CONH), 9.30 (s, 4 H, -2′-H), 8.82 (d, $J_{HH}$ = 6 Hz, 4 H, 6′-H), 8.04 (d, $J_{HH}$ = 8 Hz, 4′-H), 7.84 (d, $J_{HH}$ = 2 Hz, 4 H, 3-H, 6-H), 7.69 (d, $J_{HH}$ = 2 Hz, 4 H, 1-H, 8-H), 7.18 (dd, $J_{HH}$ = 6 Hz, 8 Hz, 4 H, 5′-H), 1.77 (br. s, 12 H, $CH_3$), 1.38 (br. s, 36 H, *t*Bu) ppm. $C_{70}H_{76}Br_4N_8O_6Pd_2 \cdot H_2O$ (1657.84): calcd. C 50.17, H 4.69, N 6.69; found C 50.40, H 4.54, N 6.45.

**[Pd$_2$Cl$_4$(μ-2)$_2$] (4):** A solution of the ligand **2** (0.0154 g; 0.026 mmol) in $CH_2Cl_2$ (10 mL) was added to a solution of [$PdCl_2$(NCPh)$_2$] (0.010 g; 0.026 mmol) in $CH_2Cl_2$ (10 mL). The solution was stirred overnight and the product was isolated as above. Yield: 0.013 g. $^1$H NMR ($CD_2Cl_2$/$CD_3OD$), isomer (**a**): $\delta$ = 9.15 (s, 2 H, 2′-H), 8.80 (d, $J_{HH}$ = 6 Hz, 2 H, 6′-H), 8.20 (br. t, 2 H, CONH), 7.68 (d, $J_{HH}$ = 8 Hz, 2 H, 4′-H), 7.65 (s, 2 H, 3-H, 6-H), 7.56 (s, 2 H, 1-H, 8-H), 7.16 (dd, $J_{HH}$ = 8 Hz, 6 Hz, 2 H, 5′-H), 4.36 (s, 4 H, $CH_2$), 1.66 (s, 6 H, $CH_3$), 1.33 (s, 18 H, *t*Bu) ppm. Isomer (**b**): $\delta$ = 9.20 (s, 2 H, 2′-H), 8.70 (d, $J_{HH}$ = 6 Hz, 2 H, 6′-H), 8.45 (br. t, 2 H, CONH), 7.88 (d, $J_{HH}$ = 8 Hz, 2 H, 4′-H), 7.67 (s, 2 H, 3-H, 6-H), 7.59 (s, 2 H, 1-H, 8-H), 7.48 (dd, $J_{HH}$ = 8 Hz, 6 Hz, 2 H, 5′-H), 4.23 (s, 4 H, $CH_2$), 1.64 (s, 6 H, $CH_3$), 1.30 (s, 18 H, *t*Bu) ppm. $C_{74}H_{87}Cl_4N_8O_6Pd_2$ (1539.16): calcd. C 57.86, H 5.51, N 7.29; found C 57.84, H 5.85, N 7.32.

**[Ag$_2$(μ-2)$_2$][CF$_3$SO$_3$]$_2$ (5a):** A solution of the ligand **2** (0.046 g, 0.078 mmol) in THF (10 mL) was added to a solution of $AgO_3SCF_3$ (0.020 g, 0.078 mmol) in acetone (10 mL). The solution was stirred overnight. The solvent was evaporated to give a white solid, which was washed with hexane and dried under vacuum. Yield: 0.055 g. $^1$H NMR ($CD_2Cl_2$/$CD_3OD$): $\delta$ = 9.17 (t, $J_{HH}$ = 6 Hz, 4 H, CONH), 8.53 (s, 4 H, 2′-H), 8.44 (d, $J_{HH}$ = 5 Hz, 4 H, 6′-H), 7.81 (d, $J_{HH}$ = 2 Hz, 4 H, 3-H, 6-H), 7.76 (d, $J_{HH}$ = 8 Hz, 4 H, 4′-H), 7.63 (d, $J_{HH}$ = 2 Hz, 4 H, 1-H, 8-H), 7.37 (dd, $J_{HH}$ = 5 Hz, 8 Hz, 4 H, 5′-H), 4.53 (d, $J_{HH}$ = 6 Hz, 8 H, $CH_2$), 1.66 (s, 12 H, $CH_3$), 1.33 (s, 36 H, *t*Bu) ppm. $C_{76}H_{84}Ag_2F_6N_8O_{12}S_2 \cdot H_2O \cdot$THF: calcd. C 53.81, H 5.31, N 6.28; found C 53.85, H 5.17, N 6.08. Colourless plate crystals of **5a**·4$CHCl_3$ were obtained by slow diffusion of a concentrated solution of ligand **2** in chloroform into a concentrated solution of [$AgO_3SCF_3$] in acetone.

Similarly were prepared: **[Ag$_2$(μ-2)$_2$][CF$_3$CO$_2$]$_2$ (5b):** Yield: 34%. $^1$H NMR ($CD_2Cl_2$/$CD_3OD$): $\delta$ = 9.02 (br. t, 4 H, CONH), 8.47 (br. s, 4 H, 2′-H), 8.38 (d, $J_{HH}$ = 6 Hz, 4 H, 6′-H), 7.80 (d, $J_{HH}$ = 2 Hz, 4 H, 3-H, 6-H), 7.78 (br. m, 4 H, 4′-H), 7.62 (d, $J_{HH}$ = 3 Hz, 4 H, 1-H, 8-H), 7.27 (br. dd, $J_{HH}$ = 6 Hz, 8 Hz, 4 H, 5′-H), 4.53 (br. d, $J_{HH}$ = 4 Hz, 8 H, $CH_2$), 1.66 (s, 12 H, $CH_3$), 1.33 (s, 36 H, *t*Bu) ppm. $C_{78}H_{84}Ag_2F_6N_8O_{10} \cdot 2CH_2Cl_2 \cdot 2H_2O \cdot 2(CH_3)_2CO \cdot C_5H_{12}$ (1623.29): calcd. C 54.18, H 5.80, N 5.55; found C 54.39, H 4.95, N 5.64. **[Ag$_2$(μ-2)$_2$][NO$_3$]$_2$ (5c):** Yield: 84%. $^1$H NMR ($CD_2Cl_2$/$CD_3OD$): $\delta$ = 9.23 (br. t, $J_{HH}$ = 6 Hz, 4 H, CONH), 8.52 (br. s, 4 H, 2′-H), 8.42 (d, $J_{HH}$ = 5 Hz, 4 H, 6′-H), 7.82 (br. d, $J_{HH}$ = 8 Hz, 4 H, 4′-H), 7.81 (d, $J_{HH}$ = 2 Hz, 4 H, 3-H, 6-H), 7.64 (d, $J_{HH}$ = 3 Hz, 4 H, 1-H, 8-H), 7.34 (dd, $J_{HH}$ = 5 Hz, 8 Hz, 4 H, 5′-H), 4.48 (br. d, $J_{HH}$ = 4 Hz, 8 H, $CH_2$), 1.67 (s, 12 H, $CH_3$), 1.33 (s, 36 H, *t*Bu) ppm. $C_{76}H_{90}Ag_2N_{10}O_{12} \cdot 6H_2O$: calcd. C 52.60, H 5.34, N 6.46; found C 52.74, H 5.51, N 6.12.

**ESI-MS:** All ESI mass spectra were recorded with a Micromass LCT spectrometer and were calibrated with NaI at a concentration of 2 μg/μL in propan-2-ol/water (50:50). The injection flow rate at 20.0 μL/min was used throughout all experiments. The procedure for anion exchange between **5a** and $Bu_4N^+NO_3^-$ was as follows. A stock solution of $Bu_4N^+NO_3^-$ in acetonitrile ($5 \times 10^{-3}$ M) was used to prepare standard solutions of $Bu_4N^+NO_3^-$ at varying concentrations. To a solution of **5a** in acetonitrile (1 mL, $5 \times 10^{-4}$ M) was added a solution of $Bu_4N^+NO_3^-$ in acetonitrile (1 mL, $7 \times 10^{-4}$ M). After 30 min, the ESI-MS was recorded and the ratio of [Ag$_2$(μ-**2**)$_2$($O_3SCF_3$)]$^+$ to [Ag$_2$(μ-**2**)$_2$($NO_3$)]$^+$ was estimated. The procedure was repeated at several concentrations of $Bu_4N^+NO_3^-$. The same procedure was used to study anion exchange between complex **5a** and $Bu_4N^+X^-$ (X = $HSO_4^-$, $ClO_4^-$, $BF_4^-$, and $PF_6^-$).

**X-ray Structure Determinations:** Crystals were mounted on glass fibers, and data were collected at 150 K with a Nonius Kappa-CCD diffractometer with COLLECT (Nonius, 1998) software. The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using the Nonius DENZO package. The data were scaled using SCALEPACK (Nonius, 1998). The SHELXTL-NT V6.1 (G. M. Sheldrick, Madison, WI) program package was used to solve and refine the structures by direct methods. The hydrogen atom posi-

tions were calculated geometrically and were included as riding on their respective carbon atoms. Details of the data collection and refinement are given in Table 1. In all three structures, the molecule had a crystallographically imposed center of symmetry.

Orange plate-like crystals of [$Pd_2Cl_4$(μ-**1**)$_2$]·4MeCN were grown from $CH_2Cl_2$/MeCN/MeOH. The crystal was twinned and the twin law was determined by using ROTAX, and confirmed by successful refinement. All heavy atoms were refined anisotropically but there were some anomalous thermal parameters and a large $R_{int}$, associated with imperfect treatment of the crystal twinning and with unresolved disorder of the solvent molecules.

Yellow crystals of [$Pd_2Br_4$(μ-**1**)$_2$]·4MeCN were grown from $CH_2Cl_2$/MeCN/MeOH, a concentrated dichloromethane/acetonitrile/methanol solution. One MeCN molecule was well ordered, but the other was not and its geometry was constrained to be the same as the well-ordered one.

Colorless crystals of [$Ag_2$(μ-**2**)$_2$][$CF_3SO_3$]$_2$·4$CHCl_3$, were grown from $CHCl_3$/$Me_2CO$. The refinement was straightforward in this case.

CCDC-632844 to -632846 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Single-Crystal Structure and Magnetic Behavior of a Molecule-Based Ferrimagnet $Mn[Mn_{0.2}Cr_{0.8}(CN)_6]\cdot 4H_2O$

Xiao-Ping Shen,[a,b] Yi-Zhi Li,[a] You Song,[a] Zheng Xu,*[a] and Guo-Cong Guo[c]

**Keywords:** Prussian blue analogue / Crystal structure / Magnetic properties / Chromium / Manganese

The compound with the stoichiometry $Mn^{III}[Mn^{III}_{0.2}Cr^{III}_{0.8}(CN)_6]\cdot 4H_2O$ (**1**), which was prepared by slow diffusion of an aqueous solution of $K_3[Cr(CN)_6]$ and a methanol solution of [Mn(saltn)]$ClO_4$ [saltn = *N*,*N*′-1,3-propylenebis(salicylideneiminato) dianion] through a U-shaped tube containing silica gel, has been characterized by elemental analysis, ICP analysis, XPS, single-crystal X-ray structure analysis, and magnetic measurements. The complex has a face-centered cubic lattice analogous to Prussian blue and indicates ferrimagnetic ordering below $T_c$ = 63 K.

## Introduction

There has been continuous interest in the molecule-based magnetic materials of cyano-bridged dimetallic assemblies because of their interesting magnetic, magneto-optical and optoelectronic properties.[1,2] It is known that Prussian blue (PB) analogues, derived from hexacyanometalate ions $[M(CN)_6]^{n-}$ and simple transition metal ions, exhibit magnetic ordering at critical temperatures as high as 376 K and form a family of magnetic materials.[2] On the basis of powder XRD results, PB analogues are generally thought to have a face-centered cubic structure, but detailed structural studies are still limited because of the difficulty in obtaining single crystals.[3] On the other hand, in order to clarify the magnetostructural correlation of cyano-bridged dimetallic systems, a wide variety of hybrid Prussian blue complexes derived from $[M(CN)_6]^{n-}$ (M = Fe, Cr, Mn, Co) and coordinatively unsaturated transition metal complexes have been studied structurally and magnetically.[4] These complexes assume oligonuclear, 1D, 2D, and 3D structures and exhibit ferro-, ferri-, and metamagnetic behavior. For instance, the reaction between [Mn(salen)]$ClO_4$ [salen = *N*,*N*′-ethylenebis(salicylideneiminato) dianion] and $[M(CN)_6]^{3-}$ (M = Fe, Cr) has already led to two dimetallic heptanuclear $Mn_6M$ clusters.[5] Recently, we had expected to obtain another cyano-bridged $Mn^{III}$–$Cr^{III}$ cluster by using [Mn(saltn)]$ClO_4$ [saltn = *N*,*N*′-1,3-propylenebis(salicylideneiminato) dianion] instead of [Mn(salen)]$ClO_4$ as a building block. Surprisingly, we found a novel PB analogue $Mn[Mn_{0.2}Cr_{0.8}(CN)_6]\cdot 4H_2O$ (**1**), which has a face-centered cubic lattice and shows ferrimagnetic ordering below 63 K. Here we report on its synthesis, crystal structure, and magnetic properties.

## Results and Discussion

### Synthesis and Characterization

Complex **1** was obtained as brown-yellow, quasi-ball-shaped single crystals by slow diffusion of a methanol solution of [Mn(saltn)]$ClO_4$ and an aqueous solution of $K_3[Cr(CN)_6]$ through a U-tube containing silica gel. It is insoluble in usual inorganic and organic solvents and stable in air. The elemental and inductively coupled plasma (ICP) analyses confirm the composition of **1** (see Experimental Section). The IR spectrum of **1** shows a sharp $\nu$(C≡N) peak at 2161 $cm^{-1}$. The blue shift of the band $\nu$(C≡N) relative to that of $K_3[Cr(CN)_6]$ (2130 $cm^{-1}$)[6] suggests the formation of cyano bridges. A strong broad band around 3400 $cm^{-1}$ indicates the presence of $H_2O$. The characteristic peaks from the ligand saltn are not found in the IR spectrum. The X-ray photoelectron spectroscopy (XPS) of **1** shows the peaks for Cr($2p_{3/2}$) at 576.95 eV and for Mn($2p_{3/2}$) at 641.9 eV, with a molar ratio Cr/Mn = 1:1.6. As shown in Table 1, the Mn $2p_{3/2}$ binding energy of **1** is close to those found for $K_3[Mn^{III}(CN)_6]$ and $Mn_2O_3$, and obviously different from those of $Mn^{II}_3[Cr(CN)_6]_2\cdot 16H_2O$, MnO, and $MnO_2$, which supports the oxidation state of +3 for Mn. The composition of $Mn[Mn_{0.2}Cr_{0.8}(CN)_6]\cdot 4H_2O$ for complex **1** is in agreement with the results of the crystal structural analysis and magnetic studies as discussed below.

Table 1. Manganese $2p_{3/2}$ binding energies [eV] of some manganese compounds.

| Complex **1** | $Mn_3[Cr(CN)_6]_2\cdot 16H_2O$[3e] | $K_3[Mn(CN)_6]_3$ | MnO | $Mn_2O_3$ | $MnO_2$ | Ref. |
|---|---|---|---|---|---|---|
| 641.9 | 641.35 | 641.65<br>641.6 | | | | This work<br>[2g] |
| | | | 641.0 | 641.9 | 642.5 | [7] |
| | | | 640.9 | 641.8 | 642.5 | [8] |
| | | | 641.0 | 641.7 | 642.2 | [9] |

It can be inferred that the six-membered ring $MnN_2C_3$ in $[Mn(saltn)]^+$ has a lower stability with respect to the five-membered ring $MnN_2C_2$ in $[Mn(salen)]^+$ because of the less favorable entropy change required for the formation of six-membered rings.[10] Therefore, the $[Mn(saltn)]^+$ can dissociate more easily into $Mn^{3+}$, which reacts with $[Cr(CN)_6]^{3-}$ to produce the more stable complex **1**. The formation reactions for complex **1** can be shown as follows:

$[Mn(saltn)]^+ \rightarrow Mn^{3+} + saltn^{2-}$

$1.2Mn^{3+} + [Cr(CN)_6]^{3-} + 4H_2O \rightarrow Mn[Mn_{0.2}Cr_{0.8}(CN)_6]\cdot 4H_2O + 0.2Cr^{3+}$

It should be pointed out that complex **1** can only be obtained in low yields by the above slow diffusion method and cannot be synthesized as a bulk powder by directly mixing the same ingredients in solution (i.e. without the method with the U-tube); direct mixing immediately results in a black precipitate. The IR spectrum of the black product shows a $\nu(C\equiv N)$ peak at 2126 $cm^{-1}$ and a series of characteristic peaks for saltn, which suggests the formation of the $[Cr(CN)_6]^{3-}/[Mn(saltn)]^+$ adduct. Although the reason of the formation of the two different products is not clear at present, according to the reaction conditions, we infer that the synthesis of complex **1** would be dominated by thermodynamic factors, while that of the black product would be controlled by kinetic factors.

## Crystal Structure

X-ray crystallography shows that **1** belongs to the cubic space group $Fm\bar{3}m$, $a = b = c = 10.7632(7)$ Å, $V = 1246.9(1)$ Å$^3$. These data are comparable to those for $NaMn[Cr(CN)_6]$,[3a] $Mn_3[Mn(CN)_6]_2\cdot xH_2O$,[3b] $Mn_3[Cr(CN)_6]_2\cdot xH_2O$,[3e] and $K_{0.2}Mn_{1.4}[Cr(CN)_6]\cdot 6H_2O$.[3g] The crystal structure of **1** is shown in Figure 1. Each unit cell contains four $Mn[Mn_{0.2}Cr_{0.8}(CN)_6]\cdot 4H_2O$ units. The Mn1 atom occupies the position (0, 1/2, 1/2) and Cr1(Mn2) atom is in the position (1/2, 1/2, 1/2). Because of the Cr/Mn molar ratio of 2:3 on the basis of ICP analysis, the Cr atoms are partially replaced by Mn atoms and the occupancy of Cr1/Mn2 is 0.8:0.2, which is similar to that of $NMe_4Mn[(Mn, Cr)(CN)_6]\cdot 3H_2O$[3c] reported by Babel et al. In complex **1**, both the Mn and Cr atoms are six-coordinate and have an octahedral geometry, and are linked through cyano-bridges to form a face-centered cubic framework. The Cr atom is bonded to the carbon atoms of the $CN^-$ ligands as in $K_3[Cr(CN)_6]$. The Mn1 atom is coordinated to the nitrogen atoms of the $CN^-$ groups and the Mn2 atom to the carbon atoms, which would result in Mn1 and Mn2 with high-spin and low-spin ground states, respectively. The Mn1–N–C–Cr1(Mn2) linkage is linear, and the bond lengths are 2.155(9) Å [Mn1–N], 1.120(10) Å [C–N], and 2.106(14) Å [Cr1(Mn2)–C]. The Mn1···Cr1(Mn2) distance is 5.3816 Å. Because of the Jahn–Teller effect, the high-spin (HS) $Mn^{III}$ ions should usually occupy the distorted octahedral sites. For example, the structure of the $Mn^{III}$ (HS)-$Fe^{II}$ Prussian blue analogues in a low-temperature state is not face-centered cubic but tetragonal because of the Jahn–Teller effect.[11] In complex **1**, it is likely that Jahn–Teller distortion occurs, but the macroscopic X-ray diffraction technique only presents a statistical distribution of distorted $Mn^{III}$ polyhedron. Water molecules occupy the vacancies in the unit cell, and O2 is structurally disordered. It must be pointed out that the structure of complex **1** could not be solved properly according to the $Mn_3[Cr(CN)_6]_2\cdot xH_2O$ model.[3b,3e] This fact further supports the oxidation state of +3 for Mn. Generally, the structure and composition of a generic PB-like compound $A_p[B(CN)_6]_q\cdot x$H2O depend on the oxidation states of the cations A and B: for A(III) and B(III), a A/B molar ratio of 1:1 is found, while for A(II) and B(III), a ratio of 3:2 is found. For the former, the coordination spheres of A and B are $\{A(NC)_6\}$ and $\{B(CN)_6\}$, while for the latter, one third of the $[B(III)(CN)_6]$ vacancies are filled by water molecules, therefore, the coordination sphere of B is the same but the mean coordination sphere of A becomes $\{A(NC)_4(H_2O)_2\}$.[1a] Complex **1** is a unique example in which the valence of both the cations A and B is +3, but the A/B molar ratio is 3:2 instead of 1:1. The reason for the special stoichiometry that **1** presents is unclear at present.

## Magnetic Properties

The magnetic susceptibilities of complex **1** were measured with an applied field of $H$ = 100 Oe in the temperature range 2–300 K. The plot of $\chi_M T$ vs. $T$ is given in Figure 2. At room temperature, the value of $\chi_M T$ per $Mn_{1.2}Cr_{0.8}$ unit is 5.02 $cm^3\,K\,mol^{-1}$ (6.34 $\mu_B$), which is slightly higher than the spin-only value of 4.7 $cm^3\,K\,mol^{-1}$ (6.13 $\mu_B$) expected for an uncoupled spin system ($1{\cdot}S_{Mn}$ = 2, $0.2{\cdot}S_{Mn}$ = 1, $0.8{\cdot}S_{Cr}$ = 3/2) with $g$ = 2.0. On lowering the temperature, the $\chi_M T$ value gradually decreases and reaches a minimum of 4.43 $cm^3\,K\,mol^{-1}$ (5.95 $\mu_B$) at 140 K (inset in Figure 2). Upon further cooling, $\chi_M T$ increases to a maximum of 3005 $cm^3\,K\,mol^{-1}$ (155 $\mu_B$) at 52 K and then decreases below this temperature. The dependence of $1/\chi_M$ on $T$ obeys the Curie–Weiss law [$\chi = C/(T-\theta)$] in the temperature range 300–140 K with a Weiss constant of $\theta$ = –44 K. The negative Weiss constant and the shallow minimum in the $\chi_M T$ vs. $T$ curve both indicate the presence of an antiferromagnetic coupling between adjacent $Mn^{III}$ ($S$ = 2) and $Cr^{III}$ ($S$ = 3/2) [or $Mn^{III}$ ($S$ = 1)] ions through the cyanide bridges. The abrupt increase in the $\chi_M T$ value at about 65 K suggests the onset of the three-dimensional magnetic ordering. The decrease in the $\chi_M T$ value below 52 K may be due to the zero-field splitting effect and/or the field saturation of the magnetization. This is characteristic of ferrimagnetic behavior. The temperature dependence of the zero-field alternating current (ac) magnetic susceptibility taken at 10 Hz (Figure 3) shows that the real part ($\chi'$) and the imaginary part ($\chi''$) of the ac magnetic susceptibility both have a maximum at 63 K and 64 K, respectively, which indicates that $T_c$ of **1** is 63 K.

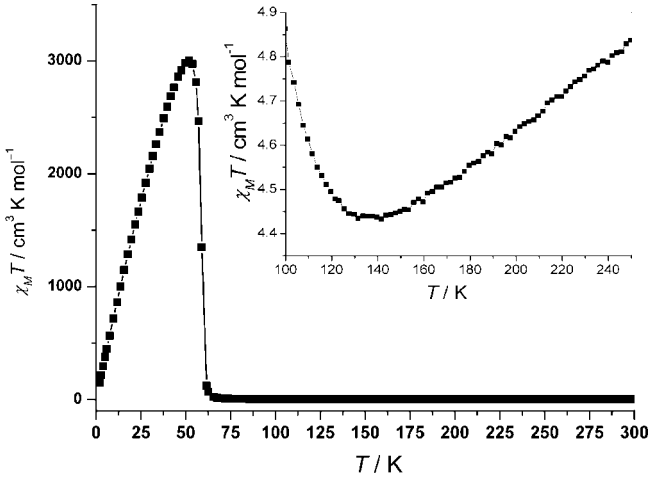

Figure 2. Temperature dependence of $\chi_M T$ for complex **1** measured at 100 Oe. Inset displays the minimum of $\chi_M T$ at 142 K, the signature of ferrimagnetism.

The field dependence of the magnetization with an applied field of 0–70 kOe, measured at 1.8, 55 and 80 K, respectively, is shown in Figure 4. At 80 K, the magnetization increases linearly and shows typical paramagnetic behavior. At 55 K, the magnetization first increases sharply and then slowly, thus displaying a property of a magnet. At

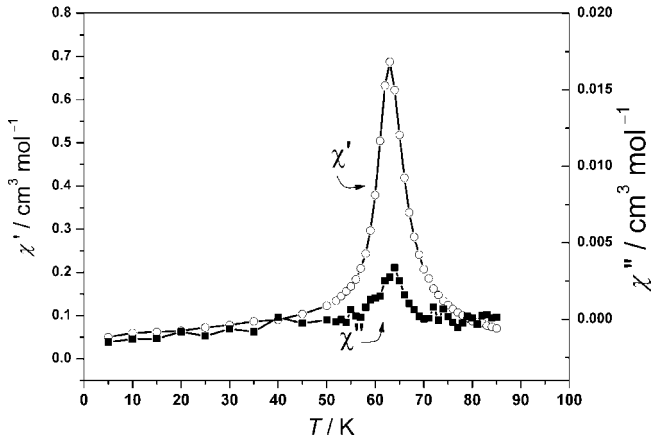

Figure 3. Real ($\chi'$) and imaginary ($\chi''$) ac magnetic susceptibilities as a function of temperature at 10 Hz for complex **1**.

