Agronomic seed vigour response
Seed disinfectant

ABSTRACT

Hydroxytyrosol-rich olive mill wastewater (HROMW) and hydroxytyrosol-rich composition (HRC) were prepared from olive mill wastewater using hydrolysis and post-hydrolysis purification processes. The HROMW and HRC showed powerful bactericidal and fungicidal activities against phytopathogens, and their minimal inhibition concentrations for fungi and bacteria were 7.18–57.4 mg l^{-1} and 7.18–14.4 mg l^{-1}, respectively. After 5 min of contact time, the disinfectant properties of the HROMW and HRC added at concentrations of 1.25% (dw/v) allowed for a reduction in bacterial viability by greater than 5 log units. However, a higher concentration of 1.5–3% (dw/v) or a longer contact time of 30 min were needed to achieve values for fungal viability reduction that were higher than the 4 log units recommended by EN 1275 [EN 1275 (1997a). Chemical disinfectants and antiseptics. Basic fungicidial activity. Test method and requirements (phase 1)]. HROMW and HRC were less effective with the most ubiquitous fungi, *Fusarium* spp., which needed 10% dw/v. The addition of HRC at 10% (dw/v) showed that the composition was a potent exogenous enhancer of growth that stimulated the seedling vigour of tomato and muskmelon, according to the conventional agronomic parameters for seed vigour. Compared to the control, the germination percentage, shoot weight, shoot height, and root length were all significantly enhanced in the HRC-treated seed plants. HRC was found to have effective disinfectant properties against seed-borne diseases. In treated seeds, the composition had significant effects on the control of damping-off disease groups at the pre-germination stage. HRC was also equally effective in the control of root rot diseases caused by *Fusarium sambucinum* and *Alternaria solani* as well as of wilts and even bacterial seed-borne pathogens. HROMW was also found to be as effective as HRC in terms of its efficacy against the three seed-borne diseases mentioned above.

1. Introduction

Root rots are reputed to be among the most devastating plant diseases. They are caused by a complex of fungal pathogens resident in the soil and have often been considered a major constraint to the establishment and development of plants in nurseries, glass houses and crops worldwide (Agrios, 2005). They are often associated with significant yield losses or decline in productivity (Tu, 1992). Studies have often reported that those fungi, either individually or associated, have severe effects on seed germination and young seedlings; observations of antagonism and synergism phenomena would then follow (Davet, Ravise, & Baroduy, 1980). Reports have also emphasised that those pathogens constitute the major factors behind the low productivity rates in many plantation fields. Based on the plant organ or growth stage that they affect, fungal disease pathogens can be divided into three groups: damping-off, root rot and wilts. Damping-off cause seed rot in pre-germination or germination stages or plant death after germination. Root rots cause rot and/or destruction of the root, restricting the absorption of water and nutrients. Wilts appear after flowering, and rarely at the juvenile stage of growth. Accordingly, many seed phytopathogenic bacteria are able to survive on dried seeds for extended periods (Ciafardini & Zullo, 2003). They, therefore, do not influence the establishment of plants but are the major means for the long-term spread of the disease. Rapid emergence can reduce root rot (Phillips, 1989); hence the presence of root rot can be directly related to the use of different sowing techniques, particularly those that support a favourable microclimate for their development (Valenciano, Casquero, & Boto, 2004). The disinfection of seeds enhances seed germination rates, increases plant growth, improves plant emergence and reduces damping-off (Gupta, Mathew, Shyam, & Sharma, 1999).

The application of pesticide seed treatment on various crops results in the improvement of plant emergence because it reduces plant mortality and losses caused by damping-off and root rot

(Tu & Zheng, 1993), thus improving the overall yield. Nevertheless, disinfectants, such as sodium hypochlorite, or fumigants, such as methyl bromide, can cause serious toxicity problems in young plants, as well as present risks to handlers and the environment (Soriano, Porras-Piedra, & Porras-Soriano, 2006). They can also cause irreparable damage to the metallic structure of green houses (Ciafardini & Zullo, 2003). Physical methods, such as heat treatment, are not adequately appropriate for application and often produce large amounts of unviable seeds (Soriano et al., 2006).

During the last few decades, the severe limitations of the use of methyl bromide prior to its complete phase-out seem to have triggered immense interest among researchers in the search of alternative solutions. In fact, the use of natural substances as alternative substitutes to synthetic chemical pesticides has often been recommended, particularly because they are less persistent and are known to have fewer non-targeted toxic impacts than traditional agrochemical aggregates. More pertinent to the aims and objectives of the current study, olive mill wastes, particularly olive mill wastewaters, have recently been reported to offer promising opportunities to overcome the problem at hand.

Olive mill wastewaters (OMW) are known to contain a number of biologically-active substances with promising potentials. The phytotoxic and antimicrobial properties of these residues have been extensively investigated and are associated with the presence of phenolic compounds (Mekki, Dhouib, Aloui, & Sayadi, 2006; Obied et al. 2005). Several investigators have reported on the inhibition of plant and microbial growth by low-molecular-weight phenols present in OMW (Fiorentino et al., 2003). Hydroxytyrosol has been identified as one of the major natural phenolic monomers present in OMW that has powerful antimicrobial activity (Fiorentino et al., 2003). Many compounds, however, still remain unidentified and controversy still persists over the exact type and amounts of phytotoxic components in OMW. Raw OMW exhibits a broad spectrum of toxicity against bacteria, fungi, plants, animals and human cells (Capasso et al., 1995; Obied, Bedgood, Prenzler, & Robards, 2007). However, OMW fractional extracts and isolated biophenols demonstrate selective or minimal toxicity (Capasso et al., 1995). For instance, Gonzalez, Moreno, Quevedo-Sarmiento, and Ramos-Cormenzana (1990) found that the antimicrobial activity of OMW phenolic acids (tested separately) did not coincide with the inhibitory effect of OMW. Some investigators have evaluated the recovery of the biological activity in soil after its treatment with OMW. Piotrowska, Iamarino, Rao, and Gianfreda (2006) observed a complete recovery of seed germination 42 days after OMW had been applied at 40 m^3 ha^{-1}. Yangui, Rhouma, Gargouri, Triki, and Bouzid (2008a, 2008b) reported on the phytopathogen suppression capacity of OMW. This helped demonstrate that OMW could be safely used as a pre-plant or seed disinfectant in plantation fields with no phytotoxic effect on plant development and crop yield.

This being so, the present study was undertaken to evaluate the potential that natural phenolic aggregates taken from olive mill wastewater might have as a biobased pesticide against a variety of seed infections. It aimed to evaluate the hypothesis that a series of biochemical compounds that are naturally-occurring in OMW could act against various seed infections. Treatment with purified and unpurified hydroxytyrosol-rich composition, and vigour-related growth parameters were also evaluated.

2. Materials and methods

2.1. Plant material

Seeds of tomato (*Lycopersicon esculentum*) and muskmelon (*Cucumis melo*) were obtained from Agricultural Garden Seeds (Sfax, Tunisia) in 11/2007 and were also obtained from the "National Institute of Agronomic Research of Tunisia (INRAT), under organic conditions and stored under normal conditions. Seeds were washed five times with sterile water, surface sterilised with 10% (v/v) commercial bleach for 15 min, and subjected to 3–4 further washes in sterile distilled water.

2.2. Preparation of hydroxytyrosol-rich composition

2.2.1. Preparation of hydroxytyrosol-rich OMW (HROMW)

A sample of about 20 l of fresh olive mill wastewater (FOMW) was taken in February 2006 from a three-phase continuous extraction factory located in Sfax, Tunisia. A fraction of 500 ml of this FOMW sample was used for physico-chemical characterisation. The pH and electrical conductivity (EC) were determined according to the standard of Sierra, Marti, Montserrat, Cruanas, and Garau (2001). Total organic carbon was determined by dry combustion (TOC Analyser multi N/C 1000). Total nitrogen was determined by Kjeldahl (1883) method. Chemical oxygen demand (COD) was determined according to Knechtel (1978) standard method. Phosphorus, iron, magnesium, potassium, sodium, calcium and copper were determined by atomic absorption (AAnalyst 200, Perkin–Elmer, Waltham, MA). The main characteristics of FOMW are: Total C measured 18.2 g l^{-1}, $N_{Kjeldahl}$: 0.5 g l^{-1} with a C:N of 36.4, P: 36.1 mg l^{-1}, K: 1.45 mg l^{-1}, Fe: 2.58 mg l^{-1}, Mg: 1.08 mg l^{-1}, Ca: 11.51 mg l^{-1}, Cu: 0.15 mg l^{-1}, Na: 1.59 mg l^{-1}, pH: 5.2, EC: 7.8 dS m^{-1}, and chemical oxygen demand was 63.5 g l^{-1}. The remainder of the FOMW sample was used to produce HROMW, according to the methods of Bilter et al. (2005) and Crea and Mateo (2008), by acidification with acetic acid to pH 3 and incubation for 6 months (from February to July) in the dark and at room temperature (varying between a minimum of 8–10 °C by night in February and a maximum of 38–40 °C by day in July). The supernatant was ultrafiltered using a 100 kDa pore size.

2.2.2. Preparation of hydroxytyrosol-rich composition (HRC)

In order to achieve the deodorisation, decolourisation and, above all, the removal/recovery of the hydroxytyrosol-rich composition, the filtered HROMW was passed through a series of XAD4, XAD7HP, and XAD16 adsorbent resins according to the procedure of Agalias et al. (2007). The hydroxytyrosol-rich composition obtained was concentrated 10 times to honeyed liquid under vacuum at 45 °C using a Büchi Rotavapor (Büchi Laboratories, Flawil, Switzerland).

2.2.3. Characterisation of fresh OMW (FOMW), hydroxytyrosol-rich OMW (HROMW) and hydroxytyrosol-rich composition (HRC)

Total phenols, total flavonoids and total flavonols were determined using Folin–Ciocalteu reagent according to the methods of Miliauskas, Venskutonis, and Van Beek (2004), Singleton and Rossi (1965) and Zqhishen, Mengcheng and Jimming (1999), respectively. Results were expressed on a dry weight basis as gallic acid equivalents (GAE), catechin equivalents(CE) and rutin equivalents (RE), respectively.

The identification and quantification of phenolic monomers were carried out by HPLC and LC–MS analysis as described by Bouaziz, Fki, Jemai, Ayadi, and Sayadi (2007). The main characteristics of fresh OMW (FOMW), hydroxytyrosol-rich OMW (HROMW) and hydroxytyrosol-rich composition (HRC) are given in Table 1 and Fig. 1.

2.3. Microorganisms

Fusarium sambucinum, *Verticillium dahliae*, *Alternaria solani* and *Pseudomonas syringae* pv tomato were originally isolated in 2003 from tomato plants that exhibited the main characteristic symp-

toms and were identified and provided by Institut de l'Olivier de Sfax, Tunisia. *Xanthomonas campestris* seed-borne phytopathogenic bacterium producing leaf spot symptoms in cruciferous plants was kindly provided by Pr. Maria Lopez from IVIA, Spain. For long-term conservation, the isolates were deposited at the Centre of Biotechnology of Sfax culture collection. For short-term conservation, bacteria were subcultured on nutrient agar (Difco; BD, Franklin Lakes, NJ) and fungi on malt extract agar (Difco) slant tubes at 25 °C for 72 h, then stored at 4 °C. Prior to use, the bacterial strains were cultured overnight on nutrient broth (Difco) and inocula were prepared by adjusting the turbidity of each bacterial culture to reach an optical comparison to that of a 0.5 McFarland standard, corresponding to approximately $1–5 \times 10^6$ CFU ml^{-1}. Fungi were cultured on malt extract agar plates for 7 days until sporulation, then the spore suspension of each fungal culture was prepared by pouring sterile buffered dilution water (SBDW) containing 0.1% of Tween 80 over the individual fungal cultures. The concentration of spore suspensions was determined by using a haematocytometer (Thoma cell) and adjusted to $1–5 \times 10^6$ spores per ml.

2.4. Bioassays

2.4.1. Antimicrobial activity

Minimal inhibitory concentration (MIC), minimal bactericidal concentration (MBC) and minimal fungicidal concentration (MFC).

MICs, MBCs and MFCs were determined by NCCLS (2000) broth dilution method. The HROMW and HRC were 2-fold serially diluted for bacteria in nutrient broth or for fungi in malt extract broth. MIC was taken as the interval of concentration between the highest dilution of HROMW and HRC that showed no detectable growth and the subsequent dilution. MFC was determined by sub-culturing all tubes that showed no visible growth.

2.4.2. Bactericidal and fungicidal activities

The bactericidal and fungicidal activities of the HROMW and HRC as natural disinfectants were evaluated according to the European Standard methods EN 1276 (1997b) and EN 1275 (1997a) under dirty conditions (3 g l^{-1} bovine albumin, 300 mg kg^{-1} $CaCO_3$) and the method of choice was the dilution-neutralisation method with 3% Tween 80, 3% saponin, 0.1% histidine, 0.1% cysteine as neutraliser and sterile hard water (300 mg kg^{-1} $CaCO_3$) as diluents. The HROMW and HRC-test concentrations were 0.5, 0.75, l.0, and 1.25% (w/v) for bactericidal activity and 1.25, 1.5, 3.0, and 6.0% (w/v) for fungicidal activity. The contact time and test temperature were: t = 5 min ± 10 s and θ = 20 °C ± 1 °C, respectively.

2.4.3. Phytotoxicity

Phytotoxicity was assessed by the determination of the germination index at two times, 36–72 h for tomato and 25–50 h for muskmelon, according to the standard method of Zucconi, Forte, Monac, and Beritodi (1981). Post-germinated seeds were transplanted in a sterile potting mix, as described in Section 2.4.4 below. Traditional seed vigour biomarkers were determined based on the total numbers of seedlings that fully emerged, shoot height, shoot weight and root length.

2.4.4. Seeds disinfection bioassays

Seed disinfection was carried out in two steps. The first step consisted of assessing all microorganisms in Petri dishes; the second involved the transplantation of the germinated seeds of fungi that exhibited symptoms of damping-off, root rot and wilt at the juvenile stage of tomato growth in plug trays.

For each microorganism, 50 g of bleached seeds were infected with 1% (v/w) of the microbial suspension which contained approximately 10^6 spores ml^{-1} for phytopathogenic fungi or 10^8 cfu ml^{-1} for phytopathogenic bacteria, and the infected seeds were then dried at room temperature for about 8 h. The contaminated seeds were divided into four parts. The first part was disinfected by placing the seeds in contact with a 10% (dw/v) sodium

hypochlorite solution for 30 min and then rinsed three times with sterile distilled water. The second part was mixed with HROMW at the ratios of 10% and 1% (dw/v) for fungi-infected and bacteria-infected seeds, respectively. The third part was mixed with HRC, using the same dosage rate used for HROMW. The fourth fraction was used, untreated, as control. After 24 h of incubation at room temperature, the seeds were transplanted into Petri dishes (10 seeds/Petri dish of 9 cm in diameter) containing sterile potting mix (twice autoclaved). The Petri dishes were then incubated at 27 °C for 52 and 72 h for muskmelon and tomato seeds, respectively. After that, the contaminated seeds were counted and the germination index was calculated, according to the method of Zucconi et al. (1981). This step was assessed to determine whether HROMW and HRC had disinfestation or disinfection properties. Accordingly, post-germinated tomato seeds were planted in a sterile potting mix (twice autoclaved) and grown in seedling plug trays (plug size 3 cm × 3 cm × 5 cm, 120 plugs per tray). The plug trays were placed under greenhouse conditions and monitored for a growing period of 4 weeks. The plants showing characteristic symptoms of the disease were noted.

2.5. Statistical analysis

The trial was established according to the randomised plots experimental design with three triplicates, including 30 plants in each replicate. Data were subjected to analysis of variance using SPSS software (Version 11; SPSS Inc., Chicago, IL). Mean values among treatments were compared by the Duncan's multiple range test at the 5% ($p = 0.05$) level of significance.

3. Results

3.1. Concentration of hydroxytyrosol in FOMW, HROMW and HRC

The analysis (Table 1 and Fig. 1) showed the effect of hydrolysis of complex phenols, such as oleuropein, into simple phenols, such as hydroxytyrosol, which was observed as a reduction in the peak height at 34–40 min and the amplification of the hydroxytyrosol peak at 10.5 min of retention. Moreover, an almost complete reduction in complex phenols detectable at 280 nm was observed for HRC with the phenols removed by separation on resin. Hydrolysis occurred during the storage of acidified FOMW for 6 months, and purification steps was also observed in the analyses. As the stages of processes progressed a significant increase in the content of hydroxytyrosol, total phenols, flavonoids and flavonols was observed (Table 1). After hydrolysis, the hydroxytyrosol concentration shifted from 0.2 g l^{-1} corresponding to 0.3% (w/dw) in FOMW to 8.4 g l^{-1} corresponding to 29.3% (w/dw) in HROMW, and the hydroxytyrosol yield of this step was 0.82% (w/v) (Table 1). After decantation, filtration and separation on resins and 10-fold concentration by water evaporation, the hydroxytyrosol concentration increased to 69 g l^{-1}, corresponding to 52.7% (w/dw) in the HRC.

3.2. Fungicidal and bactericidal potential of HROMW and HRC

Table 2 shows MICs, MBCs or MFCs of HROMW and HRC determined on the five microorganisms tested. Both HROMW and HRC inhibited the two bacteria tested, with MIC and MBC values ranging from 7.18 to 14.4 mg l^{-1}. For fungal strains, the HROMW MIC values ranged from 7.18 to 28.7 mg l^{-1} and the HRC MIC values ranged from 14.4 to 57.4 mg l^{-1}. As for those of HROMW and HRC, the MIC values were equal to the MFC values for *A. solani* and *V. dahlia* but only half those of the MFC values for *F. sambucinum*.

HROMW and HRC were bactericidal against both types of phytopathogens, *Pseudomonas* and *Xanthomonas*. Indeed, more than 5 log units of reduction in viability of *P. syringae* were achieved at a dosage rate of at least 1%, even after 5 min (Table 3). But, higher HROMW and HRC concentrations (1.25%) were actually needed to obtain 5 log units of reduction in viability for *Xanthomonas* spp. (Table 3). In the case of phytopathogen fungi, the antifungal activity shown by HROMW and HRC was moderately significant when compared to bactericidal activity. The fungicidal activity of HROMW and HRC against *A. solani* was obtained at the concentration of 3% after 5 min of contact. When the lowest dose recommended by the standard test method EN 1275 1.5% (w/v) was employed, the fungicidal activity against *V. dahlia* was achieved with the two products tested after 30 min of contact time (Table 4). *F. sambucinum* was not sensitive to the two extracts tested. In fact, a dosage rate (10%) that was higher than the one recommended by the standard test method EN 1275, 6% (w/v) was necessary to achieve the 4 log units of reduction in the viability of this fungus (Data not shown).

3.3. Phytotoxicity effect of HROMW and HRC on plant species

Seed germination was conducted on both HROMW (one dose was applied, 10%, which was used for the disinfection treatment) and HRC, and were used in comparison to those treated with water (negative control) and with sodium hypochlorite (positive control). The results showed that seed germination was strongly inhibited for the two species studied when treated with both sodium hypochlorite and HROMW (Fig. 2). HRC did not show any inhibitory effect on seed germination and the two crops represented close ratios of germination when compared to the control subjected to water treatment (Fig. 2). The application of HRC improved the germinative energy of the seeds. The index of germination at the half-period of germination was 36 and 25 h for tomato and muskmelon, respectively, and was significantly higher than that of the negative controls (Fig. 2). Treatments with HROMW and sodium hypochlorite, however, have yielded a germinative energy that was lower than the optimum (ratio <50%).

Initial vigour response was measured using traditional agronomic parameters, such as germination percentage, root length and shoot weight and height. Results indicated that vigour response was, indeed, higher in response to HRC than the other treatments (Fig. 3). HROMW, on the other hand, negatively affected the

vigour response of seeds with a significant reduction in root heights as well as in shoot heights and weights. These results were comparable to those of sodium hypochlorite treatment, where the seed vigour biomarkers were drastically affected.

3.4. Disinfectant property

The trials carried out in Petri dishes demonstrated that HRC was able to inhibit the growth of the seed-borne diseases used. In fact, HRC allowed for a highly significant control of the damping-off disease groups on the treated seeds in the pre-germination stage (Figs. 4 and 5). With regard to the application of HROMW, highly significant differences were observed with the treated seeds, as opposed to the inoculated seeds (Figs. 4 and 5). A higher damping-off control was observed in the seeds subjected to HRC + *X. campestris* when compared to those subjected to HRC + *P. syringae* pv tomato (Fig. 4).

Furthermore, the trials carried out in plug trays demonstrated that HRC was able to control root rot caused by *F. sambucinum* and *A. solani*. Under greenhouse conditions, HRC also allowed for a highly significant control of this group of seed diseases (Fig. 5). Wilts were also significantly decreased in seeds subjected to HRC + *V. dahliae* treatment (Fig. 5). Likewise, HROMW was noted to be as effective as HRC against the three seed-borne diseases under investigation.

4. Discussion

Given the fact that OMW is generated for only 3–4 months a year, and to assure a continuous industrial activity of hydroxytyrosol production, a sufficient quantity of OMW must be provided during the year. In a previous survey Feki, Allouche, Bouaziz, Gargoubi, and Sayadia (2006) demonstrated that the storage of OMW is doubly beneficial; first, hydroxytyrosol concentration increased from 0.98 to 3.5 g l^{-1} during 5 months of OMW storage. As well, OMW storage resulted in the abolition of the centrifugation step necessary for the elimination of suspended matter. Bilter et al. (2005) and Crea and Mateo, (2008) also demonstrated the addition of acid to OMW in an amount effective to produce a pH between 2 and 4, and incubating OMW for a period of 6–12 months until at least 75–90% of the oleuropein originally present in OMW has been converted to hydroxytyrosol. The HROMW remained black-coloured; consequently, further purification steps through resin separation were deemed necessary to recover the HRC from the HROMW.

The antimicrobial effect of HRC was revealed by MIC and proved through basic method against most phytopathogenic fungi and

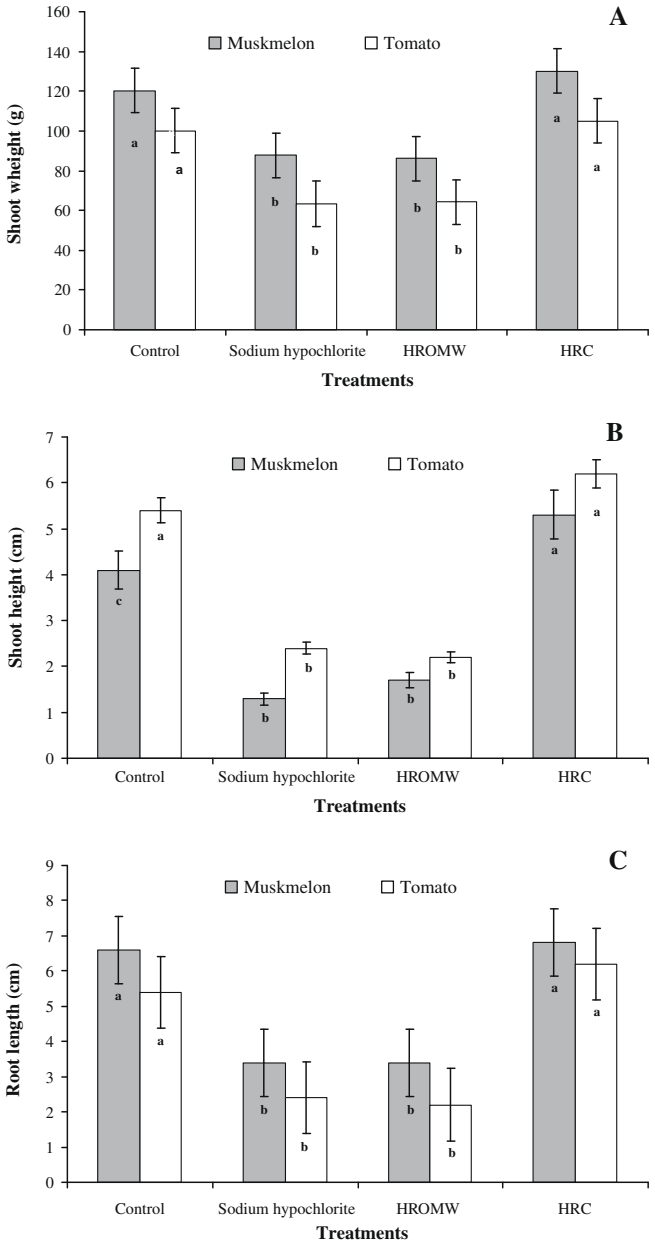

Fig. 3. The effect of germination index of distilled water (control), sodium hypochloride, HROMW, and HRC on (A) shoot weight; (B) shoot height; and (C) root length at 2 months after transplantation of tomato (*Lycopersicon esculuntum*) and muskmelon (*Cucumis melo*) plants. Histograms followed with different letters are significantly different according to the test of Duncan ($p = 0.05$).

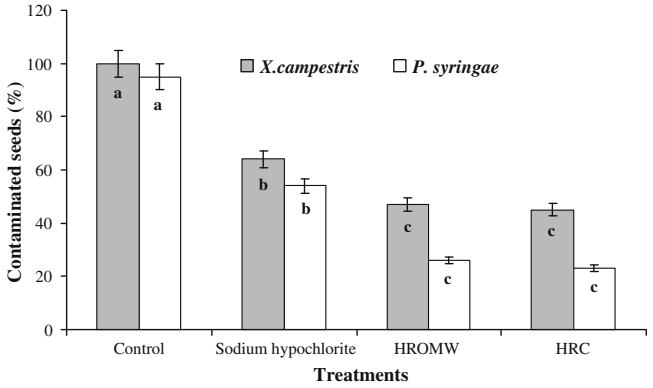

Fig. 4. Disinfection effect of water (control), sodium hypochloride, HROMW, and HRC on percentage of contaminated seeds by *Xanthomonas campestris* and *Pseudomonas syringae* pv. Tomato. Histograms followed with different letters are significantly different according to the test of Duncan ($p = 0.05$).

bacteria. Hence, most plant extracts show activity against Gram-positive bacteria. Activity against Gram-negative bacteria and fungi is also considered a critical measure of success (Ezzoubeiri et al., 2005). It was pointed out in previous studies, however, that Gram-positive bacteria are more susceptible to antimicrobial extracts of plants than the Gram-negative ones (Ezzoubeiri et al., 2005). The different activities against Gram-negative and Gram-positive bacteria may be rationalised by considering differences in cell wall composition. Gram-negative bacteria have a lipopolysaccharide component in their outer membrane that makes them more resistant to antibacterial compounds. As far as the current study is concerned, the hydroxytyrosol-rich composition inhibited the growth of Gram-negative bacteria within the recommended doses of application. The effectiveness of HRC could be attributed to the chelating of transition metals by polyphenols. Wong and Kitts (2006) reported that phenolic compounds are capable of chelating transition metals and lowering the reactivity of metal iron by forming an inert metal–ligand complex. Chelation of transition metals, such as iron and copper, reduces bioavaibility for microbial growth.

The control of tested phytopathogenic fungi is a very difficult process, even with the application of pre-harvest fungicides (Polashock, Ehlenfeldt, Stretch, and Kramer, 2005). Sampedro, D'Annibale, Ocampo, Satazi, and Gargia-Romera (2005)) demonstrated the capability of a saprophytic *Fusarium* to grow on a medium rich with phenolic compounds. This can explain the inefficacy of hydroxytyrosol-rich solutions against the soil-borne *Fusarium* strain. The effectiveness of HRC against other phytopathogenic fungi, namely *Verticillium* and *Alternaria*, can be related to the altering of microbial permeability, which can permit the loss of cytoplasmic macromolecules.

It is widely acknowledged, and as is found in numerous references, products that are rich in oleuropein demonstrate antimicrobial activity against a variety of viruses, bacteria, yeasts and fungi (Aziz, Farag, & Mousa, 1998; Bisignano et al., 1999; Fleming, Walter, & Etchells, 1973; Tassou & Nychas, 1995; Tassou, Nychas, & Broad, 1991). Since higher antibacterial effects were observed using HRC, the latter should be examined in terms of its powers as a new antimicrobial intensifier. The present *in vitro* study demonstrated that the experimental antiseptic and/or disinfectant were undeniably effective in inhibiting plant pathogens. This could be of particular interest to the nurserymen whose plants have always suffered from fungal disease pathogens. It is common for the nurserymen in Tunisia to reuse their propagation trays, which may contain the remains of contaminated substrates. Several approaches have been tried to remove the pathogens from those trays (Soriano et al. 2006), none of which is fully satisfactory. Disinfectants, such as sodium hypochlorite or formalin, can cause serious toxicity problems in young plants and create severe risks to handlers and the environment (Ciafardini & Zullo, 2003; Soriano et al., 2006). HRC can, therefore, be considered a strong alternative candidate for the current inadequate methods involving the removal of the harmful disinfectants in both seed and propagation trays.

HRC did not exhibit any inhibitory effects on seed germination and two crops presented a high germination ratio (>50%) even at half-period of germination. It can be inferred that the germination inhibition is basically due to the phenolic compounds that are present at high levels in HROMW. This is in line with previous findings by Mekki, Dhouib, Feki, and Sayadi (2008), Komilis, Karatzas, and Halvadakis (2005) and Piotrowska et al. (2006), which demonstrated that the germination inhibitory effect is partly due to the

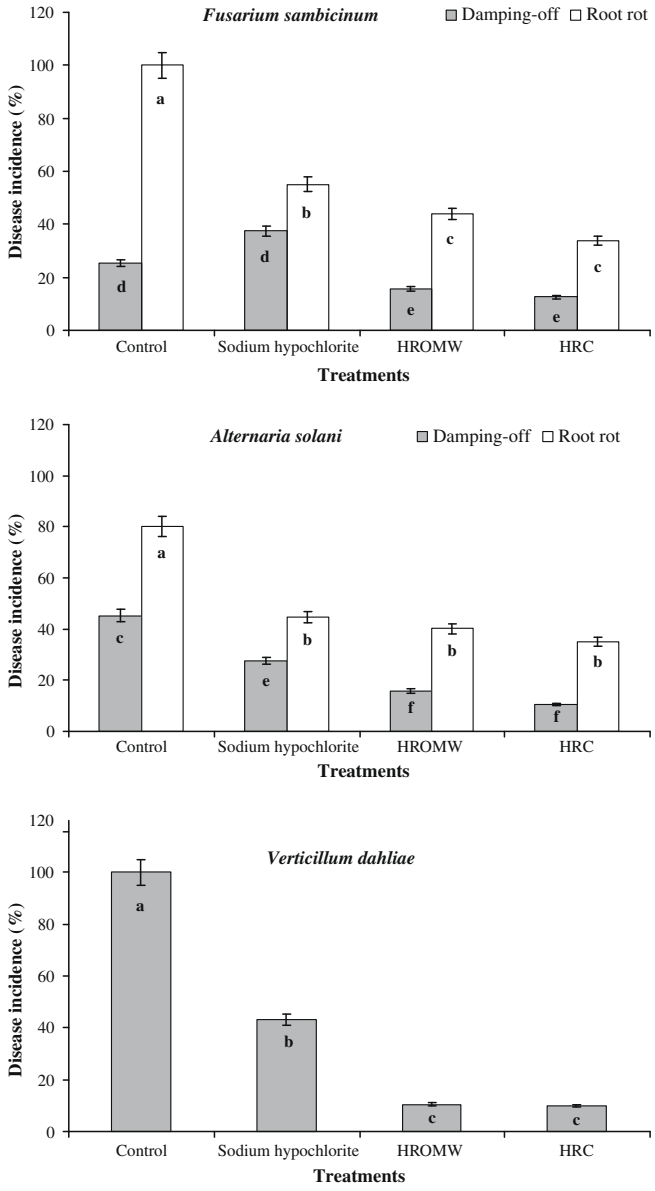

Fig. 5. Effect of treatments by distilled water (control), sodium hypochloride, HROMW, and HRC on the percentage of damping-off and root rot incidence of tomato (*Lycopersicon esculuntum*) plants caused by *Fusarium sambicinum* and *Alternaria solani* and on the percentage of *Verticillum* wilt incidence of tomato (*Lycopersicon esculuntum*) plants caused by *Verticillum dahliae*. Histograms followed with different letters are significantly different according to the test of Duncan ($p = 0.05$).

high amount of phenolic compounds and partly to the high molecular weight of phenolics present in untreated OMW. Gonzalez et al. (1990) reported that the antimicrobial activity of phenolic acids (tested separately) did not coincide with the inhibitory effect of OMW. Obied et al. (2007) also reported that crude OMW has a broad spectrum of toxicity against bacteria, fungi, algae, plants, animals and human cells and added that fractionated OMW extract and isolated biophenols, on the other hand, demonstrate selective or minimal toxicity. This could explain the reason why HRC had an antimicrobial effect with no phytotoxic effects (Table 1). In addition, the relatively high salinity of the HROMW solution may affect the germinability of the crops. This seems similar to the findings of Ramana, Biswas, Kundu, Saha, and Yadava (2002) who reported that in some crop species, such as tomato, cucumber, chilli and onion, the increase in the concentration of the highly saline effluent was paralleled by a similar decrease in the percentage of germination. The germination rate, in particular, is immensely important, for the increase in germination is usually followed by an improvement in overall seedling performance (Parera & Cantliffe, 1991). The findings of the current study indicated that the tomato and muskmelon seedlings treated with HRC similarly showed higher and average germination rates, when compared to the HROMW solution and control seedlings, respectively. Root lengths and shoot weights and heights are all vital indices of seeds' vigour. Results indicated that vigour response, in terms of those factors, is a useful approach to meeting productivity of crops (Perry, 1978). With regard to improving seed vigour through the stimulation of phenolic synthesis, it has often been suggested that exogenously applied phenolic antioxidants may be able to stimulate the endogenous phenolic content in plants (Randhir & Shetty, 2003). This stimulation is hypothesised to involve the concurrent activation of antioxidant enzyme metabolites which are dependent upon reductants (NADPH) obtained as a by-product of carbon flux through the pentose phosphate pathway, which is, itself, the source of sugar phosphate precursors required for phenolic synthesis (Randhir & Shetty, 2003).

Quick seedling emergence and even stands are essential in maximising the yield of all crops. The use of high quality, disease-free seed is the first step to producing stands. The application of HRC treatment improved the germinative energy measured at half-period of germination. Germinative energy can play an important role in achieving quick and uniform seedling emergence and in reducing damping-off incidence, thus improving the yield. Gupta et al. (1999) reported that the use of fungicides is effective in enhancing germination, emergence and growth as well as in reducing damping-off. In addition, accelerated germination is reported to help improve stress resistance and enhance overall plant growth and productivity (Pattan, Gothkar, Joshi, Chivasa, & Nyamudeza, 2001). This could account for the usefulness of the HRC solution for seed disinfection.

A further transplantation of post-germinated seeds demonstrated the compelling disinfection effect of both HRC and HROMW, and not a mere surface disinfestation of seeds. Yields were higher when seeds were treated by HRC, which led to earlier and better emergence and to improved control of both damping-off/root rot and wilt caused by *Fusarium*/*Alternaria* and *Verticillium*, respectively. Valenciano et al. (2004) demonstrated that the use of pesticides for the protection and/or disinfection of seed improved yields because it increased the number of established plants. A negative correlation exists between yield and the presence of disease in the soil and/or in the seeds because the loss of plants from root rot has a huge impact on yield (Pedroza, Teliz, de la Torre, & Campbell, 1994). Thus treatment is a fundamental operation because the initial stage in plant development is the most susceptible to adverse environmental conditions (Valenciano et al., 2004). Sodium hypochlorite is the most used solution for the disinfection of seeds as well as of the equipment used in the production of plants (Soriano et al., 2006). Nevertheless, and due to its highly corrosive nature, sodium hypochlorite must be used with extreme caution. As a matter of fact, it can seriously hurt the seeds and reduce germination. This justifies the urgent need for research on efficient alternative substitutes for the current disinfestations, disinfections or protections used for seed and propagation equipment. The results obtained demonstrate that HRC represents a class of natural products that offers an efficient substitute for the currently used commercial corrosive disinfectants such as sodium hypochlorite. In fact, it can be used to control the most resistant fungal structure (chlamydospores) produced by the species of *Fusarium* (Mavrogianopoulos, Frangoudakis, & Pandelakis, 2000), *Alternaria*, *Verticillium*, and even *Xanthomonas* and *Pseudomonas*, without causing any damage to the germination ability of crops.

In short, HRC has proven to be a solution that: (1) has high element content; (2) promotes early vigour and improves plant health; (3) provides protection against pathogens which attack germinating seeds and emerging seedlings; (4) aids in the production of healthy vigorous crops and higher yields; (5) promotes quick emergence and crop uniformity; (6) is easy to use and simple to clean up with water; and (7) is environmentally safe and not harmful for plants, animals and humans.

Volatile compounds
Solid phase microextraction
Thermal treatment
Irradiation

ABSTRACT

HS-SPME–GC–MS analysis of Aglianico del Vulture red wine from Southern Italy showed the presence of ethyl acetate, 3-methyl-1-butanol, 3-methylbutyl acetate, ethyl hexanoate, diethyl butanedioate, ethyl octanoate, and ethyl decanoate. Thermal treatment for 24 h in the 20–60 °C range showed that for most of the compounds analysed the simple transition from 20 to 30 °C induces a significant modification on the composition of volatile compounds. A sharp decrease was observed for ethyl acetate, diethyl butanedioate, and 3-methylbutyl acetate; a moderate decrease was observed for ethyl hexanoate, while an increase was observed for 3-methyl-1-butanol, ethyl octanoate, and ethyl decanoate. The temperature of 40 °C induces the maximum evolution of this type of compound. Higher temperatures induce a reduction of volatile compounds in wine. Irradiation of Barolo (red wine, Northern Italy), Amarone (red wine, Northern Italy), and Brunello di Montalcino (red wine, Central Italy), at 20 °C was performed with a 13 W neon lamp. 3-Methyl-1-butanol was affected by the irradiation. In the case of Barolo and Amarone, we observed a moderate increase, while, for Brunello di Montalcino, a decrease was observed. In the same way, esters were degraded during irradiation. In the red wine one or more components (phenols?) are able to protect esters from photodegradation. In diethyl butanedioate and ethyl hexanoate, octanoate, and decanoate we observed an initial increase of the concentration of the esters in some cases.

1. Introduction

Temperature changes can modify the amounts of volatile compounds in wine (Benítez, Castro, Natera, & Barroso, 2006; Cutzach, Chatonnet, & Dubourdieu, 2000; Pérez-Coello, Gonzáles-Viñas, García-Romero, Díaz-Maroto, & Cabezudo, 2003). Some years ago the analysis of sherry wine exposed to UV–vis radiation showed that an increase in the amount of volatile compounds can be observed (Benítez, Castro, & Barroso, 2003; Benítez et al., 2006). Esters and acids showed a sharp tendency to increase during irradiation; with the exception of 2-methyl-1-butanol, hexanol, and 2-methyl-1-propanol, the same tendency was found in alcohols present in wine. Also aldehydes and ketones increased during irradiation. This result was not in agreement with our report where solid phase microextraction was used in order to estimate the modifications occurred in volatile compounds in champagne after UV irradiation (D'Auria, Emanuele, Mauriello & Racioppi, 2003). In fact, while most of the alcohols found did not change their concentration after irradiation, a sharp reduction was observed in the amounts of esters (ethyl acetate, ethyl butanoate, ethyl 2-hydroxypropanoate, 3-methyl-1-butanol acetate, diethyl butanedioate, ethyl octanoate, and ethyl decanoate).

The esters in wine are important constituents of the aroma. In fact, the high variability of the ester fraction has an effect on the intensity of fruity notes in the aroma profile (Belitz, Grosch, & Schieberle, 2004). Furthermore, the results reported by Benítez et al. (2003, 2006) showed that the increase of the ester fraction was higher in topaz glass (cut-off near 600 nm, but 20% transmittance at 350 nm) than in transparent glass (cut-off at 300 nm). Also, the nature of the glass bottles can influence the organoleptic properties of the wine. Most of the wine is sold in supermarkets where the wine bottles are exposed for a large period to artificial light. This exposure can modify the aroma profile of the wine. We have to know the nature of all the modifications occurring in the wine after light irradiation in order to find how to prevent the loss of quality due to light irradiation.

In this report our results obtained irradiating some important Italian red wines (Barolo, Amarone, Brunello di Montalcino). We tested the temperature effect on the amount of volatile organic compounds on a red wine typical of Southern Italy (Aglianico del Vulture). We performed the irradiation of wine with a neon lamp in the original bottles in order to simulate the real situation of exposure of wine to light.

2. Materials and methods

2.1. General

Aglianico del Vulture is a typical red wine of Basilicata (Southern Italy). It is produced by using only Aglianico grapes, which are

doi:10.1016/j.foodchem.2009.03.070

of Greek origin. The sample we used was made in 2002, showed an alcoholic grade of 13.5% and a volatile acidity of 0.40 g/l.

Barolo is produced in Cuneo's province, south–west of Alba, within the region of Piemonte. The wine is produced from the Nebbiolo grape variety. The Lampia, Michet, and Rosè types are authorised. The grapes mature at the end of September. The clusters are dark blue and greyish with an abundant wax that dresses the grapes. The form of bunches is lengthened, pyramidal, with small, spherical grapes with substantial peel. The leaves are of average size with three or five lobes. The bottle we used contained wine of 2001 and showed an alcoholic grade of 14%.

Amarone della Valpolicella is produced from Corvina, Rondinella, and Molinara desiccated grapes, Grapes are harvested perfectly ripe in the first two weeks of October, by carefully choosing bunches having fruits not too close to each other, to let the air flow. Grapes are allowed to dry, traditionally on straw mats. This process is called *rasinate* (to dry and shrivel) in Italian. The length of the drying process is typically 120 days but varies according to producer and the quality of the harvest. The most evident consequence of this process is the lost of weight: 35–45% for Corvina grapes, 30–40% for Molinara and 27–40% for Rondinella. Following drying, at the end of January/beginning of February, the grapes are crushed and go through a dry low temperature fermentation process which can last up to 30–50 days. The reduced water content can slow down the fermentation process, increasing the risk of spoilage and potential wine faults, such as high volatile acidity. After fermentation, the wine is then aged in barrels made from either French or Slovenian oak. The sample we used was bottled in 2003, showed an alcoholic grade of 15.5% and a volatile acidity of 0.92 g/l.

Brunello di Montalcino must be made 100% from the Brunello clone of Sangiovese. The current ageing requirements were established in 1998 and dictate that Brunellos are to be aged in wood for 2 years and at least 4 months in a bottle before release. Traditionally, the wines are aged 3 years or so in barrel, large oak casks that impart little oak flavour but allow for the controlled softening of the wine. Modernists use small barrique which impart a more pronounced oak flavor. There is a middle ground where the wine is aged in small barrique for a short time and then spends a longer sojourn in the traditional botte. The sample we used was dated 2002 and showed an alcoholic grade of 13.5%.

2.2. SPME analysis of wine

An SPME fibre coated with 100 μm of poly(dimethylsiloxane) (PDMS) phase (Supelco 57300-U, mounted on a Supelco 57330 support) was conditioned for 1 h at 250 °C in a stream of helium. A single fibre was used for the complete study. A blank run was performed after the analysis in order to confirm that no residual compound was polluting the fibre or the column. The headspace was generated from 10 ml samples placed in a 20 ml flask. The flask was sealed and heated for 20 min in an aluminium block maintained at 45 °C (40 °C in the flask). During this time, the fibre was maintained over the sample. The fibre was then introduced into the injection port of an HP6890 Plus gas chromatograph equipped with a Phenomenex Zebron ZB-5 MS capillary column (30 m × 0.25 mm ID × 0.25 μm film thickness; Phenomenex, Torrance, CA). An HP5973 mass selective detector (mass range: 15–800 amu; scan rate: 1.9 scans/s; EM voltage: 1435) was used, with helium at 0.8 ml/min as carrier gas. The injection port, equipped with glass insert (internal diameter 0.75 mm) was at 250 °C; the injection port was maintained in splitless node for all of the chromatographic analysis. A desorption time of 1.0 min was used. The interface was maintained at 230 °C. The oven was maintained at 40 °C for 2 min, then the temperature increased to 250 °C (at 8 °C/min); finally, this temperature was maintained for 10 min. All the analyses were performed in triplicate. The chromatograms obtained from the total ion current (TIC) were integrated without any correction for coelutions and the results were expressed in arbitrary surface units (asu). All the peaks were identified from their mass spectra by comparison with spectra in Wiley6 N and NIST98 libraries and by comparison with an authentic standard for the seven compounds reported below.

2.3. Calibration curves

Calibration curves were determined by using known amounts of every compound dissolved in ethanol/water 1:9 using the methodology described above. The tested compounds were dissolved in ethanol:water in order to obtain solutions containing 2, 10, 50, 100, 300 and 500 mg l^{-1} of the analytes. The area count obtained after the analysis is plotted against the concentration. The linear regression was determined by using least squares method. All the analyses were performed in triplicate. Results: ethyl acetate: slope = 0.1103 [area count $\times 10^{-6} \times l \times mg^{-1}$], $r^2 = 0.9834$; 3-methyl-1-butanol: slope = 0.0209 [area count $\times 10^{-6} \times l \times mg^{-1}$], $r^2 = 0.9974$; 3-methylbutyl acetate: slope = 0.0063 [area count $\times 10^{-9} \times l \times mg^{-1}$], $r^2 = 0.9880$; ethyl hexanoate: slope = 0.0062 [area count $\times 10^{-9} \times l \times mg^{-1}$], $r^2 = 0.9883$; diethyl butanedioate: slope = 0.0083 [area count $\times 10^{-8} \times l \times mg^{-1}$], $r^2 = 0.9977$; ethyl octanoate: slope = 0.0096 [area count $\times 10^{-9} \times l \times mg^{-1}$], $r^2 = 0.9993$; ethyl decanoate: slope = 0.0131 [area count $\times 10^{-9} \times l \times mg^{-1}$], $r^2 = 0.9884$.

2.4. Thermal treatment of wine

Wine (10 ml) was maintained in a 25 ml Pyrex sealed vial at each selected temperature (20, 30, 40, 50, and 60 °C) for 24 h. Each experiment was performed in triplicate.

2.5. Irradiation of wine in the bottles

The red wines were in topaz bottles. Before irradiation, analysis of the wines was performed drawing samples from the bottles using a syringe. The bottles were irradiated with a Lyvia ESL 13 W 2700 K 800 lm for 7 days. The bottles were maintained at 20 °C. The lamp was at a distance of 20 cm from the bottle. A sample was analysed every 24 h using a syringe from the same bottle every day.

3. Results and discussion

The object of our work is to verify the changes in the volatile compounds in wines exposed to the light present in a standard supermarket. First of all, as preliminary work, we tested the behaviour of a red wine when it is exposed to a thermal treatment. In wines sold in tropical countries the temperature of wine could increase, modifying the volatile compounds' composition. We used an Aglianico del Vulture wine, a typical wine of Southern Italy. We tested seven volatile compounds found in the wine at 20 °C. We analysed the presence of volatile compounds by using SPME. The analyses were performed on samples maintained at the selected temperature for 24 h. The results are reported in Figs. 1–7. The amount of ethyl acetate decreased until 30 °C, and then increased to reach a maximum at 50 °C (Fig. 1). The behaviour of diethyl butanedioate (Fig. 2) and ethyl hexanoate (Fig. 3) was similar. The amount of these esters decreased at 30 °C, reached a maximum at 40 °C and, then, decreased until disappearance. Also the behaviour of ethyl octanoate (Fig. 2) and ethyl decanoate (Fig. 2) was similar. The amount of these esters increased until 40 °C, and then decreased until disappearance. The amount of 3-

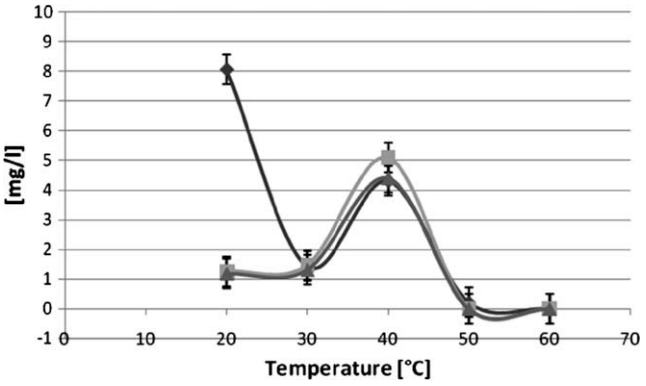

Fig. 2. Evolution of diethyl butanedioate [♦], ethyl octanoate [■] and ethyl decanoate [▲] in red wine (Aglianico) at different temperatures for 24 h.

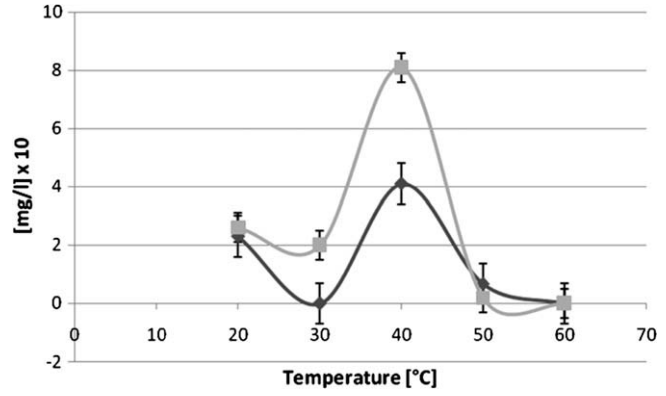

Fig. 3. Evolution of 3-methyl-1-butanol acetate [♦] and ethyl hexanoate [■] in red wine (Aglianico) at different temperatures for 24 h.

methyl-1-butanol increased until 50 °C, then decreased (Fig. 1). Finally, 3-methylbutyl acetate decreased at 30 °C, reached a maximum at 40 °C, then decreased (Fig. 3). For most of the compounds analysed in this study, the simple transition from 20 to 30 °C induces a significant modification on the composition of volatile compounds. The temperature of 40 °C induces the maximum evolution of this type of compounds. Higher temperatures induce a reduction of volatile compounds in wine.

Zoecklein, Hackney, Duncan, and Marcy (1999) found significant decreases in the concentration of most esters, after a treatment at 45 °C in Riesling (*Vitis vinifera* L.) wines. Rapp and Marais (1993) noted that acetates decreased in concentration with time and high temperature. Rapp and Mandery (1986) found that ethyl esters hydrolyse more slowly than acetate esters. Significant decreases in these types of volatile compounds were found by various authors for white wines stored at high temperature (De la Presa-Owens & Noble, 1997). Marais, Van Wyk, and Rapp (1992) observed more significant decreases in the concentration of some acetates and alcohols in wines stores at 30 °C than those stored at 15 °C. Ferreira, Escudero, Fernández, and Cacho (1997) explained the increases in the concentrations of some alcohols in wines stored under oxygen on the basis of the degradation of some of the precursors present in the wine.

We have also to note that the increase of the temperature induced the formation of compounds not present in the wine at 20 °C. In Table 1 we reported the area per cent of some compounds found at higher temperature and not quantified in this study. We can see, in agreement with the above reported results, that the maximum expression of volatile compounds was observed at 40 °C.

On the basis of these results, we performed the irradiation of some red wines at 20 °C. This temperature was selected because we showed that the temperature used can modify the aroma profile of the wine, and because this temperature is, probably, that nearest to the actual temperature in a supermarket store. We used three important Italian wines: Barolo from Piemonte, Amarone from Veneto, and Brunello from Toscana. The bottles were irradiated with a 13 W neon lamp, whose emission is showed in Fig. 4. The lamp showed emissions at λ 364, 404, 435, and 545 nm. These emissions were filtered but not cut by the glass of the bottles. As an example, we report in Fig. 4 (red line) the result obtained with the glass of Barolo wine. The emissions at 364 and 404 nm were almost completely filtered (99.1 and 98.6%, respectively); however, the emission at 435 nm remains (91.7% of the emission was filtered) as well as that at 545 nm (the emission showed 25.3% reduction). In our experiments we analysed the wine every day for a week, withdrawing the sample from the intact bottle with a syringe.

Fig. 5 represents the photochemical behaviour of ethyl acetate. In Barolo wine, after one day's irradiation, we observed an increase of the concentration of ethyl acetate and, after a week, the concentration of this compound was higher than that present at the beginning of the experiment. In Amarone wine we observed a sharp increase of the concentration of ethyl acetate after two days. After a week the concentration was more or less the same as that observed at the beginning of the experiment. In the case of Brunello wine, after a week's irradiation we observed a sharp decrease of the amount of ethyl acetate.

Fig. 6 reports the data relative to the photochemical behaviour of ethyl hexanoate. In Barolo wine it was not present at the beginning of our experiments; however, after one day's irradiation it was present in the wine and its concentration reached a maximum. In Amarone wine we observed a sharp reduction of the amount of this ester after a week irradiation; we have to note a relative maximum after two days' irradiation. The amount of ethyl hexanoate in Brunello wine showed a maximum after two days' irradiation, while, after a week, we observed a sharp decrease of its concentration in wine.

Extensive degradation after irradiation was observed also in the amounts of diethyl butanedioate (Fig. 7): however, in the case of Barolo wine, at the beginning of the experiments it was present in a very low amount and the concentration increased after a week's irradiation with a maximum after two days' irradiation. On the contrary, in Amarone wine, the concentration of this ester increased, reaching a maximum after two days' irradiation, but showing a sharp decrease after a week. Finally, in Brunello wine, we observed a sharp degradation of diethyl butanedioate during the irradiation with a relative maximum after three days.

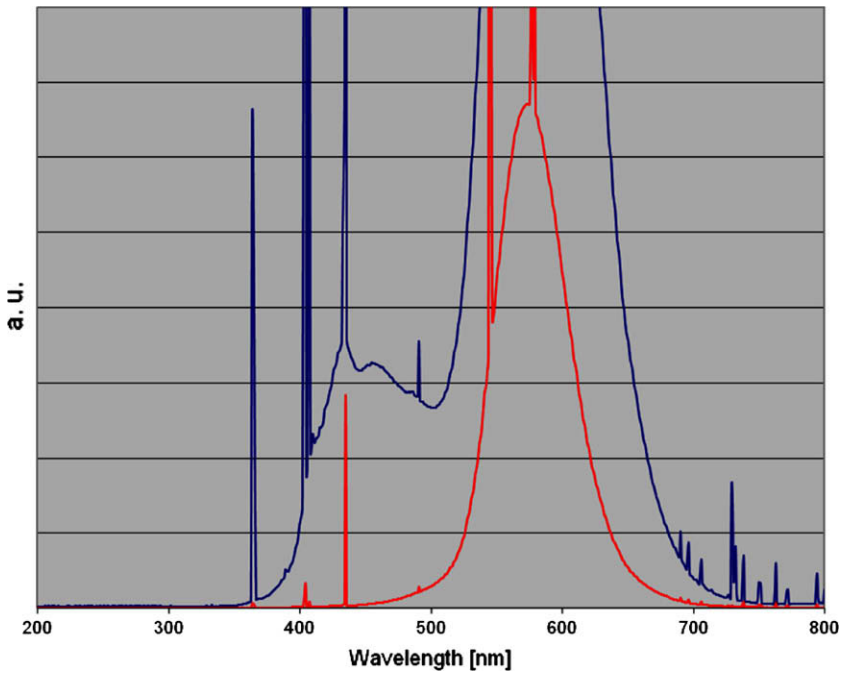

Fig. 4. Emission of the lamp used in this study (blue line) and emission filtered by the glass of bottle containing Barolo wine (red line). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 1
Unquantified compounds found in the thermal treatment of Aglianico wine.

Compound	Temperature (°C)				
	20	30	40	50	60
	Area%				
Ethyl dodecanoate	0.00	0.10	0.79	0.00	0.00
Ethyl hexadecanoate	0.00	0.09	0.26	0.00	0.00
Ethyl 2-methylpropanoate	0.00	0.00	0.19	0.15	0.00
Ethyl 2-methylbutanoate	0.00	0.00	0.09	0.00	0.00
Ethyl 3-methylbutanoate	0.00	0.00	0.14	0.00	0.00
Ethyl 9-decanoate	0.00	0.00	0.18	0.00	0.00
Ethyl tetradecanoate	0.00	0.00	0.41	0.00	0.00
Ethyl pentadecanoate	0.00	0.00	0.13	0.00	0.00
2-Methyl-1-propanol	0.00	0.00	0.00	0.44	0.38
Ethyl propanoate	0.00	0.00	0.00	0.036	0.00
Ethyl butanoate	0.00	0.00	0.00	0.036	0.00

In Barolo wine, the ethyl octanoate concentration (Fig. 8) showed a maximum after two days' irradiation while, after a week, a sharp degradation was observed: the initial concentration was 0.11 mg l^{-1} and it was reduced to 0.02 mg l^{-1} at the end of the experiment. In Amarone wine we observed a clear decrease of

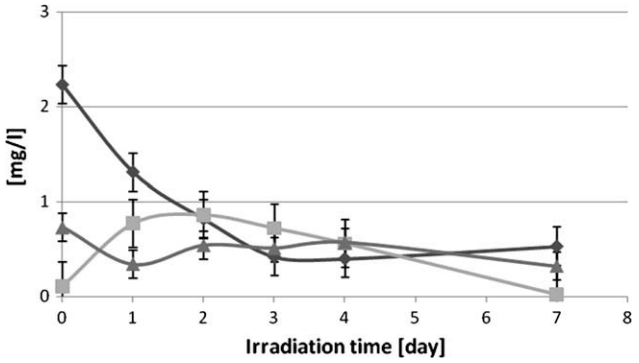

Fig. 8. Photochemical behaviour of ethyl octanoate under irradiation. [■]: Barolo; [♦]: Amarone; [▲]: Brunello.

the concentration of this ester. In Brunello wine, after a week's irradiation, we observed that the concentration of ethyl octanoate decreased from the initial value of 0.73–0.32 mg l^{-1}, with a relative maximum after four days irradiation. The same trend was observed also for ethyl decanoate (Fig. 9).

Fig. 10 reports our results obtained after irradiating the wines and analysing the photochemical behaviour of 3-methyl-1-butanol. In Barolo wine, we observed a maximum after one day irradiation and, at the end of the experiment, the concentration of this alcohol showed a moderate increase. In Amarone wine, we observed a maximum after two days' irradiation and, also in this case, a moderate increase after a week. On the contrary, the concentration of 3-methyl-1-butanol decreased in Brunello wine from the initial value of 206 mg l^{-1} to the final value of 139 mg l^{-1}.

Finally, Fig. 11 showed the fate of 3-methylbutyl acetate in the wines. In Barolo wine it was absent at the beginning of the experiment and it increased, reaching a maximum after one day's irradiation. In Amarone wine, the concentration of this ester decreased during the irradiation with a relative maximum after two days' irradiation. After a week it was absent in the wine. In Brunello wine a sharp decrease of the concentration of 3-methylbutyl acetate was observed.

Also in this case some other compounds, not quantified in this study, were found during the irradiation. The compounds were identified on the basis of their mass spectra. The area per cent is reported in Table 2.

On the basis of the above reported results we can express some comments. The only alcohol determined in this study, 3-methyl-1-butanol, is affected by the irradiation. For Barolo and Amarone, we observed a moderate increase, while for Brunello, a decrease was observed. This is a new result. Our previous reported results on champagne (D'Auria et al., 2003) showed that the alcohols were

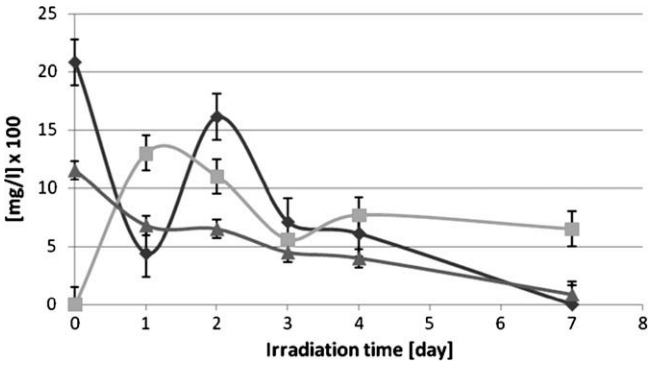

Fig. 11. Photochemical behaviour of 3-methylbutyl acetate under irradiation. [■]: Barolo; [♦]: Amarone; [▲]: Brunello.

not affected during the irradiation. Other authors reported that 2-methyl-1-propanol and 2-methyl-1-butanol decreased in wines during irradiation (Benítez et al., 2003). In the same way, esters were degraded during irradiation. These results are in agreement with our previous reported data on the photodegradation of champagne (D'Auria et al., 2003). On the contrary, Benítez et al. (2003) found an increase of the amount of esters in a red wine.

In red wine one or more components (phenols?) are able to protect esters from photodegradation. In diethyl butanedioate and ethyl hexanoate, octanoate, and decanoate we observed an initial increase of the concentration of the esters in some cases. This initial increase of the amount of esters is in agreement with the results reported in the work of Benítez et al. (2003). These authors noted that "these results are not surprising and can be explained on the basis of their hydrolysis–esterification equilibria". Other authors have reported these increases in wines stored under oxygen (Ramey & Ough, 1980). These results can be explained assuming that the photodegradation in the red wine is inhibited by some components, allowing the increase of the amount of the esters in the wine. When these components are destroyed by light, degradation starts, as in the white wine. On the other hand, the initial increase of the ester amounts could be an effect of the irradiation: light can increase the amount of esters through a Norrish Type II reaction from suitable precursors (Herrmann, 2007). In this case, white wines do not contain those suitable precursors.

The degradation process of the esters is probably an oxidative process catalysed by riboflavin. The riboflavin absorption spectrum in aqueous medium exhibits four structureless peaks centred at 446, 375, 265, and 220 nm with high molar extinction coefficients (>10^4 M^{-1} cm^{-1}). The absorption at 446 nm can occur in our samples, considering that the emission of the lamp at 435 nm is not

Table 2
Unquantified compounds found during the irradiation of Barolo, Brunello, and Amarone wines.

Wine	Compound	Irradiation time (day)					
		0	1	2	3	4	7

completely cut by the glass bottles. Riboflavin is particularly sensitive to UV and visible light and induces both Type I and Type II photosensitised oxidation mechanisms. The former involves the formation of free radicals through hydrogen or electron transfer between riboflavin triplet excited state and the substrates. The semi-oxidised substrate can undergo further oxidation in the presence of oxygen. The Type II process involves the formation of singlet oxygen by energy transfer from triplet excited riboflavin to molecular oxygen. Riboflavin is able to induce decomposition of the esters (D'Auria et al., 2003): this reaction probably occurs through a Type I photosensitised mechanism. In fact, in our knowledge, singlet oxygen is not able to attack aliphatic esters.

In conclusion, we have shown that UV–vis irradiation is able to induce a rapid photodegradation of the volatile compounds in wines. While others authors reported that 2-methyl-1-propanol and 2-methyl-1-butanol decreased in wines during irradiation (Benítez et al., 2003), the degradation of esters was reported only in a previous article on the degradation of champagne (D'Auria et al., 2003). In particular, Benítez et al. (2003) found an increase in the amount of esters in a red wine after irradiation. Red wines seem to be more protected against photodegradation, in particular in the case of aliphatic esters. In fact, our results showed that the amount of esters increases in red wine after 2 h irradiation. Longer irradiation times allowed the degradation of these components. These results can be explained assuming the presence of a protecting agent in the red wine that is destroyed by light and assuming that light can increase the amount of esters through a Norrish Type II reaction from suitable precursors. UV irradiation can act in the bottle: the use of coloured bottles protects the red wine against photodegradation but not sufficiently.

Soybean oil deodorizer distillate
Steroidal hydrocarbons
Modified Soxhlet extraction
Modified silica gel column chromatography

ABSTRACT

In the isolation of squalene from soybean oil deodorizer distillate (SODD), ca. 30% of nonpolar lipid fraction (NPLF) is hydrocarbons (HCs), which can be divided into three main groups, namely aliphatic HCs, steroidal HCs and terpene HCs. The steroidal HCs content of vegetable oil can be used as a means of identifying the oil and therefore, for detecting adulteration. The objective of this study was to isolate the steroidal HCs contained in SODD and identify the individual steroidal HCs. Isolation of steroidal HCs can be achieved in three steps: modified Soxhlet extraction, modified silica gel column chromatography, and distillation. Identification of individual steroidal HCs was accomplished by TLC, GC and GC–MS analyses. The GC chromatogram of steroidal HCs showed five major peaks. Most of the major peaks were identified as derivatives of free sterols. Special attention was needed in order to identify isomers which differ in the position of double bonds and compounds which have three double bonds in the ring system.

1. Introduction

Steroidal hydrocarbons (HCs) are formed in vegetable oils as the dehydration products of Δ^5-phytosterols, because of bleaching with acidic earth and deodorization at high temperature during the refining process. Steradienes and steratrienes are steroidal HCs that have two double bonds and three double bonds, respectively. Their contents in vegetable oils can be used as a means for identifying the oil and therefore, for detecting adulteration (Wretensjö & Karlberg, 2002). The application limit of the steroidal HCs in the virgin olive oil is between 0.01 and 4 mg/kg and that is regulated by the International Olive Oil Council. The limit of 3,5-stigmastadiene and the total steroidal HCs content in virgin olive oil have been fixed at 0.15 and 0.3 mg/kg, respectively and have become a European Economic Community regulation (Toschi, Bendini, & Lercker, 1996).

Soybean oil deodorizer distillate (SODD) is a byproduct of the refining process in obtaining refined soybean oil. Depending on the sources, SODD usually has significantly different characteristics, uses and value. It can be a good raw material for the production of tocopherols, phytosterols and fatty acids, (Nagao et al., 2005; Torres, Torrelo, Seňorans, & Reglero, 2007; Watanabe, Nagao, Hirota, Kitano, & Shimada, 2004; Winters, 1986) and squalene (Gunawan, Kasim, & Ju, 2008). Little information about detailed steroidal HCs in SODD is available in the literature. Cert, Lanzón, Carelli, and Albi (1994) and Verleyen et al. (2002) reported the presence of 3,5-stigmastadiene in olive oil and compared its quantitative analyses using GC and HPLC. Bortolomeazzi, Pizzale, Novelli, and Conte (1996) and Bortolomeazzi, Zan, Pizzale, and Conte (2000) detected the existence of steradienes and steratrienes in olive oil from the occurrence of ions at *m*/*z* 255 and 213 and at *m*/*z* 253 and 211 in the gas chromatography–mass spectrometry (GC–MS) chromatogram, respectively. Mennie, Moffat, and McGill (1994) detected the presence of steroidal HCs at different stages in the refining process of vegetable oils (maize oil, sunflower oil, rapeseed oil, palm oil and soybean oil) and succeeded in identifying 3,5-, 2,5-, 4,6-, 3,5,22-, and -4,6,22- steroidal HCs using thin-layer chromatography (TLC), gas chromatography (GC), and GC–MS. Gunawan et al. (2008) reported that, in the isolation of squalene from SODD, ca. 30–40% of nonpolar lipid fraction (NPLF) is HCs. Their preliminary results suggest that the HCs contained in NPLF can be divided into four main groups, which are aliphatic, steroidal, sesquiterpene and triterpene (squalene) HCs.

A better knowledge of the separation, purification, and chemical composition of steroidal hydrocarbons in SODD will help researchers finding a better utilization of this byproduct. The American Oil Chemists' Society (AOCS) method Cd27-96 (1997) and the International Union of Pure and Applied Chemistry (IUPAC) method pp. M7–M11 (1994) are used to analyze the steradienes content in a vegetable oil by GC. Steradienes were isolated from the unsaponifiable matters by silica gel column chromatography (Toschi et al., 1996). The weak point of these methods is the interferences of steradienes with other hydrocarbons in the chromatogram and this makes it difficult to quantify the exact steradiene amount. In order to determine the exact content and composition of steroidal HCs in

SODD, enrichment, followed by separation of these lipid classes prior to analysis, is important. The objective of this study was to isolate the steroidal HCs contained in SODD and identify the individual steroidal HC.

2. Materials and methods

2.1. Materials and reagents

SODD was donated by Taiwan Sugar Company (Tainan, Taiwan). Stigmasterol (95%) and cholesta-3,5-diene (approx. 95%) standards were obtained from Sigma Chemicals Company (St. Louis, MO). Reagents used in the isolation of steroidal HCs were of industrial grade and those used in the analyses (GC, TLC, GC–MS) were of analytical grade. Silica gel (pore size: 60 Å, 70–230 mesh) was purchased from Silicycle (Quebec, Canada). Analytical TLC silica gel plates (0.25 mm thickness) were obtained from Merck KGaA (Darmstadt, Germany). The silica gel was first activated by heating in the oven at 150 °C for 1–2 h prior to use.

2.2. Isolation of steroidal hydrocarbons from SODD

Fig. 1 shows the flow chart for the isolation of steroidal HCs from SODD. About 20 g of SODD were subjected to a modified Soxhlet extraction (Gunawan et al., 2008) to obtain a nonpolar lipid fraction (NPLF) which is rich in fatty acid steryl esters (FASEs), squalene and other HCs. The NPLF was then subjected to a modified silica gel column chromatography (MSC) to obtain the HCs fraction. Detail of the MSC was described by Gunawan, Ismadji, and Ju (2008). During MSC elution, the HCs fraction was obtained in the first 4 h. Squalene was obtained in the next two and half hours. It is important to obtain the first HCs fraction that is free of any squalene, because squalene and steroidal HCs have similar molecular weight and boiling points. If present together, it is difficult to separate them by distillation. The HCs fraction was distilled at 270–280 °C and 3–5 mTorr to obtain pure steroidal HCs in the residue. The distillate contained aliphatic, sesquiterpene, and a small amount of steroidal HCs. The steroidal HCs obtained in the residue were analyzed by GC, TLC, and GC–MS to identify the individual steroidal HC.

2.3. Gas chromatography (GC) and GC–mass spectrometry (GC–MS) studies

A Shimadzu GC-17A equipped with a split–split injector and a flame ionization detector (FID) was employed for analyzing steroidal HC. The fused silica column used was a DB-5HT, 15 m × 0.32 mm i.d., 0.1 μm film thickness (Agilent Tech. Palo Alto, California, USA). The initial column temperature was 80 °C, which then was raised to 365 °C at 15 °C/min and held for 8 min. The temperature of the injector and detector was 370 °C. For GC–MS analysis, a GC Shimadzu model GC-2010 coupled with MS model QP2010 was used. The fused silica column was a DB-5 ms, 30 m × 0.25 mm i.d., 1 μm film thickness (Agilent Tech. Palo Alto, California, USA). The initial column temperature was 80 °C, which was then raised to 320 °C at 15 °C/min and held for 14 min. The injection was in split mode (split ratio was 1:50) with helium as the carrier gas and with a linear velocity of 30.6 cm/s. The temperature of injector, interface, and ion source were, 250, 250, and 200 °C, respectively. Electron ionization was carried out at 70 eV. The mass spectra were recorded at 1250 scans/s.

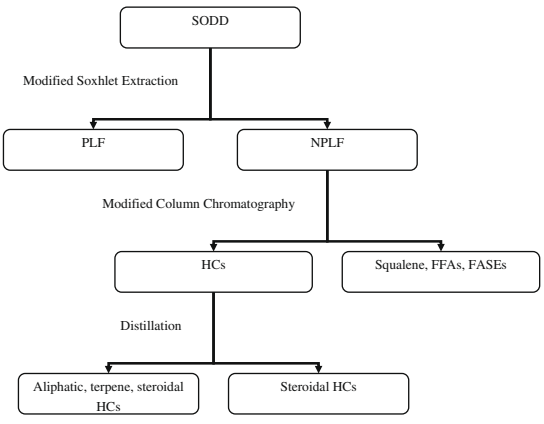

Fig. 1. Schematic diagram of steroidal HCs isolation.

2.4. Thin-layer chromatography (TLC)

The specific reagent used to detect the steroidal HCs spot was made by dissolving 50 mg $FeCl_3.6H_2O$ in 90 ml H_2O, along with 5 ml acetic acid and 5 ml sulfuric acid. The desired spot yields a red–violet colour (Fried, 2003). The mobile phase used in the TLC analyses was HPLC grade *n*-hexane (95% purity). The spot was observed at 366 nm for analytical TLC. The reagent was sprayed onto the TLC plate, and the plate was heated at 90–100 °C until the desired spot appeared.

3. Results and discussion

3.1. Isolation of steroidal HCs

Based on IUPAC and IUBMB recommendations of steroid nomenclature (1989), steroidal HCs and free sterols have similar structures. For free sterols, there is an OH group at position 3. For steroidal HCs, there is no OH group on the skeleton; however, there are double bonds in the ring system. In the bleaching process, activated (acid) earth is added to refined oil to remove colour, odour, other impurities, and residual soap. Deodorization is a high temperature, high vacuum steam-distillation process that is necessary for the removal of volatile flavour and odour compounds to transform the oil into a bland-tasting clear liquid desirable to consumers (Pryde, 1995). These processes may cause the free sterol in soybean oil to undergo isomerization reactions, such as the shifting of the double bond position and also the dehydration of sterol, to produce steroidal HCs (Biedermann, Grob, Mariani, & Schmid, 1996). The reaction scheme is shown in Fig. 2. The dominant products of this dehydration reaction are products B. This is because π-bonding in products B are the strongest bond among other products.

SODD in Taiwan typically contains about 40% FFAs and 17% triacylglycerols (TAGs) (Gunawan, 2008). The elimination of these compounds is crucial for enriching steroidal HCs due to their high contents in SODD. By using modified Soxhlet extraction, we were able to isolate all HCs in the NPLF (5 g NPLF from 20 g of SODD). TLC and HTGC analyses of the polar lipid fraction (PLF) showed the absence of HCs. More than 90% of TAGs and other polar components were concentrated in the PLF after modified Soxhlet extraction. NPLF (3 g), which contains 43.7% HCs, was subjected to modified silica gel column chromatography, using hexane as the mobile phase. All aliphatic, steroidal and sesquiterpene HCs (1.3 g) were obtained in the first fraction after eluting the column with hexane for 4 h. Analysis of this fraction showed that it contained only HCs. The first fraction had a steroidal HCs content of 11.9% (100% recovery). Modified Soxhlet extraction and modified silica gel column chromatography were efficient for the extraction of HCs using hexane as the solvent. Advantages of the current method are: a large sample to silica gel ratio, easy recovery and

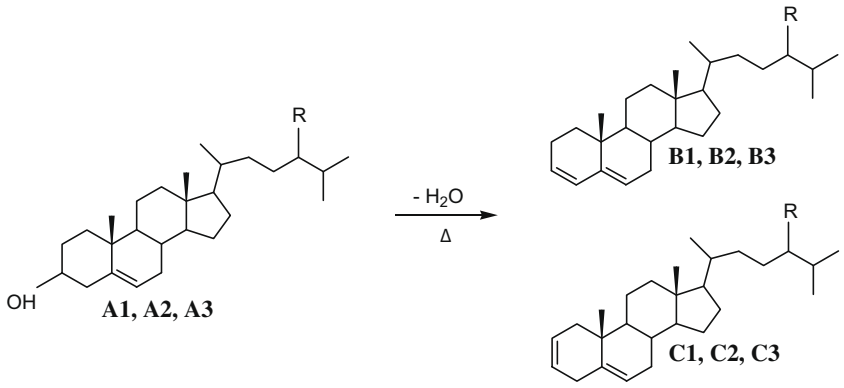

Fig. 2. Reaction scheme for isomerization during the dehydration of free sterol to become steroidal HCs, where 1: R = CH_3; 2: R i = C_2H_5; 3: R = C_2H_5 and one hydrogen removed from carbon 22 and another hydrogen from carbon 23.

reuse of solvents, and simple operational procedure. Distillation was employed for the purification steroidal HCs due to the large differences in the boiling point of steroidal HCs and other HCs. Steroidal HCs (purity 90.8%, recovery 81.3%) were obtained as residue. The quantification of the steroidal HCs is based on external calibration of cholesta-3,5-diene. The chromatogram of the steroidal HCs obtained from distillation showed that there was a small hump, as seen in Fig. 4. The calculation of steroidal HCs content is based on the summation of all resolvable steroidal HC peaks. Although the five resolvable peaks made up only 70.0% of the steroidal HCs, the steroidal HCs obtained had very high purity. This was confirmed on TLC analysis (Fig. 3). Based on the steroidal HCs content obtained in the distillation residue, we can calculate the steroidal HCs content in SODD (Gunawan, 2008), which is (2.46 ± 0.12) wt% of SODD.

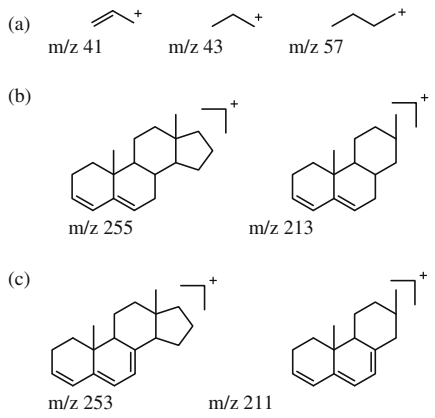

Fig. 4. Common fragmentations of steroidal HC compounds: (a) of its side chains, (b) of its ring system with two double bonds, and (c) of its ring system with three double bonds.

3.2. Identification of steroidal HCs

The identification of steroidal HCs was achieved by comparing results from GC, TLC, and GC–MS analyses. The separation between peaks in the chromatograms of both GC and GC–MS analyses is based on differences in molecular weight and boiling point of the compound that each peak represents. For GC–MS, the fragmentation of certain functional groups can be detected. By applying a standard, that has the same or similar structure as the target compound, on a TLC plate, together with the target compound, and detecting them using a specific reagent; the target compound structure or its functional group can be revealed. In this study, we used these three methods of analysis to identify the individual steroidal HCs in the mixture which was obtained from SODD.

The TLC chromatogram of the residue from distillation shows absence of aliphatic and sesquiterpene HCs (Fig. 3b). The fact that the peaks represent steroidal HCs was supported by the TLC chromatogram (Fig. 3b). TLC analysis showed that the Rf value of the residue spot (lane 2) was 0.75–0.81, which has about the same Rf value of the spot of cholesta-3,5-diene standard (lane 1). When the TLC plate was treated with a ferric chloride reagent, both spots gave a violet colour which is a specific character of compounds with sterol ring structures. The relative retention times (RRT) of the five major peaks, as well as their weight percentages, which are presented in parentheses, in Fig. 3a were 0.94 (5.21%), 0.97 (16.80%), 0.98 (16.05%), 1.00 (25.56%), and 1.01 (5.37%), for peak numbers 1 until 5, respectively. The RRT of a peak was calculated, based on the retention time of that peak divided by the retention time of peak number 4.

From the results of GC and TLC analyses of the sample, as shown in Fig. 3, there are several major peaks with different retention times in the GC chromatogram with each peak representing one particular steroidal HC. However, in the TLC chromatogram, there is only one spot appeared, which means that all steroidal HCs in the sample have almost the same polarity. Further isolation of individual steroidal HCs from the residue of distillation is extremely difficult, if not impossible. The residue was applied for GC–MS analysis to extract information on the structure of individual steroidal HCs. Table 1 shows names of the five major peaks, their

molecular weight (M_W), and mass fragmentations with their relative intensities.

Steroidal HCs have a strong π-bond in the ring system. As ions in mass spectrometry bombard steroidal HCs, side chains will be cleft first, followed by cleavage of the ring system. The mass spectrum of the cholesta-3,5-diene standard can be seen in the NIST database (2007). From this mass spectrum we were able to analyze some common fragmentations. The fragmentation of steroidal HC side chain results in groups, such as CH_3 at m/z 15, $C_3H_5^+$, at m/z 41, $C_3H_7^+$, at m/z 43, $C_4H_9^+$, at m/z 57, Fig. 4a (Johnsson & Dutta, 2003). The breakdown of the ring system in the steroidal HCs results either in groups such as fragmentations at m/z 255 and at m/z 213 (Fig. 4b), which show that the compounds have two double bonds in the ring system or in groups such as fragmentations at m/z 253 and at m/z 211 (Fig. 4c), which show that the compounds have three double bonds in the ring system (Bortolomeazzi, Zan, Pizzale, & Conte, 2000).

HTGC peak 2 shows a base peak at its molecular ion peak (Table 1). This indicates that the structure of the corresponding compound is very stable. Fragmentations at m/z 255 and 213 show that there are two pairs of double bonds inside the ring system. The compound of peak 2 has a M_W of 382; it is derived from the dehydration of campesterol (**A1** in Fig. 2, M_W = 400). Based on its fragmentations at m/z 55, 67, and 81 (Fig. 5), this compound may have double bonds at positions 3 and 5 or 2 and 5. The amount of isomer with double bonds at positions 3 and 5 is much larger than that with double bonds at positions 2 and 5, due to the fact that double bonds at positions 3 and 5 are more stable that those at 2 and 5, (Bortolomeazzi, Pizzale, Novelli, & Conte, 1996; Grob, Biedermann, Artho, & Schmid, 1994; Mennie et al., 1994). The double bonds located at positions 3 and 5 are in a conjugated system, which is why this isomer is more stable than other isomers. There are unique fragmentations at m/z 261 and 274, which are present because of side chain effect (Mennie et al., 1994). Hence, this compound is identified as **B1** in Fig. 2.

The compound of peak 4 has a molecular ion peak at m/z 396, fragmentations at m/z 255 and 213, and high relative intensities of fragmentations at m/z 55, 67, and 81 (Table 1). These show that the compound of peak 4 is **B2** (Fig. 2), which is derived from β-sitosterol (**A2** in Fig. 2, M_W = 414). There are unique fragmentations at m/z 275 and 288, which are present because of the side chain effect (Mennie et al., 1994).

The compound of peak 3 has a molecular ion peak at m/z 394. Fragmentation patterns of its side chain occur at m/z 255, 267, 282, 295, 309, 323, 337, 351 and 365. These fragmentations exist because of one double bond at the side chain that easily moves along the side chain and has a tendency to move to the end of the side chain. High relative intensities occur at fragmentations of m/z 55, 67 and 81 (Table 1). The fragmentations of the side chain appeared in reduced intensity because the side chain in this compound is not stable, due to the double bond effect in the side chain. These facts suggest that the compound of peak 3 is **B3** (Fig. 2), which is derived from stigmasterol (**A3**, M_W = 412).

The compound of peak 1 has a mass spectrum very similar to that of **B2** (Table 1). Their most favourable fragmentations are the same, namely at m/z 43, 55, 67, 81, 213 and 255. The double bond positions of compound of peak 1 and **B2** are in the same ring system. They differ at the positions inside the ring system. The compound of peak 1 is suggested as **C2** (Fig. 2). The fragmentations at m/z 67 and 81 show that the double bond is at position 5. From the fragmentation at m/z 55, the first cyclohexane ring has only one double bond, but its position has yet to be determined. Based on the area percentage ratio of **C2** and **B2**, and the isomerization scheme (Fig. 2), **B2** is more abundant than its isomer **C2**. The fragmentation patterns of **C2** will be quite similar to those of **B2** because the only difference between the structures of **C2** and **B2** are that **C2** and **B2** have double bonds at positions 2 and 3, respectively. The fragmentation of the compound of peak 1 at m/z 55 is the base peak. This fragmentation is the most favoured one because it will result in a stable butadiene fragmentation (Roderbourg & Kuzdal-Savoie, 1979). Isomers with double bounds at positions 2 and 5 may occur, but their percentages are much smaller than those of the 3,5 isomers. Hence GC–MS analyses of minor peaks in Fig. 3a were not carried out in this study.

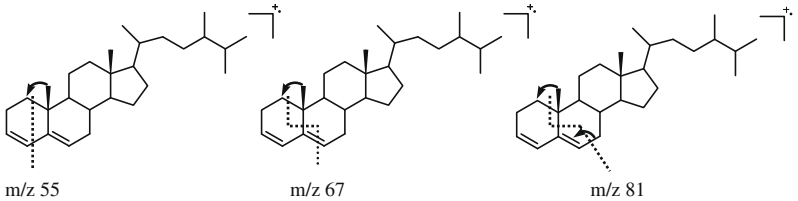

Fig. 5. Unique fragmentations which show double bond at positions 3 and 5, where (...) indicate locations where bonds can be cleft.

The compound of peak 5 has the same molecular ion as that of **B3**, at *m*/*z* 394 (Table 1). However, the compound of peak 5 has fragmentations at *m*/*z* 253 and 211 while **B3** has fragmentations at *m*/*z* 255 and 213. This compound has three double bonds inside the ring system. From the molecular ion and the fragmentations, this compound is derived from the hydroxy derivative of **A2**, (Bortolomeazzi, Zan, Pizzale, & Conte, 1999), not derived from **A3**. The fragmentations at *m*/*z* 55, 67, 81, 93, and 105 suggest that the double bonds are located at positions either 2,4,6, or 3,5,7. Fragmentations at *m*/*z* 55, 95, 107, 119, 131 and 145 suggest that the double bonds are located at positions 3, 8, and 11. This may happen because the impact energy of EI is high enough to cleave bonds in the compound and give enough energy to the compound to undergo isomerization. This is why intramolecular isomerization reactions can occur. Based on the relative intensities of fragmentations mentioned above, the 2,4,6 or 3,5,7-isomer is more abundant than is the 3,8,11-isomer. The 2,4,6- or 3,5,7-isomer forms a conjugated system, so it will result in a more preferable isomer product. Hence, the compound of peak 5 is identified as 24-ethylcholesta-2,4,6-triene.

4. Conclusion

From the analyses of steroidal HC mass spectra, it can be concluded that there are five major steroidal HCs in SODD, which are 24-ethylcholesta-3,5-diene, 24-ethylcholesta-3,5,22-triene, 24-methylcholesta-3,5-diene, 24-ethylcholesta-2,5-diene, and 24-ethylcholesta-2,4,6-triene. Their content in steroidal HCs are 25.6%, 16.0%, 16.8%, 5.21% and 5.37%, respectively, based on their weight percentages in the GC chromatogram. Most of these compounds are derived from the dehydration of free sterol in SODD. There are several minor peaks in the GC chromatogram insert of Fig. 4a. Because the amount of each minor peak is very small, it is more difficult to identify these minor peaks by GC–MS. These minor peaks are believed to be the products of unfavourable dehydration reaction of free sterol or hydroxy derivatives of free sterol.

ABSTRACT

The ultrasonic inactivation kinetics of polygalacturonase (PG) and pectin methylesterase (PME) in tomato juice were studied at a frequency of 20 kHz, amplitude of 65 μm and temperatures between 50 and 75 °C. Thermal treatments at the same temperatures were conducted to separate the effects of heat and ultrasound. The thermal inactivation of PG was described by a fractional conversion model with PG 1 remaining stable, whereas the inactivation of PG by combined ultrasonic and heat treatment (thermosonication) was best described by first order biphasic kinetics, with both PG1 and PG2 inactivated at different rates. The thermal and thermosonication inactivation of PME was described well by first order kinetics. The inactivating effect of combined ultrasound and heat was synergistic. Thermosonication enhanced the inactivation rates of both PME and PG. The inactivation rate of PME was increased by 1.5–6 times and the inactivation rate of PG2 by 2.3–4 times in the temperature range 60–75 °C, with the highest increase corresponding to the lowest temperature.

1. Introduction

One of the most important quality characteristics of tomato-based products is consistency, which is mainly determined by the pectic substances that serve as a continuous phase in which other particles are suspended (Vercet, Sanchez, Burgos, Montanes, & Buesa, 2002). The rheology of tomato-based products is affected by the modification of the pectin structure during processing, either by chemical conversion (β-elimination) or by the action of endogenous pectin-degrading enzymes, namely pectin methylesterase (PME; E.C. 3.1.1.11) and endopolygalacturonase (PG; E.C. 1.2.1.15) (Verlent, Loey, Smout, Duvetter, & Hendrickx, 2004). Following tomato crushing during processing, degradation of pectin by the synergistic action of PME and PG commences, resulting in a large decrease in viscosity. PME catalyses the de-esterification of pectin to pectic acid, with a lower degree of esterification. PG catalyses the hydrolytic cleavage of the α-1,4-hydrolytic bonds in pectin, leading to loss of viscosity and phase separation during storage. The actions of these two enzymes are synergistic as demethylated pectin is the preferred substrate for the catalytic action of PG (Fachin et al., 2003). In conventional tomato processing, these enzymes are fully or partially inactivated by thermal treatment. Two types of processes are commonly employed: hot break and cold break. In the hot break process, the pulp is rapidly heated to temperatures between 95 and 102 °C immediately after or during crushing, leading to complete inactivation of the enzymes and high consistency products. However, the severe heat treatment causes degradation of the colour, flavour and nutritional quality of the juice. In a cold break process, the pulp is heated to 60–71 °C resulting only in partial inactivation of the enzymes and consequently a low consistency product and syneresis during storage since both enzymes are relatively heat-resistant. On the other hand, quality degradation due to the thermal treatment is minimised. In addition, the low viscosity of the juice makes pumping and evaporative concentration easier and reduces fouling of heat exchangers (Vercet et al., 2002).

Increased awareness by consumers of the relationship between diet and health has in recent years created greater impetus and effort for the exploration of alternative food processing technologies, which use minimal heat and preservatives and result in fresh-like products of superior nutritional quality. In this regard, emerging technologies, such as high pressure processing, pulsed electric field and ultrasound, are being investigated by several groups around the world. The application of ultrasound in the food industry has been studied for many years. Ultrasound has two main application areas in the food industry: high frequency (1–10 MHz), low power ultrasound as an analytical tool and low frequency (20–100 kHz) high power ultrasound in food processing. Currently, high-frequency ultrasound is used in non-destructive measurements of a wide range of food process and quality attributes, such as the level in tanks, flow rate and flow profile, composition, particle size,

doi:10.1016/j.foodchem.2009.03.067

emulsion stability and state of aggregation, molecular properties and phase transitions. Low frequency ultrasound can be used in a wide range of applications, such as enhancing oxidation processes, as in the fermentation of wines and spirits, controlling enzymatic reactions (inactivation and activation), stimulation of living cells, as in the fermentation of yoghurt, increasing the efficiency of emulsification and extraction processes, and surface decontamination (Mason, Paniwnyk, & Lorimer, 1996). Inactivation of enzymes by ultrasound is mainly attributed to the mechanical and chemical effects of cavitation, which is the formation, growth and implosion of bubbles (Raviyan, Zhang, & Feng, 2005). Collapse of bubbles is accompanied by extreme localised increase in pressure (50 MPa) and temperature (5000 K) on a micro scale (Sala, Burgos, Condon, Lopez, & Raso, 1995). In addition, ultrasound makes stable cavitating bubbles vibrate, creating shock waves that cause strong shear and microstreaming in the adjacent liquid. Under these extreme conditions, sonication could cause the breakdown of hydrogen bonding and Van der Waals interactions in the polypeptide chains of proteins, including enzymes, leading to the modification of the secondary and tertiary structures. With changes in the secondary and tertiary structure, the biological activity of the enzyme is lost (Zhong, Ming, Su, & Ju, 2004). The extreme localised increase in pressure and temperature also leads to homolytic cleavage of water molecules, generating high energy intermediates, such as hydroxyl and hydrogen free radicals. The free radicals formed may react with some amino acid residues that participate in enzyme stability, substrate binding or catalytic function, with a consequent change in biological activity (Barteri, Diociaiuti, Pala, & Rotella, 2004). Low frequency ultrasound is more effective for enzyme inactivation, in combination with other inactivating methods, such as mild heat and mild pressure. The term thermosonication refers to the combination of ultrasound with mild heat whilst manothermosonication refers to the combination of ultrasound with mild heat and moderate pressure (Sala et al., 1995). The objective of this work was to study the thermosonication inactivation kinetics of pectin methyesterase (PME) and polygalacturonase (PG) in tomato juice so as to determine the potential of using this technology as a milder alternative to 'hot break' processing of tomatoes.

2. Materials and methods

2.1. Tomato juice

Ripened tomatoes (Heinz 3402 variety) were washed with chlorinated water (50 ml of Milton disinfectant solution (Probiotec, VIC, Australia), containing 0.95% w/w sodium hypochlorite added to 4 l water), to remove dirt and other extraneous matter adhering to the fruit. The extraction of tomato juice and separation of the seeds and peel from the pulp were performed using a laboratory scale juice homogeniser (Nutrifaster Australia, Model Ruby 2000, Ruby Co., USA). The juice was transferred to plastic bags in 20 ml portions and was kept frozen at −25 °C for up to 4 weeks prior to thermal and sonication experiments. Thawing was carried out by keeping the samples overnight at 4 °C. The activities of both enzymes were not affected by the freezing and the frozen storage steps.

2.2. Thermosonication and thermal inactivation experiments

The sonication experiments were carried out using a Branson 450 sonifier equipped with a horn with a diameter of 10 mm and length of 60 mm. The treatments were carried out at 20 kHz frequency and 65 μm (acoustic power input = 40 W, with a nominal energy conversion efficiency of 80%) at temperatures ranging from 50 to 75 °C. Twenty kilohertz was used as the ultrasonic treatment frequency since it is the most effective for enzyme inactivation, based on literature (Sala et al., 1995) and experience. The amplitude (65 μm) was the maximum possible with the sonifier used in the study. Samples were pre-heated to the experimental temperature by immersing in a thermostatted water bath maintained at 90 °C for 30–50 s, depending on the experimental temperature, and they were immediately transferred to the water bath in which the experiments were conducted. The time to get to the experimental temperature at the centre of the sample (the slowest heating point) was taken as the temperature equilibration time. The tip of the horn was immersed (40 mm) into 20 ml of tomato juice in a custom-made stainless steel cylindrical container (ID = 22 mm, L = 103 mm). The temperature in the samples during the sonication treatment was maintained at the experimental temperature, using a recirculating water bath at a temperature 3 °C below the experimental temperature. Thermal treatments at the same temperatures were performed to distinguish between the effects of ultrasound and heat treatment, with samples taken at suitable time intervals, depending on the experimental temperature. Timing started after the samples reached the experimental temperature. Following each treatment, the samples were cooled in ice-water for up to 10 min and were immediately analysed or kept at −18 °C until analysis. Frozen samples were thawed by keeping them overnight at 4 °C. Freezing and subsequent thawing did not have any measurable impact on the activity of the enzymes. All experiments were performed in duplicates.

2.3. Enzyme extraction

The extraction of the enzymes was performed using the method of Verlent et al. (2004) after slight modification to use it for tomato juice. The pH of the juice was adjusted to 3.0 using 0.1 M HCl, stirred for 15 min and centrifuged at 8000g and 4 °C for 20 min. The supernatant was discarded and the pellet obtained was suspended in cold distilled water (1:1 [w/v]), its pH adjusted to 3.0 with 0.1 M HCl, stirred for 15 min and centrifuged at 8000g and 4 °C for 20 min. The supernatant was discarded. The pellet was re-suspended in 1.2 M NaCl (1:1 [w/v]) solution to provide the necessary ionic strength for the extraction of PME and PG. The pH of the suspension was adjusted to 6.0 using 0.1 M NaOH. The extraction of the enzymes was conducted by stirring the suspension for 3 h at 4 °C, maintaining the pH constant by the addition of 0.1 M NaOH. This was followed by centrifugation at 10,000g and 4 °C for 20 min. The supernatant obtained was used in PME and PG activity measurements.

2.4. Pectin methylesterase assay

The activity of PME was determined by measuring the release of carboxylic acid per unit time, at 30 °C, titrimetrically. A 200–400 μl (depending on the residual PME activity) portion of crude enzyme extract was mixed with 0.35% apple pectin solution (pH = 7.5, 70–75% degree of esterification, Fluka, Australia) containing 0.125 M NaCl, which was equilibrated to 30 °C. During the hydrolysis of pectin at 30 °C, the pH was maintained at 7.5 by addition of 0.01 N NaOH solution, using an automatic pH-stat titrator (TIM854, Radiometer analytical, France). The consumption of NaOH per unit time was recorded for a 15 min reaction period. The activity of PME is proportional to the rate of NaOH consumption (dV_{NaOH}/dt). Thus, the activity of PME was calculated according to Eq. (1):

$$\text{PME (U/ml)} = \left(\frac{\left(\frac{dV_{NaOH}}{dt}\right) \cdot N \cdot 1000}{V_s} \right) \quad (1)$$

where dV_{NaOH}/dt is the rate of NaOH consumption (ml/min), N is the concentration of NaOH (Normality) and V_s is the sample volume (ml). The activity unit (U) is defined as the amount of enzyme required to release 1 μmol of carboxyl group per minute under the assay condition. All the assays were done in triplicate.

2.5. Polygalacturonase assay

The activity of PG in the samples was analysed according to the method of Gross (1982), which is based on the spectrophotometric determination of reducing sugars formed during the PG-catalysed hydrolysis of polygalacturonic acid at 35 °C. In the PG assay, the reaction mixture consisted of 100 μl of the crude enzyme extract and 300 μl of 0.3% (w/v) polygalacturonic acid solution (Sigma, Australia) in 40 mm sodium acetate buffer (pH = 4.4). The reaction mixture was incubated for 10 min at 35 °C. The reaction was stopped by adding 2 ml of 0.1 M borate solution (pH = 9.0) and 400 μl of 1% cyanoacetamide solution (Aldrich, Australia), which was followed by a 10 min incubation at 100 °C and cooling in ice-water. Following equilibration to room temperature, the absorbance of the sample was measured at 276 nm against a blank, using a UV–visible spectrophotometer (UV-1700 pharmaspec, Shimadzu). The blank consisted of the polygalacturonic acid solution and inactivated enzyme (inactivated by 5 min heating in boiling water bath) treated in the same way as the sample. The amount of reducing sugar produced was calculated from a standard curve prepared using monogalacturonic acid (Fluka, Australia), assuming that the concentration of monogalacturonic acid is proportional to the concentration of reducing sugars. All the assays were performed in triplicate.

2.6. Data analysis

The following equations were used in the analyses of the experimental kinetic data. The inactivation kinetics of enzymes is usually described by a first order reaction (Eq. (2))

$$A = A_o \exp(-kt) \tag{2}$$

where A is enzyme activity at time t, A_o is initial enzyme activity and k is the first order inactivation constant in [min^{-1}].

Eq. (1) can be linearised by logarithmic transformation into

$$\ln\frac{A}{A_o} = -kt \tag{3}$$

The temperature dependence of the inactivation rate constant can be described by the Arrhenius equation, the linearised form of which is given in Eq. (4)

$$\ln(k) = \ln(k_{ref}) - \frac{E_A}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right) \tag{4}$$

where T and T_{ref} are the experimental and reference temperatures (K), E_A is the activation energy (J/mol), R is the universal gas constant (8.314 J/mol K) and k and k_{ref} are the inactivation rate constants (s^{-1}) at T and T_{ref}, respectively.

In food processing, first order reactions are commonly described by D and z values. The decimal reduction time D is the time for 90% reduction in activity A under defined temperature conditions. It can be estimated from the slope of the $\log(A/A_o)$ versus time curve as described in Eq. (5)

$$\log\left(\frac{A}{A_o}\right) = -\frac{t}{D} \tag{5}$$

For first order reactions, the D value is related to the first order reaction rate constant, k, by Eq. (6)

$$D = \frac{2.303}{k} \tag{6}$$

The z value is defined as the temperature increase required for a 10-fold decrease of the D value. The z value is calculated from the negative reciprocal of the slope of $\log D$ versus temperature curve (Eq. (7))

$$\log D = \log D_{ref} - \frac{T - T_{ref}}{z} \tag{7}$$

where D_{ref} is the D value at a reference temperature, T_{ref}.

In cases when several isoenzymes of different stabilities exist together, the inactivation kinetics may be described by either the biphasic model or the fractional conversion model, which are special forms of the first order kinetic model (Fachin et al., 2003). If two isozyme fractions with different stabilities exist together, the inactivation kinetics are described by the biphasic model (Eq. (8))

$$A = A_s \exp(-k_s t) + A_L \exp(-k_L t) \tag{8}$$

where A_s and A_L are activities of the stable and the labile fractions, respectively, and k_s and k_L are the inactivation rate constants of the stable and the labile fractions, respectively.

If there is a residual enzyme fraction whose activity remains constant after a prolonged treatment time, enzyme inactivation kinetics follow a fractional conversion model (Eq. (9))

$$A = A_o + (A_o - A_\infty)\exp(-kt) \tag{9}$$

where A_∞ is the residual activity after prolonged treatment time, *i.e.* the activity of the stable fraction.

All data analysis was performed using table curve 2D software (version 3, Systat software Inc., USA).

3. Results and discussion

3.1. Thermal and thermosonication inactivation kinetics of PME

Fig. 1 shows the thermal inactivation curves of PME. As can be seen, thermal treatment of tomato juice at 50 °C did not cause significant inactivation of PME. At temperature higher than 50 °C, significant inactivation of tomato PME was observed. The thermal inactivation kinetics of tomato PME was described reasonably well by first order inactivation kinetics, as confirmed by visual inspection of the model fitting, as well as the correlation coefficients

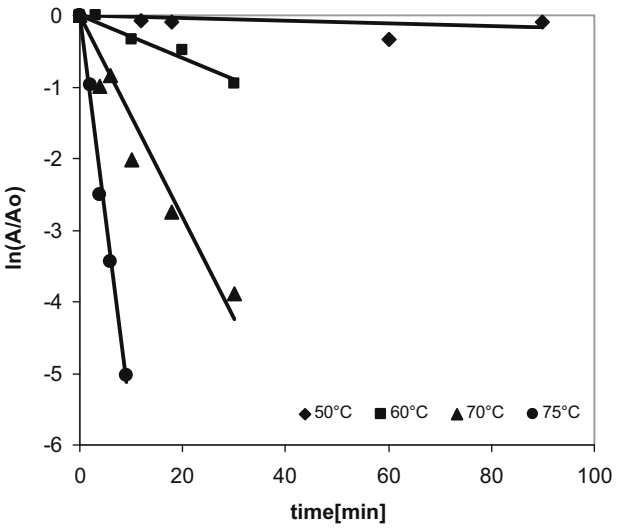

Fig. 1. Thermal inactivation curves of tomato pectin methylesterase in tomato juice.

obtained, which were in the range 0.963–0.998. The inactivation rate constants, estimated by linear regression analysis, varied from 0.026 min^{-1} at 60 °C to 0.57 min^{-1} at 75 °C, with the corresponding *D* values of 89.0 min and 4.04 min, respectively. The activation energy for the thermal inactivation of PME was determined (from the slope of the natural logarithm of the inactivation rate constant versus the reciprocal of the absolute temperature) to be 193 kJ/mol (R^2 = 0.980). The *z* value estimated from the slope of the logarithm of the *D* value versus temperature is 11.4 °C (Table 1).

The thermal inactivation kinetics of tomato PME are well studied. However, there is significant variation in the reported inactivation parameters (Anthon, Sekine, Watanbe, & Barret, 2002; Nath, Rao, & Gupta, 1983; Raviyan et al., 2005; Wu, Gamage, Vilkhu, Simons, & Mawson, 2008). For instance, *D* values ranging from 1.5 to 36.4 min (estimated from the data of Raviyan et al. (2005)), have been reported for inactivation of tomato PME at 70 °C. Our value of 16.2 min falls within this range. The reported *z* values for the thermal inactivation of tomato PME vary from 4.5 to 32 °C (Anthon et al., 2002; Nath et al., 1983; Raviyan et al., 2005). Our *z* value of 11.4 °C is in close agreement with the value of Nath et al. (1983) and Raviyan et al. (2005) who reported *z* values of 9 and 12.3 °C, respectively, for the inactivation of PME. In contrast, Anthon et al. (2002) reported a *z* value of about 5 °C, which indicates much higher temperature sensitivity of tomato PME. Several factors may be responsible for the observed discrepancies in kinetic parameters. Some of the studies were on the inactivation of PME in tomato juice and homogenates (Anthon et al., 2002; Nath et al., 1983; Wu et al., 2008), whilst others were on purified enzyme suspended in buffers at different pH values (Raviyan et al., 2005). In general an enzyme is more stable in an intact tissue or in a homogenate where it is protected by the presence of other materials, such as proteins, carbohydrates and pectins, than in its purified form (Whitaker, 1972). In addition, there are varietal differences in the tomatoes used for the different experiments. Anthon et al. (2002) reported D_{70} values of 7.2 and 10.4 min for the thermal inactivation of PME in tomato juice for cultivars BOS 3155 and CXD-199, respectively, which shows the influence of varietal differences.

The curves for ultrasound-induced inactivation of tomato PME at different temperatures are presented in Fig. 2. In contrast to thermal treatment alone, thermosonication caused significant inactivation of tomato PME at 50 °C. As can be seen in Fig. 2, the inactivation is well described by first order kinetics. The estimated first order kinetic parameters, as well as the activation energy and *z* values, are presented in Table 1. Comparing the kinetic parameters for thermal and thermosonication inactivation, it can be seen that thermosonication substantially enhanced the inactivation kinetics of pectin methylesterase in tomato juice. At 60 °C, an approximately six times increase in the inactivation rate was observed compared to the thermal inactivation rate at the same temperature. This decreased to 1.5 times as the temperature increased to 75 °C. Clearly the observed inactivation effect of heat and ultrasound on PME in this study is synergistic rather than additive. The inactivation rate constants for thermosonication are much higher

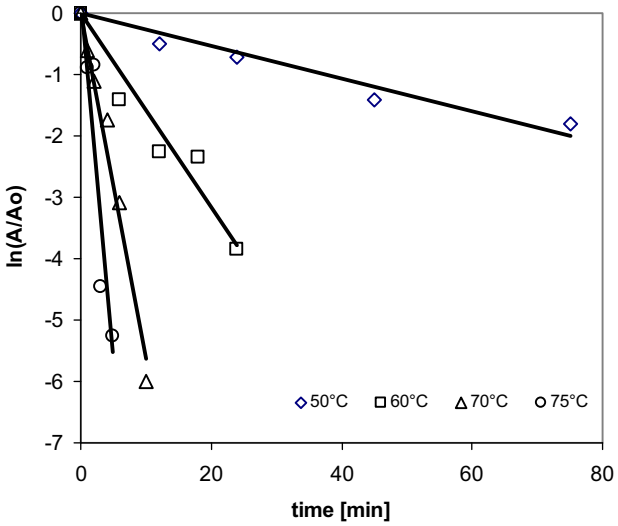

Fig. 2. Ultrasound (20 kHz, 64 μm) inactivation curves of pectin methylesterase in tomato juice at different temperatures.

than what can be obtained from the sum of the thermal inactivation constant and the ultrasound inactivation constant (the inactivation at 50 °C can be considered to be solely due to ultrasound as thermal inactivation at that temperature is insignificant) at a given temperature. For instance, the thermosonication inactivation constant at 60 °C is 0.16 min^{-1}, whilst the additive rate constant would be 0.053 min^{-1} (obtained from the sum of the thermal inactivation rate constant at 60 °C (0.026 min^{-1}) and the ultrasonic inactivation rate constant at 50 °C (0.027 min^{-1}), which shows that the effects of heat and ultrasound are synergistic, with the thermosonication rate constant about three times that of the additive rate constant. This is illustrated in Fig. 3.

A few studies have been reported on the effects of thermosonication on tomato PME (Raviyan et al., 2005; Wu et al., 2008). In all cases, the application of ultrasound resulted in significant enhancement of the rate of tomato PME inactivation, with the degree of enhancement dependent on the media in which the enzyme is suspended and the ultrasound processing conditions. Raviyan et al. (2005) reported a 39- to 374-fold increase in the inactivation rate of crude tomato PME extract under thermosonication (20 kHz, 20 μm, 100 W) compared to just thermal treatment at 61 °C. The effect was dependent on sample volume. The maximum increase in the inactivation rate was observed in the sample with the smallest volume (50 ml), where the acoustic power density (~2 W/ml) and hence the cavitation intensity (0.012 mg/l H_2O_2 generation/min) were the highest. The lowest effect was observed in the sample with the largest volume (200 ml). The efficacy of ultrasound was less at 72 °C with 36- to 84-fold increases in the rate of inactivation for sample volumes ranging from 50 to 200 ml (Raviyan et al., 2005). Significantly less pronounced effects were

Table 1
Estimated kinetic parameters for the inactivation of tomato pectin methylesterase by thermal and thermosonication treatments.

Temperature (°C)	Thermosonication			Thermal treatment		
	k (min^{-1})	D (min)	R^2	k (min^{-1})	D (min)	R^2
50	0.027 ± 0.002[a]	86.5 ± 6.1	0.980	–	–

[a] Standard error.

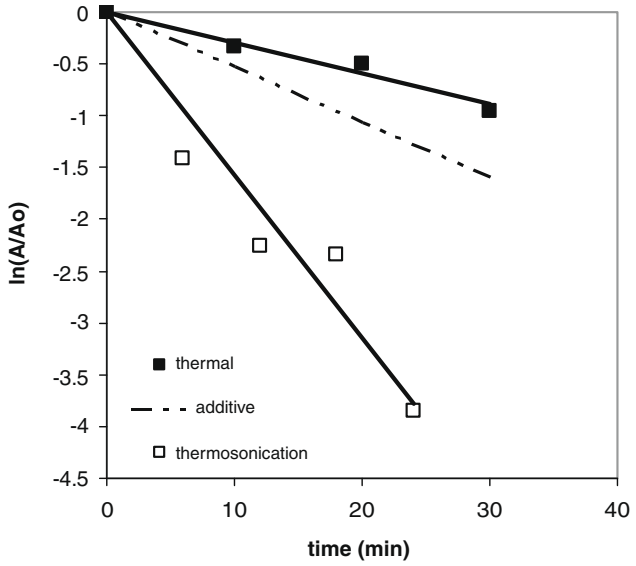

Fig. 3. Inactivation curves for tomato pectin methylesterase at 60 °C illustrating the synergistic effect of heat and ultrasound (determined at 50 °C where no thermal effect was observed).

reported for the inactivation of this enzyme in tomato juice under thermosonication (24 kHz, 25–75 μm) with about 2.3- and 2.1-fold decreases in *D* value at 55 and 65 °C compared to thermal treatment at the same temperatures, whilst the effect of ultrasound diminished as the temperature increased to 70 °C (Wu et al., 2008). As in the case of Wu et al. (2008), we observed much less enhancement in the inactivation of PME in tomato juice compared to what was reported by Raviyan et al. (2005) for the inactivation of tomato PME in buffer. One factor may be the much higher viscosity of tomato juice compared to aqueous buffer, resulting in less cavitation in the juice compared to the buffer and less pronounced effect of ultrasound on the enzyme (Vercet et al., 2002). The different components of the juice, including pectin, may also have a protective effect on the enzyme (Whitaker, 1972). Another important factor is difference in acoustic power input density and sonotrode geometry (Sala et al., 1995). The differences in acoustic power input density and sonotrode geometry may also account for the difference between our result and that of Wu et al. (2008). The power input density in our study was about 1.6 W/ml compared to approximately 0.48 W/ml in the case of Wu et al. (2008).

The combined effect of ultrasound, heat and mild pressure (manothermosonication) on the activity of tomato PME has also been investigated in a buffer system (Lopez, Vercet, Sanchez, & Burgos, 1998) as well as in tomato juice (Vercet et al., 2002). Lopez et al. (1998) studied the inactivation kinetics of purified tomato PME in citrate buffer (pH = 4.0) during ultrasonication (20 kHz, 117 μm) in a continuous system performed at a pressure of 200 kPa and temperature of 62.5 and 37 °C. Manothermosonication at 37 °C inactivated the enzyme (*D* = 4.3 min), whereas heating under the same conditions did not affect the activity of the enzyme. At 62.5 °C, a synergistic effect was observed between heat and ultrasound with the *D* value reduced 52.9 times compared to thermal inactivation (45–0.85 min). Vercet et al. (2002) compared the effects of a manothermosonication (20 kHz, 200 kPa, 117 μm, 70 °C) treatment of tomato juice for 1 min on tomato PME with a thermal treatment at the same temperature. Complete inactivation of PME was observed following manothermosonication, whereas only 38% inactivation was achieved by thermal treatment. In our study, only about 43% inactivation of PME was observed by thermosonication after a 1 min treatment at 70 °C (calculated from the kinetic data) and atmospheric pressure. The higher pressure and ultrasound amplitude (114 μm compared to 64 μm) may have contributed to the observed higher inactivation of PME in the study of Vercet et al. (2002). High pressure, of the order of magnitude that is commonly applied in manothermosonication studies (⩽300 kPa), does not inactivate enzymes. In general, a pressure higher than 300 MPa is required for irreversible inactivation of enzymes (Hendrickx, Ludikhuyze, Vanden Broeck, & Weemaes, 1998). However, high pressure improves the efficiency and violence of bubble implosion and free radical production, since the vapour pressure of water in the bubbles is reduced (Sala et al., 1995; Vercet, Lopez, & Burgos, 1998).

The inactivation effect of ultrasound over and above thermal treatment, in this study, decreased as the temperature increased from 60 to 75 °C. This is also manifested in the lower activation energy (130 kJ/mol) and higher *z* value (16.6 °C) compared to the thermal treatment alone (see Table 1). Similarly, a higher *z* value (40 °C) was estimated for the inactivation of tomato PME in buffer by manothermosonication than for thermal treatment alone (*Z* = 5 °C), indicating that the synergistic effect between sonication and heat decreases with temperature (Lopez et al., 1998). This is attributed to the increased vapour pressure of water making the collapse of bubbles and cavitation less violent at higher temperature. Increased temperature results in increased formation and growth of bubbles as vapour pressure increases and tensile strength decreases. However, the violence of collapse decreases as high vapour pressure acts as a cushion. In addition, increased temperature results in decreased viscosity, resulting in decreased violence of implosion (Sala et al., 1995). Such decrease in the efficacy of ultrasound with increase in temperature has also been observed in the studies cited earlier. For instance, in the study of Raviyan et al. (2005), the increase in the rate of inactivation of tomato PME decreased to 84-fold at 72 °C compared to 374-fold at 61 °C for the 50 ml sample. Wu et al. (2008) did not observe any increase in the inactivation rate of PME in tomato juice by ultrasonication at 70 °C.

Low frequency ultrasound causes the inactivation of enzymes through various effects, including the localised extreme increase in temperature and pressure accompanying the collapse of cavitation bubbles, strong shear force and shock waves created by stable cavitating bubbles and the generation of free radicals that oxidise amino acid residues that participate in the stability and catalytic activity of enzymes (Barteri et al., 2004; Sala et al., 1995; Zhong et al., 2004). Cavitation-induced high shear stress and pressure have been reported to cause the dissociation of oligomeric enzymes, such as glucose-6-phosphate dehydrogenase (Rachinskaya, Karasyova, & Metelitza, 2004) and human butyrylcholinesterase (Froment, Lockridge, & Masson, 1998) and breakdown of polypeptide chains in enzymes such as trypsin (Zhong et al., 2004). Moreover, several studies suggest that free radicals, generated during sonication, play a major role in enzyme inactivation. Barteri et al. (2004) studied the inactivation of fumarase by ultrasound. They observed progressive oxidation of the cysteine residues and aggregation of the enzyme, from which they concluded that the inactivation of the enzyme was due to the formation of disulfide-linked aggregates, formed as a result of the oxidation of the cysteine residues by the free radicals generated during sonication (Barteri et al., 2004). The involvement of free radicals has also been reported in the ultrasonic-induced inactivation of trypsin (Zhong et al., 2004), horse radish peroxidase (Grintsevich, Adzerikho, Mrochek, & Metelitza, 2001), catalase (Potapovich, Eremin, & Metelitza, 2003), glucose-6-phosphate dehydrogenase (Rachinskaya et al., 2004), urease (Tarun, Adzerikho, & Metelitsa, 2003) and α-amylase (Liu, Chen, & Chou, 2003). The creation of large interfacial area by ultrasound has also been shown to contribute to the inactivation of trypsin (Zhong et al., 2004) and lactate dehydrogenase (Niven, Ip,

Mittelman, Prestrelski, & Arakawa, 1995), since that disturbs hydrophobic interaction and hydrogen bonding which play major roles in the stability of proteins (Zhong et al., 2004). The inactivation of tomato PME by ultrasound in this study may have been caused by one or more of the above-mentioned mechanisms. Amino acids, such as tryptophan, tyrosine, histidine and cysteine, are particularly susceptible to degradation by hydroxyl and superoxide free radicals (Davies, Delsignore, & Lin, 1987). Tryptophan and tyrosine residues are present at the active site of tomato PME (D'Avino, Camardella, Christensen, Giovane & Servillo, 2003). Moreover, tomato PME is stabilised by cysteine residues which are involved in disulfide bridges in the native enzyme (Markovic & Jornvall, 1992). Thus, free radical-mediated mechanisms may play significant roles in the ultrasonic inactivation of tomato PME.

3.2. Thermal and thermosonication inactivation kinetics of polygalacturonase

As in the case of PME, thermal treatment at 50 °C did not have a significant effect on the activity of polygalacturonase in tomato juice (see Fig. 4). At temperatures between 50 and 75 °C, thermal treatment resulted in partial PG inactivation. The inactivation kinetics was well described by a fractional conversion model, indicating that part of the tomato PG remained stable after prolonged treatment under these conditions. The existence of thermolabile and thermostable PG fractions in tomato is well documented. Tomato PG is reported to exist in three isoforms: PG1, PG2A and PG2B. PG2A and PG2B differ mainly in their degree of glycosylation and are usually grouped together as PG2 since they have the same thermostability. PG2 is heat-labile and is totally inactivated after a 5 min treatment at 65 °C. PG1 is a dimer formed from a structural association of PG2 with a heat-stable glycoprotein β-subunit, which confers heat-stability on it (Fachin et al., 2003; Pogson & Brady, 1993). Thus, only the labile form of PG (PG2) was inactivated under the conditions in this study. Other studies have also reported fractional conversion of polygalacturonase under mild temperature conditions. The thermal inactivation kinetics of polygalacturonase in tomato juice in the temperature range between 55 and 70 °C are described by a fractional conversion model (Fachin et al., 2003). Under higher temperature conditions, biphasic inactivation curves are commonly observed, whereby the two isozyme fractions are inactivated at different rates (Anthon et al., 2002; Fachin et al., 2003; Pogson & Brady, 1993).

The kinetic parameters for the thermal inactivation of tomato PG, estimated from non-linear regression analysis of our data, are presented in Table 2. The inactivation rate constants ranged from 0.085 min^{-1} at 60 °C to 0.57 min^{-1} at 75 °C, which is equivalent to a D value ranging from 11.7 to 1.75 min. As in the case of tomato PME, there is a wide variation in the estimated kinetic parameters for the inactivation of tomato PG in the literature. A D value of 3.99 min has been reported for the thermal inactivation rate of the labile faction of partially purified PG in sodium acetate buffer (pH = 4.4) at 70 °C (Fachin, Loey, Indrawati, Ludikhuyze, & Hendrickx, 2002), whilst a D value of 0.78 min was observed in tomato juice (Fachin et al., 2003). This is not unusual, since the stability of enzymes depends on several factors, including their source, pH and medium composition. The activation energy for the thermal inactivation of PG2 was estimated from linear regression of the natural logarithm of the inactivation constant versus the reciprocal of the absolute temperature (R^2 = 0.954) and is presented in Table 2. Our value of 116 kJ/mol is less than most published values. In the literature, activation energy values of 208–228 kJ/mol have been reported for the thermal inactivation of PG2 in tomato juice (Anthon et al., 2002; Fachin et al., 2003) whilst an activation

Table 3
Estimated kinetic parameters (k_L, k_s: inactivation rate constants of labile and stable fractions, respectively, A_L, A_s: % labile and stable fractions, respectively) for the inactivation of tomato PG by thermosonication (20 kHz, 65 μm).

Temperature (°C)	k_L (min^{-1})	k_s (min^{-1})	A_L (%)	A_s (%)	R^2
60	0.34 ± 0.16[a]	0.039 ± 0.008	56.3 ± 10.7	43.7 ± 10.7	0.998
70	0.82 ± 0.09	0.050 ± 0.009	62.5 ± 4.2	37.5 ± 4.2	0.998
75	1.31 ± 0.26	0.061 ± 0.02	64.0 ± 7.0	36.0 ± 6.5	0.997
E_A (kJ/mol)	70.0 ± 7.5 (R^2 = 0.988)	28.0 ± 3.5 (R^2 = 0.984)			

[a] Standard error.

energy value of 407 kJ/mol has been reported for the inactivation PG2 in partially purified PG (Fachin et al., 2002). The thermostable PG1 fraction (A_∞) was estimated to be about 30% of the total PG activity (see Table 2). Pogson and Brady (1993) observed 21% and 35% PG1 in Heinz 4236 and Heinz 4148 tomato varieties, which are close to our estimated value for Heinz 3402 tomatoes. Published data for the relative proportion of PG1 vary between 14% and 55% (Fachin et al., 2003; Pogson & Brady, 1993). According to Pressey (1986), the proportion of PG1 depends on the pH of the extraction solution, the concentration of sodium chloride, the amount of active pectin methylesterase and whether ammonium sulphate precipitation is used for protein concentration. If active PME is present in the system, demethylation of pectin occurs during the extraction. Therefore, some of the cationic PG1 will be bound to the anionic demethylated pectin, leading to lower proportions of PG1 in the final extract (Pressey, 1986).

The curves for the ultrasonic inactivation of PG at various temperatures are presented in Fig. 5. Ultrasound treatment caused inactivation of PG in the temperature range 50–75 °C. At 50 °C only the labile PG fraction (PG 2) was inactivated, as may be deduced from the curve. As in the case of thermal inactivation, the inactivation rate was described by a fractional conversion model. The kinetic parameters for ultrasound inactivation of PG at 50 °C are presented in Table 2, together with the thermal inactivation parameters. As in the case of thermal treatment, the stable PG 1 fraction was estimated to be about 30%. At higher temperatures, biphasic inactivation was observed, with both PG1 and PG2 inactivated at different rates. The biphasic inactivation kinetics parameters estimated from non-linear regression analysis of the data are given in Table 3. Thermosonication enhanced the inactivation kinetics of PG2 4-fold at 60 °C (compare Tables 2 and 3). The enhancement decreased to 2.3-fold at 75 °C. As in the case of PME, a lower activation energy was observed for the thermosonication inactivation of PG2 (70 kJ/mol) compared to that of thermal inactivation (116 kJ/mol). The proportion of the stable fraction PG1 was estimated to be around 40%.

The biphasic inactivation of PG can be attributed to the synergistic action of heat and ultrasound, as neither treatments alone [heat (50–75 °C) or ultrasound (50 °C)] caused inactivation of PG1 under the studied conditions. The synergy between the two is also clear from the thermal and thermosonication inactivation h rate constants for the inactivation of the thermolabile fraction, PG2. Under all temperature conditions, the inactivation rate constants for thermosonication are much higher than those that can be obtained from simple additive effects of the two treatments (see Tables 2 and 3). As mentioned in the discussion on PME, sonication can cause the breakdown of oligomeric proteins into their subunits. This would make it particularly effective for the inactivation of PG1, which is stabilised by its structural association with the heat-stable β-subunit. During thermosonication, sonication may have caused the dissociation of PG1 into the heat-labile PG2 and the heat-stable β-subunit, followed by the inactivation of PG2 by the synergistic effect of heat and sonication.

There are no reports in the literature on the effects of thermosonication on the inactivation kinetics of tomato polygalacturonases. A study on the effect of manothermosonication reported synergistic effects of heat and ultrasound for the inactivation of purified tomato PG1 and PG2 in buffer (Lopez et al., 1998). Manothermosonication (20 kHz, 117 μm, 200 kPa) enhanced the inactivation of PG1 85.8 times at 86 °C whilst the inactivation of the heat-labile PG2 was enhanced 26.3 times at 52.6 °C compared to thermal treatment. Manothermsonication also caused substantial inactivation of the two isozymes at 37 °C (D = 3.17 min and 2.23 min for PG1 and PG2, respectively), whereas thermal treatment did not have any effect (Lopez et al., 1998). Another study on the effect of manothermosonication on the activity of PG in tomato juice showed that manothermosonication (20 kHz, 117 μm, 200 kPa) at 70 °C caused 62% inactivation of PG in 1 min whilst thermal treatment under comparable conditions did not have any effect on the enzyme (Vercet et al., 2002).

4. Conclusions

Our result showed that thermosonication (20 kHz, 75 μm) processing of tomato juice at 75 °C causes almost complete inactivation of PME and about 72% inactivation of PG after 4 min. Under these conditions, the residual PG activity is unlikely to cause substantial pectin degradation as the preferred substrate for PG is demethylated pectin, which would be less available as PME is almost completely inactivated. The inactivation effect of sonication can also be further enhanced by optimisation of the processing conditions, such as by increasing the ultrasound power intensity, changing the sonotrode geometry and applying pressure in a batch or continuous system, which will be the subject of our future research work. Thermosonication has already been shown to significantly improve the rheological properties of tomato products (Wu et al., 2008). Our current work shows the separate effects of temperature, sonication and thermosonication on PME and PG, the enzymes which determine the rheological characteristics of tomato products. This provides scientific and technological bases to further develop thermosonication as an alternative to the tomato 'hot break' process.

Acknowledgments

We thank the Victorian Department of Innovation Industry and Regional Development for funding the infrastructure through the science and technology infrastructure (STI) grant. We would also like to thank Piotr Swiergon for his help with the experimental device.

Anacardium occidentale L.

ABSTRACT

The influence of organic acid and heating treatments on carotenoid degradation on a simulated cashew apple juice was assessed by high performance liquid chromatography coupled with a photodiode array and mass spectrometry detectors. A total of nineteen *carotenoids* were separated in unheated simulated cashew apple juice, with all-*trans*-β-cryptoxanthin and all-*trans*-β-carotene as the major ones. As a consequence of heating, five xanthophylls disappeared, whereas two new *cis* isomers and five epoxide or furanoid-derivatives were formed and the levels of all *cis* isomers increased. In addition, 12′-apo-β-carotenal was formed at 90 °C. Two oxidation compounds (12′-apo-β-carotenal and 5,6-epoxy-β-cryptoxanthin) were formed after β-cryptoxanthin heating at 90 °C in an aqueous-based system. In all systems, the amounts of total carotenoids lost were not compensated by those formed. These facts indicated that isomerisation and oxidation to both coloured and non-coloured compounds were the main reactions occurring during heating of carotenoids in aqueous-based and juice systems.

1. Introduction

In the last decade, the Brazilian juice industry showed rapid and intensive growth, mainly due to the increasing national and international interests in fruit juices, since these products have been strongly associated with health benefits. The global juice market registered a growth of about 8%, which is the equivalent of US$ 2 billion in sales in 2006–2007 (ACNielsen, 2008; Cooper, 2004), with Brazil producing 472,187,000 litres of fruit juice in 2007 (Abir, 2008).

The cashew apple (Fig. S1 from Supplementary data) is a tropical fruit native to Brazil, principally grown in the North and Northeast regions. The pseudo-fruit, known as the cashew apple, is the part of the tree that connects it to the cashew nut, the real fruit, a well-known product worldwide. The pseudo-fruit is commercially exploited mainly as frozen pulp, juice, and nectar. Carotenoids are the main pigments responsible for the colour of cashew apple fruits and juices, the major ones being β-cryptoxanthin in red and yellow cashew apple fruits from the hottest Northeast region of Brazil, and β-carotene in the same fruits from the Brazilian Southeast region (Assunção & Mercadante, 2003a, 2003b).

Carotenoids are highly susceptible to degradation by external agents, such as heat, low pH, and light exposure, promoting changes of colour due to the rearrangement or formation of degradation compounds such as *cis*-isomers, epoxides, short chain products, and in some cases, volatile compounds (Mercadante, 2008a). Besides colour fate, carotenoid oxidation compounds are also supposed to have detrimental effects *in vivo*, through the induction of oxidative stress, exertion of cytotoxic and genotoxic effects, and inhibition of gap junction intercellular communications (Caris-Veyrat, 2008; Hurst, Saini, Jin, Awasthi, & van Kuijk, 2005; Siems et al., 2005).

References to thermal instability of carotenoids are found in the pioneering work of Zechmeister (1944), with emphasis on the *trans*- to *cis*-isomerisation. This topic has been intensively investigated and striking examples are found in literature (Aman, Schieber, & Carle, 2005; Dhuique-Mayer et al., 2007; Doering, Sotiriou-Leventis, & Roth, 1995; Kuki, Koyama, & Nagae, 1991; Rios, Borsarelli, & Mercadante, 2005).

On the contrary, the effect of acid on carotenoids was reported in fewer studies. Carotenoids were found to be mono and diprotonated by nitric acid and moderately strong acids, such as trichloroacetic and trifluoroacetic acids (Mortensen & Skibsted, 2000). Organic acids liberated during the processing of fruit juices are strong enough to promote rearrangements of 5,6-epoxide groups to 5,8-furanoid groups of carotenoids (Assunção & Mercadante, 2003a; Dhuique-Mayer et al., 2007; Meléndez-Martínez, Vicario, & Heredia, 2007a).

In a food system, the mechanisms involved in the nutrient degradation are complex, and therefore, insights into the mechanism of carotenoid thermal degradation can be derived from model systems, which are more easily controlled than foods and the formation of initial, intermediate, and final compounds can be

doi:10.1016/j.foodchem.2009.03.071

more easily monitored (Mercadante, 2008a). In addition, considering that *cis* isomers are expected to be formed, analysis should be done by high performance liquid chromatography (HPLC) connected at least to a photodiode array detector (PDA). The carotenoid separation should be carried out on a C_{30} column, since among reversed-phase columns, the C_{30} is the only one capable of resolving peaks of geometrical isomers at the same position but at opposite ends of asymmetrical carotenoids, such as β-cryptoxanthin (Emenhiser, Sander, & Schwartz, 1995; Mercadante, 2008b).

Thus, the objectives of this study were threefold: (1) to separate and identify, by HPLC–PDA connected to mass spectrometry (MS/MS), the non-volatile degradation compounds derived from carotenoids during the heating of a simulated cashew apple juice; (2) to verify the influence of organic acids, at the same concentration as that found in a juice, on the carotenoid degradation; and (3) to indicate the main carotenoid thermal degradation pathways in such systems. In addition, for the first time, thermal degradation of β-cryptoxanthin in an aqueous-based system was evaluated.

2. Materials and methods

2.1. Samples and standards

Red cashew apple fruits (*Anacardium occidentale* L.), from the Petrolina region (Pernambuco State, Northeast region, Brazil), were acquired in a supermarket in Campinas city (São Paulo State, Brazil), during their harvest season (October, 2006) and kept frozen at −18 °C until carotenoid extraction.

Standards of all-*trans*-lutein, all-*trans*-zeaxanthin, all-*trans*-β-cryptoxanthin, all-*trans*-β-carotene, 9-*cis*-β-carotene, 13-*cis*-β-carotene, all-*trans*-α-carotene, β-apo-8′-carotenal, β-apo-10′-carotenal, and β-apo-12′-carotenal were donated by DSM Nutritional Products (Basel, Switzerland), with purities ranging from 95.0% to 99.9%, as determined by HPLC–PDA.

2.2. Simulated cashew apple juice

The carotenoids were extracted with acetone, transferred to petroleum ether/diethyl ether, saponified overnight at room temperature with 10% methanolic KOH, followed by alkali removal and concentration on a rotary evaporator (<35 °C). Due to the high oil content in the cashew apple peel, it was necessary to physically remove the oil, as follows: prior to ether transference, the carotenoid extract was kept in the freezer at −18 °C for 2 h, followed by filtration using cold glassware and washing with cold acetone (De Rosso & Mercadante, 2007a). The dried cashew apple carotenoid extract was flushed with nitrogen (99.0%) and kept at −35 °C.

The cashew apple extract, containing about 200 μg carotenoid in 5 ml of ethanol, was added to 25 ml of Milli-Q water (Millipore, Billerica, USA) acidified at pH 3.8 with *ca.* 300 μl of 0.5 M citric acid (simulated juice). The acid concentration allowed the addition of less than 1% of the total system volume to achieve the pH value found in commercial cashew apple juice.

The simulated cashew apple juice was distributed into glass tubes, sealed and heated for 1, 2, and 4 h at 60 °C and 90 °C in a water bath. After each time, tubes were taken from the bath and immediately cooled in current water.

In order to confirm whether the thermal degradation compounds were derived from β-cryptoxanthin or β-carotene, 100 μg of synthetic all-*trans*-β-cryptoxanthin was used to elaborate systems as described above, with and without acid. These systems were monitored by HPLC–PDA–MS/MS and by a UV–visible diode array spectrophotometer (Agilent, model 8453, Palo Alto, USA). In addition, UV–vis spectra of the β-cryptoxanthin acidified system were recorded at room temperature during 120 min.

2.3. Carotenoid analysis in the simulated juice

The carotenoids were exhaustively extracted from the simulated juice with ethyl acetate, by vortexing (Phoenix, model AP 56, Araraquara, Brazil) during 1 min. The organic phases were transferred to a separatory funnel, washed with water until neutral pH was obtained, and dried under a N_2 stream. Prior to HPLC-PDA-MS/MS analysis, the carotenoid extract was completely solubilised in methanol/methyl *tert*-butyl ether (MeOH/MTBE) (70:30) and filtered through Millipore membranes (0.22 μm).

The carotenoids were analysed in a Shimadzu HPLC (Kyoto, Japan), connected in series to a PDA detector (Shimadzu, model SPD-M20A) and a mass spectrometer with an ion-trap analyser and atmospheric pressure chemical ionisation (APCI) source from Bruker Daltonics, model Esquire 4000 (Bremem, Germany). The UV–visible spectra were obtained between 250 and 600 nm, and the chromatograms were processed at 286, 347, and 450 nm. The MS parameters were set as previously reported (De Rosso & Mercadante, 2007a). For all samples, carotenoid separation was carried out on a C_{30} YMC column (3 μm, 250 × 4.6 mm id.) (Waters, Wilmington, USA) using as mobile phase, a linear gradient of MeOH/MTBE from 95:5 to 70:30 for 30 min, to 50:50 for 20 min. To verify the presence of degradation compounds with low molecular weight which may elute in the dead volume using the mobile phase described above, another linear gradient of MeOH/MTBE/H_2O from 85:5:10 to 95:5:0 for 30 min, to 89:11:0 for 25 min, to 75:25:0 for 40 min, to 50:50:0 for 60 min was used. Independent of the mobile phase, the flow rate was set at 0.9 ml/min and column temperature was kept at 22 °C.

The carotenoids were identified considering the combined information obtained from the following parameters: elution order on the C_{30} HPLC column, co-chromatography with authentic standards, UV–visible spectrum characteristics (λ_{max}, spectral fine structure (% III/II), and *cis* peak intensity (% A_B/II)), and mass spectrum (molecular ion and fragments) compared to standards and data available in the literature (Britton, Liaaen-Jensen, & Pfander, 2004; De Rosso & Mercadante, 2007a, 2007b; Enzell & Back, 1995; Mercadante, Steck, & Pfander, 1999).

The carotenoids were quantified using external calibration curves for all-*trans*-lutein, all-*trans*-zeaxanthin, all-*trans*-β-cryptoxanthin, all-*trans*-β-carotene, and all-*trans*-α-carotene with a minimum of five concentration levels. Neoxanthin, neochrome, antheraxanthin, mutatoxanthin, *cis*-violaxanthin, luteoxanthin, and auroxanthin were quantified using the curve of lutein; the β-cryptoxanthin epoxides, 12′-apo-β-carotenal, using the curve of all-*trans*-β-cryptoxanthin; α-cryptoxanthin and zeinoxanthin by the curve of all-*trans*-α-carotene; β-carotene epoxides by the curve of all-*trans*-β-carotene; and the *cis*-isomers of lutein, β-cryptoxanthin and β-carotene using the curve of the corresponding all-*trans*-isomers. Total carotenoid content was calculated considering all identified peak areas.

3. Results and discussion

3.1. Identification of carotenoids

The carotenoids separated in all systems were identified based on the combined information obtained from chromatographic elution, co-chromatography with standards, UV/visible and mass spectra characteristics (Table 1). Since a detailed description of carotenoid identification using the above information was already reported by De Rosso and Mercadante (2007a, 2007b), only considerations regarding the carotenoids not identified in the previous reports were discussed below.

Table 1
Chromatographic, UV–Vis and mass spectra characteristics of carotenoids detected in the β-cryptoxanthin system and in the simulated cashew apple juice.

Peak[a]	Carotenoids	t_R range (min)[b]	λ_{max} (nm)[c]	III/II (%)	A_B/II (%)	$[M + H]^+$ (m/z)	MS/MS (m/z)
1	12′-Apo-β-caroten-12′-al	7.8–7.8	421–423	0	0	351	333 [M + H − 18], 295, 227 [M + H − 18 − 106], 209, 177, 119
2	*cis*-Neoxanthin	8.4–8.4	326, 415, 437, 468	72	0	601	583 [M + H − 18], 565 [M + H − 18 − 18], 547 [M + H − 18 − 18 − 18], 509 [M + H − 92], 221
3	Neochrome	9.6–10.0	399, 421, 447	80	0	601	583 [M + H − 18], 565 [M + H − 18 − 18], 547 [M + H − 18 − 18 − 18], 221

[a] Numbered according to Figs. 1 and 3.
[b] Retention time on the C_{30} column.
[c] Linear gradient of MeOH/MTBE.
[d] Not calculated.
[e] Not detected.
[f] Tentatively identified as 15-*cis*-β-cryptoxanthin or 15′-*cis*-β-cryptoxanthin.
[g] Tentatively identified as 13-*cis*-β-cryptoxanthin or 13′-*cis*-β-cryptoxanthin.
[h] Tentatively identified as 9-*cis*-β-cryptoxanthin or 9′-*cis*-β-cryptoxanthin.

Peak 1 was identified as 12′-apo-β-caroten-12′-al, considering the lack of spectral fine structure and λ_{max} at 423 nm, early elution order (7.8 min), a protonated molecule at m/z 351, and co-elution with an authentic standard. The MS/MS spectrum showed fragments at m/z 333, due to the loss of water from the protonated molecule, and at m/z 227 resulting from the combined elimination of water and xylene. The 12′-apo-β-caroten-12′-al was detected in both simulated cashew apple juice and all-*trans*-β-cryptoxanthin systems only after 1 h of heating at 90 °C, suggesting that this apocarotenoid was derived from the thermal degradation of all-*trans*-β-cryptoxanthin (peak 18).

Peak 4 was identified as auroxanthin by its characteristic λ_{max}, high spectral fine structure and a protonated molecule at m/z 601. The second order tandem MS spectrum showed fragments due to consecutive losses of one (583 u), two (565 u), and three (547 u) water molecules, elimination of toluene (509 u), and toluene plus water (491 u). The presence of an epoxide and/or furanoid group in the 3-hydroxy-β-ring was confirmed by the presence of a fragment at m/z 221.

Antheraxanthin (peak 7) was identified considering the UV–visible and the highest intensity of the protonated molecule ion (585 u) as compared to that from the loss of water (567), as observed in the MS of zeaxanthin. As cited above for auroxanthin, the presence of an epoxide and/or furanoid group in the 3-hydroxy-β-ring was confirmed by the fragment at m/z 221. Peak 8 showed the same MS features as peak 7, but an hypsochromic shift of 20 nm, being identified as mutatoxanthin.

3.2. Effect of heating and acid addition on β-cryptoxanthin degradation in an aqueous-based system

Fig. 1 shows the chromatograms obtained for non-heated and heated synthetic all-*trans*-β-cryptoxanthin systems. The initial systems were found to contain 94.7% of all-*trans*-β-cryptoxanthin,

along with five isomers in small amounts (5.3%), as shown in Table 2.

In the non-acidified system, the total amounts of *cis* isomers increased from 5.3 to 14.7 μg/ml and a further increase to 17.4 μg/ml, respectively, after 1 and 2 h of heating at 90 °C. As a result of citric acid addition to the system, similar amounts of the *cis* isomers of β-cryptoxanthin were detected, namely 14.9 μg/ml after 1 h and 16.1 μg/ml after 2 h of heating. Di-*cis* isomers of β-cryptoxanthin were not detected in these systems.

Two oxidation compounds (peaks 1 and 12, Fig. 1), not previously detected in the unheated system, were formed in small amounts after heating all-*trans*-β-cryptoxanthin in both non- and acidified systems at 90 °C (Table 2). Although the levels of 5,6-epoxy-β-cryptoxanthin increased with heating time, especially in the acidified system, the amount of citric acid added was not strong enough to induce the epoxy to furanoid rearrangement. In fact, the detection of 5,6-epoxy-β-cryptoxanthin in this system after 2 h of heating is surprising, considering that 5,6-epoxides of carotenoids are easily rearranged to their corresponding 5,8-furanoids during thermal processing of foods (Dhuique-Mayer et al., 2007; Meléndez-Martínez, Vicario, & Heredia, 2007b) and that small amounts of 5,8-epoxy-β-cryptoxanthin were detected in some cashew apple processed products (Assunção & Mercadante, 2003a). Di-epoxides of β-cryptoxanthin were not detected. The apocarotenoid, 12′-apo-β-carotenal, was only formed after heating at 90 °C for 1 h; however, it was not detected anymore after 2 h of heating. Other apocarotenoids with lower molecular weight or higher polarity containing the 3′-hydroxy β-end-group of β-cryptoxanthin were not detected, although another mobile phase with water was used (chromatogram not shown).

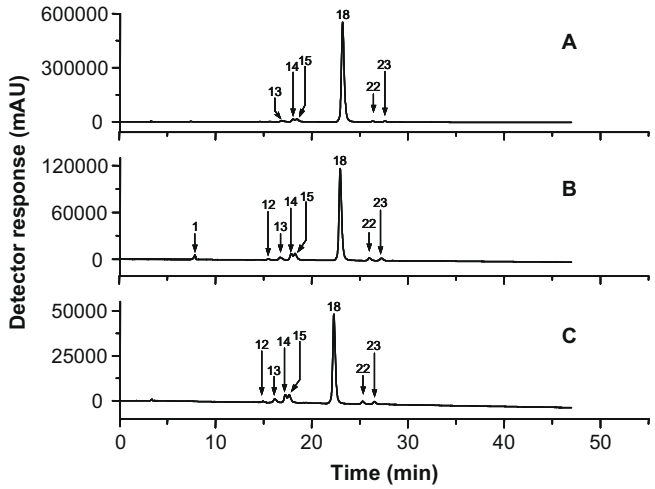

Fig. 1. Chromatogram processed at 450 nm, obtained by HPLC-PDA-MS/MS, of the synthetic β-cryptoxanthin in an aqueous-based acidified system, unheated (A), after 1 h heated at 90 °C (B), and after 2 h heated at 90 °C (C). See text for chromatographic conditions, peak characterisation is given in Table 1.

In addition, in the present study, a high stability of all-*trans*-β-cryptoxanthin was observed in a system at room temperature in the presence of citric acid. The absorptions in the red (700 nm) and near red infrared (950 nm) regions, corresponding respectively to mono and diprotonated carotenoids (Mortensen & Skibsted, 2000), were not observed (Fig. S2 from Supplementary data). This fact was not a surprise, since only strong and moderately strong acids, such as nitric and trifluoroacetic acids, were able to form protonated carotenoids (Mortensen & Skibsted, 2000). When all-*trans*-β-cryptoxanthin was heated in a non-acidified system at 90 °C, a decrease was also observed in the visible region at 440–520 nm with concomitant formation of soft coloured products in the near visible (~400 nm) and non-coloured compounds in the UV region (<360 nm) (inset of Fig. S3 from Supplementary data). These facts clearly indicated that heat was responsible for the major route of all-*trans*-β-cryptoxanthin degradation in an aqueous-based system.

Since similar qualitative and quantitative carotenoid profiles were found in both systems, with the absence and presence of citric acid in a similar concentration as that found in commercial tropical fruit juices, addition of acid did not affect the type of compounds formed during thermal degradation of all-*trans*-β-cryptoxanthin. In addition, the results from Table 2 showed that heating all-*trans*-β-cryptoxanthin for 60 min yielded the same *trans*/*cis* ratio values, 79:21, in non-acidified and acidified systems. Further heating for 120 min changed this isomeric proportion to 60:40 in non-acidified and to 63:37 in acidified systems.

Taking into account the structures of the thermal degradation products formed in both β-cryptoxanthin heated aqueous systems, isomerisation from *trans* to *cis* configurations, epoxidation and cleavage were the main degradation reactions observed in the present study (Fig. 2). Moreover, degradation to non-coloured compounds was also observed since the amounts of β-cryptoxanthin degraded was not compensated by the amounts of products formed (Table 2). In fact, Kanasawud and Crouzet (1990) proposed a reaction mechanism with mono- and di-epoxides of β-carotene as intermediates for the formation of carotenoid-derived volatiles from β-carotene in a heated aqueous medium.

The predominant *cis* isomers formed were 13-*cis*- + 13′-*cis*-β-cryptoxanthin, 7.0 and 7.3%, followed by smaller amounts of 9-

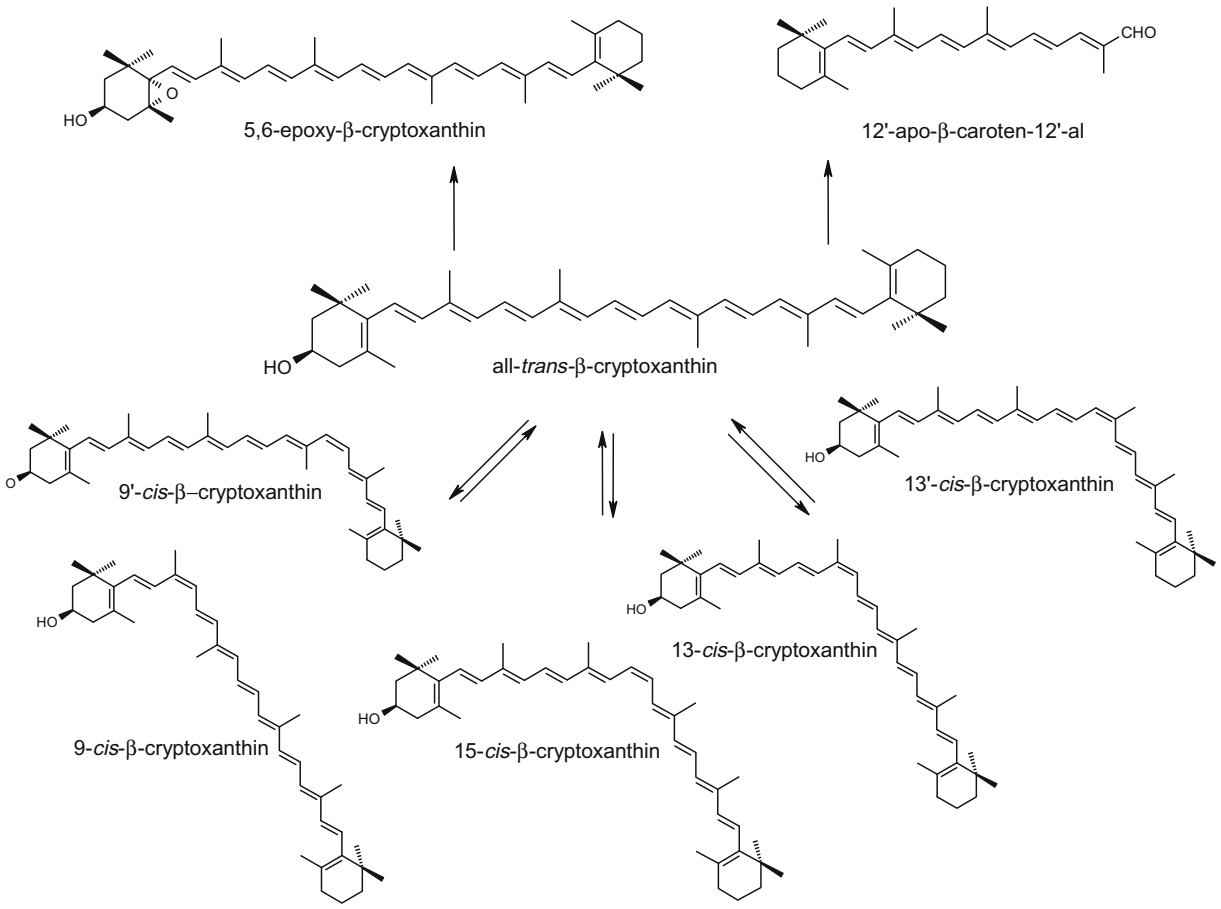

Fig. 2. Proposed mechanism for thermal degradation of all-*trans*-β-cryptoxanthin to coloured compounds in aqueous-based systems.

cis- + 9′-*cis*- isomers (5.3 and 5.9%) and 15-*cis*- or 15′-*cis*-β-cryptoxanthin (2.9 and 3.1%), respectively in non- and acidified aqueous systems after heating for 1 h at 90 °C (Table 2). The predominance of β-cryptoxanthin isomers with *cis* double bonds closer to the molecule centre is explained by the lower activation energy for *trans* to *cis* isomerisation about the central double bond as compared to those about other double bonds, as previously reported for β-carotene (Zechmeister, 1944).

3.3. Influence of heating on carotenoid degradation in a simulated cashew apple juice

The impact of thermal treatment on the composition of carotenoids in a simulated cashew apple juice can be seen in Fig. 3 and Table 3. In general, as expected, the levels of all-*trans* carotenoids decreased with a concomitant increase in the amounts of *cis* isomers and oxidation products, as time and heating temperature increased. Moreover, breakdown non-coloured compounds were also formed since the increased levels of *cis* isomers and oxidation compounds did not compensate for the losses of total carotenoid contents.

A total of 19 different carotenoids were separated in the simulated cashew apple juice not submitted to heat (Fig. 3A). All-*trans*-β-cryptoxanthin was the major carotenoid (57.7%), followed by all-*trans*-β-carotene (22.1%). As a consequence of the heat treatment at both 60 and 90 °C, *cis*-neoxanthin, neochrome, *cis*-violaxanthin, lutein and all-*trans*-α-cryptoxanthin disappeared, whereas two *cis* isomers (*cis*-lutein and 15-*cis*-β-carotene) and four epoxide-derivatives (auroxanthin, mutatoxanthin, 5,6-epoxy-β-cryptoxanthin and 5,8-epoxy-β-carotene) were formed (Table 3). Additional luteoxanthin and one short-chain product 12′-apo-β-carotenal were only formed at 90 °C (Table 3, Fig. 3B).

These facts indicated that the geometric isomerisation and formation of oxidation compounds already observed in the β-cryptoxanthin systems also occurred for the major carotenoids in the simulated cashew apple juice. However, epoxy-furanoid rearrangement was confirmed to have occurred in the simulated cashew ap-

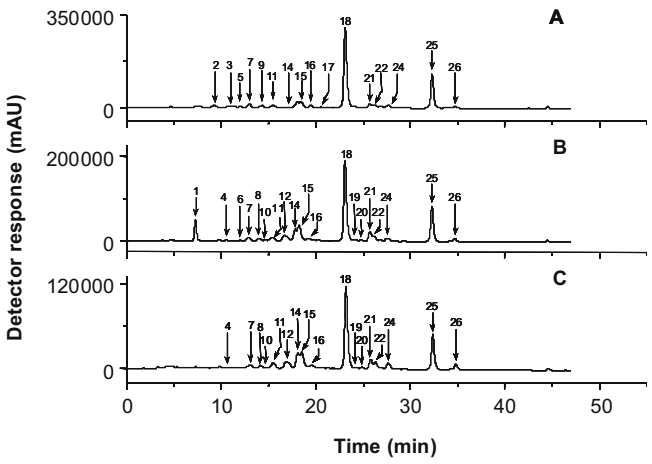

Fig. 3. Chromatogram processed at 450 nm, obtained by HPLC-PDA-MS/MS, of carotenoids from simulated cashew apple juice, unheated (A), after 1 h heated at 90 °C (B), and after 4 h heated at 90 °C (C). See text for chromatographic conditions, peak characterisation is given in Table 1.

[a] Mean and standard deviation of two independent experiments.
[b] n.d. not detected.
[c] Tentatively identified as 13-*cis*-β-cryptoxanthin or 13′-*cis*-β-cryptoxanthin.
[d] Tentatively identified as 9-*cis*-β-cryptoxanthin or 9′-*cis*-β-cryptoxanthin.

ple juice at both heating temperatures. Despite the high number of stereoisomers of β-carotene and β-cryptoxanthin that can be formed by heating, our experiments confirmed that the 13-*cis*- isomers of both carotenoids were preferentially formed, as previously reported (Dhuique-Mayer et al., 2007; Doering et al., 1995; Kuki et al., 1991; Mercadante, 2008a).

Similar *trans*/*cis* ratio values were found for β-cryptoxanthin and β-carotene in all the simulated cashew apple juice systems, changing respectively from 93:7 to 80:20 and from 92:8 to 79:21 after 1 h of heating at 90 °C. Further heating for 4 h changed the ratio values to 68:32 for β-cryptoxanthin and 69:31 for β-carotene.

Heating at both temperatures also caused loss of lutein, along with formation of *cis*-lutein. Violaxanthin thermal degradation followed the epoxy-furanoid rearrangement, through two sequential transformations of 5,6-epoxy to 5,8-furanoid end-groups, giving rise respectively to luteoxanthin and auroxanthin. It is known that violaxanthin easily undergoes this type of rearrangement, based on the example of the reported losses of 46.4% of violaxanthin and 19.7% of *cis*-violaxanthin after pasteurisation of Valencia orange juice (Lee & Coates, 2003). In addition, violaxanthin was found in fresh cashew apples; however, in commercially processed cashew juice, violaxanthin was not detected while auroxanthin, not present in the fruits, appeared at a detectable level, due to the conversion of the 5,6-epoxide groups of violaxanthin to the 5,8-furanoid groups of auroxanthin (Assunção & Mercadante, 2003a, 2003b).

Since neochrome was the only 5,8-epoxide found in unheated systems, the epoxy-furanoid rearrangement of *cis*-neoxanthin had probably already occurred during extraction or system preparation. It is interesting to note that in twenty-two of the twenty-five genotypes of orange, whenever neoxanthin was found, neochrome was also detected (Fanciullino et al., 2006).

In summary, the overall results show losses of non-detected low molecular weight degradation compounds, isomerisation of *trans* to *cis*-configuration, accompanied by epoxide to furanoid rearrangement and formation of oxidation compounds during carotenoid heating in aqueous-based systems. All reactions were induced mainly by heat in both synthetic β-cryptoxanthin and simulated cashew juice systems. It is important to consider that in the fruit, carotenoids are part of a much more complex system, and are in close proximity to other components such as protein and lipids, frequently in organised and ordered structures such as membranes and vesicles (Britton, 1995). However, heat treatment can facilitate the interaction between acids and carotenoids in the real juice.

Dangyuja extract
Antioxidant activity
ORAC
Antidiabetic activity
Rat intestinal α-glucosidase inhibition

ABSTRACT

Dangyuja is a citrus fruit of Cheju Island in Korea, which is known to have a high content of flavanone glycosides, such as naringin and neohesperidin. Flavanone glycosides of *Dangyuja* (*Citrus grandis* Osbeck) extract were converted into their aglycones by naringinase and hesperidinase, and into their hydroxylated forms by *Aspergillus saitoi*. *Dangyuja* extract treated with *A. saitoi* had significantly higher antioxidant and antidiabetic activity than both its glycosides and aglycones in oxygen radical absorption capacity (ORAC) and supercoiled DNA strand scission assay, rat intestinal α-glucosidase and porcine pancreatic α-amylase inhibition, suggesting that the fermentation of flavanone aglycones of *Dangyuja* extract with *A. saitoi* can increase antioxidant and antidiabetic activity, compared to their glycosides and aglycones. This result suggests that *Dangyuja* extract prepared with enzymatic and microbial treatments could be used for the development of pharmaceutical foods to control the blood glucose level of diabetic patients by inhibiting α-amylase and α-glucosidase in the intestinal tract.

1. Introduction

Type 2 diabetes mellitus (T2DM) is a common, progressive and complex disorder that is difficult to treat effectively in the long term. Recent studies have demonstrated that absorption inhibitors have a role in the prevention of T2DM in high-risk populations (Cheng & Josse, 2004). Inhibitors of intestinal α-glucosidase enzymes retard the rate of carbohydrate digestion, thereby providing an alternative means to reduce postprandial hyperglycaemia (Krentz & Bailey, 2005). Several α-glucosidase inhibitors, such as acarbose (Schmidt et al., 1977), trestatin (Watanabe, Furumai, Sudoh, Tokose, & Maruyama, 1984), amylostatin (Murao, Ohyyama, & Ogura, 1977) and valiolamine (Horii et al., 1987) have been isolated from microorganisms. Acarbose isolated from *Actinoplanes sp.* is commonly used in the management of Type 2 diabetes. The main drawback of using drugs such as acarbose is side effects such as abdominal distention, flatulence, meteorism and possibly diarrhoea (Hollander, 1992). It has been suggested that such adverse effects might be caused by the excessive inhibition of pancreatic α-amylase, resulting in abnormal bacterial fermentation of undigested carbohydrates in the colon (Horii et al., 1987). Natural α-amylase and α-glucosidase inhibitors from food-grade plant sources offer an attractive strategy to control post-prandial hyperglycaemia. Natural inhibitors from plants, which have been shown to have a low inhibitory effect against α-amylase activity and a strong inhibition activity against α-glucosidase, can be used as an effective therapy for postprandial hyperglycaemia with minimal side effects (Horii et al., 1987).

Recently, extensive studies of citrus flavanones have reported that naringenin (NE; 4',5,7-trihydroxyflavanone) reduced glucose uptake to inhibit intestinal and renal Na^+-glucose co-transporter (SGLT1) (Li, Chen, Lau, Leung, & Cheng, 2006), and naringin (NI; naringenin-7-rhamnoglycoside) and hesperidin (HI; hesperetin-7-rutinoside) both significantly increased the glucokinase mRNA level, whilst NI also lowered the mRNA expression of phosphoenolpyruvate carboxykinase and glucose-6-phosphatase in the liver (Jung, Lee, Park, Kang, & Choi, 2006). However, there have been few studies on α-glucosidase inhibition activity. Our previous analyses have demonstrated that aglycone forms (NE and hesperetin; HE; 3,5,7-trihydroxy-4-methoxyflavanone) of citrus flavanones showed significantly higher inhibitory activity than glycoside forms (NI and HI) on baker's yeast α-glucosidase enzyme assay. In addition, both glycoside and aglycone forms of citrus flavanones exhibited moderate inhibitory activity on rat intestinal α-glucosidase enzyme. It has been reported that most baker's yeast α-glucosidase inhibitors did not show any activity against mammalian α-glucosidase, due to the difference of molecular recognition in the target binding site of this enzyme (Gao & Kawabata, 2005), and that 5,6,7-trihydroxyflavanone structure was crucial for exerting high activity (Gao & Kawabata, 2004). Miyake et al. (2003) reported that hydroxylated flavanones were produced with *Aspergillus saitoi* from hesperidin or naringin, which are flavanone glycosides in citrus fruit, and the hydroxylated flavanones produced from naringin were identified as carthamidin (6-hydroxynaringenin) and isocarthamidin (8-hydroxynaringenin), and that from hesperidin was identified as

8-hydroxyhesperetin (8-HHE). These products demonstrated more antioxidant capacity than both glycoside and aglycone forms using the DPPH radical-scavenging assay (Miyake et al., 2003).

The flavonoids of citrus fruit have three types: flavanones, flavones and flavonols; there exist about 60 species (Rhyu, Kim, Bae, & Park, 2002). The citrus flavanones have two forms, glycone and aglycone, present in the metabolic process. The glycoside forms include NI, narirutin (NR; naringenin-7-rutinoside), HE and neohesperidin (NHI; hesperetin-7-neohesperidoside), and aglycone forms include NE and HE. In past, citrus flavanones such as NI and NHI had been recognised as bitter components, which affect consumer acceptability. However, lately these citrus flavanones have become components of special interest, through the development of a debittering method, which converts NI into its aglycone (Puri, Banerjee, & Banerjee, 2005), as well as the antioxidant activity (Di Majo et al., 2005), hypotensive effect (Son, Kim, Kwon, & Ju, 1992), and anti-inflammatory and anti-tumuorigenic efficacies of HI (Sakata, Hirose, Qiao, Tanaka, & Mori, 2003), the anti-cholesterol effect of HE through inhibition of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase and acyl coenzyme A (ACAT) (Lee et al., 1999), and hypolipidaemic and hypoglycaemic effects of NI and HI (Jung et al., 2006).

Unshiu orange, citrus Unshiu is a major citrus fruit of Cheju Island in Korea. Recently, Unshiu orange fell in price due to overproduction. Therefore, the development of an alternative fruit is considered to be an important subject. *Dangyuja*, *Citrus grandis* Osbeck is a citrus fruit of Cheju in Korea has potential as a substitute for Unshiu orange. HPLC analysis has indicated that *Dangyuja* has a higher content of total flavanones than Unshiu orange (data not shown). The major flavanones of *Dangyuja* are neohesperidin and naringin, which are high in the seedcase of unripe citrus fruits (Chung, Kim, Choi, Song, & Kim, 2000) and its extract showed antioxidant activity through free radical-scavenging *in vitro* and to reduce reactive oxygen species in H_2O_2-treated HepG2 cells (Lim, Yoo, Moon, Jeon, & Cho, 2006).

In this study, we carried out the conversion of flavanone glycosides of *Dangyuja* extract into their hydroxylated flavanones (carthamidin, isocathamidin and 8-HHE) by the sequential treatments with naringinase and hesperidinase, and *A. saitoi*. Antidiabetic and antioxidant activity was investigated using rat α-glucosidase and porcine α-amylase inhibition assay, and ORAC and DNA strand scission assay, respectively.

2. Materials and methods

2.1. Materials

Dangyuja powder was kindly supplied by Kunpoong Bio Co. Ltd. (Cheju, Korea). *A. saitoi* IAM 2210 was purchased from the Institute of Applied Microbiology at Tokyo University (Tokyo, Japan). Hesperidin, naringin, neohesperidin, hesperetin, naringenin, yeast α-glucosidase enzyme powder, rat-intestinal acetone powder, *p*-nitrophenyl-α-glucopyranoside (pNPG), porcine pancreatic α-amylase enzyme powder, naringinase, hesperidinase, dimethylsulfoxide (DMSO), fluorescein, potato dextrose agar (PDA) and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox) were purchased from Sigma Chemical Co. Ltd. (St. Louis, MO). Narirutin was purchased from Indofine Chemical Company, Inc. (Hillsborough, IL). 2,2'-Azobis(2-amidinopropane) dihydrochloride (AAPH) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

2.2. Preparation of Dangyuja extract

Four and a half grams of *Dangyuja* powder were suspended in 300 ml of distiled water, and the suspension was heated in autoclave at 121 °C for 15 min. After filtration with filter paper (Whatman No. 1), the filtrate was lyophilised using a vacuum freeze dryer (Biotron Co. Ltd., Puchon, Korea). The extract was kept at −20 °C until analysed.

2.3. Conversion of glycosides in Dangyuja extract by enzymatic and microbial treatment

Preparation of converted samples refers to the slightly modified method of Miyake et al. (2003). Half a gram of *Dangyuja* extract was dissolved in 1 ml of DMSO, and 99 ml of 10% potato dextrose agar solution was added. The mixture was incubated at 37 °C for 1 day with naringinase and hesperidinase powder (each at a concentration of 2.5 mg/ml). After the incubated mixture has been adjusted to pH 5.0 with 0.1 N HCl, it was sterilised at 121 °C for 15 min. After the sterilised solution was inoculated with 1 ml of *A. saitoi*; the inoculated solution was shake-cultured with the shaking incubator (Vision Scientific Co. Ltd., Seoul, Korea) at a speed of 100 rpm/min and 30 °C. Five millilitre aliquots of solution were periodically taken out during the incubation and culture period and blended by tissue tearer (Biospec Products, Inc., Bartlesville, OK). All blended samples were measured for antidiabetic and antioxidant activity.

2.4. HPLC analysis

HPLC analysis was performed on a Tosoh (Tosoh Corporation, Tokyo, Japan) 8010 series equipped with a diode-array UV–Vis detector (UV 8010), a degasser (SD-8023) and a column oven (CO-8010). The instrument was also equipped with a Futecs gradient controller (NS-1000A) and gradient pump (Acuflow Series IV; Futecs Co., Daejeon, Korea); integration and data elaboration were performed by MultiChro software (Yullin Technology, Seoul, Korea). The column used was RP 5 μm C_{18}, (15 cm × 4.5 cm); (Daiso Co. Ltd., Osaka, Japan). HPLC analysis of sample used the method of Kanaze, Kokkalou, Georgarakis, and Niopas (2004), with slight modifications. The mobile phase consisting of methanol/water/acetic acid (25:73:2, v/v/v) was filtered through a 0.45 um pore size cellulose acetate filter (Sartorius, Goettingen, Germany) and degassed by ultrasonic treatment before use. The HPLC system was isocratically operated at a flow rate of 1 ml/min at 45 °C and the detector was set at 288 nm. Before the measurement, DMSO solution was added to all samples at the same amount.

2.5. In vitro antioxidant activity assay

2.5.1. Oxygen radical absorbance capacity (ORAC) assay

The ORAC assay was carried out on a Tecan GENios multi-functional plate reader (Salzburg, Austria) with fluorescent filters (excitation wavelength: 485 nm and emission wavelength: 535 nm). In the final assay mixture, fluorescein (40 nM) was used as a target of free radical attack with either AAPH (20 mM) as a peroxyl radical generator in peroxyl radical-scavenging capacity ($ORAC_{ROO\cdot}$) assay (Kurihara et al., 2004) or H_2O_2–$CuSO_4$ (H_2O_2, 0.75%; $CuSO_4$, 5 μM) as mainly a hydroxyl radical generator in hydroxyl radical-scavenging capacity ($ORAC_{OH\cdot}$) assay (Cao, Sofic, & Prior, 1997). Trolox (1 μM) was used as a control standard and prepared fresh daily. The analyser was programmed to record the fluorescence every 2 min after AAPH or H_2O_2–$CuSO_4$ was added. All fluorescence measurements were expressed relative to the initial reading. Final results were calculated based on the difference in the area under the fluorescence decay curve between the blank and each sample. $ORAC_{ROO\cdot}$ and $ORAC_{OH\cdot}$ were expressed as micromoles of Trolox equivalents (TE). One ORAC unit is equivalent to the net protection area provided by 1 μM Trolox.

2.5.2. pBR322 DNA strand scission assay

Plasmid supercoiled strand DNA (pBR322 DNA) was dissolved in 10 mM PBS (pH 7.4). DNA (2 μg/ml) was mixed with sample

solution in PBS before the oxidation initiators were added. For generating the peroxyl radical, AAPH in PBS, pH 7.4, was added to a final concentration of 5 mM, and reaction mixtures were incubated at 37 °C for 2 h (Lim, Hu, & Kitts, 2001). Gel electrophoresis was performed in a Tris acetic acid EDTA buffer (40 mM Tris, 2 mM EDTA, pH 8.5), using a horizontal submarine gel electrophoresis apparatus (Amersham Pharmacia Biotech, Uppsala, Sweden) at 3 V/cm for 1.4 h. DNA strands were stained with ethidium bromide (0.5 μg/ml in deionised water), visualised under ultra-violet light and photographed. Photographic negatives were scanned and analysed by imaging densitometer with molecular analysis software to quantitate DNA breakage in term of percentage of supercoiled DNA which was nicked by peroxyl radicals. The protective effects of samples were compared by the retention percentage (% retention), calculated by the following equation:

$$\text{Retention}(\%) = (\text{concentration}_{\text{sample}}/\text{concentration}_{\text{control}}) \times 100,$$

where $\text{concentration}_{\text{sample}}$ and $\text{concentration}_{\text{control}}$ represent the concentrations of supercoiled DNA with oxidative radical and without oxidative radical, respectively.

2.6. Antidiabetic activity assay

2.6.1. Rat intestinal -glucosidase inhibition assay

Rat intestinal α-glucosidase assay referred to the method of Kwon, Vattem, and Shetty (2006) with slight modification. One gram of rat-intestinal acetone powder was suspended in 3 ml of 0.9% saline, and the suspension was sonicated twelve times for 30 s at 4 °C. After centrifugation (10000*g*, 30 min, 4 °C), the resulting supernatant was used for the assay (Ohta, Sasaki, Oohori, Yoshikawa, & Kurihara, 2002). Fifty microlitres of sample solution were pre-incubated with 100 μl of rat-intestinal α-glucosidase solution at 37 °C for 10 min. After pre-incubation, 50 μl of 5 mM *p*-nitrophenyl-α-D-glucopyranoside solution in 0.1 M phosphate buffer (pH 6.9) were added. The reaction mixtures were incubated at 37 °C for 15 min. Absorbance readings were recorded at 405 nm by ELISA absorbance reader (Tecan Trading AG, Salzburg, Austria) and compared to a control which had 50 μl of solvent in place of the sample solution. The rat α-glucosidase inhibitory activity was expressed as inhibition (%) and was calculated as follows:

$$\text{Inhibition}(\%) = [(A_0 - A_1)/A_0] \times 100$$

where A_0 was the absorbance of the control, and A_1 was the absorbance of the sample.

2.6.2. Porcine pancreatic -amylase inhibition assay

Porcine pancreatic α-amylase inhibition referred to the method of Kwon et al. (2006). Two hundred microlitres of sample solution and 500 μl of 0.02 M sodium phosphate buffer (pH 6.9 with 0.006 M sodium chloride) containing α-amylase solution (0.5 mg/ml) were incubated at 25 °C for 10 min. After pre-incubation, 500 μl of a 1% starch solution in 0.02 M sodium phosphate buffer were added. The reaction mixture was then incubated at 25 °C for 10 min. The reaction was stopped with 1.0 ml of dinitrosalicylic (DNS) acid, colour reagent. The reaction mixture was then incubated in a boiling water bath for 5 min and cooled to room temperature. The reaction mixture was then diluted after adding 10 ml of water, and absorbance was measured at 540 nm with ELISA microplate reader (Tecan Trading AG).

2.7. Statistical analysis

All data are presented as means ± SD. Statistical analyses were done using SPSS (Statistical Package for Social Science, SPSS Inc., Chicago, IL) program, and significance of each group was verified with one-way ANOVA followed by Duncan's test ($p < 0.05$).

3. Results and discussion

3.1. The flavanone content of Dangyuja extract

The flavanones of *Dangyuja* powder were extracted using autoclaving (121 °C, 15 min) in water and analysed using HPLC. The total content of flavanone glycosides tended to change with the harvesting time. Their percentage increased in order: October (4.02%) < September (6.66%) < August (10.48%) < July (20.66%). The result was consistent with those reported by previous researchers (Chung et al., 2000; Rhyu et al., 2002). Rhyu et al. (2002) reported that the content of flavonoid decreased with maturing of citrus fruit and Chung et al. (2000) reported that naringin and hesperidin rapidly decreased during maturation. Referring to these results, we extracted *Dangyuja* harvested in July. The yield of extraction was 58.66%, and the content of NHI was the highest (16.52%) amongst flavanone glycosides, compared to NR (0.12%), NI (11.12%) and HI (0.80%). This well agrees with the report that *Dangyuja* has a higher content of NI and NHI than other flavanones (Rhyu et al., 2002).

3.2. Conversion of flavanone glycosides of Dangyuja extract into their hydroxylated flavanones by enzymatic and microbial treatment

Flavanone glycosides of *Dangyuja* were subsequently converted into their aglycones and hydroxylated flavanones by naringinase and hesperidinase, and *A. saitoi*, respectively. The conversion of flavanone glycosides was confirmed using HPLC. The retention time of NR, NI, HI and NHI, flavanone glycosides, were 6.18 min, 7.05 min, 8.15 min and 9.32 min, respectively. Those of NE and HE, flavanone aglycones, were 14.48 min and 19.95 min, respectively. Deglycosylation of flavanone glycosides was done by treatment with naringinase and hesperidinase for one day. The result of deglycosylation (Table 1) indicates that all flavanone glycosides were converted into their aglycones. NE (6.04%) was made from NR (0.12%) and NI (11.12%), and HE (12.28%) was derived from HI (0.8%) and NHI (16.52%).

According to Table 1, when the flavanone aglycones of Dangyuja extract were treated with *A. saitoi* for 6 days, the concentration of NE decreased from 6.04% to almost 0%, suggesting that all NE may be converted into its hydroxylated forms by *A. saitoi*. On the other hand, the content of HE decreased from 12.28% to 5.40% after treatment for 2 days and then increased from 5.40% to 7.68% between 2 and 6 days. Miyake et al. (2003) has reported that hydroxylated flavanones were produced with *A. saitoi* from hesperidin or naringin, flavanone glycosides in citrus fruit, and the hydroxylated flavanones produced from NE and HE were identified as carthamidin (6-hydroxynaringenin) and isocarthamidin (8-hydroxynaringenin), and 8-hydroxyhesperetin (8-HHE), respectively (Fig. 1). This result indicates that most of flavanone aglycones such as NE and HE could be converted, by hydroxylation with *A. saitoi,* into carthamidin and isocarthamidin, and 8-hydroxyhesperetin, respectively. The increase of HE concentration between 2 and 6 days treatment with *A. saitoi* may be due to the hydroxylated forms, such as carthamidin (6-hydroxynaringenin) and isocarthamidin (8-hydroxynaringenin), and 8-hydroxyhesperetin (8-HHE) derived from NE and HE, which were eluted at a retention time close to HE under our conditions of HPLC analysis. Even though hydroxylated forms of NE and HE were not identified in the HPLC profile, it was assumed that the flavanone aglycones decreased because they were converted into carthamidin, isocarthamidin and 8-HHE. The antioxidant activities of these hydroxylated flavanones have been reported as being higher than those of flavanone glycosides (Miyake et al., 2003). The structure of carthamidin is similar to that of baicalein which is crucial for exerting high activity on rat intestinal α-glucosidase inhibition (Gao & Kawabata, 2004).

Table 1
The flavanone content of *Dangyuja* extract harvested in July (De), treated with naringinase and hesperidinase (E), and fermented with *A. saitoi* for 2–6 days (F2, F4, and F6).

Sample	Content (%)					
	Narirutin	Naringin	Hesperidin	Neohesperidin	Naringenin	Hesperetin
De	0.12 ± 0.01	11.12 ± 0.04	0.8 ± 0.02	16.52 ± 0.08	ND	ND
E	ND[a]	ND	ND	ND	6.04 ± 0.04	12.28 ± 0.06
F2	ND	ND	ND	ND	2.96 ± 0.04	5.40 ± 0.05
F4	ND	ND	ND	ND	0.32 ± 0.02	6.48 ± 0.08
F6	ND	ND	ND	ND	ND	7.68 ± 0.05

Data are presented as mean values ± standard deviation. Values are presented as g/100 g of extract (dry weight basis).
[a] Not detectable.

3.3. Antioxidant activity of converted Dangyuja extract

The antioxidative activity of *Dangyuja* extract containing flavanone glycosides and aglycones, and hydroxylated compounds formed due to treatment with enzyme and *A.* saitoi, was measured by using the ORAC assay, which has been used successfully to analyse the scavenging capacity for peroxyl and hydroxyl radicals, the most harmful and reactive oxygen species (Aruoma, 1994). ORAC assay was carried out with AAPH as a peroxyl radical generator, and $CuSO_4$ and H_2O_2 as a hydroxyl radical generator. All antioxidant capacities were indicated in terms of Trolox equivalant (TE). The capacity to scavenge peroxyl radical increased in order of F6 (18.31 TE) < De (21.86 TE) < E (22.98 TE) < F4 (23.65 TE) < F2 (24.59 TE) at 2 μg/ml of sample concentration (Fig. 2), and the hydroxyl radical-scavenging activity increased in order of De (33.07 TE) < F6 (33.25 TE) < E (37.68 TE) < F4 (40.96 TE) < F2 (41.21 TE) at 10 μg/ml of sample concentration (Fig. 3). The treatment with naringinase and hesperidinase converted flavanone glycosides of *Dangyuja* extract into their aglycones, which contributed to an increase in the antioxidant activity of *Dangyuja* extract, which is in good agreement with published results (Kim, Jung, & Jang, 2008). Furthermore, after the treatment with naringinase and hesperidinase, the fermentation of *Dangyuja* extract with *A. saitoi* for 2 or 4 days caused a significant increase in its ability to scavenge peroxyl and hydroxyl radicals, indicating that hydroxylated forms from flavanone aglycones of *Dangyuja* extract may significantly demonstrate higher antioxidant activity in scavenging peroxyl and hydroxyl radical than their glycosides or aglycones. Therefore,

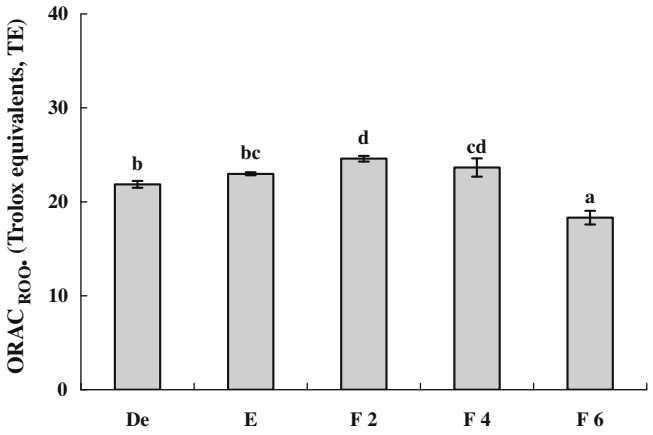

Fig. 2. Effect of enzymatic and microbial treatment on the peroxyl radical-scavenging activity of *Dangyuja* extract. De = *Dangyuja* extract; E = *Dangyuja* extract treated with naringinase and hesperidinase; F2 = *Dangyuja* extract fermented with *A. saitoi* for 2 days; F4 = *Dangyuja* extract fermented with *A. saitoi* for 4 days; F6 = *Dangyuja* extract fermented with *A. saitoi* for 6 days. All values are mean ± S.D. Means with the same letter are not significantly different ($p < 0.05$).

the conversion of flavanone glycosides of *Dangyuja* extract into hydroxylated forms by their sequential treatment with naringinase and hesperidiase, and *A. saitoi* could increase the ability of the extract to scavenge peroxyl and hydroxyl radical.

Most oxidative damage occurring in biological systems is due to peroxyl radicals that have comparatively long half-lives and thus greater affinity to diffuse into biological fluids in cells and tissues (Halliwell, Aeschbach, Lőliger, & Aruoma, 1995). While the reactions of peroxyl radicals are slower than those of hydroxyl radicals, they are more specific. This suggests that peroxyl radicals may be more efficient than hydroxyl radicals in damaging important cellular macromolecules, such as DNA, proteins, and carbohydrates (Lee, Kwon, Shetty, & Jang, 2004).

The protection effect of *Dangyuja* extract prepared with enzymatic and microbial treatment on the oxidative damage of pBR322 plasmid DNA caused by peroxyl radical was shown in Fig. 4. In each lane, the lower band was due to supercoiled DNA (SC) and the upper to open-circular DNA (OC). Only a single strand scission caused the conversion of SC into OC. Second strand scission converts OC into linear DNA that is located between SC and OC on agarose gel electrophoresis (Yang & Schaich, 1996). Therefore, the measurement of SC in plasmid DNA treated with peroxyl radicals could indicate the effectiveness of protective activity against oxidative stress of plasmid DNA. The percentage of retention increased in order of F6 (5.04%) < E (7.04%) < F2 (14.89%) < De (32.09%) < F4 (43.77%) at 10 μg/ml of sample concentration (Fig. 3). *Dangyuja* extract treated with *A. saitoi* for 4 days, containing hydroxylated forms from NE and HE, showed the highest protective effect against the oxidative DNA damage induced by peroxyl radical amongst samples tested. However, *Dangyuja* extract having flavanone aglycones, treated with naringinase and hesperidinase, demonstrated lower protective activity against oxidative stress of plasmid DNA than extract containing flavanone glycosides; the reason why was unclear.

3.4. Antidiabetic effect of converted Dangyuja extract

The α-glucosidase inhibitors, which interfere with enzymatic action in the brush-border of the small intestine, could slow the liberation of D-glucose from oligosaccharides and disaccharides, resulting in delaying glucose absorption and decreasing postprandial plasma glucose levels (Gao & Kawabata, 2005). Our previous experiment using yeast α-glucosidase assay indicated that aglycones such as NE and HE had significantly higher inhibitory activity than glycosides, such as NI and NE. However, both glycosides and their aglycones exhibited low inhibitory activity, and there was no difference between glycosides and aglycones on rat α-glucosidase inhibition activity (data not shown). It has been reported that most yeast α-glucosidase inhibitors did not show any activity against mammalian α-glucosidase, due to the difference of molecular recognition in the target binding site of enzymes (Gao & Kawabata, 2005), and that a 5,6,7-trihydroxyflavanone structure was crucial for exerting high activity (Gao & Kawabata, 2004), Therefore, we prepared *Dangyuja* extract having hydroxylated forms of flavanone by the conversion using the fermentation method with *A. saitoi* and investigated the inhibitory activity on rat intestinal α-glucosidase.

With rat α-glucosidase inhibition assay, the inhibitory activity of hydroxylated flavanone was compared with those of their glycoside and aglycone forms. The inhibition activity increased in order of De (16.66%) < F6 (27.43%) < E (30.86%) < fermentation < F2 (45.65%) < F4 (73.15%) (Fig. 5). *Dangyuja* extract prepared with *A. saitoi* for 4 days after the enzymatic treatment showed the highest inhibitory activity amongst all samples tested. On the other hand, the fermentation of *Dangyuja* extract with *A. saitoi* for 6 days decreased the inhibition activity on rat intestinal α-glucosidase. The inhibitory activity on porcine pancreatic α-amylase assay was conducted using the same samples and concentration in rat α-glucosidase inhibition assay. The inhibition activity increased in order of De (−2.63%) < E (3.28%) < F2 (11.58%) < F6 (16.17%) < F4 (48.15%) (Fig. 6). This result indicates that the tendency of *Dangyuja* extract to inhibit porcine α-amylase is similar to its tendency to inhibit rat intestinal α-glucosidase.

According to the result of Gao and Kawabata (2004), carthamidin was shown to exert substantial activity on rat intestinal α-glucosidase inhibition amongst hydroxylated flavanones, such as carthamidin, isocarthamidin and 8-HHE produced from NE and HE with *A. saitoi*. As shown above, the present finding of *Dangyuja* extract prepared by fermenting with *A. saitoi* for 4 days to inhibit

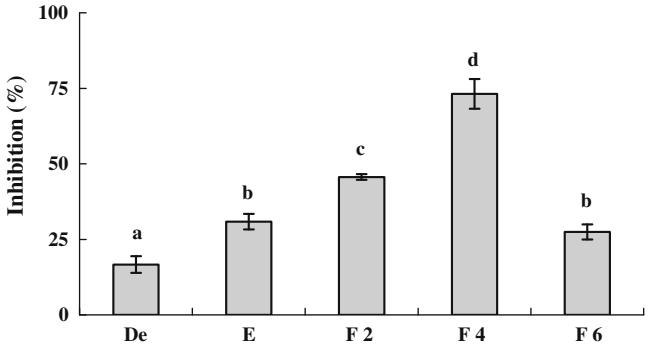

Fig. 5. Effect of enzymatic and microbial treatment on rat intestinal α-glucosidase inhibitory activity of *Dangyuja* extract. De = *Dangyuja* extract; E = *Dangyuja* extract treated with naringinase and hesperidinase; F2 = *Dangyuja* extract fermented with *A. saitoi* for 2 days; F4 = *Dangyuja* extract fermented with *A. saitoi* for 4 days; F6 = *Dangyuja* extract fermented with *A. saitoi* for 6 days. All values are mean ± S.D. Means with the same letter are not significantly different ($p < 0.05$).

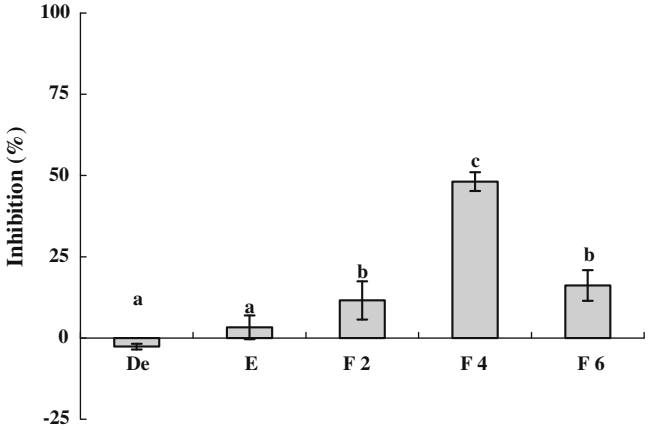

Fig. 6. Effect of enzymatic and microbial treatment on porcine pancreatic α-amylase inhibitory activity of *Dangyuja* extract. De = *Dangyuja* extract; E = *Dangyuja* extract treated with naringinase and hesperidinase; F2 = *Dangyuja* extract fermented with *A. saitoi* for 2 days; F4 = *Dangyuja* extract fermented with *A. saitoi* for 4 days; F6 = *Dangyuja* extract fermented with *A. saitoi* for 6 days. All values are mean ± S.D. Means with the same letter are not significantly different ($p < 0.05$).

significantly both rat intestinal α-glucosidase and porcine pancreatic α-amylase suggests that it may contain hydroxylated flavanone as carthamidin or other bioactive inhibiting compounds. Recent studies have demonstrated that absorption inhibitors have a role in the prevention of Type 2 diabetes in high-risk populations (Cheng & Josse, 2004; Krentz & Bailey, 2005). Therefore, it is suggested that hydroxylated product from *Dangyuja* extract with enzymatic and microbial treatment may be used for the development of pharmaceutical foods to control the blood glucose level of diabetic patients by inhibiting α-glucosidase and α-amylase in the intestinal tract.

4. Conclusions

Flavanone glycosides of *Dangyuja* extract were efficiently converted into their aglycones by naringinase and hesperidinase and their hydroxylated flavanones by *A. saitoi.* Antioxidant capacity was analysed using oxygen radical absorbance capacity (ORAC) and supercoiled DNA strand scission assay. Antidiabetic activity of flavanone products of *Dangyuja* was measured using rat intestinal α-glucosidase and porcine pancreatic α-amylase. Hydroxylated flavanones of *Dangyuja* extract prepared with enzymatic and microbial treatment showed significantly higher antioxidant and antidiabetic activity than both their glycosides and aglycones in ORAC and supercoiled DNA strand scission assay, and rat intestinal α-glucosidase and porcine pancreatic α-amylase inhibition, suggesting that the fermentation of flavanone aglycones of *Dangyuja* extract with *A. saitoi* can increase antioxidant and antidiabetic activities, compared to their glycosides and aglycones. These results indicate that the hydroxylated product from *Dangyuja* extract with enzymatic and microbial treatment could be used for the development of pharmaceutical foods to control the blood glucose level of diabetic patients by inhibiting α-amylase and α-glucosidase in the intestinal tract.

ABSTRACT

We investigated the effect of selenium-polysaccharide (SPS) isolated from selenium-enriched mycelia of *Coprinus comatus* on hypoglycaemic, hypolipidemic and antioxidant activities in diabetic mice. Compared with untreated diabetic mice, the administration of SPS for 20 days caused a significant decrease ($p < 0.05$) in blood glucose levels. Simultaneously, the alteration in lipid metabolism was partially attenuated as evidenced by decreased serum total cholesterol (TC), triglyceride (TG) and low-density lipoprotein cholesterol (LDL) levels and by increased high-density lipoprotein cholesterol (HDL) concentration in diabetic mice ($p < 0.05$). In addition, the SPS caused a significant decrease ($p < 0.05$) in the level of malondialdehyde (MDA) and a significant increase ($p < 0.05$) in the activities of enzymic antioxidants and the levels of non-enzymic antioxidants in liver and kidney of diabetic mice. Furthermore, the effects of SPS was more potent than that of polysaccharide (PS) from mycelia of *C. comatus* at the same dose.

1. Introduction

The essential trace element selenium, element number 34 with atomic weight of 78.84, forms a key constituent of selenoproteins such as glutathione peroxidases (Beckett & Arthur, 2005), and acts as a critically important antioxidant in many different cell types (Mukherjee, Anbazhagan, Roy, Ghosh, & Chatterjee, 1998). Selenium has also been found to have insulin-mimetic activities in vitro and in vivo (Stapleton, 2000), and has been shown to stimulate glucose uptake in adipocytes in vitro (Ezaki, 1990) and to regulate vital metabolic processes such as glycolysis and gluconeogenesis (Becker et al., 1996). Since it is generally believed that organic selenium compounds are better and safer than inorganic selenium as a dietary supplement, a variety of selenium-enriched biological products including garlic, yeast and lactic acid bacteria have been commercialised. The selenium supplementation using microorganisms has received much attention in the past decade (Chasteen & Bentley, 2003). In our previous study, it was reported that *Coprinus comatus*, a rare edible fungus, is able to absorb and accumulate the trace element selenium (Yu, Cui, Cui, & Wang, 2008).

The basidiomycete, *C. comatus*, is a delicious and highly nutritious edible fungus, and is also considered as a source of valuable medicinal compounds. It possesses various bioactive functions such as immunomodulation, hypoglycaemic, hypolipidemic, antitumor, and antibacterial effects (Fan et al., 2006). However, there is little information regarding the biological activity of these polysaccharides isolated from the fermentation mycelia of *C. comatus* and selenium-enriched fermentation mycelia of *C. comatus*. Moreover, no study has even compared the effects of these polysaccharides on hypoglycaemic, hypolipidemic and antioxidant activities in diabetic mice. In addition, several studies have shown that tissue (particularly in liver and kidney) antioxidant status may be an important factor in the aetiology of diabetes and that antioxidant treatment reduces diabetic complications (Kakkar, Mantha, Radhi, Prasad, & Kalra, 1998; Mohamed, Bierhaus, & Schiekofer, 1999). Therefore, this study evaluated the effect of these polysaccharides on blood glucose, blood lipid metabolism and oxidant stress in alloxan-induced diabetic mice.

