Abstract

Ab initio calculations have been performed using the 6-31G* basis set for different structures of water clusters (H₂O)_n, n = 1–10, 15. When increasing the number of water molecules, it appears that for n > 5, we observe a transition from planar to three-dimensional structures. All the different clusters present many stable geometries that are all very close in energy. To be sure that a minimum of the energy potential surface has been reached, vibrational frequencies for both (H₂O)_n and (D₂O)_n were calculated. When n increases, the O–O distance is always decreasing. From this study, we deduced that in the temperature range –10 to 100 °C, the most abundant clusters in liquid water at density 1 g/ml contain more than five water molecules.

1. Introduction

Although in the recent years, much information has been obtained on the nature of water clusters, the contribution of these clusters to the properties of liquid water may not have been developed to the fullest possible extent. The hydrophobic effect is a dominant force in biomolecular conformation and stability. For instance, in proteins nonpolar residues cannot participate in hydrogen-bonding interactions with bulk water (Lipscomp, Zhou, & Williams, 1996).

Despite the enormous amount of information now available, the mystery of the structure of water remains unsolved. In fact, different models have been proposed but they are either mutually or contradicting and complementary approaches. They are represented by using the continuum models (uniformist) and the mixture

models (cluster approaches). In the first description model, each water molecule is depicted as being surrounded in the same way by other molecules in distorted positions. In that case, the hydrogen bonding (Jeffrey, 1997) is supposed to be complete and thus water molecules are considered as a three-dimensional network of hydrogen-bonds that interconnect the water molecules in a dynamical process. The molecules have a continuous distribution of bond angles, as well as the associated hydrogen-bond network considering distances and angles, and bond energies. However, it should be pointed out that the continuum models are incompatible with some thermodynamic particular properties such as the compressibility minimum and the density maximum (Horne, 1972). In the second description model, liquid water is considered to be a mixture of a small number of distinctly different species that are in equilibrium. Most mixture models assume that water molecules exist in few classes of structural species that are more or less well defined. Then, numerous works have been published and correspond to different theoretical approaches (Chaplin, 1999; Dougherty & Howard, 1998; Frank & Wen, 1957; Hagler, Scheraga, & Nemethy, 1972; Jorgensen, Chandrasekhar, Madura, Impey, & Klein, 1983; Maheshwary, Patel, Sathya-murthy, Kulkarni, & Gadre, 2001; Nemethy & Scheraga,

In order to understand more about the hydrophobic effects in biomolecules, we decided to focus our attention in a first step on water molecules and clathrate hydrates. These latter water clusters provide a good model for describing the water molecules which are organized around the hydrophilic and hydrophobic aminoacid side chains in globular proteins and particularly for explaining the behavior of water towards nonpolar side groups.

The classical vibrational spectroscopy of liquid water has been reviewed by Scherer (Scherer, 1980). In this review, the first figure gives the scarcity of Raman spectral data for H₂O in the solid, liquid and near gaseous states. Different points are then discussed such as the OH-stretching bands (shift from above 3600 cm⁻¹ at high temperature and low density to below 3200 cm⁻¹ in the spectra of ice at low temperature) and the HOH-bending modes.

Thus, we have calculated the structures, geometries, and vibrational spectra (see Table 1) of water molecules increasing the number of molecules.

2. Material and methods

2.1. Quantum mechanical procedures

Using the program Gaussian'94 and then the '98 version (Frisch et al., 1994), with Hartree–Fock calculations at a 6-31G* level, we have calculated the energy minimized structures for (HOH)₁, (HOH)₂, (HOH)₃, (HOH)₄, (HOH)₅, (HOH)₆, (HOH)₇, (HOH)₈, (HOH)₉, (HOH)₁₀ and (HOH)₁₅ as well as their deuterated analogs.

Standard quantum chemistry yields a stable molecule. It is well known that within Hartree–Fock approximation, the computed water structure has an HOH angle slightly too wide relative to experimental data, but the correct value is easily obtained by correlating the electron's motions.