1.8 K, the magnetization increases sharply in the low-field region and reaches saturation above ca. 1.0 kOe. The saturation magnetization $M_s$ = 3.1 N$\beta$ is much higher than the expected value of 1.2 N$\beta$ for the antiferromagnetic $Mn_{1.2}Cr_{0.8}$ system. The inconsistency in $M_s$ values was also observed in some other PB analogues.[2a,2f,3a] The higher $M_s$ value of **1** is perhaps due to the disorder of the paramagnetic ions.[2f] The magnetic hysteresis loop at 1.8 K (Figure 5) reveals no significant hysteretic behavior typical of a soft magnet, which is consistent with the symmetrical cubic three-dimensional structure.[2a–2c,3a] The antiferromagnetic interaction between the $Mn^{III}$ ($S$ = 2) and $Cr^{III}$ ($S$ = 3/2) [or $Mn^{III}$ ($S$ = 1)] ions can be rationalized in terms of the overlap of the magnetic orbitals of these ions.[1a]

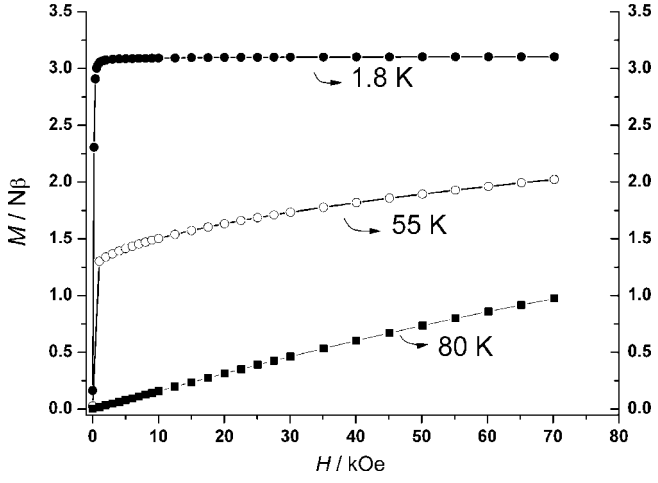

Figure 4. Field dependence of the magnetization at 1.8, 55, and 80 K for complex **1**.

It should be mentioned that the magnetic properties of complex **1** are similar to those of the $Mn^{II}/Cr^{III}$ complexes, such as $[Mn(en)]_3[Cr(CN)_6]_2{\cdot}4H_2O$ ($T_c$ = 69 K),[4d,4m] $Mn_3[Cr(CN)_6]_2{\cdot}12H_2O$ ($T_c$ = 63 K),[4m] $NaMn[Cr(CN)_6]$ ($T_c$ = 60 K),[3a] and $K_{0.2}Mn_{1.4}[Cr(CN)_6]{\cdot}6H_2O$ ($T_c$ = 66 K).[3g] Especially, it is somewhat surprising that the $Mn^{III}$-based

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

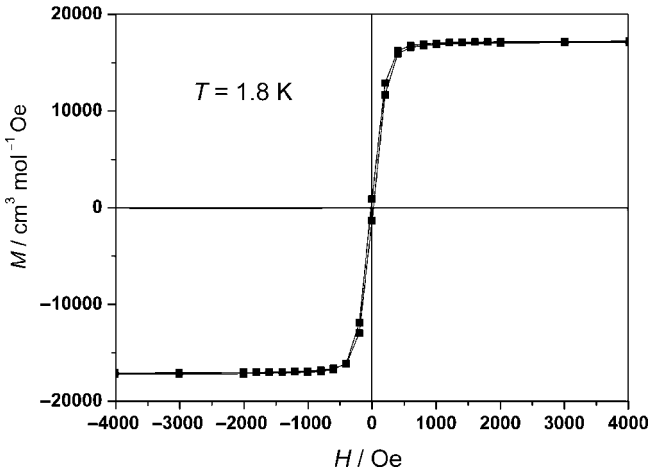

Figure 5. Magnetic hysteresis loop at 1.8 K for complex **1**.

system of **1** has such a low coercive field as found for $Mn^{II}$-based systems since both high- and low-spin (LS) $Mn^{III}$ are much more anisotropic than high-spin (HS) $Mn^{II}$. This may be related to the extremely complex magnetic properties of the $Mn^{III}$ (LS) species because of strong spin-orbit coupling. In addition, it is interesting to note that $[Mn(en)]_3[Cr(CN)_6]_2\cdot 4H_2O$ has a higher magnetic phase-transition temperature ($T_c$) than the ligand-free $Mn^{II}/Cr^{III}$ and $Mn^{III}/Cr^{III}$ systems. Lu et al.[3g] recently demonstrated that the $T_c$ value of $K_{0.2}Mn_{1.4}[Cr(CN)_6]\cdot 6H_2O$ can be substantially modulated through a dehydration/rehydration treatment and increases to 99 K after dehydration in which a weight loss of 23.4% is reached. This indicates that the $T_c$ value is sensitive to subtle changes in structure and composition. By considering the fact that the $Mn^{II}/Mn^{III}$ Prussian blue analogues, such as $Mn^{II}_3[Mn^{III}(CN)_6]_2\cdot xH_2O$ ($T_c$ = 35.5 K) [3b] and $CsMn^{II}[Mn^{III}(CN)_6]\cdot 1/2H_2O$ ($T_c$ = 31 K),[12] have lower magnetic phase-transition temperatures than the $Mn^{II}/Cr^{III}$ analogues, it would be expected that the partial substitution of low-spin $Mn^{III}$ for $Cr^{III}$ in complex **1** would reduce its $T_c$ value. On the other hand, unlike complex $Mn_3[Cr(CN)_6]_2\cdot 12H_2O$,[4m] complex **1** does not have $[Cr(CN)_6]^{3-}$ vacancies in the crystal structure, which would increase the $T_c$ value. The above two factors counteract each other, which results in a value of $T_c$ = 63 K in complex **1**. From the magnetic point of view, complex **1** is essentially a ternary metal Prussian blue system [high-spin $Mn^{III}$/low-spin $Mn^{III}/Cr^{III}$]. Hashimoto et al.[13] have systematically investigated the magnetic behavior of a series of ternary-metal Prussian blue analogues $(Ni^{II}_xMn^{II}_{1-x})_{1.5}[Cr^{III}(CN)_6]\cdot zH_2O$, which incorporate both ferromagnetic $Ni^{II}$–$Cr^{III}$ ($J_{NiCr}$) and antiferromagnetic $Mn^{II}$–$Cr^{III}$ ($J_{MnCr}$) exchange interactions. The magnetic properties such as the saturation magnetization, the Weiss constant, and the coercive field could be tuned by changing the molar ratios $x$. However, the $T_c$ values of these complexes almost remained the same (≈ 70 K). In complex **1**, both $Mn^{III}$(HS)–$Cr^{III}$ and $Mn^{III}$(HS)–$Mn^{III}$(LS) exchange interactions are antiferromagnetic. Therefore, unlike the situation in the $(Ni^{II}_xMn^{II}_{1-x})_{1.5}[Cr^{III}(CN)_6]\cdot zH_2O$ system, the magnetic properties of **1** could not change from antiferromagnetic to ferromagnetic by changing the molar ratios of the metal ions.

## Conclusions

A novel Prussian blue type ferrimagnet $Mn[Mn_{0.2}Cr_{0.8}(CN)_6]\cdot 4H_2O$ has been structurally and magnetically characterized. The complex has a cubic lattice and shows ferrimagnetic ordering below 63 K. This temperature is relatively high in all cyano-bridged complexes characterized by single-crystal structure analysis.[3,4] To the best of our knowledge, complex **1** is the first A(III)-B(III) type PB analogue characterized by single-crystal structure analysis and provides a unique example for the study of structure and magnetic properties of the PB analogues.

## Experimental Section

**Measurements:** Elemental analyses for C, H and N were performed with a Perkin–Elmer 240C analyzer. Mn and Cr analyses were carried out with a Jarrell–Ash 1100+2000 inductively coupled plasma quantometer. IR spectra were recorded on a Nicolet FT-170SX spectrometer with KBr pellets in the 4000–400 $cm^{-1}$ region. X-ray photoelectron spectra (XPS) were obtained by using an ESCALAB MK-II spectrometer. The magnetic measurements were performed on microcrystalline powder obtained from crushed single crystals by using a Quantum Design MPMS-XL SQUID magnetometer. Diamagnetic corrections were made by using Pascal's constants. Effective magnetic moments were calculated with the equation $\mu_{eff} = 2.828(\chi_M \times T)^{1/2}$, where $\chi_M$ is the magnetic susceptibility per formula unit.

**Preparations:** All chemicals and solvents were reagent grade and were used without further purification. $[Mn(saltn)]ClO_4$ was synthesized by mixing $Mn(OAc)_3\cdot 2H_2O$, saltn$H_2$, and $NaClO_4$ in a molar ratio of 1:1:1.5 in methanol according to a method reported previously.[14] $K_3[Cr(CN)_6]$ was prepared by the literature method.[15]

**Caution:** Perchlorate salts of metal complexes with organic ligands are potentially explosive and should be handled in small quantities with care.

**$Mn[Mn_{0.2}Cr_{0.8}(CN)_6]\cdot 4H_2O$ (1):** Complex **1** was obtained as brown-yellow, quasi-ball-shaped single crystals by slow diffusion of a methanol solution (15 $cm^3$) of $[Mn(saltn)]ClO_4$ (0.15 mmol) and an aqueous solution (15 $cm^3$) of $K_3[Cr(CN)_6]$ (0.15 mmol) through a U-tube containing silica gel at room temperature. The resulting crystals were collected, washed with $H_2O$ and EtOH, and dried in air. This complex is insoluble in usual inorganic and organic solvents and stable in air. Yield: 4.8 mg. $C_6H_8Cr_{0.8}Mn_{1.2}N_6O_4$ (335.71): calcd. C 21.46, H 2.4, Cr 12.39, Mn 19.64, N 25.04; found C 21.21, H 2.61, Cr 12.3, Mn 20.0, N 24.95. IR: $\tilde{\nu}_{max}$ = 3400 (vs), 2161 (s), 1613 (s), 990 (m), 478 (s) $cm^{-1}$.

**X-ray Crystallography:** Diffraction data were collected at 293(2) K on a Bruker SMART APEX CCD area detector diffractometer by using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) with the $\phi$ and $\omega$ scan mode. Empirical absorption correction was made with SADABS. The structures were solved by direct methods and refined by full-matrix least-squares techniques based on $F^2$ with the SHELXTL-97 program package. Crystal data for **1**: $C_6H_8Cr_{0.8}Mn_{1.2}N_6O_4$, $M$ = 335.71, cubic, space group $Fm\bar{3}m$, $a$ =

# Highly Organosoluble Metal-Free Phthalocyanines and Metallophthalocyanines: Synthesis and Characterization

**Ahmet Bilgin,*[a] Beytullah Ertem,[b] and Yaşar Gök[c]**

**Keywords:** Soluble phthalocyanine / Phthalonitrile / Macrocycles / Nickel / Zinc

The syntheses and characterization of metal-free and metal-containing (Zn and Ni) derivatives of a symmetrically octa-substituted phthalocyanine derived from 4,5:12,13-bis(4′-*tert*-butylbenzo)-8,9-(4′′,5′′-dicyanobenzo)-6,11-ditosyl-6,11-diaza-2,15-dithiacyclohexadeca-4,8,12-triene and CuPc from 4,5:12,13-bis(4′-*tert*-butylbenzo)-8,9-(4′′,5′′-dibromobenzo)-6,11-ditosyl-6,11-diaza-2,15-dithiacyclohexadeca-4,8,12-triene were carried out. Pentanuclear silver(I) and palladium(II) complexes have also been prepared from nickel(II) phthalocyaninate derivatives. The prepared phthalocyanines were semiconducting materials in the range of $10^{-5}$ to $10^{-10}$ S cm$^{-1}$ in vacuo and under atmospheric pressure. The extraction abilities of NiPc and detosylated phthalocyanines were evaluated in chloroform/water by using several heavy-metal picrates such as $Ag^{+}$, $Cd^{2+}$, $Cu^{2+}$, $Hg^{2+}$, $Pb^{2+}$, $Pd^{2+}$, and $Zn^{2+}$. The extraction affinities of NiPc and detosylated phthalocyanines for $Ag^{+}$ were found to be the highest in solvent extraction experiments. The new compounds were characterized by using elemental analysis, UV/Vis, FTIR, NMR, MS spectroscopic data and DTA/TG.

## Introduction

Phthalocyanines have been shown to have very interesting properties coupled with excellent stability to heat, light, and harsh chemical environments. Their optical and electronic properties have been exploited in various applications such as pigments in paints and printing inks, infrared security devices, information storage, and computer disk writing, conducting polymers and photoconductors, catalysts for oxidation of thiols, disulfides, chemical sensors, and in photodynamic therapy of cancer.[1,2] Transition-metal-based phthalocyanines have attracted attention in the areas of fuel cells, gas sensors, and biosensors.[1,2] Most of these applications require the use of phthalocyanines in the form of thin films. Further, it is desirable to have ordered, well-packed, and oriented molecular layers of phthalocyanines on various substrates.

Applications of peripherally unsubstituted phthalocyanines are restricted because of their insolubility in common solvents and water.[3,4] Phthalocyanines own an extended π-conjugated electron system which allows π stacking (aggregation) between planar macrocycles, provided the distance between the macrocycles is small.[5] By the peripheral attachment of bulky (e.g. *tert*-butyl),[6] long-chain groups (e.g. alkyl or alkoxy),[7] N-tosyl derivatives,[8] crown ether analogs[9–12] or macrobicyclic[13,14] and macrotricyclic[15] moieties to the macrocycles, transition-metal phthalocyanine complexes and their bridged systems can be made soluble in common organic solvents, for example chloroform or toluene,[4–6] because these substituents increase the distance between the stacked phthalocyanines and enable their solvation.[5,16] The *tert*-butyl group is especially suitable to increase the solubility of phthalocyanines in organic solvents.[5] Heteroatom-functionalized substituents were introduced onto the periphery of the phthalocyanine nucleus.[8–17] These peripheral groups are capable of binding alkali metal ions and provide donor sites for binding transition-metal ions, which leads to homo- and heteronuclear complexes.

Unfortunately, for many applications it is preferable to have both soluble and symmetric phthalocyanines. With this idea in mind, we set out to synthesize symmetrical di-*tert*-butylphtholonitrile and di-*tert*-butyl-*o*-dibromobenzene derivatives for condensation to very soluble symmetrical octa-*tert*-butyl-substituted phthalocyanines in this study. The electrical conductivities of the phthalocyanines as Au/MPc/Au sandwiches in vacuo and air atmosphere were examined. Additionally, the heavy metal extraction properties of **11** and **14** were investigated.

## Results and Discussion

### Synthetic Procedure and Characterization

The synthetic routes to **3**–**10** are summarized in Scheme 1 and **11**–**14** are summarized in Scheme 2. 1,2-Bis(4-*tert*-bu-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tyl-2-nitrobenzylthio)ethane (**3**) was prepared by a modified literature[18] procedure by the reaction of 1,2-ethandithiol (**1**) with 4-*tert*-butyl-2-nitrobenzyl chloride (**2**) in methanol in 62% yield. In this work, we were able to easily obtain nitro derivative **3** as a pure solid by simple crystallization, whereas Sakata and coworkers[18] obtained an oily product

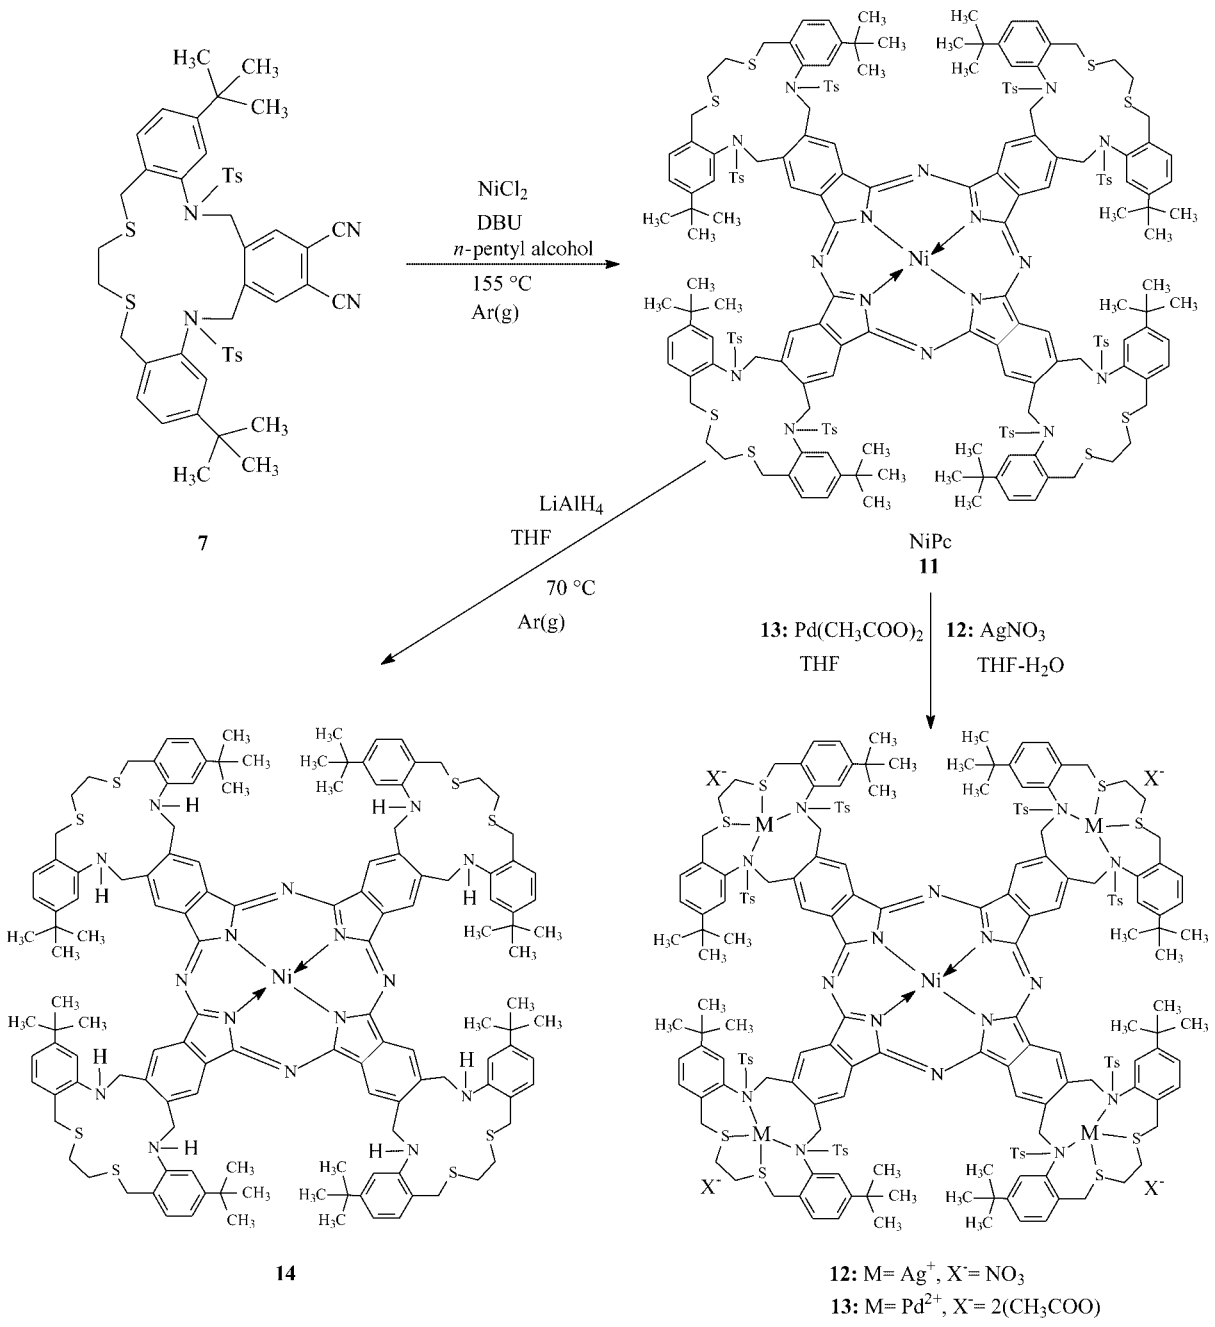

Scheme 2. Synthesis of nickel phthalocyanine and its derivatives.

after a more exhausting and time consuming column chromatography method. This compound was characterized spectroscopically and analytically. The $^1$H NMR spectrum of **3** showed characteristic signals for Ar–$CH_2$–S and S$CH_2$–$CH_2$S protons at $\delta$ = 4.20 and 2.70 ppm, respectively. The $^{13}$C NMR spectrum of this compound also clearly indicates the presence of expected signals related to the above-mentioned groups at $\delta$ = 31.90 and 32.45 ppm, respectively. The IR spectrum featured a band at 684 cm$^{-1}$, which is attributable to the C–S bonds. The EI mass spectrum of this compound exhibited a molecular ion peak at $m/z$ = 476.23 $[M]^+$, that also supports the structure.

Diamino derivative **4** was obtained by the reduction of **3** with 10%Pd/C (palladium activated charcoal), hydrazinium hydrate, and *n*-butyl alcohol in 78% overall yield. Because this method is more advantageous than the others, we preferred this one.[19] The disappearance of the signals for the $NO_2$ groups at 1543 and 1340 cm$^{-1}$ and the appearance of the signals of the $NH_2$ groups at 3430–3320 cm$^{-1}$ and bending signals at 1610 cm$^{-1}$ in the IR spectrum confirmed the formation of amino derivative **4**. The $^1$H and $^{13}$C NMR spectra of **4** were very similar to those of precursor compound **3** except for the signals of the $NH_2$ groups at $\delta$ = 3.82 and 145.56 ppm, respectively. The EI mass spectrum

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

displayed the $[M]^+$ parent ion peak at $m/z$ = 416.09, which confirms the same structure.

Reaction of *p*-toluenesulfonyl chloride with compound **4** in dry pyridine[20] afforded compound **5** in 97.5% yield. The IR spectrum of compound **5** shows the signals related to the tosyl groups at 1343–1140 $cm^{-1}$ and the N–H groups at 3270–1592 $cm^{-1}$, which indicates that the tosylation reaction was clearly achieved. A molecular ion peak at $m/z$ = 724.19 $[M]^+$ in its mass spectrum together with elemental analysis data clearly supports the structure of compound **5**. The $^1H$ NMR spectrum of compound **5** exhibits signals for both the N–H and tosyl groups at $\delta$ = 8.29 ppm and $\delta$ = 7.85–7.35 (Tosyl–Ar–H) and 2.32 ppm (Tosyl–$CH_3$), respectively. The $^{13}C$ NMR spectrum shows the signals at $\delta$ = 148.56 ppm (Ar–C–NH) and 144.62, 135.32, 130.23, 127.44 ppm (Ts–Ar), and 21.34 (Tosyl–$CH_3$), respectively. All these spectroscopic data confirm the proposed structure.

Dibromobenzene derivative **6** was obtained from the reaction of compound **5** and α,α′-dibromomethyl-4,5-dibromobenzene in 36% yield as a pale brown solid. From the IR spectrum, the formation of the C–Br bond was confirmed by the presence of the peak at 632 $cm^{-1}$, and the signals for the N–H group of compound **5** at 3270–1592 $cm^{-1}$ disappeared. Other IR peaks are similar to those of compound **5**. The N–H signals observed for compound **5** at $\delta$ = 8.29 ppm in the $^1H$ NMR spectrum disappeared and a new peak arose at $\delta$ = 7.75 ppm, which results from α,α′-dibromomethyl-4,5-dibromobenzene. The $^{13}C$ NMR spectra of **6** was very similar to that of the precursor compound **5** except for the carbon signal at $\delta$ = 149.41 ppm for the Ar–C–N– group. MS (FAB positive): $m/z$ = 983.3 $[M]^+$ also confirmed the structure.

Substitution of the bromo groups in **6** with cyanide moieties by a Rosenmund–von Braun reaction with cuprous cyanide[21] afforded corresponding phthalonitrile **7** in 58% yield. In the IR spectrum of **7**, the signal at 632 $cm^{-1}$ for the C–Br bond vanished and a new peak at 2224 $cm^{-1}$ appeared which was attributed to the dicyano groups. In the $^{13}C$ NMR spectrum of this compound, the presence of the signal at $\delta$ = 115.62 ppm, attributable to the nitrile carbon atom, indicated that the conversion had taken place; the $^1H$ NMR spectrum displayed similarities with that of precursor compound **6**. The mass spectrum of compound **7** should a peak at $m/z$ = 876.29 $[M]^+$ and this is in a good accord with the suggested structure.