2. Materials and methods

2.1. Chemicals

Alloxan and 3, 3′-diaminobenzidine (DAB) were purchased from Sigma Chemical Company (St. Louis, Mo). Sodium selenite was obtained from Tianjin Kemi Chemical Research Center (Tianjin, China). Blood glucose test strips were from Tyson Bioresearch Inc. (Taiwan, China). Reagent kits for the determination of TC, HDL, LDL and TG were from Beijing BHKT Clinical Reagent Co., Ltd (Beijing, China). Reagent kits for the determination of MDA, Vc, V_E, GSH, SOD, CAT and GSH-Px were from Jiancheng Bioengineering Institute (Nanjing, China). All other chemicals

were of the highest commercial grade available on the domestic market. The freshly prepared redistiled water was used in the present study.

2.2. Selenium-enriched fermentation mycelia of C.comatus

The seed of *C. comatus* was purchased from Shanxi Agricultural University of China.

First, the seed was grown at 28 °C for 5 days on PDA comprehensive medium slants (1000 ml 20% potato extract liquid + 20.0 g dextrose + 2.0 g peptone + 2.0 g KH_2PO_4 + 1.0 g $MgSO_4 \cdot 7H_2O$ + 0.01 g VB_1 + 20.0 g agar) and then maintained at 4 °C in a refrigerator. Three to four pieces of the mycelia of *C. comatus* were transferred from a slant into a 250 ml Erlenmeyer flask containing 100 ml liquid medium (1000 ml 30.0 g maize power + 30.0 g dextrose + 4.0 g peptone + 2.0 g KH_2PO_4 + 1.0 g $MgSO_4 \cdot 7H_2O$ + 0.01 g VB_1). The culture was incubated at 25 °C on a shake platform at 100 r/min for 4 days.

The 4-day-old liquid culture was homogenised using a sterilized blender and inoculated to a 250 ml Erlenmeyer flask containing 70 ml fermentation medium (1000 ml 40.0 g maize power + 20.0 g glucose + 4.0 g peanut meal + 2.0 g KH_2PO_4 + 1.0 g $MgSO_4 \cdot 7H_2O$ + 10.0×10^{-3} g VB_1 + 4.4×10^{-3} g Na_2SeO_3). The volume of inoculums was 3.5 ml, which was then cultivated under the same condition. After 5 days, selenium-enriched fermentation mycelia of *C. comatus* were harvested, washed with distiled water and stored at −20 °C.

2.3. Fermentation mycelia of C. comatus

The fermentation mycelia of *C. comatus* was produced using the same method to produce selenium-enriched fermentation mycelia of *C. comatus* except that there was no Na_2SeO_3 in the fermentation culture medium.

2.4. Preparation of polysaccharides

The fresh selenium-enriched fermentation mycelia of *C. comatus* was agitated into a homogenate with a blender, and then was treated with a microwave for 3 min. The sample was extracted with 2-fold volumes of distiled water for 4 h at 70 °C. After centrifuging to remove debris fragments (7000 r/min, 10 min), the solution was concentrated 3-fold in a rotary evaporator. Protein was removed with Sevag method (Vilkas & Radjabi-Nassab, 1986). The solution was dialysed in a DEAE cellulose bag against distiled water for 2 days to remove low-molecular-weight materials. Then, the solution was precipitated with 3-fold volumes of absolute ethanol for 48 h at 4 °C. The precipitates were collected by centrifugation (7000 r/min, 10 min), and then vacuum-dried at 50 °C, giving a brown selenium-polysaccharide powder (SPS).

The polysaccharide (PS) from the fermentation mycelia of *C. comatus* was produced using the same method to produce selenium-polysaccharide.

2.5. Analysis of polysaccharides

The content of polysaccharide was determined by the phenol–sulphuric acid method (Dubois, Gilles, Hamilton, Rebers, & Smith, 1956) and the selenium content was determined by the method of Cheng (1956). In addition, protein in the polysaccharide was quantified according to Bradford's method (1976) using bovine serum albumin (BSA) as the standard.

The infrared spectra of samples (KBr disc) were recorded, as were the ultraviolet spectra of samples.

2.6. Animal and experimental design

Fifty male Kun-Ming mice weighing 28 ± 3 g were obtained from Guangdong Research Animal Center at Guangzhou, China. The mice were housed in a room maintained at 24–26 °C with a normal day/night cycle. Mice were provided with a basal diet (purchased from Guangdong Research Animal Center, Guangzhou, China) and free access to drinking water. The ingredient and nutrient compositions of the basal diet are shown in Table 1. The approval of this experiment was obtained from the Institutional Animal Ethics Committee of Shantou University (Shantou, China).

Mice were adapted to diet for 1 week before the experiment began. After a 12-h fasting, 40 mice were induced with a single injection of alloxan prepared freshly at a dose of 260 mg/kg body weight. Seventy-two hours later after alloxan injection, whole blood samples were obtained from the tail vein of the overnight fasted mice and their glucose levels were tested by blood glucose test strips (Tyson Bioresearch Inc., Taiwan, China). The mice having blood glucose levels greater than 11.1 mmol/l were considered diabetic and were used for the study.

Mice were randomly divided into four experimental groups with six mice each: Group I (NM): normal mice, received intraperitoneal injection with physiological saline; Group II (DM): alloxan-induced, untreated diabetic mice received intraperitoneal injection with physiological saline; Group III (DM + PS): diabetic mice, received intraperitoneal injection with 150 mg/kg body weight of the PS (without selenium); Group IV (DM + SPS): diabetic mice, received intraperitoneal injection with 150 mg/kg body weight of the SPS (organic selenium content: 15.21 μg/g). The treatments lasted for 20 days. At the end of the experiment, the body weight and blood glucose level were measured when the mice were fasted overnight. Blood samples were collected and immediately centrifuged for 5 min at 7000 r/min at 4 °C to obtain serum. Organs (liver and kidney) were excised from the animal and stored at −70 °C.

2.7. Biochemical analysis

Blood samples were obtained from the tail vein of the overnight fasted mice and their glucose levels were tested by blood glucose test strips (Tyson Bioresearch Inc., Taiwan, China).

The serum concentration of total cholesterol (TC), high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL) and triglyceride (TG) were determined using commercially available kits (BHKT Clinical Reagent Co., Ltd, Beijing, China) and according to the kits' manuals. Lipid peroxidation (as malondialdehyde, MDA) levels in liver and kidney were estimated by the

Table 1
The composition of basal diet.

Ingredients	Content (%)
Corn starch	59.00
Casein	18.00
Sucrose	8.50
Soybean oil	4.00
α-cellulose	5.00
L-cystine	0.50
Premix of minerals and trace elements (without selenium)[a]	3.50
Premix of vitamins[b]	1.00
Choline chloride	0.50

[a] Minerals and trace elements added per kg diet: Ca, 5000 mg; P, 1761 mg; K, 3400 mg; Na, 1091 mg; Cl, 1852 mg; S, 300 mg; Mg, 753 mg; Fe, 100 mg; Mn, 75 mg; Cu, 10 mg; Zn, 30 mg; I, 0.5 mg; F, 0.8 mg; Mo, 0.2 mg; Co, 0.25 mg.

[b] Vitamins added per kg diet: vitamin A, 13,000 IU; vitamin D, 1000 IU; vitamin E, 40 IU; vitamin K, 3 mg; vitamin B_1, 8 mg; vitamin B_2, 10 mg; vitamin B_6, 6 mg; vitamin B_{12}, 0.02 mg; niacin, 45 mg; pantothenic acid, 17 mg; Biotin, 0.2 mg; vitamin C, 150 mg.

method of Jain, Levine, Duett, and Hollier (1990), based on thiobarbituric-acid reactivity.

The superoxide dismutase (SOD), glutathione peroxidase (GSH-Px) and catalase (CAT) activities in liver and kidney samples were measured using commercially available kits (Jiancheng Bioengineering Institute, Nanjing, China) and according to the kits' manuals. The levels of V_C and V_E and glutathione (GSH) were also estimated using commercially available kits (Jiancheng Bioengineering Institute, Nanjing, China) and according to the kits' manuals.

2.8. Statistical analyses

All results are expressed as mean ± SD for six mice in each group. To determine the effect of treatment, data were analyzed using one-way ANOVA repeated measures. *p*-values of less than 0.05 were regarded as significant. Significant values were assessed with Duncan's multiple range test. Data were analyzed using the statistical package "SPSS 12.0 for Windows".

3. Results

3.1. Result of analysis of samples

Content of the polysaccharide in PS and SPS were both more than 99%, and organic selenium were 0 and 15.21 μg/g, respectively. The data on UV and IR analysis of samples are shown in Figs. 1 and 2. It had a negative response to the Bradford test and no absorption at 280 or 260 nm in the UV spectrum, indicating the absence of proteins and nucleic acids. The IR spectrum of the PS showed a strong band at 3421.2 cm^{-1} attributed to the hydroxyl stretching vibration of the polysaccharide. The bands in the region of 2927.5 cm^{-1} are due to C–H stretching vibration, and the bands in the region of 1654.7 cm^{-1} are due to associated water. The band at 920.5 cm^{-1} was ascribed to α-D-Glucopyranose. The absorptions at 1027.9, 1078.0 and 1151.3 cm^{-1} also indicated the α-pyranose form of the glucosyl residue. Moreover, the SPS revealed similar spectral characteristic to the PS. Therefore, we can only surmise that the combination of selenium may not affect the main structure of the polysaccharide.

3.2. Changes of body weight and blood glucose in diabetic mice after PS and SPS administration

The body weight and blood glucose level of different experimental groups are shown in Table 2. The alloxan-induced diabetic mice exhibited a significant increase ($p < 0.05$) in fasting blood glucose and a significant loss of body weight ($p < 0.05$) when compared with NM group. The administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days in diabetic mice caused a significant decrease in blood glucose levels ($p < 0.05$) when compared with DM group. Simultaneously, the body weight of diabetic mice was also observed after administration of the PS and SPS, but there was no significant increase ($p > 0.05$) when compared with DM group. The administration of SPS showed more effective than that of PS.

3.3. Effect of PS and SPS administration on concentration of serum TC, TG, HDL and LDL in diabetic mice

Diabetes mellitus usually is complicated with hyperlipoproteinemia. The concentration of serum TC, TG, HDL and LDL in different experimental groups are shown in Table 3. The present results showed that the TC, TG and LDL concentrations in the serum were significantly increased ($p < 0.05$), whereas serum HDL level was significantly decreased ($p < 0.05$) in the alloxan-induced diabetic mice when compared with the NM group. The administration of the PS (150 mg/kg body weight, without selenium) for 20 days, the alteration in lipid metabolism was partially attenuated as evidenced by decreased serum TC and TG levels and by increased HDL concentration in diabetic mice ($p < 0.05$), and the administration of the SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days, the alteration in lipid metabolism was partially attenuated as evidenced by decreased serum TC, TG and LDL levels and by increased HDL concentration in diabetic mice ($p < 0.05$) when compared with the DM group. The effect of SPS was more potent than that of PS.

3.4. Effect of PS and SPS administration on MDA level and the activities of antioxidant enzymes and concentration of non-enzymic antioxidants in liver and kidney in diabetic mice

The MDA level and the activities of antioxidant enzymes like SOD, GSH-Px and CAT and the concentration of non-enzymic antioxidants like GSH, vitamin C and vitamin E in liver and kidney of mice in different experimental groups are shown in Table 4. There appears to be a significant increase ($p < 0.05$) in the level of MDA associated with the diminution of the activities of SOD, GSH-Px and CAT and the levels of GSH, vitamin C and vitamin E in liver and kidney of mice in the DM group in comparison with those of the NM group. The administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days caused a significant decrease in the level of MDA ($p < 0.05$) and a significant increase in the activities of enzymic antioxidants ($p < 0.05$) and

[b] $p < 0.05$ compared to the DM group.

the levels of non-enzymic antioxidants ($p < 0.05$) when compared with DM group. Moreover, the effect of SPS was more prominent compared with that of PS.

4. Discussion

Alloxan is widely used to induce experimental diabetes in animals. The mechanism of action in beta-cells of the pancreas is mediated by reactive oxygen species. The action of reactive oxygen species with a simultaneous massive increase in cytosolic calcium concentration causes rapid destruction of beta-cells (Szkudelski, 2001). In the present experiment, the alloxan-induced diabetic mice exhibited a significant increase ($p < 0.05$) in fasting blood glucose and a significant loss of body weight ($p < 0.05$) when compared with normal mice. The administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days caused a significant decrease in blood glucose levels ($p < 0.05$) when compared with untreated diabetic mice. However, it did not normalise the body weight completely as it remained lower than normal mice. The decrease in body weight observed in diabetic mice might be the result of protein wasting due to unavailability of carbohydrate for utilisation as an energy source (Chen & Ianuzzo, 1982). Diabetes mellitus is one of the most common human metabolic diseases, and derangements in lipid metabolism in diabetes are often important determinants of the course and status of the diseases (Fumelli, Romagnoli, Carlino, Fumelii, & Boemi, 1996). When compared with normal mice, the present results also showed that the TC, TG and LDL concentrations in the serum were significantly increased ($p < 0.05$), whereas serum HDL level was significantly decreased ($p < 0.05$) in the alloxan-induced diabetic mice. After administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days, the alteration in lipid metabolism was partially attenuated when compared with untreated diabetic mice. Our study revealed that the hypoglycaemic and hypolipidemic effects of SPS was more prominent compared with that of PS.

Diabetes mellitus is associated with generation of reactive oxygen species leading to oxidative damage particularly in liver and

kidney (Kakkar et al., 1998; Mohamed et al., 1999). Oxidative stress in diabetes coexists with a decrease in the antioxidant status (Picton, Flatt, & Mcclenghan, 2001), which can increase the deleterious effects of free radicals. Antioxidants play a major role in protecting biological systems against reactive oxygen species and reflect the antioxidant capacity of the system (Irshad & Chaudhuri, 2002). The components of the defence system that have evolved to reduce the injury from free radical attack include several enzymes and a few free radical scavenger molecules (Vendemiale, Grattagliano, & Altomare, 1999). In the present experiment, we have also observed a significant increase ($p < 0.05$) in the level of MDA associated with the diminution of the activities of SOD, GSH-Px and CAT and the levels of GSH, vitamin C and vitamin E in liver and kidney of diabetic mice in comparison with normal mice. These results further confirm that there is a strong correlation between oxidative stress and diabetes occurrence. The administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days, caused a significant decrease in the level of MDA ($p < 0.05$) and a significant increase in the activities of enzymic antioxidants ($p < 0.05$) and the levels of non-enzymic antioxidants ($p < 0.05$) in liver and kidney of diabetic mice. Our study also revealed that the antioxidant effect of SPS was more potent than that of PS.

Vitamin C is a potent antioxidant, which widely acts on oxygen free radicals as well as by interaction with vitamin E (Garg & Bansal, 2000). Both the vitamin C and vitamin E significantly decreased in the liver and kidney of diabetic mice. The administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days increased the vitamin C and vitamin E levels. This indicates that vitamin E is used in combating free radicals and if vitamin C is present, vitamin E levels are preserved. Also vitamin C regenerates vitamin E from its oxidised form. GSH has a multifactorial role in antioxidant defence. It is a direct scavenger of free radicals as well as a co-substrate for peroxide detoxification by GSH-Px. Loven, Schedl, Wilson, and Diekus (1986) suggested that the decrease in tissue GSH could be the result of decreased synthesis or increased degradation of GSH by oxidative stress in diabetes. We observed a decrease in GSH in the liver and kidney of diabetic mice. The administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days increased the content of GSH in the liver and kidney of diabetic mice. This indicates that the PS and SPS can either increase the biosynthesis of GSH or reduce the oxidative stress leading to less degradation of GSH, or have both effects.

SOD has been postulated as one of the most important enzymes in the enzymatic antioxidant defence system which catalyses the dismutation of superoxide radicals to produce H_2O_2 and molecular oxygen (Mc-Crod, Keele, & Fridovich, 1976), hence diminishing the toxic effects caused by their radical. The observed decrease in SOD activity could result from inactivation by H_2O_2 or by glycation of enzymes (Sozmen, Sozmen, Delen, & Onat, 2001). The superoxide anion has been known to inactivate CAT, which involved in the detoxification of hydrogen peroxide (Chance, Green Stein, & Roughton, 1952). Thus, the increase in SOD activity may indirectly play an important role in the activity of catalase. CAT is a hemeprotein which catalyses the reduction of hydrogen peroxides and protects the tissues from highly reactive hydroxyl radicals (Searle & Wilson, 1980). This decrease in CAT activity could result from inactivation by glycation of the enzyme (Yan & Harding, 1997). Reduced activities of SOD and CAT in the liver and kidney have been observed in diabetic mice. The administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days increased the activities of SOD and CAT in the liver and kidney of diabetic mice. GSH-Px plays a primary role in minimising oxidative damage. Glutathione peroxidase (GSH-Px), an enzyme with selenium, and glutathione-s-transferase (GST) works together with glutathione in the decomposition of H_2O_2 or other organic hydroperoxides to non-toxic products at the expense of reduced glutathione (Bruce, Freeman, & James, 1982). Reduced activity of GSH-Px may result from radical-induced inactivation and glycation of the enzyme (Hodgson & Fridovich, 1975). Reduced activities of GSH-Px in the liver and kidney has been also observed in diabetic mice. The administration of the PS (150 mg/kg body weight, without selenium) and SPS (150 mg/kg body weight, organic selenium content: 15.21 μg/g) for 20 days increased the activity of GSH-Px in the liver and kidney of diabetic mice. This means that the PS and SPS can reduce the potential glycation of enzymes or they may reduce reactive oxygen free radicals and improve the activities of antioxidant enzymes.

In conclusion, the present investigation showed that the PS and SPS possess potent antioxidant activity, which may be directly or

indirectly responsible for its hypoglycaemic and hypolipidemic properties. Furthermore, the effect of SPS was more potent than that of PS which may due to the co-effect of polysaccharide and selenium. Therefore, the SPS should be considered as a candidate for future studies on diabetes.

Browning
Free amino group
Antioxidant activity

ABSTRACT

Maillard reaction products (MRPs) were prepared from casein–glucose by refluxing for 130 min at 102 °C and initial pH 12.0 without pH control to investigate the characteristics of casein–glucose Maillard reaction and the antioxidant activity difference among different fractions of MRPs. Browning and intermediate products increased, however, the pH of the system decreased with increase in the heating time. Free amino group content decreased 78% during first 10 min and did not change nearly thereafter. Amino acid analysis indicated that lysine and arginine decreased significantly, and casein was partially hydrolysed to peptides or free amino acid. High molecular weight compounds were dominant in the MRPs, determined by high performance gel-filtration chromatography. After ultrafiltration, antioxidant activity of each MRPs fraction was investigated by DPPH radical-scavenging activity, reducing power, Fe^{2+} chelating activity and lecithin oxidation assay. MRPs of different molecular weight exhibited distinctly different antioxidant activities.

1. Introduction

Maillard reaction (MR) is a very complex reaction between carbonyls and amines. It occurs spontaneously during food processing and storage, mainly by the reaction between reducing sugars and the amino groups of proteins (Liu, Yang, Jin, Hsu, & Chen, 2008). MR usually produces a wide range of products with odors and colours, antioxidant, antiallergenic, antimicrobial and cytotoxic properties (Liu et al., 2008; Plavsic, Cosovic, & Lee, 2006; Rufian-Henares & Morales, 2006). MR also leads to the reduction of protein nutrition, digestive incompatibility and potential toxicity (Ajandouz, Desseaux, Tazi, & Puigserver, 2008).

Maillard reaction products (MRPs) of amino acid–sugar have been found to exhibit strong antioxidant activity. Various mechanisms are involved in the antioxidant activity of MRPs, like radical chain-breaking activity (Eichner, 1981; Morales & Jimenez-Perez, 2001), scavenging of reactive oxygen species (Bersuder, Hole, & Smith, 2001), decomposing hydrogen peroxide and metal chelation (Wijewickreme, Kitts, & Durance, 1997).

The high molecular weight melanoidins prepared from xylose and glycine has been found to possess a higher browning, reducing power and antioxidant activity (Yamaguchi, Koyama, & Fujimaki, 1981). Yen and Tsai (1993) investigated the antioxidant activity of partially fractionated MRPs prepared by refluxing glucose (0.5 M) and tryptophan (0.5 M) at pH 11.0 and 100 °C for 10 h, the results showed that the high molecular weight fraction achieved higher reducing power and antioxidant activity. Rufian-Henares and Morales (2007) investigated the effect of in vitro enzymatic digestion on antioxidant activity of coffee melanoidins and fractions. The results acquired two plausible options: modifying/releasing the ionically bound compounds and/or genesis of new more active structures from the melanoidin skeleton after enzymatic treatment.

Most studies have been done to investigate the mechanism of MR from proteins and sugars. More than half a century ago, Lea and Hannan (1949) published some valuable kinetic data on the influence of temperature, pH and water activity on the Maillard reaction in a glucose–casein model system. In subsequent kinetic studies, model systems such as those based on soy proteins, egg albumin (Kato, Matsuda, Kato, & Nakamura, 1989) and milk were used (Brands & Van Boekel, 2003).

MRPs of protein–sugar have been investigated as suitable encapsulant to protect sensitive core material against oxidation (Augustin, Sanguansri, & Bode, 2006; Drusch et al., 2009; Kosaraju, Weerakkody, & Augustin, 2009). Glycation of casein with glucose or lactose resulted in an enhancement of antioxidant activity when compared with native casein (McGookin & Augustin, 1991), but the antioxidant mechanism and the active components are not understood clearly. The objectives of this study were (1) to describe the characteristics of casein–glucose MR at high pH, the possible changes in chemicals during heating and (2) to investigate the

possible antioxidant activity difference among different fractions of MRPs.

2. Materials and methods

2.1. Chemicals

Ferrozine and 2, 2-diphenyl-1-picrylhydrazyl (DPPH) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Casein, an isoelectric precipitate containing 14.5% nitrogen, was obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Lecithin was purchased from East China Norm University Chemical Reagent Co., Ltd. (Shanghai, China). The other solvents/chemicals used were of analytical grade and obtained from Shanghai Chemical Reagent Co., Ltd. (Shanghai, China).

2.2. Preparation of Maillard reaction products

Casein–glucose model systems were used as reported by Drusch et al. (2009) with some modifications. The model consisted of casein (5.0 g) and glucose (10.0 g), dissolved in distilled de-ionised water (dd H_2O) and adjusted to pH 12.0 with 5.0 M NaOH and 1.0 M HCl solution, the substrate concentration was adjusted to 20% (w/v) with ddH_2O. The solution was transferred to a 250 ml 3-neck round-bottom flask and heated at 102 °C for 130 min under refluxing in an oil bath with magnetic stirring at 40 rpm. The heated casein–glucose mixtures were termed as Maillard reaction products (MRPs). Five milliliters sample of MRPs was removed with a pipet at different intervals and placed in an ice bath to cool down. The samples from the heating for 130 min were lyophilised with Stoppering Tray Dryer (LABCONOCO, USA) for further chemical and biological experiments. The lyophilisation was proceeded under 0.12 mbar vacuum with four different segments in the order of (1) 1.0 h at −30 °C, (2) 20 h at −10 °C, (3) 20 h at −4 °C, (4) finally 0.5 h at 15 °C. All determinations were carried out at least two times and mean values were calculated.

2.3. Ultrafiltration of the Maillard reaction products

Water-soluble MRPs were isolated by ultrafiltration according to the method as described by Yen and Tsai (1993). Briefly, after ice bath cooling, MRPs obtained from 130 min heating were adjusted to pH 7.0 with 1 M NaOH and then centrifuged at 3000 rpm for 15 min to obtain the water-soluble MRPs. Two hundred milliliters water-soluble MRPs diluted solution was subjected to ultrafiltration, using an Amicon ultrafiltration cell model 8400 (Amicon, Beverly, MA, USA) equipped with 50 30, 10, 5, and 1 kDa nominal molecular mass cut-off membrane. The 20 ml retentate was topped up to 200 ml with water and washed again. Washing step was repeated at least three times. Each fraction was collected and lyophilised, then stored in desiccators at 4 °C until analysis.

2.4. Measurement of pH

A pH meter (Model SP-71, METTLER TOLEDO, Inc., Shanghai, China) was used for the determination of system's pH values.

2.5. Measurement of the absorbance

The absorbance of the heated solutions was measured using a spectrophotometer (UNICO UV-2100, Shanghai, China) at 294 and 420 nm, as markers at the intermediate and final stages of the reactions, respectively (Ajandouz, Tchiakpe, Ore, Benajiba, & Puigserver, 2001). Samples were diluted 100 and 50-fold with 0.1% (w/v) sodium dodecyl sulfate (SDS) to obtain absorbance value at 294 and 420 nm, respectively.

2.6. Measurement of free amino group content

The quantity of available amino groups was determined by the modified *o*-phthaldialdehyde (OPA) method (Guan, Qiu, Liu, Hua, & Ma, 2006). The OPA reagent was prepared daily. Forty milligram of OPA was dissolved in 1.0 ml of methanol and 3.0 ml ddH_2O and named as CA. Twenty five milliliter 100 mM sodium tetraborate, 2.5 ml of 20% sodium dodecyl sulfate (SDS) and 100 μl of β-mercaptoethanol were mixed, and then diluted to a final volume of 50 ml with water, this solution was termed as CB. Two hundred microliter sample solution was added to the mixture of 0.3 ml CA and 3.7 ml CB. The solution was mixed briefly and incubated for 2 min at ambient temperature, and the absorbance was read at 340 nm using a UNICO UV-2100 spectrophotometer. The blank was determined in the same manner, except that ddH_2O was used instead of sample. A calibration curve was obtained by using 0.25 ∼ 2 mM L-lysine as a standard. Amino group loss was calculated from the ratio of the volume of OPA used after heating to the volume of OPA used for original sample. Casein was heated without glucose under identical conditions as the preparation of MRPs for 130 min, and termed as casein heated. Total nitrogen content was determined using the Kjeldahl method and confirmed the protein content of each solution. Results were the average of three measurements and expressed as free amino group loss (%).

2.7. Amino acid analysis

The samples were hydrolysed with 6 M hydrochloric acid at 110 °C for 24 h under vacuum. The hydrolysate was submitted to automated online derivatisation with *o*-phthalaldehyde and reversed phase high performance liquid chromatography (RP-HPLC) analysis in Agilent 1100 (Agilent Technology, Palo Alto, CA, UAS) assembly system using a Zorbax 80A C_{18} column (4.6 i.d. × 180 mm), running at 0.5 ml/min. The results acquired were analysed with the aid of ChemStation for LC 3D software (Agilent Technology, Palo Alto, CA, USA). Results were expressed as percentage (%) of amino acid of the measurement.

2.8. Estimation of molecular weight (MW) distribution

The high performance gel-filtration chromatography (HPGFC) was performed with HPLC system (Waters 600, Waters Inc., USA) equipped with a column (Ultrahydrogel™Linear 300 mm × 7.8 mmid × 2) and Empower ChemStation. A refractive index detector was used to detect samples eluting from the column. The effluent was 0.1 M $NaNO_3$ at 0.9 ml/min. The standard compounds for molecular weight estimation were: (1) MW 2000 kDa (2) MW 133.8 kDa (3) MW 7.1 kDa (4) MW 2.5 kDa and (5) MW 0.18 kDa. The sample was injected after being dissolved in effluent and filtrated with 0.45 um membrane. The molecule weight was calculated as follows;

$$\text{Log MW} = 12.6 - 0.479\,T \quad (1)$$

where MW means molecular weight and *T* means elution time.

2.9. Determination of reducing power

The reducing power of MRP samples was determined according to the method of (Oyaizu, 1986) with some modifications. One milliliter of MRPs sample (100-fold dilution) was mixed with 1.0 ml of 0.2 M sodium phosphate buffer (pH 6.6) and 1.0 ml of 1% potassium ferricyanide ($K_3Fe(CN)_6$). The reaction mixtures were incubated in a temperature-controlled water bath at 50 °C for 20 min,

followed by addition of 1.0 ml of 10% trichloroacetic acid after cooling to room temperature. The mixtures were then centrifuged at 750 g using a centrifuge (TG16-WS, Xiangyi, Changsha, China) for 10 min at 25 °C. The supernatant obtained (1.0 ml) was treated with 1.0 ml of distilled water and 200 μl of 0.1% $FeCl_3$. The absorbance of the reaction mixture was measured at 700 nm with UNICO UV-2100 spectrophotometer. Reducing power was expressed as absorbance at 700 nm, the lowest value of the tests was used as the initial reference value, and an increase in absorbance was used as the measure of the increased reducing power. For the comparison, the assay was conducted in the same manner but butylhydroxytoluene (BHT) was added instead of sample solution. The results were expressed as absorbance units (AU).

2.10. Determination of DPPH radical-scavenging activity

DPPH radical-scavenging activity was determined according to the method of Benjakul, Visessanguan, Phongkanpai, and Tanaka (2005) with some modifications. An aliquot of MRPs sample (1.0 ml) was added to 2.0 ml of 0.1 mM DPPH in ethanol. The solution was then mixed vigorously and allowed to stand at room temperature in the dark for 20 min. The mixture was centrifuged for 10 min at 750g. The absorbance of supernatant was measured at 517 nm using a UNICO UV-2100 spectrophotometer. The blank was prepared in the same manner, except that distilled water was used instead of MRPs samples. For the control, the assay was conducted in the same manner but ethanol was added instead of DPPH solution. For the comparison, the assay was conducted in the same manner but BHT was added instead of sample solution. The percentage of DPPH radical-scavenging activity was calculated as follows;

$$\text{Radical-scavenging activity}(\%) = \left[1 - (A517\ \text{nm}_{\text{sample}} - A517\ \text{nm}_{\text{control}})/A517\ \text{nm}_{\text{blank}}\right] \times 100 \quad (2)$$

where A517 nm_{sample} is the absorbance of sample, A517 $nm_{control}$ is the absorbance of the control and A517 nm_{blank} is the absorbance of the blank.

2.11. Determination of chelating activity on Fe^{2+}

Chelating activity of MRPs was determined by the method of Dinis, Madeira and Almeida (1994) with modifications. One milliliter sample solution was mixed with 1.85 ml ddH_2O and 0.05 ml 2.0 mM $FeCl_2$, the mixture was allowed to rest at room temperature (28 °C) for 30 s. The reaction mixture thus obtained was later added with 0.1 ml 5 mM ferrozine (Sigma, St. Louis, MO, USA) and mixed, absorbance at 562 nm was determined with UNICO UV-2100 spectrophotometer after 10 min resting time at room temperature and 5 min centrifugation at 3000 rpm. For the blank, the assay was conducted in the same manner but ddH_2O was added instead of sample solution. The percentage of chelating activity was calculated as follows;

$$\text{Chelating activity}(\%) = \left(1 - A562\ \text{nm}_{\text{sample}}/A562\ \text{nm}_{\text{blank}}\right) \times 100 \quad (3)$$

where A562 nm_{sample} is the absorbance of sample and A562 nm_{blank} is the absorbance of the blank.

2.12. Inhibition of lipid peroxidation induced by iron

Lecithin was suspended in phosphate buffered saline (0.01 M, pH 7.4) at a concentration of 10.0 mg/ml with magnetic stirring (Yi, Meyer, & Frankel, 1997). The solution was labeled as LLS. Fifteen gram trichloroacetic acid (TCA), 0.37 g thiobarbituric acid (TBA) and 2 ml concentrated hydrochloric acid (HCl) were added to ddH_2O, and the volume was adjusted to 100 ml with ddH_2O. The solution was labeled as TCA–TBA–HCl. One milliliter LLS, 1.0 ml 400 uM $FeCl_3$, 1.0 ml 400 uM ascorbic acid and 1.0 ml sample solution were mixed to the flasks in order and mixed well. The solution was placed in water bath at 37 °C in dark for 60 min, and then 2.0 ml TCA–TBA–HCl was added. The system was cooled down with ice water after heating in water bath at 90 ~ 100 °C for 15 min. The pink solution was centrifuged at 750g for 10 min, and the absorbance of the supernatant was read at 532 nm, and called as As. The blank was made with 1.0 ml ddH_2O substitution for 1.0 ml sample, named as Ac. The inhibition percentage (%) was calculated as formula;

$$\text{Inhibition percentage}\ (\%) = (\text{Ac} - \text{As})/\text{Ac} \times 100. \quad (4)$$

2.13. Statistical analysis

Collected data were expressed as mean ± standard deviation (SD). Analysis of variance (ANOVA) was performed and means comparisons were carried out by Student–Newman–Keuls' tests. A value of $p < 0.05$ was considered significant. Data were analysed by using a statistical software package (SPSS for Windows, 13.0, 2005, SPSS Inc. USA).

3. Results and discussion

3.1. Changes of pH

The pH of casein-glucose system decreased as the heating time is extended up to 130 min (Table 1). The pH decreased at a higher rate during the first 30 min, thereafter, it slightly decreased up to 130 min, and the pH of casein–glucose MRPs decreased from approximately 12.0 to 5.5 ~ 6.5. The phenomena may be due to the production of formic and acetic acid from glucose, which is partially degraded to these compounds when it is heated at high pH with protein or not (Rufian-Henares, Delgado-Andrade, & Morales, 2006). Other acids such as lactic, levulinic, propionic, butyric, pyruvic, citric and saccharinic acids might have been formed (Brands & Van Boekel, 2003).

At the intermediate stage of the MR, because of the generation of some acidic compounds with buffering capacities including formic acid, acetic acid, methylglyoxal, glyoxal, etc. and the inhibition of acidity to MR, decrease in pH was leveled off with prolonged heating time. Therefore, it can be concluded that the consumption of amino group, together with formation of acids, could be the mechanism of pH decreasing tendency in the MR system (Liu et al., 2008).

3.2. Changes in absorbance

The color progress in MR was investigated by measuring absorbance at 420 nm. As can be seen from Table 1, a sharp increase

Table 1
Changes in pH and absorbance (mean ± SD) at different wavelengths of the mixture during heating to 130 min.

Heating time (min)	pH	Absorbance at 420 nm	Absorbance at 294 nm
0	$12.0^{a} \pm 0.21$	$0.007^{a} \pm 0.002$	$0.138^{a} \pm 0.023$
10	$9.41^{b} \pm 0.71$	$0.511^{b} \pm 0.051$	$2.311^{b} \pm 0.035$
30	$7.63^{c} \pm 0.37$	$0.697^{c} \pm 0.072$	$2.533^{c} \pm 0.097$
60	$6.86^{c,d} \pm 0.42$	$0.757^{c,d} \pm 0.108$	$2.602^{c} \pm 0.069$
90	$6.51^{d} \pm 0.35$	$0.803^{c,d} \pm 0.054$	$2.623^{c} \pm 0.036$
130	$6.10^{d} \pm 0.55$	$0.853^{d} \pm 0.076$	$2.658^{c} \pm 0.012$

[a–d]Different letter superscripts denote significant difference ($p < 0.05$). SD: standard deviation from triplicate determinations.

browning was observed during the first 30 min. The similar results were obtained by Rufian-Henares, Garcia-Villanova, and Guerra-Hernandez (2004), although the colour intensity in the paper was higher. This difference could be related to the different pH used. The initial pH value of the reaction system was considered to affect Maillard reaction significantly. In alkaline condition, Schiff-base formed easily and promoted the MR further. Consequently, the brown components of MR system were produced quickly. During the development of brown color caused by the MR, caramelisation can occur simultaneously. Caramelisation reactions contribute to overall non-enzymatic browning, especially in the alkaline pH ranges (Ajandouz et al., 2001; Benjakul et al., 2005).

The slight increases in browning intensities of MRPs samples were observed after 30 min of heating (Table 1).The results might be due to the consumption of the amino group and production of acid by MR, shifting systems into more acidic condition and lowered the browning reaction.

Absorbance at 294 nm was used to investigate the formation of the intermediate compounds of the MR (Ajandouz et al., 2001). A significant increase ($p < 0.05$) in A294 nm of MRPs samples was observed during 30 min of heating (Table 1). However, no significant changes in A294 nm of MRPs were found with prolonged heating time up to 130 min. The results suggested that intermediate products were produced to a great extent within the first 30 min. During extended heating, some intermediate products might undergo polymerisation to form the melanoproteins whereas only a small amount of intermediate products was generated (Lertittikul, Benjakul, & Tanak, 2007).

3.3. Changes in free amino group content

Table 2 shows the results of amino group changes determined with the OPA method. Since no amino groups were modified on native casein, all results were reported relative to 100% of the amino groups of native casein. When casein was heated without glucose at pH 12, thirteen percent amino groups could not been detected (Table 2). This may be due to the S–S covalent bond between *k*-casein and steric obstruction. Amino group losses have been previously reported in proteins heated alone (Smith & Friedman, 1984).

As can be seen in Table 2, a significant ($p < 0.05$) decrease in free amino group content of MRPs was observed when heated for the first 10 min. About 78% free amino groups were lost due to the attachment to the reducing compounds. Then the amino group loss was not changed significantly with the extended heating time to 130 min. This indicates that heating quickly induces alkali catalysed interaction of free amino groups, such as ε-NH_2 groups of lysine, with sugar via glycation process within 10 min. High pH quickly induced the condensation reaction between free amino groups of casein and the carbonyl groups of glucose and its degradation products (Brands & Van Boekel, 2003).

From the above results, the decrease in free amino group was in accordance with the increase in browning and absorbance at 294 nm (Table 1). The reaction rate of glycation between casein and sugar depended on the percentage of the acyclic form and the electrophilicity of the carbonyl groups (Naranjo, Malec, & Vigo, 1998). As the pH of the casein–sugar systems dropped during the extended heating time and in addition, due to protonation of the lysine residues, the reactivity of the protein decreased, resulting in the insignificant changes in the free amino group loss after 10 min heating.

Table 2
Free amino group loss percentage (mean ± SD) in casein–glucose MRPs heated for different time and in heated casein in absence of glucose.

Samples	Free amino loss (%)
0 min	$0^{a} \pm 0.73$
10 min	$78.07^{b} \pm 2.63$
30 min	$79.83^{b} \pm 0.88$
60 min	$80.71^{b} \pm 0.72$
90 min	$80.92^{b} \pm 1.35$
130 min	$78.07^{b} \pm 2.47$
Casein heated	$13.16^{c} \pm 0.65$

[a–c]Different letter superscripts denote significant difference ($p < 0.05$); SD: standard deviation from triplicate determinations.

3.4. Amino acid analysis

The amino acids in the MRPs of MW higher than 50 kDa decreased almost 21.73% compared with native casein (Table 3). Amino acid percentage composition of all three types of MRPs showed that MR caused a significant loss in lysine and arginine compared to native casein. Moreover, arginine and lysine of unfractioned MRPs decreased to 1.43% and 7.77%, respectively (Table 3) compared to the original values in the native casein. This indicated that glucose and glucose degraded products attached to casein or casein peptides. The lost amino groups were probably originated largely from the side chains of lysine residues, but guanidino groups of arginine might also have been involved. Losses in cystine and lysine with the application of heat have also been attributed to the formation of cystine-derived crosslink. Heat results in the formation of a dehydroalanyl residue from cystine, which is capable of binding with the ε-amino group of lysine to form lysinoalanine. This indicates that lysinoalanine can be formed only at basic pH (Ajandouz et al., 2008).

Amino acids can be seen in the MRPs of MW from 5 to 10 kDa, though the quantity is small (Table 3). It showed that casein was degraded to peptides or free amino acid when casein was heated at high pH and high temperature. These compounds can react with glucose and its degraded products.

3.5. Molecular weight distribution of MRPs

Three peaks are found as shown in Fig. 1. Area of peak 1 was the largest, which means that the high molecular weight MRPs dominate in the mixture. According to the formula (1), the molecular weight distributions were: peak1, 4.404–2.400 kDa; peak2, 0.765–4.404 kDa; peak3, 0.018–0.765 kDa.

MRPs from casein–glucose comprise a wide range of compounds. Casein was covalently attached to glucose and glucose degradation products (GDPs), which results in high MW MRPs (melanoproteins). Caramelisation of glucose heated at high pH induces the formation of low and medium MW compounds, while casein hydrolysates reacted with glucose and GDPs also contribute to this kind of MRPs (Drusch et al., 2009).

3.6. Reducing power

During the reducing power assay, the presence of reductants in the tested samples result in reducing Fe^{3+}/ferricyanide complex to the ferrous form (Fe^{2+}). The Fe^{2+} can therefore be monitored by measuring the formation of Perl's Prussian blue at 700 nm (Yoshimura, Iijima, Watanabe, & Nakazawa, 1997).

Reducing power of MRPs increased with the increased concentration of MRPs (Table 4), it reached to 0.668 of absorbance at 700 nm with concentration of 2 mg/ml, but increased slightly afterwards. This result revealed that MRPs could function as electron donors, but its reducing power was less than that of BHT (Table 4).

Reducing power of each fraction of MRPs and the unfractionated MRPs are shown in Table 5, reducing power was found in this order, MW higher than 50 kDa = MW 10–30 kDa > MW 1–5 kDa = unfractionated MRPs > MW 5–10 kDa = MW lower than 1 kDa =

Table 3
Amino acid percentage composition (%) of native casein and different types of Maillard reaction products (MRPs).

Amino acids	Casein	MW[a] > 50 kDa[b] MRPs	Unfractioned MRPs	MW 5–10 kDa MRPs

MW > 50 kDa MRPs: the MRPs of molecular weight higher than 50,000 Da; unfractioned MRPs: MRPs without ultrafiltration; casein: native casein; MW 5–10 kDa MRPs: MRPs of molecular weight from 5000 to 10,000 Da.
[a] MW means molecular weight.
[b] kDa means kilo Dalton.

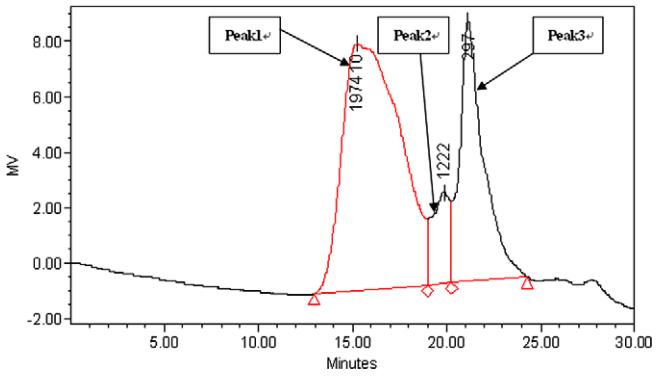

Fig. 1. Distribution of molecular weight of casein–glucose MRPs by high performance gel-filtration chromatography.

MW 30–50 kDa. The mixture of the heated casein–glucose was a wide range of compounds, consisting of glucose degradation products, protein, protein hydrolysates, caramelisation products, glycated protein, glycated peptides, etc. Each kind of product might exhibit distinctly different reducing power. The high molecular weight (MW higher than 50 kDa) MRPs exhibited the highest reducing power. Hydroxyl groups of advanced MRPs may play a role in reducing activity. Additionally, the intermediate compounds of MRPs were reported to break the radical chain by donation of a hydrogen atom (Eichner, 1981). These results are also in agreement with the previous reports of Delgado-Andrade, Rufian-Henares, and Morales (2005) and Yamaguchi et al. (1981), who described that a high molecular weight of melanoidin prepared from xylose and glycine achieved a higher browning and reducing power.

3.7. DPPH radical-scavenging activity

DPPH radical-scavenging activity increased as the concentration of MRPs increased. This activity increased drastically ($p < 0.05$) at the low concentration of MRPs, while nearly reached a plateau after that concentration (Table 4). DPPH radical was scavenged by MRPs by donation of hydrogen to form a stable DPPH-H molecule. The color change from purple to yellow by acceptance of hydrogen radical from MRPs and it become a stable diamagnetic molecule (Benjakul et al., 2005).

Either intermediates or the final brown polymer can function as hydrogen donors, sugar caramelisation can also contribute to the antiradical activity measured by DPPH test (Benjakul et al., 2005) As can be seen from Table 4, the DPPH radical-scavenging activity of MRPs was less stronger than that of BHT. Based on the reducing power and radical-scavenging activity of MRPs from the casein–glucose, however, it can be used as antioxidant for food products.

As Table 5 indicates, the radical-scavenging activity of low MW MRPs was greater than that of high MW MRPs. This phenomenon was not consistent with the results of reducing power. This may be due to the complexity of MRPs, which quench hydrophilic radicals more efficiently than hydrophobic (Jing & Kitts, 2002). The higher ability to quench hydrophilic radicals is due to the higher water solubility of the melanoproteins. More investigation needs to be conducted to elucidate this phenomenon.

3.8. Chelating activity on Fe^{2+}

Ferrous ion chelating activity of MRPs from casein–glucose is shown in Table 4. The chelating activity increased as the concentration of MRPs increased. Chelating activity increased from 31.24% to 93.87% as the MRPs concentration increased from 0.50 to 2.0 mg/ml. MRPs have been found to be effective as metal chelating compounds (Wijewickreme et al., 1997)

High MW fractions exhibited higher metal-chelating power, whereas low MW fractions did not show this kind of activity (Table 5). The high molecular weight MRP was reported to possess greater metal chelating potential than low molecular weight MRPs. The chelating activity can possibly be attributed to hydroxyl groups originating from MRPs (Yoshimura et al., 1997).

3.9. Inhibition of lipid peroxidation

As far as lipid peroxidation is concerned, free radicals abstract hydrogen from a fatty acid double bond to produce fatty acid free radicals, which further react with oxygen to produce fatty acid hydroperoxide. The hydroperoxide is unstable and decomposes readily to shorter chain hydrocarbons such as aldehydes, etc. The intermediate products can be determined as thiobarbituric acid reactive substances (TBARS) assay. Table 4 shows the inhibition

Table 4
Reducing power, radical-scavenging activity, chelating activity and lipid peroxidation inhibition percentage of MRPs or BHT (mean ± SD).

Concentration of MRPs[a] or BHT[b] (mg/ml)	Reducing power[d]	Radical-scavenging (%)	Chelating activity of MRPs (%)	Inhibition percentage of MRPs (%)
0.5 (0.1)	$0.572^{a} \pm 0.033$ ($0.553^{a} \pm 0.041$)	$28.52^{a} \pm 2.37$ ($59.34^{a} \pm 3.76$)	$31.24^{a} \pm 2.16$	$9.10^{a} \pm 1.12$
1.0 (0.2)	$0.609^{a,b} \pm 0.056$ ($0.807^{b} \pm 0.025$)	$33.33^{a,b} \pm 2.76$ ($63.08^{a,b} \pm 4.31$)	$62.26^{b} \pm 1.73$	$20.96^{b} \pm 1.31$
2.0 (0.3)	$0.668^{b,c} \pm 0.037$ ($1.038^{c} \pm 0.072$)	$34.78^{b} \pm 1.74$ ($70.25^{b} \pm 5.02$)	$93.87^{c} \pm 3.27$	$31.73^{c} \pm 2.09$
4.0 (0.4)	$0.720^{c} \pm 0.043$ ($1.342^{d} \pm 0.042$)	$36.41^{b} \pm 3.12$ ($78.48^{c} \pm 4.18$)	—[c]	$38.32^{d} \pm 2.15$
8.0 (0.5)	$0.758^{c} \pm 0.038$ ($1.418^{d} \pm 0.059$)	$38.52^{b} \pm 3.26$ ($80.47^{c} \pm 3.17$)	—	$41.21^{d} \pm 2.83$

[a–d]Different letter superscripts denote significant difference ($p < 0.05$). SD: standard deviation from triplicate determinations. The data in parentheses are antioxidation results of BHT.
[a] MRPs: Maillard reaction products were prepared as the Section 2.2 report, the heating time was 130 min.
[b] BHT means butylhydroxytoluene and the concentration is indicated in the parenthesis.
[c] — : not determined.
[d] Absorbance of the reaction mixture was measured at 700 nm.

Table 5
Reducing power, radical-scavenging activity, chelating activity and lipid peroxidation inhibition percentage of different MRPs fractions of different molecular weights (mean ± SD).

Samples	Reducing power[c]	Radical-scavenging activity (%)	Chelating activity (%)	Inhibition percentage (%)
MW[a] < 1 kDa[b]	$0.4845^{a} \pm 0.019$	$40.39^{c,d} \pm 1.68$	0	$33.82^{c} \pm 1.03$
MW 1–5 kDa	$0.5235^{b} \pm 0.024$	$42.96^{d} \pm 3.10$	0	$57.11^{d} \pm 2.45$
MW 5–10 kDa	$0.501^{a} \pm 0.004$	$22.86^{b} \pm 0.28$	0	$61.72^{e} \pm 3.51$
MW 10–30 kDa	$0.5395^{c} \pm 0.018$	$36.06^{c} \pm 4.29$	0	$57.83^{d} \pm 1.12$
MW 30–50 kDa	$0.471^{a} \pm 0.027$	$19.81^{b} \pm 1.19$	$59.43^{a} \pm 1.61$	$62.24^{e} \pm 3.6$
MW > 50 kDa	$0.5685^{c} \pm 0.015$	$5.52^{a} \pm 0.32$	$88.27^{b} \pm 2.20$	$6.87^{a} \pm 0.88$
Unfractionated MRPs	$0.520^{b} \pm 0.021$	$24.04^{b} \pm 3.24$	$85.42^{b} \pm 1.93$	$24.75^{b} \pm 4.21$

[a–e]Different letter superscripts denote significant difference ($p < 0.05$).
[a] MW means molecular weight.
[b] kDa means kilo Dalton; unfractioned MRPs: MRPs without ultrafiltration; SD: standard deviation from triplicate determinations.
[c] Absorbance of the reaction mixture was measured at 700 nm.

percentage of MRPs to lecithin oxidation, inhibition percentage increased evidently with increased concentration of MRPs.

As can be seen from Table 5, MW 30–50 and 5–10 kDa fractions of MRPs had greater lecithin antioxidant inhibition percentage than others, and close to the 1–5 and 10–30 kDa fractions. The results are partially not consistent with the other three antioxidant tests. In the presence of MRPs, the propagation step might be inhibited and lead to lower oxidation. Owing to chelating property of the ferrous ions, MRPs might retard the lipid oxidation by eliminating their pro-oxidant activity. It was likely that higher concentration of MRPs prevented oxidation in lecithin system via greater iron chelating potential (Benjakul et al., 2005). In general, MRPs of casein–glucose are very complicated, and the mechanism of lipid oxidation assay is very complex to elucidate.

4. Conclusion

Casein–glucose model system was chosen to prepare MRPs at high pH. The decrease in free amino groups and pH were consistent with the increase in browning and absorbance at 294 nm of the MR system. Amino acid analysis indicated that casein and glucose both degraded partially, all the compounds of the mixture took part in a complicated reaction. High molecular weight MRPs are the dominant compounds in the mixture of heated casein–glucose by HPGFC analysis. MRPs showed increased antioxidant activity with increasing concentration, different fractions of ultrafiltrated MRPs exhibited different antioxidant activity; this may be due to the complexity of MRPs, which could act simultaneously with different mechanisms of action. In this respect, research on the mechanisms of formation and the identification of the structure for the active compounds in Maillard reaction are also needed in the future study.

White asparagus spears quality
Edible coatings
Texture
Anthocyanins
Lignification

ABSTRACT

The effects of edible coatings and plastic packaging on quality aspects of refrigerated white asparagus spears were studied using two different experimental protocols. The first included four coating formulations based on carboxymethyl-cellulose and sucrose fatty acid esters, whey protein isolate alone and in combination with stearic acid, and pullulan and sucrose fatty acid esters, and an uncoated sample serving as a control. The second set consisted of four treatments; uncoated asparagus spears (control), coated with a carboxymethyl-cellulose formulation, packaged in plastic packaging and combination of coated and packaged asparagus spears. All products were stored at 4 °C and the quality parameters such as weight loss, texture, visual appearance, lignin and anthocyanins concentration, and colour were evaluated during their storage. Edible coatings exhibited a beneficial impact on the quality of asparagus by retarding moisture loss, reducing hardening in their basal part and slowing down the purple colour development. The plastic packaging had a remarkable influence in reducing weight loss and retarding hardening but its impact to the rest of the quality parameters was similar to that of the edible coatings. The combination of packaging and edible coating did not seem to offer any additional advantage on asparagus spears apart from the fact that the product had a brighter appearance at the middle part of the stem compared to the packaged spears alone.

1. Introduction

Asparagus (*Asparagus officinalis*, L.) has very short shelf life due to its high respiration rate, which continues after harvesting. White asparagus undergoes a sequence of considerable physiological and biochemical changes which quickly influence its chemical composition and lead to quality loss, mainly due to an increase of hardness, water loss and the synthesis of anthocyanins (Chang, 1987). Therefore, ensuring an extended shelf-life by adequate post-harvest conservation appears to be very challenging for commercialization of this highly valued vegetable (Villanueva, Tenorio, Sagardoy, Redondo, & Saco, 2005). Postharvest treatments to increase storage and shelf life included storage in modified atmosphere packaging (MAP) (Siomos, Sfakiotakis, & Dogras, 2000) and prestorage hot water treatments (Siomos, Gerasopoulos, & Tsouvaltzis, 2005).

The role of packaging on vegetable conservation, distribution and marketing is also quite popular and is frequently used in combination with other conservation methods, an approach called hurdle technology (Hoover, 1997). However, the final disposal of the packaging materials leads to ecological problems and additional recycling costs (Viña et al., 2007). On the other hand, the application of edible coatings appears to be one of the most innovative approaches to extend the commercial shelf life of fruits and vegetables by, among other mechanisms, acting as a barrier against gas transport and showing similar effects to storage under controlled atmospheres (Park, 1999). Indeed, over the last two decades the development and use of bio-based packaging materials to prolong the shelf-life and improve the quality of fresh products has been receiving increased attention. The reasons for such an interest are mainly related to environmental issues due to disposal of conventional synthetic food-packaging materials. However, in order such edible films and coatings to be used at a commercial level in food products they must fulfill some basic requirements: acceptable sensorial characteristics, appropriate barrier properties, good mechanical strength, reasonable microbial, biochemical and physicochemical stability, safety, low cost and simple technology for their production (Diab, Biliaderis, Gerasopoulos, & Sfakiotakis, 2001). The effectiveness of edible coatings for protection of fruits and vegetables also depends on controlling the wettability of the coating solutions, which affects the coating thickness (Park, 1999). Thus, edible coating formulations must wet and spread uniformly on the vegetable's surface and, after drying, a coating that has adequate adhesion, cohesion and durability to function properly must be formed (Ribeiro, Vicente, Teixeira, & Miranda, 2007).

doi:10.1016/j.foodchem.2009.03.076

Edible films and coatings are generally based on biological materials such as proteins, lipids and polysaccharides. The main polysaccharides that can be included in edible coating formulations are starch and starch derivatives, cellulose derivatives, chitosan, pectin, alginate and other gums. Carboxymethyl-cellulose is a cellulose derivative that has received considerable attention with several examples of applications in many fruits and vegetables. A commercial edible coating formulation based on carboxymethyl-cellulose and sucrose fatty acid esters, named Semperfresh™, has been applied to pears (Zhou et al., 2008), cherries (Yaman & Bayoindirli, 2002) and many other fruits. Pullulan, an extracellular polysaccharide produced by *Aureobasidium pullullans*, also is capable of forming edible films but has not been largely exploited as a coating material in fruits and vegetables, presumably because of its high water solubility. One example of pullulan used as a coating hydrocolloid was for strawberries and kiwifruit (Diab et al., 2001). Proteins that can also be used in formulations of edible coatings for fruits and vegetables include those derived from animal sources, such as casein and whey proteins, or obtained from plant sources, like corn zein, wheat gluten and soy protein (Vargas, Pastor, Chiralt, McClements, & Gonzalez-Martinez, 2008). Whey protein based coatings have been extensively used to extend the shelf life of fruits and vegetables (Cisneros-Zevallos & Krochta, 2003; Lerdthanangkul & Krochta, 1996).

To the best of our knowledge there are no available data regarding the effect of edible coatings on postharvest quality aspects of white asparagus spears. Therefore, the aims of the present work were to evaluate the effect of different edible coating formulations on quality parameters of white asparagus spears during refrigerated storage, to compare the impact of one of these edible coatings with that of a plastic packaging on the extension of asparagus postharvest life, and to explore if there is any additional beneficial effect of a combined treatment using edible coating and packaging with the synthetic film.

2. Materials and methods

2.1. Plant material

White asparagus (*Asparagus officinalis*, L.) spears were harvested from commercial farms in the regions of Imathia and Pella, Greece. The spears were hydrocooled and transported to the laboratory within 3 h after harvest, under refrigerated conditions. Straight, undamaged samples, around 18–22 mm in diameter, with closed bracts were carefully selected and cut at 18 cm from the tip.

2.2. Coating solutions preparation and application

Sodium carboxymethyl-cellulose (CMC 2500F Tic Gums, USA), whey protein isolate (WPI) (Bi-Pro®, Davisco Foods International, USA) and pullulan (Hyashibara Biochem Laboratory Inc., Okayama, Japan) were used as biopolymer matrices in the coating formulations. Other substances used were sucrose fatty acid ester F-50 with an HLB value of six (Dai Ichi Kogyo Seyaku Co., Ltd., Tokyo, Japan), polyethylenoglycol PEG 400 (Merck, Darmstadt, Germany), sorbitol and stearic acid (Sigma–Aldrich GmbH, Steinheim, Germany). Ethyl alcohol was reagent grade and water used in all experiments was distilled.

The carboxymethyl-cellulose based coating (CMC) was prepared by firstly dissolving the CMC (0.2% w/w) in a water–ethanol mixture (4:1 v/v) under magnetic stirring at 60 °C and then adding the plasticizer PEG (0.1% w/w) and the sucrose fatty acid ester F-50 (0.8% w/w), followed by stirring for 1 h. Two different coatings using the whey protein isolate were prepared; WPI 1 and WPI 2, which included 4% w/w WPI and 1% w/w sorbitol as a plasticizer, both dissolved in distilled water. The solutions were denatured for 30 min in a 90 °C water bath under continuous shaking and then were rapidly cooled in an ice bath, in order to stop further protein denaturation, and finally equilibrated to room temperature. WPI 2 also included 1% w/w stearic acid as a lipid constituent, which was incorporated to the coating solution just after the denaturation step by homogenization at 19,000 rpm for 4 min using an UltraTurrax T25 homogenizer (IKA Labortechnik, Staufen, Germany). The pullulan based coating solution (P) was obtained by dissolving pullulan (5% w/w) in distilled water under magnetic stirring at 60 °C with subsequent addition of sorbitol (1% w/w) and a sucrose fatty acid ester F-50 (1% w/w), followed by stirring for 1 h. All the coating solutions were left overnight at 4 °C in order to eliminate air bubbles. The composition of the coatings used in this work was selected among a large number of other coatings examined in preliminary trials.

Coating was carried out at room temperature by dipping the asparagus spears for 30 s in the formulated suspensions and then slow drying at ambient conditions, by turning them from time to time, for about 2 h. After the coating treatment the samples were placed in plastic trays and subjected to cold storage.

2.3. Coating characterization

The surface tension of each suspension was measured by the Ring Method using a Kruss tensiometer at 20 °C. Rheological characterization of the coating formulations was conducted by a rotational Physica MCR 300 rheometer (Physica Massterchnic GmbH, Stuttgart, Germany) using a double gap cylindrical geometry; temperature was regulated by a Paar Physica circulating bath and a controlled peltier system (TEZ 150P/MCR) with an accuracy of ±1 °C. The data of the rheological measurements were analyzed with the supporting software US200 V2.21. Flow curves were performed by measuring steady shear viscosity (η) over a range of shear rates between 0.1 and 1200 s^{-1} at 25 °C. The contact angles at the asparagus surface were measured following the Choi and Han procedure (Choi & Han, 2002), using a digital microscope (Intel QX3, Mattel Inc., El Segundo, CA). All the liquid drops used for the measurements were axecimetric.

The estimation of the critical surface tension (γ_C) of the white asparagus surface was obtained by extrapolation from the Zisman plot (Zisman, 1964), which was developed using water (HPLC grade), glycerol, ethylene glycol and dimethyl sulfoxide (DMSO) (Sigma–Aldrich GmbH, Steiheim, Germany), as reference liquids. Their surface tensions are 72.8, 63.4, 48.0 and 44.0 mN/m^2, respectively. To avoid changes on the asparagus surface, the measurements took place in less than 30 s. Ten replicates of contact angle measurements were obtained at 20 (±1) °C.

2.4. Sample treatments

Two different experimental sets were adopted. The first (set A) included application of four different coatings, CMC, WPI 1, WPI 2 and P on white asparagus spears and uncoated spears served as control (C). The samples were placed in a cold room at 4 °C and 95% RH for 11 days and the quality parameters were evaluated on days 6 and 11 after harvest. In the second experimental set (set B), four different treatments were employed: (a) uncoated samples (control – C), (b) CMC coated spears, (c) packaged asparagus in plastic trays wrapped with a 16 μm stretch film (Fabri Arti Grafiche S.R.L.-Vignola, Modena, Italy). The synthetic film had O_2 and CO_2 transmission rates of 583 and 1750 $ml\ m^{-2}\ h^{-1}\ atm^{-1}$, respectively, and a moisture vapor transmission rate of 14.6 $g\ m^{-2}\ h^{-1}\ atm^{-1}$ at 39 °C and 90% RH (film permeabilities were measured by the manufacturer) (Pack). The fourth treatment (d) involved a combination of CMC coating and the above packaging (Pack + CMC), in order to investigate if there is any additional

effect when combining edible coating and synthetic film packaging. All trays were placed in cold storage at 4 °C and 95% RH for 17 days. The determination of asparagus quality was held at the day of harvest (day 0) and at days 11 and 17. Each sample, containing five lots (6–7 spears/lot), was included for each experimental set, storage condition and sampling time.

2.5. Weight loss

Weight loss was measured periodically by weighting five trays containing 6–7 spears, for each treatment. The results were expressed as the percentage loss of initial weight.

2.6. Texture determination

The asparagus spears, 18 cm in length, were marked at 6-cm intervals from the tip and then sectioned at the ink markings into three cylindrical portions; apical, middle and basal, since it is known that there is evidence for significant differences in texture over the different parts of white asparagus (Rodríguez et al., 2004). The texture was measured at the middle of each of the three sections of each spear by applying the cutting test using a Texture Analyzer (TA-XT2i, Stable Microsystems). Values were expressed as maximum force (kg), using a Warner–Blatzler cell with a blade (0.3 cm width) that cut the spears at a speed of 5 mm/s (average of 20 replicates).

2.7. Visual evaluation of appearance

The general appearance of the products was assessed by at least 10 trained panelists. Samples were evaluated using the following hedonic scale: 1 = bad, 2 = fairly good, 3 = good, 4 = very good and 5 = excellent. A value of three was considered as the commercial acceptability threshold.

2.8. Colour measurements

Colour readings of the spears were performed with a chromatometer (Minolta CR-400/410, Minolta, Osaka, Japan), equipped with an 8-mm measuring head. The meter was calibrated using the manufacturer's standard white plate. Colour changes were quantified in the L^*, a^*, b^* colour space. Chroma value ($\text{Chroma} = \sqrt{a^{*2} + b^{*2}}$) was also calculated in order to compare changes among treatments. On each spear two readings in two different areas were taken; the first at 2 cm from the tip, in order to study if there is a violet colour development, and the second at 10 cm, so as to explore if there is any 'greying' appearance on the spear surface.

The colour was also assessed visually by a 10-member trained panel using the following hedonic scale: 5 = total white, 4 = violet colour development at 2 cm from the tip, 3 = violet colour at 3 cm, 2 = violet colour at 4 cm, 1 = violet colour at 5 cm and 0 = violet colour development over longer distance.

2.9. Lignin determination

The lignin content of the different parts of the asparagus spears (apical, middle, and basal) was determined with the thioacidoglycolysis method, as described by Bruce and West (1989). About 150 g of tissue was homogenised with 95% ethanol for 5 min. The mixture was vacuum filtered, the residue was washed with 100 ml of ethanol and then dried at 50 °C for 24 h. About 0.25 g of the above dry residue was mixed with 7.5 ml of 2 N HCl and 0.5 ml of thioglycolic acid which was then boiled with occasional shaking for 4 h and centrifuged at 7500*g* for 15 min. The residue (lignin thioglycolate) was washed with 10 ml of water, suspended again in 10 ml of 0.5 N NaOH with occasional shaking for 18 h at room temperature and centrifuged; 2 ml of concentrated HCl was added to the supernatant liquid. The lignin thioglycolic acid complex was precipitated at 4 °C for 4 h, centrifuged (7500*g*, 15 min) and the residue was dissolved in 10 ml of 0.5 N NaOH. After the appropriate dilutions, the absorbance was read at 280 nm, using a Metertech UV/vis SP8001 (Taipei, Taiwan) spectrophotometer. Quantification was carried out using a standard lignin curve. The lignin standard was purchased from Sigma–Aldrich GmbH (Steinheim, Germany).

2.10. Anthocyanin determination

The anthocyanin content was determined on the peel of asparagus, which was obtained by a sharp razor from 1 cm from the tip until 6 cm from the tip; this region is where most of the colour development occurs. The method of Fuleki and Francis (1968) was employed for the determination of anthocyanins with a few changes which were proposed by Flores, Oosterhaven, Martínez-Madrid, and Romojaro (2005). The plant tissue was chopped in a mortar, and 2 g were extracted with 5 ml of extractant solution; the latter was 100% ethanol/0.5 N HCl (85:15 v/v), and was kept in agitation with the tissue for 1 min. The resulting homogenate was incubated for 4 h in darkness. Every step was carried out in an ice bath in order to keep the temperature at 4 °C. The homogenate was then centrifuged at 7500*g* for 15 min and the supernatant was used to perform the spectrophotometric measurement at 533 nm, using the extraction medium as blank. The extinction coefficient of anthocyanins, 984 $(\text{g}/100\ \text{ml})^{-1}\ \text{cm}^{-1}$, was used for calculation of the anthocyanin content in the peel of white asparagus (Fuleki & Francis, 1968). The results were expressed as mg anthocyanins per g FW of peel.

2.11. Statistical analysis

All results are means ± s.e., and the data were statistically evaluated by ANOVA with mean differentiation by the Duncan's multiple range test ($\alpha = 0.05$). The statistical software used was the SPSS, version 15.0.

3. Results and discussion

3.1. Coating characterization

For coating solutions, Cisneros-Zevallos and Krochta (2003) have found that the average liquid film thickness on coated apples is a function of viscosity, draining time, density of the biopolymer solutions, surface tension of the fruit, surface tension of the liquid, and the surface roughness. Since the film thickness can greatly affect the gas and water barrier properties of the coatings, it was considered important to study the asparagus surface properties and the surface tension and rheological properties of the coating solutions.

The critical surface tension of the white asparagus peel, derived from the Zisman plot, was 26.7 mN/m. This indicates that the asparagus peel is a solid surface with low surface energy. Several authors have reported the values of critical surface tension obtained from a Zisman plot for various fruits and vegetables like garlic peel with a value of 18.3 mN/m (Hershko & Nussinovitch, 1998), strawberry with a value of 18.8 mN/m (Ribeiro et al., 2007), and tomato and carrot with values of 17.4 and 24.1 mN/m, respectively (Casariego et al., 2008). The peel or surface of many fruits and vegetables has low surface tension for protection purposes; however, this natural advantage is a shortcoming for application of aqueous coatings on plant tissues (Viña et al., 2007).

Table 1
Characterization of the coating formulations.

Coating formulation	Surface tension (mN/m)	Apparent viscosity at 100 s^{-1}, η_{ap} (mPa s)
CMC	37.1 ± 1.0	52.9
WPI 1	50.0 ± 1.0	2.8
WPI 2	49.2 ± 1.0	3.5
P	38.3 ± 0.6	19.6

The surface tension of a coating suspension is an essential factor for determining coating success. Table 1 shows the surface tensions of the four different coatings applied on white asparagus spears. The coatings CMC and P had a surface tension of 37.0 and 38.3 mN/m, respectively. These values were significantly lower than those of coatings based on whey protein isolate; the WPI 1 and WPI 2 had values of 50.0 and 49.0 mN/m, respectively, typical for protein solutions. The first two coatings, CMC and P, had a low surface tension due to the sucrose fatty acid ester which was included in their formulation as a surface active ingredient. Another reason for the low surface tension of the CMC coating may be the fact that the diluent was a water–ethanol mixture 4:1. These results show that the CMC and P coatings were more prone to spreading on white asparagus peel since their surface tension values were closer to the critical surface tension of the asparagus peel obtained from the Zisman's plot, compared to the respective values of WPI 1 and WPI 2.

The flow properties of a film forming liquid greatly affect its coating quality in the solid state. Moreover, the smoothness of the surface to be coated has a strong influence on the coating appearance. Levelling of the coating surface takes place after application of the liquid and during drying, due to solvent evaporation and is a crucial part of the coating process. The levelling of irregularities in liquid coating depends on the rheological properties and surface tension of the liquid, the effects of gravity and the characteristics of the surface to coat. A positive characteristic of coatings in the liquid state is the presence of a yield stress or a viscosity (η_0) high enough to prevent gravity effects (sagging and dripping), but sufficiently small to allow capillarity-driven levelling (Peressini, Bravin, Lapasin, Rizzotti, & Sensidoni, 2003).

In Table 1, the apparent viscosities at 100 s^{-1} of the four different coatings applied on white asparagus are given. The CMC coating exhibited a pseudoplastic behavior (flow curves not shown) as the viscosity decreased with the increase of shear rate and it showed the highest apparent viscosity at 100 s^{-1} (52.9 mPa s), compared to the rest of the coating solutions. The pullulan-based (P) coating showed Newtonian behavior with an apparent viscosity of 19.6 mPa s. The whey protein isolate coating solutions, WPI 1 and WPI 2, also showed Newtonian-like behavior and their apparent viscosities were lower than the others, with values of 2.8 and 3.5 mPa s, respectively. The addition of stearic acid in the whey protein solution did not seem to alter the apparent viscosity to a great extent. In a previous study, starch-based coatings exhibited a pseudoplastic behavior and the most viscous formulation (medium amylose content starch-based with 20 g l^{-1} of glycerol) showed an apparent viscosity of 22.6 mPa s at 512 s^{-1} (Garcìa, Martino, & Zaritzky, 1998).

3.2. Weight loss

This quality parameter is quite crucial, since every loss in weight is translated into an economic loss. Additionally, the weight loss has a strong impact on the spear appearance, due to shrinkage, and an 8% weight loss makes asparagus spears unsaleable (Siomos, 2003). Fig. 1 shows the weight loss of the asparagus spears for both experimental sets A and B. The weight loss increased progressively

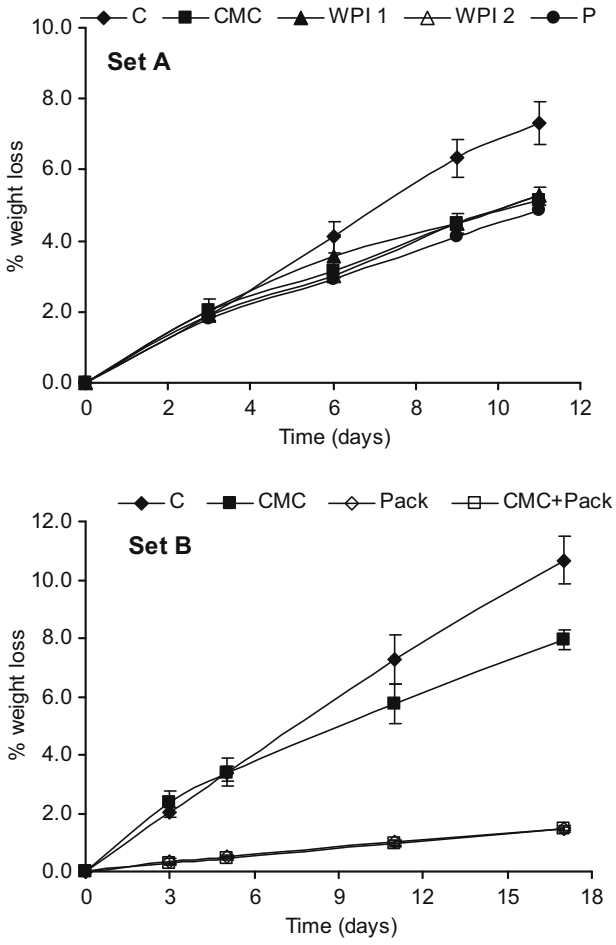

Fig. 1. Effect of various edible coating formulations and packaging on weight loss (%) of white asparagus spears during storage at 4 °C for 11 days (set A) and for 17 days (set B); the vertical bars represent the standard deviation ($n = 5$).

upon storage, and is mainly attributed to the water loss by transpiration due to differences in the water vapour pressure of water between the atmosphere and the asparagus surface (Park, Chinnan, & Shewfelt, 1994). After 11 days of storage (set A), the weight losses of the control and the coated samples were 7.3% and ~5.0%, respectively. The edible coatings applied on white asparagus spears significantly reduced the weight loss, probably due to the hydrophobic ingredients they contained, such as the sucrose fatty acid ester, and stearic acid, which may had decreased the water vapour permeability of the surface. However, the WPI 1 coating, without including any of these substances, also acted as a water vapour barrier, presumably due to denaturation of its protein components. Among all the coatings employed, there were no major differences, in spite of the variation in the solids content, biopolymer type and other substances used.

Several studies had dealt with the effect of various coatings based on polysaccharides in controlling the weight loss of several fruits and vegetables. Many of them referred to the application of commercial formulations that contained carboxymethyl cellulose and sucrose fatty acid esters, e.g., Semperfresh™ and TAL Pro-long, exerting a better weight loss control of many products such as cherries (Yaman & Bayoindirli, 2002). Pullulan coatings applied on strawberries and kiwifruit also exhibited a positive impact by extending their shelf life (Diab et al., 2001). Furthermore, the properties of protein based films have been extensively studied in applications of fruits and vegetables. More specifically, whey protein edible films attracted much of attention as it was found that

they can afford moderate potential as moisture barriers for food systems. The reduction in water vapour permeability of WPI based films could be further enhanced through the addition of lipids (McHugh & Krochta, 1994). Placing the asparagus spears in plastic packaging significantly reduced their weight loss, as shown in Fig. 1 for set B, whereas the combination of coating with packaging offered no additional protection to weight loss, compared to the packaging alone. The prevention of weight loss due to the maintenance of a high relative humidity environment is a major advantage of vegetable packaging; the beneficial effect of this approach in asparagus spears, as evidenced by the present findings is in agreement with the findings of Siomos et al. (2000). In another work, the effects of starch-based coatings and combination treatments of plastic film packaging with the coatings on weight loss of Brussels sprouts were studied (Viña et al., 2007); the coatings did not seem to reduce the weight loss during storage, whereas the plastic packaging substantially reduced the weight loss below the maximum admissible level in coated or uncoated sprouts.

3.3. Visual evaluation of appearance

After six days of refrigerated storage (set A) the appearance of the coated samples was rated as "excellent" or "very good", in contrast to the uncoated control C which fell into the "good" category. The uncoated asparagus spears exhibited a more dehydrated surface than the coated spears. The differences among the four different coating treatments were significant, with the WPI 1 and P giving the highest rating values in the appearance, probably because of the glossiness that these coating formulations imparted to the surface of the plant tissue. Samples coated with WPI 2 had the lowest score, possibly due to the incorporation of stearic acid which can lead to an undesirable opaque appearance after drying. After 11 days of storage the uncoated samples showed a strongly dehydrated surface, especially at the basal part of the spears, thus leading to quality ratings well below the acceptability threshold. Instead, all the asparagus spears treated with the CMC, WPI 1, WPI 2 and P coatings maintained their quality above the acceptance threshold level (see Fig. 2).

With respect to experimental set B, after 11 days of refrigerated storage, the uncoated product exhibited significantly lower quality levels compared to the other treatments and far below the acceptance level. In contrast, the treatments with CMC, Pack and the combination Pack + CMC did not differ significantly in their quality ratings. At day 17, the asparagus spears that were not packaged showed significantly lower quality ratings, compared to the treatments of Pack and Pack + CMC which were ranked under the "very good" category. No differences were observed among the last two treatments (Pack, Pack + CMC), probably because the packaging in a plastic container has a stronger impact on quality preservation than the edible coating alone.

3.4. Texture

The texture of asparagus has been related to fibrousness and the process of hardening that occurs after harvesting; the latter is accompanied by the lignification of the pericyclic (schlerenchyma) fibres (Rodríguez et al., 2004). Additionally, changes in texture may also reflect losses of tissue water and increases in other phenolic compounds apart from lignin. Several methods have been developed to determine textural changes along with the fibre content and the degree of lignification. Currently, textural measurements involve shearing through the asparagus spears by using the Warner–Blatzler geometry (Rodríguez et al., 2004).

Fig. 3 represents the texture of the three distinct asparagus parts for the different treatments of set B samples, measured as maximum cutting force F_{max}. Regarding the apical part of asparagus

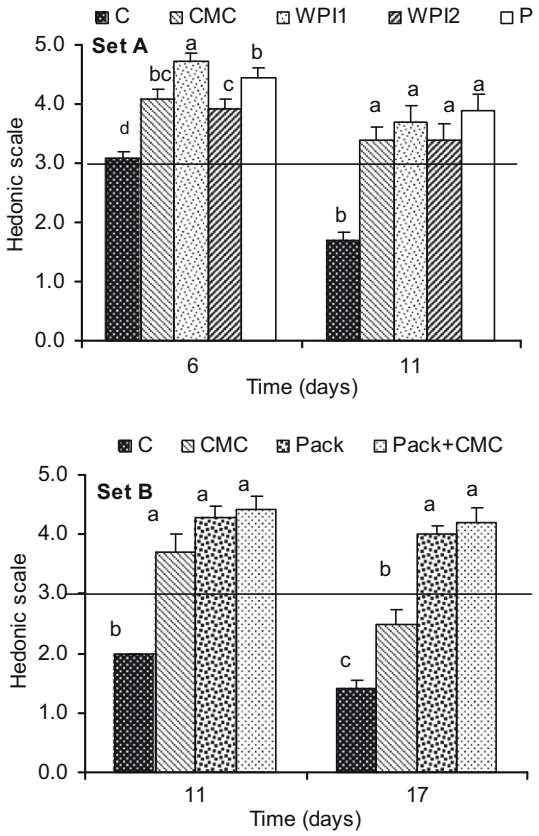

Fig. 2. Effect of different edible coatings and packaging on the visual evaluation of appearance of white asparagus spears during storage at 4 °C for 11 days (set A) and for 17 days (set B). The line corresponds to the commercial acceptability threshold (value three in the hedonic scale). Means with different superscript letters are significantly different ($p < 0.05$) for each sampling time; the vertical bars represent the s.e.

spears all the samples (C, CMC, Pack and Pack + CMC) exhibited significantly increased firmness values during storage, compared to the day of harvest (day 0). On the other hand, the firmness values in the middle part of samples Pack and Pack + CMC were maintained to similar levels with the fresh asparagus (day 0), while the uncoated (C) and the coated with CMC spears showed significantly increased values compared to the day of harvest (day 0). Similarly, the basal parts of the packaged samples (Pack and Pack + CMC) retained their texture values during storage at levels similar to the fresh asparagus. The basal part of CMC coated asparagus seemed to maintain its texture to initial firmness levels after 11 days of storage, but after 17 days the firmness value significantly increased. The CMC coating used is expected to modify the internal gas composition of white asparagus, especially by reducing oxygen and elevating carbon dioxide concentration, thus retarding the biochemical reactions that lead to hardening; the latter might explain the slower textural changes observed for the basal part of the coated spears. Additionally, the packaging helped maintain the texture of asparagus spears. In a previous work it was found that the use of Modified Atmosphere Packaging in green asparagus exhibited a beneficial effect in retarding the hardening process, especially of the basal part of the stalks (Villanueva et al., 2005). Finally, the uncoated spears exhibited significantly higher firmness value in the basal part during storage compared to the day of harvest.

3.5. Lignin content

Lignin is the cell wall component frequently associated with tissue hardening. The lignification in asparagus is controlled by

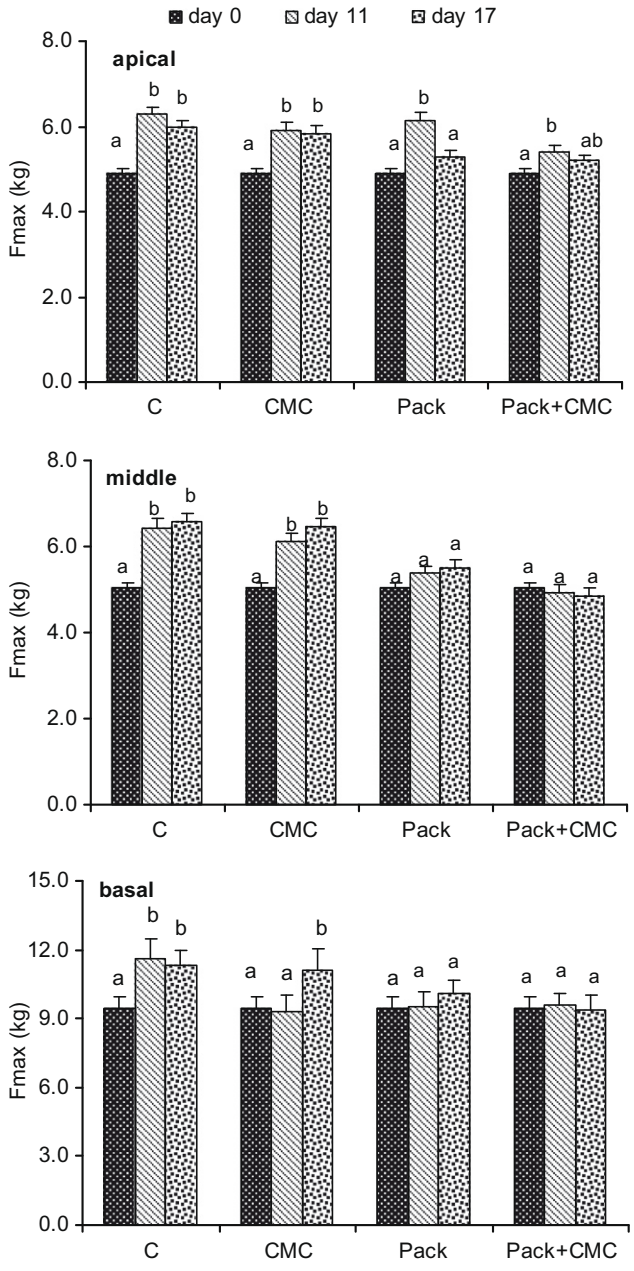

Fig. 3. Texture of asparagus expressed in maximum cutting force F_{max} (kg) for the apical, middle and basal parts during storage for 17 days (set B). Means with different superscript letters are significantly different ($p < 0.05$) for each treatment; the vertical bars represent the s.e.

different enzymes, among them phenylalanine ammonia-lyase (PAL) which is a key enzyme in the biosynthetic pathway of flavonoids such as anthocyanins and lignin; its activity is stimulated by low temperature and light (Flores et al., 2005). Therefore, the inhibition or regulation of this enzyme activity could help to maintain some of the white asparagus quality attributes.

Fig. 4 represents the lignin content of the three distinct asparagus parts for the different treatments of set B samples, expressed in mg of lignin/kg fresh weight (FW). All three parts of asparagus spears, for all the samples (C, CMC, Pack and Pack + CMC) exhibited significantly increased lignin content during storage, compared to the day of harvest, showing that none of the treatments applied was able to maintain the lignin levels close to those of the fresh product.

According to Rodrìguez, Jiménez, Guillén, Heredia, and Fernández-Bolaños (1999), lignin is concentrated mainly in the middle and basal sections of fresh white asparagus upon refrigerated storage, i.e., the lignin content of the apical section remains unchanged, while those of the middle and basal parts increase. They also suggested that the tissue toughening process is not simply related to the concentration of lignin, as has been previously proposed (Lipton, 1990), but it may be connected to the macromolecular structure of lignin and to its cross-linking with other cell wall components, either polysaccharides or proteins or both. Both monomeric and dimeric (cross-links) phenolic acids have been isolated and characterized from several plant sources, and have been suggested as important texture determinants of some fruits and vegetables (Rodrìguez et al., 1999). Indeed, Jaramillo et al. (2007) have recently attributed the process

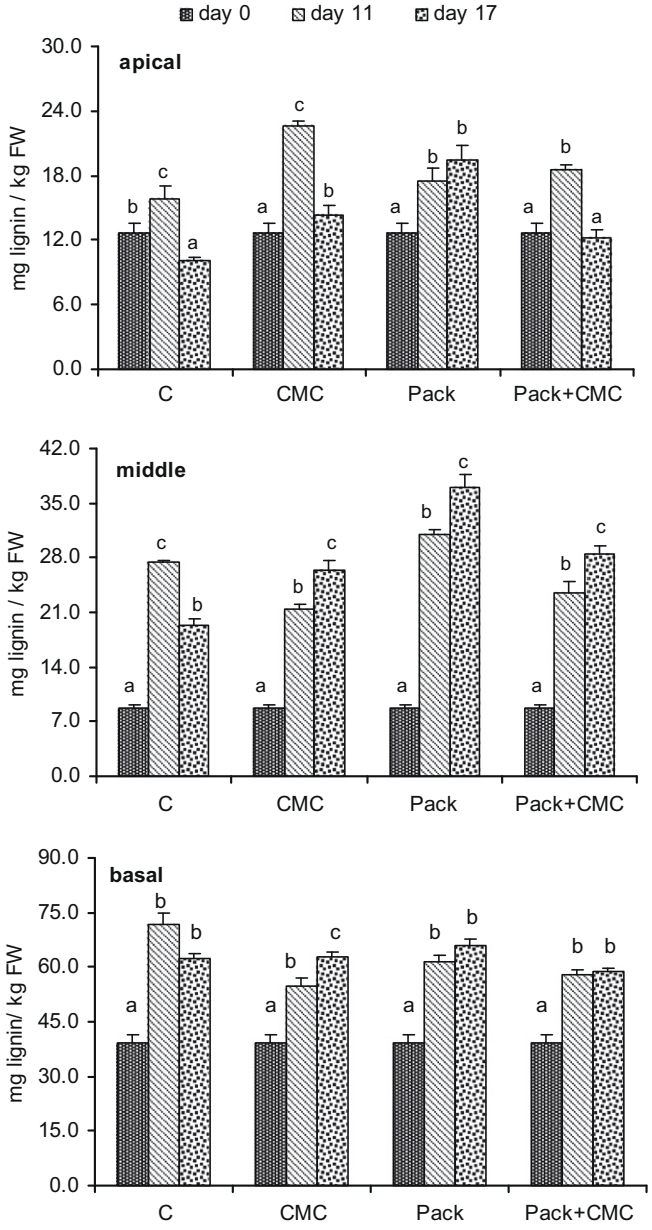

Fig. 4. Lignin concentration in asparagus spears, expressed in mg of lignin/ kg of fresh weight (FW), for the apical, middle and basal parts during storage for 17 days (set B). Means with different superscript letters are significantly different ($p < 0.05$) for each treatment; the vertical bars represent the s.e.

of toughening of white asparagus spears to the accumulation of diferulates.

3.6. Anthocyanins and colour assessment

The degree of tip colouration is a basic quality characteristic for shorting white asparagus into commercial grades (Commission of the European Communities, 1999); spears with a purple colour are judged to be of an inferior quality. The presence of anthocyanins in white asparagus spears is the reason for the purple colour developing mostly in their apical part. Evaluation of colour development is based on three different methods: determination of anthocyanins concentration in the peel of asparagus, visual assessment and colourimetric assessment.

Biosynthesis of anthocyanins in the epidermis of white asparagus spears either requires or is enhanced by light and the key enzyme regulating the accumulation of these pigments, i.e., phenylalanine ammonia-lyase (PAL) (Flores et al., 2005). Although very little is known about the regulation of anthocyanin synthesis in harvested white spears, undesirable colouration could be reduced by the use of modified atmosphere packaging (MAP) with semi-permeable plastic films (Siomos et al., 2000). These authors also found that, after an initial stimulation by light, anthocyanin synthesis occurs in harvested white asparagus spears, irrespective of temperature and light conditions during storage in air (Siomos et al., 2000).

The degree of purple colouration in the surface of asparagus was visually assessed, for both experimental sets A and B (Fig. 5). In experimental set A, the coated samples retained their white colour in higher levels compared to the control, as shown for day 11. This may be due to the fact that edible coatings can function as gas barriers, thus modifying the internal atmosphere in the asparagus spears (high levels of CO_2 and low levels of O_2) and this in turn may retard the biochemical reactions leading to anthocyanins synthesis. In experimental set B, for both days of assessment, the control C showed the lowest score, about 2.5; instead, the treatments CMC and Pack + CMC seemed to retain their original white colour for the storage period of 11 and 17 days, with scores around 4.0. Regarding the uncoated packaged samples (Pack), it was noticed that on day 11 they had developed purple colouration at the same levels as the control, but on day 17 the scores obtained from colour assessment did not differ significantly between the control and the coated treatments CMC and Pack + CMC.

Fig. 6 represents the concentration of anthocyanins in the peel of asparagus spears during storage for the different treatments of experimental set B. After 11 days of storage, the uncoated control C and the uncoated packaged samples (Pack) showed a significant increase in anthocyanins content; instead, the coated treatments CMC and Pack + CMC exhibited lower levels of anthocyanins. Similar results were obtained for day 17, where the control exhibited the highest value of anthocyanins concentration compared to the rest of the treatments. From the above findings, it is obvious that the CMC coating can slow down significantly the anthocyanin synthesis as previously discussed for experimental set A.

In Table 2, the data obtained from the colourimeter readings at 2 and 10 cm from the tip are given (i.e., values L^*, a^* and Chroma); the 2 cm colour values represent the purple colour formation in that part of the asparagus spears. The coated samples, CMC and Pack + CMC at day 17 had higher, but no significantly different L^* values compared to the control C. After 17 days of storage the uncoated control C exhibited a significantly higher ($p < 0.05$) a^* value, compared to the coated samples, CMC and Pack + CMC; a high a^* value and above zero indicates purple colour formation. The middle part (10 cm from the tip) of the packaged spears (treatment Pack) became grayish, as indicated by a decline in the L^* values (Table 2). In contrast, the control, the CMC coated and the combination Pack + CMC did not seem to darken, since their L^* values showed no significant changes over the harvest values, and were significantly higher than those of the packaged spears without the coating after 17 days of storage. These findings may indicate that the packaging can have a negative effect on the asparagus surface appearance; however, the combination treatment with edible coating CMC can minimize this impact.

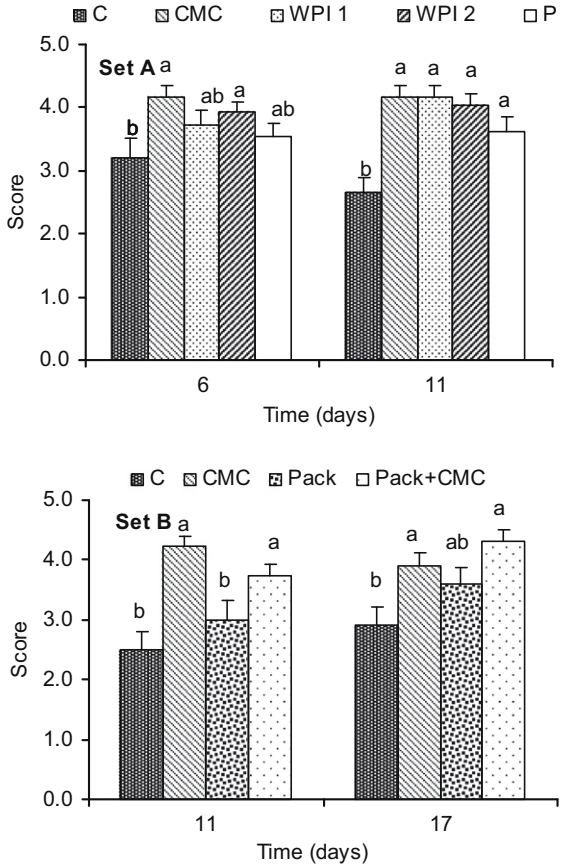

Fig. 5. Visual assessment of colour in asparagus spears for the two different experimental sets, A and B. Means with different superscript letters are significantly different ($p < 0.05$) for each sampling time; the vertical bars represent the s.e.

		CMC	80.18^{ab}	−1.46^{a}	12.00^{ab}
		Pack	78.72^{a}	−1.02^{b}	13.84^{bc}
		Pack + CMC	80.35^{b}	−1.43^{a}	11.87^{a}

4. Conclusions

The edible coatings CMC, WPI 1, WPI 2 and P seemed to have a beneficial impact on white asparagus spears quality retention during refrigerated storage by retarding their weight loss, the purple colour formation on the surface of the tips, and by maintaining the spears in high quality levels; however, no significant differences were observed among these coatings. In a second experimental set, the carboxymethyl-cellulose based coating (CMC) appeared to reduce hardening in the basal part of the stored products and anthocyanin synthesis. These results most likely reflect the ability of the coating to act as a protective gas barrier, modifying the internal atmosphere by increasing the levels in carbon dioxide and decreasing oxygen levels. Such changes affect the metabolic processes involved in lignification and anthocyanins synthesis. The plastic packaging seemed to be the most effective approach for white asparagus quality preservation since it showed the largest reductions in weight loss, remarkably retained the quality of the spears and it seemed to retard the processes of hardening. Combination treatment of CMC coating and plastic packaging did not impart any further quality improvement of the asparagus spears quality attributes, compared to the packaging alone, apart from the fact that it reduced the 'grayish' appearance of the packaged spears; the latter was attributed to the glossiness offered by the coating solution on the spear sample surface. Among all treatments examined, the combined action of carboxymethyl-cellulose based coating with plastic packaging was the most effective in preserving the quality attributes of the white asparagus spears.

Bread

ABSTRACT

Chempedak (*Artocarpus integer*) seed flour (CSF) was substituted for wheat flour at different levels (0%, 10%, 20%, 30% w/w) in bread. Assessment on the *in vitro* starch hydrolysis was carried out to evaluate the hydrolysis index (*HI*) and estimated glycaemic index (*EGI*) of bread substituted with different levels of CSF. Kinetics of *in vitro* starch hydrolysis in all bread samples (with the exception for white bread) indicated a gradual increase with respect to time intervals. Bread of 30% CSF exhibited significantly lower ($p < 0.05$) *in vitro* starch hydrolysis, as compared with the other samples. Results showed that *HI* value decreased significantly ($p < 0.05$) as the levels of CSF substitution increased. Resistant starch (RS) content in bread samples was inversely related with *HI* value as CSF substitution levels increased, thus lowering the *EGI* value.

1. Introduction

Chempedak (*Artocarpus integer* Merr.), which belongs to the Moraceae family, is found abundantly in Peninsular Thailand, Borneo and Peninsular Malaysia, particularly in Perak and Kedah. Chempedak flesh is usually eaten fresh or cooked, while the seeds are considered as waste. Jansen (1991) reported that chempedak seeds are made up of 10–25% of the fresh fruit weight, comprised mainly of carbohydrate, protein and dietary fibre.

Carbohydrates constitute a major proportion of food consumed and represent the primary energy source, contributing to nearly 55–70% of the total energy consumed (Osorio-Díaz et al., 2002). Nutritionally, carbohydrate is classified as available (starch and sugar) and unavailable carbohydrates (non-digestible food components, i.e., dietary fibre) (Ahmad, 1995).

Bread is the best source of nutritional needs among cereal and cereal products. Bread is a valuable source of vitamins, e.g., B-complex vitamins and minerals, e.g., calcium and iron (Dhingra & Jood, 2001). Since starch is the main component of bread (Hug-Iten, Handschin, Conde-Petit, & Escher 1999), the glycaemic index (*GI*) for bread is high, due to rapid carbohydrate breakdown in the digestive system which raises blood glucose (Cavallero, Empilli, Brighenti, & Stanca 2002).

GI is a way of ranking food products, particularly carbohydrate-based, on the postprandial blood glucose response, compared to a reference food (Jenkins et al., 1981). The main factor that affects *GI* is the rate or absorption of carbohydrate in the presence of food products. Regular consumption of foods with high *GI* values, particularly refined or processed carbohydrate, is associated with the development of certain chronic diseases, such as obesity, Type II diabetes, increased risk of cardiovascular diseases and certain forms of cancer (Marques et al., 2007; Schnell, de Delahaye, & Mezones, 2005).

Foster-Powell, Holt, and Brand-Miller (2002) reported that addition of fibre to food products reduced their *GI* value. Resistant starch (RS) is another functional material that has a similar effect to some dietary fibres. In the small and large intestines, RS increased the indigestible carbohydrate ingested, thus lowering the *GI* value of food products (Yamada et al., 2005). This is attributed to the starch digestion rate, which subsequently releases glucose into the bloodstream at a slower rate, resulting in reduced glycaemic and insulinemic postprandial responses for food products containing high amounts of dietary fibre (Jenkins et al., 1982; Tovar, Sáyago-Ayerdi, Peñalver, Paredes-López, & Bello-Pérez, 2003).

The addition of non-wheat flour to conventional wheat bread to improve the nutritive value in terms of dietary fibre, essential mineral and lysine are of predominant interest among food researchers. Wheat flour was substituted with barley, cowpea and jackfruit seed at different levels in bread formulation and physicochemical properties of the bread were assessed (Cavallero et al., 2002; Dhingra & Jood, 2001; Tulyathan, Tanuwong, Songjinda, & Jaiboon 2002).

The objectives of this study were to assess the utilisation of chempedak seeds as a substitute to wheat flour at different percentage levels in bread formulation and to evaluate the effect of

the substitution on the *in vitro* starch hydrolysis and RS content in the bread samples.

2. Materials and methods

Chempedak seeds were obtained from a local farm in Baling, Kedah, Malaysia. All the ingredients for breadmaking were purchased from Sim Co., Penang, Malaysia.

2.1. Processing of chempedak seed flour

Chempedak seed flour (CSF) was prepared according to the modified method of Tulyathan et al. (2002). Chempedak seeds were cleaned and the seed coats were peeled off. The seeds were boiled for 30 min, chopped into small pieces, air-dried for 24 h at 60 °C (AFOS Mini Kiln; AFOS Ltd., Hessle, UK) and ground to 0.25 μm diameter (Universal Bench Top Grinder, Germany). The flour was then stored in an airtight plastic container at 5 °C prior to use.

2.2. Preparation of bread samples

Bread samples were prepared by slight modification of the Sponge and Dough Method procedure in AACC (2000). CSF was substituted with wheat flour at four different levels (0%, 10%, 20%, 30% w/w), with the addition of 100 ppm α-amylase (M500FL) (Millbo, S.p.A., Trecate, Italy) and maltodextrin (DE 15) (Behn Meyer FoodTech, Subang Jaya, Malaysia). All ingredients were mixed and baked at 165 °C for 25 min. Bread samples were allowed to cool at ambient temperature for an hour prior to analyses.

2.3. Proximate composition

Chempedak seed, CSF and bread samples were analysed for moisture (Method 44–15A), crude protein ($N \times 6.25$) (Method 46–13), crude fibre (Method 32–10), crude fat (Method 30–25) and ash (Method 08–01) content according to AACC (2000).

Carbohydrate was determined by difference:

$$[100 - (\text{moisture} + \text{crude protein} + \text{crude fibre} + \text{crude fat} + \text{ash})].$$

All analyses were carried out in triplicate.

2.4. Starch digestibility

2.4.1. Resistant starch content

Resistant starch (RS) content was determined according to the *in vitro* method of Goñi, García-Diz, Mañas, and Saura-Calixto (1996). Briefly, defatted sample (100 mg) was pre-incubated with pepsin solution (Sigma–Aldrich, St Louis, MO) (40 °C, 60 min, pH 1.5) and then α-amylase solution (Sigma–Aldrich) was added for starch hydrolysis with constant agitation (37 °C, 16 h, pH 6.9).

After amylolysis, the sample was centrifuged (3000*g*, 15 min) and the residue (isolated RS) was washed twice with distilled water. The final residue was dispersed with KOH (30 min, room temperature with constant shaking) and further incubated with 80 μl amyloglucosidase (23,000 units/g solids; Sigma–Aldrich) at 60 °C (45 min, pH 4.75). Glucose was determined in the aliquots by using glucose solution in the GOD-PAP kit (Randox Laboratories Ltd., Crumlin, UK). RS concentration of the sample was calculated as mg of glucose × 0.9. RS content was analysed in triplicate.

2.4.2. In vitro kinetics of starch digestion

In vitro kinetics of starch digestion was determined according to the method of Goñi, García-Diz, and Saura-Calixto (1997), and Goñi and Valentín-Gamazo (2003). Bread sample (50 mg) was incubated with pepsin solution at 40 °C (60 min, pH 1.5) for protein hydrolysis. The sample solution was added with Tris-maleate buffer and pH was adjusted to 6.9.

Starch hydrolysis was initiated by addition of 5 ml of Tris-maleate containing 2.6 IU porcine pancreatic α-amylase solution (Sigma–Aldrich). The sample solution was then incubated at 37 °C with moderate agitation. At 30 min intervals, over 0 to 3 h, 1 ml of sample was taken out and placed in a different tube. The α-amylase was inactivated immediately by incubating at 100 °C for 5 min with vigorous shaking. The digested starch was completely hydrolysed into glucose by adding 60 μl amyloglucosidase (23,000 units/g solids). Glucose was measured as mg of glucose × 0.9. The rate of starch digestion was expressed as the percentage of total starch (TS) hydrolysed at different times. Each sample was analysed in triplicate.

A non-linear model established by Goñi et al. (1997) was applied to describe the kinetics of starch hydrolysis. The area under the hydrolysis curve (*AUC*) was calculated using the first order equation:

$$AUC = C_\infty(t_f - t_0) - (C_\infty/k)[1 - \exp - k(t_f - t_0)].$$

C_∞ corresponds to the concentration at equilibrium (t_{180}), t_f is the final time (180 min), t_0 is the initial time (0 min) and k is the kinetic constant. The hydrolysis index (*HI*) was obtained by dividing the area under the hydrolysis curve of each sample by the corresponding area of a reference sample (white bread). The estimated glycaemic index (*EGI*) was calculated using the following equation:

$$EGI = 39.71 + (0.549HI).$$

3. Results and discussion

3.1. Proximate composition

The proximate composition of chempedak seed and chempedak seed flour (CSF) is presented in Table 1. Processing of chempedak seeds into flour significantly reduced ($p < 0.05$) the protein and ash content. Mubarak (2005) reported that a similar result was obtained in raw mung bean when subjected to boiling. However, the crude fibre in CSF was found to be higher than jackfruit seed flour as reported by Tulyathan et al. (2002).

Ultimate level of CSF substitution in bread samples showed a significant increase ($p < 0.05$) in the moisture, crude fibre and ash contents while the carbohydrate and crude fat content decreased significantly ($p < 0.05$) (Table 2).

The amount of water added to the bread formulation increased with increase in CSF substitution level. Non-wheat flour induces a higher water absorption capacity than wheat flour (Tulyathan et al., 2002; Wang, Rosell, & Benedito de Barber 2002). The higher

amount of fibre in non-wheat flour binds a relatively large amount of water through the hydroxyl groups existing in the fibre structure (Wang et al., 2002). Water content played a significant role in the final quality of the bread as it affects the gelatinisation of starch in bread (Thorvaldsson & Skjöldebrand, 1998).

3.2. Resistant starch content

Resistant starch (RS) content in CSF was significantly lower ($p < 0.05$) than in raw chempedak seed (Table 1). Processing of starchy foods promotes disintegration and/or microstructural damage of the seeds and affects the water absorption capability (Niba, 2003).

At a higher substitution level of CSF, the RS in bread samples increased significantly ($p < 0.05$); (Table 3). RS content increased by 16.3% in 10% CSF bread, compared with control bread. Meanwhile, RS content in 20% and 30% CSF bread samples increased by almost twofold, compared with the control bread.

According to Niba (2003), heat treatment followed by cooling in breadmaking resulted in formation of retrograded starch (RS3), due to an increase in gelatinised starch. Thus, repeated heating and cooling process applied during breadmaking resulted in higher RS content in bread samples (Niba, 2003).

RS formation is associated with retrogradation of starch, particularly amylose molecules, whereby enzyme-resistant amylose-amylose linkages are formed (Onyango et al., 2005). Åkerberg, Liljeberg, and Björck (1998) stated that apart from amylose content, amylopectin plays a significant role in RS formation in bread. They suggested that linear molecules of amylopectin might participate in starch retrogradation, consequently increasing RS content in bread samples.

Although amylose/amylopectin concentration is closely related to starch retrogradation and RS formation, other factors such as presence of other food components and type of processing applied contributes to RS content of food products (Rosin, Lajolo, & Menezes 2002). High molecular weight (HMW) molecules of maltodextrin reassociate to form double helices among themselves or with starch molecules. Therefore, at low maltodextrin concentration, the presence of starch in bread may help the reassociation of HMW molecules of maltodextrin and further increase the RS content (Wang & Jane, 1994). Furthermore, the extent of RS formation was also affected by the amount of dietary fibre and moisture content, which promotes the degree of starch gelatinisation (Tas & El, 2000).

3.3. In vitro starch hydrolysis

An *in vitro* starch hydrolysis method was carried out in this study, to simulate the *in vivo* situation of carbohydrate digestion characteristics and to estimate the metabolic glycaemic response to a food (Goñi et al., 1997).

The kinetics of *in vitro* starch hydrolysis for white bread (reference) and bread substituted with different levels of CSF with the addition of maltodextrin and α-amylase are summarised in Table 4. According to Cavallero et al. (2002), bread exhibits a sponge structure which is highly accessible to α-amylase and tends to elicit high glycaemic responses.

At a higher CSF substitution level, there was significantly lower ($p < 0.05$) *in vitro* starch hydrolysis. In the first 90 min the degrees of *in vitro* starch hydrolysis in 10% and 20% CSF breads were not significantly different ($p > 0.05$). Meanwhile, the 30% CSF bread underwent significantly lower ($p < 0.05$) *in vitro* starch hydrolysis as compared to the other bread samples at all time intervals. *In vitro* starch hydrolysis for 10%, 20% and 30% CSF breads was significantly reduced ($p < 0.05$) by 9.5%, 11.0% and 22.6%, respectively, as compared with control bread.

The profile of *in vitro* starch hydrolysis (Fig. 1) exhibited a gradual increment in all tested bread samples as time increased. White bread underwent a higher starch hydrolysis during 30–120 min, when compared with the other bread samples.

Table 3 showed the resistant starch (RS), hydrolysis index (*HI*) and estimated glycaemic index (*EGI*) for bread substituted with different levels of CSF with the addition of maltodextrin and α-amylase. At higher CSF substitution levels, *HI* decreased significantly ($p < 0.05$). *HI* values of 10%, 20% and 30% CSF bread samples decreased by 6.8%, 9.9% and 16.2%, respectively, when compared to control bread. Significant decreases of *HI* value in bread samples corresponded with significantly decreased ($p < 0.05$) *EGI*.

El (1999) reported that bread with the addition of a mixture of 10% rye flour and 15% wheat bran exerted a hypoglycaemic effect. Soluble dietary fibre reduced the dietary carbohydrate absorption rate by forming a viscous gel in the small intestine, hence reducing

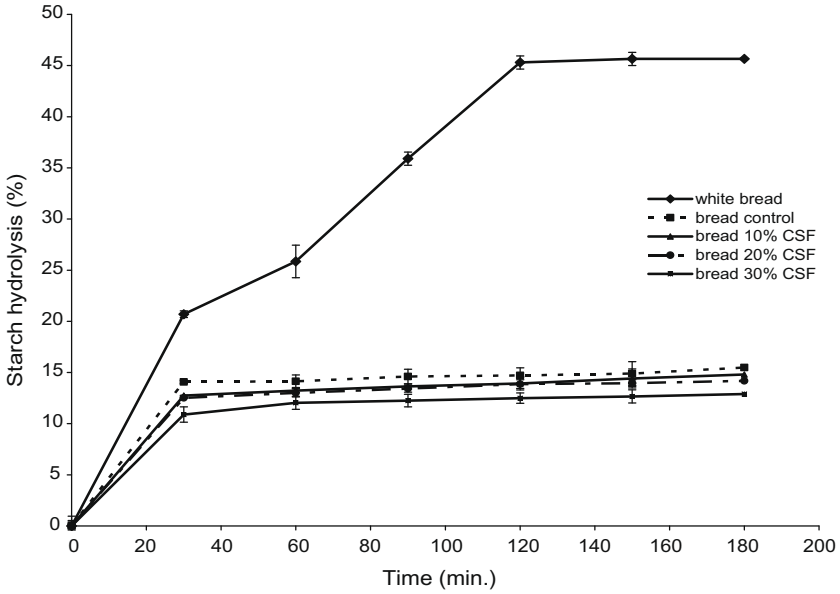

Fig. 1. Profile of *in vitro* starch hydrolysis (%) in white bread (reference) and bread substituted with different levels of chempedak seed flour (CSF) added with maltodextrin and α-amylase.

the postprandial blood glucose response. However, Wolever (1990) strongly suggested that encapsulation of nutrients within plant cell walls in insoluble dietary fibre inhibits starch digestion, which is more important in the further decrease of the glycaemic index.

The glycaemic effects of food depend on the food texture and particle size (Tovar et al., 2003), type of starch (amylose:amylopectin ratio) (Behall & Schofield, 2005), physical entrapment of starch molecules within the food, food processing and other ingredients, such as sugars, fat (Marques et al., 2007), protein, dietary fibre and antinutrient content (Cavallero et al., 2002; El, 1999). Products with high content of RS were reported to have lower glycaemic and insulinaemic responses in healthy human subjects (Åkerberg, Liljeberg, & Björck, 1998; Behall & Schofield, 2005).

From the results obtained, RS content in bread samples with higher CSF substitution levels is inversely related with *HI* value ($y = -2.1747 + 110.48$); ($R^2 = 0.8164$) (Fig. 2). The result is in agreement with previous studies that higher RS content leads to a reduction of *in vitro* starch hydrolysis rate, hence reducing the *GI* value of a food product (Åkerberg et al., 1998; Behall & Schofield, 2005; Goñi & Valentín-Gamazo, 2003; Rosin et al. 2002; Yamada et al., 2005). RS is known to exert a similar effect to some dietary fibres, by increasing the indigestible carbohydrate portion in small and large intestines (Yamada et al., 2005), thus reducing the rate of dietary carbohydrate absorption (El, 1999).

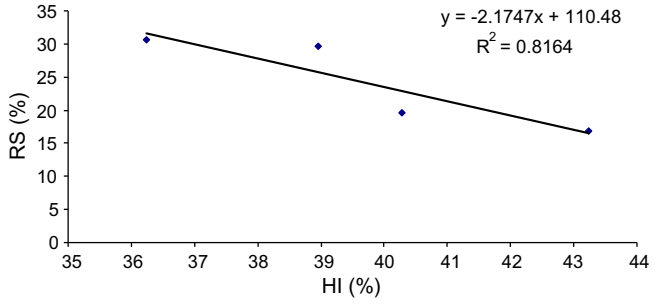

Fig. 2. Correlation between resistant starch (RS) content and hydrolysis index (*HI*) value in bread substituted with different levels of chempedak seed flour (CSF) added with maltodextrin and α-amylase.

4. Conclusion

From the study conducted, *in vitro* starch hydrolysis of bread samples was significantly affected ($p < 0.05$) by the amount of chempedak seed flour added in the bread formulation. Resistant starch content increased significantly ($p < 0.05$) by twofold in 20% and 30% CSF bread samples, compared with the control. Hence, *in vitro* starch hydrolysis is closely related to the amount of RS present in bread samples. RS content is inversely related with hydrolysis index value, which resulted in lower estimated glycaemic index values at higher added CSF levels.

Protein solubility

ABSTRACT

The glycation of rice proteins with reducing sugars was investigated in an attempt to improve their solubility and functionality. Rice proteins isolated from a Chinese milled medium-grain rice were glycated with glucose, lactose, maltodextrin, or dextran in 2% aqueous dispersions. The sugar that provided the most improvement of the solubility, emulsification activity (*EA*) and emulsification stability (*ES*) of the Maillard reaction products was glucose. The optimum reaction conditions were at pH 11, 100 °C, and reaction time 15 min, which increased the solubility, *EA* and *ES* of rice protein from 20%, 0.46 and 11.1 to 92%, 0.64 and 18.2, respectively. Extending the reaction time beyond 15 min continued the development of latter-stage Maillard browning products without improvements in the functional properties of the Maillard reaction products. SEC–HPLC analysis with light scattering detection showed a decrease of the weight-averaged molecular weight from 500 to 100 K during the initial 15 min.

1. Introduction

Rice protein has been considered to have a high biological value and low hypoallergenic characteristics. However, the use of rice protein as an ingredient in foods has been limited, due to its poor functional properties, such as solubility. Whole rice grains contain different types of proteins which have been isolated and characterised. Over 80% of rice proteins are glutelins, which have low solubility at neutral pH. With low solubility the presence of other functional properties, such as foaming, gelling and emulsifying, are also limited (Agboola, Ng, & Mills, 2005).

Numerous attempts have been made to improve the functional properties of proteins through physical, chemical, enzymatic and genetic modifications (Matheis & Whitaker, 1984; Matsudomi, Sasaki, Kato, & Kibayashi, 1985). A chemical method to improve the functional properties of proteins has been the reaction of proteins with reducing sugars via the Maillard reaction (Wooster & Augustin, 2006). The modified proteins have often showed better solubility and improved emulsifying properties (Oliver, Melton, & Stanley, 2006). This reaction is natural and spontaneous and does not require the addition of extraneous chemicals. Thus it has been considered a promising approach to the improvement of the functional properties of proteins for food uses.

Different proteins, such as ovalbumin, lysozyme and soy proteins, have been conjugated with various sugars, in order to improve their solubility, emulsifying, and heat stability properties (Chevalier, Chobert, Popineau, Nicolas, & Haetle, 2001; Miralles, Martinez-Rodriguez, Santiago, van de Laemaat, & Heras, 2007). The improvement of the functionality of rice proteins by the Maillard reaction has not been reported. However, rice proteins contain a moderately high ratio of lysine, which has a free amino group that is liable to undergo Maillard reaction.

There are two approaches, which have been used to carry out the Maillard reaction (Guan, Qiu, Liu, Hua, & Ma, 2006). The first method involves the heating of a dry dispersion of a protein and saccharide under controlled temperature and relative humidity conditions. A disadvantage of this method is that some of the products are insoluble aggregates with poor surface wetting properties; a second method, which can overcome some of these problems, is to carry out the reaction in an aqueous solution or dispersion (Jing & Kitts, 2002; Lertittikul, Benjakul, & Tanaka, 2007). The latter method has the advantage of better control and shorter reactions times. Its disadvantages include the removal of the water and buffer when recovering the products.

In our initial studies, rice protein was reacted with sugars by dry heating. Initial results showed that the modified rice proteins exhibited slightly improved emulsifying activity, but there was no significant improvement in solubility. The goal of this study was to improve the solubility and emulsifying properties of rice proteins by glycation under wet reaction conditions. The influence of pH, type of sugar, the weight ratio of protein:sugar, reaction temperature and reaction time were studied. The degree of substitution and browning were also studied. The use of high pHs was chosen to solubilise the rice proteins and to enhance the rate of

Maillard reaction, with the hypothesis that improvements in solubility and emulsifying properties would be made.

2. Materials and methods

2.1. Preparation of rice protein concentrate

The common method for the separation of rice protein from the starch of milled rice grains is by alkali solubilisation of the proteins followed by acid precipitation (Connor, Saunders, & Kohler, 1977; Yamamoto, Sumie, & Toshio, 1973). In this study, milled medium-grain rice (Nan Jing 39 from Jiangsu Baobao Group Co., Rudong, China) was washed with deionised water, and then soaked in three times its weight of deionised water for 15 h. The rice and water were then placed in a food blender and blended into a slurry. The protein was extracted from the slurry with 0.1 M NaOH at 40 °C (the ratio of slurry to NaOH solution was 1:3 w:w). The slurry was continuously stirred for 2 h and then centrifuged (6000*g* for 10 min). The supernatant was removed, and its pH was adjusted to 5.5 using 0.1 M HCl. It was left undisturbed for a cold precipitation overnight (4 °C). The supernatant was carefully siphoned off from the precipitate. The precipitate was washed 4 times with deionised water. The final slurry was neutralised to a pH 7.0 with 0.1 M NaOH and lyophilised. The protein content of the lyophilised substrate was determined by the Kjeldahl method (The value of 5.95 was used as a protein conversion factor), and the obtained rice protein content was 92% (dry weight).

2.2. Preparation of Maillard reaction products (MRPs) from rice protein–sugar model systems

Rice protein (2.4 g) was dispersed in 200 ml deionised water and the pH was adjusted to 12 with 10 M NaOH. The protein was thoroughly dispersed by vigorous and continuous agitation for 1 h. Glucose (2.4 g) was added to the dispersion. The pH of dispersion was readjusted to pH 11 with 0.1 M HCl. Aliquots of 15 ml were transferred to each of twelve 50 ml screw-capped glass tubes; they were capped to prevent evaporation during heating. The samples were heated in a water bath at 100 °C. Two sample tubes were removed during heating at the following times: 0, 5, 10, 15, 20, and 30 min. When removed the tubes were immediately placed in an ice-bath and then stored at 4 °C prior to analysis. Two additional samples were removed after 15 min of heating and freeze–dried and used for further experiments. Samples with other pH values, reaction temperatures, and ratios of protein to reducing sugar were prepared by the same procedure.

2.3. Solubility measurement of MRPs

Ten millilitres of an MRP sample was diluted with 10 ml of various buffers (0.05 M sodium phosphate buffer, pH 5, 6.5 and 8; 0.05 M sodium hydrogen carbonate buffer, pH 9.5 and 11; 0.05 M citrate buffer, pH 3.5 and 0.05 M KCl–acetic acid buffer, pH 2). The pH of the solution was readjusted to the buffer pH with 0.1 M HCl or NaOH. Samples were centrifuged for 20 min at 10,000*g*. Protein content in the supernatant was determined by the Kjeldahl method. Solubility was expressed as a percentage of protein in the supernatant to the total protein content.

2.4. Measurement of hydrophobicity

The hydrophobicity of the MRPs was determined according to the ANS method. A freeze–dried MRP sample was dissolved in 0.01 M phosphate buffer (pH 8) at different concentrations. The sample was centrifuged at 7000 rpm for 20 min. The concentration of the protein in the supernatant was measured by the Folin method. An aliquot of 2 ml was mixed with 40 μl of 1-anilinonaphthalene-8-sulfonic Acid (ANS) (8 mM) at 25 °C. The fluorescence intensity was measured with a fluorimeter. The excitation and emission wavelengths were set at 394 and 473 nm, respectively. The fluorescence intensity was measured as a function of protein concentration. The slope of the function was expressed as the hydrophobicity index.

2.5. Emulsifying activity and stability measurement of MRPs

The emulsifying properties of the samples were determined by the method of Pearce and Kinsella (1978) with some modifications. An MRP sample was diluted with buffer (0.05 M sodium phosphate buffer, pH 8) to a final protein concentration of 0.4% for the analysis of emulsifying properties. To form an emulsion, 15 ml of a 0.4% sample solution and 5 ml of soy oil were mixed together, with continuous agitation. The crude emulsion was homogenised using an Ultra-Turrax T25 homogeniser (IKA Werke GmbH & Co. KG, Staufen, Germany) at 10,000 rpm for 1 min. A sample of the emulsion (50 μl) was taken from the bottom of the test tube at 0, 3, 5, and 10 min and immediately diluted with 5 ml of 0.1% sodium dodecyl sulphate solution. The absorbance of the diluted emulsion was then determined at 500 nm. The emulsifying activity (*EA*) was determined from the absorbance measured immediately after the emulsion had formed (0 min). The emulsion stability (*ES*) was determined as the half-life of the initial turbidity of the emulsion (Pearce & Kinsella, 1978; Tang, Hettiarachchy, Horax, & Eswaranandam, 2003).

2.6. Determination of the degree of substitution of the MRPs

The degree of substitution (*DS*) of the rice proteins was determined from the analysis of the free amino groups in the rice proteins and MRPs. The level of free amino groups in the rice protein–sugar MRPs was determined with the TNBS method (Adler-Nissen, 1979). A protein sample (1.2% w/v) was dispersed in 0.1% SDS to obtain a solution with 0.2% protein concentration. It was then mixed with 2.0 ml of 0.21 M phosphate buffer, pH 8.2 and 1.0 ml of 0.1% 2,4,6-trinitrobenzenesulfonic acid (TNBS) solution. The solution was thoroughly mixed and placed in a temperature-controlled water bath at 50 °C for 1 h in the dark. The reaction was terminated with the addition of 2.0 ml of 0.1 M sodium sulphite. The mixture was cooled at room temperature for 30 min. The absorbance was measured at 340 nm.The degree of substitution was determined as:

$$DS\,(\%) = ((A_o - A_t)/A_o) \times 100\%,$$

where A_o was the absorbance of the sample before heating, and A_t was the absorbance of the sample after heating for t min.

2.7. Colour measurement of MRPs

For measurement of the extent of browning, MRPs were diluted in 0.1% SDS to a concentration of 0.2% of protein. The extent of browning was recorded as a measure of the absorbance at 420 nm.

2.8. Fluorescence analysis of MRPs

MRPs were dissolved in 0.2 M borate buffer (pH 8.5), then centrifuged at 7000 rpm for 20 min. The fluorescence intensity of the supernatant was measured with a fluorescence spectrometer (Hitachi 650-60). The excitation wavelength was 347 nm, and a spectrum was recorded from 380 to 480 nm with a slit width of 5 nm.

2.9. Amino acid analysis of MRPs

Measurement of the amino acid content of the MRPs was carried out by HPLC analysis on an Agilent 1100 series HPLC system (Agilent Technologies, Santa Clara, CA) with on-line pre-column derivation by o-phthaldialdehyde (OPA) and 9-fluorenylmethyl chloroformate (FMOC-Cl, for proline analysis). Analysis was performed on a Hypersil ODS C_{18} column (4.6 mm × 150 mm, 5 μm film thickness). The UV detector was set at a wavelength of 338 nm. The column temperature was 30 °C. Gradient elution was used. The gradients were formed by 20 mM sodium acetate (**A**) and 20 mM sodium acetate:methanol:acetonitrile (1:2:2 V/V/V; solvent **B**). The elution system was:–10 min, 50% **B**; 10–20 min, 50–100% **B**; 20–25 min, 100–50% **B**. The flow rate was 1.0 ml/min.

2.10. Size exclusion chromatography – multi-angle laser light scattering analysis of MRPs

The high performance size-exclusion chromatography/multi-angle laser light scattering (HPSEC/MALLS) system consisted of an HP1050 series pump, an HP1050 autoinjector (Hewlett Packard, Valley Forge, PA), a MALLS detector (Dawn DSP-F, Wyatt Technologies, Santa Barbara, CA), a differential refractometer detector (ERC-7512, ERMA Incorporated, Tokyo, Japan) and a UV detector (Shimadzu, Kyoto, Japan). For the SEC analysis, two PL aquagel-OH linear columns (Polymer Laboratories, Amherst, MA) were connected in series, and an aqueous solution of 0.1 N $NaNO_3$ was used as the mobile phase at a flow rate of 0.6 ml/min. The column temperature was maintained at 50 °C with a column heater (Bio-Rad, Hercules, CA).

3. Results and discussion

Many cereal proteins lack functionality, largely due to their insolubility. The covalent bonding of polysaccharides or smaller reducing sugars with proteins *via* the Maillard reaction can be a useful way of increasing their solubility and functionality. For other proteins this has been shown to be the case (Oliver et al., 2006). However, the establishment of optimum reaction conditions for preparing useful MRPs is needed for the synthesis of more functional rice proteins. An important functional property of MRPs is their emulsifying properties. The emulsifying properties of MRPs depend on the degree of the glycation of the protein. The emulsifying properties have been reported as being enhanced during the early stages of conjugation, and at longer times, they gradually decreased. To produce an effective emulsifying agent there should be a good balance between the degrees of hydrophobic and hydrophilic properties. In addition, the loss of emulsifying power is presumably caused by the degradation of initial MRPs, which has been suggested by the appearance of low molecular weight products found by electrophoresis gel analysis at longer reaction times (Miralles et al., 2007).

3.1. Influence of varieties of sugars

The effect of the type of saccharide (glucose, lactose, maltodextrin, or dextran) on the functionality of MRPs formed by glycation of rice proteins (weight ratio of protein:sugar of 1:1) at pH 11 was investigated at a reaction temperature of 100 °C (Table 1). The *DS* and solubility of the MRPs increased with a decrease in size of the reactant saccharide. Several investigations have shown that the reaction mechanisms of monosaccharides and disaccharides differ and that reaction products obtained from monosaccharides are different from those obtained from disaccharides (Kato, Matsuda, Kato, & Nakamura, 1988). There has been reported a linear correlation between the *DS* and the saccharide size (Nacka, Chobert, Burova, Leonil, & Haertle, 1998).

There were effects on other properties of the MRPs as well. There was little difference observed between MRPs formed with glucose or lactose as compared to larger differences between the MRPs formed with maltodextrins or dextrans. Lactose showed a greater effect than glucose on the emulsion activity (*EA*), and glucose had a greater affect on the emulsion stability (*ES*). Lactose had a greater extent of browning, and lowering of pH, but both saccharides had greater effects on these properties than the maltodextrin and dextran. The lower reactivity of the maltodextrin and dextran have been reported to be related to steric hindrance effects (Kato, 2002).

The effect of saccharide type on *DS*, pH, and extent of browning was measured at intervals over a 30 min heating period. The *DS* increased during the first 15 min of heating and remained rather constant upon continued heating (Fig. 1). The rice protein–glucose MRPs exhibited the highest *DS*. Similar trends for the solubility, *EA*, and *ES* were also observed (not shown). The extent of browning and acidity also increased during the first 15 min of heating (Huiying, Tao, Dongxiang, & Fang, 2007), and continued to increase during the latter 15 min of the 30 min period (Fig. 2). The reduction of pH occurring during the Maillard reaction could be partially due to the degradation of MRPs into acids, such as formic and acetic acids (Brands & Van Boekel, 2002). On the other hand, the decrease in pH could also be attributed to the reaction of amines to form compounds of lower basicity (Van Boekel & Brands, 1998).

The extent of browning of the protein–lactose MRPs was greater than the MRPs formed with other sugars, and the pH of the protein–lactose MRPs decreased more than other MRPs. Brands and Van Boekel (2001) reported that compared to monosaccharide systems, about four times more formic acid was formed with disaccharide-casein MRPs. The pH of all MRPs decreased markedly from their initial values within the first 15 min. Thereafter, the reduction of pH values was less during the last 15 min. It has been reported that pH has an effect on both the reaction rate and the reaction mechanism (Brands & Van Boekel, 2002).

From these results, it appeared that useful functional properties for the MRPs were optimum when formed with glucose at 15 min, and they did not appear to increase with longer reaction times. The best solubility of the MRPs (90%) was obtained with glucose. How-

Table 1
Effect of saccharide type on Maillard browning reaction products (MRPs) formed with rice protein after 15 min at 100 °C*.

Saccharide	Degree of substitution (%)	Solubility (%)	Emulsifying activity	Emulsifying stability	Browning absorbance (420 nm)	pH
No saccharide	0^{a}	20.0^{a}	0.496^{a}	10.3^{a}	0.07^{a}	11^{e}
Glucose	28.0^{b}	90.0^{e}	$0.620^{b,c}$	18.0^{d}	0.247^{d}	8.7^{b}
Lactose	26.8^{b}	83.2^{d}	$0.618^{c,d}$	16.5^{c}	0.268^{e}	8.3^{a}
Maltodextrin	17.7^{c}	73.0^{c}	0.589^{b}	13.6^{b}	0.223^{c}	9.3^{c}
Dextrin	12.2^{d}	60.1^{b}	0.585^{b}	13.6^{b}	0.128^{b}	10.6^{d}

* Concentrations of initial reactants were 1% saccharide and 1% rice protein. Values are means of three replicate values and different superscript letters within the same column represent a significant difference ($p < 0.05$).

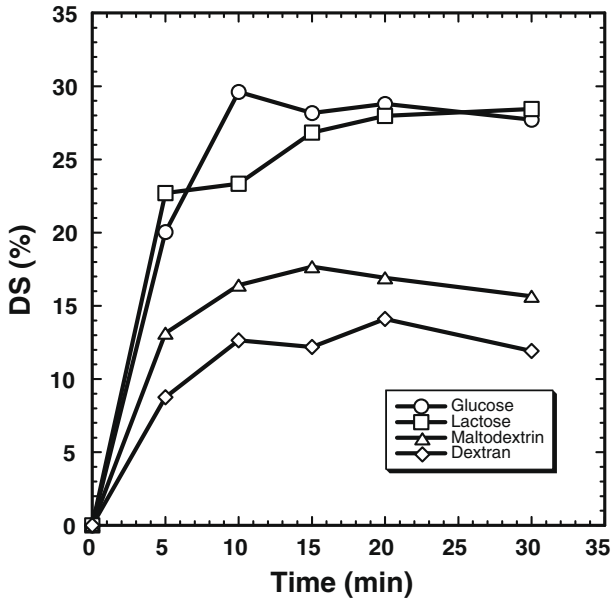

Fig. 1. The effect of saccharide on the degree of substitution (*DS*) of the free amino groups on rice proteins was measured over 30 min at 90 °C and an initial pH of 11.

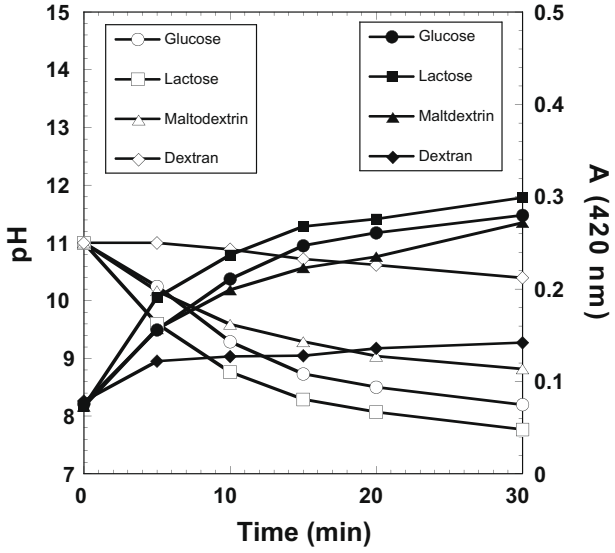

Fig. 2. The effect of saccharide on the pH and extent of browning of the reaction of saccharide with rice proteins was measured over 30 min. The open symbols represent the pH values, and the closed symbols represent absorption (*A*) at 420 nm.

ever, an increase in the extent of browning and reduction of pH continued throughout the 30 min reaction period.

3.2. Study of the effect of reaction conditions on the formation of MRPs

For rice proteins, pH may have several roles in the formation of MRPs. High pH enhances rice protein solubility and increases the rate of glycation. Rice proteins were glycated with glucose (weight ratio 1:1) at pH values 10 and 11 at 100 °C. The *DS* for the MRPs at pH values of 10 and 11 increased rapidly during the first 10 min and reached values of 10% and 34%, respectively. With continued heating after 10 min, the *DS* values increased more slowly, to reach values of 12% and 37%, respectively, after 30 min.

When the rice proteins were reacted with glucose at 100 °C with different weight ratios (*WR*) of protein:glucose (2:1, 1:1 and 1:2) with the same total weight (2%) for 30 min, differences among the functional properties of the MRPs were observed. Even though the *DS* values for the *WR* 1:2 and 2:1 showed the same overall trend as *WR* 1:1 over the reaction period (Fig. 1), the *DS* values at 15 min were 26, 28, and 21 for the *WR*s of 1:2, 1:1, and 2:1, respectively. The ranking of the final *DS* values at 30 min was the same as the 15 min ranking order. The trends of the pHs of the reaction mixtures and development of brown colour (420 nm) of the *WR*s 1:2 and 2:1 were also similar to the *WR* 1:1 (Fig. 2). The pH values at 15 min were 8.0, 8.7 and 9.1 for the *WR* of 1:2, 1:1, and 2:1, respectively. Likewise, the absorbances at 420 nm were 0.33, 0.25, and 0.22 for *WR* 1:2, 1:1, and 2:1, respectively. Thus for a fixed total concentration (2% w/w) of glucose and protein, the *WR* of 1:1 gave the highest *DS*. The reduction of pH and development of brown colour increased with an increase in *WR* of glucose under these conditions.

The effect of three reaction temperatures (80, 90, and 100 °C) on the solubility of the MRPs formed with *WR* 1:1 with the above reaction conditions was measured. After 15 min, MRPs were isolated from the reaction mixtures with *WR* of 1:1 and their solubility was measured. The solubilities of the MRPs were 15%, 86% and 90% at 80, 90, and 100 °C, respectively.

With a *WR* of 1:1 (2% w/w), and initial pH of 11, the effect of reaction times between 0 and 30 min was evaluated at 100 °C (Table 2). Both *DS* and degree of solubility of the MRPs showed rapid increases during the first 10 min and became constant after 15 min. The degree of hydrophobicity decreased with the increase in *DS* and solubility, as would be expected. The *EA* and *ES* values increased during the first 15 min and then showed a slight decrease in their values during the latter 15 min. A maximum in the *EA* and *ES* values at 15 min may suggest that the best balance between the hydrophobic and hydrophilic balance had been obtained at that time. As compared to native rice proteins, the amounts of the amino acids S-Cys, Lys, Pro and Arg decreased by 61.1%, 48.3%, 28.7% and 10.9% in the MRPs, which were formed after 15 min, respectively. Lys is commonly believed to be the most reactive amino acid in terms of glycation with reducing sugars. Arg (Yen, Tsai, & Lii, 1992), S-Cys (Billaud, Maraschin, & Nicolas, 2004) and Pro (Davidek, Clety, Devaud, Robert, & Blank, 2003) were also found to be lost in the Maillard reaction with proteins. The decrease of S-Cys content also reduces the chance of protein aggregation through –S–S bonds, which could help to increase the solubility of the MRPs in water.

The objective of this work was to improve the functional properties of rice proteins by the formation of MRPs. The results suggest that the reaction conditions which favoured the formation of useful MRPs with limited amounts of latter-stage products were WR 1:1, pH 11, 100 °C for 15 min. These MRPs had optimum emulsifying activity and solubility. In order to confirm that reaction times of longer than 15 min did produce latter-stage MRPs, several experiments were made to detect evidence for their production.

3.3. Analysis of latter-stage MRPs

The Maillard reaction is associated with the development of fluorescent compounds formed prior to the generation of brown pigments (Morales, Romero, & Jimenez-Perez, 1996; Morales & Van Boekel, 1997), which may be precursors of brown pigments. The presence of fluorescent compounds was analysed during the course of the reaction, in order to find possible markers of the development of latter-stage MRPs. The development of fluorescent compounds was found to increase with longer heating times of the rice protein and glucose (Fig. 3). It appeared that after 10 min of heating at 100 °C there was a large increase in the concentration of fluorescent compounds. Even as these compounds may have been formed prior to the generation of brown pigments, their con-

Table 2

	30	27.7[b]	90.0[d]	1143[a]	0.563[b,c]	14.4[b,c]	0.28[e]	8.2[a]

Values are means of three replicate values and different superscript letters within the same column represent a significant different ($p < 0.05$).

centrations continued to increase during the latter 15 min, as the *EA* and *ES* values were decreasing and the solubility of the MRPs showed no significant change. This suggested that at longer heating times the rate of production of latter-stage MRPs did increase, which was also supported by the increase in brown colour (Table 2).

In order to further study the latter-stage MRPs, HPSEC-MALLS was used with UV detection at 280 nm and multi-angle laser light scattering. With HPSEC-MALLS the MRPs were separated by molecular weight. With a laser light scattering detector the weight-averaged molecular weights (*Mw*) of the larger region were measured. Chromatographs of the products from each reaction time (0, 5, 10, 15, 20 and 30 min) were recorded; each was divided into two fractions, the first fraction had a low *Mw* cutoff of 10,000 Daltons and the second was the fraction, which had *Mw*s of less than 10,000 (Fig. 4). For each fraction, the integration of absorbencies at 280 nm was calculated. For the high *Mw* fraction, the recovered mass increased during the first 15 min and remained relatively constant during the latter 15 min of heating. This trend was similar to the increase in solubility of the MRPs (Table 2). The *Mw* of the larger molecular weight fraction decreased from 500 to 80 kDa during the first 15 min and then remained relatively constant during the latter 15 min. This suggested that initially the rice proteins may have been aggregated. During the initial 15 min of the reaction, the degree of aggregation decreased with the formation of MRPs. The final *Mw*s of these fractions for the heating times after 10 min of heating were between 100 and 80 kDa. For the lower

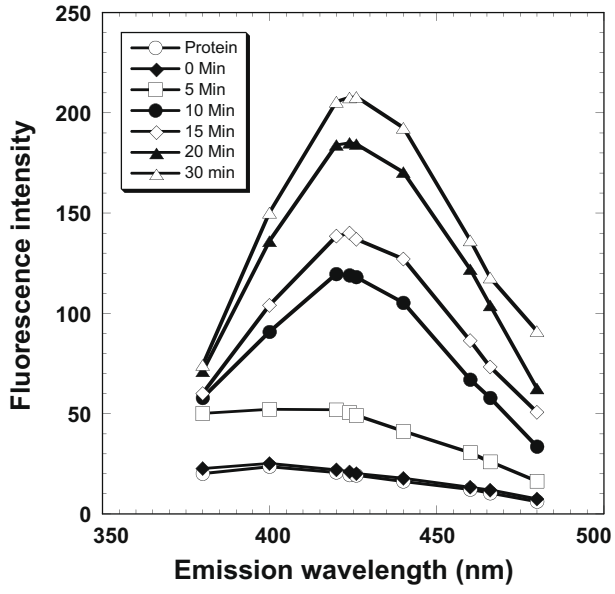

Fig. 3. The effect of reaction time on the fluorescence spectra of glucose MRPs measured with an excitation frequency of 347 nm. The MRPs were formed at 100 °C.

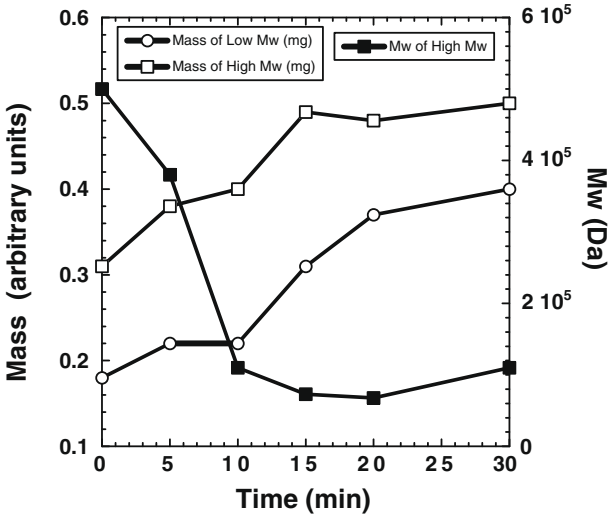

Fig. 4. Glucose MRP products analysed by HPLC size-exclusion analysis. The collection samples were divided into two fractions. The high molecular fraction was in the range of 1000–10 kDa. The low *Mw* range is that below 10 kDa. The recovered mass of each fraction is in arbitrary units. *Mw* is the weight average of the molecular weight of each fraction.

Mw fraction, there was little change in the recovered mass during the first 10 min and its Mw was also constant at 40 kDa. At later times the concentrations of the low *Mw* species absorbing at 280 nm increased continuously and the final *Mw* was 20 kDa. These products may have been latter-stage MRPs, which were compounds that were dissociated from glycated proteins, and contained chromophores absorbing at 280 nm.

4. Conclusion

The Maillard reaction can be successfully used as a coupling method for rice protein and glucose to form MRPs with improved functional properties. Using methods to detect latter-stage MRPs, optimum reaction conditions were found which provided improved functional properties of rice proteins with reduced levels of latter-stage MRPs. At a reaction time of 15 min the MRP had the best emulsifying capacity and solubility. The conditions for obtaining these MRPs were a 2% (w/w) protein:glucose (*WR* 1:1) aqueous dispersion with an initial pH of 11 which was heated for 15 min at 100 °C. At these conditions, the functional properties (the emulsifying activity, emulsifying stability and solubility of the MRPs) increased by factors of 1.29, 1.77 and 8.30 times, respectively. However, there was a loss of 48% of the original lysine content of the rice proteins. Longer reaction times did not improve the yield or functional properties and there was evidence that at longer times other products were formed.

Partitioning

ABSTRACT

The effect of glycosylation on the ability of flavonoids to inhibit lipid oxidation in comminuted muscle tissue has not been previously examined. This work examined the ability of quercetin and quercetin-β-D-glucoside to inhibit lipid oxidation in mechanically separated turkey (MST). Quercetin inhibited formation of lipid peroxides and thiobarbituric acid reactive substances (TBARS) more effectively compared to quercetin-β-D-glucoside during frozen storage ($p < 0.05$). The possible mechanisms that cause glycosylation to decrease inhibition of lipid oxidation were also examined. Hydroxyl radical scavenging activity was similar when comparing quercetin and quercetin-β-D-glucoside, which indicated that the free hydroxyl group in 3 position of C ring in quercetin did not enhance its hydroxyl radical scavenging ability. Since muscle membrane lipids are susceptible to lipid oxidation, the ability of quercetin and quercetin-β-D-glucoside to incorporate into cellular membranes was studied. After adding quercetin and quercetin-β-D-glucoside to minced chicken muscle, flavonol content in the membrane fraction was determined. Around 32% of added quercetin partitioned into the membranes whereas quercetin-β-D-glucoside was not detected in the membranes. Similar trends were observed when each flavonol was added to isolated membranes. These studies suggest that glycosylation of flavonols weakens their ability to inhibit lipid oxidation in muscle tissue partly by decreasing the amount of flavonols in the membrane phase. In order to understand whether metal chelation by flavonols is a likely mechanism involved in the inhibition of lipid oxidation in MST, the role of endogenous metals in promoting lipid oxidation was examined. Addition of the metal chelators ethylenediamine tetraacetic acid (EDTA) and tetrakis(2-pyridylmethyl) ethylenediamine (TPEN) to MST did not inhibit lipid oxidation, which suggests that endogenous metals present in MST were not promoters of lipid oxidation. Hence it seems unlikely that the mechanism of inhibition by flavonols involved metal chelation in the comminuted muscle.

1. Introduction

Muscle foods are susceptible to lipid oxidation which negatively affects the quality and economic value of the muscle products. Incorporation of antioxidants into foods can effectively retard lipid oxidation (Labuza, 1971). In our previous work, we found that a fraction isolated from an amphiphilic extract prepared from cranberry juice powder was an effective inhibitor of lipid oxidation in mechanically separated turkey (MST). The compound responsible for the inhibitory activity was then identified as quercetin. It was evident from these studies that glycosylated quercetin in the extract did not contribute to the efficacy of the isolated fraction in MST (Kathirvel, Gong, & Richards, 2009).

For a better understanding of how glycosylation of flavonols affects the antioxidant activity in comminuted muscle tissue systems, a comparative study between quercetin and quercetin-β-D-glucoside was conducted. Quercetin and quercetin-β-D-glucoside belong to the class of flavonoids known as flavonols. Quercetin and quercetin-β-D-glucoside are structurally similar flavonols except for the presence of a glucose moiety at 3-hydroxy position in quercetin-β-D-glucoside (Fig. 1). Flavonols are widely distributed in plant foods (Bahorun, Luximon-Ramma, Crozier, & Aruoma, 2004; Justesen, Knuthsen, & Leth, 1998; Vvedenskaya & Vorsa, 2004) and have received considerable attention for their antioxidant properties (Crozier et al., 2000; Mira et al., 2002; Plumb, Price, & Williamson, 1999). The structure–activity relationship of flavonols depends on the test system used to determine lipid oxidation. The antioxidant activity of flavonols has been extensively studied in methyl lineolate, liposome systems and fish lipids (Hopia & Heinonen, 1998; Liao & Yin, 2000; Pazos, Gallardo, Torres, & Medina, 2005). Free radical scavenging and metal chelation have been described to be the key factors responsible for the antioxidative

activities of flavonols (Bors, Heller, Michel, & Saran, 1990; Mira et al., 2002).

Partitioning of flavonols in octanol and water phases has been reported (Rothwell, Day, & Morgan, 2005) and has been described as a useful way to determine the behaviour of flavonols towards the membrane phase. In muscle foods, membrane phospholipids are believed to be the most susceptible lipid fraction to lipid oxidation compared to neutral lipids (e.g. triacylglycerols), mainly due to the higher degree of fatty acid unsaturation and increased surface area of the membranes (Pikul, Leszczynski, & Kummerow, 1984). Partitioning of antioxidants to sites where the lipids are most susceptible to oxidation might be important in reducing the extent of lipid oxidation in muscle foods. Studies that probe the importance of flavonoid partitioning in muscle membranes are still lacking. The purpose of the work here was to compare the ability of two commonly occurring flavonols in plant foods, quercetin and quercetin-β-D-glucoside to inhibit lipid oxidation in mechanically separated turkey (MST) as well as to assess the possible mechanisms by which these flavonols exhibit their antioxidative properties in muscle tissue. MST was used as a substrate for oxidation study mainly due to its high susceptibility to lipid oxidation and use as a raw material in formulation of processed meats such as bologna and wieners. This study helps in the better understanding of how structural changes influence the antioxidant activity of flavonols in a muscle tissue matrix.

2. Materials and methods

2.1. Materials

Mechanically separated turkey (MST) was obtained from Kraft-Oscar Mayer (Newberry, SC) and was vacuum packaged and stored at −80 °C until use. Broiler chicks (Cornish Rock) obtained from Sunnyside Farms, WI were raised in the Poultry Research Lab (PRL), UW-Madison. Chicken breast muscle used for partitioning studies was harvested from broiler chickens raised in the PRL. Sealable, polyethylene bags (10 cm × 15 cm) and vacuum pouches (3 ml standard barrier) were purchased from Koch Supplies (Chicago, IL). Ethanol (absolute, 200 proof) was obtained from Aaper Alcohol and Chemical Co. (Shelbyville, Kentucky). 2-Thiobarbituric acid, sodium chloride, potassium hydroxide, sodium hydroxide, disodium ethylenediamine-tetraacetic acid, propyl gallate, potassium dihydrogen phosphate, deoxyribose, ferric chloride, ferrous sulphate, hydrogen peroxide, sodium ascorbate, Proteinase, HEPES buffer (N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid buffer hemisodium salt), ethylene diamine tetraacetic acid (EDTA), tetrakis(2-pyridylmethyl) ethylenediamine (TPEN), quercetin dihydrate and quercetin-β-D-glucoside were procured from Sigma A/S (St. Louis, MO). Ammonium thiocyanate, barium chloride, hydrochloric acid, sulphuric acid, trichloroacetic acid, sodium carbonate, methanol, 1-butanol and chloroform were purchased from Fisher Scientific (Chicago, IL). The solvents used were of HPLC grade.

2.2. High Performance Liquid Chromatograph (HPLC) apparatus and chromatographic conditions

HPLC analysis of flavonols were performed on a Agilent 1100 HPLC system equipped with an Agilent 1100 series binary pump and photodiode array detector (Agilent, Wilmington, DE). A C18 reversed phase column (Discovery 5 μm, 25 cm × 0.46 cm i.d.) (Supelco, Bellefonte, PA) was used. The binary solvent system used was: Solvent A, 0.1% trifluoroacetic acid in water and solvent B, 0.1% trifluoroacetic acid in methanol. To determine the flavonols that partitioned into the membranes, membrane lipids were extracted using chloroform:methanol (1:1 v/v) and NaCl solution and both the chloroform and methanol/water phases were analyzed. To analyze the chloroform phase, it was first evaporated and lipids were redissolved in methanol:butanol (1:1v/v) before injecting into the HPLC system. A linear gradient of 0–100% B from 0 to 40 min was carried out at a flow rate of 1 ml/min. Multiwavelength detection was monitored at 280, 320, 360 and 520 nm. Quercetin and quercetin-β-D-glucoside were used as standards.

2.3. Addition of flavonols to MST

MST was vacuum packaged in 500 g portions and stored at −80 °C until use. The frozen packs were then thawed for 2 h at room temperature (without breaking the vacuum seal) before using them for treatments. Quercetin and quercetin-β-D-glucoside were added at 100 μmol/kg MST and thoroughly mixed with a spatula to ensure uniform distribution. All samples were stored in zip-lock polyethylene bags at −4 °C during the study period. The carrier solvent was 100% ethanol and was used at 1% of the final sample weight. A control sample containing 1% ethanol without the flavonols was also prepared for the respective trials.

2.4. Isolation of crude membranes from MST

The method described by Raghavan and Hultin (2005) was used for the isolation of crude membranes from MST. Ten grams of muscle was mixed with four volumes of cold 0.1 M HEPES buffer containing 0.2% (w/v) sodium ascorbate (pH 7.5) and homogenized at speed 6 for 40 s using a Kinematica Polytron PT 10–35 homogenizer (Brinkmann Instruments, Westburg, NY). The pH of the homogenate was adjusted to 7.5 and was centrifuged at 10,000*g* for 20 min at a sample temperature of 7–9 °C using a Beckman

L5–65 ultracentrifuge (Beckman Instruments Inc., Palo Alto, CA). The supernatant obtained was centrifuged at 130,000*g* for 30 min to obtain crude membrane as sediment.

2.5. Addition of quercetin and quercetin-β-D-glucoside to crude membranes isolated from MST

A 2 ml methanol:water solution containing approximately 367 μg quercetin or 464 μg quercetin-β-D-glucoside were added to membranes prepared from 10 g MST and hand homogenized using a Potter-Elvehjem tissue grinder for 2 min. The level of addition of flavonols to the membranes corresponds to the level used for the oxidation study in MST (100 μmol/kg MST). This suspension was then centrifuged at 130,000*g* for 30 min. The flavonol content in the supernatant was quantified by HPLC. The resulting membrane pellet was then resuspended in 3 ml of 0.1 M HEPES buffer and was used for lipid, phospholipid and flavonol determinations.

2.6. Adddition of quercetin and quercetin-β-D-glucoside to chicken breast muscle

Broiler chickens (8-weeks old) raised at UW-Madison were sacrificed by asphyxiation using carbon dioxide. The chickens were bled before collecting the breast muscles. Breast muscles were removed and stored at 0–4 °C until used (10–16 h). The muscles were ground twice through 5 mm perforations in a KitchenAid model KSM90 grinder (KitchenAid Inc., St. Joseph, MI). Sodium ascorbate and proteinase (a proteolytic enzyme preparation) were added to ground muscle at 0.2% and 0.005% (w/w) respectively and minced for 20 s in the food processor. Proteinase was added to break down structural proteins and to aid the release of membrane material. Sodium ascorbate provided protection to the flavonols added to the muscle. The minced muscle was then incubated for 1 h at refrigerated conditions (0–4 °C). After incubation, quercetin and quercetin-β-D-glucoside were added to the muscle at 100 μmol/kg using 1% ethanol as a carrier solvent and minced for 30 s in the food processor. An incubation period of around 20 min was implemented prior to isolating the membranes. Membranes were then isolated from 10 g of muscle as described above and suspended in 3 ml of 0.1 M HEPES buffer which was then used for lipid, phospholipid and flavonol determinations. All the procedures were done in iced conditions unless otherwise noted.

2.7. Total lipid, phospholipid and flavonol determination

Total lipid content of membranes were determined by extracting 3 ml of membrane suspension with 30 ml of 1:1 (v/v) chloroform/methanol mixture in a separatory funnel using 12 ml of 0.5% (w/v) NaCl solution for phase separation (Sigfusson & Hultin, 2002). The funnel was stored at refrigerated temperatures during phase separation. For extraction of muscle lipids, 10 g of muscle sample was homogenized using a Kinematica Polytron PT 10–35 homogenizer (Brinkmann Instruments, Westburg, NY) at speed 6 for 60 s with 100 ml chloroform/methanol mixture. The homogenate was filtered through Whatman #4 filter paper into a separatory funnel, followed by the addition of 40 ml of 0.5% (w/v) NaCl solution for phase separation. The chloroform layer was separated and aliquots of chloroform were used for total lipid, phospholipid and flavonol determination. Total lipid content was determined by driving off the chloroform layer using nitrogen gas. For determining quercetin and quercetin-β-D-glucoside in membrane lipids, lipid obtained by driving off an aliquot of chloroform layer was redissolved in 1 ml of methanol:butanol (1:1v/v) and filtered through 0.45 μm pore size PTFE disk filters prior to injection to the HPLC. The methanol:water phase was also analyzed for the presence of flavonols.

The phosphorous content of the membrane lipid extract was determined spectrophotometrically (Anderson & Davis, 1982). In brief, aliquots of the chloroform layer obtained after lipid extraction were transferred to test tubes and dried under nitrogen gas. Concentrated sulphuric acid (98%) (0.1 ml) was added to the samples, vortexed and digested at 155 °C for 10 min. Tubes were then cooled and samples were oxidized with hydrogen peroxide at 155 °C for 40 min. After cooling the tubes, 2 ml of distilled water was added and mixed properly. This was followed by the addition of 0.8 ml of ammonium molybdate-ascorbate solution (1:1 v/v) and the mixture was heated for 7 min in a boiling water bath. The absorbance was then read at 797 nm after cooling of the samples. Sodium phosphate (dibasic) was used as a standard. A factor of 25 was used for converting lipid phosphorous to phospholipids, based on an average molecular weight of phosphatidylcholine divided by the atomic weight of phosphorous.

2.8. Hydroxyl radical scavenging assay

The scavenging activity of quercetin and quercetin-β-D-glucoside on the hydroxyl radical ($OH^{\cdot}$) was measured by the deoxyribose method (Aruoma, 1994). The only exception was that Adenosine Triphosphate (ATP) was used as the iron chelator instead of EDTA. This assay uses the Fenton reaction to generate $OH^{\cdot}$ in the presence of ascorbic acid which then attacks the sugar deoxyribose to form products that on heating with thiobarbituric acid yields a pink chromogen detected at 532 nm. The reaction mixture contained the following reagents at final concentrations stated: deoxyribose (2.8 mM), $FeCl_3$ (25 μM), ATP (100 μM) [ATP and $FeCl_3$ are mixed prior to the addition of deoxyribose], H_2O_2 (2.8 mM), KH_2PO_4/KOH buffer at pH 7.4 (10 mM), quercetin and quercetin-β-D-glucoside at two concentrations of 18 μg and 36 μg. In order to avoid the interference caused by solvents and to make the flavonols soluble in aqueous media, stock solutions of flavonols were prepared by dissolving 2.5 mg of flavonols in 100 μl of 2 N NaOH and then solution made up to 25 ml with distilled water. The pH of the flavonol solution was adjusted to 7.4. The reaction was started by adding ascorbate (100 μM). The final reaction volume was 1.2 ml. The reaction mixture was incubated in a water bath for 1 h at 37 °C. After incubation, 1 ml of 1% (w/v) thiobarbituric acid and 1 ml of 2.8% (w/v) trichloroacetic acid were added to the mixture and heated in a boiling water bath at 100 °C for up to 20 min. The sample was then cooled and the absorbance was measured at 532 nm. The reaction mixture not containing flavonols was used as control. The hydroxyl radical scavenging activity (HRSA) was expressed as

$$\mathrm{HRSA}(\%) = \left[1 - \frac{\text{Absorbance at 532 nm in the presence of flavonols}}{\text{Absorbance at 532 nm in the absence of flavonols}}\right] \times 100$$

2.9. Ability of metal chelators to inhibit lipid oxidation in MST

In order to indirectly understand whether metal chelation by flavonols were one of the mechanisms by which they inhibit lipid oxidation in MST, metal chelators were added to MST to see whether the chelators bind endogenous metals present in MST and prevent lipid oxidation. Ethylene diamine tetraacetic acid (EDTA) and tetrakis (2-pyridylmethyl) ethylene diamine tetraacetic acid (TPEN) were used as metal chelators. EDTA is an aqueous metal chelator where as TPEN is a membrane permeable metal chelator. EDTA and TPEN were added at 2 mM/kg MST and were thoroughly mixed with a spatula. The carrier solvent was 100% ethanol and was used at 1% of the final sample weight. Since EDTA was

not soluble in ethanol, it was first dissolved in distilled water followed by ethanol before adding to MST. A control sample containing 1% ethanol without any metal chelators was also prepared for the respective trials. All samples were stored in zip-lock polyethylene bags at −4 °C during the study period.

2.10. Determination of thiobarbituric acid reactive substances (TBARS)

The progress of lipid oxidation in MST was followed by periodically removing samples and quantifying TBARS formed by the method described by (Lemon, 1975). Approximately, 1 g of the sample was mixed with 6 ml of trichloroacetic acid (TCA) solution (7.5% TCA, 0.1% disodium ethylenediamine tetraacetic acid [EDTA], 0.1% propyl gallate) and homogenized with a Polytron Type (PT) 10/35 (Brinkmann Instruments, Westbury, NY) for 30 s. The homogenate was filtered through Whatman no. 1 filter paper. One millilitre of the filtrate was then mixed with 1 ml of thiobarbituric acid (TBA) (0.02 M) and incubated at 100 °C for 40 min. After cooling the reaction mixture in cold water for 5 min and centrifuging (2000*g* for 5 min) in a Beckman J-6B centrifuge (Beckman Instruments, Inc., Palo Alto, CA), the absorbance was measured at 532 nm. TBARS value was expressed as μmol TBARS/kg of tissue. A standard curve was constructed using tetraethoxypropane as a precursor of malonaldehyde.

2.11. Determination of lipid peroxides

Lipid peroxides were determined according to the method described by Richards and Dettman (Richards & Dettmann, 2003). Approximately 0.3 g of the tissue was homogenized using a Kinematica Polytron PT 10–35 homogenizer (Brinkmann Instruments, Westburg, NY) at speed 6 for 30 s in 10 ml of chloroform:methanol (1:1 v/v). A volume of 3.08 ml of 0.5% NaCl was then added to separate the mixture into two phases. The mixture was then centrifuged at 2000*g* for 5 min and 2.0 ml of chloroform layer was removed using a glass syringe. A volume of 1.33 ml of chloroform: methanol (1:1 v/v) was added to the removed aliquot followed by addition of 25 μl of ammonium thiocyanate and 25 μl of fresh ferrous chloride solution (made by mixing equal volumes of barium chloride (8 g/l) in 0.4 N HCl and ferrous sulfate (20 g/l)). After incubation at room temperature for 20 min, absorbance was read at 500 nm. The standard used was cumene hydroperoxide.

2.12. Statistical analysis

The MIXED procedure of the SAS system was used to analyze the data obtained from lipid oxidation and partitioning studies. This procedure implements random effects in the statistical model and permits modeling the covariance structure of the data (Littell, Henry, & Ammerman, 1998). For lipid oxidation studies, two separate reaction mixtures for each treatment were prepared and used as the source of variation for the statistical analysis. Two indicators of lipid oxidation were measured for each treatment during the storage study. Means were separated by least significance difference test. Samples were drawn from each experimental unit at various time points and hence repeated measures were obtained for each treatment. In this model, the variation between the experimental units within a treatment is specified by the 'random' statement where as the covariation within the experimental units is specified by the 'repeated' statement. Since the repeated measures were not taken at equal intervals of time, 'sp(pow)(d)' was fitted into the model to account for this variation. Partitioning studies in isolated MST membranes were done in duplicates. For determining the partitioning of quercetin and quercetin-β-D-glucoside in chicken breast muscle membranes, two separate studies were done. In each study, the treatments were conducted in duplicates. For the partitioning and scavenging studies, Student's t-test was performed. Significance was defined at $p \leqslant 0.05$.

3. Results

3.1. Ability of quercetin and quercetin-β-D-glucoside to inhibit lipid oxidation in MST

A direct comparison between quercetin and quercetin-β-D-glucoside to inhibit lipid oxidation was carried out in MST at −4 °C. The level of addition was 100 μmol/kg MST. The antioxidative activity was measured by the ability of the flavonols to inhibit the formation of TBARS and lipid peroxides in MST during the storage study (Fig. 2). With regard to TBARS formation, the lag phase was defined as the time it took for TBARS values to exceed 20 μmol/kg of MST during the storage period. TBARS reached 20 μmol/kg within a 14 day period in the control, whereas the samples containing quercetin-β-D-glucoside and quercetin took an additional 3 days and 13 days respectively to reach the 20 μmol/kg threshold. Significant inhibition ($p < 0.05$) in TBARS formation was observed in samples with quercetin compared to samples with quercetin-β-D-glucoside. There was no significant difference ($p > 0.05$) in terms of inhibiting lipid oxidation when comparing control and samples containing quercetin-β-D-glucoside. Similarly significant inhibition ($p < 0.05$) in lipid peroxide formation was observed in quercetin treated samples when compared to samples containing quercetin-β-D-glucoside.

3.2. Partitioning of quercetin and quercetin- β-D-glucoside in crude membrane isolates

To study the partitioning of querectin and quercetin- β-D-glucoside, a model system consisting of membranes isolated from MST and aqueous methanolic solutions of flavonols were used. Quantification of flavonols was done by HPLC. Quercetin dissolved in methanol:water (1:1 v/v) was added to membrane at 367 μg, homogenized and centrifuged. The concentration of quercetin in

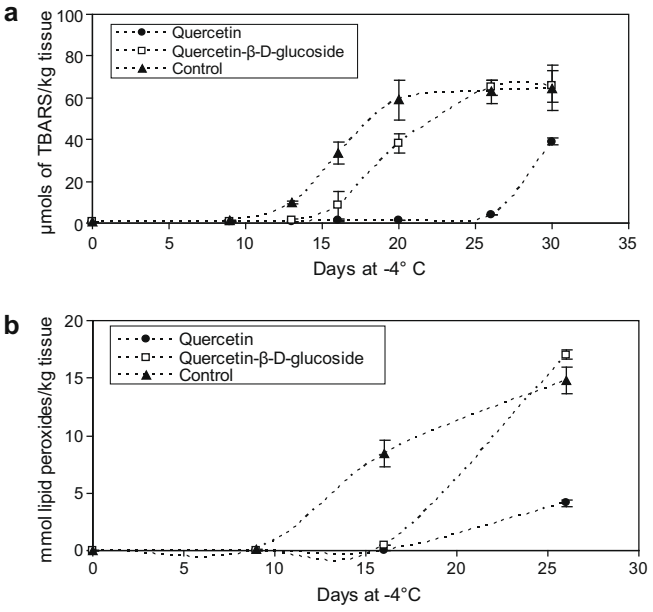

Fig. 2. Effect of quercetin and quercetin-β-D-glucoside on the formation of (a) TBARS and (b) lipid peroxides in MST. Both quercetin and quercetin-β-D-glucoside were added at 100 μmol/kg MST. Ethanol was used as the carrier solvent at 1% of the final sample weight. Results are expressed as average ± standard deviation from duplicate samples.

Table 1
Partitioning of quercetin and quercetin-β-D-glucoside in crude membrane suspensions[a].

Sample	Flavonol added to membranes[b] (μg)	Flavonol recovery (μg)		
		Supernatant phase[c]	From membranes	
			Methanol:water phase[d]	Chloroform phase[d]
Quercetin	367	267.5 ± 0.002	43 ± 0.01	2.41 ± 0.75
Quercetin-β-D-glucoside	464	368.0 ± 0.70	35 ± 5.65	ND

ND – not detected. Results are expressed as average ± standard deviation from duplicate samples.
[a] $n = 2$, where n = number of replicates for each experiment.
[b] Amount of quercetin and quercetin-β-D-glucoside (μg) added to membranes isolated from 10 g of MST.
[c] The amount of quercetin and quercetin-β-D-glucoside determined in the solution after sedimentation of the membranes by ultracentrifugation.
[d] The amount of quercetin and quercetin-β-D-glucoside that partitioned into the membranes and recovered from methanol:water and chloroform phases used for extracting lipids and flavonols from membranes.

the supernatant was 267.5 μg. The quercetin that partitioned from the aqueous suspension into the membrane pellet was then extracted using chloroform:methanol and the two phases were separated using sodium chloride solution. Quercetin from the membranes was found to partition between methanol-water (43 μg) and chloroform phases (2.41 μg). When quercetin-β-D-glucoside was added to membranes at 464 μg, the supernatant contained 368 μg of glucoside whereas the recovery of the glucoside in the methanol–water phase was 35 μg. No glucoside could be detected in the chloroform layer (Table 1). When expressed on a percentage basis, around 12.4% of added quercetin partitioned into the membranes whereas only 7.5% of added quercetin-β-D-glucoside partitioned into the membranes ($p = 0.09$).

3.3. Partitioning of quercetin and quercetin-β-D-glucoside in chicken breast muscle

There was a low membrane total lipid ratio (around 0.38) in membranes isolated form MST (Table 2). This indicated a substantial amount of contamination of neutral lipids with the membrane phospholipids. This is problematic when estimating the amount of flavonols that partitions into the membrane phase when flavonols are first added to muscle. Membranes isolated from minced, chicken breast muscle had a membrane phospholipid/total lipid ratio ranging from 0.63–0.72 which indicated a relatively pure membrane preparation. The chemical characteristics of membranes obtained from MST and chicken breast muscle are shown in Table 2. The higher neutral lipid contamination in membranes isolated from MST is likely due to the higher amount of neutral lipid present and greater amount of shearing and tissue disruption when preparing MST compared to minced chicken breast.

Quercetin and quercetin-β-D-glucoside dissolved in ethanol (1% muscle weight) were added to minced chicken breast muscle at 100 μmol/kg tissue and minced for 30 s. The cellular membranes were then physically isolated from the muscle. The isolated membranes were then dissolved in a mixture of chloroform and methanol followed by addition of sodium chloride solution in an effort to capture all of the flavonols since these compounds could have some solubility in each of the different solvent phases. Quercetin that separated with the isolated membranes partitioned into both the chloroform phase and methanol-water phase resulting in recoveries of 20.26 μg and 88.42 μg, respectively (Table 3). This constituted a 32.1% recovery based on the added level (338.26 μg quercetin/10 g muscle). When quercetin-β-D-glucoside was added to the breast muscle, the compound was not detected in either the chloroform or the methanol-water phase (Table 3). Recovery of flavonols was calculated based on the assumption that the concentration of flavonols in the membrane fraction obtained by centrifugation was the same as that of the unrecovered fraction of membranes in the muscle tissue.

Table 2
Comparison of chemical characteristics of mechanically separated turkey (MST) and chicken breast muscle (CBM).

Sample	Membrane TL content (mg)	Membrane PL content (mg)	PL(membrane)/TL(membrane)	PL(mem)/PL(muscle)
MST	16.45 ± 0.07	6.12 ± 0.73	0.38 ± 0.03	0.22 ± 0.02
CBM	24.20 ± 1.41	16.24 ± 1.06	0.67 ± 0.08	0.35 ± 0.02

The abbreviations TL and PL represent total lipid and phospholipid contents respectively. Membrane TL content indicates the total lipid extracted from membranes obtained from 10 g of MST or minced chicken breast muscle. Membrane PL content indicates the phospholipid content of membranes obtained from 10 g of MST or minced chicken breast muscle. PL (muscle) indicates the phospholipid content of 10 g of MST or chicken breast muscle. Results are expressed as average ± standard deviation from duplicate measurements.

Table 3
Partitioning of quercetin and quercetin-β-D-glucoside in membranes after each flavonol was added to minced chicken breast muscle[a].

Sample	μg added flavonol/10 g muscle[b]	Flavonol recovery (μg)		% Flavonol recovery[d]
		Methanol:water phase[c]	Chloroform phase[c]	
Quercetin	338.26	88.42 ± 4.79	20.26 ± 2.39	32.13%
Quercetin-β-D-glucoside	464.38	ND	ND	–

ND- not detected. Results are expressed as average ± standard deviation.
[a] n = 4, where n = number of replicates for each experiment.
[b] Amount of quercetin and quercetin-β-D-glucoside (μg)/10 g of minced chicken breast muscle.
[c] The amount of quercetin and quercetin-β-D-glucoside that partitioned into the membranes isolated from 10 g of muscle and recovered from methanol:water and chloroform phases used for extracting lipids and flavonols from membranes.
[d] Recovery of flavonols was calculated based on the assumption that the concentration of flavonols in the membrane fraction obtained by centrifugation was the same as that of the unrecovered fraction of membranes in the muscle tissue.

Table 4
Hydroxyl radical scavenging activities of quercetin and quercetin-β-D-glucoside. Results are expressed as average ± standard deviation from duplicate samples.

Flavonol (μg/1.2 ml reaction mixture)	HRSA (%)
Quercetin – 18 μg	22.81 ± 0.20
Quercetin – 36 μg	35.05 ± 0.13
Quercetin-β-D-glucoside – 18 μg	24.95 ± 2.01
Quercetin-β-D-glucoside – 36 μg	37.24 ± 1.14

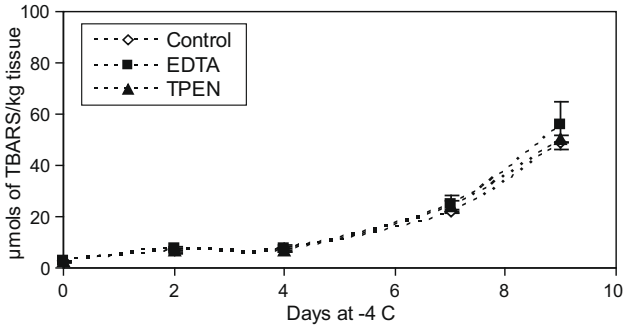

Fig. 3. Effect of metal chelators, EDTA and TPEN on the formation of TBARS in MST. Both the metal chelators were added at 2 mM/kg MST. Ethanol was used as the carrier solvent at 1% of the final sample weight. Results are expressed as average ± standard deviation from duplicate samples.

3.4. Hydroxyl radical scavenging activity

It was thought that part of the mechanism by which quercetin more effectively inhibited lipid oxidation in MST compared to quercetin-β-D-glucoside could be due to differences in free radical scavenging abilities. The deoxyribose assay was used to assess the ability of each flavonol to scavenge hydroxyl radicals. The scavenging ability of quercetin and quercetin-β-D-glucoside at concentrations of 18 and 36 μg per 1.2 ml of reaction mixture are shown in Table 4. Both quercetin and its glucoside at varying concentrations exhibited similar scavenging activities.

3.5. Ability of metal chelators to inhibit lipid oxidation in MST

Another mechanism by which flavonols act as antioxidants involves the chelation of metals ions like iron and copper. Neither EDTA nor TPEN inhibited lipid oxidation in MST during the storage study (Fig. 3). Thus, endogenous metals present in MST did not seem to play a role as lipid oxidation catalysts in MST which makes it unlikely that the mechanism of inhibition by flavonols involved metal chelation in the muscle matrix.

4. Discussion

The growing interest in the substitution of synthetic food antioxidants by naturally occurring phenolic compounds in fruits and vegetables has led to the screening of compounds in food systems for their antioxidative efficacy. Quercetin and quercetin-β-D-glucoside (Fig. 1) are two flavonols commonly found in berries, citrus fruits, onions, leafy vegetables, etc. (Crozier et al., 2000). Even though the antioxidant efficacy of flavonols have been studied in liposomes, fish lipids and mitochondria (Liao & Yin, 2000; Pazos et al., 2005; Ratty & Das, 1988), little attention has been given towards the structure–activity relationship of flavonols in comminuted muscle food systems. The reason for choosing quercetin and quercetin-β-D-glucoside for comparative study was due to the fact that quercetin identified in a fraction isolated from cranberry juice powder extract was a potent inhibitor of lipid oxidation in MST whereas its glycosylated counterpart did not contribute to the efficacy of the fraction in MST (Kathirvel et al., 2009).

When quercetin and quercetin-β-D-glucoside were added separately to MST, quercetin effectively inhibited lipid oxidation in MST compared to quercetin-β-D-glucoside (Fig. 2). In muscle foods, membrane lipids are the substrates most susceptible to oxidation compared to neutral lipids. Location of flavonols at sites where lipids are prone to oxidation might be an important prerequisite for inhibiting lipid oxidation in MST. In our partitioning study, we did find that quercetin partitioned into the membranes more effectively than quercetin-β-D-glucoside (Tables 1 and 3). The results indicate that the presence of sugar in quercetin-β-D-glucoside was affecting its inhibitory properties in muscle tissue probably by partitioning it away from the membranes. When quercetin-β-D-glucoside was added to minced chicken muscle, no glucoside could be determined in the membranes, which indicates that the polarity conferred by the sugar moiety affected the membrane incorporation of quercetin-β-D-glucoside in the muscle matrix. On the contrary, the non-polar nature of quercetin compared to its glucoside might have enabled quercetin to interact with the polar head groups of phospholipids at the lipid-water interface through the formation of hydrogen bonds. Such an association with the membranes is necessary to scavenge the free radicals at the lipid-water interface and inhibit the propagation of lipid oxidation in the muscle tissue. Studies in membranes composed of dipalmitoylphosphatidylcholine indicated that flavonoids rich in hydroxyl groups strongly interact with the polar portion of the phospholipid molecule at the lipid-water interface (Ollila, Halling, Vuorela, Vuorela, & Slotte, 2002). Quercetin, a planar flavonol has been shown to intercalate into the organized structures of the phospholipids within the vesicle membranes when compared to naringenin, a non-planar flavonone (van Dijk, Driessen, & Recourt, 2000).

The partitioning coefficient (log P) of quercetin in octanol-water was significantly higher than quercetin-3-glucoside, which demonstrates higher lipophilicity of quercetin than its glucoside (Rothwell et al., 2005). In this study, log P of quercetin was 1.82 compared to 0.76 for quercetin-3-glucoside. Log P best represents how a compound behaves in a membrane environment. In the partitioning study carried out in chicken muscle, quercetin-3-glucoside did not associate with the muscle membranes (Table 3). Even though the experimentally determined log P value for quercetin-3-glucoside shows that it partitions into the octanol phase comparatively lesser than quercetin, it seems that the actual partitioning of glycosylated quercetin in biological membranes is quite different. One possible explanation for this difference in partitioning could be due to the complex characteristics of the muscle system compared to the octanol–water system. The different partitioning data obtained while using isolated membranes from MST and chicken muscle system could also be due to the differences in the test system studied. When the glucoside is added directly to the isolated membrane system, the chances of glucoside interacting with the membranes are higher compared to when it is added directly to muscle. It seems that when the glucoside is added directly to muscle, it comes in contact with the myofibrillar proteins and the aqueous phase of the muscle and remains there without becoming incorporated into the muscle membranes because of its hydrophilic nature compared to quercetin.

A potential mechanism of inhibition involves the ability of flavonols to scavenge hydroxyl radicals. Hydroxyl radicals form in muscle tissue mostly due to the ability of low molecular weight metals like iron and copper to react with hydrogen peroxide (Koppenol, 1993; Rowley & Halliwell, 1983). Our results indicated similar hydroxyl radical scavenging abilities of quercetin compared to quercetin-β-D-glucoside (Table 4). The 3′, 4′ hydroxyl groups in the

B ring (catechol group), the 2, 3 double bond in conjugation with the 4-oxo group in the C ring and the presence of hydroxyl groups in position 3 and 5 are believed to be responsible for the free radical scavenging activity of quercetin (Hudson & Lewis, 1983; Pietta, 2000)(Fig. 1). Our data suggests that the presence of the hydroxyl group in position 3 of C ring in quercetin did not enhance its hydroxyl radical scavenging ability compared to quercetin-β-D-glucoside in which the 3 position is occupied by linkage to the sugar moiety. Since both the flavonols showed similar aqueous radical scavenging abilities, it seems that scavenging chain-propagating lipid radicals at the lipid-water interface or the hydrophobic core of the membrane by quercetin is necessary to inhibit lipid oxidation in MST rather than the scavenging of radicals in the aqueous phase of the muscle tissue. Quercetin showed a greater protective effect than rutin in inhibiting autoxidation of rat cerebral membranes (Saija et al., 1995) where as quercetin showed lesser antioxidant activity than rutin in inhibiting Fe^{2+}induced lipid oxidation in both liposome and human erythrocyte membrane ghost systems (Liao & Yin, 2000). In the first case, the protective effect could be attributed to quercetin interacting with the membranes and scavenging the free radicals produced near the membranes thereby inhibiting the propagation of lipid oxidation. In the second case, rutin being hydrophilic was able to interact with water soluble oxidants like $Fe^{2+}$and prevent lipid oxidation where as quercetin associated more with the membranes and was not available to scavenge the aqueous radicals. These studies support the fact that the antioxidant activity of flavonols not only depends on the ability of flavonols to associate with the biomembranes, but also the type of oxidants involved in the test system being studied. Trace amounts of lipid peroxides have been reported to be present in muscle tissue (Nakamura, Tanaka, Higo, Taira, & Takeda, 1998) and has been shown to promote methemoglobin induced lipid oxidation in fish muscle (Richards & Hultin, 2000) and Cu^{2+}stimulated oxidation of low density lipoproteins (Thomas, Kalyanaraman, & Girotti, 1994). Lipid radicals such as alkoxyl and peroxyl radicals are constantly generated in the membranes by the breakdown of preexisting lipid peroxides by trace metals and heme proteins (Kanner, German, & Kinsella, 1987; Patel, Svistunenko, Wilson, & Darley-Usmar, 1997). These lipid radicals generated can abstract a hydrogen atom from neighboring polyunsaturated fatty acids and propagate further lipid peroxidation. Hence the presence of flavonols at or near the membranes might be conducive to scavenge the free radicals and inhibit lipid oxidation processes. The results from partitioning as well as oxidation studies demonstrates how differences in the ability of quercetin and quercetin-β-D glucoside to partition into the muscle membranes influenced the inhibitory properties in muscle tissue.

Another antioxidant mechanism of flavonols involves chelation of metal ions like iron and copper which can be promoters of lipid oxidation in muscle tissue. The metal chelates once formed are only slightly active in the promotion of free-radical reactions. Quercetin has been shown to reduce $Fe^{3+}$to $Fe^{2+}$and chelate Fe^{2+} (Mira et al., 2002). This study described pH dependant changes in metal complexation sites of flavonols. At pH 5.5, the complexation site was probably between the C5 hydroxyl group and 4-oxo group whereas the chelating ability of the catechol group increased at alkaline pH (7.4) due to ionization of phenolic groups at high pH. This suggests that the better ability of quercetin to inhibit lipid oxidation in MST compared to its glucoside was not due to metal chelating differences between C5 hydroxyl group and 4-oxo group as these groups are available in both compounds. Another study with rutin, a flavonol glycoside, and quercetin showed similar abilities of both the compounds to prevent Cu^{2+}induced peroxidation of LDL which suggests that the presence of a sugar moiety at position 3 of the C ring did not affect the Cu^{2+}chelating ability of rutin (Brown, Khodr, Hider, & Rice-Evans, 1998). In other words, this study suggests that the 3′, 4′ hydroxyl groups in the B ring (catechol group) of flavonols is responsible for metal chelation rather than the 4-oxo group in the C ring with either of its adjacent hydroxyl groups.

Even though sufficient information regarding the metal chelating abilities of flavonols is available from literature, we wanted to test if the metals present in MST were promoters of lipid oxidation in muscle tissue. This would help us understand whether metal chelation by flavonols is a significant contributor towards the antioxidant activity of flavonols in the muscle matrix. Two metal chelators, EDTA and TPEN were added to MST and their ability to inhibit the formation of TBARS was determined. EDTA is a known water soluble metal chelator where as TPEN has been shown to permeate the membranes and chelate metals (Karck et al., 1992). MST has some calcium content because its preparation process involves the passage of turkey frames and necks through a deboner which can incorporate fine bone fragments in the tissue. The content of calcium in MST has been estimated to be 145 mg per 100 g tissue where as iron and copper contents have been reported to be 1.61 mg and 0.093 mg per 100 g tissue respectively (USDA nutrient database). Since metal ions like iron and copper are considered to be promoters of lipid oxidation in muscle tissue, the metal chelators were added in excess at 2 mM/kg MST to allow for all of the iron and copper to be chelated along with any of the calcium. Neither of the metal chelators inhibited lipid oxidation (Fig. 3), which suggests that endogenous metals present in MST were not promoters of lipid oxidation in MST. Based on this study, it seems that metal chelation did not contribute towards the ability of flavonols to inhibit lipid oxidation in MST. Studies on the inhibitory effects of flavonoids on LDL oxidation induced by heme protein (metmyoglobin) suggests that metal chelation is less important compared to peroxyl radical scavenging activity (Rice-Evans, Miller, & Paganga, 1996).

One of the reasons for the high propensity of MST to lipid oxidation is due to its compositional nature. MST is rich in hemoglobin, lipids and low levels of tocopherol (Dawson & Gartner, 1983). Studies show that flavonoids can interact with hemoglobin and cause conformational changes to the heme protein (Xi & Guo, 2007). Moreover their study showed that the binding capacity of rutin, a flavonol glycoside, to bovine hemoglobin is lower compared to quercetin. One plausible explanation for this difference is due to the steric hindrance caused by the bulky sugar moiety in rutin which affects its penetration into the hydrophobic pocket of hemoglobin. It is not known whether structural differences between quercetin and quercetin-β-D-glucoside could cause any change in the mode of binding to hemoglobin in MST and whether the binding characteristics could influence hemoglobin-mediated lipid oxidation in MST. If such a mechanism occurred in MST, based on the results from the oxidation study (Fig. 2) and aforementioned study, it seems that querectin may be able to bind hemoglobin better than its glucoside and inhibit heme protein-mediated lipid oxidation in MST.

Flavonoids have been reported to induce changes in membrane fluidity which is a determinant in the rate of membrane oxidation. Increase in membrane fluidity causes an increased motion of fatty acids which was described to lower the probability of lipid radical interactions with other fatty acids thereby reducing the propagation of lipid oxidation (Oteiza et al., 2005). The antioxidant activity of flavonoids in liposomes composed of dipalmitoylphospatidylcholine has been related to its capacity to induce a decrease in the membrane transition temperature (T_m), which is indicative of a less ordered membrane (Saija et al., 1995). On the other hand, an increase in T_m has been described for the flavonoids in 1-stearoyl-2-linoleoylphosphatidylcholine liposome membranes (Arora, Byrem, Nair, & Strasburg, 2000). These opposite findings have been attributed to the different composition of the membranes studied. In the first study, the liposomes composed of dipalmitoyl-

phospatidylcholine had an ordered arrangement that was interrupted by the incorporation of the flavonoids between the acyl chains of the phospholipids whereas in the second study the liposomes composed of 1-stearoyl-2-linoleoyl phosphatidylcholine had a less ordered phase first that was modified to a highly ordered phase and thus an increased T_m due to the flavonoid incorporation in the bilayer core. Apart from membrane fluidity changes, the localization of flavonoids in the membrane layer can sterically hinder diffusion of free radicals and thereby decrease the kinetics of free radical reactions (Arora et al., 2000). The ability of quercetin to effectively inhibit lipid oxidation in MST might be due to its ability to cause changes in the membrane fluidity as well as to form a barrier against the access of oxidants into the membranes layer. Further research is required to understand how different flavonoids modulate the fluidity of biological membranes and how these changes influence lipid oxidation processes.

In conclusion, our studies indicate that quercetin is a potent inhibitor of lipid oxidation in MST compared to its glycoside. The presence of the sugar moiety decreased the inhibitory properties of quercetin-3-D-glucoside in MST, probably by partitioning it away from the membranes. The activity of quercetin in MST seems to be due to its higher membrane affinity which enables it to be an efficient free radical scavenger. Factors such as changes in membrane fluidity and flavonol–hemoglobin association also may have contributed to increased oxidative stability of MST. The physical location and orientation of flavonols at sites where the lipids are prone to oxidation is likely to be a determinant in reducing lipid oxidation in muscle tissues. Future research should focus on investigating strategies to drive the flavonols into membrane lipids which are the target sites of lipid oxidation in muscle tissue.

Flaxseed
Chemical composition
Unsaturated fatty acids

ABSTRACT

Flaxseed has recently gained attention as a functional food, and the effect of adding flaxseed (10%, 15%, and 20%) to tortillas was evaluated. The physicochemical characteristics and the free fatty-acid (FFA) content of the oil extracted from flaxseed-added corn tortilla were determined. The results showed that the lipid (4.27%) and protein content (9.10%) of the control sample was statistically lower ($p \leqslant 0.01$) than the tortillas added with flaxseed. In general, the total amylose content did not change with the flaxseed-added content; however, the amylose apparently decreased with the amount of flaxseed, indicating the presence of starch–lipid complexes. The saponification value was 95.37 (mg KOH/g oil) in the tortilla added with 10% flaxseed and increased to 100 (mg KOH/g oil) for the 20% flaxseed treatment. The peroxide value was observed to increase ($p < 0.05$) when the flaxseed flour was added at 10%, 15%, and 20%. In this study, the tortillas exhibited a high amount of total unsaturated fatty acids, 26.32–30.08% (oleic acid). Thus, the flaxseed-added corn tortilla could represent a valuable staple in improving the nutritional value of the original food product.

1. Introduction

In Mexico and some Central American countries, tortillas are the main source of protein (50%) and calories (70%) in the diet of the people with low economic resources (Bressani, 1990; Gomez, Rooney, & Waniska, 1987). Masa for tortillas is traditionally made by cooking corn in a calcium carbonate solution, steeping, and milling to produce nixtamal (Martínez-Flores, Martínez-Bustos, Figueroa, & González-Hernández, 2002; Ortega, Villegas, & Vasal, 1986; Vivas, Waniska, & Rooney, 1987); however, amaranth also was nixtamalised for tortilla production (Valdez-Niebla, Paredes-López, Vargas-López, & Hernández-López, 1993). Recently, in order to improve the nutritional quality of tortilla, transgenic maize (genetically modified maize with the cDNA of amarantin) was nixtamalised and some technological and nutritional characteristics were evaluated (Ayala-Rodriguez et al., 2009). On the other hand, dry instant corn-masa flours have been developed for industrial production and introduced into the marketplace (Almeida-Dominguez, Cepeda, & Rooney, 1996). Dry instant corn-masa has a much longer shelf-life than the traditional wet corn-masa, and contains other added ingredients, such as amaranth flour, vitamins and minerals, hydrocolloids (Rendón-Villalobos, Agama-Acevedo, Islas-Hernández, Sánchez-Muñoz, & Bello-Pérez, 2006), etc., to increase the functionality of these flours. As a result, the demand for instant corn-masa is increasing in Mexico and the United States.

The whole nixtamalised corn kernel includes the germ (embryo), which contains most of the oil of the grain. The germs are ground in the process of making instant corn-masa, liberating oil and coating the endosperm particles with oil (Vidal-Quintanar, Love, Love, White, & Johnson, 2003). Nixtamalised corn may also be a good source of essential fatty acids contained in the germ oil. It is known that corn oil is a good source of unsaturated fatty acids, such as linoleic acid, which are essential fatty acids for human beings. Essential fatty acids cannot be produced by humans and need to be ingested from food. Generally, corn oil contains 61.9% of linoleic acid (Weber, 1999). According to Ulusoy, Karabulut, and Turan (2004), oils are not stable products, and the factors that are responsible for their low stability include light, oxygen, temperature, unsaturated fatty acids content, and the presence or absence of antioxidants. Oxidation of unsaturated fatty acids can lead to the production of free radicals that create hydroperoxides that may represent a potential danger to human health. However, highly polyunsaturated corn oil is a reasonably stable oil, because it contains high levels of natural antioxidants and <1% linolenic acid (Martínez-Flores, Garnica-Romo, Romero, & Yahuaca, 2006). Linolenic acid is considered as being unstable because it is easily oxidised and is responsible for the development of off-flavour and off-odour in the oil. At present, nutritionists consider that the ideal edible oils should contain about 3.0% linolenic acid (Yoshida, Kanrei, Tomiyama, & Mizushina, 2006).

Flaxseed is a natural source of flavonoids, lignans, and phenolic compounds. It is making its mark on the world's food supply as a functional food because of its nutrients. Flaxseed is rich in

doi:10.1016/j.foodchem.2009.03.080

polyunsaturated fatty acids (PUFAs), lignan, dietary fibre, and protein. Furthermore, flaxseed does not contain gluten (Wu, Huff, & Hsiehi, 2007).

The health benefits derived from flaxseed include prevention of cardiovascular disease, stroke, cancer, osteoporosis, diabetes, and improvement of immune function, blood pressure, and kidney function (Morris, 2004). Several flaxseed food products are now available in the market. For example, whole or ground flaxseed is added to rolls, muffins, bagels, pasta, cereal, energy bars, and dry mixes for pancakes (Ahmed, 1999; Manthey, Lee & Hall, 2002; Morris, 2004; Muir & Westcott, 2000; Nesbitt & Thompson, 1997). Furthermore, consumers can also purchase whole and ground flaxseed and flaxseed oil in the supermarkets or health food stores.

Phospholipids (PLs) composed of PUFAs, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) have attracted attention as important minor nutrients (Siswoyo, Mukoyama, & Morita, 2000). Recently, PLs have been extensively used throughout the world as an emulsifier, to improve the functional properties in food processing: improvement in bread texture and volume, dough tolerance, baking properties, and to retard the bread-becoming state (Kweon et al., 1994; Lin & Czuchajowska, 1998). The PUFA-PLs can also improve the quality of bread and retard the retrogradation of starch, owing to the formation of complexes between starch and lipids. Supplementation of bread with the PUFA-PLs is another way to obtain these nutrients for people who dislike eating fish (Siswoyo et al., 2000).

Research has been conducted on the characterisation of flaxseed, but less attention has been paid to the effect of incorporating whole flaxseed meal into foods.