2.2. Normal coordinates of water

One of the major problem in simulations of water is that (i) by using ab initio calculations one simulates the gaseous state or a semi-liquid state, (ii) by using empirical methods the results are very sensitive to the used potential. A rigorous calculation of the normal coordinates of liquid water requires a detailed knowledge of the structure and of the intra- and intermolecular force constants for numerous hydrogen-bonding states. However, the corresponding force field for the liquid water remained not appropriate for efficient simulations and very difficult to be precisely derived. The usual

internal coordinates R_i of the water molecule may be defined as the two OH Δr₁ and Δr₂ stretching coordinates and the Δα valence angle bending coordinate. For empirical procedures, the force constants have been determined from fitting between harmonic and observed frequencies. It is well known (Scherer, 1980), that the totally symmetric OH stretch as has very little contribution from the bending coordinate. Similarly, the bending mode has little contribution to the stretching mode. However, these modes are very sensitive depending for instance upon environment and temperature.

3. Results and discussion

The classical vibrational spectroscopy of liquid water has been reviewed by Scherer (1980). Very precise calculations were done using a lot of quantum models (see in this series, the paper of Starzak and Mathlouthi, 2003). However, increasing the number of water molecules, (H₂O)_i+H₂O ↔ (H₂O)_{i+1}, even for few water molecules in the small water clusters, leads to clusters presenting many stable geometries that are all very close in energy. Thus, in these cases one has to face a difficult minimization problem. Moreover, it should be pointed out that the cluster study provides also very interesting geometrical arrangements of hydrogen bonded structures, leading to clathrate or to be precise in that case “clathrate-like” complexes. Similar behaviours obtained both from theoretical calculations (quantum mechanics and Monte-Carlo computations) and from experimental data obtained using far-infrared laser Vibration–Rotation Tunneling (VRT) spectroscopy were observed by Saykally and coworkers (Liu, Brown, Carter et al., 1996; Liu, Brown, Cruzan, & Saykally, 1996; Liu, Cruzan, & Saykally, 1996; Cruzan et al., 1996; Gregory, Clary, Liu, Brown, & Saykally et al., 1997). Nevertheless, because of statistical fluctuations, it is very unlikely that one could build up indefinitely the cluster size. As it was recently proved, the most stable conformations of the cluster appear to be like water tubes with a four or five water molecules basis (Krallafah, 2002; Maheshwary et al., 2001).

From the obtained optimized structures, it appears that, when the number of water molecules exceeds $n=5$, there are a lot of different stable conformations. These conformations are very close in energy. The minimized structure of the pentamer is always the same (not focusing on the flip-flop of OH orientation) no matter what the starting structure is. Using such calculation, it seems to be impossible to obtain the tetrahedral conformation as a stable one in an isolated environment. Similar data were obtained from both experimental evidences and computational results (Liu, Brown, Cruzan et al., 1996).

However, when $n=6$ or more, it also becomes evident that the corresponding water clusters seem to prefer to adopt one or more three-dimensional optimised structures rather than a single cyclic structure. For instance, for $n=6$, one cyclic structure, one bipyramidal structure with a square base, one prism structure and one cage structure are found as optimised solutions (Fig. 1). For $n=7-9$, a lot of different spatial structures coexist. Moreover, it seems that for even numbers of water

molecules very high symmetric conformations should be preferred. For the 10-mer water cluster, the most favorable computed structure corresponds to that drawn in Fig. 1.

When, the size of the cluster increases, it seems evident that hydrogen-bond cooperativity exists: the O–O distance is always decreasing. It also should be noted that, whereas bifurcated hydrogen bonds are often found in proteins or in biomolecules which possess

Fig. 1. Some of the low energy structures for $n=3, 4, 5, 6, 10$ and 15 .