Because of the eight *tert*-butyl and eight tosyl peripheral groups, all phthalocyanines except for **12** and **13** possess good solubility in common organic solvents and they can be purified by column chromatography by using appropriate solvent systems as coeluents that break up the molecular aggregation and increase the mobility of these compounds on silica gel or neutral alumina columns.

Metal-free phthalocyanine **8** was synthesized from the reaction of phthalonitrile derivative **7**, dry *n*-pentyl alcohol, and a catalytic amount of DBU. According to the IR spectrum of **8**, the signals for the C≡N groups at 2224 $cm^{-1}$ for compound **7** disappeared and new peaks appeared at 3320–1040 $cm^{-1}$ and 1630 $cm^{-1}$ that are dedicated to the N–H and C=N bonds in the phthalocyanine core of **8**, respectively. In the $^1H$ NMR spectrum, a peak at $\delta$ = –5.24 ppm, which is very characteristic for metal-free phthalocyanines, was detected and confirmed the suggested structure. The peak related to the C≡N groups in the $^{13}C$ NMR spectrum of **7** vanished in the case of metal-free phthalocyanine **8**. Other $^1H$- and $^{13}C$ NMR spectra peaks resembled those of precursor compound **7**. The mass spectrum of **8** was measured as $m/z$ = 3507.45 $[M]^+$ and is in good accord with the suggested structure.

Cyclization of **7** with zinc(II) acetate or nickel(II) chloride in the presence of DBU in *n*-pentyl alcohol then furnished the corresponding (phthalocyaninato)metal complexes **9** or **11**. The elemental analysis and mass spectroscopic data of **9** ($m/z$ = 3570.31 $[M]^+$) and **11** ($m/z$ = 3563.15 $[M]^+$) are consistent with their calculated values. The $^1H$ NMR spectra of these compounds were almost identical to those of metal-free phthalocyanine **8**. The differences in the $^1H$ NMR spectra of $H_2Pc$, ZnPc, and NiPc were the broad signals encountered in the case of compound **9** and **11** as a result of the aggregation of phthalocyanine cores at the considerable high concentration used for the NMR measurements.[22] The other characteristics of these compounds were quite similar to those of **7** and **8**. Cyclotetramerization of **7** was confirmed by the disappearance of the sharp C≡N stretching vibration at 2224 $cm^{-1}$ in the IR spectrum. The IR spectra of NiPc and ZnPc are also very similar to that of the precursor $H_2Pc$ except for the disappearance of the N–H vibration of the phthalocyanine core.

Copper(II) phthalocyanine (**10**) was synthesized directly from dibromo derivative **6**, CuCN, and quinoline in 42% yield. The comparison of the IR spectra obtained from **6** and **10** confirmed the conversion of the bromo groups into the characteristic skeleton moiety of phthalocyanine. In this case, the C–Br band at 632 $cm^{-1}$ disappeared and a C=N stretching vibration at 1642 $cm^{-1}$ appeared. The mass spectrum of **10** showed a peak corresponding to $[M + 1]^+$ at $m/z$ = 3568.15.

Metal-free phthalocyanine **8** and metallophthalocyanines **9**–**11** and **14** displayed typical UV/Vis electronic spectra with two significant absorption bands, one of them in the visible region at about 710–600 nm corresponding to the Q band, and the other in the UV, approximately at 300 nm. The Q band absorptions of **8** in chloroform at $\lambda_{max}$ = 710, 672, and 656 nm and the other absorption at 376 and 310 nm are consistent with the results obtained previously for similar phthalocyanines (Figure 1A).[23] The Q band absorption present in **8** can be attributed to the fact that the symmetry of the metal-free phthalocyanine is nondegenerate ($D_{2h}$) and is split in a $Q_x$ and a $Q_y$ peak as shown in the spectrum.[24] The bands between 300–500 nm show superimposed bands of phthalocyanine due to the existence of the Soret band of phthalocyanine (Pc).

The UV/Vis absorption spectra of metallophthalocyanines **9** and **10** are given in Figure 1A and **11** and **14** are given in Figure 2 in chloroform at room temperature. These compounds showed the expected absorptions at the main

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

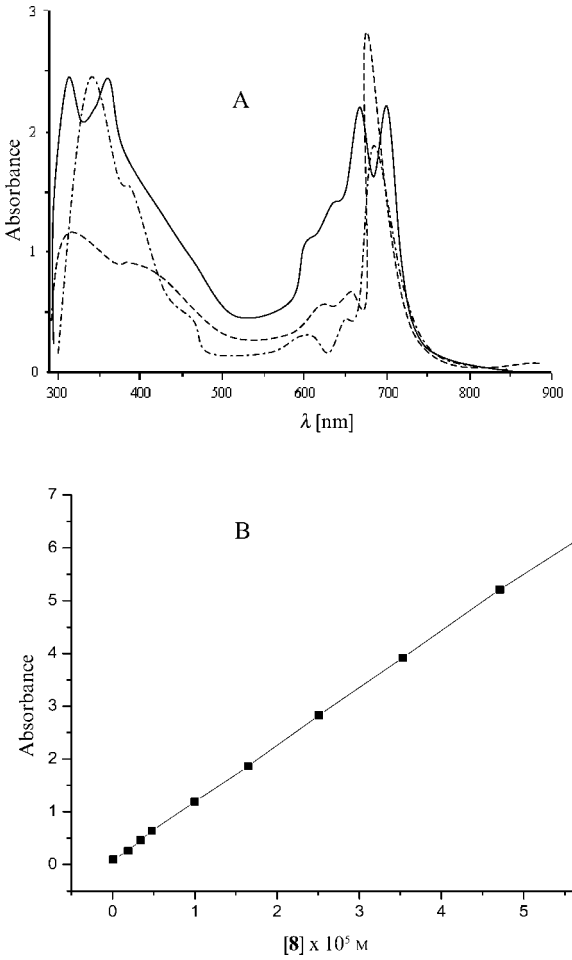

Figure 1. A) UV/Vis spectra of **8** (——), **9** (----) and **10** (-·-·-·) in chloroform ($1 \times 10^{-5}$ M). B) Plot of the Q-band (624 nm) absorbance versus concentration (from $2.5 \times 10^{-7}$ to $5.80 \times 10^{-5}$ M) in chloroform.

peaks of the Q- and B bands appearing at $\lambda_{max}$ = 690, 692, 694, 683 nm and 330, 355, 341, 332 nm, respectively. This result is typical of metal complexes of substituted and unsubstituted Pc with $D_{4h}$ symmetry.[2,25] Although ZnPc (**9**), CuPc (**10**), and NiPc (**11**) have a typical spectral pattern in the UV/Vis region for metallophthalocyanines, CuPc, NiPc, and detosylated **14** showed the new absorption bands at around 400 nm (466, 419, and 460 nm, respectively) in addition to the B band.[26] These new bands are sometimes observed, which can be ascribed to metal-to-ligand charge-transfer or ligand-to-metal charge-transfer transitions because metal ions have partially filled d orbitals. Alternatively, when the UV/Vis spectra data of **11** and **14** are compared, the Q bands in the UV/Vis spectra of **14** are shifted to shorter wavelengths with a decrease in the molar absorption coefficient as a result of the tendency to undergo aggregation.

Because of the eight bulky *tert*-butyl and eight tosyl substituents, these phthalocyanines are expected to be relatively nonaggregated in solution. This was confirmed by variable-concentration UV/Vis studies of compounds **8**–**11** in

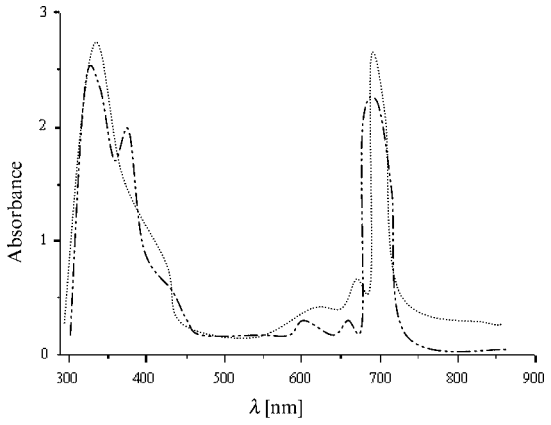

Figure 2. UV/Vis spectra of **11** (···) ($1 \times 10^{-5}$ M) and **14** (–··–··) in chloroform ($1 \times 10^{-5}$ M).

$CHCl_3$. For these four compounds, plots of the Q-band absorbance versus concentration (from $2.50 \times 10^{-7}$ to $5.80 \times 10^{-5}$ mol $L^{-1}$) gave nearly straight lines, which shows that the compounds follow the Beer–Lambert law. This observation indicates that the compounds mainly exist in the monomeric form under the conditions employed. Complex **14**, however, is slightly aggregated at higher concentrations (ca. $10^{-4}$ mol $L^{-1}$). This situation can be attributed to an increase in the intermolecular interaction between the phthalocyanine units after removing the bulky tosyl groups in **11**.

Nickel(II) phthalocyaninate derivatives of pentanuclear silver(I) complex **12** and palladium(II) complex **13** were prepared by treatment of **11** with $AgNO_3$ or $Pd(CH_3COO)_2$, respectively. From the IR spectra of products **12** and **13**, the vibrations belonging to the $NO_3^-$ groups are observed at 1382 $cm^{-1}$ and also symmetrical and asymmetrical vibrations of the $CH_3COO^-$ groups are observed at 1580 and 1420 $cm^{-1}$, respectively, which confirmed the complexation of silver(I) or palladium(II) cations. The $^1H$ NMR spectra of **12** and **13** show downfield changes in all the chemical shifts of the protons in the macrocyclic rings upon complex formation. This can be attributed to the fact that the silver(I) and palladium(II) cations are strongly coordinated to the N and S atoms in the macrocyclic rings. The chemical shifts assigned to the acetate groups, which were observed at $\delta$ = 2.39 ppm, also confirmed the formation of target pentanuclear complex **13**. The FAB mass spectra of products **12** and **13**, which were recorded in a triflouroacetic acid/*m*-nitrobenzyl alcohol matrix, show peaks at *m*/*z* 4244.92 $[M + 2]^+$ and 4242.56 $[M]^+$, and 4461.50 $[M + 1]^+$, 4460.02 $[M]^+$, respectively. Elemental analyses of **12** and **13** also confirmed the formation of complexes with silver(I) or palladium(II) ions.

The tosyl groups in **11** were removed by treatment with excess $LiAlH_4$ in THF to give complex **14** containing free amino groups. Comparison of the IR data gives sufficient support for the proposed structure. The difference between the spectra of tosylated and free amino groups is clear from the presence of $SO_2$ vibrations in **11** at 1140 and 1343 $cm^{-1}$ and the free N–H stretching vibrations for **14** at 3290 $cm^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The tosyl groups' signals observed for compound **11** in the $^1$H NMR spectrum disappeared and a new peak appeared at $\delta$ = 3.21 ppm belonging to the N–H signals in **14**. After detosylation, the tosyl groups' signals in the $^{13}$C NMR spectrum of **14** disappeared. The mass spectrum of compound **14** was 2338.08 $[M + Li]^+$and 2332.14 $[M + 1]^+$. All these spectroscopic data confirm the proposed structure.

The structures of the obtained phthalocyanines were an Au/MPc/Au sandwich in the configuration commonly used for the electrical conductivity measurements.[27] To prepare the samples, powdered materials were pressed at a load of 4 tons for 5 min into disk-shaped compacts with a thickness of 0.55–0.62 mm. The a.c. conductivity and parallel capacitance were measured with an Autolab 30 Voltammetry-FRA 2 impedance analyzer. The frequency range was 100 Hz to 1 MHz and the applied amplitude (rms) was 10 mV. The electrical conductivities of the obtained phthalocyanines were measured in a vacuum and under atmospheric pressure. Table 1 shows the a.c. electrical conductivities of phthalocyanines **8**–**14**. The conductivity values obtained under atmospheric pressure were higher than those under vacuum for all phthalocyanines probably because of absorbed oxygen.[27] These values correspond with those for semiconductive materials as encountered in a number of substituted phthalocyanine derivatives.[28] Relative to the conductivities of **11** and **14**, detosylated **14** shows a partial increase in the conductivity that is due to the removal of the bulky tosyl groups, which prevent the interaction of delocalized π-electrons on the phthalocyanine planes. Sixteen-membered diazadithiamacrocyclic substituents are expected to provide new chances to enhance the stacking of phthalocyanine units whereas their size and donor atoms are extremely harmonius to bond with transition metal cations in a 1:1 (metal/macrocycle ring) ratio.[29] Similar to the alkali metal complexes of analogous crown ether substituted phthalocyanines, planarity of the phthalocyanine nucleus will be extended. As a result, interaction of π-electrons will be achieved to realize charge transport. A.c. conductivities of nickel(II) phthalocyanine with four silver(I) or palladium(II) cations in the diazadithiamacrocyclic rings indicate a clear increase in the case of nitrate or acetate counterions.

The thermal properties of the synthesized macrocyclic compounds were investigated by DTA/TG.[30] Phthalocyanines are resistant to thermal oxidation. The DTA curves exhibited exothermic changes for all phthalocyanines **8**–**14** in the region investigated.[31] The initial decomposition temperature decreased in the order **9** > **7** > **11** > **8** > **13** > **14** > **6** > **10** > **12** (Table 2). Cu-containing phthalocyanine **10** was the most rapidly degrading metallophthalocyanine whereas Zn- and Ni-containing metallophthalocyanine showed good thermal stability under the working conditions. These results are in good agreement with the literature.[32] The DTA thermogram of **12** showed an endothermic peak at 230 °C, which is due to the dissociation of the nitrate groups. The thermal stabilities of **12** and **13** were lower than that of compound **11**. The thermal stabilities of **12** and **13** indicate that the dopants are rather weakly bound in the macrocyclic cavities because the bulky tosyl and *tert*-butyl groups in the macrocyclic ring have a steric effect.

The heavy metal binding ability of N–S-macrocyclic units is a well-known property. The binding abilities of the heavy metal ions in the N–S-macrocyclic units were esti-

mated by solvent extraction of heavy metal picrates from the aqueous phase to an organic phase (Table 3). Picrate was used as the counter anion for all compounds. As depicted in Table 3, the highest extraction affinities of **11** and **14** were determined as 55.62 and 86.23% for $Ag^+$, respectively. The extraction affinity of **14** was more than that of **11** for all working cations. This indicates that cations are able to bind to **14** easier than they can to **11** after the bulky tosyl groups were removed.

## Conclusions

In this paper, we have described the synthesis and characterization of new very soluble octa-substituted metal-free phthalocyanines and metallophthalocyanines (M = 2 H, Zn, Cu, and Ni) by using proper materials. Zn- and Ni-containing phthalocyanines showed good thermal stability whereas Cu-containing phthalocyanine degraded the most rapidly. The DTA thermogram of **12** showed an endothermic peak at 230 °C, which is due to the dissociation of the nitrate groups. Also, the thermal stabilities of **12** and **13** were lower than that of compound **11**. The electrical conductivities of the obtained phthalocyanines were found to be $10^{-10}$–$10^{-5}$ $Scm^{-1}$ in vacuo and air. The extraction abilities of **11** and **14** were evaluated by using a solvent extraction technique and the highest extraction affinities were observed for $Ag^+$ for all working conditions. The extraction affinity of **14** was more than that of **11** for all working cations.

## Experimental Section

**Materials:** Reactions were performed under an atmosphere of argon. 4-*tert*-Butyl-2-nitrobenzyl chloride (**2**) was prepared according to the literature.[18] All other reagents and solvents were of reagent grade quality, purchased from commercial suppliers, and they were dried before use as described in the literature.[33] Silica gel (70–230 mesh) and Merck 90 active neutral alumina were used for chromatographic separations.

**Measurements:** Melting points were determined with an electrothermal apparatus and are uncorrected. $^1H$ and $^{13}C$ NMR spectroscopic data were recorded with a Varian XL-200 spectrometer and IR spectra were obtained with a Perkin–Elmer Spectrum One spectrometer. Optical spectra in the UV/Vis region were recorded with a model Shimadzu 1601 UV/Vis spectrometer with the use of 1-cm pathlength cuvettes at room temperature. The a.c. conductivity was measured with an Autolab 30 Voltammetry-FRA 2 frequency analyzer. The frequency range was 100 Hz to1 MHz and the applied amplitude (rms) was 10 mV. Mass spectra were measured with a Varian MAT 711 or a Micromass Quatro LC/ULTIMA LC-MS/MS spectrometer by using triflouroacetic acid/*m*-nitrobenzyl alcohol as the matrix. Elemental analyses were determined with a CHNS-932 LECO instrument. The metal content of the metallophthalocyanines was determined with a Unicam 929 AA spectrophotometer.

**1,2-Bis(4-*tert*-butyl-2-nitrobenzylthio)ethane (3):** 1,2-ethandithiol (2 mL, 60 mmol), 4-*tert*-butyl-2-nitrobenzyl chloride (11.35 g, 50 mmol), and methanol (10 mL) were stirred inside a washing bottle at 50 °C while ammonia gas was bubbled through the solution for 2 h. The mixture was then cooled down to room temperature, benzene (100 mL) was added, and the salt was removed by filtration. The solvent was evaporated and methanol (15 mL) was added to the residue, which was then kept inside the refrigerator overnight. The yellow crystals were separated by filtration, dried in vacuo, and then recrystallized from *n*-butyl alcohol. Yield: 7.3 g (62%). M.p. 139–142 °C. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 8.01–7.48 (m, 6 H, Ar-H), 4.20 (s, 4 H, Ar-$CH_2$-S), 2.70 (t, 4 H, -$SCH_2$-$CH_2$S-), 1.32 [s, 18 H, $(CH_3)_3$C-] ppm. $^{13}C$ NMR (50 MHz, $CDCl_3$): $\delta$ = 149.5 (Ar-C-$NO_2$), 147.2, 128.2, 124.3, 119.3, 117.2, 34.1 [Ar-C-$(CH_3)_3$], 32.5 (S-$CH_2$-$CH_2$-S), 31.9 (Ar-$CH_2$-S), 30.6 [(-$CH_3)_3$] ppm. IR (KBr): $\tilde{\nu}$ = 3043 (CH aromatic), 2954–2849($CH_2$ aliphatic), 1543, 1340 ($NO_2$), 684 (C–S) $cm^{-1}$. MS (EI): *m*/*z* = 477.01 $[M + 1]^+$, 476.23 $[M]^+$, 475.30, 285.12, 284.07, 193.24, 192.15 $[M - C_{13}H_{18}NO_2S_2]^+$. $C_{24}H_{32}N_2O_4S_2$ (476.12): calcd. C 60.49, H 6.72, N 5.88, S 13.47; found C 60.32, H 6.92, N 5.69, S 13.62.

**1,2-Bis(4-*tert*-butyl-2-aminobenzylthio)ethane (4):** 1,2-Bis(4-*tert*-butyl-2-nitrobenzylthio)ethane (7.3 g, 153 mmol) was dissolved in *n*-butyl alcohol (200 mL) and heated at 80 °C. The temperature was then adjusted to 60 °C and 10%Pd/C (0.91 g) was added, and the reaction mixture was heated at reflux. Hydrazinium hydrate (30.6 mL) was added dropwise to the reaction mixture over a period of 30 min. After the addition, the mixture was heated at reflux for 10 h, and then the reaction was filtered over celite while it was hot. *n*-Butyl alcohol was removed under reduced pressure, and methanol (25 mL) was added to the residue, which was then kept in the refrigerator overnight. The precipitated white crystals were filtered off and washed several times with petroleum ether and dried in vacuo. Yield 3.5 g (78%). M.p. 106–108 °C. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 7.29–6.56 (m, 6 H, Ar-H), 3.82 (br. s, 4 H, -$NH_2$), 3.62 (s, 4 H, Ar-$CH_2$-S), 2.91 (t, 4 H, -$SCH_2$-$CH_2$S-), 1.29 [s, 18 H, $(CH_3)_3$C-] ppm. $^{13}C$ NMR (50 MHz, $CDCl_3$): $\delta$ = 145.6 (Ar-C-$NH_2$), 143.2, 127.1, 123.3, 118.8, 116.5, 34.0 [Ar-C-$(CH_3)_3$], 31.6 (S-$CH_2$-$CH_2$-S), 30.8 (Ar-$CH_2$-S), 30.2 [(-$CH_3)_3$] ppm. IR (KBr): $\tilde{\nu}$ = 3430–3320 ($NH_2$), 3025 (C–H aromatic), 2965–2864 ($CH_2$ aliphatic), 1610 ($NH_2$, bending), 1512, 1450, 1234 and 670 (C–S) $cm^{-1}$. MS (EI): *m*/*z* = 417.23 $[M + 1]^+$, 416.09 $[M]^+$, 254.15, 163.17 $[M + 1 - C_{13}H_{20}NS_2]^+$, 162.08 $[M - C_{13}H_{20}NS_2]^+$. $C_{24}H_{36}N_2S_2$ (416.12): calcd. C 69.21, H 8.65, N 6.73, S 15.40; found C 68.97, H 8.54, N 6.86, S 15.65.

**1,2-Bis(4-*tert*-butyl-2-tosylaminobenzylthio)ethane (5):** *p*-Toluenesulfonyl chloride (1.233 g, 6.47 mmol) in pyridine (2.5 mL) was added dropwise over a period of 2 h to a –10 °C solution of 1,2-bis(4-*tert*-butyl-2-aminobenzylthio)ethane (**3**; 1.344 g, 3.23 mmol) in pyridine (2.5 mL). The reaction was stirred overnight at –10 °C and then stirred at room temperature for 15 h under a nitrogen atmosphere. The reaction mixture was gently poured into ice (50–100 g), conc. HCl (6 mL) was added, and the mixture stirred for 24 h. The precipitated solid was filtered off and washed several times with deionized water until the washing solvent was neutral. The pale yellow solid product was then dried in vacuo and recrystallized from acetone. Yield 2.28 g (97.5%). M.p. 220–222 °C. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 8.29 (s, 2 H, N-H), 7.85 (d, 4 H, Tosyl-Ar-H), 7.35 (d, 4 H, Tosyl-Ar-H), 6.40–6.98 (m, 6 H, Ar-H), 3.67 (s, 4 H, Ar-$CH_2$-S), 2.73 (t, 4 H, -$SCH_2$-$CH_2$S-), 2.32 (s, 6 H, Tosyl-$CH_3$), 1.27 [s, 18 H, $(CH_3)_3$C-] ppm. $^{13}C$ NMR (50 MHz, $CDCl_3$): $\delta$ = 148.6 (Ar-C-NH), 144.6 (Ts-Ar), 143.4, 135.3 (Ts-Ar), 130.2 (Ts-Ar), 127.4 (Ts-Ar), 127.2, 123.4, 118.9, 116.2, 34.1 [Ar-C-$(CH_3)_3$], 31.3 (S-$CH_2$-$CH_2$-S), 30.6 (Ar-$CH_2$-S), 30.2 [(-$CH_3)_3$], 21.5 (Ar-$CH_3$) ppm. IR (KBr): $\tilde{\nu}$ = 3270 (N–H), 3050 (CH aromatic), 2990–2835($CH_2$ aliphatic), 1592 (N–H bending), 1343 and 1140 ($SO_2$), 674 (C–S) $cm^{-1}$. MS (FAB+): *m*/*z*: = 725.30 $[M + 1]^+$,

724.19 $[M]^+$, 570.42 $[M + 1 - Ts]^+$, 471.41, 470.12, 415.08 $[M + 1 - 2Ts]^+$, 414.14$[M - 2Ts]^+$. $C_{38}H_{48}N_2O_4S_4$ (724.24): calcd. C 62.96, H 6.62, N 3.87, S 17.71; found C 62.74, H 6.40, N 3.73, S 17.85.