In recent years, considerable interest has been generated in the development and consumption of foods enriched with various healthy ingredients. However, there is no information available about the chemical changes that occur in the lipid fraction of tortilla with added flaxseeds. Therefore, the objective of this study was to supplement nixtamalized corn flour (NCF) with flaxseed to evaluate the physicochemical characteristics and free fatty-acid content of oil extracted from flaxseed-added corn tortilla.

2. Materials and methods

2.1. General

Corn tortillas were produced in the Quality Control Laboratory, CEPROBI-IPN. The NCF (MASECA®, León, Mexico) and flaxseed flour (Nutrisa®, SA de CV, Distrito Federal, México) were obtained from selected supermarket in Cuernavaca, Mor. Mexico.

2.2. Tortilla preparation

Corn tortillas were produced using the method described by Islas-Hernández, Rendón-Villalobos, Agama-Acevedo, Tovar, and Bello-Pérez (2007). Tortillas were processed from 100% NCF (control) and from a mixture of 10%, 15%, and 20% flaxseed flour with NCF, respectively, followed by the addition of water to form masa. The masa was pressure-molded and extruded into thin circles to make tortillas of 1 mm thickness. Tortillas were baked in a gas-fired domestic oven for 1 min per side at ≈250 °C, cooled to 30 °C, and then freeze-dried in liquid nitrogen.

2.3. Proximate analyses

Moisture content of the sample was determined by heating a sub-sample of 3 g in a vacuum oven at 50°C for 1 h (44–15, AACC International, 2000). Ash and protein were analysed according to the Approved Methods 08–01 and micro-Kjeldahl method 46–1 (AACC International, 2000). The total dietary fibre (TDF) was measured according to the AOAC method 985.29 (AOAC, 2000). Samples were gelatinized with a heat-stable -amylase (pH 6, 100 °C, 30 min), and then enzymatically digested sequentially with protease (pH 7.5, 60 °C, 30 min) and amyloglucosidase (pH 6, 0 °C, 30 min) to remove protein and starch. The TDF was precipitated with ethanol, and after washing and drying, the residue was weighed. The results were corrected for protein and ash. Lipid content was assessed with the 30–25 AACC method (AACC International, 2000). The amylose content of the isolated starches was expressed as the apparent amylose and total amylose content using the method of Hoover and Ratnayake (2002).

2.4. Oil extraction

Free lipids (oil) were extracted from each sample with ethyl ether as a solvent, for 5 h using a Soxhlet extractor, following the AACC Method 30-25 (AACC International, 2000).

2.5. Determination of saponification and peroxide values, and free fatty-acid (FFA) contents

The saponification value (SV) was determined by AOAC (2000) method 920.160. In duplicate, about 2 g of the oil sample was added to a flask with 30 ml of ethanolic KOH, and then attached to a condenser for 30 min to ensure that the sample was fully dissolved. After the sample was cooled, 1 ml of phenolphthalein was added and titrated with 0.5 M HCl until a pink endpoint was reached. Tortilla oil oxidation was determined using the official AOCS Peroxide Value (PV) method Cd 8–53 (AOCS, 1997, revised 2004). This iodometric titration method measures the peroxides and hydroperoxides that are the initial products of lipid oxidation (Pike, 1994). The results were expressed as milliEquivalents (mEq) of active oxygen per kg of oil. The FFA content in the oil was determined by using a modified FFA method (AOCS, 1997 revised 2004). Heated (60 °C) isopropyl alcohol (0.75 ml) was added to 75 mg of oil in a 25-ml Erlenmeyer flask. Then, phenolphthalein (0.5% in 95% ethanol) was added to the solution. The fatty-acid content was determined by titrating with 0.001 N NaOH.

2.6. Statistical analysis

All the tests were carried out in triplicate and the values were expressed as mean ± SE. Differences among the treatments were evaluated by one-way ANOVA with *post hoc* mean ranking test using Tukey. Mean values with a statistical difference of $p \leqslant 0.05$ were considered as significant. The data figures were plotted using Sigmaplot 2.0 (Systat Software, Inc. San Jose, CA, USA).

3. Results and discussion

3.1. Proximate analyses

Moisture value in the flaxseed-added tortilla decreased; however, the flaxseed level did not show any statistical difference ($p < 0.05$) (Table 1). This pattern might be related with the hydrophobic character of the flaxseed oil. An increase in the protein content was observed with respect to the level of flaxseed added to the tortilla. Flaxseed flour has 21% higher protein level (Ramcharitar, Badrie, Mattfeldt-Bemam, Matsuo, & Ridley, 2005) than that in the NCF (9.33%) (Agama-Acevedo et al., 2004), which influenced this parameter. Figueroa et al. (2001) observed 3% higher protein content when the tortilla was fortified with 4% of defatted soy. This increase in the protein content in flaxseed-added tortilla might be important to increase the essential amino acid level that is deficient in corn.

Table 1
Average chemical composition (%) of tortilla containing different flaxseed level.

Sample	Protein[A,B]	Ash[A]	TDF	Moisture
Control	9.10 ± 0.12[a]	1.31 ± 0.01[a]	16.45 ± 0.23[a]	47.60 ± 0.34[a]
Tortilla + 10% flaxseed	10.87 ± 0.03[b]	1.54 ± 0.01[a]	19.75 ± 0.04[b]	43.80 ± 0.58[b]
Tortilla + 15% flaxseed	11.60 ± 0.32[b,c]	1.44 ± 0.01[a]	21.84 ± 0.06[c]	44.10 ± 0.32[b]
Tortilla + 20% flaxseed	12.93 ± 0.03[d]	1.64 ± 0.03[a]	23.50 ± 0.17[d]	44.13 ± 0.32[b]

Results are means of three replicates ± SEM. Means with the same superscript letters within a column are not significantly different at $p < 0.05$ level by Tukey's multiple range test.
SEM: standard error of the means ($n = 9$).
TDF = total dietary fiber.
[A] Composition expressed on a dry weight basis.
[B] $N \times 5.85$.

As judged from the equivalent ash concentration recorded in both types of tortillas, the substitution level employed was not enough for altering the mineral content of the baked products in a significant way ($p > 0.05$). Similar result was obtained for tortillas added with amaranth flour (1.4% for tortilla from 100% maize, and 1.5% for corn/amaranth tortilla) (Islas-Hernández et al., 2007).

Furthermore, a significant increase in the TDF content was also obtained with the flaxseed-flour addition (approximately between 20% and 50%), demonstrating that flaxseed is a good TDF source (28%) (Ramcharitar et al., 2005). Today, flaxseed is used as a good source of soluble and insoluble fibre to reduce blood cholesterol and promote laxation (Payne, 2000). Soluble fibre is approximately a quarter of the total fibre in the flaxseed. Most of the soluble fibre is made up of mucilaginous gum, and up to 7–10% flaxseed is mucilage (Carter, 1993). Mucilage is mostly composed of pentosan and arabinoxylan (Erskine & Jones, 1957; Garden-Robinsosn, 1994; Muralikrishna, Salimath, & Tharanathan, 1987), which has water-binding properties similar to guar gum (Fedeniuk & Biliaderis, 1994). Owing to this increase in the TDF, flaxseed-added tortilla can be considered as a nutraceutical food, because dietary fibre content is one of the interesting health-related features of food (Sambucetti & Zuleta, 1996).Therefore, tortilla could represent a valuable staple in improving the nutritional value of the original food product, providing additional health benefits These types of products are commonly known as functional foods, defined as "food similar in appearance to conventional foods that are consumed as part of the normal diet and have demonstrated physiological benefits and/or reduce the risk of chronic disease beyond basic nutritional functions" (Health Canada, 1998) .

The amount of lipids in the flaxseed-added tortilla increased approximately between 100% and 200% (Table 2). This increase is important in two senses: from (1) the nutritional point of view, because flaxseed contains 40–60% lipid, in which about 50% is α-linolenic acid (ALA) (Dorrel, 1970). The ALA, a short-chain omega-3 fatty acid, is the precursor fatty acid for the synthesis of EPA and DHA, both of which have been linked to controlling cardiovascular diseases (Bibus, Stitt, & Holman, 1998; Goodnight, 1993; Simopoulos, 1999), and (2) the technological point of view, where the lipids decrease the starch retrogradation of the starchy products and increase the shelf-life, owing to the formation of amylose–lipid complexes (Biliaderis, 1991), as was demonstrated in bread.

Certain starches contain lipids, and additional lipids or surfactants are added to modify the texture. For example, emulsifiers are added to reduce the stickiness in pasta, mashed potato, and candy, and to prolong the shelf-life of bread (Biliaderis, 1991; Eliasson & Wahlgren, 2004). In general, the total amylose content was not different ($p < 0.05$) in the diverse tortilla analysed (Table 2). This pattern is due to the fact that flaxseed has a low level of starch (Carter, 1993) that does not influence the amylose content of flaxseed-added tortilla. When the apparent amylose level was determined in the tortilla, this parameter decreased when the flaxseed level increased in the blend (Table 2). This pattern demonstrates that amylose complexed with lipids when they are eliminated, and no difference was observed in the total amylose quantified among the different tortillas analysed. However, the apparent amylose amount is in agreement with the oil content determined in the flaxseed-added tortilla. When amylose is quantified using the iodine staining method, the results depend on whether the starch has been defatted or not, to separate the lipid of the amylose and determine the polysaccharide. However, both amylose and amylopectin can form inclusion complexes with lipid-like molecules. The inclusion complex in itself is probably very similar between the two starch polymers; however, the organisation and supramolecular structures differ between them (Eliasson & Wahlgren, 2004). On the other hand, the enzymatic hydrolysis of amylose in the amylose–lipid complexes was reduced, and a delay in the amylolysis of the amylose in the amylose–lipid complexes was observed (Cui & Oates, 1999; Tufvesson, Skrabanja, Björck, Liljeberg, & Eliasson, 2001). The presence of starch polymer–lipid complexes in the flaxseed-added tortilla, determined by the apparent amylose content, is in agreement with the higher resistant starch content and lower hydrolysis percentage when the flaxseed level in the tortilla increased (Rendón-Villalobos, Bello-Pérez, and Tovar, 2009).

Table 2
Oil and amylose content (%) in tortilla containing different flaxseed level.

Sample	Oil	Total amylose	Apparent amylose
Control	4.27 ± 0.03[a]	26.29 ± 0.16[a]	24.53 ± 0.39[a]
Tortilla + 10% flaxseed	8.23 ± 0.01[b]	25.27 ± 0.00[a]	22.38 ± 0.16[b]
Tortilla + 15% flaxseed	9.98 ± 0.08[c]	24.92 ± 0.32[a]	21.02 ± 0.32[b]
Tortilla + 20% flaxseed	12.00 ± 0.16[d]	24.34 ± 0.16[a]	18.67 ± 0.32[c]

Results are means of three replicates ± SEM. Means with the same superscript letters within a column are not significantly different at $p < 0.05$ level by Tukey's multiple range test.
SEM: standard error of the means ($n = 9$).

3.2. Saponification value (SV)

The results of this study revealed that the SV increased when the flaxseed level rose in the tortilla (Fig. 1). The increase in SV value is owing to the formation of higher amount of short fatty acids and glycerides (Sankaram, 1966), because when higher amount of lipids are present, a determined level of them are complexed with amylose and the rest are free, because during the cooking of the tortilla, the free lipids are degraded to short fatty acids.

However, the SV determined in the flaxseed-added tortilla is considered low, when compared with other usual vegetable oils, such as castor (176–184), soybean (188–198), and rapeseed (170–180) (Codex Alimentairus, 1993), suggesting better stability (Bisht, Sivasankaran, & Bhatia, 1993; Sivasankaran et al., 1988) because flaxseed-added tortilla presented low probability of rancidity problem.

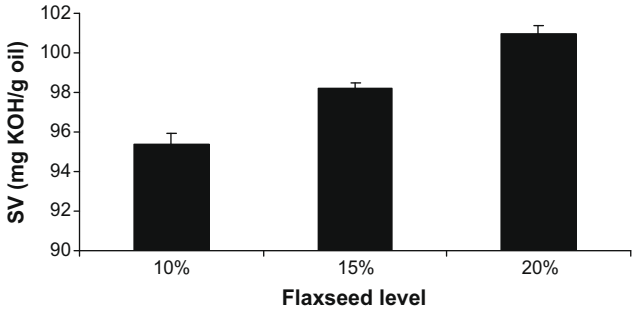

Fig. 1. Saponification value (SV) of oil extracted from tortillas added with different flaxseed level. Error bars represent standard error of the means ($n = 9$).

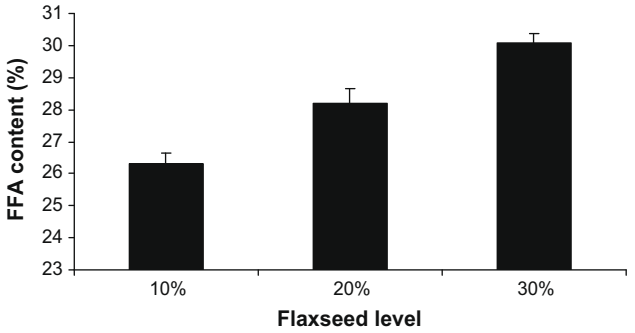

Fig. 3. Free Fatty Acid (FFA) content of oil extracted from tortillas added with different flaxseed level. Error bars represent standard error of the means ($n = 9$).

The high degree of unsaturation of $n-3$ fatty acids indicates that they can become highly susceptible to rancidity, owing to factors, such as heat, light, and oxygen during processing and storage (Goh, Ye, & Dale, 2006).

3.3. Peroxide values (PV)

The results demonstrated the occurrence of a gradual increase ($p < 0.001$) in the PV when the flaxseed flour was added (Fig. 2). This pattern was similar to that of the SV. The PV value is related to the oil oxidation and consequently to the rancidity. These values are below 10, observed in the majority of conventional oils (Codex Alimentarius, 1993).

It was reported that flaxseed oil had a PV value of 0.24 (Jaswir, Kitts, Che Man, & Hassan, 2005), which was lower than those determined in the commercial oils, such as olive (3.37), castor (0.46), and soybean oil (0.5) (Miyasawa, Fujimoto, Kinoshita, & Usuki, 1994; Moh & Stang, 1999; Vekiari, Papadopoulou, & Kiritsakis, 2007), which reflects the low PV value in the flaxseed-added tortilla. The low PV value is an additional characteristic of the flaxseed-added tortilla, because it can be stored for a longer time with no rancidity problems and with soft texture.

3.4. Free fatty-acid (FFA)

The FFA content of the tortilla increased with the level of flaxseed flour added, ranging between 26.32% and 30.08%, with statistical difference ($p > 0.05$) (Fig. 3). The quantification of FFA is related to the SV and PV levels, because the FFA are more susceptible to oxidation and therefore must be taken into consideration with respect to the stability and shelf-life of the food products (Pérez de, Alfaro, & Padilla, 1999). The FFA content is a problem in the food stability, because they are the substrates for lipoxygenase that oxidises unsaturated FFA, resulting in rancidity. The FFA content in durum flour has been reported to range from 9% to 9.9% (Lin, Youngs & D'Appolonia, 1974; Skarsaune, Youngs, & Gilles, 1970).

The monounsaturated fatty acids have great importance owing to their nutritional implication and effects on the oxidative stability of the oils (Aguilera, Ramírez-Tortosa, Mesa, & Gil, 2000). Mixtures of linoleic acid and ALA, as FFA, have been reported to prevent elevations of blood cortisol and cholesterol levels that accompany stressful situations, and check the rapid and repeated eye blinking in rats, following chemical induction of dopamine depletion (Mostofsky, Yehuda, Rabinovitz, & Carasso, 2000).

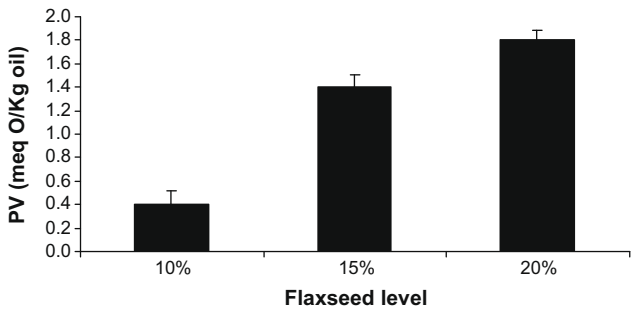

Fig. 2. Peroxide value (SV) of oil extracted from tortillas added with different flaxseed level. Error bars represent standard error of the means ($n = 9$).

4. Conclusions

Flaxseed is a valuable source of various biologically active compounds (essential PUFAs, proteins, phenolic acids, etc.), which serves as the base for a number of effective drugs and prophylactic preparations, as well as important nutritional additives. The formation of starch polysaccharide–lipid complexes was evident owing to the detection of minor apparent amylose content when the flaxseed level increased in the tortilla. Therefore, flaxseed-added corn tortilla could represent a valuable staple in improving the nutritional value of the original food product.

ABSTRACT

Changes in colour and stability of anthocyanins have been evaluated over pH range 2.0–8.7. The study was made on crude extract (XAD-7 Amberlite-retained fraction) as well as on the following pure pigments isolated from tamarillo fruit (*Solanum betaceum* Cav.): delphinidin 3-*O*-(6″-*O*-α-rhamnopyranosyl-β-glucopyranosyl)-3′-*O*-β-glucopyranoside, delphinidin 3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside, cyanidin 3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside and pelargonidin 3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside. The relationships between the colour and the hydroxylation degree of the B ring and the pH have been studied for the first time on rutinosides. The peel extract showed much more colour stability than the jelly extract at all the pH values studied. The replacement of the 3′-OH with a glycosyl group increased the stability of the colour to pH changes, although this substitution yields a less colourful (higher L^* and lower C^*_{ab}) compound (Dp 3-rut-3′-glc), having both hypsochromic and hypochromic shifts relative to the non-glycosylated molecule (Dp 3-rut). Moreover, the influence of the hydroxylation degree of the B ring on the quality and stability of colour, as well as on the antioxidant activity, was determined.

1. Introduction

Most foodstuffs are exposed to some kind of processing before being consumed, which can cause loss of some quality properties, such as colour, aroma or taste; hence producers face the need of replacing these characteristics. Additives (e.g., colourings and flavourings) are used to recover or to emphasize original features, to ensure uniformity, and to guarantee quality.

Pigments are chemical components absorbing radiation in the visible region of the electromagnetic spectrum. The colour is due to a specific molecular group (chromophore) which absorbs energy and, as consequence, the excitation of an electron of external orbitals with major energy occurs; the non-absorbed energy is reflected and refracted and detected by the eyes, where impulses are generated and sent to the brain, and then, interpreted as colour (Delgado-Vargas, Jiménez, & Paredes-Lopez, 2000). Based on the chromophore chemical structure, pigments can be classified as chromophore with conjugated systems (carotenoids, anthocyanins, betalains, caramel and synthetic pigments) or porphyrins with coordinated metals (myoglobin, chlorophyll, and their derivatives).

In the conjugated systems, anthocyanins are specifically important because they are responsible for some red colours in the nature, as monomeric, oligomeric and polymeric anthocyanins. The use of natural extracts of these pigments as food additives has some limitations, due to colour variation caused by pH changes, light exposure and oxygen (Bridle & Timberlake, 1997; Markakis, 1982).

In general, anthocyanins show their highest colour intensity in the flavylium ion form (Harborne & Williams, 1995). It has been demonstrated that anthocyanin stability is influenced by substituents in their structures, sugars and acyl groups (Giusti & Wrolstad, 2003). In recent years, research on anthocyanin chemical structure has increased (Bjorøy, Fossen, & Andersen, 2007; Byamukama, Kiremire, Andersen, & Steigen, 2005; Cabrita, Frøystein, & Andersen, 2000; Fossen & Andersen, 2003; Mateus et al., 2003, 2006; Tian, Giusti, Stoner, & Schwartz, 2006; Wang, Race, & Shrikhande, 2003); however, it is important to study in depth the relationships between colour and chemical composition, which may help to understand the basic principles that influence the anthocyanins' colour.

In Colombia, the tamarillo or tree tomato (*Solanum betaceum* Cav.) is a promising product for export, due to its colour; the red variety has been the most accepted internationally. In this work the stability of tamarillo fruit extracts and isolated individual

anthocyanin rutinosides (Fig. 1) to pH changes has been evaluated by means of colorimetric studies, to obtain more precise information about the change of colour in both crude extracts and individual anthocyanins.

2. Materials and methods

2.1. Chemicals and supplies

The 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox) and Amberlite XAD-7 were obtained from Rohm and Haas, Darmstadt, Germany. HPLC-grade acetonitrile, ACS-grade *n*-butanol, methanol, *tert*-butyl methyl ether (TBME), formic acid, hydrochloric acid and potassium persulfate were purchased from Merck, Bogotá, Colombia. CD_3OD, CF_3COOD, and CF_3COOH (TFA) were obtained from Sigma–Aldrich (St. Louis, MO).

2.2. Plant material

Tamarillo fruits (5.09 kg) were collected in Puente Nacional (Santander, Colombia). A voucher specimen was coded as Col 343584 at the Instituto de Ciencias Naturales at Universidad Nacional de Colombia.

2.3. Isolation of crude anthocyanins extract

Fresh ripe fruits were washed and peeled; the seeds and the surrounding jelly were manually separated from the flesh. The jelly (250 g), filtered through glass wool, was applied onto an Amberlite XAD-7 column (800 mm long, 40 mm i.d.). The column was washed with 1.25 l of water, and elution of anthocyanins was carried out with 300 ml of a mixture of methanol:acetic acid (19:1, v/v). The eluate was concentrated under reduced pressure at 35 °C and the aqueous solution was lyophilised (crude jelly extract). This procedure was repeated four times to obtain 4.35 g of the crude jelly extract.

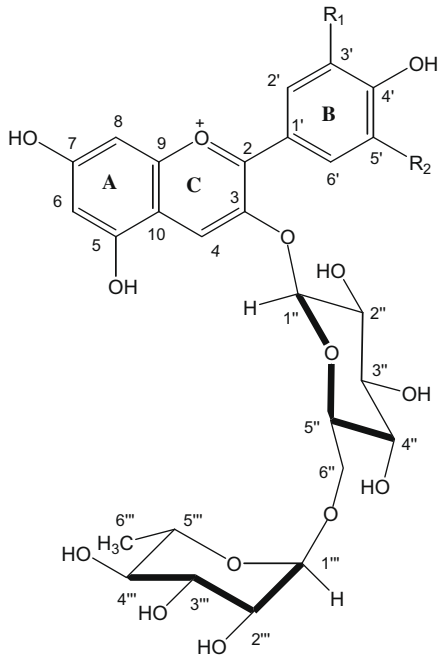

Fig. 1. Basic structure of tamarillo anthocyanins (*Solanum betaceum* Cav). Dp 3-rut-3′-glc = delphinidin 3-*O*-(6″-*O*-α-rhamnopyranosyl-β-glucopyranosyl)-3′-*O*-β-glucopyranoside (R_1 = O-glc, R_2 = OH), Dp 3-rut = delphinidin-3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside (R_1 = R_2 = OH), Cy 3-rut = cyanidin-3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside (R_1 = OH, R_2 = H), Pe 3-rut = pelargonidin-3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside (R_1 = R_2 = H). glc = glucopyranoside.

The peelings (2.51 kg) were cut into small pieces (2 cm^2) and extracted with 2 l of methanol:acetic acid (19:1, v/v) for 12 h (maceration). After filtration the organic solvent was evaporated at 35 °C using a rotary evaporator and the remaining aqueous phase was applied onto a XAD-7 column (800 mm long, 40 mm i.d.). The pigments were eluted as indicated before (Degenhard, Knapp, & Winterhalter, 2000), to give an enriched anthocyanins extract of 0.935 g (crude peelings extract). Then, the XAD-7 isolates of jelly and peelings were fractionated by multilayer coil countercurrent chromatography (MLCCC).

2.3.1. Countercurrent chromatography (CCC)

A multilayer coil countercurrent chromatograph (P.C. Inc., Potomac, MD) with tubular column of PTFE (400 ml total volume) was used. Solvent system consisted of *n*-butanol:TBME:acetonitrile:water (2:2:1:5) v/v/v/v, acidified with 0.1% TFA (Degenhard et al., 2000). The organic phase was used as the stationary phase; therefore elution mode was head to tail. Crude anthocyanins extract was dissolved in 5 ml of a mixture of stationary phase and mobile phase (1:1 v/v), and introduced through the injection port. The mobile phase was pumped at 1 ml min^{-1}, while centrifugation was carried out at 800 rpm. Four-millilitre fractions were collected. The sample loads in MLCCC were high (0.6 g), so fractionation of up to several hundred milligrams of sample was achieved in a single MLCCC run. To check the purity, each fraction was analysed by HPLC, and further purification was carried out using preparative HPLC.

2.3.2. High performance liquid chromatography

The analytical HPLC results were obtained with an Agilent 1100 HPLC system (Agilent, Santa Clara, CA) fitted with a photodiode array detector and a Zorbax-SB C_{18} column (4.6 mm × 250 mm; 5 μm film thickness). Two solvents were used for elution: **A** = acetonitrile:formic acid:water (3:10:87, v/v/v) and **B** = acetonitrile:formic acid:water (50:10:40, v/v/v). The elution profile consisted of a gradient from 6% to 20% **B** at 0–10 min, 20% to 40% **B** at 10–20 min, 40 to 50% **B** at 20–30 min, 50% to 6% **B** at 30–35 min. Aliquots of 100 μl (0.1 mg ml^{-1}) were injected and the flow rate was 0.8 ml min^{-1}. Prior to injection, all samples were filtered through a 0.45 μm Millipore membrane filter.

Preparative HPLC was performed using a Luna C_{18} column (10 mm × 250 mm: 5 μm film thickness) and a 6000LP UV detector. An isocratic elution profile was applied (95% **A**, 5% **B**) using acetonitrile, formic acid and water (solvent **A**: 3:10:87, v/v/v; solvent **B**: 50:10:40, v/v/v). The flow rate was 4 ml min^{-1} for 20 min and aliquots of 40 μl (250 mg ml^{-1}) were injected.

2.3.3. Spectroscopy

UV–Vis absorption spectra of anthocyanins were recorded online during HPLC analysis, and the spectral measurements were made over the wavelength range 300–680 nm in steps of 2 nm. ESI–MS analyses were performed on a Shimadzu QP-8000 mass spectrometer (Shimadzu, Japan). The electrospray voltage applied was 4.5 kV, nebuliser gas flow of 4.5 l min^{-1}, probe voltage 4.5 kV, curved desolvation line (CDL) voltage 130 V, CDL temperature of 230 °C, deflector voltage at 45 and 60 V and acquisition from *m/z* 50 to *m/z* 800 in positive ionisation mode. A solution of 1 mg ml^{-1} of each purified pigment was dissolved in a 1:1 mixture of solvent **A** (water:formic acid 9:1) and solvent **B** (acetonitrile:formic acid 9:1). The anthocyanin solutions were injected directly into the system at a flow rate of l00 μl min^{-1}. Low-resolution fast atom bombardment MS of the pigments was performed on an

AutoSpec-Q (Waters Corporation, Milford, MA) in a glycerol-NaI matrix, using positive detection and acquisition from *m/z* 50 to *m/z* 900. Argon was used as collision gas. The complete structures of isolated anthocyanins were established by ^{1}H- and ^{13}C NMR analysis. Full assignments were performed with TOCSY, COSY, HSQC and HMBC experiments. Isolated anthocyanins dissolved in a mixture of CD_3OD:CF_3OOD (19:1, v/v) were measured using a Bruker AMX-500.

Thus, the identities of anthocyanins were determined to be: delphinidin 3-*O*-(6″-*O*-α-rhamnopyranosyl-β-glucopyranosyl)-3′-*O*-β-glucopyranoside (Dp 3-rut-3′-glu), delphinidin 3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside (Dp 3-rut), cyaniding 3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside (Cy 3-rut) and pelargonidin 3-*O*-(6″-*O*-α-rhamnopyranosyl)-β-glucopyranoside (Pe 3-rut). The chemical structures of these anthocyanins are shown in Fig. 1.

2.4. Quantification of total phenols and determination of anthocyanic indices in the crude extracts

Total phenols (TP) were estimated using the Folin–Ciocalteu method (Singleton & Rossi, 1965). Sample aliquots of 0.5 ml were added to 0.5 ml of water, 5 ml of Folin–Ciocalteau reagent (0.2 N), and 4 ml of a saturated solution of sodium carbonate (75 g/l), and mixed thoroughly. The absorbance was measured at 765 nm with an HP8452 spectrophotometer (Hewlett Packard, Palo Alto, CA) after incubation for 2 h at room temperature. Quantification was made based on a standard curve, generated with 2.6, 5.2, 7.9, 13.1 and 26.2 mg of gallic acid. TP values were expressed in % w/w (100 × mg gallic acid/mg crude extract).

The anthocyanic indices represent approximate measurements of the phenolic constituents and they can be used in comparative evaluations. The anthocyanin extracts include both monomeric anthocyanins and polymeric pigments. When a solution containing anthocyanins is treated with an excess of SO_2 an immediate decolouration of the solution occurs, so the residual colour existing after such treatment is due to polymeric pigment forms.

Aqueous solutions (2 mg ml^{-1}, pH 5.2) of crude extracts were prepared for the chemical indices determination. The index of polymeric pigments (*IPP*) was measured at 520 nm and total anthocyanic colour (*AC*) was measured in 1 M HCl at 520 nm. Polymeric colour (*PC*) was assumed to be equal to 5 × *IPP*/3, and the colour of the monomeric anthocyanins (*MC*) in 1 M HCl was obtained by difference ($MC = AC - (5\ IPP/3)$). The concentration of total monomeric anthocyanins (*AT*) in 1 M HCl was expressed as delphinidin 3-glucoside chloride (molecular mass 500.5) using the molar absorptivity value (ε) of 23,700 l mol^{-1} cm^{-1} (Heredia, Francia-Aricha, Rivas-Gonzalo, Vicario, & Santos-Buelga, 1998) at 520 nm. Hence, *AT* (mg/l) = 21.1 *MC* (Somers & Evans, 1977).

2.5. Determination of the total antioxidant capacity

The total antioxidant capacity was determined by the TEAC method (Re et al., 1999), which is based on the capacity of antioxidants to capture the radical 2,2′-azino-bis-(3-ethylbenzothiazoline-6-sulfonic acid) ($ABTS^{\cdot+}$). It was performed using the HP8452 spectrophotometer in kinetic mode. $ABTS^{\cdot+}$ radical cation was produced by reacting 7 mM 2,2′-azino-bis-(3-ethylbenzothiazoline-6-sulfonic acid) diamonium salt and 2.45 mM potassium persulfate, after incubation at room temperature in the dark for 16 h. The $ABTS^{\cdot+}$ solution was diluted with ethanol to an absorbance of 0.70 ± 0.1 at 734 nm. The filtered sample was diluted with ethanol, so as to give 20–80% inhibition of the blank absorbance with 20 μl of sample. $ABTS^{\cdot+}$ solution (1 ml; absorbance of 0.70 ± 0.1) was read at 734 nm and 20 μl of the sample were added and mixed thoroughly. Trolox standards of final concentration 0–15 μM in ethanol were prepared and assayed under the same conditions. Trolox equivalent antioxidant capacity of sample was calculated based on the inhibition exerted by standard Trolox solution at 6 min.

2.6. Colorimetric study

The evaluation of the colour was based on the spectrophotometric measurement of the transmission spectrum in the visible region (380–770 nm) using an HP8452. The colour parameters were obtained through weighted ordinates method ($\Delta\lambda = 2$ nm) from transmission spectra, by using the CromaLab® software (Heredia, Álvarez, González-Miret, & Ramírez, 2004), which takes into consideration the International + Commission on Illumination recommendations (CIE, 2004). D65 standard illuminant, corresponding to the natural daylight, and 10° standard observer were considered in the calculations. Reference blank measurements were made with the cuvette filled with distilled water. CIE 1976 ($L^*a^*b^*$) (CIELAB) uniform colour space was taken into account for the colorimetric analysis. Within the CIELAB uniform space a psychometric index of lightness, L^* (ranging from 0, black, to 100, white), and two colour coordinates, a^* (which takes positive values for reddish colours and negative values for greenish ones) and b^* (positive for yellowish colours and negative for the bluish ones), are defined. From these coordinates, other colour parameters are defined: the hue angle (h_{ab}) is the qualitative attribute of colour, and the chroma (C^*_{ab}) is the quantitative attribute of colour intensity.

2.6.1. The pH effect

The CIELAB parameters (L^*, a^*, b^*, C^*_{ab}, h_{ab}) were determined in 5×10^{-5} M solutions of each anthocyanin at different pH values, ranged from 2.0 to 8.7. Modifications in pH were made by addition of small volumes of NaOH (1 M or 10 M). Crude extracts were diluted in water until 0.8 absorbance units at $\lambda = 520$ nm were obtained in order to study the influence of the pH on the colour; the concentration of the diluted jelly extract was 2.1 mg/ml, and that of the diluted peelings extract was 35 mg/ml.

The colour differences ΔE^*_{ab} were calculated between the initial pH value (pH = 2.0) and after each increase of pH, considering the Euclidean distance between the two colour points: $\Delta E^*_{ab} = ((\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2)^{1/2}$. Data consisted of the average of two experimental values.

3. Results and discussion

Once both jelly and peelings crude extracts were obtained, different chemical characteristics were determined (anthocyanic indices). The XAD-7 jelly extract showed higher content of total phenols (TP) and total anthocyanins (TA), while the peelings extract showed higher index of polymeric pigments (*IPP*). The higher content of TP and TA in the crude jelly extract is in accordance with the higher antioxidant capacity of this extract (Table 1).

3.1. Influence of the pH on the colour of the anthocyanin crude extracts

The colour variation in the aqueous solutions of anthocyanin crude extracts was studied within the pH range 2.0–6.2, that is to say under and above the most common pH values in foods. As revealed in Table 1 both jelly and peelings extracts showed reddish hues at the lowest pH value (peelings: 32.1°; jelly: 35.0°). As the pH increased to 6.2 the colour of the peelings extract gradually changed towards orange hues (until $h_{ab} = 64.9°$) and the jelly extract towards red-purple hues (until $h_{ab} = 0.4°$). The colour differences ΔE^*_{ab} regarding the pH = 2.0 sample (the most colourful sample) are summarised in Table 2. These differences were higher

for the jelly extract across the pH range, which is evidence of the lower colour stability (higher sensitivity to pH changes) of this extract. The higher stability of the peelings extract may be due not only to the higher polymeric anthocyanins content, which are components more stable to pH changes (Somers & Evans, 1977), but also to the possible presence of some compounds stabilising the colour in the extract, i.e., phenolic acids, flavones, flavonols, flavanones, flavanols and organic acids (Eiro & Heinonen, 2002; Markovic, Petranovic, & Baranac, 2000; Rein & Heinonen, 2004). The crude extracts were shown to be relatively more stable under low acid conditions (pH 2.0–3.4); however, even in the crude peelings extract (more stable) the colour differences were up to 3 CIELAB units (Table 2) indicating that they can be visually discriminated (Martínez, Melgosa, Pérez, Hita, & Negueruela, 2001).

3.2. UV–vis spectroscopy of individual anthocyanins

For this study, the following anthocyanins isolated from the fruit were studied: Dp 3-rut-3′-glc, Dp 3-rut, Cy 3-rut and Pe 3-rut. The maximum absorption in the visible spectrum of the aqueous solution (5×10^{-5} M; pH 2.0) and the molar absorption (ε) of each anthocyanin are shown in Table 1. Comparing the three rutinosides, of which the structural differences are the number of hydroxyl groups in the B ring, it is observed that Pe 3-rut, having one hydroxyl group, shows a λ_{max} at 500 nm. However, as the number of hydroxyl groups in the *ortho* position increases (Cy 3-rut and Dp 3-rut) the maximum absorption shifts towards higher wavelengths and the absorption intensity decreases. Analysing the spectral characteristics of the delphinidin derivatives, it can be observed that the replacement of the 3′-hydroxyl of the Dp 3-rut with a glucose moiety causes both hypsochromic and hypochromic shifts in the visible spectrum (Table 1).

The spectral measurements were important to study the effect of hydroxylation and glycosylation in the B ring of the aglycone on the visible spectrum; however, with only this data we do not have enough information to explain the chromatic characteristics of the anthocyanins. It is well known that the properties of anthocyanins, including the colour expression, are influenced by the chemical structure and pH (Heredia et al., 1998).

i = initial (lowest pH value of the range); f = final (highest pH value of the range).

3.3. Influence of pH on the colour of the individual anthocyanins

Fig. 2 represents the chromatic characteristics of the rutinosides solutions on the (a^*b^*)-diagram. This study reveals the impact of anthocyanins structures, such as hydroxylation and glycosidation, on colour and stability at various pH values. The pigments represent variation of the hydroxylation grade of the B ring of many anthocyanins isolated from fruits and vegetables (Brouillard, 1982). Aqueous solutions (5×10^{-5} M) of Dp 3-rut-3′-glc, Dp 3-rut, Cy 3-rut and Pe 3-rut were studied at two pH range: (2.0–3.4) and (3.4–6.2). According to the CIELAB parameters (L^*, a^*, b^*, C^*_{ab}, h_{ab}, ΔE^*_{ab}) their colour stabilities depend highly on the pH and the structure (Fig. 2, Table 2). At the lowest pH value (pH 2.0, where anthocyanins exit basically in flavylium form), Dp 3-rut-3′-glc, Dp 3-rut and Cy 3-rut showed reddish hues (h_{ab} = 28.6°, 14.4° and 26.1°, respectively), while Pe 3-rut showed orange ones (h_{ab} = 54.7°). At this pH, the number of hydroxyl groups of the B ring clearly influenced the colour characteristic; the hue angle (h_{ab}) and lightness (L^*) values were clearly higher for Pe 3-rut (only one OH), followed by Dp 3-rut-3′-glc (two OH), Cy 3-rut (two OH) and Dp 3-rut (three OH). Dp 3-rut-3′-glc underwent small decreases of the hue angle as the pH increased from 2.0 to 6.2, while great decreases in hue were found for Dp 3-rut, Cy 3-rut and Pe 3-rut. It is noticeable that anthocyanins containing aglycones with only two or three hydroxyl groups on the B ring (Cy 3-rut and Dp 3-rut) showed smaller colour differences (ΔE^*_{ab}) in the more alkaline region pH (3.4–6.2), contrary to Pe 3-rut (one OH) which showed greater colour differences (ΔE^*_{ab}) at these pH values (Table 2). On the other hand, at the most acid pH (2.0–3.4) the Dp 3-rut (three OH) was more unstable (the highest ΔE^*_{ab}).

Comparing the ΔE^*_{ab} values at both pH ranges, it was observed that Dp 3-rut, Cy 3-rut and Pe 3-rut were clearly more unstable than Dp 3-rut-3′-glc. The loss of colour occurring due to the base attack on the pigment structure could be related to the solvating grade of each molecule, in such a way that the greater the solvating grade was the higher the stability to pH changes. According to a study on flavonoids (Rezende, Moll, González, Beezer, & Mitchell, 1999), the internal hydrogen bonding (intramolecular interactions) between neighbouring OH reduces the availability of these groups (by both steric and electronic factors) to interact with the solvent. This could explain the lowest colour stability of Dp 3-rut (lowest solvating) at low pH (2.0–3.4). Nevertheless, at pH 3.4–6.2, which induces the formation of quinoidal bases (Brouillard, 1982), different behaviours were observed. Anthocyanins having two or three hydroxyl groups on the B ring showed similar colour differences, ΔE^*_{ab} being 27.4 and 24.9 CIELAB units for Dp 3-rut and Cy 3-rut, respectively. This can be also explained based on intramolecular interactions between neighbouring OH, since it is reasonable to suppose that two neighbouring OH groups allow the formation of hydrogen bonding, which would yield to the most stable system. According to these results, it is evident the existence of relations between the colour and the chemical composition, so that solvating degree significantly influences the final colour characteristics.

With the purpose of observing the effect of replacing the 3′-hydroxyl of Dp 3-rut with a glucosyl group (giving Dp 3-rut-3′-glc) on the colour characteristics and stability to pH changes, the chromatic characteristics of the dilutions of these two pigments are presented on the (a^*b^*)-plane (Fig. 3). The net red hue (h_{ab} values between 10° and 30°) at very acid pH, gradually changed to yellow hues as the pH increased. It is clear that the glycosidic substitution at the 3′- position of the aglycone compared to non-substitution produced relative large decrease of h_{ab}, and less intense colour (C^*_{ab}: 32 and L^*: 79.7 CIELAB units), at pH = 2.0 (Table 2); however, Dp 3-rut-3′-glc is the most resistant to colour changes (lowest ΔE^*_{ab}) as described above. The major colour stability of this anthocyanin compared to the other pigments could be explained by the presence of three sugars in the molecule which protect the flavylium ion from the base attack, due to the "sandwich" configuration of this type of compound (Giusti & Wrolstad, 2003), restricting the hydration possibilities.

On the other hand, the antioxidant capacity of the four pure anthocyanins was determined: Dp 3-rut, Cy 3-rut, Pe 3-rut and Dp 3-rut-3′-glc (all of them glycosylated in the 3-position of the C ring). Dp 3-rut-3′-glc has an additional glycoxyl group in the 3′ position of the B ring. The results showed that the isolated anthocyanins have higher capacity to capture free radicals in aqueous

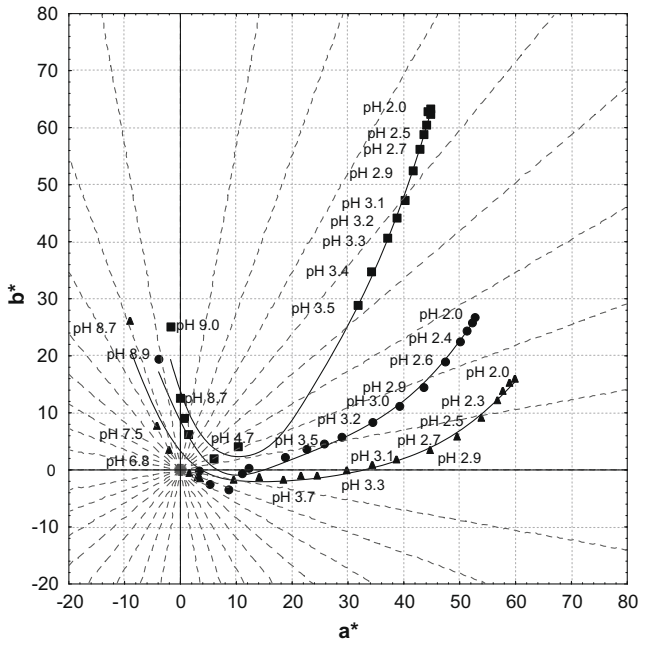

Fig. 2. (a^*b^*)-diagram. Colour changes of the major anthocyanins studied at different pH values (■ Pe 3-rut; ● Cy 3-rut; ▲ Dp 3-rut).

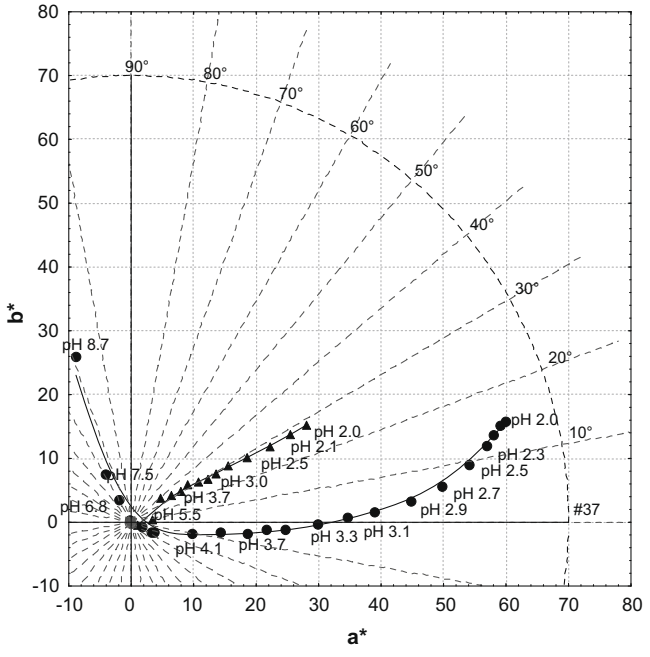

Fig. 3. (a^*b^*)-diagram. Colour changes of Dp 3-rut-3′-glc (▲) and Dp3-rut (●) at different pH values.

solution (pH 5.2) than ascorbic acid (Table 1). It was also observed that the hydroxylation degree of the isolated rutinosides have great influence on the antioxidant capacity.

As observed in Table 1, Dp 3-rut was more efficient at capturing the ABTS radical than Cy 3-rut, and this in turn was more efficient than Pe 3-rut. Thus, the rutinosides having hydroxyl groups in *ortho* position of the B ring, as in the case of Dp 3-rut, Cy 3-rut and Dp 3-rut-3′-glc, have a greater efficiency in capturing free radicals, which can be attributed to the fact that hydroxyl groups in the *ortho* position confer high stability on the formed radical, that is to say they stabilise the formation of the *O*-semiquinone radical (Rice-Evans, Miller, & Paganga, 1996). In comparison, Dp 3-rut-3′-glu, having an additional glycosyl in the 3′-position, was less efficient in capturing radicals in aqueous solution than the similar Dp 3-rut. This indicates that a different glycosylation pattern can considerably modify the antioxidant activity of the anthocyanins, and the extent of this change also depends on the aglycone type.

In summary, the characteristics of colour, stability and antioxidant activity of the crude extracts and isolated rutinosides pigments of Tamarillo fruit have been studied in aqueous solution. Through the application of tristimulus colorimetry, the relations of chemical structure and antioxidant pigments' colour, and their relevance in pH change have been shown.

A relationship between antioxidant activities *in vitro* and phenolic contents has been observed in crude extracts; however, whether this antioxidant potential has an effective role *in vivo* remains to be demonstrated. This study shows the potential value of these extracts as antioxidants and in the improvement of nutritional value of foods and their preservation. Furthermore, the possible use of the peelings (usually waste material) for the production of anthocyanins or natural antioxidant extracts can provide some economic benefits and added value to this material.

Soybean

ABSTRACT

Many studies of purification technology have focused on the development of supports of substrates for isolating enzymes. In this study, superparamagnetic particles modified by epichlorohydrin and other cross-linking agents to coat with starch were used as a purification support for isolating amylases from soybean proteins after precipitation with ammonium sulphate. The recovery of amylase activity from the crude amylase was 17.50% with a 194-fold purification. The molecular weight of the purified amylase was estimated to be 70 kDa by SDS–PAGE. Both crude and purified amylases showed an optimum pH of 6.0 with optimum temperatures of 70 and 60–70 °C and thermal stability of 20–70 and 20–60 °C, respectively. Since the affinity magnetic carrier could adsorb the target proteins efficiently, the superparamagnetic particles technology can be further combined with other separation technologies in the industries to enhance their purification efficiency.

1. Introduction

Magnetite is used as a magnetic carrier in the magnetic carrier technology that is widely used in the field of medical diagnostics, DNA and RNA purification, enzyme immobilization, immunoassay, environmental analysis, and ferrofluids applications (Liu, Guan, Shen, & Liu, 2005; Sonti & Bose, 1997; Zheng, Shu, & Yan, 2003). The magnetic carrier technology, first developed in 1973, is a novel technique in the separation science in which a non-magnetic target is specifically bound to the customised magnetic particles to form a magnetised complex. When a magnetic field is applied to this complex, the magnet-bound target could be mobilised and separated easily, resulting in the purification of target component (Cui, Gu, Xu, & Shi, 2006; Liu et al., 2005; Sonti & Bose, 1997).

The advantages of this technology are: (1) its operation is rapid; (2) it causes significant reduction in the operation cost; and (3) it facilitates simple separation and recovery of the enzyme (Akgöl, Kacar, Denizli, & Arıca, 2001; Jiang, Long, Huang, Xiao, & Zhou, 2005).

Amylase exists widely in animal, plants, bacteria and fungi (Prigent, Matoub, Rouland, & Cariou, 1998). Starch is the major energy storage of the plant and until now its metabolic pathway is not completely understood. For a long time, it was thought that the α-amylase, β-amylase, debranching enzyme, starch phosphorylase and α-glucosidase were released to decompose plant starch (Lizotte, Henson, & Duke, 1990). β-Amylase is the major starch-hydrolysing enzyme in soybean (Gertler & Birk, 1965), which is an exo-amylase that hydrolyses the α-1,4-glucosidic linkage of a non-reducing polysaccharide. β-Amylase might exist in the cytoplasm, vacuole and chloroplast, and its activity is controlled by several factors such as the stage of the plant growth, carbohydrates, non-biological stress, and plant hormone (Lee, 2007).

The present study was designed to determine the effectiveness of using the starch-coated superparamagnetic iron oxide (starch-SPIO) particles method to further purify β-amylase from the protein precipitated by 40–70% ammonium sulphate. The result demonstrated that the starch-SPIO method was able to recover 17.50% of β-amylase activity with a 194-fold purification of the crude enzymes.

2. Materials and methods

2.1. Materials

Soybean was kindly provided by Chen (University of Illinois, Champaign-Urbana, Illinois, USA). Soluble starch, ammonium sulphate $(NH_4)_2SO_4$, and sodium chloride (NaCl) were purchased from ACROS, Japan. Ferric chloride ($FeCl_3$), ferrous chloride tetrahydrate ($FeCl_2 \cdot 4H_2O$), epichlorohydrin, and ammonia (NH_4OH) were purchased from Fisher Scientific, USA.

2.2. Preparation of superparamagnetic particles

The chemical co-precipitating method with heating and alkalization was used for preparing superparamagnetic iron oxide

doi:10.1016/j.foodchem.2009.03.089

(SPIO). Briefly, 3 mol $FeCl_3$ and 2 mol $FeCl_2 \cdot 4H_2O$ were dissolved in 100 ml distilled water, and the pH was adjusted to 11 with 28% ammonia water. The solution was heated to 80 °C for 30 min to cause precipitation. The precipitate was washed with distilled water and ethyl alcohol to remove the impurities such as iron chloride and sulphates, and the particles were dried at 80 °C for 8–10 h in an oven (Koneracka et al., 1999). The dried iron oxides were the superparamagnetic particles. The major component of the magnetic particles was Fe_3O_4, and the water content was about 35%.

2.3. Preparation of affinity superparamagnetic particles

One gram of superparamagnetic particles was mixed with 10 ml of epichlorohydrin. After stirring for 30 min, the precipitate was washed with distilled water, and then 20 ml of 2% soluble starch was added to it and shaken for 2 h. The precipitate was washed with distilled water several times and was dried. The dried particles were used as affinity superparamagnetic particles (starch-SPIO) (Cesar, Olga, Roberto, & Jose, 2000).

2.4. Extraction of crude soybean enzyme

Soybean was soaked in distilled water until germination. The germinated soybean was washed with water and then pureed twice for 5 min to homogenise with Tris buffer (10 mM Tris–HCl, pH 7.0) containing 10 mM NaCl. The homogenate was centrifuged (12,900*g*, 30 min at 4 °C) and the supernatant was called crude soybean enzyme (Mohamed, 2004). The fraction containing crude soybean enzyme was heated at 65 °C in a water bath for 30 min, and was then centrifuged at 12,900*g* for 30 min. The supernatant was precipitated with 40–70% ammonium sulphate and the precipitate was further processed by dialysis, redissolving, and centrifugation. The resulting supernatant was the partially purified soybean enzyme (crude enzyme). The protein-staining method was followed for the determination of protein with bovine serum albumin as the standard (Field, Spielman, & Hand, 1989).

2.5. The absorption and elution of affinity supermagnetic particles

The crude enzymes were mixed and reacted with affinity supermagnetic particles for 2 h. The enzymes adsorbed on the supermagnetic particles were isolated by applying a magnetic field, and the un-adsorbed proteins were washed out with distilled water. The solution of 0.5 M NaCl phosphate buffer having a pH of 7.0 was added to the soybean enzymes adsorbed on the affinity supermagnetic particles. After shaking, the solution was eluted for 1 h. The same procedure was run using a solution of 1.0 M NaCl phosphate buffer having a pH of 7.0. In both cases the solid and liquid were separated by applying a magnetic field. The recovered eluate was the SPIO-purified soybean amylase (Zeng & Cohen, 2000).

2.6. Determination of amylase activities

Soluble starch (2% w/v) was used as a substrate to determine amylase activity. One millilitre of soluble starch solution was mixed with 0.1 ml of the enzyme preparation and was reacted at 37 °C for 10 min. The reaction was stopped by adding 1 ml of 3,5-dinitrosalicylic acid and by heating the reaction mixture in boiling water for another 10 min. After the reaction mixture had been cooled in cold water, the absorbance of 0.1 ml reaction mixture diluted with 0.9 ml distilled water was measured at 546 nm using maltose as the standard. One unit of activity was defined as the amount of enzyme that is able to produce 1 μg of maltose per minute at 37 °C (Zakowski, Gregory, & Bruns, 1984).

2.7. SDS–PAGE electrophoresis

Acrylamide at 12.5% was used as the resolving gel and 3.75% acrylamide was used to prepare the stacking gel. The electrophoresis equipment was Bio-rad, set at a fixed voltage of 120 V and was applied to versatile mini-protein three electrophoresis cells with running buffer having a pH of 8.3 (10 mM tris–glycine). After 2 h, the gel was stained with Coomassie brilliant blue R-250 light for 30 min, and was then decolored for 2–3 h (Wanderley, Torres, Moraes, & Ulhoa, 2004).

2.8. Zymogram method

The enzyme was mixed homogeneously with the running buffer (10 mM tris–glycine, pH 8.3, without β-mercaptoethanol) and the mixture was applied on the polyacrylamide gel, (two gels were simultaneously run in one test). The operation was carried out at a fixed voltage of 120 V for 2 h at 4 °C. One polyacrylamide gel was stained with Coomassie brilliant blue R-250 for 30 min and was then decolored for 2–3 h. The other polyacrylamide gel was reacted with a 2% soluble starch solution (containing 1% (v/v) Triton-X-100) for 2 h at room temperature, and was then washed with distilled water to remove the surface substance on the polyacrylamide gel. The polyacrylamide gel was then stained with iodine until clear bands appeared (Wang et al., 2001).

2.9. Effect of pH on enzyme activity

The amylase activity was determined in the pH range from 2 to 12 using glycine–HCl buffer having pHs 2.0 to 3.0, phosphate–citrate buffer having pHs 4.0 to 7.0, tris–HCl buffer having pHs 8.0 and 9.0, $NaHCO_3$–NaOH buffer having pH 10.0 and NaOH–HCl buffer having pHs 11.0–12.0. The molarity of all the buffered solutions was adjusted to 0.2 M and the reaction was run at 37 °C for 10 min (Prigent et al., 1998).

2.10. Effect of temperature on enzyme activity

The amylase activity was determined in the temperature range from 20 to 100 °C by using 0.1 M phosphate buffer having a pH of 7.0 and the reaction was run for 10 min (Raquel et al., 2006).

2.11. Thermal stability of enzyme activity

The enzyme was first incubated in the temperature range from 20 to 100 °C for 30 min, and the amylase enzyme activity was then determined in 0.1 M phosphate buffer having a pH of 7.0 at 37 °C for 10 min (Muralikrishna & Nirmala, 2005).

3. Results

3.1. Purification of soybean amylase

The crude soybean extract after having been heated in 65 °C water bath for 30 min retained most of the original amylase activity as evidenced from Table 1 showing 96% of the original enzymatic activity with a slight increase in the specific activity (1.18-fold increase). This heated extract was subsequently precipitated with a 40–70% of ammonia sulphate solution. The amylase-specific activity of the precipitated protein was increased by 8.42-fold but only retaining 19.54% of the original activity. The precipitated protein was further purified by the starch-SPIO method, which increased the specific activity of the precipitated protein by 23-fold while retaining 90% of its total amylase

Table 1
Purification of amylase from soybean.

Procedure	Total activity (unit)	Total protein (mg)	Specific activity (unit/mg)	Purification fold	Yield (%)
Crude	318,400	18,790	16.95	1.00	100
Heating 30 min, at 65 °C	306,860	15,966	19.22	1.13	96.38
$(NH_4)_2SO_4$ fraction (40–70% sat'n)	62,225	436	142.69	8.42	19.54
Starch-SPIO	55,734	17	3286.18	193.87	17.50

activity. In terms of the original enzyme activity, the starch-SPIO method is highly effective in isolating amylase from proteins precipitated with 40–70% of ammonia sulphate with a 194-fold increase in the specific activity and retaining 17.5% of the original enzymatic activity.

3.2. The molecular weight of soybean amylase

Fig. 1 compares SDS–PAGE gels of various degrees of purification to the marker proteins. There was not much difference between the crude extract (lane 2) and the one after having been heated at 65 °C for 30 min (lane 3). Lane 4, however, showed that the band corresponding to amylase was enhanced after heating the extract in a hot water bath, and followed by precipitation by ammonium sulphate. The final purification by the affinity superparamagnetic particles (starch-SPIO) gave mostly a sharp band of amylase, suggesting that miscellaneous proteins had been removed effectively from the crude soybean extract. The molecular weight of the β-amylase purified by the starch-SPIO method was estimated to be 70 kDa.

3.3. Zymogram method

Fig. 2A and B depict the Zymogram method, which demonstrates Iodine staining and Coomassie brilliant Blue R-250 staining. The molecular weight of amylase from soybean was estimated to be 72 kDa, which is presumably the same as 70 kDa of the amylase purified by the starch-SPIO method.

Fig. 1. Comparison of the SDS–PAGE of purified amylase to crude enzymes from soybean.

3.4. Optimum pH

The crude enzyme was not very sensitive to pH changes from 3 to 9 as depicted in Fig. 3. The amylase activity was around 90% at pH 3, which peaked at pH 6.0 and slightly decreased to about 85% as the pH was increased to 9.0. Even at very alkaline pHs, substantial enzymatic activity remained. As compared to the crude amylase, the purified enzyme was more sensitive to pH changes. The purified amylase activity peaked at pH 6.0 and decreased gradually either by decreasing or by increasing pH from the optimum pH of 6.0.

3.5. Optimum temperature

The optimum temperature for amylase activity of both the crude and purified soybean amylases is illustrated in Fig. 4. The crude amylase was not very sensitive to temperature between 20 and 70 °C as evidenced from <10% change in the amylase activity with an increase in the temperature from 20 to 70 °C. When the temperature was raised from 70 to 100 °C, the crude amylase lost its activity gradually. Thus, the highest activity was observed at a temperature of 70 °C.

In contrast to the crude amylase, the starch-SPIO-purified amylase exhibited temperature sensitivity as normal enzymes do. The amylase activity increased from 35% to 100% as the temperature was raised from 20 to 60 °C and reached a plateau between 60 and 70 °C. The amylase activity decreased sharply to <10% at 80 °C. Thus, the temperature range for the amylase activity of the purified enzyme is narrower than that for the crude enzyme in this study.

3.6. Thermal stability of amylase

As depicted in Fig. 5, the crude amylase from soybean was very stable between 20 and 60 °C, and its activity decreased sharply when the temperature was over 70 °C. The soybean amylase purified by affinity superparamagnetic particles was also stable between 20 and 50 °C, its activity decreased sharply at the temperature of 60 °C and it became inactivated at the temperature of 70 °C and higher.

4. Discussion

The present study using the starch-SPIO method as the final step of the purification of amylase from soybean yielded a protein with an estimated molecular weight of 70 kDa, which is presumably similar to 61.7 kDa molecular weight of β-amylase purified from soybean flour by Gertler and Birk (1965). The molecular weight of β-amylase appears to be different depending on the species: 54 kDa for amylase from wheat seed; 18 kDa for amylase from wheat germ (Sharma, Sharma, & Gupta, 2000), 50 kDa for amylase from sweet potato (Teotia, Khare, & Gupta, 2001), 55–57 kDa for amylase from pea hypocotyls (Lizotte et al., 1990). There are two iso-amylases in the first stage of barley germination with the molecular weight of 43 kDa and 22.5 kDa (Machaiah & Vakil, 1984). Thus, the molecular weight of amylase differs depending on different origins, species, and development stages of the plants.

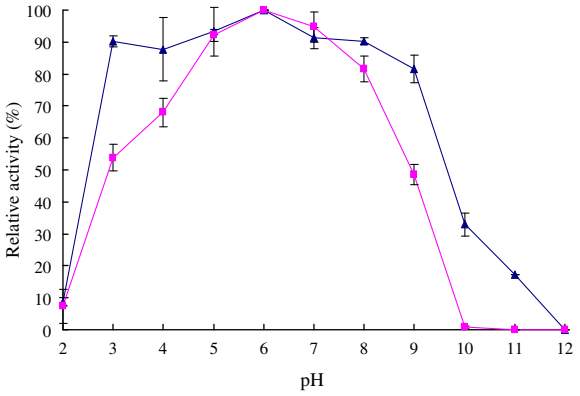

Fig. 3. Effect of pH on the activity of amylase from soybean. (▲) Crude enzyme; (■) Starch-SPIO (starch-coated affinity superparamagnetic particles)-purified enzyme.

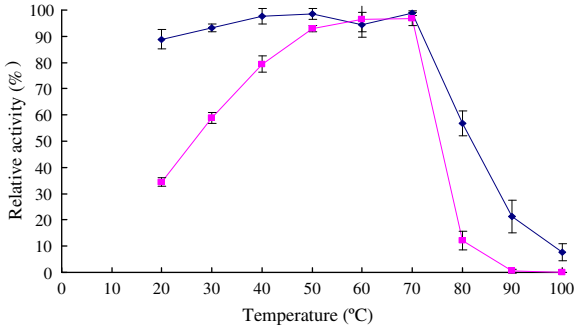

Fig. 4. Effect of temperature on the activity of amylase from soybean. (♦) Crude enzyme; (■) Starch-SPIO (starch-coated affinity superparamagnetic particles)-purified enzyme.

The results of our experiment that examined pH optimum for the purified amylase activity were similar to those of the other studies which showed the optimum pH to be between 5.0 and 6.0: the amylase of *Termitomyces clypeatus* had an optimum pH of 5.5 (Ghosh & Sengupta, 1987); the amylase of *Eleusine clypeatus*, pHs 5.0–5.5 (Nirmala & Muralikrishna, 2003); the β-amylase of soybean, pHs 5–6 (Gertler & Birk, 1965; Kumar, Vishwanath, Singh,

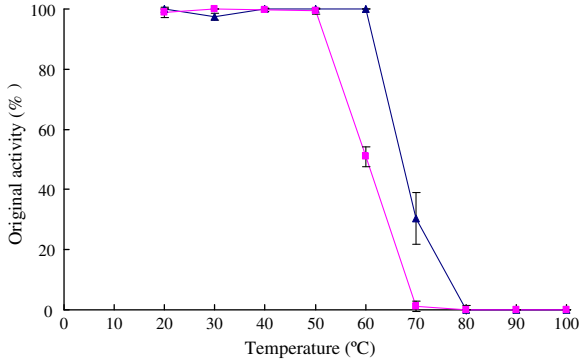

Fig. 5. Thermal stability of amylase from soybean. (▲) Crude enzyme; (■) Starch-SPIO (starch-coated affinity superparamagnetic particles)-purified enzyme.

& Rao, 2006); and the amylase in fermented cassava flour, pH 6.0 (Ganiyu, 2005). However, two acidic α-amylases of *Bacillus stearothermophilus* exhibited pH optimum at 4.5 and 5.0, respectively.

The present study indicated that soybean amylase was stable up to 60 °C. In contrast, the animal amylases are more labile to high temperature. For example, the amylase from *Prostephanus truncates* was unstable when the temperature was over 40 °C (Olaya, Jiménez, Rodríguez, Frier, & Labra, 2000), the amylase activity of *Ruditapes variegates* was stable between 4 and 35 °C, but its activity was sharply lost when the temperature was higher than 40 °C (Hsu, 2003). The relative α-amylase activity of tilapia was reduced to 20% when the temperature was over 50–60 °C and the relative α-amylase activity of *Toxoplasma gondii* was <20% when the temperature was over 64 °C (Ferre, Hoebeke, & Bout, 1999). In comparison to the above results, the amylase from soybean is more stable at higher temperature than the animal amylase. Taking advantage of the temperature stability, we had used heating of the crude extract at 65 °C as the initial step in the process of purifying amylase protein.

The present study demonstrated that the affinity superparamagnetic particles could be used as carrier support to absorb and purify the soybean amylase and that the technology of affinity purification can be widely used in protein purification. Compared to the traditional chromatography used in the purification of proteins, this novel affinity superparamagnetic particles technology

is rapid, provides a low cost of operation with simple facility for separation and recovery of enzymes.

ABSTRACT

Individual free amino acids, yeast assimilable amino acid (YAN) content, ammonia, organic acids, and simple sugars of berries from vines infected with GLRaV-2 or -3 were compared with paired vines free of these viruses. Samples were taken from two commercial vineyards during two growing seasons (2005 and 2006), with three different rootstock/scion combinations. Vines infected with GLRaV-2 did not differ significantly from their healthy counterparts in individual free amino acids, ammonia, or YAN content. Vines infected with GLRaV-3 were significantly lower in valine and methionine from *Vitis riparia* rootstock/'Pinot noir' clone 114 (VY2a) samples, and lower in glutamic acid from self-rooted/'Pinot noir' clone Pommard (VY2b) samples, compared to samples from their healthy counterparts. Samples from VY2b (self-rooted/'Pinot noir' clone Pommard) infected vines had significantly lower levels of malic acid and total organic acids compared to samples from their healthy counterparts. There were no significant differences between healthy and infected vines from all three rootstock/scion pairs in ammonia or free amino acids in samples taken during the weeks before ripening and at commercial harvest. This is the first study to report the influence of GLRaV-2 and -3 on 'Pinot noir' berries nitrogen (N) compounds significant to fermentation. Individual free amino acids may be inferior to phenolic compounds as indicators of GLRaV infection status.

1. Introduction

Nitrogen-containing compounds found in grapes have been reported to vary, depending on cultivar, vine nutrition, vineyard management, soil type, soil moisture content, vine virus status, grape maturity and growing season (Bell & Henschke, 2005 references therein; Conde et al., 2007; Kliewer & Lider, 1976; Stines et al., 2000; Ueno, Kinoshita, Togawa, & Iri, 1985). Vineyard management practices and environmental factors that influence the amount of nitrogen (N) found in grapes and wine have been reported (Bell & Henschke, 2005).

Amino acids are primary metabolites that are important to grapevines' survival, but are also valuable nutrients for the yeasts and bacteria responsible for alcohol and malolactic fermentations (Bell & Henschke, 2005). Ammonia and certain free amino acids, which are primary amines, impact fermentation rate and the completion of fermentation, and these compounds are known as yeast assimilable nitrogen (YAN). Grape cultivar, must pH, yeast strain, and other factors have been reported to influence the utilisation of the available must N during fermentation (Bell & Henschke, 2005; Garde-Cerdan & Ancin-Azpilicueta, 2008; Monteiro & Bisson, 1991; Taillandier, Portugal, Fuster, & Strehaiano, 2007). Low grape YAN can lead to stuck or sluggish fermentation and potentially produce undesirable compounds in the resulting wine, such as sulfur and thiol-containing compounds like hydrogen sulfide, or fusel alcohols (Bell & Henschke, 2005; Beltran, Esteve-Zaraoso, Rozes, Mas, & Guillamon, 2005; Vilanova et al., 2007). Fermentation conditions (must temperature, oxygen level, timing of N addition, form of N addition, etc.) and juice components such as sugar and vitamin levels alter the yeast fermentation kinetics for different forms of available N (Arias-Gil, Garde-Cerdan, & Ancin-Azpilicuta, 2007; Beltran et al., 2005; Taillandier et al., 2007). It is still unknown if YAN compounds derived from grape are superior to N supplements from diammonium phosphate (DAP) for a healthy fermentation of N-deficient must into fine wine. Some amino acids are precursors to particular volatile compounds and recent studies have demonstrated that the addition of free amino acids increased a number of wine volatiles (Garde-Cerdan & Ancin-Azpilicueta, 2008; Hernandez-Orte, Cacho, & Ferreira, 2002).

'Pinot noir' grapes and wines are major economic contributors to the state of Oregon, where 'Pinot noir' is the dominant cultivar grown, and made up more than 50% of the 38,000 tons of wine grapes produced in 2007. 'Pinot noir' production in Oregon is followed, in order of tons produced, by 'Pinot gris', 'Chardonnay', 'Riesling', and 'Cabernet Sauvignon' (National Agricultural Statistics Service, 2008a).

The presence of grapevine leafroll associated viruses (GLRaV) has been reported in Oregon vineyards (Martin, Eastwell, Wagner, Lamprecht, & Tzanetakis, 2005). GLRaV status has the potential to alter berry composition, beyond changes in their phenolic profiles (Lee & Martin, 2009; Singh Brar, Singh, Swinny, & Cameron, 2008), and N containing compounds (Kliewer & Lider, 1976; Ueno et al., 1985). To the best of our knowledge, there are only reports on the impact of GLRaVs on free amino acids of 'Burger' ('Burger' scion grafted onto 'Dogridge' rootstock), 'Zenkoji', and 'Koshu' grapes (Kliewer & Lider, 1976; Ueno et al., 1985), and none on the cultivar 'Pinot noir'.

GLRaVs are phloem-limited viruses that can result in reduced net leaf photosynthesis, decreasing % soluble solids and reducing vine productivity. Because of this, there is interest in exploring how GLRaV infections alter berry sugars and organic acids that contribute greatly to the taste and final alcohol content of the wine (Bertamini, Muthuchelian, & Nedunchezhian, 2004; Cabaleiro, Segura, & Garcia-Berrios, 1999; Christov et al., 2007; Guidoni, Mannini, Ferrandino, Argamante, & Di Stefano, 1997; Kliewer & Lider, 1976; Lee & Martin, 2009; Ueno et al., 1985).

It is well established that GLRaVs impact grape differently depending on cultivar, rootsock, scion, vine age, and causal virus (Cabaleiro et al., 1999; Golino, 1993; Guidoni et al., 1997; Kliewer & Lider, 1976; Kovacs, Hanami, Fortenberry, & Kaps, 2001; Krake, 1993; Lee & Martin, 2009; Singh Brar et al., 2008; Wolpert & Vilas, 1992). A recent report conducted in our laboratories (Lee & Martin, 2009) demonstrated that GLRaVs imparted a significant decrease in individual and total anthocyanins in 'Pinot noir' berries from *Vitis riparia* rootstock/'Pinot noir' clone 114 scion, with other minor differences in non-anthocyanin phenolics, but no significant difference in anthocyanins from GLRaV were observed in the other two rootstock/scion combinations examined (unknown rootstock/'Chardonnay' interstock/'Pinot noir' scion [clone unknown] and self-rooted/'Pinot noir' clone Pommard). It is important to understand how GLRaVs impact compounds beyond phenolics (i.e., N-containing compounds) that influence wine grape quality and healthy fermentations.

The objective of this study was to compare the compounds important for a healthy fermentation (i.e., simple sugars, organic acids, ammonia, and free amino acids) of 'Pinot noir' berries from vines infected by GLRaV-2 or -3 with berries from vines free of these viruses, to better understand how GLRaVs impact 'Pinot noir' grape quality.

2. Materials and methods

2.1. Plant material

Details of the samples, vineyards, vines, collection dates, and harvest dates were presented in Lee and Martin (2009), but for convenience, the information has been reproduced with modifications in Table 1, with the same abbreviations being used for this paper. All grapes were obtained from commercial fields. Briefly, four clusters were randomly taken from each presumptively identified healthy or infected vine (at each reported collection date; Table 1) and stored at −23 °C, until virus status was determined for each vine by RT-PCR in the laboratory. All clusters from a vine were grouped for chemical analysis. Vineyards one (VY1; one rootstock/scion combination) and two (VY2a and VY2b representing the two different rootstock/scion combination sampled from vineyard 2) were approximately 40 km apart. Both vineyards were located in Oregon's Willamette Valley (USA).

2.2. Reagents, chemicals, and standards

All chemicals for ammonia, organic acids, simple sugars, and free amino acid standards analyses were obtained from Sigma Chemical Co. (St. Louis, MO). Chemicals for the in-line derivatisation prior to HPLC injection were purchased from Agilent Technologies Inc. (Santa Clara, CA). All solvents and chemicals for this investigation were analytical and high performance liquid chromatography (HPLC) grade.

2.3. Virus detection

Virus status was determined as reported previously (Martin et al., 2005). Alterations to the detection procedure were described in Lee and Martin (2009).

2.4. Extraction and sample preparation

Berries were excised from the clusters (four clusters per vine from 5 to 11 vines depending on virus status; Table 2). Whole berries were puréed with a hand blender for 3 min (which macerated skin, pulp, and seeds), then centrifuged for 10 min at 4000 rpm. The resulting supernatants were then filtered with disposable 25 mm GD/X syringe filters (Whatman Inc., Florhan Park, NJ) prior to organic acids, simple sugars, and ammonia determination. Disposable Millex-FH syringe filters (Millipore, Bedford, MA) were used for supernatants prior to free amino acid determination.

2.5. HPLC conditions for organic acids, sugars, and free amino acids analyses

An Agilent HP1100 system (Agilent Technologies Inc.) equipped with a diode array detector (DAD) connected to refractive index detector (RID), and a Rezex ROA-organic acid H + (300 mm × 7.8 mm, 8 μm; Phenomenex, Torrance, CA) column were used for organic acid and sugar analyses. A ratio of 80% diluted sulfuric acid (2.5 mM sulfuric acid solution) to 20% acetonitrile was used as the mobile phase (m.p.) at a flow rate of 0.5 ml/min under isocratic conditions. The analytical column compartment was maintained at 55 °C during the 15 min analysis. Organic acids were detected at 210 nm with a DAD. RID was used for simple sugar identification and quantification. Tartaric acid, malic acid, fumaric acid, glucose, and fructose external standards were used. The malic acid standard was corrected for the fumaric acid contamination that occurs in all malic acid standards. Sugar and organic acid values were expressed as mg/100 ml.

HPLC/DAD was used for individual free amino acid analysis. Zorbax Eclipse AAA analytical (150 mm × 4.6 mm, 5 μm, Agilent Technologies Inc.) and guard (12.5 mm × 4.6 mm, 5 μm; Agilent Technologies Inc.) columns were used for free amino acid determination. Inline-derivatisation by *o*-phthalaldehyde (OPA) and 9-fluorenylmethyl chloroformate (FMOC) was performed by the autosampler immediately prior to injection, as described in detail by Henderson, Ricker, Bidlingmeyer, and Woodward (2006). Mobile phase A was 40 mM sodium phosphate (adjusted to pH 7.8 with 10 N sodium hydroxide solution). Mobile phase B was a mixture of acetonitrile: methanol: water (45:45:10, v/v/v). HPLC mobile phase conditions were extended from the gradient program described by Schuster (1988) and Henderson et al. (2006) to suit our HPLC and column set-up. Three min extension of the gradient (m.p. B was 57–81% and the rest of the m.p. was made up by m.p. A

Table 1

Table 2
Virus status, simple sugars, organic acids, ammonia, individual free amino acids, total free amino acids (FAN) and yeast assimilable nitrogen (YAN) at harvest from all locations are listed. All sampled vines tested positive for RSPaV. Different lower case letters indicate significant differences ($p \leqslant 0.05$) within the pair of samples (e.g., samples from GLRaV-2 positive versus negative vines from vineyard 1). Different upper case letters indicate significant differences ($p \leqslant 0.05$) among the three healthy 'Pinot noir' samples (comparison among VY1, VY2a, and VY2b). No lower or upper case letters after values indicate no significant difference. Values in parenthesis are standard errors.

from 43% to 19%) was included at the end of the analytical conditions described by Henderson et al. (2006). OPA-derivatised amino acids were monitored at 338 nm and FMOC-derivatised amino acids were monitored at 262 nm. Purchased standards of each individual amino acid (Sigma Chemical Co.) were used for identification and quantification (external standard method). Two internal standards, norvaline for OPA-derivatised amino acids and sarcosine for FMOC-derivatised amino acids, were used. Individual free amino acid values were expressed as mg N/l.

2.6. Ammonia concentration and calculation of YAN values

Ammonia was quantified by an enzymatic assay (Sigma ammonia assay kit; Sigma Chemical Co.) using a spectrophotometer (SpectraMax M2 microplate reader; Molecular Devices Corp., Sunnyvale, CA). Manufacturer instructions were followed. One-centimeter path length disposable semi-micro cuvettes (Fisherbrand, Thermo Fisher Scientific Inc., Waltham, MA) were used for ammonia measurements. YAN content was calculated by combining the

ammonia concentration found in the berries with primary free amino acids. Primary free amino acid content was determined by excluding hydroxyproline and proline contents from total free amino acids found in the berry samples. Ammonia and YAN were expressed as mg N/l.

2.7. Statistical analysis

Statistica for Windows version 7.1 was used (StatSoft, Inc., Tulsa, OK) for *t*-test calculations and one-way analysis of variance (ANOVA) for the pair of samples from infected and healthy vines with the same rootstock/scion combination ($\alpha = 0.05$). Correlation between organic acid values determined by HPLC and titratable acidity (values from Lee and Martin (2009)), sugars determined by HPLC and % soluble solids (values from Lee and Martin (2009)), and between ammonia and primary amino acid values were calculated ($\alpha = 0.05$). Differences among the three different rootstock/scion the values were compared using Fisher's LSD (least significant difference; $\alpha = 0.05$).

3. Results and discussion

Again, details of the vineyard location and vine virus status were reported in the first part of this project (Lee & Martin, 2009). Briefly, all vines despite their GLRaV status in both vineyard locations tested positive for grapevine Rupestris stem pitting-associated virus (RSPaV). GLRaV-infected vines from VY1 had co-infection of RSPaV and GLRaV-2. VY2a and VY2b GLRaV-positive vines were co-infected with RSPaV and GLRaV-3. Vineyard and virus data are summarised in Table 1. The observed results in this study were assumed to be due to GLRaV status despite the co-infection with RSPaV. RSPaV has been reported as having little or no significant impact on the yield components of titratable acidity, and pH in five grape cultivars ('Kerner', 'Michurinetz', 'Okanagan Riesling', 'Madeleine Sylvaner', and 'Ortega'; Reynolds, Lanterman, & Wardle, 1997). Additional details of the vineyards and vines can be found in Lee and Martin (2009). There was no significant interaction between growing season and vine virus status, so the data of two seasons are pooled and presented in Table 2.

3.1. Simple sugars and organic acids

Two simple sugars, glucose and fructose, were found in all samples; glucose and fructose as reported by others (Diakou et al., 1997; Kliewer, 1967; Kliewer, Lider, & Schultz, 1967). In general, sugar content in all samples steadily increased during the sampling period up to harvest (Fig. 1). The ratio of glucose to fructose ranged from 0.91 to 1.02. There were no significant differences between fruit from infected and healthy vines in their glucose and fructose contents throughout the sampling periods (Fig. 1; Table 2). GLRaV infection status did not alter sugar composition or content.

Tartaric acid and malic acid were the two main organic acids identified in 'Pinot noir', which have been reported by others (Diakou et al., 1997; Kliewer et al., 1967). When both seasons were combined, there were no differences in tartaric and malic acids at commercial harvest between healthy and infected vines from VY1 or VY2a (Table 2). Samples from healthy vines in VY2b had significantly higher levels of malic acid and total organic acids compared to those from GLRaV-3 infected vines when both growing season values were compared (berry sizes were not significantly different; Lee & Martin, 2009). In 2006, samples from VY2a vines infected

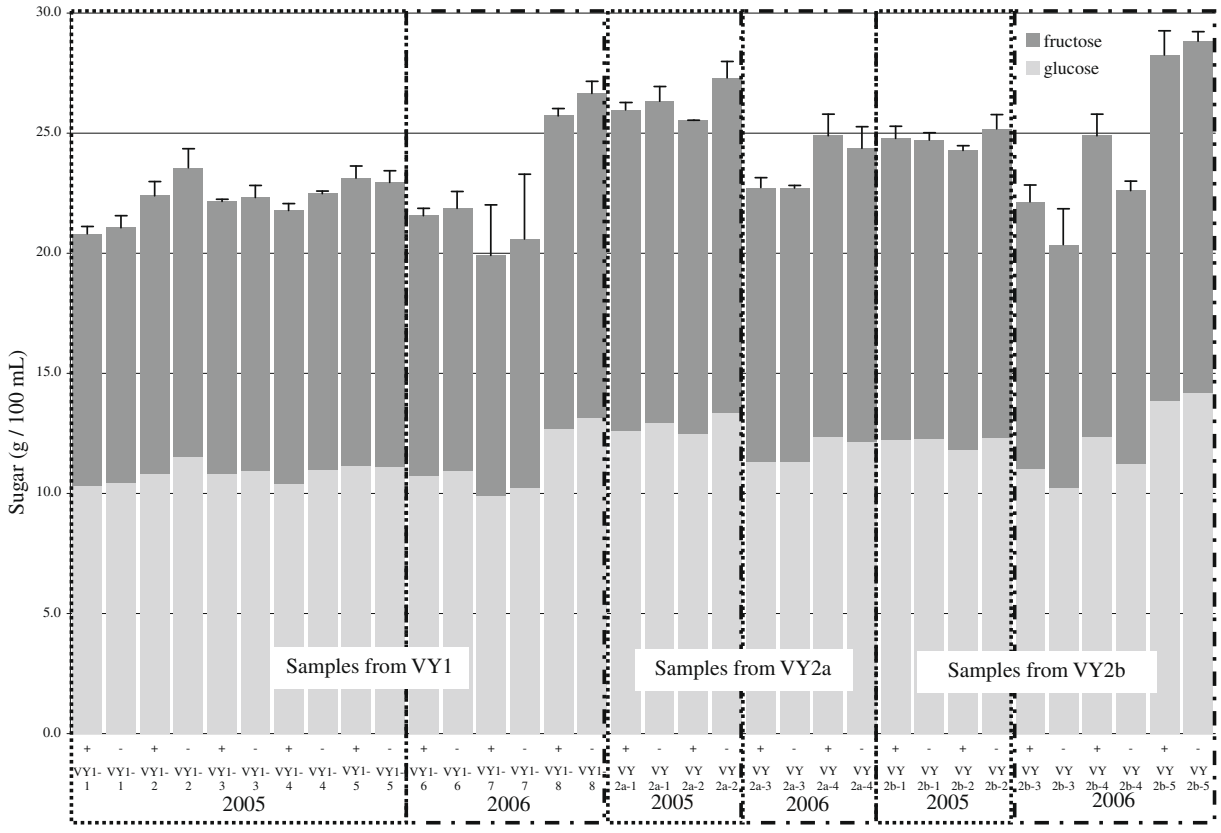

Fig. 1. Simple sugars during the sampling periods from VY1, VY2a, and VY2b. The '+' indicates GLRaV-positive and '–' indicates GLRaV-negative by RT-PCR. VY1-5, VY1-8, VY2a-2, VY2a-4, VY2b-2, and VY2b-5 indicate commercial harvest. The corresponding sampling dates (e.g., VY1-1 sampled 9/19/2005) are listed in Table 1. Sugar values were obtained by HPLC as g/100 ml. No pairs were significantly different at $p \leqslant 0.05$ (infected versus healthy). Error bars indicate standard errors.

with GLRaV-3 were significantly higher in malic acid at harvest compared to healthy vines (Fig. 2), which was not observed in 2005 and did not significantly alter total organic acid content.

Total sugar and total organic acid values obtained in this study were highly correlated (r values of 0.964 and 0.605, $p \leqslant 0.05$) to °Brix and titratable acidity values, respectively (Lee & Martin, 2009).

GLRaV (type not reported) eliminated (negative) 'Zenkoji' and 'Koshu' grapes had higher levels of glucose and fructose (Ueno et al., 1985) compared to their infected cohorts. Guidoni et al. (1997) reported no significant difference in malic and tartaric acids in 'Nebbiolo' healthy vines versus vines infected with GLRaV-3. GLRaV (type not reported) positive 'Burger' grapes (Kliewer & Lider, 1976) were reported to have higher levels of titratable acidity, malic acid, and tartaric acid compared to healthy vines.

A comparison among the healthy vines from the three rootstock/scion combinations were made, and VY2b samples were significantly higher in glucose, fructose, and total sugar compared to VY1 samples (Table 2) at the time of harvest. Healthy VY1 samples were significantly higher in malic acid and total organic acids, although tartaric acid was not different among the three different rootstock/scion combinations.

3.2. Ammonia, FAN (free amino acids), and YAN of grapes

Ammonia content (main mineral N source) ranged from 19.0 to 49.2 mg N/l at harvest (contributed to 10–14% of grape YAN; Table 2). Grapes from VY1 had overall higher levels (more than double) of ammonia (Table 2 and Fig. 3) than VY2a and VY2b samples. There were no significant differences in ammonia content between GLRaV-infected and healthy vines in the weeks prior to harvest or at commercial harvest in VY1, VY2a, and VY2b samples (Fig. 3).

Twenty-one free amino acids (Asp, Glu, Asn, Ser, Gln, His, Gly, Thr, Cit, Arg, Ala, Tyr, Val, Met, Trp, Phe, Ile, Leu, Lys, Hyp, and Pro; in the order of HPLC elution) were found in all samples, and are listed in Table 2. ARG was the main free amino acid, contributing to 30–62% of total free amino acids (FAN), in all 'Pinot noir' grapes, as reported by Huang and Ough (1991) and Stines et al. (2000).

Individual free amino acids, FAN, and YAN were not significantly different between the grapes from healthy and infected vines in VY1. Val and Met contents of VY2a healthy vines were significantly higher, compared to their infected counterparts. Only one amino acid, Glu from VY2b grapes, was significantly higher in grapes from healthy compared to infected vines. Overall, GLRaV infection did not impact N-containing compounds when the summation (YAN and FAN values) was compared in 'Pinot noir' grapes. The same statistical results were obtained when individual amino acid values were compared as mg of amino acids/l as well (data not shown). FAN and ammonia contents were not significantly different throughout the sampling period either (Fig. 3).

At harvest, all samples had an acceptable level of YAN (above 150 mg N/l) from the general guidelines of Bely, Sablayrolles, and Barre (1990), who recommends additional must nutrients (N supplementation in the must) if YAN is below 140 mg N/l for a healthy fermentation. Free amino acids were the major contributor to YAN values (86–90% of YAN was from free amino acids) in these samples at harvest as reported previously (Butzke, 1998).

Butzke (1998) performed a survey on commercial must of 'Pinot noir' grapes ($n = 88$) and found ammonia of 92 mg N/l, primary

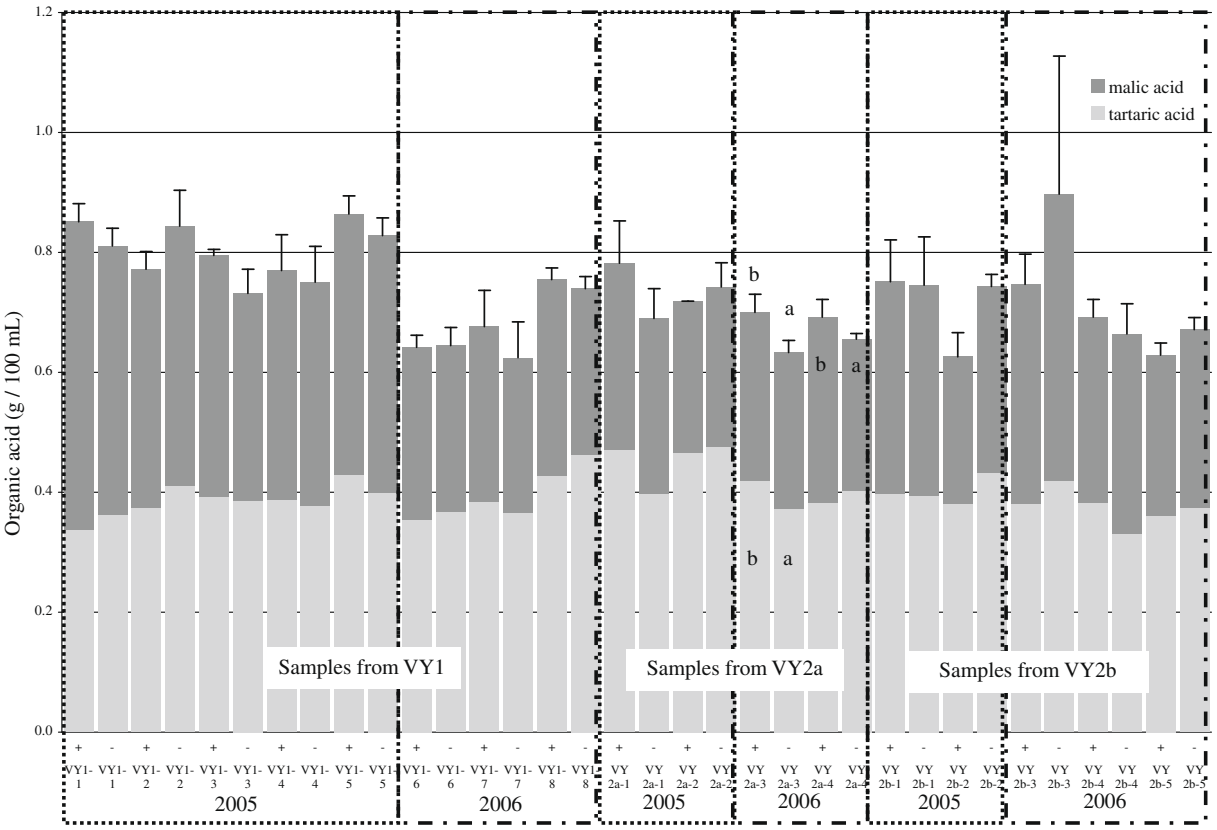

Fig. 2. Organic acids during the sampling periods from VY1, VY2a, and VY2b. The '+' indicates GLRaV-positive and '–' indicates GLRaV-negative by RT-PCR. VY1-5, VY1-8, VY2a-2, VY2a-4, VY2b-2, and VY2b-5 indicate commercial harvest. The corresponding sampling dates (e.g., VY1-1 sampled 9/19/2005) are listed in Table 1. Organic acids were obtained by HPLC as g/100 ml. Different lower case letter indicates significant differences at $p \leqslant 0.05$ for the pair of samples (infected versus healthy). No lower case letter indicates no significant difference between healthy and infected vines. Error bars indicate standard errors.

amino acids 142 mg N/l, and YAN content at 236 mg N/l on average. Samples from VY2a and VY2b, despite virus status, were within what Butzke (1998) reported, but VY1 samples were well above these values.

Individual free amino acids were grouped into the following five groups: Ala-Val-Leu family (Ala, Val, and Leu), aromatic amino acid family (Phe, Tyr, His, and Trp), Asp family (Asp, Thr, Asn, Met, and Ile), Ser family (Ser and Gly), Glu family (Glu, Gln, Cit, Arg, Hyp, and Pro), and Lys, based on chemical similarities and biosynthesis pathways. There were no significant differences between samples from healthy and infected vines for all three rootstock/scion combinations. It appears that GLRaV did not alter the profile of amino acids in these rootstock/scion combinations when values were compared as grouped amino acid families.

At harvest, GLRaV-infected 'Burger' berries had significantly more ARG and less PRO than those from healthy vines (Kliewer & Lider, 1976) when compared to cluster-thinned vines. In 'Zenkoji' and 'Koshu' grapes, N and the majority of the free amino acids were lower in fruit from virus-eliminated vines (Ueno et al., 1985). These two previous publications and the work presented here demonstrate the varying impacts from GLRaV infection among grape cultivars, GLRaV type, etc.

The individual amino acids, FAN, YAN, and ammonia were compared among the samples from the healthy vines from the three rootstock/scion combinations at harvest (Table 2). Berries from VY1 were significantly higher in individual free amino acids (except for Asp, Asn, Gly, Tyr, Val, Met, and Lys of VY2a samples or Asp, Gly, Val, Met, and Lys of VY2b samples), FAN, YAN, and ammonia than VY2a and VY2b samples. Berries from VY2a were significantly higher in Val and Met, compared to samples from VY1 or VY2b. These observed variations might be due to rootstock/scion combinations, as was found in 'Chardonnay' (Treeby, Holzapfel, Walker, & Nicholas, 1998) and 'Shiraz' (Holzapfel & Treeby, 2007), or the disparity in vineyard management practices (i.e., levels, timing, and rate of N application in the vineyard; Bell & Henschke, 2005; Holzapfel & Treeby, 2007).

There was a significant correlation between primary amino acids and ammonia content in the juice samples ($r = 0.86$ from all the juice samples and $r = 0.924$ from time of commercial harvest $p \leqslant 0.05$), which was not observed by Butzke (1998). He reported no correlation between primary amino acids and ammonia, and r of 0.29.

This preliminary work provides some insight into the minor differences in individual free amino acids, ammonia content, and YAN content of juice imparted by GLRaV infection. The lack of magnitude in the measured differences during this study might be due to decreased vine stress imposed by the Oregon vineyard practice of low crop load (average 2.8 tons per acre in Oregon for 2007; National Agricultural Statistics Service, 2008a) compared to other grape growing regions (e.g., on average 6–8 tons per acre in California for 2007; National Agricultural Statistics Service, 2008b).

Future work is needed to determine and clarify how vine age, virus infection period, rootstock/scion combination, and virus type influences the relationships among amino acids, sugars, and organic acids in an experimental vineyard setting, in order to eliminate the variability of commercial vineyard management. This future controlled study will allow us to understand the direct impact of GLRaVs.

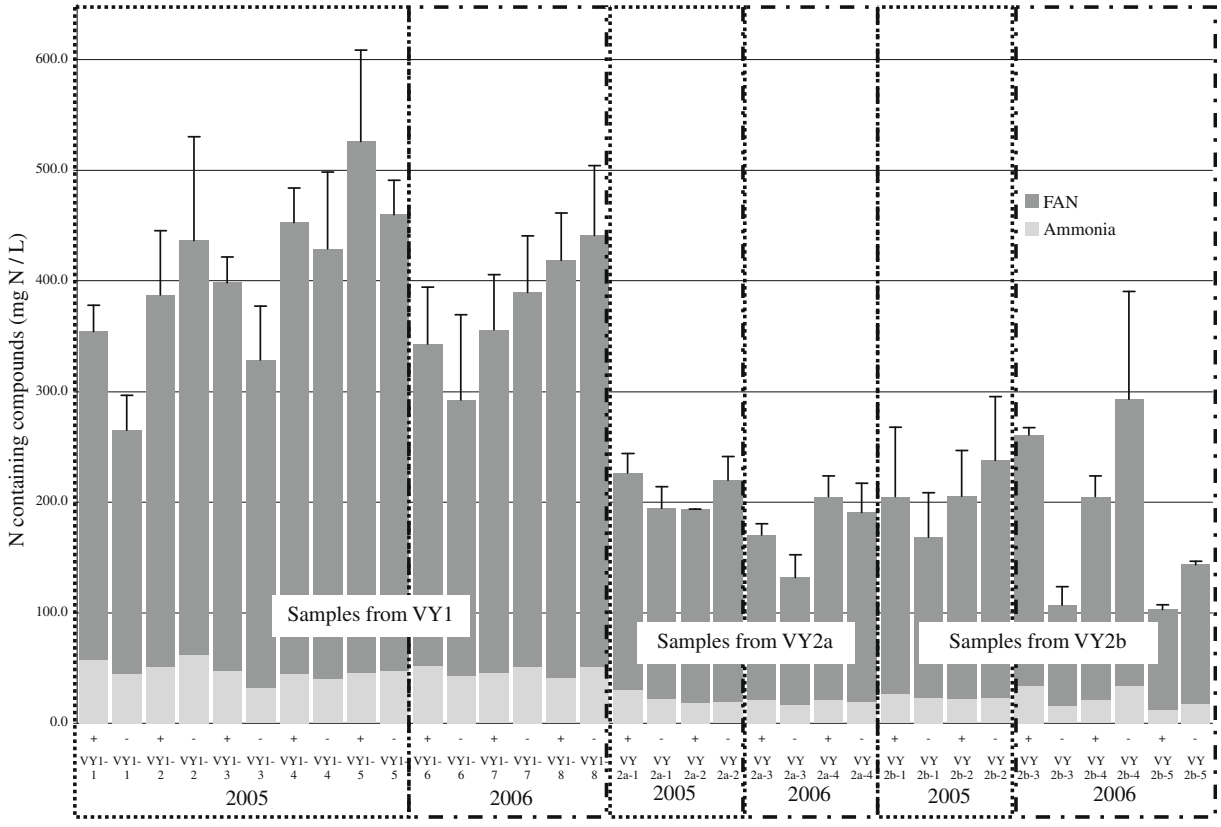

Fig. 3. FAN and ammonia values during the sampling periods from VY1, VY2a, and VY2b. The '+' indicates GLRaV-positive and '–' indicates GLRaV-negative by RT-PCR. VY1-5, VY1-8, VY2a-2, VY2a-4, VY2b-2, and VY2b-5 indicate commercial harvest. The corresponding sampling dates (e.g., VY1-1 sampled 9/19/2005) are listed in Table 1. FAN were obtained by HPLC as mg of N/l. Ammonia (mg N/l) were determined by enzymatic assay. None of the paired samples were significantly different from each other. Error bars indicate standard errors.

4. Conclusion

To the best of our knowledge, this is the first report upon the investigation of how GLRaVs impacted N-containing compounds, simple sugars, and organic acids in 'Pinot noir' berries from commercial vineyards in Oregon. In most comparisons, GLRaV did not significantly alter organic acids, simple sugars, ammonia, YAN, or FAN between fruit from healthy and infected vines. The exceptions were malic acid, total organic acid, Val + Met (in *V. riparia* rootstock/'Pinot noir' clone 114; VY2a), and Glu (in self-rooted/'Pinot noir' clone Pommard; VY2b) in GLRaV infected samples, compared to their GLRaV-negative cohorts. Among the healthy vines of the three rootstock/scion combinations, there was an apparent difference in the N-containing compounds, sugars, and acids, but this has been established for differing rootstock/scion combinations within a cultivar.

Keywords:
Chinese mahogany
Rosemary
Fresh sausage
Volatile compound

ABSTRACT

The purpose of this study was to evaluate the effect of rosemary or Chinese mahogany, at levels of 500, 1000 and 1500 ppm, of the phenolic compounds, on the quality of fresh chicken sausage stored at 4 °C for 14 days. The results showed that sausages with addition of Chinese mahogany or rosemary underwent less pH value reduction. The intense colour of Chinese mahogany or rosemary resulted in samples with lower *L* values and higher *a* values. Samples with more Chinese mahogany or rosemary added had higher total phenolic compounds. Lower TBA (thiobarbituric acid) and VBN (volatile basic nitrogen) values, and lower total plate counts were observed for the samples with Chinese mahogany or rosemary added. Samples with Chinese mahogany added had higher overall acceptance than had samples with rosemary added. Some volatile compounds, including alcohols, acids, esters, aldehydes, ethers and phenolic compounds, were isolated from the samples and identified.

1. Introduction

Sausage is one of the oldest known forms of processed meat products and is very popular in many areas. Fresh sausages, e.g. fresh pork sausage, country-style pork sausage, fresh kielbasa (Polish), Korr (Swedish), Italian sausage, bratwurst, bockwusrt, chorizo (fresh) and thuringer (fresh), are some common examples (Romans, Costello, Carlson, Greaser, & Jones, 1994). The cited authors indicate that fresh sausage is a sausage "made from selected cuts of fresh meat (not cooked or cured) and must be stored in a refrigerated (or frozen) state prior to being consumed." Therefore, adding "curing agents" (mainly nitrites and nitrates) to a formula, or not, is the major criterion used to judge whether the product belongs to "fresh sausage" or cured sausage. Also, raw materials of fresh sausage should not be cooked. No typical thermal treatments, such as drying, smoking or cooking, should be applied when making fresh sausages.

Lipid oxidation, resulting in rancidity, is one of the most important quality defects of meat or meat product during storage. Antioxidants can retard lipid rancidity in foods and prolong product shelf life. Since consumers have concerns regarding synthetic antioxidants, such as butylated hydroxy anisole (BHA), butylated hydroxy toluene (BHT) and propyl gallate (PG), natural antioxidants may be applied in foods (Aruoma, Halliwell, Aeschbach, & Löligers, 1992). Many herbs and spices contain phenolic compounds, which have some antioxidative properties.

Rosemary (*Rosmarinus officinalis* L.), like other aromatic herbs and spices, which has been planted in many areas and used in Mediterranean and other cuisine, is not only used to improve or modify flavours of foods, but also to provide some functionality. For example, its extract has been widely used as an antioxidant in the food industries. Carnosol, carnosic acid and rosmarinic acid have been identified as major constituents that contribute to the antioxidant activity of rosemary (Aruoma et al., 1992). Utilising DPPH and ABTS radical-scavenging assays, and the ferric thiocyanate test, Erkan, Ayranci, and Ayranci (2008) pointed out that rosemary extract had a higher phenolic content than had blackseed (*Nigella sativa* L.) essential oil, thus leading to a higher antioxidant activity. Many reports have indicated that rosemary extracts can retard lipid oxidation and prolong the shelf life of meat products (Georgantelis, Ambrosiadis, Katikou, Blekas, & Georgakis, 2007; Georgantelis, Blekas, Katikou, Ambrosiadis, & Fletouris, 2007; Sebranek, Sewalt, Robbins, & Houser, 2005). In addition, rosemary extracts have been shown to have some antimicrobial effect (Angioni et al., 2004).

Chinese mahogany, also known as *Toona sinensis* Roem, is a perennial tree that has become widely grown in Taiwan and China (Edmonds & Staniforth, 1998). Its leaves have a special aroma and are often consumed in Taiwan. Several reports regarding the medical uses of this plant, such as for treatment of enteritis, dysentery and itch (in the practice of oriental medicine) and for anticancer and hypoglycaemic effects have also appeared (Edmonds & Staniforth, 1998). Hseu et al. (2008) reported that *T. sinensis* aqueous extracts, at levels up to 100 μg/ml, showed some antioxidant activities, including the scavenging of free and superoxide anion

doi:10.1016/j.foodchem.2009.03.083

radicals, reducing power and metal chelation. Methanol extracts of *T. sinensis* also demonstrated strong DPPH radical-scavenging activities and inhibitory effects on lipid peroxidation Cho et al. (2003). Similarly, some potent antioxidative components in the young leaves and shoots of *T. sinensis* let to a promising healthy-promoting food (Wang, Yang, & Zhang, 2007). Even though, *T. sinensis* was reported to have some antimicrobial activity (Shi, 2003), limited information regarding the antimicrobial effect of this plant is available.

Therefore, the aim of this study was to compare the effects of rosemary or Chinese mahogany on the quality of fresh chicken sausage during refrigerated storage. We also wanted to identify the volatile compounds from Chinese mahogany, rosemary and sausages with rosemary or Chinese mahogany added.

2. Materials and methods

2.1. Rosemary and Chinese mahogany preparation

Rosemary, which was obtained from a local spice company in Taiwan, was comminuted with a grinder (DIAX 600, Heidolph, Germany) into approximately 2 mm lengths, and stored in a moisture-proof cabinet (BK236, Bossmen, Taiwan). Chinese mahogany leaves, which were obtained from a local farm in Pingtung, Taiwan, were dried in an oven at 60 °C for 8 h, ground with the same grinder to approximately 2 mm in length, and then stored in the moisture-proof cabinet.

A pre-measurement of the total phenol contents in rosemary and Chinese mahogany was first conducted according to the Folin–Ciocalteu method of Tsau (2006) and is described briefly as follows. Two grams of ground rosemary or Chinese mahogany were mixed with 100 ml of distilled water, boiled and extracted for 20 min, cooled rapidly, and filtered. The filtered liquid was combined with phenol reagent (Sigma) and saturated Na_2CO_3 (Union Chemical Works Ltd., Hsinchu, Taiwan), vortexed, and then held for 1 h. The optical density values were determined using a spectrophotometer (U3210, Hitachi, Japan) at 700 nm wavelength. A standard curve was prepared with gallic acid added and regression determined as $Y = 2.35X - 0.0472$, where Y represents OD (optic density) and X represents the concentration of the total phenol contents of the solution (mg/ml). Total phenol contents of rosemary or Chinese mahogany were determined according to the formula: Total phenol content (mg/g) = $(X \times 10 \times 100)/2 \times 1000$. Based on the preliminary test results, 395 and 82 mg/g total phenol contents were determined for the Chinese mahogany and rosemary, respectively, in this study. Therefore, amounts of 1.265, 2.530, or 3.795 g of ground Chinese mahogany were added to 1 kg of sausage mixtures, respectively, in order to have 500, 1000 or 1500 ppm of phenolic compounds, respectively. Similarly, amounts of 6.1, 12.2, or 18.3 g of ground rosemary were added to 1 kg of sausage mixtures, respectively, in order to have 500, 1000, or 1500 ppm of phenolic compounds, respectively.

2.2. Sausage preparation

Fresh chicken tenderloin, chicken skin, pork backfat and salted natural pork casing were purchased from local markets in Nantou, Taiwan. Chicken meat, chicken skin and pork backfat were first frozen at −20 °C and then ground. Chicken meat was ground through a 9 mm plate, whereas chicken skin and pork backfat were ground through a 6 mm plate. Ground chicken (75%) was mixed thoroughly with salt (1.8%) and polyphosphates (0.15%) with a mixer (DITO, BM10) for 1.5 min, and then other spices and seasonings were added, including 0.5% sugar, 0.3% monosodium glutamate, 0.1% white pepper powder, 0.075% nutmeg powder, 0.03% parsley powder, 0.03% thyme powder, 0.03% onion powder, pre-assigned amounts of ground Chinese mahogany leaves or rosemary and non-lean tissue (25%, in which the ground chicken skin:ground pork backfat ratio = 1:2), then mixed for another 1.5 min. The mixtures were cured at 4 °C for 16 h, and then stuffed (Stuffer, Dick D-73779, Germany) into pork casings which were soaked in water prior to use. Raw sausages were manually linked, packed in a tray with PVC film and stored at 4 °C.

2.3. Proximate composition and pH

Samples were first ground (with a grinder, 31BL91, Blender, USA). Proximate compositions of samples including moisture, crude fat, crude protein and ash contents, were measured according to the AOAC (1990) method. Crude fat was measured using a fat extractor (Sotec System HT 1043 Extraction Unit, Tecator Co. Sweden). Crude protein was measured using the Kjeldahl method using a digester (Model 2006, Foss tecator, Sweden) and a distillation unit (Model 2100, Foss tecator, Sweden). Ten gram samples were blended with 90 ml of distilled water in a polyethylene bag for 1 min using a stomacher (Stomacher 400, Seward Ltd., England) at high speed for 2 min, and then the pH of the mixture was measured using a pH meter (Micro-Computer pH meter, Model 6210, Taiwan).

2.4. Instrumental colour measurement

Ground samples were placed in a measuring container, and then the Hunter *L* (lightness), *a (redness)* and *b* (yellowness) values of samples were measured with a colour meter (Spectrophotometer, Model TC1, Tokyo Co., Ltd., Japan). A standard plate, with "*Y*" = 86.53, "*X*" = 82.45, and "*Z*" = 91.28, was used as a reference.

2.5. Total phenol contents in products

Fifty grams of ground sausage samples were mixed with 100 ml of distilled water, boiled and extracted for 20 min, cooled rapidly, filtered, and then put through the same method as described in Section 2.1 to determine the total phenol contents in products.

2.6. Thiobarbituric acid (TBA) values and volatile basic nitrogen (VBN)

TBA values of the samples were determined according the methods described by Faustman, Specht, Malkus, and Kinsman (1992). TBA value was expressed as mg malonaldehyde/kg of meat. Volatile basic nitrogen was determined according to CNS (1982) by the Conway micropipette diffusion method.

2.7. Microbial evaluation

At a specified sample time, sausages were aseptically removed from the bags. Ten gram samples were placed in a sterile bag containing 90 ml of sterile water and homogenised with a stomacher (Stomacher blender, Model 400, Seward) for 2 min. Serial dilutions were then made. Plate count agar (PCA, Merck) was used for enumeration of total plate count, and the pour plate method was used for enumeration of bacteria. Total microflora were incubated at 37 °C for 48 h. Microbial counts in this study were expressed as $\log_{10}$ colony forming units (CFU) per gram of sample.

2.8. Sensory evaluation

At days 0, 7 and 14, during storage, sausages were first cooked on a grill at 160 °C for 15 min, cooled at room temperature (approximately 25 °C), sliced (approximately 0.25–0.30 cm thickness), and then served to a sensory panel which consisted of 12

meat science-majored faculty and students. Sensory attributes, including colour, aroma, off-odour, flavour and overall acceptance were determined using 1–7 point hedonic scale, with 1, 4 and 7 representing extremely dislike, neither like nor dislike and extremely like, respectively, for the attributes.

2.9. Volatile compounds analysis

Volatile compounds were analysed according to the methods of Wang, Liu, and Chen (1998), and are described briefly as follows: 500 g of ground sausage samples was treated with 1 l of saturated sodium chlorine solution, homogenised for 30 s, transferred to a 5 l round-bottom flask attached to a Likens–Nickerson apparatus, and extracted for 4 h. A mixture of pentane (Merck) and diethyl ether (Merck) at 1:1 ratio (v/v) was used as an extracting solvent. After adding anhydrous sodium sulphate (Merck) to the extracted solution, extracted solution was filtered (Whatman No. 1), and condensed to 1–2 ml. The Likens–Nickerson concentrates were analysed by injecting 0.2 μl into a gas chromatograph (Model 5890 II, Hewlett–Packard, Palo Alto, CA, USA) coupled to a gas chromatograph–mass spectrometer (GC–MS, Hewlett–Packard, USA). The GC was equipped with a capillary fused silica column (CP-Wax 52 CB, 60 m × 0.25 mm i.d., Chrompack Inc., The Netherlands). Carrier gas was hydrogen (1.0 ml min^{-1} flow rate) and the column temperature was initially maintained at 40 °C for 5 min and subsequently programmed from 40 to 250 °C at a rate of 5 °C min^{-1}. The mass spectra were obtained by electron impact at 70 eV. Identification of the volatiles was based on comparison of the spectra with the spectra of the Wiley Spectrum Library.

2.10. Statistical analyses

Data were analysed using the general linear model (GLM) of Statistical Analysis System's Procedures (SAS Institute Inc., Cary, NC) with a 5% level of significance. Means were separated using the Duncan's new multiple range test.

3. Results and discussion

3.1. Proximate composition and pH

The contents of moisture, crude protein, crude fat and ash, of the fresh chicken sausages, were 59.8–61.8%, 15.7–16.4%, 20.1–22.4% and 2.70–2.95%, respectively. Three samples for each replicate and, totally, three replicates, were analysed for the proximate composition in this study. The pH values of the sausage remained stable and were approximately 6.4–6.6 during the first 10 days of refrigerated storage, and significantly ($P < 0.05$) decreased thereafter. This pH reduction was probably due to the fact that some existing oxygen inside the package might trigger fat oxidation, thus resulting in the decrease of pH values. At day 14, the pH value of the control samples decreased dramatically to 5.90, whereas, in the samples treated with rosemary or Chinese mahogany, it ranged from 6.00 to 6.14. A comparatively smaller pH reduction was observed for the samples with more rosemary or Chinese mahogany added.

3.2. Instrumental colour measurement

Fig. 1 illustrates the *L* and *a* colour value changes of the samples during storage. It shows that addition of rosemary or Chinese mahogany significantly decreased sample *L* values and increased sample *a* values. The more rosemary or Chinese mahogany that was added into the formula, the lower were the *L* values and the higher were the *a* values of the sausages. The *a* values of the control samples decreased during refrigerated storage while those of the samples with either rosemary or Chinese mahogany added increased. More intense colours of rosemary or Chinese mahogany itself led the sausages to have lower *L* values and higher *a* values, which resulted in darker colours. A possible browning reaction, occurring in the rosemary or Chinese mahogany added, might also contribute to this colour change. Polyphenol oxidases (PPOs), which are widespread enzymes in many plants, are responsible for browning in plants (Dogan & Dogan, 2004). In the presence of oxygen, the cited authors explained that these PPOs would oxidise plant phenolic compounds to corresponding quinones, which then condense to form darkened compounds.

Sebranek et al. (2005) reported that frozen pork sausages with 2500 ppm rosemary extract added had better red colour retention than did BHA/BHT-treated sausages during 84 days of storage. In the same study, they also reported that there was no significant difference of the $a*$ values between BHA/BHT treated, rosemary extract treated and controls for the refrigerated sausages, while a significant difference of colour loss occurred during 14 days of refrigerated storage. In contrast, Georgantelis and Blekas, et al. (2007) reported that $a*$ values of both rosemary extract treated and control beef burgers decreased during frozen storage for 180 days and addition of rosemary extract improved colour stability when compared to the controls. In the same study, they reported that a combination of chitosan and rosemary extract significantly improved sample colour stability and red colour retention. Georgantelis and Blekas, et al. (2007) explained that many factors, such as differences in the oxidation pattern of oxymyoglobin under conditions of reduced enzymatic activity, storage temperature, packaging method, muscle type and light intensity and differences in the meat species studied, might contribute to the variations in rosemary colour retention efficiency between different studies. In addition, types of antioxidative components added, for example, dried rosemary but not extract in this study, could also influence its efficiency.

3.3. Phenolic compounds in sausages

In this study, a higher content of total phenolics in Chinese mahogany, of 395 mg/g was observed, when compared to 65.0 mg/g, as reported by Chen, Lin, and Hsieh (2007), and 139 mg/g, reported by Yang et al. (2006). This deviation was probably due to various measuring conditions (i.e. absorbance measured at 700 or 750 nm) applied in these studies. In addition, drying conditions of Chinese mahogany leaves might not be the same in these studies (60 °C for 8 h in this study, but not reported by Chen et al. (2007). The phenolic compounds in sausages decreased with storage time for all the treatments (Fig. 2). This reduction of phenolic compounds in sausages during storage is in agreement with other studies. Daood, Vinkler, Markus, Hebshi, and Biacs (1996) reported that some antioxidative compounds, existing in spices, such as α-tocopherol, ascorbic acid and β-carotene, would lose their antioxidative ability dramatically during drying and storage. A dramatic decrease in the concentration of antioxidant compounds and loss of active antioxidation performance was observed during the late stage of storage, which resulted in an increase of fat oxidation. This phenomenon of progressive lipid oxidation, due to loss of protection by antioxidants after storage for a period of time, was also indicated by the dramatic increase of TBA values. The samples treated with Chinese mahogany showed comparatively higher total phenolic compound residuals at the end of storage when compared to the samples treated with rosemary at the same level. This more advanced protection against oxidation might be the reason that the samples with Chinese mahogany added had comparatively lower TBA values.

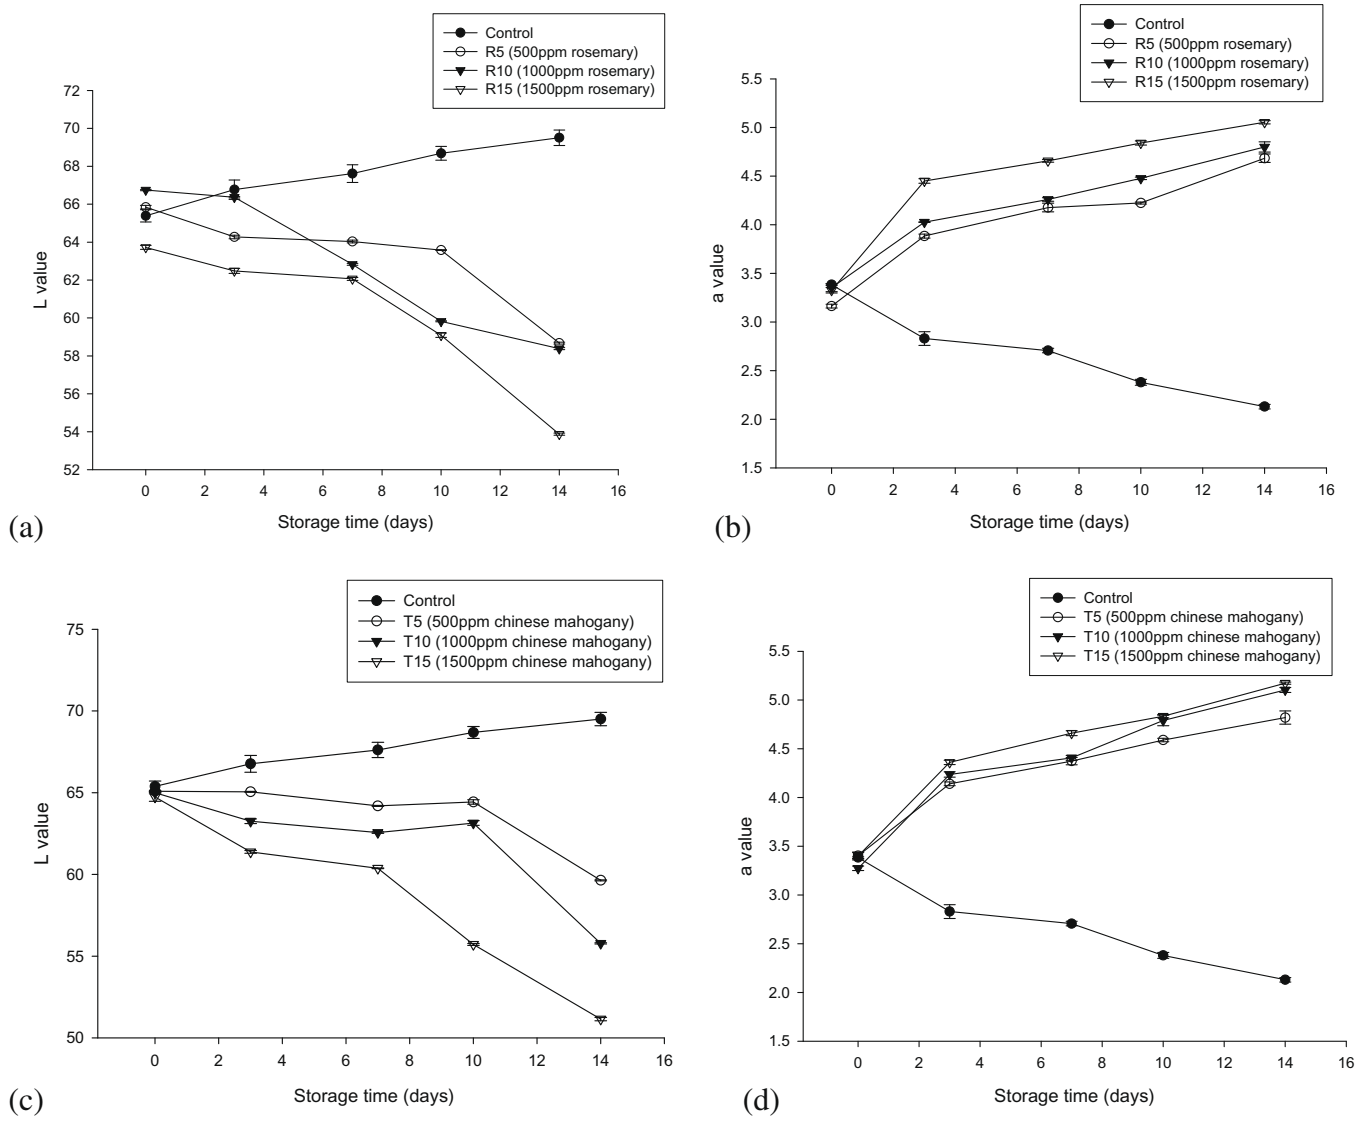

Fig. 1. Changes of (a) *L* values, (b) *a* values of fresh chicken sausages with addition of rosemary, (c) *L* values and (d) *a* values of fresh chicken sausages with Chinese mahogany during storage at 4 °C.

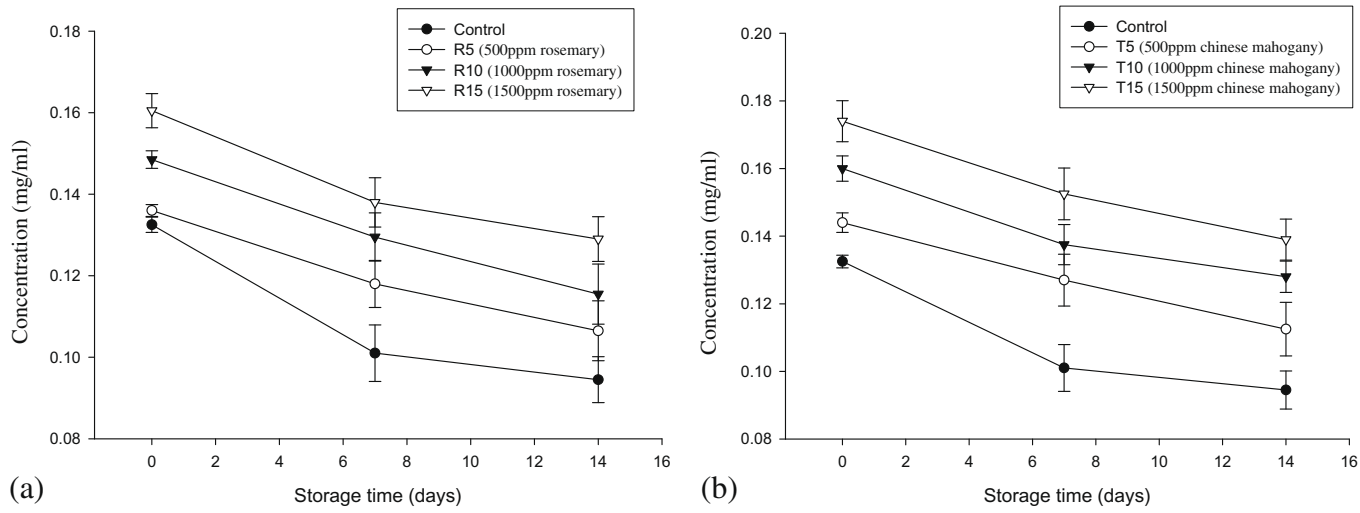

Fig. 2. Changes of residual amounts of phenolic compounds of fresh chicken sausages with addition of (a) rosemary or (b) Chinese mahogany during storage at 4 °C.

3.4. TBA and VBN

TBA values, which are indicators of lipid oxidation, are shown in Fig. 3. The TBA values of the sausage samples increased with refrigerated storage time during the first 3 days, indicating that lipid oxidation had occurred during this stage. This increase of TBA values of fresh sausages during storage has also been reported by other researchers. In this study, TBA values increased up to a maximum point at day 3, and then decreased gradually, and this tendency agreed with a study reported by Gokalp, Ockerman, Plimpton, and Harper (1983). Kuo, Dresel, Huang, and Ockerman (1987) explained that, during storage, malonaldehyde, which is an intermediate by-product during lipid oxidation, is further oxidised to other organic acids and alcohols that can not react with TBA agent. This might be the reason why the TBA values increased then decreased.

In this study, the TBA values of the samples with rosemary or Chinese mahogany added were lower than those of the controls. At day 3, the TBA values of the controls increased from 1.15 to 1.54 mg malonaldehyde/kg, while the TBA values of the Chinese mahogany treated samples were 1.30, 1.21, and 1.17 mg malonaldehyde/kg for T5 (500 ppm Chinese mahogany), T10 (1000 ppm Chinese mahogany), and T15 (1500 ppm Chinese mahogany) samples, respectively, and were significantly lower than the controls. Similarly, samples with rosemary added had significantly lower TBA values of 1.42, 1.40 and 1.25 malonaldehyde/kg for R5 (500 ppm rosemary), R10 (1000 ppm rosemary) and R15 (1500 ppm rosemary) samples, respectively. During storage, between day 3 and 14, the TBA values decreased for all treatments. The TBA value of the controls decreased to 1.10 mg malonaldehyde/kg at day 14, while the TBA values of the samples with rosemary added ranged from 1.00 to 1.05 mg malonaldehyde/kg for R5, R10, R15, and from 0.93 to 1.01 mg malonaldehyde/kg for T5, T10, and T15 samples, respectively. These decreases of TBA values were probably due to both the rosemary and Chinese mahogany, which are reported to have some antioxidative ability, and to retard fat oxidation. The results in this study demonstrate that the addition of rosemary or Chinese mahogany inhibited the lipid oxidation of fresh chicken sausages, and agree with other studies. In agreement with our findings, the positive effects of use of rosemary to prevent lipid oxidation have been well documented. Addition of 1000 ppm of rosemary extract was as effective as a combination of 100 ppm BHA plus 100 ppm BHT to maintain low TBARS values of precooked-frozen pork sausage (Sebranek et al., 2005). Yu, Scanlin, Wilson, and Schmidt (2002) reported that water-soluble rosemary extracts significantly decreased TBARS values of cooked turkey during 13 days of storage at 4 °C when compared to the controls, and higher levels of extracts added at 100, 250, or 500 ppm, were more effective in delaying lipid oxidation. The authors explained that free radical-scavenging and transition metal-chelating activities of water-soluble rosemary extract might contribute to the inhibitory effects on lipid peroxidation in cooked samples. Carnosol has been recognised as a major antioxidant in rosemary (Wei & Ho, 2006). Similarly, some phenolic diterpenes, such as carnosic acid, carnosol, rosmanol, rosmariquinone and rosmaridiphenol, which break free radical chain reactions by donation hydrogen atoms, have been reported to be associated with the antioxidant activity of rosemary extracts (Aruoma et al., 1992).

Hseu et al. (2008) reported that *T. sinensis* aqueous extracts, at 25–100 μg/ml, had some effective antioxidant activities, including the scavenging of free and superoxide anion radicals, reducing power, and metal chelation. Methanol extracts of *T. sinensis* have also demonstrated strong DPPH radical-scavenging activities and inhibitory effects on lipid peroxidation (Cho et al., 2003). Similarly, some potent antioxidative components in the young leaves and shoots lead *T. sinensis* to become a promising healthy-promoting food (Wang et al., 2007). Chen et al. (2007) reported that triterpenes and phenolic compounds, isolated from *Toona* species, were responsible for its antioxidant activity. In the DPPH radical-scavenging assay, Wang et al. (2007) reported that the 80% acetone extract of Chinese toon (the fresh young leaves and shoots of *T. sinensis*) had considerable antioxidant activity. Furthermore, the authors reported that gallic acid and its derivatives, gallotannins and flavonoids, were the main constituents contributing to its antioxidant ability. The antioxidative compounds contained in rosemary and Chinese mahogany might contribute to the antioxidative activity, thus retarding the fat oxidation of products during storage.

Increase amounts of volatile basic nitrogen (VBN), which is the result of decomposition of protein during storage by microorganisms, can be an index of meat product freshness. Fig. 4 illustrates that VBN values of the sausage samples increased as expected when storage time increased. In this study, VBN values, as well as the microbial counts, increased significantly during storage. In addition, samples that had more rosemary or Chinese mahogany added had significantly ($P < 0.05$) lower VBN values. At day 14, the control samples had significantly higher VBN value of 30.7 mg%, compared with those of the samples with rosemary added (24.4, 23.9 and 21.4 mg% for the R5, R10 and R15 samples,

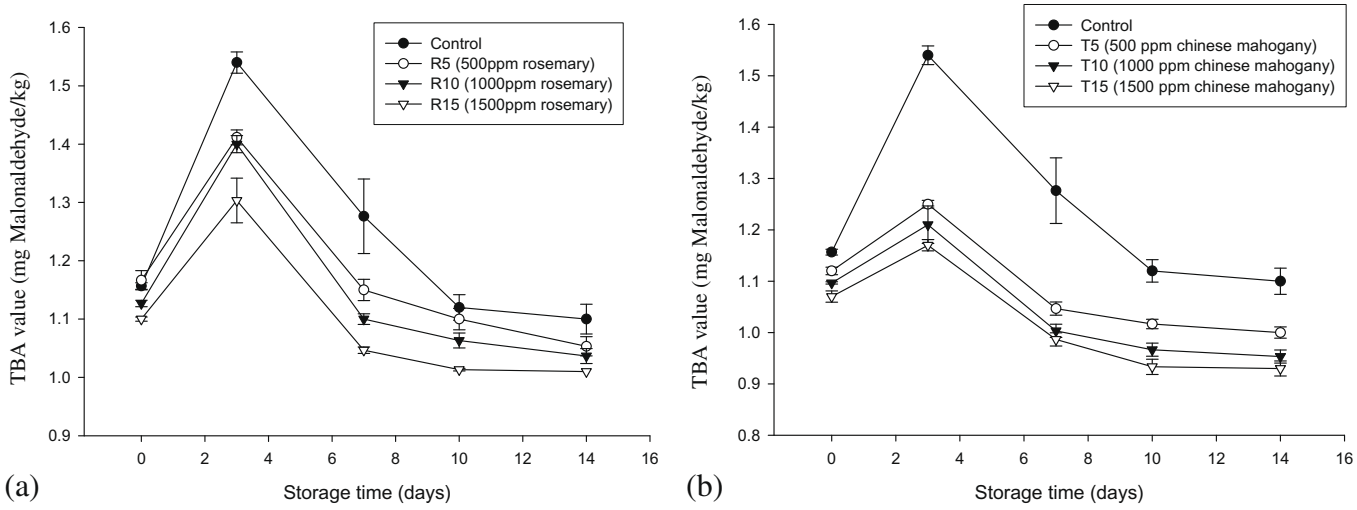

Fig. 3. Changes of TBA values of fresh chicken sausages with addition of (a) rosemary or (b) Chinese mahogany during storage at 4 °C.

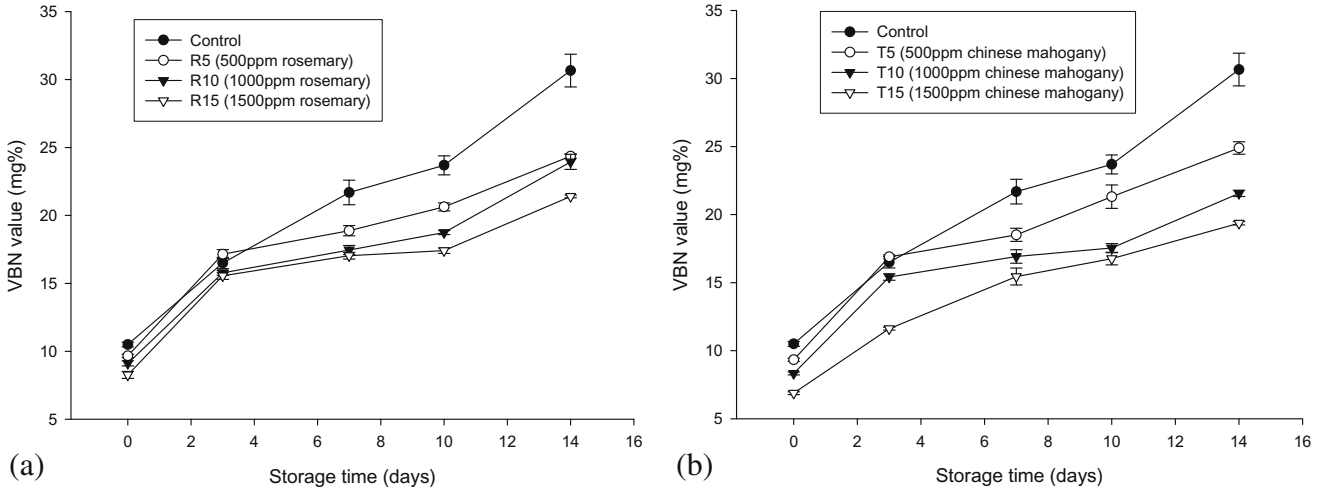

Fig. 4. Changes of VBN values of fresh chicken sausages with addition of (a) rosemary or (b) Chinese mahogany during storage at 4 °C.

respectively). Similarly, the samples with Chinese mahogany added had significantly lower VBN values (24.9, 21.6 and 19.4 mg% for the T5, T10 and T15 samples, respectively). The more rosemary or Chinese mahogany that was added to sausages, the lower were the VBN values of the samples observed. In this study, lower VBN values might suggest smaller bacterial populations for the samples with more rosemary or Chinese mahogany added, which is in agreement with the microbial counts shown in this study. These decreases of sample VBN values were probably because rosemary or Chinese mahogany contained some antimicrobial compounds. Carnosol and ursolic acid, which were the two antioxidant compounds extracted from rosemary, were demonstrated to inhibit the growth of 6 strains of food-associated bacteria and yeasts (Collins & Charles, 1987). Less microbial growth in sausages, due to the addition of rosemary or Chinese mahogany to the formula, thus led to less protein decomposition and lower VBN values.

3.5. Microbial qualities

The total plate counts of all samples increased during refrigerated storage (Fig. 5). Those with rosemary or Chinese mahogany added had comparatively lower microbial counts. At day 14, the total plate counts of sausages with the addition of rosemary at the levels of 500 ppm (R5), 1000 ppm (R10) and 1500 ppm (R15) were 5.99, 5.72 and 5.55 log CFU/g, respectively, which were significantly ($P < 0.05$) lower than that of the controls (6.08 log CFU/g). Similarly, total plate counts of 5.75, 5.59 and 5.30 log CFU/g were obtained for the sausages with 500 ppm (T5), 1000 ppm (T10) and 1500 ppm (T15) of Chinese mahogany added, respectively. In addition, samples with Chinese mahogany added had comparatively lower microbial counts than had the rosemary-treated sausages in this study. This difference was probably due to the total phenol content of Chinese mahogany which was higher than that of the rosemary (395 mg/g vs. 82 mg/g). Such antimicrobial effects due to the addition of rosemary or Chinese mahogany were also reported by other researchers.

Georgantelis and Ambrosiadis, et al. (2007), reported that the fresh pork sausages with addition of rosemary extract at level of 260 mg/kg had significantly lower ($P < 0.05$) Enterobacteriaceae, pseudomonad and yeast/mould counts than had the controls. Addition of carnosol, which was isolated from rosemary at levels of 50 μg/ml and 150 μg/ml, could significantly inhibit *Staphylococcus aureus* and *Escherichia coli* (Collins & Charles, 1987). Rosemary extracts have been demonstrated to have some inhibitory effects on the selected lactic acid bacteria and *Listeria* in an agar diffusion test (Fernández-Lopez, Zhi, Aleson-Carbonell, Pérez-Alvarez, &

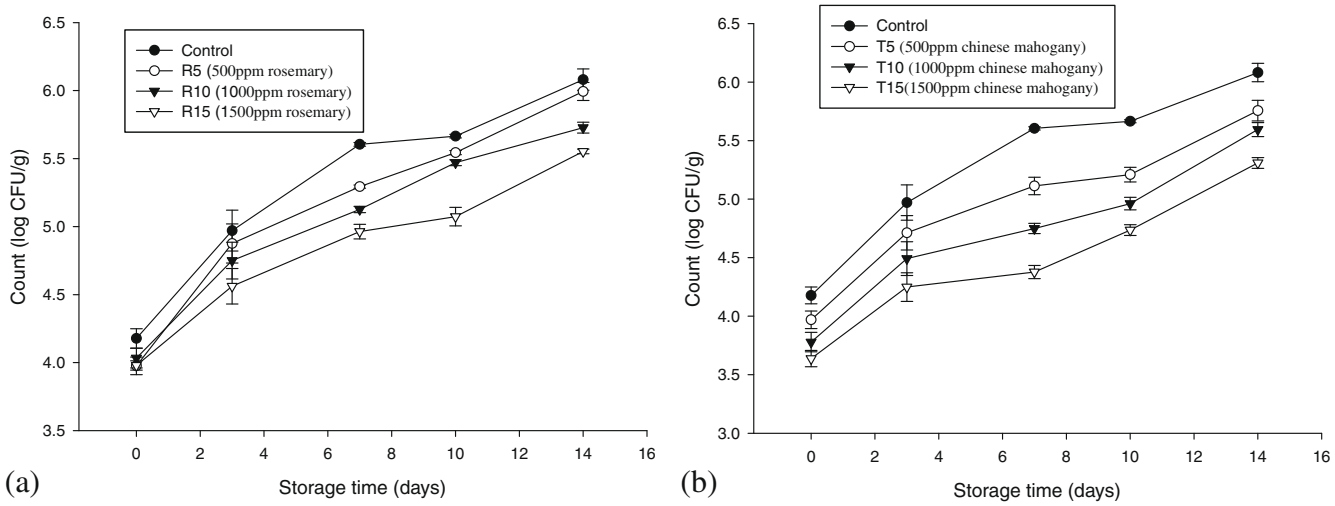

Fig. 5. Changes of total plate counts of fresh chicken sausages with addition of (a) rosemary or (b) Chinese mahogany during storage at 4 °C.

Kuri, 2005). Some non-polar components, such as phenolic diterpenes, which were isolated from rosemary, were indicated to be responsible for its antimicrobial properties, especially towards Gram-positive bacteria (Fernández-Lopez et al., 2005). Furthermore, when in combination with factors which can disturb cell membrane integrity and/or its permeability, such as lowered pH values, increased NaCl concentrations, combined with chitosan, phenolic diterpenes could further be used to inhibit Gram-negative bacteria (Georgantelis and Blekas, et al., 2007).

3.6. Sensory evaluation

Results of the sensory evaluation of the sausage during the 14-day storage period are presented in Table 1. A 7-point hedonic scale test was used in this study, with scores 1, 4 and 7, representing extremely dislike, neither like nor dislike, and extremely like, respectively. At day 0, colour scores of each treatment were less than 5, among which R15 (1500 ppm rosemary added) had the lowest colour score. In addition, the R15 (1500 ppm) colour score was significantly lower than those of R5 (500 ppm) and R10 (1000 ppm). No significant difference ($P > 0.05$) of aroma between treatments was observed. However, there was a significantly higher off-odour of 3.33 for the R15 (rosemary 1500 ppm added) than of 1.92 for the control sample. This higher off-odour of the samples might be due to a too condensed aroma due to higher level addition of rosemary. Samples with Chinese mahogany added had significantly higher flavour and overall acceptance scores than had the samples with rosemary added. At day 7, control samples had significantly higher colour scores than had those of the other treatments. This result was probably because colours of the samples with either rosemary or Chinese mahogany added became darker, which could have decreased sensory preference. On the other hand, samples with rosemary or Chinese mahogany added tend to have higher aroma scores, while the controls tended to have higher off-odours, even without significance. Addition of rosemary or Chinese mahogany seemed, not only to enhance the aroma of samples, but also to retard off-odour produced by fat oxidation. Samples with Chinese mahogany added (T5, T10 and T15) tended to have higher overall acceptance than did rosemary-added samples (R5, R10 and R15). At day 14, samples with 1500 ppm Chinese mahogany (T15) had significantly lower colour scores because of the darker colour of Chinese mahogany after being stored for a long time. This less preferred darker colour could also be evaluated subjectively by the lower *L* and higher *a* colour values. At the same level of addition, samples with Chinese mahogany had higher total overall acceptance.

3.7. Volatile component analysis

Flavour is one of the most important factors influencing the eating quality of meat and consumer decisions. Less aroma is sensed when meat is uncooked, while a complex series of thermally induced reactions occur between non-volatile components of lean and fatty tissues during cooking (Mottram, 1998). These thermally induced reactions and some volatile compounds formed during cooking thus contribute to specific aroma and flavour of meats (Mottram, 1998). In addition, not only enhancing colours, addition of some seasonings or spices, such as rosemary or Chinese mahogany, used in this study, also provides some unique aromas and flavours for meat products. Some volatile compounds, including esters (etheyl acetate), alcohols (ethanol) and acids (formic acid and acetic acid), were identified in fresh chicken sausage. Alcohols (ethanol, 1,8-cineole, L-terpineol, α-terpineol, mytenol, and ρ-cymen-8-ol), ketones (acetone and camphor), an ether (ε-anethole), alkenes (α-pinene, camphene, β-pinene, myrcene, and verbenene), acids (formic acid and acetic acid), and esters (etheyl acetate and methyl eugenol) and phenols (estragol, thymol and carvacrol), were identified from the fresh chicken sausage with 1500 ppm rosemary added. Alkenes (α-pinene, β-pinene, limonene, phellandrene and anethole), alcohols (ethanol, linalool, L-terpineol and α-terpineol), acids (formic acid and acetic acid), esters (etheyl acetate and ethyldicanoate), phenol (2-acetylfuran), and ethers (safrole and myristicin), were identified in the fresh chicken sausage with 1500 ppm Chinese mahogany added.

Unsaturated fatty acids are more readily oxidised than are saturated fatty acids. Therefore, a comparatively much higher proportion of unsaturated fatty acids leads phospholipids to become a more important source of volatile compounds during cooking than

[2] C = control, R5 = 500 ppm rosemary, R10 = 1000 ppm rosemary, R15 = 1500 ppm rosemary, T5 = 500 ppm Chinese mahogany, T10 = 1000 ppm Chinese mahogany and T15 = 1500 ppm Chinese mahogany.

triglycerides (Mottram, 1998). In addition to verbenone, which was the major component (35.4%), Mata et al. (2007) identified several components, including α-terpineol (7.2%), camphor (5.5%), 4-terpineol (3.9%), 1,8-cineole (3.1%), caryophyllene oxide (2.4%), β-caryophyllene (2.3%), borneol (2.1%), α-bisabolool (2.1%), linalool (1.9%) and α-humulene (1.2%), in the essential oil of rosemary. Carvalho, Moura, Rosa, and Meireles (2005) explained that the chemical compositions of rosemary volatile oil and extracts varied widely, probably because of the difference in agricultural conditions of cultivation and the extraction technique used.

4. Conclusion

This study showed that smaller pH reduction was observed for the samples with more rosemary or Chinese mahogany added. Addition of rosemary or Chinese mahogany significantly decreased sample *L* values and increased sample *a* values. The phenolic compounds in sausages decreased during storage. Addition of rosemary or Chinese mahogany resulted in lower TBA, VBN values and microbial counts of the samples. Samples with addition of Chinese mahogany had significantly higher overall acceptance. The main volatile compounds of fresh chicken sausage were alcohols, acids, esters, aldehydes, ethers and phenolic compounds. In conclusion, Chinese mahogany and rosemary, applied in this study, have been demonstrated to improve meat products quality and function as a promising natural ingredient applied to food.

Extrusion
Antioxidant activity
Physiological property
Mitogenic response

ABSTRACT

Antioxidative and physiological property changes of freeze-dried, hot air-dried and extruded products made from two different colours of sweet potatoes (yellow and orange) were investigated. The results showed that there were no significant differences of dietary fibre content amongst all the treatments, except that the extruded products of orange sweet potatoes had higher dietary fibre contents. However, the water solubility index (WSI) values and antioxidant content were significantly different between yellow and orange sweet potatoes, and significantly different amongst freeze-dried, hot air-dried and extruded samples. The WSI values of the extruded samples were significantly higher than those of the hot air- and freeze-dried samples. The freeze-dried samples of orange sweet potatoes had more total phenolic compounds, β-carotene, and anthocyanin and had better scavenging effect on DPPH radicals than had freeze-dried yellow sweet potatoes. However, the scavenging effect on DPPH radicals was appreciably greater for hot air-dried than freeze-dried yellow sweet potatoes, but this trend was opposite for orange sweet potatoes. The extrusion process significantly increased the WSI values, scavenging effect on DPPH radicals and total phenolic compounds but decreased the β-carotene and anthocyanin for both yellow and orange sweet potatoes. At lower concentration (25–50 μg/ml), the methanolic extract of freeze-dried yellow sweet potatoes possessed a greater capacity of increasing the mitogenic response than did freeze-dried orange sweet potatoes; at higher concentration (100–200 μg/ml), the proliferation of the lymphocytes increased when stimulated with mitogen Con A for all the samples. This suggests that mitogen Con A selectively promotes T-cell-dependent proliferative activity.

1. Introduction

Sweet potatoes (*Ipomoea batatas*) represent the sixth most important food crop in the world. In Taiwan the total production of sweet potatoes harvested in 2006 was 235,203 metric tons, ranking first in the coarse grains (COA, 2006). To promote the consumption of sweet potatoes in Taiwan, interest has been focused on the development of new uses, particularly making sweet potatoes into bioactive functional foods. The high dietary fibre content of sweet potatoes is well known. Dietary fibre, one of the important bioactive functional food sources, can prevent coronary heart disease, hypertension and serum hyperlipidemia (Prosky & DeVries, 1992). Lund (1984) compared the cholesterol-binding capacities of 28 fibre samples from a variety of the common tropical fruits and vegetables and found that sweet potatoes were the most effective binder.

Several other investigators have reported the antioxidant activity and suppression of melanogenesis of mouse melanoma B16 by sweet potato extract, as well as the reducing effects of sweet potato juice against carbon tetrachloride-induced liver injury (Hayase & Kato, 1984; Shimozona, Kobori, Shimoto, & Tsushida, 1996; Suda, Furuta, Nishiba, Matsugano, & Sugita, 1997). Active oxygen species and free-radical-mediated reactions have been reported in degenerative or pathological processes such as aging, cancer, coronary heart disease and Alzheimer's disease (Ames, 1983; Ames, Shigena, & Hegen, 1993; Diaz, Frei, Vita, & Keaney, 1997; Smith, Perry, Richey, & Sayre, 1996). Antioxidants inhibit *in vivo* initiation and progression of a range of human diseases, such as coronary heart disease, carcinogenesis, neuronal disease, and age-related macular degeneration (Ames, 1989; Diplock et al., 1998). The antioxidative effects in vegetables were reported to be mostly due to phenolic compounds (Chu, Chang, & Hsu, 2000; Philpott, Gould, Markham, Lewthwaite, & Ferguson, 2003; Zhan, 1996). Hayase and Kato (1984) found that 70% methanol extract of sweet potatoes had a strong antioxidative activity. They also identified the major phenolic components contained in the extract. These were chlorogenic acid and isochlorogenic acid −1, −2 and −3. Additionally they found that the effective antioxidant activity of the sweet potato extract was due to the synergistic effect of phenolic components with amino acids. On the other hand, Hou et al.

doi:10.1016/j.foodchem.2009.03.084

(2001) found that the 33 kDa trypsin inhibitor, one of the major sweet potato root storage proteins, had scavenging activity against the 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical and the hydroxyl radical. Philpott et al. (2003) found that hydroxycinnamic acid was the major antioxidant component of sweet potatoes. Recently, anthocyanins from sweet potatoes have been shown to possess potent antioxidative activity *in vitro* (Oki et al., 2002; Philpott, Gould, Lim, & Ferguson, 2004; Stintzing, Stintzing, Carle, Frei, & Wrolstad, 2002) and the stoichiometric and kinetic values of phenols against DPPH· were also determined (Cevallos-Casals & Cisneros-Zevallos, 2003). A recent study found that phenols, flavonoids, and anthocyanins of sweet potato flours were significantly positively correlated with the DPPH radical scavenging effects (Huang, Chang, & Shao, 2006) but not β-carotene bleaching (Teow et al., 2007). Steam treatment also increased the DPPH radical scavenging effect of sweet potatoes (Huang et al., 2006).

A rapid colorimetric method based on the capacity of viable cells to cleave the tetrazolium salt MTT (3-[4,5-dimethyl thiazol-2-yl]-2,5-diphenyl tetrazolium bromide) to MTT formazan has been used to measure the proliferation and activation of cells (Chen, Campbell, & Newman, 1990; Mosmann, 1983). Several kinds of foods or their components have been analysed, utilising the MTT colorimetric method to identify antiproliferation activity, e.g. the adlay seed (Kuo, Shih, Kuo, & Chiang, 2001), phenolic compounds (Kasugai, Hasegawa, & Ogura, 1991), lycopene (Hwang & Bowen, 2004) and isoflavone (Kayisli, Aksu, Berkkanoglu, & Arici, 2002). According to a study of the antiproliferation activity of sweet potatoes, the water extract of storage roots showed the second highest antiproliferation activity, using human lymphoma N84 cells (Huang, Lin, Chen, & Lin, 2004).

Extrusion cooking has certain unique features compared to other heat processes because the material is subjected to intense mechanical shear (Harper, 1979). However, sweet potato extrusion researches have been extensively focused on chemical composition changes (Iwe, van Zuilichem, Ngoddy, & Lammers, 2001) and the effects of physical properties (Iwe, van Zuilichem, Stolp, & Ngoddy, 2004; Iwe, Wolters, Gort, Stolp, & van Zuilichem, 1998) but only sporadically on the bioactivity.

There are two very important cultivars of sweet potatoes in Taiwan–Tainong 57 (yellow sweet potato, YSP) and Tainong 66 (orange sweet potato, OSP). The former is whitish to yellowish in colour and suitable for producing sweet potato flakes. The latter is of an orange colour and suitable for producing sweet potato flakes and chips (Chen & Chiang, 1985). The effects of extrusion on the amount and activity of antioxidants contained in sweet potatoes has so far been only sporadically studied. This research was carried out to study the physicochemical and physiological properties and bioactivity of sweet potato dry products (chips and extruded products) made from yellow and orange sweet potatoes by using different processes (freeze-drying, hot air-drying, and extrusion).

2. Materials and methods

2.1. Materials

Two cultivars of sweet potatoes–Tainong 57 (yellow sweet potato, YSP) and Tainong 66 (orange sweet potato, OSP) – were obtained from a local market. The sweet potatoes were processed within 24 h after purchasing.

2.2. Sweet potato chip making process

The process procedure of the sweet potato chips was modified according to Chen (1987) and Chen and Chiang (1985). Washed sweet potatoes were cut into 1 mm thick slices with a conventional food slicing machine. To prevent discoloration of sliced sweet potatoes during dehydration, the slices were soaked in 0.5% sodium bisulfite ($NaHSO_3$) solution for 30 min, and then soaked in running water for 1 h. The prepared slices were dried in a tunnel drier (Si Dien Co., Taichung, Taiwan) at 80 °C for 1 h according to the commercial preparation procedure. The conditions of the tunnel drier were: total length 15 m, conveyor speed 0.25 m/min, air humidity less than 40% relative humidity, air speed 2.7 m/s, and water content of the final product less than 5%. The slices, without a $NaHSO_3$ solution soaking treatment, were freeze-dried. All processing treatments were done in triplicate.

2.3. Extrusion

Hot air-dried sweet potato chips were ground in a stainless grinder to pass a 100 mesh sieve (Geng Sin Co., Taipei, Taiwan). Extrusion was done by a twin screw extruder (Hungyang Co., Yulin, Taiwan), using a screw length of 120 cm (barrel length:diameter = 20:1) and a pitch of 36.7 mm. Each of the dies was 2.5 mm in diameter. Temperature settings for the feeding, kneading, compression, kneading, metering and die zones were room temperature, 100, 100, 110, 115, and 115 °C, respectively. Temperature settings were monitored and adjusted using a thermocouple. The extruder screw speed was 120 rpm, feed rate was 60 kg/h and feed moisture was 5.53 kg/h. Received samples were stored in polyethylene bags and used in the subsequent analyses. All processing treatments were done in triplicate.

2.4. Colour analysis

The sweet potato chips were ground into powder of less than 40 mesh with a commercial blender. Hunter colour of the sweet potato samples was determined for the colour analysis with a colorimeter (Nippon Denshoku Σ90, Kogyo Co., Tokyo, Japan). The reported values are the averages value of four duplicate tests for each sample. Results were expressed as tri-stimulus values (L: lightness (0 = black, 100 = white), a ($-a$ = greenness,+a = redness) and b ($-b$ = blueness,+b = yellowness)) of the Hunter colour scale. The instrument was set in reflectance mode. A white standard plate (X = 93.28; Y = 95.12; Z = 113.14) was used for calibration. Numerical total colour difference (ΔE), hue angle and chroma were calculated by

$$\Delta E = \left[(L - L_o)^2 + (a - a_o)^2 + (b - b_o)^2\right]^{1/2}$$

$$\text{Hue} = \left[\tan^{-1}(b/a)\right]$$

$$\text{Chroma} = \left[\left(a^2 + b^2\right)\right]^{1/2}$$

where L_o, a_o and b_o were the L, a, and b values of the reference sample which here is the freeze-dried sample.

2.5. Water solubility index (WSI)

The WSI of sweet potato samples was measured by the modified method of Anderson, Conway, Pfeifer, and Griffin (1969). A 2.5 g sample, with 30 ml of distiled water, was incubated in a 30 °C water bath for 30 min. The mixture was centrifuged at 3000 g for 10 min; the supernatant was then poured into a weighing bottle and dried at 105 °C, overnight, to determine the soluble solids weight:

$$\text{WSI (\%db)} = \text{soluble solids weight (g)} / \text{sample weight (g, dry mass)} \times 100\%$$

2.6. Dietary fibre analysis

Dietary fibres of sweet potato samples were determined according to the AOAC method (Prosky, Asp, Schweizer, DeVries, & Furda, 1988). A one gramme sample (dry matter) was treated with a heat-stable α-amylase (EC 3.2.1.1, Catalogue No. A3306, Sigma, St. Louis, MO) for 15 min in a boiling water bath, and then treated with protease (Catalogue No. P3910, Sigma, St. Louis, MO) and amyloglucosidase (Catalogue No. A3513, Sigma, St. Louis, MO) for 30 min at 60 °C. The residue, as water insoluble dietary fibre (IDF), was recovered by filtering with a glass crucible and dried at 105 °C overnight and weighed. The weight was corrected for ash and residual protein contents. Subsequently, 60 °C −95% alcohol, in the amount of four times the filtrate volume, was added to the filtrate and the filtrate was allowed to set and precipitate for 1 h. The precipitate, as water-soluble dietary fibre (SDF), was dried at 105 °C overnight and weighed after being recovered by filtering with a glass crucible. The weight was further corrected for ash content. The total dietary fibre (TDF) content was the sum of IDF and SDF.

2.7. β-Carotene analysis

Sweet potato sample powder (5 g) was mixed with approximately 2 g of calcium carbonate, 1 g of diatomaceous earth, and 25 ml of methanol. A hexane–acetone (1:1) mixture (50 ml) was added and the whole stirred (Chen, 1987). The mixture was filtered under vacuum through a funnel with a fritted disc. The residue in the funnel was washed twice more with 25 ml of methanol and then by 50 ml of the hexane–acetone mixture. All of the extracts were combined in a 250 ml separating funnel and washed with water. Drops of saturated sodium chloride solution were added to the funnel until phase separation appeared. The aqueous phase was discarded and the upper layer was evaporated to 15 ml in a vacuum evaporator. The concentrate was purified by pouring into a 30 ml glass filter with 10 cm height of absorbent (magnesium oxide: diatomaceous earth = 1:3) and washed with petroleum ether (with 3% acetone) until all of the orange colour had disappeared. The filtrate was diluted to give an absorbance of <1.2 at 436 nm. Commercial β-carotene (Catalogue No. C9750, Sigma, St. Louis, MO) was used as a standard.

2.8. Total anthocyanins assay

Content of anthocyanins was determined by following the procedures of Mancinelli, Huang Yang, Lindquist, Anderson, and Rabino (1975). The sweet potato flour (0.5 g) was treated with 20 ml of acidified methanol (1% HCl) in a rotary mixer at a 45° angle and 200 rpm for 30 min in the dark. After centrifuging at 450 g and 4 °C for 15 min, the supernatant was diluted to an appropriate concentration and the absorbance was read at 657 nm (A657) and 530 nm (A530). The anthocyanin content was calculated on the basis of the following equation:

$$\text{Anthocyanin content}(\mu g/g,\ \text{dry matter}) = (A530 - 0.33 \times A567) \times V \times DF/W$$

where V = volume of sample, DF = dilution factor, W = sample weight (g).

2.9. Preparation of the methanolic and ethanolic extracts

Twenty grammes of powder from each sample were extracted with 200 ml of methanol or ethanol, stirred on a stirring plate at room temperature for 24 h, and then filtered through #1 filter paper (Whatman Inc., Hillsboro, OR). The filtrate was concentrated *in vacuo* to dryness to obtain methanolic or ethanolic extract. The dried filtrates were weighed to determine the extraction ratio of soluble constituents.

$$\text{Extraction ratio}\ (\%) = \text{dried filtrate weight}(g)/\text{sample weight}(g, \text{dry mass}) \times 100\%$$

The methanolic or ethanolic extract was then stored at −20 °C to determine the scavenging effect on the α,α-diphenyl-β-picrylhydrazyl (DPPH) radicals. The methanolic extract was also used to determine the total phenolic compound and mitogen responses of spleen lymphocytes.

2.10. Determination of the scavenging effect on DPPH radicals

The experimental method in this study was that of Kuo et al. (2002). A 400 μM solution of DPPH was prepared in 100% methanol. Instead of reading samples spectrophotometrically, the assay was performed in a microplate. 50 μl of sample (methanolic or ethanolic extract, final concentration 0–3000 μg/ml) and 150 μl of DPPH· solution were added to a well in a 96-well flat-bottom EIA microtitration plate. After thorough mixing, the solutions were kept in the dark for 90 min. The absorbency of the samples was measured using an Optimax automated microplate reader (Molecular Devices, CA) at 517 nm against methanol without DPPH· as the blank reference. Each sample was tested four times and the values were averaged. For the determination of EC_{50} (which is the efficient concentration of antioxidant, defined as 50% of the initial DPPH concentration), each sample was measured at more than five different concentrations in the DPPH· test. EC_{50} was obtained by interpolation from linear regression analysis (Fig. 1).

2.11. Total phenolic compounds

Total phenolic compounds were measured with Folin–Ciocalteu reagent, using catechin as a standard (Maillard, Soum, Boivin, & Berset, 1996). 5 ml of Folin–Ciocalteu reagent (diluted tenfold in distiled water), 2 ml of 200 g/l sodium bicarbonate solution, and 2 ml of distiled water were added to 1 ml of the raw methanolic extract of sweet potato samples. After 1 h at 20 °C, the absorbance at 755 nm was read.

2.12. MTT colorimetric assay for detecting mitogen responses of spleen lymphocytes

The experimental method in this study was that of Kuo (2001). Eight to twelve week-old male BALB/c mice were used as spleen

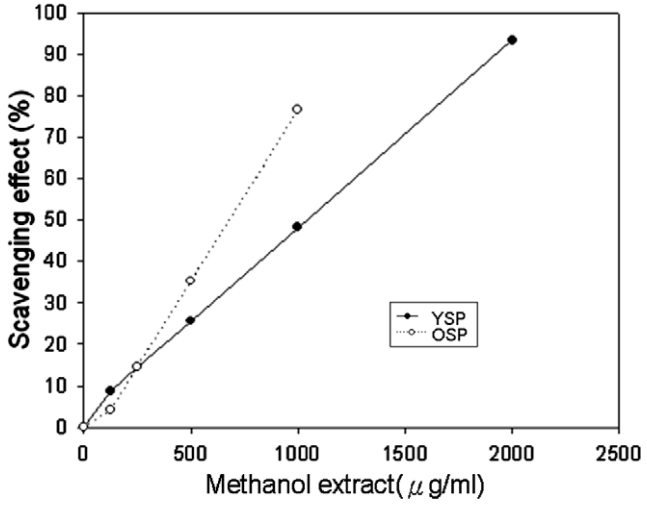

Fig. 1. EC_{50} of the methanolic extracts of two cultivars of raw sweet potato in scavenging effect on DPPH radicals. (YSP: yellow sweet potato; Tainong 57; OSP: orange sweet potato, Tainong 66).

donors. Mice were sacrificed by cervical dislocation. The spleen was removed aseptically and washed 3 times by RPMI-1640 medium. The spleen was gently teased into a single cell suspension with toothed forceps. The cell suspension was filtered with a nylon mesh screen (53 mesh). The murine spleen cells were put into a 96-well microplate and were adjusted to a concentration of 2×10^6 cells/ml in RPMI-1640 medium with 10% FCS, 1 μg/ml mitogen Con A and various concentrations (0–200 μg/ml) of test samples in a total volume 200 μl, then cultured in 5% CO_2 at 37 °C for 72 h. Following this initial incubation, 25 μl of MTT solution (5 mg/ml) were added to all wells and incubated at 37 °C for 4 h, and 100 μl of lysis buffer were then applied to each well and incubated at 37 °C overnight (about 16 h) to dissolve the dark blue crystals. The absorption of formazan solution at 570 nm was then measured using an Optimax automated microplate reader (Molecular Devices, CA). Index of mitogenic response was the absorbance percentage of control. Each sample was tested four times and the values were averaged.

2.13. Statistical analysis

Data were analysed by analysis of variance (ANOVA), using general linear model, or by the *t*-test model. Duncan's multiple range tests was used to determine the differences amongst samples. Significant levels were defined as probabilities of 0.05 or less. All processing treatments were done in triplicate.

3. Results and discussion

3.1. Change of colour

The *L*, *a*, *b*, Δ*E*, chroma (saturation) and hue values of sweet potato chips were compared (Table 1). The results showed that the colour change was greater between the two drying methods for yellow sweet potatoes than for orange sweet potatoes. For yellow sweet potatoes (YSP, Tainong 57), the *a* value, *b* value, hue and chroma were significantly different between two drying methods. For orange sweet potatoes (OSP, Tainong 66), only the *L* value was significantly different between the two drying methods. According to the results for yellow sweet potatoes, the colour of hot air-dried samples was yellowish orange whereas the colour of freeze-dried samples was yellowish green, and the colour of the former was more saturated (intensive) than was the latter. For orange sweet potatoes, the hot air-dried samples were darker than were freeze-dried samples.

3.2. WSI value and dietary fibre

Water solubility index (WSI) and content of dietary fibre (insoluble dietary fibre and soluble dietary fibre) of the sweet potato samples are shown in Table 2. The WSI values of the sweet potato samples were significantly different amongst the freeze-dried, hot air-dried and extruded samples for both cultivars of sweet potatoes. No differences were found in the contents of dietary fibre in terms of the insoluble dietary fibre (IDF), soluble dietary fibre (SDF), and total dietary fibre (TDF) between the hot air-dried and freeze-dried samples. The soluble dietary fibre (SDF) and total dietary fibre (TDF) of the extrudate of orange sweet potatoes (OSP–EXT, Tainong 66) were significantly higher than those of the hot air- and freeze-dried samples. The content of dietary fibre after extrusion cooking was either increased, decreased or unchanged, depending on the raw material condition and parameter of extrusion. Fornal, Soral-Smietana, Smietana, and Szpendowski (1987) investigated the chemical characteristic changes of an extruded mixture of buckwheat, barley and corn starch and found that the dietary fibre content decreased after extrusion. Shih and Chiang (1992) and Artz, Warren, and Villota (1990) investigated the chemical characteristic changes of an extruded mixture of corn and soy milk residue and corn fibre/corn starch blend, and found that the dietary fibre contents were similar before and after extrusion. Rinaldi, Ng, and Bennink (1999) used wet okara, combined with soft wheat flour, to produce two different formulations (33.3% and 40% okara) and extruded using four combinations of two screw configurations and two temperature profiles. Extrusion of the formulations resulted in decreased insoluble fibre (< = 25.5%) and increased soluble fibre (< = 150%) contents of the extrudate.

In general, the WSI value is related to the degradation of the starch (Gomez & Aquilera, 1984). The higher the WSI after processing, the higher is the soluble material, and the more severe is the starch decomposition. According to the results in Table 2, the hot air-drying and extrusion process significantly increased the decomposition of starch. The results also showed that the orange sweet potatoes (OSP, Tainong 66) had higher WSI value than had the yellow sweet potatoes (YSP, Tainong 57), regardless of the processing methods. But the delta WSI values between hot air- and freeze-dried samples (WSI value of hot air-dried sample minus WSI value of freeze-dried sample) of these two cultivars of sweet potatoes were similar (3.3 for the YSP and 3.7 for the OSP). Meanwhile, the delta WSI values between extruded and hot air-dried samples (WSI value of extrusion sample minus WSI value of hot air-dried sample) of these two cultivars of sweet potatoes were similar (26.6 for the YSP and 25.5 for the OSP). These values imply that the decompositions of starch during hot air-drying and extrusion were similar for these two sweet potatoes.

According to the correlation analysis, the WSI value was significantly ($p < 0.05$) positively correlated with soluble dietary fibre

Table 1

** WSI: water solubility index, referred to dry weight sample (db).
*** IDF as insoluble dietary fibre; SDF as soluble dietary fibre; TDF as total dietary fibre, and TDF = IDF + SDF, all these values referred to dry weight sample (db).
[a–d] Within a column, results followed by the same letter do not differ at the 5% level by Duncan's multiple range test ($n = 3$).

(SDF) (r = 0.8521) and total dietary fibre (TDF) (r = 0.8560). This means that the increase of SDF may, in part, contribute to the increase of the WSI of the extruded products in our study.

3.3. Antioxidant components

Antioxidant components (total phenolic compounds (from the methanolic extract), β-carotene and anthocyanin) of sweet potato samples with different treatments are shown in Table 3. The total phenolic compounds of freeze-dried samples of orange sweet potatoes (OSP–FD, Tainong 66) were higher than those of yellow sweet potatoes (YSP–FD, Tainong 57). However, the effects of the drying process on the total phenolic compounds for these two cultivars of sweet potatoes were significantly different. There was almost no difference in the total phenolic compounds of yellow sweet potatoes (YSP, Tainong 57) between freeze-dried and hot air-dried samples, but there was a significant difference for the orange sweet potatoes (OSP, Tainong 66) between the two different drying treatments. The drying process could cause damage of cell structures of tubers and allowed easier extraction of antioxidant components from the tuber itself or those from the diffusing to the tuber, which increased the phenolic compounds of air-dried samples (Huang et al., 2006). Hot air-drying may also decrease the phenolic compounds of marionberries, strawberries and corn grown by conventional, organic, or sustainable agricultural practises compared with freezing and freeze-drying (Asami, Hong, Barrett, & Mitchell, 2003). In general, air-drying at temperatures >60 °C is regarded as unfavourable, due to the possibility of inducing oxidative condensation or decomposition of thermolabile compounds, such as (+)-catechin. Since the phenolic content of the two sweet potato hot air-dried samples (YSP–AD and OSP–AD) showed opposite results, this showed that the distributions of phenolic compounds between these two colours of sweet potato may be different.

For both sweet potatoes the phenolic contents of the extrudate were higher than that of the freeze-dried sweet potatoes. The effects of extrusion on the amount and activity of antioxidants contained in food have so far been only sporadically studied. A more thorough study has been carried out by Zieliński, Kozłowska, and Lewczuk (2001) and has revealed that the ferulic acid content may increase by three times due to extrusion. Gumul and Korus (2006) studied extruded rye and found, irrespective of rye cultivar and the parameters of processing, that the ferulic acid and diferulic acid contents increased two times, and the *p*-coumaric acid content increased by 70% due to extrusion. The increase in the levels of phenolic acids (particularly ferulic acid) after extrusion can be attributed to the release of the acid and its derivatives from the cell walls of the plant matter.

The β-carotene content in orange sweet potatoes (OSP, Tainong 66) is greater than that in yellow sweet potatoes (YSP, Tainong 57) (Table 3). For both of the sweet potatoes, the β-carotene contents of hot air-dried (YSP–AD and OSP–AD) and extruded samples (YSP–EXT and OSP–EXT) were significantly lower than that of freeze-dried samples (YSP–FD and OSP–FD) (Table 3). This indicates that the hot air-drying and extrusion treatments had greater impacts, than did freeze-drying, on the decrease of β-carotene content of sweet potatoes. There is general agreement that, amongst the several ways of processing foods, drying and dehydration involve the highest carotenoid losses (Arya, Natesan, Parihar, & Viijayaraghavan, 1979). Decaying affects colour, nutritive value, texture and flavour of vegetables during dehydration and storage. Pinheiro-Santana, Stringheta, Brandao, Paez, and Queiroz (1998) analysed the influence of dehydration and different preparation methods, during home-processing, related to α-carotene, β-carotene and total carotenoid stabilities in carrots and found that dehydration promoted the greatest degradation of all three. Marty and Berset (1988) found that extrusion cooking caused degradation of all-trans-beta -carotene.

Orange sweet potatoes (OSP, Tainong 66) have a higher content of anthocyanins than have yellow sweet potatoes (YSP, Tainong 57) (Table 3). However, there were no significant differences in the contents of anthocyanin amongst the extruded, hot air-dried and freeze-dried samples of yellowish sweet potatoes (YSP, Tainong 57). In contrast, the anthocyanin content of the extruded product of orange sweet potatoes (OSP, Tainong 66) was significantly lower than those of the hot air- and freeze-dried samples (Table 3). Lohachoompol, Srzednicki, and Craske (2004) examined the effect of cabinet drying on the anthocyanin content of blueberries (*Vaccinium corymbosum* L.) and found a 49% loss after drying. Sugawara (2001) used extrusion as a sterilization treatment to examine the change of sweet potatoes under various conditions and found that the anthocyanin count in the product was decreased by extrusion treatment. However, for the genotypes of sweet potatoes with low anthocyanin contents in our study, hot air-drying and extrusion treatments showed little effect except on the extruded product of orange sweet potatoes (OSP, Tainong 66).

3.4. The scavenging effect on DPPH radicals

Antioxidative activities of sweet potato samples with different treatments are shown in Table 4. The results showed that, for freeze-dried samples, the extraction ratio of methanolic and ethanolic extracts of the orange sweet potato (OSP–FD, Tainong 66) was higher than that of the yellowish sweet potato (YSP–FD, Tainong

Table 3
Antioxidant components of different sweet potato samples.

Sample*	Total phenolic compound** (mg equiv catechin/g db)	β-Carotene (μg/g db)	Anthocyanin (μg/g db)
YSP–FD	6.38[d]	9.7[d]	3.6[b]
YSP–AD	6.45[d]	7.5[d]	2.5[b]
YSP–EXT	8.18[c]	4.3[e]	2.0[b]
OSP–FD	10.9[b]	83.3[a]	8.5[a]

** Extraction ratio: dried filtrate weight (g)/total sample weight (g, dry mass) × 100%, all these values referred to dry weight sample.
*** EC_{50} (μg/ml): the efficient concentration of antioxidant decreasing initial DPPH· concentration by 50%.
[a–e] Within a column, results followed by the same letter do not differ at the 5% level by Duncan's multiple range test (n = 3).

57). The extrusion treatments showed the same results. However, the effects of the hot air-drying on the extraction ratio of methanolic and ethanolic extracts are quite different between these two cultivars of sweet potatoes. The extraction ratio of the methanolic extract of the yellow sweet potatoes (YSP, Tainong 57) was decreased after hot air-drying. On the other hand, the extraction ratio of the ethanolic extract of the orange sweet potatoes (OSP, Tainong 66) was increased after hot air-drying. In contrast, the extraction ratio of the methanolic extract of the orange sweet potatoes (OSP, Tainong 66) and the extraction ratio of ethanolic extract of the yellow sweet potatoes (YSP, Tainong 57) were not significantly different before and after hot air-drying. However, extrusion treatment will significantly increase the extraction ratio, no matter whether it is the methanolic or ethanolic extract.

Fig. 1 shows that the scavenging effect on DPPH radicals of the methanolic extract of the orange sweet potatoes (OSP–FD, Tainong 66) was higher than that of the yellow sweet potatoes (YSP–FD, Tainong 57) for freeze-dried samples. However, after hot air-drying, the scavenging effect on DPPH radicals of the yellow sweet potatoes (YSP–AD, Tainong 57) was significantly increased, but was decreased for the orange sweet potatoes (OSP–AD, Tainong 66) (Table 4). Hayase and Kato (1984) reported that a 70% methanol extract solution of sweet potatoes had the highest antioxidative activity amongst three different solvents –70% methanol, ethyl ether and hexane. Our study revealed that the antioxidative activity of the methanolic extract solution was higher than that of the ethanolic extract, as indicated in Table 4. Masuda et al. (2002) examined 36 edible and medicinal plant species from the Okinawa region of Japan and showed that ethanolic extracts from sweet potatoes had strong protective effects against oxidative cell death. Hayase and Kato (1984) observed the same antioxidative effect between sweet potatoes, Kintoki and Kokei No. 14, in another experiment. Oki et al. (2002) found that red sweet potatoes were radical scavengers. However, in our study, the antioxidative effect is significantly different between the two chosen colours of sweet potatoes. Therefore, the change of antioxidative activity during hot air-drying may be dependent on the types of sweet potatoes being chosen.

The extrusion process will significantly increase the scavenging effect on DPPH radicals for both sweet potato samples.

From the values of the scavenging effect on DPPH radicals, it was concluded that the hot air-dried samples of the yellow sweet potatoes (YSP–AD, Tainong 57) had higher antioxidative activity than had the freeze-dried samples (YSP–FD). This may be attributed to the browning reaction induced by the hot air-drying process. Since the browning reaction may produce the antioxidative activity, as reported by Bressa, Tesson, Rdsa, Sensidoni, and Tubaro (1996), other studies have demonstrated that thermal processing may increase the antioxidant activity of tomatoes (Dewanto, Wu, Adom, & Liu, 2002), sweet corn (Dewanto, Wu, & Liu, 2002) and sweet potatoes (Huang et al., 2006). In the study of Zieliński and Troszyńska (2000), the antioxidant activity of rye extrudates was substantially higher than that of raw grain. Similar conclusions were reached by Baublis, Clydesdale, and Decker (2000) and Miller, Rigelhof, Marguart, Prakash, and Kanter (2000), who found that extracts from extruded cereal grain or cereal bran exhibited a greater antioxidant activity than did those from unprocessed grain or bran.

As shown by another study (Zieliński & Troszyńska, 2000), the antioxidant activity of rye grain increased after extrusion. An earlier study, carried out by Grela, Jensen, and Jakobsen (1999), suggested that extrusion lowers the levels of natural antioxidants, as well as tocopherols and carotenoids, in plant material. Other investigations provided evidence to the contrary, indicating that extrusion may positively influence the phenolic content of cereals (Baublis, Lu, Clydesdale, & Decker, 2000; Baublis et al., 2000; Zieliński & Troszyńska, 2000; Zieliński et al., 2001).

It is well known that the amounts of phenolic compounds, β-carotene, and anthocyanin may affect the antioxidative activity of food. Hayase and Kato (1984) isolated six phenolic compounds from sweet potatoes by HPLC and concluded that the effective antioxidative activity of a sweet potato extract was mainly due to the synergistic effect of phenolic compounds with amino acids. Zhan (1996) found sweet potato extract had high antioxidative activity resulting from the presence of phenolic acids, including chlorogenic, isochlorogenic, 4-O-caffeoylquinic and neochlorogenic acids. Philpott et al. (2004) showed that anthocyanin acts as an antioxidant *in situ* within the sweet potato storage roots. Furuta, Suda, Nishiba, and Yamakawa (1998) reported that the purple-fleshed sweet potato cultivars had a higher radical-scavenging or antioxidant activity than had those with white, yellow or orange flesh. Furthermore, anthocyanins and phenols were the major DPPH radical-scavengers in purple-fleshed sweet potatoes (Oki et al., 2002). Similar results were found by Huang et al. (2006). Although it is well known that the amounts of phenolic compounds, β-carotene, and anthocyanin may affect the antioxidative activity of food, there was no correlation ($p > 0.05$) amongst the WSI, total content of phenolic compounds, β-carotene, or anthocyanin and the scavenging effect on DPPH radicals in our study.

3.5. Mitogenic effect of the methanolic extracts of sweet potato in in vitro murine splenocyte cultures

A methanolic extract is usually used for immunomodulatory activity research. Therefore, in this study the methanolic extract was selected to evaluate the immunomodulatory activity of sweet potatoes. The lectin concanavalin A (Con A) has been used extensively as a T-cell-specific mitogen and Con A-induced T-cell activation is one of the classical models for assessing materials with immunomodulatory activity. In order to determine whether the methanolic extracts of sweet potatoes had immunostimulatory effects, the mitogenic response of splenocytes from BALB/c mice was tested in *in vitro* cultures with various concentrations of the methanolic extracts of sweet potatoes. The results are shown in Fig. 2. All of the methanolic extracts from sweet potatoes increased the proliferation of Con A-stimulated splenocytes in a concentration-dependent manner. However, the methanolic extract of the yellow sweet potatoes (YSP, Tainong 57) had greater capacity to increase

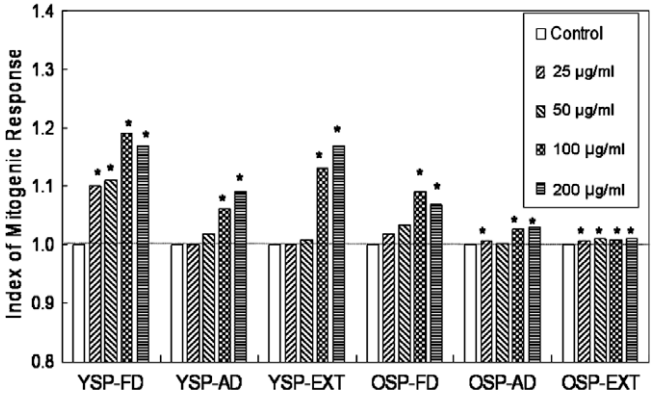

Fig. 2. Effect of the methanolic extracts from sweet potato on T-lymphocyte transformation assay. T-lymphocyte transformation was measured by mitogen Con A-induced proliferation of splenocytes from BLAB/c mice. Murine splenocytes were cultured in 96 well microtitre plates (3.6×10^5/ml), in the presence of Con A (1 μg/ml) and various concentration of test samples for 72 h. Mitogenic response was measured by the MTT colorimetric assay. Index of mitogenic response was indicated as absorbance percentage of control. ($n = 4$) ($^*p < 0.05$). YSP: yellow sweet potato (Tainong 57); OSP: orange sweet potato (Tainong 66); AD: sweet potato treated with 0.5% sodium bisulfite before hot air-drying; FD: freeze-dried sweet potato and no sodium bisulfite treated; EXT: extrusion treatment.

the mitogenic response than had that of the orange sweet potatoes (OSP, Tainong 66), in lower concentrations (25–50 μg/ml) for freeze-dried samples. In addition, the methanolic extract from freeze-dried sweet potatoes seems to preserve the most immunostimulatory constituents because of the highest mitogenic index as compared to that of samples prepared from hot air-drying and extrusion processing, for both yellow (YSP, Tainong 57) and orange (OSP, Tainong 66) sweet potatoes. However, all freeze-dried, hot air-dried and extruded sweet potato samples exhibit great ability in the proliferation of lymphocytes when stimulated with mitogen Con A. This suggests that these agents selectively promote T-cell-dependent proliferative activity. According to the study of Huang et al. (2004), the water extract of sweet potatoes showed the second highest antiproliferation activity amongst the storage roots used by human lymphoma N84 cells and some activity may be contributed by trypsin inhibitor (Huang, Sheu, Chen, Chang, & Lin, 2007). Chen et al. (2005) studied the immunological effects of physiological doses of purple sweet potato leaves and found that consumption of purple sweet potato leaves modulates various immune functions, including increased proliferation responsiveness of PBMC, secretion of cytokines IL-2 and IL-4, and the lytic activity of NK cells.

The T-lymphocyte is responsible for propagating both humoral and cell-mediated immunity via proliferation and subsequent secretion of a plethora of lymphokines, including interleukin-2 (IL-2), IL-4, IL-5 and IL-6. Several studies have used the *in vitro* murine splenocyte cultures method in food or its components, such as the adlay seed (Kuo, 2001; Kuo et al., 2001), EPA and DHA (Jolly, Jiang, Chapkin, & McMurray, 1997), whey protein (Hwang & Bowen, 2004) and bifidobacteria cells (Kado-Oka, Fujiwara, & Hirota, 1991). Because the aging process is associated with deterioration of the responsiveness of the immune system, several studies have reported a decline in T-cell-mediated immunity, including a compromised ability to proliferate in response to T-cell mitogens in laboratory animals. Thus, this study supported the idea that sweet potatoes may benefit elderly people and act as anti-aging immunomodulators.

It is believed that beta-carotene (Albanes, Heinonen, & Taylor, 1996), anthocyanins (Konczak-Islam, Yoshimoto, Hou, Terahara, & Yamakawa, 2003) and phenolic compounds (Kampa et al., 2004) have antiproliferative activity. Konczak-Islam et al. (2003) found that aqueous extracts of an anthocyanin-producing sweet potato line exhibited higher potency (antiproliferative and antimutagenic potential) than did extract from field-grown crops. The responsible determinants of sweet potatoes remain to be elucidated, as does the biological significance of the present observations.

Inhibitors

ABSTRACT

High performance liquid chromatography (HPLC) was used to characterise phenolic profile and to select the most effective anti-browning compound(s) on fresh lettuce. Four anti-browning agents, ascorbic acid, cysteine, citric acid and oxalic acid were tested for their effectiveness on preventing loss of phenolic compounds in lettuce during processing and storage. Aliquots of the reaction mixture were withdrawn at different times varying from 0 to 24 h, and directly analysed by HPLC. Protocatechuic acid, chlorogenic acid, ferulic acid, caffeic acid, *p*-coumaric acid and phloridzin were identified in fresh lettuce. Degradation of phenolic compounds followed a first-order kinetic pattern. The effect of anti-browning agents on first-order degradation rates of phenolic compounds was determined. Lettuce treated with oxalic acid and ascorbic acid maintained a higher level of phenolic compounds than citric acid and cysteine. Interestingly, cysteine had no positive effect for the prevention of oxidation of phenolic compounds even though it prevented browning in lettuce.

1. Introduction

Minimally processed lettuce has become an important area of potential growth in the rapidly expanding fresh-cut produce industry because of its fresh-like character and convenience. A major challenge faced by the produce industry is to manipulate the quality of fresh-cut produce so that the shelf-life is long enough to ensure efficient marketing (Gonzalez-Aguilar et al., 2005). Fresh-cut produce deteriorates faster than intact produce because of internal and external browning of the cut surface. Browning detracts from the appearance of the slices and reduces their marketability. Physical damage during the peeling and cutting process also causes an increase in respiration rates, biochemical changes and microbial spoilage, which often result in degradation of colour, texture, nutrient and flavour of the produce (Buta, Moline, Spaulding, & Wang, 1999).

Phenolic compounds are plant secondary metabolites synthesised mostly through the phenylproponaid pathway and are involved in the defence of plants against invading pathogens. Therefore, they are widely distributed in plant-derived foods significantly affecting their stability, colour, flavour, taste, nutritional and aesthetic value. In fact, plant secondary metabolites account for most antioxidant properties (Pati, Losito, Palmisano, & Zambonin, 2006). Today, it is believed that regular consumption of dietary antioxidants may reduce the risk of several diseases. Among natural antioxidants, plant polyphenols play a very important role. Most of the beneficial health effects of flavonoids are attributed to their antioxidant and chelating abilities; the protective effects can be ascribed to their capacity to transfer electron-free radicals, chelate metal catalysts, activate antioxidant enzymes, reduce α-tocopherol radicals and inhibit oxidases (Heimler, Isolani, Vignolini, Tombelli, & Romani, 2007).

Being deprived of their natural protecting matrices, the phenolic compounds are exposed to oxygen during processing and may therefore be oxidised to quinones. Various classes of phenolic compounds, showing a great diversity of structures such as catechins, hydroxycinnamic acid derivatives and anthocyanins have been found to contribute to non-enzymatic and enzymatic browning of foods (Pati et al., 2006).

Basically, enzymatic browning can be defined as an initial enzymatic oxidation of phenolic compounds into slightly coloured *o*-quinones, catalysed by polyphenol oxidase (PPO). Although PPOs are localised in plastids, their phenolic substrates are mainly located in the vacuole so that enzymatic browning only occurs when this sub-cellular compartmentation is lost (Rigal, Gauillard, & Richard-Forget, 2000).

Various approaches to control the extent of browning have been investigated. In general, enzymatic browning can be avoided by thermal inactivation of PPO, but heat can cause unwanted softening of the tissues. Instead of blanching, chemical additives have been used to prevent enzymatic browning (Tortoe, Orchard, & Beezer, 2006). Reducing agents, antioxidants, and enzymatic inhibitors prevent browning by chemically reducing the *o*-quinones to

colourless diphenols. Acidulants, such as citric, oxalic, malic, or phosphoric acid, can also inhibit PPO activity by reducing pH and/or chelating copper in a food product (Ibrahim, Osman, Saari, & Abdul-Rahman, 2004).

In agricultural products, phenolic compounds and PPO may react more or less during processing or storage resulting in a decrease of phenolic content. Phenolic compounds have a significant role in oxidation processes as antioxidants and as substrates in browning reactions (Robards, Prenzler, Tucker, Swatsitang, & Slover, 1999). In both roles, the key process is oxidation. Anti-browning agents were used to prevent or delay oxidation in different ways, but their effect on the phenol profile of fresh-cut produce is unclear. In this work, high-performance liquid chromatography (HPLC) has been used to investigate how various inhibitors influence the polyphenol profile of lettuce during enzymatic oxidation processes.

2. Material and methods

2.1. Material

Lettuce was obtained from a local market in Ankara. Oxalic acid (OA), ascorbic acid (AA) and cysteine were purchased from Merck, and citric acid (CA) from Carlo Erba. Caffeic acid, chlorogenic acid and gallic acid were purchased from Acros. Protocatechuic acid, chlorogenic acid, ferulic acid and caffeic acid were obtained from Sigma.

2.2. HPLC analysis of phenolic compounds in lettuce

Three grams of lettuce were homogenised in 9 ml of distilled water, AA (0.5%), cysteine (0.05%), CA (0.5%) and OA (0.5%) solutions, respectively. Aliquots were taken from the slurry at 0, 0.25, 0.5, 1, 2, 4, 6 and 24 h. The slurry was centrifuged at 15,000 g for 15 min. The supernatant was used for HPLC analysis.

Chromatographic analyses were performed on an Agilent 1200 HPLC system consisting of a photodiode array detector, quaternary pump, autosampler and column oven. Phenolic compounds were separated on a Waters Atlantis C18 column (250 mm × 4.6 mm, 5 μm) using a linear gradient elution programme with a mobile phase containing solvent A (formic acid/H_2O, 1:99, v/v) and solvent B (methanol) at a flow rate of 0.8 ml/min. The solvent gradient was programmed as follows: linear gradient elution from 10% B to 60% B, 0–15 min; isocratic elution of 60% B, 15–20 min; linear gradient elution from 60% B to 10% B, 20–25 min; isocratic elution of 10% B, 25–30 min. The chromatograms were recorded at 280 nm by monitoring spectra within a wavelength range of 190–400 nm. Identification of phenolic acids was accomplished by comparing the retention time and absorption spectra of peaks in samples to those of standard compounds. The quantitation of phenolic compounds was based on calibration curves built for each of the compounds identified in the samples.

3. Results and discussion

The profile of phenolic compounds in fresh lettuce extract was determined by HPLC analysis. Relative changes in the concentration of individual phenolic compounds in lettuce with time as influenced by the addition of 0.5% AA, 0.05% cysteine, 0.5% CA and 0.5% OA at 25 °C were compared to that of the control. Protocatechuic acid, chlorogenic acid, caffeic acid, *p*-coumaric acid, ferulic acid and phloridzin were identified by matching the retention time of the compounds determined in the lettuce extract to those of pure standards (Fig. 1). The chemical structures of the peaks identified in the lettuce extract were further confirmed by comparing their UV spectra to those of pure standards.

As a result of enzymatic oxidation, a sharp decrease in the concentration of phenolic compounds was observed in the control lettuce. Loss of individual phenolic compounds identified in lettuce was expressed in terms of the first order degradation rate constant (k). The results are summarised in Table 1. The results are in agreement with the results obtained by others (Nourian, Ramaswamy, & Kushalappa, 2003). Phenolic compounds and PPO originally exist separately in different organelles in plant cells. When the plant is damaged, phenolic compounds and PPO come into contact and react and parts of the phenolic compounds are isomerized (Rigal et al., 2000).

Adding of anti-browning agents is one of the typical methods used to inhibit the browning reactions. Treatments with AA, cysteine, CA and OA were more effective in delaying polyphenol oxidation in lettuce during storage. Fig. 2 illustrates relative changes in chlorogenic acid concentration in the presence or absence of various inhibitors. It was observed that the effectiveness of anti-browning compounds in reducing polyphenols content diminished with the length of storage (except for cysteine). These results are in agreement with our previous findings (Altunkaya & Gökmen, 2008).

3.1. Effect of ascorbic acid on lettuce enzymatic oxidation

The concentrations of phenolic compounds identified in the lettuce extract have been monitored up to 24 h in the presence of AA. Aliquots of the sample were withdrawn after 0, 1, 3, 6 and 24 h for HPLC analyses. AA showed effective protection against oxidation. Moreover, the rate of degradation of all identified phenolic compounds was decreased slowly in lettuce when 0.05% of AA was added (Table 1).

AA is an important nutrient and very likely to decompose during storage. It was reported that temperature, pH, oxygen concentration, metals (iron, copper) and light are important parameters for the destruction of AA (Jung, Kim, & Kim, 1995). Degradation of AA has been also implicated with colour changes as well as reduced nutritional quality.

AA is a reducing compound but it does not directly inhibit PPO. Following enzymatic oxidation, AA reduces the *o*-quinone formed by the enzyme to the original diphenol to limit browning through a process known as "reaction deactivation". Unfortunately, AA offers only temporary inhibition of browning (Altunkaya & Gökmen, 2008). During oxidation, it appears that AA is most likely converted to dehydroascorbic acid (DHAA) and further degraded to 2,3 diketo-gluconic acid (Gökmen, Kahraman, Demir, & Acar, 2000). AA content of lettuce treated with 0.5% AA have been previously shown to follow a similar pattern (Gonzalez-Aguilar et al., 2005).

AA acts as a protector of pigments preserving them from chemical and biochemical oxidation by competing amides and amine–carbonyl interactions that result in browning. An alternative mode of action may be suppression of free radical formation involved in the browning reaction. There is also evidence that AA has polyphenol-protective and -enhancing activities, probably due to the reduction of oxidised phenols and regeneration of polyphenols. A cooperative action between AA and polyphenols could be beneficial in enhancing the ability of the latter to rescue cells from damage induced by an oxidative stress (Gonzalez-Aguilar et al., 2005).