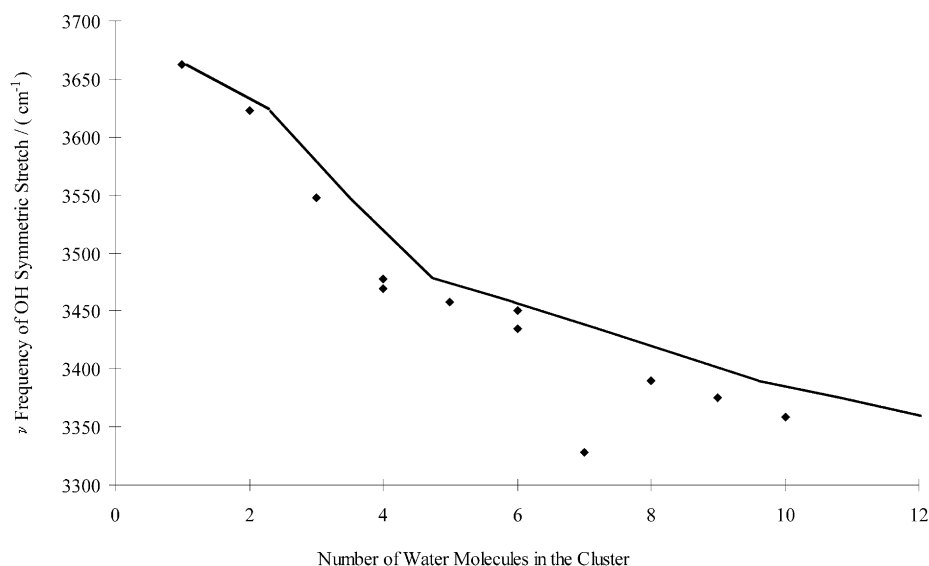

Fig. 2. Frequency of $\nu_s(\text{OH})$ symmetric stretch (cm^{-1}) versus n number of water molecules in the cluster.

numerous hydroxyl groups such as carbohydrates, this type of H-bond does not exist in these clathrate hydrates.

Of particular interest is the calculated HOH totally symmetric stretching vibrational mode (which is strongly active in the classical Raman effect) involving the symmetric displacement of the O–H bonds in all (HOH)_n molecules which is found to monotonically decrease in frequency when the number of water molecules in the cluster increases (Fig. 2). The used scaling factor (see Table 1) was determined by the results of vibrational analyses for the water monomer, dimer and relevant experimental data.

In the field of food research, it has long been recognized that water presents different properties than free and bulk water and is referred as bound water (Fennema, 1976). The major characteristics of this bound water are its unfreezability even at very low temperatures (Leung & Steinberg, 1979), low vapor pressure, and also include reduced molecular mobility (Labuza, 1977).

Water molecules may be associated with food components by different ways as described below. Nevertheless, the structures and properties of water in foods differ considerably from those of ordinary free water, so by studying the nature and forces of binding between

water molecules and food components (depending upon their chemical structures), it is possible to study the effect of water on texture and other quality aspects of foods. Thus, association of water molecules with food components could be (i) like water of crystallization strongly chemically bound water, (ii) like water adsorbed on hydrophilic specific sites by very low hydrogen bonding, (iii) like water organized as structured water molecules, close to the surface of the considered macromolecules in clathrate types and (iv) like water molecules in solutions. In this latter case, one can find, in solution, a lot of different small solute molecules such as linear sugars or carbohydrates, salts which can depress the activity of water molecules.

4. Conclusion

Studying both the structures and their corresponding energies and the vibrational data, it seems evident that hydrogen-bond cooperativity exists in these clathrate hydrate models. We noted a correlation for the experimental frequency corresponding to the maximum Raman intensity versus temperature. Thus, we deduced that in the temperature range –10 to 100 °C, the most abundant clusters in liquid water at density 1 g/ml

contain more than five water molecules. For $n = 10$ and $n = 15$, we can obtain specific hydrate models like cages that allow to entrap either ions or small molecules. Some conformations ($n = 15$) or those recently obtained by Maheshwary and coworkers have a tube shape, and an internal diameter similar to those observed in pore proteins. However, from these results, the view of liquid water has to be approached from a random, dynamical and three-dimensional network of hydrogen bonds.