**4,5:12,13-Bis(4′-*tert*-butylbenzo)-8,9-(4′′,5′′-dibromobenzo)-6,11-ditosyl-6,11-diaza-2,15-dithiacyclohexadeca-4,8,12-triene (6):** A 500-mL three-necked round-bottomed flask containing anhydrous DMF (100 mL) and fitted with a condenser was evacuated, refilled three times with argon gas and connected to a vacuum line. Under an argon atmosphere, the flask was charged with **5** (2.28 g, 3.15 mmol) and finely ground anhydrous $K_2CO_3$ (2.174 g, 15.75 mmol). The reaction mixture was stirred for 1 h at 45 °C. α,α′-Dibromomethyl-4,5-dibromobenzene (1.349 g, 3.15 mmol) in anhydrous DMF (50 mL) was added dropwise to the reaction mixture over a period of 6 h, and the reaction mixture was heated at reflux under an argon atmosphere for 6 d. The reaction was monitored by thin layer chromatography [chloroform/petroleum ether (7:3)]. At the end of this period, the mixture was cooled to room temperature, filtered, and washed with dry DMF and dichloromethane. The filtrate and the washing solvents were combined and the solvents evaporated to dryness under reduced pressure. The residue was added to ice (100 g) and stirred for 1 d. Thus, a pale brown solid was obtained and washed with deionized water (50 mL) and then dried in vacuo. The final purification of the product was carried out by column chromatography on silica gel (chloroform) to give a pale brown solid. Yield 1.12 g (36%). M.p. 264–265 °C. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 7.75 (s, 2 H, Ar-H), 7.57 (d, 4 H, Tosyl-Ar-H), 7.30 (d, 4 H, Tosyl-Ar-H), 6.51–6.78 (m, 6 H, Ar-H), 4.92 (s, 4 H Ar-$CH_2$-N), 3.71 (s, 4 H, Ar-$CH_2$-S), 2.70 (t, 4 H, -$SCH_2$-$CH_2$S-), 2.40 (s, 6 H, Tosyl-$CH_3$), 1.22 [s, 18 H, $(CH_3)_3$C-] ppm. $^{13}$C NMR (50 MHz, $CDCl_3$): $\delta$ = 149.4 (Ar-C-N-), 144.9 (Ts-Ar), 142.7, 139.4, 134.7, 130.5, 127.5, 127.0, 125.5, 124.4, 119.7, 117.5, 49.7 (Ar-$CH_2$-N-Ar), 34.3 [Ar-C-$(CH_3)_3$], 31.7 (S-$CH_2$-$CH_2$-S), 31.7 (Ar-$CH_2$-S), 29.3 [(-$CH_3)_3$], 21.8 (Ar-$CH_3$) ppm. **Metal-Free Phthalocyanine 8:** Under a dry argon atmosphere, a standard Schlenk tube was charged with phthalonitrile derivative **7** (150 mg, 0.171 mmol), dry *n*-pentyl alcohol (1.5 mL), and 3–4 drops of DBU, and the mixture was degassed several times. The reaction mixture was heated at reflux (155 °C) for 16 h, cooled to room temperature, and diethyl ether (2–3 mL) was added. The precipitated light green solid product was filtered off and dried. This product was purified by column chromatography on silica gel [dichloromethane/methanol (100:1)]. The combined solvents were evaporated and light green metal-free phthalocyanine **8** was obtained and then dried in vacuo. Yield: 42 mg (28%). M.p. >300 °C. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 8.06 (s, 8 H, Ar-H), 7.72–6.72 (m, 56 H, Ar-H), 4.78 (s, 16 H, Ar-$CH_2$-N), 3.69 (s, 16 H, Ar-$CH_2$-S), 2.80 (t, 16 H, -$SCH_2$-$CH_2$S-), 2.48 (s, 24 H, Tosyl-$CH_3$), 1.27 [s, 72 H, $(CH_3)_3$C-], –5.24 (br. s, 2 H, N-H) ppm. $^{13}$C NMR (50 MHz, $CDCl_3$): $\delta$ = 156.3, 146.4, 143.9, 141.6, 141.0, 137.1, 131.5, 129.4, 128.1, 126.8, 122.2, 119.8, 112.7, 53.1, 34.1, 31.8, 30.3, 29.5, 22.2 ppm. IR (KBr): $\tilde{\nu}$ = 3320 (N–H), 3054 (CH aromatic), 2963–2874 ($CH_2$ aliphatic), 1630 (C=N), 1510, 1480, 1340 and 1150 ($SO_2$), 1040 (N–H), 750, 680 (C–S) cm$^{-1}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ (log$\varepsilon$) = 710 (5.34), 672 (5.35), 656 (5.19), 624 (5.08), 376 (5.38), 310 (5.39) nm. MS (FAB+): *m*/*z* = 3507.45 $[M]^+$. $C_{192}H_{210}N_{16}O_{16}S_{16}$ (3506.96): calcd. C 65.70, H 5.99, N 6.39, S 14.63; found C 65.96, H 5.90, N 6.57, S 14.97.

**Phthalocyaninato Zinc(II) (9):** Under a dry argon atmosphere, a standard Schlenk tube was charged with phthalonitrile derivative **7** (100 mg, 0.114 mmol), dry *n*-pentyl alcohol (1.5 mL), $Zn(CH_3COO)_2 \cdot 2H_2O$ (6.4 mg, 0.029 mmol), and 3–4 drops of DBU, and the mixture was degassed several times. The reaction mixture was heated at reflux (160 °C) for 15 h, cooled to room temperature, and diethyl ether (2–3 mL) was added. The precipitated green solid product was filtered off, washed with ethanol, water, and diethyl ether, respectively, and then dried. The obtained light green product was purified by column chromatography on silica gel [dichloromethane/methanol (100:1)]. The collected solvents were evaporated and light green $Zn^{II}$ phthalocyaninate **9** obtained and then dried in vacuo. Yield 38.7 mg (38%). M.p. > 300 °C. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 7.90 (br. s, 8 H, Ar-H), 7.67–6.50 (m, 56 H, Ar-H), 4.70 (s, 16H Ar-$CH_2$-N), 3.63 (s, 16 H, Ar-$CH_2$-S), 2.73 (t, 16 H, -$SCH_2$-$CH_2$S-), 2.39 (s, 24 H, Tosyl-$CH_3$), 1.22 [s, 72 H, $(CH_3)_3$C-] ppm. $^{13}$C NMR (50 MHz, $CDCl_3$): $\delta$ = 153.1, 145.9, 142.4, 141.1, 139.6, 137.3, 130.5, 129.4, 128.3, 127.0, 122.1, 119.7, 110.6, 52.2, 34.9, 32.5, 31.3, 29.5, 22.0 ppm. IR (KBr): $\tilde{\nu}$ = 3050 (CH aromatic), 2990–2848 ($CH_2$ aliphatic), 1632 (C=N), 1512, 1485, 1341 and 1134 ($SO_2$), 756, 672 (C–S) cm$^{-1}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ (log$\varepsilon$) = 690 (5.45), 665 (4.90), 627 (4.83), 390 (4.96), 330 (5.07) nm. MS (FAB+): *m*/*z* = 3571.54 $[M + 1]^+$, 3570.31 $[M]^+$, 3506.12 $[M + 1 - Zn]^+$. $C_{192}H_{208}N_{16}O_{16}S_{16}Zn$ (3570.34): calcd. C 64.53, H 5.83, N 6.27, S 14.37, Zn 1.83; found C 64.28, H 5.69, N 6.43, S 14.61, Zn 1.71.

**Phthalocyaninato Copper(II) (10):** A mixture of dibromo derivative **6** (250 mg, 0.254 mmol), CuCN (68.2 mg, 0.762 mmol), and quinoline (1 mL) was placed in a stoppered Schlenk tube under an argon atmosphere, gently heated to 205 °C and refluxed for 22 h. The reaction mixture was then cooled to room temperature, ethanol (10 mL) added, stirred for 15 min, and filtered. The solid product was heated with a 3 N NaCN solution (3 × 25 mL) in order to remove excess CuCN over a period of 5 h. The dark green residue was filtered off and dried. This product was charged into a Soxhlet extraction column and extracted with chloroform for 18 h. The solvent was removed and solid product obtained. This green $Cu^{II}$ phthalocyanine derivative was purified by column chromatography on neutral alumina (chloroform) to give a dark green solid product.

**Silver(I) Complex of 11 (12):** Nickel(II) phthalocyanine derivative **11** (0.10 g, 0.028 mmol) was dissolved in tetrahydrofuran/water (5.1:0.1) in a 100-mL three-necked round-bottomed flask. Silver nitrate (0.038 g, 0.225 mmol) in the same solvent mixture (5.1:0.1) was added. The mixture was heated at reflux for 4 h, and a bluish–green product formed. The product was filtered off and washed with hot water, hot ethanol, and then diethyl ether. The deep blue product was then dried with $P_2O_5$ in vacuo. Yield: 0.069 g (58%). $^1$H NMR (200 MHz, $CF_3COOD$): $\delta$ = 7.95 (br. s, 8 H, Ar-H), 7.70–6.52 (m, 56 H, Ar-H), 4.80 (s, 16 H, Ar-$CH_2$-N), 3.69 (s, 16 H, Ar-$CH_2$-S), 2.84 (t, 16 H, -$SCH_2$-$CH_2$S-), 2.41 (s, 24 H, Tosyl-$CH_3$), 1.21 [s, 72 H, $(CH_3)_3$C-] ppm. IR (KBr): $\tilde{\nu}$ = 3045, 2942, 1615, 1480, 1382 ($NO_3$), 1340, 1235, 1120, 1100, 1048, 1015, 840, 760, 681 $cm^{-1}$. MS (FAB+): *m/z* = 4244.92 $[M + 2]^+$, 4242.56 $[M]^+$, 4180.26 $[M – NO_3]^+$, 4118.17 $[M – 2NO_3]^{2+}$, 4056.08 $[M – 3NO_3]^{3+}$. $C_{192}H_{208}Ag_4N_{20}NiO_{28}S_{16}$ (4243.14): calcd. **Palladium(II) Complex of 11 (13):** Metallophthalocyanine **11** (0.10 g, 0.028 mmol) was dissolved in tetrahydrofuran (5 mL) and a solution of $Pd(CH_3COO)_2$ (0.0503 g, 0.2236 mmol) in THF (5 mL) was added. The color became bluish–green while heated at reflux for 5 h and then precipitation occurred. The product was separated by centrifugation and washed several times successively with hot water, hot ethanol, and then diethyl ether. The bluish–green product was filtered off and dried with $P_2O_5$ in vacuo. Yield: 0.081 g (65%). $^1$H NMR (200 MHz, $CF_3COOD$): $\delta$ = 8.12 (br. s, 8 H, Ar-H), 7.75–6.50 (m, 56 H, Ar-H), 4.79 (s, 16H Ar-$CH_2$-N), 3.70 (s, 16 H, Ar-$CH_2$-S), 2.85 (t, 16 H, -$SCH_2$-$CH_2$S-), 2.43 (s, 24 H, Tosyl-$CH_3$), 2.39 (s, 24 H, $CH_3COO$), 1.21 [s, 72 H, $(CH_3)_3$C-] ppm. IR (KBr): $\tilde{\nu}$ = 3055, 2980, 1630, 1580 (asym.$CH_3COO$), 1503, 1470, 1420 (sym. $CH_3COO$), 1343, 1220, 1110, 1090, 1040, 1010, 740, 674 $cm^{-1}$. MS (FAB+): *m/z* = 4461.50 $[M + 1]^+$, 4460.02 $[M]^+$, 4400.13 $[M – CH_3COOH]^+$. $C_{208}H_{232}N_{16}NiO_{32}Pd_4S_{16}$ (4461.26): calcd. C 55.95, H 5.20, N 5.02, S 11.50, Ni 1.32, Pd 9.54; found C 56.14, H 5.32, N 4.87, S 11.65, Ni 1.49, Pd 9.75.

**Detosylation of 11 with $LiAlH_4$ – Compound 14:** A solution of **11** (0.100 g, 0.028 mmol) in dry THF (100 mL) was slowly added to a stirred suspension of $LiAlH_4$ (0.11 g, 2.8 mmol) in dry THF (100 mL) at room temperature under an argon atmosphere. The resulting mixture was stirred and heated at reflux for 5 d. A mixture of ethyl acetate and water was carefully added with stirring at 0 °C to decompose the excess $LiAlH_4$. The resulting precipitate was filtered and washed thoroughly with ethyl acetate and $CH_2Cl_2$. The combined filtrates were dried ($MgSO_4$) and the solvents evaporated. The residue was purified by chromatography on silica gel [$CH_2Cl_2$/$CH_3OH$/$NH_4OH$ (98:1:1)]. Evaporation of the solvent gave **14** as a green solid. Yield: 0.016 g (25%). $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 7.94 (br., 8 H, Ar-H), 7.17–6.59 (m, 24 H, Ar-H), 4.69 (s, 16H Ar-$CH_2$-N), 3.65 (s, 16 H, Ar-$CH_2$-S), 3.21 (br. s, 8 H, N-H, $D_2O$ exchange), 2.78 (t, 16 H, -$SCH_2$-$CH_2$S-), 1.24 [s, 72 H, $(CH_3)_3$C-] ppm. $^{13}$C NMR (50 MHz, $CDCl_3$): $\delta$ = 152.6, 150.1, 147.8, 139.4, 136.3, 127.8, 123.8, 122.6, 118.5, 112.3, 45.6, 34.0, 32.5, 31.1, 28.9 ppm. IR (KBr): $\tilde{\nu}$ = 3290 (N–H), 3040 (CH aromatic), 2960–2859 ($CH_2$ aliphatic), 1632 (C=N), 1500, 1490, 1240, 1120 (N–H), 760, 672 (C–S) $cm^{-1}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ (log$\varepsilon$) = 683 (5.33), 658 (4.38), 606 (4.51), 460 (4.80), 379 (5.30), 332 (5.39) nm. MS (FAB+): *m/z* = 2338.08 $[M + Li]^+$, 2332.14 $[M + 1]^+$, 2331.16 $[M – Li]^+$. $C_{136}H_{160}N_{16}NiS_8$ (2331.18): calcd. C 70.01, H 6.86, N 9.61, S 11.00, Ni 2.52; found C 70.21, H 6.68, N 9.54, S 11.27, Ni 2.69.

**Measurements of Heavy Metal-Binding Properties of 11 and 14:** The extraction properties of **11** and **14** were investigated under liquid–liquid phase and neutral conditions by using heavy metal picrates ($Ag^+$, $Cd^{2+}$, $Cu^{2+}$, $Hg^{2+}$, $Pb^{2+}$, $Pd^{2+}$, and $Zn^{2+}$) as substrates and by measuring with UV/Vis the amounts of metal picrate in the aqueous phase before and after treatment with the related compounds. Heavy metal picrates were prepared by the mixture of metal nitrates ($4 \times 10^{-2}$ M) and picric acid ($1.5 \times 10^{-2}$ M) in deionized water. We also prepared solutions ($3 \times 10^{-3}$ M) of related compounds **11** and **14** in dichloromethane. Equal volumes of both metal picrate solutions and compound solutions were then added into plastic bottles, kept closed, and shaken for 10 h by a shaker at 25 ± 1 °C. After shaking, the aqueous phases were separated and the percent of picrate salt extracted ($E$%) was determined by UV spectrophotometry. For each combination of host and metal picrate, the picrate extraction was conducted on three different samples and the average value of percent picrate extracted, with standard deviation, was calculated. The picrate extraction results are presented in Table 3. In the absence of host, blank experiment, no metal ion picrate extraction was detected. The extractability was determined on the basis of the absorbance of picrate ions in the aqueous solutions. The extractability was calculated by using the equation below:

$$E(\%) = [(A_{before} - A_{after})/A_{before}] \times 100$$

where $A_{before}$ is the absorbance in the absence of ligand. $A_{after}$ denotes the absorbance in the aqueous solution phase after extraction.

# Preparation and Reactivity of Hydridorhenium Complexes with Polypyridine and Phosphonite Ligands

**Gabriele Albertin,*[a] Stefano Antoniutti,[a] Jesús Castro,[b] Soledad García-Fontán,[b] and Giorgio Schipilliti[a]**

**Keywords:** Hydrido ligands / P ligands / Protonation / Rhenium / Vinyl complexes

The hydrido complexes $[ReH(Cl)(N–N)P_3]BPh_4$ [P = $PPh(OEt)_2$; N–N = 2,2′-bipyridine (bpy), 5,5′-dimethylbipyridine (5,5′-$Me_2$bpy), 1,10-phenanthroline (phen)] have been prepared by allowing $ReCl_3P_3$ to react with the polypyridine in refluxing ethanol. The dihydrido $[ReH_2(bpy)P_3]BPh_4$ complex has also been prepared by treating $[ReHCl(bpy)P_3]^+$ cation with $NaBH_4$ in ethanol. Similarly, the hydrido tricarbonyl derivative $[ReH_2(bpy)(CO)_3]BPh_4$ has been synthesized by allowing $[ReH(bpy)(CO)_3]$ to react with $HBF_4·Et_2O$. All complexes have been characterized spectroscopically (IR and NMR spectroscopic data) and the $[ReHCl(bpy)\{PPh(OEt)_2\}_3]BPh_4$ derivative by X-ray crystallography. Protonation of both $[ReHCl(bpy)P_3]BPh_4$ and $[ReH_2(bpy)P_3]BPh_4$ with $HBF_4·Et_2O$ leads to the classical cations $[ReH_2Cl(bpy)P_3]^{2+}$ and $[ReH_3(bpy)P_3]^{2+}$, respectively. The vinyl complexes $[Re\{CH=C(H)R\}_2(bpy)P_3]BPh_4$ (R = Ph, *p*-tolyl, *tert*-butyl) have also been prepared by allowing the dihydrido derivative $[ReH_2(bpy)P_3]BPh_4$ to react with an excess of terminal alkyne in 1,2-dichloroethane.

## Introduction

The chemistry of rhenium polyhydrido complexes has received considerable attention in recent years due to their various reactivity modes and unusual structural properties, including the presence of $\eta^2$-$H_2$ ligands.[1–4] The ancillary ligands used in this chemistry mainly involve π-acceptors such as carbonyls and mono- or polydentate tertiary phosphane groups.[1–4] In contrast, much less attention has been devoted to the use of nitrogen-donor ligands, and only one paper[5] has reported the use of polypyridines as supporting ligands[6,7] in rhenium polyhydrido complexes. This is somewhat surprising because rhenium complexes with polypyridine ligands are used in photo- and electrocatalytic reduction of $CO_2$.[6,7c,8] Changes in the nature of the ancillary ligands may also greatly change both the properties of complexes and the reactivity of the M–H bond, and recent results from our laboratory have confirmed the important influence of polypyridine ligands in the chemistry of classical and non-classical hydrido complexes of the iron triad.[9]

We have developed the chemistry of hydrido complexes of transition metals over several years using monodentate phosphites as supporting ligands.[9,10] Recently, in the case of rhenium, we reported the synthesis and reactivity of mono- and polyhydrido complexes of the type $[ReH(CO)_nP_{5-n}]$, $[Re(\eta^2\text{-}H_2)(CO)_nP_{5-n}]^+$, $ReH_5P_3$, $ReH_3P_4$, $Re_2H_8P_4$, and $[ReH_4(\eta^2\text{-}H_2)P_3]^+$ (P = phosphite; $n$ = 1–4).[11] We have now extended these studies, with the aim of introducing nitrogen-donor ligands such as 2,2′-bipyridine and 1,10-phenanthroline into rhenium polyhydrido chemistry. Our results on the synthesis and reactivity of mixed-ligand cationic hydridorhenium complexes with phosphonite and polypyridine are reported here.

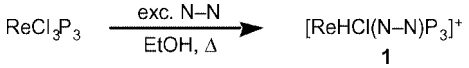
## Results and Discussion

### Synthesis of Hydrido Complexes

The trichlorido complex $[ReCl_3\{PPh(OEt)_2\}_3]$ was treated with an excess of polypyridine (N–N) in refluxing ethanol to give the cation $[ReHCl(N–N)\{PPh(OEt)_2\}_3]^+$, which was isolated as its $BPh_4$ salt and characterized (Scheme 1).



Scheme 1. P = $PPh(OEt)_2$; N–N = 2,2′-bipyridine (bpy) **a**, 5,5′-dimethyl-2,2′-bipyridine (5,5′-$Me_2$bpy) **b**, 1,10-phenanthroline (phen) **c**.

The reaction proceeds with substitution of the chlorido ligand by the polypyridine and formation of a heptacoordinate hydrido cation. The hydrido ligand presumably arises from abstraction of hydrogen from the ethanol solvent. Although this could not be proved conclusively, numerous precedents[1a] support this hypothesis.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The nature of the phosphane ligand is crucial for the synthesis of heptacoordinate hydrido complex **1**, which was obtained in pure form only with the phosphonite $PPh(OEt)_2$. The reaction of the related precursors $[ReCl_3(PPh_2OEt)_3]$ with polypyridines gave a mixture of products containing only small amounts of the $[ReHCl(N–N)(PPh_2OEt)_3]^+$ derivatives.

The hydrido complexes $[ReHCl(N–N)P_3]BPh_4$ (**1**) were treated with $NaBH_4$ in ethanol to give the dihydrido cations $[ReH_2(N–N)P_3]^+$ which, in the case of the bpy ligand, was isolated in good yield and characterized (Scheme 2). The reaction of **1** with $NaBH_4$ also proceeded with 5,5′-dimethylpyridine and 1,10-phenanthroline as a ligand but, in these cases, complexes **2** were rather unstable and decomposed during crystallization.

$$[ReHCl(N–N)P_3]^+ \xrightarrow[EtOH,\ \Delta]{NaBH_4} [ReH_2(N–N)P_3]^+$$
**1** **2a**

Scheme 2. P = $PPh(OEt)_2$; N–N = 2,2′-bipyridine (bpy) **a**.

Hydridorhenium complexes containing polypyridine as a supporting ligand are rare[5,6] and the only known examples were obtained from polyhydrido $[ReH_7(PPh_3)_2]$ or $[ReCl(bpy)(CO)_3]$ precursors. The reaction of $[ReCl_3P_3]$ with polypyridine in ethanol is therefore a new method for preparing mixed-ligand hydridorhenium complexes.

Hydrido complexes **1** and **2a** are dark-green (**1**) or red-brown (**2a**) solids that are stable in air and in solution in polar organic solvents, where they behave as 1:1 electrolytes.[12] The analytical and spectroscopic (IR, NMR; Table 1) data confirm the proposed formulation for the complexes. Further support comes from the X-ray crystal structure of $[ReHCl(bpy)\{PPh(OEt)_2\}_3]BPh_4$ (**1a**), the cation of which is shown in Figure 1. The geometrical parameters of the anion were as expected and do not require further comment.

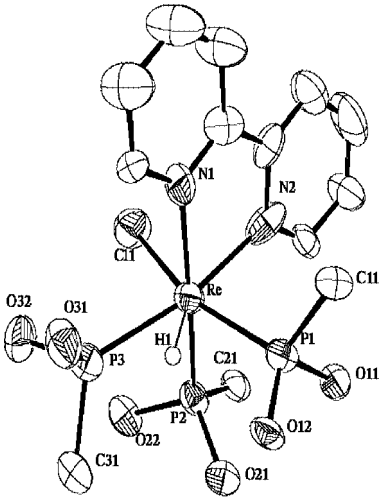


Figure 1. Perspective view of the crystal structure of the cation $[ReHCl(bpy)\{PPh(OEt)_2\}_3]^+$ **1a**, with thermal ellipsoids drawn at the 50% probability level. The ethyl and phenyl groups of the phosphites are omitted for clarity.

The rhenium atom in the cation is coordinated by three phosphorus atoms from three phosphonite ligands, two nitrogen atoms from the bipyridine ligand, and a chlorine atom. There is also significant residual electronic density close to the rhenium atom (at 1.23 Å; see Experimental Section), probably due to the presence of the hydrogen atom in this region, but unfortunately its position could not be refined due to the well-known inability of X-ray diffractometry to detect hydrido ligands coordinated to third-row transition metals. The presence of this ligand was also confirmed by the values of the angles around the metal, which are far from the theoretical values for an octahedron as a consequence of the heptacoordinate environment of the metal. Without knowing the position of the hydrido ligand it is difficult to propose a geometry around the metal. The N(1)–Re–P(2) axis [171.7(2)°], for example, could indicate a monocapped octahedron or a pentagonal bipyramid. The chelate angle N(1)–Re–N(2) has a value of only 75.7(4)° – virtually the same as that found in other 2,2′-bipyridine complexes of $Re^{III}$[13] – and is an important source of distortion since one of the nitrogen atoms is in the axis and the other in the equatorial plane. The angles in the plane for a pentagonal bipyramidal geometry should be close to 72°, although the different steric requirements of the hydrido and the rest of the ligands may enlarge these angles. The angles in the cation complex range from 79.2(2)° to 90.6(1)°. This, and the distortion of the axis, allows us to propose a monocapped octahedral geometry around the metal, with the hydrido ligand situated in the trigonal face occupied by the three phosphorus atoms.

The Re–N [2.172(10) and 2.180(9) Å] and Re–Cl [2.450(3) Å] bond lengths are slightly longer than those found for other octahedrally coordinated complexes,[13] as expected due to the increase in coordination number. The Re–P bond lengths range from 2.286(3) to 2.365(3) Å and are slightly shorter than those found in the cationic complex $[ReCl(PhN_2)\{PPh(OEt)_2\}_4]BPh_4$,[14] the only example of a complex containing both $Re^{III}$ and a phosphonite $PPh(OEt)_2$ ligand found in the CCDC (version 5.27, update August 2006).[15] This shortening is due to the pseudo *trans* effect exerted by the nitrogen or chlorine atoms in the heptacoordinate complex when compared with the cited octahedral cation, which has the phosphonite ligands mutually *trans*.