AA can react either with the radicals generated in chemical ways, or it can regenerate polyphenols from their oxidised forms due to its antioxidant potential. In order to obtain synergy *via* regeneration reactions between AA and phenolic compounds, these two reactions must compete efficiently with the other reactions in which AA is oxidised (Beer, Joubert, Gelderblom, & Manley, 2005). Based on standard reduction potentials, it has been predicted and confirmed by kinetic studies that ascorbate regenerates plant phenolic compounds in homogeneous solutions from their

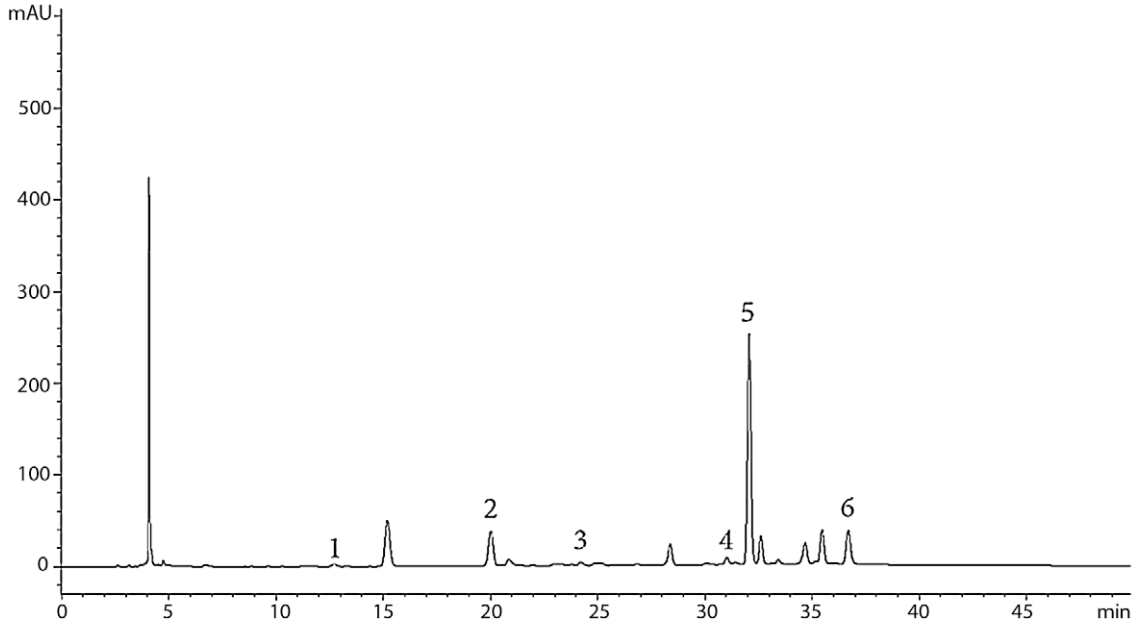

Fig. 1. HPLC profile of phenolic compounds in fresh lettuce. Peaks identified are: (1) protocatechuic acid; (2) chlorogenic acid; (3) caffeic acid; (4) *p*-coumaric acid; (5) ferulic acid; (6) phloridzin.

Table 1
First-order degradation rate constants of individual phenolic compounds identified in lettuce.

Phenolic compound	Rate constants (1/min)				
	Control	Ascorbic acid	Cysteine	Citric acid	Oxalic acid
Protocatechuic acid	0.557	0.056	0.576	0.447	0.083
Chlorogenic acid	0.333	0.036	0.667	0.434	0.055
p-Coumaric acid	0.668	0.030	0.386	0.183	0.080
Ferulic acid	0.890	0.016	0.929	0.862	0.396
Phloridzin	0.985	0.027	0.113	0.167	0.068

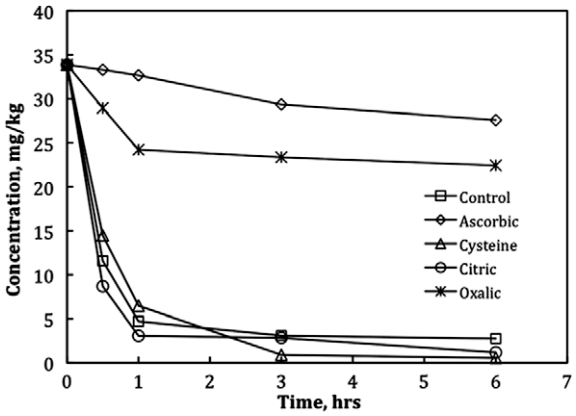

Fig. 2. Changes in chlorogenic acid concentration with time in the presence of various inhibitors (□: control, ◇: 0.5% ascorbic acid, Δ: 0.05% cysteine, ○: 0.5% citric acid, ∗: 0.5% oxalic acid).

oxidised form (Jovanovic, Steenken, Tosic, Marjanovic, & Simic, 1994). Polyphenols have a higher redox potential than ascorbate and consequently oxidise it to the ascorbyl radical (Bors, Heller, Michel, & Saran, 1990).

Lettuce also contains high levels of ascorbate oxidase activity which oxidise AA to DHAA after the lettuce is cut and exposed to oxygen. The amount of AA could be decreased during oxidation due to this reason (Yamaguchi et al., 2003). As a consequence, the assuring stability of AA during storage has been a major problem for preventing browning and phenol destruction.

3.2. Effect of cysteine on lettuce enzymatic oxidation

The concentrations of phenolic compounds were monitored in lettuce in the presence of 0.05% cysteine. It was determined that the degradation rates of individual phenolic compounds in the presence of cysteine were similar to those obtained in the control sample without anti-browning agent. It should be noted here that the lettuce sample with 0.05% of cysteine showed no enzymatic activity against catechol as determined by a spectrometer at 420 nm (data not shown).

The action of cysteine is complex. During enzymatic oxidation, it traps the *o*-quinone by forming cysteine adducts. These adducts are not substrate, but competitive inhibitors of PPO with a slightly higher affinity than their polyphenol precursors (Richard-Forget, Goupy, & Nicolas, 1992). In the presence of an excess amount of thiols such as cysteine (cysteine/phenol > 1), phenolic compounds are fully converted to their corresponding cysteine adducts, and in theory they are protected against enzymatic browning. The strong inhibition of polyphenol degradation by PPO in the presence of cysteine is explained primarily by the competitive inhibition of the enzyme, and by the secondary effect of the coupled oxidation by *o*-quinone, leading to phenol regeneration (Richard-Forget et al., 1992).

Gorny, Hess-Pierce, Cifuentes, and Kader (2002) have demonstrated that sulphites act as a reducing agent at a pH below 4. At a pH above 4, quinones form colourless adducts with sulfites, cysteine or glutathione. Nucleophilic attack of quinones by cysteine may be more effective at a neutral pH since the thiol group of cysteine has a pKa of 8.33. Because the vegetable tissue is at neutral pH values, cysteine alone is effective as an inhibitor of enzymatic browning.

A consideration of biochemical changes inside the lettuce samples may be just as important as appearance in selecting treatments to extend the shelf life of fresh-cut lettuce. It is important to mention that the concentrations of anti-browning agents that were used in the present study did not affect the sensorial characteristics of fresh-cut lettuce except for cysteine. Due to the excess amount of cysteine, lettuce samples treated with cysteine became yellow and did not turn pink.

3.3. Effect of citric acid and on lettuce enzymatic oxidation

CA was found to protect lettuce against browning. Moreover, the rate of degradation of individual phenolic compounds decreased in lettuce within 24 h of storage when 0.05% of CA was added (Table 1). Acidification of samples appeared to have an important function to stabilise phenolic compounds in lettuce.

CA has been reported extensively for its inhibitory effect on PPO, so it is recommended as a potential anti-browning agent in minimally processed fruits and vegetables (Ahvenaien, 1996). It lowers the pH and chelates the copper at the active site of the PPO. Its inhibitory effect could be related to the phenolase Cu-chelating power. Especially, at pH values below 4, the looser binding of copper at the active enzyme site causes the PPO activity to decrease further, permitting the CA to remove the copper (Ibrahim et al., 2004). The effect of CA on flavanols have been previously considered as both anti-browning and antioxidant agent (Wang, Kim, & Park, 2003). The acidification and chelating function of CA works together. Therefore, it could be correct to presume that CA has a protective effect on phenolic compounds.

3.4. Effect of oxalic acid on lettuce enzymatic oxidation

OA was found more effective than CA and cysteine in preventing browning and oxidation of individual phenolic acids in lettuce during storage (Table 1). It showed almost the same anti-browning effect as AA. OA seems to inhibit PPO by chelating copper from the active site of the enzyme since OA has a high affinity to form metal complexes with a copper ion. The extent of inhibition is influenced by both OA concentration and pH. OA has been previously shown to diminish catechol-quinone formation (Zheng et al., 2007).

OA has been reported as the most potent inhibitor among a number of dicarboxylic acids by Son and others (2001). The ability of carboxylic acids to inhibit browning depends on their chemical structure. Inhibitory effects of dicarboxylic acids decreases with increasing chain length and dissociation constants, signifying the possible role of steric interference in the interaction of the longer chains with the enzyme and of the degree of their ionisation in solution. OA has been shown to reduce the rate of phenol oxidation in the presence of hydrogen peroxide, iron and copper due to its chelating ability and lowering of pH (Kayashima & Katayama, 2002). When present in the human diet, OA may combine with essential minerals such as calcium, iron, magnesium, and potassium to form less soluble salts known as oxalates and hinder the bio-availability (Palaniswamy, Bible, & McAvoy, 2004). This fact, together with our study, suggests that treatment with OA is safe and seems to be a promising method for controlling browning in minimally processed fresh-cut lettuce.

4. Conclusion

The degradation of individual phenolic compounds during enzymatic oxidation followed a first-order kinetic model. The degradation rate constants obtained for individual phenolic compounds in the presence of cysteine and CA were found significantly higher than that of AA and OA. Higher k values indicated more rapid degradation of phenolic compounds in lettuce. AA and OA could be recommended to prevent enzymatic browning and loss of phenolic compounds.

Among the anti-browning agents tested, OA and AA had a great capability for the prevention of the degradation of phenolic compounds in fresh-cut lettuce. Hence, it appears that they have strong potential for practical applications.

Degradation rates of phenolic compounds with cysteine were almost the same as the control. It allowed permanent protection against enzymatic browning, but phenolic compounds could not be protected against oxidation using cysteine. Loss of phenolic compounds is undesirable from a nutritional point of view.

Two of the important properties of phenolic compounds involve antioxidant activity and oxidative browning. They are both good browning substrates and good antioxidants. In both systems, the potential oxidising agents are PPO and free radicals when phenolic compounds act as substrates and antioxidants (Robards et al., 1999).

Enzymatic browning in foods is reasonably well understood, but prevention of browning is not the only factor to take into account to be sure of quality. Besides the anti-browning property of inhibitors, protection of nutritional properties should be taken into consideration to maintain a fresh like quality. As a consequence, formulations including additives have to be optimised to succeed in the control of enzymatic browning and loss of the nutritional quality.

ABSTRACT

The aim of the work was to study the effects of processing on the unsaponifiable matter, sterols and fatty and triterpenic alcohol in ripe olive fat (Manzanilla and Hojiblanca cultivars) and to disclose the most influential factors using GLM, PCA and DA. There were significant effects of cultivars or ps on unsaponifiable matter, β-sitosterol, Δ^5-avenasterol, total sterols, 1-docosanol, 1-tetracosanol (ps), erythrodiol and percentage erythrodiol + uvaol. The values of most of these parameters were within the limits established by the EU Directives for olive and pomace oils but classification of the respective oils was not conclusive. Predictive discriminant analysis using these variables permitted 100% success in the classification according to cultivars and ps (68% in the case of cross validation). Results revealed that some influential steps should be re-designed, particularly the storage phase, in order to minimise changes in the studied fat components during ripe olive processing.

1. Introduction

Table olives constitute an important part of the Mediterranean diet and its world production reached a total of 1,762,000 tons in the 2005/2006 season (IOOC (International Olive Oil Council), 2007). One of the most common styles is ripe olives (California style). In brief, fruits for producing ripe olives (by alkaline oxidation) are previously preserved in an aqueous solution (brine or acidic water) and darkened throughout the year according to demand. Darkening consists of several treatments of dilute NaOH solutions and water washes (with aeration between them), immersion in a lactate or gluconate iron solution and packing in light brine (Garrido-Fernández, Fernández-Díez, & Adams, 1997). The successive treatments may affect the composition of the olives.

Apart from moisture, oil is the major component of table olives (López, Montaño, García, & Garrido, 2006). However, studies on the composition of this fat are scarce (Borzillo, Iannotta, & Ucella, 2000; Ünal & Nergiz, 2003). The unsaponifiable matter of olive oil and its components are essential for its classification into diverse categories (Directives (CEE) 2568/91 and 1989/2003); it consists of groups of components, mainly phytosterols, of recognised biological effects like cytostatic activity (Saenz, García, Ahumada, & Ruiz, 1998), blood cholesterol control (Richelle et al., 2004) or cancer prevention (Normén et al., 2001). Triterpenic compounds from "orujo" olive oil elicit vasorelaxation in aorta from spontaneously hypertensive animals (Rodríguez-Rodríguez, Perona, Herrera, & Ruiz-Gutierrez, 2006).

Sterol and alcohol profiles are used to characterise virgin olive oils and to detect the adulteration of olive oil with hazelnut oil (Vichi, Pizzale, Toffano, Bortolomeazzi, & Conte, 2001) or virgin olive oil with olive-pomace oil (Reina, White, & Jahngen, 1997).

Chemometric studies have been used for the characterisation of varietal olive oils based on their sterols and other fatty components (fatty acids, tocopherols, diacylglycerols or triacylglycerols) (Matos et al., 2007) to classify Portuguese olive oils according to the Protected Denomination of Origin (Rui Alves, Cunha, Amaral, Pereira, & Oliveira, 2005) and to discriminate between virgin olive oils from different olive varieties (Sánchez Casas, Osorio Bueno, Montaño García, & Martínez Cano, 2004). Several hazelnut cultivars have also been characterised based on their chemical, fatty acid and sterol composition (Amaral et al., 2006).

The amount of unsaponifiable matter in olive oil is about 1% (Aparicio & Harwood, 2003). In oils extracted from commercial table olives, the proportion of unsaponifiable matter ranged from 2% to 5% and the greatest proportion was found in ripe olives (López-López, Montaño, Ruíz-Méndez, & Garrido-Fernández, 2008). The cause of such a high level is unknown but it is likely that the treatments involved in their processing may affect the proportion of unsaponifiable matter and their composition (particularly sterols, fatty alcohols and triterpenic alcohols) with the subsequent loss of their physiological activities and quality. However, there is no information on these changes.

Nomenclature

DA	discriminant analysis
GC	gas chromatography
GLM	general linear model
MANOVA	multiple analysis of variance
PCA	principal component analysis
PCs	principal components
ps	processing step
PVC	polyvinyl chloride
TCL	thin layer chromatography

The aim of this work was (i) to study the changes caused by the successive processing steps in ripe olive oil, particularly in the content of unsaponifiable matter, sterols, fatty alcohols and triterpenic dialcohols, according to cultivars, (ii) to contrast the characteristics of this oil with the criteria established in the EU Directives for the classification of olive oil into categories, and (iii) to apply chemometric techniques to disclose relationships among these compounds, revealing the most influential steps and checking their potential to discriminate among processing steps and cultivars. Results from this research are useful for the identification and redesign of the most influential processing steps so that changes in olive fat and its components can be minimised.

2. Materials and methods

2.1. Cultivars

Olives were of the Hojiblanca and Manzanilla cultivars, which are the most popular cultivars for preparing ripe table olives in Spain.

2.2. Previous storage

The olives (15 kg each cultivar) were stored in 25 L PVC fermenters for six months. Initial brines consisted of an acidified solution (corrected to pH 4.2 with acetic acid) containing 9% NaCl. To compensate for salt absorption by the olives, the proportion of NaCl was raised periodically to reach equilibrium at 8% (w/v). Periodically (8 h/day) air was bubbled through the brine by means of a column introduced into the interior of the fermenters. A more detailed description of the storage system can be found elsewhere (Garrido-Fernández et al., 1997).

2.3. Darkening process

Olives were treated in a cylindrical stainless steel container with successive lye solutions of 1.5%, 1.0% and 1.0%, which progressively penetrated the flesh until the alkali reached the pit at the end of the last immersion. Between lye treatments, olives were suspended in tap water to remove the excess alkali and air was injected through the bottom of the container. When the skin was black, the washings were prolonged until the pH reached 8.0 and then a 0.1% ferrous gluconate solution with pH corrected to 4.5 was added to fix the colour. The fruits were then canned in a 3.5% NaCl solution acidified with acetic acid to pH 4.5, subjected to sterilisation for 20 min at 130 °C and cooled down to room temperature with tap water.

2.4. Equilibrium period for the packed product

Sterilised olives were stored at room temperature for 30 days to permit equilibrium to take place before cans were opened and analysed.

2.5. Fat extraction

Olives were pitted, mixed with a homogeniser Ultraturax T25 (IKA-Labortecnik, Staufen, Deutschland) and then boiling water (100 °C) was added to the paste. The resulting suspension was subjected to malaxation for 40 min at room temperature (22 °C ± 2) and the liquid was removed by centrifugation using ABENCOR equipment (Abengoa, Madrid, Spain), similar to that used for the estimation of olive oil yield in olive mills (Martínez, Muñoz, Alba, & Lanzón, 1975). The liquid phase was allowed to decant and the oil was obtained, filtered and subjected to analysis. This method was used to prevent changes in the oil quality as much as possible. During extraction, one duplicate sample corresponding to Manzanilla raw material was irreversibly lost.

2.6. Determination of the unsaponifiable fraction

The unsaponifiable matter was determined by saponification of the oil with potassium hydroxide in an ethanolic solution and extracted with diethyl ether (AENOR (Asociación Española de Normalización y Racionalización), 2001).

2.7. Determination of sterols and triterpenic dialcohols

This analysis was performed according to the method described by the Official Journal of the European Communities (European Union Commission, 1991). The lipid with added α-cholestanol and betulin as internal standards was saponified and the unsaponifiable matter was extracted as mentioned above. The bands corresponding to the sterols and triterpenic alcohol fractions were separated from the extract by TLC on a basic silica gel plate. The sterols and erythrodiol and uvaol recovered from the plate were transformed into trimethylsilyl ethers and the mixture was analysed by GC using an HP 5890 Series II gas chromatograph (Hewlett–Packard, Minnesota, USA) equipped with a flame ionisation detector and a 30 m × 0.32 mm i.d. Tracsil TRB-5 (95% dimethylpolysiloxane–5% diphenyl, film thickness 0.25 μm) capillary column (Teknokroma, Barcelona, Spain). The chromatographic conditions were: injector 300 °C, isothermal column 275 °C, and detector 300 °C. Split ratio was 1:50. Hydrogen carrier gas was used at 1.0 mL/min.

2.8. Determination of fatty alcohols

This analysis was performed according to the method described by the Official Journal of the European Communities (European Union Commission, 2002). The fatty substance, with 1-eicosanol added as internal standard, was treated as mentioned in the determination of lipid and unsaponifiable fraction section. The alcohol fraction was separated from the unsaponifiable matter by chromatography on a basic silica gel plate. The alcohols recovered from the silica gel were transformed into trimethylsilyl ethers and analysed using capillary gas chromatography. The equipment and chromatographic conditions were the same as those mentioned above

for sterols and triterpenic dialcohols, except that oven temperature was as follows: 215 °C (5 min); 3 °C/min increase to 290 °C and held for 2 min. All analyses were performed in duplicate.

2.9. Statistical analyses

Data from the previous determinations were arranged in a 28 × 20 matrix array, where rows were cases (cultivars × processing steps) and columns were variables (sterols, and fatty and triterpenic alcohols). Data were analysed first using GLM nested factorial design to estimate cultivar and processing step means as well as to detect significant differences between processing steps for each individual compounds within the cultivar.

Before being subjected to the chemometric analysis, data were standardised using the auto scale procedure, which is the most commonly used scaling technique (Kowalski & Bender, 1972). The procedure standardises a variable m according to:

$$y_{mj} = \frac{(x_{mj} - \bar{x}_m)}{s_m}$$

where y_{mj} is the value j for the variable m after scaling, x_{mj} is the value j of the variable m before scaling, $\bar{x}_m$ is the mean of the variable m and s_m is the standard deviation for the variable m. The result is a variable with zero mean and a unit standard deviation.

Standardised data were successively studied by multiple analysis of variance (MANOVA) to test overall differences between groups across the different variables, principal component analysis (PCA), and discriminant analysis (DA). PCA was carried out using a varimax rotation to detect the data structure and to determine the relationships among the different components and to derive common dimensions in order to classify the samples and to map the different population groups into these dimensions. For the selection of the number of Principal Components (PCs), the Kaiser criterion (Jolliffe, 1986) was followed and only factors with eigen values higher than 1.00 were retained. Then, the loadings of the original variables were projected onto the factorial plane formed by the first and second component.

The selection of variables containing the most powerful information for the correct classification of the olive samples from the two cultivars (Manzanilla and Hojiblanca) or the four elaboration steps for the ripe olive processing categories (raw material, storage, oxidation and packing-sterilisation) was carried out on the basis of the canonical analysis of data, using the backward stepwise analysis option, which first includes all the variables in the model and then, at each step, eliminates the variable that least contributes to membership prediction. The process continues until only the important variables that contribute most to discrimination between groups are in the model. The values of probability to enter or to remove were fixed at 0.05 and 0.10, respectively. The number of steps was fixed at 100, the minimum tolerance at 0.001 and no variable was forced to enter into any model. The scores of table olive samples were plotted on the canonical axes (discriminant coordinates, called Factors). These axes were determined in such a way that the rate of the variance between groups compared to the variance within groups is maximised (Rencher, 1995).

DA classification was achieved by means of the corresponding classification functions. For k groups, k linear combinations of variables are constructed, called classification functions. The calculation of the values of these functions for each sample makes it possible to allocate this sample to the group for which the probability of belonging is the highest. Prior probabilities were established in proportion to the number of samples in each group.

A leaving-one-out cross validation procedure was performed for assessing the performance of the classification rule. In this last step, the sample data minus one observation was used for the estimation of the classification functions and then the omitted variable was classified from them. The procedure was repeated for all samples. Consequently, each sample was classified by classification functions which were estimated without its contribution (Rencher, 1995).

The different statistical techniques used in this work were implemented using STATISTICA, release 6.0 (GLM and PCA analyses) and SYSTAT, release 10.2 (DA analysis).

3. Results and discussion

3.1. Changes in ripe olive oil components (unsaponifiable, sterols and fatty and triterpenic alcohols) due to processing step

The content in unsaponifiable matter in the oils from the different processing steps is shown in Table 1. The analysis of variance of the nested GLM showed significant differences among elaboration steps within cultivars. The initial content (raw material) was higher in Manzanilla (1.45 g/100 g oil) but, at the end (the sterilised product), it was higher in Hojiblanca (1.36 g/100 g oil). Apparently, the oxidation process had opposing effects, depending on cultivars; these changes were closely related to those observed during the storage/fermentation phase, which can be due to the activity of the microorganisms present in this step. However, average contents throughout the processing steps remained fairly constant (1.28 ± 0.04 and 1.24 ± 0.05 g/100 g oil for Hojiblanca and Manzanilla, respectively) but slightly higher than the average proportion of unsaponifiable matter found in olive oil, which is usually about 1% (Aparicio & Harwood, 2003). Apparently, this difference is due not only to the effect of the processing steps but also to cultivar (Manzanilla raw material) (Table 1).

The total content of sterols was always higher than fatty and triterpenic alcohols (Tables 2 and 3). On average, the proportion of sterols in the oil obtained from the diverse steps of ripe olive processing ranged from 1088 to 2543 mg/kg oil, which is approximately within the proportion ranges found in olive oil (Aparicio & Harwood, 2003). In the raw material, the concentrations of total sterols were higher in Hojiblanca than in Manzanilla (Table 2) whilst the levels of fatty and triterpenic alcohols were similar in both cultivars (Table 3) because the values of Manzanilla were always within the confidence limits of the Hojiblanca cultivar bearing in mind the standard error and t value for this cultivar. The concentrations of total sterols in the oils from the raw material (fresh fruits) were similar to those found by Sánchez Casas et al. (2004) in olive oils from Carrasqueña, Cacereña, Cornezuelo, Corniche, Morisca, Picual and Verdial cultivars. So, the presence of sterols in olive oil and table olive cultivars does not differ. In the raw material, the proportion of β-sitosterol was about 87% (Hojiblanca) and 84% (Manzanilla) of the total sterols and the next abundant sterol was Δ^5-avenasterol, which accounted for about 4.4% and 5.6% in Hojiblanca and Manzanilla, respectively; the concentration of campesterol was also remarkable (about 2.8% regardless of cultivar). The concentrations of β-sitosterol in the raw material oil were similar to those reported by Sánchez Casas

Table 1
Average (±standard error) unsaponifiable matter (g/100 g oil) throughout processing steps, according to cultivars.

Processing step	Hojiblanca	Manzanilla
Raw material	1.090 (0.031)	1.453 (0.086)
End storage	1.369 (0.058)	1.112 (0.109)
End oxidation	1.191 (0.062)	1.346 (0.050)
Sterilised product	1.357 (0.035)	1.140 (0.030)

Nested GLM analysis of variance showed significant differences among processing steps within cultivars ($F = 4.42$, with 6 and 20 degrees of freedom, respectively; $P = 0.005$).

[a] Data without replicates. Values are means of duplicate analyses of replicates.

et al. (2004) in the above-mentioned oils or Rui Alves et al. (2005) in oils from Portuguese cultivars. The proportion of β-sitosterol in virgin olive oils from Cornicabra had a mean of 84% (Rivera del Álamo, Fregapane, Aranda, Gómez-Alonso, & Salvador, 2004), which is similar to the values found in this work. Then, regardless of cultivars and olive destination, the most abundant phystosterol was β-sitosterol but it was 3% higher in Hojiblanca. The β-sitosterol content in the raw material was always higher than those of any food included in the phytosterol data base of fatty foods consumed in Sweden and the Netherlands (Normén et al., 2001). This fact emphasises the role played by table olives as a source of phytosterols. However, the levels Δ^5-avenasterol, on average (60.3 ± 2.9 and 42.8 ± 1.9 mg/kg oil for Hojiblanca and Manzanilla cultivars, respectively), were lower than those found by Sánchez Casas et al. (2004), Rui Alves et al. (2005) or Rivera del Álamo et al. (2004). Apparently, the levels of this compound were systematically lower in oils from cultivars devoted to table olives.

The content of cholesterol in the raw material, about 3.0 mg/kg oil, regardless of cultivar, was approximately of the same order as those found by Cañabate-Díaz et al. (2007) either in virgin olive oils or in pomace olive oils but was higher than those reported by Rivera del Álamo et al. (2004) in virgin olive oils from Cornicabra. So, cholesterol concentration in oils from table olives showed an intermediate position with respect to data found in the literature. In any case, the cholesterol contents found were lower than those reported for numerous plant oils (Behrman & Gopalan, 2005). Some compounds were not detected in the raw material (Δ^7-campesterol and Δ^7-stigmastenol) or in other samples (Δ^7-campesterol, Δ^7-stigmastenol and $\Delta^{5,24}$-stigmastadienol), a circumstance which prevented their use in the chemometric studies. The concentrations of the rest of sterols in the raw material were lower (Table 2) than the levels given for them in the above-mentioned references. This fact may be related to the table olive cultivars of this study.

Fatty alcohol contents (Table 3) in oils from the raw material were markedly lower than sterols and their overall averages were 266 and 203 mg/kg in Hojiblanca and Manzanilla cultivars, respectively. The most abundant was 1-docosanol (C22) (132 mg/kg oil in Hojiblanca, 79 mg/kg in Manzanilla), followed by 1-octacosanol (C28) and 1-hexacosanol (C26) (in Hojiblanca) or tetracosanol (C24) (in Manzanilla).

The total triterpenic alcohol content was higher in the Manzanilla raw material (54 mg/kg oil) than in Hojiblanca (39 mg/kg oil) whilst uvaol was not detected in this or in other samples, a circumstance which prevented its use in PC and DA. Levels were reversed in Hojiblanca (uvaol, 33.0 mg/kg and erythrodiol 6.3 mg/kg). The concentrations of these compounds were markedly higher than those reported by Rivera del Álamo et al. (2004) in virgin olive oils obtained from the Cornicabra cultivar during several seasons. Apparently, fat from table olive cultivars may be a better source for these compounds than that obtained from olive oil cultivars.

The processing steps produced changes in the contents of the different sterols, fatty alcohols and triterpenic alcohols, which were diverse according to cultivars (Tables 2 and 3). The overall content in sterols remained fairly constant throughout the diverse processing steps, except in the sterilised product from the Hojiblanca cultivar which showed the highest levels (Table 2), close to the values reported by Cañabate-Díaz et al. (2007) for pomace olive oil (2200–2900 mg/kg oil) and higher than the levels in virgin and refined olive oils. This behaviour was mainly due to the increase observed in β-sitosterol after the sterilisation process of Hojiblanca. However, levels of β-sitosterol in Manzanilla showed

an increase after oxidation. The trend in Δ^5-avenasterol was the opposite of that shown by β-sitosterol but similar changes were produced for this compound after packing. Table 2 shows the changes observed in the rest of the sterols.

Processing treatments produced diverse changes in fatty and triterpenic alcohols. For instance, 1-docosanol, had a marked decrease during processing regardless of cultivar and its level in the final product was always lower than in fresh fruits. On the contrary, the erythrodiol content increased with processing in both cultivars but always maintained higher levels in Manzanilla. The percentage of erythrodiol + uvaol showed a clear increase in Manzanilla during storage and oxidation and showed a slight decrease after sterilisation; in Hojiblanca, the level remained constant during the first three phases of elaboration but increased after sterilisation; however, Manzanilla kept higher contents in the final product. Table 3 shows the changes for other components of this group.

3.2. Comparison of ripe olive oil characteristics with the criteria established in the EU Directives for the classification of olive oil into categories

The characteristics of these oils (restricted to only those compounds determined in this work) were also compared with the parameters used to classify olive or pomace oils into categories. The comparison was carried out to identify the most influential steps on these parameters and to check the quality of the processed product oil as an approximation for the overall evaluation of the canned olives, bearing in mind that fat is the most abundant component in these fruits. The estimated percentages of cholesterol, brassicasterol, campesterol, stigmasterol, apparent β-sitosterol, Δ^7-stigmastenol, percentage of erythrodiol + uvaol, and total sterols for olives in the diverse processing steps and the final products vs. the limits established for them in the Directives (CEE) 2568/91 and 1989/2003 are shown in Table 4. The overall average and the contents in the final products of cholesterol, campesterol and stigmasterol were below such limits in both cultivars; however, the proportions of cholesterol was above its legal limit at the end of the storage period (Hojiblanca) and at the end of oxidation (Manzanilla) and the causes of these increases deserve future investigation. Initial contents of brassicasterol in Hojiblanca and Manzanilla were above the limits established for this parameter but storage and oxidation reduced its level to below limits, except in Manzanilla. The influence of these treatments should also be clarified. The level of apparent β-sitosterol (expressed by the sum of the content of β-sitosterol and another five chromatographically adjacent phystosterols) was within the limit in the final products of either cultivar but above them after storage (both cultivars) and oxidation (Manzanilla). The regulatory minimum limit established for apparent β-sitosterol is in fact an indication that the sum of the remaining sterols does not surpass 7%, thereby confirming the authenticity of the corresponding oil (Sánchez Casas et al., 2004). The percentage of erythrodiol + uvaol was always <4.5 (limit for virgin extra, virgin, refined olive oil, mixtures of virgin and refined and lampante, a classification which also depends on wax content) for Hojiblanca but was above this level for Manzanilla. The total concentration of sterols was always >1000 mg/kg oil regardless of cultivar and processing step, a circumstance that would permit its classification as virgin extra, virgin, refined olive oil, mixtures of virgin and refined olive oils and even lampante olive oil. In some cases, the samples could also be classified as crude or refined oil according to this parameter alone. However, even virgin olive oils can exceed some of the limits established by the EU. Rivera del Álamo et al. (2004) reported that the proportion of campesterol was higher than 4% in Cornicabra olive oils. As shown, processing steps affected classification variables in diverse directions which should be investigated in deeper detail. In addition, most of the components in the final product seam to be within the limits established by the EU for the classification of virgin oil and olive and pomace oils but results were not conclusive and, apparently, not representative of the actual sensations perceived by the consumer when the final product is eaten. Further research is still necessary to develop new methods for measuring such quality "on site". This research must take into account not only the fat but also its relationships with other compounds present in olives such as polyphenols, fibre, organic acids, minerals and proteins.

3.3. Chemometric study

Some of the studied variables were correlated among them. The highest correlation was found between the following pairs: β-sitosterol vs. Δ^5-avenasterol (0.79), cholesterol vs. Δ^5-campesterol (0.78) and 1-octacosanol vs. 1-hexacosanol (0.77) or 1-tetracosanol (0.74); other less correlated variables were 1-tetracosanol vs. 1-hexacosanol (0.65), Δ^5-avenasterol vs. erythrodiol (−0.63) and campesterol vs. clerosterol (−0.56). These correlations suggest that variables could be reduced to a lower number of factors which could represent most of the original variance. After subjecting data to PCA analysis, only four eigen values higher than 1.00 were obtained. Their values (and the percentage of total variance explained) were: 3.79 (27.08%), 2.94 (21.10%), 1.96 (14.03%) and 1.53 (10.74%), which accounted for a cumulative 73.06% of the

[h]Obtained as (erythrodiol + uvaol) × 100/(total sterols + erythrodiol + uvaol).

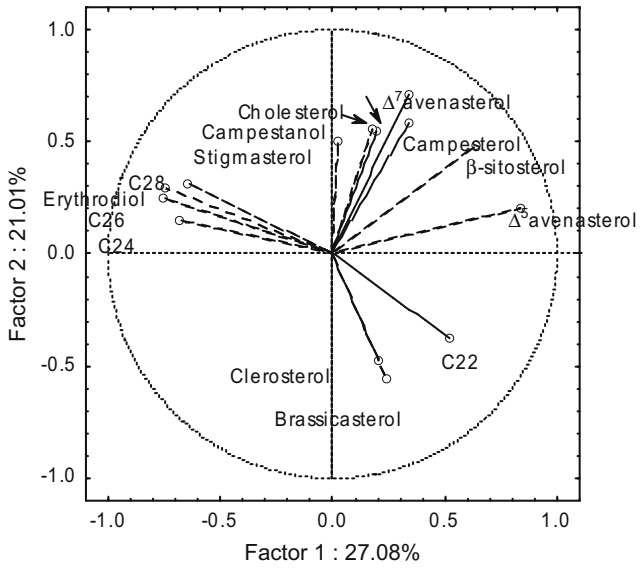

Fig. 1. Projection (loadings) of the variables subjected to chemometric analysis on the plane of the first two Principal Components.

variance. The loadings of each variable on these four principal components (PCs) can identify the main contributors to them. PC1 was mainly associated with Δ^5-avenasterol (0.84, factor variable correlation), 1-hexacosanol (−0.76), erythrodiol (−0.74), 1-octacosanol (−0.68) and 1-tetracosanol (−0.64); PC2 was related to Δ^7-avenasterol (0.71), campesterol (0.58) and brassicasterol (−0.56); PC3 was related to cholesterol (−0.59) and clerosterol (−0.54); PC4 was related to stigmasterol (−0.72) and campestanol (0.59). The projections of the loadings on the plane of the two first PCs are illustrated in Fig. 1. These projections allow for a visualisation of the position of the variables in the plane and the correlations among them and with the corresponding PCs. In this 2D graphical representation, the variables fall in a circle, called the correlation circle, with the pair of PCs as its axes. Correlations of variables and PCs can be deduced from their position with respect to the axes and the sign of the PC coordinates. Two distant variables (the angle between the corresponding variables is 90°) are not correlated because the correlation coefficient is the cosine of their angle (0, in this case) (Cichelli & Pertesana, 2004). Fig. 1 shows that clerosterol, brassicasterol and 1-docosanol (C22) are highly correlated as well as 1-tetracosanol (C24), 1-hexacosanol (C26), erythrodiol and 1-octacosanol (C28). There was, however, a high negative relationship between these two groups because they form an angle close to 180°. Stigmasterol, campestanol, cholesterol, Δ^7-avenasterol and, campesterol were strongly related but there was a low association among these and Δ^5-avenasterol. β-sitosterol was situated between these two last groups. The contribution of diverse variables to each PC (axes) can be easily deduced from Fig. 1. However, when the scores for the cases were plotted as a function of PC1 vs. PC2 no evident segregation among cases according to treatments and cultivars was observed (data not shown).

Then DA, a more powerful tool for discrimination, was used. The analysis of variance showed significant differences between cultivars and/or ps for unsaponifiable matter (ps), β-sitosterol, Δ^5-avenasterol, total sterols, 1-docosanol, 1-tetracosanol (ps), erythrodiol (ps), and percentage of erythrodiol + uvaol. The predictive DA was applied to the standardised data matrix to prevent the effect of scaling among variables. The multivariate analyses of the standardised data showed that β-sitosterol ($P = 0.01$), Δ^5-avenasterol ($P < 0.01$), 1-hexacosanol ($P = 0.024$) and erythrodiol ($P < 0.01$) showed significant differences among elaboration steps and cultivars whilst 1-docosanol ($P < 0.01$), 1-tetracosanol ($P < 0.01$) were significantly different between cultivars. Apparently data were thus appropriate for DA.

The selection of variables containing the most powerful information for the correct classification of olives was achieved by estimating the canonical discriminant functions (Table 5). The most discriminant variables among cultivars were: erythrodiol (*F* to remove, 40.64; tolerance, 0.444), β-sitosterol (34.87; 0.094), and campestanol (18.60, 0.190) as well as clerosterol, campesterol, Δ^7-avenasterol, and Δ^5-avenasterol with progressively lower *F* to remove values. The contribution of each one to discrimination can be deduced from the standardised coefficients for the variables vs. each factor (Table 6). The highest contribution was due to β-sistosterol (−2.79), followed by campestanol (1.745), and erythrodiol (1.311). Therefore, fatty alcohols did not contribute to discrimination between cultivars but mainly sterols and the triterpenic alcohol erythrodiol. The application of the classification functions led to a correct classification of all samples into the two cultivars. The validation procedure, cross classification, led to the same level of correct classifications (100%). These results are in agreement with data found in the literature; the content of sterols and the percentage of erythrodiol + uvaol in virgin olive oils have been successfully used for the classification of virgin olive oils from cultivars of Extremadura (Sánchez Casas et al., 2004). The sterol composition of monovarietal olive oils from the most important cultivars of north-eastern Portugal (Cobrançosa, Madural and Verdeal) and numerous samples of olive oils with Protected Denomination of

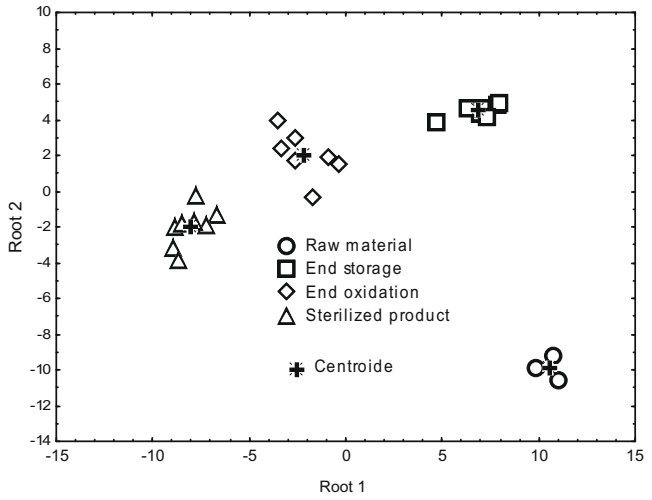

Fig. 2. Plot of the ripe olive sample scores as a function of the first two canonical discriminant functions, according to processing steps.

Origin from the same region was the base for their differentiation by chemometric methods (Rui Alves et al., 2005).

The most contributing variables for discrimination among processing steps (Table 5) were: β-sitosterol (*F* to remove, 20.11; tolerance, 0.031), Δ^5-avenasterol (16.18; 0.036), cholesterol (10.53; 0.297), 1-tetracosanol (10.16; 0.530), 1-docosanol (10.10; 0.450) and others with lower *F* values. The contribution of each variable depended on function. For Function 1, the most contributing variable was β-sitosterol (standardised coefficient, 5.179), Δ^5-avenasterol (−4.709), cholesterol (1.435) and 1-docosanol (−1.270) (Table 6). For Function 2, the most outstanding contributions were from: 1-tetracosanol (1.002), campestanol (−0.949), and cholesterol (0.536). Similarly, for Function 3 they were: erythrodiol (−1.343), β-sitosterol (−0.869), Δ^5-avenasterol (−0.753) and cholesterol (0.544). So cholesterol always had a marked effect whilst other variables contributed to specific functions: β-sitosterol to Function 1; 1-docosanol to Function 2 or erythrodiol to Function 3. Visualisation of the discrimination among elaboration steps on the plane of the first two functions led to a fairly good separation among the different groups (Fig. 2). Furthermore, the classification led to a hundred percent correct classification (Table 7). However, cross classification had a lower discriminant efficiency, mainly due to the inclusion of samples from sterilised products into those belonging to the end of oxidation and the end of storage, but its overall classification was still fairly good (68% correct). In any case, the classification must be taken with precaution due to the limitations derived from the application of the DA to a reduced number of samples. In addition, it must be emphasised that DA was mainly applied in this case to disclose possible differences introduced by processing and cultivars rather than with the aim of using the classification functions as a tool for the future assignation of new samples.

4. Conclusions

It was observed that storage increased the cholesterol content (and its proportion with respect to the other sterols) in processed Hojiblanca and Manzanilla oils, possibly due to the growth of microorganisms during this period. Modifications to the current system for preventing such changes should be studied. In Hojiblanca, β-sitosterol percentage markedly increased after sterilisation. Cultivar also had also a marked effect on the erytrodiol + uvaol levels, which was always higher in Manzanilla. At the end of the process (sterilised product), the unsaponifiable proportion (sterilised product) ranged from 1.14 to 1.36 g/100 g oil, the overall concentrations of phytosterols ranged from 1088 (Manzanilla) to 2543 (Hojiblanca) mg/kg oil, the most abundant sterol in the final product was β-sitosterol (average 947–2223 mg/kg oil), followed by Δ^5-avenasterol (average 39.2–68.1 mg/100 g oil) and the fatty alcohols were relatively scarce with total averages between 232 (Hojiblanca) and 289 (Manzanilla) mg/kg oil. Concentrations of erythrodiol were higher in Manzanilla whilst uvaol was not detected in all samples but the proportion of erythrodiol in the obtained oil significantly increased during some of the processing steps. These levels in the final product can be considered similar to those found in the literature for olive oil and for commercial table olives. In any case, after this work, it can be stated that ripe table olives are a very low cholesterol food and a good source of phytosterols.

Most of the parameters of the extracted oils were within the limits established by the EU Directives used for classification into the diverse categories of olive and pomace oils but the evaluation of the consubstantial quality of the fat in the intact table olive using this method was not conclusive. Chemometric methods were useful for disclosing relationships among variables and differences between cultivars and processing steps. PCA extracted four eigen values higher than 1 and showed the relationships among the different components on the plane of the first two components but did not properly separate the samples. However, predictive DA led to a hundred percent discrimination between cultivars and processing steps (68% for cross validation).

This work provides reference data related to the contents and changes in the unsaponifiable matter of ripe olive oil, particularly sterols and fatty and triterpenic alcohols (important biologically active compounds), during processing. It also represents a first approximation to the evaluation of the fat quality in the final product (actually eaten by consumers). In addition, the study was useful to disclose the effects of processing steps on the content and characteristics of these compounds and may help to minimise unfavourable transformations by re-designing the most influential phases.

ABSTRACT

A series of selected 4-methylcoumarins (4-methyl-2*H*-1-benzopyran-2-ones) were synthesised and tested for radical-scavenging ability using the stable 1,1-diphenyl-2-picrylhydrazyl radical, and for reducing power ability with a test based on the reduction of ferric to ferrous cation. All studied compounds showed activity comparable to Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid), an already known antioxidant, which is used as standard in most of the testing methods. Observations from the study were made with regard to structural features that regulated the behaviour of the compounds. The antioxidant activity of some 4-methylcoumarin representatives is presented here for the first time and extends our knowledge of the range of valuable biological activities and possible roles in therapy and for food preservation associated with this group of compounds.

1. Introduction

Coumarins (2*H*-1-benzopyran-2-ones) occupy an important place in the realm of natural products and synthetic organic chemistry. They have been used as anticoagulants (Cravotto, Nano, Palmisano, & Tagliapietra, 2001), additives in food and cosmetics, and in the preparations of insecticides (O'Kennedy & Zhorenes, 1997).

As substitutions can occur at any of the six available sites of their basic molecular moiety, these compounds are extremely variable in structure and activity. This structural diversity leads to coumarins displaying multiple biological properties that promote human health and help reducing the risk of diseases. Coumarins comprise a vast array of biologically active compounds ubiquitous in plants, many of which have been used in traditional medicine for thousands of years. The medicinal properties of coumarins include inhibition of platelet aggregation, cytochrome P450, and steroid 5α-reductase, spasmolytic, anticoagulant, antibacterial, anticancer, and antiHIV activities (Hoult & Paya, 1996; Kostova, 2005, 2007). A number of coumarins were found to affect the formation and scavenging of reactive oxygen species (ROS), and reactive nitrogen species (RNS), exhibiting tissue-protective antioxidant properties (Bermejo, Pinero, & Villar, 2008; Surveswaran, Cai, Corke, & Sun, 2007; Wu, Huang, Lin, Ju, & Ching, 2007), which may include numerous different molecular mechanisms and are probably related to their structural analogy with flavonoids and benzophenones. Such studies are of importance in view of the presence in the human diet of many coumarins and other plant polyphenolics, some of which are attracting interest on account of their antioxidant properties and possible roles in therapy and for food preservation (Grace, 2005). Many coumarin structures can be found in dietary products, as flavouring additives or as natural components, such as wine and other alcoholic beverages, tobacco products, citrus fruits, vegetables, bakery products and cereals (Lake, 1999; Sproll, Ruge, Andlauer, Godelmann, & Lachenmeier, 2008).

Coumarins have been essentially found in green plants belonging to the family of Rutaceae and Umbelifferae. These compounds can be obtained from plants by different extraction methods. However, the extraction from plants is a time consuming job and needs sophisticated instruments to get the pure product. Therefore, the chemical synthesis of coumarin derivatives is done to fulfil their requirements in vast applications. Chemically, coumarins can be synthesised by several synthetic routes such as Pechmann, Perkin, Knoevenagel, Reformatsky and Wittig reactions (Sethna & Shah, 1945). However, due to simple and relatively inexpensive starting materials, the Pechmann reaction was widely used for the syntheses of coumarins.

The importance of free radicals, especially ROS in the pathogenicity of various diseases, including hepatic and vascular diseases has of late received greater attention. Antioxidants are now forged as the drug candidates to combat these diseases. Minor dietary constituents have been seriously considered to counter the ill effects of the oxygen radicals. In addition, some natural coumarins also affect the formation and scavenging of ROS and influence free radical-mediated oxidative damage (Grace, 2005). Very few systematic studies have been reported on structure-antioxidant activity correlations in coumarins. In a study of superoxide scavenging

doi:10.1016/j.foodchem.2009.03.087

capacity, performed with sixteen synthetic or plant-derived coumarins with different substitution patterns, Paya found that only 7,8-dihydroxylated coumarins were active (Paya, Goodwin, De Las Heras, & Hoult, 1994). Similarly, it has been recently reported that DPPH· scavenging activity in furanocoumarins correlates with the number of phenolic hydroxyl groups present in their structures (Kogure et al., 2004; Piao et al., 2004). Tyiagi demonstrated that the amino group is an effective substitute for the hydroxyl group for antioxidant property of 4-methylcoumarins (Tyagi et al., 2005).

The purpose of this study was to compare the antioxidant activities of selected 4-methylcoumarins obtained by two different testing methods. Special attention was paid to the number and position of the functional groups attached to the benzenoid part of the coumarin molecule. We have examined 4-methylcoumarin possessing methyl-, methoxy- and hydroxy-, acetoxy-, and benzoxy-groups in the benzenoid ring. The majority of them are known as natural compounds. They have shown very good antioxidant and radical-scavenging properties, also comparable to Trolox.

2. Materials and methods

2.1. Chemicals

All applied chemicals and reagents were of the highest purity available and purchased from the Sigma–Aldrich Chemical Company.

2.2. Syntheses of 4-methylcoumarin and its derivatives

4-Methylcoumarin, and its derivatives, containing methyl-, methoxy-, and hydroxy-groups on the benzene ring of a molecule, (**2a**–**k**), were synthesised. The reaction route is given in Fig. 1. The syntheses of coumarins were carried out according to the slightly modified Pechmann method (Horning, 1955), which involves the condensation of phenols with β-keto esters in the presence of acidic condensing agents, such as concentrated sulphuric acid and anhydrous aluminium chloride. Hydroxy-derivatives of 4-methylcoumarin were acetylated and benzoylated in order to obtain the corresponding acetoxy- (**3f**–**k**) and benzoxy-derivatives (**4f**–**k**) of 4-methylcoumarin. Esterification reactions were carried out according to the slightly modified Fischer method (Fischer & Speier, 1895), involving the acetic anhydride and concentrated phosphoric acid, and benzoyl chloride in basic media.

Products were identified by determination of melting points (Kofler micro-hot stage apparatus), using elemental analysis (Perkin–Elmer 2400 CHN Analyzer), GC/MS (Hewlett–Packard GC 6890 series II and MSD 6890 series II) and NMR (Bruker DPX 300 NMR spectrometer) techniques.

2.3. Sample preparation

Stock solutions of synthesised 4-methylcoumarins were prepared in dimethyl-sulfoxide (DMSO) in concentration of 0.10 mol/l. Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) was used as a positive probe for antioxidant testing, and it was prepared in same concentration as tested coumarins.

2.4. 1,1-Diphenyl-2-picrylhydrazyl radical-scavenging activity

The ability of the 4-methylcoumarin and its derivatives to a donate hydrogen atom or electron and scavenge a 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical was determined by the slightly modified method of Brand-Williams, (Brand-Williams, Cuvelier, & Berset, 1995). The concentrations of the tested samples ranged from 0.10 to 0.0001 mol/l. A portion of the sample solution (200 μl) was mixed with 3.0 ml of 5.25×10^{-5} mol/l DPPH· in absolute ethanol. Decreasing of absorbance of tested mixtures was monitored every 1 min for 30 min at 517 nm using a Perkin–Elmer Lambda 25 UV/Vis spectrophotometer. Absolute ethanol was used to zero the spectrophotometer, DPPH· solution was used as a blank sample, and Trolox was used as a positive probe. The DPPH· solution was freshly prepared daily, stored in a flask covered with aluminium foil, and kept in the dark at 4 °C between measurements. All experiments were carried out in triplicate.

The radical-scavenging activity of the tested samples, expressed as percentage inhibition of DPPH, was calculated according to the formula IC (%) = $[(A_0 - A_t)/A_0] \times 100$ (Yen & Duh, 1994), where A_t is the absorbance value of the tested sample and A_0 is the absorbance value of blank sample, in particular time. Percent inhibition after 30 min was plotted against concentration, and the equation for the line was used to obtain the IC_{50} value. A lower IC_{50} value indicates greater antioxidant activity.

2.5. Evaluation for reducing power

The reducing power test is based on reduction of ferric to ferrous by the potent antioxidant. In presence of cyanide ions, and adding a new amount of Fe^{3+}, blue colour of $Fe_4[Fe(CN)_6]_3$ develops.

The reducing power of samples was determined by a slightly modified method (Chung, Kurisawa, Kim, & Kobayashi, 2004; Duh & Yen, 1997), as described below. Sample of 1.0 ml of various dilutions (from 0.10 to 0.001 mol/l) was mixed with 2.50 ml of phosphate buffer (0.2 mol/l, pH 6.6) and 2.50 ml of 1% potassium-ferricyanide. The mixtures were incubated at 50 °C for 20 min. After incubation 2.50 ml of 10% trichloracetic acid was added to the mixture, which was then centrifuged at 3000 rpm for 10 min. The upper layer (0.5 ml) of solution is mixed with 2.5 ml of distilled water and 100 μl of 0.1% $FeCl_3$ and the absorbance was measured at 700 nm. The control sample contained 1.0 ml distilled water, 2.50 ml of phosphate buffer, 2.50 ml of 1% potassium-ferrocyanide and 2.50 ml of 10% trichloracetic acid. The blank sample contained 1.0 ml distilled water, 2.50 ml of phosphate buffer, 2.50 ml of 1% potassium-ferricyanide and 2.50 ml of 10% trichloracetic acid. Trolox was used as positive control.

The reducing power of samples was calculated by the following formula: RP (%) = $(A_B - A_A) \times 100$; where: RP – reducing power; A_B – absorption of controlling sample (100%); A_A – absorption of tested sample. Percent inhibition was plotted against concentration, and the equation for the line was used to obtain the RP_{50} value. The lower RP_{50} value indicates greater reducing power ability. All determinations were carried out in triplicate.

3. Results and discussion

3.1. Syntheses of 4-methylcoumarin and its derivatives

The coumarins (**2a**–**k**) were synthesised by the well-known Pechmann condensation in quantitative yield. The preparation of acetoxy- and benzoxy-derivatives of hydroxy 4-methylcoumarins is based on the methodology used by Fischer and Speier (1895). The synthetic routes are outlined in Fig. 1.

Structural confirmation was done using ^{1}H NMR and EI mass spectra. The ^{1}H NMR spectra showed characteristic peaks of 4-methyl position at δ 2.22–2.47, and peaks of protons from benzenoid part of molecule at δ 6.15–7.46, for all of the synthesised compounds. Series of functional groups attached at the aromatic part of coumarin molecules revealed peaks at δ 3.30 for methyl-group (**2b–c**), δ 3.84–3.99 for methoxy-group (**2d**–**e**), δ 9.13–9.81 for hydroxy-group (**2f**–**k**), δ 2.13–2.41 for acetoxy-group (**3f**–**k**), and at δ

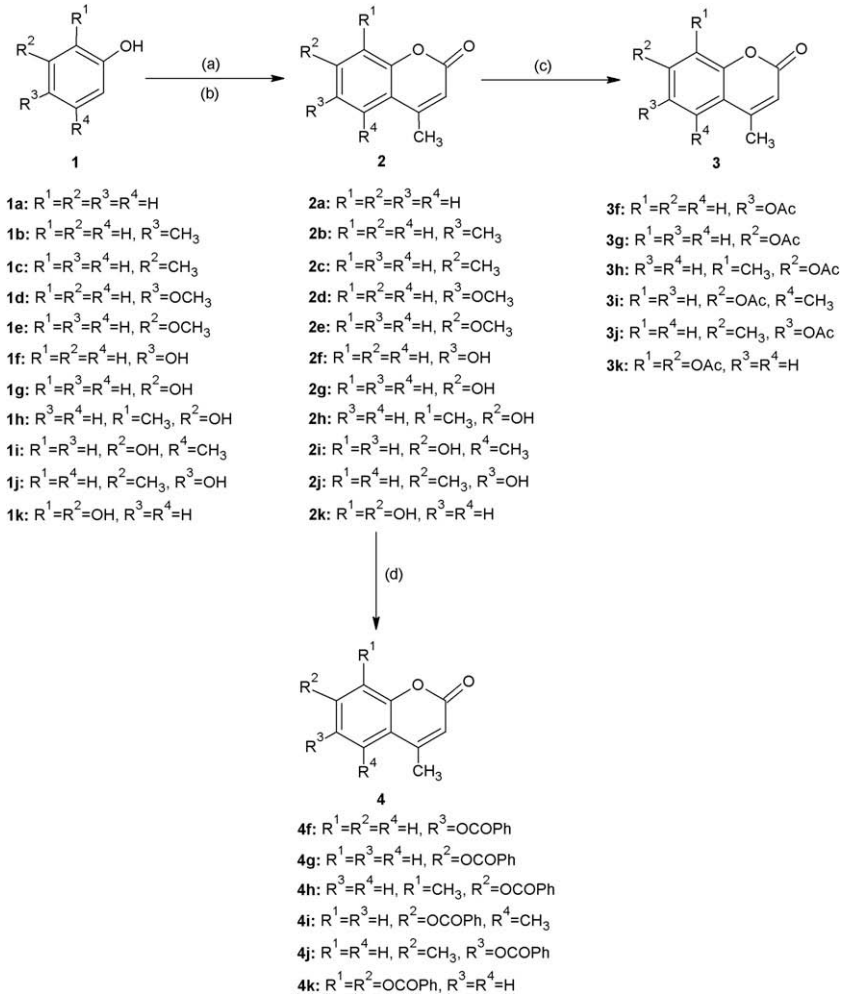

Fig. 1. Syntheses of selected 4-methylcoumarins. Reagents and conditions: (a) anhydrous aluminium chloride, nitrobenzene, ethylacetoacetate, 100–130 °C; (b) concentrated sulphuric acid, ethylacetoacetate, 0–10 °C; (c) acetic acid anhydride, concentrated phosphoric acid, 0–10 °C; (d) benzoyl chloride, 5% aqueous sodium hydroxide, 0–10 °C.

8.02–8.27 for benzoxy-group (**4f**–**k**). Finally, the structures of synthesised 4-methylcoumarins were supported by their EI mass spectra. All compounds showed characteristic molecular $[M]^+$peaks, *m*/*z* 160 (**2a**), *m*/*z* 174 (**2b**–**c**), *m*/*z* 190 (**2d**–**e**, **2h**,–**j**), *m*/*z* 176 (**2f**–**g**), *m*/*z* 192 (**2k**), *m*/*z* 218 (**3g**), *m*/*z* 232 (**3h**–**j**), *m*/*z* 276 (**3k**), *m*/*z* 280 (**4f**–**g**), *m*/*z* 294 (**4h**–**j**), and *m*/*z* 400 (**4k**). Moreover, all examined compounds revealed peaks characteristic for fragmentation of coumarin structure, such as $[M^+-CO]$, or $[M^+-CH_3]$.

3.2. 1,1-Diphenyl-2-picrylhydrazyl radical-scavenging activity

A number of methods are available for the determination of free radical-scavenging activity but the assay employing the stable 2,2-diphenyl-1-picrylhydrazyl radical (DPPH·) has received most attention owing to its ease of use and its convenience. This assay is the most widely used *in vitro* test through which to assess free radical scavenger capacities. In the DPPH· assay, the antioxidant activity of a compound is evaluated spectrophotometrically by monitoring the decrease in absorbance at 517 nm as DPPH· (purple) is transformed to the reduced form DPPH-H (yellow).

Tested coumarins were able to reduce the stable violet DPPH· to the yellow DPPH-H, reaching 50% of reduction with IC_{50} values ranking from $(1.21 \pm 1.00) \times 10^{-5}$ mol/l, for 7,8-dihydroxy-4-methylcoumarin (**2k**), to $(9.72 \pm 2.10) \times 10^{-2}$ mol/l, for 4-methylcoumarin (**2a**), (Table 1). These values are comparable to Trolox, $(1.60 \pm 0.30) \times 10^{-4}$ mol/l, whose antioxidant properties are already well known (Aliaga, Rezende, & Arenas, 2009). Fig. 2 shows the reaction progress of some selected 4-methylcoumarins at the same conditions. From the mentioned figure it can be noticed that a substituent at the benzenoid moiety of coumarin molecule has an influence on the reaction kinetic progress, besides the influence on the antioxidant activity. This is probably due to the steric and resonance effects which will be discussed in the next sections.

3.3. Evaluation for reducing power

In order to compare results given above, we tested reducing ability of 4-methylcoumarins using a spectrophotometric method for determination of ferric ion content which were reduced by tested coumarins. Assayed compounds were able to reduce the ferric (Fe^{3+}) ions to corresponding ferrous (Fe^{2+}) ions, reaching 50% of reduction with RP_{50} values ranking from $(2.23 \pm 0.30) \times 10^{-4}$ mol/l, for 7,8-dihydroxy-4-methylcoumarin (**2k**), to $(1.42 \pm 0.04) \times 10^{-1}$ mol/l, for 4-methylcoumarin (**2a**), (Table 1). Gained results are comparable to Trolox, which RP_{50} value was $(3.06 \pm 0.60) \times 10^{-4}$ mol/l.

3.4. Comparison of two testing methods

In general, the antioxidative effectiveness of phenolic compounds depends on the reaction activity of the phenol towards

the chain-carrying peroxyl radicals and on the stability of the phenoxyl radical formed in the reaction.

The reaction mechanism is based on an electron transfer (ET) reaction whilst the hydrogen atom abstraction is a marginal reaction pathway, because it occurs slowly in strong hydrogen-bond accepting solvents, such as methanol and ethanol. As occurs in other ET-based assays, the scavenging capacity against DPPH· is strongly influenced by the solvent and the pH of reaction (Magalhães, Segundo, Reis, & Lima, 2008). The steric accessibility of the DPPH· is a major determinant of the reaction, since small molecules that have better access to the radical site have relatively higher antioxidant capacity. On the other hand, many large antioxidant compounds that react quickly with radicals may react slowly or may even be inert in this assay. Then this might be the reason why introducing a benzoxy group into coumarin molecule displays relatively weak antioxidant properties against the DPPH·.

The examined compounds showed weaker activity in reducing Fe^{3+} ions compared to the scavenging radicals. This might be explained by the presence of aqueous media, where coumarins were less soluble and resonance structures of resulting phenoxyl radicals are less stable. However, coumarins still showed antioxidant activity, comparable with DPPH radical-scavenging method (Fig. 3).

As shown in Table 1 and Fig. 3, 7,8-dihydroxy-4-methylcoumarin posses the strongest antioxidant activity, both in radical-scavenging and reducing power tests. Foti and co-workers (1996) indicated that coumarins containing a catechol moiety were stronger than the others to scavenge the peroxyl radical, which was supported by the observations from other groups (Yu, Zai, & Liu, 1999). Since a large number of experimental and theoretical studies revealed that the catechol group was beneficial in enhancing the radical-scavenging activity of natural antioxidants, it is not surprising to see the catechol group playing a key role in enhancing the antioxidant activity of coumarins.

Our results show that the position and type of the substituent attached at the aromatic part of coumarin molecule have an influence on the radical-scavenging ability. In general, substitution at the six-position gives stronger feature to coumarin for scavenging

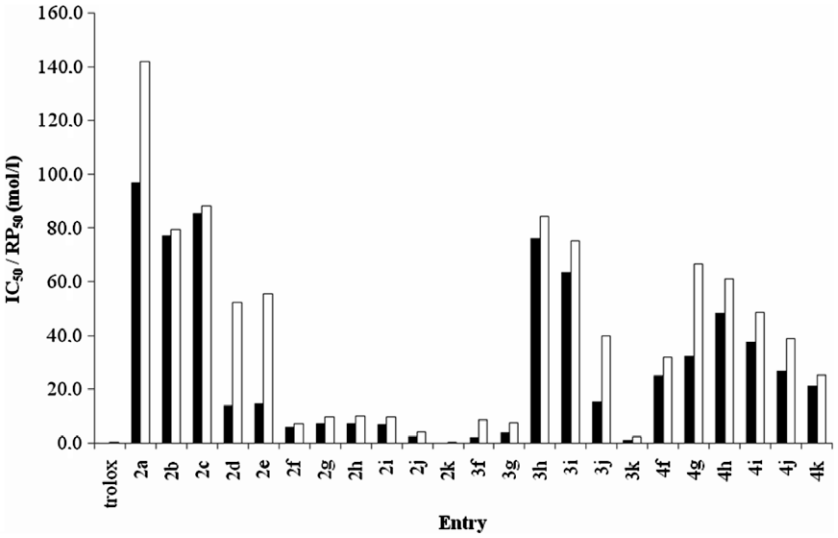

Fig. 3. Antioxidant activity of selected 4-methylcoumarins. ■, IC_{50}, the concentration of coumarin required to inhibit radical formation by 50%; □, RP_{50}, the concentration of coumarin required to reduce ferric to ferrous ions by 50%.

free radical than substitution at the seven-position. The results are consistent with a previous report that proved that resonance structures of the radicals derived from coumarins with substitution at the six-position are especially stable because of the *ortho*-quinone form (Lin et al., 2008). In addition, the type of substituent has an intense influence on the action of coumarins as antioxidants. Our results indicate that the hydroxy group has the strongest influence, while the methyl group has the smallest. A similar correlation was also reported for flavonoids (Heim, Tagliaferro, & Bobilya, 2002). Previously published data indicate that the pyrone ring of the coumarin moiety has little influence on the antioxidant activity of coumarins, due to its rather weak electronic effect (Zhang & Wang, 2004).

To the best of our knowledge, there is no published experimental data about structure elucidation of products for these kinds of reactions. Few authors gave proposed mechanisms of action (Foti et al., 2005) and theoretical elucidation of structure–activity relationships (Zhang & Wang, 2004) for coumarins to scavenge radicals. This issue will be subjected to our further research.

4. Conclusions

Antioxidants may be classified according to their mode of action as being free radical terminators, chelators of metal ions involved in catalysing lipid oxidation or oxygen scavengers that react with oxygen in closed systems. In this study we presented the antioxidant activity of selected 4-methylcoumarins using two comparable methods, 1,1-diphenyl-2-picrylhydrazyl radical-scavenging activity test and assay for evaluation of reducing power. The synthesised compounds scavenged the DPPH radical and reduced Fe^{3+}cations in a concentration and a time-depend manner.

These experiments were prompted, first, by the upsurge of interest in the contribution of reactive oxygen species and oxygen-derived free radicals to tissue damage and human diseases, and, second, by the increasing awareness that antioxidants that counteract oxidative stress may exert valuable protective actions. It was also noted that several of the plant-derived phenolic coumarins might play a role as dietary antioxidants because of their consumption in the human diet in fruits and vegetables.

Polyphenol oxidase
Enzymatic browning
Characterisation

ABSTRACT

Four isoforms of polyphenol oxidases (PPOs) were characterised in purified extracts of coats (PPOIa and PPOIb) and pods (PPOIIa and PPOIIb) of green bean (*Phaseolus vulgaris* L.). The molecular weights of four isoforms have been estimated to be from 57.5 to 39.0 kDa by SDS–PAGE. The PPOII (mixture of PPOIIa and PPOIIb) was used to characterise the PPO of green bean pods. All isoforms activities were stable between pH 6.8 and pH 7.2. PPOIa and PPOII have similar thermal inactivation profiles, and PPOIb has higher thermal stability than that of PPOIa and PPOII. PPOs showed the highest affinity to pyrogallol in all selected substrates. Although activities of PPOs were markedly inhibited by L-ascorbic acid, the activity of PPOI (mixture of PPOIa and PPOIb) was significantly activated by $MnSO_4$ and $CaCl_2$.

1. Introduction

Polyphenol oxidase (PPO: EC 1.10.3.1) is a copper-containing enzyme responsible for the hydroxylation of monophenols to *o*-diphenols and oxidation of *o*-diphenols to *o*-diquinones. PPO is compartmentalised in plastids and their phenolic compounds are located in the vacuoles for most plant tissues. Action of PPO only occurs when this compartmentation is disrupted after tissues are wounded, as observed in diseased tissues or cell disruption caused by processing and storage (Mazzafera & Robinson, 2000). The production of the browning reaction may modify plant proteins and be more toxic to potential phytopathogens (Aydemir, 2004). The reactions also produce undesirable blackening in the products during food processing, or in post-harvest of plant products resulting in a reduction of their sensory properties and nutritional value. For this reason, the PPO have been characterised in several plants, such as butter lettuce (Gawlik-Dziki, Zlotek, & Swieca, 2008), broccoli (Gawlik-Dziki, Szymanowska, & Baraniak, 2007), coffee (Mazzafera & Robinson, 2000), potato (Marri, Frazzoli, Hochkoeppler, & Poggi, 2003), *Ferula* sp. (Erat, Sakiroglu, & Kufrevioglu, 2006), avocado (Gomez-Lopez, 2002), Chinese cabbage (Nagai & Suzuki, 2001), and Marula fruit (Mdluli, 2005).

Green beans (*Phaseolus vulgaris*, L.) are among the most important vegetables produced in China. They are generally harvested seasonally, and the outdoor varieties are excellent in nutrition, colour, texture, and flavour (Martins & Silva, 2004). Consumption of canned green beans has decreased in the last years, but that of fresh bean products has increased continuously (Cano, Monreal, Ancos, & Alique, 1998). Therefore, fresh green beans are more appreciated by consumers due to their sensorial and nutritional characteristics. The quality and shelf life of green beans varies depending on cultivars, maturity, processing, and storage conditions. It is a common phenomenon that browning decreases the storage period and commercial value of green beans. In green beans, the relation between green bean quality and PPO activity is not well known, although it has been described that PPO is one of several reasons causing green bean blackness during storage (Lian et al., 2006). In the literature, there are few studies reported on the purification and characterisation of PPO from green beans. This work covers investigations of purification of PPOs, effects of pH and temperature on PPO activity and stability, effects of inhibitors on PPO activity, and substrate specificity of PPO from green bean coats and pods. The research can lead to understanding the properties of the PPO that catalyses the browning reaction during storage. The results would provide information and effective methods for controlling browning and extending shelf-life.

2. Materials and methods

2.1. Samples and chemicals

Mature green beans of a major cultivar, *P. vulgaris* L., were obtained from a local farm (Heilongjiang Academy of Agricultural

doi:10.1016/j.foodchem.2009.03.088

Science, Harbin, China). The green bean samples were transported to the laboratory within 2 h on the day of harvest and stored at 8 °C until extraction.

Catechol, L-dopa, 4-methylcatechol, pyrogallol, polyvinylploypyrolidone (PVPP), L-ascorbic acid, L-tyrosine, L-cysteine, sodium metabisulphite, Sephadex G-100, and DEAE-cellulose were obtained from Sigma Chemical Co (St. Louis, USA). Molecular Markers (M.W., 14.4–116.0 kD) were purchased from Fermentas Inc. (Glen Burnie, MD, USA). Acrylamide, bis-acrylamide, TEMED, ammonium persulfate and SDS were obtained from Amersham Pharmacia Biotech AB (Björkgatan, Uppsala, Sweden). Other reagents were all of analytical grade.

2.2. Enzyme extraction and partial purification from green bean

One hundred gram fresh green bean pods (or 20 g fresh green bean coats) were homogenised in 300 ml (or 50 ml) of 0.1 M phosphate buffer (pH 6.8, 10% PVPP) for 20 s at 4 °C (HR1724, Philips, Netherlands). The homogenate was filtered through four layers of cheesecloth and centrifuged at 15,000*g* for 20 min at 4 °C (Anke TGL-16G, Anting Scientific Instrument Factory, Shanghai, China). The supernatants were treated with $(NH_4)_2SO_4$ to obtain 60% saturation at 0 °C and then centrifuged at 15,000*g* for 20 min at 4 °C. The crude enzyme extracts were used for further purification.

For further purification of PPO from green bean coats, the precipitate, which was extracted and centrifuged from green bean coats, was dissolved in 0.01 M phosphate buffer (pH 6.8). The crude extract enzyme was extensively dialysed against the same buffer at 4 °C for 24 h with four changes of the buffer during dialysis. The dialysed enzyme solution was fractionated by a Sephadex G-100 column (1.6 cm × 50 cm). The column was equilibrated with 0.01 M phosphate buffer (pH 6.8). The 1.0 ml dialysed enzyme solution was passed through the column and was eluted by same phosphate buffer. The elution rate was adjusted to 30 ml/h. An elution of 5 ml was collected each time. The elution process was continued until obtaining zero absorbance at 280 nm. Protein was qualitatively detected by Protein Nucleic Acid Analyzer (HD-93–1, Kingdom Biochemical Instrument Co., Shanghai, China) at 280 nm. Each isolated PPO sample was then determined for their activity. Thus, values obtained were plotted against the sample numbers. The fractions having PPO activity were collected and purification degrees were determined by measuring specific activity before and after purification. Then the fractions were stored at 0 °C for subsequent analysis.

For the further purification of the PPO extracted from the green bean pods, the extracted and centrifuged precipitate was dissolved in 0.01 M Tris–HCl buffer (pH 7.1). The crude extract enzyme was extensively dialysed against the same buffer at 4 °C for 24 h with four changes of the buffer during dialysis. The dialysed enzyme solution was fractionated by a DEAE-cellulose column (1.6 cm × 10 cm). The column was equilibrated with 0.01 M Tris–HCl buffer (pH 7.1). The 2.0 ml dialysed enzyme solution was passed through the column and was eluted by 0.01 M Tris–HCl buffer (pH 7.1) NaCl at a flow rate of 30 ml/h. Enzyme activity was eluted with a linear gradient of 0–0.5 M NaCl in a total 600 ml of buffer. Fractions of 2.5 ml were collected and assayed for PPO activity and protein content. The fractions having PPO activity were collected and purification degrees were determined by measuring specific activity before and after purification. Then the fractions are stored at 0 °C for subsequent analysis.

2.3. PPO activity assay

PPO activity was determined according to the method of Yamamoto, Yoshitama, and Teramoto (2002) with some modification. The catechol was used as a substrate, and the quinone formation was measured on a spectrophotometer at 410 nm (Spectrum 754PC, Spectrum Instruments Co., Ltd, Shanghai, China). The sample contained 0.5 ml of 0.1 M catechol, 2.0 ml of 0.1 M phosphate buffer (pH 6.8) and 0.5 ml of the enzyme solution. The blank sample contained only 3.0 ml of substrate solution. The sample and blank were kept at ambient temperature for 30 min. PPO activity was assayed in triplicate measurements. One unit of enzyme activity was defined as the amount of enzyme that caused a change in absorbance of 0.001 per min. The initial rate was calculated from the slope of the absorbance–time curve.

2.4. Estimation of molecular weight

The purified PPO was subjected to determine molecular weight based on SDS–polyacrylamide gel electrophoresis (SDS–PAGE) under denaturation conditions by a vertical electrophoresis unit (DYCZ-24D, Liuyi Instrument Factory, Beijing, China). The PPO preparation was followed by heating the PPO in boiling water for 3 min with 2% SDS and β-mercaptoethanol. The SDS–PAGE test employed 12% polyacrylamide gels and the buffer system. Electrophoresis was run at 10–25 mA for 2.0 h at ambient temperature. Gels were stained with Coomassie Brilliant Blue R-250. Molecular markers used were β-galactosidase (*M*r, 116.0 kDa), bovine serum albumin (*M*r, 66.2 kDa), ovalbovine (*M*r, 45.0 kDa), lactate dehydrogenase (*M*r, 35.0 kDa), restriction endonuclease Bsp981 (*M*r, 25.0 kDa), and β-lactoglobulin (*M*r, 18.4 kDa). The Gel-pro Analyzer 4.0 was applied to determine the molecular weight.

2.5. Effect of pH on PPOs activities and stability

The purified PPO (0.5 ml) was mixed with 2.5 ml of 0.1 M citrate buffer (pH 3.0–6.0) and 0.1 M phosphate buffer (pH 6.1–8.0) at the appropriate pH with 0.2 pH unit intervals. The PPO activity, as a function of pH, was determined at different pH values.

To determine pH stability, 0.5 ml purified PPO fractions which were originally isolated from green bean pods and green bean coats were mixed with 2.5 ml of 0.1 M citrate buffer (pH 3.0–6.0) and 0.1 M phosphate buffer (pH 6.1–8.0) at the appropriate pH with 0.2 pH unit intervals. After mixing of the sample and buffer, the pH was re-checked. The mixtures were kept at ambient temperature for 24 h, and then the mixtures were adjusted to pH 7.0. The residual PPO activity was determined.

2.6. Effect of temperature on PPOs activities and stability

A quantity of 2.5 ml substrate solution (0.1 M catechol in 0.1 M, pH 6.8 phosphate buffer) was pre-heated from 0 to 80 °C (at 10 °C intervals) in a water bath for 5 min. Then 0.5 ml PPO fraction was added into the substrate. PPO activity was determined as a function of temperature. PPO activity was calculated in the form of percent residual PPO activity at the optimum temperature.

To determine the thermal stability of PPO (0–95 °C), the test was divided into two temperature ranges. In first temperature range, each 0.5 ml PPO fraction (PPOIa, PPOIb and PPOII) was added into the 2.5 ml substrate solution (0.1 M catechol in 0.1 M, pH 6.8 phosphate buffer). After the mixtures were incubated 30 min at 0–80 °C (at 10 °C intervals), the samples were rapidly cooled in an ice bath for 5 min. Then residual PPO activity was determined at ambient temperature. In second temperature range, 0.5 ml PPOI (mixture of PPOIa, PPOIb) or PPOII (mixture of PPOIIa and PPOIIb) was treated same as above, but the differences were that samples were incubated 5 min at 85–95 °C (at 5 °C intervals). The residual activity was calculated as a percentage of unheated enzymes.

The kinetic data analysis of thermal inactivation can be described by the first-order reaction (Rapeanu, Loey, Smout, & Hendrickx, 2006):

$$\frac{dA}{dt} = -kA \quad (1)$$

where A is the enzyme at treatment time t and k is the reaction rate constant at the temperature studied. For constant extrinsic/intrinsic factors, in the case of a first-order reaction, the kinetics can be described by the following equations:

$$\log A = \log A_0 - \frac{t}{D} \quad (2)$$

or

$$\ln A = \ln A_0 - kt \quad (3)$$

where A_0 is the initial activity, and A is the activity at time t, and D is the decimal reduction time. At each temperature, the decimal reduction time D and the rate constant k were estimated using linear regression analysis on, respectively, Eqs. (2) and (3). The temperature-dependence of the D-value is characterised by the z_T value, which is the temperature increase necessary to induce a 10-fold reduction in D,

$$\log D = \log D_0 - \frac{T - T_0}{z_T} \quad (4)$$

The z_T value was estimated using linear regression analysis of Eq. (4). The temperature-dependence of the inactivation rate constants can be estimated using the Arrhenius model (5).

$$\ln(k) = \ln(k_0) + \left[\frac{E_a}{R} \cdot \left(\frac{1}{T_0} - \frac{1}{T}\right)\right] \quad (5)$$

where T and T_0 are the absolute and the reference temperatures (K), k_0 is the rate constant at T_0, E_a is the activation energy (kJ/mol) and R is the universal gas constant (8.314 J/mol/K). The activation energy was estimated using linear regression analysis of Eq. (5).

2.7. Substrate specificity

PPO activity was measured with six substrates at various concentrations, depending on their solubility; 0.1 M for catechol, 4-methylcatechol, L-dopa, pyrogallol and tannin, and 2.5 mM for L-tyrosine. Substrates were dissolved in 100 mM (pH 7.0) phosphate buffer. At each substrate concentration, the PPO activity was determined at each optimum wavelength. The Michaelis–Menten constant (K_m) and maximum reaction velocity (V_m) were determined using four substrates (catechol, 4-methylcatechol, pyrogallol and L-dopa) at five different concentrations and under standard conditions. Data were plotted as $1/V$ and $1/[S]$ concentration according to the method of Lineweaver and Burk.

2.8. Effect of inhibitors on PPO activity

The inhibitors, L-ascorbic acid, citric acid, L-cysteine, sodium metabisulphite, NaCl, $CaCl_2$, $MnSO_4$ and thiourea, were employed at three different concentrations. When 0.5 ml of catechol (0.1 M), 0.5 ml PPO fraction and 0.3 ml stated inhibitor were added into 1.7 ml phosphate buffer (0.1 M, pH 6.9), the PPO activity was measured in the standard reaction medium in the presence or absence of the stated concentration of inhibitor.

2.9. Statistical analysis

All analytical values represent the means of triplicate measurements. One-way analysis of variance (ANOVA) was used to compare the means. Differences were considered significant at $P < 0.05$. All statistical analyses were performed with SAS 8.0 (SAS Institute, Cary, NC).

3. Results and discussions

3.1. Purification of PPOs

The crude enzyme extracts from green bean coats and pods were precipitated by ammonium sulphate. The precipitates were dialysed by the buffer. The dialysed enzymes were purified 3.5-fold for coat and 3.7-fold for pod (Table 1) comparing with crude enzyme extracts. The dialysed enzyme extract from green bean coat was applied to a Sephadex G-100 column and eluted with phosphate buffer. The dialysed enzyme was eluted and four peaks observed that indicated four forms of PPO were isolated in fresh green bean coats (Fig. 1a). However, only the first two fractions had PPO activities (designated PPOIa and PPOIb). Compared to the crude enzyme extract of green bean coats, the purification degrees of PPOIa and PPOIb were 17.0-fold and 9.4-fold respectively (Table 1).

The dialysed enzyme from green bean pods was applied to a DEAE-cellulose column and eluted with a linear gradient of NaCl (0–0.5 M). The results showed that four forms of PPO were isolated from the dialysed enzyme (Fig. 1b), however, only the last two peaks indicated that the fractions had PPO activities (designed PPOIIa and PPOIIb). Comparing with a crude enzyme extract of green bean pods, the purification degrees of PPOIIa and PPOIIb were 6.6-fold and 3.8-fold, respectively (Table 1). The activities of PPOIIa and PPOIIb were significantly lower than the activity of PPOIa and PPOIb indicated that the green bean coats are easier to brown than the pods, because PPO activity and phenolic compounds mainly contribute to the enzymatic browning of fruits and vegetables. Gao and Li (2008) reported that PPO activity in the peel of sweet potato was higher than that in the tissue of sweet

potato, and the peel was easier browning than that of tissue. Dong, Wang, Gong, Zhang, and Wang (2007) detected the PPO activities and browning degree of pericarp, sarcocarp and core in three varieties pears. The results demonstrated that the PPO activity in the core was significantly higher than that of pericarp and sarcocarp of pears, and then the browning degree of the core was significantly higher than that of the pericarp and sarcocarp of pears. For green bean, it was demonstrated that green bean coat was easier browning than that of pod during storage (Guo & Ma, 2008).

Both green bean coats and pods with two active PPO fractions were identified. Partington and Bolwell (1996) reported two types of PPO in potato tuber. Three types of PPO have been identified in peach (Flurkey & Jen, 1980) and artichoke (Aydemir, 2004). Park and Luh (1985) observed four forms of PPO as isoenzymes in kiwi fruit, and Ho (1999) found similar results in aerial roots. It is possible that the numbers of PPO isoenzymes are different among varieties (Marri et al., 2003; Yamamoto et al., 2002).

3.2. Estimation of molecular weight

The molecular weight of the purified fractions PPOIa, PPOIb, PPOIIa and PPOIIb were determined to be 57.5, 54, 46.0 and 39.0 kDa, respectively, by SDS–PAGE (Fig. 2a and b). The molecular weights of two PPO isoforms in green bean pods were smaller than that in the green bean coat. The results suggest that the activity of PPO may depend on its molecular weight. The high molecular weight fractions of PPO showed a higher activity. To our knowledge, there has never been a detailed comparative investigation of isoenzymes and molecular weights of PPO from the green bean coats and pods in the same plant. But similar results can be found in many various plants. Mazzafera and Robinson (2000) found that the molecular weights of PPO in coffee leaves and fruit endosperm were 46 and 50 kDa, respectively. The molecular weights of potato PPO were found to be 60 and 69 kDa (Partington & Bolwell, 1996). Four PPO fractions were purified from the aerial roots of an orchid, and their molecular weights were estimated to be 68, 48, 68, and 48 kDa, respectively (Ho, 1999). The molecular weight of PPO from other plants has been reported as follows: William pears, 43 kDa (Gauillard & Richard, 1997); butter lettuce, 60 kDa (Gawlik-Dziki et al., 2008); broccoli, 51.3–57 kDa (Gawlik-Dziki et al., 2007); and marula fruit, 71 kDa (Mdluli, 2005). Others reports of purified PPO are 30–70 kDa (Fujita et al., 1995; Marri et al., 2003; Nagai & Suzuki, 2001).

3.3. Effect of pH on PPO activity and stability

3.3.1. Effect of pH on PPO activity

The pH is one of the key factors that greatly influence the enzyme activity. The pH profiles of PPO activity in green beans were determined by using catechol as a substrate at a wide range of pH (3.0–8.0) with 0.2 pH unit intervals. For green bean coats, the optima pH of PPOIa and PPOIb were 6.8 and 7.0, respectively (Fig. 3a). The natural pH of green bean coat is 6.8. It means that green bean coat easy brown at its natural pH, because PPOIa and PPOIb have their higher activities between pH 6.8 and pH 7.0. The relative enzymatic activities were significantly ($p < 0.05$) decreased below pH 6.6 (72.7%) and above pH 7.0 (85.2%) for PPOIa, and below pH 6.8 (90.6%) and above pH 7.2 (76.1%) for PPOIb. The results indicated that PPOIa and PPOIb have narrow optimum pH ranges. These results are similar to the optimum pH range between 6.8 and 7.3 for PPO in kiwi (Park & Luh, 1985) and in marula fruit (pH 7.0) (Mdluli, 2005).

The PPO's concentration in green bean pods was very much lower, and thus it was hard to get the factions of PPOIIa and PPOIIb. Therefore, the eluted mixture of PPOIIa and PPOIIb (designed PPOII) was used to determine its pH profile. Two maximal activities of PPOII occurred at pH 4.0 and 7.0 (Fig. 3a). The results may be explained as an effect of a mixture of isoenzymes because PPO II was a mixture of PPOIIa and PPOIIb. Similar results have been found by other researchers, e.g. about pH 4.4, 7.5 and about pH 4.7, 7.5 for two varieties of avocado crude PPO extract (Gomez-Lopez, 2002), and pH 5.5 and 7.0 for crude enzyme extracts of Anamur banana (Unal, 2007). Gomez-Lopez (2002) thought that those two optima pH were contributed by isoenzymes. For PPOII, the relative enzymatic activities were significantly reduced ($p < 0.05$) in the range of pH 4.5–6.8 for both activity peaks. The relative enzymatic activities were also reduced above pH 7.2 (66.9%) for the secondary activity peaks. Therefore, PPOs of green bean coats and pods have narrow optimum pH ranges. Although different plants have different optima pH, the narrow optimum pH (6.8–7.0) range can be found in several plants (Erat et al., 2006; Ho, 1999; Jiang, Zauberman, & Fuchs, 1997; Mazzafera & Robinson, 2000).

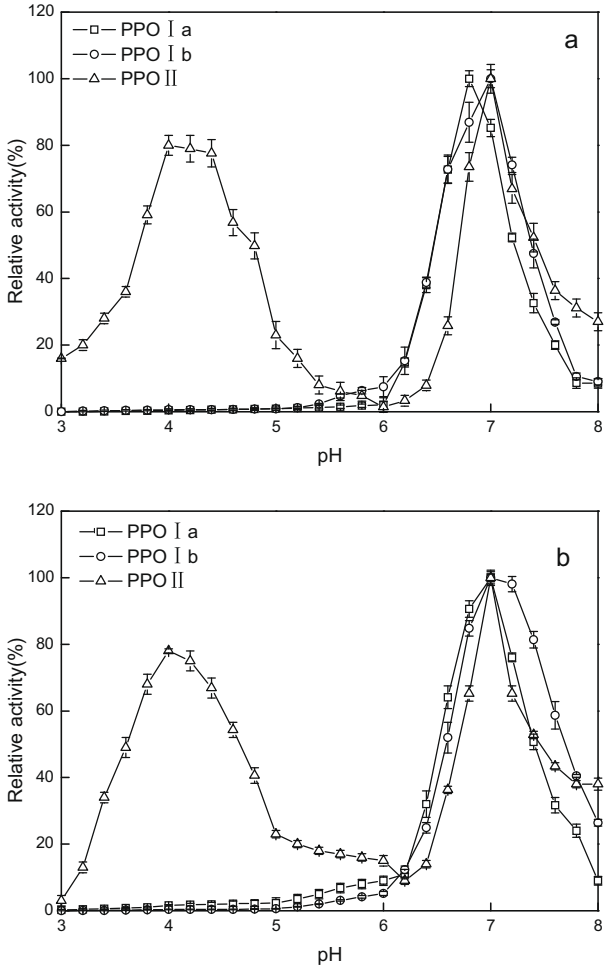

Fig. 3. pH-activity profiles (a) and pH-stability profiles (b) for green bean coat PPOIa and PPOIb and green bean pod PPOII.

3.3.2. Effect of pH on PPO stability

The stabilities of PPOs were determined by keeping preparations of PPOIa, PPOIb and PPOII in various pH states at ambient temperature for 24 h. As shown in Fig. 3b, PPOIa and PPOIb retained more than 95% of their original activities between pH 6.8 and pH 7.0 and in the range of pH 7.0–pH 7.2, respectively, but both lost 90% of their original activities when adjusted to a pH below 6.2 or above 8.0. Like their pH-activity profile, PPOIa and PPOIb have a narrow stable pH range. The results indicate that the change of pH would greatly influence the stability of PPO in green beans. Several researchers found that PPOs were stable near neutral pH and were unstable in acidic media, such as for longan fruit and yali pear (pH 7.0) (Jiang, 1999; Zhow & Feng, 1991), artichoke (pH 6.0–7.0) (Aydemir, 2004), and marula fruit (pH 6.0) (Mdluli, 2005).

For green bean pod, isolated PPOII retained more than 95% of its original activity at pH 4.0–4.2 and pH 7.0. However, there was an 80% loss in its original activity between pH 5.4 and pH 6.4, and below pH 3.2 (Fig. 3b).

The natural pH of green bean coats and pods are 6.8 and 5.8, respectively. In green bean coats, PPOIa and PPOIb have their maximum activities and the most pH stability at pH 6.8–7.0, so PPOIa and PPOIb keep their highly enzymatic activity in natural state. In green bean pods, the activity and pH stability of PPOII were 4.8% and 16% of its original activity, respectively, at pH 5.8. These results can be used to explain the reason that green bean coats are more susceptible to browning than that of the pods.

3.4. Effect of temperature on PPO activity and stability

3.4.1. Effect of temperature on PPO activity

The effects of temperatures between 0 and 80 °C on the PPOs' activities showed that optima temperatures for PPOIa, PPOIb and PPOII were 20, 30, and 50 °C, respectively (Fig. 4a). The high temperature may cause inactivation of PPO in green beans. For plants' PPO activity, optima temperatures between 20 and 35 °C were reported by other authors (Dincer, Colak, Aydin, Kadioglu, & Guner, 2002; Gawlik-Dziki et al., 2008; Jiang, 1999; Rapeanu et al., 2006; Unal, 2007). Higher optima temperatures for the PPO activities of strawberry have been reported (Serradell et al., 2000) and for litchi (Jiang et al., 1997) were 50 and 70 °C, respectively. The optima PPO for two varieties of hybrid sunflowers were 55 and 60 °C (Singh, Singh, Kaur, & Singh, 1999). The activity loss of PPOIa and PPOIb were 72.4% and 53.3% at 40 °C, respectively. However, the PPOIa and PPOIb were completely inactivated at 70 °C. The results suggested that PPOIa and PPOIb are sensitive to heat, and that their activities decreased with elevating temperature. Whereas the activity loss of PPOII was 66.7% at 70 °C, PPOII still retained 32.9% of its original activity even at 80 °C. PPOII retained more than 50% of its original activity between 20 and 65 °C. Therefore, PPOII tolerated changes in temperature as compared with PPO isolated from green bean coats.

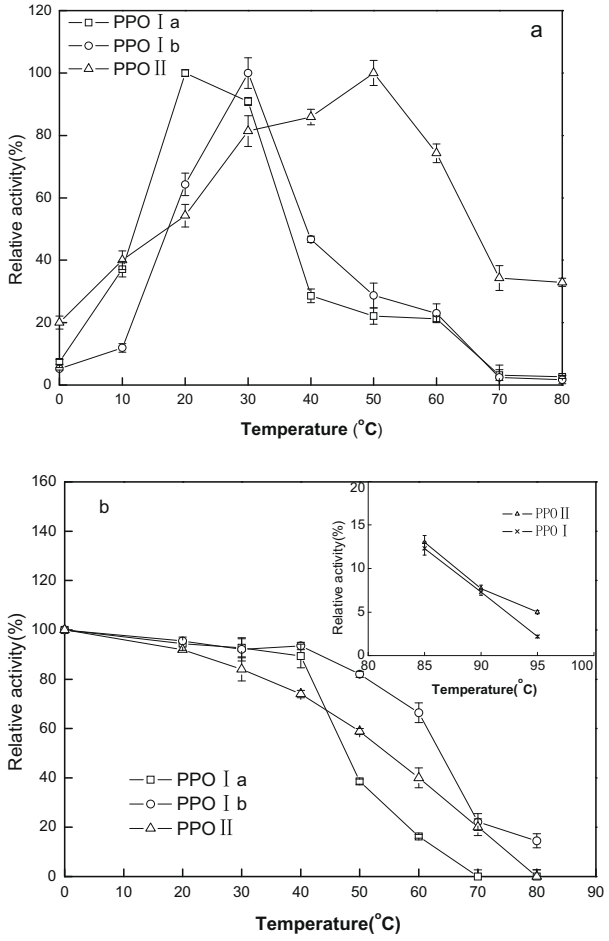

Fig. 4. Thermal activity profiles (a) and thermal stability profiles (b) for green bean coat PPOIa and PPOIb and green bean pod PPOII.

3.4.2. Effect of temperature on PPO stability

Thermal stability profiles for PPOs, presented in the form of the residual percentage activity, were investigated in two temperature ranges (0– 80 °C for 30 min and 85–95 °C for 5 min). In 0–80 °C, PPOs were stable between 0 and 40 °C (Fig. 4b). The enzyme activities were rapidly lost at higher temperatures. For instance, the temperature was increased from 40 °C to 80 °C, the residual relative activities of PPOIa and PPOII decreased from 89.4% to 0% and 93.5% to 0%, respectively. However, the residual relative activity of PPOIb decreased from 93.5% to 14.5% and from 40 °C to 80 °C. In 85–95 °C, thermal stability profile of PPOI (mixture of PPOIa and PPOIb) and PPOII was shown in Fig. 4b (small figure). At 95 °C (5 min), the residual relative activities of PPOI and PPOII were original 5.0% and 2.2%, respectively. But PPOI and PPOII were completely inactivated at 95 °C and 6 min. In consideration of industrial processing of green bean, at storage temperature (0 °C and 8 °C) of fresh green bean, PPOs have the highest stability, but the activities of PPOs are very low (Fig. 4a). When green bean was pre-treated by hot air of 50 °C, the relative activities of PPOs were decreased (PPOIa, 38.5%; PPOIb, 82.1%; PPOII, 44.3%). However, more than 95% PPOs were inactivated when green bean was blanched at 95 °C and 5 min.

Based on the results of thermal stability, kinetics of PPOs was studied in 50– 80 °C (Table 2). The higher inactivation temperature the inactivation proceeds faster. In the temperature range of 50–80 °C, the *D*-value of PPOs linearly decreased with increasing temperature. The *D* values of PPOIb are significantly higher than that of PPOIa and PPOII, and the range of temperatures required for the inactivation of PPOIb also was higher than those required for PPOIa and PPOII. Therefore, these results indicate that PPOIb is more thermostable than PPOIa andPPOII.

Considerable PPOs' inactivation at higher temperature is probably the result of changes in the enzyme tertiary structure (Dincer et al., 2002; Duangmal & Owusu Apenten, 1999). It appears that isoenzymes PPOIa and PPOIb have different thermal properties and stabilities. These results are consistent with some thermal stability profiles that have been found in tobacco isoenzyme PPOs (Dai, Shi, Tang, & Liu, 2001) and *Lentinus edodes* isoenzyme laccases (Wang et al., 2007). In addition, different molecular forms from the same source may have different thermostabilities (Zhow & Feng, 1991). The thermostability of PPOs varies considerably from plant to plant. However, several researchers have indicated that plant PPOs were stable between 20 and 40 °C (Arslan, Temur, & Tozlu, 1997; Aydemir, 2004; Duangmal & Owusu Apenten, 1999; Fujita et al., 1995; Gawlik-Dziki et al., 2008; Jiang, 1999). The higher thermal stabilities were found in the PPO from bananas at 60 °C for 30 min (Yang, Fujita, Ashrafuzzaman, Nakamura, & Hayashi, 2000), and leaves and fruit endosperm of coffee at 50 °C for 30 min (Mazzafera & Robinson, 2000).

3.5. Substrate specificity and enzyme kinetics

The substrate specificities of PPOs (PPOIa, PPOIb and PPOII) were examined using monophenols, diphenols, and triphenol as substrates. The Michaelis–Menten constant (K_m) and maximum reaction velocity (V_m) were determined using four substrates (catechol, 4-methylcatechol, pyrogallol, and L-dopa) at five different concentrations and under optimum analysis conditions. Data were plotted as $1/V$ and $1/[S]$ concentration according to the method of Lineweaver and Burk (Table 3). Catalytic efficiency and substrate affinity were the highest for pyrogallol, followed by catechol, 4-methylcatechol, and L-dopa. With pyrogallol, the V_m values of PPOIa and PPOIb were similar, but the K_m of PPOIa was nearly twice that of PPOIb. This may be indicative of their differences in affinity with pyrogallol. PPOIa and PPOIb were very similar in relation to their K_m and V_m with catechol, 4-methylcatechol and L-dopa. The V_m and K_m of PPOIa and PPOIb were higher than those for PPOII with these same substrates. When the activities of PPOs

using catechol as substrate were set at 100%, the relative activities of PPOs using the substrate pyrogallol were 958% (PPOIa), 718% (PPOIb), and 733% (PPOII), respectively (Table 3). Therefore, it can be summarised that the isolated PPOs from green beans have substrate-binding sites with highly affinity for pyrogallol and catechol. Pyrogallol is the best substrate for green bean PPOs. The green beans PPOs showed no activity towards L-tyrosine or tannins. These results suggested that PPOs in green beans, lack monophenolase (cresolase) activity. Catechol and 4-methylcatechol are substrates that are often chosen for determining the activity of polyphenol oxidase isolated from food and plant sources (Aydemir, 2004; Gawlik-Dziki et al., 2007; Gawlik-Dziki et al., 2008; Gomez-Lopez, 2002; Mdluli, 2005). However, PPOs from litchi and longan have high affinities for pyrogallol (Jiang, 1999; Jiang et al., 1997). Edible burdock PPO strongly oxidised 1,2,3-trihydroxybenzene (pyrogallol), but no activity toward monophenols or diphenols (Murao, Oyama, Nomura, Tono, & Shin, 1993). Martinez and Whitaker (1995) indicated that all of the PPOs discovered have the ability to convert *o*-dihydroxyphenols to *o*-benzoquinones, using O_2 as the second substrate (catecholase activity), but not all PPOs hydroxylate monophenols. Considering their substrate specificity, the green bean PPOs seem inclined toward *o*-diphenols and 1,2,3-trihydroxybenzenes.

3.6. Effect of inhibitors on PPO activity

Eight inhibitors with three different concentrations were employed to determine their potential for inhibition of PPOI (PPOIa + PPOIb) and PPOII (Table 4). These inhibitors include metal ions and reducing agents. Relative activity was calculated as a percentage of the residual activity occupying original activity (without any inhibitor). Of all inhibitors used in the study, L-ascorbic acid was the most effective for inhibition of PPOIand PPOII, followed by sodium metabisulphite and L-cysteine, since the three compounds induced a high degree of inhibition even at low concentration. The results are similar to the results with Victoria grape obtained by Rapeanu et al. (2006) and medlar fruit PPOs (Ayaz, Demir, Torun, Kolcuoglu, & Colak, 2008; Dincer et al., 2002).

The mechanism of L-ascorbic acid inhibition involves the reduction of quinones generated by PPO. PPO catalyses the oxidation of phenolic substrate to *o*-quinones whilst L-ascorbic acid converts *o*-quinones back to phenolic compounds (Duangmal & Owusu Apenten, 1999). L-ascorbic acid has also been reported to cause irreversible enzyme inhibition (Aydemir, 2004; Rapeanu et al., 2006). Two other mechanisms for inhibition involving direct interaction with the enzyme have been reported: chelation of the copper at the active site and reduction of Cu^{++} to Cu^{+} (Gawlik-Dziki et al., 2007; Gomez-Lopez, 2002).

The action of sulphite in the prevention of enzymatic browning can be explained by the actions on *o*-quinones and PPO. The formation of a quinone–sulphite complex prevents quinone polymerisation. A further action of metabisulphite on PPO is directly on the enzyme structure, leading to the inactivation of PPO (Duangmal & Owusu Apenten, 1999). It has been suggested that sulphite reacts with disulphide bound within PPO. This leads to a change in the tertiary structure of the enzyme and its inactivation (Duangmal & Owusu Apenten, 1999). Because L-cysteine can easily form complexes with *o*-quinones, PPO was inhibited by the formation of additional products. L-cysteine has been suggested to prevent enzymatic browning in processed fruit products (Jiang, 1999). The effectiveness of an inhibitor depends on the variety (Gomez-Lopez, 2002). L-ascorbic acid was the most efficient inhibitor for *Allium* sp. PPO (Arslan et al., 1997), Taro PPO, potato PPO (Duangmal

Table 4
Effects of various compounds on the activities of PPOI from green bean coat and PPOII from green bean pod.

Compounds	PPOI		PPOII

& Owusu Apenten, 1999), butter lettuce (Gawlik-Dziki, Zlotek, & Swieca, 2008), cabbage (Fujita et al., 1995) and banana (Unal, 2007; Yang et al., 2000). But L-ascorbic acid was a median inhibitor for longan PPO (53% inhibition at 1.0 mM) (Jiang, 1999), and litchi (69% inhibition at 1.0 mM) (Jiang et al., 1997). It has been reported by several authors that L-cysteine and metabisulphite were strong inhibitors for plant PPO (Aydemir, 2004; Duangmal & Owusu Apenten, 1999; Erat et al., 2006; Gomez-Lopez, 2002; Jiang, 1999; Jiang et al., 1997), However, L-cysteine was a medium inhibitor for butter lettuce PPO (16.8% inhibition at 1.0 mM) (Gawlik-Dziki, Zlotek, & Swieca, 2008).

In this study, NaCl, thiourea, and citric acid were poor inhibitors. Several workers have reported that the inhibitory effectiveness on PPO activity is quite low at low NaCl concentrations (Erat et al., 2006; Fujita et al., 1995; Jiang, 1999; Rapeanu et al., 2006; Unal, 2007; Yang et al., 2000). On the other hand, higher concentrations of NaCl can achieve higher inhibition. It was shown that the inhibition of PPOs from two varieties of avocado by 0.8 M NaCl were 37% and 39% (Gomez-Lopez, 2002). It is believed that the action of NaCl is due to its interaction with the copper at the active centre of the enzyme (Duangmal & Owusu Apenten, 1999; Gomez-Lopez, 2002).

The relative activities of PPOI were significantly promoted by $MnSO_4$ and $CaCl_2$, but the relative activities of PPOII were not significantly changed, compared with the original activity. The relative activities of PPOI influenced by 10 mM $MnSO_4$ and $CaCl_2$ were increased to 174.8% and 209.4% respectively. Similar results have been found in longan, cabbage and litchi (Fujita et al., 1995; Jiang, 1999; Jiang et al., 1997). But Aydemir (2004) found that 30–32% inhibition of PPO activity was observed at 10 mM of $MnCl_2$ and $CaCl_2$. The two compounds also inhibited PPO in medlar fruit (Ayaz et al., 2008) and Japanese pear (Aydemir, 2004).

4. Conclusion

This study describes the isolation and characterisation of four isoforms of PPO from green beans and also compares their properties. In some properties, the four isoforms of PPOs present significant differences in molecular weights, pH-profiles, temperature profiles, enzyme kinetics, substrate specificity and effect of inhibitors. The molecular weights of four isoforms were 57.5 kDa (PPOIa), 54 kDa (PPOIb), 46.0 kDa (PPOIIa) and 39.0 kDa (PPOIIb), respectively. The optimal pH of PPOs were 6.8 (PPOIa), 7.0 (PPOIb), 4.0 and 7.0 (PPOII), respectively. All four isoforms activities were stable between pH 6.8 and pH 7.2. The natural pH of green bean coats and pods are 6.8 and 5.8, respectively. Therefore, in natural sate, PPOIa and PPOIb from green bean coats keep their highly enzymatic activity and PPOII from green bean pods was greatly inhibited at its lower pH value. The optimal temperatures for PPOIa, PPOIb and PPOII were 20, 30 and 50 °C, respectively. PPOIa and PPOII have similar thermal inactivation curves. PPOs are stable at 0–40 °C, but PPOIb has higher thermal stability than that of PPOIa and PPOII from 50 to 80 °C. So the higher temperatures can efficiently inactivate PPO activity. PPOs of green bean have substrate-binding sites with highly affinity for pyrogallol and catechol. Pyrogallol is the best substrate for green bean PPOs. The green beans PPOs lack monophenolase (cresolase) activity. Although activities of PPOI and PPOII were markedly inhibited by L-ascorbic acid, the activity of PPOI was significantly activated by $MnSO_4$ and $CaCl_2$.

Further investigation of the molecular structure and origin of different PPOs and the role of an individual PPO in cellular metabolism could help in understanding their functions in green beans, especially in understanding the browning mechanism.

Antioxidant activity

ABSTRACT

Supercritical fluid carbon dioxide (SF-CO_2) extraction (SFE) of cajaninstilbene acid (CSA) and pinostrobin (PI) from pigeonpea leaves and antioxidant activity were investigated for the first time. SFE gave higher extraction yields than conventional heat-refluxing extraction (HRE) because of the severe breakage of cell morphology caused by SF-CO_2, which was observed by scanning electron microscopy (SEM). CO_2 flow rate, modifier composition and liquid to solid ratio were firstly optimised, 12 kg/h, and 80% EtOH with a liquid to solid ratio of 10 ml/g raw material exhibited better extraction performance. Then a central composite design (CCD) combined with response surface methodology was used to study the effects of extraction pressure, temperature and time on the extraction yields of CSA and PI, the optimal parameters were 30 MPa, 60 °C and 2 h. An antioxidant activity investigation showed SFE extracts exhibited better free radical-scavenging activity than HRE extracts with an IC_{50} value of 0.2259 mg/ml.

1. Introduction

Pigeonpea [*Cajanus cajan* (L.) Millsp.], also known as red gram, Congo pea, Dhal, no eye pea and pois caja, etc., is a famous and multi-use grain legume crop in semi-tropical and tropical developing countries. It has been used for centuries in intercropping systems, and ranks sixth in area and production in grain legumes worldwide. It is an ideal source of protein and Vitamin B in human diet, especially in the vegetarian population (Salunkhe, Chavan, & Kadam, 1986). Besides its usage as food, green vegetables, fodder, firewood, soil improvement in agriculture (Sharma, Sreelatha, & Dayal, 2006), pigeonpea has many uses as traditional folk medicinal plants. It has been used for many years for treating diabetes, expelling bladder stones, stabilising the menstrual period, applying to sores, skin irritations, hepatitis, measles, jaundice, dysentery and many other illnesses (Grover, Yadav, & Vats, 2002; Morton, 1976). In China, pigeonpea leaves are used as expectorant, against sore gums, in child delivery, as anhelminthic, etc. (Morton, 1976). It was also found that pigeonpea leaves exhibited notable vulnerary, anti-biotic, anti-sickling activities and inhibited *Leishmania* and capillary permeability.

A chemical composition investigation indicated that there are a number of phenolic phytoalexins in pigeonpea leaves, including flavonoids (Fu et al., 2008) and stilbenes (Cooksey, Dahiya, Garratt, & Strange, 1982; Inman & Hoppe, 2002), etc. In preliminary investigations on active constituents in pigeonpea leaves, cajaninstilbene acid (CSA) and pinostrobin (PI), which belongs to stilbenes and flavonones, respectively, have been found in higher content with remarkable pharmacological activities. CSA is stilbene-2-carboxylic acid, which rarely exists in plants (Cooksey et al., 1982). It has hypoglycemic, hypotriglycerimic activity (Inman, 2002, 2003) and potential action in the treatment of postmenopausal osteoporosis (Zheng, Yang, Chen, & Sun, 2007), it was also found to be a good antioxidant in our previous study (Wu et al., 2009). PI, a potent flavonoid inducer, shows an extraordinarily high ability to induce mammalian phase 2 detoxication enzymes and antioxidant enzymes, it has a concentration required to double the quinone reductase induction of 0.5 μM in a microtiter plate assay with murine hepatoma cells (Fahey & Stephenson, 2002). It also possesses the ability to inhibit the human placental aromatase and decrease the proliferation of MCF-7 cells induced by dehydroepiandrosterone sulphate and 17β-estradiol (Le Bail, Aubourg, & Habrioux, 2000). It is known that many stilbenes and flavonoids are natural antioxidants (Alén-Ruiz, García-Falcón, Pérez-Lamela, Martínez-Carballo, & Simal-Gándar, 2009). Pigeonpea leaves are

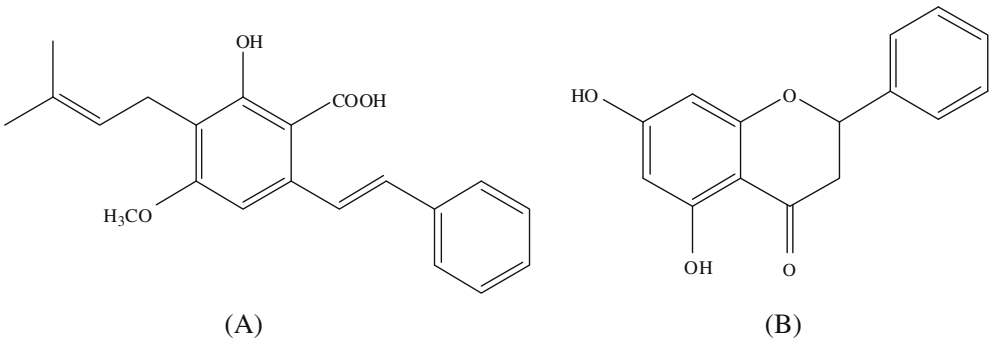

Fig. 1. Structures of CSA (A) and PI (B).

abundant as a natural resource, and the constituents CSA and PI with good antioxidant activity, are of high content in pigeonpea leaves, therefore, it is of great interest to investigate the extraction of CSA and PI from pigeonpea leaves as natural antioxidants.

The structures of CSA and PI are shown in Fig. 1. They are relatively non-polar or slightly polar compounds, and are difficult to dissolve in water. Therefore, higher concentrations of organic solvent and higher temperature are needed to guarantee a better extraction performance. PI has been extracted with ether, ethanol and methanol (Cannon & Martin, 1977; Duker-Eshun, Jaroszewski, Asomaning, Oppong-Boachie, & Brogger-Christensen, 2004; Mohamad et al., 2004). While for the extraction of CSA, methanol and ethanol (Cooksey et al., 1982) have been used. However, organic solvent is quite harmful to human health and environment, so therefore, its use in food, cosmetic and pharmaceutical industries has many restricts. Regarding the extraction of antioxidants, supercritical fluid extraction with CO_2 is an alternative method for replacing organic solvent, it has received considerable attention recently (Abbas, Mohamed, Abdulamir, & Abas, 2008). CO_2 is abundant, inert, non-toxic, environmentally friendly solvent and acceptable in food industry. The extracts obtained by SFE are of outstanding quality and the yields are comparable with those of organic solvent extraction methods (He et al., 2005). SFE extracts were generally recognised as safe (GRAS) to be used in food products. Therefore, SFE may serve as a promising technology in food and pharmaceutical processing (Abbas et al., 2008).

In the present study, SFE of CSA and PI from pigeonpea leaves was studied for the first time. Extraction yields of SFE and HRE were compared and the morphological changes of leaves before and after extraction were observed by SEM. The effects of modifier composition, liquid to solid ratio, and CO_2 flow rate were studied by single factor test, while three operating parameters including extraction pressure, temperature and time on the extraction yields were investigated and optimised by central composite design combined with response surface methodology. Furthermore, the antioxidant activity of extracts, obtained under optimised SFE conditions was determined by means of 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical-scavenging assay.

2. Materials and methods

2.1. Plant material

Pigeonpea leaves were collected from Hainan province, China, and authenticated by Professor Shao-quan Nie from the Key Laboratory of Forest Plant Ecology, Ministry of Education, Northeast Forestry University, PR China. Voucher specimens were deposited in the herbarium of this Laboratory. The leaves were dried in the airy shade for 30 days. After that, the dried leaves were pulverised, parts of them were sieved to sizes of 40–60 mesh. The sieved leaves were dried to a constant weight, then, kept away from light in a desiccator at room temperature until used.

2.2. Chemical and reagents

Carbon dioxide (purity 99.99%, Liming gas Corp., China), ethanol (99.7%, A.R., Harbin Xinchun chemical reagents Corp., China), methanol (J & K Chemical Ltd., China), formic acid (96%, DIMA Technology Inc., USA), 2,2-diphenyl-1-picrylhydrazyl (DPPH) and ascorbic acid (VC) were purchased from Sigma–Aldrich, Steinheim, Germany. The water used in all experiments was bi-distilled water. Employed reference compounds CSA ($\geqslant$98%, HPLC grade) and PI ($\geqslant$95%, HPLC grade), were separated and purified in the same Key Laboratory. The structures were confirmed by comparing their UV, MS, ^{1}H NMR and ^{13}C NMR data with the data from literatures (Cooksey et al., 1982; Cuong, Sung, Kamperdick, & Adam, 1996).

2.3. Heat-refluxing extraction

A conventional method of heating-refluxing extraction using ethanol–water (80:20, v/v) was performed to compare the extraction performances with SFE. According to the preliminary investigation, target compositions were extracted by adding 20 g of pigeonpea leaves into 400 ml of solvent in a round bottom flask. The extraction was employed to optimum condition of 65 °C for 2 h under magnetic stirring at 500–700 rpm. The extracting solution was filtered by membrane filtration and analysed by HPLC. The extraction results were compared with that using SFE.

2.4. SF-CO_2 extraction

The SF-CO_2 extraction experiments were performed using an HA121-50-01 SFE device (Hua'an Supercritical Fluid Extraction Corp., Nantong, China), the schematic flow diagram was described in detail in a previous study (Wang, Pan, Sheng, Xu, & Hu, 2007). Briefly, the operating methodology was as follows: liquid CO_2 supplied from a gas cylinder was cooled by ethanol to −5 °C. The cooled CO_2 and aqueous ethanol from the modifier tank were pressurised, respectively, to the desired pressure, then mixed, heated to a specified temperature and passed to the device, the entire device was also pre-pressurised. For each experiment, approximately 100 g pigeonpea leaves were filled into a steel cylinder equipped with mesh filters (6.5 μm) on both ends, the loaded cylinder was then introduced into the extraction vessel, which was placed in a heating muff, the desired extraction temperature and pressure were adjusted, after that, the CO_2 feed was started. The extracts were deposited in the separators and collected together in plastic bottles loop.

A 2^3 factorial portion central composite design (CCD) combined with response surface methodology was used for optimising

extraction pressure (X_1), temperature (X_2) and time (X_3). In the CCD test, 14 experiments and six replicates at the centre were employed to fit the full quadratic equation model. The general equation is:

$$Y = \beta_0 + \sum_{j=1}^{k} \beta_j X_j + \sum_{j=1}^{k} \beta_{jj} X_j^2 + \sum \sum_{i<j} \beta_{ij} X_i X_j \quad (k = 3)$$

where Y is the predicted response, β_0, β_j, β_{jj} and β_{ij} are the regression coefficients for intercept, linearity, square and interaction, respectively, while X_i and X_j are the independent coded variables. The variables of each factor were transferred to range between −1 and 1 for the appraisals, while the dependent variable was the extraction yield of CSA and PI. Coded variables were used according to the equation:

$$X_i' = \frac{X_i - X_{0i}}{\Delta X_i} \quad (i = 1, 2, 3)$$

where X_i' is the coded value of the independent variable. X_i is the real value of the independent variable. X_{0i} is the real value of the independent variable at the centre point. ΔX_i is the step change of the real value of variable 'i'. The actual and coded levels of the independent variables used in the experimental design are shown in Table 1.

During all of the experimental process, CO_2 flow rate ranged from 3.8 to 14.0 kg/h. The extraction pressure varying from 15 to 40 MPa and temperature varying from 35 to 70 °C were controlled by adjusting valves according to the meter on the front panel. Aqueous ethanol was delivered by a high pressure liquid pump. Once the scheduled time was achieved, the extraction vessel was depressurised and the extracts were collected from the separation vessel. The accumulated product samples were collected and concentrated to give the extracts mass, which was used for the following tests.

2.5. Scanning electron microscopy

The morphological changes of samples before and after extraction were observed by SEM. After removing the solvent, the remaining pigeonpea leaf samples were plunged into liquid nitrogen and cut with a cold knife. The sectioned particles were fixed on a specimen holder with aluminium tape and marked, then sputtered with gold in a sputter-coater. All the samples were examined with a Quanta-200 SEM (FEI Company, USA) under high vacuum and at an accelerating voltage of 15.0 kV (20 μm, 1000 × magnification).

2.6. Determination of CSA and PI

The Agilent 1200 reversed-phase HPLC system was employed for CSA and PI determination. An HIQ sil C_{18}W column (150 mm × 4.6 mm i.d., 5 μm) fit with an Alltech C_{18} guard column (8 mm × 4.6 mm i.d., 5 μm) was used. The column temperature was set at 25 °C. The mobile phase was chosen as solvent A (0.1% formic acid in water, v/v) and B (methanol) at a flow rate of 1.0 ml/min. A linear gradient lasted for 60 min: 0–10 min, keep A with 67%; from 10 to 30 min, changing A from 67% to 35% in 20 min; then from 30 to 40 min, changing A from 35% to 10% in 10 min and keep this scale for 10 min; finally, changing A to 67% in 10 min for the balance.

The CSA at wavelength of 259.2 nm and PI at 280.8 nm was verified and used for the RP-HPLC quantification. Eight experimental points were employed for establishing a calibration curve. The calibration curves for CSA and PI were $Y = 80876\ X - 771.79$, $Y = 36591\ X + 703.22$, respectively, where Y is the peak area of the analyte, and X is the concentration of the analyte (mg/g). The correlation coefficients (R^2) were 0.9996 and 0.9932, respectively. The recovery of CSA and PI varied between 94.3% and 106.8%, and RSD were less than 5%.

2.7. Antioxidant activity

The DPPH radical-scavenging activity (anti-free-radical activity) is based on the determination by 2,2-diphenyl-1-picrylhydrazyl (DPPH) at a steady state in ethanol solution after adding the mixture of antioxidants. Following the detailed method of Liyana-Pathiranan and Shahidi (2005), the extract was dissolved in 10 ml of absolute ethanol to give a final concentration of 4 mg/ml, then 2 ml of 0.004% DPPH (0.2 mM) in ethanol was added to 1 ml of the extract solution. After shaking the mixture vigorously, the decrease of absorbance was measured at 517 nm until the

reaction reached a plateau. Absolute ethanol was used as the control and ascorbic acid, a stable antioxidant, was used as synthetic reference. The DPPH radical-scavenging activity in percentage of sample was calculated according to the following equation: DPPH scavenging activity (%) = $(1 - A_{517}$ sample$/A_{517}$ DPPH solution$) \times 100$.

2.8. Statistical analysis

All data collected from central composite design SFE experiments were centred by using three parallel measurements of mean ± SD. Then, the data was analysed using a response surface analysis procedure (Statistica 6.0). Analysis of variance was performed for calculations and modelling the optimum conditions for SFE of CSA and PI from pigeonpea leaves. P values <0.05 were regarded as significant and P values <0.01 as very significant.

3. Results and discussion

3.1. Comparison of SFE with HRE

The comparison of SFE with HRE was conducted with the same experimental condition of 65 °C for 2 h, 80% EtOH as the solution. In SFE, the pressure was 30 MPa, with a CO_2 flow rate of 14.0 kg/h, while in HRE, magnetic stirring was employed at 500–700 rpm.

The extraction yields of CSA and PI obtained using SFE were 11.17 ± 0.58 mg/g and 2.73 ± 0.61 mg/g, which were higher than those of HRE (8.31 ± 0.94 and 1.99 ± 0.61 mg/g, respectively). The amount of extract was weighed after removing the solvent to determine the yields, the extracts yield obtained by SFE was 81.42 ± 7.49 mg/g, which was lower than using HRE (208.51 ± 16.43 mg/g). The contents of CSA and PI in SFE extracts

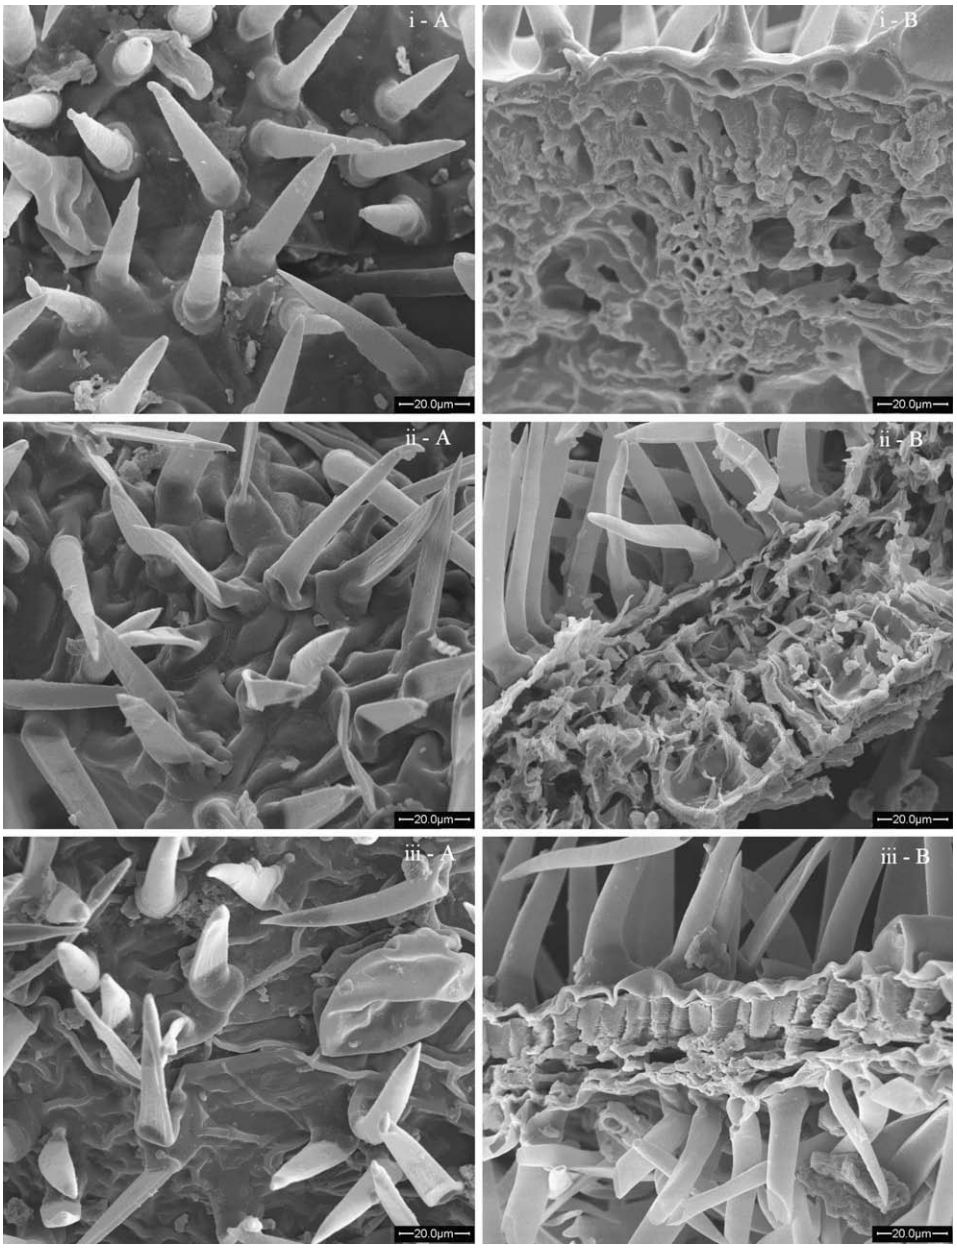

Fig. 2. Scanning electron micrographs of untreated pigeonpea leaves sample (i), sample after HRE (ii) and sample after SFE (iii); (A) surface-observation of sample, (B) cutting plane-observation of sample. Each figure was scanned at the same accelerating voltage of 15.0 kV (20 μm, 1000× magnification).

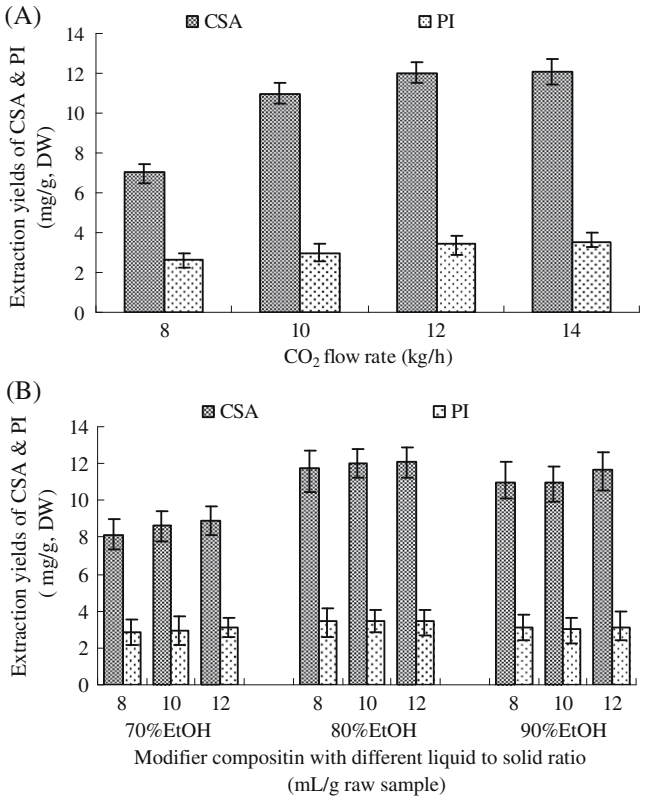

Fig. 3. Effect of CO_2 flow rate (A), modifier composition with different liquid to solid ratio (B) on extraction yields of CSA and PI ($n = 3$).

reached 138.24 ± 9.51 and 33.12 ± 3.47 mg/g, which were 3.47- and 3.53-fold to those in HRE extracts. The result demonstrated that SFE could selectively extract CSA and PI, because SFE is suitable for non-polar or slightly polar compounds and less volatile compounds (Brunner, 2005).

Moreover, SEM was used to elucidate the morphological changes during each extraction procedure. Fig. 2 shows the micrographs of the untreated sample, HRE sample and SFE sample, respectively. As shown in Fig. 2i-A, ii-A and iii-A, the surface morpha observed in HRE were hardly wrinkled from that of the untreated sample. However, obvious wrinkling took place on the surface of sample after SFE. When compared with the profiles shown in Fig. 2i-B, ii-B and iii-B, the palisade parenchyma and spongy parenchyma of pigeonpea leaf sample were slightly changed after HRE, but greatly changed or destroyed after SFE. The observation suggested that SFE influences the structure of mesophyll cells, because the supercritical fluids have the diffusivity of a pressure–temperature dependent density and modifier sensitivity (Chakraborty, Kumbhar, & Sarkar, 2007), the pressurised solvent in supercritical or, more generally, near-critical state flows continuously through the bed of particles and dissolves out the solute (Sovová, 2005).

The above result presented a clear advantage of SFE in enriching CSA and PI. The optimisation of SFE and quality evaluation of the optimum SFE extracts in terms of antioxidant activity is discussed below.

3.2. Optimisation of SFE procedure

3.2.1. Effect of CO_2 flow rate, modifier composition and liquid to solid ratio

Fig. 3 shows the effects of CO_2 flow rate, modifier composition and liquid to solid ratio. The effect of CO_2 flow rate was studied with the following conditions: 100 g pigeonpea leaves were extracted at a temperature of 55 °C, pressure 30 MPa, 80% EtOH with liquid to solid of 10 ml/g raw material and extraction time of 2 h, and a CO_2 flow rate were 8, 10, 12, 14 kg/h, respectively. It can be seen from Fig. 3A, at the range of 8–14 kg/h, the extraction yields obviously increased with the CO_2 flow rate. After a CO_2 flow rate of 12 kg/h was achieved, the extraction yields did not increase much further with the increase of CO_2 flow rate. At the range of this trial, the mass transfer parameter increased with the supercritical fluid flow rate until it reached a constant value. Salgın (2007) reported similar results in the SFE of seed oil. Soybean isoflavones recovery tended towards the same value (Zuo, Zeng, Yuan, & Yu, 2008) when higher amounts of carbon dioxide were used. In this study, extraction at the CO_2 flow rate of 12 kg/h gave the highest extraction yields for the targets.

The effects of modifier composition (70–90% EtOH) and liquid to solid ratio (8–10 ml/g raw material) were investigated at a temperature of 55 °C, pressure of 30 MPa, CO_2 flow rate of 12 kg/h and extraction time of 2 h. The results are shown in Fig. 3B. The modifier of 80% EtOH with liquid to solid ratio of 10 ml/g raw material gave the highest extraction yields of CSA and PI, followed by 90% and 70% EtOH. As shown in this figure, as EtOH concentration was higher than 80%, the extraction yield decreased. Lower EtOH concentration yielded stronger polarity of the modifier, which favored the extraction of polar compounds. On the contrary, CSA and PI are slightly polar compounds, and much lower EtOH concentration limited their solubility, resulting in declined extraction yields. In addition, water could swell the plant material, which increases the contact area between solvent and plant sample, therefore proper water in solvent could enhance the extraction ratio (Hemwimon, Pavasant, & Shotipruk, 2007). Hence, 80% ethanol solution with liquid to solid ratio of 10 ml/g raw material was selected for the following tests.

3.2.2. Optimisation of SFE operating parameters

The objective of the present study is to optimise the operating conditions to achieve an efficient extraction of CSA and PI from pigeonpea leaves. Because various parameters potentially influence the SFE process, the optimisation of the operating conditions plays a critical role in the development of a SFE method. Central composite design (CCD) combined with response surface methodology was used for optimising. According to the preliminary test, material size was sieved to 40–60 mesh, CO_2 flow rate was 12 kg/h, and a modifier of 80% EtOH with liquid to solid ratio of 10 ml/g raw material was employed. Three parameters including extraction pressure, temperature and time were optimised by a 2^3 factorial portion central composite design. All trial results obtained from 20 runs of the experiment and their predicted data from the model based on the experimental data were summarised in Table 1.

As shown in Table 1, the extraction yields of CSA and PI in the trial were similar to those expected and the results demonstrated the accuracy of predictive model. According to the analysis of variance (ANOVA), correlation coefficients (R^2) of 0.942 and 0.939, respectively, were obtained for CSA and PI with the calculated model. In addition, high significant levels for these ($P < 0.001$) were obtained by statistical analysis.

Eqs. (I) and (II) were obtained by statistical analysis, and show the relationship between the extraction yields of CSA and PI with extraction pressures, temperatures and time, respectively

$$Yc = 11.9123 + 0.7897X_1 + 1.4698X_2 + 0.9424X_3 + 0.2754X_1X_2 + 0.0694X_1X_3 - 0.5046X_2X_3 - 1.2478X_1^2 - 0.9426X_2^2 - 0.5601X_3^2 \quad (I)$$

$$Yp = 3.3686 + 0.3307X_1 + 0.3479X_2 + 0.2746X_3 - 0.0151X_1X_2 - 0.1611X_1X_3 - 0.1084X_2X_3 - 0.2441X_1^2 - 0.3016X_2^2 - 0.2366X_3^2 \quad \text{(II)}$$

where Yc is the extraction yield of CSA (mg/g) and Yp is the extraction yield of PI (mg/g); X_1 the extraction pressure (MPa), X_2 is the extraction temperature (°C) and X_3 is the extraction time (h).

By solving the Eqs. (I) and (II), the maximum predictive extraction yield of CSA 12.82 mg/g and PI 2.96 mg/g were obtained. The

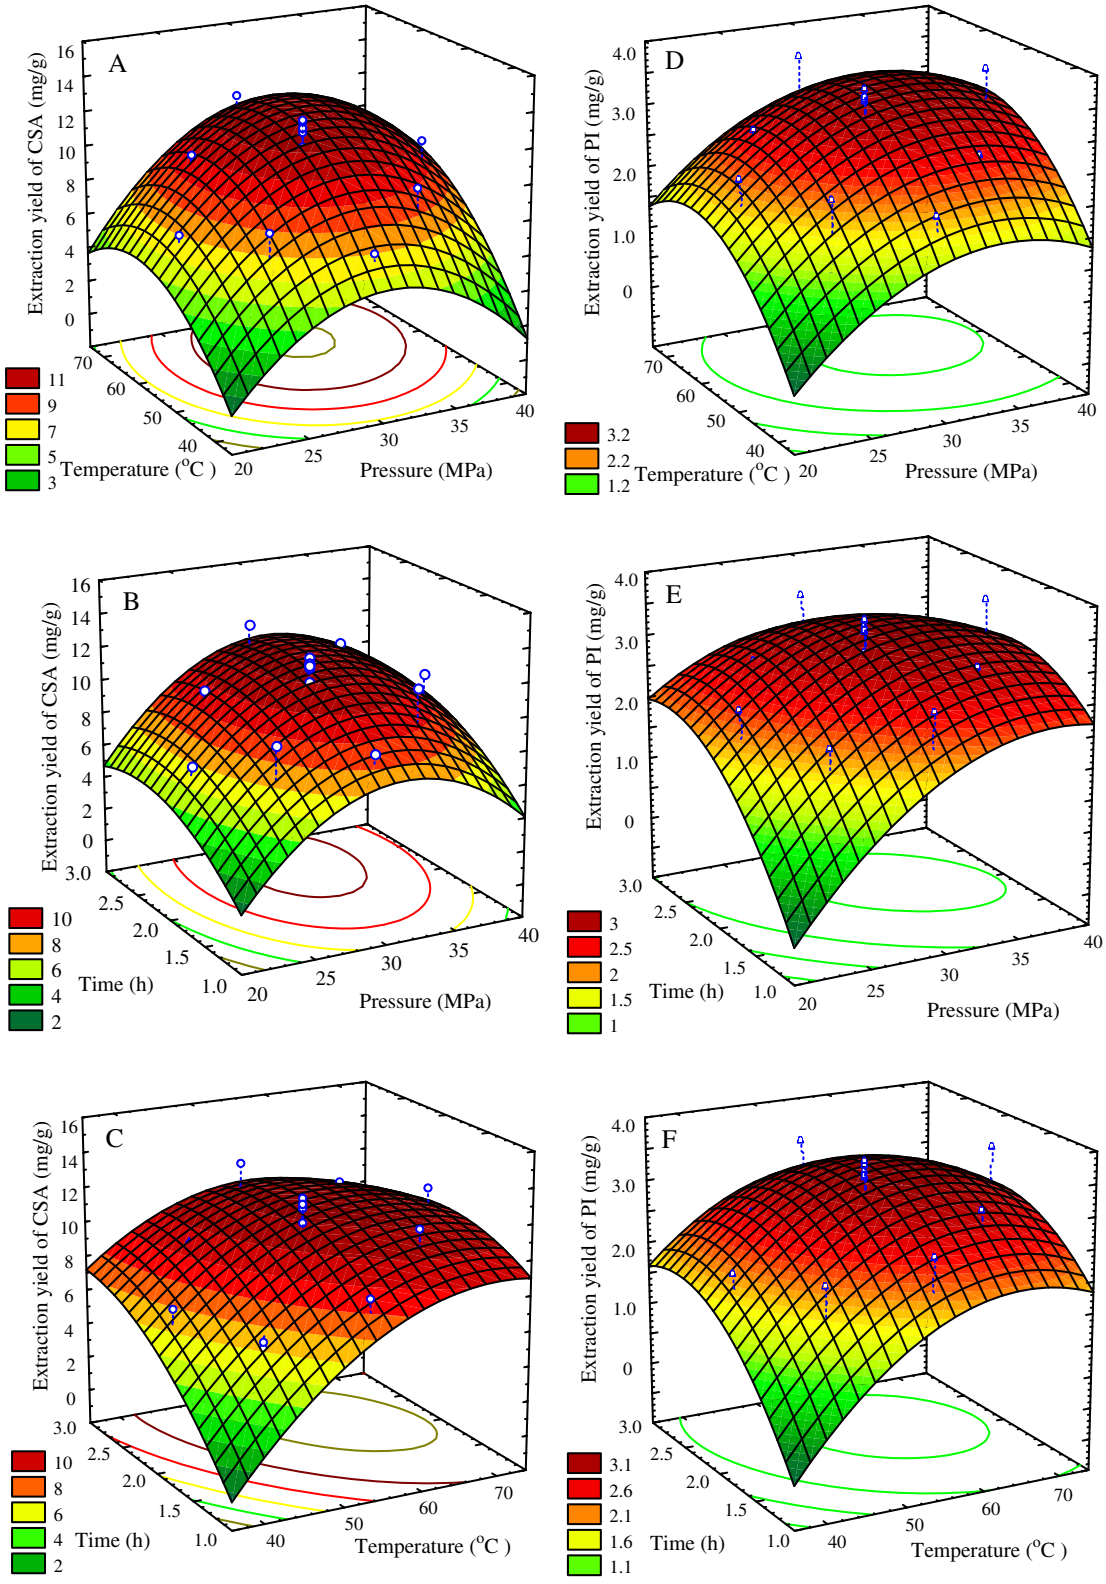

Fig. 4. Response surfaces for CSA (A–C) and PI (D–F) from pigeonpea leaves: (A and D) varying extraction temperature and pressure; (B and E) varying extraction pressure and time; (C and F) varying extraction temperature and time.

predictive values of relevant parameters for CSA were pressure 31.90 MPa, temperature 60.90 °C and time 2.24 h, while for PI they were: pressure 40.12 MPa, temperature 61.06 °C and time 1.74 h.

Meanwhile, Fig. 4A–F of three-dimensional profiles of multiple non-linear regression models were used to depict the interactive effects of operational parameters for CSA and PI, respectively.

As shown in Fig. 4A and D, increase of temperature from 35 to 60 °C with extraction pressure increasing from 20 to 30 MPa enhanced the extraction yields of CSA and PI simultaneously. It was expected that CO_2 density increased with pressure, and therefore increased the solvent power to dissolve the solute. Once the extraction pressure was higher than 30 MPa at 65 °C, the extraction became difficult, due to the interactive effect of density and solute vapour pressure for the extraction yield (Machmudah et al., 2008; Wang, Yang, Dua, & Yi, 2008). It was also observed that as temperature increased, the solubility changed accordingly, which would enhance the extraction efficiency. From Fig. 4A and D, an approximate temperature of 60 °C produced the highest extraction yields of CSA and PI (suggesting 60 °C could offer the suitable surface tension of extraction temperature for CSA and PI enriched extract). Wang et al. (2008) reported a similar result for flavonoid enriched extracts.

Response surfaces for CSA and PI with varying extraction pressure and time are shown in Fig. 4B and D. For increased pressure from 25 to 35 MPa with an increase of extraction time from 1 to 3 h, the CSA extraction yield was slightly enhanced, while for PI, there was nearly no effect. The result suggested, during experimental procedure or statistic analyses, that the interactive effect between extraction pressure and time on the extraction efficiency of CSA and PI could be ignored.

Fig. 4C and F describe the interactive effect of extraction temperature and time on CSA and PI. It can be seen that with an increase in temperature from 35 to 75 °C along with an increase in extraction time from 1 to 2 h, the CSA and PI extraction yields were enhanced. It is indicated that an increase in temperature could accelerate the mass transfer ratio from plant material to solvent, thus increasing the extraction yield. However, the extraction yields of CSA and PI decreased after 2 h extraction with a temperature of 65 °C. This could be because as the extraction time prolongs, the chemical decomposition of bioactive compounds presented in extracts may occur, resulting in the decrease of extraction yields (Huang, Xue, Niu, Jia, & Wang, 2008). It was also observed in the experiment that as temperature increased, the solvent capability changed, which extracted more impurities.

In summary, the optimal parameters of pressure 30 MPa, temperature 60 °C and time 2 h were selected on the basis of response surface. Those were within the investigation ranges. In comparison with the predictive values from Eqs. (I) and (II), the extraction parameters for CSA were accorded with predictive values. For PI the extraction temperature was a little lower, because some non-significant effects from response surface were eliminated but they were involved in the predictive equations. Accordingly, the better SFE process was obtained as follows: modifier composition 80% EtOH solution with liquid to solid ratio 10 ml/g raw material, CO_2 flow rate 12 kg/h, extraction pressure 30 MPa, temperature 60 °C and extraction time 2 h. Under the optimised conditions, the extraction yields of CSA and PI reached 12.17 ± 0.88 and 3.22 ± 0.56 mg/g, respectively, which were increased 1.46- and 1.77-fold to those by HRE. Furthermore, the contents of CSA and PI in the SFE extracts were 149.64 ± 8.26 and 39.08 ± 1.88 mg/g, which were 3.76- and 4.17-fold to the contents of HRE extracts. The above results were attributed to SF-CO_2 efficiently enhancing the release of lower polarity CSA and PI from the insoluble mesophyll tissue of pigeonpea leaves, therefore higher extraction yields and higher contents were obtained.

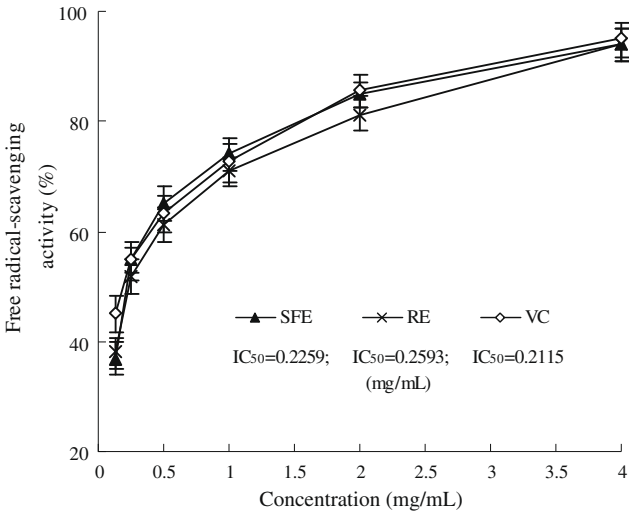

Fig. 5. Free radical-scavenging activity of SFE extracts, HRE extracts and VC (n = 3).

3.3. Antioxidant activity

Antioxidant activities of the SFE extracts and HRE extracts were tested by 1,2-diphenyl-2-picrylhydrazyl (DPPH) radicals. The reduction of the DPPH absorbance at 517 nm after 70 min incubation with the sample in darkness was measured, the results are presented in Fig. 5. The concentration of sample producing a 50% reduction of the radical absorbance (IC_{50}) was used as an index to compare the antioxidant activity.

The samples were assayed over a range of dilutions. It was observed that SFE extracts from pigeonpea leaves exhibited notable DPPH radical-scavenging activity, with an IC_{50} value of 0.2259 mg/ml nearly equal to that of the reference VC (0.2115 mg/ml), and superior to that of HRE extracts (0.2593 mg/ml). The values for SFE extracts ranged from 94.06 ± 2.85% to 36.79 ± 2.80%, with concentrations varying from 4 to 0.25 mg/ml, the decrease in the extract concentration resulted in the reduction of its free radical-scavenging activity. In the authors' previous paper (Wu et al., 2009), IC_{50} values of CSA of 0.3012 and PI with more than 0.500 mg/ml have been reported. These results combined with the data in this test, indicated that CSA should be one of the most efficient antioxidants in pigeonpea leaves. In comparison with HRE, SFE extracts with higher CSA and PI content showed higher antioxidant activity. Although PI did not present *in vitro* antioxidant activity by DPPH (Wu et al., 2009), it strongly induced mammalian phase 2 detoxication enzymes and antioxidant enzymes (Fahey & Stephenson, 2002). Hence, further studies on the antioxidant activity of SFE extracts *in vivo* are urgently needed. The present result provides evidence that the SFE extracts of pigeonpea leaves could be used in the field of food industries and other fields because of its excellent antioxidant activity.

4. Conclusions

In the present study, the SFE operating conditions were optimised to achieve an efficient extraction of CSA and PI from pigeonpea leaves, and the antioxidant activity of the resulting extracts have been evaluated *in vitro* by DPPH. The optimal performance was obtained under the operating pressure 30 MPa, temperature 60 °C, time 2 h, and 80% EtOH solution as the modifier with a liquid to solid ratio of 10:1 and CO_2 flow rate of 12 kg/h. Compared with HRE, the SFE method obtained higher extraction yields (12.17 ± 0.88 and 3.22 ± 0.56 mg/g for CSA and PI, respectively) and higher contents (149.64 ± 8.26 and 39.08 ± 1.88 mg/g for CSA

and PI, respectively), and the SFE extracts showed better antioxidant activity with an IC_{50} value 0.2259 mg/ml. SFE could be a prospective alternative to the traditional HRE for the efficient extraction of natural constituents CSA and PI from pigeonpea leaves. Meanwhile, the present research indicates that SFE extracts of pigeonpea leaves might be a valuable natural antioxidant resource and have potential use in food industries and other fields for its excellent antioxidant activity. However, further studies should be conducted *in vivo* for screening the antioxidants of SFE extracts from pigeonpea leaves.

Protein–phenolic complex
Antioxidative activity
Emulsifying properties

ABSTRACT

Antioxidative activity and emulsifying properties of cuttlefish skin gelatin modified by different oxidised phenolic compounds including caffeic acid, ferulic acid and tannic acid at different concentrations were investigated. Oxidised phenolic compounds were covalently attached to gelatin as indicated by the decrease in amino groups. Fourier transform infrared spectroscopic studies indicated the presence of an aromatic ring and a hydroxyl group in gelatin after modification. Modified gelatin had the increased antioxidative activity but the decreased surface hydrophobicity. Gelatin modified with 5% oxidised tannic acid had no change in emulsifying properties. Emulsion stability and oxidative stability of menhaden oil-in-water emulsion stabilised by 0.5% and 1.0% gelatin without and with modification by 5% oxidised tannic acid were studied. Both gelatins at a higher concentration (1.0%) yielded an emulsion with a smaller particle size. Modified gelatin inhibited the formation of TBARS in the emulsion more effectively than the control gelatin throughout the 12 days of storage.

1. Introduction

Proteins are widely used as emulsifiers in food products because of their ability to improve the stability of oil-in-water emulsions (McClements, 2004). Although low molecular mass surfactants, such as lecitin, mono- and diglycerides etc., are more effective than protein in reducing the interfacial tension, foams and emulsions formed by such surfactants are mostly unstable (Damodaran, 2005). In addition to lowering interfacial tension, proteins can form a continuous viscoelastic membrane-like film around oil droplets, whereas the low molecular mass surfactants cannot form such a viscoelastic film (Damodaran, 1997). A major potential advantage of proteins as emulsifiers in foods is their ability to protect lipids from iron catalysed oxidation (Hu, McClements, & Decker, 2003). At pH values below their isoelectric point (pI), proteins form positively charged interfacial membranes around oil droplets, which electrostatically repel any Fe^{2+} and Fe^{3+} ions present in the aqueous phase, thereby preventing oxidation of polyunsaturated lipids within the droplets (Surh, Decker, & McClements, 2005). Moreover, amino acids in protein can scavenge free radical and chelate prooxidative metals (Djordjevic, Cercaci, Alamed, McClements, & Decker, 2008).

Gelatin is commercially made from skins and skeletons of bovine and porcine. It has been used extensively in the medical, food, photographic and other industries (Derkatch, Petrova, Izmailova, & Tarasevitch, 1999). Gelatin is surface-active and is capable of acting as an emulsifier in oil-in-water emulsions (Lobo, 2002). However, the occurrence of bovine spongiform encephalopathy (BSE) and foot/mouth diseases has led to the increasing interest of other gelatin sources, especially fish skin and bone from seafood processing. Nevertheless, gelatin from marine resources had the poorer emulsifying properties, compared with mammalian gelatin (Aewsiri, Benjakul, Visessanguan, & Tanaka, 2008).

Plant phenolics are defined as compounds possessing one or more aromatic ring bearing a hydroxyl substituent(s), and can be found in many foods and drinks from plant origin, e.g. fruits, vegetables, coffee (Parr & Bolwell, 2000). Phenolic compounds can interact with proteins through non-covalent and covalent interaction. However, covalent bonding seems to play an important role in protein-phenol interaction, which is used to improve functional properties of proteins. Foam formation and the stability of a Tween 20/β-lactoglobulin mixed system was improved by (+)-catechin due to (+)-catechin-induced cross-linking of proteins in the

adsorbed layer (Sarker, Wilde, & Clark, 1995). Additionally, antioxidative activity of proteins can be modified by phenolic compounds (Rohn, Rawel, & Kroll, 2004). Nevertheless, little information regarding the modification of gelatin with phenolic compounds and its impact on stability and lipid oxidation of emulsion systems has been reported. Therefore, the objectives of this study were to investigate the effect of cuttlefish skin gelatin modified by oxidised phenolic compounds, including ferulic acid, caffeic acid and tannic acid, on stability and lipid oxidation of fish oil emulsion.

2. Materials and methods

2.1. Chemicals

Ferulic acid (FA), tannic acid (TA), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS), 1,1-diphenyl-2-picrylhydrazyl (DPPH), 2,4,6-tripyridyl-triazine (TPTZ), 2,4,6-trinitrobenzenesulfonic acid (TNBS), Trolox and menhaden oil were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Caffeic acid was purchased from Fulka (Buchs, Switzerland). Hydrogen peroxide (H_2O_2), trichloroacetic acid (TCA), 2-thiobarbituric acid (TBA), Folin–Ciocalteu's phenol reagent, sodium sulphite and ferric chloride were obtained from Merck (Darmstadt, Germany). All chemicals were of analytical grade.

2.2. Preparation of cuttlefish skin

The ventral skin of cuttlefish (*Sepia pharaonis*) was obtained from a dock in Songkhla, Thailand. Cuttlefish skin was stored in ice with a skin/ice ratio of 1:2 (w/w) and transported to the Department of Food Technology, Prince of Songkla University within 1 h. Upon arrival, cuttlefish skin was washed with tap water and cut into small pieces (1 × 1 cm), placed in polyethylene bags and stored at −20 °C until use. Storage time was not longer than 2 months.

2.3. Extraction of gelatin from cuttlefish skin

Cuttlefish skin was treated with 10 volumes of 0.05 N NaOH for 6 h with a gentle stirring at room temperature (26–28 °C). The solution was changed every 1 h for up to 6 h. Alkali treated skin was then washed with distilled water until the neutral pH of wash water was obtained. The prepared skin was subjected to bleaching with 10 volumes of 5% H_2O_2 at 4 °C for 48 h at room temperature and then washed with 10 volumes of water 3 times. Gelatin was extracted from the bleached skin using distilled water (60 °C) for 12 h with a sample/water ratio of 1:2 (w/v). During extraction, the mixture was stirred continuously. The extract was centrifuged at 8000×*g* for 30 min using a refrigerated centrifuge (Sorvall Model RC-B Plus, Newtown, CT, USA) to remove insoluble material. The supernatant was collected and freeze-dried using a freeze dryer (Model Dura-Top™ μP/Dura Dry™ μP, FTS® System, Inc., Stone Ridge, NY, USA).

2.4. Modification of cuttlefish skin gelatin by phenolic compounds

Cuttlefish skin gelatin was dissolved in distilled water containing 0.02% sodium azide (NaN_3) to obtain a final concentration of 1.2% protein. The pH of the gelatin solution was adjusted to 9 using 1 M NaOH. To prepare the solutions of phenolic compounds, caffeic acid, ferulic acid and tannic acid at the concentration of 2% (w/v) were dissolved in distilled water, followed by a pH adjustment to 9 with 1 M NaOH. Solutions were then bubbled with oxygen at 40 °C for 1 h to convert the phenolic compounds into oxidised form. To 75 ml of the gelatin solution, oxidised phenolic solutions at different concentrations (5%, 10%, 25% and 50%, based on protein content) were added. The final volume was raised to 90 ml using distilled water (pH 9) to obtain a final concentration of 1% protein. The mixture was stirred continuously using a magnetic stirrer (RO 10 power IKAMAG®, IKA LABORTECHNIK, Selangor, Malaysia) at a speed of 200 rpm at room temperature for 12 h. Thereafter, the samples were dialysed for 24 h against 20 volumes of water to remove free phenolic compounds (unbound to proteins). The control was prepared in the same manner except that phenolic compound was excluded. Gelatin–phenolic complexes were subjected to analyses.

2.5. Determination of free amino group content

The free amino group content of samples was determined according to the method of Benjakul and Morrissey (1997). To diluted samples (125 μl), 2.0 ml of 0.2125 M phosphate buffer, pH 8.2 and 1.0 ml of 0.01% TNBS solution were added. The solution was mixed thoroughly and placed in a temperature-controlled water bath (Model W350, Memmert, Schwabach, Germany) at 50 °C for 30 min in dark. The reaction was terminated by adding 2.0 ml of 0.1 M sodium sulphite. The mixtures were cooled at room temperature for 15 min. The absorbance was read at 420 nm and free amino group content was expressed in terms of L-leucine.

2.6. Determination of total phenolic content

The total phenolic content of samples was measured according to the method of Slinkard and Singleton (1977) with some modifications. The sample solution (1 ml) was 100-fold diluted with deionised water prior to mixing with 200 μl of the freshly prepared Folin–Ciocalteu reagent using a vortex mixer. After 3 min, 3 ml of sodium carbonate (15%, w/v) were added and the mixture was allowed to stand for 30 min at room temperature. The absorbance at 760 nm was measured using a UV–vis spectrophotometer (UV-160, Shimadzu, Kyoto, Japan). The blank was prepared by using deionised water instead of Folin–Ciocalteu reagent. The total phenolic content was expressed as ΔA_{760} after blank substraction.

2.7. Determination of surface hydrophobicity

Surface hydrophobicity (S_0ANS) was determined as described by Benjakul, Seymour, Morrissey, and An (1997) using 1-anilinonaphthalene-8-sulphonic acid (ANS) as a probe. Gelatin solution (4 mg/ml) was diluted in 10 mM phosphate buffer (pH 6.0) containing 0.6 M NaCl to obtain the protein concentrations of 0.1%, 0.2%, 0.3% and 0.5%. The diluted protein solution (2 ml) was mixed with 20 μl of 8 mM ANS in 0.1 M phosphate buffer (pH 7.0). The fluorescence intensity of ANS-conjugates was immediately measured at an excitation wavelength of 374 nm and an emission wavelength of 485 nm. The initial slope of the plot of fluorescence intensity versus protein concentration was referred to as S_0ANS.

2.8. Fourier transform infrared (FTIR) spectroscopy

The spectra of gelatin modified without and with oxidised phenolic compounds were obtained using a Bruker Model EQUINOX 55 FTIR spectrometer (Bruker, Ettlingen, Germany) equipped with a deuterated l-alanine tri-glycine sulphate (DLATGS) detector (Bruker, Ettlingen, Germany). The Horizontal Attenuated Total Reflectance Accessory (HATR) was mounted into the sample compartment. The internal reflection crystal (Pike Technologies, Madison, WI, USA), which was made of zinc selenide, had a 45° angle of incidence to the IR beam. Spectra were acquired at a resolution of 4 cm^{-1} and the measurement range was 4000–600 cm^{-1} (mid-IR region) at room temperature. Automatic signals were collected in

16 scans at a resolution of 4 cm^{-1} and were ratioed against a background spectrum recorded from the clean, empty cell at 25 °C. Analysis of spectral data was carried out using the OPUS 3.0 data collection software programme (Bruker, Ettlingen, Germany).

2.9. Determination of emulsifying properties

Emulsion activity index (EAI) was determined according to the method of Pearce and Kinsella (1978) with a slight modification. Soybean oil (2 ml) and gelatin solution (1% protein, 6 ml) were homogenised using a homogeniser (model T25 basic, IKA LABORTECHNIK, Selangor, Malaysia) at a speed of 20,000 rpm for 1 min. Emulsions were pipetted out at 0 and 10 min and 100-fold diluted with 0.1% SDS. The mixture was mixed thoroughly for 10 s using a vortex mixer. A_{500} of the resulting dispersion was measured using a spectrophotometer (UV-160, Shimadzu, Kyoto, Japan). EAI at 0 and 10 min were calculated by the following formula:

$$\mathrm{EAI}(m^2/g) = (2 \times 2.303\,A)\mathrm{DF}/l\phi C$$

where A, A_{500}; l, path length of cuvette (m), DF, the dilution factor (100); ϕ, oil volume fraction and C, protein concentration in aqueous phase (g/m^3).

2.10. Determination of antioxidative activities

2.10.1. DPPH radical scavenging activity

DPPH radical scavenging activity was determined as described by Binsan et al. (2008) with a slight modification. To the diluted sample (1.5 ml), 1.5 ml of 0.10 mM 1,1-diphenyl-2-picrylhydrazyl (DPPH) in 95% ethanol was added. The mixture was then mixed vigorously and allowed to stand at room temperature in the dark for 30 min. The absorbance of the resulting solution was measured at 517 nm using a UV–vis spectrophotometer (UV-160, Shimadzu, Kyoto, Japan). The standard curve of Trolox (60–600 μM) was prepared in the same manner. The activity was expressed as μmol Trolox equivalent (TE)/mg protein.

2.10.2. ABTS radical scavenging activity

ABTS free radical scavenging assay was determined according to the method of Re et al. (1999) with a slight modification. 2,2′-azinobis(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) free radical was generated by reacting 7.4 mM ABTS and potassium persulfate (2.6 mM) at a ratio of 1:1 (v/v) and leaving at room temperature in the dark for 12 h. ABTS free radical solution was diluted by mixing 1 ml of ABTS solution with 50 ml of methanol to obtain an absorbance of 1.1 ± 0.02 units at 734 nm using an UV–vis spectrophotometer (UV-160, Shimadzu, Kyoto, Japan). To 150 μl of sample, 2850 μl of ABTS**.**+ solution was added and mixed thoroughly using a vortex mixer (Vortex genie® 2, Scientific Industries, Bohema, NY, USA). The extent of quenching of the ABTS**.**+ was measured at 734 nm after 2 h incubation at room temperature in dark. The standard curve of Trolox (60–600 μM) was prepared in the same manner. The activity was expressed as μmol TE/mg protein.

2.10.3. Ferric reducing antioxidant power (FRAP)

FRAP was determined as described by Benzie and Strain (1996) with a slight modification. 2.85 ml of freshly prepared FRAP solution (2.5 ml of a 10 mM TPTZ solution in 40 mM HCl plus 2.5 ml of 20 mM $FeCl_3 \cdot 6H_2O$ solution and 25 ml of 300 mM acetate buffer, pH 3.6) was incubated at 37 °C for 30 min before mixing with 150 μl of sample. The mixture was allowed to react in dark at room temperature. The absorbance was measured at 593 nm after 30 min of reaction. The standard curve of Trolox (60–600 μM) was prepared in the same manner. FRAP was expressed as μmol TE/mg protein.

2.10.4. Determination of Fe^{2+} chelating activity

Chelating activity towards Fe^{2+} was measured by the method of Boyer and McCleary (1987) with a slight modification. The diluted sample (4.7 ml) was mixed with 0.1 ml of 2 mM $FeCl_2$ and 0.2 ml of 5 mM ferrozine. The reaction mixture was allowed to stand for 20 min at room temperature. The absorbance was then read at 562 nm. The blank was prepared in the same manner except that distilled water was used instead of the sample. The chelating activity was calculated as follows:

$$\text{Chelating activity} = [(B - A)/B] \times 100$$

where A is A_{562} of sample and B is A_{562} of the blank.

2.11. Effect of gelatin modified without and with oxidised tannic acid on emulsion stability and lipid oxidation of menhaden oil emulsion

Menhaden oil-in-water emulsions were prepared by homogenising the mixture of menhaden oil and gelatin solution (1:9, v/v) at a speed of 10,000 rpm for 2 min (IKA LABORTECNIK, model T25 basic, Selangor, Malaysia). Gelatin modified without and with oxidised tannic acid (5% of protein) at concentrations of 0.5% and 1% protein were used. These coarse emulsions were then passed through a two-stage high-pressure valve homogeniser (M-110P, Microfluidizer, Newton, MA, USA) at 10,000 psi 2 times. NaN_3 (0.02%) was added to the emulsions as an antimicrobial agent. The fish oil emulsions were then stored at room temperature (28–30 °C) for 12 days. The samples were taken every two days for analyses.

2.11.1. Measurement of zeta potential and particle size

Zeta potential and particle size of emulsions were determined with ZetaPlus zeta potential analyzer (Brookhaven Instruments Corporation, Holtsville, NY, USA) at room temperature. Prior to analysis, the samples were properly diluted with deionised water.

2.11.2. Measurement of thiobarbituric acid reactive substances

Thiobarbituric acid reactive substances (TBARS) were determined as described by Buege and Aust (1978). Two ml of fish oil emulsion sample were dispersed in 10 ml of thiobarbituric acid solution (0.375% thiobarbituric acid, 15% trichloroacetic acid and 0.25 N HCl). The mixture was heated in boiling water for 10 min, followed by cooling in running tap water. The mixture was centrifuged at 3600×g for 20 min at room temperature. The absorbance of the supernatant was measured at 532 nm. The standard curve was prepared using malonaldehyde (2–10 ppm) and TBARS were expressed as mg malonaldehyde/l.

2.12. Protein determination

Protein content was determined by the Biuret method (Robinson & Hodgen, 1940) using bovine serum albumin as a standard.

2.13. Statistical analysis

The experiments were run in triplicate. All data were subjected to Analysis of Variance (ANOVA) and differences between means were evaluated by Duncan's multiple range test. For pair comparison, T-test was used (Steel & Torrie, 1980). The SPSS statistic program (Version 10.0) (SPSS Inc., Chicago, IL, USA) was used for data analysis.

3. Results and discussion

3.1. Modification of cuttlefish skin gelatin by oxidised phenolic compounds

3.1.1. Changes in free amino group content of gelatin

The free amino group contents of cuttlefish skin gelatin modified by different oxidised phenolic compounds at various levels

Table 1
Free amino group content and emulsifying properties of cuttlefish skin gelatin modified with different oxidised phenolic compound at various levels.

Oxidised phenolic compound	Concentration (%w/w of protei)	Free amino group content (mM)	Emulsion activity index (m^2/g)	
			0 min	10 min
Control (unmodified)		3.84 ± 0.12i*	20.86 ± 1.24f	10.58 ± 0.08 h
Ferulic acid	5	3.61 ± 0.19gh	19.93 ± 0.48def	10.67 ± 0.50 h
	10	3.61 ± 0.02gh	18.63 ± 0.63bcd	10.15 ± 0.47 h
	25	3.55 ± 0.14 g	18.63 ± 0.24bcd	8.95 ± 0.81 fg
	50	3.34 ± 0.03f	18.75 ± 0.95bcd	7.92 ± 0.99def

* Different letters in the same column indicate significant differences ($p < 0.05$).

are shown in Table 1. Gelatin modified by oxidised phenolic compounds had the lower free amino group content than the control gelatin (without oxidised phenolic compound) ($p < 0.05$). It indicated that nucleophilic amino groups might interact with electrophilic quinone, an oxidised form of phenolic compounds. A reaction of protein with oxidised phenolic compounds led to a decrease in free amino group content (Rawel, Kroll, & Rohn, 2001). Furthermore, the oxidised phenolic compound can react with other nucleophilic groups, such as tryptophan, cysteine, methionine, histidine, tyrosine and *N*-terminal proline of the protein molecule (Kroll, Rawel, & Rohn, 2003). The rate of loss in free amino group of gelatin depended on the type and concentration of oxidised phenolic compounds used. At the same level of oxidised phenolic compounds, the higher loss in free amino groups was observed in gelatin modified by oxidised caffeic acid ($p < 0.05$), followed by that found in gelatin modified with oxidised tannic acid and oxidised ferulic acid, respectively. In general, the loss in free amino groups was increased when the concentration of oxidised phenolic compounds used increased ($p < 0.05$). Oxidised caffeic acid (MW ~ 180) exhibited the higher interaction with amino groups of gelatin, compared with oxidised tannic acid (MW ~ 1,701). The smaller molecules might disperse uniformly and could interact with amino groups of gelatin more effectively. Although oxidised ferulic acid (MW ~ 194) had the similar molecular mass to oxidised caffeic acid, the loss in free amino groups of gelatin modified with oxidised ferulic acid was lower. Ferulic acid, with one hydroxyl of caffeic acid replaced by $-OCH_3$, is considerably less reactive. Rawel et al. (2001) reported that ferulic acid cannot be oxidised to its corresponding quinone derivative. The formation of a semiquinone radical with lower reactivity was presumed, compared with oxidised caffeic acid and oxidised tannic acid. Quinone is known as an electrophilic compound, which can interact with nucleophilic amino group of proteins (Kroll et al., 2003).

3.2. Changes in total phenol content

Total phenol contents of cuttlefish skin gelatin modified by different oxidised phenolic compounds at various levels determined by Folin–Ciocalteu method are expressed as A_{760} (Fig. 1A). The increases in A_{760} were observed in gelatin modified with all oxidised phenolic compounds when the levels of introduced compounds increased ($p < 0.05$). This result indicated that oxidised phenolic compounds were incorporated with gelatin molecules to a higher extent when the higher level of oxidised phenols was introduced. At the same level, no differences in A_{760} were noticeable between

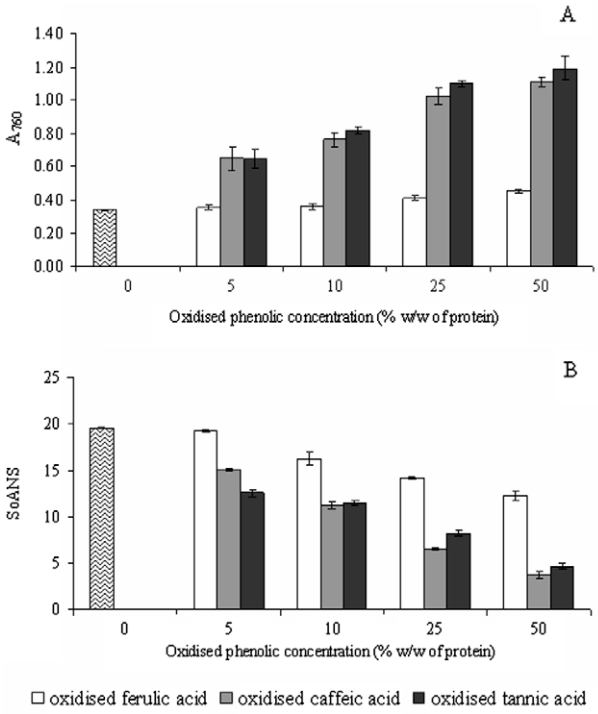

Fig. 1. A_{760} (A) and surface hydrophobicity (B) of cuttlefish skin gelatin modified with different oxidised phenolic compounds at various levels. Bars represent the standard deviation from triplicate determinations.

gelatin modified with oxidised caffeic acid and oxidised tannic acid ($p > 0.05$). A_{760} of gelatin modified by oxidised ferulic acid was lowest ($p < 0.05$). This result was associated with the lowest loss in the free amino groups of gelatin modified by oxidised ferulic acid. The result suggested that oxidised ferulic acid could incorporate with amino group of protein to some extent. Although the loss in free amino groups of gelatin modified with oxidised tannic acid was less than that of gelatin modified by oxidised caffeic acid (Table 1), no differences in A_{760} were observed between gelatin modified with both oxidised compounds. Tannic acid possessed a greater number of hydroxyl groups attached to the aromatic benzene ring as compared to caffeic acid. Those hydroxyl groups were converted to quinone, which was able to interact with the amino groups of gelatin molecules. During dialysis to remove unbound oxidised

phenols, the reduction of free quinone groups to hydroxyl groups of phenolic compounds attached to gelatin could probably take place to some degree. The similar number of reduced free hydroxyl groups between gelatin modified by oxidised caffeic acid and oxidised tannic acid more likely contributed to the similar reducing ability of Folin–Ciocalteu reagent, as indicated by the similar A_{760} between both modified gelatins. A_{760} observed in the control gelatin solution was more likely due to the presence of amino acid residues including tyrosine, tryptophan, cysteine, histidine and asparagines (Lowry, Rosebrough, Farr, & Randall, 1951). Those amino acids were able to reduce the Folin–Ciocalteu reagent as evidenced by the increase in A_{760}.

3.3. Changes in surface hydrophobicity

Changes in surface hydrophobicity of cuttlefish skin gelatin modified with different oxidised phenolic compounds at various levels are shown in Fig. 1B. Generally, gelatin modified with oxidised phenolic compounds showed a decrease in surface hydrophobicity, compared with the control gelatin ($p < 0.05$). The surface hydrophobicity of gelatin modified with all oxidised phenolic compounds decreased with increasing concentrations of compounds used ($p < 0.05$). ANS, a fluorescence probe, has been found to bind to hydrophobic amino acids containing an aromatic ring, such as phenylalanine and tryptophan, and can be used to indicate the surface hydrophobicity of protein (Benjakul, Seymour, Morrissey, & An, 1997). The decrease in surface hydrophobicity of the resulting gelatin indicated that phenolic compounds bound with gelatin most likely contributed to the increased hydrophilicity at the surface of gelatin molecules. This result was in agreement with Rawel, Czajka, Rohn, and Kroll (2002) who reported that the surface hydrophobicity of soy protein decreased when reacted with phenolic compounds. The decrease in surface hydrophobicity of gelatin derivatives was possibly caused by hydroxyl and carboxyl groups of phenolic compounds attached to gelatin. Kroll et al. (2003) reported that the covalent attachment of the phenolic compound to proteins causes the blocking of the hydrophilic groups like amino and thiol groups. On the other hand, there is also an increase in the amount of apolar groups (benzene ring) and polar groups (hydroxyl and carboxyl groups as in the case of the phenolic acids) being introduced. Amongst all phenolic compounds introduced, gelatin modified with oxidised caffeic acid or oxidised tannic acid had the lower surface hydrophobicity than that modified by oxidised ferulic acid ($p < 0.05$). At the same amount of oxidised phenolic compounds introduced, gelatin modified with oxidised tannic acid and oxidised caffeic acid exhibited similar surface hydrophobicity ($p > 0.05$). Thus, the introduction of oxidised phenolic compounds resulted in the altered hydrophobicity of resulting gelatin.

3.4. Changes in emulsifying properties

Emulsion activity index (EAI) of cuttlefish skin gelatin modified with oxidised phenolic compounds at various levels expressed as the turbidity of emulsion at wavelength of 500 nm is shown in Table 1. At the lowest level of oxidised phenolic compounds introduced (5 wt.% of protein), gelatins modified with oxidised caffeic acid showed a decrease in EAI both at 0 and 10 min when compared with the control ($p < 0.05$). Nevertheless, no change in EAI of gelatin modified with oxidised tannic acid and oxidised ferulic acid was observed ($p > 0.05$). However, at the concentration of oxidised phenolic compounds introduced above 5% (w/w of protein), EAI of gelatin modified with all oxidised phenolic compounds decreased for both at 0 and 10 min. The decrease was more pronounced as the concentration of oxidised phenolic compounds increased. This was possibly associated with the decreases in surface hydrophobicity of gelatin modified with oxidised phenolic. Kato and Nakai (1980) reported that the surface hydrophobicity of protein is generally associated with a better surface activity, in which the reduction in interfacial tension and the increase in emulsifying activity are achieved. The decrease in surface hydrophobicity of gelatin modified with oxidised phenolic compounds might lower the ability of gelatin to localise at the oil–water interface. Moreover, interactions of oxidised phenolic compounds with gelatin probably led to the aggregation of gelatin molecules. As a result, gelatin might not unfold at the oil–water interface and form the film around the oil droplet effectively (McClements, 2004). However, the improvement of foam and emulsion stability of proteins by phenolic compounds has been reported (Viljanen, Halmos, Sinclair, & Heinonen, 2005). The addition of blackberry and raspberry juices in oil-in-water emulsion using whey proteins as an emulsifier resulted in the enhanced stabilisation of the interface formed during emulsification. Sarker et al. (1995) reported that (+)-catechin, at 0.1 M ratio, could improve foam formation and stability of Tween 20/β-lactoglobulin mixed system, because of (+)-catechin-induced cross-linking of proteins in the adsorbed layer. Therefore, the incorporation of oxidised phenolic compounds into gelatin to a high level showed the detrimental effect on the emulsifying property of modified gelatin.

3.5. Changes in antioxidative activities

3.5.1. DPPH radical scavenging activity

DPPH radical scavenging activities of gelatin modified with different oxidised phenolic compounds at various levels are depicted in Fig. 2A. DPPH radical scavenging activity of the control gelatin was 249.87 μmol TE/mg protein. When gelatin was incorporated with 5% oxidised ferulic acid, caffeic acid and tannic acid, the activity was increased to 292.57, 420.69 and 491.68 μmol TE/mg protein, respectively. These results indicated that phenolic compounds introduced to gelatin contributed to the increased antioxidative activity of gelatin. The effect of antioxidants on DPPH radical scavenging was thought to be due to their hydrogen-donating ability (Binsan et al., 2008). The increase in DPPH radical scavenging activity was observed in all gelatins modified with all oxidised phenolic compounds when the higher concentrations of oxidised phenolic compound were used ($p < 0.05$). The maximum activity was observed when gelatin was modified with 50% oxidised phenolic compound ($p < 0.05$). This was in agreement with Rohn et al. (2004) who found that the antioxidative activity of bovine serum albumin (BSA) derivatised by covalent attachment of quercetin increased with increasing concentration of quercetin.

At the same concentration of oxidised phenolic compounds used, gelatin modified with oxidised tannic acid had the highest DPPH radical scavenging activity, followed by those modified with oxidised caffeic acid and oxidised ferulic acid, respectively. The result revealed that DPPH radical scavenging activity of gelatin modified by oxidised phenolic compounds was governed by the type of phenolic compound used and the degree of incorporation of phenolic compounds into gelatin. The result indicated that free quinones of oxidised phenolic compounds were mostly reduced to hydroxyl groups. Those hydroxyl groups could donate hydrogen to DPPH radicals.

3.5.2. ABTS radical scavenging activity

Gelatin modified with different oxidised phenolic compounds showed different ABTS radical scavenging activities (Fig. 2B). A similar result was found when comparing with DPPH radical scavenging activity (Fig. 2A). The gelatin modified with oxidised tannic acid and oxidised caffeic acid showed an increase in ABTS radical scavenging activities with increasing concentration used. This result suggested that tannic acid and caffeic acid attached with gel-

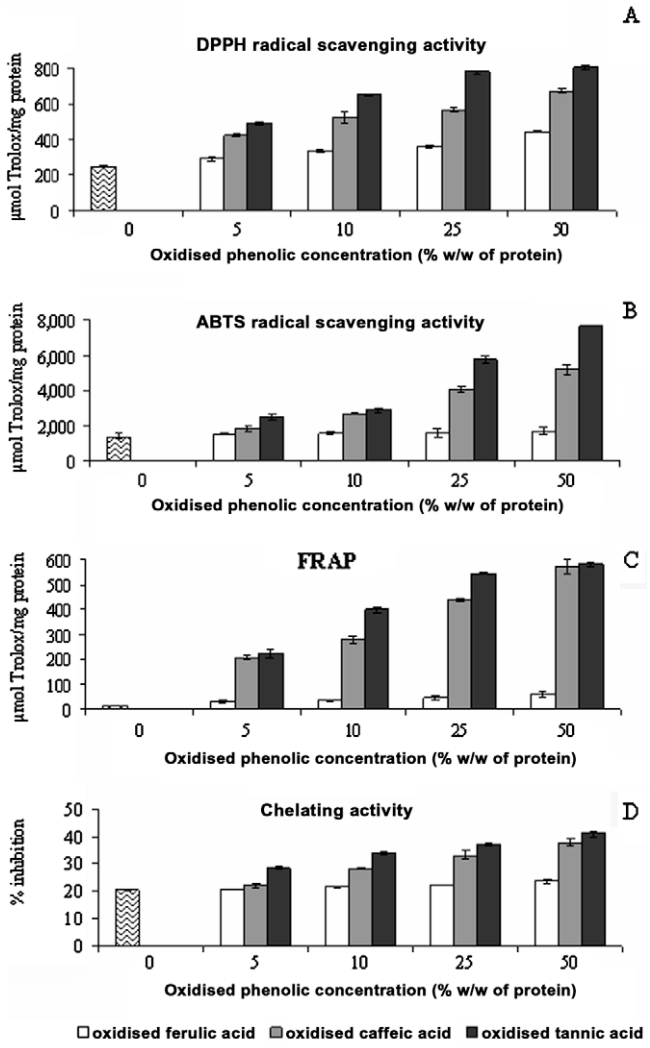

Fig. 2. DPPH radical scavenging activity (A), ABTS radical scavenging activity (B), ferric reducing antioxidant power (FRAP) (C) and chelating activity (D) of cuttlefish skin gelatin modified with different oxidised phenolic compounds at various levels. Bars represent the standard deviation from triplicate determinations.

atin could scavenge the radicals, forming a more stable product, thereby terminating the radical chain reaction. Nevertheless, gelatin modified with oxidised ferulic acid had no changes in ABTS radical scavenging activity even when a higher level of oxidised ferulic acid was used. The result suggested that ferulic acid attached to gelatin might not be able to quench ABTS radicals. ABTS radical assay is an excellent tool for determining the antioxidative activity, in which the radical is quenched to form ABTS radical complex (Binsan et al., 2008). It reconfirmed that the radical scavenging activity of gelatin was determined by the type of phenolic compounds attached.

3.5.3. Ferric reducing antioxidant power

Ferric reducing antioxidant power (FRAP) generally measures the reducing capacity of the ferric ion and has been correlated to the radical scavenging capacity (Moure, Domínguez, & Parajó, 2006). The FRAP of gelatin modified with different oxidised phenolic compounds at various levels is shown in Fig. 2C. The FRAP of gelatin modified with oxidised ferulic acid, oxidised caffeic acid and oxidised tannic acid at a level of 5% was 28.08, 206.71 and 222.72 µmol TE/mg protein, respectively, which was higher than that of the control gelatin (13.20 µmol TE/mg protein). As the concentration of oxidised phenolic compounds increased, FRAP activities increased ($p < 0.05$). A marked increase in FRAP of gelatin was observed in gelatin modified with oxidised caffeic acid and oxidised tannic acid, in comparison with the control gelatin, especially at the high concentration used. It was noted that the FRAP of gelatin modified with oxidised ferulic acid slightly increased. The antioxidative activity of phenolic acids depends on the number and position of hydroxyl groups bound to the aromatic ring (Sroka & Cisowski, 2003). The result was generally in agreement with those of DPPH and ABTS radical scavenging activities (Fig. 2A and B).

3.5.4. Chelating activity

The ability of gelatin modified with different oxidised phenolic compounds at different levels in metal chelating is depicted in Fig. 2D. Generally, the metal chelating activity of gelatin increased as the concentration of oxidised phenolic compounds increased ($p < 0.05$). At the same level of oxidised compounds introduced, gelatin modified with oxidised tannic acid exhibited the highest metal chelating activity, followed by those modified by oxidised caffeic acid and oxidised ferulic acid, respectively. Ferrous ion (Fe^{2+}) is the most powerful prooxidant amongst various species of metal ions, which can catalyse the generation of reactive oxygen species, hydroxyl radical ($OH^{\cdot}$), by which the lipid peroxidation chain reaction is accelerated (Stohs & Bagchi, 1995). Thus gelatin attached with phenolic compounds had the enhanced ability in metal chelation, in which prooxidative metals can be sequestered, leading to the lowered oxidation.

3.6. Changes in FTIR spectra

Due to the high antioxidative activity of gelatin modified with 5% oxidised tannic acid without any change in EAI, gelatin modified with 5% oxidised tannic acid was characterised by FTIR. FTIR spectroscopy at 4000–400 cm^{-1} was used to monitor the changes in the secondary structure of gelatin with and without the modification with 5% oxidised tannic acid (Fig. 3A). A spectra of cuttlefish skin

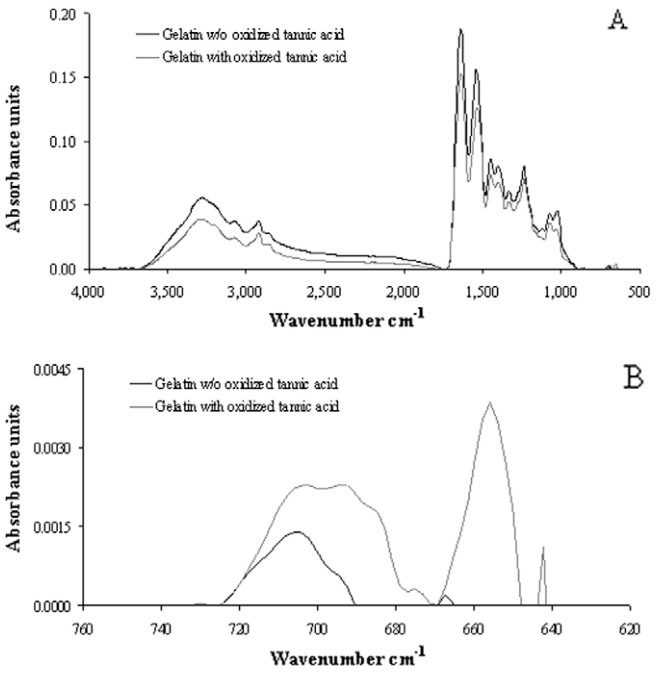

Fig. 3. Fourier transform infrared (FTIR) spectroscopic spectra of gelatin modified with 5% oxidised tannic acid.

gelatin displayed the major bands at 3278 cm^{-1} (amide A, representative of NH-stretching, coupled with hydrogen bonding), 1635 cm^{-1} (amide I, representative of C=O stretching/hydrogen bonding coupled with COO^-), 1535 cm^{-1} (amide II, representative of NH bending coupled with CN stretching) and 1236 cm^{-1} (amide III, representative of NH bending). Similar spectra were observed between gelatin with and without modification with 5% oxidised tannic acid. However, decreases in the amplitude of amide A, I, II and III bands was observed in gelatin modified with oxidised tannic acid. These changes are indicative of greater disorder (Friess & Lee, 1996) in gelatin and are associated with the loss of the triple helix state (Muyonga, Cole, & Duodu, 2004). The shift to a lower wavenumber of amine I, II and III peaks was observed from 1637, 1541 and 1238 cm^{-1} in the control gelatin to 1635, 1535 and 1236 cm^{-1} in gelatin modified with oxidised tannic acid, respectively. A shift of peaks to lower wavenumbers is associated with a lower molecular order (Payne & Veis, 1988). Muyonga et al. (2004) reported that the amide I and II peak of collagen extracted from adult Nile perch was at a higher frequency than the young fish skin collagen, due to more intermolecular cross-links in the adult fish collagen (Muyonga et al., 2004). On the other hand, the shift to a higher wavenumber of amine A peaks from 3278 cm^{-1} to 3296 cm^{-1} was observed when gelatin was modified with oxidised tannic acid. The peaks at wavenumber of 3400–3300 cm^{-1} were attributable to the OH stretch of alcohols and phenols (Smith, 1999). The result indicated the incorporation of tannic acid with a OH group into gelatin molecule. Moreover, the obvious increases in the amplitude of the peak at wavenumber 1080 cm^{-1} was found in gelatin modified with oxidised tannic acid, suggesting the stretching of the C–O bonds in secondary and tertiary alcohols (Smith, 1999) in modified gelatin. These results suggested that oxidised tannic acid might induce the changes in secondary structure and functional groups of the resulting gelatin.

The bands situated at 720–680 cm^{-1} and 655 cm^{-1} were observed in gelatin modified with oxidised tannic acid, whilst the band with a wavenumber of 720–690 cm^{-1} was found in the control gelatin. (Fig. 3B). The wavenumber at ~690 ± 10 and ~655 cm^{-1} were attributable to the bending of the C–C bonds in the aromatic and the out of plane bending of OH group in phenol, respectively (Smith, 1999). This result indicated that oxidised tannic acid could bind with the gelatin molecules and the unbound quinone groups were more likely reduced during dialysis as indicated by the additional OH band in phenol found in gelatin modified by oxidised tannic acid. Thus the modification could introduce the aromatic ring and hydroxyl group in gelatin.

3.7. Effect of gelatin modified with oxidised tannic acid on emulsion stability and lipid oxidation of menhaden oil-in-water emulsion

3.7.1. Zeta potential and particle size of emulsion

When tested at pH 7, zeta potential of menhaden oil emulsion droplets stabilised by control gelatin (without modification) and gelatin modified with oxidised tannic acid was −38.98 ± 0.77 and −32.16 ± 1.2 mV, respectively (Table 2). The negative charge of the emulsion droplets might be due to the negatively charged amino acid in the gelatin surrounding the oil droplet. At a pH lower than pI, the carboxyl groups are negatively charged (–COO^-), whereas most of the amino groups are neutral (–NH_2) (Onsaard, Vittayanont, Srigam, & McClements, 2006). The emulsion droplets were covered by a biopolymer with an appreciable electrical charge. Electrostatic repulsion may play an important role in stabilising them against droplet aggregation (McClements, 2005). The lower negative charge was observed in emulsion stabilised by gelatin modified with oxidised tannic acid, when compared with that of emulsion stabilised by control gelatin. These differences might be due to the differences in the number of ionisable amino acids in the gelatin. It was suggested that the occupation of amino groups by oxidised tannic acid might introduce the positive charge of phenolic compound to gelatin. As a consequence, the lower negatively charged complex was obtained. Moreover, the hydroxyl groups of tannic acid might interact with the carboxyl groups of protein *via* hydrogen bonding, leading to a loss of negative charge of the resulting complex.

Table 2
Particle size and zeta potential of menhaden oil-in-water emulsion stabilised by 0.5% and 1.0% gelatin with and without the modification with 5% oxidised tannic acid at pH 7.

Gelatin	Concentration (% protein)	Particle size (μm)	Zeta potential (mV)
Control (unmodified)	0.5	2.24 ± 0.19c*	–
	1.0	0.33 ± 0.02a	−38.98 ± 0.77a
Modified with 5% oxidised tannic acid	0.5	2.65 ± 0.09d	–
	1.0	0.37 ± 0.02b	−32.16 ± 1.2b

Mean ± SD from triplicate determinations.
* Different letters in the same column indicate significant differences ($p < 0.05$).

The particle diameter of oil droplets of 10% menhaden oil-in-water emulsion stabilised by 0.5% and 1.0% gelatin modified without and with oxidised tannic acid is shown in Table 2. The particle size of emulsion stabilised by 0.5% and 1.0% control gelatin was 2.24 ± 0.19 and 0.33 ± 0.02 μm, respectively, whereas that of emulsion stabilised by gelatin modified with oxidised tannic acid was 2.65 ± 0.09 and 0.37 ± 0.02 μm, respectively. Droplet size of the emulsion decreased markedly when the higher concentration of gelatin either with or without modification was used. A sufficient amount of proteins at the oil–water interface is required to cover oil droplet completely. This result was in agreement with Surh, Decker, and McClements (2005) who found that an increase in fish gelatin concentration from 0.5% to 4.0% protein could increase the fraction of small droplets and decrease the fraction of large particles. When the protein amount is limited, there is no longer sufficient protein to fully stabilise the droplet interface, and therefore larger particles may be formed as a result of coalescence or bridging flocculation. The increase in protein concentration enhanced protein adsorption and surface coverage of oil droplets, which effectively inhibited droplet aggregation or coalescence (Sun & Gunasekaran, 2009). The larger particle size was observed in the emulsion stabilised by gelatin modified with oxidised tannic acid when compared with that found in the emulsion stabilised by the control gelatin. The decreased surface hydrophobicity might not favour the migration of gelatin modified by oxidised tannic acid to the oil droplets, which were lipophilic. Thus, the amount of modified gelatin occupied at oil droplet might be slightly lower. This led to the lower emulsifying property of modified gelatin.

3.7.2. Changes in particle size of emulsion during storage

Changes in particle size of emulsions stabilised by 1.0% gelatin and gelatin modified with oxidised tannic acid during storage at room temperature for 12 days are shown in Fig. 4A. Particle size of both emulsions gradually increased with increasing storage time. For emulsions stabilised by the control gelatin, the particle size increased from 0.33 ± 0.02 to 0.44 ± 0.02 μm within 12 days of storage, whereas that of the emulsion stabilised by gelatin modified with oxidised tannic acid increased from 0.37 ± 0.02 to 0.46 ± 0.03 μm. This result might be due to individual droplet growth (Ostwald ripening) or droplet aggregation (flocculation or coalescence) during storage (Djordjevic et al., 2008). At day 12 of storage, no difference in the size of the oil droplet was noticeable between both emulsions though a smaller size of droplet was found in the emulsion stabilised by control gelatin at day 0. This indicated that gelatin modified by oxidised tannic acid yielded

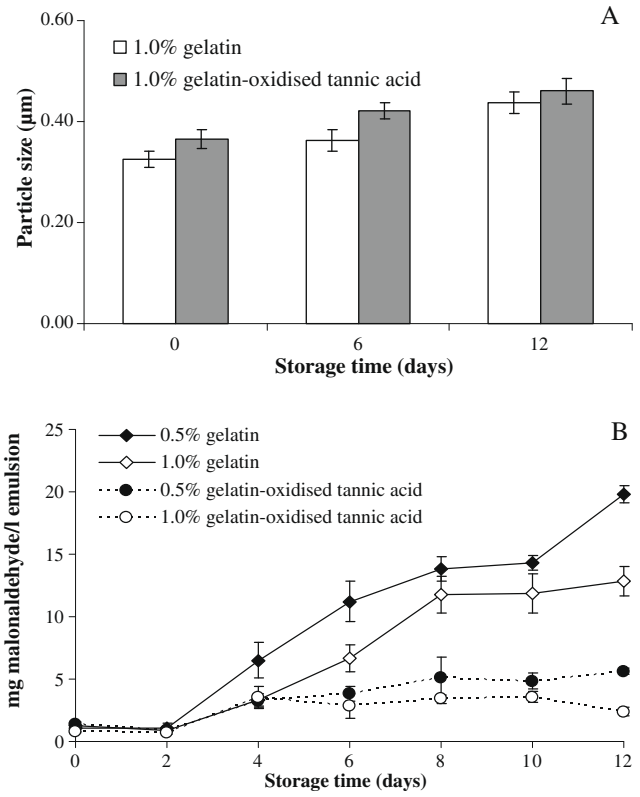

Fig. 4. Particle size (A) and TBARS value (B) of menhaden oil-in-water emulsion stabilised by 0.5% and 1.0% gelatin with and without the modification with 5% oxidised tannic acid during storage at room temperature for 12 days. Bars represent the standard deviation from triplicate determinations.

the similar emulsion stability to gelatin without modification at the extended storage.