The IR spectra of monohydrido complexes $[ReHCl(N–N)P_3]BPh_4$ (**1**) show the bands characteristic of polypyridine and phosphonite ligands ($\nu_{PO}$ = 1098–1020 $cm^{-1}$), but none attributable to the $\nu_{ReH}$ of the hydrido ligand. However, its presence was confirmed by the $^1H$ NMR spectra, which show signals for the $PPh(OEt)_2$ and polypyridine ligands and a multiplet between $\delta$ = –7.98 and –8.30 ppm that is characteristic of a hydrido ligand. As the $^{31}P\{^1H\}$ NMR spectrum is an $A_2M$ multiplet for all complexes **1** in the temperature range between +20 and –80 °C, the hydrido pattern can be simulated by an $A_2MX$ model (X = $^1H$), with the parameters listed in Table 1. In addition, the values of the two $J_{P,H}$ coupling constants are similar, which suggests that the hydrido is in a mutually *cis* position with re-

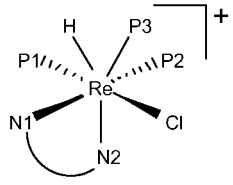
spect to all the phosphonite ligands. Lastly, the two methyl substituents of the 5,5′-dimethyl-2,2′-bipyridine ligand are magnetically inequivalent in **1b** (two methyl singlets at $\delta$ = 2.34 and 2.22 ppm in the $^1$H NMR spectrum of the complex).

The geometry of the heptacoordinate hydrido complexes **1** may be discussed in terms of three limiting structures, namely pentagonal bipyramidal, monocapped octahedral, or monocapped trigonal prismatic. The spectroscopic data do not allow us to distinguish between these possible structures, although it is plausible that the same geometry observed in the solid state for **1a** is also maintained in solution. A monocapped octahedral geometry of type **I**, which contains two magnetically equivalent phosphites that are different from the third and the hydrido ligand in a *cis* position with respect to each of the three phosphite groups, is in full accordance with the observed NMR spectroscopic data.

The $^1$H and $^{31}$P NMR spectra of the [ReH$_2$(bpy)P$_3$]$^+$ cation **2a** indicate that the complex is fluxional. The broad signals present at room temperature in the $^{31}$P NMR spectrum resolve into an $AM_2$ multiplet at –30 °C, thereby suggesting the presence of two phosphonites that are magnetically equivalent and different from the third. At the same temperature, the $^1$H NMR spectrum shows sharp signals



**I**

attributable to phosphonite and bpy ligands and a multiplet at $\delta$ = –5.31 ppm for the hydrido ligands. Variable-temperature $T_1$ measurements (200 MHz) on this signal gave a $T_{1min}$ value of 104 ms (Table 2), in agreement[16] with the classical nature of the dihydrido derivative **2a**. The hydrido multiplet at $\delta$ = –5.31 ppm can also be simulated with an $AM_2X_2$ (X = $^1$H) model, with the parameters listed in

Table 2. $^1$H NMR spectroscopic data (200 MHz; $\delta$ values, ppm) in the hydrido region for some rhenium complexes.

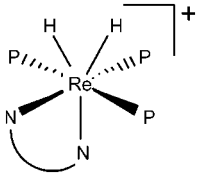
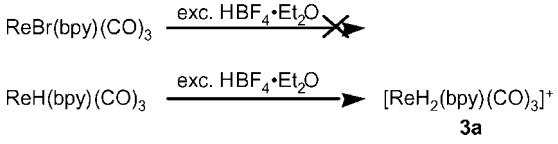
Table 1, and the good fit between experimental and calculated spectra indicates the magnetic equivalence of the two hydrido ligands.

The spectroscopic data strongly support the proposed formulation for complex **2a** but do not allow us to unambiguously assign its geometry in solution. However, by analogy with the related monohydrido **1**, a monocapped octahedral geometry of type **II** may also be proposed for dihydrido complex **2a**; this ligand arrangement fits the reported NMR spectroscopic data.



**II**

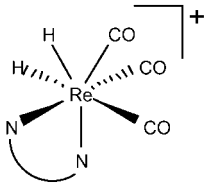
The easy synthesis of mono- and dihydridorhenium(III) complexes **1** and **2a** prompted us to extend our studies to related complexes containing carbonyl ligands. The method used was the protonation of $Re^{I}$ compounds of the type $[ReH(bpy)(CO)_3]$[17] and $[ReBr(bpy)(CO)_3]$ (Scheme 3).



Scheme 3.

Although $[ReBr(bpy)(CO)_3]$ was found to be unreactive toward an excess of $HBF_4$, $[ReH(bpy)(CO)_3]$ reacts quickly with $HBF_4$ to give the dihydrido cation $[ReH_2(bpy)(CO)_3]^+$, which was isolated as its $BPh_4$ salt and characterized. Good analytical data were obtained for complex **3**, which is a yellow solid that is stable in air and in solution in polar organic solvents, where it behaves as a 1:1 electrolyte.[12] The IR spectrum of **3a** shows three strong absorptions in the $\nu_{CO}$ region attributable to three carbonyl ligands in a mutually *fac* position. Besides the signals of the bpy ligand and the $BPh_4$ anion, the $^1H$ NMR spectrum shows two doublets at $\delta$ = –13.07 and –17.47 ppm ($J_{H,H}$ = 3.4 Hz) for the two hydrido ligands, which means they are magnetically inequivalent. $T_1$ measurements on these hydrido signals were also performed and gave $T_{1min}$ values near 112 ms, in good agreement[16] with the classical nature of these hydrido ligands. On this basis, we hypothesize that the reaction of $[ReH(bpy)(CO)_3]$ with $HBF_4$ does not proceed by protonation of the Re–H bond to give an $\eta^2$-$H_2$ ligand but involves the oxidative addition of $H^+$ to yield the formal cationic $Re^{III}$ derivative $[ReH_2(bpy)(CO)_3]^+$. Oxidative addition of $H^+$ to a $Re^{I}$ complex is rather rare[3e] as formation of the dihydrogen [Re]-$\eta^2$-$H_2$ complex is the more usual result of protonation.[3i,4a,11b] The presence of the bpy ligand probably strongly influences the course of the protonation reaction that leads to the $Re^{III}$ species **3**.

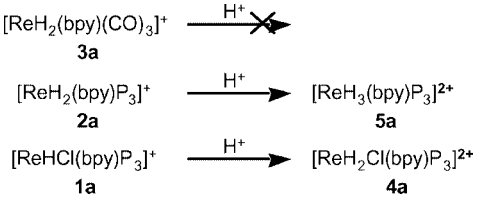
Although the IR and NMR spectroscopic data do not allow us to assign geometries to the complex, a monocapped octahedral geometry of type **III**, like those proposed for complexes **1** and **2a**, fits the spectroscopic data and may be tentatively proposed for the $[ReH_2(bpy)(CO)_3]^+$ derivative **3a**.



**III**

## Reactivity

Protonation of the new hydrido complexes **1**, **2a**, and **3a** with a Brønsted acid was studied with the aim of testing whether $\eta^2$-$H_2$ complexes could be formed. The results show that, although $[ReH_2(bpy)(CO)_3]^+$ (**3a**) is unreactive towards an excess of $HBF_4$·$Et_2O$, phosphonite complexes **1a** and **2a** give the new $Re^{V}$ hydrido complexes **4** and **5**, respectively, as shown in Scheme 4.



Scheme 4. P = $PPh(OEt)_2$.

The protonation was carried out at variable temperature and was monitored by $^1H$ and $^{31}P$ NMR spectroscopy. The addition of $HBF_4$·$Et_2O$ to a $CD_2Cl_2$ solution of the dihydrido cation $[ReH_2(bpy)P_3]^+$ (**2a**) at –80 °C caused the disappearance of the hydrido signal at $\delta$ = –5.4 ppm in the $^1H$ NMR spectrum and the appearance of two new multiplets with an intensity ratio of 2:1 at $\delta$ = –2.2 and at –3.1 ppm, respectively. Variable-temperature $T_1$ measurements (Table 2) on these signals gave $T_{1min}$ values (200 MHz) of 65 and 83 ms, respectively, which suggests a classical structure for the protonated $[ReH_3(bpy)P_3]^+$ derivatives. Protonation of the dihydrido cation $[ReH_2(bpy)P_3]^+$ therefore proceeds by oxidative addition of $H^+$ to the metal center to give the octacoordinate $Re^{V}$ trihydrido derivative **5a**. It should be noted that a twofold excess of $HBF_4$·$Et_2O$ must be used to complete the formation of **5a**, the $^{31}P$ NMR spectrum of which shows an $A_2B$ multiplet at –80 °C that can be simulated with the parameters listed in Table 1.

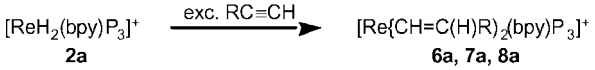
Addition of an excess of $NEt_3$ to a solution of **5a** regenerates the starting dihydrido complex $[ReH_2(bpy)P_3]^+$ and, although complex **5a** was not isolated, its spectroscopic data strongly support its formulation as the mixed-ligand rhenium(V) trihydrido complex $[ReH_3(bpy)P_3]^{2+}$, which contains three phosphonites and a bipyridine.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Protonation of cationic hydrido complexes has been reported previously[9,19] and often proceeds, in the presence of a large excess of Brønsted acid, to give $\eta^2$-$H_2$ derivatives. The relatively easy oxidative addition of $H^+$ to a cationic $Re^{III}$ hydrido complex to yield a $Re^V$ polyhydrido complex similar to **5a** may be due to the presence of the polypyridine ligand, which is able to stabilize classical dicationic hydrido complexes in a high oxidation state.

Reaction of the hydrido-chlorido $[ReH(Cl)(bpy)P_3]^+$ cation **1a** also proceeds with $HBF_4{\cdot}Et_2O$ at –80 °C to give the new hydrido cation $[ReH_2Cl(bpy)P_3]^{2+}$ (**4a**) (Scheme 4), although in this case a large excess of acid is required to complete the reaction. The $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopic data also suggest the presence of two isomers for **4a**, which shows two multiplets at $\delta$ = –5.50 and –7.84 ppm in the $^1H$ NMR spectrum and two $A_2M$ multiplets in the $^{31}P$ NMR spectrum. $T_1$ measurements on the hydrido proton multiplets (Table 2) confirmed the classical nature of the protonated complex, which suggests that oxidative addition of $H^+$ also takes place in the hydrido-chlorido complexes to yield the rhenium(V) polypyridine derivative **4a**. The two $Re^{III}$ hydrido complexes **1a** and **2a**, which contain a polypyridine and phosphonites as supporting ligands, therefore show parallel behavior during the oxidative addition of $H^+$ and afford a dicationic octacoordinate polyhydrido $Re^V$ complex.

Reactivity studies on hydrido cations **1** and **2a** were extended to substitution and insertion reactions, and the results revealed the relatively high stability of both complexes. Substitution reactions with carbonyl, phosphane, nitrile, or isocyanide ligands and insertion reactions with unsaturated molecules such as $ArN_2^+$, $RCH{=}CH_2$, $CO_2$, $CS_2$, etc. proved impossible for both complexes. However, one reaction was observed for **2a**, which reacts with terminal alkynes to give the bis(vinyl) derivatives $[Re\{CH{=}C(H)R\}_2(bpy)P_3]^+$ (**6a**, **7a**, and **8a**), as shown in Scheme 5.



Scheme 5. P = $PPh(OEt)_2$; R = Ph **6a**, *p*-tolyl **7a**, *tert*-butyl **8a**.

The reaction is quite slow at room temperature, and the synthesis of pure vinyl complexes **6a**–**8a** can be achieved only at reflux conditions. In every case, the reaction proceeds with the insertion of two alkynes into the Re–H bond to give only bis(vinyl) derivatives **6a**, **7a**, and **8a**. The absence of any mono-insertion product such as $[ReH\{CH{=}C(H)R\}_2(bpy)P_3]^+$ is probably due to a faster insertion rate of the second alkyne with respect to the first into the Re–H bond of **2a**. The need for reflux conditions to obtain the vinyl complexes may be explained by the fact that the mechanism proposed[20] for the insertion of an alkyne into an M–H bond usually requires a vacant site, and only at higher temperatures can the substitution of one ligand by an alkyne take place.

Vinyl complexes of rhenium are rare[21] and in some cases have been proposed only as intermediates.[22] Our reaction of dihydrido compound **2a** with a terminal alkyne provides new examples of this class of derivatives. Vinyl complexes **6a**–**8a** are green solids that are stable in air and in solution in polar organic solvents, where they behave as 1:1 electrolytes.[12] The analytical and spectroscopic data (Tables 1 and 3) support their proposed formulation. Thus, besides the signals of the polypyridine, phosphites, and the $BPh_4$ anion, the $^1H$ NMR spectrum shows a slightly broad multiplet at around $\delta$ = 6.45–6.51 ppm due to $H_\beta$ of the vinyl ligand. This multiplet was correlated in a COSY experiment with a signal overlapping the phenyl resonances at $\delta$ = 7.04–7.09 ppm, which was attributed to the $H_\alpha$ proton of the vinyl ligand. As the $^{31}P$ NMR spectrum in the temperature range between +20 and –80 °C is an $AB_2$ multiplet, the $H_\alpha$ and $H_\beta$ vinyl signals can be simulated with an $AB_2XY$ (X = $H_\alpha$, Y = $H_\beta$) model with the parameters listed in Table 1. The values of the proton-proton coupling constants $J_{X,Y}$ of 7.7 (**7a**) and 8.4 Hz (**8b**) also suggest a *cis* arrangement[23] of the two vinyl protons.

Table 3. $^{13}C\{^1H\}$ NMR spectroscopic data for vinyl complexes **7a** and **8a**.

| Compound | $^{13}C\{^1H\}$ NMR[a] | |
|---|---|---|
| | $\delta$ | Assignment |
| **7a** | 165–122 (m) | Ph + bpy |
| | 131.2 (s) | $=CH_\beta$ |
| | 128.6 (m) | $=CH_\alpha$ |
| | 67.4 (d) | $CH_2$ |

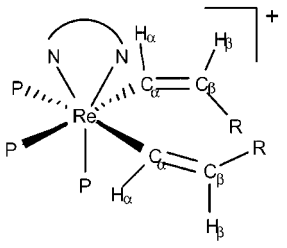
[a] In $CD_2Cl_2$ at 25 °C. Chemical shifts are given in ppm and coupling constants in Hz.

The $^{13}C$ NMR spectra (Table 3) confirm the presence of the vinyl group in compounds **6**–**8** by the presence of a multiplet at $\delta$ = 128–129 ppm attributed to $C_\alpha$ and another at $\delta$ = 123–131 ppm attributed to $C_\beta$ of the vinyl ligand. HMQC and HMBC experiments confirmed this assignment as the multiplets at $\delta$ = 123–131 ppm in the $^{13}C$ spectra are correlated to the proton signals near $\delta$ = 6.5 ppm due to the $H_\beta$ vinyl resonance, whereas the $^{13}C$ signal at $\delta$ = 128–129 ppm is correlated with the signal at $\delta$ = 7.04–7.09 ppm due the $H_\alpha$ vinyl proton, in agreement with the proposed assignment of these signals.

These spectroscopic data strongly support the proposed formulation for the complexes but do not allow us to unambiguously assign geometries to the complexes. Assuming a monocapped octahedral geometry for these vinyl complexes as well, a structure of type **IV**, with two magnetically equiv-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

alent vinyl groups and two magnetically equivalent phosphonites that are different from the third, fits the spectroscopic data. However, the absence of any X-ray crystal structure due to the poor quality of the obtained crystals means that geometry **IV** is only a tentative proposal.



**IV**

## Conclusions

We have described the synthesis of the mixed-ligand hydridorhenium(III) complexes $[ReHCl(N–N)P_3]BPh_4$ (**1**) and $[ReH_2(N–N)P_3]BPh_4$ (**2a**), both of which contain phosphonite and polypyridine ligands. The hydrido carbonyl cations $[ReH_2(bpy)(CO)_3]^+$ have also been obtained by the oxidative addition of $H^+$ to $Re^I$ derivatives. The structural parameters for the heptacoordinate $[ReHCl(bpy)P_3]^+$ cation have been obtained by X-ray crystallography. Among the properties shown by the new $Re^{III}$ hydrido complexes we can highlight the easy protonation of cationic complexes **1** and **2a** to give classical $Re^V$ hydrido derivatives, and the reaction of **2a** with terminal alkynes to afford new examples of vinyl complexes of rhenium.

## Experimental Section

**General:** All synthetic work was carried out under an inert atmosphere (Ar, $N_2$) using standard Schlenk techniques or a dry box (Vacuum Atmospheres, Mecaplex, CH). All solvents were dried with appropriate drying agents, degassed on a vacuum line, and distilled into vacuum-tight storage flasks. $Re_2(CO)_{10}$ was a Pressure Chemical Co. (USA) product, while Re powder was purchased from Chempur (Germany); both were used as received. The phosphonite $PPh(OEt)_2$ and phosphinite $PPh_2OEt$ were prepared according to Rabinowitz and Pellon.[24] Other reagents were purchased from commercial sources with the highest available purity and used as received. IR spectra were recorded with a Nicolet Magna 750 or Perkin–Elmer Spectrum One FT-IR spectrophotometer. NMR spectra ($^1H$, $^{31}P$, $^{13}C$) were obtained with an AC200 or Avance 300 Bruker spectrometer at temperatures between –80 and +30 °C, unless otherwise noted. $^1H$ and $^{13}C$ NMR spectra are referenced to internal tetramethylsilane; $^{31}P\{^1H\}$ chemical shifts are reported with respect to 85% $H_3PO_4$, with downfield shifts considered positive. The COSY, HMQC, and HMBC NMR experiments were performed using the standard programs. Values of $T_{1min}$ (±10%) were determined by the inversion recovery method between –90 and +30 °C in $CD_2Cl_2$ with a standard 180°–τ–90° pulse sequence. The SwaN-MR software package[25] was used to treat NMR spectroscopic data. The conductivity of $10^{-3}$ M solutions of the complexes in $CH_3NO_2$ at 25 °C was measured with a Radiometer CDM 83. Elemental analyses were determined by the Microanalytical Laboratory of the Dipartimento di Scienze Farmaceutiche of the University of Padua, Italy.

**Synthesis of Complexes:** $[ReCl_3P_3]$, $[ReBr(CO)_5]$, and $[ReH(CO)_5]$ [P = $PPh(OEt)_2$, $PPh_2OEt$] were prepared following the previously reported methods.[11a,26]

**$[ReHCl(N–N)\{PPh(OEt)_2\}_3]BPh_4$ (1) [N–N = 2,2′-bipyridine (bpy) (a), 5,5′-dimethylbipyridine (5,5′-$Me_2$bpy) (b), 1,10-phenanthroline (phen) (c)]:** $[ReCl_3\{PPh(OEt)_2\}_3]$ (0.50 g, 0.56 mmol) and the appropriate polypyridine N–N (1.7 mmol) were placed in a 50-mL, three-necked, round-bottomed flask and dissolved in 30 mL of ethanol. The resulting mixture was refluxed for 5 h and then the solvent was removed under reduced pressure to give a brown solid from which the hydrido complex was extracted with five 10-mL portions of $CH_2Cl_2$. The combined extracts were evaporated to dryness to give an oil, which was treated with ethanol (5 mL) containing an excess of $NaBPh_4$ (1.7 mmol, 0.58 g). A dark-green solid separated out. This solid was filtered and crystallized from $CH_2Cl_2$ and ethanol. Yields: 0.45 g for **1a** (62%), 0.48 g for **1b** (65%), 0.33 g for **1c** (45%).

**1a:** $C_{64}H_{74}BClN_2O_6P_3Re$ (1292.7): calcd. C 59.47, H 5.77, Cl 2.74, N 2.17; found C 59.39, H 5.63, Cl 2.58, N 2.24. $\Lambda_M$ = 54.9 $S\,cm^2\,mol^{-1}$.

**1b:** $C_{66}H_{78}BClN_2O_6P_3Re$ (1320.7): calcd. C 60.02, H 5.95, Cl 2.68, N 2.12; found C 59.87, H 6.02, Cl 2.80, N 2.21. $\Lambda_M$ = 51.3 $S\,cm^2\,mol^{-1}$.

**1c:** $C_{66}H_{74}BClN_2O_6P_3Re$ (1316.7): calcd. C 65.38, H 5.66, Cl 2.69, N 2.13; found C 65.16, H 5.75, Cl 2.86, N 2.05. $\Lambda_M$ = 52.8 $S\,cm^2\,mol^{-1}$.

**$[ReH_2(bpy)\{PPh(OEt)_2\}_3]BPh_4$ (2a):** $[ReCl_3\{PPh(OEt)_2\}_3]$ (0.50 g, 0.56 mmol) and 2,2′-bipyridine (0.266 g, 1.7 mmol) were placed in a 50-mL, three-necked, round-bottomed flask and 20 mL of ethanol was added. The mixture was stirred and refluxed for 5 h and then allowed to reach room temperature. An excess of $NaBH_4$ (0.211 g, 5.6 mmol) in ethanol (10 mL) was then added and the mixture refluxed for 1 h. The solvent was removed under reduced pressure to give an oil, from which the hydrido complex was extracted with five 10-mL portions of $CH_2Cl_2$. The extracts were evaporated to dryness to give an oil, which was triturated with ethanol (5 mL) containing an excess of $NaBPh_4$ (1.7 mmol, 0.58 g). A red-brown solid slowly separated out. This solid was filtered and crystallized from $CH_2Cl_2$ and ethanol. Yield: 0.40 g (57%). $C_{64}H_{75}BN_2O_6P_3Re$ (1258.2): calcd. C 61.09, H 6.01, N 2.23; found C 61.25, H 5.84, N 2.12. $\Lambda_M$ = 54.7 $S\,cm^2\,mol^{-1}$.

**$[ReH(bpy)(CO)_3]$:** This compound was prepared by a new method rather than that reported in the literature.[6] Thus, $[ReH(CO)_5]$ (0.35 mL, 2.05 mmol) and one equivalent of 2,2′-bipyridine (0.32 g, 2.05 mmol) were placed in a 250-mL, three-necked, round-bottomed flask and 100 mL of toluene was added. The reaction mixture was refluxed for 4 h and then the solvent was removed under reduced pressure to give an oil, which was triturated with ethanol (5 mL). An orange solid slowly separated out from the resulting stirring solution. This solid was filtered and dried under vacuum. Yield: 0.307 g (35%). $C_{13}H_9N_2O_3Re$ (427.43): calcd. C 36.53, H 2.12, N 6.55; found C 36.71, H 2.05, N 6.42. IR (KBr): $\tilde{\nu}$ = 2032 (m), 1976 (s), 1912 $cm^{-1}$ [s ($\nu_{CO}$)]. $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 9.13–7.56 (m, bpy), –13.02 (s, ReH) ppm.

**$[ReBr(bpy)(CO)_3]$:** This compound was prepared by a slight modification of the reported method.[27] Thus, $[ReBr(CO)_5]$ (1 g,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2.46 mmol) and 2,2′-bipyridine (1.15 g, 7.38 mmol) were placed in a 100-mL, three-necked, round-bottomed flask and 30 mL of toluene was added. The mixture was stirred, refluxed for 5 h, and then allowed to reach room temperature. A yellow solid separated out which, after 1 h of stirring, was filtered and dried under vacuum. Yield: 1.01 g (81%). $C_{13}H_8BrN_2O_3Re$ (506.32): calcd. C 30.84, H 1.59, N 5.53; found C 30.66, H 1.68, N 5.40. IR (KBr): $\tilde{\nu}$ = 2012 (m), 1905 (s), 1882 $cm^{-1}$ [s ($\nu_{CO}$)]. $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 9.06–7.53 (m, bpy) ppm.

**[$ReH_2$(bpy)$(CO)_3$]$BPh_4$ (3a):** An excess of $HBF_4{\cdot}Et_2O$ (2.3 mmol, 0.33 mL of a 54% solution in diethyl ether) was added to a solution of [ReH(bpy)$(CO)_3$] (0.100 g, 0.23 mmol) in $CH_2Cl_2$ (7 mL) at –196 °C. The reaction mixture was then brought to room temperature and stirred for 2 h. The solvent was removed under reduced pressure to give an oil, which was triturated with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.46 mmol, 0.157 g). A yellow solid slowly separated out from the resulting solution. This solid was filtered and crystallized from $CH_2Cl_2$ and ethanol; yield 0.134 g (78%). $C_{37}H_{30}BN_2O_3Re$ (747.67): calcd. C 59.44, H 4.04, N 3.75; found C 59.27, H 4.01, N 3.68. $\Lambda_M$ = 53.5 $S cm^2 mol^{-1}$.

**[$ReH_2$(Cl)(bpy){PPh$(OEt)_2$}$_3$]$^{2+}$ (4a) and [$ReH_3$(bpy){PPh$(OEt)_2$}$_3$]$^{2+}$ (5a):** These cationic complexes were prepared in $CD_2Cl_2$ solution by protonation of the precursors [ReH(Cl)(bpy)$P_3$]$BPh_4$ (**1a**) and [$ReH_2$(bpy)$P_3$]$BPh_4$ (**2a**) with $HBF_4{\cdot}Et_2O$. In a typical experiment, a $CD_2Cl_2$ solution (0.5 mL) of **1a** or **2a** (30–40 mg, 0.02–0.03 mmol) was placed in a screw-cap 5-mm NMR tube placed in a dry box. The tube was sealed, cooled to –80 °C, and then increasing amounts (from one to four equivalents) of $HBF_4{\cdot}Et_2O$ were added with a microsyringe. The tube was then transferred into the instrument's probe, which had been pre-cooled to –80 °C, and the spectra collected.