3.7.3. Changes in lipid oxidation of emulsion during storage

Lipid oxidation of menhaden oil-in-water emulsion stabilised with gelatin modified with and without oxidised tannic acid was monitored and expressed as TBARS values during the 12 days of storage (Fig. 4B). Generally, no TBARS were found in the oil-in-water emulsion within the first 2 days of storage. Thereafter, the marked increase in TBARS was observed, especially in emulsion stabilised by control gelatin ($p < 0.05$). Emulsion stabilised by gelatin modified with oxidised tannic acid had the lower TBARS ($p < 0.05$). This result was in accordance with the antioxidative activity of gelatin modified with oxidised tannic acid (Fig. 2). Antioxidative activity of gelatin modified with or without oxidised tannic acid increased with increasing concentration used. Additionally, the preventive effect of gelatin at the higher level used on lipid oxidation might be associated with the thicker film around the oil droplet. This could prevent the penetration of oxygen into an oil droplet more effectively. Therefore, gelatin modified with oxidised tannic acid had the ability to retard TBARS formation in the oil-in-water emulsion system. This result was in agreement with Almajano and Gordon (2004) who reported that interaction of BSA and epigallocatechin gallate (EGCG) could induce the formation of a BSA-antioxidant adduct and cause a synergistic increase in the oxidative stability of sunflower oil-in-water emulsion effectively, when compared with BSA or EGCG alone.

4. Conclusion

Attachment of 5% oxidised phenolic compounds to cuttlefish skin gelatin enhanced antioxidative activity with no detrimental effect on emulsifying properties of resulting gelatin. Use of gelatin modified with oxidised tannic acid could inhibit lipid oxidation of menhaden oil-in-water emulsion effectively. The efficacy was dose dependent. Therefore, cuttlefish skin gelatin modified with oxidised tannic acid could be used as emulsifier possessing antioxidative activity in emulsion systems.

Culinary treatment
Sous-vide
Fatty acids

ABSTRACT

The effects of desalting and boiling, with or without vacuum-packaging, on the composition of the subcutaneous adipose tissue of dry-cured pork forelegs were investigated. The adipose tissue contained 7.1% water and 91.0% lipids. The main fatty acids in glycerides (about 89% of total lipids) were oleic (39.6%), palmitic (23.9%), linoleic (13.7%) and stearic (12.6%) acids. The main fatty acids in free fatty acids (about 11% of total lipids) were oleic (36.0%), linoleic (28.4%) and palmitic (13.1%). The culinary treatment (desalting and boiling) caused significant decreases in dry matter and lipid contents. These decreases were not as great in vacuum-packaged samples because the lipid losses were prevented during the boiling stage. No significant changes in lipid fraction proportions (glycerides and free fatty acids) were observed. The samples boiled with vacuum-packaging showed higher contents of polyunsaturated fatty acids than did the samples boiled without vacuum-packaging.

1. Introduction

The subcutaneous adipose tissue is an important component of dry-cured products and is normally eaten by consumers. Its fatty acid composition and its changes (lipolysis and oxidation) during the manufacturing process influence the acceptance of these products by consumers (Gandemer, 2002). The dry-cured pork foreleg ("Lacón Gallego") is manufactured in the northwest of Spain (Galicia). This product is made by following the same steps as in dry-cured ham, although the length of the process is shorter. The studies on the composition of dry-cured pork forelegs have been done only on muscles (Veiga, Cobos, Ros, & Díaz, 2003) or on whole pieces with no bones or skin (Lorenzo, García Fontán, Franco, & Carballo, 2008; Lorenzo, Prieto, Carballo, & Franco, 2003; Rodríguez, Carballo, & López, 2001). However, there are no studies on the composition of the subcutaneous adipose tissue of dry-cured pork forelegs. The lipid composition and the changes that take place during processing are different, in subcutaneous fat and muscle lipids, in dry-cured pork products. During the processing of dry-cured hams, the hydrolysis of glycerides in the subcutaneous fat is very important (Coutron-Gambotti & Gandemer, 1999; Flores, Nieto, Bermell, & Miralles, 1985; Narváez-Rivas, Vicario, Constante, & León-Camacho, 2007). In muscles of dry-cured pork forelegs, meat lipids undergo lipolysis and oxidation; the former affects only the phospholipid fraction (Veiga et al., 2003). However, the levels of phospholipids in subcutaneous fat are very low (Flores et al., 1985; Perona & Ruiz-Gutierrez, 2005); so, the lipolysis of this fraction is negligible.

"Lacón Gallego" is usually consumed after a process in which it is desalted and boiled in a restaurant or at home and people normally eat subcutaneous adipose tissue and muscles together with other ingredients, mainly vegetables. This culinary treatment can be done on the whole forelegs (Cobos, Veiga, & Díaz, 2004). However, the desalting and cooking of dry-cured pork foreleg pieces decreases the total time necessary to desalt and boil them; moreover, the *sous-vide* cooking technology (boiling the pieces after vacuum-packaging) can be used. This technology excludes oxygen; thus, it might prevent or reduce the oxidation process during the boiling of the dry-cured pork foreleg pieces. The effects of this culinary treatment on the chemical and lipid composition of dry-cured pork forelegs have been studied in muscles (Cobos, Veiga, & Díaz, 2008) and only the ash contents were significantly different between samples boiled with and without vacuum-packaging. However, the effects in subcutaneous adipose tissue might be different from those in muscle due to their different compositions and/or to their oxygen access.

One objective of this study was to know the composition of the subcutaneous adipose tissue of dry-cured pork forelegs. Furthermore, the effects of desalting and boiling, with or without vacuum-packaging, on the composition of the subcutaneous adipose tissue of deboned pieces of dry-cured pork forelegs were studied.

2. Materials and methods

2.1. Processing of forelegs and sampling

Four dry-cured pork forelegs were manufactured, as described by Cobos et al. (2004), by a local industry. Three deboned portions

of similar size and shape (ca. 500 g), including the skin, subcutaneous adipose tissue and *pectoralis profundus*, *coracobrachialis*, *biceps brachii* and *triceps brachii* muscles, were obtained from each dry-cured pork foreleg. From one portion, a sample of subcutaneous adipose tissue was taken, while the other two whole portions were desalted. The desalting was done in water at 4 °C for 24 h (4 l of water/kg piece); the water was changed after 10 h. Afterwards, one of the desalted portions was vacuum-packed in a polypropylene/polyamide laminated pouch, using a Stephan Alval vacuum-packer (mod. 190). Both desalted portions were inserted directly into boiling water (11 l of water/kg piece) and cooked for 2.5 h. After they were cooled, samples of subcutaneous adipose tissue were taken from each portion.

2.2. Analytical methods

The subcutaneous adipose tissue samples were finely minced in a blender (Polytron PT 10–35). AOAC methods (1995) were used for dry matter and ash determinations. The lipids were extracted and purified from the former homogenised sample according to the Bligh and Dyer method (Hanson & Olley, 1963). The total lipids were gravimetrically determined; 50 mg of lipids were taken for the determination of cholesterol content by an enzymic method, using the laboratory kit from Sigma Diagnostics. The extent of lipid oxidation was assessed by the thiobarbituric acid (TBA) method described by Pikul, Leszczynski, and Kummerow (1983).

Total lipids (100 mg) were separated into neutral lipids, free fatty acids and phospholipids in NH_2-aminopropyl minicolumns according to the method described by Kaluzny, Duncan, Merritt, and Epps (1985). The neutral lipid fraction is mainly composed of glycerides and this term will be used throughout the text. Amounts of glycerides, phospholipids and free fatty acids were quantified by weighing (Vaghela & Kilara, 1995) and the results were expressed as a percent of the total weight obtained. The fatty acid compositions of glycerides and free fatty acids were determined by gas liquid chromatography of methyl esters prepared under basic conditions (KOH: methanol) for glycerides and acidic conditions (H_2SO_4: methanol) for the free fatty acids. The gas chromatograph was a Hewlett–Packard apparatus (HP 5890) equipped with a dual flame ionisation detector. The fused silica capillary column (30 m, internal diameter 0.25 mm) was packed with OV-225 (0.1 μm). Analyses were performed using an initial isothermic period (150 °C, 2 min); thereafter the temperature was raised to 210 °C at an increasing rate of 4 °C/min, and finally held at 210 °C for 15 min. The injector and detector were maintained at 250 °C. For quantitative analyses, a Hewlett–Packard HP3394A integrator was used. The identification of different fatty acid methyl esters was performed by comparison of the retention times with those of authentic standards (Sigma Chemical Co., St. Louis, MO). Amounts of fatty acids from glycerides and free fatty acids were expressed as a percent of the total area of injected methyl esters.

2.3. Statistical analyses

The means were compared by *t*-test for dependent samples. A significance level of $p < 0.05$ was used for all means evaluations (SPSS version 10.1. for Windows, 2000).

3. Results and discussion

3.1. Chemical and lipid composition

Table 1 shows the chemical and lipid composition of subcutaneous adipose tissue from dry-cured pork foreleg pieces (DF) and from dry-cured foreleg pieces subjected to culinary treatment by desalting and boiling (BDF) or by desalting and vacuum-packed boiling (VBDF).

Table 1
Chemical and lipid composition (means ± SD) of subcutaneous adipose tissue from dry-cured foreleg pieces (DF) and from dry-cured pieces subjected to culinary treatment by desalting and boiling (BDF) or by desalting and vacuum-packed boiling (VBDF) ($n = 4$).

	DF	BDF	VBDF
Dry matter (g/100 g tissue)	92.89 ± 3.16a	81.11 ± 3.28b	87.32 ± 2.47b
Ash (g/100 g tissue)	1.51 ± 0.66ab	0.80 ± 0.42a	1.26 ± 0.20b
Ash (g/100 g dry matter)	1.64 ± 0.75	0.99 ± 0.57	1.45 ± 0.23
Lipids (g/100 g tissue)	91.02 ± 3.41a	75.22 ± 3.82b	85.94 ± 2.41c
Lipids (g/100 g dry matter)	97.99 ± 1.16a	92.73 ± 2.48b	98.42 ± 0.57a
Cholesterol (g/100 g lipids)	0.11 ± 0.02	0.08 ± 0.04	0.11 ± 0.05
Cholesterol (mg/100 g tissue)	92.5 ± 15.07	58.9 ± 27.55	95.4 ± 37.56
TBA value (mg MDA/kg lipids)	10.2 ± 5.01	5.23 ± 3.18	8.42 ± 2.83
TBA value (mg MDA/kg tissue)	9.22 ± 4.36ab	3.85 ± 2.11a	7.21 ± 2.36b
Glycerides (g/100 g lipids)	88.7 ± 2.68	90.6 ± 0.84	92.4 ± 2.08
Free fatty acids (g/100 g lipids)	11.1 ± 2.69	9.44 ± 0.72	7.60 ± 2.08

Means with different letters in the same row differ significantly ($p < 0.05$).
TBA: thiobarbituric acid; MDA: malonaldehyde.

The subcutaneous adipose tissue of dry-cured pork forelegs contained 7.11% water, 91.02% lipids and 1.51% ash. Cholesterol accounted for 0.11% of total lipids. The cholesterol content was close to those obtained for intermuscular fat in pork (Chizzolini, Zanardi, Dorigoni, & Ghidini, 1999).

The mean value of TBA was 10.2 mg malonaldehyde/kg lipids. This value was higher than that observed by Coutron-Gambotti and Gandemer (1999) in subcutaneous adipose tissue of dry-cured hams (1.49 mg malonaldehyde/kg lipids). Rodríguez et al. (2001) have reported that dry-cured pork forelegs show a very intense oxidation, higher than those of other traditional meat products, due to their higher sodium chloride content and to their greater surface area.

The glycerides represented 89% and the free fatty acids 11% of the total lipid content in subcutaneous fat of dry-cured forelegs. The content of phospholipids was negligible. Very low levels of phospholipids have also been reported in subcutaneous fat of dry-cured hams (Flores et al., 1985). The high content of free fatty acids revealed that lipolysis is important during the processing of this product although the length of the manufacturing process is short (approximately 35 days). The level of free fatty acids was similar to that observed in subcutaneous adipose tissue of dry-cured hams after several months of processing (Coutron-Gambotti & Gandemer, 1999; Flores et al., 1985); these authors reported that these fatty acids come mainly from triglyceride hydrolysis. Veiga et al. (2003) also observed a high level of free fatty acids (10.6%) in muscle lipids of "Lacón Gallego" but lipolysis only affected the phospholipids fraction of muscle lipids. Timón, Ventanas, Carrapiso, Jurado, and García (2001b) observed that lipolytic processes occur more intensively in subcutaneous fat than in intermuscular fat of dry-cured Iberian hams. Therefore, glycerides of subcutaneous fat could be more susceptible than glycerides of muscular lipids to lipases.

The culinary treatment (desalting and boiling) caused significant decreases in the dry matter, ash and lipid contents of subcutaneous adipose tissue. The decreases in the dry matter content can be due to increases in water content or to ash and lipid losses during culinary treatment. In VBDF, these decreases are only due to increases in water content of subcutaneous adipose tissue during culinary treatment. The vacuum-packaging of the pieces before boiling prevented the ash and lipid losses (as can be observed when the results are expressed in g/100 g dry matter). Nevertheless, the culinary treatment caused water loss in the muscles (Cobos et al., 2008). This was related to the fact that, during wet heating, collagen was solubilised and denatured; it absorbed water

and turned to gelatine. It is also possible that part of the water loss in the muscles might migrate to the subcutaneous adipose tissue. In BDF, the decrease in dry matter content is probably due to both reasons: increases in the water content of the subcutaneous adipose tissue and the loss of ash and lipids in cooking water during boiling.

In the samples studied, no significant differences were found in the cholesterol contents of the subcutaneous fat of dry-cured pork forelegs (DF, BDF and VBDF). However, the cholesterol content in BDF was lower than those in DF and VBDF. The culinary treatment of whole dry-cured pork forelegs caused a significant decrease in the cholesterol content in muscles (Cobos et al., 2004). This loss of cholesterol might be related to the formation of cholesterol oxide products. The vacuum-packaging of the pieces before boiling (VBDF samples) could probably help to prevent the oxidation of cholesterol due to the exclusion of oxygen during heating.

The TBA values were lower in BDF and VBDF than in DF. Decreases in TBA values have also been observed in meat lipids after the culinary treatment of the pieces of dry-cured forelegs (Cobos et al., 2008), after boiling beef muscles (Badiani et al., 2002) and after grilling pork muscles (Nuernberg et al., 2006). The explanation of these results might be the degradation or denaturation of aldehydes that make the TBA-reactive substances less assessable for measurement (Nuernberg et al., 2006). The losses of malonaldehyde could also be due to their volatility when heated (Hernández, Navarro, & Toldrá, 1999). The TBA values were lower in BDF than in VBDF. This could be due to the fact that the malonaldehyde was included in lipid losses of the subcutaneous adipose tissue during boiling without vacuum-packaging; so, the possible effects against oxidation of vacuum-packaging of samples before boiling were not reflected in TBA values.

There were no significant differences in the levels of glycerides and free fatty acids between the different batches (DF, BDF and VBDF). There are no studies about the effects of the heating process in lipolysis of glycerides from adipose tissue. It is possible that more intensive heat could cause an increase in free fatty acids, due to thermal hydrolysis, as occurs in pork meat lipids, during boiling (Hernández et al., 1999). In this way, while there is no increase in the content of free fatty acids in muscle lipids during the culinary treatment of the deboned pieces of "lacón gallego" (Cobos et al., 2008), during the culinary treatment of dry-cured pork forelegs (a longer process), there is an increase in free fatty acids (Cobos et al., 2004). However, this increase was related to phospholipid hydrolysis since no changes were observed in the content of glycerides.

3.2. Fatty acid composition

Table 2 shows the fatty acid profiles (expressed as% of total fatty acids) in DF, BDF and VBDF of the glycerides and the free fatty acids fraction of subcutaneous fat.

In glycerides, the monounsaturated fatty acids were the most abundant (46.0%), followed by the saturated fatty acids (38.2%) and the polyunsaturated fatty acids (15.8%). Oleic (39.6%), palmitic (23.9%), linoleic (13.7%) and stearic (12.6%) acids were the main fatty acids. These results differ from those reported in triacylglycerols of abdominal adipose tissues of Iberian pigs (Perona & Ruiz-Gutierrez, 2005) and subcutaneous fat from dry-cured Iberian hams (Timón, Martín, Petrón, Jurado, & García, 2001a; Timón et al., 2001b) where the contents of C-18:1 were higher (51–54%) and the percentages of C-18:2 were lower (8–9%). These differences could mainly be due to the breed, the diet or to the localisation of the deposit of fat in the carcass; it is known that the fatty acid profiles of the subcutaneous fat of pigs are influenced by the breed (Lo Fiego, Santoro, Macchioni, & De Leonibus, 2005b), by the diet (Lo Fiego, Macchioni, Santoro, Pastorelli, & Corino, 2005a; Martin, Antequera, Gonzalez, Lopez-Bote, & Ruiz, 2007; Ruiz et al., 1988; Timón et al., 2001a) and by the localisation of the subcutaneous fat in the carcass (Franco, Escamilla, García, García Fontán, & Carballo, 2006; Monziols, Bonneau, Davenel, & Kouba, 2007). A higher content of C-18:2 and total polyunsaturated fatty acids in the subcutaneous adipose tissue from the shoulder than in that from the ham has been reported (Monziols et al., 2007).

The fatty acid composition of the glycerides in the subcutaneous fat from dry-cured pork forelegs shows some differences from that reported in glycerides in muscle lipids from dry-cured forelegs from pigs fed with the same diet (Cobos et al., 2008). The contents of saturated fatty acids of muscle lipids were higher (42.7%) and the percentages of polyunsaturated fatty acids of muscle lipids were lower (11.9%) than those found in subcutaneous fat. These differences were due to a higher content of C-16:0 (28.6%) and a lower content of C-18:2 (10.2%), respectively. In accordance with

Table 2
Fatty acid profiles (% of total fatty acids) (means ± SD) of the glyceride and free fatty acid fractions of subcutaneous fat from dry-cured pork foreleg pieces (DF) and from dry-cured pieces subjected to culinary treatment by desalting and boiling (BDF) or by desalting and vacuum-packed boiling (VBDF) ($n = 4$).

Means of the same fraction with different letters in the same row differ significantly ($p < 0.05$).
SFA: saturated fatty acids; MUFA: monounsaturated fatty acids; PUFA: polyunsaturated fatty acids.

these results, Franco et al. (2006) have reported that the intramuscular fat of pigs shows higher values of saturated fatty acids and a lower content of polyunsaturated fatty acids than do subcutaneous dorsal and ventral fat.

No significant differences between fatty acid composition of glycerides in the subcutaneous fat of dry-cured pork forelegs (DF) and the subcutaneous fat in samples subjected to culinary treatment (BDF and VBDF) were observed. However, there were significant differences between BDF and VBDF. The samples of pieces boiled with no vacuum-packaging (BDF) showed a significantly lower content of C-18:2 and C-18:3 and total polyunsaturated fatty acids than did the samples which were vacuum-packed before boiling (VBDF). This result could be due to two reasons. First, it could be related to the oxidation of fatty acids. The vacuum-packaging of the pieces probably protects against the oxidation of polyunsaturated fatty acids. Secondly, the lipid losses observed in BDF in relation to VBDF could contain glycerides in adipose tissue with relatively more polyunsaturated fatty acids than saturated fatty acids. However, an increase in polyunsaturated fatty acids in total lipids has been reported in the culinary treatment of dry-cured pork forelegs (Cobos et al., 2008) and in the cooking of meat and meat products (Ono, Berry, & Paroczay, 1985; Ramamurti, 1986; Rodriguez-Estrada, Penazzi, Caboni, Bertacco, & Lercker, 1997; Scheeder et al., 2001) and it was related to drip losses, containing mainly triglycerides with relatively more saturated fatty acids than unsaturated fatty acids. Thus, a more plausible explanation for the higher content of polyunsaturated fatty acids in VBDF is related to the effects of vacuum-packaging on the pieces; it reduces and/or prevents the oxidation of these fatty acids. In contrast to subcutaneous fat, when comparing BDF to VBDF no significant differences were observed in polyunsaturated fatty acids of glycerides in meat lipids in the pieces of dry-cured forelegs (Cobos et al., 2008). Hence, it is possible that boiling with no vacuum-packaging affects the polyunsaturated fatty acids of subcutaneous fat but does not affect the polyunsaturated fatty acids of muscle lipids. These differences are probably due the fact that this is a better chance for the oxidation of the subcutaneous fat. The idea that the hydrolysis of phospholipids might protect the polyunsaturated fatty acids from oxidation in dry-cured hams has also been reported (Gandemer, 2002). In subcutaneous fat, this protection is not possible, due to the low levels of phospholipids.

In free fatty acids in the subcutaneous fat from dry-cured pork forelegs, the monounsaturated fatty acids were the most abundant (46.1%), followed by the polyunsaturated fatty acids (34.5%) and the saturated fatty acids (19.5%). Oleic (36.0%), linoleic (28.4%) and palmitic (13.1%) were the main fatty acids. These results differ from those reported in free fatty acids of adipose tissues from dry-cured hams (Coutron-Gambotti & Gandemer, 1999; Timón et al., 2001a, 2001b), where the contents of C-18:1 were higher (46–52%) and the percentages of C-18:2 were lower (7–13%). As in the fatty acid composition of glycerides, these differences were probably due to the diet or to the localisation of the deposit of fat in the carcass.

The fatty acid composition of free fatty acids in subcutaneous fat is very different from those reported for fatty acid composition of free fatty acids in muscles of dry-cured forelegs from pigs fed the same diet (Cobos et al., 2008) and, as has previously been commented, this could be due to the fact that the free fatty acids in the muscles of dry-cured pork forelegs probably come from phospholipids (Veiga et al., 2003) while the free fatty acids in subcutaneous fat probably come mainly from glycerides, as has been reported for the subcutaneous adipose tissue of dry-cured hams (Coutron-Gambotti & Gandemer, 1999; Flores et al., 1985). Furthermore, the fatty acid compositions of free fatty acids and glycerides in subcutaneous fat show important differences. The proportion of palmitic and stearic is lower in FFA and the contents of linoleic and total polyunsaturated fatty acids are higher than in glycerides. The increase in polyunsaturated fatty acids suggests a preferential hydrolysis of these fatty acids in glycerides in subcutaneous fat. This result has also been observed by Coutron-Gambotti and Gandemer (1999) in dry-cured hams. These authors indicated that the physical state of triacylglycerols might affect their rate of lipolysis; the triacylglycerols containing saturated fatty acids (palmitic and stearic) are solid at the temperature of dry-cured pork forelegs ripening, which limits their hydrolysis by lipases. In contrast, the triacylglycerols containing polyunsaturated fatty acids are in the liquid state, which would favour the action of lipases at the water-oil interface.

As in glycerides, the samples of pieces which were vacuum-packed before boiling (VBDF) showed a significantly higher content of polyunsaturated fatty acids than did the samples boiled with no vacuum-packaging (BDF); the vacuum-packaging of the pieces before boiling probably protected the fatty acids from oxidation.

4. Conclusions

The desalting and boiling of pieces of dry-cured forelegs caused a decrease in dry matter, ash and lipid contents of the subcutaneous adipose tissue. These decreases were not as great in vacuum-packaged samples because the lipid and ash losses were prevented during the boiling. The culinary treatment did not produce changes in the glyceride and free fatty acid proportions. The samples boiled with vacuum-packaging showed a higher content of polyunsaturated fatty acids than did the samples boiled without vacuum-packaging and this might be because the vacuum-packaging helps to reduce and/or prevent the oxidation of these fatty acids. Thus, vacuum-packaging might be useful in order to protect polyunsaturated fatty acids of subcutaneous fat.

Essential oil
GC–MS
Antioxidant
Inhibition of NO production
Acetylcholinesterase and butyrilcholinesterase inhibition

ABSTRACT

The essential oils of *Origanum ehrenbergii* and *O. syriacum* collected in Lebanon were analysed by GC and GC–MS and evaluated for their anticholinesterase, NO production inhibitory activities, and antioxidant properties. *O. ehrenbergi* essential oil was characterised by the presence of 37 components, representing 94.9% of the total oil of which thymol (19%) and *p*-cymene (16.1%) were the main abundant compounds. Thirty-six compounds characterised the *O. syriacum* essential oil, representing 90.6% of the total oil. The most abundant components were thymol (24.7%) and carvacrol (17.6%). *O. ehrenbergii* demonstrated interesting scavenging effects on DPPH with an IC_{50} value of 0.99 μg/ml. In addition, both *O. ehrenbergii* and *O. syriacum* oils inhibited oxidation of linoleic acid after 30 min of incubation, as well as after 60 min of incubation with IC_{50} values of 42.1 and 33.6 μg/ml, and 46.9 and 58.9 μg/ml, respectively. Interestingly, *O. ehrenbergii* oil inhibited NO production in the murine monocytic macrophage cell line RAW 264.7 with an IC_{50} value of 66.4 μg/ml. Acetylcholinesterase (AChE) and butyrylcholinesterase (BChE) inhibition was assessed by modifications of the Ellman's method. *O. ehrenbergii* exhibited a strong activity against both cholinesterases with IC_{50} values of 0.3 μg/ml. The data suggest that *O. ehrenbergii* and *O. syriacum* oils could be used as a valuable new flavour with functional properties for food or nutriceutical products with particular relevance to supplements for the elderly.

1. Introduction

The functional role of herbs and spices and their constituents is a hot topic in food related plant research. Spices, in fact, are actually not only evaluated for their seasoning properties, but are also appreciated for their bioactive efficacy as antioxidants, and nutrients (Hirasa & Takemasa, 1998). In recent years, there has been growing interest in finding natural antioxidants, including volatile chemicals, in plants because they inhibit oxidative damage and may consequently prevent inflammatory conditions (Khanna et al., 2007), ageing and neurodegenerative disease (Fusco, Colloca, Lo Monaco, & Cesari, 2007). The market constantly addresses its attention to new and underutilised spices, to check their properties and to evaluate their use in the industry. Most of the chemical constituents of essential oils are terpenoids, characterised by a low molecular weight which allows easy transport across cell membranes to induce different biological activities, including antioxidant, antiinflammatory and anticholinesterase effects (Chao et al., 2005; Kulisić, Krisko, Dragović-Uzelac, Milos, & Pifat, 2007; Loizzo et al., 2007).

The genus *Origanum* (Lamiaceae) is characterised by a large morphological and chemical diversity. Forty-nine taxa divided into 10 sections belong to this genus, most of them having a very local distribution around the Mediterranean. The essential oils of *Origanum* species vary in respect of the total amount produced by plants as well as in their qualitative composition. *Origanum* essential oils are characterised by a number of main components which are implicated in the various plant odours. A wide chemical diversity is found even within a single *Origanum* species e.g. the widely used *O. vulgare* where the pattern of variation of quantitative and qualitative essential oils depends on geographical distribution or on the time of plant collection (Kokkini, 1996). Today, *O. vulgare* (oregano) can be considered one of the most important spices both in

doi:10.1016/j.foodchem.2009.03.095

Mediterranean countries and elsewhere. The overall market of oregano is about 350–500 tonnes in France, 600 tonnes in Germany, 500 tonnes in the UK and 150 tonnes in the Netherlands (Maftei, 1992). The popularity of oregano is increasing as a result of scientific developments achieved in the area of its cultivation and utilisation and its flavour is almost irreplaceable in several food preparations or as a herbal tea. Dried *Origanum* species are also used for the production of essential oil and aromatic water (Dundar et al., 2008) and they are used as stimulants, analgesics, antitussives, expectorants, sedatives, antiparasitisc and antihelminthics in folk medicine; but mostly for gastrointestinal complaints (Başer, 2002). Lebanon, located on the Mediterranean littoral, presents a climatic and ecological diversity that is unique to the eastern Mediterranean region and the whole country is recognised as a centre of plant diversity. An estimated 2600 plant species are recorded in Lebanon, of which 221 are broad endemics and 90 are narrow endemics (Khouzami, Bassil, Fortunat, & Hayek A., 1996). *O. ehrenbergii* Boiss. is endemic in Lebanon and it is used as a condiment, although the less strongly flavoured *O. syriacum* L. is preferred (Figuérédo, Chalchat, & Pasquier, 2005).

Alzheimer's disease (AD) is the most common form of neurodegenerative disorders, neurochemically characterised by a consistent deficit in cholinergic neurotransmission, particularly affecting cholinergic neurons in the basal forebrain. Symptoms of AD and other forms of dementia can be treated by the use of agents which restore the level of acetylcholine through inhibition of both the two major forms of cholinesterase: acetylcholinesterase (AChE) and butyrylcholinesterase (BChE). In late stages of AD, levels of AChE decline by up to 85% and BChE represents the predominant cholinesterase in the brain. BChE, primarily associated with glial cells but also with specific neuronal pathways, cleaves ACh in a manner similar to AChE to terminate its physiological action. Such studies, together with a statistically slower decline in the cognitive performance of dementia patients possessing specific BChE polymorphisms that naturally lower BChE activity, have targeted BChE as a new approach to intercede in the progression of AD (Ballard, Greig, Guillozet-Bongaarts, Enz, & Darvesh, 2005). Recently, Hodges (2006) demonstrated that the inhibition of AChE holds a key role not only to enhance cholinergic transmission in the brain but also to reduce the aggregation of β-amyloid and the formation of the neurotoxic fibrils in AD.

In recent years, oxidative stress has been described in the pathological changes that occur in AD (Pratico & Delanty, 2000). Nitric oxide (NO) is a diatomic free radical produced from L-arginine by constitutive and inducible nitric oxide synthase (cNOS and iNOS) in numerous mammalian cells and tissues. NO, superoxide (O_2^-) and their reaction product peroxynitrite ($ONOO^-$) may be generated in excess during the host response against infections and inflammatory conditions, contributing to some pathogenesis by promoting oxidative stress, tissue injury and even neurodegenerative disease (De Palma et al., 2008). The mechanism of inflammation injury is attributed, in part, to release of reactive oxygen species from activated neutrophils and macrophages. This over production leads to tissue injury by damaging macromolecules and lipid peroxidation of membranes (Gutteridge, 1995). In addition, ROS propagate inflammation by stimulating release of mediators such as NO and cytokines such as interleukin-1, tumour necrosis factor-α and interferon-γ, which stimulate recruitment of additional neutrophils and macrophages. Thus free radicals are important mediators that provoke or sustain inflammatory processes and, consequently, their neutralisation by antioxidants and radical scavengers can attenuate inflammation (Geronikaki & Gavalas, 2006). Nizri, Hamra-Amitay, Sicsic, Lavon, and Brenner (2006) showed that cholinergic up-regulation obtained with the use of AChE inhibitors was associated to an antiinflammatory effect through the suppression of lymphocyte proliferation and pro-inflammatory cytokine production. Following this view, in recent years, an increased interest has emerged directed to finding products from edible plants able to inhibit both of these events. The present study was planned to evaluate Lebanese *O. ehrenbergii* and *O. syriacum* for antioxidant, antiinflammatory, and cholinesterase inhibitory activities taking into account the chemical composition of the oils.

2. Materials and methods

2.1. Chemicals

Dimethylsulphoxide (DMSO), chloroform, ethanol were obtained from VWR International s.r.l. (Milano, Italy). Phosphate buffered saline (PBS), β-carotene, anhydrous sodium sulphate, ascorbic acid, propyl gallate, 2,2-diphenyl-1-picrylhydrazyl (DPPH), linoleic acid, limonene, Tween 20, sodium phosphate buffer, sodium potassium tartrate tetrahydrate, acetylthiocholine iodide (ATCI), butyrylthiocholine iodide (BTCI), 5,5′-dithiobis [2-nitrobenzoic-acid] (DTNB), physostigmine, acetylcholinesterase from *Electrophorus electricus* (EC 3.1.1.7, Type VI-S) and butyrylcholinesterase from equine serum (EC 3.1.1.8), Dulbecco's Modified Eagle's Medium (DMEM), L-glutamine, foetal bovine serum (FBS), penicillin/streptomycin, trypan blue, sulphonamide, Griess reagent (1% sulfanamide and 0.1% *N*-(1-naphtyl) ethylenediamine dihydrochloride in 2.5% H_3PO4), MTT (3-(4,5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide), LPS and indomethacin were purchased from Sigma–Aldrich S.p.a. (Milano, Italy). Murine monocytic macrophage cell line RAW 264.7 were purchased from European Collection of Cell Cultures, London, UK.

2.2. Plant material

Origanum ehrenbergii Boiss and *O. syriacum* L. were collected on Baskinta Mountain at an altitude of up to 1500 m, Lebanon, in June 2004 and authenticated by Prof. S. Safi, Biology Department, Faculty of Sciences II, Lebanese University. A voucher specimen (AS32; AS36) was deposited in the Herbarium, Faculty of Sciences II, Lebanese University.

2.3. Oil Isolation

The flowering aerial parts (1 kg) of *O. ehrenbergii* Boiss and *O. syriacum* L. were subjected to hydrodistillation for 3 h using a Clevenger-type apparatus (Loizzo et al., 2007). Each oil was dried over anhydrous sodium sulphate to remove traces of moisture. Samples of essential oil were stored in a brown bottle in a freezer prior to further analysis.

2.4. Gas chromatography–mass spectrometry

To determine the composition of the essential oils from *O. ehrenbergii* and *O. syriacum*, analysis was carried out using a GC system (Hewlett–Packard Co., model 6890 N) with a fused capillary column (30 m length; 0.25 mm i.d.; 0.25-m film thickness; static phase methylsilicone SE-30) directly coupled to a selective mass detector (Hewlett Packard 5973 N). Electron impact ionisation was carried out at an energy of 70 eV. Helium was used as carrier gas. Injector and detector were maintained at 250 °C and 280 °C, respectively. Column temperature was initially kept at 50 °C for 5 min, then gradually increased to 250 °C at 5 °C/min rate and finally held for 10 min at 250 °C. The mass range from 50 to 550 amu was scanned at a rate of 2.9 scans/s. Analyses were also run by a HP-Innowax capillary column (30 m length, 0.25 mm i.d., 0.25 μ film thickness) under the same GC conditions. For

analysis, essential oils were dissolved in dichloromethane (1 mg/ml) and aliquots (1 μl) were directly injected. Most constituents were identified by gas chromatography by comparison of their GC retention indices with those of the literature or with those of standards available in our laboratories. The retention indices were determined in relation to a homologous series of *n*-alkanes (C8–C24) under the same operating conditions. Further identification was made by comparison of their mass spectra on both columns with those stored in the Wiley 138 library or with mass spectra from literature (Table 1) (Adams, 2001).

2.5. Gas chromatography

A Shimadzu model GC 17 gas chromatograph equipped with a FID detector and a capillary column (30 m length; 0.25 mm i.d.; 0.25 μ film thickness; static phase methylsilicone SE-30) and controlled by Borwin software was employed. The carrier gas was nitrogen. The percentage composition of *O. ehrenbergi* and *O. syriacum* oils was computed by the normalisation method from the GC peak areas related to GC peak area of an external standard injected into the GC equipment in isothermal conditions at 100 °C. The percentage of total area was obtained by their addition. All determinations were performed in triplicate and averaged.

2.6. Determination of hydrogen donation ability (DPPH Test)

Free radical scavenging activity of essential oils was performed according to the procedure of Conforti, Statti, Uznov, and Menichini (2006). The absorbance was measured using a Perkin Elmer Lambda 40 UV/VIS spectrophotometer at 517 nm against a blank, which was without DPPH. All tests were run in triplicate and averaged. Ascorbic acid was used as a positive control. A decrease of DPPH solution absorbance indicates an increase of DPPH radical scavenging activity. This activity is given as% DPPH radical-scavenging that is calculated by the following equation:

$$\%\ \text{DPPH radical-scavenging} = [1 - (\text{sample absorbance with DPPH-sample absorbance without DPPH/control absorbance})] \times 100$$

2.7. β-Carotene Bleaching Test

Antioxidant activity was determined using a β-carotene bleaching test (Conforti et al., 2006). Briefly 1 ml of β-carotene solution (0.2 mg/ml in chloroform) was added to 0.02 ml of linoleic acid and 0.2 ml of 100% Tween 20. After evaporation of chloroform and dilution with water, 5 ml of the emulsion was transferred into

Table 1
Chemical composition (%) of *O. ehrenbergi* and *O. syriacum* essential oils.

different test tubes containing 0.2 ml of samples in 70% ethanol at different concentrations. A standard (propyl gallate) at the same concentration as the samples was used for comparison. The tubes were then gently shaken and placed at 45 °C in a water bath for 60 min. The absorbance of the samples, standard and control was measured at 470 nm using a Perkin Elmer Lambda 40 UV/VIS spectrophotometer against a blank, consisting of an emulsion without β-carotene. The measurement was carried out at initial time (t = 0) and successively at 30 and 60 min. All samples were assayed in triplicate and averaged. The antioxidant activity (AA) was measured in terms of successful bleaching of β-carotene by using the following equation:

$$AA = \{1 - [(A_0 - A_t)/(A_0^{\circ} - A_t^{\circ})]\} \times 100$$

2.8. Bioassay for Anticholinesterase Activity

Inhibition of AChE and BChE were assessed by a modified colorimetric Ellman's method (Loizzo et al., 2007), which is based on the reaction of released thiocoline to give a coloured product with chromogenic reagent *E. electricus* (EC 3.1.1.7, Type VI-S) AChE and equine serum (EC 3.1.1.8) BChE were used, while acetylthiocholine iodide (ATCI) and butyrylthiocholine iodide (BTCI), respectively, were used as the substrates of the reaction. 40 μl of AChE or BChE (0.36 U/ml in buffer pH 8) and oils at different concentrations (20 μl) were added to 2 ml of buffer pH 8 and pre-incubated in an ice bath at 4 °C for 30 min. Tested oils and control oils were dissolved in 5% MeOH. Duplicate tubes were also treated this way with 20 μl of physostigmine (0.1 mM) to allow interference of the test substances in the assay to be assessed, and to control any hydrolysis of acetylcholine or butyrylcholine not due to enzyme activity. The reaction was started by adding 5,5′-dithiobis [2-nitrobenzoic-acid] (DTNB) solution (20 μl of 0.05 mM in buffer pH 7) and (ATCI) or (BTCI) (20 μl 0.018 mM in buffer pH 7) and tubes were allowed to stand in a water bath for 20 min at 37 °C. The reaction was halted by placing the assay solution tubes in an ice bath and adding physostigmine (20 μl 0.018 mM in buffer pH 7). The hydrolysis of acetylthiocholine and butyrylthiocholine was monitored by the formation of the yellow 5-thio-2-nitrobenzoate, immediately recorded on a spectrophotometer (Jenway 6300) at 405 nm and the percentage inhibition was calculated. All the reactions were performed in triplicate. The inhibition rate (%) was calculated by equation:

$$\text{Inhibition}\,\% = \frac{[(\text{Blank} - \text{Blank positive control}) - (\text{Experiment} - \text{Experiment control})]}{(\text{Blank} - \text{Blank positive control})}$$

2.9. Cell culture

The murine monocytic macrophage cell line RAW 264.7 was grown in a plastic culture flask in DMEM with L-glutamine supplemented with 10% FBS and 1% penicillin/streptomycin solution under 5% CO_2 at 37 °C. After 4–5 days cells were removed from the culture flask by scraping and centrifuged for 10 min at 1500 rpm. The medium was then removed and the cells were re-suspended with fresh DMEM. Cells counts and viability were performed using a standard trypan blue cell counting technique. The cell concentration was adjusted to 1×10^6 cells/ml in the same medium. Hundred microlitre of the above concentration were cultured in a 96-well plate for one day to become nearly confluent. Concentrations ranging from 10–200 μg/ml of the samples were prepared from the stock solutions by serial dilution in DMEM to give a volume of 100 μl in each well of a microtiter plate (96-well). Then cells were cultured with the vehicle and *Origanum* oils in the presence of 1 μg/ml LPS for 24 h.

2.10. Assay for cytotoxic activity

Cytotoxicity was determined using the MTT assay (Tubaro et al., 1996) with some modification. The assay for each concentration of samples was performed in triplicate and the culture plates were kept at 37 °C with 5% (v/v) CO_2 for one day. After 24 h of incubation, 100 μl of medium was removed from each well. Subsequently, 100 μl of 0.5% w/v MTT, dissolved in phosphate buffer saline, was added to each well and allowed to incubate for a further 4 h. After incubation, 100 μl of DMSO was added to each well to dissolve the formazan crystals. Absorbance values at 550 nm were measured with a microplate reader (GDV DV 990 B/V, Roma, Italy). Cytotoxicity was expressed as CD_{50} which is the concentration to reduce the absorbance of treated cells by 50% with reference to the control (untreated cells).

2.11. Inhibition of nitric oxide (NO) production in LPS-stimulated RAW 264.7 cells

The presence of nitrite, a stable oxidised product of NO, was determined in cell culture media by Griess reagent (1% sulfanamide and 0.1% *N*-(1-naphtyl) ethylenediamine dihydrochloride in 2.5% H_3PO_4) (42). 100 μl of cell culture supernatant was removed and combined with 100 μl of Griess reagent in a 96-well plate followed by spectrophotometric measurement at 550 nm using a microplate reader (GDV DV 990 B/V, Roma, Italy). Nitrite concentration in the supernatants was determined by comparison with a sodium nitrite standard curve.

2.12. Statistical analysis

Data were expressed as means ± SD. Statistical analysis was performed by using Student's t test. Differences were considered significant at $P \leqslant 0.05$. The inhibitory concentration 50% (IC_{50}) was calculated from the Prism dose–response curve (GraphPad, Prism version 4.0 for Windows, GraphPad Software, San Diego, CA, USA) obtained by plotting the percentage of inhibition versus the concentrations.

3. Results and discussion

3.1. Composition of the essential oils

The yields of *O. ehrenbergii* and *O. syriacum* essential oils were 0.6% (w/w) and 0.5% (w/w), respectively. In order to identify putative active compounds present within the essential oils, gas chromatography systems were employed. The chemical composition of the oils is reported in Table 1. Both oils are characterised by a very high content of monoterpenes. *O. ehrenbergi* essential oil was characterised by the presence of thirty-seven components, representing 94.9% of the total oil. Thymol (19.6%), *p*-cymene (16.1%), 2-isopropyl-1-methoxy-4-methylbenzene (14.9%), γ-terpinene (11.8%), carvacrol (6.7%), β-myrcene (3.2%), α-terpinene (2.9%) and β-bisabolene (2.7%) were the major constituents. Two populations of *O. ehrenbergii* harvested in Lebanon were previously studied by Figuérédo et al. (2005). The oils of one of the populations were uniform and rich in carvacrol, while the other population displayed a variable chemical composition, including thymol, thymol-carvacrol and *p*-cymene/γ-terpinene chemotypes.

Thirty-six compounds characterised the *O. syriacum* essential oil, representing 90.6% of the total oil. The most abundant components were thymol (24.7%), carvacrol (17.6%), γ-terpinene (12.6%), *p*-cymene (8.7%), 2-isopropyl-1-methoxy-4-methylbenzene (7.9%) and α-terpinene (2.5%). Alma, Mavi, Yildirim, Digrak, and Hirata (2003) reported γ-terpinene, carvacrol, *p*-cymene and β-caryo-

phyllene as main constituents of Turkish *O. syriacum* essential oil. Previously, it was reported that *O. syriacum* var. *bevanii* growing in Turkey contained carvacrol (64.1%) and *p*-cymene (12.3%) as major components (Başer, Kürçüolu, Demirci, & Özek, 2003). On the other hand, while essential oil from *O. syriacum* from Israel contained thymol (59.9%) and carvacrol (80.2%) as a major component, the essential oil from the same plant from Egypt contained only carvacrol (76.7%) as the main constituent (Fleisher & Fleisher, 1991).

3.2. Antioxidant activity of the essential oils

The antioxidant potential of an essential oil or compound can be mainly attributed to its reducing power, radical scavenging ability and singlet oxygen quenching ability. Therefore, to be able to evaluate the total antioxidant activity of an essential oil, two activities were measured i.e. the DPPH radical scavenging assay and β-carotene bleaching test. The effect of antioxidants on the DPPH radical is thought to be due to their hydrogen donating ability. The scavenging effects of *O. ehrenbergii* and *O. syriacum* on DPPH were examined at different concentrations. As shown in Table 2, both essential oils exhibited a significant activity. In particular *O. ehrenbergii* oil showed the higher activity (IC_{50} 1.0 μg/ml) while *O. syriacum* oil had IC_{50} 1.7 μg/ml. Antioxidant activity, which was demonstrated by the ability of the samples to inhibit the bleaching of β-carotene, was measured and compared to that of the control which contained no antioxidant component. Both *O. ehrenbergii* and *O. syriacum* inhibited oxidation of linoleic acid after 30 min of incubation as well as after 60 min of incubation with IC_{50} of 42.1 and 33.6 μg/ml, and 46.9 and 58.9 μg/ml, respectively, indicating that its activity was not correlated with the time of heating. Previously, Alma et al. (2003) reported that *O. syriacum* oil from Turkey exhibited a considerable reducing power that was higher than those of essential oil from the leaves of another common spice *Laurus nobilis*. The antioxidant activity may be attributed primarily to the high content of phenolic components of the essential oil (Ruberto, Baratta, Sari, & Kaabache, 2002). The chemical composition of *O. syriacum* essential oil indicates that compounds such as carvacrol, carvacrol methyl ether and thymol methyl ether are relatively rich in the essential oil. In fact, recently it has been reported that these compounds have antioxidant ability (Mastelić et al., 2008). No previous studies were done on the antioxidant activity of *O. ehrenbergii*.

3.3. Inhibition of NO production

Inhibition of NO production may result in anti-inflammatory activity and was studied *in vitro* by analysing the effect of *O. ehrenbergii* and *O. syriacum* essential oils on chemical mediators released from macrophages. Once activated by a pro-inflammatory stimulus, macrophages produce a large number of cytotoxic molecules. Treatment of RAW 264.7 macrophages with LPS (1 μg/ml) for 24 h induces NO production, as assessed by measuring the accumulation of nitrite, a stable metabolite of NO, in the media by a colourimetric procedure based on the Griess reaction. NO, a macrophages-derived mediator, is considered to play a key role in inflammatory response, based on its occurrence at inflammatory sites and its ability to induce many of the hallmarks in the inflammatory response. The beneficial effect of *O. ehrenbergii* on the inhibition of production of inflammatory mediators in macrophages can be mediated through oxidative degradation of products of phagocytes, such as O_2^- and HOCl. As shown in Table 3, incubation of RAW 264.7 cells with *O. ehrenbergii* induced a significant inhibitory effect on the LPS-induced nitrite production in a dose-dependent manner, with an IC_{50} value of 66.37 μg/ml. This effect, which is comparable to the positive control indomethacin, is probably due to the presence of thymol, one of the major components of the oils which has a phenolic structure, and has been credited with a series of pharmacological properties, including antimicrobial, antioxidant and anti-inflammatory effects (Braga et al., 2006). Carvacrol showed anti-inflammatory properties (Sosa et al., 2005). The high content of this compound in *O. ehrenbergii* oil is probably the reason for its high activity.

Table 2
Free radical scavenging and antioxidant activity of *Origanum* essential oils (IC_{50} μg/ml).

Essential oil	DPPH assay	β-carotene bleaching test	
		30 min	60 min
O. ehrenbergii	1.0 ± 0.05	42.1 ± 0.9	46.9 ± 1.0
O. syriacum	1.7 ± 0.01	33.6 ± 0.8	58.9 ± 1.2
Ascorbic acid	2.0 ± 1.2		
Propyl gallate		1.0 ± 0.01	1.0 ± 0.01

Data are given as means ± S.D. (n = 3). Ascorbic acid and propyl gallate were used as positive control.

Table 3
Inhibition of NO production in LPS induced RAW 264.7 macrophages by *Origanum* essential oils.

Essential oil	IC_{50} (μg/ml)
O. ehrenbergii	66.4 ± 1.6
O. syriacum	>200
Indomethacin	52.8 ± 1.2

Data are given as means ± S.D. (n = 3). Indomethacin was used as positive control.

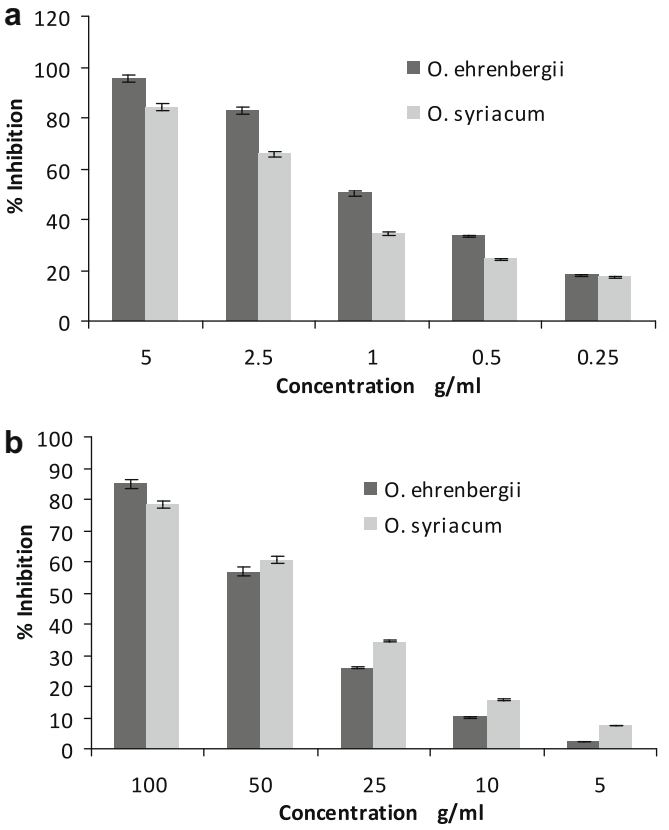

Fig. 1. (a) Free radical scavenging and (b) antioxidant activity after 30 min of incubation of *Origanum* essential oils. Data are given as means ± S.D. (n = 3).

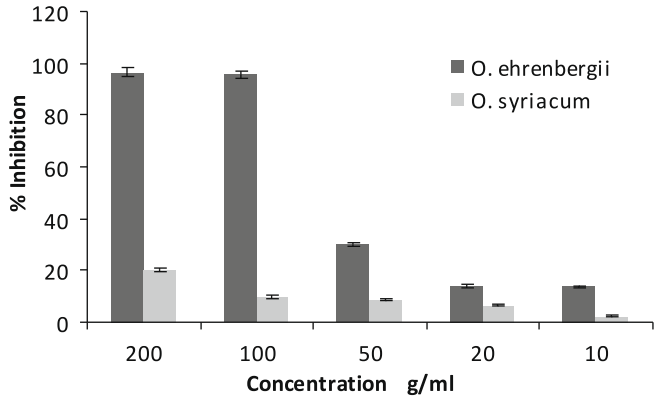

Fig. 2. Inhibition of NO production in LPS induced RAW 264.7 macrophages by *Origanum* essential oils. Data are given as means ± S.D. (n = 3).

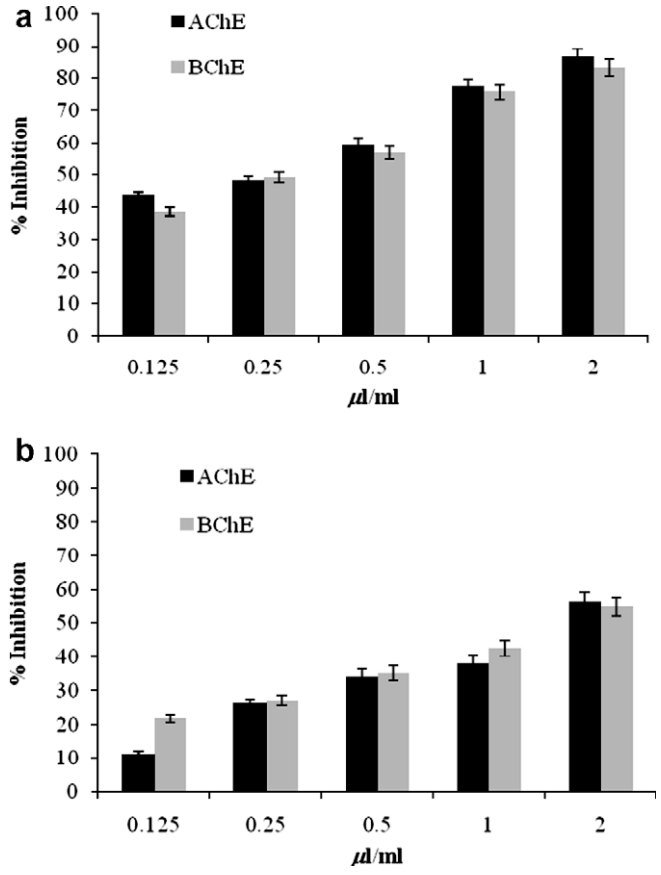

Fig. 3. Dose-dependent anticholinesterase inhibitory activity of *Origanum ehrenbergii* (a) and *O. syriacum* (b). Data are given as means ± S.D. (n = 3).

3.4. Anticholinesterase activity

AChE plays an important role in the central nervous system. It is one of the fastest known enzymes and catalyzes the cleavage of acetylcholine in the synaptic cleft after depolarisation. Inhibitors of AChE, such as galanthamine, are used frequently in the pharmacotherapy of AD. The less specific BChE has recently been a focus of research, because BChE concentration stays the same, or is even up-regulated, while AChE is dramatically down-regulated in the brains of patients suffering from AD (Giacobini, 2004). Since a large amount of evidence demonstrates that oxidative stress is intimately involved in age-related neurodegenerative diseases,

Table 4
Cholinesterase inhibitory activity of *O. ehrenbergii* and *O. syriacum* essential oil (IC_{50} μg/ml).

Essential oil	AChE	BChE	SI (BChE/AChE)
O. ehrenbergii	0.3 ± 0.02	0.3 ± 0.04	0.9
O. syriacum	1.7 ± 0.8	1.6 ± 0.05	1.0
Physostigmine	0.1 ± 0.003	0.2 ± 0.07	2.4

IC_{50} values are mean ± S.D. (n = 3).

there have been a great number of studies which have examined the positive benefits of antioxidants to reduce or to block neuronal death occurring in the pathophysiology of these disorders (Ramassamy, 2006). *O. ehrenbergii* exhibited an interesting activity against both cholinesterases in a dose-dependent manner (Figs. 1–3) with IC_{50} values of 0.3 μg/ml for both AChE and BChE, and a selectivity index of 0.9. On the contrary *O. syriacum* showed a lower activity (Table 4). Previously, Salah and Jäger (2005) reported that *O. syriacum* was recommended by herbalists for the treatment of AD and other neurological conditions. It was previously reported that essential oils rich in monoterpenes exhibit a strong inhibitory activity against both enzymes. Moreover, the AChE inhibitory property was recently demonstrated for thymol and carvacrol, the main components of both oils (Loizzo, Tundis, Menichini, & Menichini, 2008).

The significant activity on BChE is of a certain interest since in late stages of AD, levels of AChE decline by up to 85% and BChE represents the predominant cholinesterase in the brain. Such studies have targeted BChE as a new approach to intervene in the progression of AD (Ballard et al., 2005).

Beside being appreciated for their aromatic properties, *O. ehrenbergii* and *O. syriacum* essential oils provide interesting properties from a functional perspective in prevention of neurodegenerative disorders. In fact, both oils exhibited a good antioxidant and antiradical activity, with some properties relevant to an anti-inflammatory action. Moreover, even at very small concentrations, both *O. ehrenbergii* and *O. syriacum* oils demonstrated an interesting inhibitory activity on AChE and BChE, key enzymes in the pathogenesis of AD. The ability of these oils to act in a multi-factorial pattern leads to the suggestion that they may be candidates for valuable new flavours with functional properties in food, or for nutriceutical products with particular relevance in supplements for the elderly.

Plasma antioxidant capacity
Ascorbate
Urate

ABSTRACT

The consumption of antioxidant-rich foods has already been associated with acute significant increases in plasma total antioxidant capacity (TAC) in humans, but there is no consensus among different literature reports. Furthermore, the acute rise in plasma TAC observed after consumption of several non-berry fruits seems not to be necessarily related to the absorption of dietary antioxidants, such as micronutrients and phenolic substances, but is attributed to the relevant increase of endogenous urate in serum. In this study, we first compared the nutritional quality of strawberry fruits from different genotypes, all cultivated in the same experimental field. Significant genotype-to-genotype differences were observed in the antioxidant capacity and in the vitamin C, folate and phenolic contents of the fruits. Second, in order to investigate the individual effects of the selected strawberry genotypes on the post-prandial plasma antioxidant status in humans, we assessed the acute effects of a single dose of strawberries in healthy subjects. The variation of plasma TAC through the FRAP and TEAC assays, and any eventual changes in ascorbate and urate levels in serum, were measured during the three hours following the strawberry intake. The acute intake of strawberries resulted in a significant increase in plasma FRAP values in all the subjects, independently of the individual TAC baseline levels. Interestingly, the lowest increases in plasma TAC and in serum ascorbate levels were associated with consumption of the nutritionally-poorest cultivars. In addition, significant increases in ascorbate, but not in urate, concentrations were observed in serum. These findings suggested that the fructose-dependent hyperuremic effect, observed after the intake of non-berry fruits, is not responsible for the plasma antioxidant changes following strawberry consumption.

1. Introduction

Increase in the consumption of foods rich in antioxidants, micronutrients and phytochemicals has long been proposed as a preventive measure to decrease the risk of several chronic diseases caused by oxidative stress. In particular, the improvement in plasma antioxidant status (and the increase in serum antioxidants) has been recognised as a potential tool to prevent the development of cardiovascular, proliferative, degenerative and other diseases (Kay & Holub, 2002).

Significant increases in the plasma total antioxidant capacity (TAC) have already been reported in human studies following both the acute and long-term consumption of antioxidant-rich foods and beverages, such as several fruits and vegetables, red wine and tea (Cao, Booth, Sadowski, & Prior, 1998; Cao, Russell, Lischner, & Prior, 1998; García-Alonso, Ros, Vidal-Guevara, & Periamo, 2006). However, there is no absolute consensus among the literature reports. For instance, other studies have not confirmed the same correlation between fruit consumption and plasma antioxidant status in humans (Bub et al., 2003; Duthie et al., 2006). In parallel, although relevant health-promoting effects have been associated *in vitro* with the polyphenol antioxidants contained in fruit, such as flavonoids (Hollmann, 2001; Yi-Fang, Jie, Xianzhong, & Rui, 2002), a clear *in vivo* demonstration of polyphenol absorption

and plasma circulation is still lacking, and their contribution to the plasma antioxidant status seems to be negligible. Firstly, this could be partly due to persistent analytical and methodological difficulties in recovering and identifying phenolic metabolites in complex biological fluids (Day & Morgan, 2003). Secondly, it is hardly likely that the rapid rise in plasma TAC, often observed after flavonoid-rich food intake, could be mainly ascribed to the direct contribution of these dietary compounds. For instance, the increase in plasma TAC after the consumption of antioxidant-rich berry fruits and juices has usually been attributed to the high levels of polyphenolic antioxidants provided by the berries. However, many recent short-term human intervention studies have reported that flavonoid compounds, such as anthocyanins, which are among the most represented phenols in berries, show a rapid but very poor absorption (Manach, Williamson, Morand, Scalbert, & Rémésy, 2005). These substances seem to reach only very low concentrations in human plasma and only immediately after the consumption of flavonoid-rich foods. Furthermore, the derivative chemical structures resulting from the extensive hepatic metabolism of the ingested flavonoids seem not to necessarily express the native antioxidant activities (Natsume et al., 2004). Finally, from a recent comparison of different analytical methods for assessing the TAC of human serum, it was found that the major contributors to TAC values were uric acid and vitamin C, followed by protein, bilirubin, and α-tocopherol (Cao & Prior, 1998). Other antioxidants, including plasma/serum phenols and polyphenolic compounds, have been thought to contribute about 5% of the FRAP values, so that the contribution of polyphenols to FRAP could be considered negligible (Cao & Prior, 1998).

On the other hand, several research groups have recently paid renewed attention to the putative role of other non-phenolic substances contained in fruit, both micronutrients and macronutrients, which could be directly or indirectly responsible for the postprandial variations in the plasma antioxidant pool (Lotito & Frei, 2006). Interestingly, a great number of investigators observed relevant increases of serum urate after consumption of several fruits, which otherwise did not contain urate or its precursors (Lotito & Frei, 2004). This endogenous metabolite expresses high reducing and free radical-scavenging activities, thus acting as an antioxidant, and alone may contribute to up to 60% of the plasma TAC, when evaluated by the FRAP assay. Thus, the rapid increase in the antioxidant status in humans after fruit consumption could not be ascribed to the absorption of dietary flavonoid or non-flavonoid antioxidants, but rather to an overproduction and circulation of endogenous antioxidant metabolites (Day & Stansbie, 1995; Natella, Nardini, Giannetti, Dattilo, & Scaccini, 2002). The mechanisms implicated in this hyperuremic response to fruit consumption have been partly explained and related to the absorption of fructose and related carbohydrates (Heuckenkamp & Zollner, 1971), responsible for accelerating the degradation of AMP to urate (Mayes, 1993).

Meanwhile, fructose-rich but vitamin-C-poor foods and beverages have often been tested in the *in vivo* studies carried out up to now, so that hyperuremic effects were observed while the contribution of vitamin C in the increase of plasma TAC was negligible and the role of serum urate resulted as a predominant factor.

In this study, strawberry was chosen as the fruit model to evaluate the possible acute plasma effects resulting from a high single dose intake. Compared to other non-berry fruits previously used in human studies (Lotito & Frei, 2004), strawberry is a relevant source of antioxidants and micronutrients, being among the richest natural food source of vitamin C and folate (Olsson et al., 2004), and it possesses a higher water content, a lower content of low molecular weight carbohydrates and a greater glucose/fructose ratio (Olsson et al., 2004; Vinson, Bose, Proch, Al Kharrat, & Samman, 2008). Among berries, the strawberry also possesses a more equilibrated phenolic composition (Aaby, Ekeberg, & Skrede, 2007) and is the most commonly consumed fruit, therefore having a major potential impact on human health (Hannum, 2004).

Six different strawberry genotypes were selected for the *in vivo* study. First, the antioxidant, micronutrient (vitamin C and folate) and phenolic contents of the selected fruits were analysed and compared, in order to calculate the individual intake corresponding to a single dose of strawberries consumed during the test, and to identify any relevant genotype-to-genotype differences in the nutritional quality of the fruits. Second, the eventual genotype-to-genotype differences in the plasma response to acute strawberry consumption were investigated, in order to test the influence of the nutritional quality (NQ) of the fruits on the changes in plasma TAC and in serum ascorbate and urate concentrations. Six parallel feeding tests were carried out involving healthy nonsmoking subjects; furthermore, for an internal control and a check of any genotype-dependent differences in plasma response to the acute intake, a subgroup of the subjects was asked to consume strawberries from two different genotypes with a washout period of at least one week between the two intakes.

2. Materials and methods

2.1. Test strawberries

In May 2006, six different strawberry genotypes (“Alba”, “Irma”, “Patty”, “Adria”, “Sveva”, “AN99.78.51”), cultivated in the experimental field for genetic improvement of the Azienda Agraria Didattico Sperimentale (Marche Polytechnic University), were selected for the *in vivo* acute test.

During three separate sessions, corresponding to the main harvest times of the selected clones, fruits were harvested and distributed to the subjects within one hour. Fruits from each studied genotype were also collected for composition analyses, immediately stored at −20 °C and at −80 °C (see vitamin C and folate measurement) and analysed within three months. Compounds extraction was carried out *via* homogenisation or *via* sonication, depending on the analysis to be performed. For spectrophotometric general assays, frozen strawberries were thawed for 60 min at 4 °C; then, 10 g aliquots of the fruits were added to 100 ml of the extraction solution (1:10 w/v), consisting of an 80% methanol aqueous solution, containing 0.1% formic acid (FA). Fruits were homogenised using an Ultraturrax T25 homogeniser (Janke & Kunkel, IKA Labortechnik) at medium-high speed for 2 min, and the extraction was maximised by stirring the suspension for 2 h in the dark at room temperature. Then tubes were centrifuged at 3500 rpm for 15 min (twice sequentially), to sediment solids, and supernatants were filtered through a 0.45 μm Minisart filter (PBI International), transferred to 5.0 ml amber glass vials and stored at −20 °C prior to analysis.

2.2. Standard colorimetric methods

The TAC of the hydroalcoholic extracts of the fruits was assessed by two methods, the trolox equivalent antioxidant capacity (TEAC) assay and the ferric reducing antioxidant power (FRAP) assay, as described below. Results are expressed as moles of trolox equivalents (TEq) per kg of fresh weight of strawberries (mmoles TEq/kg FW). The results represent the mean values ± SD of eight measurements. The total phenolic content of the hydroalcoholic extracts was determined by the Folin–Ciocalteu colorimetric method, as modified by ,Slinkard and Singleton (1977), quantifications were calculated through a calibration curve, daily prepared with known concentrations of gallic acid (GA) standards and results were expressed as grammes of GA equivalents per kg of fresh

weight of strawberries (g GAEq/kg FW, mean value ± SD of eight measurements). The total flavonoids was determined according to a colorimetric method previously described (Dewanto, Wu, Adom, & Liu, 2002) and catechin (C) was used as reference standard compound. Results were expressed as grammes of C equivalents per kg of fresh weight of strawberries (g CEq/kg FW, mean value ± SD of eight measurements). The total anthocyanins was measured using a modified pH differential method previously described (Giusti, Rodriguez-Saona, & Wrolstad, 1999) with slight modifications, and absorbance readings were converted to quantifications through a calibration curve obtained by known concentrations of pelargonidin-3-glucoside (Pg-glc) standards. Results are expressed as Pg-glc equivalents per kg of fresh weight of strawberries (g Pg-glcEq/kg FW, mean value ± SD of eight measurements).

2.3. Measurement of vitamin C content

For vitamin C and folate measurements, fruits stored at −80 °C were snap-frozen in liquid nitrogen, and ground to a fine powder by using a precooled coffee grinder (IKA A11 basic); the frozen powders were stored at −80 °C prior to analysis. Immediately before analysis, 2 ml of ice-cold extraction solution were added to 0.5 g FW of frozen powder weighed in 10 ml ice-cold glass tubes, and the mixture was sonicated in the dark at 4 °C for 15 min. For vitamin C quantification, the extraction solution consisted of MilliQ water containing 5% meta-phosphoric acid and 1 mM diethylenetriaminepentaacetic acid (DTPA), stirred well prior to use, sonicated until dissolved and stored in a refrigerator. After the ultrasound-assisted extraction, the cell walls and proteins were precipitated by centrifugation at 2500 rpm for 10 min at 4 °C; the surnatant was filtered through a 0.2 μm PTFE filter into 1.8 ml HPLC vials, and immediately analysed. Vitamin C in the fruits was analysed by reversed-phase HPLC, as previously described by our group (Tulipani et al., 2008). The HPLC system consisted of a Waters 600 controller, a Waters 996 Photodiode array (PDA) detector set at absorbances of 262 and 244 nm, and a column incubator at 30 °C. The HPLC column used was a YMC Pack Pro, 150 × 4.6 mm. The elution was isocratic with 50 mM potassium phosphate (KH_2PO_4) in MQ water, leading to pH 3.2 by adding orthophosphoric acid, and analysis consisted of a 10 min run, after which the column was cleaned with 50% acetonitrile. Vitamin C eluted at RT ≈ 5.3 min. Quantification of the vitamin C content was carried out through a calibration curve prepared by running standard concentrations of vitamin C prepared as were the extracts, and measured in duplicate at the beginning and at the end of the analysis. Results are expressed as g vitamin C (vit C) per kg of fresh weight of strawberries (g vit C/kg FW, mean value ± SD of three measurements).

2.4. Measurement of folate content

The total folate content in strawberries was quantified by a microbiological assay (MA), which used the growth response of a folate-dependent test micro-organism (generally *Lactobacillus rhamnosus* ATCC 7469) in extracts that were enzymatically treated to release the bound vitamin. For folate extraction, 0.15 g FW strawberry frozen powder was added to 1.5 ml of ice-cold extraction solution, consisting of 0.1 M sodium acetate (CH_3CO_2Na) buffer containing 0.1% ascorbic acid and 20 μm 1,4-dithiothreitol (DTT), pH 4.7. The mixture was vortexed, sonicated for 5 min, and kept for 10 min at 100 °C in a boiling water bath to denature any eventual enzyme before the deconjugation treatment. The deconjugation treatment involved incubating, for 4 h at 37 °C, 300 μl of strawberry extract with 450 μl of deconjugation working solution, consisting of a 1:24 (v/v) dilution of a 1.2% human plasma (w/v) and 0.7% 2-mercaptoethanol aqueous solution in 0.1 M sodium acetate solution, pH 4.7. Both the untreated (control) and the enzyme-treated strawberry extracts were then heated in a boiling water for 5 min, to denature enzymes, and filtered through 0.22 μm PTFE sterile filters (Acrodisc, GelmanSciences). The strawberry folate-dependent *Lactobacillus rhamnosus* growth was determined by measuring the increase in optical density at 580 nm, using a ninety-six-well microplate reader Emax (Molecular Devices Corporation, Sunnyvale, Calif.), as previously described (Sybesma, Starrenburg, Tijsseling, Hoefnagel, & Hugenholtz, 2003). Results were expressed as μg folate (Fol) per kg of fresh weight of strawberry fruit (μg Fol/kg FW, mean value ± SD of four measurements).

2.5. Subjects

Eight healthy nonsmoking subjects (3 men and 5 women) were recruited for the study. The subjects aged 26 to 45 years, with body mass indeces ranging from 22 to 27 kg/m^2 (Table 1). The main exclusion criteria were a case history of allergy to strawberries or other berries and the diagnosis of any chronic disease which could interfere with alignment to the guide lines of the test. Smokers and subjects with acute inflammatory disease or taking dietary supplements or medications were also excluded from the test. All participants were in good health, as confirmed by the results from clinical laboratory tests, and all biochemical parameters at the baseline time were within the normal reference ranges for adults (see Table 4 below). The human study was reviewed by the local ethics committee of the Marche Polytechnic University and Regional Hospital of Torrette-Umberto I (Ancona, Italy); the experimental design was carefully explained to the volunteers prior to the test, and their written informed consent was obtained.

2.6. Study design

The subjects were asked to abstain from eating fruits, vegetables and their juices, wine, tea or coffee for 12 h before the test to partially standardise the baseline points, and to maintain the usual intake of antioxidant compounds during the days before the experiment. After a night of fasting, they were invited to eat 1 kg of strawberries within a space of 10 min, and to refrain from consuming other foods or beverages during the test. Heparinized plasma was obtained immediately before (baseline timepoint) and up to 3 h after the consumption of the fruits, and stored at −80 °C until analysis.

2.7. Plasma and serum assays

2.7.1. Measurement of plasma total antioxidant capacity (TAC)

As for the fruits, plasma TAC was determined using (in parallel) the TEAC and FRAP assays. The TEAC assay was carried out as recently modified by a flow injection analysis (FIA) system (Bompadre, Leone, Politi, & Battino, 2004). The improved TEAC method, also called FIA–ABTS decolorization assay, is based on the ability of antioxidant compounds to quench the 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) radical cation ($ABTS^{\cdot+}$) and reduce the radical to the colourless neutral form. The undiluted plasma

Table 1
Physical characteristics of the subjects involved in the study (mean value ± standard deviation).

Subjects (*n*)	8
Gender (F/M)	5/3
Age (years ± standard deviation)	30 ± 6
Height (m ± standard deviation)	1.70 ± 0.1
Body mass (kg ± standard deviation)	70 ± 8
Body mass index (kg/m^2 ± standard deviation)	24 ± 2

sample (5 μl) is injected into a serpentine-knotted reaction coil and allowed to react with the $ABTS^{\cdot+}$ working solution pumped into the coil at a flow rate of 1.2 ml/min. The extent of decolorization, expressed as percentage of inhibition of absorbance, is then plotted as a function of concentrations of the antioxidants in the plasma sample. Each sample was analysed in four replicates and TEAC results were expressed as plasma millimolar concentration (mM) of trolox equivalents.

The FRAP assay was carried out as described by Benzie and Strain (1996), with minor modifications. Trolox aqueous dilutions were used for calibration. Each sample was analysed in eight replicates and FRAP results were expressed as plasma micromolar concentration (μm) of trolox equivalents.

2.7.2. Measurement of serum vitamin C and uric acid levels

The concentrations of ascorbic and uric acids in serum were measured by HPLC with electrochemical detection, as previously described by Lotito and Frei (2004). Briefly, 200 μl of plasma was mixed with an equal volume of ice-cold 5% (w/v) aqueous solution of metaphosphoric acid (MPA), vortexed and incubated at 4 °C for 10 min in the dark. The samples were centrifuged at 10,000 rpm for 5 min to remove the precipitated proteins. The supernatant was collected and diluted 1:6 in the mobile phase (see below). A 20 μl aliquot of this solution was immediately injected into the HPLC system, consisting of a Supercosil C-18 column (25 cm × 4.6 mm, 5 μm particle size) as stationary phase. The mobile phase consisted of 40 mM sodium acetate, 0.54 mM Na_2EDTA and of the ion pairing agent 3 mM hexadecyltrimethylammonium bromide (CTAB, Acros Organics), adjusted to pH 4.75 with glacial acetic acid. Ascorbic and uric acids were determined by amperometric electrochemical detection by using a model 5100A Coulochem II EC detector (ESA, Inc.) equipped with a dual analytical cell (model 5020).

For optimum detection of the compounds, the electrode potentials for the electrodes 1 (E1) and 2 (E2) were set at 200 and 350 mV, respectively. These potentials provided peak area responses with minimum background and allowed quantitative analysis. Peak area analysis was provided by Star WS software (Varian Inst. Inc.), based on calibration curves generated for each of the two compounds. Each sample was analysed in four replicates, and results were expressed as serum micromolar concentrations (μm).

2.8. Statistical analysis

Statistical analyses of both strawberry fruits and plasma data were performed using the STATISTICA software package (Statsoft Inc., Tulsa, OK, USA). For all the parameters evaluated in the strawberry fruits, results were subjected to the HSD Tukey' multiple range test. Plasma and serum values were subjected to the Wilcoxon paired samples test. Data are reported as means ± standard error (SEM) and as% changes from the baseline values (see Table 4 below). Differences at $p < 0.05$ were considered statistically significant.

3. Results and discussion

The strawberry fruits under study came from six different clones with a well-known genetic background, all previously selected for their different antioxidant and phenolic content (Battino & Mezzetti, 2006; Tulipani et al., 2008).

Table 2 shows the micronutrient and phytochemical contents of the strawberries analysed in this study, corresponding to the single dose consumed by the subjects (1 kg). Significant differences were observed among strawberry genotypes, confirming that the genetic background has an important role in influencing the nutritional value of the fruits. The results of the TEAC and FRAP assays for total antioxidant activity were similar and outlined the same cultival-to-cultivar differences, thus confirming that the two assays are almost comparable and inter-changeable for fruit analysis. FRAP values were, in each case, slightly lower than the corresponding TEAC values (Table 1), nevertheless a strongly significant correlation between the two methods was observed ($r = 0.95$, $p < 0.0001$). The variety Sveva showed the highest TAC values and the highest total phenolic and flavonoid contents, followed by the varieties Adria, Alba and the selection AN99.78.51, while the highest folate and anthocyanin contents were found in the selection AN99.78.51, together with the variety Alba. In keeping with previous observations (Prior et al., 1998), our data confirmed that the association between the TAC of the fruit and the proportion of phenolics present as anthocyanins was not very evident in strawberry. Even if individual anthocyanin compounds have strong antioxidant properties, several other phenolic compounds seem to give an important cumulative contribution to the TAC of the fruits, and the quantitative variation of the non-anthocyanin antioxidant phenolics among genotypes could explain why the total antioxidant capacity of the extracts is not strongly correlated with the anthocyanin content.

Similar vitamin C contents were observed among the TAC-richest genotypes Alba, Adria, Sveva and AN99.78.51 (Alba > Adria > Sveva > AN99.78.51). These clones also showed higher vitamin C values than the two remaining cultivars (Patty > Irma), confirming that the latter were the nutritionally-poorest fruits for all the parameters studied (Table 2).

The TAC of plasma samples was estimated, from their capacity to quench $ABTS^{\cdot+}$, reducing the radical to the colourless neutral form, using the TEAC assay, and by evaluating the plasma ability to reduce ferric iron by the FRAP assay. Table 3 shows the changes of plasma TAC (measured by both FRAP and TEAC assays) and of serum ascorbate and urate after the intake of strawberries. The data represent the mean values among all the strawberry genotypes consumed, and are reported both as absolute values

Table 2
Antioxidant and phenolic content of the selected strawberry genotypes corresponding to the single dose (1 kg) consumed by each subject. Means ± standard deviation in the same row with different superscript letters are significantly different at $p < 0.05$, using HSD Tukey' multiple range test.

Parameter	Cultivar/selection

Table 3
Average changes in plasma TAC (measured by FRAP and TEAC assays) and in serum levels of ascorbic and uric acids among all the subjects, after consumption of a single dose (1 kg) of strawberry fruits. Data are presented as means ± SEM. Values in brackets indicate the % variation from the baselines.

	FRAP (μmol TE/l)	TEAC (mmol TE/l)	Ascorbic acid (μm)	Uric acid (μm)
Baseline	34.8 ± 3	3.2 ± 0.1	28.8 ± 1	124 ± 13
After 1 h	40.0 ± 2* (+18.1%)	3.2 ± 0.1 (+0.1%)	49.5 ± 1* (+73.7%)	125 ± 13 (+0.8%)
After 2 h	42.9 ± 3* (+22.8%)	3.2 ± 0.1 (+0.1%)	55.9 ± 2* (+96.0%)	125 ± 14 (0.0%)
After 3 h	42.0 ± 3* (+22.0%)	3.2 ± 0.1 (+0.6%)	55.8 ± 2* (+95.4%)	125 ± 14 (- 0.4%)

* $P < 0.05$ in respect to baseline values (0 h), using the Wilcoxon paired samples test.

Table 4
Biochemical parameters of the volunteers during the acute study, as measured by clinical laboratory tests. Results are expressed as mean values among all the subjects ± SEM ($n = 8$).

Parameter	Glucose (mg/dl)	Uric acid (mg/dl)	Cholesterol (C) (mg/dl)	HDL-C (mg/dl)	C/HDL-C ratio	LDL-C (mg/dl)	Triglycerides (mg/dl)	Albumin (mg/dl)
Reference value	60–110	2.5–7.0	<200	(M) > 40 (F) > 45	0.0–6.0	<130	<170	3.5–5.0
Baseline	90.0 ± 1.1	4.2 ± 0.4	158 ± 5.1	52.2 ± 2.0	3.03	95.2 ± 5.9	65.1 ± 9.9	4.8 ± 0.1
After 1 h	90.8 ± 3.4	4.2 ± 0.4	160 ± 5.2	53.8 ± 2.2	2.96	95.6 ± 5.9	57.8 ± 8.6*	4.9 ± 0.1
After 2 h	87.4 ± 1.3*	4.0 ± 0.4*	157 ± 4.8	53.3 ± 2.3	2.94	93.8 ± 5.2	48.7 ± 6.6*	4.8 ± 0.1
After 3 h	86.7 ± 1.1*	4.1 ± 0.4*	159 ± 4.5	53.8 ± 2.0	2.95	95.6 ± 5.3	55.5 ± 7.1	4.9 ± 0.0

* Significant difference in respect to baseline values ($p < 0.05$), using the Wilcoxon paired samples test.

(means ± SEM) and as percentage variations from the baseline level (values in brackets). In confirmation of findings previously reported by similar short-term studies (Cao & Prior, 1998; Netzel et al., 2002; Pedersen et al., 2000), a significant acute increase in plasma TAC was shown only by the FRAP assay (Table 3), already 1 h after fruit intake (18.1% increase) and this persisted during the following 2 h (22–23% increase); by contrast, no significant variation in plasma TAC was measured by the TEAC assay. The lack of correlation between the two assays has been previously reported (Cao & Prior, 1998) and traced back to the different technologies and specificities of the two methods, leading to different responses to the antioxidant compounds present in plasma. Particularly, the main difference between FRAP and TEAC specificities lies in the FRAP lack of sensitivity for SH group-containing antioxidants, so that plasma proteins such as albumin have a smaller influence on the FRAP data, while they make a greater relative contribution to the TEAC values (Benzie & Strain, 1996). This suggests that the absence of any evident changes in the TEAC values after strawberry consumption could be explained by the masking effects of SHgroup-containing plasma antioxidants, with respect to the finer variation of less representative compounds.

Together with the rise in FRAP values, the chromatographic quantification of the two main FRAP-responsive hydrophilic antioxidants in serum showed a highly significant increase in the serum concentration of ascorbate (74% increase after 1 h from the strawberry intake and up to 96% increase during the following 2 h) but, interestingly, no changes in the serum urate levels of the subjects throughout the test (Table 3).

These data indicated that vitamin C absorbed from strawberries probably did make a significant contribution to the change in plasma antioxidant capacity, observed in our study. The quantity of fruits consumed provided about 320 mg of vitamin C, a much higher dose compared to other fruits previously studied. For example, the 1 kg dose of apples recently used in a similar acute intake study (Lotito & Frei, 2004) furnished approximately 60 mg of vitamin C, and hence plasma ascorbate increased only slightly after apple consumption. Moreover, the lack of significant changes in the serum uric acid levels was surprising, even if a high interindividual variability was observed for this parameter, ranging from 7% decrease to 16% increase one hour after fruit intake. In addition, when urate levels were measured by routine clinical-chemical automatised laboratory tests (Analysis Laboratory of Torrette–Umberto I Regional Hospital, Ancona, Italy), a small but significant average reduction in the serum concentrations was revealed 2 and 3 h after fruit intake (Table 4).

This finding clearly conflicts with the hypothesis of an acute hyperuremic effect following strawberry intake, and with the data obtained by previous fruit consumption studies. For instance, fructose in consumed apples was recently shown to elevate plasma urate, and this correlated with the plasma antioxidant activity (FRAP) increase measured (Lotito & Frei, 2004). Moreover, the relevant differences between the apple study and our strawberry experiment included the lower fructose concentration, the lower total sugar content and the greater glucose/fructose ratio generally found in strawberries (Cordenunsi, Oliveira do Nascimento, Genovese, & Lajolo, 2002; Olsson et al., 2004) compared to apples (Lotito & Frei, 2004; Wrolstad & Shallenberger, 1981).

The absence of a relevant contribution of uric acid in the significant increase of plasma TAC after strawberry intake should be confirmed after a prolonged consumption of strawberries, and a check of whether the inter-individual variation persists over a medium-term period. Few studies have been published on the effects of berry consumption and urate metabolism and excretion, and results are controversial. The most interesting results come from the study of cherries. Clinical case reports of patients with gout showed that consumption of a daily serving of cherries and cherry products for up to three months reduced plasma urate to normal levels and alleviated arthritic pain and gout (Blau, 1950). Recent experimental studies, conducted to determine the extent of these effects on healthy subjects, have confirmed a decrease in plasma urate after cherry consumption, supporting the reputed anti-gout efficacy of cherries (Jacob et al., 2003). Anyway, we still do not know which compounds or which synergistic combination in cherries might be responsible for these actions. The findings suggest the need for further investigations to confirm the clinical data and to check for the potential effects of other berry fruits.

Finally, Figs. 1 and 2 illustrate the percentage variation, from baseline, of the analysed parameters according to the genotype of strawberries consumed by the subjects. The changes in plasma TAC measured by the FRAP test are represented in Fig. 1, while the trends in ascorbic and uric acid serum concentrations are in Fig. 2. No data referring to the statistical significance of the observed genotype-dependent changes are reported in Figs. 1 and 2, since only two subjects were tested for each strawberry

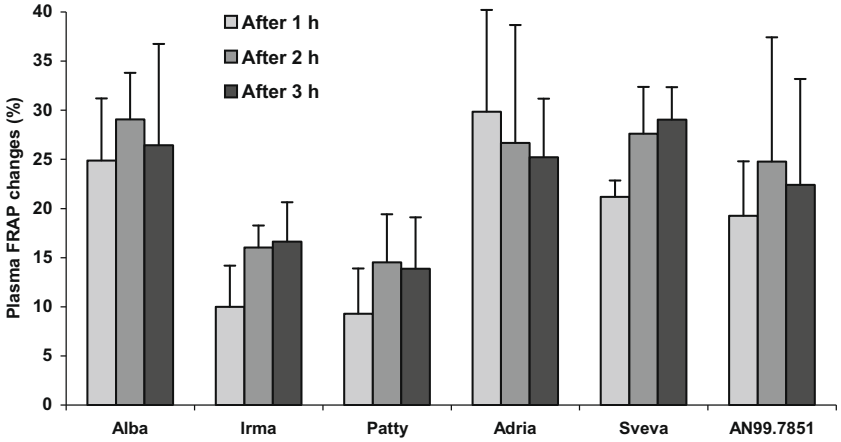

Fig. 1. Plasma% variation of total antioxidant capacity following acute intake of strawberries from different genotypes, when measured by FRAP assay. Data are presented as mean% changes from baseline value ± SEM.

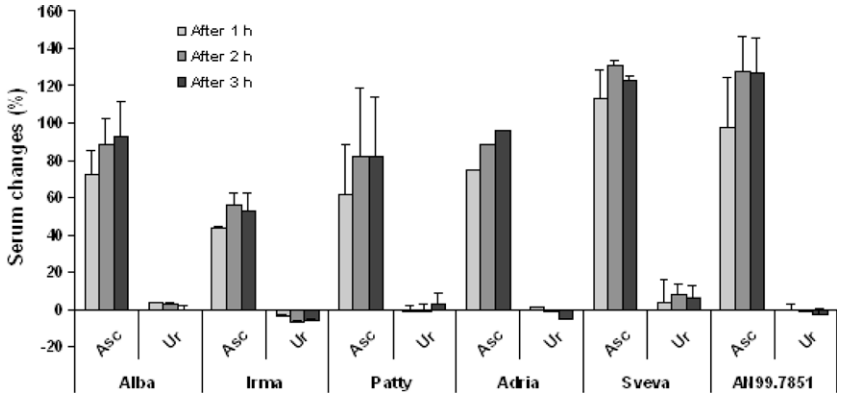

Fig. 2. Serum% variation in the levels of vitamin C ("Asc" columns) and uric acid ("Ur" columns) following acute intake of strawberries from different genoypes. Data are presented as mean% changes from baseline value ± SEM.

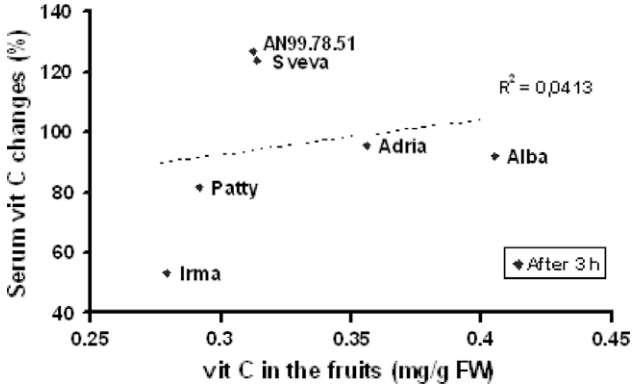

Fig. 3. The% increase of serum ascorbate 3 h after the strawberry consumption plotted against the original vitamin C content in the individual strawberry genotypes. The squared correlation coefficient (R^2) is shown.

clone. The highest increases in plasma TAC were clearly observed, in correspondence with the intake of Sveva > Adria > AN99.78.51 > Alba while, in keeping with their poorest antioxidant, micronutrient and phytochemical contents, the consumption of strawberry cultivars Irma and Patty was associated with the lowest acute increases in plasma TAC (Fig. 1). The intake of the vitamin C-poorest cultivar (Irma) was also correlated with the lowest serum increase of this vitamin (Figs. 2 and 3), while an over 2-fold higher serum ascorbate increase was observed after the consumption of Sveva and AN99.78.51 fruits. The intake of Adria and Alba fruits corresponded to an intermediate rise in serum ascorbate, thus no linear correlation between the vit C contents in the fruits and the human% absorption was observed (Fig. 3). Even when evaluating the data for each strawberry genotype consumed, no significant changes in serum uric acid concentration were observed after strawberry intake.

No correlation was found between the extent of increase in plasma FRAP and the genotype-dependent content of anthocyanins, which are the most represented class of antioxidant polyphenols in strawberries. This finding may confirm that dietary anthocyanins ingested with a strawberry meal do not crucially contribute to the acute increase in the plasma TAC observed.

Finally, together with the putative strawberry-dependent changes in urate levels in serum, Table 4 illustrates the main biochemical parameters analysed throughout the acute study. Results are expressed as means ± SEM, and reference values are indicated for all the parameters measured. Interestingly, a postprandial decrease in serum triglycerides was observed within the two hours following fruit consumption, together with a slight non-significant decrease in the cholesterol/HDL-cholesterol ratio. In a recent study, the effects of the fructose ingested, through a typical American diet, on plasma lipids were evaluated (Bantle, Raatz, Thomas, & Georgopoulos, 2000), and a diet providing 17% of energy as fructose produced significantly higher fasting, postprandial and

daylong plasma triacylglycerol concentrations than did a nearly fructose-devoid diet. Our data did not necessarily conflict with the mentioned study, due to the lower intake of fructose obtained through the strawberry consumption. However, our findings suggested a putative acute effect of strawberry intake on plasma lipids, and further investigations are strongly recommended for a deeper interpretation of the results.

4. Conclusion

Based on our results, it is reasonable to suggest that the increase in plasma TAC observed immediately after the ingestion of strawberries might not be caused by an increase in serum uric acid due to the rapid metabolism of fructose and/or other sugars in the fruits. A similar acute strawberry consumption study should be repeated in the future, and blood collected for up to several hours after the intake of the fruits, in order to evaluate whether 3 h is a sufficient time to allow the metabolism of strawberry fructose to uric acid, in the digestive tract of the average subject.

In the present study, significant genotype-to-genotype differences were observed in the antioxidant capacity and in the vitamin C, folate and phenolic contents of the selected fruits. The individual effects of the selected strawberry genotypes on the postprandial plasma antioxidant status were evaluated in healthy subjects and, interestingly, the lowest increases in plasma TAC and in serum ascorbate levels were associated with the consumption of the nutritionally-poorest cultivars. These findings underlined the importance of evaluating and distinguishing the NQ of fruits used for human consumption studies. Furthermore, the data confirmed the importance of the breeding approaches currently used to increase the content of specific bioactive compounds in strawberry fruits, since higher levels of micronutrients and phytochemicals in fruit may be an important tool to support a higher antioxidant intake, even in the case of low fruit consumption.

Further investigations should also be undertaken to assess the contribution of dietary flavonoids to the total antioxidant capacity of plasma in humans. For this reason, renewed attempts will be made to optimise analytical technologies and methodologies. Finally, the evaluation of medium- and long-term effects of strawberry consumption on the plasma and cellular antioxidant status should be considered.

Temperature effect

ABSTRACT

The specific impact of the yeast strain on the wine flavour and aroma has not been well characterised yet because this effect is usually combined with other variables during the winemaking. In this study, the contribution to wine flavour of two *Saccharomyces cerevisiae* strains widely used in wine production, VIN13 and EC1118, was evaluated after fermentation at 15 °C. Chemical defined grape juice media fermented with the EC1118 strain showed higher solvent, fatty and pineapple aroma attributes, while that fermented with the VIN13 strain exhibited higher banana, fruity, yeasty and green attributes. Sensorial and chemical analyses evidenced that the production of flavour-active compounds is significantly affected by the yeast strain, as well as by the temperature of fermentation, as shown by comparing the former data with those from fermentations carried out at 28 °C under identical culture conditions.

1. Introduction

The sensory character of wines fermented with *Saccharomyces cerevisiae* starter cultures can differ significantly from those fermented with the indigenous grape flora (Domizio et al., 2007; Fleet, 2003; Lambrechts & Pretorius, 2000). Different strains of *S. cerevisiae* can produce significantly different flavour profiles when fermenting the same must. This is a consequence of both, the differential ability of wine yeast stains in releasing varietal volatile compounds from grape precursors, as well as the differential capacity to synthesise *de novo* yeast-derived volatile compounds (Swiegers, Francis, Herderich, & Pretorius, 2006; Ugliano, Bartowsky, McCarthy, Moio, & Henschke, 2006; Vilanova & Sieiro, 2006; Wondra & Boveric, 2001). Therefore, the selection of the proper yeast strain can be critical for the development of the desired wine style. At present, a wide range of wine yeast strains are commercially available giving winemakers the opportunity to explore different strains and include this selection as an additional variable in winemaking.

Among the hundreds of volatile compounds present in wine, only a subset is sensory detectable. Several fermentative aroma compounds show an olfactory impact despite being present in very low concentrations (micrograms or nanograms per litre) due to their low sensory detection thresholds (Lambrechts & Pretorius, 2000), or to the additive effect of compounds with similar chemical or aromatic properties (Ferreira, Escudero, Campo, & Cacho, 2008; Loscos, Hernandez-Orte, Cacho, & Ferreira, 2007). The odour activity value (OAV) – defined as the ratio between the concentration of the compound and its detection threshold – is usually used to evaluate the potential sensory contribution of a given compound (Guth, 1997), although it provides only a rough evaluation of the real contribution of each compound to the global aroma. In fact, the volatility and the perception of aroma compounds are significantly affected by the basic wine chemical composition, which can both mask the odour impact of certain compounds present in concentrations above their detection thresholds and favour the detection of other molecules present in concentrations below their detection thresholds (Ferreira et al., 2008). Thus, to detect differences in aroma perception between wines – and alcoholic solutions as well – discriminant sensory studies and quantitative descriptive analysis are frequently used (Campo, Ferreira, Escudero, & Cacho, 2005; Gómez-Míguez, Cacho, Ferreira, Vicario, & Heredia, 2007; Loscos et al., 2007). In addition, gas chromatography–olfactometry (GC–O) has become a fundamental tool in sensory characterisation of volatile compounds allowing both their separation from complex samples and the sensory detection and description of the corresponding aroma.

The aim of this work was to evaluate the fermentation performance and the formation of yeast-derived volatile compounds of

two related commercial yeast strains widely employed by the wine industry: VIN13 strain, recommended for the elaboration of white wines with high thiol and ester content; and EC1118 strain, suggested for a wide range of fermentation temperatures and with relatively neutral flavour and aroma contribution. The statistical significance of the variables 'yeast strain' and 'fermentation temperature' on the production of each yeast-derived volatile compound were evaluated.

2. Materials and methods

2.1. Yeast strains and growth conditions

Two commercial wine yeasts, *S. cerevisiae* strain EC1118 (Lalvin, Canada) and *S. cerevisiae* strain VIN13 (Anchor Yeast, South Africa) were used in this study. The latter is a hybrid strain derived from *S. cerevisiae* N96 – equivalent to EC1118 – and *S. cerevisiae* 228 – also known as N76. The yeasts were grown separately in 3 ml of YPD medium (1% yeast extract, 2% peptone and 2% glucose) at 28 °C, then transferred to shake flasks containing 50 ml of modified MS300 culture medium (see below) with no anaerobic factors and with half the amount of sugar (60 g/l of glucose and fructose each), and grown overnight at 25 °C under aerobic conditions. This culture was used as inoculum for the wine fermentations carried out in 1-l Bioflo 110 bioreactors (New Brunswick Scientific, Edison, NJ, USA), in 800 ml of medium. Modified MS300 culture medium contained 120 g/l of glucose and 120 g/l of fructose, yeast assimilable nitrogen at a concentration of 300 mg/l (ammonium and amino acids), salts, vitamins and anaerobic factors (15 mg/l ergosterol, 5 mg/l sodium oleate and 0.5 ml/l Tween 80, dissolved in 5 ml of ethanol), as described elsewhere (Varela, Pizarro, & Agosin, 2004). This defined medium simulates standard grape juice, but does not contain grape varietal aromas or grape odourless precursors. Nitrogen was sparged to eliminate the oxygen from the medium before inoculation. The bioreactors were inoculated with 10^6 cells/ml of *S. cerevisiae* VIN13 or *S. cerevisiae* EC1118. Temperature was maintained at 15 °C, pH at 3.5, and agitation at 120 rpm. Fermentations were carried out in triplicate. Cell number, dry cell weight (DCW), optical density at 600 nm (OD_{600}), residual sugar, and the concentration of yeast-derived volatile products and organic acids were determined at different stages of the fermentation, as described below.

2.2. Analytical techniques

The concentrations of glucose, fructose, ethanol, glycerol, malic acid, citric acid and acetic acid were measured by high-performance liquid chromatography (HPLC) using a Bio-Rad HPX-87H column, as described in Molina, Swiegers, Varela, Pretorius, and Agosin (2007). Ammonia concentration and free α-amino nitrogen (FAN) concentration was determined as described in Molina et al. (2007).

2.3. HS-SPME-GC–MS using SIDA

Volatile compounds synthesised during fermentation were quantified using headspace solid-phase microextraction coupled with gas chromatography–mass spectrometry (HS-SPME-GCMS), with polydeuterated internal standards for stable isotope dilution analysis (SIDA), as described in Siebert et al. (2005). A gas chromatograph Agilent 6890 (Agilent Technologies) equipped with a Gerstel MPS2 multi-purpose sampler and coupled to a HP 5973 N mass selective detector was used. The control of the instrument and the data analysis were accomplished with Software ChemStation G1701CA (Agilent Technologies). A Phenomenex fused silica capillary column ZB-Wax ~60 m × 0.25 mm and 0.25 μm film thickness was used, and helium (Air Liquid or BOC, Ultra High Purity) as the carrier gas, with 36 cm/s of linear velocity and 2.0 ml/min of flow rate, in constant flow mode. The oven was started at 40 °C, held for 4 min, then increased to 220 °C at 5 °C/min and held at this temperature for 20 min. The inlet was fitted with a borosilicate glass SPME inlet liner (0.75 mm I.D., Supelco) and held at 200 °C. Sample preparation involved 1:10 and/or 1:100 dilution, injection of 100 μl of polydeuterated internal standard solution, salting out with NaCl and heating to 35 °C. A Carbowax/divinylbenzene (CW/DVB) 65 μm fibre (Supelco) was exposed to the sample headspace for 10 min. Then the fibre was desorbed in pulsed splitless mode, and after 30 s the splitter was opened (25:1). The fibre was baked in the inlet for 10 min. The mass spectrometer quadrupole temperature was set at 106 °C, the source at 230 °C, and the transfer line was held at 250 °C. Positive ion electron impact spectra at 70 eV were recorded in selective ion monitoring (SIM). The dwell times, the target and qualifier ions used for identification and quantitation, were the same than in Siebert et al. (2005), as well as the sample preparation. Thirty one volatile compounds were analysed, including ethyl- and acetate-esters, fatty acids and alcohols, but only 23 volatile compounds were identified and quantified in the collected samples. Principal Component Analysis (PCA) was performed using this data as detailed below. The odour activity value (OAV) of each compound was calculated by dividing the concentration of the compound by its detection threshold.

2.4. GC–Olfactometry analysis

Fermented musts were also analysed by GC-sniffing. Aroma extracts were obtained after liquid extraction with dichloromethane. The internal standard 4-nonanol was spiked into the samples prior to extraction to a final concentration of 3.5 μg/l. An Agilent 6890 gas chromatograph (Agilent Technologies, Santa Clara, CA, USA), equipped with a polyethylene glycol DB-WAX column (Agilent Technologies), was employed. At the end of the column, the effluent was split evenly between a flame ionisation (FID) detector and a Sniffer 9000 port (Brechbühler Inc., Houston, TX, USA) connected by a Y shaped glass splitter. Helium, adjusted to a flow rate of 1.9 ml/min, was used as carrier gas. The injector was set at 180 °C and three microliters of extract were injected in splitless mode. The temperature program used was: 40 °C for 5 min, rise of 3° C/min up to 230 °C, 230 °C for 9 min, rise of 40 °C/min up to 240 °C, and 240 °C for 5.4 min. The temperature of the FID detector was 250 °C, the air flow 450 ml/min, and the hydrogen flow 49 ml/min. The sniffing port was kept at 190 °C with permanent humidification.

A panel of eight judges, five women and three men, sniffed all extracts in two sessions of 35 min each, one session a day. Half of the panel had an extensive experience with GC–O. The judges with no previous experience were subjected to an eight session training during which they became familiar with aroma standards, the description vocabulary, the detection of different intensities and the use of the evaluation scale system. An intensity scale of seven scores (0–3, including half values) was used as previously described (Gómez-Míguez et al., 2007). The aroma descriptor and intensity were recorded using the software Nose to Text® (Brechbühler Inc., Houston, TX, USA). The modified frequency (MF) was calculated based in the intensity (I) and frequency (F) of the aroma detection, according to the following formula (Campo et al., 2005): $MF(\%) = \sqrt{F(\%) \times I(\%)}$.

The MF values from attributes belonging to common aroma categories (floral, fatty, green-vegetal, etc.) were added to compare the total aromatic impact of each category for each sample. Few particular attributes (caramel, solvent, fruity and floral) were detected by the panel in the non-fermented control medium, at spe-

cific elution times. The MF values of the latter were subtracted from each corresponding category.

2.5. GC–MS

The aroma extracts employed for the GC-sniffing analysis were also analysed by GC–MS for identification of the volatile compounds. An Agilent 6890 gas chromatograph connected to an Agilent 5972 mass detector (Agilent Technologies, USA) was used. The same column, injection and temperature conditions than for the GC-sniffing analysis were applied in order to obtain comparable chromatograms. The data acquisition was carried out using Chemstation® software (Agilent Technologies), in full scan mode within the range 35–550 m/z, with 1.5 scans/s^{-1}. The data was analysed by Chemstation® and AMDIS (Stein, 1999) softwares.

2.6. Quantitative descriptive analysis and discriminant sensory evaluation

Quantitative descriptive analysis (QDA) using orthonasal evaluation was carried out by a panel of eight trained judges. Seven sensory terms were selected by the panel during preliminary sessions to describe and differentiate the samples. Standards for the selected descriptors were prepared, and a scale from 0 to 9 was used to score each attribute's intensity. At the end of the training period, the reproducibility and consistency of the panel evaluation was verified by ANOVA.

Discriminant sensory evaluation was performed through triangular tests to assess the significant differences between the fermented chemical media, in duplicate. The panel was the same than for QDA. An odourless colorant was added to the samples to remove the possible effect of colour differences in the evaluation.

2.7. Statistical analysis

Principal Component Analysis (PCA) and QDA data analysis were carried out employing the Senstools® software version 3.0.11 (OP&P Product Research, The Netherlands). For PCA, a correlation matrix was used in order to normalise the data. Multifactor Analysis of Variance (ANOVA) was performed using Statgraphics 4.0 in order to determine the statistically significant effect of the factors 'yeast strain' and/or 'fermentation temperature' on the final concentration of each volatile compound. Type III sums of squares was chosen so as the contribution of each factor is measured after removing the effects of all other factors.

3. Results

3.1. Fermentation parameters

The commercial wine yeast strains *S. cerevisiae* VIN13 and *S. cerevisiae* EC1118 were grown under wine fermentation conditions at 15 °C. For both strains, fermentation parameters were calculated and yeast-derived volatile compounds quantified. The EC1118 strain fermented faster than VIN13 and reached 4 g/l of residual sugar (wine dryness) approximately 400 h after inoculation. VIN13 needed 500 h to complete wine dryness.

Both strains showed a similar maximum growth rate (Table 1), although a significantly higher amount of glycerol was produced by VIN13. EC1118 showed a higher maximum rate of glucose and fructose consumption. No significant differences in the final ethanol content were observed between both fermentations.

3.2. Differential production of yeast-derived aroma compounds

Fermented musts were sensory evaluated by a trained panel. Triangular tests were used to determine if the global aroma of musts fermented with each strain was significantly different. The analysis revealed that these musts could be clearly differentiated with a 95% confidence (data not shown). Quantitative descriptive analysis showed that musts fermented with EC1118 had the highest score for the attribute 'pineapple', while musts fermented with VIN13 had the highest scores for the descriptors 'caramel', 'banana', 'raisins' and 'yeasty' (Fig. 1a).

Volatile products of the fermented musts were quantified by HS-SPME-GC–MS. The modified MS300 culture medium does not contain grape varietal aromas or precursors, allowing the exclusive determination of aroma compounds synthesised by wine yeast. Odour activity values (OAVs) for the most significant volatile compounds are summarised in Table 2. Thirteen compounds associated with the attributes 'nail polish remover', 'roses', 'banana', 'apple', 'pineapple', 'floral' and 'fruity' showed OAVs > 1 for both strains, suggesting that these compounds could significantly contribute to the perceived global aroma. Ethyl hexanoate and ethyl octanoate, associated to 'fruity', 'apple' and 'pineapple' descriptors, had the highest OAVs for both strains. In particular, the concentration of ethyl octanoate was higher in musts fermented with EC1118, coinciding with the higher 'pineapple' aroma obtained during the sensory descriptive analysis for these musts (Fig. 1a).

Sniffing analysis of the fermented musts using GC–Olfactometry permitted to further analyse the contribution of each single volatile compound to the aroma perception. The modified frequency (MF), indicating the aroma impact of each compound, was calculated based on the frequency and the intensity of detection of each volatile compound by the panel of judges, as detailed in the section Materials and Methods. Most of the compounds present in concentrations higher than their detection thresholds (OAV > 1) were detected by the panel, although at diverse intensities (Table 2). In addition, some volatile compounds present in concentrations below their detection threshold (OAV < 1) were sensed in the GC–O. An MF value higher than 70 – representing all the intermediate combinations from 'detection of high intensity aroma by half of the panel' to 'detection of medium intensity aroma by the entire panel' – was only observed for acetic acid, 2-methyl butanoic acid and 3-methyl butanoic acid, associated to the negative characters 'vinegar', 'rancid' and 'cheesy'. The rest of the volatile compounds

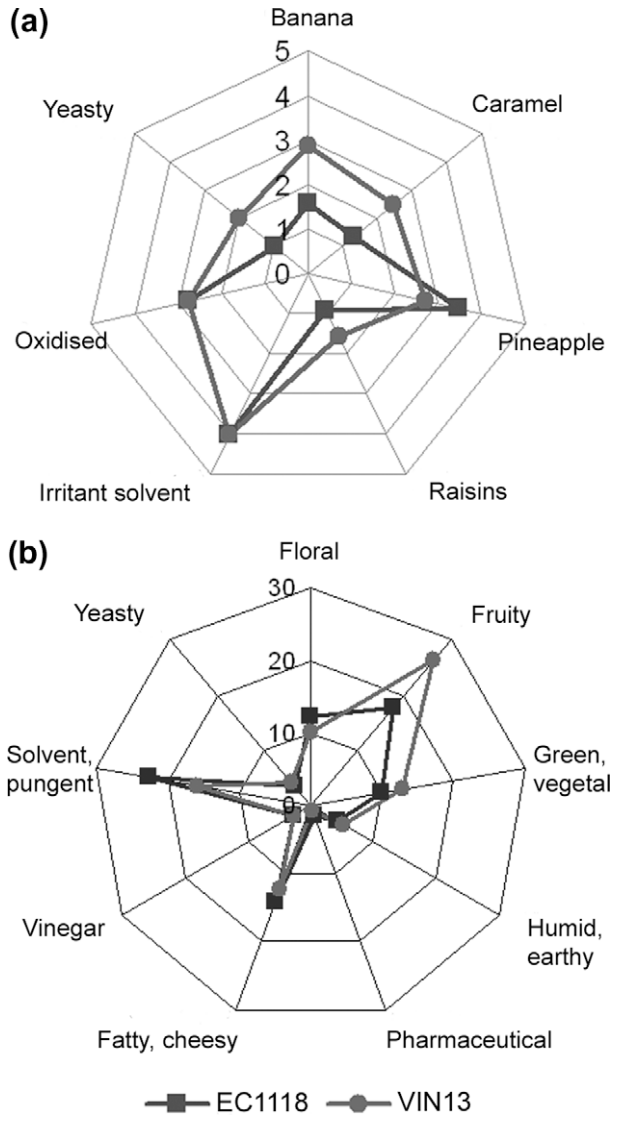

Fig. 1. Sensory evaluation of musts fermented with *S. cerevisiae* strains EC1118 and VIN13 at 15 °C. (a) Quantitative descriptive analysis. (b) Added MF values for descriptors of common aroma categories identified by a panel of judges by GC–O. Values are mean of two fermentations.

with OAV > 1 showed MF values between 50 and 70, meaning that they were detected in medium to low intensities or that they were not detected by the entire panel.

The major differences in volatile compounds among both strains were found for ethyl esters. Ethyl hexanoate and ethyl octanoate were strongly detected by the panel in fermentations carried out with EC1118, while ethyl decanoate was not detected in EC1118 fermentations and only barely detected in VIN13 fermentations. On the contrary, short chain ethyl esters were produced in higher concentrations by VIN13. Indeed, the calculated OAV for ethyl propanoate and ethyl butanoate agreed with the slightly higher MF values. Two compounds, ethyl 2-methyl propanoate and ethyl 2-methyl butanoate, had OAVs > 1 only in fermentations with VIN13, suggesting that the 'fruity' and 'strawberry' characters might characterise the musts fermented with this strain. Surprisingly, these two compounds were not detected by the judges in the GC–O analysis.

Among alcohols, the concentration of 2-phenyl ethanol was higher in musts fermented with EC1118, which agrees with a higher sensory perception of 'flowery' and 'roses' attributes detected by GC–O (Table 2). Conversely, 3-methyl butanol was produced in higher concentrations by strain VIN13, but it was sensed with higher MF values in musts fermented with strain EC1118. Acids other than acetic acid, 2-methyl butanoic acid and 3-methyl butanoic acid had OAV's < 1, but MF values ranging from 56 to 42, representing an intermediate detection of 'sweaty', 'onion', 'harsh', 'rancid' and 'cheesy' characters. A higher detection of the 'banana' attribute was found in musts fermented with strain VIN13 in the quantitative descriptive analysis (Fig. 1a), agreeing with the higher concentration of the associated compound 3-methyl butyl acetate (Table 2). Alternatively, 2-phenyl ethyl acetate was produced in concentrations slightly higher than its detection threshold by both strains, and was only weakly detected by the GC–O panel.

The aroma descriptors detected by GC–O were classified into eleven general aroma categories: fruity, banana, floral, fatty-cheesy, green-vegetal, solvent-pungent, yeasty, humid-earthy, pharmaceutical, vinegar (Fig. 1b). For each category, the MF values were added, including descriptors with unknown chemical identity. Both yeast strains produced musts with similar aroma composition (characterised by the "shape" of the spider webs). However, musts fermented with VIN13 showed higher values for the attributes 'fruity', 'green-vegetal', 'fatty-cheesy' and 'sweet-caramel' than musts fermented with EC1118 (Fig. 1b). Both strains had similar scores for the general categories 'floral' and 'solvent-pungent', while the attributes 'banana', 'yeasty', 'humid, earthy', 'vinegar' and 'pharmaceutical' resulted in modified frequencies below 200, and no significant differences between both strains.

3.3. Influence of the yeast strain and temperature on the production of volatile compounds

PCA was used to evaluate the statistical effect of the variables 'yeast strain' and 'temperature of fermentation' on the production of yeast-derived volatile compounds. For this purpose, data from the present study and from work previously published by our group (Molina et al., 2007) were used. Thus, three different fermentation conditions were analysed: VIN13 – 15 °C, EC1118 – 15 °C, and EC1118 – 28 °C. Strain VIN13 was not able to complete the fermentation at 28 °C (data not shown).

The first two Principal Components (PCs) explained 87% of the variance (PC1: 62%; PC2: 25%). Replicates of each 'strain-temperature' condition (VIN13 – 15 °C, EC1118 – 15 °C and EC1118 – 28 °C) were grouped and separated from the other conditions (Fig. 2). PC1 attributes with the highest weights (indicated in parenthesis) included hexanoic acid (1.00), 2-methyl butanoic acid (0.97), 2-methyl butanol (0.96), and ethyl propanoate (0.93). The concentrations of these compounds were higher in the VIN13 fermentations at 15 °C which grouped together on the right side of the graph. EC1118 Fermentations carried out at 28 °C had the lowest scores for both PC1 and PC2, and clustered in the lower left quadrant. Indeed, the highest negative weights in PC1 were assigned to 2-phenyl ethyl acetate (−0.97) and 2-methyl butyl acetate (−0.88), which were produced in higher concentrations in the EC1118 fermentations at 28 °C. Finally, EC1118 fermentations at 15 °C formed a separate group on the upper middle part of the graph and had the highest scores of PC2. This axis was characterised by decanoic acid (0.94) and ethyl decanoate (0.77) with the highest positive weights, and ethyl 2-methyl butanoate (−0.72) with the highest negative weight.

The significance of the effect of the yeast strain and the temperature of fermentation on the production of volatile compounds was assessed by Multifactor Analysis of Variance. The factor 'yeast strain' had a statistically significant effect at the 95% confidence level (p-value < 0.05) on 15 of the quantified volatile compounds, 12 of which had also a statistically significant effect from the factor 'temperature of fermentation' (Table 3). Additionally, the factor

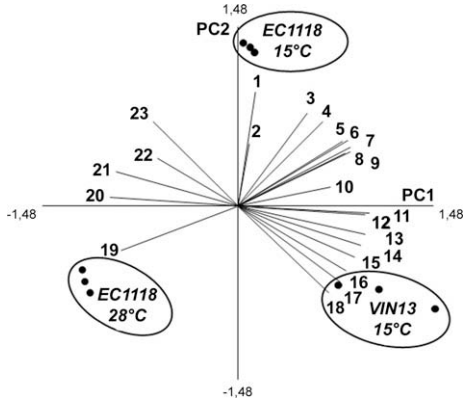

Fig. 2. Principal Component Analysis of fermentative volatile compounds produced during fermentation of a chemically defined must by *S. cerevisiae* strains VIN13 and EC1118 at 15 °C, and EC1118 at 28 °C. Each condition was tested in triplicate. 1: decanoic acid; 2: 2-methyl propanol; 3: ethyl decanoate; 4: octanoic acid; 5: ethyl butanoate; 6: ethyl acetate; 7: ethyl hexanoate; 8: ethyl octanoate; 9: 3-methyl butyl acetate; 10: 3-methyl butanol; 11: hexanoic acid; 12: 2-methyl butanol; 13: 2-methyl butanoic acid; 14: ethyl propanoate; 15: ethyl 2-methyl propanoate; 16: 2-methyl propanoic acid; 17: 3-methyl butanoic acid; 18: ethyl 2-methyl butanoate; 19: 2-methyl butyl acetate; 20: 2-phenylethyl acetate; 21: 2-phenylethanol; 22: 2-methyl propyl acetate; 23: acetic acid.

'temperature of fermentation' alone significantly affected the final concentration of six additional compounds. Neither of the two factors had a statistically significant effect on the final concentrations of 2-methyl propanol and 3-methyl butanol.

4. Discussion

In this study, the differential impact of two commercial *S. cerevisiae* wine strains on the aroma profiling and on the synthesis of volatile compounds was demonstrated. Strains EC1118 and VIN13 were selected because of their known differential contribution to wine aroma even though partially sharing their genetic background (EC1118 is a parental of the hybrid strain VIN13). Musts fermented by these two strains differed in sensory perception and descriptive analysis. The judges sensed slightly higher intensities of some descriptors in must fermented with VIN13, indicating a more complex aroma of these musts compared to musts fermented with EC1118. Twenty three volatile compounds were found to be produced by both strains, and most of them showed different final concentrations. VIN13 produced fifteen compounds in concentrations over the corresponding sensory thresholds, while EC1118 produced thirteen. The differential production of volatile compounds by VIN13 and EC1118 could result, at least in part, from the genetic contribution of the other parental strain, *S. cerevisiae* 228, to the genetic background of VIN13.

Musts fermented with VIN13 exhibited the highest concentration of short and branched-chain ethyl esters, and were characterised by sweet and fruity aroma characters. Both features constitute positive traits for VIN13 in the production of fresh and young white wines. This 'aroma producer' capacity is complemented by the good ability of VIN13 to release thiol precursors from grapes, thus enhancing the tropical flavours in Sauvignon Blanc wines (Swiegers et al., 2006).

Table 3
Analysis of variance (ANOVA) of the effect of the yeast strain and the temperature of fermentation on the final concentrations of yeast-derived volatile compounds.

Aroma compound	Temp		Strain

* *p*-Value < 0.05 denotes a statistically significant effect of the factor on the final concentration of the volatile compound at the 95% confidence level. To determine the contribution of each factor, the effects of all other factors were removed.

VIN13, which is recommended for white wine fermentation between 12 °C and 16 °C, was not able to complete fermentation at 28 °C in the conditions used in this study. In contrast, EC1118, known for its tolerance to a wide range of fermentation temperatures, showed excellent performances both at 15 °C and 28 °C (Molina et al., 2007). When fermenting at 15 °C each strain presented different favourable winemaking properties. EC1118 strain had a higher rate of sugar consumption, and fermented faster than VIN13, while the latter produced more glycerol and less acetic acid, traits associated to wine quality.

The volatile compounds present in the wine matrix were extracted and quantified by HS-SPME using isotopically labelled internal standards. Compared with static head space gas chromatography, in which extraction of the compounds depends mostly on their volatility, in SPME the use of fiber involves selection of the extracted compounds depending on their partitioning among the liquid sample, the vial head space and the fiber. The method used in this study was specially optimised for accurate and precise quantification of key fermentative aroma compounds present in wines (Siebert et al., 2005). The use of labelled internal standards allowed overcoming the disadvantage of differential selectivity of the compounds, as well as matrix related effects. Equilibrium condition and affinity were assumed to be equal for each compound and its deuterated standard.

Based on their concentrations, the main volatile compounds allowing discrimination between both strains were 3-methyl butanoic acid, ethyl 2-methyl butanoate, 2-phenyl ethanol, 2-phenyl ethyl acetate, and acetic acid. Sniffing analysis pointed out further distinctive compounds. In addition to 3-methyl butanoic acid, 2-phenyl ethanol and acetic acid, compounds such as ethyl hexanoate, ethyl octanoate and 3-methyl butyl acetate showed different aroma contributions. Quantitative descriptive analysis matched these results, i.e. 'banana' attribute, associated to 3-methyl butyl acetate, characterised fermentations carried out with VIN13; while the 'pineapple' attribute, associated to ethyl octanoate, characterised fermentations with EC1118.

When using GC–O to quantify the impact of several odorant compounds, the number of judges in the panel is more decisive than the selection or experience of the judges (Ferreira, Pet'ka, Aznar & Cacho, 2003). In the present study, a panel of 8 judges was used to detect a number of volatile compounds. Since the detection threshold can vary from one person to the other, compounds present in concentrations near their reported detection thresholds were frequently sensed by part of the panel. However, ethyl 2-methyl propanoate and ethyl 2-methyl butanoate, two compounds produced in concentrations over their sensory thresholds only in fermentations with VIN13, were not detected by GC–O. These compounds probably co-eluted with other compounds that masked their aromas, and thus, further adjustments of the extraction method and the chromatographic run are necessary in order to detect these compounds by GC–O.

The factors 'yeast strain' and 'temperature of fermentation' have critical effects on the production of most yeast-derived volatile compounds. In a previous work, statistically significant effects of grape variety, yeast strain and fermentation temperature on the production of organic acids and higher alcohols were evidenced, and interactions between yeast type and temperature, and between temperature and grape variety were detected (Aragon, Atienza, & Climent, 1998). Our results agree with that previous report, and incorporate the statistical effect of yeast strain and fermentation temperature to additional fermentative aroma compounds as several fatty acids, ethyl esters and acetate esters.

In this study, the use of chemical defined grape juice media permitted to eliminate the effect of grape variety from yeast strain on the production of volatile compounds. However, the utilisation of natural grape must may change the effect that yeast strain and temperature can have on the level of volatile compounds, as complex interactions between grape variety, must nitrogen content and other variables may take place (Carrau et al., 2008; Delfini et al., 2001; Loscos et al., 2007; Ugliano et al., 2006). The results presented here demonstrate that both yeast strain and temperature of fermentation are critical variables influencing the aroma composition of a fermented must, and that the modulation of their effects could have a major impact on the final aroma and wine style.

Acknowledgments

We thank Robyn Kievit for her assistance with fermentations. Characterisation

ABSTRACT

Polyphenol oxidase (PPO) of *Vanilla planifolia* Andrews beans was extracted and purified through ammonium sulphate precipitation, dialysis, and gel filtration chromatography. PPO activity was measured by improved UV technique using 4-methylcatechol and catechol as substrates increasing substantial sensitivity of previous procedure. The optimum pH and temperature for PPO activity were found to be 3.0 and 3.4 and 37 °C, respectively. K_m and V_{max} values were found to be 10.6 mM/L and 13.9 OD_{300} min^{-1} for 4-methylcatechol and 85 mM/L and 107.2 OD_{300} min^{-1} for catechol. In an inhibition test, the most potent inhibitor was found to be 4-hexylresorcinol followed by ascorbic acid. The thermal inactivation curve was biphasic. Activation energy (E_a) and z values were calculated as 92.10 kJ mol^{-1} and 21 °C, respectively.

1. Introduction

Polyphenol oxidase (PPO) is a copper-containing oxidoreductase widely distributed in nature, which plays important roles in many plant metabolic processes. It is responsible for the enzymatic browning of fruits and vegetables. In the presence of oxygen, PPO catalyses two reactions: the hydroxylation of monophenols to diphenols (monophenolase EC 1.14.18.1) and oxidation of catechols to quinones (diphenolase EC 1.10.3.1), most of which are subsequently polymerised to dark pigments (Martinez & Whitaker, 1995; Matheis & Whitaker, 1984).

Enzymatic browning catalysed by PPO is generally considered detrimental to food quality from both sensory and nutritional points of view. Due to the importance of this reaction in the food industry, PPO has been intensively studied in several plants. Recent reports have shown that in some plants the protein is encoded by a multi gene family with a tissue specific expression pattern (Pereira, Donizeti, Murad, De Oliveira, & Evangekista, 2003; Yoruk & Marshall, 2003). The differences between PPOs may be identified by their physical, chemical or enzymatic properties such as electrophoretic mobility, optimal temperature and pH, substrate specificity and pI (Lu, Tong, Long, & Feng, 2006; Wang et al., 2007; Yoruk & Marshall, 2003).

It is well established that vanilla owes its flavour, aroma, and taste primarily to different enzymatic transformations that take place during the curing process. The traditional curing method is characterised by four phases: pod killing, sweating, drying and conditioning. From our point of view, the most important step of the curing process is pod killing. The objective of killing is to stop further vegetative development in the fresh pod and initiate wall disassembly by disrupting the cell membrane (Mariezcurrena, Zavaleta, Waliszewski, & Sanchez, 2008). Polyphenol oxidase in vanilla beans plays an important role in the colour qualities and commercial properties of cured beans. Importantly, vanilla bean browning appears to be driven by enzymatic activity. For example, prolonged or extreme heating during the curing process inhibits browning of the beans, probably due to enzyme denaturation. PPO driven browning in vanilla pods may result mostly from the oxidation of tyrosine, caffeic and chlorogenic acids, as well as other phenolic compounds (Havkin-Frenkel, French, Pak, & Frenkel, 2005).

Very little is known about PPO activity during growth, maturation and curing of vanilla beans. Wild-Altamirano (1969) studied dried acetone green vanilla powder and measured polyphenol oxidase activity in 14 substrates at pH 7 at an ambient temperature: however, these reaction conditions are not optimal for vanilla PPO, and the reaction products were measured for all substrates at a fixed 265 nm wavelength. Under these conditions, the highest substrate PPO affinities were to catechol and pyrogallol, but it is now well known that each substrate shows different reaction conditions with PPO (pH, temperature, substrate and enzyme concentration), and each substrate reaction product has different maximum absorbance wavelengths (Richard-Forget, Rouet-Mayer, Goupy, Philippon, & Nicolas, 1992). Debowska and Podstolski (2001) investigated PPO properties from vanilla shoot primordia culture revealing three isoenzymes shared the same optimum pH activity between pH 3 and 4.

doi:10.1016/j.foodchem.2009.03.118

Considering the importance of cured vanilla as a worldwide, it is important to understand the biochemical properties of vanilla bean PPO. The degree of enzymatic browning depends on the PPO activity, but also on the nature and amount of endogenous phenolic compounds, the presence of oxygen, reducing substances, pH, and temperature.

The aim of this paper was to extract, purify and characterise polyphenol oxidase from mature vanilla beans to determine kinetic parameters, optimum reaction conditions (pH and temperature), thermal stability, and inhibitor effects of various chemical compounds. In addition, the activation energy (E_a) and z values were calculated. In addition, an improved UV procedure for PPO quantification using 4-methylcatechol and catechol as substrates was developed.

2. Materials and methods

2.1. Plant material

Vanilla beans (*Vanilla planifolia*) with yellow apices were obtained from a recognised producer (Mr. Victor Vallejo, Papantla, Veracruz, México). Beans were washed with distilled water, cut into 1 cm pieces, lyophilised and stored in refrigeration in polypropylene vacuum bags.

2.2. Enzyme extraction and purification

Twenty-five grams of lyophilised beans were powdered using a domestic coffee grinder prior to homogenisation. The powder was homogenised for 5 min at 4 °C in an Ultra Turrax T 25 homogenizer (Ika Works Inc, Wilmington, NC) in the presence of 200 mL of 150 mM bis–tris-propane (BTP) buffer (pH 8.0) with 2 mM ethylenediamine–tetraacetic acid (EDTA), 3 mM of DL-dithiothreitol (DTT) and 1.25 g of polyvinylpolypyrolidone (PVPP). The homogenate was centrifuged at 37500×*g* for 20 min at 4 °C and filtered through a Whatman 1 paper filter (Dignum, Kerler, & Verpoorte, 2001). The enzyme extract was ultrafiltered in a Millipore stirred cell with a 10 kDa membrane and unfiltered solid was used as a crude enzymatic extract. The enzyme extract was submitted to protein precipitation with solid ammonium sulphate. Protein fractions at 30%, 30–40%, 40–50%, 50–60%, 60–70% and 70–80% of ammonium sulphate were separated by centrifugation at 10000×*g* for 20 min at 4 °C and the supernatant was removed. Each precipitate was dissolved in a small amount of 100 mM phosphate buffer (pH 7.0) and dialysed at 4 °C against the same buffer with four buffer changes every 6 h. For further purification, a dialysed enzyme aliquot was fractionated by gel filtration chromatography using a Sephacryl S-200 column with a 100 mL bed volume and equilibrated with 100 mM phosphate buffer (pH 7.0) and the elution rate was adjusted to 20 mL/h. The dialysed enzyme solution was applied to the column and 3 mL fractions were collected. The elution process continued until no absorbance at 280 nm was detected. The fraction with PPO activity was collected and the degree of purification was determined by measuring specific activity before and after purification. For determining PPO specific activity, a quantitative protein measurement was carried out. The protein concentration was determined using the Bradford (1976) method with Coomassie Plus Protein Assay Reagent (Pierce Chemical Co.) and bovine serum albumin was used as a protein standard.

2.3. PPO activity assay

The PPO assay was adopted and modified from Gauillard, Richard-Forget, and Nicolas (1993) technique. PPO activity was determined in a 2.0 mL assay mixture in a spectrophotometer (Beckman DU 7500) by measuring the increase in absorbance at 294 nm. Absorption spectrums collected during vanilla PPO reaction with catechol and 4-methylcatechol have shown the maximum wavelength of absorbance of the reaction product at 294 nm, and it is a major difference from the absorbance at 410–420 normally used to determine polyphenol oxidase activity with these substrates. The reaction mixture consisted of 0.9 mL of 0.1 M citrate buffer pH 3.0, 0.1 mL of enzyme, 0.5 mL of catechol or 4-methylcatechol in 0.1 M citrate buffer. The reaction was stopped by addition of 0.5 mL of 6% trichloroacetic acid. PPO activity measurements were performed over a 10 min reaction period and results were expressed as the mean. One unit of enzyme activity was defined as the amount of enzyme that caused 0.001 changes in absorbance at 294 nm per min. All runs were conducted in triplicate and the relative standard deviations were less than 1%.

2.4. SDS–PAGE electrophoresis

SDS–PAGE was performed according to Laemmli (1970), using a Bio-Rad Mini Gel system. The protein samples were fully denatured by boiling with β-mercaptoethanol and SDS and separated in a 12% polyacrylamide resolving gel and 4% stacking gel. Proteins were stained with Coomassie Blue and molecular weights were estimated by comparison with the molecular weight markers (Bio-Rad Precision Plus Protein Standard 161-0373).

2.5. Determination of isoelectric point

Preparative isoelectrofocusing was performed according to manufacturer's instructions for a Rotofor preparative cell (Bio-Rad) with a pH gradient from 3 to 10. Proteins were focused at 15 W constant electric power for 4 h at 4 °C. Twenty fractions, each of 2.5 mL were collected, their pH was measured and the samples were monitored at 280 nm for protein detection. This was followed by a Coomassie assay for protein and PPO activity to determine the location of PPO in collected fractions.

2.6. pH activity profile and pH stability

The PPO activity profile was analysed over a range of pH 3–7 using the following buffers: 0.05 M citrate buffer of pH 3–5 and 0.1 M phosphate buffer of pH 6–7. Catechol and 4-methylcatechol were used as substrate at 20 mM/L. PPO activity was assayed using the standard reaction mixture, but only changing the buffer. The optimum pH found for this enzyme was used in all other later studies. The purified enzyme was analysed for pH stability at the appropriate pH, ranging from 2.5 to 10 at 30 °C for 30 min prior to the assay for residual activity at a fixed pH of 3.4.

2.7. Temperature activity profile and heat inactivation

The optimal temperature was determined by measuring PPO activity under standard conditions using catechol as a substrate in a temperature range of 20–60 °C at pH 3.4. Thermal inactivation of purified PPO was studied at selected temperatures (60, 65, 70, 75, 80 and 85 °C) for various times in a glass tube. Tubes containing 900 μL of 0.1 M acetate buffer were heated to the selected temperature before addition of 100 μL of the enzyme solution than kept for isothermal inactivation. The time to reach the equilibrium temperature was measured, and this was taken into consideration in experiments and subtracted when calculating the inactivation time. At different time intervals, one tube was taken out of the water bath and rapidly cooled in an iced water bath to stop thermal inactivation for 30 min of the storage period, than transferred to a water bath at 37 °C. To conduct the enzymatic reaction for

10 min, 500 μL of 20 mM catechol in 0.1 M acetate buffer pH 4.8 at 37 °C was added. The experiments were performed in three repeated runs for each temperature. An enzyme sample that had not been heated was used as a blank. The percentage of residual activity was calculated by comparison with the unheated sample. The first-order inactivation constant (k) was calculated from the slope of the time course of denaturation using the equation: ln (A/A_0), where A_0 was the initial enzyme activity and A was the activity at time t. The slopes of these plots were determined by linear regression, and the rate constants were plotted. The half-life of the enzyme was calculated as $t_{1/2} = 0.693/k$. The decimal reduction time (D value) was estimated as $D = 2.303/k$. The z value, which is the temperature increase required for a $\log_{10}$ reduction (90% of decrease) of the D value, was determined from a plot of $\log_{10}D$ against temperature. The slope of the graph is equal to $1/z$ and the activation energy of denaturation (E_a) was calculated by multiplying the slope of the Arrhenius plot (ln (k) vs. $1/T$) by the universal gas constant R.

2.8. Enzyme kinetics

In order to determine the Michaelis-Menten constant (K_m) and maximum velocity (V_{max}), PPO activity was measured using catechol and 4-methylcatechol as substrates at various concentrations of 1–40, and 0–400 mM, respectively. K_m and V_{max} values of the enzyme were calculated from a plot of $1/V$ against $1/S$ using the method of Lineweaver and Burk method. Measurements were carried out in triplicate.

2.9. Effect of selected chemicals on enzyme activity

The purified PPO was incubated for 60 min at 4 °C in the presence of the following compounds (1 mM): L-ascorbic acid, dithiothreitol (DTT), β-mercaptoethanol, EDTA, metabisulfite, 4-hexylresorcinol, benzoic acid, cysteine, citric acid, borax, and sodium azide previously dissolved in 0.5 M citrate phosphate buffer (pH 3.8). SDS was used in this study but at a concentration of 1%. The presence of ethanol (0–90%) was also analysed after enzyme incubation for 48 h. The residual activity was measured by the standard assay technique (as described previously).

2.10. Effect of metal ions

The purified PPO was preincubated for 60 min at 4 °C in the presence of 1 mM of various metal ions (Mg^{+2}, Cu^{+2}, Ca^{+2}, K^{+1}, Mn^{+2}; Fe^{+2} and Hg^{+2}) previously dissolved in 0.5 M citrate phosphate buffer (pH 3.8). This was followed by measurement of the residual enzymatic activity.

2.11. Statistical analysis

Results are average of three determinations were analysed for variation (ANOVA) and statistical significance by t-test.

3. Results and discussion

3.1. Extraction and purification of PPO

The highest PPO activity of the precipitate was observed under conditions of 30–75% ammonium sulphate saturation, and this saturation point was used for all the extraction processes. Polyvinylpyrolidone was used during extraction to bind phenols that could inactivate the PPO. It is well documented that oxidation of phenolics by PPO produces quinones which can inhibit PPO (Matheis & Whitaker, 1984).

After ammonium sulphate precipitation, the PPO activity level in the dialysed extract decreased to 47.3%. This was probably due to loss of copper ions from the medium during dialysis (Matheis & Whitaker, 1984).

The results of PPO purification are shown in Table 1. The column was calibrated using a commercial protein kit containing five proteins of known molecular weights. The calibration protein graph had a linear regression equation of $y = 0.0135x + 3.3498$ ($R^2 = 0.9624$) and was used to calculate the molecular weight of PPO. The degree of purity was 9.5 after ammonium sulphate precipitation, and was 29.8 after gel filtration chromatography. The results of vanilla PPO purification by gel filtration chromatography are shown in Fig. 1. The active fractions of 30–41 eluates were collected to determine the degree of enzyme purity and for further characterisation studies. The molecular weight calculated by column chromatography was ~34 ± 2 kDa ($R^2 = 0.96$).

$(NH_4)_2SO_4$	456.3	30.7	1.1	1.1	403.8	29.8

* Ultrafiltration on 10 KDa membrane.

3.2. Molecular weight and purity

After PPO isolation, the purity of the preparations and the molecular weight of the enzyme were examined by polyacrylamide slab gel electrophoresis, and the results after protein staining are shown in Fig. 2. In lane 2 of the Coomassie stained gel, the presence of several other proteins can be detected in the crude extract. Lane 3 represents the most active peak from the Sephacryl column, and the others bands have been eliminated leaving a pure PPO band. By comparing the molecular weight of PPO according to the gel with the known molecular weight of native PPO, we concluded that native PPO in vanilla bean is in a monomeric form of ~34 kDa. The molecular weight has previously been reported for coffee PPO (29 kDa) (Pereira et al., 2003), grape juice PPO (40 ± 2 kDa) (Okuda, Pue, Fujiyama, & Yokotsuka, 1999), marula PPO (71 kDa) (Mdluli, 2005), wheat PPO (40 kDa) (Kihara, Murata, Homma, Kaneko, & Komae, 2005) and apple PPO (45 kDa) (Ni Eidhin, Murphy, & O'Beirne, 2005).

3.3. Isoelectro focusing

Fig. 3 shows the PPO activity and pH profiles of the collected fractions resulting from the isolectro-focused preparations. The protein profile determined by absorbance at 280 nm showed only one peak. The peak obtained in fraction 5 corresponded to a pI of 4.0. Previous studies have shown that the pI of marula PPO was 5.4 (Mdluli, 2005) whilst, a pI of 3.6 was observed in palmito PPO (Robert, Rouch, Richard-Forget, Pabion, & Cadet, 1996).

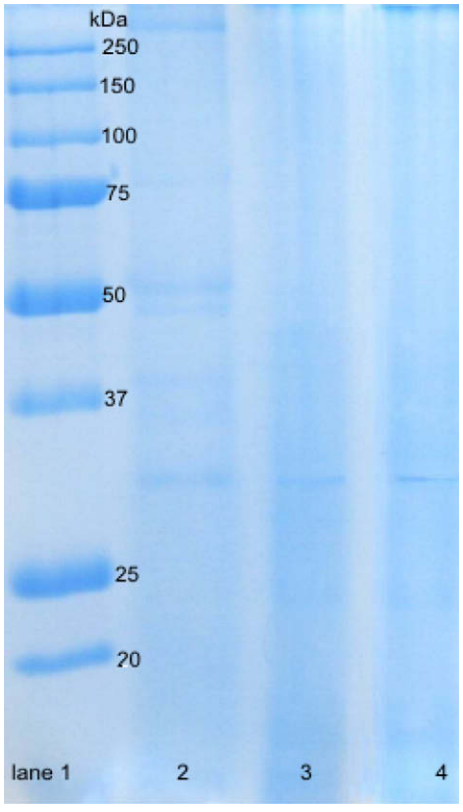

Fig. 2. SDS–PAGE of the purified PPO fractions. Lane 1, proteins standard; lane 2, crude enzyme extract; lane 3, PPO fraction after gel filtration; and lane 4, PPO fraction after preparative isoelectric focusing.

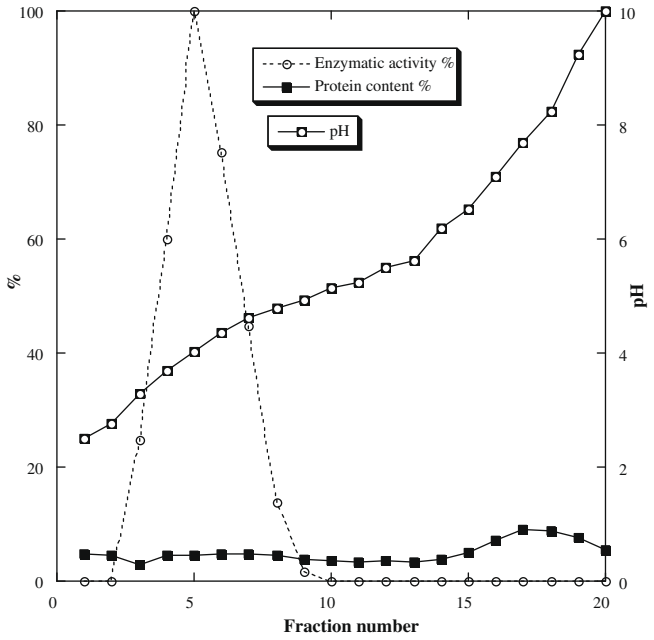

Fig. 3. Isoelectric focusing profile of PPO. Totally 20 fractions were collected at pH interval of 2–10.

3.4. PPO activity measurement

Many substrates were studied and compared for PPO activity, and showed that PPO has the best activity, the highest specificity and sensitivity toward catechol and 4-methylcatechol (Gauillard et al., 1991; Anil Kumar, Kishor Mohan, & Murugan, 2008; Dincer, Colak, Aydin, Kadioglu, & Guner, 2002; Gawlik-Dziki, Szymanowska, & Baraniak, 2007; Ngalani, Signoret, & Crouzet, 1993; Özen, Colak, Dincer, & Güner, 2004). Normally, PPO activity is measured by colorimetric method by estimation of oxidation products at very wide range of spectra at 390–430 nm. In fact, oxidation products of catechol and 4-M methylcatechol show two maxima absorbance, the highest and strong peak at 294 nm which clearly appeared after 10 min of reaction and the second weak and very wide peak indicating low sensitivity at 420 nm (Fig. 1), whilst the absorbance at 280 nm, characteristic for catechol and 4-methylcatechol slowly disappeared. To increase substantially assay sensitivity, we propose PPO assay activity with catechol and 4-methylcatechol at 294 nm after 10 min of reaction stopped by TCA. It offers advantage over colorimetric technique at 420 nm due to increase of measurement sensitivity as well as larger time of the linear period of the oxidation and large stability of oxidation products. Enzyme activity was measured for up to 10 min and stopped with TCA and the time of reaction of the linear part of absorbance vs incubation time. The initial rate was calculated from the slope of the absorbance–time curve. The increase in absorbance was linear with time for the first 15 min.

3.5. Optimal pH

Vanilla PPO had maximum activity at a pH approximately 3.4 for catechol and 3.0 for 4-methylcatechol (Fig. 4), which suggests that the enzyme may be found in acidic environments, such as the vacuole (Deepa & Arumughan, 2002). The optimum pH has previously been reported for Emir grape PPO 4.2 (Ünal & Sener, 2006). Erat, Sakiroglu, and Kufrevioglu (2006) found ferula leaf and stem samples optimum PPO activity for catechol (pH 7.0) and for 4-methylcatechol (pH 6.0), respectively. The optimum pH values for *Uapaca kirkiana* peel and pulp PPO were found to be 7.0 and

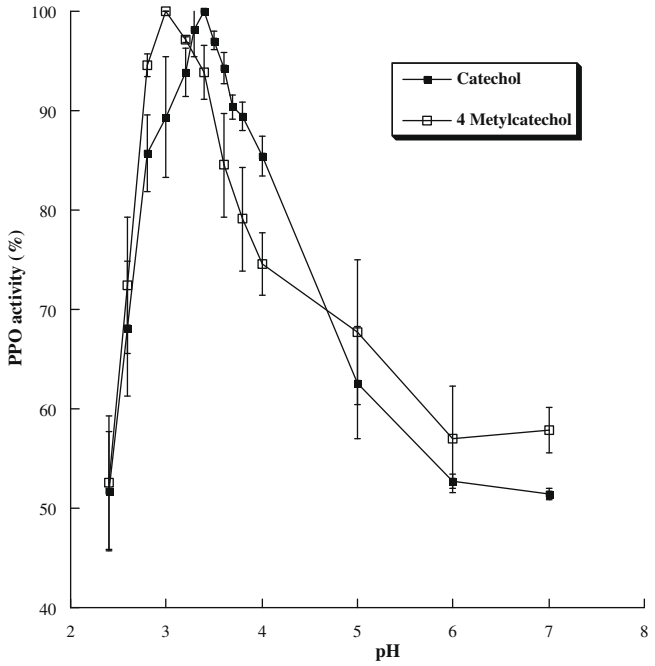

Fig. 4. pH optima of the purified vanilla bean PPO at 37 °C.

8.0, respectively (Muhuweti, Mupure, Ndhalala, & Kasiyamhuru, 2006). Chinese water chestnut PPO had an optimum pH of 6.5 with catechol (Lu et al., 2006) whilst marula fruit PPO showed optimum activity with catechol at pH 7.0 (Mdluli, 2005). In another study with catechol, pawpaw fruit (Fang, Zhang, Sun, & Sun, 2007) and mango pulp (Wang et al., 2007), PPO showed optimum pH of 7.0. These results do not coincide with the optimum pH of vanilla bean PPO, but a recent study reported that the optimum pH for PPO activity depends on the plant variety of the PPO, the nature of phenolic substrate and the extraction methods used (Ünal & Sener, 2006).

3.6. Effect of pH on PPO stability

The purified vanilla PPO showed the highest stability in an interval of pH 7–10 after 26 h of the enzyme incubation at 15 and 30 °C (Fig. 5). Whilst the enzymatic activity declined rapidly at pH below 5, the enzyme showed the least residual activity at pH 3. Erat et al. (2006) reported that *Ferula* PPO was more stable at pH 5.2 than at other pH values, whilst marula PPO was most stable at pH 6.0 (Mdluli, 2005). Grape juice PPO was stable at pH 6–8 (Okuda et al., 1999), whilst apple PPO was found to be most stable at pH 5.5–6.5 (Ni Eidhin et al., 2005). Chinese water chestnut PPO showed the highest stability at pH 6.5, which corresponded to the pH for optimal enzyme activity, but the relative activity at pH 3.0 was less than 10% (Lu et al., 2006). Enzyme instability at a low pH has also been reported for apple PPO (Ni Eidhin et al., 2005). This variation in PPO stability may be caused by differences in the binding ability of the substrate to the active site of the enzyme under ambient conditions (Martinez & Whitaker, 1995).

3.7. Optimal temperature

The effect of temperature on PPO activity was investigated in the range of 20–60 °C (Fig. 6). The optimum temperature for maximum vanilla PPO activity for catechol and 4-methylcatechol was found to be 37 °C, and the enzyme was active over relatively broad temperature range of 20–50 °C. The enzyme retained 80% or more activity between 30 and 45 °C. At temperatures above 50 °C the decline in enzymatic activity was more drastic, and only 10% of the activity was remained at 60 °C. Previous reports of thermal stability of PPO in other fruits have shown that, ferula PPO has an optimum temperature of 12 °C for catechol and 25 °C for 4-methylcatechol (Erat et al., 2006), *Uapaca kirkiana* PPO has an optimum temperature of 35 °C (Muhuweti et al., 2006), Emir grape PPO

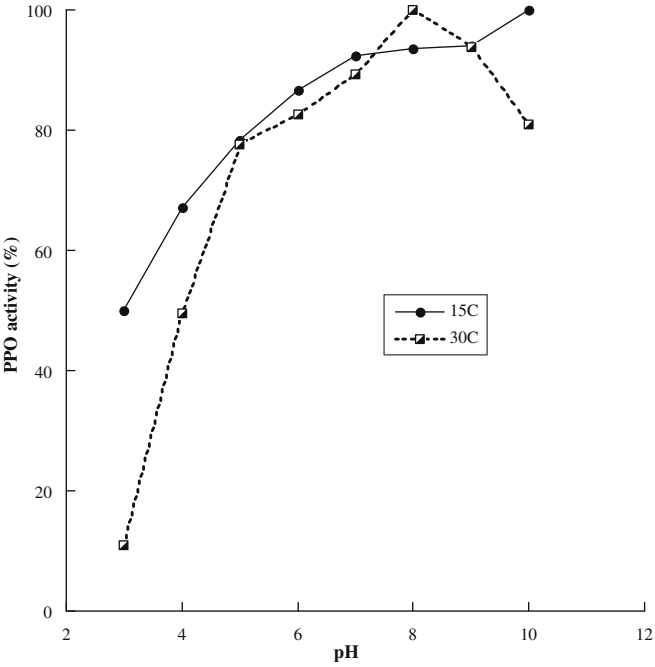

Fig. 5. Effect of pH on enzyme stability after the enzyme preparation incubation for 26 h at 15 and 30 °C in buffer solutions at various pH (3–10).

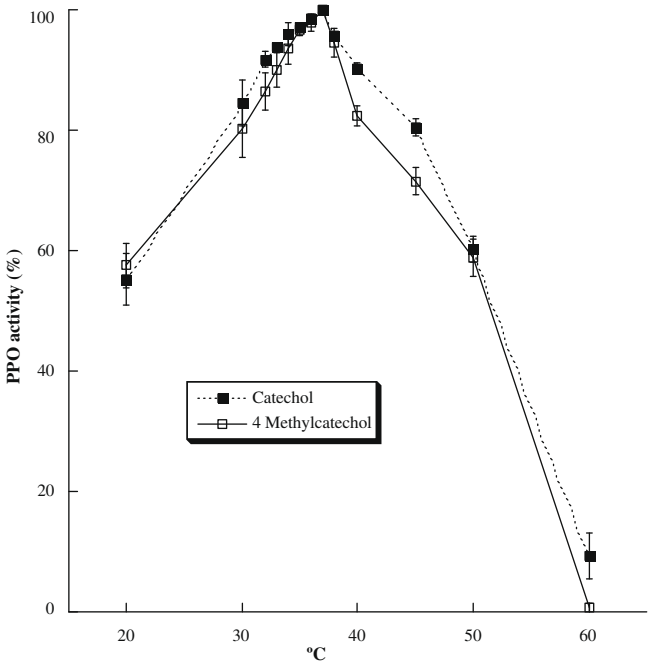

Fig. 6. Effect of temperature on PPO activity at pH 3.4 for catechol and pH 3.0 for methylcatechol. Results are means of duplicate + analyses of two replicates.

has optimum temperature of 25 °C (Ünal & Sener, 2006), the optimum temperature for grape juice PPO ranges 25 and 30 °C (Okuda et al., 1999), and apple PPO has an optimum temperature of 30 °C (Ni Eidhin et al., 2005).

3.8. Thermal inactivation

The thermal inactivation profile of vanilla PPO expressed as percentage of residual activity is shown in Fig. 7. The thermal inactivation profile is biphasic, which is more pronounced at 80 and 85 °C. The first phase represents thermolabile behaviour and the second phase thermoresistant behaviour. The biphasic behaviour may indicate the presence of two different isoenzymes with different thermal properties, which was not confirmed by gel electrophoresis. The enzyme was thermos table at 65 °C and retained up to 90% of activity after 20 min of heating. Biphasic thermal inactivation behaviour has been reported for Emir grape PPO (Ünal & Sener, 2006), Ferula PPO showed a decrease in activity of 40%, 65% and 100% at 30, 40 and 50 °C, respectively after 60 min of heat treatment and the enzyme was completely inactivated after 40 min at 60 °C (Erat et al., 2006). In comparison to other studies, marula fruit PPO treated at 60 °C was relatively thermostable retaining up to 60% of enzyme activity after 16 min of heating (Mdluli, 2005). Wheat PPO activity decreased below 30% after heat treatment at 70 °C for 10 min (Kihara et al., 2005).

Fig. 8 shows the Arrhenius plot of the kinetic expression for the thermal inactivation of PPO. Inactivation parameters were calculated from the initial part of the inactivation curve (Table 2). The half-life ($t_{1/2}$) value is an important parameter used in the characterisation of enzyme stability. The half-life values in the temperature range 60–85 °C varied between 2.6 and 0.2 min. In comparison with data from the literature, half-life values for marula fruit PPO at 60 and 70 °C were 1.4 and 0.8 min, respectively (Mdluli, 2005). Ünal and Sener (2006) reported half-life values for Emir grape PPO of 64.2 and 1.5 min at 65 and 80 °C, respectively. Since the half-life of inactivation obtained for vanilla PPO was low (0.8 min at 75 °C), and was less than the half-life of inactivation for Emir grape PPO (4.0 min at 75 °C), it is probable that vanilla PPO is less thermostable than other PPOs.

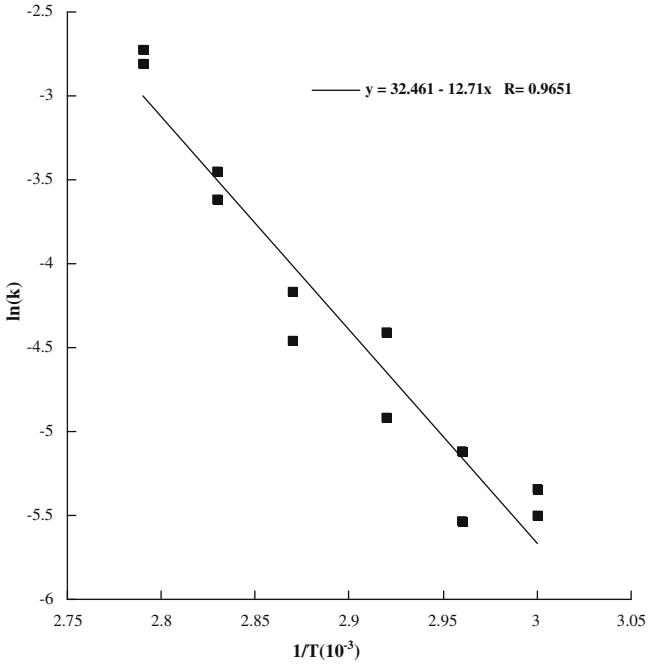

Fig. 8. The Arrhenius plot for heat inactivation of the purified PPO.

Table 2
Thermal inactivation parameters of purified PPO.

Temperature (°C)	$\Delta H^{\#}$ (J mol^{-1})	$\Delta G^{\#}$ (J mol^{-1})	$\Delta S^{\#}$ (J mol^{-1}K^{-1})	$t_{1/2}$ (min)	D_{value} (min)
60	89331.4	96848.8	−22.57	2.608	8.667
65	89289.9	98031.6	−25.86	2.425	8.056
70	89248.3	97612.5	−24.39	1.263	4.197
75	89206.7	98119.2	−25.61	0.871	2.893
80	89165.2	97305.2	−23.06	0.396	1.317

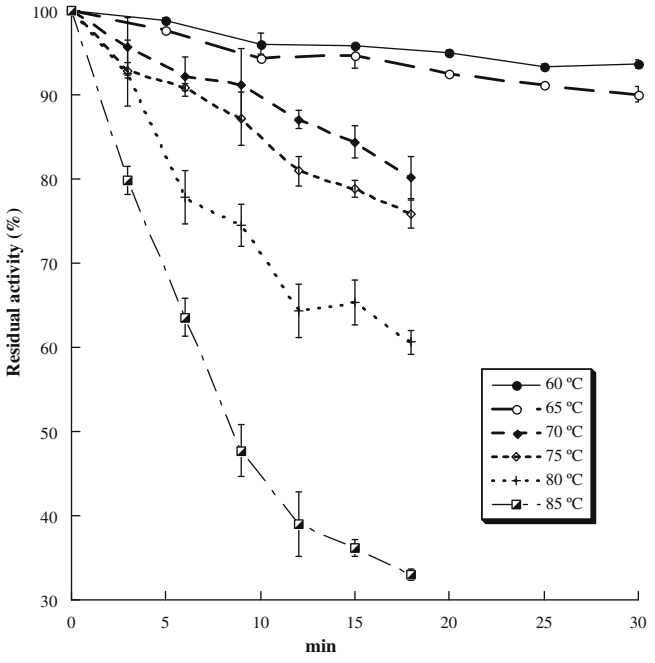

Fig. 7. Thermal inactivation profile for PPO. Values are means for duplicate analyses of two replicates.

The decimal reduction time (D value) is a parameter commonly used in the characterisation of enzyme stability and is defined as the time needed for a 90% reduction of the initial activity. D values for vanilla PPO ranged between 8.7 and 0.6 min at the temperatures studied (Table 2). D values previously reported for marula PPO were 4.6 and 2.5 min at 60 and 70 °C, respectively (Mdluli, 2005), whilst the D values of Emir grape PPO ranged between 213.2 and 4.9 min at 65 and 80 °C respectively (Ünal & Sener, 2006),

The z value is characterised by the temperature dependence of the decimal enzyme reduction activity time, which is the temperature increase needed for a $\log_{10}$ reduction (90% of decrease) in the D value. In general, low z values indicate greater enzyme sensitivity to heat, and high activation energy (E_a) values reflect a greater sensitivity of the enzyme to temperature change. Interestingly, z values may be influenced by the degree of ripeness and preparation method (Chutintrasri & Noomhorm, 2006) E_a and z values for vanilla PPO were calculated as 92.1 kJ mol^{-1} ($r^2 = 0.97$) and 21 °C ($r^2 = 0.94$), respectively. Some of the reported E_a values for PPO include 251 kJ mol^{-1} for Emir grape 25 °C (Ünal & Sener, 2006), and 37.9 kJ mol^{-1} for marula fruit (Mdluli, 2005). The E_a value for vanilla PPO is within the range of these values. Reported z values for PPO include 8.92 °C for Emir grape (Ünal & Sener, 2006) and 13 °C for an unspecified variety of grape (Weemaes, Ludikhuyze, Broeck, Hendricks, & Tobback, 1998). The z value found in this study is in agreement with these results.

Other transition state parameters, namely, $\Delta G^{\#}$, the activation Gibbs free energy change is considered as the energy barrier for enzyme inactivation, $\Delta H^{\#}$, enthalpy change, a measure of the number of covalent bonds broken, and $\Delta S^{\#}$, the entropy change, which is a measure of net enzyme and dissolvent disorder, were calculated using equations described by Forsyth, Owusu Apenten, and Robinson (1999). The $\Delta H^{\#}$ value found in this study is within the range of previously reported values of other PPO's. Mdluli (2005) reported values of $\Delta H^{\#}$ for marula PPO between 36168 and 34919 in a temperature interval of 60–90 °C. However, Forsyth et al. (1999) raised questions about the suitability of use of isolated $\Delta H^{\#}$ values as indicators of enzyme stability.

3.9. PPO kinetic parameters

The substrate specificity of PPOs varies widely depending on the source and purity of the enzyme. The affinity of a PPO for a particular substrate may even vary amongst multiple samples from of a particular preparation. It has often been suggested that the preferred substrate is the most abundant phenolic compound, which is not always the case. Catechins, cinnamic acid esters, 3,4-dihydroxyphenylalanine (DOPA) and tyrosine are the most important natural phenolic substrates of PPOs in fruits and vegetables (Matheis & Whitaker, 1984).

The kinetic parameters were measured at pH 3.4 and 3.0 for 4-methylcatechol and catechol, respectively at 37 °C. K_m and V_{max} were calculated using a Lineweaver–Burk plot. The K_m values for vanilla PPO were 10.6 mM and 85 mM using 4-methycatechol and catechol, respectively. K_m is a measure of the affinity of the enzyme for the substrate with smaller values representing a greater affinity. The affinity of vanilla PPO is low, as evidenced by its high K_m values. The affinity of plant PPOs for phenolic substrates is relatively low, usually around 1–10 mM. Ünal and Sener (2006), reported a K_m for Emir grape PPO of 25.1 mM for catechol, whilst ferula PPO had a K_m value of 2.34 mM for catechol and 6.58 for 4-methylcatechol (Erat et al., 2006). The K_m for marula PPO was 4.99 and 1.45 mM for catechol and 4-methylcatechol, respectively (Mdluli, 2005), whilst butter lettuce showed higher affinity to 4-methylcatechol than to catechol (Gawlik-Dziki, Zlotek, & Swieca, 2008) The Chinese water chestnut PPO K_m value for catechol was 10.32 mM (Lu et al., 2006) whilst mango PPO K_m was only 6.30 mM (Wang et al., 2007). The maximum reaction velocity (V_{max}) values for vanilla PPO were found to be 13.6 $OD_{300}\,min^{-1}$ and 107.2 $OD_{300}\,min^{-1}$ for 4-methylcatechol and catechol, respectively.

3.10. Effect of various chemicals on enzyme activity

The effects of inhibitors on vanilla bean PPO activity were studied at various concentrations using catechol as a substrate at pH 3.4. The results are given as a percentage of PPO inhibition in Table 3. It may be concluded that the most potent inhibitors were 4-hexylresorcinol and ascorbic acid. Ascorbic acid, cysteine and 4-hexylresorcinol when added to mango puree produced important PPO activity decreased (Guerrero-Beltran, Swanson, & Barbosa-Canovas, 2005). In addition, cysteine and ascorbate significantly inhibited cherry PPO activity (Anil Kumar et al., 2008). Ascorbic acid and metabisulfite are reducing agents that can reduce o-quinones to form stable colourless products (Ünal & Sener, 2006). There has been substantial interest in using ascorbic acid alone or with citric acid as a sulphite substitute. Due to safety concerns, sulphite was banned from use in fresh fruit and vegetables by the Food and Drug Administration (Martinez & Whitaker, 1995). In our study, citric acid was the least potent inhibitor and its inhibitory effect is normally attributed to its pH lowering effect and chelate formation with copper. In the case of vanilla PPO, citric acid produced two combined effects: it acted as a PPO activator by lowering pH (the optimum pH for catechol is 3.4), and as an inhibitor by chelate formation with copper. The inhibitor reaction mechanism varies depending on the inhibitor agent employed. Inhibition by thiol compounds is attributed to either the stable colourless products formed by an addition reaction with o-quinones, or by binding to the active centre of PPO (Muhuweti et al., 2006; Yoruk & Marshall, 2003).

Table 3
Effect of chemical compounds on PPO activity.

Compound (1 mM)	Residual activity (%)
Borax	110.52 ± 0.71
Citric acid	79.03 ± 7.20
Sodium azide	49.30 ± 1.98
Cysteine	22.54 ± 2.72
Benzoic acid	21.45 ± 1.91
EDTA	19.99 ± 0.11
Sodium dodecyl sulphate (1%)	18.30 ± 3.25
Sodium metabisulphite	6.46 ± 0.44
β-Mercaptoethanol	3.95 ± 0.46
Dithiothreitol	1.25 ± 0.17
Ascorbic acid	0.23 ± 0.03
4-Hexylresorcinol	0.15 ± 0.02

Values represent the mean of three replicates.

Table 4
Effect of metal ions on PPO activity.

Metal ion (1 mM)	Residual activity (%)
$FeCl_2$	165.7 ± 8.7
$CaCl_2$	80.4 ± 6.9
$MnCl_2$	81.6 ± 6.2
$MgCl_2$	79.7 ± 2.4
$HgCl_2$	48.8 ± 7.1
$CuCl_2$	89.2 ± 1.4

Values represent the mean of three replicates.

SDS is known to modify the tertiary and quaternary structures of proteins, resulting in 80% inactivation of vanilla PPO. In a previous study on PPO of *Vicia faba*, the presence of SDS in the reaction medium eliminates PPO activity at acid pH and greatly increases PPO activity at a neutral pH (Jimenez & Garcia-Carmona, 1996). EDTA, a metal chelator also resulted PPO inhibition of 80%. The enzyme was inhibited by thiol compounds such as cysteine by 78%.

PPO activity decreased as the ethanol concentration was increased. At an ethanol concentration of 10%, the enzyme lost 30% of its activity, at a 20% ethanol concentration, the loss in activity of PPO was almost 90% and at a concentration of 30% ethanol, the enzyme activity was completely inhibited. A decrease in enzymatic activity in the presence of ethanol has previously been reported for bromelain (total inhibition at 50% ethanol) (Hasan, Rasheedi, & Khatun, 2003).

3.11. Effect of metal ions on enzyme activity

Table 4 shows the effect of metals ions at a concentration of 1 mM on PPO activity. Some halides activated the enzyme, and this activation may be caused by the substitution between a halide ion and copper in the enzyme. This result indicates that metal ions are involved in PPO enzymatic activity, as has previously been described.

4. Conclusions

This study describes the quantification, isolation and characterisation of PPO from vanilla beans. To increase substantially assay

sensitivity, we propose PPO assay activity with catechol and 4-M methylcatechol at 294 nm after 10 min of reaction. The activity of vanilla PPO has some similarities with other plant PPO's. The enzyme has the greatest substrate specificity for 4-methylcatechol over catechol at an optimum temperature of 37 °C, and at pHs of 3.0 and 3.4 for each substrate, respectively. The most potent inhibitor was 4-hexylresorcinol, followed by ascorbic acid. PPO plays an important role in the colour qualities and commercial properties of cured beans and their final alcoholic extract. The data obtained in this study may help understand vanilla bean PPO activity mainly when heat treatment is used to fruit killing during curing process. Vanilla bean PPO utilises mono- and diphenols to catalyse the oxidation of various cellular substrates, probably including vanillin and this reaction may decrease vanillin content in the cured bean.

Nutritional supplement
Selenium
UV-B radiation

ABSTRACT

St. John's wort (*Hypericum perforatum* L.) was grown under different levels of UV-B radiation, with selenium (10 mg l^{-1} Se applied by foliar spraying in the form of sodium selenate) or without foliar Se application. The different levels of UV-B radiation comprised an enhanced level simulating 17% ozone depletion, ambient level, and a reduced level of UV-B radiation. The concentration of Se in unsprayed plants was from 20 ng g^{-1} to 120 ng g^{-1}. The concentration of Se in the organs of plants foliarly sprayed with Se ranged from 1000 ng g^{-1} to 12,000 ng g^{-1}, the highest concentration being detected in plants grown under reduced levels of UV-B radiation. Foliar application of Se fertiliser is feasible and effective in St. John's wort and results in Se-enriched nutritional supplements.

1. Introduction

St. John's wort herb is traditionally used in Europe to relieve mild or moderate depression. Its extracts are also known for their *in vitro* antimicrobial and free radical-scavenging activity (Radulovic et al., 2007; Silva, Ferreres, Malva, & Dias, 2005; Silva, Malva, & Dias, 2008). Several new products were developed recently, which contain St. John's wort herb or its extracts as additives; several brands of food, beverages and yoghurts include St. John's wort herb (Ang et al., 2004; Silva et al., 2005). The consumption of its products has much increased, St. John's wort now being one of the most consumed of medicinal plants.

Seed soaking, or spraying of plants with a selenium (Se) solution may enrich the utilisable plant parts with Se compounds in concentrations of nutritional importance (Germ, Stibilj, Osvald, & Kreft, 2007; Ožbolt, Kreft, Kreft, Germ, & Stibilj, 2008; Smrkolj, Stibilj, Kreft, & Germ, 2006). In the case of plant products, which are part of food additives, a higher concentration of Se is desired to balance diets, otherwise deficient in Se. In fact, Se could be added to the preparation, or simply supplemented to the diet. However, among consumers, at least in Europe, is a growing interest for the original plant constituents and not for chemicals added to the preparations or foods.

Interactions between the effect of UV-B radiation and Se addition on its uptake in plants are known for buckwheat (Ožbolt et al., 2008). St. John's wort is a plant which thrives in direct sunshine, including natural UV-B radiation. However, as far as the present authors know, no studies have been carried out concerning the impact of UV-B radiation and/or supplementation with selenium (Se) by foliar spraying on the Se concentration in St. John's wort.

The studies of Gaberščik, Vončina, Trošt, Germ, and Björn (2002), Kreft, Štrukelj, Gaberščik, and Kreft (2002), Liang, Huang, Zhang, Zhang, and Zhou (2006), and Alonso-Amelot, Oliveros-Bastidas, and Calcagno-Pisarelli (2007) revealed that UV-B radiation affects the synthesis of secondary substances.

The aim of this work was to investigate the impact of Se spraying of young plants, and of UV-B radiation on the concentration of Se in the herb of *Hypericum perforatum*, in order to achieve concentrations of nutritional importance for food supplements or drugs.

2. Materials and methods

2.1. Plants and growth conditions

St. John's wort (*H. perforatum* L.) seedlings were obtained by cloning a sibling plant. Seedlings were planted in May 2005 in

Abbreviations: DM, dry mass; Se, selenium; Se0, without selenium; Se+, with selenium; UV−, reduced UV-B level; UV0, ambient UV-B level; UV+, enhanced UV-B level.

sandy soil in pots (15 × 15 × 15 cm), one plant per pot, on an outdoor research plot (Botanical Garden, University of Ljubljana: 320 m above sea level, 46°35′N, 14°55′E). The plants for each treatment were chosen randomly out of 100 specimens.

A stepwise UV-B supplement system was used. Three different treatments were used: a reduced level of UV-B radiation (UV-B(−)), using Mylar foil which cuts out wavelengths below about 320 nm (Gehrke et al., 1996); elevated UV-B radiation, simulating 17% ozone depletion (UV-B(+)), using Q-Panel UV-B 313 lamps with cellulose diacetate filters, which block the UV-C range (wavelengths lower than 280 nm); ambient radiation (UV-B(0)), produced with Q-Panel UV-B 313 lamps, filtered with Mylar foil to correct for the effects of UV-A radiation (control). Lamps were positioned at a distance of 25 cm from each other. Above the plants (80 cm) was placed an UV-B transmitting shield, to minimise the differences among treatments, due to wind, precipitation or temperature. The Mylar foil filter was positioned 80 cm above the plants. The systems were timer controlled. The biologically effective UV-B ($UV\text{-}B_{BE}$) doses were calculated and adjusted weekly using the programme of Björn and Murphy (1985), based on the generalised plant action spectrum of Caldwell (1968). During the experiment the methodology established during EU project UV-AQUTER (PL 970637) was strictly followed.

Three weeks after planting, plants were sprayed with a solution of detergent (Triton T-100, Sigma, 0.2 ml l^{-1}), with Se (Se+) (10 mg l^{-1} Se, in the form of sodium selenate) or without Se (Se0), to wet the whole plant. Detergent was added for uniform distribution of sprayed solutions on plants. There were six different groups: all combinations of 3 UV-B treatments and 2 Se treatments (with and without Se, respectively). In each UV-B and Se treatment group there were 10 plants, used randomly for analysis. At the time of Se foliar spraying, the young plants had no more than four leaves. These first four lower leaves (until the termination of the experiment they mainly developed into runners) were not included in the samples of leaves for analysis, to avoid possible contamination by Se not absorbed by the plants. Plants were harvested in week 14 after planting.

Samples were lyophilised, milled and stored in a refrigerator until analysed.

2.2. Determination of the Se content

Se content in stems, leaves and flower samples was determined by hydride generation atomic fluorescence spectrometry (HG–AFS) (Smrkolj & Stibilj, 2004). Digestion of samples was carried out in closed Teflon tubes under the following conditions: To 0.150–0.200 g of lyophilised sample of leaves, stems or flowers, 1.5 ml HNO_3 and 0.5 ml H_2SO_4 were added. Tubes were heated for 60 min at 130 °C in an aluminium block. Two millilitres of H_2O_2 were added and the samples were reheated at 115 °C for 10 min. Then, 0.1 ml 40% HF were added (only to leaves and stem samples) and the samples were heated at 115 °C for 10 min. Again 2 ml of H_2O_2 was added and the tube reheated at 115 °C for 10 min. After digestion, the solutions were cooled to room temperature and 0.1 ml of V_2O_5 in H_2SO_4 were added and the tubes were again heated at 115 °C for 20 min. Reduction of Se^{VI} to Se^{IV} with 2.5 ml of conc. HCl was carried out at 100 °C for 10 min. Samples were diluted and Se was determined by HG–AFS. Optimal measurement conditions are as follows: carrier flow rate 1 ml/min, argon flow rate 260 ml/min, nitrogen flow rate 3 ml/min, concentration of $NaBH_4$ 1.2%, concentration of HCl for hydride generation 2 M and concentration of HCl in the carrier 2 M. A schematic presentation of the procedure was published by Stibilj, Mazej, and Falnoga (2003). Each sample was analysed at least in duplicate.

The accuracy and precision of the method was checked by analysis of the certified reference material "Trace Elements in Spinach Leaves", NIST 1570a. Good agreement was found between the analysed and certified values of 119 ± 8 ng g^{-1} (four determinations) and 117 ± 9 ng g^{-1}, respectively.

All results are given on a dry mass basis (DM).

2.3. Statistical analyses

The data were evaluated by ANOVA (Statgraphics Version 4) and significance accepted at $p < 0.05$.

3. Results and discussion

The concentration of Se in unsprayed plants was from about 20 ng g^{-1} to 120 ng g^{-1} (Fig. 1). The concentration in foliarly sprayed plants was in the range from about 1000 ng g^{-1} to 12,000 ng g^{-1}, lowest in stem, higher in flowers and with the highest concentration in the leaves (Fig. 2). No visual symptoms of Se toxicity appeared on Se-sprayed plants, nor any symptoms due to UV-B irradiation of plants, or any other damage.

The present study revealed that a high amount of Se was efficiently transported from treated leaves to new, young leaves, emerging after the foliar treatment. It is known from previous studies that Se is easily transferred to other parts of the buckwheat plant when foliarly applied in low amounts (Germ & Stibilj, 2007; Smrkolj et al., 2006). Potato tubers and leaves of chicory, developed after Se spraying, contained significantly more Se, in comparison to Se-untreated plants (Germ, Kreft, Stibilj, & Urbanc-Berčič, 2007; Germ, Stibilj, Osvald, & Kreft, 2007).

Among the Se-sprayed plants the highest concentration of Se was found in plants exposed to reduced UV-B radiation (Fig. 2). The transformation of selenate into the plant's own Se-species and their translocation to the new, younger leaves depends on energy availability (Germ, Kreft, Stibilj, & Urbanc-Berčič, 2007; Germ & Osvald, 2005; Germ & Stibilj, 2007; Germ, Stibilj, & Kreft, 2007; Germ, Stibilj, Osvald, & Kreft, 2007). Plants not exposed to UV-B stress, had enough energy for efficient uptake of Se and its distribution in their tissue.

In contrast, among plants not sprayed with Se its concentration in leaves and stems was the highest in those plants exposed to enhanced UV-B radiation (Fig. 1), where the need for antioxidative effects was the highest.

The mass of the flowers was less than 200 mg per plant in the conditions of enhanced UV-B radiation with or without Se treatment, and therefore their analysis was not performed (Figs. 1 and 2).

No significant effects of UV-B or Se treatment were found on the length of the main shoot or the mass of shoots, except for the mass of shoots of plants treated both with Se+ and UV-B+, which was only 72% of that of untreated plants. In any case, Se-sprayed plants protected from UV-B radiation showed the highest concentration

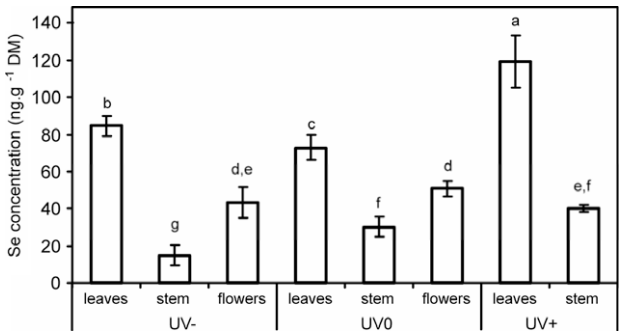

Fig. 1. Concentration of Se in plants not treated with Se (in ng g^{-1} DM ± SD, $n = 4$; UV−, reduced UV-B level; UV0, ambient UV-B level; UV+, enhanced UV-B level).

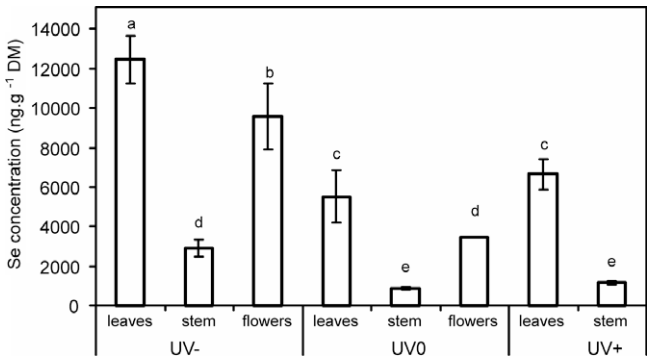

Fig. 2. Concentration of Se in plants treated with Se (in ng g^{-1} DM ± SD, $n = 4$; UV−, reduced UV-B level; UV0, ambient UV-B level; UV+, enhanced UV-B level).

of Se, and, hence, from the point of view of Se, this would be the most suitable way to grow St. John's wort for food supplements.

The recommended dietary intake of Se for adults is 55 micrograms per day (Food and Nutrition Board, 2000). Thus, a considerable part of this could be covered by products containing St. John's wort, subjected to foliar spraying with Se in the young plant phase. In conclusion, foliar application of Se fertiliser is feasible and effective in St. John's wort and results in Se-enriched products. This is in addition to its other important constituents, relieving mild or moderate depression, and exerting antimicrobial and free radical-scavenging activities.

Mineral composition

ABSTRACT

The influence of muscle on the physicochemical characteristics, proximate analysis, and mineral composition of meat from 10 ostriches (10–12 months old), slaughtered according to commercial abattoir procedures, were evaluated. Muscle had no influence ($p > 0.05$) on L^*-values (32.5), a^*-values (11.9), water-holding capacity (11.9%), final pH (pH_{24}) values (6.07), and ash contents (1.12 g/100 g edible meat). However, intramuscular lipid contents varied ($p < 0.05$) from 0.88 (*M. fibularis longus*) to 1.44 (*M. flexor cruris lateralis*) g/100 g edible meat, at a mean value of 1.16 g/100 g edible meat for 10 different muscles. Sodium (34.7 mg/100 g edible meat) and iron (3.14 mg/100 g edible meat) contents, both influenced ($p < 0.05$) by muscle, possessed substantially lower and higher values, respectively, than values reported for beef and chicken.

1. Introduction

Despite domestication of the ostrich (*Struthio camelus*) in the middle of the 19th century due to a fashion for ostrich feathers, this animal remained unknown as a potential meat producer till the beginning of the 1990s. At this time the single channel marketing scheme was lifted by the Klein Karoo Agriculture Co-operative, Oudtshoorn, South Africa, and ostriches and ostrich products could be marketed freely worldwide (Drenowatz, Sales, Sarasqueta, & Weilbrenner, 1995). Surprisingly, notwithstanding little and fragmented research, several reviews (Balog & Almeida Paz, 2007; Hoffman, 2005, 2008; Paleari, Corsico, & Beretta, 1995; Sales, 1999; Sales & Horbańczuk, 1998; Sales & Oliver-Lyons, 1996) have been produced on ostrich meat. From the above it has been concluded that ostrich meat is characterised, relatively to meat from other species, by a

(1) high (>6.0) final pH (pH_f), which is beneficial for the colour and water-binding capacity of meat, but is undesirable for keeping quality and flavour,
(2) low intramuscular lipid content,
(3) low sodium (Na) content, and
(4) high iron (Fe) content.

Although several studies have evaluated the lipid and fatty acid composition of ostrich meat, a single study (Sales & Hayes, 1996) has determined the mineral profile of ostrich meat, with concentrations of iron (Fe) (Lombardi-Boccia, Lanzi, & Aguzzi, 2005; Lombardi-Boccia, Martinez-Dominguez, & Aguzzi, 2002), selenium (Se) (Duan & Åkesson, 2004), zinc (Zn) (Lombardi-Boccia et al., 2005), and copper (Cu) (Lombardi-Boccia et al., 2005) reported by some others. Furthermore, mineral concentrations have been evaluated in a limited number of different muscles, the unit used to sell ostrich meat. In addition to diet, hormones, age, gender and region, mineral concentrations vary among different muscles in the animal carcass, due to varying intensity of physical activity and the effects of fibre type (Doornenbal & Murray, 1981; Lin et al., 1989).

In order to evaluate the nutritional potential of ostrich meat, and to extend current knowledge, the present study aimed at evaluation of selected physicochemical characteristics, proximate analysis, and mineral composition of ostrich meat as influenced by muscle.

2. Materials and methods

2.1. Animals and sampling

Ostriches, predominantly from the subspecies *S. camelus australis* (Blue Neck), were reared on a commercial ostrich farm in Paprotno, Poland, on a commercial ostrich starter (16% crude

doi:10.1016/j.foodchem.2009.03.100

protein, 9.6% fibre, 9.7 MJ/kg) feed mixture (pellets) till 3 months of age, whereafter a commercial (14.5% crude protein, 10.7% fibre, 9.5 MJ/kg) ostrich grower (pellets) was supplied. Ten ostriches (males) were slaughtered at the age of 10–12 months in a commercial abattoir for cattle and swine in Chruścina, Poland, with the slaughtering process adapted for ostriches. Ostriches were fasted for 24 h, and stunned with a captive bolt stunner. The unconscious birds were shackled by one leg, hoisted to a height and bled by severance of the heart, carotid artery and jugular vein through the thoracic inlet, anterior to the sternum plate. After feather and skin removal internal organs were removed. Carcasses were divided into two sides, and chilled for 24 h at 4 °C. Subsequently, legs and thighs were excised from the pelvic limbs.

The following 10 muscles were excised from the left side of each carcass: *M. gastrocnemius*, *M. fibularis longus*, *M. obturatorius medialis*, *M. flexor cruris lateralis*, *M. iliofibularis*, *M. femorotibialis medius*, *M. iliotibialis lateralis*, *M. iliofemoralis externus*, *M. ambiens*, and *M. iliotibialis cranialis*. External fat and epimysial connective tissue were removed and muscles were divided perpendicularly to their longitudinal axis into two equal parts. Whereas the caudal part of each muscle was stored at −18 °C till analysed for thawing and cooking losses, the cranial part was ground twice through a 4 mm sieve to ensure homogeneity of samples. The latter was portioned into two separate parts, with one of them being stored at −18 °C for proximate analysis and assaying mineral concentrations, and the second used fresh for immediate determination of meat colour, water-holding capacity (WHC), and final pH (pH_{24}).

2.2. Physicochemical characteristics

Six muscles (*M. gastrocnemius pars interna*, *M. fibularis longus*, *M. iliofibularis*, *M. femorotibials medius*, *M. iliotibialis lateralis*, and *M. iliotibialis cranialis*) were used for evaluation of physicochemical characteristics. To evaluate thawing and cooking losses of the thawed meat, the caudal part was weighed and then frozen at −18 °C for 2–3 months. Meat juice losses during thawing were calculated based on the difference of sample weight before freezing and after a 24-h thawing period at 4 °C (in a household refrigerator). These losses were expressed as a percentage in relation to the weight of the sample before freezing.

For determination of cooking losses, 100 g samples, 20 mm thick, were cut from the muscles after thawing, and placed in 500 ml glass jars and covered with 300 ml water. Glass jars with meat samples were closed and placed in a water bath until a temperature of 85 °C was obtained inside the muscles, according to Baryłko-Pikielna, Kossakowska, and Baldwin (1964). Thereafter, meat samples were removed from the glass jars and exposed to dripping and cooling in a household refrigerator at 4 °C for a period of 30 min. Cooking losses were calculated based on the difference in sample weights before and after cooking, expressed as a percentage of sample weight before cooking.

The following determinations were made on fresh ground meat tissue from the cranial part of each muscle.

2.2.1. Colour measurements

These were taken after keeping ground meat samples in measurement cells in a household refrigerator at 4 °C for 20 min, to enable myoglobin oxygenation on the surface layer of meat. Colour was measured using a HunterLab MiniScan XE Plus 45/0 apparatus with a measuring port diameter of 31.8 mm, adopted for measuring the colour of ground meat, applying the CIELAB $L^*a^*b^*$ scale (Commission Internationale de l'Eclairage (CIE), 1976) and a D65 illuminant and 10° standard observer. Standardisation of the apparatus was done in relation to black and white colour standard references with the following coordinates: $X = 78.5$, $Y = 83.3$ and $Z = 87.8$ (for D65 illuminant and 10° standard observer).

2.2.2. Water-holding capacity

This was based on the percentage of free water in meat, according to the method of Grau and Hamm (1953), as modified by Pohja and Niinivaara (1957). Ground meat samples, 0.3 g each (weighed accurately to 0.001 g), placed on Whatman No. 1 paper-filter, were exposed to 2 kg pressure between two glass plates for a period of 5 min. Thereafter, using a planimeter, the area of two spots created by extruded meat juice and meat, respectively, was determined (in cm^2). In order to determine the percentage of free water in meat, the infiltrate area expressed in cm^2 obtained from the difference in the areas of these two spots was divided by the weight of the sample.

2.2.3. pH_{24} measurement

This was done 24 h after slaughter with a combined glass electrode (ESAgP-306 W type) of a CyberScan 10 pH-meter (Eutech Cybernetics Pte Ltd., Singapore) in a water extract (distilled water), with a 1:1 meat to water ratio, after 1 h of extraction.

2.3. Proximate analysis

The following chemical constituents were determined on thawed ground samples of all muscles according to the official methods of analysis of the AOAC (2003): moisture content by oven drying a *ca.* 2-g test sample at 102 °C to a constant weight (950.46B, see p. 39.1.02); ash content by igniting a *ca.* 3–5-g test sample in a muffle furnace at 550 °C until light grey ash results (920.153, see p. 39.1.09); crude protein content by the classical macro-Kjeldahl method (981.10, see p. 39.1.19); and lipid (crude) content by petroleum ether extraction using a Soxhlet apparatus (960.39 (a), see p. 39.1.05).

2.4. Mineral composition

Chemical elements in the examined material were determined by inductively-coupled argon plasma optical emission spectrometry (ICP-OES), using a Perkin–Elmer Optima 2000 DV system, after prior mineralisation in an Anton Paar Multiwave microwave oven (Anton Paar Ltd., Hertford, UK). Meat samples, *ca.* 0.5 g each, were weighed exactly to four decimal places, and transferred to pressurised quartz vials, into which 5.0 ml 65% HNO_3 and 0.5 ml 35% HCl were added. Vials were sealed with Teflon plugs, secured in mineralisation bomb units, and placed in a microwave oven equipped with a permanent temperature and pressure control system in each quartz vessel. Mineralisation was conducted after selecting the "Meat" procedure proposed by the equipment manufacturer: 0–5 min – power gradient from 100 to 600 W; 6 to 10 min – 600 W (constant); 11 to 20 min – 1000 W or less after reaching critical values (75 MPa or 300 °C); 21 to 35 min – vial cooling. The cooled mineralisate was diluted with deionised water to a final volume of 10 ml. The following minor chemical elements were determined in the prepared solutions: boron (B), barium (Ba), cobalt (Co), chromium (Cr), Cu, Fe, manganese (Mn), nickel (Ni), Se, silicon (Si) and Zn. In order to obtain an optimum concentration range for the ICP method, calcium (Ca), potassium (K), magnesium (Mg), Na and phosphorus (P) concentrations were determined after a 100-fold dilution of the mineralisate. As a standard, the certified multi-element standard solution "ICP Multi-element Standard IV" (Merck, Darmstadt, Germany) was used.

2.5. Statistical analysis

Results were analysed using the ANOVA procedures of the software STATISTICA (data analysis software system, Version 7.1; StatSoft, Tulsa, OK). Individual animals were used as blocks to remove variation, due to differences among animals, from the error sum of

squares (Sales, 1996). Means for individual muscles were compared using Tukey's HSD tests.

3. Results and discussion

3.1. Physicochemical characteristics

Measured objective values for lightness (L^*), and the difference between red and green (a^*), did not differ ($p > 0.05$) among the six muscles evaluated for colour. However, the *M. iliotibialis cranialis*, compared to the *M. gastrocnemius pars interna*, *M. fibularis longus*, *M. femorotibialis medius*, and *M. iliotibialis lateralis* (Table 1), showed a higher ($p < 0.05$) intensity of yellow than blue (b^*).

Although present values for L^* correspond to values (27.4–34.4) reported for 10 different muscles from different subspecies (South African Black, Zimbabwean Blue, hybrids) of ostriches by Hoffman, Muller, Cloete, and Brand (2008), the latter study found significant differences among muscles, with the *M. fibularis longus* possessing the darkest muscle. Similarly, significant differences in a^*-values (10.7–17.1) have been indicated among muscles in the latter study. However, in agreement with present results, the highest (8.3–9.3) and lowest (6.0–6.7) b^*-values have been found in *M. iliotibialis cranialis* and *M. fibularis longus*, respectively. Results for lightness found in the present study are contradictory to subjective colour measurements presented by Morris et al. (1995), who found significant differences in lightness among 10 different muscles from the ostrich carcass, with the highest degree of lightness in the *M. iliotibialis cranialis*. The above differences among studies could partly result from the use of different *post-hoc* statistical tests, to identify differences among muscles. However, colour determination on ground meat in the present study *versus* whole muscles in other studies could be another contributing factor. Fragmentation of the muscle structure by grinding assists in the release of liquids from the interior of muscle cells, including soluble protein such as myoglobin, and destruction of some of the muscle's aerobic-reducing system, which could influence colour development in the final product (Fernández-López, Pérez-Alvarez, & Aranda-Catalá, 2000). Although L^*- and a^*-values were within ranges (27.4–38.0 and 5.48–22.8, respectively) reported for ostrich meat by several studies (summarised by Hoffman et al., 2008), b^*-values in the current study were considerably higher than 0.06–6.57, indicating that muscles showed a higher yellow intensity with less blue undertones. Fernández-López et al. (2000) reported a significant decrease in a^*- and increase in b^*-values with grinding of pork, partly attributed to higher metmyoglobin formation. Furthermore, the incorporation of air and consequent formation of oxymyglobin could contribute to higher b^*-values in ground meat than whole muscle.

Neither WHC nor pH_{24} differed ($p > 0.05$) among muscles (Table 1), in contrast to studies by Sales (1996) and Hoffman et al. (2008), which reported significant differences in pH_{24} among different ostrich muscles. However, the pH_{24} of around 6 found in the present study is typical for ostrich muscles (Sales & Mellett, 1996). Thawing losses differed ($p < 0.05$) among muscles (Table 1), and are comparable to losses of 1.28–4.28% reported for ostrich *M. femorotibialis medius* at different thawing rates by Hong et al. (2005). Cooking losses, with the highest ($p < 0.05$) value presented by the *M. femorotibialis medius*, were higher than values of 31.9–37.7 (Sales, 1996) and 28.6–38.7% (Hoffman et al., 2008) found with different ostrich muscles immersed in a water bath at 75 °C (50 min) and 80 °C (60 min), respectively.

3.2. Proximate analysis

Despite significant differences among muscles, dry matter contents varied with 1.66% units between the highest (*M. obturatorius medalis*) and lowest (*M. iliofibularis*) mean values (Table 2), and presented an overall mean moisture content (76.27 g/100 g edible meat) that are in the upper limit of that (69.5–76.5 g/100 g edible meat) reported for raw mammalian and poultry muscles (Forrest, Aberle, Hedrick, Judge, & Merkel, 1975). A similar tendency has been found for protein content, with an overall mean value of 21.16 g/100 g edible meat for all muscles.

However, intramuscular lipid content varied from a mean value of 0.88 g/100 g edible meat in the *M. fibularis longus* to 1.44 g/100 g

Table 1
Physicochemical characteristics of different ostrich muscles (mean ± SD).

Muscle	L^*	a^*	b^*	Water-holding capacity (%)	Thawing losses (%)	Cooking losses (%)	pH_{24}

Proximate analysis (g/100 g edible meat) of ostrich muscles (mean ± SD).

Muscle	Dry matter	Protein	Intramuscular lipid	Ash
M. gastrocnemius pars interna	23.3 ± 1.20^{bcd}	21.3 ± 0.73^{abc}	0.90 ± 0.16^{b}	1.10 ± 0.05
M. fibularis longus	23.3 ± 1.12^{bcd}	21.5 ± 0.81^{ab}	0.88 ± 0.23^{b}	1.12 ± 0.05
M. obturatorius medalis	24.5 ± 0.69^{a}	21.7 ± 0.49^{a}	1.22 ± 0.27^{ab}	1.14 ± 0.08
M. flexor cruris lateralis	24.2 ± 1.39^{ab}	21.5 ± 0.92^{ab}	1.44 ± 0.31^{a}	1.14 ± 0.06
M. iliofibularis	22.8 ± 0.93^{d}	20.7 ± 0.52^{bc}	1.10 ± 0.25^{ab}	1.07 ± 0.07
M. femorotibialis medius	23.0 ± 1.14^{cd}	20.8 ± 0.67^{bc}	0.95 ± 0.11^{b}	1.15 ± 0.07
M. iliotibialis lateralis	23.8 ± 1.05^{abcd}	21.4 ± 0.58^{abc}	1.21 ± 0.22^{ab}	1.17 ± 0.08
M. iliofemoralis externus	23.8 ± 1.29^{abc}	20.7 ± 0.79^{bc}	1.22 ± 0.12^{ab}	1.14 ± 0.14
M. ambiens	24.1 ± 1.04^{ab}	21.3 ± 0.53^{abc}	1.34 ± 0.35^{a}	1.09 ± 0.06
M. iliotibialis cranialis	24.4 ± 1.49^{a}	20.6 ± 0.78^{c}	1.36 ± 0.24^{a}	1.13 ± 0.12
Mean	23.7 ± 1.24	21.2 ± 0.76	1.16 ± 0.29	1.12 ± 0.08

$^{a–d}$Values with different superscript letters in the same column are different ($p < 0.05$).

edible meat in the *M. flexor cruris lateralis* (Table 2). Studies of the influence of muscle on lipid content of ostrich meat are contradictory (summarised by Hoffman, 2005). Substantially lower values (mean of 0.48 g/100 g edible meat) have been reported for 10 different ostrich muscles and muscle groups by Sales (1996). However, similarly to present results, the *M. flexor cruris lateralis* (0.82 g/100 g edible meat) and *M. fibularis longus* (0.24 g/100 g edible meat) were the muscles with the highest and lowest lipid contents, respectively. It is important to emphasise that lipid contents will depend on the methodology of the lipid analysis, with different solvents used for extraction causing different results (Jensen, 2004). In accordance with findings by Sales (1996), ash content did not differ ($p > 0.05$) among muscles (Table 2), and were comparable to an overall mean value of 1.14 g/100 g edible meat presented by the former study.

3.3. Mineral composition

Although mean Ca values varied from 4.76 (*M. iliofemoralis externus*) to 6.03 (*M. ambiens*) mg/100 g edible meat, no significant differences were detected among muscles (Table 3). The *M. flexor cruris lateralis* was the muscle with the highest ($p < 0.05$) mean contents of Mg (25.4 mg/100 g edible meat) and P (228 mg/100 g edible meat), whereas the lowest ($p < 0.05$) contents of Mg (23.3 mg/100 g edible meat) and K (234 mg/100 g edible meat), and highest ($p < 0.05$) content of Na (39.0 mg/100 g edible meat), were found in the *M. ambiens*.

Values for Ca, a mineral receiving a great deal of attention in nutrition, are somewhat lower than 7.29–9.00 mg/100 g edible meat reported for ostrich *M. gastrocnemius pars interna*, *M. iliofibularis* and *M. femorotibialis medius* by Sales and Hayes (1996), with no significant differences due to muscle found in the latter study. However, higher contents than in the present study for Na (40.6–46.6 mg/100 g edible meat) and K (266–272 mg/100 g edible meat), with contents of Mg as 20.6–22.7 mg/100 g edible meat and P as 206–220 mg/100 g edible meat, were presented by Sales and Hayes (1996). Calcium showed a mean overall value of 5.43 mg/100 g edible meat, comparable to 7 mg/100 g reported for lean beef (Holland et al., 1991), but considerably lower than a value of 12 mg/100 g for chicken without skin (USDA, 1979). With the adverse effects of excessive Na consumption, ostrich meat, with an overall mean Na content of 34.7 mg/100 g edible meat found in the present study, would be beneficial compared to values of 61 (Holland et al., 1991) and 77 (USDA, 1979) mg/100 g reported for lean beef and chicken without skin, respectively.

Iron content varied from a mean value of 2.32 in the *M. iliofibularis* to 4.02 mg/100 g edible meat in the *M. flexor cruris lateralis* (Table 3), with an overall mean value of 3.14 mg/100 g edible meat, substantially higher than 2.1 mg/100 g found in lean beef (Holland et al., 1991), and 0.9 mg/100 g (USDA, 1979) in chicken without skin. Values in the present study for Fe are higher than 1.97–2.51 mg/100 g edible meat reported (Sales & Hayes, 1996) for ostrich *M. gastrocnemius pars interna*, *M. iliofibularis* and *M. femorotibialis medius*, and 2.34–2.57 mg/100 g edible meat found in raw ostrich fillet, sirloin and leg (Lombardi-Boccia et al., 2005). Furthermore, contradictory to present results, the highest Fe content (2.51 mg/100 g edible meat) in the former study has been presented by the *M. iliofibularis*.

Contents of Cu, Se, Si and Zn were variable among muscles (Table 3), with overall mean values of 0.14, 0.03, 1.33 and 3.13 mg/100 g edible meat, respectively. These were comparable to 0.08–0.10 mg/100 g edible meat for Cu content, and in the upper limit of values (1.06–3.10 mg/100 g edible meat) for Zn content, reported in earlier studies (Lombardi-Boccia et al., 2005; Sales & Hayes, 1996) on the mineral composition of ostrich meat. Substantially higher values have been found for Se content (0.11 mg/100 g)

Table 3
Mineral composition (mg/100 g edible meat) of different ostrich muscles (mean ± SD).

of raw emu (*Dromaius novaehollandiae*) meat (Pegg, Amarowicz, & Code, 2006), and in three muscles (*M. obturatorius medalis*, *M. iliotibialis lateralis*, *M. iliofibularis*) from rhea (*Rhea americana*) (0.07–0.09 mg/100 g edible meat; Ramos, Cabrera, del Puerto, & Saadoun, 2009). However, Se content of meat is highly correlated to the Se contents of soil, grass, and feed ingredients (Ramos et al., 2009). No differences ($p > 0.05$) were found in contents of Co, Ni and Ba among muscles, whereas differences ($p < 0.05$) in contents of Mn and Cr are small, probably without any practical significance (Table 3).

Results from the present study are presented in the way that the product would be traded and is applicable to nutritionists and dieticians, namely a fresh tissue basis (Lin et al., 1989). It can be concluded that this study contributes to a description of the physicochemical and proximate composition of ostrich meat, obtained on several different muscles, which could be use to extend existing information. Furthermore, the mineral composition of a wide range of ostrich muscles are presented, some of the minor elements for the first time, in order to establish a database on the nutrient composition on ostrich meat for further use in research on human consumption of this relative unknown type of meat.

Moro orange

ABSTRACT

Fruit juices of pigmented and non-pigmented new citrus hybrids obtained by crossing clementine cv. Oroval with different cultivars of blood oranges were analysed to determine parameters related to fruit quality (total soluble solids titratable acidity, pH), and the content of ascorbic acid, total phenolics, flavanones, anthocyanins and phenolic acids. Antioxidant properties were evaluated by oxygen radical absorbance capacity (ORAC), and inhibition of induced linoleic acid peroxidation (InLAP) assays. The results of this study show that some hybrids with high antioxidant activity owing to considerable polyphenol content may be considered rich sources of phytochemicals. The OTA 9 hybrid was shown to be richest in polyphenols, suggesting that consumption of OTA 9 fruit or juice could be useful in health promotion and a disease-preventing diet. Moreover, the juice of this hybrid could be used as raw material to produce antioxidant ingredients for dietary, pharmaceutical, or cosmetic purposes.

1. Introduction

Citrus fruit contains vitamin C and other bioactive compounds, including flavonoids and hydroxycinnamic acids, with potential health-promoting properties (Widmer & Montanari, 1996). Flavanone glycosides are the most abundant phenolic compounds present in citrus fruit, but significant concentrations of other flavonoids such as methoxylated flavones, flavonols and anthocyanins (the last only in blood oranges) have also been found (Horowitz, 1961). Previous studies have shown that hesperidin, a member of the flavanone class, has antioxidant, anticancer and anti-inflammatory properties (Attaway, 1994). Hydroxycinnamic acids possess significant antioxidant activity and chemoprotective effects, as shown by *in vitro* and *in vivo* studies (Natella, Nardini, Di Felice, & Scaccini, 1999). Anthocyanins have also been associated with potentially beneficial effects against various diseases, such as capillary fragility, diabetic retinopathy and human platelet aggregation (Mazza & Miniati, 1993). In addition, anthocyanins are known to be potent antioxidants (Kähkönen & Heinonen, 2003; Wang, Cao, & Prior, 1997) and anthocyanin-rich fruit or juice has been associated with higher antioxidant capacity.

Blood (pigmented or red) oranges (Moro, Tarocco and Sanguinello) are the most cultivated varieties of sweet oranges [*Citrus sinensis* (L.) Osbeck] in Italy. The main characteristic that distinguishes these cultivars is the presence of anthocyanins in the flesh, as well as a higher content of vitamin C, flavanones and hydroxycinnamic acids compared to blond (or common) orange varieties (Rapisarda, Bellomo, & Intrigliolo, 2001). Previous studies have demonstrated that the major anthocyanins in blood orange juice are cyanidin 3-glucoside (Cy3G) and cyanidin 3-(6″malonyl)-glucoside (Cy3MG) (Maccarone, Rapisarda, Fanella, Arena, & Mondello, 1998), and their level in the fruit always varies according to the following order: Moro > Sanguinello > Tarocco. Moreover, marked differences in anthocyanin content among individual Tarocco clones have been observed (Rapisarda & Russo, 2000). The antioxidant activity of blood orange juices is higher than that of blond orange juices, and the antioxidant efficiency appears to be correlated with the anthocyanin level (Rapisarda, Tomaino, Lo Cascio, Bonina, & De Pasquale, 1999). Thus, a breeding programme that focuses on the bioactive phytochemical content of fruit, such as vitamin C, anthocyanins and other phenolics, represents a new and important strategy in the citrus industry. Since 1951, the CRA-Centro di Ricerche per l'Agrumicoltura e le Colture Mediterranee (CRA-ACM) has been working on a genetic improvement programme for extant blood orange cultivars and the development of new pigmented citrus hybrids with ease of peeling, increased size, new original sensory characteristics, and a high

anthocyanin content. New pigmented hybrids were obtained by crossing some clones of clementine (*C. clementina* Hort. ex Tan.) with different blood orange [*C. sinensis* (L.) Osbeck] varieties.

In order to investigate the heritability of traits, such as phenolic content and antioxidant activity, the fruit juices of pigmented and non-pigmented new citrus hybrids belonging to the OTA (Oroval clementine × Tarocco orange) and OMO (Oroval clementine × Moro orange) groups were analysed, to evaluate parameters related to fruit quality, as well as the content of health-promoting components such as ascorbic acid, total phenolics, flavanones, anthocyanins and phenolic acids. In addition, the total antioxidant capacity of the juices was measured using two different *in vitro* tests, oxygen radical absorbance capacity (ORAC) and inhibition of induced linoleic acid peroxidation (InLAP).

2. Materials and methods

2.1. Crosses

OTA and OMO hybrids were obtained by conventional citrus breeding methods. Controlled pollination between Oroval clementine (*C. clementina* Hort. ex Tan.), used as the female parent, and Tarocco 57-1E-1 or Moro NL 58-8D-1 [*C. sinensis* (L.) Osbeck], used as the male parent, was carried out. Seeds obtained from the fruit of these crosses were placed in pots, and the hybrid seedlings were grown in a greenhouse. After two years, scions from the apical part of the seedlings were cut and grafted onto *Poncirus trifoliate* L. Raf. rootstocks. One year later, the grafted plants were transferred to the Palazzelli experimental farm of CRA-ACM, where fruiting occurred after four years. For this study, the OTA 8, OTA 9, OTA 20, OTA 31, OTA 43, OMO 24 and OMO 30 hybrids were selected from the F1 progeny.

2.2. Chemicals

Ascorbic acid, hydroxycinnamic acids (*p*-coumaric, ferulic, caffeic and sinapic acids), Folin–Ciocalteu's phenol reagent, AAPH (2,2́-azobis(2-methylpropionamidine)dihydrochloride), Trolox (6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid), fluorescein, linoleic acid and lipoxygenase (E.C.1.13.11.12) were purchased from Sigma–Aldrich (Milan, Italy). Hesperidin, cyanidin 3-glucoside and (±)-catechin were from Extrasynthèse (Geney, France). All other chemicals were of analytical grade and the solvents used for chromatography were HPLC grade (Merck, Darmstadt, Germany).

2.3. Plant material

Fruits were harvested from three trees for each genotype: in December 2006, the Oroval clementine; in February 2007, the Tarocco 57–1E-1 orange; in March 2007, the Moro NL 58–8D-1 orange and the different hybrids (OTA 8, OTA 9, OTA 20, OTA 31, OTA 43, OMO 24 and OMO 30). Juice was extracted by a domestic squeezer and used for chemical analyses and antioxidant activity determination.

2.4. Physicochemical analysis

Total soluble solids (TSS), titratable acidity (TA) and pH were determined according to conventional methods. The ascorbic acid concentration was evaluated by liquid chromatography using a Waters Alliance 2695 HPLC (Waters Corporation, Milford, MA) equipped with a Waters 996 photodiode array detector and Empower software (Rapisarda & Intelisano, 1996). Briefly, 5 ml of centrifuged juice was poured into a flask and made up to 50 ml with 3% metaphosphoric acid solution. An aliquot of the solution was 0.45 μm filtered, and 20 μl injected into the HPLC. The mobile phase was 0.02 M H_3PO_4 and the detector was set at 260 nm.

The orange juices were analysed for total phenolics by the Folin–Ciocalteu (FC) colorimetric method (Singleton, Orthofer, & Lamuela-Raventos, 1999). Appropriately diluted samples (1 ml) were mixed with 5 ml of FC commercial reagent (previously diluted with water, 1:10 v/v) and 4 ml of a 7.5% sodium carbonate solution. The mixture was stirred for 2 h at room temperature away from strong light. The absorbance of the resulting blue solution was measured spectrophotometrically at 740 nm and the concentration of total phenolics was expressed as (±)-catechin equivalents (mg/l). Total anthocyanin content was determined spectrophotometrically (Varian UV–vis spectrophotometer, model Cary 100 Scan; Varian Inc., Palo Alto, CA) by the pH differential method (Rapisarda, Fanella, & Maccarone, 2000) and expressed as cyanidin 3-glucoside equivalents (mg/l).

Individual anthocyanin analysis was carried out by HPLC. A sample of 5 ml of centrifuged juice was loaded onto a C_{18} Sep-Pak cartridge, previously conditioned with 5 ml of methanol and 5 ml of pure water. The cartridge was eluted with acidified methanol (0.1% HCl). One millilitre of the extract was filtered through a 0.45 μm cartridge and injected into a Waters 600-E liquid chromatograph equipped with a Waters 996 photodiode array detector (PDA); the data were processed by Millennium 3.2 software. The column was a 250 mm × 4.6 mm i.d., 5 μm, Hypersil ODS (Phenomenex, Torrance, CA) and the solvent system was **A**, water:formic acid (85:15) and **B**, water:formic acid:acetonitrile (35:15:50). The percentage of **B** was increased linearly from 10% to 30% in 30 min at a flow rate of 1 ml/min. Elution was monitored at 520 nm, and the column temperature was maintained at 35 °C.

Flavanone glycosides, expressed as hesperidin equivalents (mg/l), were determined by HPLC (Rouseff, Martin, & Yotsey, 1987) using the HPLC-PDA equipment described above. A sample of centrifuged juice was diluted at a ratio of 1:5 with the mobile phase, 0.45-μm filtered, and injected directly into the column. The eluent used was water:acetonitrile:acetic acid (79.5:20:0.5), and the flow rate was 0.8 ml/min. The column effluent was monitored at 280 nm.

Hydroxycinnamic acids (*p*-coumaric, ferulic, caffeic and sinapic acids) were extracted from the juice by solid-phase extraction after alkaline hydrolysis of hydroxycinnamic esters (Rapisarda, Carollo, Fallico, Tomaselli, & Maccarone, 1998). A 10-ml sample of centrifuged juice was added to 10 ml of 2 M sodium hydroxide and stored at room temperature in the dark. Complete hydrolysis of bound hydroxycinnamic acids occurred in 4 h. The solution was then acidified with 2 M HCl to pH 2.5 and passed through a C_{18} SPE cartridge (Waters). Hydroxycinnamic acids were eluted with 0.1% HCl in methanol. The alcoholic solution was 0.45-μm filtered, and 20 μl of the solution was analysed by HPLC as above. The eluents used were water:acetic acid (98:2) (solvent **A**) and methanol (solvent **B**) with a gradient transition from 95% to 70% of solvent **A** over 35 min. The flow rate was 1 ml/min, and detection was at 300 nm.

2.5. Antioxidant activity

Antioxidant activity was determined using the ORAC assay, as described by Ou, Hampsch-Woodill, and Prior (2001), with some modifications. Briefly, the measurements were carried out on a Wallac 1420 Victor III 96-well plate reader (EG & Wallac, Turku, Finland) with a fluorescence filter (excitation 485 nm, emission 535 nm). Fluorescein (116 nM) was the target molecule for free radical attack from AAPH (153 mM) as the peroxyl radical generator. The reaction was conducted at 37 °C and pH 7.0, with Trolox (10 μM) as the control standard and 75 mM phosphate buffer

(pH 7.0) as the blank. All solutions were freshly prepared prior to analysis. All sample were diluted with phosphate buffer (1:25–100, v/v) prior to analysis and results were reported as micromoles of Trolox equivalents per 100 ml of juice.

Antioxidant activity was also determined through the inhibition of induced linoleic acid peroxidation (InLAP) assay. The enzymatic oxidation of linoleic acid was obtained by adding lipoxygenase from soybean (E.C.1.13.11.12) (Lo Scalzo, Iannoccari, Summa, Morelli, & Rapisarda, 2004), and monitored in the absence (blank test) and presence (sample test) of orange juice by recording the linear increase in absorbance at 234 nm (A_{max} of conjugated diene peroxides from linoleic acid oxidation). In the sample test, InLAP was measured in a solution containing 2.65 ml of 0.1 M phosphate buffer (pH 7.0), 0.3 ml of 2.28 mM linoleic acid–water emulsion, 0.05 ml of orange juice, and 0.025 ml of lipoxygenase solution (15 mg of lipoxygenase standard in 25 ml of 0.1 M phosphate buffer at pH 7.0). In the blank test, orange juice was substituted with 0.05 ml of 0.1 M phosphate buffer (pH 7.0). Antioxidant activity was expressed as the protection percentage of linoleic acid enzymatic degradation, where the blank represents 100% degradation of linoleic acid.

2.6. Statistical analysis

One-way ANOVA was performed for each genotype to obtain a statistical assessment of the physicochemical parameters and antioxidant activity. Means were separated by the Tukey's test at $p \leqslant 0.05$, $p \leqslant 0.01$ and $p \leqslant 0.001$ significance. A correlation analysis of antioxidant activity values *versus* ascorbic acid or phenolic components (anthocyanins, flavanones, hydroxycinnamic acids and total phenolics) was performed using MSTAT WIN 10.

3. Results

3.1. Fruit quality parameters

TSS, TA, TSS/TA and pH of the different genotypes studied are shown in Table 1. The TSS and TA values of clementine, Tarocco and Moro juices ranged within known values for mature fruit. As expected, the TSS/TA was higher in clementine (12.35) than in Tarocco (10.84) and Moro oranges (10.04), mainly due to the higher acidity of the blood orange varieties. Since the TSS/TA is related to maturity in citrus fruit, it is possible that OTA 9, OTA 31, OMO 24 and OMO 30 matured in March, while OTA 43 reached fruit maturity early. The high acidity found in OTA 8 and OTA 20 suggests that this is a persistent trait also in over-ripened fruits, since fruit senescence and drop were observed after March. The pH values of the hybrids and their parents reflect the acid content of these genotypes.

Table 1
Fruit quality parameters of OTA and OMO hybrids and their parents.[a]

	Genotype	pH		TA (%)		TSS (%)		TSS/TA	
OTA group	Clementine	3.86	A	1.02	E	12.64	D	12.35	B
	Tarocco	3.52	CD	1.12	D	12.18	E	10.84	C
	OTA 8	3.33	E	1.45	B	10.85	F	7.47	D
	OTA 9	3.45	D	1.22	C	13.09	C	10.69	C
	OTA 20	3.32	E	2.25	A	13.52	B	6.01	E
	OTA 31	3.54	CD	1.05	E	13.69	B	13.01	B
	OTA 43	3.75	B	0.87	F	15.10	A	17.29	A
OMO group	Clementine	3.86	A	1.02	C	12.64	A	12.35	A

[a] Values in the same column for each genotype having different letters are significantly different ($p \leqslant 0.01$).

3.2. Antioxidant components

Similar values for ascorbic acid were observed in OTA 8 and clementine, while the other hybrids showed higher levels than the female parent (Table 2). In addition, OTA 20 and OTA 31 juices exhibited higher ascorbic acid contents than the Tarocco orange, which is known as the richest source of vitamin C among orange varieties. The ascorbic acid level in OMO 24 was intermediate between those of the clementine and Moro orange, while the value obtained for the OMO 30 hybrid was similar to that of the male parent.

Total phenolics measured by the Folin–Ciocalteu (FC) assay were different depending on the genotype studied. The OTA 9 hybrid had a much higher content of total phenolics than the other citrus genotypes (Table 2). The mean content of total phenolics found in the other hybrids was intermediate between their respective parents, with higher values found in those hybrids that were richer in ascorbic acid or flavanones. Folin–Ciocalteu's phenol reagent is nonspecific for phenolic compounds since it measures sample reducing capacity through electron transfer-based antioxidant capacity and, thus, it can be reduced by many non-phenolic compounds, such as vitamin C (Huang, Boxin, & Prior, 2005). Therefore, due to the contribution of ascorbic acid, the response of some genotypes, such as OTA 20, OTA 31 and OTA 43, to the FC assay was high.

Crossbreeding between clementine and the two blood orange varieties produced pigmented and non-pigmented hybrids in both the OTA and OMO groups. In the former, OTA 9 and OTA 20 were pigmented, while in the latter, only OMO 30 contained anthocyanins. The anthocyanin contents in OTA 20 and OMO 30 were lower than those observed for the Tarocco and Moro juices, respectively, whereas the pigment concentration reached about 500 mg/l in the OTA 9 hybrid, an almost 5-fold higher value with respect to its male parent (Table 3). The anthocyanin profiles of pigmented hybrids, Moro and Tarocco orange juices are shown in Figs. 1 and 2. Peak assignments were made on the basis of their retention time, UV–vis spectra, and co-chromatography with authentic standards, as discussed in previous works (Maccarone et al., 1998; Rapisarda, Pannuzzo, Romano, & Russo, 2000). Even though the pattern of anthocyanins present both in male parents and hybrids was similar, a different distribution of individual anthocyanins was noted. In all genotypes studied, cyanidin 3-glucoside (peak 2) was the major anthocyanin, with delphinidin 3-glucoside (peak 1), delphinidin 3-(6″malonyl)-glucoside (peak 3), and cyanidin 3-(6″malonyl)-glucoside (peak 4), representing the other predominant anthocyanins.

[c] Relative percentage of anthocyanins was based on HPLC peak areas.

Oranges and clementines mainly accumulate the tasteless flavanones rutinoside, narirutin, and hesperidin (Horowitz, 1961), but other flavonoids such as polymethoxylated flavones, flavonol glucosides, and flavone C-glycosides also occur in these species (Caristi, Bellocco, Gargiulli, Toscano, & Leuzzi, 2006; Leuzzi, Caristi, Panzera, & Licandro, 2000). The major flavanone glycoside found in the parental and all hybrid fruit juices was hesperidin, representing about 50–80% of the total flavonoids (Table 4). Narirutin and dydimin were also present, confirming that hybrids resulting from crosses between oranges and clementines principally contain patterns of rutinosyl glycosides. The hybrid representing the richest source of flavonoid glycosides (not including anthocyanins) was OTA 9, with 1018.34 mg/l, followed by OMO 30, with 307.66 mg/l. A study is currently in progress to identify the minor anthocyanins and other flavonoids present in these hybrids using HPLC-ESI-MS/MS.

The particular trend observed for OTA 9 was also reflected in the concentration of hydroxycinnamic acids, the values of which made OTA 9 the richest hybrid in polyphenols content. Total hydroxycinnamic acid (HCA) content in most non-pigmented hybrids (OTA 31, OTA 43 and OMO 24) was similar to that of the clementine, whereas higher values than in the female parent were observed in pigmented hybrids (OTA 20, OMO 30) (Table 5). The HCA content in the OTA 9 was about 1.5 times higher than in the Tarocco orange, its male parent. The distribution of individual phenolic acids in the hybrids with respect to their parents showed higher values of *p*-coumaric and ferulic acids in the OTA 9 and *p*-coumaric acid in the OMO 30 hybrids, while caffeic acid was higher in the OTA 20 and OTA 43 hybrids. In the other hybrids, the amount of individual hydroxycinnamic acids was lower than, or comparable to, that of the two parents.

3.3. Antioxidant activity

All juices tested showed an apparent antioxidant effect that may be mostly attributed to their high content of polyphenols (Table 6). The OTA 9 hybrid exhibited higher ORAC activity than its parents, whereas that of the female parent clementine was the lowest. Statistically significant differences were observed between pigmented and non-pigmented hybrids in both OTA and OMO groups, with higher values found in anthocyanin-containing hybrids. The correlation between anthocyanins content and ORAC

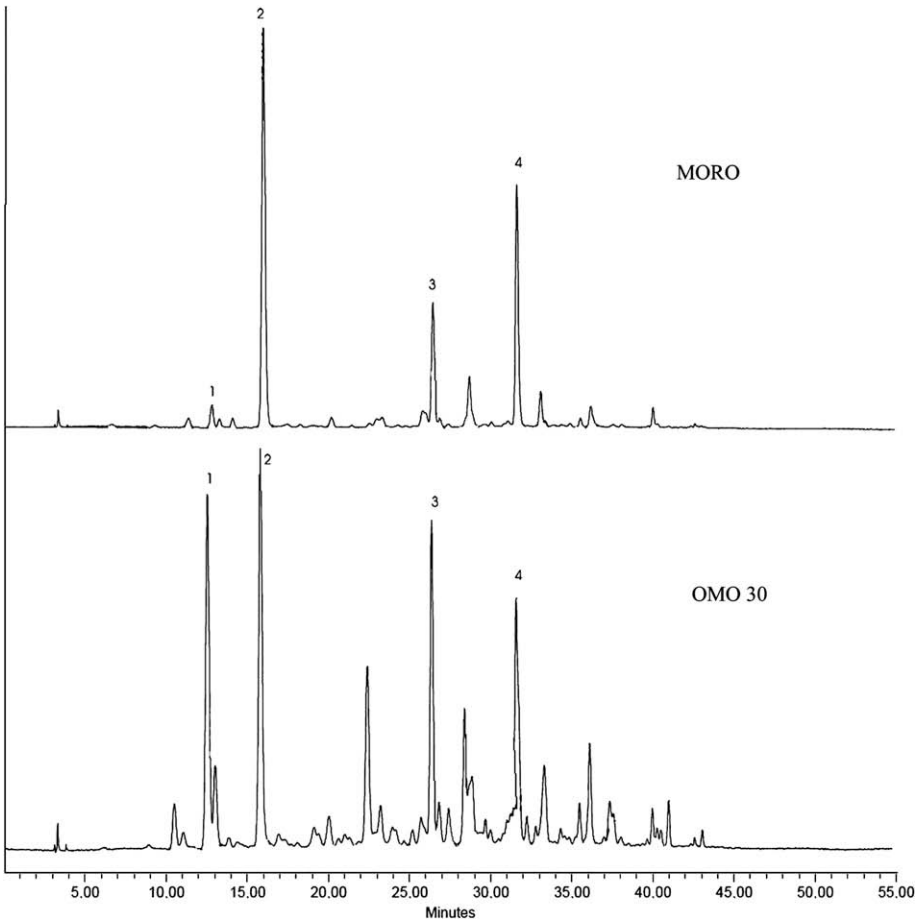

Fig. 1. HPLC chromatograms detected at 520 nm showing the anthocyanins present in Moro and OMO fruit juices. Peaks: 1, delphinidin 3-glucoside; 2, cyanidin 3-glucoside; 3, delphinidin 3-(6″malonyl)-glucoside; 4, cyanidin 3-(6″malonyl)-glucoside. Detector was set at 520 nm.

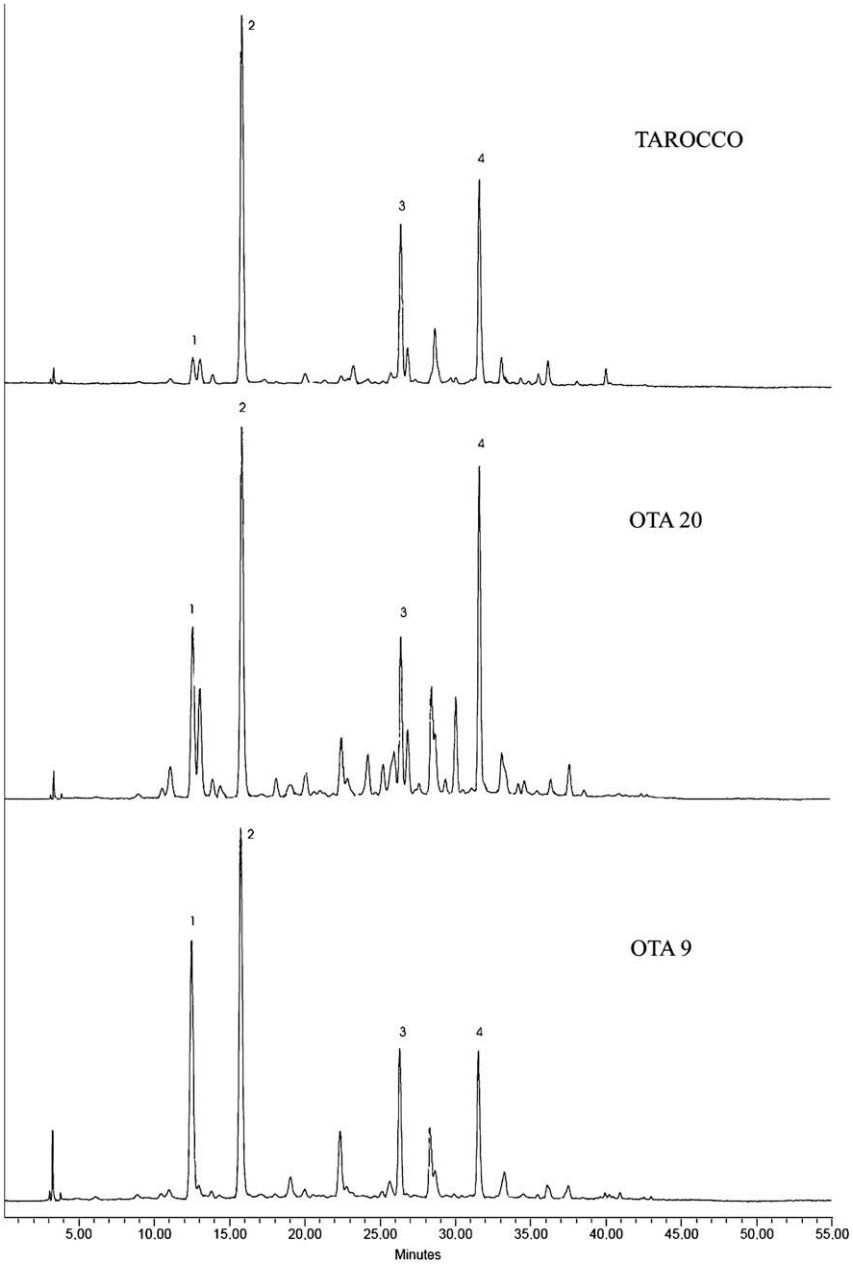

Fig. 2. HPLC chromatograms detected at 520 nm showing the anthocyanins present in Tarocco and OTA fruit juices. Peaks: 1, delphinidin 3-glucoside; 2, cyanidin 3-glucoside; 3, delphinidin 3-(6″malonyl)-glucoside; 4, cyanidin 3-(6″malonyl)-glucoside. Detector was set at 520 nm.

activity for the pigmented hybrid group was highly significant ($r^2 = 0.99$, $p \leqslant 0.001$ and $n = 9$). A high positive correlation was also found between ORAC and total phenolics ($r^2 = 0.98$, $p \leqslant 0.001$ and $n = 9$), flavanones ($r^2 = 0.96$, $p \leqslant 0.001$ and $n = 9$) and hydroxycinnamic acids ($r^2 = 0.85$, $p \leqslant 0.001$ and $n = 9$) in the pigmented hybrid group. Only a weak correlation was observed between flavanones and ORAC in the non-pigmented hybrids group ($r^2 = 0.42$, $p \leqslant 0.05$ and $n = 12$).

The OTA 9 and OTA 20 hybrids demonstrated significant activity in the InLAP assay, with respect to clementine and Tarocco parents. The formation of a conjugated diene at 234 nm was inhibited approximately 88% and 81% by the OTA 9 and OTA 20 juices. The InLAP values obtained for the other hybrids within the OTA group, ranged from 66% to 71%. No relevant differences were noted for OMO hybrids with respect to the Moro orange, although their antioxidant activity was higher than that of the female parent. Moreover, significant correlations between InLAP and polyphenols, such as anthocyanins ($r^2 = 0.81$, $p \leqslant 0.01$ and $n = 9$), flavanones ($r^2 = 0.72$, $p \leqslant 0.05$ and $n = 9$) and total phenolics ($r^2 = 0.88$, $p \leqslant 0.001$ and $n = 9$) were observed in pigmented hybrids, whereas only a high correlation between InLAP and flavanones ($r^2 = 0.81$, $p \leqslant 0.001$ and $n = 12$) was found in non-pigmented fruit.

4. Discussion

Improvement of fruit quality and agronomic performance has been a major breeding objective in the citrus industry. Due to the suggestion by certain epidemiological studies that antioxidant consumption can positively influence health, breeders have recently shown greater interest in developing citrus fruit with higher antioxidant activity. For this goal, it is important to study the heritability of certain traits, such as the chemicals level that contrib-

utes to antioxidant activity. Therefore, the evaluation of vitamin C, phenolics and antioxidant activity are useful tools when the aim is to produce citrus fruit with high antioxidant potential.

In this study, we revealed that the progeny of clementine × blood oranges produced fruit with different sugar-acid ratios. The acid levels in OTA 8 and OTA 20 were very high and, thus, neither of these two hybrids was fit to eat as a dessert fruit.

The ascorbic acid content of most hybrids was higher than that of the female parent. Therefore, the introduction of orange parentage enhanced the vitamin C level in these hybrids. High contents of ascorbic acid were found in OTA 20 and OTA 31, with values that were about 16% and 25%, respectively, higher than the Tarocco orange. The balanced level of sugar and acid and the observed highest content of ascorbic acid, mark the OTA 31 fruit as both excellent for eating and a significant source of dietary vitamin C.

Blood orange anthocyanins have been associated with potentially beneficial effects on various diseases, attributed in part to their antioxidant activity (Maccarone et al., 1998). The anthocyanin content of the pigmented hybrids was very low with respect to that of their parents, with the exception of OTA 9, which demonstrated the highest total anthocyanin concentration observed. This result demonstrates that OTA 9 hybrid may be selected on the basis of its superiority in total anthocyanin content in the fruit and/or juice. In addition, since cyanidin 3-glucoside, the major anthocyanin present in the OTA 9 hybrid, has a stronger antioxidant activity than other common anthocyanins (Wang et al., 1997), consumption of OTA 9 fruit or juice might be useful for disease prevention and health promotion. Moreover, the isolated and purified anthocyanin extract from this hybrid could be used in the pharmaceutical industry.

The OTA 9 fruit also contains higher concentrations of flavanones and hydroxycinnamic acids than other hybrids and their parents. These components are of great interest as pharmaceutical agents in human health and nutrition (Benavente-Garcia, Castillo, Marin, Ortuño, & Del Rio, 1997; Silva, Borges, Guimarães, Lima, & Matos et al., 2000). As a result, their recovery from a plentiful source might be economically important.

Table 6
Antioxidant activity of OTA and OMO juices determined by ORAC and InLAP assays [a].

	Genotype	ORAC units[b]		InLAP (% In.)[c]	
OTA group	Clementine	1592.34	E	67.41	D
	Tarocco	3369.63	B	73.32	C
	OTA 8	1969.74	D	71.39	CD
	OTA 9	6688.65	A	88.51	A
	OTA 20	2953.08	C	81.56	B
	OTA 31	2016.03	D	71.25	CD
	OTA 43	1766.02	DE	66.28	D
OMO group	Clementine	1592.34	D	67.41	B
	Moro	4535.43	A	75.30	A
	OMO 24	2027.94	C	78.30	A
	OMO 30	2964.22	B	79.05	A

[a] Values in the same column for each genotype having different letters are significantly different ($p \leqslant 0.01$).
[b] ORAC units are expressed as μmol Trolox equivalents/100 ml.
[c] Percentage of linoleic acid enzymatic-degradation inhibition.

Recent research has demonstrated the possibility of recovering anthocyanins, flavanones and hydroxycinnamic acids from blood orange juice or citrus byproducts (Rapisarda et al., 2001) and using this extract as an antioxidant ingredient for dietary supplements. A standardised red (blood) orange extract (ROE) containing 3.1% anthocyanins, 2.07% hydroxycinnamic acids, 8.1% flavanones and 5.0% ascorbic acid has shown strong antioxidant activity *in vitro* and a photoprotective effect against UVB-induced skin erythema

in vivo (Bonina, Saija, Tomaino, Lo Cascio, & Rapisarda et al., 1998). In addition, ROE has been demonstrated to be capable of protecting DNA from UV-induced damage (Russo et al., 2002) and decreasing oxidative stress in diabetic patients (Bonina et al., 2002). Having the highest concentration of polyphenols, the OTA 9 juice represents a richer source of antioxidant compounds than blood orange juice; it could potentially be used as raw material to make functional food or pharmaceutical and cosmetic products.

In order to measure the antioxidant activity of different citrus genotypes, two methods were used: the ORAC and the InLAP assays. The former measures the antioxidant scavenging activity against peroxyl radical induced by AAPH, and the latter evaluates the ability to inhibit lipid peroxidation by antioxidants. ORAC assay represent a hydrogen atom transfer (HAT) reaction mechanism, which is most relevant to human biology (Prior et al., 2003). Induced linoleic acid peroxidation (InLAP) is an assay in which the hydrophilicity or lipophilicity of antioxidants plays an important role in the evaluation of antioxidant capacity. To comprehensively study different aspects of antioxidants in orange and hybrid juice samples, both kind of assays have been performed.

The radical-scavenging activities of flavonoids and phenolic acids have been extensively reviewed (Cao, Sofic, & Prior, 1997; Rice-Evans, Miller, & Paganda, 1996). It has been demonstrated that anthocyanins and other flavonoids have 2–6 times the antioxidant activity of common antioxidants, such as ascorbic acid, glutathione, etc. (Prior et al., 1998). Therefore, the hybrid juices containing anthocyanins and/or high levels of flavanones or hydroxycinnamic acids, such as OTA 9, OTA 20, and OMO 30, showed the highest antioxidant activity. The absence of correlation between ORAC and ascorbic acid values demonstrated that the contribution of vitamin C to the ORAC activity was relatively low. The same results were obtained by Wang et al. (1997) for orange juice and Prior et al. (1998) for *Vaccinium* species.

Regarding InLAP assay, data showed significant correlations between InLAP and flavonoids, such as flavanones and anthocyanins, probably due to the lipophilic characteristics of hesperidin, narirutin, and dydimin and to the ability of anthocyanins to accumulate within the water phase of the emulsion and, therefore, to maintain their antioxidant efficiency (Kähkönen & Heinonen, 2003). The results of this study demonstrate an increasing trend in the oxygen radical absorption capacity (ORAC) with increased total phenolic content of the different genotypes. The InLAP assay showed a similar trend, suggesting that the phenolic compounds were likely to be significant contributors to the antioxidant activity.

In conclusion, we have identified two new citrus hybrids, OTA 9 and OTA 31, as novel sources of polyphenolic complex and vitamin C, respectively. In addition, these hybrids have shown a high antioxidant activity, suggesting that their consumption could be useful in the prevention of diseases in which free radicals are involved. Finally, extracts of new citrus hybrids, such as OTA 9, might have potential application as an antioxidant ingredient in nutraceutical, pharmaceutical, or cosmetic products.

ABSTRACT

Cereals are an important source of sterols and stanols in the human diet. The present study underlines the effect of genotype and weather conditions in bread wheat, on total sterol and stanol content (TSS), agronomic traits, proteins and ash content under organic conditions. Variations in TSS as well as other characters between two sowing dates were observed. A broad genotypic variability was also reported since extreme genotypes differed by more than 30 mg 100 g^{-1} DW for TSS, with total stanol content varying twofold. Moreover, two groups of genotypes that differed in agronomic production, ash and protein content were depicted, based on their response to an increase in temperature. This result suggests that the genotypic factor prevails over the sowing date factor for determining sterol and stanol traits in wheat cultivated under organic conditions. Nevertheless, a strong interaction exists between the two factors, which can be used to drive bioaccumulation of these molecules.

1. Introduction

Cereal grains contain a wide variety of nutrients and bioactive molecules that play an important role in disease prevention (Halvorsen et al., 2002). Among these molecules, much attention has been focused on phytosterols in the last few years. As minor constituents of lipids, they constitute a group of cholesterol-like molecules and are characterised by the presence of a methyl or ethyl group at carbon 24 of the basic cholesterol chemical structure (Moreau, Whitaker, & Hicks, 2002). Phytosterols occur in plants as free sterols and conjugated forms (Piironen, Lindsay, Miettinen, Toivo, & Lampi, 2000). They are key compounds for the formation of plant plasma membrane microdomains (Roche et al., 2008). These molecules play an essential role in the regulation of membrane fluidity and permeability by affecting the proteins associated to membranes. Moreover, they are precursors of brassinosteroids and are involved in embryogenesis (Schaller, 2003).

Phytosterols have been described as cancer-preventive bioactive molecules and have an immuno-modulating activity (Bouic, 2001). However, the most important property of phytosterols is their beneficial effect in reducing the low density lipoprotein (LDL) cholesterol level (Calpe-Berdiel, Escolà-Gil, & Blanco-Vaca, 2009). According to Valsta et al. (2004), even if the sterol level in cereals is lower than that of oilseeds, cereals remain the major source of natural sterols in the human diet due to the large amounts consumed daily. A comparison between sterol content in cereals was performed by Piironen, Toivo, and Lampi (2002). It appears clearly that rye, wheat and barley grains exhibit the highest sterol–stanol content whereas oat presented the lowest level of these same compounds. Moreover, wheat is one of the most important food crops and is grown worldwide.

Phytosterols in cereals are present in two forms: sterols and their completely saturated forms, stanols. This fact has oriented clinical experiments to focus on stanol versus sterol efficiency in reducing LDL cholesterol, and it seems that stanols are more efficient (Santos et al., 2007).

Several authors have studied the total phytosterol content in grains of different cereals (Moreau, Singh, Nunez, & Hicks, 2000) and in cereal by-products (Hakala et al., 2002; Jiang & Wang, 2005; Nyström, Paasonen, Lampi, & Piironen, 2007). However, in these studies, sterol content was measured on commercial samples, which considerably limits source traceability. Other experiments have been carried out to study sterol and stanol levels in

oat (Määttä et al., 1999), rye (Piironen et al., 2002; Zangenberg, Boskov Hansen, Jorgensen, & Hellgren, 2004), corn (Harrabi et al., 2008) and bamboo (Lu, Ren, Zhang, & Gong, 2009) across locations as influenced by genotype under conventional conditions. However, information on the effects of genotype and environmental conditions on the stanol and sterol composition of wheat is lacking. Moreover, the effect of water deficit or high temperatures on technological traits as sterols content and protein content was studied under conventional conditions where pests and diseases were managed by chemicals (Dupont et al., 2006; Määttä et al., 1999; Zangenberg et al., 2004). In contrast, organic culture, conducted without chemicals, can be considered as stress for plants. Thus, this agricultural method may influence molecules composition in wheat grain.

Phytosterols used in industrial preparations are chemically extracted from oil plants, and phytostanols are obtained by hydrogenation of sterols (Mouloungui, Roche, & Bouniols, 2006), often by using harsh chemical methods that are not always in accordance with European Union recommendations and REACH legislation. It has in fact been recommended to decrease different inputs, particularly chemicals, in agriculture, and to develop environmentally-friendly production and extraction methods. This latter goal could be easily reached by the improvement of sterol thresholds in plant organs.

The objectives of this work were therefore to study the genotypic variability of phytosterols and phytostanols in bread wheat cultivated under organic conditions and to examine the effect of weather conditions during grain filling on target compound content in the kernel. Relationships between sterols–stanols and protein and ash content, which are the most important quality traits, are also examined.

2. Materials and methods

2.1. Plant material

Twenty bread wheat (*Triticum aestivum* L.) cultivars varying in yield potential and technological traits were used in this study, as well as three other synthetic populations currently used in organic culture in France. The details of genotype characteristics are presented in Table 1.

Table 1
Cultivars of bread wheat used in this study.

Cultivar	Origin	Type of genotype
Apache	France	Improved variety

Bulk 2[a]	France	Synthetic population
Bulk 3[a]	France	Synthetic population

[a] Bulks 1, 2 and 3 are synthetic populations currently used in organic agriculture in south-west France.

2.2. Crop management and experimental conditions

Trials were carried out at the Regional Organic Agriculture Experimental Station in Auch (near Toulouse, south-west France, 43°38′47″ N, 0°35′08″ E). Two sowing dates were chosen. The first sowing was done on 24 November 2005. The second sowing was performed on 15 January 2006.

The crops were completely managed under organic and rainfed conditions without any chemical supply. Crushed feathers were applied as an organic fertiliser at a rate of 60 units ha^{-1} in April and May for the conventional (SD1) and later (SD2) sowings, respectively. Weeds were mechanically eliminated.

The soil was a clay-loam (organic matter content: 3.2%; pH 8.1) with a depth of about 1.2 m. Table 2 shows the temperature and rainfall during the plant cycle. The growing season was characterised by a total rainfall of 405 and 385 mm for SD1 and SD2, respectively. These amounts are 110 and 50 mm lower than the half-century average rainfall observed for the same period in our area. In contrast, temperature during the grain filling period was 18.4 and 22.4 °C in SD1 and SD2, respectively. These temperatures were at least 2 °C higher than the observed average temperature during the 50 past years in our region. It is clear that the grain filling period in SD2 coincided with higher temperatures and lower water availability.

The field experiments were conducted as a randomised complete block design with three replicates. Seeds were sown in 22.5 m^2 plots with seven rows per plot (20 cm between rows and 3 cm between plants). Anthesis occurred from beginning to mid-May and from mid-May to end-May for SD1 and SD2, respectively. Maturity took place at the end of June for SD1 and the first week of July for SD2.

2.3. Trait measurements

2.3.1. Agronomic measurements

The number of grains per ear was noted at maturity on ten ears (randomly selected) per plot. Plants were therefore separately harvested by plot in each block. The grain yield was determined by weighing and expressed in tonnes ha^{-1}. Two samples of 1000 grains were taken and then weighed in order to determine the 1000 grains weight of each genotype in each plot. Two aliquots, each of 10 g, were sampled in order to analyse protein and sterol–stanol content separately.

2.3.2. Sterol–stanol, protein, ash and moisture determination

The method of sterol determination was adapted from the one performed by Toivo, Lampi, Aalto, and Piironen (2000). Wheat samples (1.3 g) were added to each tube containing 100 μg of cholestanol (dihydrocholesterol; Aldrich Chemicals Co.), used as an internal standard. Saponification was performed by adding ethanolic KOH (1 M) (TITRINORM, Prolabo) for 60 min at 75 °C. One millilitre of distilled water was added to the samples and the unsaponifiable fraction was extracted from the saponified lipids with 6 ml of *iso*-hexane (Merck). Sterols and stanols were silylated by *N*-methyl-*N*-trimethylsilyl-heptafluorobutyramide (MSHFBA; Macherey-Nagel) mixed with 1-methyl imidazole (Sigma). One microlitre of sterol and stanol trimethylsilyl ether derivatives were injected into a Perkin–Elmer GC equipped with a CPSIL 5CB 30 m column (i.d.: 0.25 mm), and an on-column injector. Detection was performed with a flame ionisation detector. The thermal regime was the following: 160 °C (0.5 min), 10 °C min^{-1} to 260 °C,

Table 2
Prevailing weather conditions during the plant cycle at two different sowing dates (conventional (SD1) and late (SD2) sowings) in Auch (south-west France, near Toulouse). Comparisons are made with the half-century average values of precipitation and temperatures in the same location.

Phenological period	Weather parameter	2005–2006		Last 50 years	
		SD1	SD2	SD1	SD2
Grain filling	Rainfall (mm)	95.8	78.0	112.9	81.0
	Mean temperature (°C)	18.4	22.4	16.7	19.7
	Temperature sum (°C/day)	1120.2	1369.7	1014.7	1203.8
Plant cycle	Rainfall (mm)	405.0	385.4	515.0	434.1
	Mean temperature (°C)	9.9	13.3	11.3	12.4
	Temperature sum (°C/day)	2398.7	2922.4	2452.9	2839.7

2.5 °C min^{-1} to 300 °C, 25 °C min^{-1} to 350 °C, and 350 °C (1.5 min) for the oven temperature; 55 °C (0.5 min), 200 °C min^{-1} to 320 °C, 30 °C min^{-1} to 350 °C, and 350 °C (2.5 min) for the injector temperature; and 365 °C for the detector temperature. Total phytosterols and phytostanols detected included desmethylsterols (β-sitosterol, stigmasterol, campesterol, Δ-7 stigmastenol, Δ-7 avenasterol), campestanol and sitostanol. A typical GC chromatogram of the compounds analysed is shown in Fig. 1.

Grain protein content was determined by NIRS (AACC method 39-11, American Association of Cereal Chemists, 2000).

The moisture content of the samples was determined by drying them (5.0 g) at 105 ± 2 °C overnight. Ash content (expressed in mg g^{-1} dry weight) was determined after complete combustion of the powder aliquot in a muffle furnace at 900 °C and subsequent weighing of the residue. Each sample was analysed at least three times.

2.3.3. Statistical analyses

All the data were subjected to variance analysis using the GLM procedure of SAS (SAS Institute, 1987, Cary, NC, USA). Since genotypes were different in terms of flowering, there were differences for the number of days from sowing to heading. This trait was therefore taken as a covariate in an ANOVA and adjusted means were generated to overcome the effect of flowering date on other traits. The mean pairwise comparisons were based on the means test at 0.5% probability level. Correlation analysis was performed to determine the relationships between the traits using the SAS CORR procedure.

3. Results

3.1. Effect of genotype on sterol–stanol, protein and ash content in grain

In the collection studied, total sterols consisted of 21.3% stanols and 78.7% sterols, where the mean value of sterols + stanols was 65.6 mg 100 g^{-1} DW. The most abundant sterol was β-sitosterol, which represented nearly 70% of the total sterols and more than half of the sterols + stanols. Campestanol and sitostanol represented nearly one-third and two-third of the total stanol content, respectively (Table 3).

Significant differences were observed among the studied genotypes for sterol–stanol level and for both protein and ash content (Table 3). Total sterol (sterols and stanols, TSS) content varied between 49.4 (Bulk 3) and 79.6 mg 100 g^{-1} DW (Caphorn). The largest genotypic difference was observed for stanols since values varied twofold between Orpic (highest value, richer one) and Palladio (lowest one, poorer one). From the point of view of relative value, the latter genotype was the poorest genotype in terms of stanols compared to TSS, whereas stanols represented more than a quarter of TSS in the case of Kalongo. There were significant differences among bread wheat genotypes in our collection for each sterol and stanol. Caphorn, which showed the highest value of TSS, was the richest genotype in sterols, whereas Apache and ORP, the two other richest genotypes in TSS, exhibited the highest values in stanols. In contrast, PR22, the poorest cultivar in TSS, presented the lowest value of sterols.

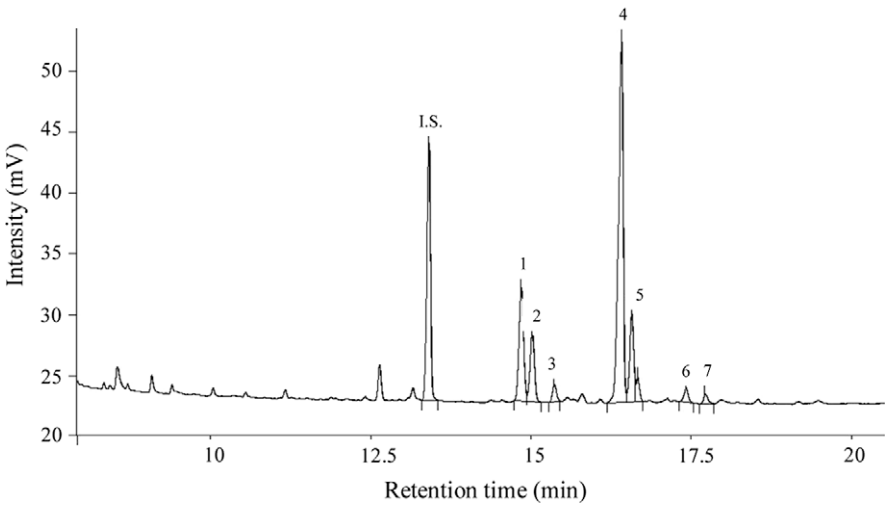

Fig. 1. A typical GC chromatogram of sterols and stanols found in bread wheat kernel. I.S. (internal standard) cholestanol, (1) campesterol, (2) campestanol, (3) stigmasterol, (4) β-sitosterol, (5) stigmastanol, (6) Δ-7 stigmastenol, (7) Δ-7 avenasterol.

Table 3
Sterol and stanol content (mg 100 g^{-1} DW), grain protein content (%), ash content (mg g^{-1} DW) grain yield (tonnes ha^{-1}), number of grains per spike (NGS), and 1000 grains weight (TGW, g) of 23 genotypes of bread wheat grown under rainfed conditions in Auch (south-west France) at two sowing dates (conventional (SD1) and late (SD2)).

Values presented are mean (across genotypes) and standard error (SE) values. Means indicated by a different letter are significantly different ($P \leqslant 0.05$). LSD: least significant difference. For each trait, *F*-value and degrees of freedom (df) of the genotype, sowing date and their interactions (G × SD), as well as the covariate effect of the number of days from sowing to heading (DH), are also displayed. ** and *** significance at 0.01 and 0.001 probability levels, respectively. ns: not significant. C/SSr: ratio of campesterol to stigmasterol + β-sitosterol; C/Sn: ratio of campestanol to sitostanol.

A wide variability was observed among the studied genotype for ash content. This trait varied from 19.7 (Pactole) to 60.0 mg g^{-1} DW (Quebon), with a mean value of 39.3 mg g^{-1} DW. Protein content varied less than sterol and ash content. Pollux contained nearly 3% more proteins than Aubusson, while Caphorn and Bulk 3, extreme genotypes for TSS, showed intermediate values for protein content.

3.2. Effect of sowing date on sterol–stanol, protein and ash content in grain

The objective of different sowing dates was to study the effect of the contrasting temperatures that occurred during grain filling. In this region, late sowing delays grain filling, which in turn coincides with high temperatures. Higher protein and ash content values were observed for later sowing.

Sowing date has shown a significant impact on sterol and stanol content in grain, except on stigmasterol, β-sitosterol, d_7-stigmasterol content and TSS. Two response patterns were depicted. The increase in temperature during grain filling (by sowing at the later date rather than the conventional date) improved the content for several sterols but did not significantly increase the most abundant one (i.e., β-sitosterol) and the total sterol level (Table 3). In contrast, and surprisingly, sitostanol, campestanol and total stanol content decreased when temperatures increased. Despite this, a strong increase of the campestanol/sitostanol ratio was observed for delayed sowing (Table 3). A significant increase of the ratio of campesterol to β-sitosterol + stigmasterol was observed in grain for late sowing (Table 3). The genotype by sowing date interaction was also significant for all traits (Table 3).

Two genotypic groups were different in response to high temperatures. A group made up of 18 genotypes reduced its TSS from the conventional (SD1) to the late sowing date (SD2) by more than 4.0 mg 100 g^{-1} DW, mainly due to the decrease in stanol content (Table 4). This group included Aubusson, Lona, Palladio, Quebon and the three bulk genotypes. In contrast, the second group composed of five genotypes (Fiorenzo, Kalongo, Orpic, Renan and Stefanus) increased TSS by nearly 13.0 mg 100 g^{-1} DW (2.1 mg 100 g^{-1} DW of stanols and 10.4 mg 100 g^{-1} DW of desmethylsterols) from SD1 to SD2 (Table 4). Moreover, the difference between SD1 and

Table 4
Mean values of sterol content, stanol content, grain protein content, ash content and agronomic traits of two groups contrasted for their response to delayed sowing. Group 1 consisted of five genotypes and Group 2 of 18 genotypes. The 23 genotypes of bread wheat were grown under rainfed conditions in Auch (south-west France) at two sowing dates (conventional (SD1) and late (SD2)).

Trait	Group 1			Group 2		
	SD1	SD2	LSD	SD1	SD2	LSD
Campesterol (mg 100 g^{-1} DW)	9.8^{B}	12.1^{A}	1.3	10.3^{A}	10.5^{A}	1.3

Grain yield (tonnes ha^{-1})	2.6^{A}	2.3^{A}	0.5	2.6^{A}	2.2^{B}	0.3

C/SSr: ratio of campesterol to stigmasterol + sitostanol; C/Sn: ratio of campestanol to β-sitosterol.

SD2 was more pronounced for the genotypes of the former group than for the group of the five genotypes for the agronomic traits (Table 4).

3.3. Effects of sowing date and genotypes on agronomic traits

Both sowing date and genotype effects significantly influenced agronomic traits. Interaction between the two factors was also significant for all traits (Table 3).

Plants sowed at the conventional date produced more grains by spike and filled those more than grains sowed later. Consequently, grain yield was higher for conventional compared to late sowing. Large and significant genotypic differences were observed within the collection studied for agronomic traits. Saturius produced three times more grain than Esperia. Grains of Renan were more than two times heavier than those of Orpic. PR22 yielded two times more than Pollux.

4. Discussion

4.1. Effects of genotype and sowing date on agronomic traits, protein and ash content

Differences were observed in agronomic traits, ash and protein content within the collection of genotypes studied (Table 3). Grain yield varied twofold between extreme genotypes. These differences resulted from the variability in yield components (Table 3). These results were expected since genotypic variability in agronomic traits had been widely reported in cereals (Asseng & Milroy, 2006; Merah, Deléens, Souyris, & Monneveux, 2001; Xu, Yuan, Li, & Monneveux, 2007). Similarly, protein and ash content varied considerably among the studied genotypes (Table 3), confirming results of previous reports in several cereals (Ma et al., 2007; Merah et al., 2001; Roussel, Branlard, Vezine, Bertrand, & Balfourier, 2005; Xu et al., 2007).

Significant differences were observed for all traits between the two sowing dates (Table 3). Late sowing induced a decrease in agronomic characteristics. This decrease is probably related to the difference in weather conditions between the two sowing dates, primarily during the grain filling period (Merah, Deléens, & Monneveux, 1999; Xu et al., 2007). It clearly appears that terminal drought and higher temperatures were more pronounced at the late sowing date (Table 2). This may explain the differences in grain yield between SD1 and SD2, resulting from the decrease in the number of grains per ear and the grain weight due to increasing stress (Asseng & Milroy, 2006; Spiertz et al., 2006).

The negative correlation between ash content and grain yield ($r = 0.50$, $P > 0.01$, df = 44) found in our study is in agreement with reports of Xu et al. (2007) and Merah et al. (2001, 1999). These reports suggest that minerals accumulate in grains by phloem transport rather than passively from the transpiration stream. Therefore, mineral accumulation in the grain primarily depends on translocation from the leaves and on minerals removed from the lower parts of the plant after the onset of senescence. As a consequence, genotypes that cannot maintain high rates of stomatal conductance and photosynthesis during grain filling would fill their grains through retranslocation of photoassimilates from preanthesis reserves, and of minerals from early senescent vegetative tissues (Merah et al., 2001). The ash concentration in grain could be an indication of the importance of the retranslocation processes during grain filling (Merah et al., 1999). These results suggest that grain ash content is higher in genotypes more affected by drought and higher temperatures during grain filling. Moreover, Xu et al. (2007) reported that higher temperatures, drought or both induced an increase of grain ash content, regardless of genotype tolerance.

Differences between SD1 and SD2 in grain protein content were also observed. This result means that variation in protein content was a consequence of agronomic practices (late sowing in this case) due to differences in weather conditions, for the same location and the same genotype. Previous studies have emphasised the increase of protein content in grain or in flour as a result of moisture stress (Saint-Pierre et al., 2008) and high temperatures (Asseng & Milroy, 2006; Dupont et al., 2006; Spiertz et al., 2006). It has been reported that higher temperatures as well as water stress during the grain filling period induces more of an increase in nitrogen accumulation than in dry weight accumulation, leading to higher protein content in grain (Asseng & Milroy, 2006; Dupont et al., 2006; Spiertz et al., 2006). In our study, the average temperature during grain filling was 4 °C higher for plants that were grown later than the conventional sowing date, in conjunction with low water availability (Table 2). As a consequence, plants sowed later accumulate less dry matter per grain but increase their protein content (Table 3). A 1000 grains weight was in fact 6 g lower in SD2 than in SD1, whereas the grain accumulated more proteins in late sowing than in conventional sowing (Table 3), thereby confirming previous reports. This is also supported by the negative correlation found between protein content and grain yield ($r = -0.71$, $P < 0.001$, df = 44).

4.2. Effects of genotype and sowing date on phytosterol and phytostanol content

In our study, the range of genotypic variation was from 49.4 to 79.6 mg 100 g^{-1} DW. This wide range of variation was similar to those reported for wheat grain in other studies. Piironen et al. (2002) reported a mean value of two wheat genotypes of 69.0 mg 100 g^{-1}. Analysis of whole grains of commercial samples revealed 78.3 mg 100 g^{-1} DW (Nyström et al., 2007). It is clear that the range of variation in total sterol level in bread wheat grain observed within our collection is similar to those reported in the few studies done on wheat grain. Nevertheless, our results cannot be compared to those observed elsewhere. There are several reasons for this discrepancy. The main studies dealing with sterol content in grain or other plant organs were done on commercial samples. These samples may come from bulk grains of several genotypes obtained from crops in different locations and under different climates, and information on growing conditions in these studies was inadequate. Moreover, our study was done under organic conditions that are considered to be stressed growing conditions and that probably influence the potential expression of the genotypes.

The second reason is the difference in analytical methodology for sterol analysis. In our study, we focused on sterols and steryl fatty acid esters, whereas Nyström et al. (2007) and Piironen et al. (2002) also assessed conjugated forms. In spite of this difference, our values were similar to those of Piironen et al. (2002).

The third reason was that results reported in the different studies were expressed in lot of units and the comparison was therefore not possible. This fact has already been reported by Zangenberg et al. (2004). These authors, as well as Määttä et al. (1999), highlighted the influence of genotypes on sterol content in cereal grains, which could also partially explain the different values observed between our study and the other studies mentioned above.

The fourth reason was that the studies differed by the number and the genotypes used for the evaluation of sterol and stanol content. A large variation was observed for sterol and stanol content within the collection of bread wheat genotypes studied. Genotypic variation was reported for sterol content among seven oat cultivars (Määttä et al., 1999) and three rye cultivars (Zangenberg et al., 2004). Piironen et al. (2002) also reported differences in four cereals. In the latter study, the difference reported between the two

genotypes used was 5.0 mg 100 g^{-1} DW. This difference represents nearly a quarter of the observed genotypic range within our collection. For the other cereal species, genotypic ranges for TSS were quite lower than those observed in our study (Määttä et al., 1999; Piironen et al., 2002; Zangenberg et al., 2004). Even if the range of genotypic variation for stanol content was wider in our study, the mean reported value was quite equivalent to the values reported by Piironen et al. (2002) in wheat.

A difference was observed between the two sowing dates for campesterol. Surprisingly, sitostanol strongly decreased in later sowing, which in turn induced a reduction of stanol content in the grain. Consequently, TSS was lower in later sowing. In rye, a decrease of sitostanol was observed for three genotypes across years (Zangenberg et al., 2004). Unfortunately, climatic conditions were not recorded in this study and we can therefore not effectively compare our results to those obtained by Zangenberg et al. (2004).

In sunflower, high temperatures (late sowing) induce an increase of sterol content in the kernels (Roche, Bouniols, Mouloungui, Barranco, & Cerny, 2006; Valsta et al., 2004). Other studies have reported that variations in temperature may cause a difference in sterolic profiles, mostly for campesterol vs. stigmasterol + β-sitosterol (Hartmann, 1998; Schaller, 2003). In our study, we observed that the ratio of campesterol to stigmasterol + β-sitosterol (hereafter C/SSr) was not significantly different between SD1 and SD2. In contrast, the ratio of campestanol to sitostanol (hereafter referred to as C/Sn) strongly increased at the later sowing date (Table 3). This was due to the concomitant decrease of sitostanol with the slight reduction of campestanol in the grain from later sowing.

However, this is a general tendency and the two groups were differentiated on the basis of their response to higher temperatures. The first one (GRP1), made up of five genotypes, increased its TSS as a result of the increase in the stanol level and of desmethylsterols, in particular. In contrast, the second group (GRP2), composed of 18 genotypes, high temperatures led to a decrease of sterol and particularly stanol content (Table 4). Moreover, the genotypes of the former group had increased levels of mainly β-sitosterol and sitostanol from the conventional to the delayed sowing. These two components were the main molecules that were reduced by high temperatures in the second group. Sterols and stanols play an important role in membrane fluidity and permeability (Moreau et al., 2002; Schaller, 2003). Changes in the physical properties of membranes reflect variations in their composition resulting from alterations in metabolic processes. These processes are accompanied by an increase in the sterol-to-phospholipid ratio (Borochov & Woodson, 1989; Itzhaki, Borochov, & Mayak, 1990). Moreover, membrane fluidity is not only influenced by the level of sterols but also by the change in their composition (Moreau et al., 2002; Schaller, 2003). It seems that the increase in β-sitosterol content increases membrane fluidity, which in turn changes metabolic cell functioning. In contrast, the increase of campesterol content reduces the physical properties of the membrane, thus leading to increased fluidity. Variation in desmethylsterols (represented in our study by C/SSr) may result from the activity of sterol-methyl-transferase 2 (SMT2) (Schaeffer, Bronner, Benveniste, & Schaller, 2001). Interestingly, Schaller (2003) reported the importance of genotypic factor on this ratio, which is in accordance with our results (Tables 3 and 4). Moreover, our study emphasised the effect of temperature on C/SSr in grain, confirming previous reports on *Arabidopsis* (Schaeffer et al., 2001). Delayed sowing coincided with high temperatures during grain filling (Table 2). These conditions induced an increase in β-sitosterol and sitostanol from conventional to delayed sowing in GRP1. A decrease of these sterols and stanols was observed for GRP2 with high temperatures (Table 4). In addition, the C/SSr ratio as well as the C/Sn ratio remained fairly constant in the former group, whereas these ratios increased for GRP2 due to the decrease of β-sitosterol and sitostanol (Table 4).

In our study, different responses to high temperatures of the two groups of genotypes for agronomic traits were found. Grain yield and its component decreased with high temperature. This decrease was more pronounced in GRP2 than in GRP1 (Table 4). Similarly, genotypes of GRP2 accumulated 1.5 times more minerals in their grains in SD2 than in SD1, whereas genotypes belonging to GRP1 maintained a constant ash content (Table 4). We hypothesised that the difference in tolerance of high temperature and water shortage exists between the two groups of genotypes. Among the numerous mechanisms involved in this expressed genotypic difference, there is a difference in the maintenance of membrane fluidity. This could be the result of an increase in sterol content, which induces the changes in the physical properties of membranes and may therefore cause alterations in cell functioning and plant development, depending on the timing of the alterations during the plant cycle (Borochov & Woodson, 1989; Itzhaki et al., 1990). Our results also suggest that the genotype effect was the main factor influencing sterol content.

No significant correlation was found between sterols and agronomic traits (data not shown). Sterol content was not related to protein content in our study ($r = 0.05$, df = 44). The relationship between sterol and protein content has not been studied in cereals. However, phytosterols are distributed in endosperm, germ and pericarp (Harrabi et al., 2008), while proteins are localised in the aleurone cell layer. This fact could explain the lack of correlation in the accumulation of the two compounds. In sunflower cultivated under different water availability conditions, no significant correlation was found between protein and sterol content in the grain (Roche, 2005). This result is very interesting. If confirmed, it would mean that improvement of both sterol and protein content is possible and may be easily feasible within a selection programme.

5. Conclusion

Wheat is among the major sources of sterols and stanols. A wide variability of sterol and stanol content exists in bread wheat cultivated under organic conditions. Although the main factor remained the genotype, our data revealed a strong interaction with weather conditions that could easily be managed to promote the accumulation of targeted sterols or stanols and to provide added value to the wheat grain. Sterol and stanol content seems to be independent from other technological traits and, therefore, may be easily improved without any negative interaction with other characters of interest. These results are interesting and should be studied under other climatic conditions and with other genotypes. Much attention is being focused on functional foods at this time. The accumulation of compounds of interest such as sterols in plants should facilitate their extraction by soft methods, ultimately benefiting the consumer.

Colour

ABSTRACT

The aim of this study was to determine the effects of extraction temperature on the colour as well as on the phenolic and parthenolide content of feverfew (*Tanacetum parthenium*) aqueous extracts, with a view to incorporating the extracts into a beverage. Results showed that extraction temperatures of 20–70 °C yielded dark-coloured extracts with low total phenol and a relatively high total tannin concentration. However, increasing the temperature to 75 °C produced lighter-coloured extracts with a significantly higher concentration of total phenols, lower total tannin fraction and maximum extraction of parthenolide. Higher extraction temperatures (80–100 °C) yielded suitably pale extracts rich in total phenols, but with progressively higher total tannin to non-tannin ratio and lower parthenolide content. The compromise temperature of 80 °C was found to provide extracts rich in parthenolide content, phenolic content and with a desirable colour, suitable for incorporation into a functional beverage.

1. Introduction

The utilisation of naturally-occurring bioactives as potential sources of functional food ingredients and, in particular, phytochemicals has increased in the recent years, because of their beneficial health effects. Consumer demand for health-related products, providing immune support, energy enhancement, healthy joint function and promoting overall well-being has led to the development of functional foods and beverages. One major success story in this regard is the use of beverages as dietary vehicles for phytosterols (Devaraj, Autret, & Jialal, 2006; Goncalves, Maria, Silva-Herdade, Silva, & Saldanha, 2007). The inclusion of these plant extracts in food products requires not only an optimum concentration of bioactives, but also a minimisation of the potential detrimental effect this inclusion could have on the taste and appearance of the food product. For example, the colour of the plant extract can impart an unfavourable green or brown hue to the final beverage, whilst the presence of large amounts of tannins could impart significant bitterness.

Phytochemical-rich plants have played a significant role in diet-based therapies to prevent and cure various ailments (Butt, Nazir, Sultan, & Schroen, 2008). Feverfew (*Tanacetum parthenium*), a medicinal herb commonly found throughout Europe, has a potential for use in functional foods. It has been used for years for the treatment of arthritis and migraine, due to its anti-inflammatory activity (Johnson, Kadam, Hylands, & Hylands, 1985; Williams, Harborne, Geiger, & Hoult, 1999). Feverfew has also been used for treating conditions like epilepsy, fever, stomach ache, toothache and insect bites (Jager, Gauguin, Adsersen, & Gudiksen, 2006; Jain & Kulkarni, 1999). Traditionally, feverfew leaves were used fresh, but preparations made from dried feverfew are more common today in the form of teas, tablets and capsules (Piela-Smith & Liu, 2001).

Pharmacological studies have shown that parthenolide is the main bioactive ingredient of feverfew, probably due to the presence of the α-methylene-γ-lactone ring and the epoxide group in this molecule (Bejar, 1996; Jain & Kulkarni, 1999; Kwok, Koh, Ndubuisi, Elofsson, & Crews, 2001; Macias, Galindo, Castelleno, & Valesco, 1999; Miglietta, Bozzo, Gabriel, & Bocca, 2004; Piela-Smith & Liu, 2001). The biological activity of feverfew is also due to its content of phenolic compounds, including apigenin, luteolin and tanetin (McVean, Xiao, Isobe, & Pelling, 2000; Pettit et al., 1996; Williams et al., 1999; Wu et al., 2006).

Several methods have been used to extract and quantify the bioactive compounds in feverfew. Solvent extraction and supercritical fluid extraction have been used for the extraction of sesquiterpene lactones (Kaplan, Simmonds, & Davidson, 2002) and bottle stirring, sonication and Soxhlet extraction have been used for the extraction of parthenolide (Fonseca, Rushing, Thomas, Riley, & Rajapakse, 2006; Zhou, Kou, & Stevenson, 1999). Wu et al. (2006) extracted parthenolide, luteolin, apigenin from feverfew in 80% alcohol.

Whilst these extraction methods have been carried out with the objective to obtain the maximum concentration of active

doi:10.1016/j.foodchem.2009.03.103

constituents, the use of organic solvents prohibits the subsequent use of these extracts in beverages. Moreover, there is little or no information in the literature on the aqueous extraction of feverfew with a view to obtaining extracts suitable for the manufacture of functional foods and beverages. Therefore, the objective of this study was to determine the effect of extraction temperature on the total phenol and parthenolide contents, and the colour of aqueous feverfew extracts, for incorporation into a beverage with anti-inflammatory properties.

2. Materials and methods

2.1. Plant material

Feverfew was organically grown and harvested in Roscommon, Ireland. On the day of harvest the aerial parts of feverfew were transferred to the laboratory and frozen at −20 °C. The frozen plant material was subsequently dried for 72 h using a freeze dryer (Edwards Super Modulyo, Davidson & Hardy Ltd., Dublin, Ireland). The dried samples were then ground into a moderately fine powder (180–355 μm) (WHO (World Health Organization), 1998) using a lab mill (Christy and Norris Ltd., Christy Turner, Ipswich, UK). The dried samples were placed in brown Kraft envelope bags (Paper Nature's Packaging, Ireland) and stored in polypropylene buckets containing silica gel. The buckets were then sealed and stored at ambient temperature. Previous studies in our laboratory have shown that these storage conditions resulted in no appreciable loss of phenolics or parthenolide during the duration of the present study (unpublished data).

2.2. Extraction

To prepare aqueous extracts, the dried feverfew powder (2.5% w/w) was put into distilled water, and heated at 20, 60, 70, 75, 80, 90 and 100 °C for 10 min using a stirring hot plate (Ika® Werke GmbH and Co., Staufen, Germany). The extracts were cooled in ice to <10 °C and filtered under vacuum using Whatman No. 1 filter paper with a micro pore size of 11 μm. All the filtrates were stored in sterile containers (Sarstedt, Nümbrecht, Germany) at −20 °C prior to analysis.

Extraction under vacuum at 20 °C was also performed. The dried plant material (2.5 g) was weighed into a conical flask covered with a nylon cloth and placed in a vacuum desiccator connected to a vacuum pump for 40 min. Extraction was carried out in 100 ml distilled and degassed water. The water was degassed for two hours using a sonication bath (Ultrawave Ltd., Cardiff, UK).

Additional filtration using Acrodisc® premium 25 mm syringe with 0.2 μm GHP (hydrophilic polypropylene) membrane (Pall Life Sciences, Portsmouth, UK) was used to prepare filtrates for HPLC analysis.

2.3. Colour determination of feverfew extracts

The colour of feverfew extracts was determined using a Chroma metre CR-300 (Minolta Ltd, Milton Keynes, UK). The Hunter Lab scale was used with L^*, a^* and b^* axes expressing the lightness, redness–greenness and blueness–yellowness, respectively. To determine the effects of extraction temperature on the colour of the extracts, the hue angle (h°) and chroma (C^*) were calculated according to McGuire (1992). Hue angle is defined as a colour wheel with red–purple at an angle of 0°, yellow at 90°, bluish-green at 180° and blue at 270°.

The absorbance of the extracts was also measured at 430 nm using a UV–Vis spectrophotometer (UV-1240, Shimadzu, Kyoto, Japan).

2.4. Quantification of the total phenolic content

The total phenolic content was analysed according to the Folin–Ciocalteu method (Singleton & Rossi, 1965). A standard curve was prepared using gallic acid (Reagent grade; Sigma–Aldrich, St Louis, MO) of known concentrations (0–350 mg/l). The standards (0.2 ml) or feverfew extracts were mixed with 0.5 ml Folin–Ciocalteu reagent (Reagent grade, Merck, Darmstadt, Germany), 1.5 ml of 20% sodium carbonate (Reagent grade, Merck) and 7.8 ml of distilled water and allowed to stand for 2 h. Absorbance was measured at 760 nm using a UV–Vis spectrophotometer (UV-1240, Shimadzu). The total phenolic content of the extract was calculated as mg of gallic acid equivalents (GAE)/g of dry weight (d.b.) of the feverfew powder.

2.5. Separation of total tannin and non-tannin fraction

The total tannin (condensed and hydrolysable tannins) and non-tannin (flavonoids and simple phenols) fraction were separated according to the cinchonine precipitation method of Peri and Pompei (1971). The extract (1 ml) was mixed with 1 ml of 0.5% cinchonine hemisulfate (Reagent grade, Sigma–Aldrich) and placed in a 2 ml micro-centrifuge tube. The tubes were shaken well and centrifuged in a micro-centrifuge (Davidson & Hardy Ltd.) at 5668*g* for 5 min. The supernatant representing the non-tannin fraction was analysed using the Folin–Ciocalteu procedure. The total tannin fraction was determined by difference.

2.6. Separation and quantification of parthenolide

The extracts were analysed using a system comprising a P4000 pump, an AS3000 autosampler and a UV2000 ultraviolet detector (Thermo-Separation products, San Jose, CA) as described by Zhou et al. (1999) by HPLC. Reversed-phase chromatography was performed using a Phenomenex Luna C_{18} column (150 × 4.6 mm i.d., 5 μm), mobile phase of acetonitrile (HPLC grade, Sigma–Aldrich): water (55:45 v/v), flow rate of 2 ml/min and UV detection at 210 nm. The injection volume was 20 μl.

2.7. Coomassie protein assay

Coomassie dye was prepared by dissolving 100 mg of Coomassie Brilliant Blue G-250 (Reagent grade, Sigma–Aldrich) in 50 ml of 95% ethanol (Reagent grade, Sigma–Aldrich). The solution was added to 100 ml of phosphoric acid (85%) (Reagent grade, Sigma–Aldrich) and diluted to 200 ml with distilled water. This stock solution was stored in a dark bottle at 4 °C. The assay reagent was prepared with 25% (v/v) of dye stock in distilled water.

The protein assay was carried out according to the dye-binding method of Boyes, Strubi, and Dawes (1997).

2.8. Determination of polyphenol oxidase (PPO) activity

An aliquot of feverfew powder (2.5 g) was extracted in 100 ml of 0.02 M phosphate buffer (pH 6.8) at ambient temperature for 10 min. The extract was filtered through a Whatman filter paper No. 1 and incubated in a water bath at different temperatures (30–100 °C) for 10 min each. The extracts were cooled on ice prior to analysis. PPO activity was determined according to the method of Wakayama (1995). Absorbance at 420 nm was measured with time using a UV–Vis spectrophotometer (UV 4, ATI Unicam Ltd., Cambridge, England). One unit of enzyme activity was defined as the amount of enzyme that caused an initial change in absorbance of 0.001 per minute.

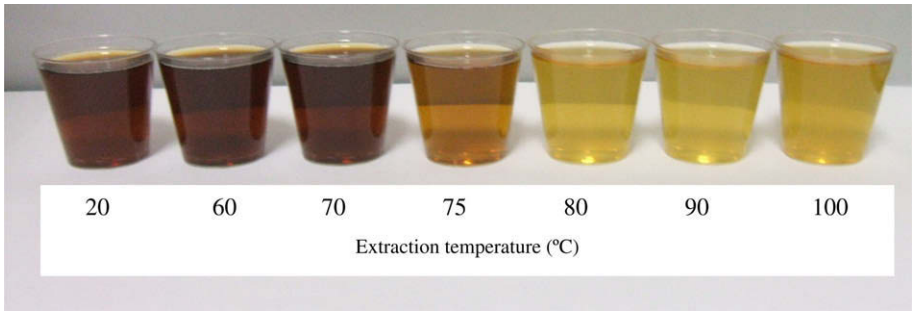

Fig. 1. Image of feverfew samples extracted in water at different temperatures.

2.9. Statistical analysis

Extraction at each temperature was carried out in triplicate and one measurement was carried out on each extract. Measurement of the PPO activity was carried out in triplicate. Statistical analysis was performed using SAS software (SAS Institute, Cary, NC) Version 9.1.3. Tukey pairwise comparison test was used for comparison of means. Mean values represented by the same letters were considered not significantly different at $p \geqslant 0.05$.

3. Results and discussion

3.1. Colour of feverfew extracts

Extraction of feverfew samples in distilled water at different temperatures yielded extracts with different colour intensities (Fig. 1). Generally, extraction temperature had a substantial effect on the lightness, chroma and hue angle of the extracts. The samples extracted at 20 to 70 °C had a brownish appearance with a hue angle of 348 ± 4°, chroma of 1 ± 0.1 and lightness of 49 ± 0.4, whereas samples extracted at higher temperatures of 80–100 °C were yellow in appearance with a hue angle of 55 ± 5°, chroma of 11 ± 3 and lightness of 57 ± 2 (Table 1). This dramatic change in colour with extraction temperature was unexpected, as herbal infusions extracted at higher temperatures usually contain more phenolic bioactives and are darker than those extracted at low temperatures. In order to determine the general chemical composition of the feverfew extracts, the concentration of total phenols, total tannin and non-tannin fractions and parthenolide were analysed.

Table 1
Hue angle, chroma and lightness of feverfew samples extracted at different temperatures in distilled water.

Extraction temperature (°C)	Hue angle ($h°$)	Chroma (C^*)	Lightness (L^*)
20	346 ± 3^{a}	1.0 ± 0.1^{c}	49.3 ± 0.3^{d}
60	351 ± 3^{a}	1.1 ± 0.1^{c}	49.1 ± 0.5^{d}
70	347 ± 3^{a}	1.2 ± 0.1^{c}	49.0 ± 0.6^{d}
75	20 ± 2^{c}	5 ± 2^{b}	51 ± 2^{cd}
80	56 ± 3^{b}	13 ± 2^{a}	59 ± 1^{a}
90	59 ± 6^{b}	13 ± 2^{a}	58 ± 3^{ab}
100	49 ± 3^{b}	8 ± 1^{b}	55 ± 1^{bc}

[a–d]Mean values ± standard deviations with the same letters within the same column are not significantly different at $p \geqslant 0.05$.

3.2. Total phenols, total tannins and non-tannins in feverfew extracts

The effect of extraction temperature on the total phenols is shown in Fig. 2. Results showed that extraction temperatures of 20 to 70 °C did not affect the total phenol content significantly ($p \geqslant 0.05$). An increase in temperature to 75 °C led to a significant increase in total phenols and further increasing the extraction temperature increased the total phenol concentration significantly, with the highest amount of 31 ± 1 mg/g GAE d.b. extracted at 100 °C. The effect of extraction temperature on the total tannin and non-tannin fractions is shown in Fig. 3. The total tannin fraction was not significantly affected by the extraction temperature, except for an increase at 100 °C. Extraction temperatures of 20–70 °C led to low non-tannin fractions, although increasing the temperature to 75 °C resulted in a significant increase. However, a further increase in temperature from 75 to 100 °C did not affect the non-tannin content. From these results it appears that the

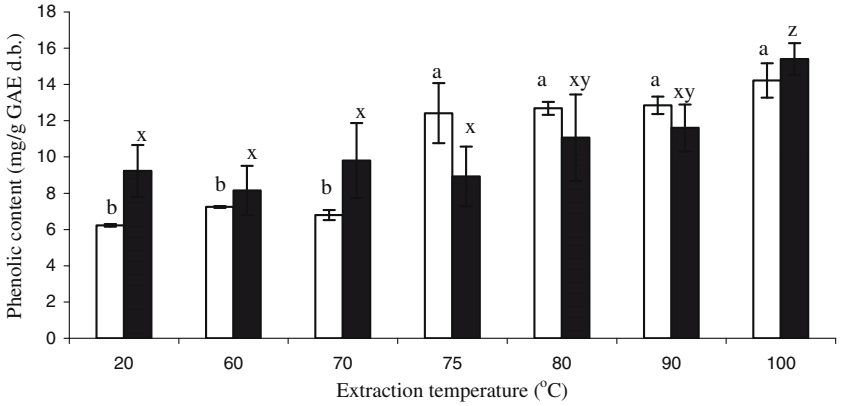

Fig. 3. Effect of extraction temperature on the total tannin (■) and non-tannin (□) fractions of aqueous feverfew extracts. Bars with the same letters (a–b, x–z) are not significantly different at $p \geqslant 0.05$.

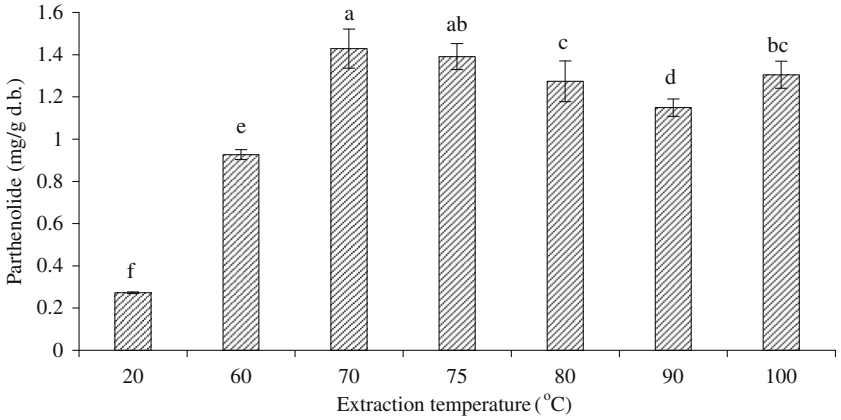

Fig. 4. Effect of extraction temperature on the parthenolide concentration in aqueous feverfew extracts. Bars with the same letters (a–f) are not significantly different at $p \geqslant 0.05$.

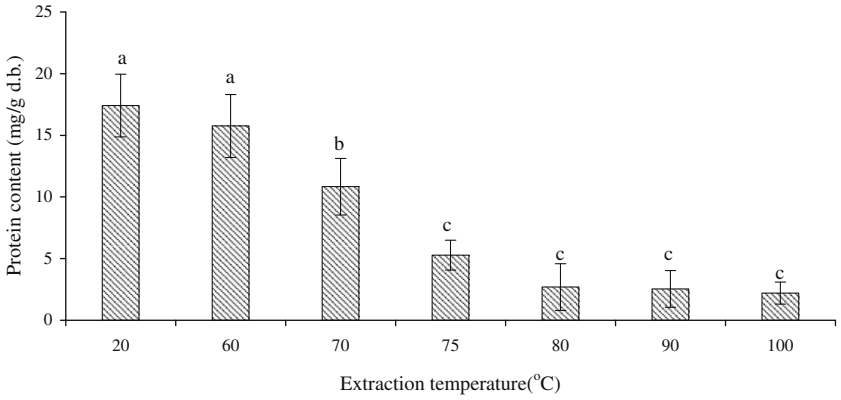

Fig. 5. Effect of extraction temperature on the protein content in aqueous feverfew extracts. Bars with the same letters (a–c) are not significantly different at $p \geqslant 0.05$.

significant increase in the total phenols content noticed at temperatures above 75 °C is due solely to an increase in the non-tannin fraction. But this significant increase in non-tannins at high temperatures could not explain the change in extract colour.

3.3. Parthenolide content in feverfew extracts

The effect of extraction temperature on the parthenolide content in aqueous feverfew extracts is shown in Fig. 4. Partheno-

Table 2
Evolution of absorbance at 430 nm on exposure to air for samples extracted *in vacuo* at 20 °C.

Time after extraction (min)	Abs at 430 nm
5	1.03
25	1.08
165	1.20
1440	1.52

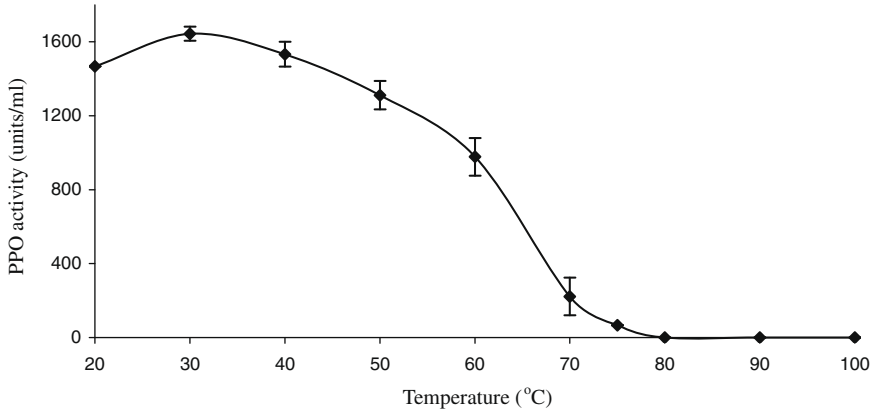

Fig. 6. Effect of temperature on the polyphenol oxidase activity in feverfew extracts.

lide concentration increased significantly with increasing extraction temperature from 20 to 70 °C. There was no significant difference ($p \geqslant 0.05$) in the amount of parthenolide extracted at 70 or 75 °C, but a slight decrease in the parthenolide content was observed with increasing extraction temperature above 75 °C. These results indicate that temperature had a significant effect on the recovery of parthenolide from the plant material. As reported by Smith and Burford (1992) parthenolide is present in the plant matrix at different sites, some of which can be readily extracted whilst others are tightly bound. Therefore, the increase in temperature may have influenced the release of the tightly bound parthenolide. However, the decrease in parthenolide content above 75 °C could be due to slight thermal degradation. This is in agreement with the results of Cretnik, Skerget, and Knez (2005) on the degradation of parthenolide at 80 °C.

3.4. Protein content in feverfew extracts

As some proteins are known to form complexes with phenolic compounds, the amount of protein in the extracts was measured using the Coomassie Blue assay. The effect of extraction temperature on the protein content in the feverfew extracts is shown in Fig. 5. At low extraction temperatures (below 70 °C), the amount of protein was found to be high (17.4 ± 3.0 mg/g d.b.) and four times higher than that found in the high temperature extracts (75–100 °C). These results showed that there is a relationship between the protein content and the colour of the extracts. At extraction temperatures of 20–70 °C when the extracts are brownish, the protein content is relatively high. Temperatures of and above 75 °C produce yellowish extracts with low amounts of protein. Quinones either extracted from the plant material or formed through oxidation of polyphenols are known to bind to proteins and may give brown pigments, which are observed at lower extraction temperatures. At higher temperatures, when the proteins and oxidising enzymes are denatured, the extracts are light-coloured. In order to examine this last hypothesis, the polyphenol oxidase activity of the extract prepared was measured. An extraction *in vacuo* at room temperature was performed first to determine if the quinones are present in the extract ab initio or are formed by the enzymatic oxidation of some phenols.

3.5. PPO activity

The feverfew sample extracted under vacuum at 20 °C yielded a significantly ($p \leqslant 0.05$) higher amount of phenols (23.5 ± 0.4 mg/g GAE d.b.), compared to the samples extracted in the presence of air. This extract was also significantly lighter in colour than the low temperature extracts prepared in presence of air, indicating that the quinones more than likely arise from enzymatic oxidation of phenols. Browning of this extract was measured spectrometrically at 430 nm (Table 2). Absorbance at 5 min (1.03) was low and the same as the absorbance of the samples extracted at 90–100 °C. The extract then progressively browns over time, increasing in absorbance to 1.52 after 24 h, comparable to that of samples extracted at 20 °C in the presence of air. The slow browning of this extract could be due to the slow oxidation of phenols to quinones, which then react irreversibly with protein, forming brown pigments (Harborne, 1984). In order to validate this hypothesis of enzymatic browning, the samples extracted at 20 °C in 0.02 M phosphate buffer (pH 6.8) were incubated at different temperatures (30–100 °C) and polyphenol oxidase (PPO) activity measured using catechol as the substrate. The effect of temperature on the PPO activity is shown in Fig. 6. The highest activity of PPO (1644 ± 38 units/ml) was exhibited at 30 °C. Increasing the temperature from 40 °C to 75 °C decreased the PPO activity from 1533 to 67 units/ml. No activity was detected in the samples extracted at 80–100 °C, probably due to temperature denaturation and inactivation of the enzyme. This agrees with the denaturation temperature (near 70 °C) of PPO in litchi pericarp reported by Liu et al. (2007).

4. Conclusion

The results obtained in this study demonstrate a strong relationship between the amount of total phenols, total tannins, non-tannins and the colour of the extracts at different extraction temperature as a result of PPO activity. At temperatures of 70 °C or below, when the PPO is enzymatically active, the oxidation of some non-tannin phenolics resulted in brown extracts with significantly lower amounts of total phenols. Inactivating the PPO at temperatures above 70 °C resulted in lightly coloured extracts with a higher total phenol content. The highest concentration of parthenolide was extracted at 70–75 °C. Feverfew extracts prepared at 80 °C were rich in parthenolide and phenolics, and had a desirable colour. These extracts may therefore be promising sources of natural ingredients for incorporation into a beverage with anti-inflammatory properties.

Proteomic analysis

ABSTRACT

Artemisia annua was enzymatically hydrolyzed by five proteases and seven carbohydrases. All enzymatic extracts scavenged DPPH, hydroxyl and alkyl radicals. Especially, the Protamex among the various proteases and Maltogenase among the various carbohydrases extracts exhibited the highest scavenging activity on hydroxyl radical. The extracts of *A. annua* clearly reduced neuronal cell death from H_2O_2-induced damage. In addition, a proteomic analysis, two-dimensional electrophoresis (2-DE) and matrix assisted laser desorption ionisation-time of flight/time of flight (MALDI-TOF/TOF) was used to identify the proteins of the neuronal cells whose expressions were or were not altered by the treatment of the Maltogenase extracts which showed the highest hydroxyl radical scavenging activity among all enzymatic extracts for 24 h. The protein characterisation revealed that translation elongation factor Tu (EF-Tu), Immunoglobulin E (IgE) and voltage-dependent anion channel 1 (VDAC-1) were involved in the cell survival effects against H_2O_2-induced apoptosis. These results suggest that EF-Tu, IgE and VDAC-1 have an important role in the reduction of neuronal apoptosis by oxidative stress, and the enzymatic extracts of *A. annua* shows potent antioxidative activities by regulating EF-Tu, IgE and VDAC-1.

1. Introduction

It has been reported that there is an inverse relationship between the antioxidative status and the occurrence of human diseases (Delanty & Dichter, 2000; Je, Park, & Kim, 2004). In addition, antioxidant compounds can be isolated and then used for the prevention and treatment of free radical-related disorders (Middleton, Kandaswami, & Theoharides, 2000; Packer, Rimbach, & Virgili, 1999). Therefore, research for identifying antioxidant compounds is an important issue.

Proteomic analysis using 2-DE and MALDI-TOF is a very useful tool for examining protein changes comprehensively before and after drug treatments. Recently, some researches examined the cytotoxic effect of xanthoangelol on drug-resistant neuroblastoma, and induction of apoptosis of the tumour cells, and also investigated the mechanism of this xanthoangelol-induced apoptosis in neuroblastoma using proteomic analysis (Motani et al., 2008).

Artemisia annua (sweet or annual wormwood, family Asteraceae) is an annual herb endemic to the northern parts of Chahar and Suiyuan provinces in China where it is known as 'quinghao' (green herb), and has been used to treat chills and fever for more than 2000 years (Klayman, 1985). During the past 30 years or so after its discovery in China in the early 1970s, artemisinin, which is a derivation of *A. annua,* has been widely promoted as a component of artemisinin combination therapies for treating drug-resistant malaria (Duffy & Mutabingwa, 2004; Woodrow, Haynes, & Krishna, 2005). Furthermore, artemisinin produces rapid parasite clearance, which is significantly faster than that of any other antimalarial drugs (Sriram, Rao, Chandrasekhara, & Yogeeswari, 2004).

However, while literature on the chemistry of *A. annua* and clinical trials reporting its effects are vast, research into the antioxidant effects of *A. annua* is scarce, or even non-existent. Thus, the present study aimed to investigate the free radical scavenging activities of enzymatic extracts from *A. annua* by ESR spectroscopy and their possible protective effects on cells against oxidative stress.

2. Materials and methods

2.1. Materials

Propidium iodide (PI), 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO), 2,2-azobis(2-amidinopropane) hydrochloride (AAPH),

2,2-diphenyl-1-picrylhydrazyl (DPPH) and (4-pyridyl-1-oxide)-*N*-tert-butylnitrone (4-POBN) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). RNase A, pBR 322 DNA and Tween-20 were purchased from Novagen Inc. (Darmstadt, Germany), Takara Biomedicals (Tokyo, Japan) and USB Co. (Cleveland, OH, USA), respectively. DMEM (Dulbecco's Modified Eagle Medium), Trypsin–EDTA (ethylenediaminetetraacetic acid), penicillin/streptomycin and certified foetal bovine serum were supplied by Invitrogen Co. (Carlsbad, CA, USA). The seven carbohydrases including Promozyme, Celluclast 1.5L FG, Maltogenase L, Viscozyme L, Termamyl SC, Dextrozyme E and AMG 300L, and the five proteases including Protamex, Flavourzyme 500 MG, Neutrase 0.8L, Pancreatic Trypsin Novo, Alcalase 2.4L FG were obtained from Novozyme (Novozyme Nordisk, Bagsvaerd, Denmark). Triton X-100 and MW electrophoresis calibration kits were purchased from Amersham-Pharmacia (Piscataway, NJ, USA). All of the chemicals used for 2-DE and MS were purchased from either BioRad (Hercules, CA, USA), or Applied Biosystems (Foster City, CA, USA). In addition, *A. annua* was obtained at a local oriental medicine market (Busan, Korea). All other reagents were of the highest grade available commercially.

2.2. Preparation of enzymatic extract from Artemisia annua

The samples were pulverised into powder using a grinder. The optimum pH, temperature and characterisation of the various enzymes used are summarised in Table 1. The enzymatic extracts were obtained according to the method described by Park et al. (2005). One hundred millilitres of buffer solution were added to 2 g of the dried sample, and then 40 μl (or mg) of each enzyme were added after pre-incubation for 30 min. The enzymatic hydrolysis reactions were performed for 8 h to achieve an optimum hydrolytic level and immediately heated at 100 °C for 10 min. Finally, the enzymatic extracts were obtained after filtering the supernatants, lyophilising, and were then stored at −20 °C until use (within 3 days).

2.3. Determination of total phenolic contents

The phenolic contents of the various enzymatic extracts were determined using a protocol similar to that of Chandler and Dodds (1983) described by Shetty, Curtis, Levin, Witkowsky, and Ang (1995). Briefly, 20 μl of the enzymatic extracts from *A. annua*, 20 μl of 95% EtOH, 100 μl of distilled water and 10 μl of 50% Folin–ciocalteu reagent were mixed. The mixtures were allowed to react for 5 min, followed by the addition of 20 μl of 5% Na_2CO_3, and then mixed thoroughly and placed in the dark for 1 h. Their absorbance was measured at 650 nm by an ELISA reader (Tecan, Grodig, Austria).

2.4. DPPH radical scavenging activity

DPPH radical scavenging activity was measured using the method described by Nanjo et al. (1996). A sample solution of 60 μl of each enzymatic extract was added to 60 μl of DPPH (60 μM) in methanol solution. After mixing vigorously for 10 s, the solution was then transferred into a 100 μl Teflon capillary tube, and the scavenging activity of each enzymatic extract on DPPH radical was measured using a JES-FA ESR spectrometer (JEOL Ltd., Tokyo, Japan). The spin adduct were measured on an ESR spectrometer exactly 2 min later. The experimental conditions were as follows: central field, 3475 G; modulation frequency, 100 kHz; modulation amplitude, 2 G; microwave power, 5 mW; gain, 6.3×10^5; and temperature, 298 K.

2.5. Hydroxyl radical scavenging activity

Hydroxyl radicals were generated by the iron-catalysed Haber-Weiss reaction (Fenton-driven Haber-Weiss reaction); these generated hydroxyl radicals can be rapidly reacted with nitrone spin-trap DMPO (Rosen & Rauckman, 1984). The resultant DMPO-OH adducts were then detected using an ESR spectrometer. Briefly, 0.2 ml of each enzymatic extract with various concentrations was mixed with 0.2 ml of DMPO (0.3 M), 0.2 ml of $FeSO_4$ (10 mM) and 0.2 ml of H_2O_2 (10 mM) in a phosphate buffer solution (pH 7.2) and then transferred into a 100 μl Teflon capillary tube. After 2.5 min, ESR spectrum was recorded using an ESR spectrometer. The experimental conditions were as follows: central field, 3475 G; modulation frequency, 100 kHz; modulation amplitude, 2 G; microwave power, 1 mW; gain, 6.3×10^5; and temperature, 298 K.

2.6. Alkyl radical scavenging activity

Alkyl radicals were generated by AAPH. The PBS (pH 7.4) reaction mixtures containing 10 mM AAPH, 10 mM 4-POBN and indicated concentrations of tested samples were incubated at 37 °C in a water bath for 30 min and then transferred to 100 μl Teflon capillary tube. The spin adduct was recorded on an ESR spectrometer. The measurement conditions were as follows: central field, 3475 G; modulation frequency, 100 kHz; modulation amplitude,

2.7. Protective effect of the enzymatic extracts from Artemisia annua against H_2O_2-induced DNA damage

To study the protective effects of the enzymatic extracts against DNA damage by H_2O_2, the reaction was conducted in an eppendorf tube at a total volume of 13 μl containing 0.5 μg of pBR 322 DNA, 3 μl of 50 mM phosphate buffer (pH 7.4), 3 μl of 2 mM $FeSO_4$ and 2 μl of the enzymatic extracts at various concentrations. Then 4 μl of 30% H_2O_2 were added, and the mixture was incubated at 37 °C for 1 h (Rosen & Rauckman, 1984). Finally, the mixture was subjected to 0.8% agarose gel electrophoresis. The DNA bands (supercoiled, linear and open circular) were stained with ethidium bromide.

2.8. Flow cytometer analysis

For sub-G1 and cell cycle analysis, PC-12 cells were suspended in ethanol with 0.5% Tween-20 and left for 24 h at 4 °C. The cells were harvested by centrifugation and resuspended in 1 ml PBS with 0.05 mg/ml propidium iodide and 10 μl/ml. RNase A, and incubated at 37 °C for 30 min. Apoptotic cell death was assessed by measuring the hypodiploid DNA contents of the cells using a flow cytometer (FACS-caliber, Becton Dickinson, Franklin Lakes, NJ, USA). The cells belonging to the sub-G1 population were considered apoptotic cells and the percentage of cells in each phase of the cell cycle was determined.

2.9. 2-DE

Neuronal cells strips untreated or treated enzymatic extracts from *A. annua* prior to treatment with 1 mM H_2O_2 for 24 h were homogenised in 2-DE buffer containing 8 M urea, 2 M thiourea, 65 mM DTT, 2% CHAPS and 16 complete protease inhibitor cocktail (Roche Applied Science, Wiesbaden, Germany). The homogenates were centrifuged at 12,000*g* for 10 min at 10 °C and the supernatants were collected. The protein concentrations were determined using BioRad (Hercules, CA, USA) protein assay reagents with BSA as standard. The protein homogenates were diluted with rehydration buffer containing 8 M urea, 0.28% DTT, 0.5% CHAPS, 10% glycerol, 0.5% appropriate ampholyte and 0.002% bromophenol blue. The IPG strips (pH 3–10 nonlinear) were rehydrated at 50 V for 12 h at 20 °C in 80 μg of whole cell protein extract. IEF was carried out sequentially with a BioRad Protein IEF Cell system at 100 V for 2 h, 250 V for 1 h, 500 V for 1 h, 1000 V for 1 h, 3000 V for 1 h, 5000 V for 1 h and 8000 V for 9 h at 20 °C. After IEF, the individual strips were equilibrated for 20 min in 10 mL of equilibration solution containing 50 mM Tris–HCl (pH 6.8), 6 M urea, 20% glycerol, 2% SDS, 0.01% bromophenol blue and 5 mM tributylphosphine. The equilibrated strips were transferred onto 12% acrylamide SDS gels, and a potential of 30 V was applied for 1 h followed by a potential of 80 V until the bromophenol blue marker reached the bottom of the gel. To visualise the proteins, the gels were incubated for 1 h in fixing solution containing 50% methanol, 12% acetic acid and 0.05% formaldehyde, and then washed twice for 20 min, each time in 50% ethanol. Sensitisation was carried out for 1 min in 0.02% $Na_2S_2O_3$. After three consecutive washes with distilled water, each for 20 s, the gels were impregnated with 0.1% silver nitrate solution containing 0.075% formaldehyde for 20 min. Excess silver nitrate was washed with distilled water for a few seconds and the gels were developed with a solution of 0.0002% $Na_2S_2O_3$, 0.025% formaldehyde and 3% Na_2CO_3 for 10 min. The development was stopped by the addition of 1.5% EDTA. The densities of silver-stained spots from three different experiment sets were detected and counted by both automation and manual spot detection, and statistically analysed with PDQuest software (Version 7.1.1, BioRad).

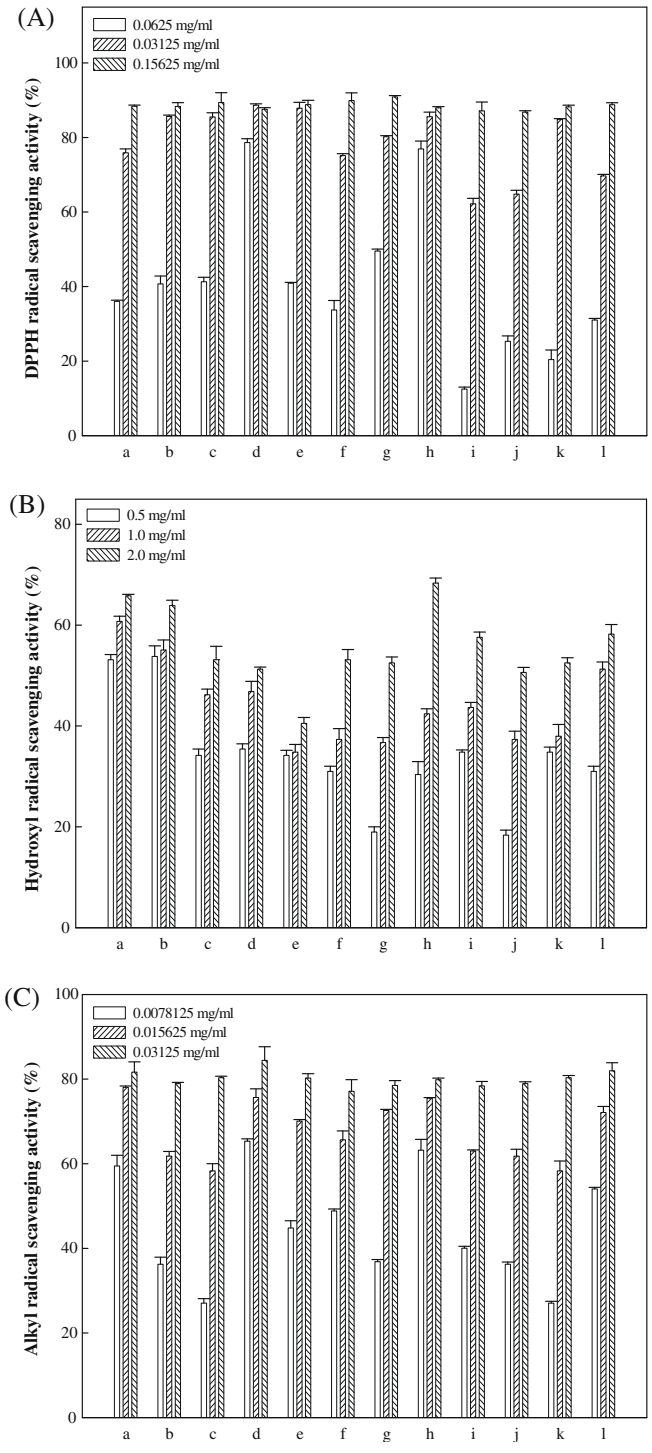

Fig. 1. DPPH (A), hydroxyl (B) and alkyl (C) radical scavenging activity of various enzymatic extracts from *Artemisia annua* obtained in various system at various concentrations. a, Protamex; b, Flavourzyme; c, Neutrase; d, Pancreatic trypsin; e, Alcalase; f, Promozyme; g, Celluclast; h, Maltogenase; I, Viscozyme; j, Termamyl; k, Dextrozyme; l, AMG. Means ± SD of determinations were made in triplicate experiments.

2.10. In-gel digestion and MS of protein spots

The silver-stained protein spots were excised from the stained gel and destained with freshly prepared 15 mM $K_3[Fe(CN)_6]$/ 50 mM $Na_2S_2O_3$ for 10 min. The gel pieces were washed with 50% ACN and 100 mM NH_4HCO_3 three times for 15 min. After dehydrating the spots with ACN for 15 min, each spot was dried in a SpeedVac centrifuge for 10 min. The samples were then reduced with DTT, and subsequently, alkylated with iodoacetamide. Finally, the samples were digested in 20 mL of digestion buffer (12.5 ng/mL trypsin in 20 mM NH_4HCO_3) at 37 °C for at least 16 h. The peptide samples were extracted with 50 mL of 50% ACN/0.1% formic acid and dried in a SpeedVac centrifuge. The extracts were resuspended in 10 mL of 0.1% TFA, and desalted with ZipTip C18 columns (Millipore) according to the manufacturer's instructions. The peptide samples were then mixed (1:1) with a matrix consisting of a saturated solution of CHCA prepared in 50% ACN/0.5% TFA. Aliquots of the samples (1 ml) were spotted onto stainless-steel sample target plates. Peptide mass spectra were obtained by a MALDI-TOF/TOF mass spectrometer (AB4700, Applied Biosystems) in the positive ion reflector mode. For the precursor ion selection, all fractions were measured in single MS before MS/MS was performed. For MS/MS spectra, the peaks were calibrated by default. The 10 most abundant precursor ions per sample were selected for subsequent fragmentation by high-energy CID. The collision energy was set to 1 keV and air was used as the collision gas. The criterion for precursor selection was a minimum S/N of 20. The mass accuracy was within 100 ppm for the mass measurement and within 0.2 Da for the CID experiments. The other parameters for searching were of trypsin, 1 missed cleavage, variable modification of carbamidomethyl, oxidation, propionamide and pyro-glu (N-term), peptide charge of 1+, and monoisotopic. For database searches, known contamination peaks such as keratin and autoproteolysis peaks were removed before searching. The spectra were processed and analysed by the Global Protein Server Explorer 3.0 software (Applied Biosystems). This uses an internal MASCOT (Matrix Science, UK) program for matching MS and MS/MS data against database information. The data

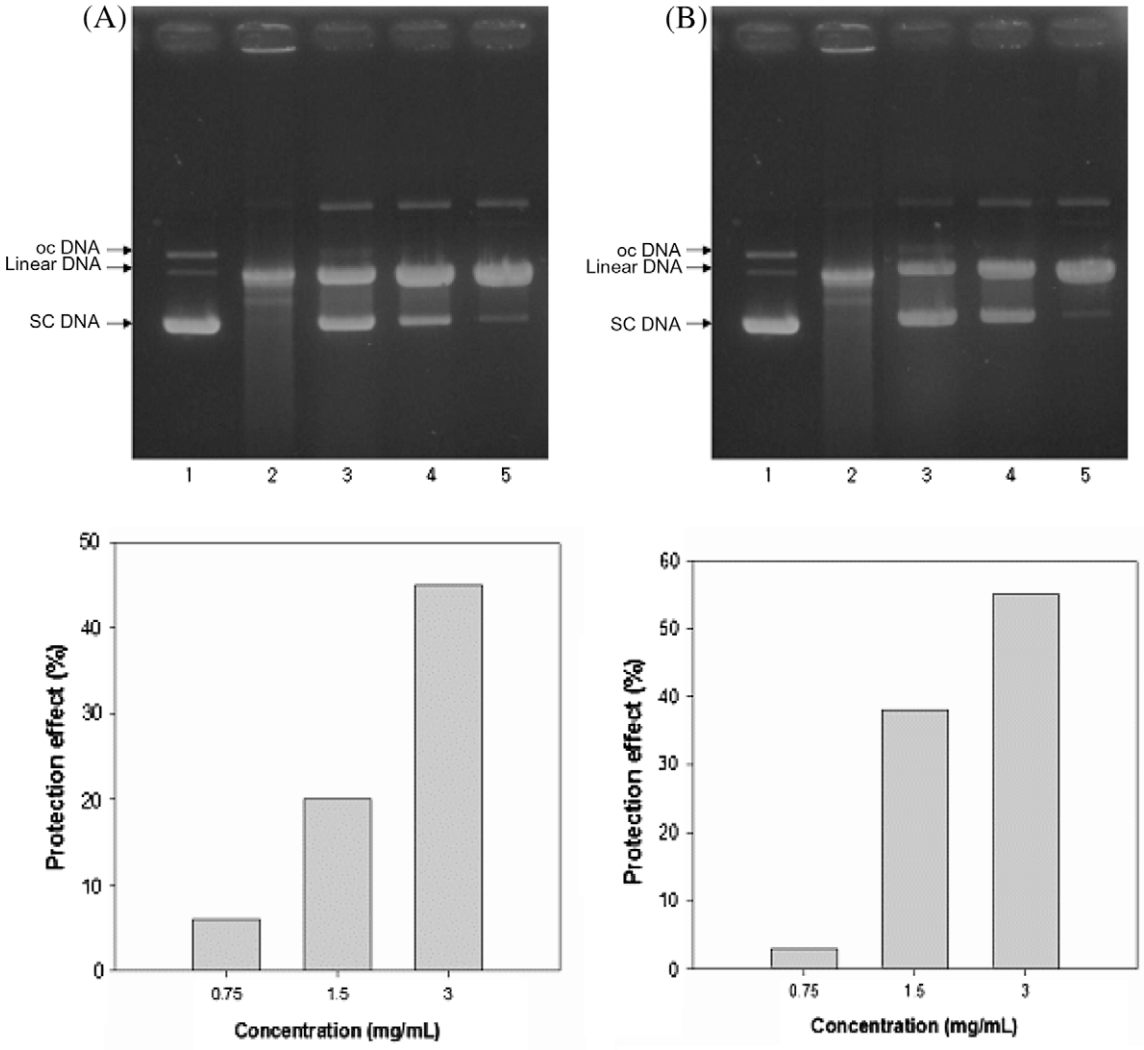

Fig. 2. Agarose gel electrophoretic patterns of plasmid DNA breaks by OH generated from a Fenton reaction in the presence of Protamex (A) and Maltogenase (B) extracts of *Artemisia annua*. An amount of 0.5 μg of pBR 322 DNA was incubated at 37 °C for 1 h in 2 mM $FeSO_4$ and 30% H_2O_2 with the following additive combinations: Lane 1, no addition (plasmid DNA control); Lane 2, $FeSO_4$ and H_2O_2 (DNA damage control); Lanes 3–5, $FeSO_4$ and H_2O_2 in the presence of Protamex and Maltogenase extracts from *Artemisia annua* with concentrations of 3, 1.5 and 0.75 mg/ml, respectively.

obtained were screened against rat databases downloaded from both NCBI (http://www.ncbi.nlm.nih.gov) and the Swiss-Prot/TrEMBL homepage (http://www.expasy.ch/sprot). Further confirmations of the protein identifications were obtained by using the MS-Fit (http://prospector.ucsf.edu) and ProFound (http://www.prowl.rockefeller.edu) programs.

2.11. Statistics

The experimental results were recorded as the mean ± SD of three parallel measurements. A variance analysis using the Duncan's multiple range test was performed to determine differences between the means of the treatments at $p < 0.05$.

3. Results and discussion

3.1. Total phenol contents of enzymatic extracts from Artemisia annua

Phenolic compounds, such as flavonoids, phenolic acids and tannins are considered to be major contributors to the antioxidative activity of medicinal plants. These antioxidants also possess diverse biological activities, such as anti-inflammatory, anti-carcinogenic and anti-atherosclerotic activities. These activities may be related to their antioxidative activity (Chung, Wong, Huang, & Lin, 1998).

The total contents of the proteolytic extracts by Pancreatic trypsin, Alcalase, Protamex, Neutrase and Flavourzyme from *A. annua* were 41.85, 35.94, 35.63, 32.43 and 27.67 μg/mg, respectively, (data not shown). The total contents of the extracts by carbohydrase such as Celluclast, Viscozyme, AMG, Maltogenase, Termamyl, Dextrozyme and Promozyme from *A. annua* were 53.74, 52.26, 45.67, 41.21, 31.84, 26.92 and 23.98 μg/mg, respectively (data not shown). It was observed that the total phenol contents of all the various protease and carbohydrase extracts fell within the range of 23.98–53.74 μg/mg of extract. Meanwhile, the enzymatic extracts with higher phenolic contents did not have higher flavonoid contents and antioxidative capacity. There was no significant relationship between the total phenol content and antioxidant capacity as similar to Maisuthisakul, Suttajit, and Pongsawatmanit (2005).

3.2. DPPH radical scavenging activity

DPPH is a stable free radical, which has been used to evaluate the free radical scavenging activity of natural antioxidants. In this study, the DPPH radical scavenging activities of the various protease and carbohydrase extracts are shown in Fig. 1A. The proteolytic extracts by Neutrase, Alcalase, Protamex, Flavourzyme and Pancreatic trypsin from *A. annua* had DPPH radical scavenging activities of 89.38%, 88.82%, 88.40%, 88.34% and 87.58% at 0.0625 mg/ml, respectively. The radical scavenging activity occurred in a concentration dependent manner. It was observed that the extracts by carbohydrase such as Celluclast, Promozyme, AMG, Maltogenase, Dextrozyme, Viscozyme and Termamyl had DPPH radical scavenging activities of 90.91%, 89.92%, 88.79%, 87.99%, 88.24%, 87.15% and 86.81% at 0.0625 mg/ml, respectively. In addition, the Neutrase and Celluclast extracts exhibited the strongest scavenging activities, among five proteases and seven carbohydrases extracts and their IC_{50} values were 18.71 and 15.83 μg/mg, respectively. These results indicate that all the enzymatic extracts possessed a scavenging activities against DPPH radicals.

3.3. Hydroxyl radical scavenging activity

Hydroxyl radicals generated in the Fe^{2+}/H_2O_2 system were trapped by DMPO, forming spin adducts detected by an ESR spectrometer, which may be due to the paramagnetic impurities contained in unpurified commercial DMPO (Bindoli, Rigobello, & Deeble, 1992). As shown in Fig. 1B, it was observed that the hydroxyl radical scavenging activities of the Protamez, Flavourzyme, Neutrase, Pancreatic trypsin and Alcalase extracts from *A. annua* were 65.82%, 63.92%, 53.16%, 51.27% and 40.51% at 2 mg/ml, respectively, which indicated that their scavenging capabilities followed the order: Protamex > Flavourzyme > Neutrase > Pancreatic trypsin > Alcalse. As shown in Fig. 1B, it was observed that 2 mg/ml of the extracts prepared with the seven types of carbohydrases such as Promozyme, Celluclast, Maltogenase, Viscozyme, Termamyl, Dextrozyme and AMG had hydroxyl radical scavenging activities of 53.16%, 52.53%, 68.35%, 57.59%, 50.63%, 52.53% and 58.23%, respectively, which indicated that their scavenging capabilities followed the order: Maltogenase > AMG > Viscozyme > Promozyme > Celluclast, Dextrozyme > Termamyl, and the radical scavenging activities were concentration-dependent. In addition, the Protamex and Maltogenase extracts had the highest scavenging activities among the various proteases and carbohydrases extracts and their IC_{50} values were 1.54 and 1.29 mg/ml, respectively.

3.4. Alkyl radical scavenging activity

The alkyl radical spin adduct of 4-POBN/free radicals were generated from AAPH at 37 °C for 30 min, and the decrease in the ESR

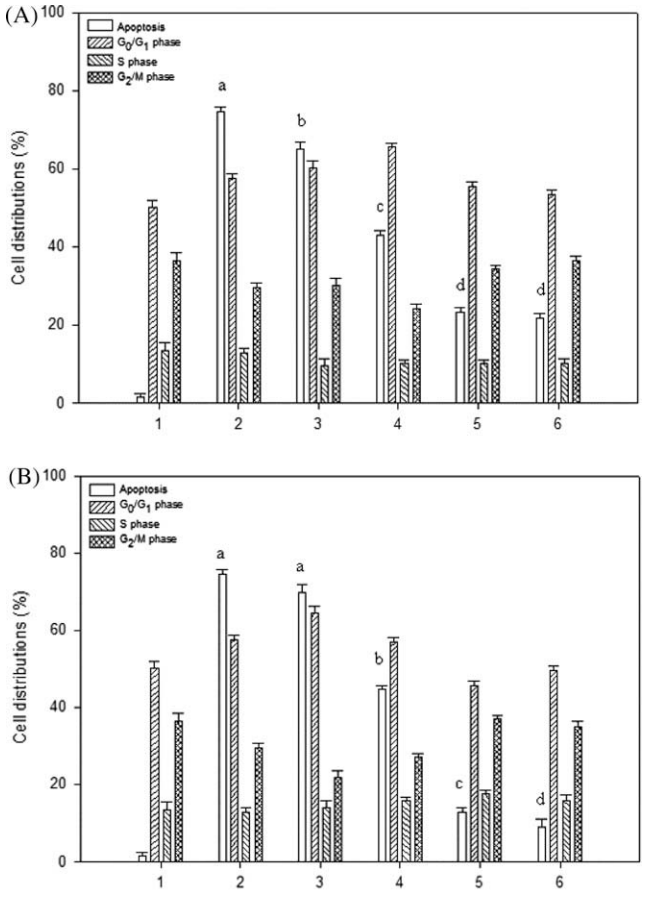

Fig. 3. Cell death and cell cycle of PC-12 cells after treating Protamex (A) and Maltogenase (B) extracts from *Artemisia annua* prior H_2O_2 treatment. The cells were treated with various concentrations of Protamex and Viscozyme extracts from *Artemisia annua* prior 1 mM H_2O_2 treatment for 24 h. Means ± SD of determinations were made in triplicate experiments. 1; control, 2; H_2O_2 1 mM, 3; 0.0625 mg/ml, 4; 0.125 mg/ml, 5; 0.25 mg/ml, 6; 0.5 mg/ml. (a–d) Values with different alphabets are significantly different at $p < 0.05$ as analysed by Duncan's multiple range test compared to H_2O_2 1 mM.

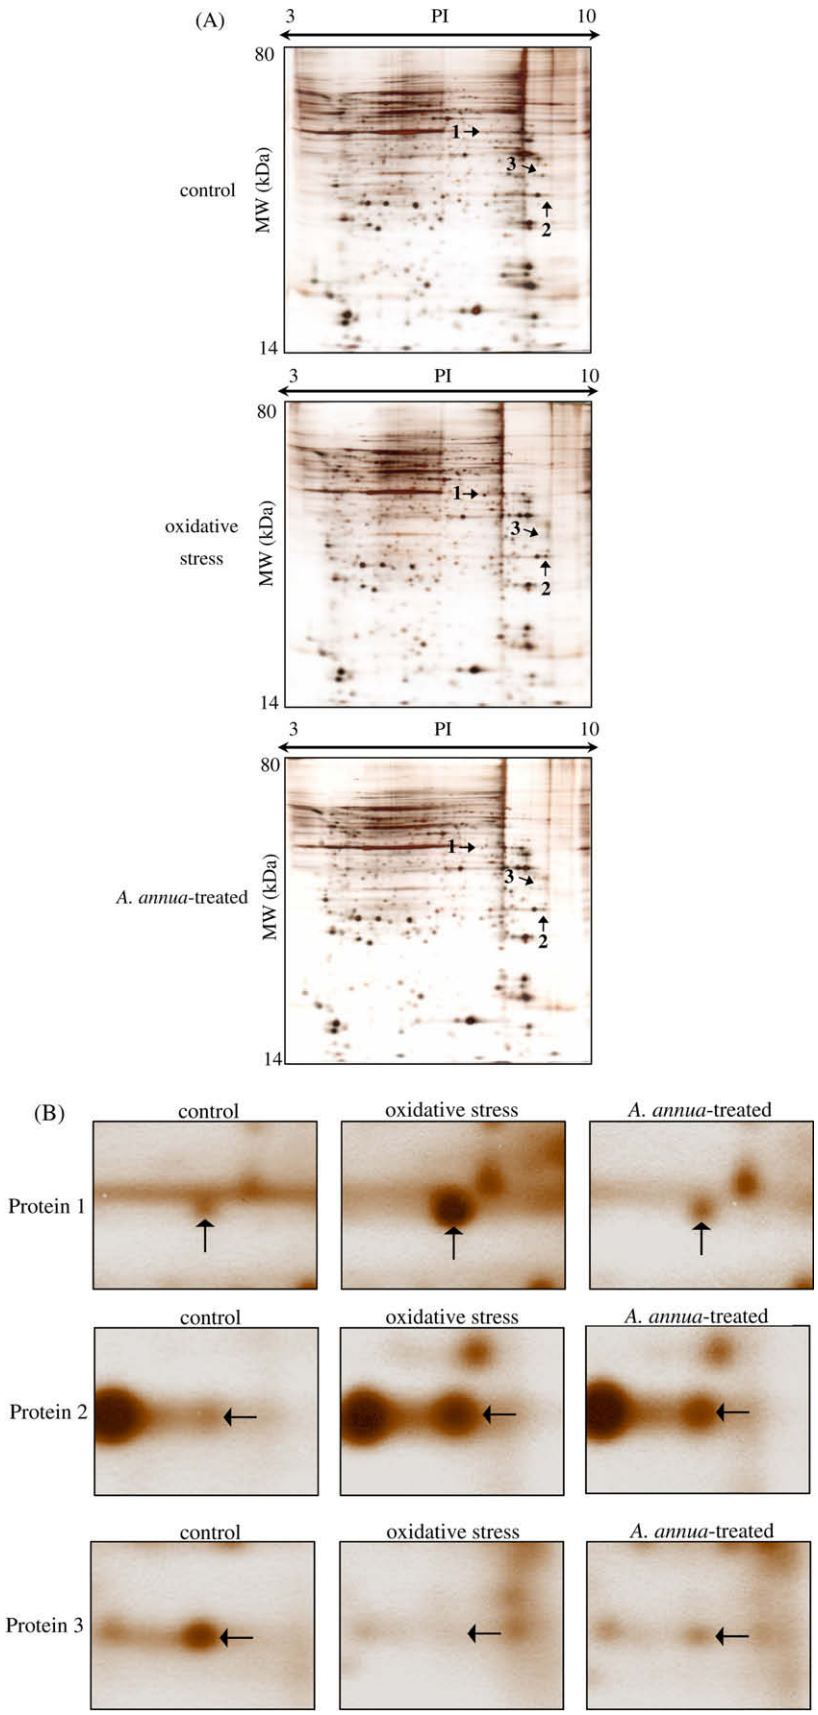

Fig. 4. Silver-stained 2-DE gels of rat neuronal cells proteins. A total of 80 μg of proteins were extracted and separated by 2-DE. A shows the control. The cells were treated without (oxidative stress) or with (*A. annua*-treated) 1 mg/ml enzymatic extracts from *Artemisia annua* prior 1 mM H_2O_2 for 24 h (A). It is showed enlarged-each protein (B). Arrows show proteins subsequently examined by MALDI-TOF/TOF. The numbers indicated in the gels correspond to the numbers in Table 2.

signals were observed with the dose increment of all the enzymatic extracts (Fig. 1C). All the proteases extracts from *A. annua* exhibited alkyl radical scavenging activities, and the scavenging activities of Pancreatic trypsin, Protamex, Neutrase, Alcalase and Flavourzyme were 84.40%, 81.63%, 80.32%, 80.24% and 78.93% at 0.03125 mg/ml, respectively (Fig. 1C). In addition, the extracts hydrolysed from A. annua by the seven types of carbohydrases such as AMG, Dextrozyme, Termamyl, Maltogenase, Celluclast, Viscozyme and Promozyme had alkyl radical scavenging activities of 81.97%, 80.31%, 79.85%, 78.93%, 78.49%, 78.38% and 77.13% at 0.03125 mg/ml, respectively (Fig. 1C). Furthermore, The Pancreatic trypsin and AMG extracts showed the highest alkyl radical scavenging activities among the various proteases and carbohydrases extracts, and the IC_{50} values were 5.98 and 7.23 μg/ml, respectively.

3.5. Protective effect of the enzymatic extracts from Artemisia annua against hydroxyl radical-induced DNA damage

The antioxidative effects of the enzymatic extracts from *A. annua* were evaluated by their protective effects against free radical-induced plasmid pBR 322 DNA damage in vitro. DNA is broken into three forms: supercoiled (SC), open circular (OC) and linear form (Linear) when exposed to hydroxyl radical derived from a Fenton reaction. A supercoiled circular DNA molecule comprises 4361 base pairs (Watson, 1988). This is a 'model' DNA system which has the advantage that damage may be easily assessed by means of a simple gel electrophoretic protocol (Bates & Maxwell, 2005). In the present study, the Protamex and Maltogenase extracts were selected to investigate the protective effects against hydroxyl radical-induced DNA damage because the two extracts had the highest hydroxyl radical scavenging activities among the various protease and carbohydrase extracts. The protective effects of the Protamex and Maltogenase extracts from *A. annua* against free radical-induced DNA damage were shown in Fig. 2. The SC form of the DNA was completely converted to the linear form under the treatment of the hydroxyl radicals generated from the Fenton reaction (Lane 2) when compared with the plasmid DNA control (Lane 1). According to the results, the Protamex and Maltogenase extracts from *A. annua* protected against hydroxyl radical-induced DNA damage at concentrations of 1.5 and 3.0 mg/ml, however, they had no effects at 0.75 mg/ml (Lanes 3–5).

3.6. Neuroprotective effect against H_2O_2-induced damage

Hydrogen peroxide has been reported to induce apoptosis in cells of the central nervous system (Chandra, Samali, & Orrenius, 2000). In this study, the Protamex and Maltogenase extracts were selected to investigate the neuroprotective effects against H_2O_2-induced damage because the extracts showed the highest protective activities at 1.0 mg/ml among the various protease and carbohydrase extracts in a preliminary experiment. Their protective effects on H_2O_2-induced neuronal cells damage were confirmed by flow cytometric analysis. The Protamex and Maltogenase extracts clearly reduced apoptosis in dose dependent manners, as shown in Fig. 3. The PC-12 cells were incubated with increasing concentrations of the Protamex extract from *A. annua* for 24 h. The percentages of apoptotic cells were 23.4%, 23.7%, 43.1% and 65% at 0.5, 0.25, 0.125 and 0.0125 mg/ml, respectively, whereas the percentage of apoptotic cells was 74.6% for the 1.0 mM H_2O_2 treated cells. When the PC-12 cells were incubated with 0.5, 0.25, 0.125 and 0.0125 mg/ml of Maltogenase extract from *A. annua* for 24 h, the percentages of apoptotic cells were 9.1%, 12.9%, 44.8% and 69.9%, respectively, whereas the percentage of apoptotic cells was 74.6% for the 1.0 mM H_2O_2 treated cells. These results indicate that the enzymatic extracts of *A. annua* exhibited protective effects against H_2O_2-induced neuronal cell damage.

3.7. Isolation and identification of proteins in neuronal cells

To identify the proteins responsive to oxidative stress in the neuronal cells, the cells were treated with 1.0 mg/ml of Maltogenase extract, which showed the highest hydroxyl radical scavenging activity, and were co-treated with 1.0 mM H_2O_2 after 1 h. Then after 24 h, the proteins were separated using the 2-DE technique. The separated proteins were visualised with silver staining and analysed with PDQuest software. Fig. 4A–C shows the typical 2-DE gels of total rat neuronal cell proteins for the control and with or without 1.0 mg/ml Maltogenase extract of *A. annua* exposure prior to the 1.0 mM H_2O_2 treatment. More than 80 proteins may be seen in each gel, with isoelectric pH values of pH 3–10 and MW of 14–18 kDa. The MALDI–TOF/TOF analyser identified 10 prominent proteins and we selected 3 proteins involved in cell survival. Table 2 identifies the proteins.

3.8. Neuronal cell proteins with changes in levels after Maltogenase extract of Artemisia annua treatment

The proteins markedly altered in expression by the 1.0 mg/ml Maltogenase extract treatment of *A. annua* prior to 1.0 mM H_2O_2 treatment were identified. The No. 1 protein, EF-Tu was altered by 0.337-fold in the Maltogenase extract-treated strips compared with the untreated strips (oxidative damage group). The main function of EF-Tu and its eukaryotic counterpart eEF1A are to deliver aminoacyl-tRNA to the A-site on the ribosome. In addition to this, multiple secondary functions have been reported for EF-Tu. EF-Tu is an essential host-donated subunit of the replicative complex of

the Q^{β} phage, and it may interact with the transcriptional apparatus as a positive regulator of RNA synthesis (Travers, Kamen, & Schleif, 1970). Recently, it has been shown that eEF1A is implicated in oxidative stress-induced apoptosis. In fact, in a cardiomyocites cell line, eEF1A levels undergo a rapid increase upon treatment with hydrogen peroxide, suggesting that the up-regulation of eEF1A plays an important role in the execution of the apoptotic program in response to an oxidative stress (Chen, Proestou, Bourbeau, & Wang, 2000; Duttaroy, Bourbeau, Wang, & Wang, 1998). The No. 2 protein, IgE was altered by 0.480-fold in Maltogenase extract-treated strips compared with the untreated strips (oxidative damage group). IgE is a protein that is released by our body in large amounts to battle the alleged invaders. In addition, the extracellular membrane-proximal domain (EMPD) of human membrane IgE is a key control element of apoptotic signalling delivered through the engagement of B cell receptors (BCR) within the context of a mature B cell. EMPDs play a key role in controlling the capacity of membrane-bound IgE to induce apoptosis in the context of a mature isotype-switched B cell (Poggianella, Bestagno, & Burrone, 2006). In this study, we assumed that IgE played essential roles in determining the apoptosis of cell signalling in the PC-12 cells. The No. 3 protein, VDAC-1 was altered by 377.107-fold in the Maltogenase extract-treated strips compared with the untreated strips (oxidative damage group). VDAC-1 is the predominant protein labelled in brain. VDAC-1 is shown to coimmunoprecipitate $GABA_A$ receptors, suggesting a functional relationship between steroid binding to VDAC-1 and modulation of $GABA_A$ receptor function (Darbandi-Tonkabon et al., 2004). Shimizu, Narita, and Tsujimoto (1999) hypothesised that apoptogenic proteins were released through the VDAC–Bax channels. The attenuated expression of VDAC in a human gastric cancer cell line (BGC823 cells) treated with DATS appears in agreement with the apoptotic process in these cells. However, VDAC-dependent apoptosis is regulated by a number of Bcl-2 proteins, some anti-apoptotic and some pre-apoptotic. Next steps will be investigating antioxidative protein derived Maltogenase extract in the mitochondrial pathway of apoptosis.

4. Conclusions

The scavenging effects on ROS of various enzymatic extracts prepared from *A. annua* were evaluated using an ESR spectrometer, DNA strand breaks and flow cytometer. The water soluble enzymatic extracts were effectively prepared by enzymatic hydrolysis with seven carbohydrases, including Promozyme, Celluclast, Maltogenase, Viscozyme, Termamyl, Dextrozyme and AMG, and five proteases including Protamex, Flavourzyme, Neutrase, Pancreatic trypsin and Alcalase. The enzymatic extracts of *A. annua* showed their highest scavenging activities against alkyl radicals. In addition, the Protamex and Maltogenase extracts showed a protective effect against hydroxyl radical-induced DNA damage, and the extracts reduced apoptosis induced by hydrogen peroxide in PC-12 cells. We also investigated the mechanism of this H_2O_2-induced apoptosis of neuronal cells using proteomic analysis. EF-Tu and IgE which are involved in many biological functions, such as cell growth and differentiation, basic metabolism and immune system were overexpressed in H_2O_2-treated group compared with control, but they were downregulated in enzymatic extract-treated group compared with H_2O_2-treated group. VDAC-1 which is involved membrane potential was downregulated in H_2O_2-treated group compared with control, but they were upregulated in enzymatic extract-treated group compared with H_2O_2-treated group. We surmise that enzymatic extracts reduce the damage against H_2O_2. Therefore, the enzymatic extracts from *A. annua* have the potential to inhibit the cell damage induced by hydrogen peroxide. And the molecular mechanism remains to be elucidated in future studies how EF-Tu, IgE and VDAC expressions and functions are mediated by enzymatic extracts from *A. annua*. Thus we concentrated on further confirmation of its effects on neuronal cells.

These result showed that EF-Tu, IgE and VDAC are the proteins regulated by treatment of enzymatic extract from *A. annua* in neuronal cells and the extract of *A. annua* were able to reduce biological damages against free radicals-induced cell damage.

Lactic acid bacteria

ABSTRACT

The present work evaluates the ability of lactic acid bacteria isolated from goat's and ewe's milk and cheeses to synthesise short-chain fatty acid esters. In order to elucidate the mechanisms of ester synthesis involved, cell-free extracts were incubated in sodium phosphate buffer containing triglyceride plus ethanol (alcoholysis) and free fatty acid plus ethanol (esterification). After 24 h incubation at 37 °C esters were extracted and determined by gas chromatography. Strains evaluated were able to synthesise ethyl esters from 2 to 10 carbon atoms, mainly ethyl butanoate and ethyl hexanoate. A great variability amongst strains was observed. In general, higher ester-forming activities by esterification were detected. In enterococci strains the alcoholysis mechanism was also involved.

These strains could be useful as adjunct cultures for small ruminants' dairy products and would contribute to the development of fruity flavour notes. A deeper understanding of ester synthesis mechanisms involved would allow the control of flavour development.

1. Introduction

Goat's and ewe's milk cheeses produced in the northwest of Argentina are semi-hard varieties made from raw milk, without addition of starter cultures. These cheeses are greatly appreciated because of their particular organoleptic characteristics.

Lipolysis, the process of milk fat hydrolysis, plays a crucial role in the development of flavour in these cheeses (Freitas & Malcata, 1998; Macedo, Costa, & Malcata, 1996; Tavaria, Silva Ferreira, & Malcata, 2004). The major flavour compounds that are released during lipolysis are free fatty acids (FFA), which directly affect cheese flavour. FFA can also be transformed by microorganisms to other and often more potent flavour compounds, including methyl ketones, lactones, esters, secondary alcohols and aldehydes, which also directly affect flavour in different cheeses (Collins, McSweeney, & Wilkinson, 2003).

Esters are part of the aroma array of cheeses made from goats' and ewes' milk (e.g., Feta, Manchego, Serra da Estrela and Roncal), but the number and type of esters found vary between cheese varieties (Dahl, Tavaria, & Malcata, 2000; Horwood, Lloyd, & Stark, 1981; Le Quere, Pierre, Riaublanc, & Demaizieres, 1998; Martínez-Castro, Sanz, Amigo, Ramos, & Martín-Alvarez, 1991; Ortigosa, Torre, & Izco, 2001). Of the esters identified in these cheeses, the five ethyl esters of the straight-chain fatty acids of C2–C10 are most frequently found (Liu, Holland, & Crow, 2004). These esters, which are potent flavour compounds at less than 5 ppm, are important for development of the characteristic "fruity" type flavours such as ethyl butanoate and ethyl hexanoate (Moio & Addeo, 1998). Esters may also mask the impact of off-flavours (e.g., pungent, sharp) imparted by high levels of short-chain FFA. Excessive levels of ethyl esters of short-chain FFA (typically ethyl butanoate and ethyl hexanoate) cause a fruity flavour defect in some raw and pasteurised milks, and Cheddar cheese (Horwood, Stark, & Hull, 1987; Whitfield, Jensen, & Shaw, 2000).

Lactic acid bacteria (LAB) are used as starter or adjuncts cultures or are present as secondary microbial flora (non-starter LAB) in cheese fermentation (Crow, Curry, & Hayes, 2001). Indigenous LAB isolated from ewe's and goat's milk and artisanal cheeses manufactured in the provinces of northwest Argentina were identified as enterococci, lactococci, leuconostoc and lactobacilli. *Enterococcus faecium* and *Lactobacillus plantarum* were the most frequently isolated species from ewe's and goat's milk and cheeses (Medina, Katz, González, & Oliver, 2001; Oliszewski, González, & Pérez Chaia, 2006).

The contribution of cheese microflora to the formation of flavour compounds occurs *via* the esterase/lipase systems of lactic and propionic acid bacteria, non-starter LAB (NSLAB), surface microorganisms, yeasts and moulds (McSweeney & Sousa, 2000). Moreover, some volatile compounds arise from microbial amino acid catabolism (Tavaria & Malcata, 2003). We have previously demonstrated that LAB isolated from goat's and ewe's dairy prod-

ucts present very complex intracellular esterolytic systems able to release C2–C6 fatty acids and thus they actively contribute to flavour development in these products. (Abeijón, Medina, Katz, & González, 2006; Abeijón Mukdsi et al., 2009; Katz, Medina, González, & Oliver, 2002; Oliszewski, Medina, González, & Pérez Chaia, 2007).

Esterases are defined as the enzymes that hydrolyse carboxyl ester linkages in water-soluble substrates (e.g., slightly water-soluble short-chain glycerides and aliphatic esters) in aqueous solutions. These enzymes can also synthesise esters under certain conditions (Bornscheuer, 2002). The mechanisms of ester synthesis are: esterification (reaction of an acid and an alcohol), alcoholysis (reaction of an ester and an alcohol), acidolysis (reaction of an acid and an alcohol) and transesterification (reaction of two esters) (Holland et al., 2005; Malcata, Reyes, Garcia, Hill, & Amundson, 1992).

Presumably, esterases from starter and NSLAB are responsible for release of short-chain FFA from milk fat at elevated water activity (a_w) and synthesis of short-chain ethyl esters as a_w decreases with ripening (Holland et al., 2005). The equilibrium existing between these processes is dependent on the a_w, the enzymes present, pH, temperature and availability of substrates characteristic of each cheese variety (Ha & Lindsay, 1992; Moio & Addeo, 1998).

The acid or acyl CoA moieties of esters are formed from the action of the cheese microflora and their enzymes on lactose, lactate, lipids and proteins of cheese curd (Urbach, 1997). Ethanol in cheese is thought to result from the activity of obligatory heterofermentative lactobacilli and/or from yeasts (Chamba & Irlinger, 2004). We have previously detected ethanol production from citrate metabolism in goat's milk fermented by enterococci (Cabral, 2005).

Evidence is provided that esterases of LAB catalyse the synthesis of esters by esterification (Liu, Holland, & Crow, 1998) and alcoholysis (Liu, Holland, & Crow, 2003a; Liu, Baker, et al., 2004). It is not known whether esterases of LAB can catalyse acidolysis and transesterification.

Even though there are many reports concerning volatile compound formation in goat's and ewe's milk cheeses manufactured with starter LAB (Abeijón Mukdsi et al., 2009; Georgala et al., 2005; Randazzo, Pitino, De Luca, Scifò, & Caggia, 2008; Tavaria, Tavares, Silva-Ferreira, & Malcata, 2006), only a few studies on ester synthesis mechanisms by these bacteria have been carried out. Some reports about ester synthesis by lactobacilli, streptococci and lactococci have been made, but no information about enterococci is available.

The aim of the present work was to evaluate the ester synthesis ability of indigenous lactobacilli and enterococci strains from goat's and ewés dairy products, and to go deeper into the elucidation of the prevalent mechanisms of ester synthesis in aqueous medium.

2. Materials and methods

2.1. Microorganisms and growth conditions

Strains provided by Laboratorio de Ecofisiología Tecnológica of the Centro de Referencia para Lactobacilos (CERELA), were isolated from Argentinean goat's and ewe's milk and cheese (Medina et al., 2001; Oliszewski et al., 2006). *Lactobacillus fermentum* ETC1, *L. delbrueckii* subsp. *bulgaricus* ETC2, *L. rhamnosus* ETC14, *L. plantarum* ETC17, *L. casei* ETC19, *Enterococcus faecium* ETC124 and *E. faecium* ETC418 were isolated from goat's milk and cheeses. *Lactobacillus plantarum* Ov156, Ov161, Ov186, Ov236, *Enterococcus faecium* Ov157, Ov167, Ov178, Ov194, Ov242, Ov254, Ov426, Ov409 and *E. durans* Ov421 were isolated from ewe's milk and cheeses.

These strains were previously selected for their ability to produce flavour compounds from sugars, citrate and proteins, and for their esterase–lipase activities (Abeijón et al., 2006; Cabral, Abeijón Mukdsi, Medina, & González, 2007; Katz et al., 2002; Oliszewski et al., 2007). *Enterococcus* strains were previously tested for vancomycin/teicoplanin resistance and haemolysin and gelatinase production (Katz, 2005; Oliszewski, 2006).

All strains were frozen at −70 °C in MRS broth (Merck, Darmstadt, Germany) containing glycerol 20% (v/v), and grown in MRS broth for 16 h. Cultures were incubated at 37 °C.

2.2. Cell-free extract preparation

Cells cultured in 400 ml of MRS broth were harvested after 16 h by centrifugation at 10,000*g* for 10 min at 4 °C, washed twice with 100 mM sodium phosphate buffer, pH 7, and resuspended at 50% (w/v) of the same buffer. The cell suspensions were disrupted by three successive passes through a French pressure cell at 1000 psi (ThermoSpectronic, NY, USA). Cellular debris was removed by centrifugation (20,000*g* for 30 min at 4 °C) and the supernatant was used as cell-free extract (CFE).

2.3. Mechanisms of ester synthesis

2.3.1. Synthesis of ethyl esters by alcoholysis

These assays were performed according to the protocol of Liu et al. (2003a) with some modifications.

Ester synthesis by alcoholysis was analysed in an assay mixture containing 100 mM sodium phosphate buffer (pH 7), 100 mM ethanol, 33 mM triglyceride (tributyrin or tricaproin) and CFE (ca. 1–3 mg/ml). The assay mixtures were incubated statically at 37 °C for 24 h. A 1 ml sample was removed and added to 2 ml diethyl ether. Extraction was performed by shaking vigorously for about 2 min, followed by centrifugation (1300*g* for 5 min). The top solvent layer was then transferred to a gas chromatography (GC) vial. Controls lacking substrates were included to check for endogenous ester production. Controls lacking CFE were also included to test for the non-enzymatic formation of esters. Both controls were incubated and processed as described above.

2.3.2. Synthesis of ethyl esters by esterification

Ester synthesis by esterification was analysed in an assay mixture containing 100 mM sodium phosphate buffer (pH 7), 100 mM ethanol, 100 mM free fatty acid (butanoic acid or hexanoic acid) and CFE (ca. 1–3 mg/ml). The assay mixtures were incubated statically at 37 °C for 24 h. A 1 ml sample was removed and processed as described above. Controls mentioned above were also included.

2.4. Gas chromatography analysis

The following ethyl esters of short-chain fatty acids were determined with a gas chromatograph (Agilent 6890N, Agilent Technologies, CA, USA) equipped with a flame ionisation detector (FID): ethyl acetate (EtC2), ethyl butanoate (EtC4), ethyl hexanoate (EtC6), ethyl octanoate (EtC8), ethyl decanoate (EtC10). An HP-5 column (length 30 m, i.d. 0.32 mm, thickness 0.25 μm) (Hewlett-Packard, CA, USA) was used. The oven was temperature-programmed at 30 °C for 5 min, followed by increasing the temperature to 250 °C at 10 °C/min and held at 250 °C for 2 min. Sample injections of 1 μl were performed in split less mode. The injector and FID detector temperatures were 270 and 300 °C, respectively. Column flow rate was 1 ml/min using nitrogen as carrier gas. The FID output signal was recorded and processed using appropriate software (Agilent ChemStation Software, Agilent, CA, USA.)

Esters were quantified from the regression curve ($R^2 > 98\%$) of the corresponding standard (Sigma, MO, USA), using external standard calibration and the GC conditions described above. To check the recovery efficiency of each ester from the different assay mixtures, a known amount of standard solution was added to each mixture. Extraction and GC analysis were performed as described above. Correction factors were calculated and used to accordingly adjust ester concentration values.

A unit of ester-forming activity was defined as the amount of enzyme that formed 1 nmol of ester in 24 h. Specific ester-forming activity was defined as units per milligram of protein.

2.5. Protein determination

Protein concentrations were determined by the method of Bradford (1976), using a kit from Bio-Rad (CA, USA) and bovine serum albumin (Sigma, MO, USA) as standard.

2.6. Statistical analysis

All experiments were repeated twice. The results were submitted to analysis of variance (ANOVA). Tukey's test was performed for multiple mean comparisons ($P < 0.05$). Relations between strains and production level of each ester were studied by means of the Multiple Correspondence Analysis (MCA) method (Abdi & Valentin, 2007). For the MCA method, all quantitative data was transformed in categorical data. Results were expressed as production (ppm) and four categories (levels) were established according to minimal and maximal production level for each ester (Tables 1 and 2). Calculations and graphics were carried out with the Infostat Professional software 2004p1.

3. Results and discussion

3.1. Synthesis of ethyl esters

3.1.1. Synthesis of ethyl esters by alcoholysis

Ester-synthesising activity by alcoholysis (transferase activity) was determined on CFE in assay mixtures containing triglyceride (tributyrin or tricaproin) plus ethanol. Results are shown in Table 3.

Table 1
Categories established according to ester production by alcoholysis.

Level	Ester production (ppm)				
	EtC2	EtC4	EtC6	EtC8	EtC10
1	⩽1.30	⩽3.10	⩽1.80	⩽0.023	⩽0.40
2	⩽2.60	⩽6.20	⩽3.60	⩽0.046	⩽0.80
3	⩽3.90	⩽9.30	⩽5.40	⩽0.069	⩽1.20
4	⩽5.20	⩽12.40	⩽7.20	⩽0.092	⩽1.60

EtC2, ethyl acetate; EtC4, ethyl butanoate; EtC6, ethyl hexanoate; EtC8, ethyl octanoate; EtC10, ethyl decanoate.

Table 2
Categories established according to ester production by esterification.

Level	Ester production (ppm)			
	EtC4	EtC6	EtC8	EtC10
1	⩽17	⩽36	⩽2	⩽0.10
2	⩽34	⩽72	⩽4	⩽0.20
3	⩽51	⩽108	⩽6	⩽0.30
4	⩽68	⩽144	⩽8	⩽0.40

EtC2, ethyl acetate; EtC4, ethyl butanoate; EtC6, ethyl hexanoate; EtC8, ethyl octanoate; EtC10, ethyl decanoate.

Strains evaluated in this work showed a great variability in their ability to synthesise ethyl esters by alcoholysis. Ethyl esters of C4 and C6 were detected when CFE were incubated in presence of tributyrin and ethanol. Amongst lactobacilli strains the highest EtC4-synthesising activity was observed in *L. casei* ETC19 and *L. plantarum* ETC17 (49.18 ± 6.28 and 41.13 ± 4.33 U/mg, respectively). Enterococci strains showed higher EtC4-forming activity than lactobacilli, displaying *E. faecium* Ov194 and *E. faecium* ETC124 the highest activities (105.56 ± 11.23 and 104.88 ± 15.04 U/mg, respectively). Amongst all of the strains evaluated, only *L. plantarum* Ov161 showed significant EtC6-synthesising activity (48.92 ± 5.66 U/mg). *E. faecium* Ov178 was the only strain displaying EtC8-forming activity (0.40 ± 0.15 U/mg). None of the strains was able to synthesise ethyl esters of C2 and C10.

In the assay mixture containing tricaproin and ethanol, EtC2-forming activity was detected in *L. plantarum* ETC17, *L. plantarum* Ov186, *E. faecium* Ov167 and *E. faecium* Ov157. Other ethyl ester-forming activities were significantly lower in evaluated strains. Only two strains were able to produce EtC4 and four strains synthesised EtC8 (Table 3). *E. faecium* Ov254 was the only strain displaying EtC6-forming activity (0.63 ± 0.22 U/mg). *L. plantarum* Ov186 showed the highest EtC10-forming activity (7.41 ± 1.03 U/mg).

Liu et al. (2003a) reported that dairy LAB can synthesise substantial amounts of EtC4 from tributyrin and ethanol in aqueous systems *via* a transferase reaction (alcoholysis) in which butyryl groups from tributyrin are transferred directly to ethanol. They also found LAB to vary in their ability to produce esters *via* alcoholysis with *S. thermophilus* and *L. fermentum* displaying the highest transferase activities amongst a range of LAB studied. It was demonstrated that the enzymes that catalyse ester biosynthesis *via* the transferase reaction are indeed esterases that display acyltransferase activities (Liu, Baker, et al., 2004).

The highest ester-forming activities observed in enterococci strains would indicate that alcoholysis would be the main ester synthesis mechanism in this genus. This fact could be explained by the high esterolytic activities of these strains, which would allow the release of fatty acids from triglycerides and their concomitant esterification with ethanol (Abeijón et al., 2006; Katz et al., 2002; Oliszewski et al., 2007).

Oliszewski et al. (2007) have reported that enterococci strains isolated from goat's milk and cheeses showed the highest esterolytic activities on α-naphthyl (α-NA) derivatives of fatty acids of 4 and 6 carbon atoms. These results are in agreement with Katz et al. (2002), who observed that enterococci strains isolated from ewes' milk and cheese had higher esterolytic activity on α-NA butyrate and caproate than lactobacilli strains. Tsakalidou et al. (1994) concluded that enterococci strains show significantly higher esterolytic activity than strains of most other genera of LAB.

Other authors have reported significant EtC4-synthesising activity in *Streptococcus thermophilus* than other LAB. This correlates with both the high esterolytic activity detected in *S. thermophilus* (Crow, Holland, Pritchard, & Coolbear, 1994) and the perceived sweet/fruity flavour notes associated with this thermophilic starter (Law, 1998). Nevertheless, some authors have observed that there is no correlation between ester-hydrolysing and synthesising activities (Gandolfi, Gaspari, Franzetti, & Molinari, 2000).

A number of studies have demonstrated that water acts as a competitive inhibitor of lipase-catalysed esterification (Liu, Holland, et al., 2004), so ester synthesis by alcoholysis, in which fatty acid groups from acylglycerols are transferred to alcohols without direct involvement of water, would be the main mechanism involved in aqueous systems. The strains with high ester-forming activity by alcoholysis may be involved in the production

Table 3

of these flavour-active compounds mainly in fermented milks, soft cheeses, and at the first stages of cheese ripening.

The multiple correspondence analysis (MCA) provides valuable information allowing the visualisation of the relations between strains and different production levels of each of the five ethyl esters analysed. The MCA of the results of ester synthesis by alcoholysis is shown in Fig. 1.

In the origin of the system (axes intersection delimiting the four quadrants) are situated all the strains having low levels of ester production (level 1). *L. plantarum* Ov186 differs significantly from the rest of the strains, being associated to the highest level of EtC10 (level 4) and intermediate level of EtC2 production (level 2) from tricaproin and ethanol. (Quadrant I).

Strains situated in the upper side of quadrant II are good producers of EtC4 from tributyrin and ethanol. *E. faecium* Ov409, Ov426, Ov194 and ETC124 showed the highest EtC4 production (level 4) when CFE were incubated in the presence of these substrates. Next to them are located some strains with level 2 production of this ester.

Strains situated in the quadrant III are good producers of ethyl esters from C2, 6 and 8. *L. plantarum* ETC17 and *E. faecium* Ov167 are associated with high production levels of EtC2 from tricaproin and ethanol (level 4 and 3, respectively). These strains are also associated with level 2 EtC4 production from tributyrin (Quadrant II). *L. plantarum* Ov161 is associated with level 4 EtC6 production. Strains associated with high EtC8 production in the medium containing tricaproin and ethanol are *E. faecium* Ov178, *E. faecium* Ov242 and *L. rhamnosus* ETC14 (level 4). *E. faecium* Ov178 is also related to level 4 EtC8 production from tributyrin and ethanol.

3.1.2. Synthesis of ethyl esters by esterification

Ester-synthesising activity by esterification was determined on CFE in assay mixtures containing free fatty acid (butanoic or hexanoic acid) plus ethanol. Results are shown in Table 4.

Large strain differences in the potential for ethyl ester formation amongst the LAB surveyed were observed. Liu et al. (1998) reported the formation of EtC4 from ethanol and butanoic acid by non-growing cells of several starter and non-starter LAB, which was both specific and strain dependent.

When CFE were incubated in an assay mixture containing butanoic acid and ethanol only EtC6-synthesising activity was observed. *L. casei* ETC19 was the only strain displaying EtC4-forming activity (88.54 ± 9.15 U/mg). In general lactobacilli strains showed higher ester-synthesising activities than enterococci when CFE were incubated with these substrates. Amongst lactobacilli strains *L. rhamnosus* ETC14 showed the highest EtC6-synthesising activity (679.20 ± 39.78 U/mg). *L. casei* ETC19 and *L. plantarum* Ov156 showed similar activities (210.12 ± 19.37 and 239.83 ± 31.20 U/mg, respectively). Only three strains of enterococci showed ester-synthesising ability: *E. faecium* ETC124, Ov178 and Ov194 (22.85 ± 2.88, 5.15 ± 1.44, 4.58 ± 0.89 U/mg of EtC6, respectively). None of the evaluated strains showed an ability to synthesise ethyl esters of C2, C8 and C10.

The fact that EtC6 was synthesised, whereas no EtC4 was formed in the presence of its immediate precursors (butanoic acid and ethanol) would indicate that other ester synthesis mechanism, besides esterification could be involved. Similar results were observed by Liu, Holland, and Crow (2003b), who reported that a commercial lipase produced EtC6 in addition to EtC4, when incubated in a cheese-based medium containing butanoic acid and ethanol. We reason that ester synthesis by acidolysis could be a tentative explanation. EtC6 can be formed by the reaction between the esters, formed by esterification between butanoic acid and ethanol, and the butanoic acid that remains in the medium. In addition, some authors suggested that cheese esters can be formed non-enzymatically (Liu, Holland, et al., 2004).

In the assay mixture containing hexanoic acid and ethanol, synthesising-activities of ethyl esters from C4 to C10 were observed, mainly EtC4 and EtC6. The highest EtC4-synthesising activities were observed in *E. faecium* ETC124 (569.46 ± 47.75 U/mg), *L. rhamnosus* ETC14 (470.43 ± 37.93 U/mg) and *L. plantarum* ETC17 (406.18 ± 42.33 U/mg).

Lactobacillus fermentum ETC1 displayed the highest EtC6-forming activity (991.38 ± 101.92 U/mg), whereas similar activities were observed in *L. rhamnosus* ETC14, *E. durans* Ov421 and *E. faecium* Ov242 (Table 4). Some strains showed EtC8 and EtC10-forming activities, being significantly lower than EtC4 and EtC6-synthesising activities (Table 4).

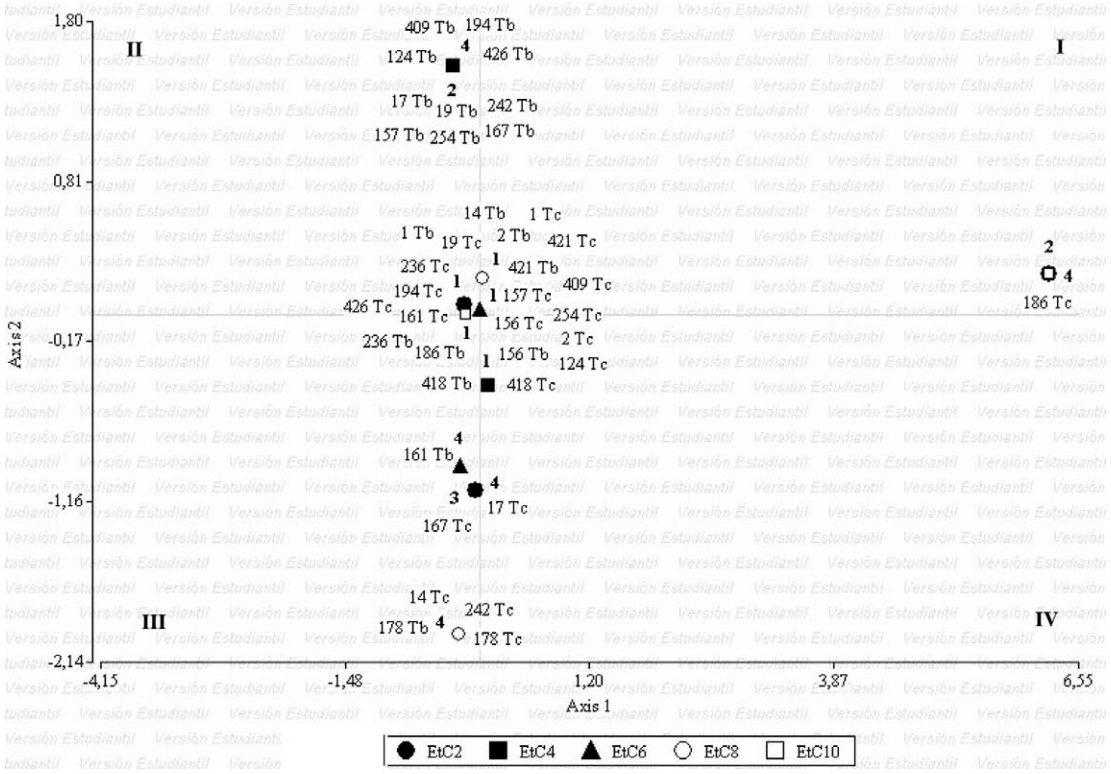

Fig. 1. Biplot obtained by Multiple Correspondence Analysis of ethyl esters of short-chain fatty acids produced by the mechanism of alcoholysis, expressed in ppm. Points are coded by strain (1, *L. fermentum* ETC1; 2, *L. delbrueckii* subsp. *bulgaricus* ETC2; 14, *L. rhamnosus* ETC14; 17, *L. plantarum* ETC17; 19, *L. casei* ETC19; 124, *E. faecium* ETC124; 418, *E. faecium* ETC418; 156, *L. plantarum* Ov156; 161, *L. plantarum* Ov161; 186, *L. plantarum* Ov186; 236, *L. plantarum* Ov236; 157, *E. faecium* Ov157; 167, Ov167; 178, Ov178; 194, Ov194; 242, Ov242; 254, Ov254; 426, Ov426; 409, Ov0409; 421, *E. durans* Ov421) and substrate (Tb, tributyrin; Tc, tricaproin). EtC2, ethyl acetate; EtC4, ethyl butanoate; EtC6, ethyl hexanoate; EtC8, ethyl octanoate; EtC10, ethyl decanoate. The position of some points was slightly modified to avoid overlapping of the labels.

[a] Results are expressed as U/mg of protein. Mean ± SD. Values in the same column with different superscript letters differ significantly ($P < 0.05$).

The MCA of the results of ester synthesis by esterification is shown in Fig. 2. Strains with low ester production levels are concentrated in the origin of the system. All of the strains are related to the lowest level of ester production in the assay mixture containing butanoic acid and ethanol, except for *L. rhamnosus* ETC14 which is related to level 3 production of EtC6. This strain is also related to level 3 production of this ester from hexanoic acid and ethanol (Quadrant IV). Very close situated in the same quadrant are

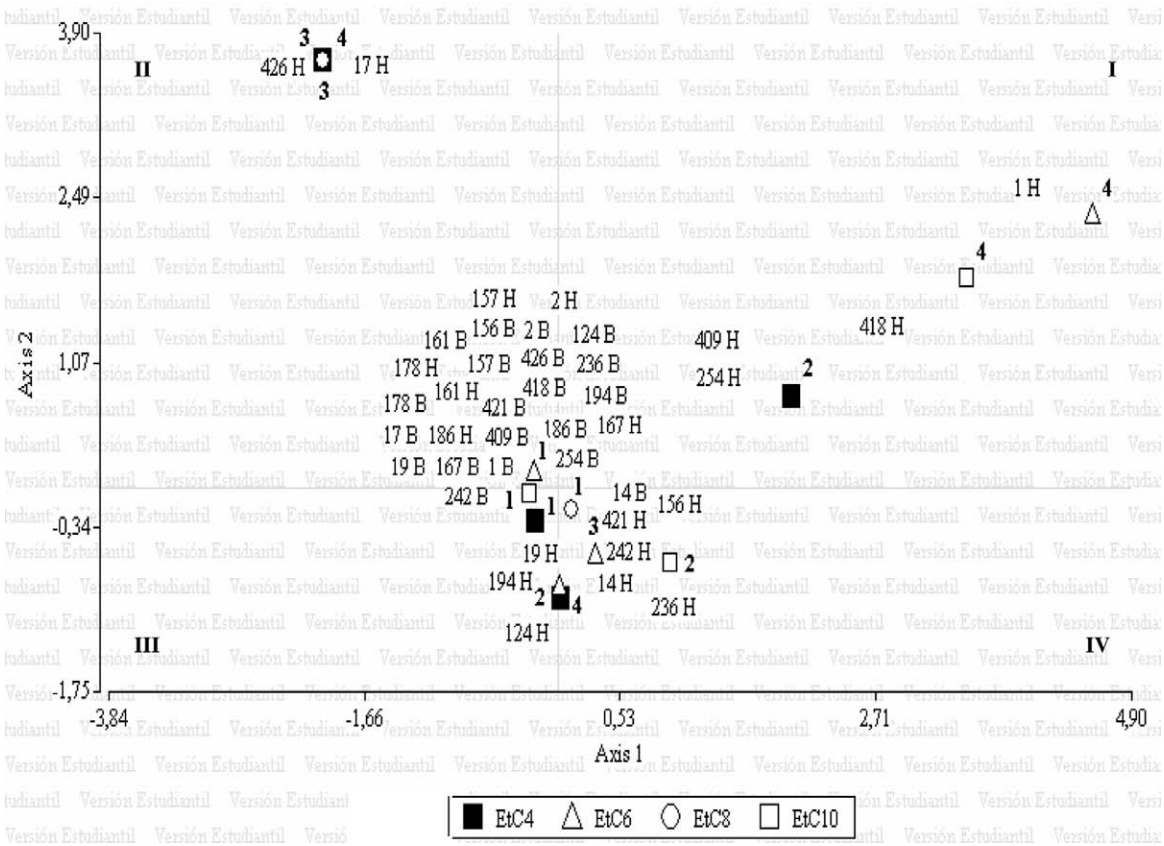

Fig. 2. Biplot obtained by Multiple Correspondence Analysis of short-chain fatty acids produced by the mechanism of esterification, expressed in ppm. Points are coded by strain (1, *L. fermentum* ETC1; 2, *L. delbrueckii* subsp. *bulgaricus* ETC2; 14, *L. rhamnosus* ETC14; 17, *L. plantarum* ETC17; 19, *L. casei* ETC19; 124, *E. faecium* ETC124; 418, *E. faecium* ETC418; 156, *L. plantarum* Ov156; 161, *L. plantarum* Ov161; 186, *L. plantarum* Ov186; 236, *L. plantarum* Ov236; 157, *E. faecium* Ov157; 167, Ov167; 178, Ov178; 194, Ov194; 242, Ov242; 254, Ov254; 426, Ov426; 409, Ov0409; 421; *E. durans* Ov421) and substrate (B, butanoic acid; H, hexanoic acid). EtC2, ethyl acetate; EtC4, ethyl butanoate; EtC6, ethyl hexanoate ; EtC8, ethyl octanoate; EtC10, ethyl decanoate. The position of some points was slightly modified to avoid overlapping of the labels.

E. durans Ov421, *E. faecium* Ov242 and *L. plantarum* Ov156, since they produce similar amounts of EtC6.

The strain *L. fermentum* ETC1 differs significantly from the rest, being associated to the highest levels of EtC6 and EtC10 production in the presence of hexanoic acid and ethanol (Quadrant I). *E. faecium* ETC418 is positioned not far but distinguishable from this first strain, in the same quadrant, since their EtC10 production is similar (both level 4).

Lactobacillus plantarum ETC17 and *E. faecium* Ov426 are very close situated in quadrant II, since they produce very similar amounts of EtC4 (level 3). They are also related to high levels of EtC8 production (level 4 and 3, respectively). *L. rhamnosus* ETC14 and *E. faecium* ETC124 are very closely located in the limit between quadrant III and IV, presenting the highest production of EtC4. This latter strain is also situated near to *E. faecium* Ov194 and *L. casei* ETC19, since they are all related to level 2 production of EtC6.

Enterococcus faecium ETC124 is associated to the highest EtC4 production by both mechanisms evaluated: alcoholysis (Fig. 1) and esterification (Fig. 2). These results could be explained by the presence of more than one esterase. Multiple esterases were found in several LAB (Abeijón et al., 2006; Katz et al., 2002; Oliszewski et al., 2007; Sarantinopoulos et al., 2001).

When comparing the ester-synthesising activity of the assayed strains by the two mechanisms evaluated (Tables 3 and 4), in general, higher ester-forming activities by esterification were observed. Enterococci strains were able to synthesise esters by alcoholysis in the presence of tributyrin, which would be related to their higher esterolytic activities. Other authors reported that in an aqueous environment, the yield of ester biosynthesis *via* alcoholysis was much higher than that of esterification (Liu, Baker, et al., 2004). In an environment where the water activity is low, such as ripened cheese, these strains may contribute to ester formation by both mechanisms (esterification and alcoholysis).

4. Conclusions

The results show that strains evaluated in this work were able to synthesise esters of short-chain fatty acids, mainly ethyl butanoate and ethyl hexanoate, which are desirable key odours in goat's and ewe's milk cheeses.

The highest ester-synthesising activities were observed when CFE were incubated in the presence of free fatty acids and ethanol, indicating that esterification is the prevalent mechanism in these strains. In enterococci strains the alcoholysis mechanism is also involved. These strains could be useful as adjunct cultures for small ruminants' dairy products and would contribute to the development of fruity flavour notes. Great variability in ester-forming activities between strains highlights the need for selecting appropriate cultures.

These results contribute to the knowledge of ester synthesis mechanisms by lactic acid bacteria and provide information about this topic in *Enterococcus* genus, which has not been reported at present. A deeper understanding of these mechanisms would allow to control ester production in fermented milk and cheese, assisting the manufacturers in their endeavour to obtain products with appropriate organoleptic characteristics.

Dairy foods

ABSTRACT

The *trans* as well as the *cis* C16:1 isomer profiles were established in 43 ewe milk fats supplemented with different dietary lipid sources representative of the variety of unsaturated fatty acids found in nature such as olive, sunflower, linseed and fish oils. Fractionation by silver-ion solid phase extraction facilitated a rapid separation of the *trans*, *cis* and saturated FA before gas chromatography analysis took place. C16:1 isomers with a double bond in positions 7, 9 and 13 in the *cis* group and 8 and 9 in the *trans* fraction were the most abundant. Dietary lipid supplementation produced a noticeable increase in the total *trans* C16:1 content and elevated correlations were observed between *trans*-8 C16:1 and *trans*-10 C18:1 as well as *trans*-9 C16:1 and *trans*-11 C18:1. These results support the idea that altering the *trans* C18:1 profile affects *trans* C16:1 isomer composition consistent with the β-oxidation products from the *trans* C18:1 isomers.

1. Introduction

Dairy fat is one of the most complex dietary fats encountered in nature. This is particularly true with respect to our nutritional knowledge of the contents of *trans* fatty acids (TFAs) currently found in milk lipids, and is of great interest due to the possible role played by these TFAs in atherosclerosis and coronary heart disease though this is still subject to controversy. The TFA composition of ruminants reflects the biohydrogenation processes of the dietary fatty acids (FAs) taking place in the rumen. A multitude of research has reported the effects of feed, dietary regimens and lipid supplementation on *trans* isomer production, mainly with respect to 18 carbon atom unsaturated FAs (Chilliard et al., 2007; Harfoot & Hazlewood, 1997) but only a few articles have provided detailed information on other minor monounsaturated TFAs in milk fat. The first report that appeared about isomeric distribution of *trans* C16:1 isomers in bovine was published by Hay and Morrison (1970). Other studies in cow (Molkentin & Precht, 1997) and human (Precht & Molkentin, 2000) milk fat have been published more recently. In ewe milk fat the information is even scarcer. Destaillats, Wolff, Precht, and Molkentin (2000) observed that in different French cheeses made with cow, goat and ewe milks and purchased locally in supermarkets, the *trans* C16:1 isomers represented about 5% of the sum of *trans* C16:1 plus *trans* C18:1 isomers, whereas Goudjil et al. (2004) reported a mean content of *trans* C16:1 of 0.25% of total FA in ewe milk fat samples collected from five different breeds. Furthermore, hardly any data on individual *cis* C16:1 isomer FA content in ewe milk lipids have been published (Destaillats et al., 2000).

In the aforementioned studies the *trans* C16:1 content was determined by using a combination of silver ion thin-layer chromatography (Ag^+-TLC) and gas chromatography (GC), because an overlapping of *cis* C16:1 and branched C17:0 FA was frequently obtained if no pre-separation step was applied. However, as the Ag^+-TLC methodology has been deemed time-consuming and labour-intensive apart from the fact that it cannot be automated, GC combined with pre-fractionation by silver ion solid phase extraction (Ag^+-SPE) has very recently been shown to be a good alternative to Ag^+-TLC for isolating specific groups of FAs in milk fat. Kramer, Hernández, Cruz-Hernández, Kraft, and Dugan (2008) applied total fatty acid methyl esters (FAME) from different milks onto Ag^+-SPE cartridges and eluted with different solvents. The Ag^+-SPE method proved to be easier than Ag^+-TLC and yielded better FA resolution in different regions of the GC chromatogram.

Although the world production of ewe milk seems insignificant compared with the cow milk market, ewe cheeses are widely consumed in some geographical areas of the world such as the Mediterranean countries. Thus, it is useful to obtain more information about the composition of ewe milk fat, and especially about its minor TFAs and any factors which cause variations. Therefore, the aim of this work was to determine the *trans* C16:1 isomer composition of ewe milk fat and to study the variations in its composition relative to the source of lipids, using the new method of Ag^+-

SPE fractionation. Since there is little published information about other minor FA eluting in the same chromatographic region (*cis* C16:1 and branched C17:0), such information was also included in this study.

2. Materials and methods

2.1. Samples

This work was made up of 43 ewe milk fats originating from previous studies. All of them were frozen at −20 °C. Milk samples were selected to cover the effects of five types of dietary lipid supplements on the ewe milk fat samples (Table 1). Briefly, the first group dealt with the impact of a control diet supplemented with 6% dry matter (DM) of olive oil a source of oleic acid, the second with 6% DM of sunflower oil a source of linoleic acid, the third with 6 and 12% linseed DM a source of α-linolenic acid, the fourth with 2% of fish oil DM a source of long chain polyunsaturated fatty acids (PUFA) and finally the fifth a combination of sunflower and fish oil. Moreover, control samples from ewes fed without lipid supplementation were also studied (Table 1). These fats were used for the purpose of comparison with samples from supplemented diets.

2.2. Ag^+-SPE fractionation

Ewe milk fats were defrosted and derivatised to FAMEs. These derivatives were prepared by base-catalysed methanolysis of the glycerides (KOH in methanol) in accordance with the ISO-IDF procedure (2002). After derivatisation FAMEs were fractionated according to the number and geometry of the double bonds by Ag^+-SPE as described by Kramer et al. (2008). Ag^+-SPE cartridges were purchased from Supelco (Bellefonte, PA, USA). Before use, the cartridges were first conditioned with 4 ml of acetone to remove any moisture followed by hexane to equilibrate them. All the FAMEs were applied onto the column and eluted with 6 ml volumes of hexane containing increasing amounts of acetone: 99:1 (v/v) eluted saturated FAMEs, 96:4 (v/v) eluted mono-*trans* FAMEs plus the *cis–cis* and *trans–trans* FAME isomers of conjugated linoleic acid (CLA) and 90:10 (v/v) eluted mono-*cis* plus *cis/trans* of CLA. All fractions were taken to dryness in a stream of nitrogen and then reconstituted in an appropriate volume of hexane for analysis by GC.

2.3. Gas chromatography

The total FA profile was recorded by analysis of FAMEs on a gas–liquid chromatograph (Agilent 6890N Network System) with auto injector, fitted with a flame ionisation detector onto a CP-Sil 88 fused silica capillary column (100 m × 0.25 mm, Varian, Middelburg, The Netherlands). Helium was the carrier gas at an inlet pressure of 193.5 kPa and a split ratio of 1:100. The injector and detector temperature was 250 °C. Linear flow velocity of carrier gas in GC was 1.0 ml/min. Total time of the chromatographic programme was 180 min: the initial oven temperature being 45 °C. After 4 min, the oven temperature was raised at a rate of 13 °C min^{-1} to 150 °C. After 98 min, the oven temperature was raised 10 °C min^{-1} to 210 °C and then held for 64 min. Saturated, mono *cis* and mono *trans* FA fractions were analysed as FAMEs on the same equipment and conditions but the split ratio was 1:2.

2.4. Identification, calibration and quantitation of fatty acids

The FA profiles of milk fat samples were compared with a FAME reference standard mixture (GLC-461, Nuchek, Elysian, MN, USA). *Iso* and *anteiso* C17:0 methyl ester standards were available from Larodan Fine Chemicals (Malmö, Sweden). Identification of the 18:1, 16:1 *cis* and *trans* FA was based on principles of fractionation by argentation and GC, selected isomers from Nuchek, and by comparison with previously published reports.

Calibration of the individual FAs was carried out using the reference material CRM-164 obtained from the Community Bureau of Reference (Commission of the European Communities, Brussels, Belgium). The quantitation of positional isomers of *trans*-16:1 and *trans*-C18:1 present in the *trans* monoene fraction was achieved with the *trans*-9 C16:1 and *trans*-16 C18:1, respectively, which had been quantitated by stearic acid in the chromatography of the unfractionated FAMEs. Furthermore, the *cis* C16:1 and *cis* C18:1 isomers were calibrated by C17:1 and *cis*-12 C18:1, respectively, which were also determined in the total FAME GC analysis.

2.5. Statistical analysis

Statistics were performed by SPSS 17.0 for Windows XP. A bivariate analysis with Pearson correlations ($p < 0.05$ level, 2-tailed) was conducted with the data to determine the relationship between different FAs.

3. Results and discussion

Table 2 contains the *trans* C16:1 total content for the different groups of samples. Milk fat from ewes fed unsupplemented diets exhibited a mean content of total *trans* C16:1 of 0.30% with an interval of variation between 0.12 and 0.41%. These results coincide with data previously reported by Destaillats et al. (2000) for different cheeses made with ewe milk purchased in French supermarkets as well as with those of Goudjil et al. (2004) for bulk ewe milk from five herds. These values (Table 2) are greater than those observed in goat and cow milk fat where the total *trans* C16:1 content was never above 0.25% (Destaillats et al., 2000; Molkentin & Precht, 1997). Even so, it should be stressed that *trans* C16:1 isomers represent less than 10% of the sum of all *trans*-monoenoics apart from being very minor isomers in ewe milk fat too.

However, regardless of the lipid source, dietary supplementation provoked an increase in the total *trans* C16:1 content (Table 2). These increases were more striking in those milks coming from animals fed sunflower oil as well as from those fed combined sun-

Table 1
Ewe milk fat samples analysed.

Group	No of samples	Type of dietary lipid supplementation (% in dry matter)	Forage/concentrate proportion
1	8	Olive oil (6%)	20/80
2	7	Sunflower oil (6%)	20/80
3a	4	Linseed (6%)	60/40
3b	4	Linseed (12%)	60/40
4	4	Fish oil (1%)	20/80
5	4	Fish oil (1%) + sunflower oil (2%)	20/80
6a	10	None	20/80
6b	2	None	60/40

flower and fish oil supplements. In these samples, total *trans* C16:1 values were nearer to 1%, reaching in some cases percentages similar to those for *cis* C16:1 (Table 3). The presence of elevated amounts of *trans* C16:1 in ruminant milks has barely been documented (Cruz-Hernández et al., 2007), but, it is well known (Bauman et al., 2006; Harfoot & Hazlewood, 1997) that dietary lipid supplementation with sources of PUFA can generate high percentages of total *trans* C18:1 FA in milk fat. Its origin is the result of incomplete biohydrogenation of the dietary C18 PUFA in the rumen. Some of these *trans* C18:1 FAs produced in the rumen are transferred to milk fat. Nevertheless the occurrence of *trans* C16:1 isomers in milk fat would not be easy to explain, since the ruminant diet did not contain relevant amounts of *cis* hexadecenoate FAs susceptible to isomerisation and/or hydrogenation in the rumen. This fact, together with the high correlation ($R^2 = 0.81$; $P < 0.01$) observed between total *trans* 16:1 and total *trans* C18:1 content could be evidence of a possible conversion pathway from C18 to C16 FA groups.

Fig. 1 shows the typical gas partial chromatograms of the C16:1 area from ewe milk fat after Ag^+-SPE fractionation. Applying of this technique in combination with GC resulted in the separation of almost all *cis* and *trans* C16:1 isomers of ewe lipids. The *cis* C16:1 isomer group is much simpler than the corresponding *trans* fraction. As expected (Table 3), *cis*-9 C16:1 (palmitoleic acid) is by far the major isomer followed by *cis*-7 and *cis*-13. The rest of the isomers were detected in very low concentrations corresponding with the values reported for ewe milk cheese fat by Destaillats et al. (2000). Palmitoleic acid in milk fat is mostly formed by the action of delta-9 desaturase in the mammary gland using the same mechanism employed to convert C18:0 to *cis*-9 C18:1. This enzyme is located in the endoplasmic reticulum of the mammary gland cells and its primary substrates are palmitic and stearic acid. Although mammalian desaturase is not always entirely specific for the 9 position, it seems likely that the remaining *cis* isomers are principally the product of rumen microbial desaturases (Hay & Morrison, 1970).

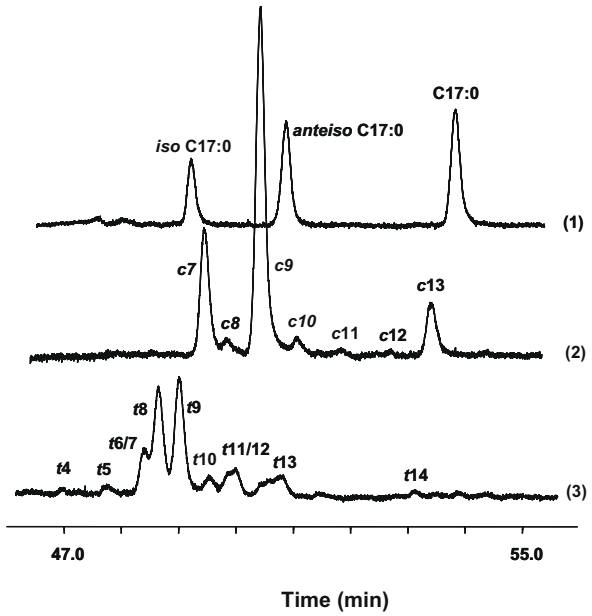

Fig. 1. Partial gas chromatograms of silver-ion solid phase extraction fractions showing saturated (1), *cis* C16:1 (2) as well as *trans* C16:1 (3) fatty acids methyl esters of ewe milk fat. *c*: *cis*; *t*: *trans*.

Milk fat from ewes fed lipid supplement diets showed lower percentages of saturated FA whereas contents of omega-3 FA were enhanced when linseed or fish oil was included in the ration (Table

3). On average, milk fats from animals fed unsupplemented diets contained about 0.2 and 0.3% of *iso* and *anteiso* C17:0, respectively (Table 3). These proportions do not substantially differ from those reported for cow milk (Kramer et al., 2008). Percentages of *iso* and *anteiso* C17:0 were lower in milk fat samples from ewe fed lipid supplements than control diets (Table 3). It is well known that secretion of odd and branched-chain FAs in milk, often resulting from microbial FA metabolism in the rumen, tends to diminish or significantly decrease with oil supplemented diets (Vlaeminck, Fievez, Cabrita, Fonseca, & Dewhurst, 2006). Ruminant diets high in lipids can contribute towards changes in the digestive microflora as well as rumen metabolism thereby modifying the milk branched FA profile.

In milk fat from ewes fed without lipid supplementation *trans*-9 (palmitelaidic acid) is the most common isomer (0.11% of total FAMEs) followed by *trans*-11 *plus* *trans*-12, whilst the rest of the *trans* C16:1 isomers appear in lower proportions (Table 2). *trans*-9 C16:1 in milk from ewes on an unsupplemented diet represented almost 40% of total *trans* C16:1, a higher level to that previously reported in cow and ewe dairy fat (Destaillats et al., 2000; Kramer et al., 2008) but in accordance with the data of the first study by Hay and Morrison (1970) in bovine milk.

There was a noticeable rise in the percentages of some *trans* C16:1 isomers (Table 2) as a result of lipid supplementation. The most remarkable increases were observed for *trans*-9, *trans*-8 and, to a lesser degree, for both *trans*-6/*trans*-7 and *trans*-11/*trans*-12 pairs. Unfortunately, due to a lack of information in literature in this field, reliable comparisons cannot be made. However, very recently, Kramer et al. (2008) observed enhanced proportions of some *trans* C16:1 isomers in milk fat from cows fed a mixture of 4.5% sunflower oil and 0.5% fish oil. The main increases corresponded to *trans*-8 and *trans*-9 C16:1 isomers as has been the case in the present study (Table 2).

A potential source of *trans* C16:1 isomers could be the result of β-oxidation, a single step 2-carbon degradation of the *trans* C18:1 FA. Peroxisomal β-oxidation is a well-recognised process in FA metabolism in cells in which FA chains are shortened (Osmundsen, Bremer, & Pedersen, 1991). *trans* Hexadecenoates would appear to originate from the shortening of *trans* octadecenoate chains as was previously suggested in different tissues (Wood, 1979). The predominance of the *trans*-9 hexadecenoate may be related to the abundance of the substrate, *trans*-11 C18:1 (Fig. 2). The same pattern could be true for *trans*-8 C16:1 and its potential precursor, *trans*-10 C18:1.

The similarity between *trans* C16:1 and *trans* C18:1 profiles suggests that the same biosynthetic pathways could be responsible for the formation of the *trans* C16:1 acids. Theoretically, it would be impossible to decide whether they originate from *trans* C18:1 isomers through β-oxidation, by biohydrogenation of dietary C16:3 or C16:2, or as a result of both mechanisms operating together. However, as was mentioned above, it is unlikely that the *trans* 16:1 isomers were formed by biohydrogenation from C16 PUFA precursors, analogous to linoleic or α-linolenic acid forming *trans* C18:1 in ruminants, since C16 PUFA are not rich in ruminant diets or lipid supplements. In this context the evaluation of correlations between such isomeric contents would be of importance.

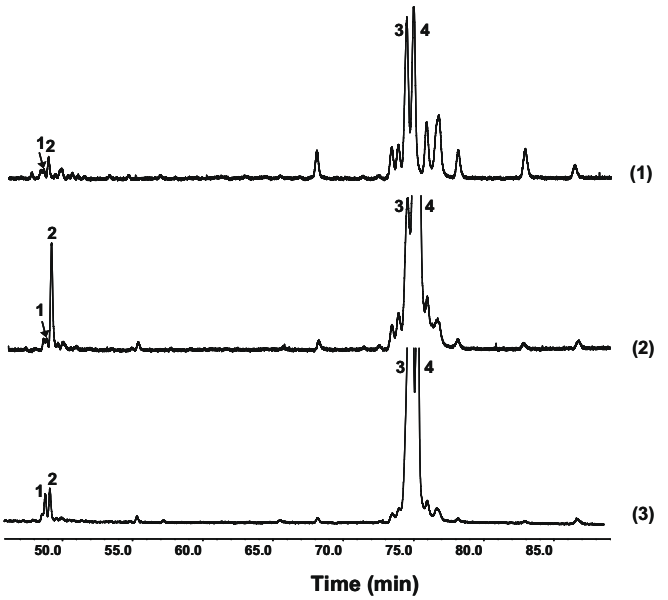

Fig. 2. Partial gas chromatograms including C16:1 and C18:1 regions of *trans* fatty acid methyl esters from control milk fat (1), *trans*-11 C18:1 (2) and *trans*-10 C18:1 (3) enriched milk fats. Control milk fat was derived from ewes fed unsupplemented diet whereas samples (2) and (3) came from ewes fed a 2% sunflower plus 1% fish oil supplement. Peak numbering: 1: *trans*-8 C16:1; 2: *trans*-9 C16:1; 3: *trans*-10 C18:1; 4: *trans*-11 C18:1.