**[Re{CH=C(H)R}$_2$(bpy){PPh$(OEt)_2$}$_3$]$BPh_4$ (6–8) [R = Ph (6a), *p*-tolyl (7a), *tert*-butyl (8a)]:** An excess of the appropriate alkyne RC≡CH (0.8 mmol) was added to a solution of [$ReH_2$(bpy){PPh$(OEt)_2$}$_3$]$BPh_4$ (0.100 g, 0.079 mmol) in 12 mL of 1,2-dichloroethane and the reaction mixture refluxed for 1 h. The solvent was removed under reduced pressure to give an oil, which was triturated with ethanol (2 mL) containing an excess of $NaBPh_4$ (0.2 mmol, 68 mg). A green solid slowly separated out from the resulting solution. This solid was filtered and crystallized from $CH_2Cl_2$ and ethanol. Yield 0.079 g for **6a** (68%), 0.081 g for **7a** (69%), 0.082 g for **8a** (73%).

**6a:** $C_{80}H_{87}BN_2O_6P_3Re$ (1462.5): calcd. C 65.70, H 6.00, N 1.92; found C 65.49, H 5.93, N 1.88. $\Lambda_M$ = 53.1 $S cm^2 mol^{-1}$.

**7a:** $C_{82}H_{91}BN_2O_6P_3Re$ (1490.6): calcd. C 66.08, H 6.15, N 1.88; found C 65.91, H 6.24, N 1.80. $\Lambda_M$ = 54.6 $S cm^2 mol^{-1}$.

**8a:** $C_{76}H_{95}BN_2O_6P_3Re$ (1422.5): calcd. C 64.17, H 6.73, N 1.97; found C 64.38, H 6.86, N 2.08. $\Lambda_M$ = 52.8 $S cm^2 mol^{-1}$.

**Crystallographic Analysis of [ReHCl(bpy){PPh$(OEt)_2$}$_3$]$BPh_4$ (1a):** Data collection was performed on a SIEMENS Smart CCD area-detector diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation. Absorption correction was carried out using SADABS.[28] The structure was solved and refined with the Oscail program[29] by Patterson methods and refined by a full-matrix least-squares procedure on $F^2$.[30] Non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in idealized positions and refined with isotropic displacement parameters except that bonded to the rhenium atom, which was neither located nor included in the model. Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from International Tables for X-ray Crystallography.[31] Details of crystal data and structural refinement are given in Table 4 and selected bond lengths and angles are listed in Table 5.

Table 4. Crystal data and structure refinement for [ReHCl(bpy){PPh$(OEt)_2$}$_3$]$BPh_4$ (**1a**).

[17] We have prepared the $[ReH(bpy)(CO)_3]$ complex by substituting carbonyl ligands with bpy in the pentacarbonyl derivative $[ReH(CO)_5]$. A *mer* arrangement of the three CO ligands is suggested by the presence of one band of medium intensity (2032 $cm^{-1}$) and two strong ones (1976 and 1912 $cm^{-1}$) in the $\nu_{CO}$ region,[18] while the presence of the hydrido ligand is confirmed by the sharp singlet at $\delta = -13.02$ ppm observed in the $^1H$ NMR spectrum. The previously reported species $[ReH(bpy)(CO)_3]$[6] was prepared from the $[Re(bpy)(CO)_3(H_2O)]^+$ cation and showed a *fac* geometry with the hydrido signal surprisingly being found at $\delta = +1.54$ ppm in the $^1H$ NMR spectrum. Such a high frequency assignment for the hydrido is questionable.

# CuO/ZnO Nanoparticles in a Matrix of Amorphous Silica as High-Surface Precursors for Methanol Synthesis

**Bernd Rohe,[a] Rainer Weiss,[b] Sascha Vukojević,[c] Christian Baltes,[c] Martin Muhler,[d] Michael Tausch,[e] and Matthias Epple*[b]**

**Keywords:** Heterogeneous catalysis / Copper / Zinc oxide / Silica / Nanoparticles / Surface coating

An intimate mixture of CuO/ZnO nanocrystals was prepared by an easy sol-gel synthesis (precipitation in methanol by hydroxide in the presence of a silane). The organic substituents of the silane were almost completely removed by a subsequent photochemical oxidation. The resulting amorphous $SiO_2$ prevented the growth of the catalytically active particles to larger crystals. The coating layer of silica can easily be penetrated by gaseous reactants, as shown by the high specific surface area of about 110–130 $m^2 g^{-1}$ (probably due to both silica and nanocrystalline CuO/ZnO) and the good catalytic activity in methanol synthesis from $CO/CO_2/H_2$ synthesis gas (7 to 37 %, compared to an industrial standard methanol catalyst). The ratio of CuO to ZnO can be easily varied by the used preparation method.

## Introduction

Cu/ZnO is a widely used model catalyst system for investigations in heterogeneous catalysis.[1] In most cases, the methanol synthesis and the steam reforming reaction are studied. The industrial catalyst is based on Cu/ZnO/$Al_2O_3$,[1,2] but often Cu/ZnO is examined as simplified binary model system.[3–15] Although copper is the more important catalytically active component,[16,17] pure ZnO is itself active in methanol synthesis[18–20] The most common preparation methods for the catalyst precursor CuO/ZnO are based on the co-precipitation of carbonates or oxalates, followed by thermolysis to the corresponding oxides.[6,8,11,14,21–23] We have recently shown that active catalysts can also be prepared by thermolysis of bimetallic coordination compounds,[24] xerogels and aerogels,[25] and tartrate mixed crystals.[26] Copper nanoparticles in liquid dispersion were recently shown to be active as methanol catalysts,[27] as well as metal-loaded mesoporous silicates[28] and metal-oxide frameworks (MOFs).[29]

Here we report on the preparation, characterization and catalytic activity of ZnO and CuO/ZnO nanocomposites which were obtained by a combination of sol-gel synthesis and photochemical oxidation which was applied earlier to prepare nanoscale ZnO.[30] By precipitating the oxides in the presence of a silane in alcohol, a highly dispersed mixture of the oxides with a high specific surface area[31] is obtained because the silane prevents the growth and agglomeration of the oxide crystals.[32] Subsequently, the organic substituents of the silane are photochemically oxidized and almost completely removed.[30] The ratio of copper to zinc can be easily varied by this method, opening a way to nanocrystalline systems of CuO/ZnO in amorphous silica with a high overall specific surface area. Copper oxide can then be reduced to Cu, resulting in Cu/ZnO/$SiO_2$, i.e. the active methanol catalyst, preserving a high specific surface area which is advantageous for a high catalytic activity. This approach to co-precipitate the nanoparticles with a porous inorganic matrix is different from the often applied approach to fill an already existing porous template.

## Result and Discussion

Four samples with different ratios of CuO/ZnO (**A**: 0.76 wt.-% Cu; **B**: 4.37 wt.-% Cu; **C**: 15.6 wt.-% Cu; **D**: 34.4 wt.-% Cu) were prepared by a combination of sol-gel synthesis and photochemical oxidation and compared to a sample of pure ZnO (**Z**), prepared by the same method.[30] The coating with silane prevented crystal growth and agglomeration of the primary oxides. The subsequent photochemical treatment almost completely destroyed the organic fragments of the silane and led to the formation of X-ray amorphous silica ("$SiO_2$").

Scanning electron microscopy (SEM) showed an agglomerated material with particle sizes of a few hundred nano-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metres (Figure 1). The "coating layer" probably results from amorphous silica which remains after the photochemical oxidation. The high specific surface area from BET experiments (Table 1) indicates a high internal porosity that we tentatively attribute to the silica. X-ray powder diffraction shows broad diffraction peaks for ZnO and CuO, confirming the nanocrystallinity of the primary particles (Figure 2). A semi-quantitative determination of the crystallite size for ZnO by the Scherrer equation[33] results in 6–7 nm. It was not possible to determine the size of the CuO particles due to peak overlap, but a visual examination of the peak in Figure 2 suggests a crystallite size of the same order. Temperature-programmed reduction (TPR) gave the amount of CuO (Figure 3), followed by the quantitative determination of the specific copper surface area with reactive frontal chromatography (RFC). All analytical results are comprised in Table 1. It should be noted that the content of zinc is in all cases lower than expected from the synthesis (Table 1). This means that copper preferentially precipitates during the synthesis.

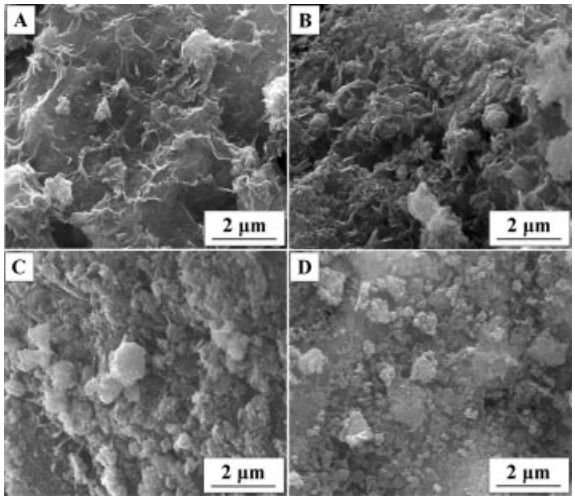

Figure 1. Scanning electron micrographs of the CuO/ZnO samples **A** to **D** (see Table 1). The samples consist of agglomerated particles with sizes of a few hundred nanometers (**A**: 0.76 wt.-% Cu; **B**: 4.37 wt.-% Cu; **C**: 15.6 wt.-% Cu; **D**: 34.4 wt.-% Cu). CuO and ZnO cannot be distinguished, i.e. they form an intimate mixture, together with X-ray amorphous $SiO_2$.

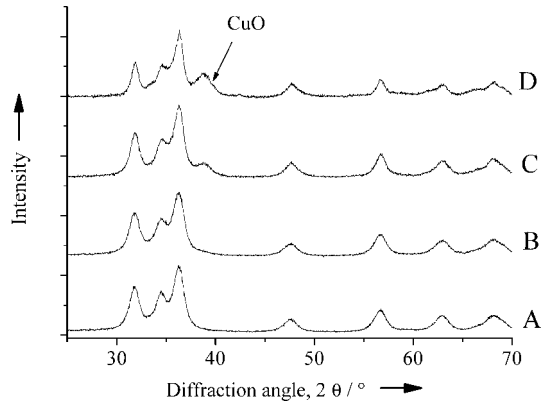

Figure 2. X-ray powder diffraction patterns of samples **A**, **B**, **C** and **D**. All reflections of the samples **A** and **B** belong to ZnO (zincite), except for the reflection at 38.9 °2$\Theta$ which belongs to CuO (tenorite). All patterns show strong peak broadening due to the small size of the primary nanoparticles (**A**: 0.76 wt.-% Cu; **B**: 4.37 wt.-% Cu; **C**: 15.6 wt.-% Cu; **D**: 34.4 wt.-% Cu).

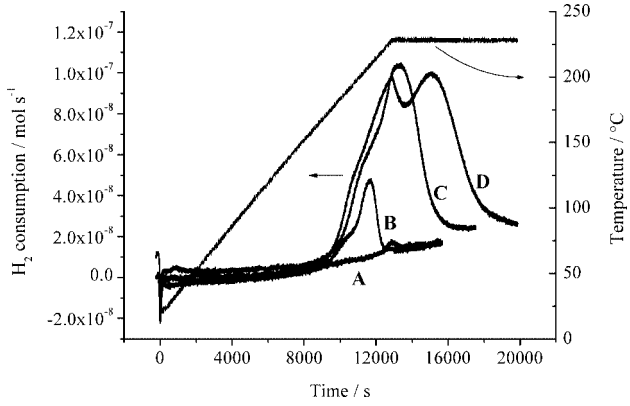

Figure 3. Reduction profiles of CuO to Cu obtained by heating under diluted hydrogen (TPR: temperature-programmed reduction; **A**: 0.76 wt.-% Cu; **B**: 4.37 wt.-% Cu; **C**: 15.6 wt.-% Cu; **D**: 34.4 wt.-% Cu).

The total specific surface area was determined by BET after drying for 2 h at 110 °C under air (Table 1). The BET surface areas were very high (higher than those of CuO/ZnO from co-precipitated carbonate precursors which are typically 40 $m^2 g^{-1}$ or less[31]). In addition, they are almost

Table 1. Chemical and morphological parameters and catalytic activity of all samples.

[a] By ICP. [b] By combustion elemental analysis. [c] The contents of zinc and copper were used to compute the amount of ZnO and CuO in the sample (stoichiometric factors 1.245 and 1.252, respectively). The sum of ZnO, ZnO, C and H was computed, and the difference to 100% was tentatively ascribed to $SiO_2$. [d] By application of the Scherrer equation;[33] the full-width at half maximum (FWHM) was typically 1.2–1.6° 2$\Theta$ for the (102), (110), and (103) peaks of ZnO with no differences among these peaks. [e] By BET. [f] By reactive frontal chromatography (RFC). [g] Compared to the activity of an ICI reference methanol catalyst, consisting of 64 wt.-% CuO, 24 wt.-% ZnO and 10 wt.-% $Al_2O_3$ (data from the manufacturer).

independent from the composition of the samples, suggesting that silica is mostly responsible for this high surface area. We conclude that the nature of the metal cation does not play a significant role for the micromorphology of the precatalyst, and we also conclude that most of the surface must be ascribed to internal pores, given the fact that the samples appear agglomerated and not nanoparticulate in SEM. The amorphous silicon dioxide which is left after photooxidation[30,32] is probably responsible for this effect, preventing the fusion of the oxide nanoparticles by formation of a porous coating layer. Note that the UV-photooxidation is not complete, as indicated by the residual content of carbon and hydrogen (Table 1) and also by weak characteristic C–H vibrations in IR spectroscopy (data not shown). In total, about 10–15 wt.-% of silica and carbon-containing residues together are present in the samples (see Table 1), both being X-ray amorphous (Figure 2).

This coating effect may explain the comparatively small specific copper surface area obtained by reactive frontal chromatography (RFC). Except for a very high content of copper, the copper surface area is small compared to the BET surface areas, unlike oxide mixtures from carbonate precursors.[31] We assume sintering of the copper particles due to the high reduction temperature (>200 °C) which caused a small specific surface area. Nevertheless, the catalytic activity of the samples is much higher than it would have been predicted from this small specific copper surface area.[12] The catalytic activity was compared to a ternary $CuO/ZnO/Al_2O_3$ benchmark catalyst (ICI Katalco 51-8) whose activity was set to 100%. This proves that the silica-embedded copper and zinc oxide particles are still well accessible by the synthesis gas. We speculate that the silica layer itself has a high internal pore surface which can be penetrated by the gaseous molecules, so it also serves as a kind of membrane on the catalytically active particles (ZnO and Cu).

We explain the mismatch between the low specific copper surface area and the good catalytic activity as follows: the specific copper surface area after TPR does not correspond to the copper surface area which is present in the active catalyst because of different reduction conditions. In TPR which is followed by RFC, CuO is reduced with diluted hydrogen (4.1% $H_2$ in Ar) at atmospheric pressure at 223 °C. Figure 3 shows that the reduction temperature is comparatively high, i.e. the copper oxide is not easily reduced (possibly not even fully, but mostly; see Table 1). In the catalytic test, the catalyst is reduced by a prescribed procedure for the commercial catalyst involving several steps, e.g. heating to 170 °C in 5% $H_2/N_2$, keeping it at that temperature for a certain period of time, then increasing the temperature and the concentration of $H_2$ and finally reaching 245 °C in pure $H_2$ under 25 bar pressure. Subsequently and prior to the measurement of the catalytic activity, the catalysts are equilibrated at the final operating pressure and gas composition mixture ($H_2/CO/CO_2$). Therefore, it is likely that there is a difference between the copper surface area measured by RFC and the copper surface area of the materials during catalytic testing (it is well known that dynamic effects are controlling the size and shape of the Cu crystals during reduction[4,7]). The fact that the content of copper found by TPR is about 20% smaller than the content of copper by elemental analysis may indicate an incomplete reduction due to a surface layer of impenetrable silica. However, this also indicates that most of the copper (about 80%) was reduced. The small specific copper surface area may be due to sintering of the crystals under the TPR conditions which does not occur upon reduction under higher pressure in the parallel reactor.

## Conclusions

$CuO/ZnO/SiO_2$ composites with high specific surface area and good catalytic activity in heterogeneous methanol synthesis can be prepared by a combination of sol-gel chemistry and photochemistry. The ratio of copper to zinc can be easily varied in the precipitation process. The primary nanoparticles of ZnO and CuO are covered by silica, but still accessible for gases as demonstrated by the high BET surface area (indicating pores in the silica) and the good catalytic activity. The catalytic activity increases with the content of copper oxide in the precatalyst. The X-ray amorphous silica prevents the fusion of the catalytically active CuO/ZnO nanoparticles and also serves as a membrane which can be penetrated by the gaseous reactants (CO, $CO_2$, $H_2$, $CH_3OH$).

## Experimental Section

**Sol-Gel Synthesis and Photochemical Oxidation:** In the first step, silane-coated CuO/ZnO was synthesized according to refs.[30,32]. 11.12 g (45 mmol) (3-methacryloxypropyl)trimethoxysilane was added to 333 g methanol at 55 °C in a 1-L round-bottomed flask. At 60 °C, zinc acetate dihydrate and copper acetate monohydrate were added (Table 2) and a solution of 50.3 g (0.89 mol) potassium hydroxide in 167 g methanol was added dropwise. The precipitate was filtered off and washed four times with methanol. After centrifugation of the gelatineous precipitate, the product was dried at 130 °C. In the second step, 1.5 g of the synthesized silane-coated CuO/ZnO were dispersed in 450 mL water and transferred into a water-cooled UV-lamp reactor. The suspension was irradiated with a 125-W mercury high-pressure lamp (HPK 125 W, Philips) for 60 min whilst stirring to destroy the organic parts of the silane while bubbling air through the dispersion. The material was then centrifuged (10 min, 2000 rpm) and dried at 150 °C for 24 h.

Table 2. Preparation conditions of all samples.

| Sample | *n*(zinc acetate dihydrate) /(mmol) | *n*(copper(II) acetate monohydrate) /(mmol) |
|---|---|---|
| **Z** | 448 | – |
| **A** | 448 | 5 |
| **B** | 448 | 23 |
| **C** | 405 | 45 |
| **D** | 336 | 123 |

**Solid-State Characterization Methods:** BET measurements were conducted with a Micromeritics instrument Flow Sorb II 2300. Ele-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mental analysis of copper and zinc were carried out with an inductively coupled plasma-optical emission spectrometer (ICP-OES) Varian VISTA MPX with a radial plasma. X-ray powder diffraction (XRD) was performed on a Siemens D 500 instrument with Cu-$K_\alpha$ radiation. Scanning electron microscopy was performed with a FEI ESEM Quanta 400 FEG instrument on gold-sputtered samples.

**Catalytic Performance:** Measurements were performed in a high-throughput 49-parallel channel reactor.[11] The samples (100 mg diluted with 200 mg quartz per well) were placed in a sample holder consisting of a stainless steel cartridge closed at the bottom by a stainless-steel sinter metal frit. Prior to the catalytic measurements the catalysts were reduced with a $H_2/N_2$ mixture at 518 K following the prescribed procedure for the commercial benchmark catalyst ICI Katalco 51-8 (see above). Before measuring the catalytic activity, all samples were equilibrated for 3 h (reaction pressure 4.5 MPa, reaction temperature 518 K, analytic flow 20 mL min$^{-1}$). The reaction gas consisted of 70% $H_2$, 24% CO, and 6% $CO_2$. A double GC system (HP GC 6890) equipped with a methanizer FID was used for online gas analysis. Oxo-product separation ($H_3COH$, $HCOOCH_3$, $H_3CCOOCH_3$, $H_3CCH_2OH$) was carried out on a SuppelcoWAX 0.53 mm column and CO, $CO_2$ and $CH_4$ were separated on a Carboxen 1006 column. Methanol productivities for all measured samples were compared to the productivity of the industrial benchmark catalyst ICI Katalco 51-8 ($P_{ICI}$ = 40 mol MeOH/($kg_{cat}$ h) at 518 K and 4.5 MPa).

**Temperature-Programmed Reduction (TPR) and Reactive Frontal Chromatography (RFC):** The set-up used for TPR and $N_2O$ RFC consisted of a gas supply unit, a specially designed reactor and furnace, and a gas analysis section. The gas supply unit was equipped with mass flow controllers and included gas lines for pure Ar, a 4.2% $H_2$/Ar gas mixture, and a 1.0% $N_2O$/Ar gas mixture. The reactor was made of two concentric quartz tubes of an optimized geometry with respect to back-mixing of gas and the axial temperature profile. The design of the reactor and the furnace followed the work of Monti and Baiker.[34] The temperature of the furnace was controlled by a programmable PID controller (Eurotherm 2416). The gas analysis section included a cooling trap (filled with isopropyl alcohol and dry ice) for water removal, a thermal conductivity detector (Hydros) to monitor the uptake of $H_2$, and an dispersive IR detector (Uras) to monitor the uptake of $N_2O$. The set-up was operated by a personal computer via a program based on the software package LabView.

The TPR experiments were carried out to determine the specific Cu content of samples and to reduce samples prior to $N_2O$ RFC. A 100 mg sample was heated from 303 K to 513 K (furnace temperature; sample temperature 500 K) with a heating rate of 2 K min$^{-1}$ and the final temperature was held for 1 h. The inlet concentration of $H_2$ was fixed to 4.2% and the total flow rate of the $H_2$/Ar gas mixture was set to 84 mL min$^{-1}$. The low values of the heating rate, the final temperature, and the inlet concentration of $H_2$ were chosen to minimize sintering of the copper particles due to heat released by the reduction process or too high temperature.

The determination of the specific Cu surface area by $N_2O$ RFC was carried out consecutively to the TPR experiment. After cooling to room temperature in the flowing $H_2$/Ar gas mixture, the reactor was flushed for 15 min with pure Ar (50 mL min$^{-1}$). After bypassing the reactor and the cooling trap the Uras IR detector was calibrated, first in pure Ar and then in a 1.0% $N_2O$/Ar gas mixture (10 mL min$^{-1}$). When the calibration was finished the reactor was set on-line and the uptake of $N_2O$ from the $N_2O$/Ar gas mixture (10 mL min$^{-1}$) was measured. The measurement was finished when no further uptake of $N_2O$ was detectable. This method is based on the decomposition of $N_2O$ on exposed Cu atoms accompanied by the formation of adsorbed atomic oxygen $O_{ads}$ and gas-phase $N_2$. For calculation of the exposed Cu surface area an average surface atom density of $1.47 \times 10^{19}$ Cu atoms m$^{-2}$ was used. The specific Cu surface area was obtained by dividing the exposed Cu surface area by the initial sample mass [35].

All gas volumes correspond to standard conditions at 0 °C and 1013 mbar.

## Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (DFG) within the scope of the Collaborative Research Center SFB 558: Metal-substrate interactions in heterogeneous catalysis. We also acknowledge the support of the experimental section of Grillo-Werke AG, Duisburg. We are grateful to Prof. F. Schüth, Mülheim/Ruhr, for helpful discussions.

# Complexation of Molybdenum(VI) with Bis(3-hydroxy-4-pyridinone)amino Acid Derivatives

M. Amélia Santos,*[a] Sofia Gama,[a] João Costa Pessoa,[a] M. Conceição Oliveira,[a] Imre Tóth,[b] and Etelka Farkas*[b]

**Keywords:** Molybdenum / Hydroxypyridinones / Hydroxypyridinonate complexes / Chelates

The molybdenum(VI) binding properties of a series of 3-hydroxy-2-methyl-4-pyridinones (3,4-HP), namely bis(3,4-HP) chelators, were investigated in solution and as solids; in particular, the complexation of $Mo^{VI}$ with iminobis{acetyl[1-(3′-aminopropyl)-3-hydroxy-2-methyl-4-pyridinone]}, IDAPr-(3,4-HP)$_2$, and ethylenediamino-*N*,*N*′-bis(methylcarboxyl)-*N*,*N*′-bis{acetyl[1-(3′-aminopropyl)-3-hydroxy-2-methyl-4-pyridinone]}, EDTAPr(3,4-HP)$_2$, as well as three model compounds: 1,2-dimethyl-3-hydroxy-4-pyridinone (DFP), iminodiacetic acid (IDA), and ethylenediaminodiacetic acid (EDDA). Solution studies show that the complexation occurs at low pH values by the coordination modes of the hydroxypyridinone moiety, and with the formation of bischelated $MoO_2^{2+}$ species. As the pH is increased, hydrolytic processes start with the formation of monochelated $MoO_3$ complexes and is followed by the total recovery of the free ligand, at pH > 8 for most of the systems, but at pH 10 for EDTAPr-(3,4-HP)$_2$. The obtained solid molybdenum complexes showed evidence for the presence of mononuclear species in solution, whereas the dinuclear species, $(MoO_2)_2$EDTAPr(3,4-HP)$_2$, were only detected for the EDTA derivative. Aqueous solution studies were performed by pH–potentiometry, spectrophotometry, $^1$H NMR and $^{17}$O NMR spectroscopy, and solid complex species were characterized by elemental analysis, IR spectroscopy, and ESI-MS.