Linear regression analysis was carried out establishing relationships between pairs of the quantitatively most relevant hexadecenoic and octadecenoic FAs present in the 43 ewe milk fat samples. The statistically highest positive correlations were found for *trans*-8 C16:1 and *trans*-10 C18:1 (R^2 = 0.97; $P < 0.01$) as well as for *trans*-9 C16:1 and *trans*-11 C18:1 (R^2 = 0.97; $P < 0.01$) (Fig. 3). From these correlations, it could be possible to deduce the existence of a conversion pathway from *trans* C18:1 to *trans* C16:1 based on a two carbon shortening mechanism of the octadecenoic TFA molecules. Such a mechanism could explain, from a quantitative point of view, how those *trans*-11 C18:1 enriched samples, the most abundant intermediate generated during linoleic and α-linolenic acid biohydrogenation (sunflower oil and linseed characteristic FAs), derived the most relevant growth of *trans*-9 C16:1. This argument would also explain why milk fats with the highest *trans*-10 C18:1 content, as a result of changes in biohydrogenation pathways associated with elevated dietary proportions of concentrate, elevated lipid supplementation or the presence of fish oil, also had the highest percentages of *trans*-8 C16:1.

Among the lipid supplements assayed in the ovine diets, only olive oil did not increase *trans*-9 C16:1 content (Table 2). The explanation for this behaviour could also be found in the biohydrogenation pathways of oleic acid. Results from experiments in ewe milk fat (Gómez-Cortés et al., 2008), which coincided with previous evidence obtained in in vitro studies (Mosley, Powell, Riley, & Jenkins, 2002), supported the idea that biohydrogenation pathways of *cis*-9 C18:1 in the rumen involved the formation of relevant amounts of a variety of *trans* monoene C18:1, except for *trans*-11. Thus, if the formation of *trans*-11 C18:1 is not promoted in the rumen, the contents of *trans*-9 C16:1 generated by β-oxidation in the tissues and subsequently excreted in the milk fat would not be elevated. The levels of *trans*-8 C16:1 in milk from ewes fed with olive oil could be justified by taking into account the production of large amounts of *trans*-10 C18:1 in the rumen from oleic acid as a precursor.

In line with that argument, the biohydrogenation pathways of α-linolenic acid should not be forgotten when considering the levels of *trans*-8 C16:1 in linseed samples, hardly different from those measured in control samples (Table 2). Among the *trans* monoene C18:1 intermediates of C18:3 in the rumen, only the *trans*-11 isomer is generated in remarkable amounts. In contrast, *trans*-10 C18:1 and other *trans* C18:1 are not frequently associated with α-linolenic acid biohydrogenation pathways (Chilliard et al., 2007; Harfoot & Hazlewood, 1997). Therefore, in linseed samples, important increases in *trans*-9 C16:1 and no changes in *trans*-8 C16:1 content were to be expected.

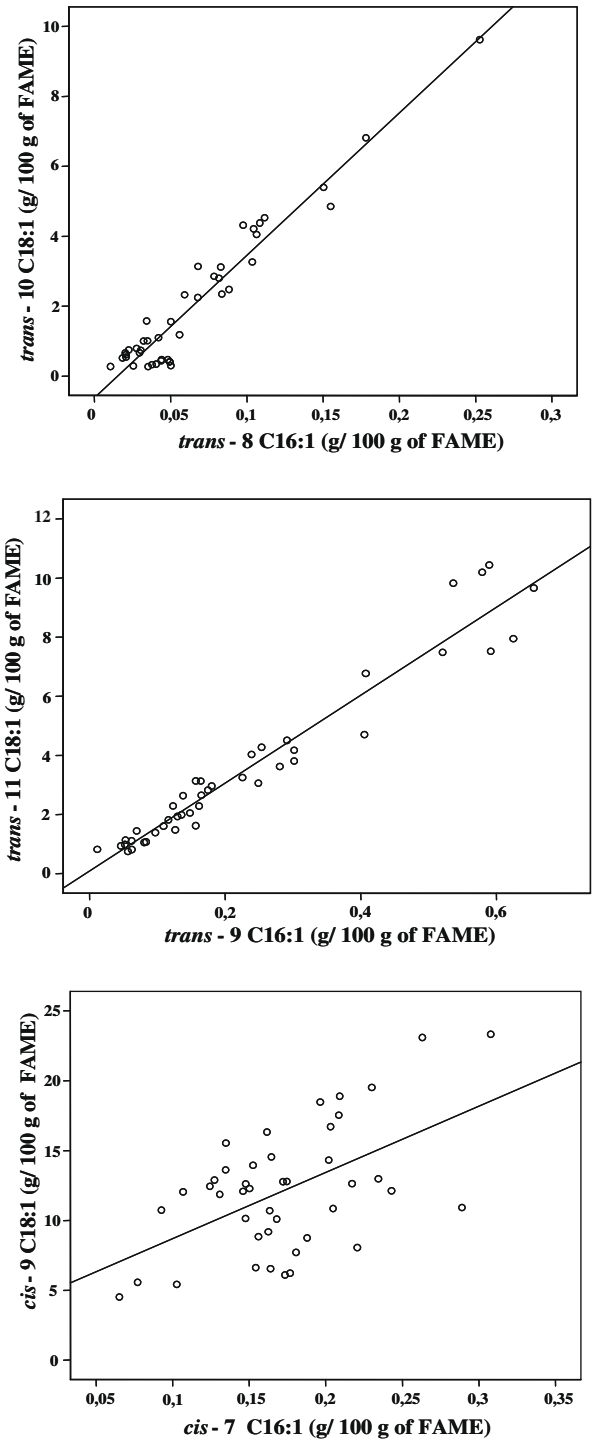

Fig. 3. Linear regression analysis establishing relationships between the pairs *trans*-8 C16:1 and *trans*-10 C18:1, *trans*-9 C16:1 and *trans*-11 C18:1, and *cis*-7 C16:1 and *cis*-9 C18:1 in 43 ewe milk fats obtained from ewes fed with different diets. FAME: fatty acid methyl esters.

Some chain shortening of the *cis* octadecenoate isomers could also occur, though to a much lesser degree than with the *trans* octadecenoates. The correlation between *cis*-7 C16:1 and oleic acid (*cis*-9 C18:1), its potential precursor, was clearly weaker ($R^2 = 0.55$, $P < 0.01$) than that reported between *trans* FAs (Fig. 3). This conclusion is also based upon the assumption that the *cis*-9 hexadecenoate that predominated in the *cis* fraction of the triglycerides was not derived to any significant extent from the chain shortening of the *cis*-11 octadecenoate isomer.

4. Conclusions

This work confirms that levels of hexadecenoic acids in ewe milk fat are similar to those found in other ruminant species. The total *trans* C16:1 content in milk obtained from ewes fed with lipid unsupplemented diets was low, but the inclusion of different sources of unsaturated FAs in ovine diets promoted increases in these FAs in milk fat, mainly *trans*-8 C16:1 and *trans*-9 C16:1 isomers. The strong correlations observed between both the *trans*-8 C16:1/*trans*-10 C18:1 pair and the *trans*-9 C16:1/*trans*-11 C18:1 pair would reveal the existence of a biosynthetic pathway linking both types of monounsaturated FAs.

ABSTRACT

Modifications in dietary fibre content of apples during industrial processing into applesauce were investigated. Samplings with different post-harvest storage times were performed at five different processing steps (apple sorting, cooking, refining, sugaring and pasteurisation) and the samples examined for their insoluble, soluble and total fibre contents, following the AOAC method. Total fibres were also estimated through preparation of alcohol-insoluble solids and polysaccharide compositions of the various fibre residues were determined. Total fibre content decreased from apple to applesauce from 2.4 to 1.7 g for 100 g of fresh weight and the soluble fraction increased. Fibre loss and soluble/insoluble redistribution occurred during processing. Refining triggered a loss of insoluble polysaccharides whilst cooking and, surprisingly, sugaring led to pectin solubilisation and further degradation due to prolonged heating. These pectic changes, moreover, seemed to be dependent on the post-maturity stage of the apples.

1. Introduction

Dietary fibres are defined today by the Association of Official Analytical Chemists (AOAC) as "the polysaccharides and remnants of plant materials that are resistant to hydrolysis (digestion) by human digestive enzymes" (Cho, Devries, & Prosky, 1997). This definition includes non-starch polysaccharides, resistant starch, lignin, and minor components, such as waxes, cutin and suberin, and has been adopted by many European countries. They may be divided into two fractions: one is soluble in water at 100 °C and one insoluble (Grigelmo-Miguel & Martin-Belloso, 1999). The methodologies based on such a definition (such as the enzymatic–gravimetric methods) are now the standards used for labelling of numerous food products. Many studies have highlighted that the consumption of foods rich in dietary fibre may improve health: recommended intake reaches 30–45 g per day and person yet current consumption of fibre in the West is only around 20 g/day person (Figuerola, Hurtado, Estevez, Chiffelle, & Asenjo, 2005; Grigelmo-Miguel & Martin-Belloso, 1999; Thebaudin, Lefebvre, Harrington, & Bourgeois, 1997).

Apple has been extensively studied as it is a widely consumed fruit and also an interesting source of insoluble (cellulose, some xyloglucans) and soluble dietary fibres (mainly pectic polysaccharides), both being mostly related to the cell-wall (Aprikian et al., 2001; Gheyas, Blankenship, Young, & McFeeters, 1997; Massiot & Renard, 1997). Industrial food products based on apple, such as applesauce, are thus nowadays often presented as a healthy and convenient alternative to candy or chocolate bars, often eaten between meals, especially in the case of children. However, few data are available on the persistence of the original apple dietary fibre content in such products. More precisely, the effects of the whole processing involved for production of apple-based foods are not known. Indeed, processing effects on dietary fibres are often studied through unit operations such as heating, drying or even enzymatic treatment (Chang & Morris, 1990; Nyman, Palsson, & Asp, 1987; Renard & Thibault, 1991). Heating effects (implicated in canning or blanching operations) have been the most studied, especially on carrot, and have been shown to trigger degradative effects on its pectic polysaccharides (Albersheim, Neukom, & Deuel, 1960; Lo, Grun, Taylor, Kramer, & Fernando, 2002; Massiot, Guiller, Baron, & Drilleau, 1992; Ng & Waldron, 1997; Sajjaanantakul, van Buren, & Downing, 1989; Sila, Smout, Elliot, Loey, & Hendrickx, 2006; Sila, Smout, Vu, Loey, & Hendrickx, 2005). Fruit processing also often involves peeling operations that may, as well,

doi:10.1016/j.foodchem.2009.03.109

be detrimental for fibre content. Indeed, the peel (epidermis) and the core zones (carpels) contain a higher proportion of cell-wall than does the flesh (Massiot & Renard, 1997). Moreover, the concentration and type of fibre-related polysaccharide differ from one tissue to the other, carpels being rich in glucans and xyloglucans and flesh containing a high proportion of pectic components (Massiot, Baron, & Drilleau, 1994). Finally, both skin and seeds appear to be rich in non-polysaccharide insoluble material (respectively, waxes and lignin). Therefore, both processing operations themselves, as well as their arrangement during the complete processing, may play a role in fibre content and in the type of fibre remaining in the final product.

Beyond the impact of processing itself, the original maturity stage of the fruit may affect the final fibre and cell wall polysaccharide content of the product. Indeed, variations in raw material quality and composition affect industrial processing of fruits. Nowadays, apples are processed all year long, mostly from the raw material remaining after sorting of table quality, thus including the use of fruits stored under controlled atmosphere. Impact of storage on apple composition is now well documented. Through maturation and post-harvest storage, losses in arabinose and galactose and solubilisation of galacturonic acid polymers of high molecular weight may be observed (Fischer & Amado, 1994; Knee, 1973; Massiot, Baron, & Drilleau, 1996; Wechsler, Strasser, & Amado, 1996). Cellulose and xyloglucan contents remain mostly unaffected (Bartley, 1976; Knee, 1973; Percy, Melton, & Jameson, 1997). However, interaction of this well-studied fruit evolution with processing impact is yet to be determined. The aim of this study was thus to investigate the response of apple dietary fibres and cell-walls to each unit operation of processing into applesauce, also taking storage into account. Two batches, corresponding to two different storage times (beginning and end of controlled atmosphere storage), were thus considered. To get a better insight of the modifications triggered by processing and storage time, cell-wall and total dietary fibres, as well as both soluble and insoluble fibre contents, were determined at each industrial step. Residues were analysed for neutral sugars and galacturonic acid.

2. Materials and methods

2.1. Industrial processing and sample preparation

Applesauce processing was carried out by a French manufacturer, using a hot-break process. The process was composed of several steps, summarised in Fig. 1: apples were first sorted and fruits presenting major visual defects were discarded. The fruits were roughly cut, then cooked (85 °C, 15 min), before refining (sieve opening 1.2 mm). A 15% proportion of glucose–fructose syrup (85 °Brix) was then added to the puree and the product was kept in a flow-regulating tank (85 °C, around 30 min) before pasteurising (90 °C, 2–3 min). In order to study the evolution of fibre content during the five main processing steps (sorting, cooking, refining, sugaring and pasteurisation), samplings were taken after each step. Samples were composed of 30 apples cut into large pieces or about 1 l of product.

To take into account the variations in apple composition, the sampling procedure was carried out twice: at the beginning (December 20th, 2005) and at the end (February 17th, 2006) of the controlled atmosphere storage period of apples. At each date, the sampling procedure was repeated twice, in order to include processing variability itself: two series of samplings were performed, one in the morning and one in the afternoon. In total, 20 different samples were thus obtained (5 processing steps × 2 dates × 2 sampling hours). Processing on December 20th will be further referred as "batch A" and processing on February 17th as "batch B". For both processing days, apple batches had the same composition: 90% of Golden apples and 10% of bicolour apples.

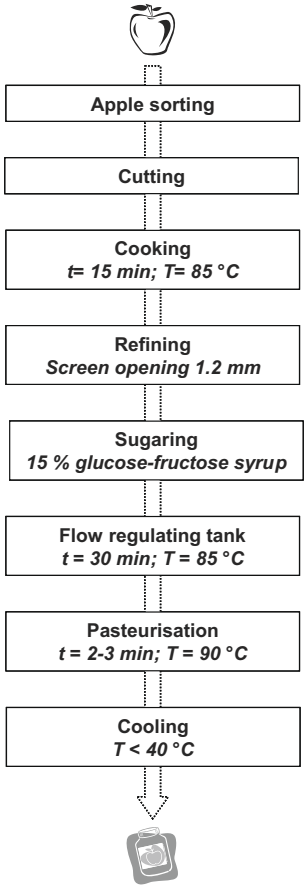

Fig. 1. Applesauce processing.

Samples were stored at −20 °C before freeze-drying of aliquots and milling in liquid nitrogen. The apple powders obtained were prepared in duplicate for each different sample, giving a total of 40 powdered samples, and stored in a desiccator under vacuum prior to analysis. Residual water content after freeze-drying was measured on each powdered sample by drying overnight at 105 °C. The final dry matter (DM) of the samples was then obtained after correction of the freeze-drying yields for this residual water content. Freeze-drying of the sweetened samples proved to be efficient, with less that 5% residual water in the powders.

2.2. Dietary fibre preparation

Insoluble (IDF), soluble (SDF) and total dietary fibre contents (TDF) were determined according to the enzymatic–gravimetric (phosphate buffer) AOAC methods (labelled 991.42, 993.19 and 985.29, respectively) with slight modifications (Cho et al., 1997). Sample duplicates (1 g of each duplicate powdered sample) were gelatinized with a thermo-stable α-amylase (Termamyl 120L, Novo Nordisk, Denmark) and successively treated with a protease (from *Bacillius licheniformis*, P3910, Sigma–Aldrich, France) and an amyloglucosidase (from *Aspergillius niger*, A9913, Sigma–Aldrich, France) to remove protein and starch, respectively. SDF and IDF were separated by filtration on a 75 ml Sep-pack prep column (Interchim, France) equipped with a sinter of porosity 20 μm. The residue obtained after filtration, containing IDF, was dried by solvent exchange (ethanol, acetone) and overnight at 105 °C and weighed. The IDF weight was corrected for protein (automated Dumas and Kjeldhal methods, protein content estimated as N × 6.25) and ash

contents (500 °C, 5 h). The filtrate, containing SDF, was precipitated with four volumes of 96% ethanol preheated to 60 °C. The SDF fraction was then recovered after filtration on a 75 ml Sep-pack prep column, dried by solvent exchange and overnight at 105 °C and weighed. A duplicate blank was run, together with each series of eight duplicated samples and SDF weight was corrected for blank weight. TDF was estimated as the sum of SDF and IDF. For each batch and processing step, a total of four estimations of dietary fibre content were obtained (duplicated sample × 2 sampling hours).

2.3. Alcohol-insoluble solids preparation

Alcohol-insoluble solid (AIS) content was determined on each duplicate powdered sample according to Renard (2005b). Apple powder was extracted with 70% ethanol at room temperature and filtered on the 75 ml Sep-pack prep columns (20 μm sinter) until the filtrate was sugar-free, as attested by the method of Dubois, Gilles, Hamilton, Rebers, and Smith (1956). The residue was then dried by solvent exchange and overnight at 40 °C. A total of four estimations of AIS content were obtained for each batch and processing step.

2.4. Chemical analysis

2.4.1. Acid hydrolysis of fibre samples

The IDF and AIS residues were submitted to acid pre-hydrolysis (13 M H_2SO_4, 1 h, 25 °C), followed by acid hydrolysis (1 M H_2SO_4, 3 h, 100 °C). The SDF samples were first solubilised in distilled water (2 mg/ml) before acid hydrolysis (1 M H_2SO_4, 3 h, 100 °C).

2.4.2. Neutral sugar analysis

The individual neutral sugars were analysed by gas chromatography (TRB-225 column, 30 m × 0.32 mm × 0.25 μm, AIT, France) after hydrolysis and derivatisation to alditol acetates, following the method described by Thomas, Crépeau, Rumpunen, and Thibault (2000). Myo-inositol was used as internal standard. Runs were performed at 200 °C, using nitrogen as carrier gas. Analysis was duplicated for each AIS residue and performed once on the IDF and SDF residues.

2.4.3. Galacturonic acid analysis

Galacturonic acid content was determined using the metahydroxydiphenyl assay (Thibault, 1979) on the IDF and AIS residues hydrolysed, as described in Section 2.4.2. The solubilised SDF residues were first submitted to saponification (0.05 M NaOH, 30 min, 25 °C), neutralised (0.05 M HCl), then analysed. Galacturonic acid was used as internal standard. Analysis was duplicated for each AIS residue and performed once on the IDF and SDF residues.

2.5. Data correction for process-added sugar

As the water content of the samples was likely to vary during processing, and because the studied applesauce was sweetened, processing effects were studied on a dry weight basis and after correction for the process-added sugar for sweetened samples (i.e. those corresponding to the sugaring and pasteurisation steps).

Apple fraction (Af, in %) of the sweetened samples was calculated, knowing the amount of sugar added (15% of glucose–fructose syrup for 85% apple puree) and its dry matter (85 g/100 g) and the dry matter of the studied sample (DM, $\text{sweetened}_{\text{sample}}$, in g/100 g), according to the formula:

$$\text{Af}(\%) = [\text{DM,sweetened}_{\text{sample}} - (15 \times 85/100)]/\text{DM,sweetened}_{\text{sample}} \times 100$$

Fibre content (on a dry weight basis), measured on these sweetened samples was then corrected according to its true apple fraction by multiplying fibre content by 100/Af.

Moreover, the dry matter relative to the apple fraction (DM, apple, in g/100 g) was also calculated for the sweetened samples, by considering that the dry matter of the sweetened samples came from the addition of the dry weight provided by 15% syrup and 85% apple puree:

$$\text{DM apple} = \text{Af} \times \text{DM sweetened}_{\text{sample}}/85$$

Statistical analyses were applied to these corrected values.

2.6. Statistical analysis

Analysis of variance (ANOVA) and the tests of mean comparison, according to Fisher least significant difference (LSD) were applied to instrumental data with the Statgraphics Plus v. 5.1 programme (Sigma Plus, France). Level of significance (α) was 0.05. Standard deviations were calculated for each series of measurement, using the sum of individual variances given by the sum of individual degrees of freedom.

3. Results

3.1. Fibre content of the fresh products

Fibre contents obtained with both AOAC and AIS methods for fresh apples and for applesauce (the finished product) are presented Table 1. On this fresh weight basis, fibre contents of unpeeled apples were similar, whatever the method, reaching 2.3 (AIS content) to 2.4 (TDF content) in g/100 g, which was consistent with values found in literature (2.0–2.7 g/100 g) (Gheyas et al., 1997; Marlett & Vollendorf, 1994; Renard, 2005b; Renard & Thibault, 1991). Around 28% of the dietary fibres were soluble: the calculated SDF/IDF ratio obtained was close to that found by Renard and Thibault (1991) on cored Golden apples and by Gheyas et al. (1997) on peeled apples (about 0.35). In the final sweetened applesauce (15% added sugar), fibre content was lower than in the fresh apples, reaching 1.7–1.8 g/100 g. Few studies report the fibre content of applesauce, yet values obtained here were slightly higher than those reported by Marlett and Vollendorf (1994) (1.4 g/100 g) but the authors did not mention whether their product was sweetened or not. The AOAC data base (Cho et al., 1997), however, mentions a TDF content of 1.2 g/100 g for unsweetened applesauce, which would give a lower fibre content than those measured here. Though the total fibre content decreased between apple and applesauce, the SDF content remained similar, indicating an increase in the soluble fibre fraction (39% in the case of applesauce).

Processing thus modified both the dietary fibre content and the ratio between soluble and insoluble fibre.

Table 1
Average fibre content (g/100 g of fresh weight) of fresh apples and applesauce, calculated on batches A and B. Standard deviations ($n = 8$) are presented in brackets.

Fibre content (g/100 g fresh weight)	Fresh apple	Applesauce
AIS	2.43 (0.09)	1.76 (0.05)
TDF	2.33 (0.09)	1.68 (0.13)
IDF	1.69 (0.08)	1.02 (0.07)
SDF	0.64 (0.08)	0.66 (0.07)
SDF/IDF ratio	0.38 (0.06)	0.65 (0.04)

Table 2
Fishers' *F*-values and *p*-values associated with two-way ANOVAs (processing step and apple-batch effects, with interaction) performed on dietary fibre content (expressed in dry weight and corrected for sugar content) and on the dry matter relative to apple content of the samples (apple DM).

Variable	Processing step effect		Apple-batch effect		Processing step × apple-batch effect	
	F	*p*	*F*	*p*	*F*	*p*
Apple DM (g/100 g)	5.4	0.002	21.9	0.0001	1.2	0.3
AIS (g/100 g)	75.8	<0.0001	3.9	0.06	2.3	0.09
TDF (g/100 g)	23.0	<0.0001	3.0	0.09	3.0	0.03
(%) IDF	34.2	<0.0001	0.0	0.98	3.6	0.02

3.2. Processing and apple-batch effects on dry matter and fibre content

Processing and batch effects were studied on a dry weight basis and after correction for the process-added sugar for sweetened samples (corresponding to the sugaring and pasteurisation steps). Two-way ANOVAs (processing step and batch effects, with interactions) were performed on the product dry matter relative to its apple fraction and on the corrected fibre contents (Table 2).

The effect of processing step was highly significant ($p < 0.001$), whatever the type of fibre content measured, whereas apple batch effect was not significant. However, some significant interactions appeared between processing step and apple batch for TDF and for the soluble/insoluble fraction. The dry matter of the product, relative to its apple fraction, was also significantly affected by both processing step and apple batch, without significant interactions. Overall, given the presence of some significant interactions, the overall modifications in fibre content and dry matter during processing are presented for each batch separately in Table 3.

The dry matter, relative to the apple fraction, showed slight but significant changes during processing (Table 3): refining (i.e. seed and skin removal by extruding of the apple slurry through a sieve) mostly led to a decrease in the dry matter (visible yet not significant in the case of batch B) which increased again at the sugaring step. The overall dry matter was lower for batch B than for batch A. AIS content modifications during processing were the same for both batches: AIS increased after cooking (+20%) then decreased at refining (−16%) and after sugaring (−18%). The TDF content for batch A followed a similar pattern but these modifications were much less marked for batch B, for which cooking and sugaring steps had no significant impact. TDF modifications were followed by variations in the soluble/insoluble ratio. For batch A, TDF increase at cooking was due to both soluble and insoluble fibres. At refining, the redistribution between soluble and insoluble fractions indicated a predominant gain in soluble fibres, whilst the slight total fibre loss at sugaring did not change the soluble/insoluble ratio. In the case of batch B, redistributions between soluble and insoluble fractions occurred at cooking and sugaring, without any significant TDF loss. At refining; however, the decrease in TDF took place without modification of the soluble/insoluble ratio.

Overall, the general impact of processing was an increase in total fibres (AIS and TDF) at cooking (however not significant for TDF content of batch B) and a decrease at refining and sugaring (again not significant for TDF content of batch B). The modifications in the soluble/insoluble fibre fraction during processing were, however, different from one batch to another. Most noticeably, the less pronounced modifications observed here for TDF content of batch B were likely to come from some marked opposite variations in the SDF and from IDF contents of this batch.

3.3. Processing and apple-batch effects on fibre composition

The compositions of AIS, IDF and SDF in apple samples during processing were calculated on original dry substances (i.e. fibre yield in mg/g × fibre composition in mg/g of fibre). Total polysaccharides content was estimated as the sum of neutral sugars and galacturonic acid. In the case of SDF, analysis of the blanks run with the samples, during dietary fibre extraction, showed that they contained significant amounts of mannose (130 mg/g) and of glucose (20 mg/g). Both sugars probably mostly arose from the various enzymatic treatments applied during the extraction procedures. These sugars were thus not considered for the study of polysaccharide content. For the other sugars, concentrations were calculated from crude SFD yield (i.e. without blank correction) to individual sugar content in the crude SDF.

Two-way ANOVAs (processing step and batch effects, with interactions) were performed on polysaccharide content and sugar composition. Except for total polysaccharide and xylose contents, the apple batch effect was always highly significant ($p < 0.0001$) and more important than the processing effect (lower *p*-values) (data not shown). However, as some significant interactions occurred, data are presented for each batch separately in Tables 4 and 5.

Table 3
Modifications during processing of dry matter relative to apple content (apple DM, in g/100 g of fresh weight), AIS and TDF contents (in g/100 g of dry weight corrected for process-added sugar) and IDF fractions (in % of TDF). IDF values are followed in brackets by contents in g/100 g of dry weight corrected for process-added sugar. Different letters in the same series indicate significant difference at the 0.05 level according to Fisher's LSD test. SD, standard deviation of the mean (degrees of freedom: 35).

Batch	Processing step	Apple DM (g/100 g fresh weight)	Fibre content (g/100 g dry weight corrected for process-added sugar)

In SDF, Glc and Man are not taken into account as they mostly arose from enzymes used during fibre analysis.
[A] Expressed in the original dry substance, and with correction from process-added sugar.

AIS composition of unpeeled apples was consistent with data found in the literature, with large amounts of glucose and galacturonic acid, followed by high proportions of arabinose and galactose (Massiot & Renard, 1997; Massiot et al., 1994; Renard, 2005b) (Table 4). The major component in the insoluble fraction was glucose but high amounts of galacturonic acid were also detectable (Table 5). The soluble fraction was composed of polymers, mainly containing galacturonic acid, arabinose and galactose, probably pectic polymers. This fraction contained less polysaccharides than did the IDF fraction, since blank weight accounted for almost 50% of the crude SDF recovered after filtration. Fruits from batch A mainly contained more arabinose and galactose and less galacturonic acid than did apples from batch B (Table 4). The same trends were also visible with the SDF and IDF fractions (Table 5), with an overall soluble polysaccharide content higher for batch B. These differences are consistent with apple cell-wall modifications reported by several authors during maturation and storage (Bartley, 1976; Jonhston, Hewett, & Hertog, 2002; Knee, 1973; Wechsler et al., 1996) and thus reflect the more advanced post-harvest maturity stage of batch B (processed two months after batch A and hence stored for two months more). The higher proportion of galacturonic acid in batch B is possibly the direct result of arabinose and galactose loss: with the loss of these pectic side-chain-related sugars (arabinans and arabino(galactans)), cell-walls are relatively more rich in homogalacturonans.

Total polysaccharide content of AIS mostly increased at cooking, then decreased at sugaring (Table 4). A decrease was also visible at refining for both batches but not significant in the case of batch B.

The most relevant changes in polysaccharide composition were related to arabinose and glucose. Arabinose decreased at refining and sugaring whilst glucose increased. The polysaccharide increase upon cooking did thus not lead to marked modifications in polysaccharide composition, except a slight decrease in the galactose fraction for batch A.

As was the case for the changes in the soluble/insoluble fraction, polysaccharide content modifications during processing differed from one batch to another (Table 4). The proportion of soluble polysaccharides increased at cooking but mostly at refining for batch A, whilst it only increased at cooking for batch B. An increase at sugaring was, however, observed for both batches. Insoluble polysaccharides increased at cooking for batch A then kept decreasing during the other processing steps. For batch B, insoluble polysaccharide content started to decrease after refining and during the next processing steps but in a more pronounced way than for batch A. Sum of soluble and insoluble polysaccharide contents gave a close estimation of AIS polysaccharide content (Table 4), except at sugaring (and pasteurisation), where it gave a higher estimation, leading to a different behaviour: an increase at this step whereas AIS polysaccharide content decreased. The polysaccharides involved in soluble and insoluble modifications mainly contained arabinose, galactose, glucose and galacturonic acid (Table 5). Arabinose decreased from the insoluble fraction throughout processing, whilst glucose increased. In the case of batch B, galacturonic acid content also slightly decreased, whilst a loss of galactose was observed at cooking for batch A. In the soluble fraction, arabinose decreased at cooking and refining (mostly for batch A). Slight modification of the galactose content occurred as well: an overall decrease during processing for batch B, and a short drop at cooking for batch A. Finally, galacturonic acid content increased at cooking for batch A.

4. Discussion

During processing of applesauce, two main mechanisms may affect the dietary fibre content and composition:

- heat treatment, leading to pectic depolymerisation;
- mechanical separation of more resistant fractions, namely seeds, skin and carpels.

Two main heat treatments occurred during processing: at cooking and at sugaring, during the storage of applesauce in the flow-regulating tank. The fibre and total polysaccharide contents surprisingly increased at cooking (Tables 3 and 4). As there was no excess water added, this could not be related to leaching of non-fibre components, such as was observed by Nyman et al. (1987) for carrots cooked in water. Two possible explanations are (i) still loss of some internal soluble matter (by dripping of sugar solution) or (ii) a sampling bias, i.e. a change in the skin/flesh/seed ratio between the fresh apples (layering of apples on the belt carrier, with smallest fruit and densest pieces, such as seeds, on the lowest part) and the slurry of cooked apples. SDF and soluble polysaccharides increased at cooking (Table 3): the temperature applied (85 °C) may have contributed to solubilisation by depolymerisation of cell wall polysaccharides previously linked to the insoluble fraction, most probably pectins (Lo et al., 2002; Massiot et al., 1992; Ng & Waldron, 1997; Sila et al., 2005, 2006). The pH of apple fruit (3.5–4.0), moreover, supports the hypothesis of pectic acid hydrolysis (Fraeye et al., 2007; Sajjaanantakul, van Buren, & Downing, 1989).

Despite a slight product concentration during sugaring, the AIS content decreased and was linked to the loss of polymers containing rhamnose and arabinose and consequent gain in glucose (Table 4), consistent with heat-related pectic solubilisation and fragmentation. The prolonged heating could then have led to pectic fragments too small to be retained and thus estimated during the AIS extraction procedures. This was not visible at cooking, either because this step was too short or because it was masked by the change in the peel/flesh/seed ratio. A cumulative temperature effect could also be visible when the sugaring step is reached. Decrease of insoluble and increase of soluble polysaccharides (Table 5) also indicates pectic solubilisation. However, pectic fragmentation due to processing can be dampened by some artefactual pectin β-elimination. Indeed, the pH and temperature conditions applied for the AOAC method is likely to trigger β-elimination (Kravtchenko, Arnould, Voragen, & Pilnik, 1992), leading to pectin fragmentation and possible overestimations of the initial SDF content. In the present case, the decrease in insoluble polysaccharides is largely compensated by an increase of the soluble polysaccharide content (Table 5) whereas total AIS polysaccharide content showed a decrease at this step (Table 4).

Mechanical separation occurred at refining, which unsurprisingly led to a slight decrease in the dry matter following the loss of low-water content tissues. It also triggered a decrease in the total fibre content (AIS and TDF) and, to some extent, in the insoluble fibre fraction (Table 3) and insoluble polysaccharide (Table 5) contents. Indeed, epidermis and carpels both contain more AIS material than do parenchyma, and probably more insoluble fibres (Massiot & Renard, 1997; Massiot et al., 1994). Interestingly, although epidermis and carpels contain high amounts of non-polysaccharidic insoluble components (suberin, cutin, waxes and lignin), their loss did not lead to a relative increase in the polysaccharide content of the fibres. This might be due to the high loss of polysaccharides induced by the discarding of carpels. AIS, IDF and SDF all not only contained proportionally less arabinose but also more glucose (AIS and IDF) or more galactose (SDF) after refining. The pectic profile could thus have been modified following the tissue change, leading to soluble polymers containing more galactose and less arabinose.

Apart from these mechanical and heat treatments, two other phenomena may influence the dietary fibre evolution:

- maturity stage of the fruits;
- co-precipitation of proteins and polyphenols from the apple fruit.

Fruits from batches A and B differed by their post-maturity storage time, with apples from batch B likely to have undergone some pectic solubilisation and pectic side-chain losses during storage. This influenced the impact of heat-processing steps. Indeed, at cooking, the soluble fraction was enriched in polymers containing galacturonic acid (possibly homogalacturonans) for batch A apples whilst the different pectic-related sugar proportions (arabinose, galactose and galacturonic acid) remained constant for batch B (Table 5). As apples from batch B have already experienced pectic solubilisation, the cooking-induced solubilisation did not significantly modify the proportions of the various pectic constituents. In the case of batch A, homogalacturonans seem to have been preferably solubilised. Ng and Waldron (1997) have already observed (on cooked carrots) that pectic fractions rich in galacturonic acid are the first solubilised, branched polymers being possibly more connected with the cell-wall matrix. At sugaring, as well, the soluble/insoluble fibre ratio was modified for batch B yet not for batch A. The insoluble fraction was enriched in glucose, with a slight loss of the pectic-related sugars, galactose and arabinose, and of galacturonic acid in the case of batch B. These differences may again be linked to sample susceptibility to pectin degradation, consequent to the post-harvest maturity stage. For batch A, the loss in insoluble fibres (pectic solubilisation) was equivalent to that of

soluble fibres (pectic intense fragmentation). For batch B, however, the gain in soluble fibre was more intense and compensated the loss of insoluble fibres, indicating that pectins were solubilised but less fragmented, maybe because the pectic profile was already modified by post-harvest storage. Yet again, the bias induced by the AOAC method could also have enhanced the differences between the two batches.

One may finally mention the formation of processing-induced insoluble complexes, possibly increasing IDF content. This includes formation of not only Maillard products during cooking but also interaction of polyphenols, especially procyanidins, with cell wall polysaccharides once the apples are cut and crushed (i.e. between sorting and cooking steps) and during cooking (Le Bourvellec, Guyot, & Renard, 2004; Le Bourvellec & Renard, 2005; Renard, Baron, Guyot, & Drilleau, 2001). Such a cooking effect on AIS content has also been reported on pear by Renard (2005a), who also observed higher AIS yields during early cooking stages (up to 1 h of cooking). In the present case, both flesh/peel/seed ratio and insoluble aggregates formation may have contributed together to an increase in insoluble polysaccharide and IDF contents at cooking, more or less compensating (depending on the batch) the insoluble polysaccharide loss by pectic solubilisation.

In conclusion, apple processing into applesauce only induced a limited loss in dietary fibres (30%, on a fresh weight basis), yet triggered redistribution between the soluble and insoluble fractions, the soluble fraction increasing from 28% to 39% of the total fibre content. The most important changes occurred at refining and sugaring (or more precisely temporary storage of apple purée in a flow-regulating tank). These steps, respectively, caused a loss of insoluble fibres through mechanical treatment and some pectic solubilisation through heat-treatment. Susceptibility to heat-processing differed according to the post-harvest maturity stage of the fruits, the intensity of pectin solubilisation and the nature of the polysaccharides involved (homogalacturonans or branched arabinans and arabinogalactans) being different. Overall, this soluble/insoluble redistribution might affect the effects of dietary fibre *in vivo*.

Acknowledgements

This research was supported by a doctoral grant provided by "Angers Loire Métropole". The authors are very grateful to Marie-Jeanne Crépeau (INRA, Nantes) for her assistance in determination of galacturonic acid content and to Marie-Christine Aumond (SONAS, Angers) for her help with the gas chromatography. Special thanks are also due to M. Le Moigne and L. Perrin for their advice on statistical treatment of the data.

Wheat
Cookies

ABSTRACT

For investigating carryover of some organophosphorus pesticide residues in the cereal food chain from grain to consumer, a study was set up on wheat bran, flour and cookies, with and without bran. Special emphasis was given to malathion and chlorpyrifos-methyl residues in cookies for better protection of consumers. Pesticide-free wheat was placed in a small-scale model of a commercial storage vessel and treated with these pesticides. The residue levels of insecticides were determined in wheat, as well as in bran, flour and cookies produced from stored wheat at various time intervals during storage. A multiresidue analysis was performed using GC–NPD and GC–MS. Malathion and chlorpyrifos-methyl residue levels were higher than the maximum residue limits (MRLs) in wheat after 240 days of storage. MRLs established by the EC for malathion and chlorpyrifos-methyl in wheat are 8 and 3 mg kg^{-1}, respectively. The residue levels of insecticides in flour samples also exceeded the MRL (2 mg kg^{-1} for both insecticides). Eight months of storage were not effective for reducing the residues in wheat to the levels below MRLs. Although, considerable amounts of the insecticides remained in the bran and flour, the cookie processing significantly reduced the concentrations in general. Chlorpyrifos-methyl was more persistent than was malathion and comparatively less degradation occurred during milling and cookie processing due to its physicochemical properties.

1. Introduction

There are increasing concerns over the use of organophosphorus insecticides linked to health, which are widely used for protecting stored commodities from pests (Collins, 2006). The grain storage pesticides were identified as among the key pesticide residues in cereals, based on their frequency of occurrence in surveys. The main residues detected were storage insecticides, such as chlorpyrifos-methyl and malathion (Balinova, Mladenova, & Obretenchev, 2006). They are applied post-harvest to wheat, as grain protectants, because of their relatively low rates of degradation in the grain under practical storage conditions. Chlorpyrifos-methyl is listed as a product unlikely to present acute toxicity and malathion is listed as a slightly hazardous compound in the WHO's recommended classification of pesticides by hazard (WHO, 1997). Malathion is a neurotoxin and toxic to aquatic organisms and certain species of birds and mammals at concentrations that may be attained in the open environment (ATSDR, 2000).

Despite the considerable amount of research that has been carried out on the application of malathion to wheat, there are limited investigations on the persistence of chlorpyrifos-methyl as residues in stored grains (Uygun, Senoz, & Koksel, 2008). Unit processes, such as washing, milling and baking, are important factors leading to reduction of residues left on grain after harvest or post-harvest treatment. These can often substantially reduce the residue levels in crops (Uygun, Koksel, & Atlı, 2005). However, in some cases, more toxic transformation products or metabolites can be formed during processing. There is still not sufficient information on the role of the baking process in degrading pesticide residues in flour and bran.

Cookies are one of the best known snack products. Consumption in Turkey currently runs at around 0.5 million tones per year, which is roughly equivalent to 40 packets (200 g) per person per year (Anonymous, 2003). They are a substantive part of children's diet. For better protection of the health of consumers, particularly children, a special emphasis has been given in this study to residues of pesticides in cookies.

The purpose of the study was to investigate the fate and magnitude of malathion and chlorpyrifos-methyl residues in wheat under local conditions of storage and to examine the reduction of the residues in flour, bran and cookies prepared according to the AACCI standard method (AACCI, 2000). The cookies, with bran (10%) and without bran, were prepared at each storage period.

2. Material and methods

2.1. Materials

Pesticide and metabolite standards, malathion, malaoxon, isomalathion and chlorpyrifos-methyl, were purchased from

Promochem Ltd. (Germany). Commercial malathion (Gold malathion 20EC) was purchased from Safa Tarim (Turkey) and chlorpyrifos-methyl (Reldan 2E) was obtained from Dow Agro Science (UK). The wheat sample (cv. Bayraktar) with known origin was supplied by Field Crops Improvement Center, Ankara, Turkey. The sample was cleaned on a Carter Dockage Tester before the treatment.

2.2. Sample treatment with the insecticides

A small-scale model (65 × 45 × 45 cm) of a commercial storage vessel was built for laboratory experiments. The inner surfaces of wooden stores were covered with thin metal sheet. Wheat was treated with malathion and chlorpyrifos-methyl according to good application practice which is regulated by the Registered Agrochemicals for Pest Management Warehouse Pest Recommendations of the Turkish Ministry of Agriculture. Malathion (190 g/l) and chlorpyrifos-methyl (227 g/l) emulsions were prepared at the doses of 650 ml/100 m^2 and 425 ml/100 m^2, respectively, and then sprayed onto the surfaces of the stores. After standing for half an hour to evaporate the excess of solvent, the wheat (10 kg) samples were placed into storage vessels by mixing to provide a homogeneous distribution of pesticide on grain. Time-zero samples were taken for the analysis after 2 h. The rest of the samples were stored at ambient temperature for three months. The grain was analysed at various time intervals during storage.

2.3. Cookie processing

The wheat samples (1 kg) were milled after each storage period in a Brabender Quadrumat Junior laboratory mill (Duisburg, Germany) to obtain straight-grade flour and bran consisting of endosperm and the outer layers of grain, respectively. Duplicate samples from whole ground grain, flour and bran were used for analysis. The cookies were prepared according to the wire-cut cookie formulation of AACCI (Method No: 10–54) (AACCI, 2000). In bran cookies, bran was substituted for a portion of wheat flour at the level of 10%.

2.4. Extraction

Wheat (50 g), bran (12.5 g) and flour (50 g) samples were homogenised with ethyl acetate (100 ml) and anhydrous sodium sulphate (5 g) in a high-speed blender for 2 min. The homogenates were filtered and the extracts were concentrated to 2 ml in vacuo at 40 °C, using a rotary evaporator. The extracts were applied onto GC and GC–MS systems without a clean-up step. The cookie samples (25 g) were extracted with ethyl acetate (100 ml), standing overnight. Then the samples, dried by anhydrous sodium sulphate, were cleaned according to the EN 1528/3 method (EN, 1996) and the cleaned extracts were concentrated to 2 ml in vacuo at 40 °C, using a rotary evaporator.

2.5. GC–NPD and GC–MS

Gas chromatography was performed using an Agilent 6890 gas chromatograph equipped with a nitrogen phosphorus detector and capillary column (DB-5 30 m × 0.32 mm ID, 0.25 μm film thickness), using helium carrier gas at a flow rate of 1 ml min^{-1}. The oven temperature programme was: initial temperature isothermal at 50 °C, then from 50 to 150 °C at 25 °C min^{-1}, from 150 to 170 °C at 10 °C min^{-1}, from 170 to 200 °C at 2 °C min^{-1}, from 200 to 250 °C at 10 °C min^{-1}, then held for 2 min at 250 °C. Injector and detector temperatures were 250 and 300 °C, respectively. Gas chromatography–mass spectrometry was performed using an Agilent 5973 mass detector under the same conditions as for gas chromatography. GC–MS was used for confirmation of the pesticide identification. Electron ionisation (EI mode) was used to obtain the mass spectra of the samples.

Identification and confirmation of the pesticides were based on their GC retention times and comparison of their sample mass spectra with the characteristic ions in the reference standards mass spectra. Single-point calibration was used to estimate pesticide concentrations (SANCO, 2003). In GC–NPD analyses, limits of detection were calculated by using a signal-to-noise ratio of 3 and determined as 0.02 and 0.01 mg kg^{-1} for malathion and chlorpyrifos-methyl, respectively.

2.6. Recovery

The recovery studies were performed by using blank samples of untreated wheat grain and pesticide-free cookies. The weights of blanks were the same as the weights of analytical samples of treated grains. Fortifications were carried out by the addition of calculated volumes of working standard solutions, in order to obtain three concentration levels of the insecticides studied: at MRLs, half of the MRLs and twice the MRLs. The fortified samples were analysed according to the method described above. Data derived from these experiments are presented in Table 1.

2.7. Statistical analysis

Data were statistically evaluated by the one-way analysis of variance (ANOVA) procedure. When significant differences were found, the LSD (least significant difference) test was used to determine the differences among means.

3. Results and discussion

3.1. Degradation of malathion in wheat during storage, milling and cookie processing

The effects of storage, milling and processing on breakdown of malathion were examined at various times during eight months of storage at ambient temperature. The results of the pesticide degradation during storage and processing are presented in Table 2. The residues in wheat were dissipated relatively quickly during the first two weeks of storage, then slightly increased the first month; thereafter, they decreased at a slower rate until the end of storage. The increase might be related to migration of a proportion of the lipophilic insecticide through the bran and germ, which have high levels of triglycerides. Although, 63% of the malathion residue in wheat was degraded after eight months, the amount left was still high (Fig. 1). Similarly, malathion residue levels in stored bran increased gradually with storage time and this was explained by the penetration of malathion into the seeds during storage (Lalah & Wandiga, 1996). In another study, the pesticide residues in faba beans and soybeans increased during storage. The residues showed a slow but definite increase with storage period, and a higher percentage was observed in stored soybeans, due to their oily nature, than in faba beans (Zayed, Farghaly, Mahdy, & Soliman, 2007).

The residue concentrations were greatly reduced during the cookie processing. The conditions used in the cookie process, such as high temperature (205 °C) and degree of moisture loss are important for the quantitative effects on residue levels. Malathion in the cookies and bran cookies, produced from the wheat stored for eight months, decreased by about 45% and 60%, respectively (Fig. 1). Rates of degradation and volatilisation of the residues were increased by the heat involved in the process.

Although, the amount of degradation was high, the levels of malathion residue were still excessive in the cookies, particularly

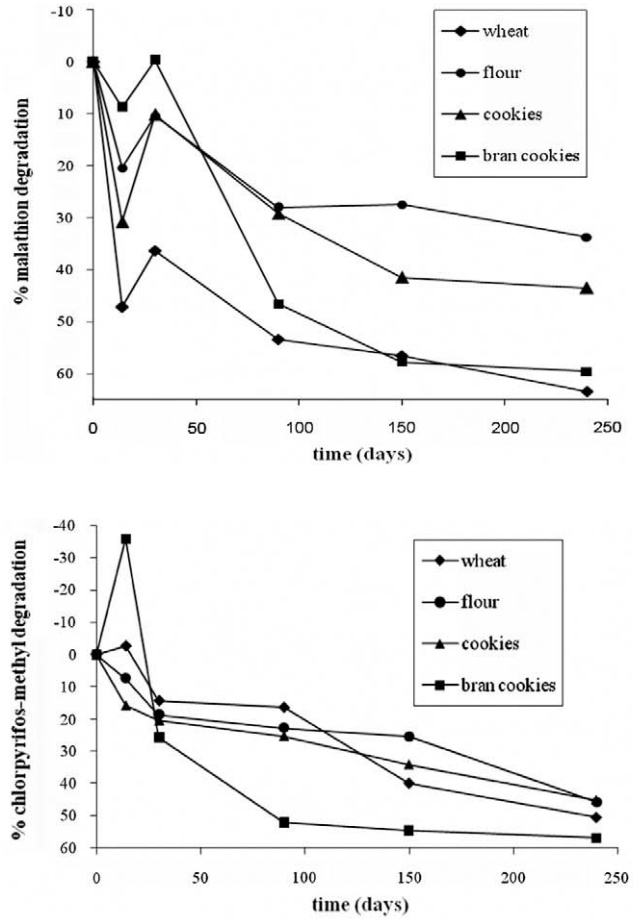

Fig. 1. Percent residue degradation of malathion and chlorpyrifos-methyl in wheat, cookies and bran cookies.

in the bran cookies. Since the residues were concentrated in the bran, the residue levels were found to be approximately 1.5–2 times higher in the bran cookies than in cookies without bran. In the cookies, the residue concentrations significantly increased during the first month of storage, in accordance with the rise in the wheat during the same period. These results were quite comparable to the results obtained from previous work carried out by Uygun et al. (2005).

The metabolites of malathion were also studied. Fortunately, no isomalathion or malaoxon was detected in any of the samples. This is probably due to the pesticide application method, in which the pesticide was applied on the surface of the store, not directly onto the grain.

3.2. Degradation of chlorpyrifos-methyl in wheat during storage, milling and cookie processing

The results showed that chlorpyrifos-methyl levels of wheat, as well as of its milling and baking products, decreased towards the end of storage (Table 3). After eight months of storage, the residues of chlorpyrifos-methyl in wheat were degraded by about 50%. The persistence of chlorpyrifos-methyl residues in wheat was found to be higher than that of malathion under the same conditions. Similar to the results of this study, it was reported that chlorpyrifos-methyl was more persistent than was malathion in stored grains (Holland, Hamilton, Ohlin, & Skidmore, 1994; Matthews, 1990). This might be related to its higher octanol–water partition coefficient and lower vapour pressure. Both malathion and chlorpyrifos-methyl are lipophilic compounds. However, log Kow values reported in the literature are 2.74 and 4.23 for malathion and chlorpyrifos-methyl, respectively (Tomlin, 1994). Therefore, higher carryover percentages from wheat to cookies of chlorpyrifos-methyl might be due to its higher log Kow value.

3.3. Carryover of the pesticides from wheat to cookies

At the beginning of storage, the carryover percentages of malathion residues were found to be about 3% and 5% from wheat to

Carryover percentages of malathion and chlorpyrifos-methyl from wheat to flour and cookies.

Time (days)	% Carryover Wheat → flour		% Carryover Flour → cookies		% Carryover Wheat → cookies		% Carryover Wheat → bran cookies	
	M	CM	M	CM	M	CM	M	CM
0	12	20	27	40	3	8	5	13
14	18	18	24	36	4	6	9	17
30	16	19	27	39	4	7	8	11
90	18	19	27	38	5	7	6	7
150	19	24	22	35	4	9	5	10
240	21	22	23	40	5	9	5	11

M: malathion; CM: chlorpyrifos-methyl.

cookies and bran cookies, respectively (Table 4). As the level of malathion decreased during storage, the carryover of the residues from wheat to cookies slightly increased. This has been interpreted as being due to the residues tending to move into the deeper layers of the grain (Holland et al., 1994).

Although, the initial concentration of chlorpyrifos-methyl in wheat was significantly lower than that of malathion, carryover percentages of chlorpyrifos-methyl from wheat to the cookie samples were higher than those of malathion (Table 4). This could be explained by lipophilic properties of the pesticide that was retained by the fat in the cookies. The retention mechanism of lipophilic pesticides in cookies could be compared with that in oil seeds. It has been reported that the dominant feature in the processing of oil seeds is the retention of lipophilic pesticides in the oil or fat fraction. Furthermore, higher residue concentrations are produced by post-harvest treatment against storage pests that can lead to elevated residue levels in the oils (Holland et al., 1994).

4. Conclusion

In this study, the approved doses of pesticides for stored grain were applied in a small-scale storage vessel. Although, the approved doses of insecticides for stored grain were used, the residue levels exceeded the MRLs during the whole storage period. MRLs for malathion and chlorpyrifos-methyl in wheat, established by the EC, are 8 and 3 mg kg^{-1}, respectively (European Commission, 2005). In 2008, the Codex Alimentarius Commission proposed new MRLs for malathion (0.5 mg kg^{-1} and 0.2 mg kg^{-1} in wheat and white flour, respectively) and 10 mg kg^{-1} for chlorpyrifos-methyl in wheat (FAO/WHO, 2008). The proposed reduction in the MRL for malathion initiated new discussions and signified the requirement for comprehensive studies on this matter.

The storage period was generally not effective enough to reduce the residues in wheat to levels at or below the MRLs of the insecticides. Malathion and chlorpyrifos-methyl residue levels were higher than the MRLs established by the EC in wheat after 240 days of storage.

For white flour, the MRLs of malathion and chlorpyrifos-methyl are 0.2 and 2 mgkg^{-1}, respectively (FAO/WHO, 2008). The residue levels in all flour samples exceeded the limits excessively. This might be due to application of pesticides on wheat at pilot scale. The chlorpyrifos-methyl residues in the flour sample produced from the wheat stored for 240 days were very close to the MRL.

In general, the cookie processing significantly reduced the concentrations of the insecticides. But, there are no official limits for pesticide residues in cookies for comparison. If the MRL for malathion in white flour proposed by Codex (0.2 mgkg^{-1}) is considered, the residue levels of the pesticides in all cookie samples were above the limit. On the other hand, if the MRL for chlorpyrifos-methyl in white flour, established by Codex (2 mgkg^{-1}), is considered, the residue levels of the pesticides in all cookie samples were below the limit, except in the bran cookies produced from the wheat stored for 0 and 14 days.

Flavour

ABSTRACT

The production of volatile compounds by the probiotic strain, *Lactobacillus plantarum* NCIMB 8826, in cereal-based media (oat, wheat, barley and malt) was investigated. Sixty compounds, including fatty acids and their esters, amides, alcohols, aldehydes, aromatic hydrocarbons, furans, ketones, peroxides and pyrans, were identified. *L. plantarum* significantly changed the aroma profile of the four cereal broths, and each substrate showed a specific volatiles profile. Oat and barley media were the substrates more influenced by the fermentation process. The most abundant volatiles detected in oat, wheat, barley and malt were oleic acid, linoleic acid, acetic acid, and 5-hydroxymethylfurfural, respectively. Analysis of these products confirmed the heterofermentative pathway of *L. plantarum*. Maillard compounds were not detected during sterilisation and fermentation. This study is the first to report the volatile composition of probiotic drinks produce with non-supplemented cereal-based media and the results obtained could contribute to the development of new non-dairy probiotic formulations.

1. Introduction

Consumers, worldwide, are becoming increasingly aware of the relationship between food or food constituents and health. Functional products, *i.e.* foods or beverages offering specific health benefits beyond basic nutrition, are increasingly valued.

Within functional foods, probiotics, with prebiotics, represent one of the fastest growing sectors. Probiotic foods are fermented formulates containing sufficient numbers of selected live microorganisms to beneficially modify the intestinal microbiota of the host (Fuller, 1989; Havenaar & Huis in't Veld, 1992a,b).

Commercial probiotic foods are primarily dairy-based, although in recent years other substrates have been explored to develop new probiotic formulations (Prado, Parada, Pandey, & Soccol, 2008). Among the tested raw materials, cereals are becoming one of the promising substrates for future developments.

Cereals are grown over 73% of the total world harvested area and account for 60% of world food production (FAO, 2006). Cereal grains and their fractions contain many functional compounds, such as essential fatty acids, phytosterols, phenolic compounds or resistant starch, and the consumption of whole grains has been associated with lower incidences of certain cancers and cardiovascular diseases (Baublis, Lu, Clydesdale, & Decker, 2000; Hudson, Dinh, Kokubun, Simmonds, & Gescher, 2000; López-Varela, González-Gross, & Marcos, 2002; Peterson, 2001; Truswell, 2002; Welch, 1995). In addition, cereals and cereal fractions have been proved to support growth of probiotic lactic acid strains (Charalampopoulos, Wang, Pandiella, & Webb, 2002a; Kedia, Vázquez, & Pandiella, 2008a, 2008b).

For centuries, fermentation with lactic acid microorganisms has been employed to preserve or upgrade the digestibility and stability of foods. Fermentation can also change the flavour and texture of the substrates and has been used to improve the organoleptic quality of foods (Gélinas & McKinnon, 2000).

These facts suggest that the use of cereals as substrates for probiotic cultures could produce a fermented food with health-promoting properties that could fulfil consumer expectations. However, the acceptance of a new probiotic formulate is not only determined by its health-promoting qualities. Although consumers are increasingly demanding products with functional properties, the consumption patterns of new products are strongly determined by their sensorial characteristics (Breslin, 2001). Flavour is one of the most important characteristics in the sensorial profile of a specific food and plays a decisive role in consumer acceptability. The analysis of volatile flavour components tends to be one of the main parameters to take into account in the development of a novel fermented food (McFeeters, 2004).

The use of oat, wheat, barley and malt substrates to support the growth of *Lactobacillus plantarum* to probiotic levels has been

previously reported (Charalampopoulos, Pandiella, & Webb, 2002b; Kedia et al., 2008b). The media used in this work are suitable for the formulation of probiotic beverages. Alternatively, flavour characterisations of some probiotic dairy products and studies of the volatile compounds of several cereals and cereal-based products have been previously reported (Grosch & Schieberle, 1997; Maga, 1978; Modzelewska-Kapituła, Kłębukowska, & Kornacki, 2008; Pelletier, Faurie, François, & Teissier, 2007; Saarela, Mogensen, Fondén, Mättöa, & Mattila-Sandholm, 2000; Zhou, Robards, Glennie-Holmes, & Helliwell, 1999; Østlie, Helland, & Narvhus, 2003). However, attempts to characterise cereal-based probiotic drinks have not yet been reported.

In this work, the direct culture of a probiotic lactic acid strain, *L. plantarum* NCIMB 8826, grown in oat, wheat, barley, and malt broths without additional growth enhancers, has been studied. The main objective was to identify and compare the volatile compounds of natural occurrence in the different media, as well as to study the production of flavour compounds by the probiotic bacteria in the cereal-based substrates.

2. Materials and methods

2.1. Cereal substrates

Three different cereals, wheat (*Triticum aestivum*), oat (*Avena sativa*), and barley (*Hordeum vulgare*), together with spray-dried malt extract (Muntons PLC, UK), were used in this study. Cereals were harvested at ripening stage and stored at 8 °C. No spoilage due to contamination from insects or fungi was detected during storage.

2.2. Microorganism and inoculum

A selected *L. plantarum* bacterial strain (NCIMB 8826; National Collection of Industrial and Marine Bacteria, UK), isolated from human saliva, was used as inoculum in this study. The strain was preserved in 40% glycerol at −30 °C. A frozen ampoule containing the lactic bacteria was thawed and transferred to a 25 ml screw-capped glass bottles with 20 ml of MRS broth (Oxoid, UK). The bottles were incubated at 37 °C to the exponential phase of growth (24 h). The bacterial suspensions were then used to inoculate the fermenting media at 1% (v/v). In all cases, the initial microbial concentration was approximately 7.5 $\log_{10}$ CFU/ml.

2.3. Fermentation

The cereal mashes used as fermentation substrates were prepared from whole-grain flour (or dried malt extract) and water at a concentration of 5% (w/w). Grains were ground in a hammer mill (Laboratory Mill 120, Perten Instruments, Sweden) equipped with a 0.8 mm sieve to produce homogeneous samples. After milling, the flour was stored in sealed bags at −30 °C to prevent contamination and to halt the action of cereal enzymes. The cereal flour without water was autoclaved (121 °C, 20 min) and afterwards mixed with sterilised distilled water to form the fermentation broth. The slurries were then inoculated and incubated for 24 h at 37 °C to produce the cereal-based probiotic drinks. All the fermentations were carried out in 500 ml screw-capped glass bottles with 400 ml of medium. Samples were taken at the end of the fermentation and kept at −30 °C for further analysis.

2.4. Volatile compounds extraction

A 35 ml sample with 20% w/v of sodium chloride (Fluka, Switzerland) was centrifuged at 4500*g* and 2 °C for 5 min. Twenty-five millilitre of the supernatant were placed in a 80 ml screw-cap flask, mixed in a proportion a 1:1 with ethyl acetate (Sigma–Aldrich, Germany) and stirred for 40 min. Then the mixture was centrifuged again (2000*g*, 2 °C, 5 min). The organic phase was transferred

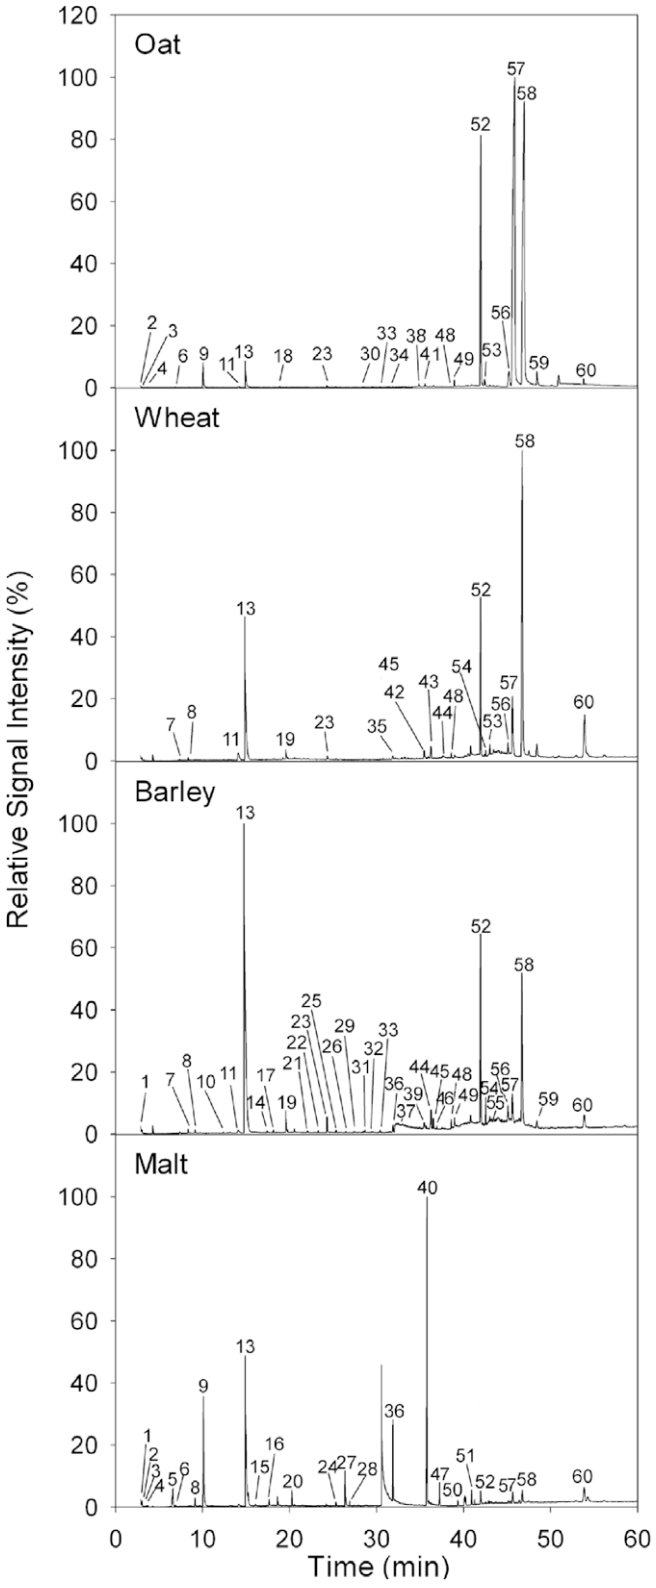

Fig. 1. Gas chromatograms of the volatile compounds produced by *L. plantarum* NCIMB 8826 in the cereal-based media: (a) oat; (b) wheat; (c) barley; (d) malt. Peak identities are shown in Table 1.

to a 100 ml round-bottom flask and concentrated to 1.5 ml using a vacuum rotary evaporator (Buchi, Switzerland) at 40 °C.

2.5. Gas chromatography–mass spectrometry (GC–MS)

GC–MS analysis was carried out with an Agilent 6890 N Series gas chromatograph (Agilent Technologies, Santa Clara, CA, USA) coupled to an Agilent 5973 Series quadrupole mass-selective spectrometer, operated in electron impact mode (70 eV). A 30 m × 0.25 mm (ID) DB-Wax capillary column (Agilent Technologies), with 0.1 μm film thickness, was used.

The sample (1 μl) was injected in split mode (1:50) and the injector temperature was 230 °C. Helium was used as carrier gas at a constant flow of 1.1 ml/min. The oven temperature was programmed as follows: at 40 °C for 7 min, increased at 5 °C/min to 220 °C, and then held constant for 17 min.

The data acquisition was performed in scan mode. The following MS parameters were applied: m/z range 29–350; scans/s 4.44; EI source temperature 230 °C; quadrupole temperature 150 °C; EM voltage + 294 V relative to the value established by the tune programme (2788). Compounds were identified by the MSD ChemStation library of mass spectra (Data Analysis Application 2003, Agilent Technologies).

All analyses were performed in triplicate. Results were reported as relative abundance expressed as $(compound_{peak\ area}/total\ compounds_{peak\ area}) \times 100$.

3. Results

Gas chromatograms of the volatile compounds in the fermented wheat, oat, barley, and malt broths after 24 h of incubation are shown in Fig. 1. Details about the peak identities and relative abundances of the volatile compounds expressed as $(compound_{peak\ area}/total\ compounds_{peak\ area}) \times 100$ are shown in Table 1. Among the identified organic compounds there are acids, amides, alcohols, aldehydes, aromatic hydrocarbons, esters, furans, ketones, peroxides, and pyrans.

High concentrations of several volatile compounds were found in all cereal media before the fermentation (Table 1), some of them detected in significant amounts in all substrates and others in specific media:

(1) Compounds found in all the substrates: oleic acid (4.9–41.9%) and linoleic acid (5.1–43.5%) showed significant peaks in all chromatograms, particularly in wheat and oat, where the sum of the two compounds represented more than 57% and 78%, respectively. Other organic acids found in all substrates were palmitic acid (5.4–21.4%) and acetic acid (2.9–39.3%).

(2) Exclusive compounds found in malt media: 5-hydroxymethylfurfural (38.3%), pyranone (12.5%), 2-ethoxyethyl acetate (7.3%) and maltol (4.7%). These four compounds account for 63% of the total volatile compounds in the malt broth before inoculation.

Other chemicals were found in smaller amounts. Butyric acid (0.4–3%) and oleamide (0.7–6.7%) were observed in all substrates. Furfural (0.8%) and 2-furanmethanol (0.8%) were present only in malt, and 1-oxiranylethanone (0.04–3.4%) and octadecenoic acid (1.5–2.6%) were found in all the media but malt.

Small amounts of 2,2-dichloroethanol, methyl 9-octadecenoate, methyl linoleate, oleic acid, bis-(2-methylpropyl)-1,2-benzenedicarboxylate, vanillin, myristic acid, nonanoic acid and linolenic acid were detected in oat, heptanoic acid, and butylated hydroxytoluene in wheat, tetradecanamide in barley, 2,3-butanediol and 2-(methoxycarbonyl)furan in malt, and caproic acid and n-tetradecane in oat and barley broths.

All the substances detected in significant amounts in the raw media were still present in the fermented product, also at considerable relative concentrations (Table 1). However, the relative concentration of these compounds dropped in most media. Only certain compounds showed a clear increase after fermentation: acetic acid in barley (39.4 → 47.3%) and malt (14.4 → 20.8%); oleic acid (41.9 → 50.6%) and linoleic acid (36.4 → 40.9) in oat; and 2-ethoxyethyl acetate in malt (7.3 → 15.7%).

A number of new compounds appeared in the fermented product. None of these were detected in all media and, in most cases, they had relatively low concentrations. Moderate amounts of isoamyl alcohol (3.23%) and 2-thiophenethanol (2.03%) were also detected in the fermented malt medium; 2-butanol (1.1%) in barley; and 1,4-dihydroxy-2-methoxybenzene in wheat and barley (0.4% and 1.7%, respectively).

Table 3
Values of pH in the cereal-based substrates before fermentation (*B.F.*) and after (*A.F.*) with *L. plantarum* NCIMB 8826.

Media	pH	
	B.F.	*A.F.*
Oat	5.96	4.34
Wheat	5.26	4.85
Barley	5.33	4.27
Malt	4.25	3.55

Lower levels of octanoic acid and methyl palmitate were exclusively detected in oat, ethyl palmitate, 1-octadecene, and 9,17-octadecadienal in wheat, 2-cyanoethyl hexyl ether, propionic acid, isobutyric acid, valeric acid, methyl laurate, isoamyl salicylate, amyl salicylate, 1,4-dimethylpiperazine, 2-dodecanol, 2-methoxyethylbenzene in barley, and 1-(2-furyl)ethanone, 2-phenylethanol, 3-(m-amino bezoyl)-2-methyl propanoate and benzocaine in malt. Small amounts of isobutanol, ethylbenzene, 1,2-xylene, 1,4-xylene, 2-ethoxyethanol, acetoin, dibutyl phthalate and palmitoleic acid were detected in several media.

The available information in the literature regarding the flavour properties of some of the detected volatile compounds is summarised in Table 2. Table 3 shows the changes of the pH in the four cereal-based broths after 24 h of fermentation with *L. plantarum*. In all cases, the pH dropped slightly, and the biggest change was observed in oats (ΔpH = −1.62). The wheat fermented drink had a small pH decrease of 0.41 units. pH drops of 1.06 and 0.7 were observed in the barley and malt broths, respectively.

4. Discussion

The aim of this study was to test the suitability of several cereal matrices to produce probiotic formulations with acceptable organoleptic properties. Previous work by this group suggests that the cereal tested can produce lactic acid bacterial populations with higher cell concentrations than the minimum requirement for a probiotic drink (10^6 CFU/ml, Sanders & Huis in't Veld, 1999). The production of major metabolites, e.g. lactic acid and acetic acid, has also been previously studied and modelled (Charalampopoulos, Pandiella, & Webb, 2003; Kedia et al., 2008a, 2008b), but knowledge regarding other volatiles that could affect flavour remains scarce.

Volatiles produced by *L. pantarum* in oat, wheat, barley and malt were extracted in ethyl acetate and later measured by GC. The fermented products show macro- and microscopical changes with respect to the raw ingredients. As expected, volatile compounds of natural occurrence in the raw cereal grains and substances generated during processing were found (see Table 1).

Cereal milling, storage conditions, enzymatic hydrolysis and the Maillard reaction during autoclaving could be responsible for the production of flavour active compounds. The Maillard reaction is actually a complex set of chemical reactions involving aminoacids and reducing sugars under heating conditions. The final products of the Maillard reaction are cyclic and polycyclic molecules that can react again and break down to form even more new compounds. These molecules are dependent on the aminoacid involved in the reaction and, depending on the substrate, hundreds of different flavour compounds can be formed.

Since all the cereal flours rich in sugars and proteins suffered a thermal treatment (121 °C, 20 min), a wide variety of Maillard compounds was expected. However, only in the malt media were compounds from thermal degradation were found. Pyranone, maltol, furfural, 2-furanmethanol, 2-(methoxycarbonyl)furan and 5-hydroxymethylfurfural, all previously reported as Maillard compounds (Kato, Nakayama, Sugimoto, & Hayase, 1982; Mori & Ito, 2004), were detected in the fermented malt media but not in other cereals. It is likely these compounds were already present in the malt before autoclaving. These aromas could have been generated during the kilning of the malt, a high temperature drying stage that takes place after germination in the malting process. Maillard compounds play a key role in the quality of foods as they are strongly related to the colour, aroma, and taste of the end-product (Adams, De Kimpe, & Van Boekel, 2008). Nevertheless, these thermal-induced compounds can enhance or negatively affect the flavour, depending on their reactive nature (Schutter et al., 2008). The impact of the Maillard compounds detected in this study on the sensory characteristics of the drinks produced could not be determined. Further characterisations by sensorial panels should be carried out in order to understand the relationship between the presence of Maillard compounds and the flavour of the probiotic drinks.

The Maillard reaction in aqueous systems is very slow, which could explain the absence of Maillard compounds generated during fermentation (Eichner & Karel, 1972). In addition, all media were acidic (see Table 3) and in these environments the amino groups are protonated and have a lower nucleophilicity, making difficult any reaction with the carbonyl group of sugars.

Another group of flavour compounds could be generated during processing due to the enzymatic activity of the lactic bacteria. According to metabolic pathways during fermentation, lactic acid bacteria can be classified in two different groups: homofermentative and heterofermentative. In homofermentative lactic acid bacteria, glucose is metabolised by the Embden–Meyerhof pathway and lactic acid is the sole final product. Heterofermentative lactic acid bacteria metabolise the glucose mainly through the pentose phosphate pathway, producing lactic acid, ethanol, and CO_2. However, the heterofermentative metabolism is affected by the presence of maltose and electron acceptors, such oxygen or fructose, and the metabolic pathways can be diverted towards acetic acid production (Sedewitz, Schleifer, & Gotz, 1984; Stolz, Vogel, & Hammes, 1995). Our results suggest that the four broths have undergone a heterofermentative process. This pathway yields less lactic acid than does the homofermentative one.

The high concentrations of acetic acid could be explained by the aerobic metabolism of *L. plantarum*. Sedewitz et al. (1984) have showed that *L. plantarum* during the stationary phase, under aerobic conditions and low glucose concentration, can consume the previously secreted lactic acid and an equivalent amount of acetic acid is released. Similar behaviour of *L. plantarum* in residual media was also reported by Vázquez, Docasal, Prieto, González, and Murado (2008). The high relative concentrations of acetic acid found in the four cereal-based broths suggest that part of the lactic acid produced could have been metabolised to acetic acid.

Inoculation with the probiotic lactic acid bacteria caused a significant change in the aroma profile of the four cereal broths. In particular, oat, and barley broths were more affected by the fermentation process. The oat medium showed a significant increment in the contents of flavour active volatiles. In barley, considerable amounts of new volatiles were generated after the fermentation. In general, the volatile production depends more on the substrate than on the microorganism. None of the new volatiles detected after fermentation is common for all media. The results obtained add to the knowledge of the volatile composition of cereals and cereal-based products, and provide useful information for further development of suitable non-dairy probiotic drinks.

Freshwater fish
ω3 and ω6 fatty acids
Amazon fish

ABSTRACT

Seasonal variations in total fatty acid compositions of tucunaré, *Cichla* sp. in the Janauacá Lake of the Amazon basin were determined by GC. Saturated fatty acids (SFAs) were found to be at higher concentrations than monounsaturated fatty acids (MUFAs) and polyunsaturated fatty acids (PUFAs) in two seasonal periods. Major fatty acids were palmitic (16:0, 48.5–51.6% of total SFA), oleic (18:1ω9, 43.9–50.2% of total MUFA), docosahexaenoic (DHA, 22:6ω3, 13.5–27.9% of total PUFA) and arachidonic acid (AA, 20:4ω6, 16.0–19.6% of total PUFA). Polyunsaturated fatty acids were the most abundant in muscle during the flood period, and more especially fatty acids 22:6ω3 (10%) and 20:4ω6 (7%). There were no significant variations amongst total lipid SFA, MUFA, and PUFA from eye sockets. The ω6 fatty acid percentages were always higher than the ω3 fatty acid percentages in tucunaré, with ω6/ω3 ratios varying between 1.02 and 1.6 in the flood and drought periods.

1. Introduction

The nutritional importance of fish consumption is closely associated with the ω3 fatty acid content of each species (Ackman, 1989; Rasoarahona, Barnathan, Bianchini, & Gaydou, 2005; Rice, 1996; Simopoulos, 1991). The quantity and composition of fatty acids from lipids are not only associated with the species, but also depend on diet, temperature, seasonality, age and gender (Ackman, 1989).

Interest in long-chain polyunsaturated fatty acids, particularly of the ω3 series (eicosapentaenoic-EPA and docosahexaenoic-DHA) stems from the fact that increased intake levels reduce blood total triacylglyceride concentrations and biochemical risk factors associated with cardiovascular diseases, arthritis, psoriasis and cancer, and also because they act directly on the processes of human growth and development (Eilander, Hundscheid, Osendarp, Transler, & Zock, 2007; Siguel, 1996; Simopoulos, 1991; Weaver & Holob, 1988). However, studies have revealed high concentrations of arachidonic acid (AA), of the ω6 series, and DHA in the milk of nursing mothers in the first weeks of breastfeeding, indicating that these nutrients are required by the newborn, and that their presence decreases at a rate directly proportional to the presence of these fatty acids in the diets of nursing mothers (Jensen, 1999; Martin et al., 2006).

Nutritionists believe that the ω6:ω3 ratio in daily nutrition should be 5:1 and that the addition of PUFA ω3 could improve nutritional condition, thus helping to prevent diseases (FAO, 1995; Muggli, 1997; Rice, 1996).

Fish and fish oil are considered the best ω3 PUFA sources, and are capable of providing balanced amounts of EPA and DHA. A comparative study, with volunteers, between vegetable-oil and fish-oil diets, showed that the ingestion of 18:3 ω3-rich flaxseed oil did not produce a sufficient amount of long-chain ω3 fatty acids, which is part of human daily requirements (Layne et al., 1996).

In Brazil, the greatest diversity of freshwater fish is found in the Amazon Basin, with over 1500 ichthyic species already described (Junk, Soares, & Saint-Paul, 1997). As a result, the *per capita* fish intake in the region has been the highest of Brazil. In the city of Manaus alone, fish consumption varied between 55 and 38.5 kg person^{-1} year^{-1} (Giugliano, Shirimpton, Arkcoll, Giugliano, & Petrere, 1978) while, in the interior of the State of Amazonas, it ranged from 510 to 600 g person^{-1} day^{-1} (Batista, Inhamuns, Freitas, & Freire-Brasil, 1998). Tucunaré (*Cichla* sp.) is an ichthyophagous fish from the Amazon Basin and amongst the most sought-after species by the local population, both for consumption and sport fishing. The meat achieves high commercial value, with an estimated production in 2003 of 1.172 tons in the main fishing discharge ports of the Amazon region (Souza et al., 2007).

The river water volume oscillations throughout the year determine harvest and off-season periods in the Amazon region. Consequently, this seasonal variation directly influences the diet and biology of animal species (Junk et al., 1997; Rasoarahona et al.,

* Corresponding author. Tel.: +55 92 3647 4049; fax: +55 92 3647 4043.

doi:10.1016/j.foodchem.2009.03.113

2005). Contreras-Guzman (1994) referred to climatic variations as being responsible for the great variability in the diet and habitat of ichthyic species throughout the year, which, in turn, cause variations in the lipid composition of fish, directly affecting fat taste and stability to oxidation, which are technological parameters of great importance in the fish industry.

Knowledge of the lipid composition, in different seasonal periods of the various fish species sold, is essential, since diets can be formulated more precisely through fatty acid quantification in tissues; it also allows processing procedures to be adequately dimensioned, considering the nutritional value and the high susceptibility to oxidation of polyunsaturated fatty acids. The residues generated by industrial processing, such as fish heads, especially the fat accumulated in the eye sockets, can be used for the production of ω3 concentrates.

2. Materials and methods

2.1. Sampling

The tucunaré (*Cichla* sp.) lots used in this study (by weekly sampling) were collected during different seasons in the Amazon Basin at the Janauacá lake (3°23′S, 60°16′W), near the city of Manaus/AM, one in the drought (ebbing) period and the other in the rainy (flood) period in the months of peak, in other words June in the flood period and December in the drought period, in a total of 25 monthly collected samples, divided into five lots.

The dorsal muscles and orbital fatty tissue from the eye socket of each sampling lot were removed, and freeze-dried, and had their total lipids extracted (Bligh & Dyer, 1959), and were then stored at −18 °C under a N_2 atmosphere for later analysis. As the samples were dehydrated, the respective percentage of water was added, close to the solvents, during the lipids extraction.

2.2. Gas chromatography analyses

Derivatization of fatty acids from total lipids was performed according to the procedure described by Joseph and Ackman (1992). The chromatographic analysis was carried out in a VARIAN, Mod 3300 gas chromatograph, equipped with a flame ionisation detector, split injector, and a DB-WAX 20 M fused silica capillary column (30 m × 0.247 mm × 0.25 μm) (WCOT, SGE, Australia), with the following operating parameters: detector temperature 280 °C; injector temperature 250 °C; column temperature 170 °C for 16 min and the apparatus was programmed at 2 °C per minute until 210 °C, remaining stable for 25 min; hydrogen was used as carrier gas at 1 ml/min, linear velocity of 38 cm/s, and an oxygen filter attached to the gas line; nitrogen was used as make up gas at 30 ml/min, with synthetic air 300 ml/min; split injection technique 1:100; 1 μl of FAME was injected. All steps, from transesterification to the injections, were performed under a nitrogen atmosphere. Retention time and the area of peaks were recorded with a Varian Mod 4290 integrator. Quantification was expressed as area percentage.

2.3. Fatty acids identification

In order to identify the fatty acids, comparisons were made between peak retention times (tr) in the sample chromatograms and retention time values of methyl ester standards (Sigma, St. Louis, MO). Equivalent chain length (ECL) values were used and calculated from the corrected retention times (tr′) for the fatty acid methyl esters (Maia, 1992; Stránsky, Jursík, & Vitek, 1997; Thompson, 1996). Identification was confirmed by fragmenting the fatty acids via electron impact at 70 eV in a Shimadzu QP 5000 gas chromatograph–mass spectrometer.

2.4. Statistical analysis

The area percentage values were submitted to analysis of variance (ANOVA) by the general linear models procedure (PROC GLM – Duncan's test at the 5% significance level), with one factor (season of the year or body part) and two levels (drought/flood or muscle/eyes). The SAS statistical package (Cary, NC) was used in this analysis.

3. Results and discussion

The captured tucunaré samples varied between 28 and 29 cm, with weights between 288 and 348 g in the flood period and 30–32 cm and 443–520 g in the drought period. The average moisture contents varied between 76% ± 1 and 78% ± 1, with average total lipid contents between 0.8% ± 0.2 and 2.1% ± 0.2 in both seasons, with a typical lean-species lipid composition (Ackman, 1989) (Table 1).

The lipid contents in fish can vary, depending on the species, age, seasonality, geographical origin, sexual maturity, body region, type of muscle and diet (Contreras-Guzman, 1994; Rasoarahona et al., 2005). In the flood period, lipid contents were equal to or lower than 1%, probably due to the high energy intake of piscivorous species in the search for food dispersed in inundated lowlands of rivers and lakes, and due to the reproduction period (Goulding, 1979). In the drought period, as the flooded area becomes smaller, food is abundant and capture is facilitated, resulting in accumulation of adipose tissue. The variation in lipid contents was inversely proportional to the variation in moisture content for both periods, which may create processing and storage problems, in addition to negatively affecting organoleptic properties (Contreras-Guzman, 1994).

Table 2 presents the fatty acids from total lipids of tucunaré in different seasonal periods. Eighty-two fatty acids (of which eight were not identified) and two dimethyl acetals were found. When tucunaré dorsal muscle and eye sockets were compared, it was observed that saturated (SFAs) and monounsaturated fatty acids (MUFAs) were predominant in the eye sockets, varying between 47.1% and 47.4%, and between 29.8% and 31.3%, respectively. Polyunsaturated fatty acids (PUFAs) were predominant in the dorsal muscle in both seasons, varying between 24.2% and 35.8%. The predominant fatty acids in both periods were: palmitic-16:0 (48.5–51.6% of total SFA), oleic-18:1ω9 (43.9–50.2% of total MUFA), docosahexaenoic-22:6ω3 (13.5–27.9% of total PUFA) and arachidonic acid-20:4ω6 (16.0–19.6% of total PUFA).

In both seasonal periods, saturated (SFAs) and monounsaturated fatty acids (MUFAs) were predominant in eye socket fat. In the flood period, major fatty acids with significantly different contents were 15:0, 17:0, 18:0, 16:1ω7, 18:1ω7, and 18:1ω9 while, in the drought, only 15:0 was significantly different.

However, polyunsaturated fatty acids were significantly higher in muscle tissue lipids in both seasons; major fatty acids of the ω3 series with significant differences in the flood period were 22:5ω3,

Table 1
Biometric index, moisture, and lipid determined for tucunaré (*Cichla* sp.) fillets in different seasonal periods.

Flood period (January–June)			Drought period (July–December)

* Analyses of 25 samples coming from five lots in each seasonal period. Abbreviations: i, iso; ai, anteiso; tr, trace (mean value below 0.1%); DMA, dimethyl acetal. Conditions: column DB-WAX 20 M (30 m × 0.247 mm × 0.25 mm); 170 °C/16 min. programmed to increase at 2 °C/min. up to 210 °C/25 min. Significant difference at a 5% level is designated by 'a' and 'b': different letters in the same period indicate a significant difference between muscle and eyes. The same letters in different periods indicate a significant difference in the referenced part of the body. Double letters (aa or bb) indicate a significant difference only between the periods. =, No significant difference in the referenced period, even with the presence of letters 'a' or 'b'. The absence of letters indicates no significant difference amongst the observations.

20:5ω3 and 16:4ω3, 22:5ω6 and 22:4ω6, while the 22:6ω3 and 20:4ω6 acids were significant in both periods and, in proportional terms, even exceeded monounsaturated fatty acids in the flood period. Polyunsaturated fatty acids varied between the seasonal periods studied, with significant difference for muscle tissue fatty acids in the flood period, with a high relative percentage when compared with the drought period.

When tucunaré polyunsaturated fatty acids were analysed, a high proportion of docosahexaenoic acid (22:6ω3) (10 ± 1%) was found in muscle during the flood period, with a low proportion of eicosapentaenoic acid (20:5ω3) (0.9 ± 0.1%), but with a high arachidonic acid content (22:4ω6) (7 ± 1%) (Fig. 1). In general, the ω6-series fatty acids showed higher proportions than did the ω3 in both seasonal periods, especially linoleic (18:2ω6) and arachidonic acid, which contributed to balance the ω6/ω3 ratio in the muscle and eyes, despite the high DHA content (22:6ω3) detected in muscle during the flood period.

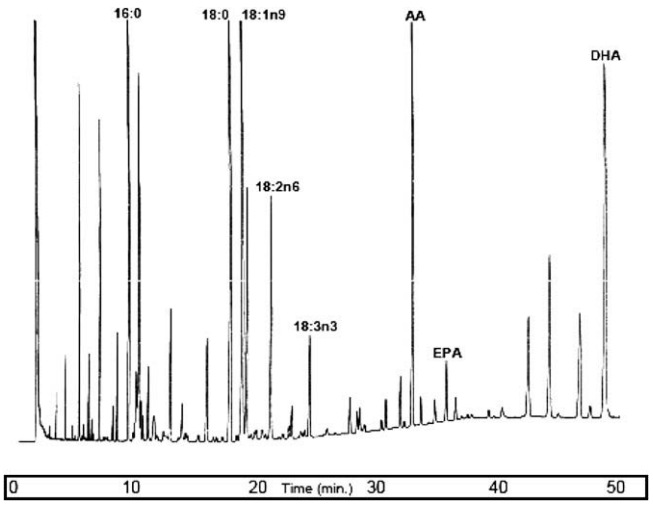

Fig. 1. Methyl esters chromatogram of tucunaré (*Cichla* sp.) fatty acids in DBWAX 20 M column (170 °C for 16 min, programmed to increase at 2 °C/min up to 210 °C with a final holding time of 25 min).

Similar results were reported by Maia et al. (1998), who analysed fatty acids in Amazonian fish without seasonal distinction and found high proportions of the 22:6ω3 (7.2%) and 20:4ω6 acids (6.5%) in tucunaré (*Cichla* sp.) muscle, with very close values for both, keeping the ω6/ω3 ratio near 1. They also observed that leaner fish, such as tucunaré, had higher polyunsaturated fatty acid contents than had fatter fish.

In seasonal studies on fatty acids of mapará muscle (*Hypophthalmus* sp.) in the Amazon region, no significant differences were found for polyunsaturated fatty acids throughout the year; however, ω6/ω3 ratios ranged from 0.6 to 0.8 (Inhamuns & Franco, 2001). In a similar study, five popular marine and freshwater fish species, sardine (*Sardinella* sp.), croaker (*Micropogonias furnieri*), tilapia (*Oreochromis* sp.), curimbatá (*Prochilodus* sp.), and shrimp (*Xiphopenaeus kroyeri*), were analysed for their fatty acids contents in two seasonal periods. The greatest ω6/ω3 ratio variations occurred in the freshwater species tilapia (*Oreochromis* sp.) and curimbatá, with values varying from 0.4 to 1.3 and from 0.8 to 1.02, respectively (Luzia, Sampaio, Castellucci, & Torres, 2003).

Rasoarahona et al. (2005) analysed the fatty acids of three tilapia species, *Oreochromis niloticus*, *O. macrochir*, and *Tilapia rendalli*, and found high AA and DHA contents, with ω6/ω3 ratios varying from 1.2 to 2.2, 0.6 to 2.0, and 0.8 to 1.7, respectively, in three seasonal periods. Özogul, Özogul, and Alagoz (2007) studied the muscle tissue composition of marine and freshwater species, and also observed that ω6 PUFA contents were higher in freshwater species.

The higher proportion of polyunsaturated fatty acids in the flood period detected in tucunaré muscle was probably due to a high energy intake during that period, as revealed by lower total lipid contents, since saturated and monounsaturated fatty acids constitute a source of energy readily available in fish, while polyunsaturated fatty acids are preserved, as they are structural constituents important for the metabolic functions of organs and tissues (Contreras-Guzman, 1994).

Tucunaré can be considered a rich source of essential fatty acids of the ω3 and ω6 series, with greater potential in muscle tissue and during the flood period in the Amazon Basin. The ω6/ω3 ratio, which varied between 1:1 and 1:6 in all periods and fractions analysed, proved to be balanced between these fatty acid groups. This result suggests that including this species in the diet may contribute to maintain the ω6/ω3 ratio recommended by FAO (1995), that is, between 5:1 and 10:1, considering the inclusion of vegetable oils frequently associated with fish consumption.

The industrial residues generated during tucunaré processing, such as heads and offal can be sent for oil extraction and concentration, to be used as nutraceuticals.

Anthocyanins
Antioxidant activity

ABSTRACT

Polyphenols and anthocyanins were extracted from *Kadsura coccinea* fruit. The contents of total phenolics and anthocyanins, influences of pH and temperature on anthocyanins, and antioxidant activities of extracts were further analyzed. The results showed that the total phenolic content of peel extracts was superior to that of pulp extracts. The total anthocyanin content of peel extracts was 180 ± 2.91 mg/100 g of fresh peel tissues. *K. coccinea* anthocyanins were stable below pH 4, whilst high temperature and extended heating time induced their degradation. Metal-chelating capacity (MCC) assay indicated that no ortho-dihydroxy aromatic moiety existed in the B-ring of the anthocyanin molecules, but there might be a catechol group in the B-ring of the polyphenol molecules. 1,1-Diphenyl-2-picrylhydrazyl (DPPH) radical-scavenging activity and reducing power of extracts decreased in the following order: peel polyphenol extracts > anthocyanin extracts > pulp polyphenol extracts. It would be worthwhile to introduce this rare fruit into more countries.

1. Introduction

Oxidation is an essential biological process for energy production in many living organisms. However, excessive reactive oxygen species, produced *in vivo* during some oxidative reactions, are not only strongly associated with lipid peroxidation but also involved in the development of some diseases (Moskovitz, Yim, & Choke, 2002). Recently, increasing numbers of reports confirm that many fruits and vegetables may afford protection against some chronic diseases caused by oxidative stress. This is mainly attributed to their antioxidant constituents, including vitamin C, vitamin E, carotenoids, flavonoids and anthocyanins (Heim, Tagliaferro, & Bobilya, 2002; Seifried, 2007). Polyphenols and anthocyanins are important components in fruit tissues. These compounds are thought to be instrumental in combating oxidative stress. They can prevent some oxidation-related diseases such as atherosclerosis, cardiovascular and neurodegenerative diseases and cancer (Kaliora, Dedoussis, & Schmidt, 2006; Pietta, Minoggio, & Bramati, 2003; Ramassamy, 2006; Wang & Stoner, 2008).

Kadsura coccinea (Lem.) A.C. Smith, a plant indigenous to South China, belongs to the family Schisandraceae. *K. coccinea* fruit is known as 'black tiger' in China. It is a novel and rare fruit with high nutritional value. The mature fruit of *K. coccinea*, with 3.5–10.5 cm cross diameter and 3.0–9.5 cm vertical diameter, is aggregated by about 30–65 small berries. Each small berry has a fruit aroma similar to apple, and peel and pulp colours similar to litchi. By atomic absorption spectrophotometry, a high content of essential trace elements, Mn, Ca, Fe, Mg, Cu and Zn, is observed in this fruit, indicating that it possesses benefits for human health (Huang, Long, Wen, & Li, 2006). In recent years, *K. coccinea* fruit has been introduced and cultivated in some provinces of China, such as Guangxi, Guangdong, Guizhou, Yunnan, Hunan and Sichuan. At present, this fruit is mainly consumed in the form of fresh fruit, juice and fruit wine. Due to its good taste and health-beneficial effect, this fruit is relatively expensive in markets. The high commercial value attracts more and more people to study and develop it. Previous researches revealed that some lignans and triterpenoids in stem or seed extracts from *K. coccinea* were effective as antitumor, anti-HIV, anti-lipid peroxidative, cytotoxic and anti-hepatitis agents (Gao et al., 2008; Liu & Li, 1995). However, there are still no reports on antioxidant activity of polyphenols and anthocyanins from *K. coccinea* fruit. *K. coccinea* fruit is rich in polyphenols and anthocyanins in its edible portion, which has a potential health benefit. The objective of the present study is to determine polyphenol and anthocyanin contents in this fruit and fur-

ther analyze their antioxidant activity. The research results will be useful for elucidating the nutritional and health values of *K. coccinea* fruit and popularising this novel fruit in countries outside China.

2. Materials and methods

2.1. Plant materials

The mature aggregate fruits of *K. coccinea* with dark purplish-red fleshy and edible peels were harvested from the northwest area of Guangxi province of China in October, 2008. The individual small berries, without defects and diseases, were selected and deseeded. Peel and pulp tissues were collected and weighed, respectively. All samples were stored at −20 °C prior to further extraction and analysis.

2.2. Chemicals and reagents

Folin–Ciocalteau reagent, gallic acid, ferrozine, 1,1-diphenyl-2-picrylhydrazyl ($DPPH^{\cdot}$), 2,4,6-tripyridyl-s-triazine (TPTZ) and ascorbic acid standard were purchased from Sigma–Aldrich (St. Louis, MO, USA). Other chemicals and reagents were of analytical grade.

2.3. Extraction and partial purification of polyphenols and anthocyanins

Polyphenols and anthocyanins were extracted from crushed fresh peel and pulp tissues (20 g) of *K. coccinea* fruit, according to the modified method of Zhang, Quantick, and Grigor (2000) and Zheng, Wang, Wang, and Zheng (2003). The extraction was performed twice at 20 °C in a shaking incubator (ZHWY-200B, Zhicheng Analytical Co., Shanghai, China). Extracting time was 30 min, and extracting solvent was 100 ml of methanol/acetone/water (3.5:3.5:3, v/v/v) containing 1% formic acid. All extracts were combined and filtered through two layers of cheesecloth. The collected filtrate was centrifuged for 15 min at 7000 *g*. The supernatant was collected and evaporated under vacuum at 35–40 °C to remove methanol and acetone. Lipophilic pigments were then eliminated from the aqueous phase by two successive extractions in a separatory funnel with a twofold volume of petroleum ether. The aqueous phase was collected and further extracted three times by ethyl acetate (ethyl acetate: aqueous phase = 1:1, v/v) in the separatory funnel. Three ethyl acetate phases were collected, evaporated and dried under vacuum at 35 °C. The residue was re-dissolved in 2 ml of ethanol and used as a partially purified polyphenol sample. The aqueous phase was also dried under vacuum at 55 °C and used as an anthocyanin sample. All samples were stored at −20 °C prior to further assays.

2.4. Determination of total phenolic content

Total phenolic content was determined using the Folin–Ciocalteau method described by Singleton and Rossi (1965) with some modifications. One millilitre of 10-fold diluted extracts by methanol/acetone/water (3.5:3.5:3, v/v/v), containing 1% formic acid, was thoroughly mixed with 1 ml of Folin–Ciocalteau reagent and stood for 3 min at the room temperature. Then, 3 ml of sodium carbonate (75 g/l) were added to the mixture, which was allowed to stand for 2 h at the room temperature. Sample aliquots were filtered through a 0.45 μm filter prior to the determination of total phenolics using a UV–visible Spectrophotometer (UV-1700, Shimadzu, Kyoto, Japan), monitoring at 760 nm. Total phenolic content was standardised against gallic acid and expressed as microgrammes of gallic acid equivalents (GAE) per millilitre.

2.5. Determination of total anthocyanin content

Total anthocyanin content of *K. coccinea* peel extracts was measured using the pH differential method described by Wrolstad and Giusti (2001) and Elisia, Hu, Popovich, and Kitts (2007) with minor modifications. The crude anthocyanin extracts were dissolved in potassium chloride buffer (KCl, 0.025 M, pH 1.0) and sodium acetate ($CH_3CO_2Na \cdot 3H_2O$, 0.4 M, pH 4.5) with a pre-determined dilution factor. The absorbances of measured samples were read at 520 and 700 nm against a blank cell containing deionized water (dd H_2O). The absorbance (A) of the diluted sample was then calculated as follows: $A = (A_{\lambda vis\text{-}max} - A_{700nm})$ pH 1.0 $- (A_{\lambda vis\text{-}max} - A_{700nm})$ pH 4.5. The monomeric anthocyanin pigment concentration in the original sample was calculated according to the following formula:

$$\text{Anthocyanin content (mg/l)} = \frac{A \times MW \times DF \times 1000}{\varepsilon \times 1}$$

in which cyanidin-3-glucoside molecular weight (MW = 449.2), the dilution factor or dilution multiple (DF = 50) and the molar absorptivity constant (ε = 29,600) were used.

2.6. Effects of pH values and heat on anthocyanin properties

Anthocyanin solutions at pH 1, 4, 7, 10 and 12 were prepared using 0.1 M HCl and 0.1 M NaOH at 25 °C. All samples were spectrophotometrically scanned from 400 to 700 nm. By comparing variations of spectrum shapes, absorption peaks, colours and maximum absorbances within 3 min, the effects of different pH values on *K. coccinea* anthocyanins were determined.

Thermal stability of anthocyanins was analyzed according to the modified method of Dyrby, Westergaard, and Stapelfeldt (2001). Five millilitres of aqueous anthocyanin solution were respectively sealed into four tubes that were well capped to avoid evaporation. These tubes were placed in thermostatic water baths operating at 20, 40, 60 and 80 °C. One anthocyanin sample at each temperature was removed after 1, 2 and 3 h, and then rapidly cooled in ice-water. The thermal degradation of anthocyanin was spectrophotometrically measured at 520 nm. The residual amounts of anthocyanin (%) = $(A_{1,\ 2,\ or\ 3h}/A_{0h}) \times 100$, where A_{0h} was the absorbance of anthocyanin sample without undergoing heating treatment, and $A_{1,\ 2,\ or\ 3h}$ was the absorbance of anthocyanin sample after heating for 1, 2 and 3 h at different temperatures.

2.7. Metal-chelating capacity (MCC)

The metal-chelating capacity was determined by the modified method of Dinis, Madeira, and Almeida (1994). Aliquots (1 ml) of 0 (control), 25, 50, 100, 250, 500 and 1000 μg/ml of polyphenol and anthocyanin extracts dissolved in ethanol were added to 2.8 ml distilled water and then mixed with 50 μl of 2 mM $FeCl_2 \cdot 4H_2O$ and 150 μl of 5 mM ferrozine. The mixture was centrifuged at 120 *g*. After 10 min, the Fe(II) was monitored by measuring the formation of ferrous ion–ferrozine complex at 562 nm. The metal-chelating capacity was calculated as follows: chelating capacity (%) = (1 − absorbance of sample/absorbance of control) × 100.

2.8. DPPH radical-scavenging activity

The DPPH radical-scavenging activity was estimated by the modified method of Bondet, Brand-Williams, and Berset (1997). Aliquots (0.5 ml) of 0 (control), 25, 50, 100, 250, 500 and 1000 μg/ml of polyphenol and anthocyanin extracts dissolved in ethanol were added to 2.5 ml of 0.2 mM $DPPH^{\cdot}$ solution in ethanol. The absorbance at 517 nm of samples was measured after 30 min of incubation at room temperature in the dark. $DPPH^{\cdot}$-scavenging activity (%) = $[1 - (A - B)/A_0] \times 100$, where A = absorbance of sam-

ple, B = absorbance of 0.5 ml of extracts + 2.5 ml of ethanol, and A_0 = absorbance of control. The 50% inhibition concentration (IC_{50}), i.e. the concentration of extracts that was required to scavenge 50% of radicals, was calculated.

2.9. Ferric reducing/antioxidant power (FRAP)

This procedure was conducted according to the modified method of Benzie and Strain (1996). The working FRAP reagent was produced by mixing 300 mM acetate buffer (pH 3.6), 10 mM TPTZ solution and 20 mM $FeCl_3 \cdot 6H_2O$ in a 10:1:1 ratio prior to use and heated to 37 °C in a water bath. A total of 3.0 ml of FRAP reagent was added to a cuvette and a blank reading was taken at 593 nm, using the spectrophotometer. In total, 100 μl of polyphenol and anthocyanin extracts and 300 μl of distilled water were added to the cuvette. After addition of the sample to the FRAP reagent, a second reading at 593 nm was performed after 40 min of incubation at 37 °C in a water bath. The changes in absorbance after 40 min from the initial blank reading were compared with a standard curve. Standards of known Fe(II) concentrations were run using several concentrations ranging from 100 to 1000 μM. A standard curve was then prepared by plotting the FRAP values of each standard versus its concentration. The final result was expressed as the concentration of antioxidant having a ferric reducing ability in 1 g of sample (μM/g).

2.10. Data analysis

All experiments were performed in triplicate ($n = 3$), and an ANOVA test (using SPSS 13.0 statistical software, SPSS Inc., Chicago, USA) was used to compare the mean values of each treatment. Significant differences between the means of parameters were determined by using the LSD test ($P < 0.05$). The results represented means ± standard error (SE) of three replicated determinations.

3. Results and discussion

3.1. Contents of total phenolics and anthocyanins

In the present study, the total phenolic content of extracts (by methanol/acetone/water/formic acid) from *K. coccinea* peel tissues (179 ± 1.95 μg/ml GAE) was superior to that from its pulp tissues (81.1 ± 1.60 μg/ml GAE). In addition, it was observed that no anthocyanin existed in *K. coccinea* pulp tissues. The total anthocyanin content of fleshy peel extracts, determined by pH differential method, was 180 ± 2.91 mg/100 g of fresh peel tissues. The result of the spectral scan showed that the anthocyanin extracts dissolved in acidified distilled water (pH 2) exhibited four absorption peaks at 280, 310, 340 and 520 nm in the wavelength range from 250 to 650 nm (Fig. 1A). This result was consistent with the reported spectral character of anthocyanins (Fig. 1B), which showed distinctive Band I peaks in the 450–560 nm region (due to the B-ring hydroxyl cinnamoyl system) and Band II peaks in the 240–280 nm region (due to the A ring benzoyl system) (Rice-Evans, Miller, & Paganga, 1996). Peaks at 310 and 340 nm further suggested that the acyl group existed in *K. coccinea* anthocyanin molecules (Yoshitama, 1978).

3.2. Effects of pH values on Kadsura coccinea anthocyanins

The variation of pH values influences anthocyanin properties, such as colour, stability, spectral shape and absorption peak. Naturally, anthocyanins contribute to the range of red to purple colours found in many fruits, vegetables, flowers and other plant tissues. The same anthocyanin may have different colours in different

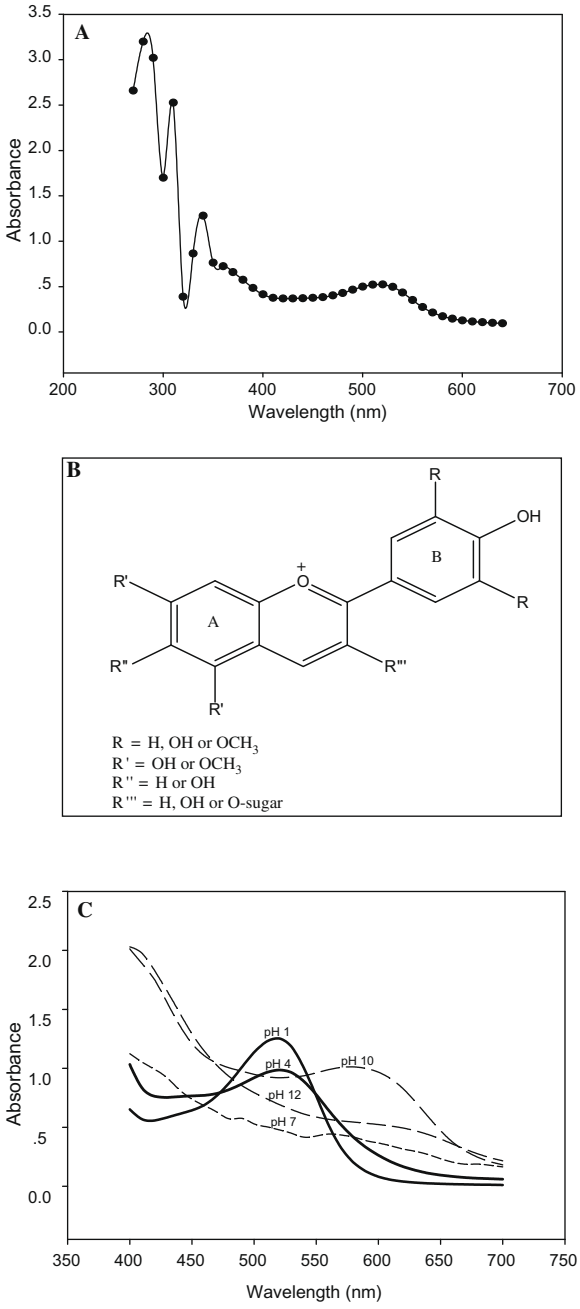

Fig. 1. Spectral character of *Kadsura coccinea* anthocyanins. (A) Absorption spectrum of *Kadsura coccinea* anthocyanin extracts dissolved in acidified distilled water (pH 2), (B) a general structure of anthocyanins and (C) absorption spectra of *Kadsura coccinea* anthocyanin extracts at different pH values.

plants, which depends virtually on the pH values of organelles (Dao, Takeoka, Edwards, Berrios, & De, 1998; Janna, Khairul, & Maziah, 2007). It is observed from Fig. 1C that the anthocyanin extracts from *K. coccinea* peels had maximum absorption around 520 nm at pH 1 and 4. Anthocyanin solutions, at both pH values, exhibited bright-red colour, and their absorbances at 520 nm varied slightly within 3 min. However, when pH values of anthocyanin solutions were above four, there were no obvious absorption peaks in the 450–560 nm regions. The colours of anthocyanin solutions gradually changed from moderate pink to brown from pH 7–12. Their absorbances at 520 nm continuously increased within 3 min. Moreover, the experimental results also showed that the colours of anthocyanin solutions presented reversible change between acidic and alkaline pH values, which was due to the high reactivity

of the flavylium cation toward nucleophilic reagents (including OH^- and H^+), resulting in the variation of chemical structures under different pH conditions (this was a reversible pH-dependent reaction) (Cooke, Steward, Gescher, & Marczylo, 2005; Março, Levi, Scarminio, Poppi, & Trevisan, 2005). By the above analysis, the anthocyanins from *K. coccinea* peels, as the antioxidants, were stable and maintained their original bright-red colour below pH 4.

3.3. Effects of heat on Kadsura coccinea anthocyanins

Heat treatment is one of the most important factors that influence anthocyanin stability (Wang & Xu, 2007). Anthocyanins are not stable at high temperature. Their thermal degradation has been found in many fruits, e.g. grape (Morais, Ramos, Forgács, Cserháti, & Oliviera, 2002), strawberry (García-Viguera & Zafrilla, 1999), sour cherry (Cemeroğlu, Velioğlu, & Işik, 1994), pomegranate (Martí, Pérez-Vicente, & García-Viguera, 2001) and blackberry (Wang & Xu, 2007). From Fig. 2, temperature and time of heat treatment affect the stability of *K. coccinea* anthocyanins. It was observed that the stability of anthocyanin in solutions gradually declined with increase of the heating temperature and extension of heating time. Placing the anthocyanin solution for 3 h in water baths at 20 °C, it was stable and retained red colour. However, heated at 40, 60 and 80 °C, the anthocyanins could break down, and their residual amounts rapidly declined within 1 h. After 3 h, the residual amounts were 92.3 ± 0.2% for 40 °C, 88.1 ± 0.7% for 60 °C and 88.0 ± 0.4% for 80 °C, which were significantly ($P < 0.05$) lower than those for 20 °C (97.8 ± 0.5%). The results suggested that *K. coccinea* anthocyanins tended to degrade at high temperatures when they were used as antioxidants.

3.4. Antioxidant properties of polyphenol and anthocyanin extracts

3.4.1. MCC assay

The MCC method depends on the ability of samples to chelate transition metals, which possess the ability to catalyse hydrogen peroxide decomposition and Fenton-type reactions (Du, Li, Ma, & Liang, 2009). In the present study, *K. coccinea* anthocyanin extracts had no metal-chelating capability, indicating that no ortho-dihydroxy aromatic moiety (the key structure for chelating transition metals) existed in the B-ring of the anthocyanin molecules. However, polyphenol extracts from peel and pulp tissues of *K. coccinea* fruit exhibited some metal-chelating capability (Fig. 3), suggesting that there was a catechol group in B-ring of these polyphenol molecules (Brouillard & Dangles, 1993). By the regression analysis, no

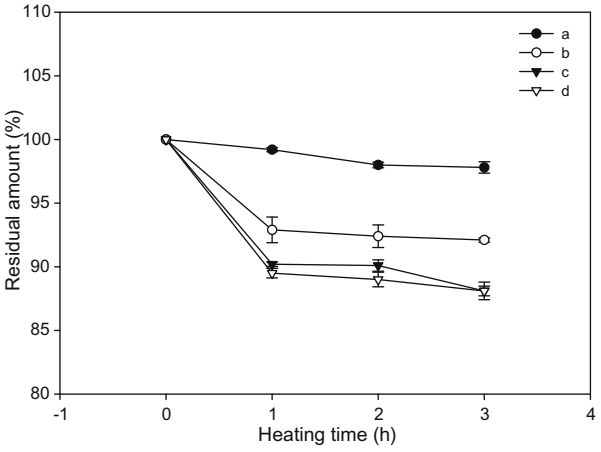

Fig. 2. Residual amounts of *Kadsura coccinea* anthocyanins at different temperatures. a, 20 °C; b, 40 °C; c, 60 °C; d, 80 °C.

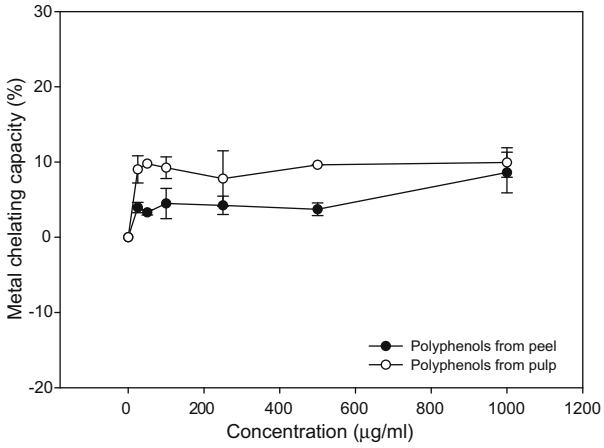

Fig. 3. Metal-chelating capacity of polyphenol extracts from peel and pulp tissues of *Kadsura coccinea* fruit.

significant correlation was found between the concentrations of polyphenol components and MCC.

3.4.2. DPPH radical-scavenging activity

DPPH radical-scavenging activity has been extensively used for screening antioxidants, such as polyphenols and anthocyanins, from fruits. $DPPH^·$ is scavenged by polyphenols and anthocyanins through the donation of hydrogen, forming the reduced DPPH–$H^•$. The colour changes from purple to yellow after reduction, which can be quantified by its decrease of absorbance at wavelength 517 nm (Bondet et al., 1997; Chang et al., 2007). Fig. 4 shows the DPPH radical-scavenging activity of polyphenol and anthocyanin extracts in *K. coccinea* fruit. A well-known antioxidant compound, ascorbic acid, was used as positive control. From Fig. 4, when sample concentration was above 25 μg/ml, the DPPH radical-scavenging activity of ascorbic acid was higher than that of polyphenol and anthocyanin extracts from *K. coccinea* fruit. Peel polyphenol extracts exhibited stronger DPPH radical-scavenging activity than did anthocyanin extracts and pulp polyphenol extracts in the concentration ranges from 0 to 1000 μg/ml. The scavenging activity of pulp polyphenol extracts was lowest amongst four antioxidants. Furthermore, in the present study, DPPH radical-scavenging activity was linearly correlated (positive) with the concentrations of peel polyphenol extracts and anthocyanin extracts in the range 0 to 1000 μg/ml and ascorbic acid in the range 0–100 μg/ml, respectively. The corresponding correlation coefficients were 0.9838 for peel polyphenol extracts ($Y = 0.0602X + 4.3267$), 0.9722 for anthocyanin extracts ($Y = 0.0255X + 1.1749$) and 0.9858 for ascorbic acid ($Y = 0.9507X + 3.93$). By the calculation of 50% inhibition concentration, it was further confirmed that the DPPH radical-scavenging activity of samples decreased in the following order: ascorbic acid (IC_{50} 48.5 ± 0.745 μg/ml) > peel polyphenol extracts (IC_{50} 759 ± 19.0 μg/ml) > anthocyanin extracts (IC_{50} 1915 ± 43.1 μg/ml) > pulp polyphenol extracts (IC_{50} 22,302 ± 2614 μg/ml).

3.4.3. FRAP assay

FRAP assay depends upon the reduction of ferric tripyridyltriazine (Fe(III)–TPTZ) complex to ferrous tripyridyltriazine (Fe(II)–TPTZ) with an intensive blue colour by a reductant at low pH (Benzie & Strain, 1996). Reductants polyphenols and anthocyanins have strong electron-donating capacity, which can induce the formation of a blue coloured Fe(II)–TPTZ from the colourless oxidised Fe(III) form (Benzie & Strain, 1996). From Fig. 5, in the concentration range 0–1000 μg/ml, the FRAP value of samples decreased in the following order: ascorbic acid > peel polyphenol extracts >

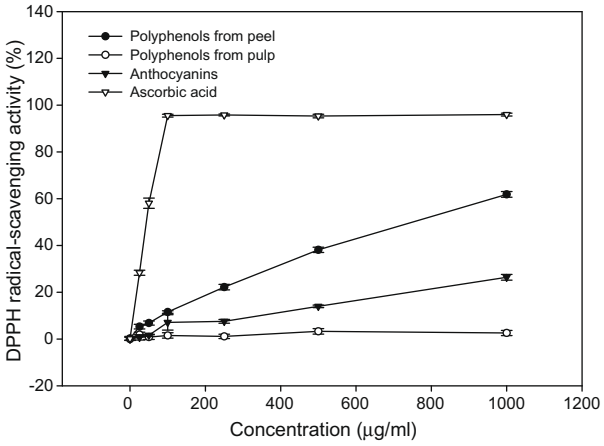

Fig. 4. DPPH radical-scavenging activity of polyphenol and anthocyanin extracts from *Kadsura coccinea* fruit.

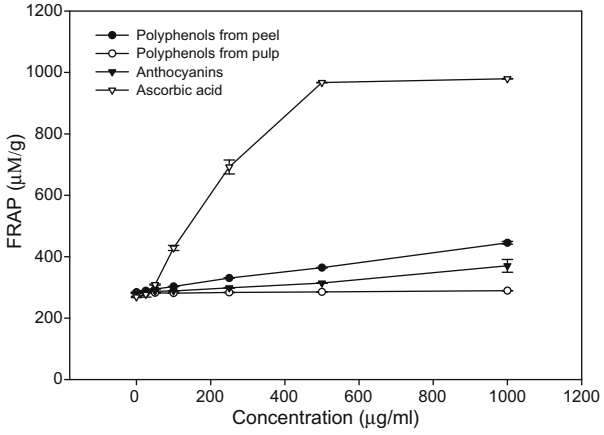

Fig. 5. Reducing power (FRAP values) of polyphenol and anthocyanin extracts from *Kadsura coccinea* fruit.

anthocyanin extracts > pulp polyphenol extracts, indicating that the ability of samples to reduce Fe(III) to Fe(II) (i.e. reducing power of samples) also decreased in the above order. In addition, by linear regression analysis, the FRAP value was positively correlated with the concentrations of peel polyphenol extracts, anthocyanin extracts and pulp polyphenol extracts in the range 0–1000 μg/ml and ascorbic acid in the range 0–500 μg/ml, respectively. The corresponding correlation coefficients were 0.9986 for peel polyphenol extracts ($Y = 0.1592X + 286.34$), 0.9789 for anthocyanin extracts ($Y = 0.0851X + 280.19$), 0.9718 for pulp polyphenol extracts ($Y = 0.0084X + 281$) and 0.984 for ascorbic acid ($Y = 1.4647X + 264.67$).

4. Conclusion

In the present study, polyphenols and anthocyanins in *K. coccinea* fruit, a novel and rare fruit with high nutritional value in South China, were extracted from fresh peel and pulp tissues. The total phenolic content of peel extracts was superior to that of pulp extracts. The total anthocyanin content of fleshy peel extracts was determined to be 180 ± 2.91 mg/100 g of fresh peel tissues. The influences of pH values and temperatures on properties of *K. coccinea* anthocyanins showed that they were stable under pH 4, whilst higher heating temperature and extended heating time induced their degradation. By measuring metal-chelating capacity, it could be estimated that no ortho-dihydroxy aromatic moiety existed in the B-ring of *K. coccinea* anthocyanin molecules, but there might be a catechol group in the B-ring of polyphenol molecules from peel and pulp tissues of this fruit. Moreover, the DPPH radical-scavenging activity and reducing power of *K. coccinea* extracts decreased in the following order: peel polyphenol extracts > anthocyanin extracts > pulp polyphenol extracts. The above results indicated that *K. coccinea* fruit possessed health benefits due to its polyphenol and anthocyanin components with antioxidant activities. It is worth developing this novel fruit to introduce it to other countries and areas.

Texture

ABSTRACT

The genetic diversity in seeds (physicochemical, hydration, textural and cooking properties) and flours (pasting and gel texture) among kidney bean lines was studied. A wide range of variation was observed for yield and yield-related traits. Seed weight, volume, density, hydration capacity, hydration index, swelling capacity, cooking time and amylose content ranged from 10.2 to 51.7 g/100 seeds, 14 to 46 ml/100 seeds, 0.51 to 2.15 g/ml, 0.03 to 0.62 g/seed, 0.16 to 0.97, 1.24 to 1.93 ml/seed, 50 to 120 min, and 0.09% to 5.02%, respectively. Hardness, cohesiveness, gumminess, springiness and chewiness of hydrated seeds ranged from 0.81 to 2.03 g, 0.18 to 0.48, 0.20 to 0.97 g, 0.31 to 0.51 and 0.08 to 0.43 g, respectively. Pasting temperature, peak viscosity, breakdown, final viscosity and setback ranged from 79 to 95 °C, 402 to 3235 cP, 9 to 393 cP, 862 to 5311 cP, and 363 to 2488 cP, respectively. Hardness, cohesiveness, gumminess, springiness, chewiness and adhesiveness of flour gels ranged from 3.9 to 5.3 g, 0.52 to 0.76, 1.47 to 23.52 g, 0.91 to 0.99, 3.21 to 23.91 and 13.2 to 178.5 g s, respectively.

1. Introduction

Legumes are the edible fruits or seeds of pod-bearing plants belonging to the order *Leguminosae* and are widely grown throughout the world. Legumes have been considered as the most significant food source for people of low incomes (Bressani & Elias, 1979). Legumes have a high food value and store well, play an important role in the diet of most of the people of the world, being second only to cereals as a source of human and animal food (Singh, Kaur, Sandhu, & Sodhi, 2004). Legumes not only add variety to the human diet, but also serve as an economical source of supplementary proteins for the large human populations in developing countries, such as India, where the majority of the population is vegetarian (Kaur & Singh, 2007b). In general, legumes are sources of complex carbohydrate, protein and dietary fibre, having significant amounts of vitamins and minerals, and high energetic value (Tharanathan & Mahadevamma, 2003). Legumes are generally soaked before cooking to ensure uniform expansion of the seed coat and cotyledon and to ensure their tenderness (Hoff & Nelson, 1965). Kidney bean (*Phaseolus vulgaris* L.) is the most widely produced and consumed food legume in Africa, India, Latin America and Mexico (FAO, 2002). This bean usually contains 20–30% protein on a dry basis, and the protein has a good amino acid composition but is low in sulphur-containing amino acids (notably methionine) and tryptophan (Gueguen & Cerletti, 1994; Sathe, 2002). Dry beans have recovered prestige in the diets of developed countries. This is due, in part, to health problems related to meat consumption, as well as the discovery of the benefits of legumes in the diet and the protection they afford against colon disease (Champ, 2001; Hangen & Bennink, 2003; Lee, Prosky, & DeVries, 1992; Mathres, 2002). Kidney beans have numerous health benefits, e.g., they reduce heart and renal disease risks, lower glycaemic index for persons with diabetes, increase satiation, and prevent cancer. Furthermore, kidney beans are regarded as an important source of protein and minerals for livestock feed production, as well as potential raw materials for processing into human food (Shimelis & Rakshit, 2007). A wide variation in chemical, thermal, pasting and textural properties of seeds, flour and starches of black gram and chickpea lines has been reported previously (Singh et al., 2004; Kaur & Singh 2005).

The objectives of the present investigation were to evaluate (i) physicochemical, hydration and textural properties of seeds from different kidney bean germplasm lines, (ii) composition, pasting and textural properties of flours and (iii) relationship between different properties of seeds and flours.

2. Materials and methods

2.1. Materials

The seed material for the present experiment comprised 50 diverse germplasm accessions (36 exotic and 14 indigenous) of kidney bean, namely EC18639, EC28758, EC45816, EC57004, EC116177, EC398501, EC398523, EC398548, EC405199, EC405179, EC405203, EC405213, EC405230, EC493713, EC498445, EC506078, EC530944,

EC530952, EC530955, EC530966, EC530968, EC530969, EC530974, EC530977, EC530978, EC530991, EC530993, EC530996, EC540796, IC11660, IC199223, IC202271, IC262749, IC278582, IC313249, IC313257, IC341755, NC2162, NC58584, PI163833, PI197967, PI204719, PI240554, PI301808, PI312296, PI339501, PLB10-1, Laxmi, Vaspa and Triloki, which were grown at the Regional Station of the National Bureau of Plant Genetic Resources (NBPGR) located in Phagli area of Shimla at latitude of 31°.06′N and longitude of 77°.10′E in the year 2006–2007. The lines for quality analysis of seed and flour were selected on the basis of genetic variability observed for various characteristics but primarily for seed size and colour. The agroclimatic conditions of the area where crop was grown: rainfall (1350 mm), topography (submountainous) and temperature (14 °C), soils are shallow to moderately shallow, having loam to clay loam texture with varying proportions of gravel.

2.2. Seed weight

Seed weight was determined in triplicate. Kidney bean grains were randomly selected and 50 kernels of kidney bean grains were counted. The counted grains were then weighed and expressed in grams.

2.3. Seed volume

Seed volume was determined in triplicate (Williams et al., 1983). Fifty seeds were transferred to a 50-ml measuring cylinder and 25 ml distiled water were added. The difference in the volume was noted down and divided by 50 to calculate the volume per seed.

2.4. Bulk density

Kidney bean grains were gently added to a 100-ml graduated cylinder, previously tared. The bottom of the cylinder was gently tapped on a laboratory bench, several times, until there was no further diminution of the sample level after filling to the 100 ml mark. Bulk density was calculated as weight of sample per unit volume of sample (g/ml). All the measurements were in triplicate.

2.5. Hydration capacity

Fifty seeds were transferred to a 125-ml Erlenmeyer flask and water was added to 100 ml. The flask was lightly stoppered and left overnight at room temperature. Next day the grains were drained, superfluous water was removed with absorbent paper and the swollen seeds were reweighed. Hydration capacity per seed was recorded as:

$$(\text{weight after soaking} - \text{weight before soaking})/50.$$

2.6. Hydration index

Hydration index was calculated as:

$$\text{hydration capacity per seed}/\text{weight of one seed}(g)$$

2.7. Swelling capacity

Swelling capacity was calculated by reweighing the soaked seeds. Seeds were transferred to a 100-ml measuring cylinder and 50 ml water were added. Swelling capacity per seed was recorded as:

$$\frac{\text{volume after soaking} - \text{volume before soaking}}{50}$$

2.8. Swelling index

Swelling index was calculated as swelling capacity per seed/volume of one seed (ml).

2.9. Textural properties of soaked seeds

Texture profile analysis (TPA) of soaked kidney bean lines was performed on a single soaked grain from each variety, using a TA/XT texture analyser (Stable Microsystems, Crawley, UK). The grain was subjected to 75% compression with a probe (P/75) at a speed of 1 mm/s. The textural parameters of hardness (maximum height of the force peak on the first compression cycle), springiness (ratio of the time elapsing between the end of first bite and the start of second bite), cohesiveness (ratio of the positive force areas under the first and second compressions), gumminess (product of hardness and cohesiveness) and chewiness (product of gumminess and springiness) were determined. Twenty repeated measurements were performed on each sample.

2.10. Cooking time

For the determination of cooking time, about 250 ml distiled water were brought to boiling point in a 500-ml beaker fitted with condenser to avoid evaporation losses during boiling and then 25 g seed was added. Boiling was continued, and boiled seeds at intervals of 2 min were drawn and tested for their softness by pressing between the forefinger and thumb. The time taken to achieve the desirable softness was recorded as the cooking time of the sample.

2.11. Preparation of kidney bean flour

About 30 g of seeds from different legume lines were ground to pass through sieve No. 72 (BIS) to obtain flour, which was packed in airtight containers.

2.12. Proximate composition

Flour samples were evaluated for their moisture, ash, fat and protein (% $N \times 6.25$) contents by employing standard methods of analysis (AOAC, 1990). Studies were conducted in triplicate.

2.13. Amylose (%)

Amylose content of the isolated starch was determined by using the method of William, Kuzina, and Hlynka (1970). A starch sample (20 mg) was taken and 10 ml of 0.5 N KOH were added to it. The suspension was thoroughly mixed. The dispersed sample was transferred to a 100 ml volumetric flask and diluted to the mark with distiled water. An aliquot of test starch solution (10 ml) was pipetted into a 50-ml volumetric flask and 5 ml of 0.1 N HCl were added, followed by 0.5 ml of iodine reagent. The volume was diluted to 50 ml and the absorbance was measured at 625 nm. The measurement of the amylose was determined from a standard curve developed using amylose and amylopectin blends.

2.14. Pasting properties of kidney bean flours

Pasting properties of legume flour gels were evaluated using Rapid Visco Analyzer (RVA4, Newport Scientific Pvt. Ltd., Warriewood, Australia) from different legume lines. Viscosity profiles of flours were recorded using flour suspensions (29 g total weight). The temperature–time conditions included a heating step from 50 to 95 °C at 6 °C/min (after an equilibration time of 1 min at 50 °C), a holding phase at 95 °C for 5 min, a cooling step from 95 to 50 °C at 6 °C/min and a holding phase at 50 °C for 2 min. A typical RVA curve for

a kidney bean flour is shown in Fig. 1. Parameters recorded were pasting temperature, peak, trough (minimum viscosity at 95 °C), final (viscosity at 50 °C), breakdown (peak-trough viscosity), and setback viscosity (final-trough viscosity). All the measurements were in triplicate. Pasting temperature is the temperature at the onset of rise in viscosity. It provides an indication of the minimum temperature required to cook the flour. Final viscosity indicates the ability of the material to form a viscous paste. Setback viscosity measures the retrogradation tendency of flours upon cooling of cooked flour pastes. Breakdown viscosity measures the ease with which the swollen granules can disintegrate.

2.15. Textural properties of flour pastes

The flour pastes prepared in the RVA were poured into aluminium canisters and stored at 4 °C to cause gelation. Textural properties of RVA gels were determined using a TA/TX2 texture analyser (Stable Microsystems). Each canister was placed upright on a metal platform and the gel was compressed at a speed of 0.5 mm/s, using a 5-kg load cell to a distance of 10 mm with a cylindrical plunger (5 mm diameter). Hardness is defined as maximum height of the force peak on the first compression cycle (first bite). The compression was repeated twice to generate a forcetime curve, from which hardness (height of first peak) and springiness (ratio of the time elapsed between the end of first bite and the start of second bite) was determined. Cohesiveness was calculated as the ratio between the area under the second peak and the area under the first peak (Bourne, 1978). Gumminess was determined by multiplying hardness and cohesiveness. Chewiness was derived from gumminess and springiness and was obtained by multiplying these two. Ten repeated measurements were performed for each sample and their average was taken.

2.16. Statistical analysis

Statistical analysis of the results was done using Minitab Release 14 Statistical Software (Minitab Inc., State College, PA). Pearson correlation coefficients (r), for the relationships between various flour properties and grain parameters, were determined.

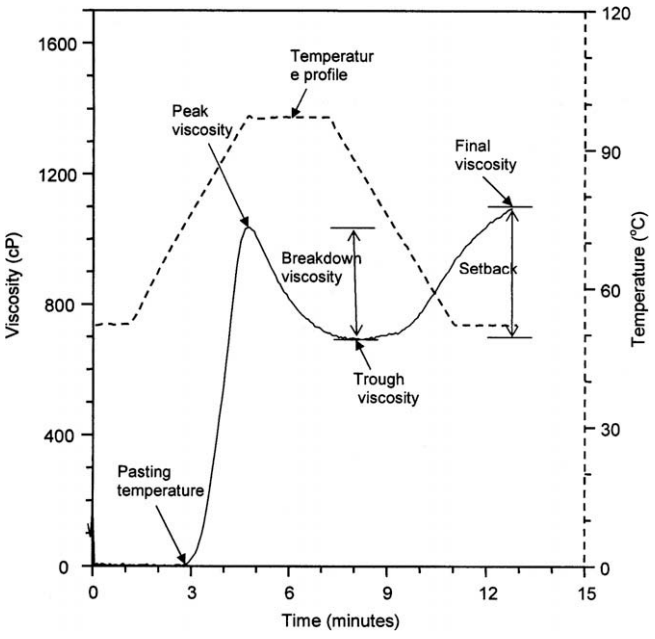

Fig. 1. Typical Rapid Visco Analyzer (RVA) Pasting Curve.

3. Results and discussions

3.1. Plant characteristics

The period for completion of 50% flowering ranged from 41 to 82 days. IC202271 completed 50% flowering in the shortest period (41 days) whereas Vaspa required the longest period (82 days). Leaflet length varied from 68 to 177 mm and it was smallest for EC498445 and longest for Vaspa and Triloki. Width of leaflet varied from 52 to 138.5 mm, EC506078 showed the smallest width (52 mm) and IC313249 had the greatest width (138.5 mm). Pod length also varied significantly among lines; IC313257 had the smallest pod length (76 mm) while Triloki had the longest (168 mm). Pod width ranged from 8 mm (EC530974) to 16 mm (EC530966, IC11660). Number of pods per plant varied from 9 to 34. EC506078 had the least pods whereas IC313257 had the highest. Days to 50% maturity ranged from 94 days for EC493713 to 140 days for EC405213. Seed width and length varied from 3.4 mm (EC116177) to 7.8 mm (EC493713), and 5.2 mm (EC498445) to 19.6 mm (PLB10–1), respectively. EC405203 gave highest yield (40 g/plant), while EC498445 gave lowest seed yield (4 g/plant). The number of seeds/pod varied between 4 (EC57004, EC398523, EC405199) and 7 (IC11660).

3.2. Physicochemical and cooking properties of grains

Various physical parameters evaluated for different lines of kidney beans were seed weight, seed volume, seed density, hydration capacity, hydration index, swelling capacity, swelling index and cooking time. PLB10-1 had the highest 100 seed weight (51.68 g/100 seeds) and seed volume (46 ml /100 seeds), whereas EC530969 showed the lowest seed weight (10.16/100 seeds). Deshpande, Sathe, and Salunkhe (1984) reported 100 seed weight of dry bean cultivars in the range between 15.0 and 50.3 g. Kaur and Singh (2007a) reported the 100 seed volume to be 34 ml for kidney beans. Lowest seed volume, i.e., 14 ml/100 seeds was observed for EC18639, EC28758, EC493713 and PI163833 whereas the highest seed volume (46 ml/100 seeds) was observed for PLB10-1. Density ranged between 0.51 to 2.15 g/ml, the lowest density was observed for EC530969 and the highest for PI163833. Deshpande et al. (1984) reported density of dry bean cultivars in the range of 1.18 to 1.36 g/ml. The cotyledon with higher density has been reported to have slower water uptake resulting in longer cooking time (Seena & Sridhar, 2005).

Hydration capacity ranged between 0.03 and 0.62 g/seed, EC530991 showed the lowest (0.03 g/seed) and PLB10-1 showed the highest hydration capacity (0.62 g/seed). Seena and Sridhar (2005) reported hydration capacity/seed of 0.08 g and hydration index of 0.1 for some under explored legumes. The higher water absorption of PLB10-1 may be attributed to the greater permeability of its seed coat and softer cotyledons (Singh et al., 2004). Hydration index ranged between 0.16 and 1.97; PI301808 showed the least and PI197967 showed the highest. These differences may be attributed to difference in size, seed coat thickness and water absorption characteristics of seeds (SefaDedah & Stanley, 1979). Swelling capacity ranged from 1.24 to 1.93 ml/seed; EC530968, EC530978, and EC530991 showed the lower swelling capacity (1.24 ml/seed) whereas PLB10-1 showed the higher swelling capacity. PI197967 possessed the lowest swelling index (4.65) whereas PI163833 the highest (11.34). Water-absorbing capacity of seeds depends on cell wall structure, composition of seed and compactness of the cells in the seed (Muller, 1967). Cooking time for different kidney bean cultivars varied significantly, ranging from 50 to 120 min. The lowest cooking time was observed for EC28758 and the highest for Vaspa. The difference in cooking times among legumes could be related to the rate at which cell

separation occurs, due to loosening of the intercellular matrix of the middle lamella upon cooking (Rockland & Jones, 1974). The varietal differences in cooking quality have been reported to exist even in the same legume (Narasimha & Desikachar, 1978). The longer cooking time requirement for PI204719 could be attributed to its larger seed weight, as seed size governs the distance to which water must penetrate in order to reach the innermost portion of seeds (SefaDedah & Stanley, 1979). Amylose content ranged between 0.09% and 5.02%; EC530974 showed the lowest while EC530968 showed the highest. The frequency distribution of physicochemical properties showed that 100 seed weight of most of the lines falls in the range between 20 and 30 g, seed volume from 20 to 24 ml/100 seeds, seed density from 1 to 1.4 g/ml, hydration capacity from 0.12 to 0.24 g/seed and swelling capacity from 1.28 to 1.60 (Fig. 2a).

3.3. Texture profile analysis (TPA) of soaked grains

The rate and degree of softening differed significantly among seeds from different kidney bean lines. Hardness of soaked kidney bean seeds ranged from 0.81 to 2.03 g. EC530993 showed the lowest hardness and PI339501 the highest. Singh, Sekhon, Bajwa, and Gopal (1992) reported that constituents like fibre, lignin, cellulose and hemicellulose are the factors responsible for hardness of grains, and lines with lower contents of these constituents had greater hardness and vice versa. Kaur and Singh (2007a) reported a hardness of 1.7 g for kidney beans. SefaDedah and Stanley (1979) reported that seed coats of lines possessing good hydration properties facilitate rapid softening of the seed during soaking.

Cohesiveness ranged between 0.18 and 0.48, EC28758 and EC398523 showed the lowest value and PI339501 showed the highest. Gumminess ranged from 0.20 g (PI197967) to 0.97 g (PI339501). Springiness was found to be the lowest for Laxmi (0.31) and the highest for EC45816 (0.51). Chewiness varied from 0.08 to 0.43 g, EC398523 showed the lowest chewiness whereas PI339501 showed the highest. Kaur and Singh (2007a) reported cohesiveness, gumminess, springiness and chewiness values of 0.30, 0.49 g, 2.55 and 1.25 g, respectively for kidney beans. The frequency distribution of textural properties of hydrated kidney bean seeds showed most lines have a hardness in the range of 1.2 to 1.5 g, cohesiveness 0.18 to 0.40, gumminess 0.25 to 0.55 g, springiness 0.40 to 0.43 and chewiness in the range of 0.1 to 0.20 g (Fig. 2b).

3.4. Proximate composition of flours

The proximate composition of flours varied significantly among different kidney bean lines. Ash content varied from 3% to 6%. EC405213, EC540796, EC530974, IC313249, PI163833, PI204719 and Triloki showed lower ash content (3%) than EC405230, IC199223 and IC313257 (6%). Protein content ranged between 16% and 26%, with the lowest for EC530974 and the highest for EC116177. Fat content ranged from 0.60% (IC11660) to 2.38% (EC540796). Seena and Sridhar (2005) reported an ash content, protein content and fat content of 3.3%, 32% and 1.9 %, respectively, for legume flour. The frequency distribution of composition of kidney bean flour showed a maximum number of lines have ash content in the range between 3.5% and 5.5%, fat 1% and 1.8%, protein 18% and 23% (Fig. 3).

3.5. Pasting properties of flour

The pasting properties of flours from different kidney bean lines differ significantly, with a range between 402 and 3235 cP, 31 and 414 cP, 362 and 2488 cP 862 and 5310 cP, and 79 and 95 °C, respectively, for pasting viscosity, breakdown, setback, final viscosity and pasting temperature. The behaviour of the viscosity during cooking (from 50 to 90 °C) reflects the capacity of the starch to absorb water and swell (Sandhu, Singh, & Malhi, 2007). Among various lines studied, EC540796 showed the highest peak viscosity (3235 cP), trough viscosity (2823 cP), final viscosity (5310 cP) and setback (2488 cP). EC398501 showed the lowest breakdown, whereas PI301808 showed the highest breakdown. The lowest breakdown of EC398501 flour indicated its high thermal stability. EC530996 showed the lowest final viscosity of 862 cP. EC530993 showed the lowest setback (362 cP), indicating

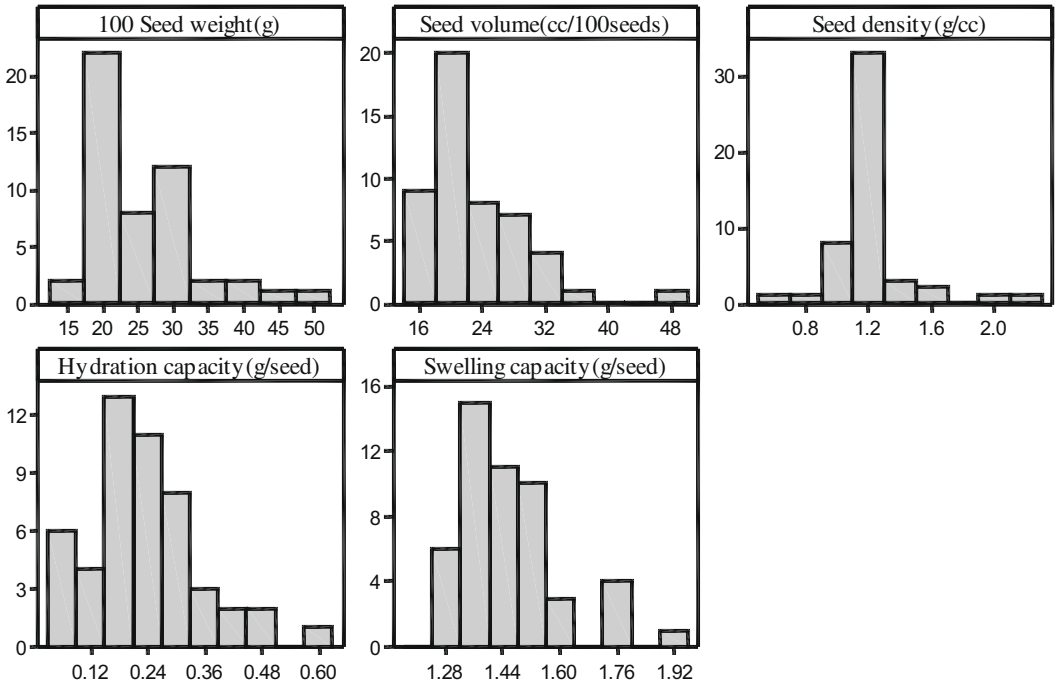

Fig. 2a. Frequency distributions for physicochemical properties of seeds of kidney bean germplasm accessions.

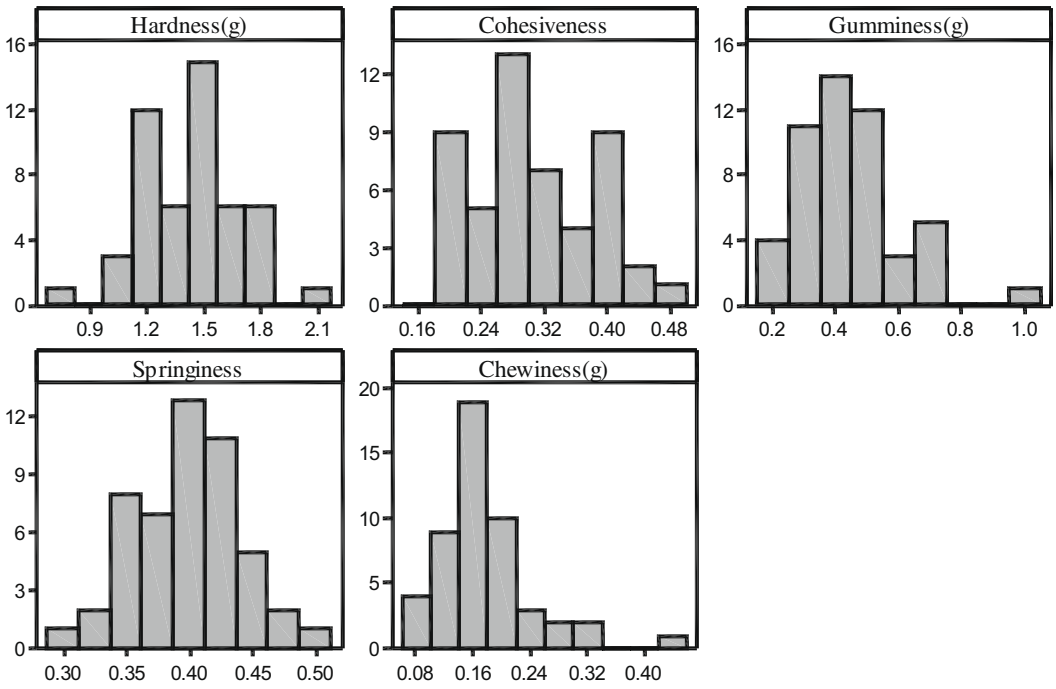

Fig. 2b. Frequency distributions for textural properties of hydrated seeds of kidney bean germplasm accessions.

its lower tendency to retrogradation (Sandhu et al., 2007). EC530966 and EC530978 showed the lowest pasting temperatures and EC530955 and NC2162 showed the highest. Pasting temperature provides an indication of the minimum temperature required to cook, as well as the temperature at which the viscosity begins to increase during the heating process. The majority of the lines showed pasting temperatures around 82 °C. A gradual increase in viscosity with increase in temperature may be attributed to the removal of water from the exuded amylose by the granules on swelling (Ghiasi, Varriano-Marston, & Hoseney, 1982). During cooling (from 95 to 50 °C), the viscosity increased, owing to the alignment of the chains of amylose (Flores-Farias et al., 2000). The frequency distribution histogram showed that the majority of lines had peak viscosity and final viscosity from 1600 to 2000 cP and 2500 to 3500 cP, respectively (Fig. 3). Setback showed a wide diversity, ranging from 363 to 2488 cP, however, the majority of lines had setback between 1200 and 1400 cP (Fig. 4).

3.6. Gel texture properties of flours

The textural parameters of gels from different kidney bean lines varied significantly. Gel hardness ranged from 2.7 to 39 g, NC2162 showed the lowest and EC530996 showed the highest. The gel firmness is mainly caused by retrogradation of starch, which is associated with the synaeresis of water and crystallisation of amylose, leading to harder gels (Miles, Morris, Orford, & Ring, 1985). Cohesiveness varied from 0.50 to 0.77, EC506078 had the highest and IC313257 had the lowest. NC2162 showed the lowest gel gumminess, with a value of 1.47, whereas EC530996 showed the highest gel gumminess (23.52). Springiness ranged between 0.86, for EC498445, and 0.99 for IC313249. Chewiness varied between 1.48 and 23.9 g. NC2162 showed the lowest chewiness, whereas EC530996 showed the highest chewiness. Adhesiveness of flour gel ranged from 13.3 to 165 g s. EC530944 showed the lowest adhesiveness, whereas NC2162 showed the highest. The results clearly showed that the lines with higher amylose content had the higher adhesiveness and vice versa. The frequency distribution of textural properties of kidney bean flour showed most lines have hardness in the range of 6 to 12 g, cohesiveness 0.6 to 0.76, gumminess 4 to 8 g, springiness 0.94 to 0.98, chewiness 2 to 7 g and adhesiveness in the range of 30 to 80 g s (Fig. 5).

3.7. Pearson correlations between different properties of grains and flours

Pearson correlation coefficients between various physicochemical, pasting and textural properties of different kidney bean lines are shown in Table 1. Seed volume was positively correlated with hydration capacity ($r = 0.563$, $p \leqslant 0.005$), swelling capacity ($r = 0.688$, $p \leqslant 0.005$), and cooking time ($r = 0.275$, $p \leqslant 0.05$), consistent with earlier reported results (Singh et al., 2004) for black gram, and negatively correlated with swelling index ($r = 0.830$, $p \leqslant 0.005$). This is in accordance with the findings reported by Khairwal, Berwal, and Sharma (1997). Seed weight was positively correlated with hydration ($r = 0.617$, $p \leqslant 0.005$) and swelling capacity ($r = 0.832$, $p \leqslant 0.005$), as reported earlier by Khattak, Khattak, Mahmood, Bibi, and Ihsanullah (2006), as well as with seed density ($r = 0.360$, $p \leqslant 0.05$), and negatively correlated with swelling index ($r = 0.444$, $p \leqslant 0.005$). Swelling capacity was positively correlated to hydration capacity ($r = 0.893$, $p \leqslant 0.005$), hydration index ($r = 0.462$, $p \leqslant 0.005$), as observed earlier by Khairwal et al. (1997) for pearl millet, and negatively correlated with amylose ($r = 0.293$, $p \leqslant 0.05$), gel hardness ($r = 0.434$, $p \leqslant 0.005$), gel gumminess ($r = 0.422$, $p \leqslant 0.005$) and gel adhesiveness ($r = 0.328$, $p \leqslant 0.05$). The water absorption of seeds depends on cell wall, seed composition and tightness of the cells in the seeds (Muller, 1967). Cooking time had a positive correlation with seed gumminess ($r = 0.546$, $p \leqslant 0.005$), also observed by Singh et al. (2004), seed cohesiveness($r = 0.575$, $p \leqslant 0.005$), seed), seed chewiness ($r = 0.550$, $p \leqslant 0.005$), gel hardness ($r = 0.288$, $p \leqslant 0.005$), gel gumminess ($r = 0.295$, $p \leqslant 0.05$), gel chewiness ($r = 0.300$, $p \leqslant 0.05$), and was negatively correlated with swelling index ($r = 0.292$, $p \leqslant 0.05$) and hydration index ($r = 0.303$, $p \leqslant 0.05$) as also reported early by Kaur, Singh, and Sodhi (2005). Swelling index was positively correlated with seed density($r = 0.594$, $p \leqslant 0.005$).

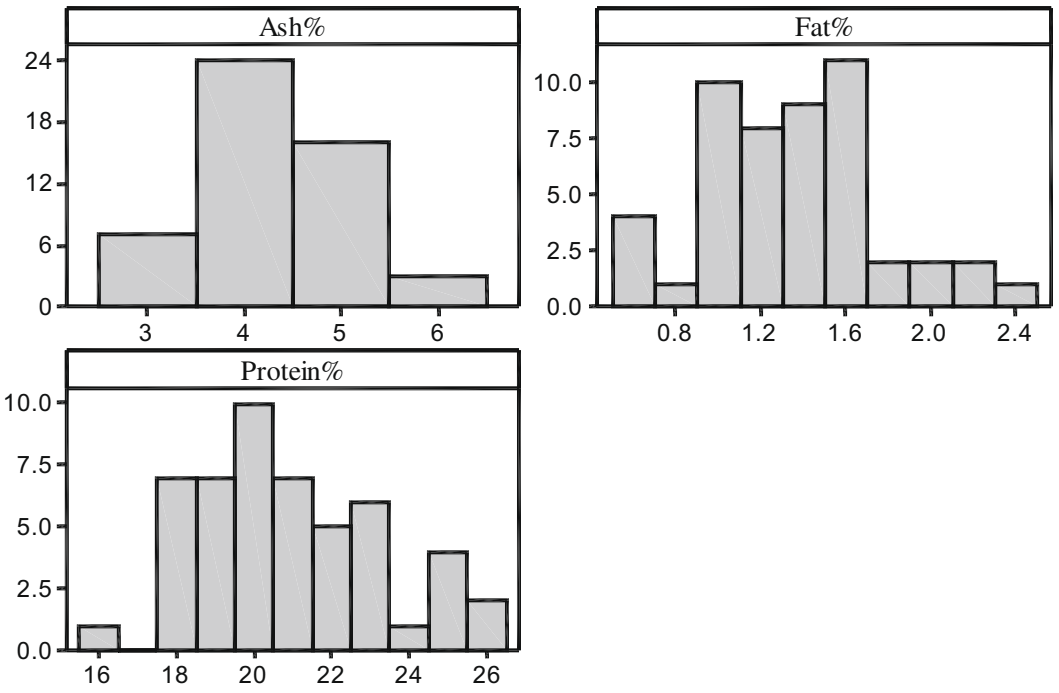

Fig. 3. Frequency distributions for chemical constituents of flours from kidney bean germplasm accessions.

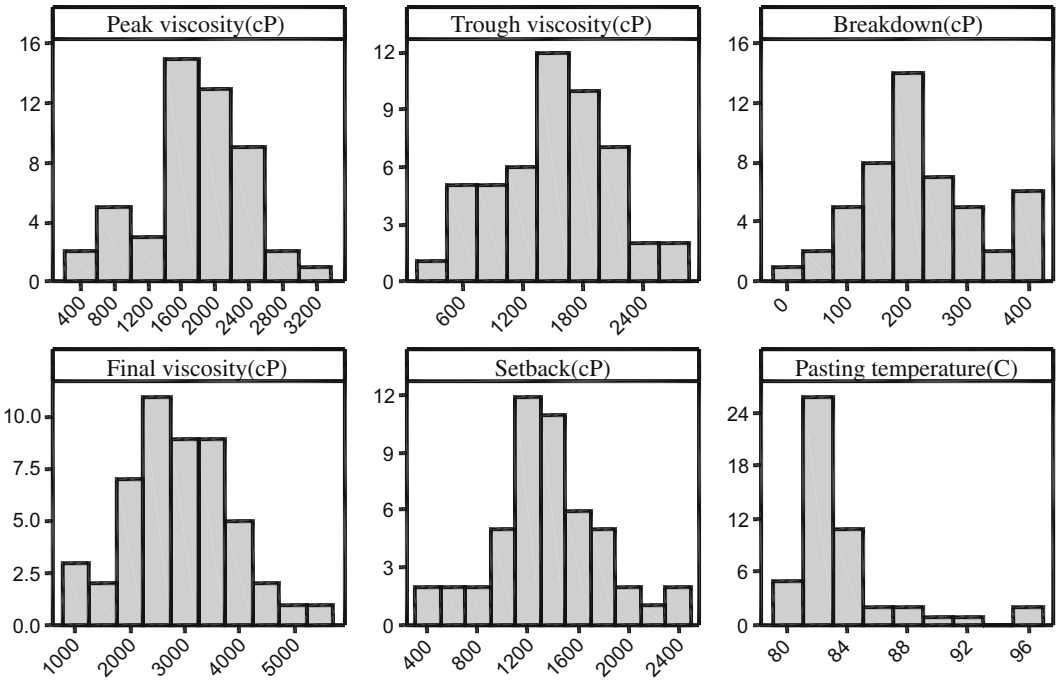

Fig. 4. Frequency distribution for pasting properties of flour from kidney bean germplasm accessions.

Hydration index was positively correlated with hydration capacity($r = 0.750$, $p \leqslant 0.005$) and negatively correlated with gel chewiness ($r = 0.397$, $p \leqslant 0.005$). Hardness of soaked seed was positively correlated with seed gumminess ($r = 0.692$, $p \leqslant 0.005$) as observed also by Kaur et al. (2005) and chewiness ($r = 0.688$, $p \leqslant 0.005$). Seed cohesiveness was positively correlated with seed gumminess ($r = 0.862$, $p \leqslant 0.005$), chewiness ($r = 0.805$, $p \leqslant 0.005$), gel hardness ($r = 0.351$, $p \leqslant 0.05$), gel gumminess ($r = 0.332$, $p \leqslant 0.05$), gel chewiness ($r = 0.343$, $p \leqslant 0.05$). Seed gumminess was positively correlated with seed chewiness ($r = 0.963$, $p \leqslant 0.005$), as observed also by Kaur et al. (2005), gel hardness ($r = 0.291$, $p \leqslant 0.05$), gel adhesiveness ($r = 0.284$, $p \leqslant 0.05$), gel gumminess ($r = 0.278$, $p \leqslant 0.05$) and gel chewiness ($r = 0.2763$, $p \leqslant 0.05$). Seed springiness was positively correlated with seed chewiness ($r = 0.308$, $p \leqslant 0.05$). Above correlations indicated a significant interdependence of these parameters.

** $p \leqslant 0.05$.
*** $p \leqslant 0.005$.

Trough viscosity of flour gel was positively correlated to peak viscosity ($r = 0.987$, $p \leqslant 0.005$), breakdown ($r = 0.479$, $p \leqslant 0.005$), amylose ($r = 0.302$, $p \leqslant 0.05$), final viscosity ($r = 0.946$, $p \leqslant 0.005$), setback ($r = 0.769$, $p \leqslant 0.005$), and negatively correlated with pasting temperature ($r = 0.532$, $p \leqslant 0.005$). Setback viscosity was positively correlated with fat ($r = 0.284$, $p \leqslant 0.05$). Similar relationships between setback and fat were reported earlier for rice starch by Liang, King, and Shih (2002). Setback viscosity was also positively correlated with peak viscosity ($r = 0.798$, $p \leqslant 0.005$), breakdown viscosity ($r = 0.596$, $p \leqslant 0.005$), final viscosity ($r = 0.924$, $p \leqslant 0.005$), gel cohesiveness ($r = 0.403$, $p \leqslant 0.005$) and negatively correlated with pasting temperature ($r = 0.494$, $p \leqslant 0.005$). Peak viscosity was positively correlated with amylose ($r = 0.286$, $p \leqslant 0.05$), breakdown ($r = 0.601$, $p \leqslant 0.005$), final viscosity ($r = 0.958$, $p \leqslant 0.005$), similar results were reported for black gram by Singh et al. (2004). Peak viscosity was also positively correlated with gel adhesiveness ($r = 0.454$, $p \leqslant 0.005$) and negatively correlated with pasting temperature ($r = 0.515$, $p \leqslant 0.005$). Final viscosity was positively correlated with breakdown viscosity ($r = 0.569$, $p \leqslant 0.05$), gel adhesiveness ($r = 0.102$, $p \leqslant 0.05$) and negatively correlated with pasting temperature ($r = 0.531$, $p \leqslant 0.005$).

Hardness of gel was positively correlated with seed chewiness ($r = 0.273$, $p \leqslant 0.05$), gel gumminess ($r = 0.981$, $p \leqslant 0.005$), gel chewiness ($r = 0.983$, $p \leqslant 0.005$), gel adhesiveness ($r = 0.764$, $p \leqslant 0.005$) and negatively correlated with hydration index ($r = 0.407$, $p \leqslant 0.005$). Gel gumminess was positively correlated with amylose ($r = 0.303$, $p \leqslant 0.05$), gel chewiness ($r = 0.997$, $p \leqslant 0.005$), gel adhesiveness ($r = 0.763$, $p \leqslant 0.005$), and negatively correlated with hydration index ($r = 0.393$, $p \leqslant 0.005$). Adhesiveness of flour gels was positively correlated with amylose ($r = 0.411$, $p \leqslant 0.005$), and gel chewiness ($r = 0.732$, $p \leqslant 0.005$), and negatively correlated with hydration capacity ($r = 0.275$, $p \leqslant 0.05$), hydration index ($r = 0.362$, $p \leqslant 0.05$), pasting temperature ($r = 0.330$, $p \leqslant 0.05$), and gel springiness ($r = 0.358$, $p \leqslant 0.05$).

4. Conclusion

This study demonstrated the diversity in physicochemical, pasting and textural properties of seeds and flours of different kidney bean lines. The study is useful in selecting lines with specific desired characteristics. PLB10-1 showed the highest hydration and swelling capacity, and hence, was most suitable for processing.

Quercetins
Flavonols
BHT
α-Tocopherol

ABSTRACT

The antioxidant properties of naturally occurring flavonols, quercetin glycosides, were examined and compared with common food antioxidants butylated hydroxytoluene (BHT) and α-tocopherol. Antioxidants were incorporated into selected polyunsaturated fatty acids (PUFA) or fish oil in aqueous emulsions and bulk oil systems. The effectiveness of quercetin was similar to or greater than quercetin glycosides in inhibiting lipid oxidation in the oil-in-water emulsion systems when oxidation was induced by heat, light, peroxyl radical or ferrous ion. In bulk fish oil, C-3 glycosylation enhanced the antioxidant activity of quercetin. The effectiveness of quercetin and its glycosides was greater than that of α-tocopherol in the emulsions. Quercetin and quercetin-3-*O*-glucoside exhibited a better antioxidant activity than BHT in bulk fish oil; however, the reverse was observed in the emulsions of omega-3 PUFA and fish oil systems in agreement with the polar paradox theory. Quercetin and its glycosides were more effective than α-tocopherol in emulsion systems.

1. Introduction

Dietary lipids, fatty acid profiles and their balance in food and within the body have received considerable attention in recent years. This is due to a better recognition that low levels of omega-3 fatty acids may be implicated in several chronic diseases (Shahidi & Miraliakbari, 2004, 2005; Simopoulos, 2002). As a result, omega-3 fatty acid-containing functional foods and nutraceuticals have been introduced into the market. However, highly unsaturated fatty acids (HUFA) in such oils are vulnerable to oxidation, thus producing various aldehydes and ketones that render unacceptable colours, odours and flavours in polyunsaturated fatty acid (PUFA) containing foods and nutraceutical products (Nawar, 1996). Moreover, products of lipid oxidation, such as propanal, acrolein and malonaldehyde, among others, possess adverse health effects due to their cytotoxic and genotoxic effects (Esterbauer, Schaur, & Zollner, 1990; Fang, Vaca, Valsta, & Mutanen, 1996). The high rate of oxidation of PUFA can be controlled by the addition of synthetic or natural antioxidants such as butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), tert-butylhydroquinone (TBHQ) and α-tocopherol. Recently, consumer health consciousness has led to a demand for 'natural' alternatives to synthetically produced food antioxidants.

Flavonols are a sub-group of flavonoids, found ubiquitously in fruits, vegetables and many medicinal and aromatic plants (Rupasinghe, 2008). Quercetin, a common flavonol, has been shown as an effective antioxidant in several *in vitro* systems such as the oxygen radical absorbance capacity (ORAC) (Ou, Hampsch-Woodill, & Prior, 2001), the ferric reducing antioxidant power (FRAP) (Pulido, Bravo, & Saura-Calixto, 2000) and the 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging assays (Kemertelidze, Tsitsishvili, Alaniya, & Sagareishvili, 2000). When compared to other flavonoids, quercetin has been shown to prolong the lag time before the initiation of low density lipoprotein (LDL) oxidation effectively (Safari & Sheikh, 2003). As well, quercetin has also been shown to inhibit lipid oxidation in cereal grains (Viscidi, Dougherty, Briggs, & Camire, 2004) and marine oils rich in PUFA (Wanasundara & Shahidi, 1998; Montero, Giménez, Pérez-Mateos, & Gómez-Guillén, 2005; Nieto et al., 1993). Heat-induced cholesterol oxidation can also be reduced by incorporation of 0.002% (w/w) quercetin (Chien, Hsu, & Chen, 2006).

In plants, quercetin occurs in the glycosylated forms such as glucoside, galactoside, rhamnoside, arabinoside and rutinoside (Herrera & Luque de Castro, 2004). In fruits such as apples, glyco-

sylation is commonly occur at the C-3 position (Rupasinghe, 2008) but the influence of C-3 glycosylation and the type of sugar moiety on its ability to inhibit omega-3 PUFA oxidation is not clear. Therefore, the objective of this research was to examine the inhibition of oxidation of omega-3 PUFA in emulsion and fish oil by selected naturally occurring quercetin glycosides and to compare their ability with common food antioxidants such as BHT and α-tocopherol, under different oxidation-induced conditions.

2. Materials and methods

2.1. Materials and chemicals

The authentic flavonol compounds were obtained as follows: quercetin-3-*O*-rhamnoside (quercitrin) and quercetin-3-*O*-galactoside (hyperin) were from Indofine Chemical Company (Hillsborough, NJ, USA); quercetin-3-*O*-glucoside (isoquercitrin) and quercetin aglycone were from Sigma–Aldrich (St. Louis, MO, USA); and quercetin-3-*O*-rutinoside (rutin) was from ChromaDex (Santa Ana, CA, USA). Methyl linolenate (MLN) and docosahexaenoic acid (DHA) were obtained from NuChek (Elysian, MN, USA). The bulk fish oil (Canadian Food Inspection Agency [CFIA] registration number 3529) was a gift from Ocean Nutrition Canada, Dartmouth, NS, Canada. The fish oil was devoide of any antioxidants. The composition of the oil was 17.6%, monounsaturates; and 77.6% polyunsaturates [61% eicosapentaenoic acid (EPA), 4.3% DHA] by weight of total fatty acids. Approximately 51% of EPA and DHA were in the triacylglycerol form. BHT, trichloroacetic acid (TCA), 2-thiobarbituric acid (TBA) and α-tocopherol were purchased from Sigma–Aldrich (St. Louis, MO, USA). 2,2′-Azobis(2-amidinopropane)dihydrocholride (AAPH) was acquired from Wako Chemicals (Richmond, VA, USA). Other chemicals were obtained from Fisher Scientific (Ottawa, ON, Canada).

2.2. The aqueous emulsion (oil-in-water) model system

The MLN, DHA and fish oil model systems were adapted from those of Okuda, McClements, and Decker (2005) and Boadi, Iyere, and Adunyah (2003) as follows: MLN or DHA (1.5 mg per mL) was suspended in a buffer solution (0.05 M TRIS–HCl, 0.15 M KCl, 1% Tween 20, pH 7.0) by homogenisation for 20 s using a Polytron homogeniser (Kinematica GmbH, Kriens, Switzerland) and placed in 13 × 100 mm borosilicate glass tubes. For fish oil emulsion (10 mg per mL), sonication (20 kHz, model 750D, VWR International, Mississauga, ON, Canada) for 30 s was performed to create the emulsion. For all experiments the test tubes were incubated using a shaker rotating horizontally at approximately 150 rpm to maintain the emulsion. For the experiments using $FeSO_4$ as a source of Fe^{2+}, the buffer solution was adjusted to pH 5. The stock emulsion was divided into individual experimental units (test tubes) before antioxidants were added. The concentration dependence of quercetin, quercetin-3-*O*-glucoside and BHT was examined at three levels (10, 50 and 100 μM) for the MLN and DHA systems. The concentration dependence for the fish oil system was examined at four levels (0.1, 1, 10 and 100 μM). The tubes were capped with test tube closures which allowed the exchange of air, vortexed and then placed on a rotational shaker (150 rpm) either at room temperature, or at 50 °C. All tests were performed in triplicate and the experiments were conducted twice, independently.

2.3. Inductions of oxidation

The oxidation systems were optimised for determination of antioxidant properties of quercetin glycosides, α-tocopherol and BHT under various oxidation–induction conditions. MLN or DHA emulsions (1 mL final volume) were incorporated with antioxidants and then subjected to oxidation under different conditions: heat, light, iron (100 μL of 10 mM $FeSO_4$ for the MLN and 100 μL of 1 mM $FeSO_4$ for the DHA), or peroxyl radical (generated using 100 μL of 100 mM AAPH). Heat-induced oxidation for emulsions was carried out by incubation of test tubes at 50 °C for 10 h using an incubator-shaker oven (model Apollo HP50, CLP Tools, San Diego, CA, USA). Light-induced induction was performed using a 13 W light source (300–640 nm with peaks at approximately 440, 490, 540, 590 and 610 nm; Model Repti Glo 2.0uvB; HAGEN, China) at a distance of 12 cm. The incubation periods for peroxyl radical- and iron-induced oxidation were 20 and 3 h, respectively. These optimum induction periods were based on preliminary experiments that were conducted to study the time-oxidation relationships of the MLN model system (data not presented).

2.4. The bulk fish oil model system

The bulk fish oil model system was prepared by oxidising 90 μL of the fish oil in 13 × 100 mm borosilicate glass tubes with caps. Antioxidants were incorporated by placing 100 μL of the desired concentration of the specific compound in methanol in each test tube, drying the solvent completely under nitrogen, and then mixing with 10 μL of ethanol and 90 μL of fish oil. The final concentrations of quercetin glycosides used were 0.1, 0.5, 1 and 5 mM. Fish oil samples were incubated using the same shaker rotating horizontally (150 rpm) at 70 °C for 3 h.

2.5. Effect of the type of sugar moiety of quercetin glycosides on the inhibition of PUFA oxidation

The antioxidant properties of four naturally occurring quercetin glycosides (quercetin-3-*O*-galactoside, quercetin-3-*O*-glucoside, quercetin-3-*O*-rhamnoside, quercetin-3-*O*-rutinoside), quercetin, BHT and α-tocopherol were determined using 1 mL of emulsion systems of MLN and DHA (mentioned above) with peroxyl radical-induced oxidation (100 μL of 100 mM AAPH). The MLN and DHA emulsions were incorporated with 100 μL of 0.1 and 0.5 mM, respectively, of the antioxidant compounds. The final concentrations of antioxidants, 10 μM for MLN and 50 μM for DHA, were chosen based on the concentration effect as shown in Fig. 1.

2.6. Thiobarbituric acid reactive substances (TBARS) assay

After completion of the duration of the oxidation-induction treatment, TBARS were quantified by a modified method of Boadi et al. (2003) and Okuda et al. (2005), as follows: One-hundred microlitres of 2% BHT in ethanol were added to all test tubes to stop the oxidation process immediately. The TBA reagent (1 mL of 15% (w/v) TCA and 0.375% (w/v) TBA in 0.25 M HCl) was then added and vortexed. The reaction mixture was placed in an 80 °C water bath for 15 min. At the end of this time, the samples were brought to room temperature and centrifuged at 2000*g* for 10 min (Model 300 Precision, Durafuge, Winchester, VA, USA). The absorbance of the supernatant was then measured at 532 nm using 96-well microplates in the FLUOstar OPTIMA plate reader (BMG Labtech, Durham, NC, USA). Percent inhibition of oxidation was calculated based on percentage of the total oxidation experienced by the system without the protection of antioxidants using the following equation:

$$\%\ \text{Inhibition of oxidation} = [1 - (\text{sample absorbance}/\text{control absorbance})] \times 100$$

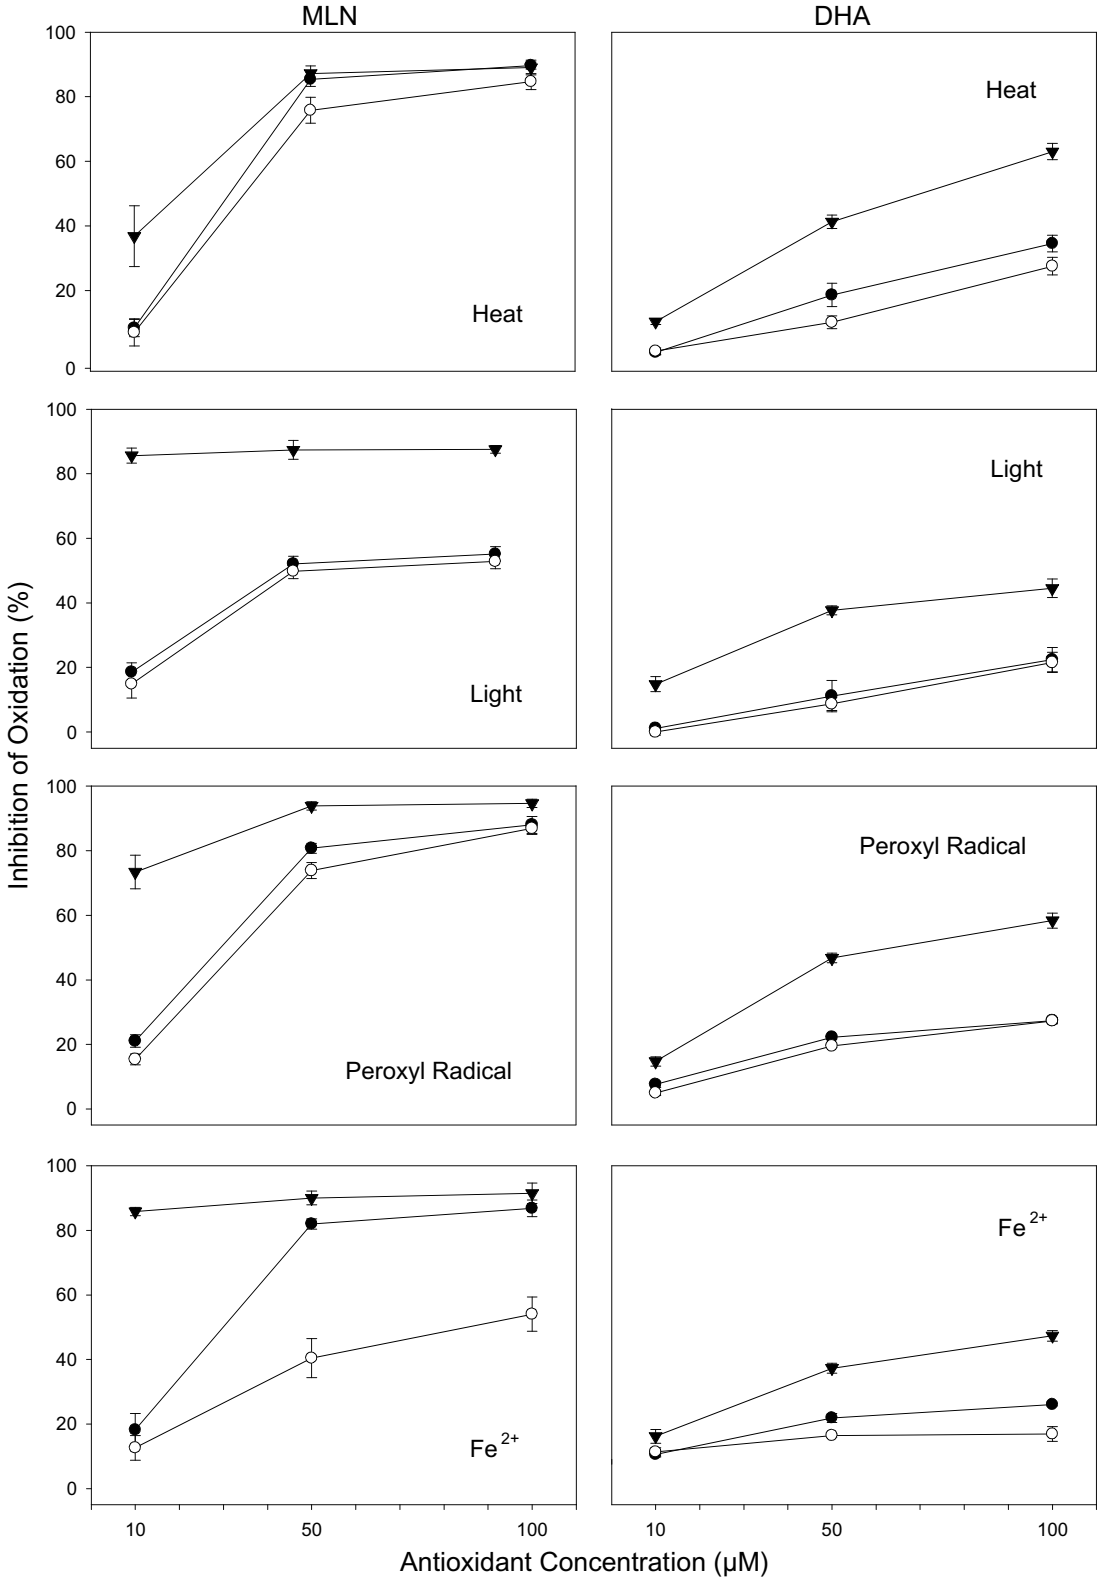

Fig. 1. Effect of different concentrations of BHT (▼), quercetin (●) and quercetin-3-*O*-glucoside (○) on the oxidation of the MLN and DHA emulsions. Oxidation was measured by the TBARS assay. Error bars represent standard error (SE). Data represent means of two independently conducted experiments in triplicate.

2.7. Experimental design and statistical analysis

The experimental design was a completely randomised one with treatments being the type and concentration of antioxidants employed. All experiments were conducted in triplicate, independently twice. A one-way analysis of variance blocked by experimental run and least significant difference (LSD) multiple means analysis was used to determine significant differences among the glycoside treatments, $\alpha = 0.05$, and assignment of letter groupings with SAS V8 (Cary, NC, USA). Graphical representations were made

using SigmaPlot 10.0 (San Jose, CA, USA). Error bars in the graphs represent standard error.

3. Results

3.1. Inhibition of PUFA oxidation by quercetin and quercetin-3-O-glucoside under various inductions

To examine the effect of C-3 glycosylation of quercetin on inhibition of PUFA oxidation, 10, 50 and 100 μM quercetin, quercetin-3-*O*-glucoside and BHT were incorporated into the aqueous emulsions of MLN and DHA and subjected to the oxidation by heat, light, peroxyl radical and Fe^{2+}, as inducers. In general, the higher the concentration of antioxidants, greater was the inhibition of oxidation of MLN and DHA (Fig. 1). In general, BHT was more effective in its inhibition of lipid oxidation than quercetin and its glucoside. However, quercetin and its glucoside at 100 μM were as effective as BHT in inhibiting heat-induced oxidation of MLN. Regardless of the type of antioxidant and induction method, inhibition of oxidation was lower in emulsions of DHA than that of MLN (Fig. 1). Meanwhile, the antioxidant activity of quercetin was similar or better than that of quercetin-3-*O*-glucoside in the omega-3 PUFA emulsions. The influence of C-3 glycosylation was more distinct when the oxidation was induced by ferrous ion.

3.2. Effect of type of sugar moiety at C-3 on the inhibition of PUFA oxidation

The effect of the type of sugar moiety at C-3 of quercetin was further studied by comparing the antioxidant activity of four quercetin glycosides (quercetin-3-*O*-glucoside, quercetin-3-*O*-galactoside, quercetin-3-*O*-rhamnoside, quercetin-3-*O*-rutinoside) with their aglycone, BHT and α-tocopherol using the peroxyl radical-induced oxidation of emulsions of MLN and DHA. For the emulsions containing DHA, 50 μM antioxidants were used instead of 10 μM due to the low inhibition of oxidation at the latter level (Fig. 1). Depending on the fatty acid used for the emulsion and the type of sugar moiety, C-3 glycosylation of quercetin had either no influence or a lower effect for inhibiting the peroxyl radical-induced oxidation (Fig. 2). When the sugar moiety was a disaccharide (rutin), its antioxidant activity in DHA emulsion was lower than the corresponding monosaccharide. BHT was significantly more effective in suppressing oxidation than flavonols and α-tocopherol (Fig. 2). α-Tocopherol exhibited a significantly lower inhibition of oxidation of MLN and DHA when compared to other antioxidants tested (Fig. 2).

3.3. Inhibition of heat-induced oxidation of fish oil emulsion and bulk fish oil by quercetin and quercetin-3-O-glucoside

Incorporation of antioxidants in fish oil emulsions exhibited a concentration-dependent antioxidant activity similar to that of MLN and DHA emulsions, but BHT was more effective than flavonols in inhibiting lipid oxidation (Fig. 3A). Quercetin and quercetin-3-*O*-glucoside at three tested concentrations rendered similar effects (Fig. 3A). In bulk fish oil, quercetin-3-*O*-glucoside at 100 and 500 μM was more effective than quercetin and BHT ($p < 0.001$, $\alpha = 0.05$), but at the 1000 μM concentration both quercetin and quercetin-3-*O*-glucoside were equally effective (Fig. 3B). The effectiveness of BHT in bulk fish oil was lower than that of quercetin and its glucoside.

4. Discussion

The C-3-glycosylated-quercetins examined in this study are commonly found in fruits and their processing by-products (Rupasinghe, 2008; Rupasinghe & Kean, 2008). An emulsion model system of MLN, DHA and fish oil was used to resemble food products which contain lipids dispersed in an aqueous phase (oil-in-water) such as milk, salad dressings, beverages, soups and sauces (McClements, 2004). Though a concentration-dependent inhibition of oxidation of the omega-3 PUFA and fish oil containing emulsions by quercetin, quercetin-3-*O*-glucoside and BHT was observed, the antioxidants tested were more effective in MLN emulsion compared to DHA and fish oil emulsions. The observed differences could be, in part, due to the fact that DHA has twice as many double bonds when compared with MLN. The oxidation of PUFA and their esters in aqueous emulsions was found to de-

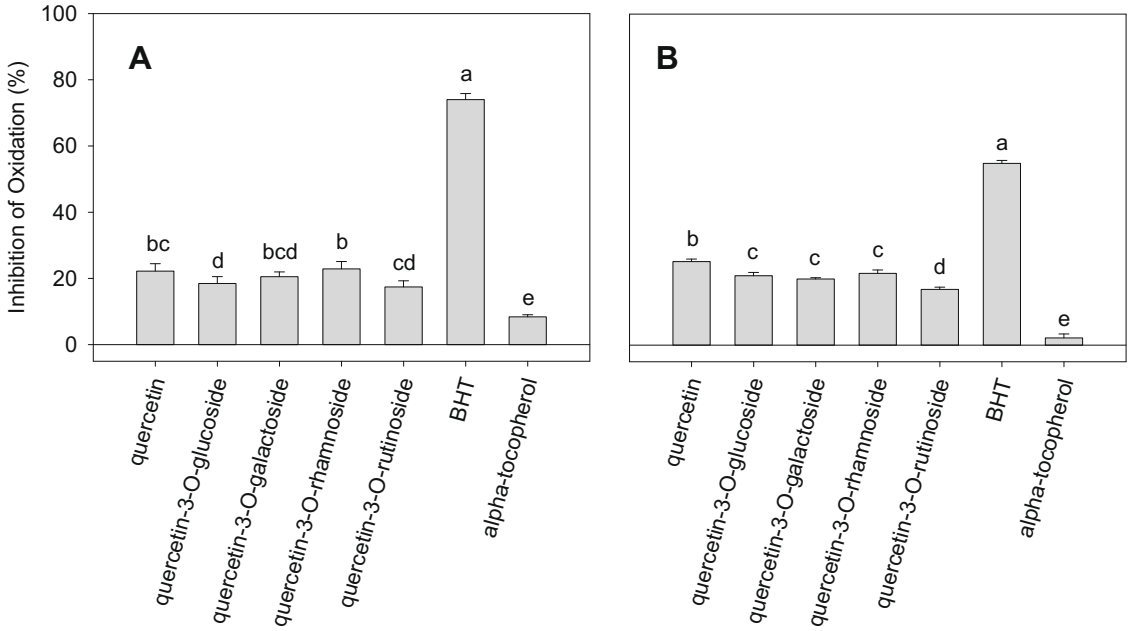

Fig. 2. Comparison of the antioxidant activity of flavonols with BHT and α-tocopherol (10 μM for MLN and 50 μM for DHA) for peroxyl radical-induced oxidation of MLN (A) and DHA (B) emulsions. Oxidation was measured by the TBARS assay. Significantly different values are represented by different letters.

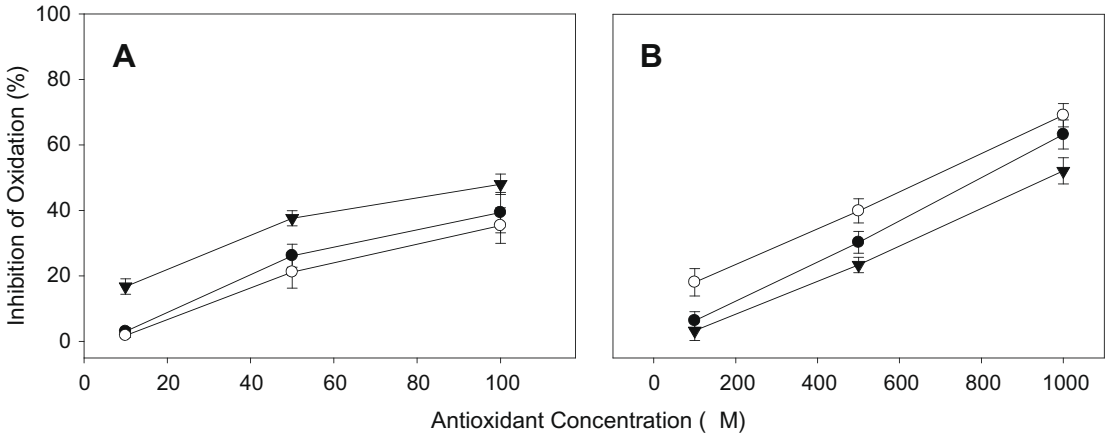

Fig. 3. Effect of different concentrations of BHT (▼), quercetin (●) and quercetin-3-*O*-glucoside (○) on the heat-induced oxidation of the fish oil emulsion (A) and the bulk fish oil. Oxidation was measured by the TBARS assay. Error bars represent standard error (SE).

crease with an increase in the number of bis-allylic positions in the fatty acids involved (Miyashita, Nara, & Ota, 1993). A higher level of UVB-radiation-induced oxidation in arachidonic acid (four double bonds) micelles than MLN micelles was also reported by Carini et al. (1998).

In the emulsion systems, quercetin-3-*O*-glucoside showed a similar or a lesser effect on the inhibition of oxidation depending on the concentration and oxidation-induction method when compared to quercetin itself. In addition, the type of sugar attached at C-3 of quercetin influenced the effectiveness of inhibition of PUFA oxidation in the emulsion systems. For example, when the oxidation of PUFA was induced by light, inhibition of oxidation by quercetin-3-*O*-glucoside and its aglycone at all tested concentrations was similar. However, a lesser effect of quercetin-3-*O*-glucoside compared to its aglycone was observed when the oxidation was induced by Fe^{2+}. It may be speculated that C-3 glycosylation could hinder the ability of quercetin to chelate ferrous ion. In general, similar to the present results of heat- and Fe^{2+}-induced oxidation, quercetin-3-*O*-rutinoside has been reported to be less effective in inhibiting lipid oxidation than its aglycone in other lipid oxidation systems i.e. Fe^{2+}- and peroxyl radical-induced oxidation in a liposomal system (Arora, Nair, & Strasburg, 1998) and Cu^{2+}-induced oxidation of an LDL emulsion system (Brown, Khodr, Hider, & Rice-Evans, 1998), which also agrees with 'the polar paradox' theory (Frankel, 1996; Porter, 1980). The polar paradox theory states that lipophilic antioxidants are more effective at inhibiting oxidation in oil-in-water emulsions, whereas hydrophilic antioxidants are more effective in bulk oil systems. This difference is thought to be due to the interfacial phenomenon, such that the hydrophilic antioxidants are positioned between the oil-air interface and the lipophilic antioxidants are dissolved in the oil droplets and thus at the water-oil interface (Frankel, 1996; Porter, 1980). Glycosylation with the disaccharide moiety, glucorhamnoside, decreased the partition coefficient (1.2–0.37) in an octanol/water mixture, or in other words, increased the hydrophilicity of the molecule (Brown et al., 1998). According to the polar paradox theory, the aglycone should have been more effective than its glycosides in both MLN and DHA emulsion systems employed. However, fatty acid emulsion models produce micellar systems as opposed to droplet systems (Decker, Warner, & Richards, 2005). Quercetin glycosides have also been shown to be less effective than their aglycone in inhibiting oxidation of PUFA in a non-emulsion system and a peroxyl radical-induced oxidation of phospholipid bilayer system (Ioku, Tsushida, Takei, Nakatani, & Terao, 1995).

Compared to α-tocopherol, the effectiveness of flavonols was greater in the MLN and DHA emulsions. However, α-tocopherol is known to be less polar than flavonols (Frankel, 1996) which according to the polar paradox theory is expected to be a more effective antioxidant in the emulsion system. This discrepancy could be due to the potential micellar form of PUFA emulsions (Decker et al., 2005). Similar to our finding, Becker, Ntouma, and Skibsted (2007) found that quercetin was as effective, if not more so, than α-tocopherol in peroxyl radical-induced oxidation of oil-in-water emulsion, phospholipid liposome and bulk oil. Carini et al. (1998) also showed that a flavonoid mixture containing catechin, catechin oligomers and gallic acid catechin ester from grape seed was as effective as α-tocopherol in a UVB-induced oxidation of PUFA micellar system.

In contrast to the activity of the tested antioxidants in emulsions, the flavonols used were more effective than BHT in bulk fish oil, which is also in agreement with the polar paradox theory in that the more polar antioxidants are more effective in the bulk oil. Similar to the present results, quercetin was shown to be a more effective antioxidant than BHT in heat-induced oxidation of fish oil (Wanasundara & Shahidi, 1998). Naturally occurring flavonols or glycosylation of quercetin seem to increase the antioxidant activity due to the enhanced polarity of the aglycone. The antioxidant nature of phenolic compounds has been shown to provide a balance between the ability of the compound to enter the lipid droplet for preventing oxidation and the amount of phenolic-metal interactions within the aqueous phase (Mei, McClements, & Decker, 1999). Also, the presence of 3′,4′-dihydroxy (catechol structure) in B ring, the C2–C3 double bond and the 4-keto group seems to be the most important structural features in scavenging free radicals or chain breaking antioxidant activity (Amic, Davidovic-Amic, Beslo, & Trinajstic, 2003) since the C-3 glycosylation did not diminish the ability of quercetin to inhibit PUFA oxidation. However, further experiments required to understand the effect of the positioning of sugar moiety of flavonols on the ability to inhibit PUFA oxidation in emulsion and bulk oil systems.

5. Conclusions

Although flavonols were found to be less effective in oil-in-water emulsions than, BHT, they were as effective as α-tocopherol. Interestingly, flavonols exhibited a better antioxidant activity in bulk fish oil than BHT. Considering the consumer preference for 'natural' products and their existence in a wide array of fruits and vegetables, naturally sourced flavonols such as quercetin glycosides could be used as effective antioxidants for stabilising omega-3 PUFA-containing foods and nutraceuticals while providing potential additional health benefits.

Garlic greening
Pyruvic acid
Yellow pigment
Structure

ABSTRACT

It was established that green pigment(s) responsible for garlic greening is composed of yellow and blue species, and pyruvic acid (a product from 1-PeCSO or 2-PeCSO under the action of alliinase) reacted with pigment precursor (PP) model compounds, 2-(1*H*-pyrrolyl) carboxylic acids to produce yellow pigments. However, the structure of the yellow pigments is unknown. In present paper, we identified three yellow pigments (Y1, Y2 and Y3) from three reaction systems containing pyruvic acid and 2-(1*H*-pyrrolyl) acetic acid (P-Gly) or 1-(2′-methyl-1′-carboxy-propyl) pyrrole (P-Val) or 1-(2′-methyl-1′-carboxy-butyl) pyrrole (P-Ile), respectively, by LC-ESI MS/MS and IT-TOF mass spectrometry. The three pigments have a UV/visible maximum absorbance between 400 and 434 nm and might be formed by dimerisation of the three corresponding PP under participation of pyruvic acid, molecular formula of which are $C_{16}H_{16}N_2O_4$ (Y1), $C_{22}H_{28}N_2O_4$ (Y2) and $C_{24}H_{32}N_2O_4$ (Y3), respectively.