## Introduction

3-Hydroxy-4-pyridinones (3,4-HP) are compounds of considerable biological interest because of their ability to form very stable complexes with several metal ions, in particular iron(III) and group 13 metal ions. They have been identified as the main candidates for medical application, either for the control of metal toxicity situations in the body (e.g. Fe[1–3] and Al[4–6]), or for clinical diagnosis (e.g. $^{67,68}$Ga, $^{111}$In).[7,8] In particular, the commercially available deferiprone (2-methyl-3-hydroxy-4-pyridinone) has been used as an orally active chelating agent for the decorporation of iron from iron-overload disease situations.[2,3] As part of an ongoing project aimed at the development of new polydentate 3-hydroxy-4-pyridinone-based derivatives,[9,10] two tetradentate bis(3,4-HP)amino acid derivatives were recently obtained. They present well-balanced lipo–hydrophilic character and improvement on metal-chelating efficacy in solution and in vivo relative to the bidentate monoderivatives; thus, good perspectives of their potential clinical use in much lower doses, to minimize drug-induced toxicity, are envisaged.[11,12]

Molybdenum complexation with 3,4-HP-based ligands has emerged as an important research target. In fact, molybdenum is of great biological relevance because of its role as the cofactor component in various redox enzymes,[13] as a determinant factor for siderophore production (e.g. secretion of azotochelin by *Azotobacter vinelandii*),[14] and also as an insulin mimetic for the prevention or amelioration of cardiac dysfunction in diabetic hearts.[15] However, research on molybdenum(VI) complexation with 3,4-HP-based ligands is quite scarce and is limited to solid-state studies with monochelators,[14–16] which is in contrast to Mo complexation with other O,O-donor ligands (e.g. hydroxamate and cathecholate siderophore analogues, for which solution studies are known[14,17,18]). Furthermore, the bis(3,4-HP) ligands are expected to form stable 1:1 complexes, and so they are better suited for optimal complexation with the $MoO_2^{2+}$ unit (with four available coordination sites) than the corresponding monoderivatives.[15,16,19] Thus, we present herein a molybdenum(VI) complexation study with two bis(3,4-HP)amino acid derivatives recently reported.[11,12] These polydentate compounds have two 3,4-HP binding groups attached to linear hydrophilic amino–carboxylic backbones (see Scheme 1), namely iminodiacetic acid (IDA) and ethylenodiaminotetraacetic acid (EDTA),

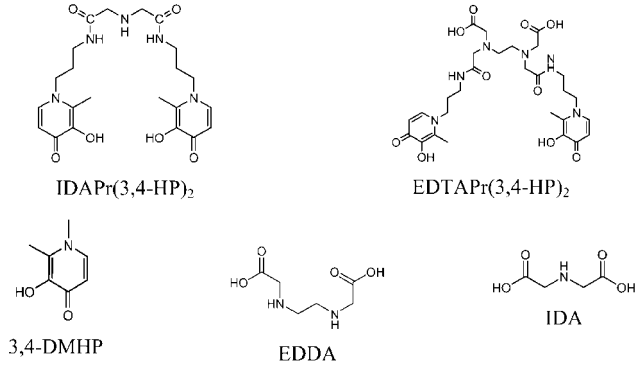
to give iminobis{acetyl[1-(3′-aminopropyl)-3-hydroxy-2-methyl-4-pyridinone]}, IDAPr(3,4-HP)$_2$, and ethylenediamino-*N*,*N*′-bis(methylcarboxyl)-*N*,*N*′-bis{acetyl[1-(3′-aminopropyl)-3-hydroxy-2-methyl-4-pyridinone]}, EDTAPr(3,4-HP)$_2$, respectively. To aid in the rationalization of the results, analogous studies are also carried out for some model compounds, namely 1,2-dimethyl-3-hydroxy-4-pyridinone (3,4-DMHP or DFP), iminodiacetic acid (IDA), and ethylenediaminodiacetic acid (EDDA). The aqueous solution study involves potentiometric and spectroscopic techniques (UV/Vis, $^1$H and $^{17}$O NMR) to evaluate the chelating affinity and the coordination modes. Several solid complexes are also characterized by elemental analysis, IR spectroscopy, and ESI-MS.



Scheme 1.

## Results and Discussion

Before starting the analysis and discussion of the results, some peculiar properties of the hydrolytic species associated with the $Mo^{VI}$-containing systems should be noted. In aqueous solution, numerous molybdenum species are present, whereas the free metal ion does not exist. As usual, $MoO_4^{2-}$ is chosen as the metal component (M) in the calculations. In aqueous solution above pH 7, $MoO_4^{2-}$ predominates, whereas below pH 7 some mononuclear species can exist but polyoxomolybdates are the main species. The equilibrium model determined previously under the conditions used in the present investigation, and the calculated overall stability constants ($\log\beta$) are summarized in Table S1. All these hydrolytic species were included in the equilibrium models to assess the complex species associated to the molybdenum(VI) ligand systems because there is always competition between the hydrolytic processes and the complex formation reactions with molybdenum(VI).[20]

One of the main objectives of this work is to study the molybdenum-binding capabilities of a set of bis(hydroxypyridinone) chelators with the IDA and EDTA backbones, namely in comparison with mono(hydroxypyridinone) derivatives. Therefore, for the rationalization of the complexation results, the interaction of $MoO_4^{2-}$ with mono(3-hydroxy-4-pyridinone), 3,4-DMHP, as well as with some parent compounds (EDDA and IDA) was also studied. The results are also compared with those previously obtained for mono- and bis(hydroxamate) ligands which proved to form very stable complexes with $Mo^{VI}$.[21]

### Mono(3-hydroxy-4-pyridinone): 3,4-DMHP

The protonation constants of 1,2-dimethyl-3-hydroxy-4-pyridinone (3,4-DMHP, Table 1) were calculated by best-fit analysis of the pH–potentiometric curve. As expected, two protons can react with the anionic form of a 3,4-DMHP molecule, and the corresponding $\log K_i$ constants are assigned to the protonation of the enolate group (9.74) and the pyridine N atom (3.66). These are in close agreement with the values previously reported (9.77 and 3.68, respectively).[22]

Table 1. Stepwise protonation constants ($\log K_i$) of the ligands 3,4-DMHP, IDAPr(3,4-HP)$_2$, EDTAPr(3,4-HP)$_2$, EDDA, and IDA, and global stability constants ($\log\beta$) for the corresponding molybdenum(VI) complex species ($I$ = 0.2 M KCl, $T$ = 25 °C).

Under the analytical concentration conditions usually used in the pH–potentiometric measurements for the complexation studies, there was some precipitation of the $Mo^{VI}$–3,4-DMHP complexes and this is indicated by the dashed lines in the pH–metric titration curves (Figure 1). Therefore, pH–metric experimental data was not used to calculate the equilibrium constants for any of the $Mo^{VI}$–3,4-DMHP complexes formed in solution. However, as complexes containing the dioxomolybdenum core usually have intense UV bands with $\lambda_{max}$ at ca. 290 nm (molar absorptivity ca. 2500 $M^{-1}cm^{-1}$),[16,20] this system could be studied by spectrophotometry. In this UV region, there are no measurable bands for the polyoxomolybdates and molybdate itself,[20] but for the ligand. Therefore, the spectral parameters (molar absorptivities, $\lambda_{max}$ values) of the pro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tonated and nonprotonated forms of 3,4-DMHP need to be independently determined. Figure 2a shows spectra recorded at several pH values for 3,4-DMHP. The individually calculated spectra (molar absorptivity versus $\lambda_{max}$) for $H_2L^+$, HL, and $L^-$ are presented in the inset of this figure. The high molar absorptivities allowed the use of quite low analytical concentrations (ca. $10^{-5}$ M) during the UV spectroscopic measurements and so, under these conditions, precipitation did not occur in the solutions containing $Mo^{VI}$ and 3,4-DMHP. Representative spectra recorded for this system at various pH values are shown in Figure 2b. Comparison of Figure 2a and Figure 2b shows significant differences between the spectra obtained, namely in the acidic solutions.

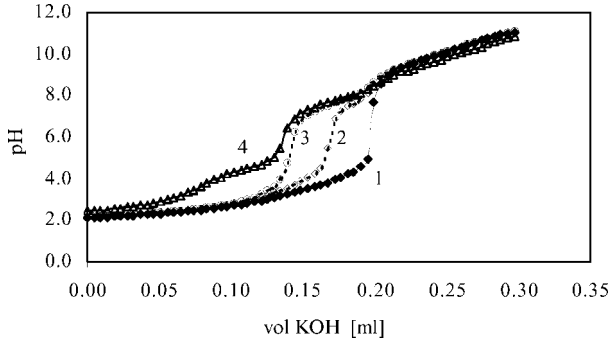

Figure 1. Potentiometric titration curves of aqueous solutions containing $Mo^{VI}$ and 3,4-DMHP. Symbols ♦ and △ represent titration points where no precipitation occurred. 1: $C_L = 4.647 \times 10^{-3}$ M; 2: $C_L = 4.650 \times 10^{-3}$ M, $C_M = 4.633 \times 10^{-3}$ M; 3: $C_L = 4.647 \times 10^{-3}$ M, $C_M = 2.315 \times 10^{-3}$ M; 4: $C_L = 1.164 \times 10^{-3}$ M, $C_M = 4.658 \times 10^{-3}$ M.

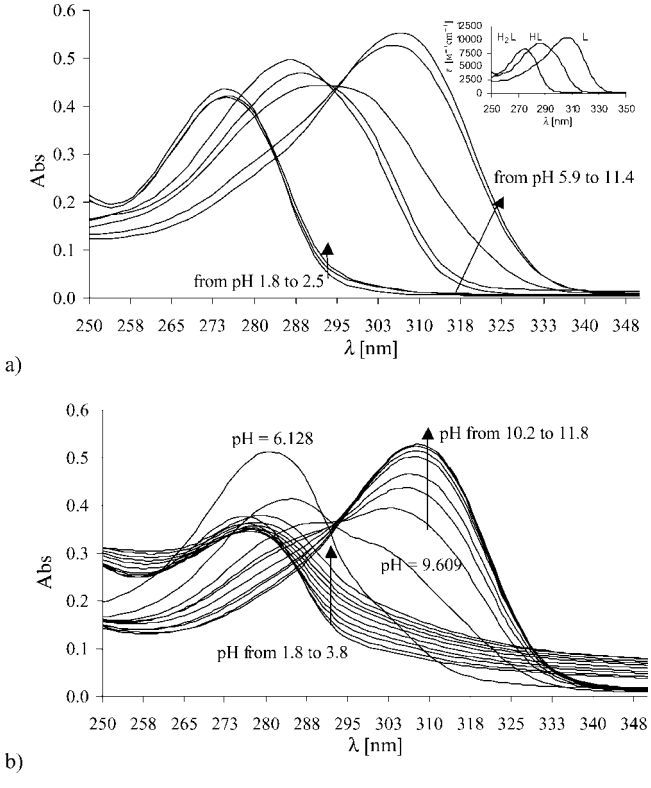

Figure 2. UV spectra for aqueous solutions containing: a) 3,4-DMHP, $C_L = 5.297 \times 10^{-5}$ M; b) $Mo^{VI}$ and 3,4-DMHP, at indicated pH values, $C_L = 4.946 \times 10^{-5}$ M, $C_M = 2.468 \times 10^{-5}$ M. ($I = 0.2$ M (KCl), $T = 25.0$ °C). The inset in a) represents individually calculated spectra for the $H_2L^+$, HL, and $L^-$ forms of the ligand.

The calculated ligand absorptivity was included in the input files of the PSEQUAD program,[23] together with the set of spectrophotometric data for the ligand in the presence of molybdenum, to fit the spectra obtained for the $Mo^{VI}$–3,4-DMHP system. The best fit was obtained with the equilibrium model and the stability constants shown in Table 1.

According to the results, within the experimental concentration range, the complexation of $Mo^{VI}$ with 3,4-DMHP involves the formation of the mono- and bischelated complexes. The stability constants obtained are presented in Table 1, and they correspond to the equilibrium processes in Equations (1) and (2).

$$MoO_4^{2-} + 2\,L^- + 4H^+ \rightleftarrows [MoO_2(L)_2] + 2\,H_2O \quad (1)$$

$$MoO_4^{2-} + 2\,L^- + 2H^+ \rightleftarrows [MoO_3(L)]^- + H_2O \quad (2)$$

Analysis of the concentration distribution curves (Figure 3a) show that if the ligand-to-metal ion concentration ratio is at least 2:1, even at very low analytical concentrations ($C_{Mo} = 2.468 \times 10^{-5}$ M), the bischelated species $[MoO_2(L)_2]$ predominates below ca. pH 4. This complex starts do decompose above ca. pH 4 by formation of the monochelated species $[MoO_3(L)]^-$. Above ca. pH 8, there is no $Mo^{VI}$–3,4-DMHP complex in solution.

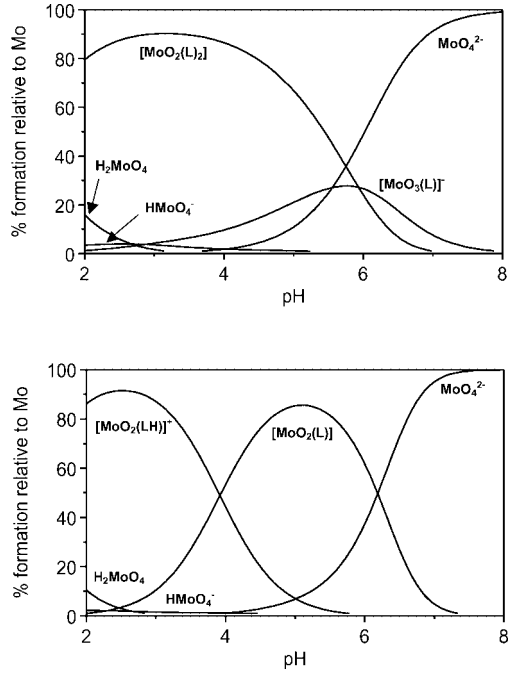

Figure 3. Concentration distribution curves of aqueous solutions containing $Mo^{VI}$ and a) 3,4-DMHP at 2:1 ligand-to-metal molar ratio and $C_M = 2.47 \times 10^{-5}$ M; b) IDAPr(3,4-HP) at 1:1 ligand-to-metal molar ratio and $C_M = 3.52 \times 10^{-3}$ M.

Similar results were previously obtained for the complexation of $Mo^{VI}$ with hydroxamate-based ligands in aqueous solution, where the bischelated complexes, $MoO_2$–(hydrox-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

amate)$_2$, predominate in acidic solution (generally below pH 3), but decompose through the formation of a trioxomolybdenum-containing monohydroxamate species, $MoO_3$–hydroxamate, at ca. pH 8.[21]

### Bis(3-hydroxy-4-pyridinone)s: IDAPr(3,4-HP)$_2$ and EDTAPr(3,4-HP)$_2$

There are three main objectives directed at the design of these bis(hydroxypyridinone)s:[11,12] (1) the improvement of the metal-binding capability, which is higher for the multichelators than the corresponding monochelators, at least in the dilute conditions that prevail under physiological conditions, (2) the reinforcement of the hydrophilic character of the ligand–metal complexes, (3) the capacity for further backbone extra-functionalization for biological interactions or pharmacokinetic modifications. Therefore, two chelating moieties are appended to hydrophilic polyaminocarboxylic acid scaffolds, IDA and EDTA. The chain size of the propylene linker was considered to be long enough to allow the wrapping of the metal moiety by the hydroxypyridinone chelating units without interference of the amino acid backbone, which could be used for further biological interactions.

### $Mo^{VI}$–IDAPr(3,4-HP)$_2$ System

The fully protonated form of this ligand involves five dissociable protons. Although only the protonation macroconstants were determined, chemical evidence and $^1$H NMR spectra recorded at different pH values indicate that the two pyridine N atoms are the less basic amino groups, whereas the hydroxy groups present the highest basicity. The imino N atom is much less basic in this molecule ($\log K$ = 5.34) than it is in the parent molecule, IDA ($\log K$ = 9.34[25]), which may be attributed to the amidation of the neighbor carboxylic groups. In spite of the quite hydrophilic nature of the IDA-based backbone of the molecule, the $Mo^{VI}$ complexes with IDAPr(3,4-HP)$_2$ are not water-soluble under the usual concentrations used for pH–metric measurements. Therefore, as spectrophotometry allows the use of much lower analytical concentrations, as in the case of the $Mo^{VI}$–(3,4-DMHP) system, this method was used to determine the stoichiometry and stability constants of the $Mo^{VI}$–IDAPr(3,4-HP)$_2$ complexes. Comparison between the spectra obtained for the free ligand (Figure S1a) and the molybdenum-containing systems (Figure S1b) in the acidic pH range shows significant differences, which can be used to establish the equilibrium model and to determine the corresponding stability constants, as well as the concentration distribution curves (Figure 3b).

For the solution containing $Mo^{VI}$ and IDAPr(3,4-HP)$_2$, the spectrum obtained at pH 9.10 corresponds to the spectrum of the free ligand (cf. Figure S1a and S1b). In the pH range 6 to 9, the spectra could not be recorded because of the absence of any buffer capacity of the solutions. By fitting all the spectra recorded in the pH range 1.7 to 5.5, the equilibrium model and overall stability constants shown in Table 1 were determined. According to this equilibrium model, two $Mo^{VI}$ complexes are formed in the acidic pH range, which corresponds to the equilibrium processes represented by Equations (3) and (4):

$$MoO_4^{2-} + L^{2-} + 5H^+ \rightleftarrows [MoO_2(LH)]^+ + 2\ H_2O \quad (3)$$

$$MoO_4^{2-} + L^{2-} + 4H^+ \rightleftarrows [MoO_2(L)] + 2H_2O \quad (4)$$

For the species $[MoO_2(LH)]^+$, both hydroxypyridinonate moieties of a single molecule are most probably coordinated to the same dioxomolybdenum core, and the imino N atom is protonated. In $[MoO_2(L)]$, this proton is released. Comparison of the $\log\beta$ values obtained for this ligand with those of the monohydroxypyridinone, and the observed decrease in the imino N basicity upon coordination with the metal ion, agree with the proposed equilibrium model and binding mode. However, it should be emphasized that it is not possible to differentiate between processes depicted in Equations (4) and (5) as both have the same pH effect.

$$MoO_4^{2-} + L^{2-} + 4H^+ \rightleftarrows [MoO_3(LH_2)] + 2H_2O \quad (5)$$

To obtain further support for this equilibrium model, $^1$H NMR titrations were carried out for ligand solutions in the absence, and in the presence of $Mo^{VI}$, to support the identification of the different species in solution as well as their pH dependence. Because the metal coordination involves the hydroxypyridinone oxygen atoms, the peaks associated with the pyridinic protons (5-H and 6-H of the hydroxypyridinone ring) are the most informative ones. Therefore, for the $^1$H NMR titration curves those chemical shifts were registered as a function of pD* (Figure S2). Analysis of these $^1$H NMR titration curves shows that in the range ca. pH 2 to 4 only one complex species is formed, which corresponds to the bischelated species. Above pH 4 a new species is detected, with a deshielding effect on those protons, whereas the free ligand also starts to be formed. The observation of this second complex species agrees with the hypothetical formation of the monochelated trioxo species. The decomposition of the complex is completed between pH 6 and 8. Thus, the profiles of these $^1$H NMR titration curves support the model involving the three species suggested by the spectrophotometric results.

### $Mo^{VI}$–EDTAPr(3,4-HP)$_2$ System

In its fully protonated form, EDTAPr(3,4-HP)$_2$ has eight dissociable protons. According to our results, two of them are released below the measurable pH region. Because the protonation microconstants were not evaluated, we cannot discuss much about the acid–base properties of the individual groups. However, on the basis of chemical evidence,[12,14] it is possible to conclude that the two hydroxy groups are the most basic groups, and that the value $\log K$ = 7.04 should be mostly attributed to the deprotonation of one of the ethylenediamine N atoms.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The EDTA derivative has two hydroxypyridinonate arms, as with IDAPr(3,4-HP)$_2$, but it also contains an EDDA moiety that may offer an alternative coordination mode (at least theoretically) for several metal ions. To compare the molybdenum(VI) binding ability of the two "multichelating parts" of the EDTAPr(3,4-HP)$_2$ molecule, studies of the Mo$^{VI}$–ethylenediaminodiacetic acid (EDDA) system were also carried out, and calculations were made for the hypothetical ternary system Mo$^{VI}$ –EDDA–(3,4-DMHP).

The potentiometric titrations of the Mo$^{VI}$–EDDA system were carried out without precipitation problems (some titration curves are included in the Supporting Information, Figure S3). These titration curves could be fitted well with an equilibrium model including the species $[MoO_2(L)]$, $[MoO_3(LH)]^-$, and $[MoO_3(L)]^{2-}$, whose stability constants are shown in Table 1. The concentration distribution curves calculated for the Mo$^{VI}$–EDDA complex species (Figure S4), under the concentration conditions used herein, indicate that an ethylenediaminodiacetate ligand cannot effectively compete with the Mo$^{VI}$ hydrolytic processes. At 1:1 metal-to-ligand molar ratio and at an analytical concentration of ca. $4\times10^{-5}$ M of the components, the maximum relative amount of the metal complex found is 20% at pH ca. 2. By increasing the pH, the Mo$^{VI}$ hydrolytic species becomes more and more dominant.

Therefore, the results obtained for the Mo$^{VI}$–EDDA system indicate that, for EDTAPr(3,4-HP)$_2$, only the hydroxypyridinonate arms are the effective binding sites for Mo$^{VI}$. The preference of the hydroxypyridinone over the EDDA coordination mode can also be clearly illustrated by the concentration distribution curves calculated for the hypothetical ternary system Mo$^{VI}$–EDDA–(3,4-DMHP) at 1:1:2 molar ratio (Figure S5). According to this speciation curves, the percentage of Mo$^{VI}$–EDDA complexes formed do not exceed 5–6% of total Mo$^{VI}$. Consequently, if there is no excess of the metal in solution, we expect simple hydroxypyridinonate-type coordination of EDTAPr(3,4-HP)$_2$ towards Mo$^{VI}$. Because the formation of dinuclear species can be expected under conditions where excess metal is present, some studies were also performed at a ligand-to-metal ion molar ratio of 1:2.

As the solubility of the complexes formed in the Mo$^{VI}$–EDTAPr(3,4-HP)$_2$ system are slightly higher than those with the former hydroxypyridinonate derivatives, it was possible to titrate some samples without precipitation (see titration curves in Figure 4).

Besides the pH–potentiometric titrations, spectrophotometric measurements were also performed, and the spectra of the free ligand and the Mo$^{VI}$–ligand system were recorded at several pH values. (Figure S6).

The best-fit for both the pH–potentiometric and spectrophotometric data was obtained with the equilibrium model and the stability constants shown in Table 1. The corresponding concentration distribution curves are shown in Figure 5.

By taking also into account the results obtained for the model ligands, EDDA and 3,4-DMHP, the following assumptions can be made regarding the equilibrium processes

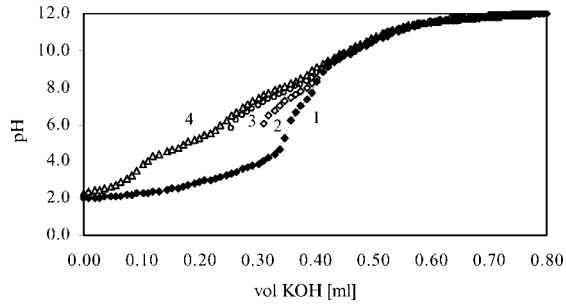

Figure 4. Potentiometric titration curves of aqueous solutions containing Mo$^{VI}$ and EDTAPr(3,4-HP)$_2$: 1: $C_L = 3.523\times10^{-3}$ M; 2: $C_L = 3.451\times10^{-3}$ M, $C_M = 1.654\times10^{-3}$ M; 3: $C_L = 3.523\times10^{-3}$ M, $C_M = 3.355\times10^{-3}$ M; 4: $C_L = 2.864\times10^{-3}$ M, $C_M = 5.732\times10^{-3}$ M.

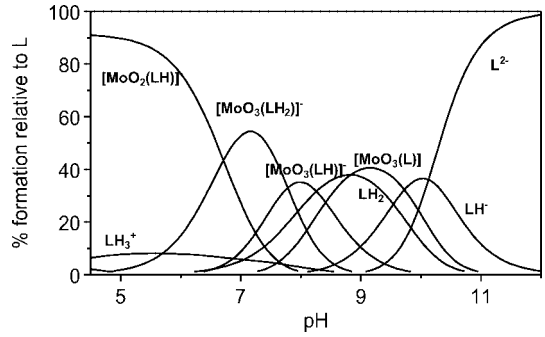

Figure 5. Concentration distribution curves for the complexes formed in Mo$^{VI}$–EDTAPr(3,4-HP)$_2$ system for solutions containing $C_L = 9.175\times10^{-3}$ M and $C_M = 8.39\times10^{-3}$ M.

and the possible bonding modes of EDTAPr(3,4-HP)$_2$: in the acidic pH range, the complex species $[MoO_2(LH)]^-$ predominates, in which the coordination of the two hydroxypyridinone moieties to the dioxomolybdenum core is the most plausible, while one of the ethylenediamine N atoms remains protonated. The corresponding equilibrium constant in Table 1 corresponds to the process shown in Equation (6):

$$MoO_4^{2-} + L^{2-} + 5H^+ \rightleftarrows [MoO_2(LH)]^- + 2H_2O \quad (6)$$

As the pH is increased, two types of processes can occur: (1) $[MoO_2(L)]^{2-}$ can be formed by the deprotonation of the noncoordinating ethylenediamine N atom,

$$[MoO_2(LH)]^- \rightleftarrows [MoO_2(L)]^{2-} + H^+ \quad (7a)$$

the calculated stability constant corresponding to Equation (7):

$$(MoO_4^{2-} + L^{2-} + 4H^+ \rightleftarrows [MoO_2(L)]^{2-} + 2H_2O) \quad (7)$$

(2) Partial hydrolysis of the complex may occur through formation of a monochelated complex with a trioxomolybdenum core, which has the noncoordinating amino and hydroxy groups in the protonated form.

$$[MoO_2(LH)]^- + H_2O \rightleftarrows [MoO_3(LH_2)]^- + H^+ \quad (8a)$$

In such a hypothesis, the stability constant in Table 1 would correspond to Equation (8):

$$(MoO_4^{2-} + L^{2-} + 4H^+ \rightleftarrows [MoO_3(LH_2)]^- + H_2O) \quad (8)$$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As the formation of $[MoO_2(L)]^{2-}$ and $[MoO_3(LH_2)]^-$ via **8a** and **7a**, respectively, have the same pH effect, they cannot be distinguished by pH-potentiometry. However, analyzing the UV/Vis spectra, we concluded that the best fit of the spectra could be obtained if the latter species was involved in the model. At ca. pH 5.5, there is a change in the UV/Vis spectra, which indicates that free hydroxypyridinone groups start to be present in the system, thus supporting the formation of $MoO_3$-type complexes in which one of the hydroxypyridinone groups is not coordinated. Further increase in the pH leads to the stepwise deprotonation of the noncoordinated groups in $[MoO_3(LH_2)]^-$ (Equations 9a and 10a), with the final formation of the molybdate anion by the complete decomposition of the metal complexes [Equation (11)].

$$[MoO_3(LH_2)]^- \rightleftarrows [MoO_3(LH)]^{2-} + H^+ \quad (9a)$$

$$(MoO_4^{2-} + L^{2-} + 3H^+ \rightleftarrows [MoO_3(LH)]^- + H_2O) \quad (9)$$

$$[MoO_3(LH)]^{2-} \rightleftarrows [MoO_3(L)]^{3-} + H^+ \quad (10a)$$

$$(MoO_4^{2-} + L^{2-} + 2H^+ \rightleftarrows [MoO_3(L)]^{2-} + H_2O) \quad (10)$$

$$[MoO_3(LH)]^{2-} + H_2O \rightleftarrows MoO_4^{2-} + LH_2 + H^+ \quad (11)$$

Because these solution equilibriums are quite complex and different isomers may correspond to the same stoichiometry, $^1H$ NMR titrations were also carried out to obtain additional information. These studies were performed for solutions containing free ligand, $EDTAPr(3,4\text{-}HP)_2$, and the $Mo^{VI}$–$EDTAPr(3,4\text{-}HP)_2$ system, under experimental conditions as close as possible to those used in the potentiometric measurements. The set of results is depicted in Figure 6.

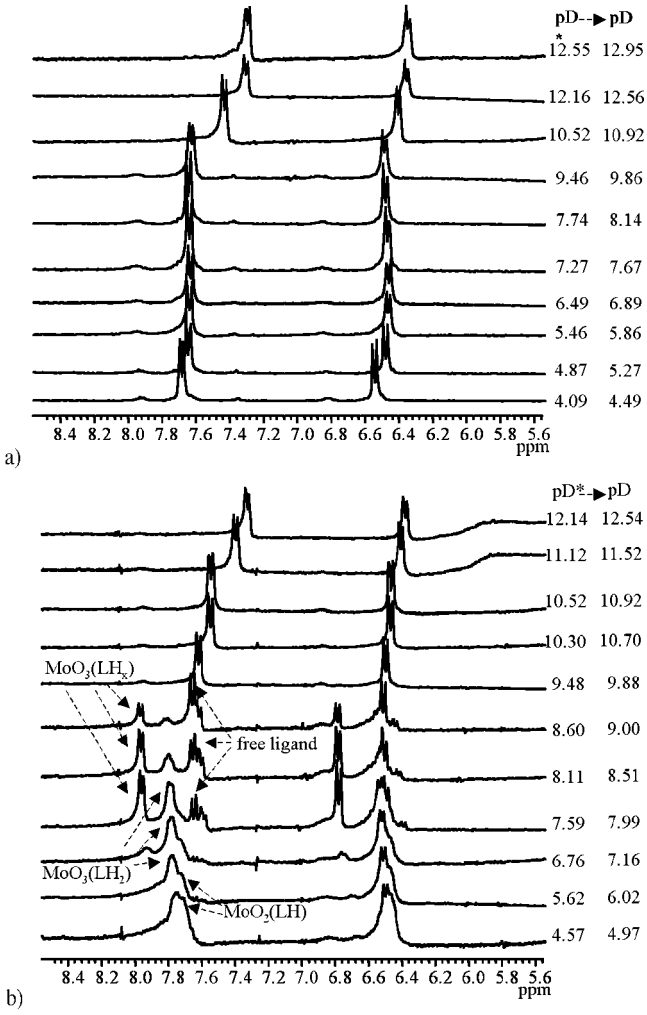

Figure 6. $^1H$ NMR spectra, at indicated pD* and pD, corresponding to the 5-H and 6-H peaks of the hydroxypyridinone ring of: a) solution containing the free ligand $EDTAPr(3,4\text{-}HP)_2$ $C_L = 8.73 \times 10^{-3}$ M; b) solution containing $Mo^{VI}$ and $EDTAPr(3,4\text{-}HP)_2$ with $C_L = 9.175 \times 10^{-3}$ M and $C_M = 8.39 \times 10^{-3}$ M.

Analysis of the $^1H$ NMR spectra obtained for the $Mo^{VI}$–$EDTAPr(3,4\text{-}HP)_2$ system and their comparison with the corresponding free ligand spectra led to the following conclusions: (1) at pH 4, there is only one complex species, (2) at pH ca. 5, another one starts to form, (3) at pH ca. 7, a third distinct complex species appears. These three species are completely hydrolyzed at pH > 9, with the formation of the free ligand. The ligand band is split between pH 6 and 9, thus indicating the existence of two types of "free ligand" hydroxypyridinone moieties in this pH range. One of them should correspond to a noncoordinated hydroxypyridinone and the other one to a species with only one of the noncoordinated arms.

With the use of the Mestre C program,[27] deconvolution of some spectra and a comparative analysis of the relative intensities of the individual peaks and their pH dependence with the species distribution curves enabled the peak attribution to the species present in solution. Table 2 includes the calculated relative percentages for each peak, and the assignment of the corresponding species. We can conclude that there is a good fit between the values obtained for the concentration distribution species on the basis of the deconvolution of the $^1H$ NMR spectroscopic signals and on the potentiometric results.

To aid in the rationalization of the present results, $^{17}O$ NMR spectroscopic studies were also performed because the chemical shifts present high-dependence on the number and type of oxo ligands bonded to the molybdenum cores. The chemical shift of $MoO_4^{2-}$ is ca. 532 ppm; *cis* $MoO_3$ appears at lower field (ca. 700 ppm) followed by the *cis* $MoO_2^{2+}$ core at ca. 900 ppm.[17,19] Therefore, to obtain further evidence for the proposed equilibrium model of the $Mo^{VI}$–$EDTAPr(3,4\text{-}HP)_2$ system in aqueous solution, two $^{17}O$ NMR titrations were carried out at 1:1 and 1:2 ligand-to-metal molar ratios. This is shown in Figure S7.

A distinct peak appears at $\delta$ = 532 ppm, which corresponds to $MoO_4^{2-}$; at ca. 680 ppm, the $MoO_3^-$ moiety can be identified between pH 7 and 9. However, it was not possible to observe any peak corresponding to the $MoO_2^{2+}$ core. This is probably due to precipitation and/or some fast chemical exchange between the oxygen atoms involved in the coordination, as a result of the intramolecular exchange between the different bonding isomers formed, which suppresses the $^{17}O$ NMR spectroscopic signal.

Table 2. Calculated speciation for the hydroxypyridinone-containing species, at indicated pD*, on the basis of the integration of the $^1$H NMR spectroscopic peaks corresponding to the 5-H and 6-H protons of the hydroxypyridinone ring. The values in parentheses represent the corresponding data obtained from the potentiometric results under the same conditions ($C_L = 9.175 \times 10^{-3}$ M, $C_{Mo}^{VI} = 8.39 \times 10^{-3}$ M).

| Peaks  | pD*=8.60 | pD*=8.11 | pD*=7.59 | pD*=6.76 | pD*=4.57 | Attributions |
|---|---|---|---|---|---|---|
| A | 45 (40) | 58 (55) | 57 (51) | 16 (13) | -- | $MoO_3LH_x$, $x$=0,1 |
| B | 5 (10) | 10 (4) | 18 (21) | 54 (55) | 0 (2) | $MoO_3LH_2$ |
| C | -- | -- | -- | 30 (20) | 100 (90) | $MoO_2LH$ |
| D | 50 (47) | 32 (37) | 25 (28) | 0 (12) | 0 (8) | Free ligand |

By taking into account the molecular structure of EDTAPr(3,4-HP)$_2$, formation of dinuclear species could be expected for solutions containing this ligand and excess of $Mo^{VI}$, with the metal centers coordinated either by the hydroxypyridinone groups or the "EDDA skeleton". However, from the experimental data obtained in aqueous solution, calculations with the PSEQUAD program[23] were not successful for all the equilibrium models in which those species were included. This means that, mathematically, it was not possible to obtain any log$\beta$ for the dimeric species, thus suggesting a low probability for the existence of dinuclear species in our solution conditions. Then again, if we consider the results obtained in the $^1$H NMR titration, and if the aliphatic part of the spectra is carefully compared (see Figure S8), there is evidence that, at high pH, the spectrum recorded for the ligand–$Mo^{VI}$ system is the same as that of the free ligand. At pH < 6, only the bands for the protons which feel the coordination of the hydroxypyridinonate chelate (1,6) show significant broadening. However, when the bischelated dioxomolybdenum species starts to decompose, and some monochelated trioxomolybdenum species starts to be formed, the hydroxypyridinonate arms become noncoordinated and different species are suggested by the spectra with the broadening and splitting of the aliphatic peaks. This means that, probably, there is a dynamic intramolecular exchange between the different binding isomers formed, and not a real exchange between the coordination of the hydroxypyridinone and the "EDDA skeleton".

## Solid State Studies

As mentioned above, for most of the systems precipitation occurred along the pH–metric titrations. Several of those solids were isolated by performing similar batch experiments, but with the use of higher concentrations of metal ion and ligand. The molybdenum solid complexes obtained were characterized by IR, elemental analysis, and ESI-MS experiments. Some relevant data of the IR results are included in Table 3. The selected IR data are representative of the differences between the free ligand and the complexes. Complex formation is confirmed by the emergence of two strong new bands characteristic of the Mo–O stretching vibrations ($\nu_{Mo=O}$, as strong peaks in the range 800–950 cm$^{-1}$).[28] Concerning the $MoO_2^{2+}$ core, its characteristic stretching bands, $\nu_{MoO_2}$ (symmetric) and $\nu_{MoO_2}$ (asymmetric), appear around 920 and 890 cm$^{-1}$, respectively.[29] For the $MoO_3$ unit, the characteristic bands normally appear around 890 and 840 cm$^{-1}$.[30] For the hydroxypyridinone derivatives there is also a characteristic infrared four-band spectral pattern between 1610 and 1400 cm$^{-1}$.[16,31,32] Those bands can be assigned to $\nu_{C=O}$ and $\nu_{ring}$ that are very difficult to differentiate. Upon coordination, this pattern is usually preserved, but a bathochromic shift and a reordering of the peaks can be observed. For the solid complexes obtained, comparison with the free ligand spectra shows that the four-band pattern remains with some change in the intensity of some of the peaks, and some small shifts to lower wavenumbers.

For the $Mo^{VI}$–(3,4-DMHP)$_2$ complex, elemental analysis fits the formulation as a monohydrated complex in which two 3,4-DMHP molecules are coordinated to one $MoO_2^{2+}$ unit [$MoO_2$(3,4-DMHP)$_2$·$H_2O$]. The IR spectrum shows a redshift of the four-band pattern corresponding to the hydroxypyridinone spectra, and two strong peaks are obtained at 919 and 892 $cm^{-1}$, which can be attributed to the two characteristic IR bands of the $MoO_2^{2+}$ unit.

Concerning the $Mo^{VI}$–IDAPr(3,4-HP)$_2$ solid complex isolated, an entirely different structure was obtained. From the elemental analysis of the yellow solid we can conclude that a complex with one ligand and three molybdenum atoms was formed: [$Mo_3O_8$(IDAPr(3,4-HP)$_2$)·3$H_2O$]. In the IR spectra of the complex, besides the bathochromic shifts of the $\nu_{C=O}$ and $\nu_{ring}$ bands, which indicate coordination through the hydroxypyridinone groups, and the two characteristic Mo–O bands at ca. 918 and 891 $cm^{-1}$, two new bands appear at 828 and 753 $cm^{-1}$ (see Table 3). By taking into account that the IR bands in the 735 to 850 $cm^{-1}$ range have been attributed to Mo–O–Mo stretching modes,[28,33–35] identical assignment can be assumed for [$Mo_3O_8$(IDAPr(3,4-HP)$_2$)·3$H_2O$]. Furthermore, on the basis of molecular structures reported in the literature for other molybdenum complexes, such as $Na_4$[$Mo_6O_8$(EDTA)$_3$·14$H_2O$],[36] [$Mo_3Cu_2O_{10}$(pz)]$_n$[28] with pz = pyrazine, and [{$MoO_2$(MCM(3,4-HP))O}$_2$]$^{2-}$[34] with MCM(3,2-HP) = 1-[(methoxycarbonyl)methyl]-3-hydroxy-2-pyridinone, we suggest that for [$Mo_3O_8$(IDAPr(3,4-HP)$_2$)·3$H_2O$], a structure with three $Mo^{VI}$ atoms bonded by oxygen bridges, that is a $\mu_3$-oxo-trismolybdenum(VI) complex exists. However, because no suitable crystals were obtained for X-ray diffraction studies, such an assumption cannot be confirmed.

From solutions containing $Mo^{VI}$ and EDTAPr(3,4-HP)$_2$, a yellow solid complex was obtained at acidic pH. Its elemental analysis indicates a dinuclear structure in which two $MoO_2^{2+}$ units are coordinated by one ligand molecule: [$(MoO_2)_2$(EDTAPr(3,4-HP)$_2$)·7$H_2O$]. The IR spectra of the solid compound showed bands at 940 and 899 $cm^{-1}$ (Table 3), which are characteristic of the $\nu_{Mo-O}$ in the $MoO_2^{2+}$ core.

Some of the solids obtained (dissolved in water) and their mother solutions were also analyzed by ESI-MS. Some ESI mass spectra were obtained from the solutions of "batch" samples of the $Mo^{VI}$–IDAPr(3,4-HP)$_2$ system, at different pH conditions. One of the spectra (see Figure S9a) contains an intense peak at *m*/*z* = 590, ascribed to the monoprotonated neutral complex {[$(MoO_2)$(L–2 H)] + H}$^+$, in which L is IDAPr(3,4-HP)$_2$, having the hydroxy groups deprotonated and coordinated to one $MoO_2^{2+}$ unit. The other spectrum (Figure S9b) shows two peaks at *m*/*z* = 484 and 612, which correspond to the ions [L + Na]$^+$ and {[$(MoO_2)$(L–2 H)] + Na}$^+$, respectively.

The mass spectrum obtained for the solutions containing $Mo^{VI}$ and EDTAPr(3,4-HP)$_2$ (Figure S10a) presents three intense peaks at *m*/*z* = 787, 825, and 863, attributed to the ions {[$(MoO_2)$(L–2 H)] + K}$^+$, {[$(MoO_2)$(L–2 H) – H] + 2 K}$^+$, and {[$(MoO_2)$(L–2 H) – 2H] + 3 K}$^+$, respectively. Also in this case, [$(MoO_2)$(L–2 H)], in which L is EDTAPr(3,4-HP)$_2$, represents the neutral complex with the two hydroxypyridinone moieties deprotonated and coordinated to the $MoO_2^{2+}$ core, but with the two carboxylic groups protonated. Therefore, the first species is just the neutral complex charged by a potassium cation. As the relative amount of $K^+$ increases with the addition of KOH to the solutions, the carboxylic groups deprotonate and the proton is substituted by K cations.

Although in the solution-phase molybdenum complexation studies with EDTAPr(3,4-HP)$_2$, dinuclear species were not found, ESI-MS data obtained for the solid material and the corresponding mother solution are in agreement with the elemental analysis results obtained for the solids. The peak at *m*/*z* = 873 presented in the spectrum of this solid (Figure S10b) is assigned to the complex ion {[$(MoO_2)_2$(L–4 H)] + H}$^+$, a dinuclear species $C_{28}H_{37}Mo_2N_6O_{14}^+$. The more intense peak at *m*/*z* = 947 corresponds to the water adduct of the cationic dinuclear complex, {[$(MoO_2)_2$(L–4 H)] + K, 2·$H_2O$}$^+$. The relative intensities of the isotopic peaks of the molybdenum-containing species agree, within experimental error, with the characteristic patterns resulting from two molybdenum atoms, which provide further support for the above assignments. [$(MoO_2)_2$(L–4 H)] represents the neutral complex with one $MoO_2^{2+}$ core coordinated by the two deprotonated hydroxypyridinone groups, and another one coordinated by the "EDDA part", which involves both the deprotonated carboxylic groups of the ligand. The spectrum also shows a much less intense peak at *m*/*z* = 749 which corresponds to the protonated mononuclear species, {[$(MoO_2)$(L–2 H)] + H}$^+$, with the relative intensities of the isotopic peaks characteristic for one molybdenum unit. The additional peak at *m*/*z* = 805 is attributed to the water adduct of the mononuclear cationic species {[$(MoO_2)$(L–2 H)] + K, $H_2O$}$^+$.

This set of results demonstrates that structure and/or stoichiometry of predominant species in diluted solutions may differ from those of precipitated solids or corresponding mother solutions. The difference observed between solution and solid-state studies can be attributed to the low water solubility of the complexes, thus rendering difficult their detection in solution, at least under dilute experimental conditions.

## Conclusions

Two bis(3-hydroxy-4-pyridinone) chelators, having IDA and EDTA backbones with two bearing 3-hydroxy-4-pyridinone chelating moieties, were shown to be able to form quite stable bischelated 1:1 $MoO_2$ complexes under acidic conditions. An increase in the pH of the solution to basic values leads to the stepwise hydrolysis of the complexes and subsequent formation of monochelate species and the free ligand. Although under dilute conditions only soluble mononuclear species with hydroxypyridinone coordination modes were found, increasing concentration conditions and excess amounts of metal lead to water-insoluble polynuclear

species. Moreover, it was shown that the ligand scaffold determines the tuning of some molybdenum complex properties, namely water solubility and stability to hydrolysis. As compared to the remaining mono- or bischelated systems, the $Mo^{VI}$–EDTAPr(3,4-HP)$_2$ system presents the most interesting behavior as a result of the EDTA scaffold. In fact, there are fewer water-insolubility problems associated with the complex, and under conditions where there is not an excess of metal, the coordination only involves the hydroxypyridinone moieties, which leaves the EDDA moiety free for further metal-ion coordination or extra-interaction with biological sites.

## Experimental Section

**General:** Unless otherwise indicated, analytical grade reagents were used as supplied. The IDAPr(3,4-HP)$_2$ and the EDTAPr(3,4-HP)$_2$ ligands were synthesized, purified and fully characterized as described previously.[11,12]

The aqueous molybdenum(VI) stock solution was prepared from the required amount of $Na_2MoO_4$ (Reanal product) dissolved in bidistilled water, and the exact metal-ion concentration was checked gravimetrically by precipitation of its quinolin-8-olate complex. The concentration of each ligand and HCl stock solutions were determined by pH–potentiometry using the Gran's method.[37] For the aqueous solution studies, a MOLSPIN pH-meter, a Methrom 6.0234.100 combined electrode, and a computer-controlled Mol-AcS microburette were used to carry out the potentiometric and also some of the spectrophotometric titrations, at 25.0 ± 0.1 °C and ionic strength of 0.2 M (KCl). The electrode calibrations were made according to the Irving method,[38] and the pH readings could therefore be converted into hydrogen ion concentration. The titrant used was a carbonate-free KOH solution (0.2 M) and its concentration was also determined by potentiometry using the Gran's method.[37] For all samples, the total volume was 3 mL, the ligand concentration was around $4 \times 10^{-3}$ M and the ligand-to-metal ion molar ratios between 1 and 4. Under the experimental conditions used, the value determined for the ionization constant ($pK_w$) was 13.76.

Spectral determinations were carried out with a HP 8453 spectrophotometer equipped with 1.0-cm-matched quartz cells at 25.0 ± 0.2 °C and $I$ = 0.2 M KCl. For solutions containing $Mo^{VI}$, the spectra were recorded in the range 200 to 350 nm by using 3.00 mL samples, ligand concentrations of ca. $5 \times 10^{-5}$ M and metal concentrations of $2.5–5.0 \times 10^{-5}$ M. The equilibrium models were established and the complex formation constants were calculated with the PSEQUAD computer program[23] by using the previously reported ($\log\beta$) values of the $Mo^{VI}$ hydrolytic species.[20]

A Varian Unity 300 instrument was used to perform the $^1$H NMR measurements. The titrations were performed at room temperature with ligand concentrations of $5–9 \times 10^{-5}$ M in $D_2O$ with DSS, sodium 3-(trimethylsilyl)-[2,2,3,3–$^2D_4$]propionate, as the internal reference. The direct reading of the $H_2O$ calibrated pH meter, here called pD*, was converted to pD values by using the expression pD = pD* + 0.4.[39]

For the $Mo^{VI}$–EDTAPr(3,4-HP)$_2$ system, $^{17}$O NMR spectroscopic measurements were carried out at 1:1 and 1:2 ligand-to-metal ion ratio with $C_M = 5.0 \times 10^{-2}$ M. The samples were prepared in 82% $H_2O$, 10% $D_2O$, and 8% $D_2O$ enriched for $^{17}$O (37.8% $^{17}$O and 48.8% $^{18}$O). The enrichment occurs in the Mo = O oxygen atoms and usually the ligand oxygen atoms are inert towards oxygen exchange. A Bruker AM 360 was used to record the spectra, and the chemical shifts are reported from the signal of the water which is considered as the internal reference, $\delta$ = 0 ppm.

The ESI mass spectra were obtained with a LCQ Duo (Finnigan, San Jose, CA, USA) ion trap mass spectrometer equipped with an electrospray ion source, operated in the positive mode. The spray voltage was kept at ±4.5 kV. The temperature of the heated capillary was set at 220 °C. The flow rate of the electrospray solution was 5 μL min$^{-1}$. Other parameters, including capillary voltage, lens and octapole voltages, and sheath gas flow rate were optimized for maximum abundance of the ions of interest.

The complex [$MoO_2$(3,4-DMHP)$_2$] was synthesized by a method similar to that described by Griffith,[29] by mixing an ammonium molybdate (5 mL, 230 mg, 1 mmol) aqueous solution with an equivalent amount of 3,4-DMHP (140 mg) previously dissolved in water (10 mL). The yellow solution was stirred for ca. 1 h at room temperature, and the precipitate was obtained, filtered, then washed with water, methanol, and ether, and dried in vacuo. A similar procedure was used for the ligands IDAPr(3,4-HP)$_2$ and EDTAPr(3,4-HP)$_2$, and the corresponding $Mo^{VI}$ complexes were obtained as yellow solids. [$MoO_2$(3,4-DMHP)$_2$.$H_2O$]: $C_{14}H_{18}MoN_2O_7$ (422.24): calcd. C 39.82, H 4.30, N 6.63; found C 39.8, H 4.1, N 6.8. [$Mo_3O_8$(IDAPr(3,4-HP)$_2$)·3$H_2O$]: $C_{22}H_{35}Mo_3N_5O_{17}$ (929.37): calcd. C 28.43, H 3.80, N 7.56, Mo 30.97; found C 28.2, H 3.9, N 7.7, Mo 31. [($MoO_2$)$_2$(EDTAPr(3,4-HP)$_2$)·7$H_2O$]: $C_{28}H_{50}Mo_2N_6O_{21}$ (998.60): calcd. C 33.68, H 5.05, N 8.42; found C 33.9, H 4.6, N 8.3.