1. Introduction

Garlic is processed as powders, purees and juices, granules and oleoresin. During processing, garlic greening occurs, representing a major concern because of loss of the economic value of these products (Adams & Brown, 2007; Kim, Cho, & Kim, 1999). In contrast, the formation of green colour is desirable and required in the traditional home-made Chinese garlic product, "Laba" garlic (Bai, Chen, Liao, Zhao, & Hu, 2005; Bai, Li, Hu, Wang, & Zhao, 2006). Based on previous studies, it was established that the mechanism of garlic greening is similar to that of onion redding, and that the discolouration is a multistep process consisting of enzymatic and nonenzymatic stages (Imai, Akita, Tomotake, & Sawada, 2006b; Joslyn & Peterson, 1960; Lee & Parkin, 1998; Shannon, Yamaguchi, & Howard, 1967a, 1967b). The first step corresponds to the conversion of S-(1-propenyl)-L-cysteine sulfoxide (1-PeCSO) into di(1-propenyl) thiosulfinate (Imai, Akita, Tomotake, & Sawada, 2006a) or 1-propenyl containing thiosulfinate (Kubec, Hrbáčová, Musah, & Velíšek, 2004; Kubec & Velíšek, 2007) under the action of alliinase. Indeed, Lukes found that 1-PeCSO is a key compound involved in the discolouration with a positive correlation with the degree of garlic greening (Lukes, 1986). Consistent with above observation, Kubec et al. suggested that discolouration occurs upon tissue disruption of any *Allium* species that contain a high enough content of 1-PeCSO (Kubec et al., 2004). Step 2 corresponds to the formation of the pigment precursors (PP) from a reaction of the di(1-propenyl) thiosulfinate and protein amino acids. Further support for this conclusion came from previous results showing that all of protein amino acids except for cysteine and proline were able to form coloured products when mixed with 1-propenyl-containing thiosulfinates (Kubec & Velíšek, 2007), and that thiosulfinate consumption in the pickling solution of "Laba" garlic is proportional to the formation of the pigments (Bai et al., 2005). Imai et al. isolated and characterised 2-(3,4-dimethyl-1*H*-pyrrolyl)-3-methylbutanoic acid (PP-Val) and 2-(3,4-dimethyl-1*H*-pyrrolyl) propanoic acid (PP-Ala) from the reaction of di(1-propenyl) thiosulfinate with L-valine or L-alanine. These two compounds were proposed to be pigment precursors due to findings that pigments were produced from the reaction of PP-Val and di(2-propenyl) thiosulfinate under heating (Imai et al., 2006a). Recent studies showed that 2-(1*H*-pyrrolyl) carboxylic acids (model compounds of PP-Val) can turn garlic puree (which was prepared from freshly harvested garlic bulbs) green (Wang, Nanding, Han, Chen, & Zhao, 2008), confirming that PP-Val is a pigment precursor for garlic greening. The catalytic conversion of 2-PeCSO by alliinase into di(2-propenyl) thiosulfinate represents the third step. Finally, formed thiosulfinate(s) reacts with PP to produce green pigment(s), corresponding to the fourth step.

However, it was found that the green pigment(s) consists of yellow and blue species which exhibited two maximal UV/visible absorbances at ~440 and ~590 nm, respectively (Bai et al., 2005; Kubec & Velíšek, 2007; Wang et al., 2008). Thus, above step 4 actually corresponds to the formation of the blue pigment(s). In parallel, a reaction between the pigment precursor (PP) and pyruvic acid resulted in the formation of the yellow species, representing a pathway of the formation of the yellow species. The combination of

doi:10.1016/j.foodchem.2009.04.021

both yellow and blue pigments finally creates the green colouration (Wang et al., 2008). However, so far, there is no information on the structure of the yellow species produced from pyruvic acid and PP. In the present study, three yellow pigments were isolated from three model systems by using column chromatography, and their corresponding structures were identified with mass spectrometry.

2. Materials and methods

2.1. Chemicals

All solvents/chemicals above were of analytical grade or purer. L-Glycine, L-valine, L-isoleucine, hydrochloric acid, acetic acid, sodium acetate anhydrous, ethyl acetate, sodium sulphate anhydrous and potassium hydroxide were obtained from Beijing Chemistry Co. (Beijing, China). 2,5-Dimethoxytetrahydrofuran was purchased from Fluka (Beijing, China). Pyruvic acid was obtained from Sinopharm Chemical Reagent Co. (Beijing, China). Formic acid ($\geqslant$98%) was supplied by Sigma–Aldrich (Chemie GmbH, Germany), and methanol and acetone were purchased from Honeywell Burdick and Jackson (SK Chemicals, Korea), and they were chromatography grade. The solid phase extraction (SPE) cartridges cleanert ODS C_{18} (12 mL, 2000 mg) were purchased from Agela Technologies (Beijing, China). Syringe filter units 0.45 and 0.22 μm were supplied by Hercules (Beijing, China).

2.2. Sample preparation

P-Gly, P-Val and P-Ile were synthesised as previously described (Wang et al., 2008). ^{1}H NMR spectra were performed with a dpx-300 MHZ NMR spectrometer (Brucker Co., Germany). Deuterium dimethyl sulfoxide (DMSO-d_6) was used as a solvent with tetramethylsilane (TMS) as an internal standard. Mass spectra were obtained by using LC–MS/MS (Alliance2695/Quattro Micro API, Waters Co., USA), and detection was performed in the positive mode. Their ^{1}H NMR spectra and MS data were identical to those in literature (Wang et al., 2008), confirming their purity and structures.

To prepare the yellow pigment(s), both P-Gly (20 mM) and pyruvic acid (20 mM) in water were mixed thoroughly with a volumetric ratio of 1:1, and then stood at room temperature (23–25 °C) for 48 h. Resultant solution was filtered through a 0.45 μm syringe filter for clean-up. In contrast, the reaction of P-Val or P-Ile with pyruvic acid was carried out by dissolving them in methanol instead of water followed by standing at 45 °C for 72 h. Other procedures are the same as those used as above for P-Gly and pyruvic acid.

2.3. Fractionation by ODS C_{18} SPE cartridge

ODS C_{18} SPE cartridge was used for further clean-up. SPE cartridge was conditioned consecutively with 8 mL of methanol and 8 mL of water. One millilitre of resultant solution mentioned above was loaded on the SPE cartridge and effluent was collected. Subsequently, a wash step was followed to elute yellow pigment retained on the SPE column. Water, acetone and methanol consecutively were subjected to the column for eluting. Only methanol eluent was collected and concentrated to a small volume with a rotary evaporator. Finally, resulting solution was filtered through a 0.22 μm syringe filter for LC–MS analysis.

2.4. LC–MS analysis

The LC–MS analysis of these yellow pigments was performed by an Alliance 2695 Separations Module containing an autosampler (Waters, Milford, MA, USA) coupled to a Micromass Quattro Micro triple-quadrupole mass spectrometer (Micromass, Manchester, UK) with MassLynx software. Twenty microlitre of the reaction solution containing P-Gly was injected onto an analytical scale reversed ASB-C_{18} column (250 × 4.6 mm, 5 μm, Venusil, Agela, USA) maintained at 29 °C. The elution mode was isocratic with a mixture of 40% methanol and 60% water containing 0.2% formic acid as mobile phase at a flow rate of 0.4 mL/min for LC–MS analysis.

The reaction solution containing P-Val or P-Ile (20 μL) was loaded to an reversed MP-C18 column (250 × 4.6 mm, 5 μm, Venusil, Agela, USA), which was maintained at 29 °C. The elution mode was also isocratic using a mixture of 45% methanol and 55% water containing 0.2% formic acid as mobile phase at a flow rate of 0.4 mL/min for LC–MS analysis. PDA detection ranging between 200 and 800 nm was performed. Yellow pigments were detected using electrospray ionisation in the positive ion mode. Used MS parameters were as follows: capillary voltage, 2.5 kV; cone voltage, 10 V; scan ranger, m/z 100–1000; source temperature, 110 °C; desolvation temperature, 400 °C; desolvation gas flow, 700 L/h nitrogen; cone gas flow, 50 L/h. High-resolution electrospray ionisation mass spectra were acquired on an FT-MS Bruker APEX IV (7.0 T) (Bruker Co., Germany) equipped with an ESI source in positive ion mode.

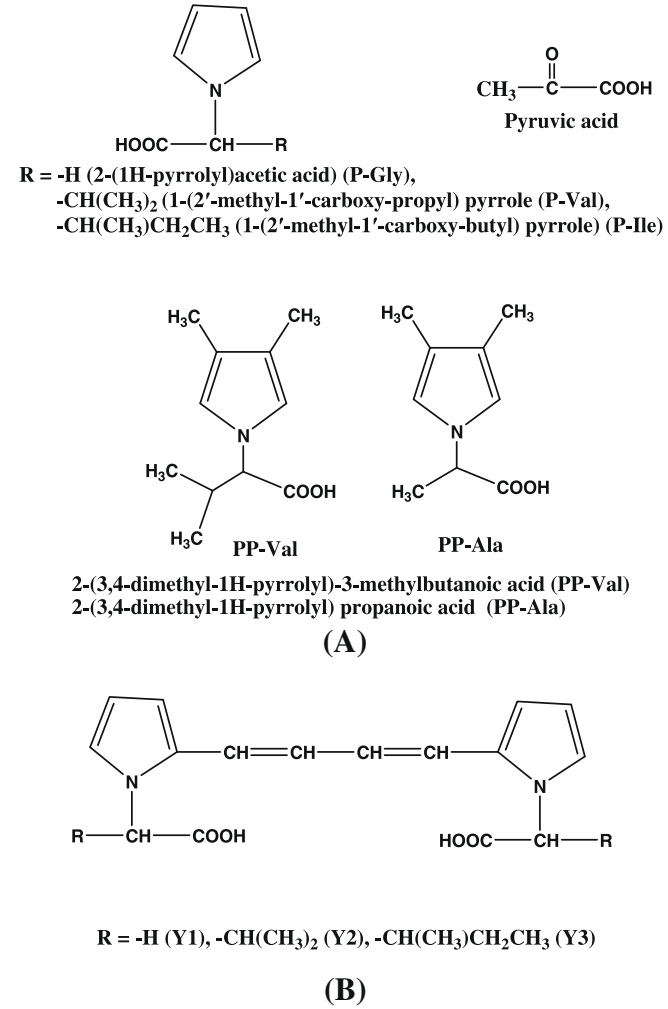

Fig. 1. (A) Structures of 2-(1*H*-pyrrolyl) acetic acid (P-Gly), 1-(2′-methyl-1′-carboxy-propyl) pyrrole (P-Val), 1-(2′-methyl-1′-carboxy-butyl) pyrrole (P-Ile) 2-(3,4-dimethyl-1*H*-pyrrolyl)-3-methylbutanoic acid (PP-Val) and 2-(3,4-dimethyl-1*H*-pyrrolyl) propanoic acid (PP-Ala) and pyruvic acid. (B) The proposed structure of the yellow pigments.

3. Results and discussion

Three model compounds P-Gly, P-Val and P-Ile (Fig. 1) were prepared mainly based on the method recently described (Wang et al., 2008). All of them have very similar structures to those of PP-Val and PP-Ala (pigment precursors, Fig. 1) (Imai et al., 2006a). Therefore, all three compounds were chosen to react with pyruvic acid, respectively, to produce the yellow species. Resultant reaction mixture of P-Gly or P-Val or P-Ile and pyruvic acid resolved only available with polar solvents, so water, acetone and methanol were used to consecutively elute the ODS C_{18} SPE cartridge which had retained the analyte above through absorption. Three kinds of solvent separated the sample into three different fractions. Since a visible yellow fraction can only be obtained through methanol eluting, this fraction was further purified by high-performance liquid chromatography (HPLC).

To achieve efficient HPLC resolution of the yellow fraction, the analytical condition first was optimised. The best separation condition was obtained on an analytical ASB-C_{18} column for Y1, and MP-C_{18} column for Y2 and Y3. A mixture of 40% methanol and 60% water containing 0.2% formic acid as mobile phase at a flow rate of 0.4 mL/min was used for Y1 while a mixture of 45% methanol and 55% water containing 0.2% formic acid was used as mobile phase for both Y2 and Y3. HPLC chromatograph of the yellow fraction containing Y1 with 400 nm as a detection wavelength was shown in Fig. 2a while HPLC spectra of the yellow fraction containing Y2 and Y3 at 440 nm as a detection wavelength were given in Fig. 2b and c. It was observed that all three yellow fractions are complex mixtures which consist of several components, a result reflecting the complexity of garlic greening. This observation is in accordance with that reported by Kubec et al. (2004), Kubec and Velíšek (2007). Since peak at 9.13 min (Fig. 2a), peak at 12.67 min (Fig. 2b) and peak at 24.63 min (Fig. 2c) were completely separated from other peaks in HPLC, they further were analysed by LC–MS/MS in conjunction with a diode array detector. UV/visible spectra of these three peaks performed by a diode array detector were displayed in Fig. 3, which were characterised by only one absorbance at 400.9 nm (Y1), 432.9 nm (Y2) and 433.9 nm (Y3) in visible region, respectively. Their absorptions were in good agreement with that of yellow pigment (440 nm) obtained from either a pickling solution of "Laba" garlic or an extraction solution of garlic puree (Bai et al., 2005; Kubec et al., 2004, Kubec & Velíšek, 2007). According to the polarity of mobile phase, it could observe that a methanol/acidic water ratio used for Y1 was less than that for Y2 and Y3; and Y1 had shorter retention time than Y2 or Y3 did, indicating that Y1 has the strongest polarity among the three compounds while Y3 exhibits the weakest. This finding is in good agreement with the polarity order of reactants, namely, P-Gly > P-Val > P-Ile.

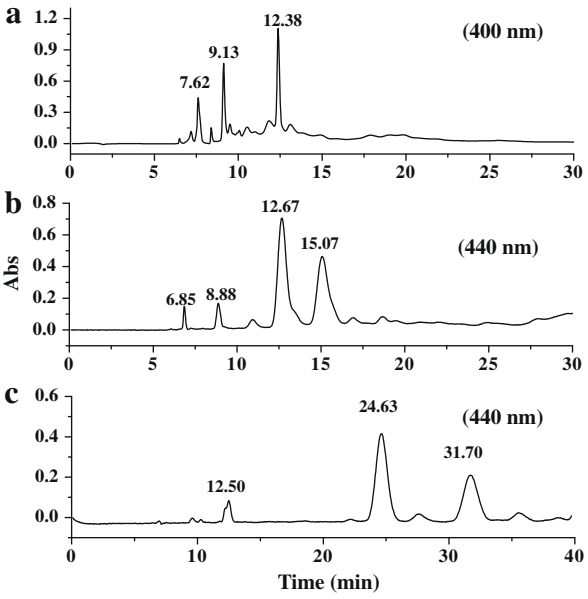

Fig. 2. HPLC chromatogram of the yellow fraction upon SOD C_{18} SPE cartridge clean-up. (a) The fraction from reaction containing pyruvic acid and P-Gly, detected at 400 nm. (b) The fraction from reaction containing pyruvic acid and P-Val, detected at 440 nm. (c) The fraction from reaction containing pyruvic acid and P-Val, detected at 440 nm.

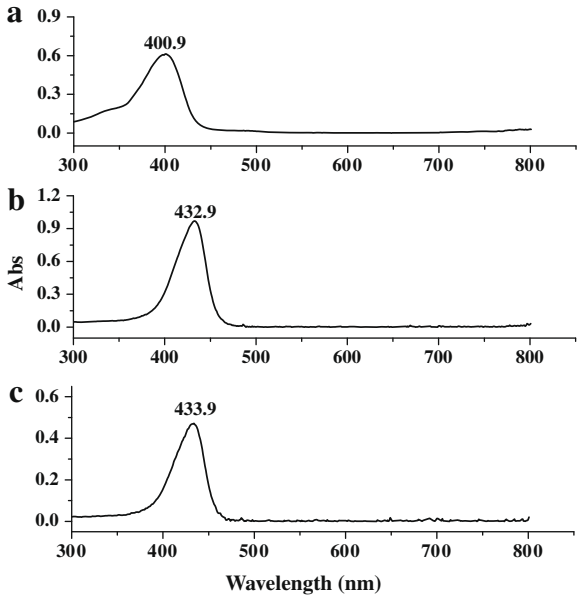

Fig. 3. UV/vis spectra of the yellow pigments. (a) The pigment (Y1) isolated from the reaction system containing pyruvic acid and P-Gly. (b) The pigment (Y2) isolated from the reaction system containing pyruvic acid and P-Val. (c) The pigment (Y3) isolated from the reaction system containing pyruvic acid and P-Ile.

Furthermore, both MS^n and high-resolution mass spectrometry were used to detect relative purity and molecular mass of the compounds. Firstly, Y1 was detected in the positive ion mode with experimental conditions as follows: capillary voltage, 2.5 kV; cone voltage, 10 V; scan ranger, m/z 100–1000, and result was given in Fig. 4a. The method used above was performed in a wider mass range scan with a lower voltage. Under present conditions, all components could be detected as their protonated adducts (Pasch, Pizzi, & Rode, 2001). There is a single prominent protonated molecular ion peak at m/z 301 $[M+H]^+$ in the MS spectrum of Y1. The accurate mass of this ion was determined to be 301.11917 by high-resolution MS (Table 1), which gives a possible molecular formula as $C_{16}H_{16}N_2O_4$. The difference in mass between the measured mass and a value calculated from their assigned formula has the least experimental error which was within 0.89 mDa unit, indicating that this formula could be the most reliable. Consistent with this formula, the number of carbon atoms was calculated to be ~16 by the observed intensity of the M+1 peak over contribution per carbon atom (1.08%) (Harris, 2003). In addition, the molecular weight of Y1 (~300) is even, suggesting that this yellow species contains an even number of N atoms in this molecule. All these data are consistent with the above proposed formula. The same MS conditions were used to analyse Y2, MS spectrum of which exhibited a single prominent protonated molecular ion peak at m/z 385 $[M+H]^+$, confirming its purity (Fig. 4b). Since Y2 was detected in the positive ion mode, its molecular weight was 384.

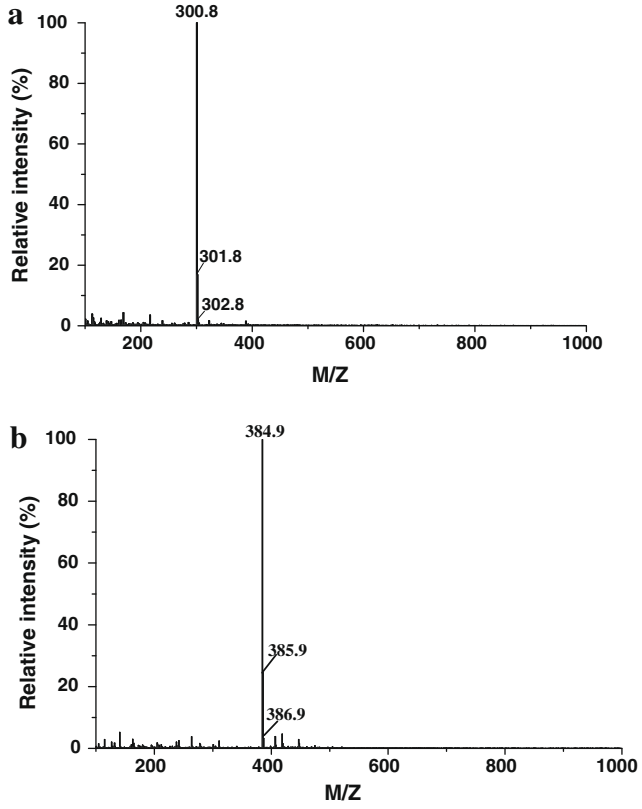

Fig. 4. MS spectra of the yellow pigments at cone voltage 10. (a) MS spectrum of Y1. (b) MS spectrum of Y2.

Molecular formula of Y2 was determined through the high-resolution MS analysis to be $C_{22}H_{28}N_2O_4$ (Table 1). Likewise, the high-resolution MS analysis for Y3 gave its molecular formula as $C_{24}H_{32}N_2O_4$ (Table 1). Based on their formula, we calculated the number of rings + double bonds (R + DB) in the molecule according to rings + double bonds formula (Eq. (1)) (Harris, 2003). The R + DB of all Y1, Y2 and Y3 were 10.

$$R + DB = c - h/2 + n/2 + 1 \quad (1)$$

From the structure of P-Gly and P-Val, it was observed that the difference in molecular weight between these two model compounds is around 42, corresponding to the mass difference between $-CH(CH_3)_2$ and –H groups, C_3H_6. Interestingly, the difference in M.W. between Y1 and Y2 is ~84, exactly the same as the mass of two C_3H_6, a resulting indicating that these two yellow species Y1 and Y2 was formed likely through dimerisation of P-Gly and P-Val, respectively. However, either Y1 (300) or Y2 (384) is not the simple adduct of two P-Gly (125) or P-Val (167) molecules according to their M.W. In addition, Y1 and Y2 have yellow colour but not contain metals (data not shown). These results suggested that both Y1 and Y2 are dimmers of their corresponding compounds, P-Gly and P-Val bridged by two conjugated double bonds as shown in Fig. 1B. Agreeing with this conclusion, the same features were found between Y2 and Y3, and between Y1 and Y3. The three new yellow species Y1, Y2 and Y3 were named as {2-[4-(1-carboxymethyl-1*H*-pyrrol-2-yl)-1-buta-1,3-dienyl]-pyrrol-1-yl}-acetic acid, 2-(2-{4-[1-(1-carboxy-2-methyl-propyl)-1*H*-pyrrol-2-yl]-buta-1,3-dienyl}-pyrrol-1-yl)-3-methyl-butyric acid and 2-(2-{4-[1-(1-carboxy-2-methyl-propyl)-1*H*-pyrrol-2-yl]-buta-1,3-dienyl}-pyrrol-1-yl)-3-methyl-pentanoic acid, respectively.

To prove above conclusion, compound Y3 was chosen to analyse its structure with MS/MS in positive mode. Increasing cone voltage could accelerate the collision of positive ions with N_2 molecules to break into a few fragments (Harris, 2003). Small cone voltage favours molecular ions whereas large voltage creates more fragments that aid in identification of analyte. Therefore, the degree of fragmentation can be controlled by adjusting the cone voltage. MS spectra with changing cone voltages in a wide range were shown in Fig. 5A. At low cone voltage (10 V), only a single peak at *m*/*z* 413 appeared, suggesting that peak 24.63 min contains one compound, Y3 (Fig. 2c). The difference in M.W. is ~1 unit between Y3 and recently reported compound purified from garlic green puree, M.W. of which is about ~411 and might contain sulphur (Lee, Cho, Kim, & Lee, 2007), a result indicating that Y3 is distinct from the reported species.

If the proposed structure of Y3 were correct, we would expect that the C–N bond between pyrrole ring moiety and α-carbon atom in Y3 be broken first due to its most instability. Indeed, with increasing the cone voltage to 70 V, this mother ion 413 $[M+H]^+$ produced its first daughter ion at *m*/*z* 298 through losing one group having mass as 413 − 298 = 115, indicating that lost fragment was the side chain of Y3, $-CH(COOH)CH(CH_3)CH_2CH_3$. The second positive ion was produced at *m*/*z* 232, a result indicating that the second group eliminated from this mother ion is pyrrole ring moiety with mass as 298 − 232 = 66. These results are in agreement with above proposed structure of Y3 (Fig. 1B). When the cone voltage increased to 80 V, three new peaks at *m*/*z* 283, 183 and 117 appeared except for the two above peaks. The peak at *m*/*z* 283 corresponds to loss of $-CH_3$ from ion with *m*/*z* 298. Cation at *m*/*z* 183 was produced through losing another side chain from the ion at *m*/*z* 298. Cation at *m*/*z* 117 was produced by several pathways depicted in Fig. 5B. Thus, all MS/MS spectra are in accordance with the proposed structures. Although Y1, Y2 and Y3 were yellow pigments, it is not known whether they were predominant yellow pigments relating to garlic greening. Previous studies showed that unidentified yellow pigments were also generated from degradation of blue species (Bai et al., 2005). However, the elucidation of the molecular structures of Y1, Y2 and Y3 would obtain insights into the mechanism of garlic greening. According to the structure of three yellow species, a possible formation pathway was proposed, which likely contains two main steps as depicted in Fig. 6. Step 1 corresponds to an nucleophilic addition reaction occurring between carbon atom in carbonyl of pyruvic acid and C-2 in pyrrole moiety of 2-(1*H*-pyrrolyl) carboxylic acid, resulting in the formation of intermediate I, which loses its –COOH group to produce intermediate II. This proposal is consistent with the fact that the reactivity of C-2 is greater than that of C-3 of 2-(1*H*-pyrrolyl) carboxylic acid due to its higher acidic property, and carbon atom of carbonyl group of pyruvic acid takes some positive charge. Step 2 corresponds to the formation of final yellow species through a dimerisation reaction in which 2 mol of intermediate II were polymerised followed by other reactions into 1 mol of corresponding yellow pigments.

Table 1
Formula of the yellow pigments observed from high-resolution electrospray ionisation mass spectra.

Pigment	Formula	Measured (*m*/*z*)	Calculated (*m*/*z*)	Error (mDa)	Error (ppm)
Y1	$C_{16}H_{16}N_2O_4$	301.11917	301.11828	0.89	2.94
Y2	$C_{22}H_{28}N_2O_4$	385.21289	385.21218	1.82	0.7
Y3	$C_{24}H_{32}N_2O_4$	413.24354	413.24348	0.15	0.06

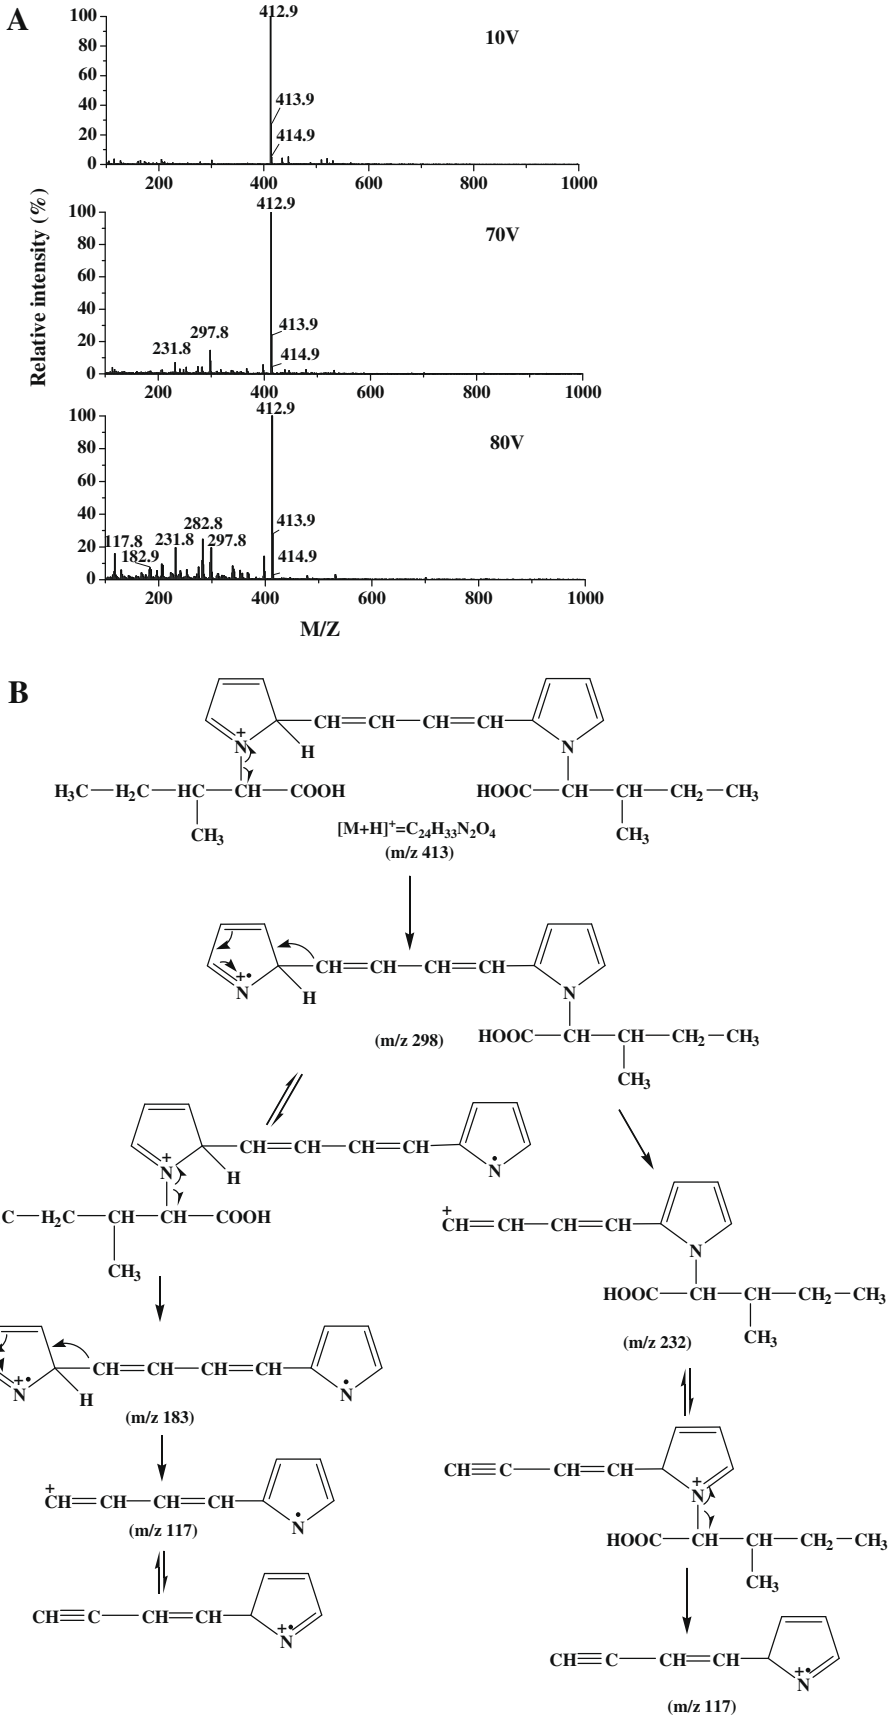

Fig. 5. (A) MS/MS spectra of the Y3 at different cone voltages 10, 70 and 80 V. (B) The proposed guideline for mass spectral data (m/z) of Y3.

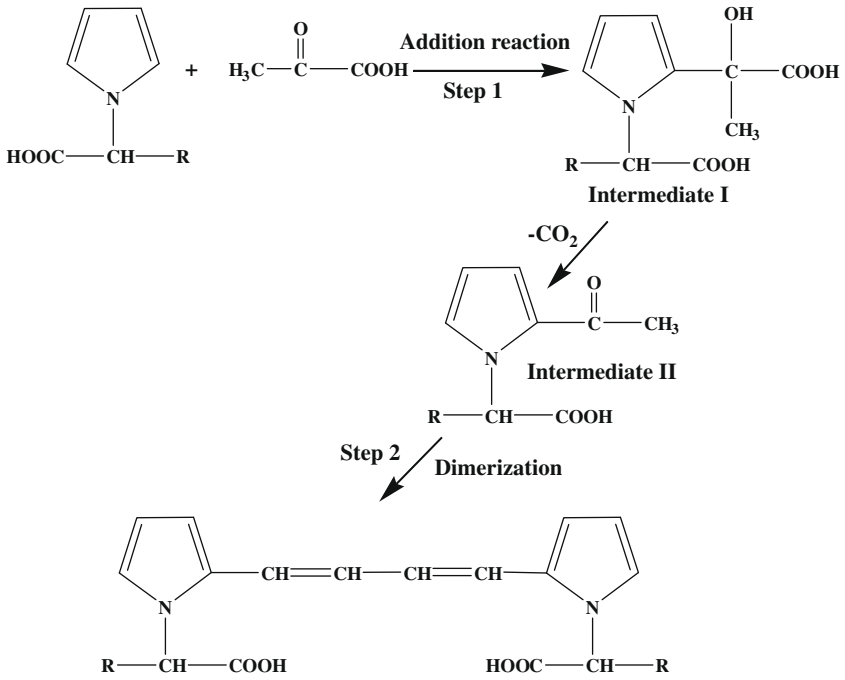

Fig. 6. Proposed two-step pathway of the formation of yellow pigments related to garlic greening.

Although the above two-step pathway was proposed, other pathways can not be excluded. More detailed mechanism about the formation of the yellow species is under investigation.

4. Conclusion

In this study, three yellow pigments from model systems were isolated and identified by HPLC, LC–MS/MS and high-resolution MS. The molecular formula of Y1, Y2 and Y3 was $C_{16}H_{16}N_2O_4$, $C_{22}H_{28}N_2O_4$ and $C_{24}H_{32}N_2O_4$, respectively. All of them contain two pyrrole ring moieties bridged by two conjugated double bonds. The elucidation of the three yellow species would benefit to understand the mechanism of garlic greening.

Linear discriminant analysis

ABSTRACT

"Oloroso" sherry wines, belonging to the denominations of origin Jerez-Xérès-Sherry (JX), Montilla-Moriles (MM) and Condado de Huelva (CH) (Andalusia, Spain), were analysed for their contents of Ca, Mg, Fe, Cu, Mn and Zn by flame atomic absorption spectrophotometry, and Na, K, Al and Sr by flame atomic emission spectrophotometry. Among the three denominations of origin, differences in the mean contents were found for Na, Mg, Fe, Al and Sr. Cluster analysis showed that these differences were significant. Linear discrimination analysis, using Na, Mg, Fe, Al and Sr, gave 100% recognition ability and 93% prediction ability.

1. Introduction

Wine is a widely consumed beverage with thousands of years of tradition. It is a complex matrix, which, besides water and alcohol, contains a great variety of inorganic and organic components. The composition of wine is due to many factors, related to the specific production area, such as grape variety, soil and climate, culture, yeast, wine-making practices, transport and storage. All of them have important influences on the quality of wine, and they are very important in the characterisation and differentiation of wines, with applications to the detection of frauds (Lara, Cerutti, Salonia, Olsina, & Martínez, 2005; Urbano, Luque de Castro, Pérez, García-Olmo, & Gómez-Nieto, 2006).

The quantity of inorganic ions in wine is of great interest, because of their influence on wine technology, as well as their toxic effects (Galani-Nikolakaki, Kallithrakas-Kontos, & Katsanos, 2002). However, one of the main interests is use of the mineral content to characterise wines by their geographical origin, taking into account the relationship between the metallic content in samples and soil composition (Frías, Conde, Rodríguez-Bencomo, García-Montelongo, & Pérez-Trujillo, 2003). Metal elements have been widely used for differentiating Spanish wines according to their geographical origin (Álvarez, Moreno, Jos, Cameán, & González, 2007a; Barbaste, Medina, Sarabia, Ortiz, & Pérez-Trujillo, 2002; Frías et al., 2003; Moreno et al., 2007; Pérez-Magariño, Ortega-Heras, González-San José, & Boger, 2004; Pérez-Trujillo, Barbaste, & Medina, 2003; Rebolo et al., 2000).

Oloroso is a type of sherry wine produced according to the dynamic ageing system formerly called the "Soleras and Criaderas" method, which is used to blend the different vintages. But, in contrast to fino sherry wine, an initial fortification to 17% by volume prevents the development of the "yeast flor film" (biological ageing), and thus the wine slowly ages in constant contact with oxygen as it descends through the traditional criaderas and solera system (oxidative ageing) (www.sherry.org). This kind of wine can be made only in certain traditional wine regions (Jerez-Xérès-Sherry, Montilla-Moriles and Condado de Huelva DOs) located in the south of Spain.

The production region of the wines protected by the Jerez-Xérès-Sherry DO includes the cities of Jerez de la Frontera, El Puerto de Santa María and Sanlúcar de Barrameda. The grapes used for their wines belong mainly to the Palomino fino variety, but also Pedro Ximenez and Muscat are used. Typical vineyard soil is "albariza", rich in limestone and clay.

Condado de Huelva DO comprises a vast region located in the southeast of the province of Huelva. At present, this DO encompasses 14 municipal districts, being the most important area of the vineyards Bollullos Par del Condado. The Zalema grape variety is the most cultivated, followed by Palomino fino and Listan. The vineyard soil is rather diverse: sandy with limestone components in the south; just gritty towards the north, and "albarizas" in the most septentrional zone. The climate is very similar to Jerez, with slight differences in pluviosity.

Montilla-Moriles DO is located some 50 km south of Córdoba. Montilla is the main production centre of this DO. With respect to their neighbouring DOs, most of the Montilla wines are produced with the Pedro Ximenez variety, which has a much higher sugar content than have Palomino Fino and Zalema varieties, and therefore gives wines with naturally higher alcohol contents. Typical vineyard soils are "albero" and "albariza". These types of soil correspond to the upper limit of the Pliocene period, which is characterised by the presence of white marls (argile-containing limestone), typical of the Guadalquivir basin. The climate of the Montilla-Moriles zone is mainly Mediterranean but with some continental features due to altitude and location.

Accordingly, soil differences and differences in grape varieties could be reflected in the metal contents of the three DO wines. Consequently, the aim of this paper is the determination of the metal content profile of oloroso wines (considering the elements Ca, Mg, Na, K, Fe, Cu, Mn, Zn, Al and Sr) for discriminating between the three DOs considered. These same mineral elements have been determined for the differentiation of "fino" wines from Jerez-Xérès-Sherry and Condado de Huelva (Álvarez et al., 2007a) and for the study of the mineral profile of Montilla-Moriles "fino" wines by Álvarez, Moreno, Jos, Cameán, and González (2007b).

2. Materials and methods

2.1. Apparatus

A Perkin Elmer AAnalyst 100 (Norwalk, CT, USA) atomic absorption spectrometer was used for metal determination, involving atomic absorption spectrometry (AAS) and atomic emission spectrometry (AES). Table 1 lists the instrumental conditions for the determination of each element.

2.2. Reagents

Panreac (Barcelona, Spain) AA standard solutions of about 1000 mg l^{-1} were used as stock solution for calibration. Other reagents were of analytical grade. Milli-Q treated water was used throughout.

2.3. Samples

Forty-one samples of oloroso wines belonging to the three DOs were used. The distribution of samples was as follows: Jerez-Xérès-Sherry (15 samples), Montilla-Moriles (12 samples) and Condado de Huelva (14 samples). All samples were provided by the Regulatory Council of each DO, to ensure the geographic origin of the wines, or purchased in markets. The alcoholic contents ranged from 18% to 19% v/v of ethanol for all samples. Each sample was identified with a code referring its origin class (JX, MM, CH), together with the sample number.

Table 1
Instrumental conditions for the determination of each element.

Element	Wavelength (nm)	Type of flame
Ca	422.7	Air/acetylene
Mg	285.2	Air/acetylene
Na	589.0	Air/acetylene
K	760.5	Air/acetylene
Fe	248.3	Air/acetylene
Cu	324.8	Air/acetylene
Mn	279.5	Air/acetylene
Zn	213.9	Air/acetylene
Al	309.3	Acetylene/nitrous oxide
Sr	460.7	Acetylene/nitrous oxide

The containers used for storing and treating the samples were cleaned to avoid contamination of the samples with traces of any metal. Containers were treated with chromic acid mixture, followed by two washes with milli-Q water.

Once opened, wine samples were digested according to the following procedure: 25 ml of wines with 15 ml of hydrogen peroxide were heated at 80 °C until a volume of about 20 ml was achieved. Then 1 ml of nitric acid was added, and the heating continued to reach a final volume of about 2 ml. This volume was mixed with milli-Q treated water up to the starting volume. Three replicated digestions were done for each sample.

Hence, from each wine sample (bottle), three equivalent aliquots were digested and analysed. The triplicates gave insight about differences in sample treatment and response, but not about sample variability, because all of the aliquots were drawn from the same bottle and the wine samples were asumed to be homogeneous. Accordingly, we used the average value from the triplicates as a central measurement of the metal content of the sample.

Metals Ca, Mg, Fe, Cu, Mn and Zn were determined by AAS, and Na and K were measured by AES, using an air/acetylene flame. Al and Sr were determined by AES, using an acetylene/nitrous oxide flame.

2.4. Statistical analysis

Univariate and multivariate analyses were carried out by using the STATISTICA 7 package of Stafsoft (2005). A data matrix was built, consisting of 10 columns (the analysed elements) and 41 rows (the samples of the three categories, DOs). Each sample was labelled with a code corresponding to its class membership, e.g., 1, 2 and 3 for CH, JX and MM DO's, respectively.

3. Results and discussion

3.1. Mineral content

The metal contents of the three different DO wines were determined. The results, always expressed in milligrammes per litre, were the averages of triplicate measurements. The corresponding descriptive basic statistic for each DO is shown in Table 2. The mean contents for the majority of these metals in the three DOs wines are consistent with the values described in the literature by other authors (Cabanis, 2000; Mareca Cortés, 1983; Ribéreau-Gayon, Glories, Maujean, & Dubourdieu, 2002; Zoecklein, Fugelsang, Gump, & Nury, 1995). In the case of sodium, our results, especially in Jerez samples, yielded greater values than those described in the majority of literature consulted. However, our values were similar to those obtained using wines made from vines exposed to considerable influence from the sea, as in Jerez samples (Frías et al., 2003).

3.2. Univariate analysis

A Kruskall–Wallis non-parametrics test was performed in order to establish the discriminant capacity of each variable, using the DO as a category. The Tukey HSD *post-hoc* test revealed which categories were particularly different from each other. The results are presented in Table 3, showing that strontium sodium, iron, aluminium and magnesium, were the most discriminant variables. Strontium is the only metal that completely differentiates the samples of each category.

Therefore, to select the most important variables for discriminating categories (JX, MM and CH), a rough feature selection, based on the Cooman's weight was performed. Thus, strontium can be

Table 2
Metal concentrations in Jerez wine samples (n = 15), Montilla-Moriles samples (n = 12) and Condado de Huelva samples (n = 14 samples).

Sr	0.0000	CH-MM, CH-JX, JX-MM

considered the most important feature for discriminating between JX and CH, JX and MM and CH and MM categories.

3.3. Multivariate analysis

Metal profiles of wines have been used as chemical descriptors for DO classification. For multivariate analysis, only those variables which showed some differences between the categories were used (in our case, Sr, Na, Fe, Al and Mg). Although our research begins from *a priori* knowledge of the class membership of wines, a cluster analysis (CA) has been applied. CA is an unsupervised technique that uses the information obtained from the measured variables to reveal the natural clusters existing between the studied samples. The dendrogram (Fig. 1) sets out the results obtained after using Ward's hierarchical method and City's block (Manhattan) distance as criteria of similarity. Two main clusters can be observed: the first one contains two subclusters, the first mainly constituted of samples of the MM category and the second of the JX samples. In the second cluster, two subclusters can also be observed, the first for JX category samples, and the second for CH samples. Accordingly, it seems that the variables used have sufficient explanatory power to detect the DO.

Linear discriminant analysis (LDA) is a widespread parametric method for classification purposes that assumes an *a priori* knowledge of the number of classes and sample class membership. The classification was performed according to the denominations of origin: Jerez (JX), Montilla-Moriles (MM) and Condado de Huelva (CH). The variables selected were strontium, sodium, iron, aluminium and magnesium. Two statistically significant discriminant functions were obtained, in which strontium, in the first function, and aluminium and magnesium, in the second, are the most important variables. The plot of both functions is represented in Fig. 2, in which a good differentiation between JX and MM categories can be visualised according to function 1, and CH category can be differen-

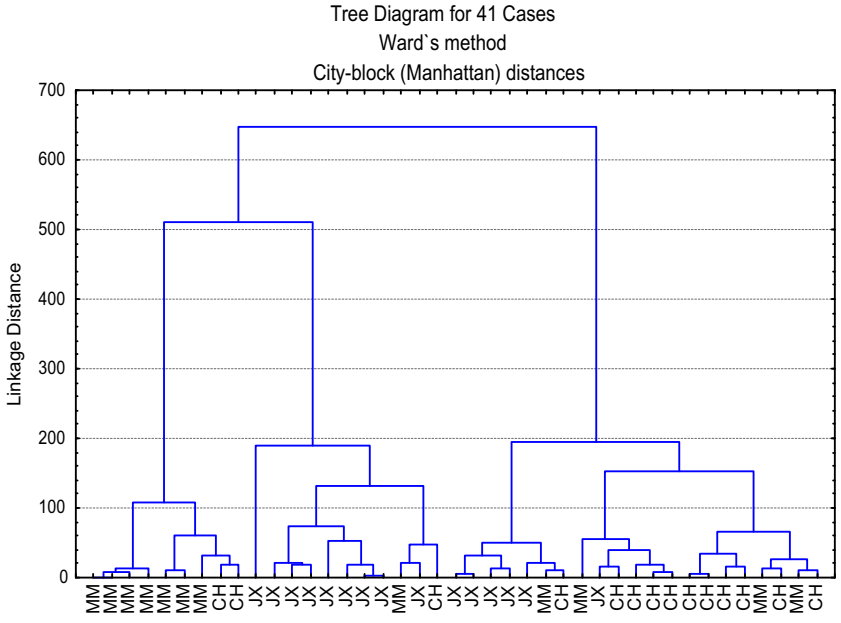

Fig. 1. Dendrogram of cluster analysis of oloroso wine samples of Condado de Huelva, Jerez and Montilla-Moriles, corresponding to classes CH, JX and MM, respectively.

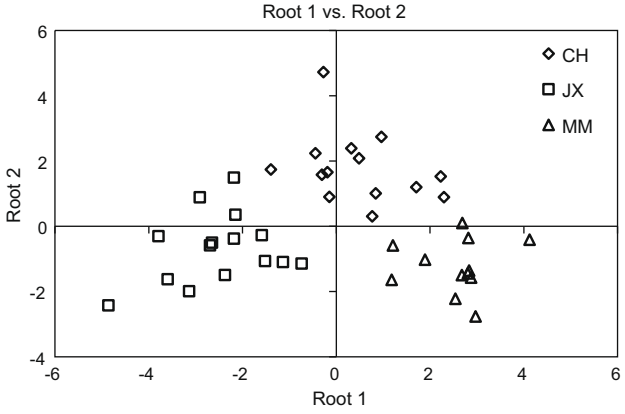

Fig. 2. Discriminant scatter plot of wine samples of Condado de Huelva, Jerez and Montilla-Moriles, corresponding to classes CH, JX and MM, respectively.

Table 4
Classification of the samples in the denominations of origin (JX, MM and CH) and recognition ability using sodium, magnesium, iron, aluminium and strontium, and LDA technique.

	Recognition ability (%)	JX	MM	CH
Jerez-Xérès-Sherry (JX)	100.0	15	0	0
Montilla-Moriles (MM)	100.0	0	12	0
Condado de Huelva (CH)	100.0	0	0	14
Total	100.0			

Table 5
Classification of the samples in the denominations of origin (JX, MM and CH) and prediction ability using sodium, magnesium, iron, aluminium and strontium, and Leave-one-out cross validation technique.

	Prediction ability (%)	JX	MM	CH
Jerez-Xérès-Sherry (JX)	93.3	14	1	0
Montilla-Moriles(MM)	100	0	12	0
Condado de Huelva (CH)	85.7	12	1	1
Total	93.0			

tiated according to function 2. Strontium contributes to differentiate between wines from JX and MM, and aluminium and magnesium to differentiate wines of CH from JX and MM. The recognition ability was 100% for the three categories (Table 4). Validation of these results was performed using leave-one-out cross-validation. During this test, a sample is removed from the data set. The classification model is rebuilt and the removed sample is classified in this new model. All the samples were sequentially removed and reclassified. The classifications obtained are presented in Table 5. The prediction ability for Montilla-Moriles is 100% and the total prediction ability is 93%.

4. Conclusions

Ten elements were used to characterise oloroso wines from Jerez-Xérès-Sherry, Montilla-Moriles and Condado de Huelva Andalusian denominations of origin. The results obtained show that the metallic contents were similar to those described in the literature, with the exception of sodium, whose content in Jerez wines was higher than that in other wines. The geographical origin of the wines influences the final metallic contents. Thus, univariate analysis showed that wines of the three denominations of origin could be differentiated using only the content of strontium. Wines of Condado de Huelva could be differentiated from those of Jerez and Montilla-Moriles by their contents of iron.

CA showed that Andalusian oloroso wines could be roughly grouped in accordance with the denomination of origin. Finally, LDA showed good recognition and prediction abilities using five elements: iron, sodium, magnesium, aluminium and strontium.

Acknowledgements

We express our gratitude to the Regulatories Councils of the Denominations of Origin which enabled us to use samples of precisely known origin, and to A.G. González for his critical review of the paper.

ABSTRACT

This study was aimed to identify compounds in bitter gourd (*Momordica charantia*) ethyl acetate extract (EAE), which inhibit lipopolysaccharide-induced prostaglandin E_2 (PGE_2) production in RAW264.7 cells. Bitter gourd EAE was partitioned between *n*-hexane and methanol/H_2O (90/10). The hexane fraction was further separated by repeated silica gel chromatographies, and a reverse phase (RP) C18 chromatography. Fraction RP-10 showed the highest inhibition effect on PGE_2 production (Max inhibition = 96%, IC_{50} = 2.3 μg/ml) and was identified to be triglycerides constituted of short and medium chain fatty acids by ^1H NMR, IR and H–HCOSY, and dicarboxylic acids by GC/MS. Fatty acids with 3–20 carbons were tested for the inhibitory activity, and capric acid exhibited the highest effect (Max inhibition = 99%, IC_{50} = 6.5 μM). In conclusion, triglycerides composed of short and medium chain fatty acids and dicarboxylic acids in bitter gourd inhibit PGE_2 production, and capric acid is the most potent inhibitor among the fatty acids.

1. Introduction

Prostaglandin E_2 (PGE_2) is an important pro-inflammatory mediator in many chronic inflammatory conditions, including rheumatoid arthritis (Robinson, McGuire, & Levine, 1975), inflammatory bowel diseases (Subbaramaiah et al., 2004), cancer (Sinha, Clements, Fulton, & Ostrand-Rosenberg, 2007), atherosclerosis (Gómez-Hernández et al., 2006), atherosclerotic plague rupture (Cipollone et al., 2004) and age-related degeneration (Wu & Meydani, 2004). In response to intrinsic cytokines (Arias-Negrete, Keller, & Chadee, 1995), or extrinsic factors, such as lipopolysaccharide (LPS) (Rhee & Hwang, 2000), macrophages release large amounts of PGE_2. PGE_2 also stimulates the production of proinflammatory cytokines (Williams & Shacter, 1997). Inhibition of the production of PGE_2 has been used to ameliorate inflammatory symptoms and suppress related diseases (Guadagni et al., 2007).

Bitter gourd (*Momordica charantia*) is a very common oriental vegetable in tropical and subtropical areas. It is traditionally regarded as a "cooling" or "fire-reducing" food. In our previous study, that characterised "heating" and "cooling" foods by their effects on PGE_2 production in LPS-stimulated RAW264.7 macrophages, we found that ethyl acetate extract (EAE) of bitter gourd inhibited PGE_2 production (Huang & Wu, 2002). This study was thus aimed to further investigate the active components in bitter gourd EAE that inhibit PGE_2 production.

2. Materials and methods

2.1. Materials

Wild bitter gourds (*M. charantia* L., strain Hualian No. 4), were kindly provided by Mr. Chong-Ho Chuan of Hualien District Agricultural Research & Extension Station. ^1H NMR and H–HCOSY spectra were obtained on Bruker AM-300 and Bruker-500 instruments, respectively. An HP 6890 series gas chromatograph (GC) equipped with a 30 m × 0.25 mm × 0.25 μm HP-5 MS column was used for the analysis of fatty acids. Mass spectral analysis was done on a JEOL JMS-HX300 mass spectrometer. Thin-layer chromatography (TLC) was performed on silica gel 60F254 TLC plates (Merck, Darmstadt, Germany). Silica gel (~230–400 μm) (Macherey-Nagel, Germany) and reverse phase C18 were used for column chromatography. Infrared spectra were obtained on a Bio-Rad FTS-40 FT-IR. The RAW 264.7 macrophage cell line (CCRC60001, originally from the American Type Culture Collection; designation, TIB-71)

was obtained from the cell bank of the Food Industry Research and Development Institute, Hsin Chu, Taiwan. Dulbecco's minimal essential medium (DMEM) and fetal bovine serum (FBS) were purchased from Gibco (Gaithersburg, MD, USA). LPS (*Escherichia coli*, serotype 026: B6) was purchased from Sigma–Aldrich (St. Louis, MO, USA). Fatty acids, propionic acid (3:0), butyric acid (4:0), caproic acid (6:0), caprylic acid (8:0), capric acid (10:0), lauric acid (12:0), myristic acid (14:0), palmitic acid (16:0) and dicarboxylic acids, octanedioic acid (suberic acid), nonanedioic acid (azelainic acid) and decanedioic acid (sebacic acid), were purchased from Sigma–Aldrich; oleic acid (18:1), linoleic acid (18:2n6), arachidonic acid (20:4n6) and conjugated linoleic acid (CLA) were purchased from Cayman (Ann Arbor, MI, USA); medium chain triglycerides (MCT) containing 67% caprylic acid (8:0), and 23% capric acid (10:0) were purchased from Mead Johnson (Evansville, IL, USA). Conjugated linolenic acid (CLN) was isolated and purified from bitter gourd in our laboratory, previously (Chuang et al., 2006); it was composed of 77% 9c, 11t, 13t-CLN, 11% stearic acid and 12% palmitic acid, based on the mass spectral data.

2.2. Preparation of water-soluble and ethyl acetate-soluble fractions of bitter gourd

Fresh whole bitter guard was homogenised and filtered through cotton cloth. The juice was centrifuged and the supernatant was lyophilised to obtain the water extract (WE). Lyophilised whole bitter guard was extracted with ethyl acetate (EA) for 48 h. The extract was filtered through Whatman no. 1 filter paper, followed by removing solvent in a rotary vacuum evaporator (Buchi, Essen, Germany), and ethyl acetate extract (EAE) was obtained. WE and EAE were tested for their effects on LPS-stimulated PGE_2 production in RAW264.7 cells.

2.3. Fractionation of bitter gourd ethyl acetate extract (EAE) in large quantity

One hundred and thirteen kilograms of bitter gourd were lyophilised to produce 7.8 kg of powder. The powder was extracted with EA twice (2×80 l) at room temperature for two days. The pooled extracts were evaporated in a rotary evaporator to remove the solvent and yielded 250 g of EAE. EAE was suspended in 1 l of *n*-hexane, and partitioned with 1 l of methanol (MeOH)/H_2O (90/10) three times. The resulting two fractions were evaporated to yield 234 g of *n*-hexane extract and 6 g of MeOH/H_2O (90/10) extract. Hexane extract was subsequently chromatographed over silica gel with an EA/hexane gradient solvent system and finally an EA/MeOH (90/10) solvent. The eluted fractions showing similar thin-layer chromatography (TLC) and ^1H NMR patterns were collected, evaporated and weighed; the evaporated crude compounds were screened for their inhibition effects upon LPS-stimulated PGE_2 production in the RAW264.7 macrophages.

Active fractions F189–191 (8.3 g) eluted by EA/MeOH (90/10) were combined, dissolved in acetone, subjected to a second silica gel column chromatography, eluted first by chloroform/ethanol (6/1), to yield two subfractions, F1–6 (4.3 g) and F8–12 (0.4 g), and then eluted by chloroform/ethanol (5/1) to yield F13–21 (2.8 g). F1–6 and F8–12, but not F13–21, were found to have the PGE_2 inhibition effect in macrophages. F1–6 (1.7 g) were dissolved in ethyl acetate, subjected to a third silica gel column chromatography, and eluted by EA/hexane (60/40). Fractions with similar TLC patterns were combined to yield seven fractions, and tested for the PGE_2 inhibition effect in macrophages. The three active fractions F1–6-2 (247 mg), F1–6-3 (237 mg) and F1–6-4 (258 mg) were combined (742 mg) and subjected to a fourth silica gel column chromatography, successively eluted by an EA/hexane gradient, starting at 90% hexane with a 5% increase in EA for every 12 fractions (150 ml/fraction) collected. Fractions with similar TLC patterns were combined to yield 16 fractions. The active fractions p11–13 (220 mg) were combined and subjected to a reverse phase (RP) C18 chromatography, eluted by MeOH/H_2O (80/20), MeOH/H_2O (90/10) and 100% MeOH. Fraction RP-10 (19.7 mg), eluted by 100% MeOH, showed the highest PGE_2 inhibition effect. RP-10 was analysed by ^1H NMR and H-HCOSY for structural identification. Fraction F1–6 was subjected to GC/MS for fatty acid analysis after saponification and methylation by the diazomethane method (Mueller, 1996).

2.4. Cell culture

RAW 264.7 cells were seeded on 96 well plates at a concentration of 5×10^5 cells/ml, and incubated for 24 h at 37 °C in 5% CO_2. The unattached cells were washed away and the cells were treated with serum-free Dulbecco's modified Eagle's medium (DMEM) containing bitter guard extracts or fatty acids in the present or absence of 100 ng/ml of LPS for 18 h. Then, the medium was collected and analysed for PGE_2 using a commercial enzyme immunoassay kit (Cayman, Ann Arbor, Mich., USA). Cell viability and cell numbers after treatments were assayed using the MTT method (Denizot & Lang, 1986).

2.5. Statistical methods

Data were expressed as means ± SD. Experiments were repeated at least three times in triplicate. The significance of difference was analysed by one way analysis of variance (ANOVA) and a Duncan's multiple rank test, using SPSS software. To calculate the percentage inhibition of LPS-stimulated PGE_2 production, PGE_2 production in the presence of 100 ng/ml of LPS was taken as 0% inhibition and basal PGE_2 production as 100% inhibition; the percentage inhibition by a sample at a specific concentration was calculated as $[1 - (PGE_2$ sample with LPS$-PGE_2$ basal$)/(PGE_2$ LPS only $- PGE_2$ basal$)] \times 100\%$. The IC_{50} value, calculated from the curve of percentage inhibition versus concentration, is the concentration of sample that results in 50% inhibition.

3. Results

3.1. Culture conditions for measuring PGE_2

PGE_2 production induced by LPS (100 ng/ml) in RAW264.7 was tested for 0, 12, 18, and 24 h and the maximal production of PGE_2

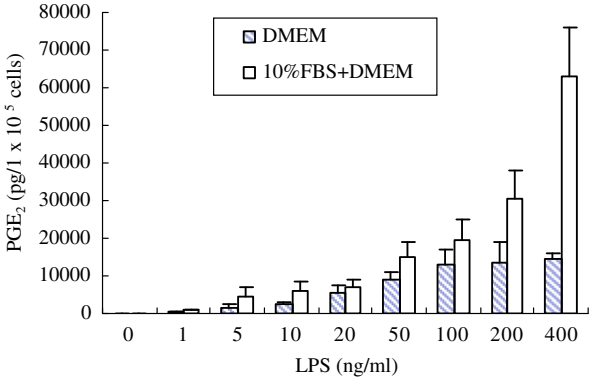

Fig. 1. PGE_2 production induced by various concentrations of LPS in RAW264.7 cells cultured with or without the addition of fetal bovine serum (FBS). The cells were treated with LPS at 0–400 ng/ml with or without 10% FBS for 18 h and medium was collected for PGE_2 analysis using an EIA. At least three batches of separate experiments were carried out with similar results. The values are means ± SD of triplicates in a representative experiment.

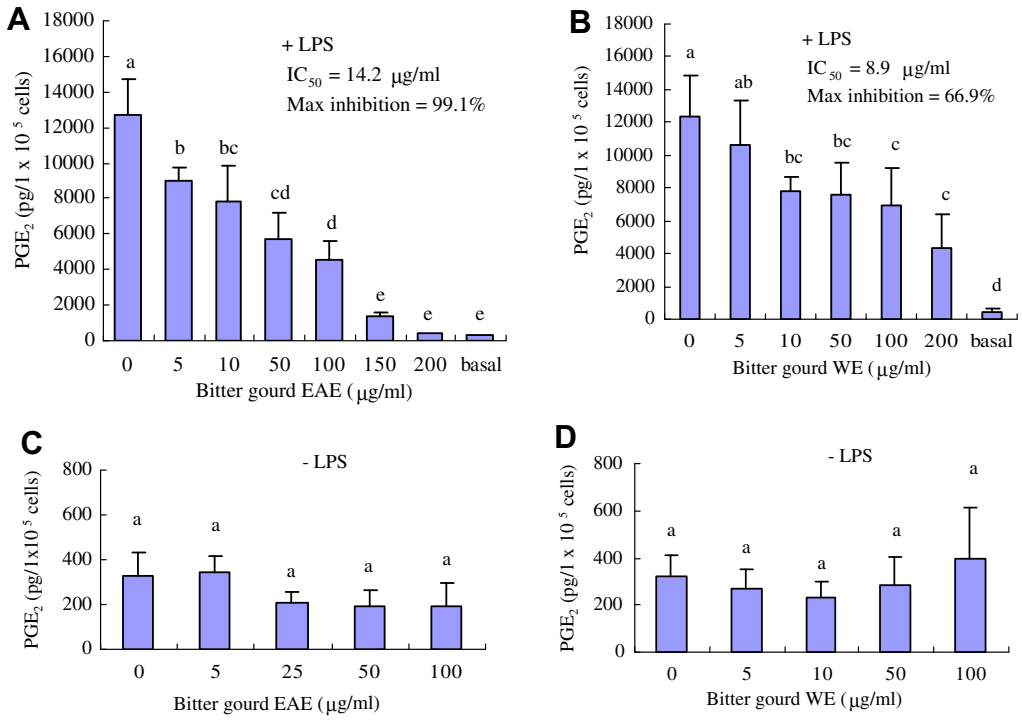

Fig. 2. Effects of ethyl acetate extract (EAE) (A and C) and water extract (WE) (B and D) of bitter gourd on PGE_2 production in RAW264.7 cells. The cells were treated with various concentrations of the extracts in the presence (+LPS) (A and B) or absence (-LPS) (C and D) of LPS (100 ng/ml) for 18 h and then medium was collected for PGE_2 analysis. The values are means ± SD of triplicates in a representative experiment. Values not sharing the same letter are significant different ($p < 0.05$). Basal: cells incubated with medium only. 0: cells treated with LPS only.

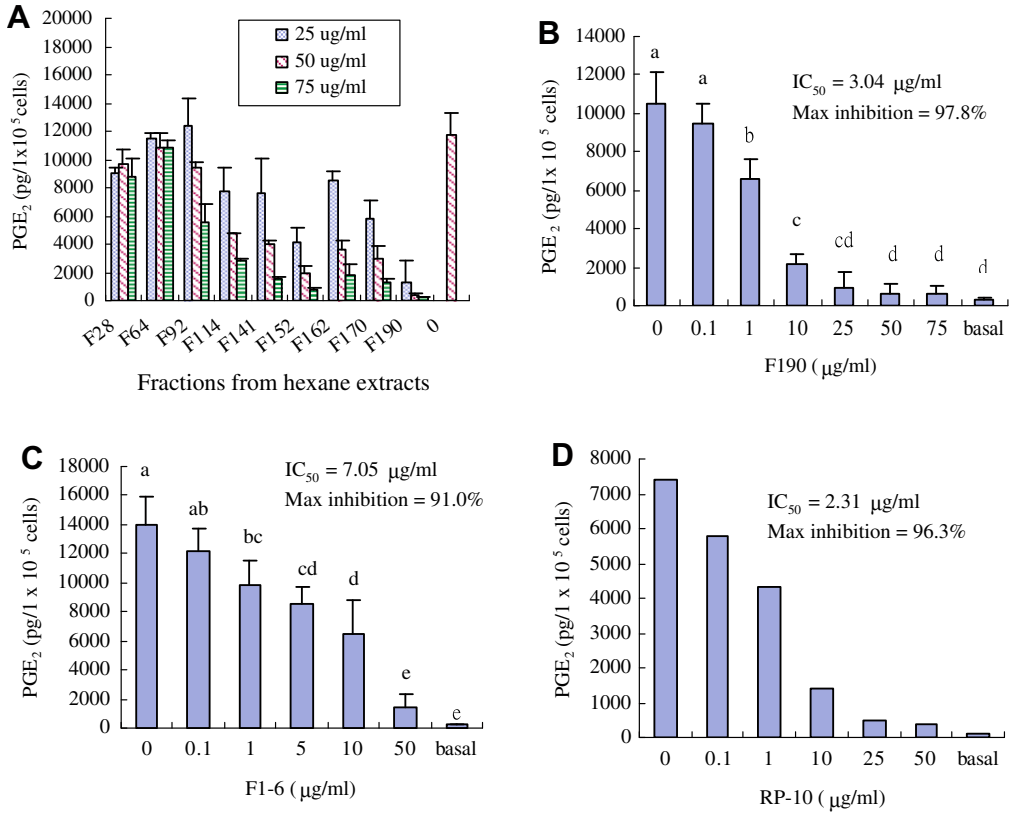

Fig. 3. Effects of different fractionations of bitter gourd EAE after chromatography on PGE_2 production in LPS-stimulated RAW264.7 cells. Bitter gourd hexane-partitioned fraction was subjected to a silica gel chromatography and eluted by EA/hexane. F28 from EA/hexane (v/v) 2/98, F64 from 5/95, F92 from 10/90, F114 from 20/80, F141 from 30/70, F152 from 40/60, F162 from 60/40, F170 from 80/20 and F190 from EA/MeOH (90/10) were tested for PGE_2 suppression effect in LPS-stimulated RAW264.7 cells (A). Dose–responses of bitter gourd active fractions F190 (B), F1–6 (C) and RP-10 (D) on PGE_2 suppression. The values are means ± SD of triplicates in a representative experiment. Values not sharing the same letter are significant different ($p < 0.05$). Basal: cells incubated with medium only. 0: cells treated with 100 ng/ml LPS only.

was found to occur at 18 h (data not shown). PGE_2 production induced by LPS at concentrations of 0, 1, 5, 10, 20, 50, 100, 200, 400 ng/ml in RAW264.7, incubated with or without 10% FBS for 18 h, was tested. At LPS concentration of 100 ng/ml, the production of PGE_2 in cells cultured without FBS reached peak level (Fig. 1) but, in cells cultured with FBS, PGE_2 production increased dramatically as the concentration of LPS increased. To avoid over stimulation, culture medium without FBS was used during LPS stimulation in the following experiments. The concentrations of extracts used to culture cells were those which did not cause cytotoxicity examined by the MTT assay.

3.2. Inhibition of PGE_2 production by bitter gourd extracts and the separated fractions

Both kinds of bitter gourd extracts, WE and EAE, decreased the secretion of PGE_2 in LPS-stimulated RAW264.7 (Fig. 2A and B), but the EAE had higher inhibition activity than had WE. Without LPS stimulation, the basal PGE_2 levels were low and not affected by either extract (Fig. 2C and D).

After partition of EAE, the hexane-soluble fraction showed higher inhibitory effect than did the MeOH/H_2O (90/10)-soluble fraction (data not shown). The hexane-soluble fraction was then separated by a silica gel chromatography. The fraction F190, eluted by EA/MeOH (90/10), showed the highest PGE_2 inhibitory activity (Fig. 3A), with maximal inhibition of 97.8% and IC_{50} of 3.04 μg/ml (Fig. 3B). Then, fractions F189–191, with similar patterns on TLC, were pooled and separated by a second silica gel chromatography. The obtained fraction F1–6, eluted by chloroform/ethanol (6/1), had the highest activity (maximal inhibition = 91.0% and IC_{50} = 7.05 μg/ml) (Fig. 3C). The fraction F1–6 was further separated by two successive silica gel chromatographies and finally a reverse phase chromatography. The fraction RP-10, eluted with methanol, showed the highest PGE_2 inhibition effect (maximal inhibition = 96.3% and IC_{50} = 2.31 μg/ml) (Fig. 3D).

3.3. Chemical structures of active components

Analysis of RP-10, using ^1H NMR and H–HCOSY, revealed that its major components were triglycerides (TGs) constituted of short and medium chain fatty acids. To identify the fatty acid composition, the F1–6 fraction was further saponified, methylated and analysed using GC/MS. As a result, common fatty acids, and three dicarboxylic acids, octanedioic, nonanedioic and decanedioic acids, were identified.

3.4. Inhibition of PGE_2 production by specific fatty acids

Of all long chain fatty acids tested, none inhibited PGE_2 production in LPS-stimulated RAW264.7, but linoleic and arachidonic acids induced dose-dependent increase in the production of PGE_2 (Fig. 4A). In contrast, among short and medium chain fatty acids, capric (10:0) and lauric (12:0) acids induced dose-dependent inhibition of PGE_2 production in LPS-stimulated RAW264.7, and capric

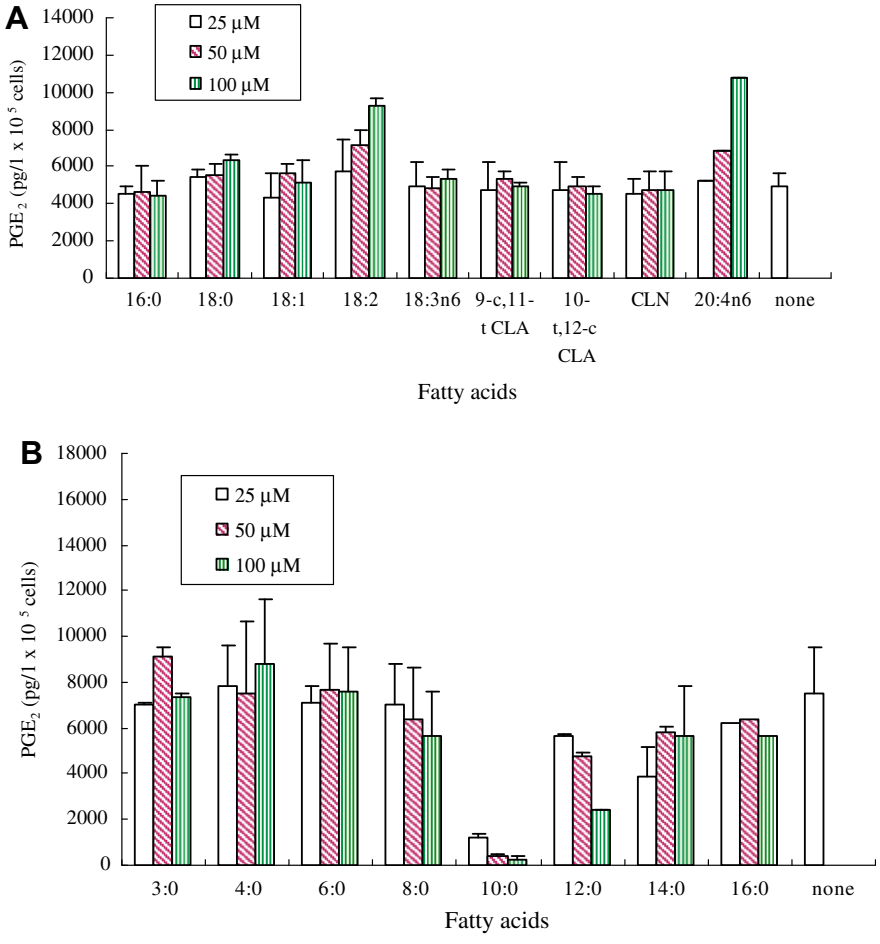

Fig. 4. Effects of different fatty acids on PGE_2 production in LPS-stimulated RAW264.7 cells. The cells were treated with long chain (A) and short and medium chain fatty acids (B) in the presence of LPS (100 ng/ml) for 18 h and then medium was collected for PGE_2 analysis. CLA, conjugated linoleic acid; CLN, 77% 9c, 11t, 13t-conjugated linolenic acid. none: cells treated with LPS only.

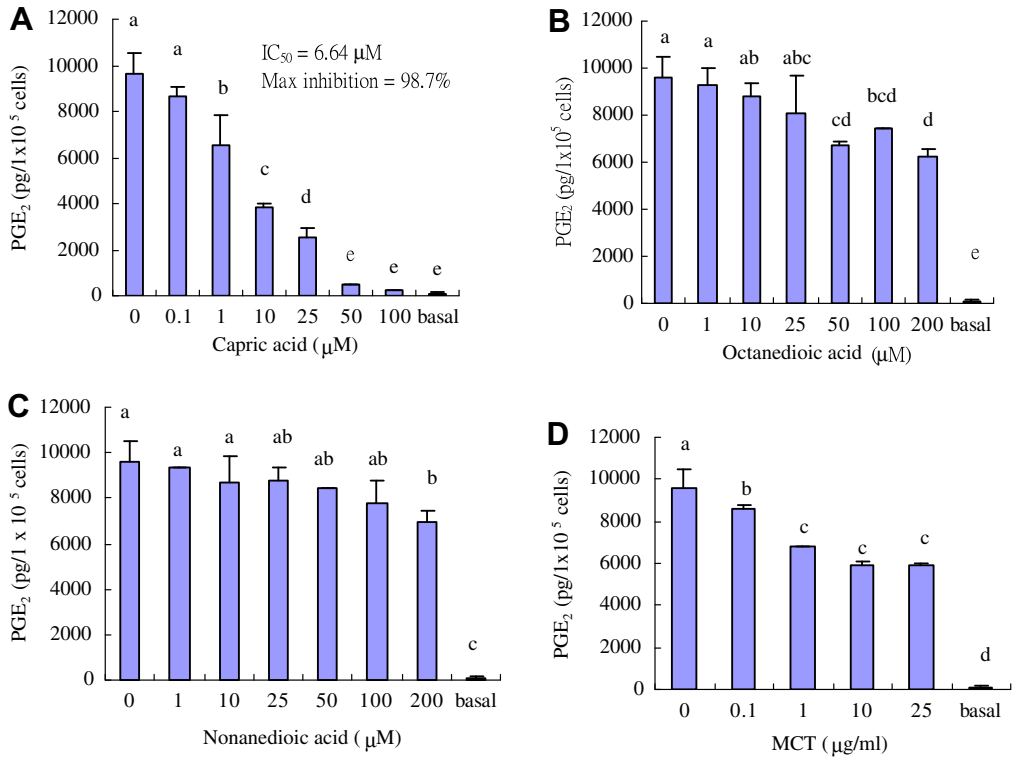

Fig. 5. Dose–response of capric acid (A), octanedioic acid (B), nonanedioic acid (C) and MCT (D) on PGE_2 suppression in LPS-stimulated RAW264.7 cells. The cells were treated with various concentrations of fatty acids or MCT in the presence of LPS (100 ng/ml) for 18 h and then medium was collected for PGE_2 analysis. The values are means ± SD of triplicates in a representative experiment. Values not sharing the same letter are significant different ($p < 0.05$). Basal: cells incubated with medium only. 0: cells treated with 100 ng/ml LPS only.

acid showed the highest inhibition activity (Fig. 4B). At a concentration of 50 μM, capric acid inhibited PGE_2 production almost completely with the IC_{50} of 6.46 μM (1.22 μg/ml) (Fig. 5A). Octanedioic and nonanedioic acids had mild PGE_2 inhibitory activities (Fig. 5B, C), but decanedioic acid failed to show any effect, even at concentration up to 200 μM (data not shown). MCT also showed significant inhibitory activity at rather low concentration (0.1 μg/ml) (Fig. 5D).

4. Discussion

Surprisingly, the present study demonstrated that the components identified in the subfraction of bitter gourd EAE with the highest suppression effect of PGE_2 production were TGs composed of short and medium chain fatty acids and dicarboxylic fatty acids. Due to similar polarities, it is difficult to further subfractionate these TG in terms of specific fatty acid composition and position. Noticeably, the active fractions were eluted by solvents with higher polarity than TGs with common long chain fatty acids, presumably because of their special fatty acid composition.

Recently, α-linolenoyl-lysophosphatidylcholine (LPC) and linoleoyl-LPC, identified in butanol extract of unripened bitter gourd placenta, where the seeds are attached, were found to contribute to the suppressive effect of bitter gourd on tumor necrosis factor-α (TNF-α) production in LPS-stimulated RAW264.7 cells (Kobori et al., 2008). Besides different parts of samples (ripened and whole vs unripened and placenta) used, our extraction procedures did not extract phospholipids or related compounds, but the effective concentration of RP-10 in this study was lower than that of purified α-linolenoyl- or linoleoyl-LPC reported by Kobori et al. (2008). Some fractions isolated in our study, also inhibiting PGE_2 production, albeit to a less extent, have not been further investigated. A predominant fatty acid, CLN, constituting 40% of bitter gourd EAE, is known to be a PPAR activator (Chuang et al., 2006), but did not change PGE_2 production in the present study (Fig. 4B).

This study was the first to find capric acid capable of inhibiting PGE_2 production in LPS-stimulated macrophages. The effective concentration of capric acid (IC_{50} = 6.46 μM) (Fig. 5A) is rather low and is likely to occur in the blood stream (Richieri & Kleinfeld, 1995). Capric acid has also been found to be the most effective among six fatty acids in killing Gram-negative bacteria by disrupting the outer membrane (Thormar, Hilmarsson, & Bergsson, 2006). The remaining fatty acids tested, including caprylic acid (8:0), lauric acid (12:0), mystic acid (14:0), palmitoleic acid (16:1) and oleic acid (18:1), had either no effect or only a low effect (Thormar et al., 2006). LPS is a major component of the outer membrane of Gram-negative bacteria, contributing greatly to the structural integrity of the bacteria. Capric acid might serve as a permeabiliser that induced the release of LPS from the outer membrane of Gram-negative bacteria as lactic acid did (Alakomi et al., 2000), and our observations indicated that it could simultaneously abolish the stimulation of LPS on PGE_2 production of macrophages.

Only few foods contain significant amounts of capric acid, of which bovine milk fat, coconut oil and MCT are major sources. Milk fat contains 2.4% capric acid, but also contains 11% myristic acid and 33% palmitic acid (Odongo et al., 2007). Coconut oil contains 6% capric acid, but also contains 49% lauric acid and 19% myristic acid (Laureles et al., 2002). The co-existence of atherogenic fatty acids may counteract the potential benefit of capric acid in these two oils. MCT oil, on the other hand, has a higher level of capric acid (23%) and is devoid of atherogenic fatty acid. Our study further showed that MCT inhibited the production of PGE_2 as well (Fig. 5D). Kono et al. (2003) compared the effects of MCT and corn oil on endotoxemia in rats, and found that MCT caused much less mortality and liver injury. Kupffer cells, isolated from rats given

MCT, showed reduced LPS-stimulated TNFα production, and CD14 expression (Kono et al., 2003), which is a cell membrane receptor of LPS (Lu, Yeh, & Ohashi, 2008).

The LPS-sensing machinery consists, primarily, of LPS-binding protein (LBP), CD14, and toll-like receptor 4 (TLR4), a signal-transducing integral membrane protein (Lu et al., 2008). Upon binding of LPS to cells, the sensing machinery then triggers intracellular signalling that leads to the expression of genes encoding proinflammatory cytokines or enzymes producing inflammatory molecules through the transcription factor nuclear factor κB (NFκB). The PGE_2 production of LPS-stimulated macrophage is known to be mediated by inducing COX-2 expression through the LPS-sensing machinery pathway (Lee & Hwang, 2006). The COX-2 expression and activity is considered the primary limiting factor for PG production in activated macrophages.

It has been demonstrated that saturated fatty acids, and especially lauric acid, which is the predominant fatty acid acylated in lipid A of LPS, could induce NFκB activation and expression of COX-2 in macrophages (Lee, Sohn, Rhee, & Hwang, 2001). The acylation and types of acylated fatty acids of lipid A determine the biological activities of LPS (Lee & Hwang, 2006). Conversely, unsaturated fatty acids inhibit lauric acid- or LPS-induced COX-2 expression (Lee et al., 2001). However, our results showed capric acid to be highly effective, and lauric acid (12:0) to a smaller extent, in inhibiting PGE_2 production, while linoleic acid (18:2n6) and arachidonic acid (20:4n6) enhanced PGE_2 production. We also found that the co-treatment with LPS and capric acid did not alter COX-2 protein expression in RAW 264.7 cells compared to treatment with LPS alone (data not shown). The discrepancy in the effect of saturated fatty acids on LPS-stimulated macrophages between our and Lee et al.'s (2003) studies might be partly explained by the differences in fatty acids tested (capric acid vs lauric acid) and experimental conditions (simultaneous treatment with fatty acids and LPS vs treatment with fatty acids prior to LPS) since lauric acid alone could have stimulated COX-2 expression (Lee et al., 2001). Besides the role of COX-2 expression, the activity of COX-2 and the availability of arachidonic acid, which is derived from the hydrolysis of phospholipids catalysed by phospholipase A_2, also affect the biosynthesis of PGE_2. The effects of capric acid on COX-2 activity and phospholipase A_2 expression and activity need further investigation.

In conclusion, the triglycerides composed of short and medium chain saturated fatty acids and dicarboxylic acids are the active components in bitter gourd EAE contributing to the inhibition of PGE_2 production, and capric acid is the most potent inhibitor among various fatty acids. Results reported here should prompt studies in other food products with similar triglyceride or fatty acid profiles. However, the potential benefits of the bioactive compounds in vegetables will need to be demonstrated in human trials.

Isoflavone
RSM
Solid phase extraction (SPE)
Liquid–liquid extraction (LLE)

ABSTRACT

Isoflavones from cotyledons of soybean sprouts were extracted with aqueous ethanol and further concentrated to obtain a product with a high concentration of isoflavone. The ethanol concentration, extraction time and reaction temperature were optimized by using response surface methodology (RSM). Isoflavones in aqueous ethanol were concentrated by a three-step procedure comprised of solid phase extraction (SPE) with Diaion HP-20 and Amberlite-XAD-2 adsorption columns, acid hydrolysis, and liquid–liquid extraction. The maximum amount of isoflavone in aqueous ethanol extracts (11.6 mg/g solid) was obtained when isoflavones in cotyledons (2.18 mg/ g solid) were extracted with 80–90% (v/v) aqueous ethanol above 90 °C for more than 100 min. The isoflavone extracts, obtained by SPE with a Diaion HP-20 column contained 100 mg/g solid. The liquid–liquid extraction (LLE) with ethyl ether further concentrated the extracts up to 229 mg/g solid, retaining 63% of the initial isoflavones.

1. Introduction

Isoflavones are a class of flavonoids in the human diet that are mainly derived from soybean-based foods. The major dietary isoflavones, daidzein and genistein, have estrogen-like activities and are classified as phytoestrogens (Hodgson, Puddey, Beilin, Mori, & Croft, 1998) since they can bind to the estrogen receptor in place of estrogen due to their structural similarities to estrogen-β (Tikkanen & Adlercreutz, 2000). Thus, isoflavones in soybean-based foods are helpful in preventing certain cancers caused by hormone therapy, reducing the risk of cardiovascular disease and improving bone health (Anderson, Johnstone, & Cooknewell, 1995; Arjmandi et al., 1996).

The amounts of isoflavones in beans differ with the bean cultivars and culture environments, such as the region and length of culture (Wang & Murphy, 1994a). Development of isoflavone-based functional foods and dietary supplements requires screening of raw materials with high amounts of isoflavones and concentrating of the isoflavones to the level of efficacy. However, 100 g of bean contains only 0.1–0.5 g of isoflavones and this isoflavone level is too low for efficacious health benefits. Besides, the strong beany flavour of soybean powder is a major drawback for its utilization as a source for isoflavones (Macleod & Ames, 1988). Therefore, highly concentrated isoflavone-rich materials, with acceptable organoleptic properties, are needed for functional food materials and dietary supplements.

The soybean sprout (Kongnamool) is a low cost but highly nutritive traditional Korean vegetable food that can be produced relatively easily. Soybean sprouts have higher amounts of isoflavones than have soybeans (Kim, Hwang, & Lee, 2003; Kim, Lee, & Chee, 2004), and soybean sprout cotyledon has the highest amounts of isoflavones among the parts of the soybean sprout, including cotyledon, hypocotyls and root (Lee et al., 2007). Therefore, the use of soybean sprout cotyledon as a source of isoflavones is advantageous. In addition, the beany flavour of soybean is caused by lipoxygenase, and soybean germination decreases the lipoxygenase activity. Hence soybean sprouts have a less beany flavour. Soybean sprouts also have many functional ingredients, such as vitamins B1, B2, C, and carotene (Hofsten, 1979).

Extraction is a very important process for production of isoflavone concentrate from rich sources. Among the extraction methods, solid phase extraction (SPE) is one of the most widely used techniques for separating functional materials. Because of their excellent sorption characteristics, Amberlite-XAD-2 and Diaion HP-20 have been used to separate isoflavones (Choi & Kim, 2005; Fedeniuk & Shand, 1998; Hennion, 1999). Liquid–liquid extraction (LLE) also has been used to separate functional materials. In LLE, hydrophobic ingredients in the raw materials are extracted from aqueous samples with a water-immiscible organic phase. Various volatile organic solvents are used, including pentane, hexane, ethyl ether, ethyl acetate, chloroform and methylene chloride (Pedersen-Bjergaard, Rasmussen, & Halvorsen, 2000). The extraction pro-

cesses are affected by process variables, such as solvent, extraction temperature, amount of solvent and extraction time.

Optimized process variables are required to efficiently produce highly concentrated isoflavone, and response surface methodology (RSM) is often used for optimization. RSM is a useful statistical technique that uses sequential experimental techniques to survey a domain of interest, focusing on the most important variables and their effects, to build an empirical model. Most RSM applications come from areas such as chemical or engineering processes, industrial research, and biological investigations, with emphasis on optimizing a process or system. The main advantage of RSM is the reduced number of experimental runs needed to provide sufficient information for statistically acceptable results (Hwang et al., 2002; Kim et al., 2002).

The use of soybean sprouts as an isoflavone rich source requires an established process for manufacturing the isoflavone-rich products. Therefore, the objective of the present study was to propose an optimized process for extraction and concentration of isoflavones from soybean sprout cotyledon, to produce highly concentrated isoflavone-rich materials.

2. Materials and methods

2.1. Reagents and materials

HPLC-grade water, ethanol and methanol were purchased from J.T. Baker Co. The standard isoflavones for quantification were daidzin (Waco Chemical Co., Japan), genistin (Fujicco Chemical Co, Japan), daidzein and genistein (Sigma Chemical Co., USA). Amberlite XAD-2 resin (surface area 300 m^2/g, pore diameter 90 Å and bead size 20–60 mesh) and Diaion HP-20 (surface area 500 m^2/g, pore diameter 260 Å and bead size 20–60 mesh) were obtained from Supelco Co. (USA). Soybean sprouts were purchased from Woo-Jung Food Co. (Korea).

2.2. Soybean sprout sample preparation

The soybean sprouts were separated into cotyledon, hypocotyl, and root. The separated cotyledon, hypocotyl and root were frozen at −70 °C and freeze-dried in a chamber Freeze-dryer (Ilshin Co., Korea). The freeze-dried parts of soybean sprout were ground in a cutting mill and passed through a 0.149 mm screen. The resulting cotyledon, hypocotyls and root powders were used for isoflavone analysis.

2.3. Isoflavone extraction

The freeze-dried cotyledons were ground in a cutting mill (Grindomix GM 200, Retsch GmbH, Germany), passed through a 0.149 mm screen, and defatted with a fivefold ratio of hexane to produce defatted soybean sprout cotyledon powder. During the defatting process, the cotyledons and hexane (1:5, w/w) were stirred with a vertical stirrer. 200 g of defatted soybean sprout cotyledon flour were suspended in 1 l of ethanol in a three neck flask reactor. Each reactor neck was attached to a thermocouple to control the temperature, a vertical stirrer for agitation and a Liebig condenser for reflux of ethanol. The concentrations of ethanol used were varied from 60% to 100%, according to the experimental design. The reactor was heated at 75–95 °C for 20–100 min in a hot water bath during the extraction process. After extraction, the suspensions were cooled to around 60 °C by immersing the reactor in a cold water bath (4 °C) immediately, and centrifuged (5000*g*) to obtain the supernatants. The floating materials in the supernatants were removed by filtering the supernatants through a nylon filter membrane (0.45 μm, Sigma Chemical Co., USA). The isoflavone-rich alcohol extract was obtained by removing the alcohols in the supernatants by vacuum evaporation with a rotary evaporator (Yamato Scientific Co., Japan).

2.4. Measurement of isoflavone

The amount of isoflavones in the extracts was analyzed using a HPLC (Waters Alliance 2690, Waters, USA) equipped with a photodiode array detector (Waters 996, Waters, USA) and Millennium^{32} chromatography manager software. A 10 μl sample was loaded onto a symmetry C18 column (Hypersil ODS, 250 × 4.6 mm, 5 μm particle size, Waters, Ireland) through an auto-sampler. The mobile phase was composed of 0.1% acetic acid in water (A) and 0.1% acetic acid in acetonitrile (B). The elution was performed with a linear gradient of A against B from 80:20 to 20:80 (A:B). The eluent flow rate was 1.0 ml/min and absorption was measured at 254 nm.

2.5. Experimental design for ethanol extraction

The process conditions for aqueous ethanol extraction of isoflavones from soybean sprout cotyledons were optimized by central composite design. Response surface methodology (RSM) was used to optimize the extraction process to yield the highest amount of total isoflavones (TI) by controlling the process variables: ethanol concentration (v/v, EC), extraction time (min, ET) and reaction temperature (°C, RT).

A five-level three-factor factorial design was adopted to optimize the extraction conditions, as shown in Table 1. Total isoflavones, including daidzein and genistein, were fitted to the quadratic response surface model as follows:

$$Y = b_0 + b_1X_1 + b_2X_2 + b_3X_3 + b_{12}X_1X_2 + b_{13}X_1X_{13} + b_{23}X_2X_3 + b_{11}X_1^2 + b_{22}X_2^2 + b_{33}X_3^2 \quad (1)$$

where Y is the amount of total isoflavones, b_i are regression coefficients for linear effects, b_{ik} are regression coefficients for effects from interaction, b_{ii} are regression coefficients for quadratic effects, and X_i are coded experimental levels of the variables. Measurements were performed in duplicate and a Statistical Analysis System was used to fit the second-order polynomial equation to the experimental data.

2.6. Concentration of isoflavones by solid phase extraction and liquid–liquid extraction

The isoflavones in aqueous ethanol were concentrated by a three-step procedure comprised of solid phase extraction, acid hydrolysis, and liquid–liquid extraction. The first step was solid phase extraction, which concentrated the isoflavones by passing through Amberlite XAD-2 and Diaion HP-20 adsorbents. The adsorbents were used as adsorption resins to separate the isoflavones. Adsorbents were subsequently washed with 2 l of methanol and 2 l of distilled water and dried at 60 °C. The dried resins were swollen in methanol (1 l) overnight, and excess methanol was removed by rinsing the swollen adsorbent with distilled water. The resins were packed in a glass column (5 cm internal diameter and

50 cm length). 500 ml of isoflavone-rich aqueous ethanol extracts were passed through the column at a flow rate of 1.2 ml/min and the column was rinsed with 2 l of distilled water to remove impurities. Isoflavones adsorbed by the column were eluted with 1.5 l of 80% aqueous ethanol at a flow rate of 1 ml/min. The glycosidic linkages were acid-hydrolyzed with 2.5 mol/l of hydrochloric acid at 85 °C for 1 h to obtain aglycones for further concentration of isoflavone. The acid-hydrolyzed isoflavones were mixed with diethyl ether in a separate funnel at a ratio of 8:2 for liquid–liquid extraction. The ether-extracted fractions were separated and dried with nitrogen gas to produce concentrated isoflavone.

3. Results and discussion

3.1. Amount of isoflavone in soybean sprout

The amounts of isoflavones in soybean sprout cotyledons, hypocotyls and roots are presented in Table 2 and are also compared with those from soybean. The isoflavone contents in soybean sprout ranged from 1.14–2.18 mg/g of dry matter and differed according to the part from which they were obtained. For example, soybean sprout cotyledon had 2.18 mg/g of dry matter, which was four times higher than the amount of isoflavones in hypocotyls. The amount of isoflavones has been reported to vary according to the type of product, as well as their cultivar, place of growth, cultivation conditions and harvest time (Kim et al., 2003; Kim et al., 2004; Wang & Murphy, 1994a; Wang & Murphy, 1994b). Likewise, the isoflavone content was higher in soybean sprouts than in soybean in the present study. This result is consistent with the report issued by Choi, Kwon, and Kim (1996), who reported an increase in total isoflavones during sprouting.

3.2. Optimization of extraction procedure

The concentration (%) of aqueous ethanol solution, the extraction time, and the reaction temperature were chosen as independent variables for optimization of the isoflavone extraction procedure. The total isoflavones (TI) in the aqueous ethanol extracts of cotyledon, prepared by controlling the independent variables at the predetermined combinations, are shown in Table 3. The combinations of coded variables were predetermined according to the central composite experimental design, and the specific coded values are shown in Table 1. The total amounts of isoflavones in ethanol extracts ranged from 9.14 to 11.6 mg/g of extracts with respect to variations in extraction conditions.

Table 4 summarizes the results of multiple regression analysis of three independent variables (X_1 = EC, X_2 = ET, and X_3 = RT) on TI in aqueous alcohol extracts, along with the results of analysis of variance (ANOVA). The regression analysis showed a significant probability of *F*-value ($p < 0.05$) in estimating TI values, which means that the three independent variables had significant effects on TI in aqueous ethanol extracts. At the 5% significance level, the significant independent variables in the TI model were the intercept ($p = 0.003$), EC ($p < 0.001$), ET ($p = 0.0408$) and RT ($p = 0.018$) in the linear term, EC^2 ($p < 0.001$) and RT^2 ($p = 0.0378$) in the quadratic term. The model could be expressed as:

$$TI = -59.76 + 0.6880X_1 + 0.1298X_2 + 0.8648X_3 - 0.003095X_1^2 - 0.004081X_3^2 \quad (2)$$

The proposed model had a sufficiently high *R*-square value ($R^2 = 0.9426$) to indicate that the TI data were adequately explained. Therefore, the model can be used as an estimate of tendency. The contour and three-dimensional plots that account for the effects of EC, RT and ET on TI were produced by the above regression equation and are presented in Fig. 1. The plots in Fig. 1 were produced for each pair of factors, whereas the third factor was taken as a constant

Table 2
Amounts of isoflavones in soybean and soybean sprouts.

Varieties	Isoflavone (mg/g)		
	Daidzein	Genistein	Total
Soybean	0.49 ± 0.02[a]	0.65 ± 0.16	1.14 ± 0.08

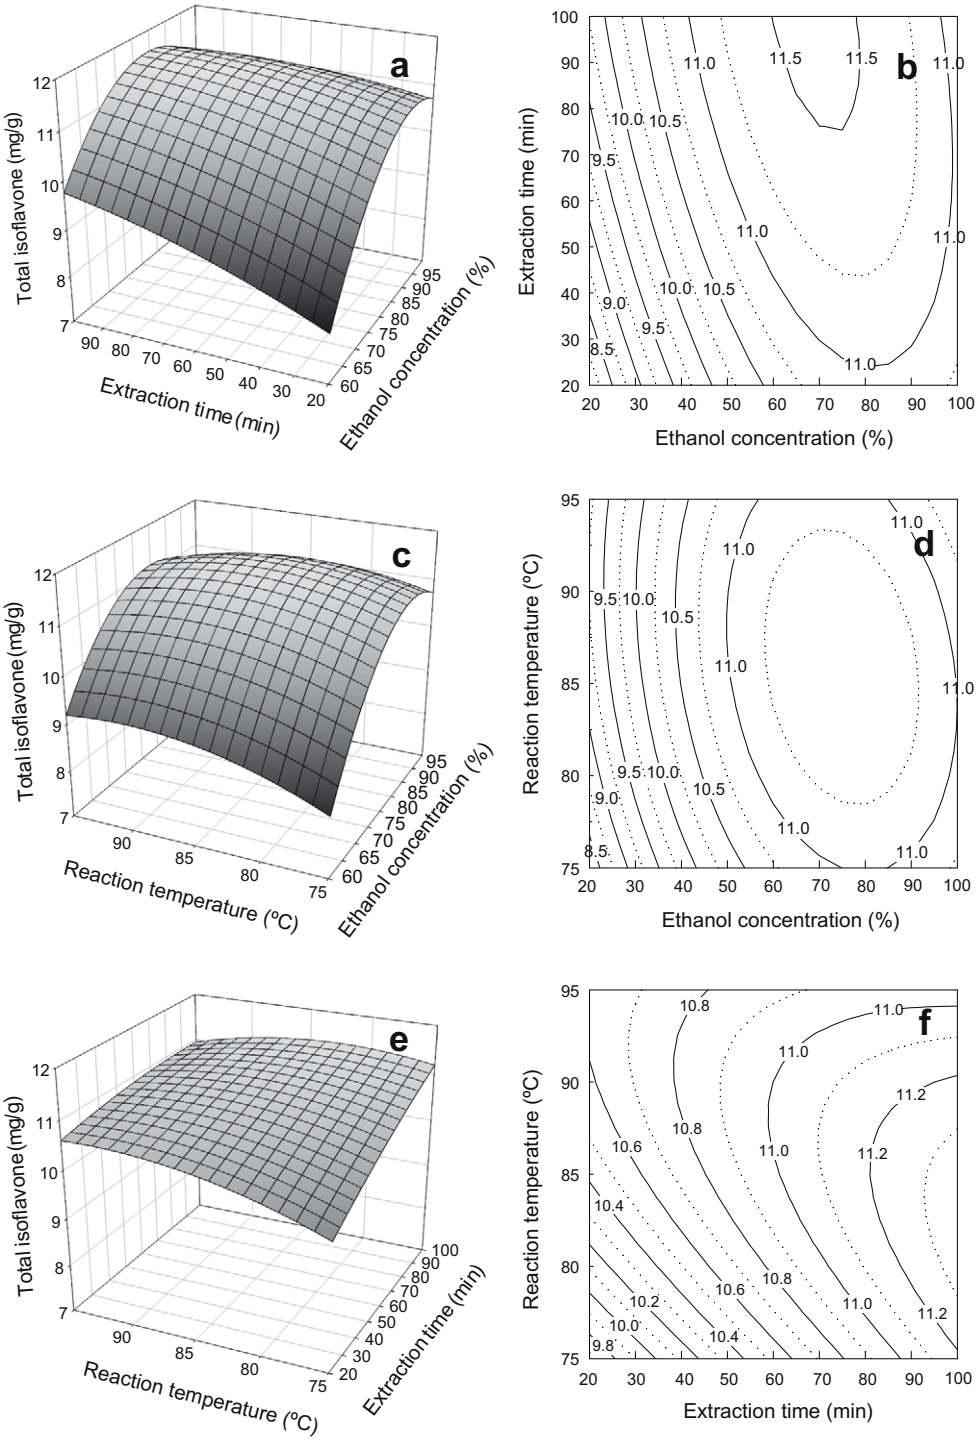

Fig. 1. Response surface and contour plots for the effects of variables on the total isoflavones (TI) in the ethanol extracts of soybean sprout cotyledon: (A and B) ethanol concentration (EC) and extraction time (ET); (C and D) ethanol concentration (EC) and reaction temperature (RT); (E and F) extraction time (ET) and reaction temperature (RT).

at its middle level. The plot a and b in Fig. 1 represent the effects of EC and ET on TI in the ethanol extracts of soybean sprout cotyledon. The maximum TI could be observed at optimized ethanol concentrations, and an increase of TI was observed with increased extraction time. The maximum TI was obtained with 80–90% aqueous ethanol solution and more than 90 min of extraction time. EC higher than 90% decreased TI due to the poor solubility of isoflavone in pure ethanol. Plots c and d in Fig. 1 illustrate the effects of EC and RT on the TI of aqueous ethanol extracts. The maximum TI was obtained with EC between 85% and 90% and RT around 85 °C. The decrease of TI with RT above 90 °C seemed be due to the unstable concentration of solvent mixture above the boiling temperature of ethanol. The effects of ET and RT on the TI of aqueous ethanol extracts are shown in plot e and f. The maximum TI could be obtained with RT around 85 °C, and an increase of TI was observed with increased extraction time. The maximum TI was obtained when the extraction procedure was operated at 85 °C for 95 min or more.

The amount of total isoflavone in extracts prepared with the above extraction conditions was 11.6 mg of isoflavone/g of extract (Table 5). The TI in aqueous ethanol extracts was 5.3 times higher

Table 5
The yield, retention and content of isoflavone in cotyledon, ethanol extracts and further concentrated isoflavone extracts.

	Isoflavone (mg/g)[a]			Yield[b] (%)	Retention[c] (%)	Content (g/100 g)
	Daidzein	Genistein	Total			
Extraction

Liquid–liquid xtraction	60.7 ± 4.28	170 ± 3.96	229 ± 4.86	0.60	63.0	22.9

[a] Experiments were performed in triplicate.
[b] Yield is the weight of dried extracts from 100 g of soybean sprout cotyledon feed (=$W_{extract} \times 100/W_{soybean\ sprout\ cotyledon\ feed}$).
[c] Retention is the weight of total isoflavone in dried extracts from 100 g of total isoflavones in soybean sprout cotyledon feed (=$(W_{TI})_{extract} \times 100/(W_{TI})_{soybean\ sprout\ cotyledon\ feed}$).

than the amount of isoflavones in cotyledon (2.18 mg/g of dry weight). Using this optimized extraction process, 90.3% of isoflavones in the soybean sprout cotyledon were retained in the aqueous ethanol extracts.

Several researchers have explored the optimal conditions for extraction of isoflavones from beans. Choi et al. (1996) compared the amounts of isoflavones in extracts according to extraction temperature, solvents and time. They reported that the optimal conditions for isoflavone extraction were 60% and 80% ethanol, 90 °C extraction temperature and 1 h extraction time. Rostagno, Palma, and Barroso (2003) optimized the solvent condition for extraction of soy isoflavones and developed an ultrasound-assisted extraction method for isoflavone determination. Their optimized condition for ultrasound-assisted isoflavone extraction was 50% ethanol concentration, 60 °C reaction temperature and 20 min of ultrasound-assisted extraction. The ultrasound-assisted extraction might be responsible for the alteration of optimal extraction conditions between their work and the present study. Zhang, Ng, and Luo (2007) optimized extraction and purification parameters for manufacturing soy isoflavone products on the basis of the yields of isoflavones. The optimum extraction conditions of their study were determined to be 80 °C for 8 h with a 96% ethanol over soybean flour ratio of 3:1 to achieve the best extraction of isoflavones, and the yield was about 0.87 mg of total isoflavones from 1 g of soybean flour. Their optimal conditions for soy isoflavone extraction are similar to those of the present study, except for extraction time. In this study, the extraction time over 90 min had only a small effect on extraction of isoflavone when isoflavone was extracted with 85% ethanol at 85 °C. Based on these studies, ethanol concentration and extraction temperature had the most profound effects on the amounts of isoflavones in aqueous ethanol extracts of soybean products.

3.3. Purification of isoflavones

The aqueous ethanol-extracted isoflavone solution was further purified by solid phase extraction (SPE) with adsorption columns packed with Diaion HP-20 and Amberlite XAD-2. The results are presented in Table 5. Solid phase adsorption with a Diaion HP-20 column performed better in separating isoflavones than did the Amberlite-XAD-2 resin column. The amount of isoflavone after SPE with Diaion HP-20 increased to 100 mg/g of sample. The isoflavone-rich fraction retained 88.5% of the soybean sprout cotyledon isoflavone with 1.95% yield. This result is in accordance with the previous work of Choi and Kim (2005) who reported the effectiveness of Diaion HP-20 in extracting phytochemicals.

After SPE, the isoflavone-rich sample was acid-hydrolyzed for 1 h at 95 °C to yield the aglycone forms of isoflavones, which had increased hydrophobicity. The presence of aglycone isoflavones is preferable, due to the ease of separation and their biological effects. The aglycones of isoflavones were further purified by ethyl ether extraction, and the results are presented in Table 5. The liquid–liquid extraction procedure increased the amount of isoflavone in extracts up to 229 mg/g of sample, and the extract retained 63% of the initial isoflavones.

The performance of liquid–liquid extraction in the present study was comparable to that in previous works on the concentration and purification of isoflavones (Chang, Cheng, & Chang, 2004; Choi et al., 2003). Chang et al. (2004) used Amberlite 16-HP resin for purification and obtained 24.7% of isoflavones when they scaled up the liquid–liquid extraction. They suggested that production of high purity total isoflavone might be significantly influenced by the feed concentration of total isoflavones. Thus, using the feed extracts obtained under optimum conditions is beneficial for purifying isoflavones (Chang et al., 2004).

4. Conclusion

The soy isoflavone concentrate was prepared by a series of procedures, comprised of ethanol extraction at optimized condition and followed by a three step concentration process, including solid phase extraction, acid hydrolysis and liquid–liquid extraction. 0.22 mg of isoflavone/g of soybean sprout cotyledon was concentrated to 229 mg/g of concentrate through a series of concentration procedures with 63% recovery of the total isoflavones. The production of highly concentrated isoflavone might allow its application as a biologically active food material since the trace amount of isoflavone in soybean sprout has limited its use in health food.

ABSTRACT

Various physicochemical and biochemical properties were compared between raw mature and immature chinook salmon (*Oncorhynchus tshawytscha*) roe. The pH, osmolality and moisture content were lower for mature salmon roe but egg size, viscosity, protein, crude lipid and ash content values were all higher. Maturity had an impact on the profile of amino acids but not on fatty acids. Maturity affected mineral and trace elements with higher Ca, Co, Mg, P, S and lower Cu, Fe, Mn, Na, Zn found in mature salmon roe. Immature roes had more α- and total tocopherols but less γ- and δ-tocopherols. Soluble proteins from mature and immature roes were similar, but the profiles of membrane-bound proteins differed. Thus maturity will affect functional and physical properties during processing and consumption of chinook roes.

1. Introduction

World production of salmon increased 2.6-fold from 1970 to 2005 as a result of increased aquaculture, with Norway, Chile, UK and Canada providing 85% of the world production of farmed salmon (Liu & Sumaila, 2008). Farmed salmon production in New Zealand increased rapidly from almost non-existing in 1983 to 9000 tons in 2002. This increase was fuelled by technological advances, consumers' perceptions of fish as healthy food option and the convenience of year-round production. This system has led to significant amounts of salmon roe of different sizes and maturity as poorly utilised by-products. Processed mature salmon roe has been used in many parts of the world. The most common salmon roe products are ikura (salted individual eggs) and suijko (salted cured whole skeins) which are produced mainly from chum salmon (*Oncorhynchus keta*) and pink salmon (*Oncorhynchus gorbuscha*) (Bledsoe, Bledsoe, & Rasco, 2003). In New Zealand, 80% of farmed salmon is chinook salmon (*Oncorhynchus tshawytscha*), which is about 50% of the world production of this species. Several studies have suggested the potential of using fish by-products, including immature fish roe, for the manufacturing of high quality protein powder (Bechtel, 2003; Bechtel, Chantarachoti, Oliveira, & Sathivel, 2007; Sathivel et al., 2004).

Farmed chinook salmon production is small compared with other salmon species and little is known of the technological properties of its components. Information on the nutritional and physicochemical properties is needed to evaluate the potential to utilise chinook salmon roes. Furthermore, apart from the expected difference in the size of eggs, there is no available information on the impact of the roe maturity on the physicochemical and nutritional properties of chinook roe.

The objective of the present study was to characterise the physicochemical properties (weight, length, grain size, pH, viscosity, osmolality, proximate analysis, fatty acid composition, amino acids profile, tocopherols content and soluble and urea soluble protein profiles) of chinook salmon roe and to investigate the impact of roe maturity on these parameters.

2. Materials and methods

2.1. Chinook roe samples

Chinook salmon (*O. tshawytscha*) roes (grade 1 for mature roe and there was no classification for immature roe; 25 kgs each) were obtained from commercial production establishment in New Zealand. The grades correspond to the classification scheme used in commercial plants and refer to the intactness. The mature salmon sample was received frozen in free flow form while the immature salmon sample was fresh. Samples were vacuum packed in about 1 kg portions, kept frozen at −20 °C and were thawed in a cool room (5 °C) overnight when required for analysis (over 6 weeks from purchase). The fish size and weight were

doi:10.1016/j.foodchem.2009.04.009

unavailable and only whole (undamaged) roe skeins were used for analysis.

2.2. Physicochemical analysis

2.2.1. Weight and length

The weight and length of individual roes were determined on thawed roes.

2.2.2. Measurements of egg size using image analysis

The imaging system consisted of a digital camera (Sony Cybershot DSC-F505 V) mounted on a stand (RSX copy stand, Kaiser, Germany), lighting system (two sets of RB 5004 HF copy lighting units, Kaiser, Germany), personal computer, and image processing and analysis software (ImageJ 1.37v, available free from <http://rsb.info.nih.gov/ij/index.html>). Skeins were cut and three lots of 10 g of fish eggs ($n = 3$), were suspended in 0.4 M phosphate buffer (pH 6.1) in a petri dish and washed twice with the same buffer. For imaging, samples in petri dishes were placed on a non-glare black surface and illuminated with standard lighting. A standard scale was included in all the images taken for subsequent image processing. The same lighting conditions were used for all the images and the still images were transferred to the PC for storage and analysis. The measurements were performed in density slice mode using the particle analysis function in ImageJ. The images were adjusted using the threshold function manually and particles touching the edge were omitted from analysis. The area and maximum diameter of individual eggs was measured.

2.2.3. Viscosity

The viscosity of the roes was determined using Brookfield Viscometer (LVDV-II+, Brookfield Engineering Laboratories, MA, USA). Roe homogenates were prepared using a hand-held blender, cooled and maintained at 5 °C in a walk-in chiller before measurements. The viscosity measurements were carried out using spindle 4 and appropriate spindle speed (within 10–90% of the total torque according to the manufacturer instruction). The viscosity in (mPa.s) was read directly off the instrument digital panel. The viscosity measurements were not possible on individual skeins, therefore five replicates of homogenates ($n = 5$) for each maturity level were used for the analysis.

2.2.4. Osmolality

A vapour pressure osmometer (VAPRO 5520, Wescor Inc., Logan, UT, USA) was used to measure the osmolality of the fish roes. The machine was calibrated with Optimol™ osmolality standards (100, 290 and 1000 mmol/kg or mOsm/kg). A 10 μl aliquot of roe homogenate (1 g roe: four parts deionised distilled water to facilitate the pipetting) was placed on the sample disc and the measurements were carried according to the manufacturer's instructions (eight readings/skein and four skeins/maturity level). The osmolality of unit weight (1 g) was expressed as (mmol/kg).

2.2.5. Chemical analysis

All the results are presented as the mean ± SD of three individual skeins for each maturity level, unless otherwise indicated.

2.2.6. pH

Measurements were carried out using a combination puncture pH electrode (InLab 427, Mettler-Toledo Process Analytical Inc., Wilmington, MA) attached to a pH meter (Hanna HI 9025, Hanna Instruments, Woonsocket, RI). For the thawed raw material and, 4–5 skeins were homogenised separately using a hand-held blender (Miniprimer MR400, Braun, Spain) until smooth blend was achieved (90s of blending). The probe was inserted directly into the homogenised samples at three different locations and pH was measured.

2.2.7. Proximate analysis

Proximate analysis was carried out in duplicate for three samples (separate skeins) per maturity level. Moisture content was determined using gravimetric measurement of water content by freeze drying (AOAC, 1995). Crude lipid content was determined according to AOAC (1995) using a Tecator Soxtec System HT 1043 Extraction Unit™ (Tecator, Högänas, Sweden). Crude protein content was determined according to AOAC (1995) using a Tecator Kjeltec Auto Sampler System 1035 Analyser™ (FOSS Tecator AB, Högänas, Sweden). Ash content was determined on freeze–dried samples. The crucibles were placed in a muffle furnace which was set to run at an initial temperature of 200 °C for 1 h before being turned up to 550 °C for 4 h. We found that without the hour at the lower temperature the samples had a tendency to explode out of the crucible. After the crucibles had cooled sufficiently (in a desiccator) they were weighed and returned to the oven. This process was repeated until a constant weight was achieved. Carbohydrates were calculated by difference [100 – the sum (moisture + lipid + protein + ash)%].

2.2.8. Amino acid analysis

All the amino acids, except tryptophan, cysteine and methionine, were determined by HPLC analysis after acid hydrolysis as described by Carducci et al. (1996).

Cysteine and methionine were analysed as cysteic acid and methionine sulphone after oxidation of the sample with performic acid followed by hydrolysis with 6 M HCl, as described by McDonald, Krueger, and Keller (1985). Amino acid analysis was carried out in duplicate for three samples (separate skeins) per maturity level.

2.2.9. Fatty acids

Lipid was extracted from 10 g of roe samples (triplicates of different skeins) using Folch, Lees, and Stanley (1957) chloroform:methanol (2:1 v/v) procedure with the modifications of West, Bickerstaffe, Annison, and Linzell (1972) using phosphate buffer (pH 6) to replace water and aid clean bi-phase partitioning. The chloroform plus lipid extract was evaporated *in vacuo* at 40 °C. Lipid was transferred to pre-weighted vials and solvent evaporated using oxygen free nitrogen at 40 °C. The resulting oil was stored under oxygen free nitrogen at −30 °C prior to analysis.

Fatty acid analysis was carried out by transmethylating 50 mg of oil (in duplicate) using H_2SO_4 (1%) in methanol as per Christie (1989). The fatty acids methyl esters (FAME) were separated using a Hewlett Packard HP-6890 GLC with split/splitless injector (250 °C, split ratio 50:1), FID (250 °C) on a capillary HP-INNO Wax Column (30 m, 0.25 mm i.d. and 0.25 μm film thickness) using programmed temperature 50–205 °C and pressure 54–200 kPa ramps over 60 min. Tridecanoic acid (C13:0) (T0502-5G, Sigma Aldrich, Bellefonte, USA) and heneicosanoic acid (C21:0), Acros Organics, USA were used as internal standards (3 mg/ml). Fatty acids were identified by comparing the retention times of FAME with standards of mixed known compositions (Nu-Check GLC-68E, GLC-68F and GLC-411, Nu-Check, Elysian, USA, Supelco 37, USA and ME 61 from Larodan, UK). Two replicate GC analyses were performed for each oil sample and the results were expressed as a percentage of the total fatty acid methyl esters present as mean values ± standard deviation. Small and unidentified peaks are shown as a percentage of other fatty acids.

2.2.10. Analysis of tocopherols

Tocopherols were determined as described by Schwartz, Ollilainen, Piironen, and Lampi (2008) with modifications. A 0.1 g of oil

sample obtained for fatty acid analysis was dissolved in 10 mL of *n*-heptane, and the extracts were filtered through a 0.45 μm nylon filter. All the samples were run with parallel spiked samples. The contents of α-tocopherol, γ-tocopherol and δ-tocopherol, respectively, were determined by HPLC equipped with a fluorescence detector set at 294 nm for excitation and 320 nm for emission. The HPLC system consisted of degasser, HPLC quaternary pump, auto-sampler with thermostat, heated column compartment and a fluorescence detector, controlled by ChemStation (version A10.02). Tocopherols were separated isocratically using a mobile phase containing *n*-heptane:tert-butylmethylether:tetrahydrofuran:methanol [79:20:0.98:0.02, v/v/v/v] and a flow rate of 1.5 ml/min. The column was a Phenomenex LiChroCART (250 mm, 4 mm ID) packed with LiChrospher 100 NH2 (5 μm). The tocopherols were separated at 30 °C and the autosampler tray was kept at 4 °C. The total run time was 20 min and calibration curves were constructed with standard solutions of each of the three tocopherols and used for quantification. Results are given in mg of α-, γ-, δ- and total tocopherols per 100 g of oil. Each oil sample was analysed in duplicate.

2.2.11. Analysis of minerals in fish roes

A 2.5 g sample of fresh roe, was placed in 50 mL graduated polycarbonate tubes and 2.5 mL of nitric acid and 0.5 mL of hydrochloric acid were added. The tubes were capped and digested for 60 min in a 90 °C heating block. The digested samples were cooled and diluted to 50 mL with deionised water. The mineral contents in the diluted digests (Al, As, B, Ca, Co, Cu, Fe, K, Mg, Mn, Na, Ni, P, S and Zn) were analysed by Inductively Coupled Plasma-Optical Emission Spectrometer (ICP-OES, Varian 720-ES). The calibrating standards were prepared as "multi-element" solutions using BDH Spectrosol standards and were diluted in a solution of 5% (v/v) nitric acid/1% (v/v) hydrochloric acid to match the acid matrix of the diluted sample digests. Caesium and Yttrium were used as internal standards. Certified reference material (NRCC-DORM-3 fish protein) and samples spiked with BDH Spectrosol standards were analysed for corresponding elements to validate the method for accuracy and precision. The recoveries of the measured elements were between 81% and 102%.

2.3. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS–PAGE)

The proteins in fish roe were fractioned into soluble protein fraction as described by Geesink, Morton, Kent, and Bickerstaffe (2000) and membrane-bound protein fraction as described by Lee, Morton, Sanderson, Bickerstaffe, and Robertson (2008). A 2 g sample of frozen fish roe was homogenised in 6 mL cool (4 °C) extraction buffer (10 mM EDTA, 2 mM DTT in 100 mM Tris–HCl, pH 8.0) for 1 min at a speed of 12,000 rpm (Polytron PT3100, Littauk Switzerland). The homogenates were centrifuged at 45,000*g* for 30 min at 4 °C. The supernatant was collected and mixed with the protease inhibitors (Mini Complete™, Roche applied Sciences) resulting in the "soluble protein fraction". The pellet was washed three times by resuspension in cold extraction buffer and re-centrifuged to remove any remaining soluble protein. The washed pellet was re-suspended in three volumes of 6 M urea followed by homogenisation and centrifugation (45,000*g* for 30 min at 4 °C). The supernatant was collected resulting in the "membrane-bound protein fraction".

Protein concentration of each protein fraction was determined using BCA Assay Reagent Kit (Pierce, Rockford, USA). Each protein fraction was mixed with SDS–PAGE sample loading buffer [58 mM Tris–HCl (pH 6.8), 1.7% SDS (w/v), 5% (v/v) glycerol, 0.002% bromophenol blue] containing 100 mM DTT and denatured at 95 °C for 4 min. After cooling, 10 μg protein samples were loaded onto a SDS–PAGE gel (15% polyacrylamide mix) and protein separation was performed according to Laemmli (1970). After electrophoresis, gels were stained with Simply Blue™ Safe Stain (Invitrogen).

2.4. Statistical analyses

The data was analysed using MINITAB (Release 14.1). For pH, viscosity, osmolality and chemical composition, tocopherol contents, amino acid and fatty acid concentrations, the analysis of variance (one way ANOVA) was used to test for maturity effect on the mean values. The significance of the difference between means was determined by Tukey's test ($P < 0.05$).

3. Results and discussion

3.1. Weight and length of raw material

We used the gonad maturity scale for teleost fishes (Kesteven, 1960) to estimate the maturity stage of the fish roes. This eight stage scale describes the developments of gonads depending on the size, shape, colour, sac fullness and ease of flow of gonad material upon applying pressure. According to this scale roes from mature salmon are in stage (VI, spawning) and immature salmon at stage (IV, developing late).

Katselis et al. (2005) reported that flathead mullet fish roe that is classified as gravid and spawning stage are suitable for production of salted dried roe. Thus mature salmon samples would probably be suitable for this type of products as well as the well-known ikura and suijko. Although developing stage gonads (such as immature salmon in our study) are not traditionally regarded as a suitable raw material, they may still be nutritionally sound or able to be presented in a different form.

Although there was no difference between the length of mature and immature salmon roes, the mature salmon roes were three times heavier ($P < 0.05$), reflecting the expected storage of nutrients required for the ova and larvae development (Zhu, 1999).

3.2. Measurements of egg size

We used image analysis to measure the size of salmon eggs from mature and immature roes to evaluate their processing potential and compare their size with the commonly known caviar and caviar-like products. Mature salmon eggs were more than twice the diameter and had six times the surface area ($P < 0.05$) of immature eggs (Table 1). Oocyte and fish egg size measurements have been carried out manually. Manual measurements can be appropriate if the size distribution is narrow, in which case a small number of eggs can be accurately measured, as in Atlantic salmon (*Salmo salar* L.) and Atlantic herring (*Clupea harengus* L.) which spawn only one batch in a season (Thorsen & Kjesbu, 2001). However, when the eggs have broader size distribution such as in the case of immature eggs, manual measurements are time consuming and image analysis will be more efficient.

Grain size is of particular importance for a caviar-like product due to desired mouth feel characteristics (Bledsoe et al., 2003). Generally caviar and caviar-like products have a diameter of >2.0 mm (Bledsoe et al., 2003; Wirth et al., 2000). Both immature and mature salmon eggs would fit within this range, however immature salmon roe (diameter range 0.16–2.64 mm) will require size screening. Alternatively, other products such as salted dried roe (karasumi), fermented roe (karashi mentaiko), or protein powder will be more suitable products for the smaller salmon eggs.

Fish egg size measurement is important in marine biology since it is linked to the quality of oocyte and fecundity (Thorsen & Kjes-

Table 1
pH, viscosity (m Pa.s), osmolality (mmol/kg), weight and length (mean ± SD, range) of raw mature and immature Chinook salmon roes and plane egg area (mean ± SD, range) and egg diameter (mean ± SD, range) of raw mature and immature chinook salmon eggs.

Parameter		Mature	Immature
Weight (g)	Mean ± SD	266.36 ± 64.85[b]	75.00 ± 19.36[a]
	Range	200.2–400.9	50.0–110.5

	Range	14.0–19.9	11.0–20.0
Egg area (mm^2)	Mean ± SD	25.35 ± 8.30[b]	3.79 ± 1.00[a]
	Range	14.00 – 57.00	0.02 – 5.48
Egg diameter (mm)	Mean ± SD	5.69 ± 0.78[b]	2.16 ± 0.41[a]
	Range	4.22 – 8.52	0.16 – 2.64
pH		5.62 ± 0.09[a]	6.13 ± 0.05[b]
Viscosity (mPa.s)		541.25 ± 157.01[b]	189.88 ± 12.13[a]
Osmolality (mmol/kg)		197.42 ± 10.69[a]	219.32 ± 13.40[b]
Colour	L^*	28.65 ± 2.55[a]	43.03 ± 13.85[b]
	a^*	20.22 ± 4.07[a]	29.51 ± 11.53[b]
	b^*	21.10 ± 4.49	25.91 ± 7.94
	C^*	29.25 ± 5.91[a]	39.59 ± 12.92[b]
	h^*	46.19 ± 2.90	44.63 ± 14.10
Proximate composition	Moisture	55.60 ± 0.36[a]	68.50 ± 0.46[b]
	Protein	26.16 ± 0.60[b]	17.69 ± 0.18[a]
	Crude lipid	10.59 ± 0.46[b]	8.45 ± 0.93[a]
	Total ash	1.42 ± 0.01[b]	1.11 ± 0.01[a]

[a,b]Values within raw with different superscripts are significantly different ($P < 0.05$).

bu, 2001) and can indicate the health and initial growth rates of produced larva (McDonough, Roumillat, & Wenner, 2003). As food, the size of fish egg can be very important since the nutrients available in fish eggs change with maturity and the consumer's perception could be influenced by size and maturity-linked pigments. From a technological point of view, the size of roes and eggs will have a great influence on the processing conditions (e.g. salting and drying times, salt/roe surface area ratio) and the suitability of the fish eggs for certain products (e.g. caviar-like products, dried products or fermented products).

3.3. pH

The average pH of mature salmon roe was 5.62 which was significantly less ($P < 0.05$) than the 6.13 for immature salmon roe (Table 1). During maturation biochemical and physical changes take place in the fish egg which lead to increased egg mass and lipid to moisture ratio (Bledsoe et al., 2003), increased protein levels (Fauvel, Omnès, Suquet, & Normant, 1993), and a decrease in ovarian fluid pH and moisture content (Fauvel et al., 1993). With over-ripening there are further changes in the composition of fish roe and reduction in ovarian fluid pH (Kaitaranta & Ackman, 1981; Vuorela, Kaitaranta, & Linko, 1979).

Our pH results for chinook salmon roe are lower than the 7.94 ± 0.04 reported for chinook salmon (Barnes, Sayler, & Cordes, 2003). This might be related to the sample preparation. Direct pH measurements on homogenised roes, as in the present study (Table 1) and other reports (Gagné & Adambounou, 1994; Katsiadaki, Taylor, & Smith, 1999) resulted in a lower pH range compared with other studies (Barnes et al., 2003; Fauvel et al., 1993; Lahnsteiner, Weismann, & Patzner, 1999) which measured the pH of the ovarian fluids after separation of solids by filtration. Thus Katsiadaki et al. (1999) reported a pH range between 5.68 and 6.96 for cod (*Gadus morhua*) roe while Fauvel et al. (1993) found the pH of ovarian fluids from turbot (*Scophthalmus maximus*) ranged from 7.0 to 8.2, and Lahnsteiner et al. (1999) reported that trout (*Salmo trutta lacustris*) roe pH ranged between 8 and 9. The pH variation within fish species due to maturity might be a specie-dependent phenomena since the pH of herring was not different across three maturity stages (Gagné & Adambounou, 1994).

It worth mentioning that the term "quality" and the relationship between the quality of fish eggs and the pH of the eggs differ in the context of food and biology studies. For Fauvel et al. (1993), Lahnsteiner et al. (1999), and Barnes et al. (2003) egg quality means the viability and fecundity of the eggs which probably increases with the increase in pH within a certain range depending on the fish species, whereas in the present work and in the study of Katsiadaki et al. (1999) fish egg quality refers to the potential eating and keeping quality of the eggs as food. The impact of pH on a food material is quite complex. On the one hand; lower pH lowers handling damage during processing, slows bacterial growth and provides a longer microbiological shelf-life. On the other hand; low pH makes food materials (especially material contains high level of lipids such as fish eggs) vulnerable to lipid oxidation (Thomsen, Jacobsen, & Skibsted, 2000).

3.4. Viscosity and osmolality

Mature salmon roe were more viscous ($P < 0.05$) than immature salmon roe (Table 1). The same factors that cause the decrease in pH with maturity can also contribute to the increased viscosity since differences in the types and amounts of proteins and lipids will affect the net charge and the ionisation of the molecules, and alter the overall viscosity of roe (Gagné & Adambounou, 1994). The viscosity of chum salmon eggs (*O. keta*) did not change with freezing (Craig & Powrie, 1988) and is similar to the viscosity range reported for immature and mature salmon in the present study.

The osmolality of mature salmon roe was lower ($P < 0.05$) than immature salmon roe. Osmolality seems to decrease with the maturity of salmon despite the lower moisture content of mature roe. This probably was due to the depletion of free amino acids during the maturation process as a mechanism to counteract the continuous reduction in yolk volume and water loss (Ronnestad, Groot, & Fyhn, 1993). The osmolality of immature and mature salmon in the present work were lower than the range (244.2–291.6 mmol/kg) reported for the ovarian fluid of rainbow trout (*Oncorhynchus mykiss*), charr (*Savelinus alpinus*), lake trout (*Salmo trutta lacustris*) and Danube salmon (*Hucho hucho*) (Lahnsteiner, Weismann, & Patzner, 1995; Lahnsteiner et al., 1999) which probably reflect maturity differences since within the same species maturity can cause wide variation in the moisture content of the roe (e.g. 66.3–90.1% moisture content range within four and five maturity stages) (Katsiadaki et al., 1999).

Osmolality is a measure of the number of moles of a solute per kilogram of solvent and thus it regulates the colligative properties of the material (e.g. freezing point depression; vapour pressure depression; osmotic pressure elevation) and consequently may affect further processing and handling processes (e.g. freezing and drying conditions of the material).

3.5. Chemical composition

The chemical composition of fish roe and caviar is affected by both intrinsic (species, maturity of the eggs, egg location within the skein) and extrinsic (diet, fish maturity, season, harvest area and processing conditions) factors (Bledsoe et al., 2003; Katsiadaki et al., 1999; Shirai, Higuchi, & Suzuki, 2006; Wirth et al., 2000). Bledsoe et al. (2003) compiled and presented comprehensive data on the chemical composition of fish roes that clearly demonstrate the inter- and intra-species variability. The data reported in the present study are within the range reported for chinook salmon by Bledsoe et al. (2003). Variation in the composition of eggs can be found in eggs produced by fish that grown under the same environmental conditions and fed identical diets (Peleitero, Lavens, Rodriguez-Ojea, & Iglesias, 1995) and even within eggs from the

same roe or the same female (Bledsoe et al., 2003; Kjorsvik, Mangor-Jensen, & Holmefjord, 1990). This variation in chemical composition of eggs/roes has been attributed mainly to diet and biological conditions (reviewed by Zhu (1999)).

Mature salmon roe had lower moisture content and higher protein, lipid and ash contents ($P < 0.05$) compared with immature salmon roe (Table 1). Katsiadaki et al. (1999) highlighted the importance of moisture content to the quality grade of raw cod roes and demonstrated the decrease in roe quality with the increase in the moisture content. The present study may support this contention since the nutritional value (represented by the contents of protein and lipid) is inversely related to the moisture content in mature and immature salmon roes.

3.6. Fatty acid composition

Palmitic acid (16:0) was the dominant saturated fatty acid in salmon roe (Table 2). Similarly, oleic acid (18:1ω9) was the most abundant monounstaturated fatty acid. Eicosapentaenoic acid [EPA; 20:5(ω3)] and docosahexaenoic acid [DHA; 22:6(ω3)] are the dominant polyunsaturated fatty acids. These are universal features for fish oils regardless of source; e.g. organ, product or by-product (Hughes, Czochanska, Pickston, & Hove, 1980; Bechtel et al., 2007; Wu & Bechtel, 2008), maturity (Kaitaranta & Ackman, 1981) and species (Hughes et al., 1980; Shirai, Suzuki, Tokairin, & Wada, 2001). Fish oils play an important role in providing the energy required by the eggs during development (for more information, see the excellent review by Tocher (2003)). Maturity had no effect on the percentage of the fatty acids. This is in agreement with earlier reports that demonstrated that diet rather than the maturation level affected the fatty acid composition (Kaitaranta & Ackman, 1981; and Pickova, Kiessling, Pettersson, & Dutta, 1999). The reported results demonstrate that the nutritional quality of the oil fraction from mature and immature salmon roes is not different (Table 2), although the contents per mass unit may be slightly different (Table 1).

Table 2
The effects of maturity on the fatty acid composition (%) of chinook salmon roe.

Fatty acid	Mature salmon	Immature salmon

[A] ND = not detected.

3.7. Mineral composition

The minerals P, S and K were the most abundant in salmon roe, followed by Na, Mg and Ca (Table 3). Small amounts of Fe, Zn, Mn, B, Cu and Al and traces of Ni, As and Co were present in salmon roe. A similar distribution of P, K, Na, Mg, Ca, Fe, Zn, Mn, Cu, Ni and As was found in immature Pollock roe (Bechtel et al., 2007). The concentrations of Ca, Mg, P, S and Co increased ($P < 0.05$) while the concentrations of Cu, Fe, Mn, Na and Zn decreased ($P < 0.05$) with the maturity of salmon roe (Table 3). The variation of the elements content between mature and immature salmon roes in the present study is in agreement with the variation range reported for cod roe at different maturation stages by Julshamn and Braekkan (1976; cited in Hellou, Warren, Payne, Blekhode, & Lobel, 1992). According to that study, the concentrations of minor (Fe, Mn, Zn, Cu, and Co) and major (K, Na, Ca and Mg) elements varied two fold within seven maturation stages of cod roe. Furthermore, the reduction of Co, Cu, Fe, Mn and Zn concentrations with the maturity of chinook salmon roe observed in the present study are similar to those found in coho salmon (Hardy, Shearer, & King, 1984).

The variation in the mineral composition with the roe maturity means that the degree of maturity of salmon roe will play an important role in determining the amount of essential mineral available in the final product and depending on the minerals of interest, either mature or immature roe may be desired as the raw material. However, it must be noted that processing may alter the mineral content as demonstrated by Bechtel et al. (2007), thus final products need to be evaluated individually.

3.8. Amino acid composition

The mean total amino acids, essential amino acids and total aromatic amino acids were about 12%, 16% and 29%, respectively,

Table 3
Effects of maturity on the concentrations of trace elements (mean ± SD, mg/kg wet weight) in chinook salmon roes.

Element	Mature salmon	Immature salmon	Limits of detection

Val	6.4 ± 1.45[b]	3.8 ± 0.20[a]
TAA	92.8	83
EAA	42.4	36.5
TSAA	4.3	4.6
TAAA	10.2	7.9
EAA/NEAA	0.84	0.78

TAA = total amino acids.
EAA = essential amino acids.
NEAA = non essential amino acids.
TSAA = total sulphur amino acids.
TAAA = total aromatic amino acids.
[a,b]Values within raw with different superscripts are significantly different ($P < 0.05$)

higher in mature salmon compared with immature salmon roe (Table 4). The profile of dominating amino acids varied with maturity of salmon roe. In agreement with the literature, glutamic acid was the dominant amino acid in mature salmon (Bledsoe et al., 2003) followed by leucine, proline, lysine and aspartic acid. Immature salmon roes contained more or less similar amounts of glutamic acid, proline, alanine, aspartic acid, lysine, and leucine (Table 4). Alanine and taurine contents decreased ($P < 0.05$) while glutamic, isoleucine, leucine and valine were increased with the maturity of salmon roe. Earlier reports demonstrated that changes in amino acid concentrations with different maturity levels do occur without consistent trends (Vuorela et al., 1979).

The uncorrected scores of essential amino acids for mature and immature roes were higher than that required for preschoolers (FAO/WHO, 1991) apart from tryptophan, which was not determined. Even at 89% digestibility level (Folador et al., 2006), all the reported essential amino acids will provide 100% of the required essential amino with the exception of leucine in immature roe. Mature salmon roe had slightly higher ratio of essential amino acids to non-essential amino acids (EAA/NEAA) compared to immature salmon roe (Table 4). Therefore, the protein quality of mature salmon roe is better than immature salmon roe. Bledsoe et al. (2003) compiled the amino acid profiles for the roes of 21 aquatic animal species. The protein quality as indicated by EAA/NEAA ration was the highest for squid's roe (0.93) and was lowest for sea urchin roe (0.65). For fin fish, mullet's roe had the lowest EAA/NEAA ratio (0.67) and the roe of chum salmon had the highest ratio (0.82). The EAA/NEAA ratios for immature (0.78) and mature salmon (0.84) in the present study are similar to those reported for immature Pollock (0.77) and chum salmon (0.82), respectively (Bechtel et al., 2007; Bledsoe et al., 2003).

Immature salmon roe contained 0.63 g/16gN of taurine which decreased to 0.2 g/16 gN with maturity (Table 4). This is similar to the level of taurine in fresh lumpfish eggs reported by Basby, Jeppesen, and Huss (1998) of 0.6 ± 0.05 g/100 g protein.

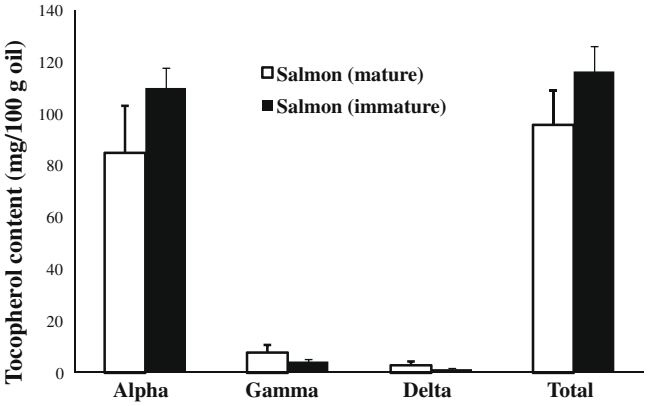

Fig. 1. Effect of maturity on the concentrations of tocopherols (α, γ, δ and total) in chinook salmon roes. The error bars represent the standard deviation of the means.

3.9. Tocopherols

The concentration of α-tocopherol numerically decreased whereas γ-tocopherol and δ-tocopherol increased with the maturity of salmon roe (Fig. 1). Overall, the total concentrations of the three tocopherols were higher in immature roe salmon (116.39 ± 9.56 mg/100 g oil) compared with mature roe salmon (96.04 ± 13.11 mg/100 g oil). The average α-tocopherol content in salmon roe (85 and 110 mg/100 g oil for mature and immature roes, respectively) is in agreement with the trend reported by Cowey, Bell, Knox, Fraser, and Youngson (1985) for *S. salar* where α-tocopherol concentration was decreased during the egg development period. The level of α-tocopherol in salmon roe is higher than that reported for vendace roe (61 mg/100 g oil) but less than that reported for Baltic herring and white fish roes (137 and 154 mg/100 g oil, respectively) (Syväoja et al., 1985).

Vitamin E (Vit E) plays a vital biochemical role in fish in addition to its function as an antioxidant (Mourente, Bell, & Tocher, 2007) and it is only obtained through diet as fish cannot synthesise Vit E. The different levels of tocopherols (γ and δ) between mature and immature salmon roes may be explained by the physical and biochemical activities of the fish during the spawning season. For example, the relative distribution of Vit E in different organs of Atlantic salmon was constant but the concentrations deposited in the organs were influenced by the dietary intake of Vit E (Hamre & Lie, 1995). Thus the amount of Vit E in fish organs will be mainly dependent on the dietary intake which may vary widely depending on environmental and physiological factors such as starving during spawning (for review see Palace & Werner, 2006). Also, the pathways regulating the transport of α, γ and δ tocopherols to different organs in Atlantic salmon may have different mechanisms (Hamre & Lie, 1997) leading to different levels of tocopherols in different organs. Interest in Vit E content in fish roe is not new with some reports on the subject are dated as early as 1949 indicating the concentration in fresh cod roe to be in the range of 5.25–7.6 mg Vit E/100 g fresh cod roe (equivalent to 350–500 mg Vit E/100 g oil based on the reported 1.5% lipid content) (Keringstad & Folkvord, 1949). However, Vit E in fish roe has not been reported widely in literature. The α-tocopherol concentration in the salmon roe in the present study is much higher than those reported for fish muscles where α-tocopherol content in the muscle of steelhead trout, rainbow trout and Atlantic salmon were 13, 19 and 18.1 mg/100 g oil, respectively (Lopéz, Satué, González, & Agramont, 1995; Zhong, Madhujith, Mahfouz, & Shahidi, 2007). This is consistent with the higher α-tocopherol contents in roe compared with the muscles in vendace, Baltic herring and white fish reported by Syväoja et al. (1985).

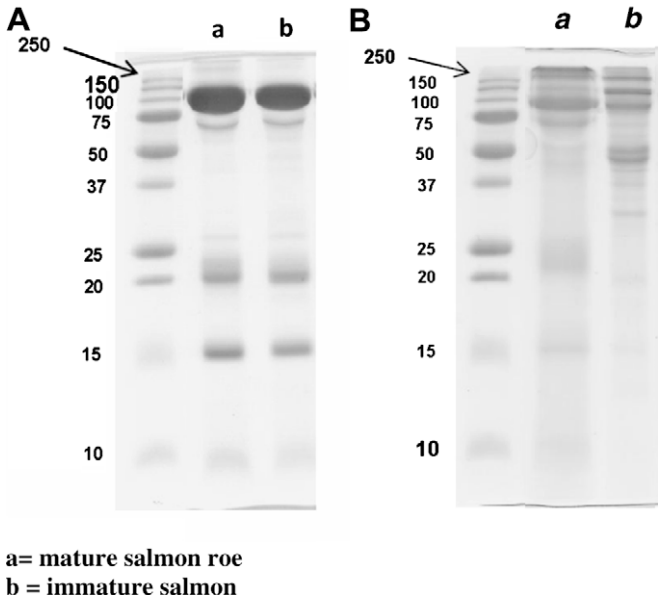

Fig. 2. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS–PAGE) profiles of soluble proteins fraction (A) and membrane-bound proteins fraction (B).

3.10. Protein profiles in mature and immature fish roes

The major bands in the soluble protein fraction in mature and immature salmon roes were identical with the major band at about 100 kDa which probably reflect a vitellin-like protein that was found at 96 kDa in the roe of *S. salar* (Scobbie & Mackie, 1990) and *O. keta* (Al-Holy & Rasco, 2006). Smaller discreet bands were present at about 67–68, 20 and 15–16 kDa (Fig. 2A). The 67–68 and 15–16 kDa bands were reported in the roes of several species including *S. salar* (Lahnsteiner, 2007; Scobbie & Mackie, 1990). The 20 kDa band seems to be not available in *S. salar* (Scobbie & Mackie, 1990) and cannot be confirmed for *O. keta* (Al-Holy & Rasco, 2006). Trace band about 9 kDa was equally present in mature and immature salmon roes. Membrane-bound proteins had different bands pattern in mature and immature salmon roes (Fig. 2B). A common band was present at 80–90 kDa. Two bands above 250 kDa were available in the membrane-bound protein fraction of mature roe where the lower molecular band of the two was present in the immature roe. This likely to represent the collagen which have molecular of 360 kDa (Al-Holy & Rasco, 2006). Several discreet bands at about 130, 45–50, 37 and 30 kDa were present only in the immature salmon roe.

The membrane-bound proteins reflect the structural proteins which are related to the degree of roe maturity (Fig. 2). While the classification of the different proteins into lipo-, glycol- and phosphoproteins was reported for fish roes (Lahnsteiner, 2007), the present proteins bands cannot be confirmed with blue staining. However, the variation in the bands in terms of quantity and patterns of different proteins means that the nutritional impact from the consumption as well as the texture of the individual grains from mature and immature will be different.

In conclusion, the maturity variation in the physicochemical characteristics of roe from salmon might indicate that different functional and physical properties during processing and consumption will arise as a result of the maturity of the roe. Also, the maturity of salmon eggs will influence the nutritional impact of consuming the raw roes as well as any products may be produced from salmon roe.

Red wines
Antibacterial activity
Free radical scavenging activity
Polyphenols
Anthocyanins

ABSTRACT

Free radical scavenging and antibacterial activities were determined for several red wines from different grape varieties from the southern Serbia wine region. The amount of polyphenols and anthocyanins in selected wines was investigated and the potential antibacterial activity of the wines against pathogenic strains of *Staphylococcus aureus* and *Escherichia coli* was also determined. The free radical scavenging and antibacterial activity of the wines was correlated with polyphenolic and anthocyanin content. The significant differences in the antioxidant and antibacterial activities between the wines from grape cultivars (*Cabernet Sauvingon* and *Pinot Noir*) and the indigenous varieties (*Vranac* and *Prokupac*) were not confirmed. The hypothesis of a protective effect of red wine is supported by our results that show that the red wines with higher amounts of polyphenols and anthocyanins had higher antioxidant and antibacterial properties.

1. Introduction

Recent studies indicate that consumption of a small amount of red wine on a regular basis reduces the risk of coronary heart disease and atherosclerosis, and this benefit is attributed to the antioxidant properties of the polyphenolic compounds (Gey, 1990; Renaud & de Lorgeril, 1992; Youdim, McDonald, Kalt, & Joseph, 2002). Several studies suggest that some phenolic compounds, when ingested at high concentrations, may exhibit certain roles in carcinogenicity, genotoxicity, thyroid toxicity and can be connected with oestrogenic activity (Lila, 2004; Meiers et al., 2001). Phenolic compounds represent one of the most important quality parameters of grapes and wines since they contribute to organoleptic characteristics such as colour, astringency and bitterness.

The phenolic composition of wine is determined initially by the phenolic composition of the grapes used for making the wine (Ribéreau-Gayon, Dubourdieu, Dončche, & Lonvaud, 1998). Exposure to sunlight and temperature are the main factors influencing the phenolic composition of grapes. These factors depend of the climate in the area, but can be modified by controlling the canopy microclimate. The other factor that influences wine phenolic composition is the extraction of phenolic compounds from the grape skins and seeds during maceration. Finally, the higher the concentration of polyphenols in wines, the higher their antioxidant capacity and physiological effects (De Beer, Joubert, Gelderblom, & Manley, 2003, 2005). Some studies suggest that wine possesses antimicrobial activity against various pathogens (Daglia et al., 2007; Daroch et al., 2001; Papadopoulou, Soulti, & Roussis, 2005; Sugita-Konishi, Hara-Kudo, Iwamoto, & Kondo, 2001; Weisse, Eberly, & Person, 1995). Phenols have an important role in the stabilization of lipid oxidation, antihypertensive and antithrombic effects, and reduce carcinostatic properties (Jang et al., 1997). Studies *in vitro* have shown that the viable count of *Enterobacteriaceae* is more rapidly reduced in wine compared to other alcohol-containing beverages (Just & Daeschel, 2003). The mechanism by which anthocyanins are absorbed and metabolised in the body is currently unclear (Munoz-Espada, Wood, Bordelon, & Watkins, 2004). The role of anthocyanins in protection from cardiovascular disease is strongly linked to oxidative stress protection (Meiers et al., 2001). Anthocyanins were found to be highly bioavailable in endothelial cells and have been correlated to their role in prevention of atherosclerosis and neurodegenerative disorders (Youdim et al., 2002). In both *in vitro* and *in vivo* research trials, anthocyanins have been shown to reduce the proliferation of cancer cells and to inhibit tumor formation (Hou, 2003). Recently, it has been reported that the anthocyanin pigments may play an important function in the prevention of carcinogenesis and in extending the life span of animals. It was also shown that dietary antioxidants may offer effective protection from peroxidation damage in living systems (Lila, 2004; Tsuda, Horio, & Osawa, 2000).

Wine consists of different phenolic compounds, so the antioxidant and the antibacterial activity of different wines are related to these compounds. Still, it is very important to determine which group of phenolic compounds is most influential in antioxidant and antibacterial properties of wine.

The south of Serbia has a longstanding tradition of viticulture and winemaking since the region's dominant soil types are very

favourable for the cultivation of wines. The aim of this study was to determine the free radical scavenging and antibacterial activities of wines produced in southern Serbia vineyards and to correlate these with total polyphenolic content and the amount of anthocyanins.

2. Materials and methods

2.1. Chemicals

2,2-Diphenyl-1-picrylhydrazyl (DPPH·) in free radical form was obtained from Sigma Chemical Co. (St. Louis, MO). Folin–Ciocalteu reagent, gallic acid and methanol were purchased from Merck Co. (Germany). All reagents were analytical grade.

2.2. Bacterial cultures

The following microorganisms were used for the antibacterial tests: *Staphylococcus aureus* (strain ATCC 28053 gram-positive) and *Escherichia coli* (strain ATCC 25922 gram-negative). The bacteria were grown on Mueller–Hinton dextrose agar.

2.3. Wine samples

The wines were produced from different grape varieties grown in southwest Serbia. Six red wines were supplied by Rubin – Kruševac: Terra Lazarica – Cabernet Sauvingon (2006); Terra Lazarica – Pinot Noir (2006); Vranac (2007); Rubinovo Crno (2007); Medvedja krv (2007) and Car Lazar (2006).

2.4. Determination of total phenolic content

The total phenol content in selected wine samples was determined spectrophotometrically according to the Folin–Ciocalteu colorimetric method (Singleton & Rossi, 1965) using gallic acid as a standard polyphenol: 0.25 ml of wine was mixed with 12.5 ml distilled water and 1.25 ml of Folin–Ciocalteu reagent. After 3 min, 5 ml of 20% Na_2CO_3 was added. The absorbance was measured after 30 min at 750 nm. The concentration of the total phenolic compounds in the wines was expressed as gallic acid equivalents (mg/l). The results in every assay were obtained from three parallel determinations.

2.5. Determination of monomeric anthocyanins

The total monomeric anthocyanin content in the wine samples was determined using the pH-differential method described by Guisti and Wrolstad (2003). Anthocyanins have a maximum absorbance at a wavelength of 520 nm at a pH of 1.0. The coloured oxonium form predominates at pH 1.0 and the colourless hemiketal form at pH 4.5. The pH-differential method is based on this reaction and permits accurate and rapid measurement of the total monomeric anthocyanins. The result, considered as the monomeric anthocyanin pigment, was calculated as mg of cyanidin-3-glucoside, by using a molar absorptivity (ε) of 26,900 and a molecular weight of 449.2. Data presented are the average of three measurements.

2.6. Determination of indices for anthocyanin pigment degradation, polymeric colour, and browning

Indices for anthocyanin degradation in wine can be derived using the pH-differential method described by Guisti and Wrolstad (2003). The absorbance at 420 nm of the bisulfite treated sample serves as an index for browning. Colour density is defined as the sum of absorbances at the maximum absorbance and at 420 nm. The ratio between polymerisation colour and colour density is used to determine the percentage of the colour that contributed by polymerised material. The ratio between the amount of monomeric and total anthocyanins can be used to determine a degradation index. The date presented are the average of three measurements.

2.7. Free radical scavenging activity

The free radical scavenging activity of the wine samples was analysed by using the 2,2,-diphenyl-1-picrylhydrazyl (DPPH·) assay (Fuhrman, Volkova, Suraski, & Aviram, 2001; Lachman, Sulc, & Schilla, 2007; Sanchez-Moreno, Larrauri, & Saura-Calixto, 1999; Turkoglu, Duru, Mecan, Kivrak, & Gezer, 2007; Villano, Fernandez-Pachon, Troncoso, & Garcia-Parrilla, 2006). The antioxidant assay is based on the measurement of the loss of DPPH· colour by the change of absorbance at 517 nm caused by the reaction of DPPH· with the tested sample. The reaction was monitored by a UV/vis spectrophotometer. Wine diluted with water (1:25 v/v) (5 ml) and 5 ml of freshly prepared DPPH· in methanol 1×10^{-4} M were put into a cuvette at room temperature. After 20 min incubation period at room temperature, the absorbance was read against a blank at 517 nm. The determinations were performed in triplicate. Inhibition of DPPH· in percent (I %) of each wine sample was calculated from the decrease of absorbance according to the relationship:

$$I\% = \left(A_{\text{blank}} - A_{\text{sample}}/A_{\text{blank}}\right) \times 100$$

where A_{blank} is the absorbance of control reaction (methanol–water with DPPH·) and A_{sample} is the absorbance of the tested wine sample.

2.8. Antibacterial activity

The disc diffusion method was used for the determination of the antibacterial activity of the wine samples (Bauer, Kirby, Sherris, & Truck, 1966; Papadopoulou et al., 2005; Turkoglu et al., 2007). The microorganisms mentioned above were incubated at 37 °C for 24 h by inoculation into Mueller–Hinton broth. The number of cells in 1 ml of suspension for inoculation measured by the McFarland nephelometer was 1×10^7 cfu/ml. A volume of 1 ml of this suspension was homogenized with 9 ml of melted Mueller–Hillton agar and poured into petri dishes. For screening, sterile 4 mm discs were impregnated with 50 μl of wine sample. After incubation for 24 h at 37 °C, inhibition zone diameters, ZI (including disc), were measured and expressed in mm. The magnitude of the inhibition zone indicates the activity of the tested wines against bacteria. The tests were done in triplicate.

2.9. Statistical analysis

All the measurements were carried out in triplicate, and presented as mean ± SEM or standard deviations (*SD*). The direction and magnitude of the correlation between the variables was quantified by the correlation factor r^2. Correlations were considered statistically significant, if the p-value was less than 0.05.

3. Results and discussion

3.1. The content of polyphenols and anthocyanins in wine samples

The phenolic composition in wines is determined by several factors, such as the variety of the grapes and the conditions under which they were grown (soil, location, and weather). Winemaking techniques also play a very important role in the extraction of polyphenols from the grape: e.g. the time of maceration and fermentation in contact with the grape skins and seeds, pressure,

maturation and ageing conditions (Sato et al., 1996, Villano et al., 2006).

Serbia, with 82,000 ha of vine area and around 2 million hl of annual wine production, is one of the middle-weight wine producers in Europe. Many of the Serbian growing districts boast remarkably good ecological conditions for the production of high-quality wines and quality wines with geographically controlled designations of origin. Vineyards of southern Serbia are focused on the old autochthonous vine varieties: *Vranac* and *Prokupac*. *Vranac* originated in Balkan and is the most common type in Serbia and Macedonia. The grapes are ripened in mid-September, when their skins are a dark-blue colour. The juice turns the colour of blood during the first minutes of breaking the grapes. They have a harmonious taste, with an excellent aroma. The skin of *Prokupac* (*Nishevka*) is a dark-blue colour, with characteristic dots. The juice is light red, with a sugar level of 22–24% and acidity of 6–8 g/l. The wine is very suitable for coupling with other red wines. These indigenous varieties are often compared to the French vine varieties *Cabernet Sauvingon, Pinot Noir* and *Gamay*.

Some relevant analytical parameters of the wines produced by the Rubin – Kruševac winery, are given in Table 1. It is obvious that this wine differs in many analytical parameters such as content of alcohol, total extract, total and free SO_2, reducing sugar, total acidity (as tartaric acid), volatile acidity (as acetic acid) and specific weight.

The phenolic content of selected wines, obtained using the Folin–Ciocalteu reagent, is presented in Table 2.

The mean concentration of the phenolic content of the Serbian wines was 3442 mg of gallic acid equivalent. This is higher than the levels quoted in the literature for wines grown in different countries (see Table 3).

The differences between the Serbian wines and the other published results may be a result of the higher levels of phenolic compounds in the Serbian grape varieties. The numerous viticultural factors could affect the grape phenolic content. The phenolic composition has an important role in stabilizing lipid oxidation and is associated with antioxidant activity. The red wines (Medvedja krv, Rubinovo Crno and Vranac) coming from indigenous grape varieties *Vranac* and *Prokupac* have a mean phenolic content of 3606 versus 3603 mg/l for red wines from *Cabernet Sauvingon* and *Pinot Noir* varieties (Terra Lazarica – Cabernet Sauvingon and Terra Lazarica – Pinot Noir).

Table 1
Some relevant analytical parameters in the wines.

Wine[a]	Specific weight	Alcohol content (vol %)	Total extract (g/l)	Free SO_2 (mg/l)	Total SO_2 (mg/l)	Reducing sugar (g/l)	Total acidity (tartaric acid) (g/l)	Volatile acidity (acetic acid) (g/l)
Terra Lazarica – Cabernet S.	0.9946	12.0	28.1	28.2	98.6	2.2	5.4	0.7
Vranac	0.9954	11.5	30.1	25.6	93.4	–	5.5	0.7

Anthocyanin composition is an important quality parameter of the red grapes since the anthocyanins influence the final colour of the resulting wines (Munoz-Espada et al., 2004). Anthocyanins have several different ionic forms in the wine based on wine pH value. At typical wine pH, between 10% and 15% of the present monomeric anthocyanins are pigments. Anthocyanin pigments undergo reversible structural transformation with a change in pH manifested by strikingly different absorbance spectra. At a pH 1.0, anthocyanins are represented by the red coloured oxonium form (the flavilium cation), however, at pH 4.5 deprotonation results in a colourless carbinol pseudobase structure (hemiketal) (Guisti & Wrolstad, 2003). The anthocyanin content is obtained by the different values of the absorbance at these two pH values, and relies on the structural transformations of the anthocyanin chromophore as a function of pH, represented in Table 2.

The mean amount of monomeric anthocyanin content of the investigated wines was 299 mg/l. The highest concentration of the anthocyanin pigment has been found in the young wine. The concentrations of the anthocyanins in the local wines Rubinovo Crno, Medvedja krv and Vranac were 336, 330 and 311 mg/l, respectively. These anthocyanin are essential for the good colour of these wines produced from the *Vranac* and *Prokupac* grapes.

As expected, the significant linear correlation (Fig. 1) was confirmed between total phenols content and the amount of the monomeric anthocyanins ($r^2 = 0.9960$, $SD = 5.6$, $p < 0.0001$, $n = 6$).

Anthocyanin extraction and stability are affected by winery production practices. Monomeric anthocyanins are subject to hydrolysis, oxidation, and polymerisation in wines. Their concentration usually decreases during the fermentation and maceration, but that process may continue throughout the life of a wine. When coloured forms of anthocyanins are combined with grape or wine polymers, they become the significant contributor to the colour expression and the colour stability. These polymeric forms are less changed by the pH value and SO_2 presence than monomeric anthocyanin forms and do not usually decrease with wine age. With ageing, a greater proportion of the wine anthocyanins becomes polymerised.

Polymeric colour was 42.2–55.3%, depending on the age of the wine and the variety of grapes used.

3.2. The correlation between the antioxidant and antibacterial activities and phenolic composition of the wine samples

The antioxidant activity of the wine samples was estimated by the ability of the sample to scavenge the stable DPPH· free radicals (Roussis, Lambropoulos, & Soulti, 2005; Yen & chen, 1995). Wine is a complex mixture of polyphenols and the antioxidative capacity can be expressed as the amount of wine needed to quench a certain amount of DPPH·. The decrease in the absorbance at 517 nm is taken as a measure of the extent of radical-scavenging. All wine samples showed a higher DPPH· radical scavenging activity after incubation with a free radical solution.

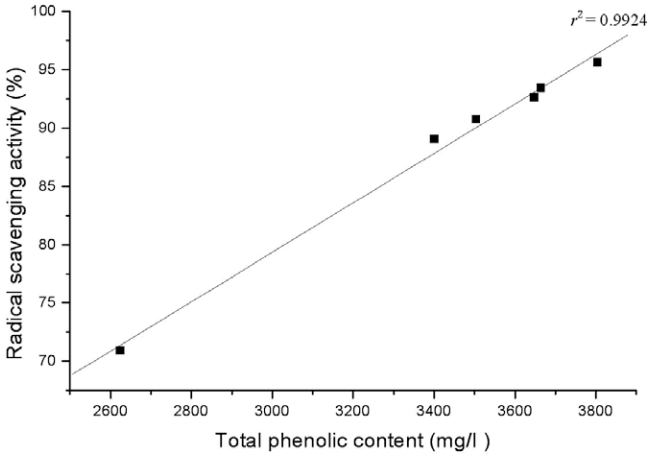

Fig. 2. Relationship between radical scavenging activity and total phenolic content of selected wine samples.

The high phenolic content in the investigated wines contributes to their increased antioxidant activity (Table 2). The investigated wines showed antioxidant behaviour in the range from 95.6% to 70%. Since structural features of phenolic compounds are responsible for the antioxidant activity, the antioxidant activities of the tested wines may be related to their total phenols content.

The percentage of DPPH· radical scavenging activity was plotted against total phenolic content of the wine samples in Fig. 2. For the investigated wines, the correlation between antioxidant activity and the total phenolic content was very good ($r^2 = 0.9924$, $SD = 0.9$, $p < 0.0001$, $n = 6$).

Also, the significant correlation between the anthocyanin content, and the DPPH· scavenging ability ($r^2 = 0.9936$, $SD = 0.8$, $p < 0.0001$, $n = 6$) of the tested wines was confirmed (Fig. 3).

Polyphenols have become a subject of much anti-infective research, due to the antibacterial, antifungal and antiviral activities (Daglia et al., 2007; Just & Daeschel, 2003; Papadopoulou et al.,

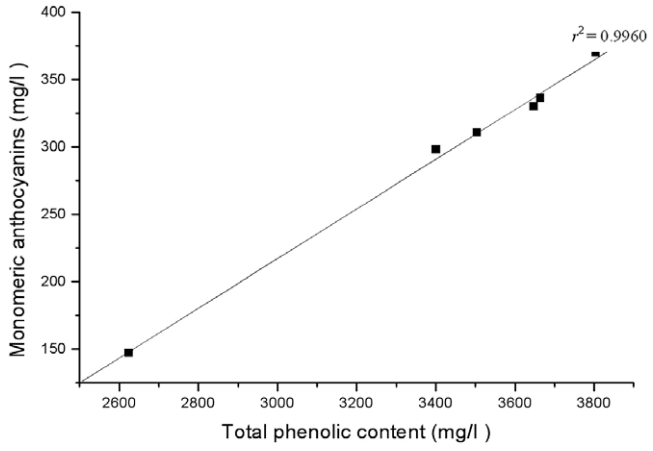

Fig. 1. Relationship between total phenolic content and monomeric anthocyanins of selected wine samples.

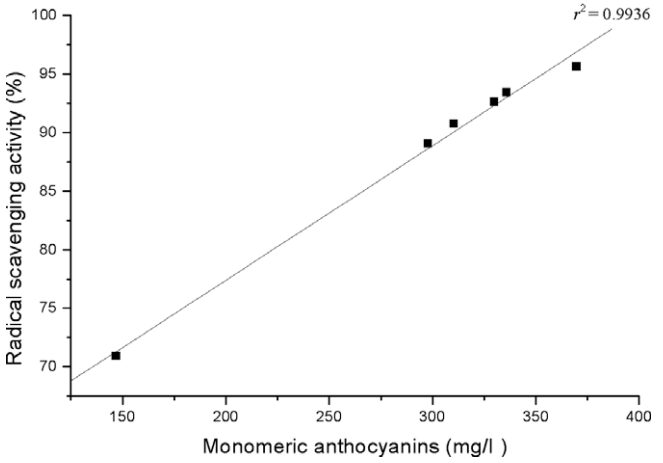

Fig. 3. Relationship between radical scavenging activity and monomeric anthocyanins of selected wine samples

Table 4
Antibacterial activities of red wines.

Wine[a]	*Staphylococcus aureus* ZI (mm)[b]	*Escherichia coli* ZI (mm)[b]
Terra Lazarica – Cabernet Sauvingon (2006)	22.0 ± 1.0	20.0 ± 0.5
Vranac (2007)	19.0 ± 0.5	18.0 ± 0.8
Rubin Crno (2007)	21.0 ± 1.2	18.5.0 ± 0.3
Medvedja krv (2007)	20.0 ± 0.5	19 ± 0.4
Terra Lazarica – Pinot Noir (2006)	17.8 ± 1.3	15 ± 1.2
Car Lazar (2006)	16.0 ± 1.2	12 ± 0.7
Penicillin (10 IU/disc)	30.3 ± 2.2	10 ± 0.0
Amoxicillin (25 μl/disc)	27.3 ± 1.2	21.3 ± 1.0

[a] 50 μl/disc.
[b] The value shown for the diameter of the inhibition zone are the means ± standard deviation values ($n = 3$).

2005). They can have an effect on the growth and metabolism of bacteria, activating or inhibiting microbial growth according to their constitution and concentration (NCCL (National Committee for Clinical Laboratory Standard), 1999). We have analysed the antibacterial activity of selected wine samples against *S. aureus* and *E. coli* strains. The diameter of inhibition zone (mm) obtained from the wine samples, reported in Table 4, shows that antibacterial activity against *S. Aureus* strains was in range from 16.0 to 22.0 mm, and against *E. coli* strains was in range from 12.0 to 20.0 mm.

It is clear, that the wines have different activities and that the different antibacterial activity is dependent on the grape varieties of tested wines.

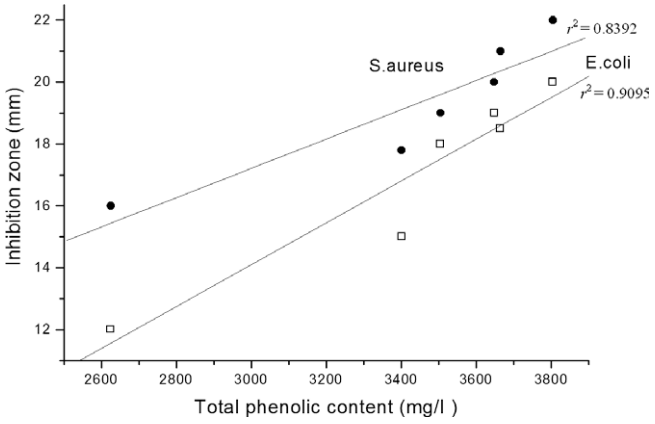

Fig. 4. Relationship between antibacterial activity against *S. aureus* and *E. coli* bacteria and total phenolic content ns of selected wine samples.

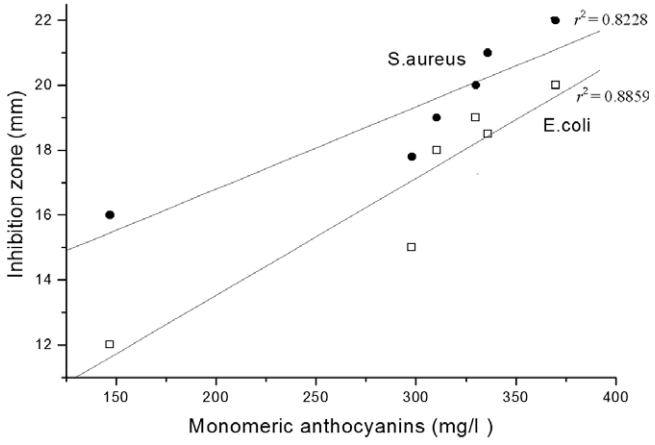

Fig. 5. Relationship between antibacterial activity against *S. aureus* and *E. coli* bacteria and monomeric anthocyanins of selected wine samples.

In all wines, the diameter of the inhibition zone for *S. aureus* was greater than the zone for *E. coli* strain, indicating that the gram-positive strain was more sensitive than the gram-negative one.

These data were used to derive a relationship between polyphenol content, anthocyanin content and antibacterial effect. The significant linear correlation was confirmed between total phenolic content (Fig. 4) and antibacterial activity against *S. Aureus* ($r^2 = 0.8392$, $SD = 190$, $p < 0.010$, $n = 6$) and against *E. coli* strains ($r = 0.9095$, $SD = 142$, $p < 0.003$, $n = 6$) (see Fig. 5).

There also was a significant linear correlation, between monomeric anthocyanins and antibacterial activity against *S. Aureus* ($r^2 = 0.8228$, $SD = 36.8$, $p < 0.012$, $n = 6$) and *E. coli* strains ($r^2 = 0.8859$, $SD = 29.5$, $p < 0.005$, $n = 6$).

It is important to determine which group of phenolic compounds is most significant in antioxidant and antibacterial activities of wines. Our results suggest that the amount of anthocyanins is very important for understanding of antioxidant and antibacterial potency of tested wines.

4. Conclusions

According to the obtained results, the free radical scavenging ability of Serbian wines is strongly correlated with phenolic and anthocyanin content. High amounts of polyphenols and anthocyanins and significant antioxidant activity were observed in the red wines produced from autochthonous vine varieties from the southern Serbia regions. Our results also show the significant correlation between the amounts of polyphenols and anthocyanins in Serbian wines with the antibacterial activity against *S. aureus* and *E. coli strains*. It can be concluded that Serbian red wines, produced from indigenous varieties *Prokupac* and *Vranac*, may serve as a very good source of potential antioxidant and antibacterial agents.

ABSTRACT

The antioxidant and tyrosinase inhibitory properties of extracts of mango seed kernel (*Mangifera indica* L.), which is normally discarded when the fruit is processed, were studied. Extracts contained phenolic components by a high antioxidant activity, which was assessed in homogeneous solution by the 2,2-diphenyl-1-picrylhydrazyl radical and 2,2′-azinobis (3-ethylbenzothialozinesulfonic acid) radical cation-scavenging assays and in an emulsion with the ferric thiocyanate test. The extracts also possessed tyrosinase inhibitory activity. Drying conditions and extraction solvent were varied, and optimum conditions for preparation of mango seed kernel extract were found to be sun-drying with ethanol extraction at room temperature. Refluxing in acidified ethanol gave an increase in yield and the obtained extract had the highest content of total phenolics, and also was the most effective antioxidant with the highest radical-scavenging, metal-chelating and tyrosinase inhibitory activity. The extracts did not cause acute irritation of rabbit skins. Our study for the first time reveals the high total phenol content, radical-scavenging, metal-chelating and tyrosinase inhibitory activities of the extract from mango seed kernel. This extract may be suitable for use in food, cosmetic, nutraceutical and pharmaceutical applications.

1. Introduction

The importance of natural antioxidants for cosmetic and food applications has been underlined by numerous works, as reported by Spigno and De Faveri (2007). The limitations of using a plant extract as a natural antioxidant are availability and cost. Conventionally, plants are harvested in a particular season, and hence the costs of plant sources vary, depending on the season. Moreover, synthetic antioxidants, such as butylated hydroxy anisole and butylated hydroxy toluene, are cheaper than are natural ones. Solid agri-food waste materials cause serious environmental problems, such as water pollution, unpleasant odours, explosions and combustion, asphyxiation, vegetation damage and greenhouse gas emissions (Zamorano, Pérez, Pavés, & Ridao, 2007). Consequently, there is considerable emphasis on the recovery, recycling and upgrading of agricultural wastes as a low-cost source of antioxidants. Many investigations on the reuse of agricultural wastes have been aimed at converting the waste materials into food ingredients, bio-fuels, and other value-added applications. Some agricultural wastes, such as grape seed and olive waste extracts, have been applied successfully for industrial scale isolation of natural antioxidants from the large quantities of plant residues (Peschel, Dieckmann, Sonnenschein, & Plescher, 2007). Solid wastes, generated from the processing of fruits and vegetables, are favourable raw materials for obtaining extracts rich in phenolic compounds with good antioxidant properties because of their low cost and the possibility of reducing environmental problems caused by waste disposal. In addition, the external fractions of vegetables (such as skins, peels, hulls, or seeds) are generally discarded, although they often have a greater concentration of phenolic compounds, potentially useful as antioxidants, than have their corresponding inner fractions (Soong & Barlow, 2004).

Mango (*Mangifera indica* L.), which belongs to the family Anacardiaceae, is the most cultivated fruit in Thailand. Processed mango products are among the major goods exported from Thailand. Therefore, several million tons of mango seed wastes are produced annually from factories. There are several varieties of mango grown in Thailand; the better known cultivars are Nam-Dok-Mai, Kaew and Chok-Anan. The Chok-Anan cultivar is popular for processing in factories and is available in all seasons. A preliminary study showed that the seed represents from 20% to 60% of the whole fruit weight, depending on the mango variety (Kaew, Nam-Dok-Mai, Khiew-Sawoey, Pimsaen, Chok-Anan, Rad, Phalun, Hua Chang, Mun Duan Kao, Ok-Rong and Maha-Chanok) and the kernel inside the seed represents from 45% to 75% of the whole seed. The Chok-Anan cultivar showed the highest seed weight of all the varieties studied.

Several studies have shown that mango seed kernels contain various phenolic compounds and can be a good source of natural antioxidants (Abdalla, Darwish, Ayad, & El-Hamahmy, 2007; Puravankara, Bohgra, & Sharma, 2000). Gallotannins and condensed

doi:10.1016/j.foodchem.2009.04.010

tannin-related polyphenols were reported to be present in mango kernels (Arogba, 1997). In addition, polyphenols from dry mango kernel meal were found to contain tannic acid, gallic acid, and epicatechin in the ratio 17:10:1, respectively (Arogba, 2000). Abdalla et al. (2007) have recently characterized the phenolic compounds in Egyptian mango seed kernels. The components included tannins, gallic acid, coumarin, ellagic acid, vanillin, mangiferin, ferulic acid, cinammic acid and unknown compounds.

Some phenolic compounds, such as ellagic acid, tannic acid and quercetin, act as potent tyrosinase inhibitors (Rompel et al., 1999; Shimogaki, Tanaka, Tamai, & Masuda, 2000). Tyrosinase is responsible for enzymatic browning in plants, and it may cause undesirable changes in colour, flavour and nutritive value of plant-derived foods and beverages (Kubo et al., 2000). This enzyme is a copper-containing enzyme which is mainly involved in melanin biosynthesis. Tyrosinase catalyses melanin biosynthesis in human skin and epidermal hyperpigmentation may cause various dermatological disorders, such as melasma, freckles and age spots (Karioti, Protopappa, Megoulas, & Skaltsa, 2007). Recently, safe and effective tyrosinase inhibitors have become important for their potential applications in improving food quality and preventing pigmentation disorders and other melanin-related health problems in humans (Miyazawa, Oshima, Koshio, Itsuzaki, & Anzai, 2003). Furthermore, tyrosinase inhibitors are also important in cosmetic applications for skin-whitening effects, because many men and women prefer a lighter skin colour. Since plants are a rich source of bioactive chemicals, and are mostly free of harmful side effects, there is an increasing interest in using them as a source of natural tyrosinase inhibitors.

The properties (e.g. antioxidant activity) of extracts from plants depend on the extraction solvent and extraction techniques used (Durling et al., 2007; Lim & Murtijaya, 2007; Spigno & De Faveri, 2007). Water and ethanol are commonly used to extract phytochemicals from plants due to absence of toxicity. Extraction with ethanol and water was investigated for isolation of possible antioxidants in the present study. A further study of the effect of the conditions for drying seed wastes on the shelf life of the raw material was also included. Since mango seeds are perishable in their fresh state, preservation of this raw material in the factory by sun-drying or hot air oven-drying, in order to preserve their desirable qualities, reduce storage volume and to extend their shelf life, is important. Moreover, most of the bound forms of phenolic compounds, after release by hydrolysis, were reported to show slightly lower antioxidant activity than do the free forms (Kumar, Nayaka, Dharmesh, & Salimath, 2006). Hence, extraction processes, which were employed to liberate free phenolics from their bound forms, were investigated. Selection of the preparation method, solvent and extraction conditions, on the basis of the free radical-scavenging capacity, metal-chelating activity, antioxidant potential, total phenolic content and tyrosinase inhibitory properties of the extract, was considered.

2. Materials and methods

2.1. Chemicals

Folin Ciocalteu's phenol reagent, 2,2-diphenyl-1-picrylhydrazyl (DPPH·), 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS·), ferrous sulfate, ferrozine, linoleic acid were purchased from Sigma Chemical Co., Ltd (St. Louise, USA). Gallic acid and ammonium thiocyanate were purchased from Acros Organics (New Jersey, USA). Dimethyl sulfoxide (DMSO), methanol and water (HPLC grade) were obtained from Merck (Darmstadt, Germany). 6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (trolox), ferrous chloride and mushroom tyrosinase were purchased from Fluka Co. (Buchs, Switzerland). Sodium bicarbonate, L-tyrosine, arbutin and the other chemicals and solvents used in this experiment were of analytical grade, purchased from Sigma-Aldrich Co., Ltd (Steinheim, Germany).

2.2. Preparation of plant sample

Three batches of sun-dried mango (*Mangifera indica* L. cultivar Chok-Anan) seeds were donated by Woraporn Co., Ltd., a mango processing manufacturer in Thailand from March to June, in 2007, as by-products. The seeds were washed and sun-dried in the greenhouse for three days and the kernels were removed manually from the seeds. The mango seed kernels (MSK) thus obtained were also oven-dried at 60°C for 72 h. The moisture content of sample materials was measured at 1, 3, 5, 10, 24, 48 and 72 h for calculation of the drying curve on a dry weight basis according to AOAC (1990). All determinations were performed in triplicate.

2.3. Preparation of mango seed kernel (MSK) extract

Each sun-dried or oven-dried sample (200 g) was extracted according to Maisuthisakul, Pongsawatmanit, and Gordon (2006). Briefly, a sample was ground using a CIM 24 SS pin mill (New York, USA) and blended with 95% ethanol (600 ml) in a blender for 1 min and shaken for 4.5 h (method 1). The supernatant was passed through Whatman filter paper (no. 4). All filtrates were evaporated under reduced pressure using a rotary evaporator at 50°C and the remaining water was removed by freeze-drying and weighed to determine the yield of soluble components. The freeze-dried extract was flushed with nitrogen and stored in aluminium foil at −20 °C until it was analysed. Extraction was repeated on each batch of plant material until at least 50 g of extract was collected for each plant material. The dried extracts and reference samples (arbutin, coumarin ellagic acid, gallic acid and tannic acid) were used to estimate the total phenolic content, chelating activity, and antioxidant capacity through various chemical assays and also the tyrosinase inhibition assay.

In order to investigate the effect of extraction and hydrolysis conditions, Dried MSK from the selected drying method was divided into three portions. Each portion (ca. 200 g) was accurately weighed. The first sample was extracted as described above (method 1). The other samples were refluxed with ethanol for 3 h (method 2) and refluxed with 1.2 M hydrochloric acid in ethanol for 3 h, after which the acid solution was neutralized with 1% sodium carbonate (method 3). The supernatant was passed through Whatman filter paper (no. 4). All filtrates were dried as described above. Extractions were performed in triplicate.

2.4. Determination of total phenolic content

The total phenolic content of extracts was determined using Folin–Ciocalteu's phenol reagent (modified from Kähkonen et al., 1999). Briefly, each extract (200 l) was mixed with one ml of Folin–Ciocalteu's phenol reagent (thoroughly). After mixing for 3 min, 0.8 ml of 7.5% (w/v) sodium carbonate was added. The mixtures were agitated and allowed to stand for a further 30 min in the dark. The absorbance of plant extracts and a prepared blank were measured at 765 nm using a spectrophotometer (UV–Vis model 1601, Shimadzu, Japan). The concentration of total phenolic compounds in all plant extracts was expressed as mg of tannic acid equivalents per g dry weight of MSK using a linear equation. All determinations were performed in triplicate.

2.5. Determination of chelating activity

The ferrous ion-chelating activity of studied samples was estimated, based on the decrease in the maximal absorbance of the

iron (Fe^{2+})–ferrozine complex according to previously reported methods (Dinis, Madeira, & Almeida, 1994), with some modifications. Briefly, 1 ml of a solution of a test compound at various concentrations dissolved in ethanol was incubated with 0.5 ml of $FeCl_2 \cdot 4H_2O$ (1.0 mM). The reaction was initiated by the addition of 1 ml of ferrozine (5.0 mM), and then the total reaction volume was adjusted to 4 ml with ethanol. After the mixture had reached equilibrium (10 min), the absorbance at 562 nm was read. The control was prepared without the test compound. Fe^{2+}-chelating activity of the test compound was calculated from the following formula: chelating activity (%) = $[(A_{control} - A_{sample})/A_{sample}] \times 100$. The chelating activity (%) was plotted against the plant extract concentration (g/ml) to determine the concentration of extract necessary to reduce chelation by 50% (CA_{50}). Samples with a lower CA_{50} had a stronger chelating activity. All tests and analyses were carried out in triplicate and averaged.

To check the ability of MSK or reference samples to chelate copper, the UV–visible spectra (200–400 nm) of the MSK extracts and their Cu-complexed counterparts were measured. The mixture, consisting of 1.0 ml of methanol, 1.0 ml of sample (16.5 mg ml^{-1}) solution and 1.0 ml of the aqueous solution of $CuSO_4$ (5–50 μM) or water (control) was incubated at 25° C for 10 min before UV–Vis spectral analysis.

2.6. Determination of antioxidant activity

The total free radical-scavenging capacity of MSK or reference samples was determined by using the DPPH· and ABTS· methods. The antioxidant activity in a linoleic acid emulsion system was also determined.

The free radical-scavenging activity of MSK or reference samples was evaluated using the stable radical, DPPH· according to the method of Masuda et al. (1999). DPPH radical in methanol (5 mM) was prepared and this solution (100 l) was added to the extract or antioxidant sample solutions in methanol (4.9 ml) at various concentrations. After 30 min, absorbance was measured at 517 nm. The percentage of DPPH radical-scavenging activity of each plant extract was calculated from: $[A_o - (A_1 - A_s)]/A_o \times 100$. A_o is the absorbance of the control solution (containing only DPPH); A_1 is the absorbance of the DPPH· solution containing plant extract; and A_s is the absorbance of the sample extract solution without DPPH·. The DPPH· activity (EC_{50}) was calculated using a plot of per cent radical-scavenging activity against concentration, as described for CA_{50}. These values were changed to antiradical activity (A_{AR}), defined as $1/EC_{50}$, since this parameter increases with antioxidant activity. All determinations were performed in triplicate.

The ABTS radical cation-scavenging activity was determined according to Re et al. (1999). The ABTS radical cation was prepared by reacting an aqueous solution of ABTS (7 mM) with potassium persulfate (2.45 mM, final concentration), which was kept in the dark at 25°C for 12–16 h. The solution was diluted in ethanol to an absorbance of 0.70 (0.20) at 734 nm before use. Aliquots of trolox or sample in water (20 l) were added to 2.0 ml of this diluted solution, and the absorbance at 734 nm was determined at 30°C exactly 6 min after initial mixing. The antioxidant solution reduces the radical cation to ABTS which reduces the colour. The extent of decolorization is calculated as percentage reduction of absorbance, and this is determined as a function of concentration and calculated relative to the equivalent trolox concentration. The activity of each antioxidant was determined at three concentrations, within the range of the dose–response curve of trolox, and the radical-scavenging activity was expressed as the trolox equivalent antioxidant capacity (TEAC), defined as mMol of trolox per gramme of sample. All determinations were performed in triplicate.

The antioxidant activity in a linoleic acid emulsion system of MSK or reference samples was determined using the thiocyanate method (Hu, Xu, Chen, & Yang, 2004), with some modifications. Each sample, at various concentrations, in 0.5 ml of absolute ethanol, was mixed with 0.5 ml of 5.21% linoleic acid in absolute ethanol, 1 ml of 0.05 M phosphate buffer (pH 7), and 0.5 ml of distilled water and placed in a screw-capped tube. The reaction mixture was incubated in the dark at 40 °C in an oven. Aliquots of 0.1 ml were removed every 24 h during incubation and the degree of oxidation was measured by sequentially adding ethanol (9.7 ml, 75%), ammonium thiocyanate (0.1 ml, 30%) and ferrous chloride (0.1 ml, 0.02 M in 3.5% HCl). After the mixture was rested for 3 min, the peroxide value was determined by monitoring absorbance at 500 nm until the absorbance of the control reached the maximum. The antioxidant activity was calculated as percentage of inhibition relative to the control. The degree of linoleic acid peroxidation was calculated using the following formula: antioxidant activity = $[(A_{control} - A_{sample})/A_{control}] \times 100$. The antioxidant activity was plotted against sample concentration in order to determine the concentration required to achieve a 50% inhibition of linoleic acid oxidation [AA_{50}]. All tests and analyses were carried out in triplicate and averaged.

2.7. Determination of tyrosinase inhibition activity

Mushroom tyrosinase (EC 1.14.18.1) was used for the bioassay because it is readily available. Since the mode of inhibition depends on the structure of both the substrate and inhibitor, L-DOPA was used as the substrate in this experiment, unless otherwise specified. Therefore, inhibitors discussed in this paper are inhibitors of diphenolase activity of mushroom tyrosinase, and their effect on the enzyme was determined by spectrophotometry, based on dopachrome formation at 475 nm. All the samples were first dissolved in dimethyl sulfoxide (DMSO) and used for the experiment at 30 times dilution. The assay was performed as previously described (Fu, Li, Wang, Lee, & Cui, 2005), with some modifications. L-DOPA solution (0.87 ml, 4.5 mM) was mixed with 0.9 ml of 0.1 M phosphate buffer (pH 6.8), and incubated at 30 °C for 5 min. Then, 0.9 ml of various concentrations of sample solutions followed by 0.03 ml of the aqueous solution of mushroom tyrosinase (4000 units) was added to the mixture and the enzyme reaction was monitored by measuring the change in absorbance at 475 nm (at 30°C), corresponding to the formation of dopachrome, for 25 min at 1 min intervals. Controls, without inhibitor but containing 3.3%DMSO, were routinely determined. The per cent inhibition of the enzyme by the active compounds was calculated as follows: inhibition (%) = $[(A_{control} - A_{sample})/A_{control}] \times 100$. The inhibitory effect (%) of the compounds was expressed as the inhibitor concentration causing 50% loss of enzyme activity (ID_{50}). All the studies were carried out at least in triplicate. The type of inhibition by MSK extracts and some reference compounds towards the enzyme was assayed by a Lineweaver–Burk plot. The inhibition constant was determined by plots of the apparent 1/Vm or km/Vm versus the concentration of the inhibitor, as described by Chen et al. (2005).

2.8. Determination of acute skin irritation

The acute skin irritation caused by the MSK extract was investigated in rabbit skin by the Thailand Institute of Scientific and Technological Research, Ministry of Science and Technology, Thailand according to the Test Guideline No. 404: Acute Dermal Irritation/Corrosion of OECD Guidelines for Testing of Chemicals (Organization for Economic Co-operation, 2002). Briefly, an area of skin approximately 10 × 10 cm on the dorso-lumbar region of each rabbit was clipped free of hairs. Two areas of the shaven skin approximately 2.5 × 2.5 cm were selected. Extract (0.5 g) was dissolved in 0.5 ml of distilled water and introduced onto a 2.5 × 2.5 cm gauze

patch, which served as the treated patch while 0.5 ml of distilled water, on another patch, served as a control patch. Both were applied to the selected skin sites on each rabbit. The patches were then secured to the skin by transpore adhesive tape. The entire trunk of the rabbit was wrapped with elastic cloth to avoid dislocation of the patch for 4 h. The scores of skin reaction were evaluated at 1, 24, 48 and 72 h after removal of the patches. Further observation was made, as necessary, to establish whether reversibility of the irritations occurred. In addition, to the observation of irritation, any lesions and other toxic effects were recorded.

2.9. Statistical analysis

Results are presented as mean values ± standard deviation (at least three replicate experiments). Analysis of variance and significant differences among means were determined by one-way ANOVA using SPSS (Version 10, SPSS Inc., Chicago, USA.). Significant differences were declared at $P < 0.05$.

3. Results and discussion

3.1. General investigations

A systematic investigation of the drying procedure, solvent type and extraction process was carried out on a laboratory scale to determine the conditions for preparation of the optimal MSK extract to use as an antioxidant or whitening agent. The effects of each process parameter on the extract yield, total phenolic content (TP), chelating activity (CA), antioxidant capacity (AC) and also tyrosinase inhibition (TIA) are discussed below.

3.2. Effects of drying procedure and solvent type on moisture content, yield, phenolic components, chelating activity, antioxidant activity and tyrosinase inhibition activity

Polyphenols are heat-sensitive (Spigno & De Faveri, 2007), therefore 60°C was chosen for drying in the hot air oven, since higher temperatures may cause excessive degradation.

Curves of moisture content versus drying time of MSK samples are shown in Fig. 1. The final moisture content of sun-dried MSK (SDMSK) was 9.81 ± 0.34% (dry weight basis). The average temperature in a greenhouse was 53°C. The moisture contents of MSK at 10 and 24 h were not different because it was night time. Usually, the final moisture content of dried natural plant products ranges from 5% to 15% (Nijhuis et al., 1998). It was found that, with hot air oven-drying of MSK (ODMSK), 4.38 + 0.47% moisture content could be reached within 48 h at 60°C. The shelf life for storage of SDMSK and ODMSK at 30°C without mould growth was more than 3 months.

The extract yield and colour, including TP, as a function of drying method and solvent type are shown in Table 1. In this study, ethanol and water were used as solvents because they are non-toxic and are accepted as ingredients in food and cosmetics. Statistical analysis indicated that drying method and extraction solvent

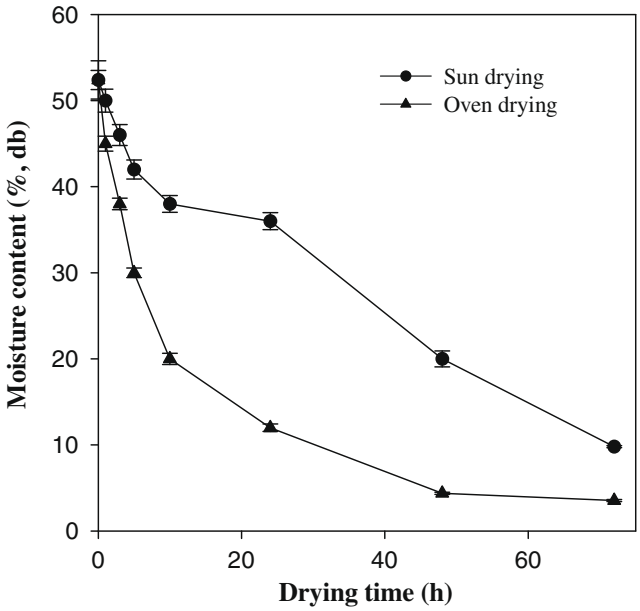

Fig. 1. Drying curves of MSK using sun-drying and oven-drying.

influenced yield for all the measured phenolic compounds ($P < 0.05$). The colour and moisture content of the extracts varied, depending on the drying conditions and solvent type (Table 1). The colour of SDMSK extracts, both with ethanol [SDMSK (EtOH)] and with water [SDMSK (H_2O)], was darker than that of both ODMSK (EtOH) and ODMSK (H_2O), while the moisture content of the SDMSK extract was higher than that of the ODMSK extract. The determination of total phenolic compounds by the Folin–Ciocalteu method was included in this study since many individual phenolic compounds, which provide antioxidant activity in fruits, cannot be identified and measured by HPLC methods (Ferreira et al., 2002). The content by the HPLC method was only 50–60% of the level analysed by the Folin–Ciocalteu method (Ferreira et al., 2002). The TP of MSK, expressed as tannic acid equivalents, varied from 44.5 ± 0.36 mg/g to 89.92 ± 0.23 mg/g. The content of phenolic compounds in our samples was slightly lower than those found in extracts of MSK extracted with methanol and water (50:50) by Soong and Barlow (2004) which were expressed as gallic acid equivalents.

Table 2 shows the CA and antioxidant activity in the linoleic acid emulsion system of extracts obtained using different drying methods and extraction solvents. In this study, the CA results were expressed as $1/CA_{50}$ values for comparison. A moderate metal-chelating effect, with ferrous ions (Fe^{2+}), of samples was observed in comparison to the standard gallic acid (Table 2). Measurements showed that the SDMSK (EtOH) extract had the highest total phenolic content (Table 1) and the highest chelating activity (Table 2).

The inhibition of lipid oxidation in the emulsion system by the standards (Table 2) followed the order: tannic acid > ellagic

acid = gallic acid > arbutin > coumarin. Antioxidant activity is generally higher in polyaromatic polyphenol compounds, such as tannic acid; but there are other factors: O–H bond dissociation energy, resonance delocalisation of the phenoxy radical and steric hindrance derived from a bulky substituent in the ortho position on the aromatic ring that also can influence this property (Rao & Gianfreda, 2000). Sánchez-Moreno, Larrauri, and Saura-Calixto (1999) reported that tannic acid was more effective than was gallic acid as an antioxidant in the linoleic acid emulsion system which was consistent with this result. The ethanolic extracts of both SDMSK and ODMSK exhibited higher antioxidant efficiency and chelating efficiency than did the extracts obtained by water extraction (Table 2). Typically, proteins and polysaccharides are also extracted when using water extraction (Shi et al., 2003). This may be the reason why yields of water extracts were higher than that of ethanolic extracts (Table 1) in contrast with the results for antioxidant efficiency and chelating efficiency (Table 2).

The scavenging of DPPH· and $ABTS^{\cdot+}$ were determined and compared to reference compounds (Table 3). Among the reference compounds studied, the order of DPPH·-scavenging activity was: ellagic acid > gallic acid > tannic acid > arbutin = coumarin, which is consistent with the DPPH·-scavenging activity of some polyphenols reported elsewhere (Kumar et al., 2006). The order of scavenging of $ABTS^{\cdot+}$ by the standards was slightly different from that of DPPH·. Arbutin showed higher $ABTS^{\cdot+}$-scavenging activity than did coumarin. This may be due to the stronger attractive interactions between the more polar arbutin and the more polar $ABTS^{\cdot+}$. Dried aqueous extracts were less effective in scavenging both DPPH· and $ABTS^{\cdot+}$ than were the ethanolic extracts. In the present study, the highest DPPH·- and $ABTS^{\cdot+}$-scavenging activities of the

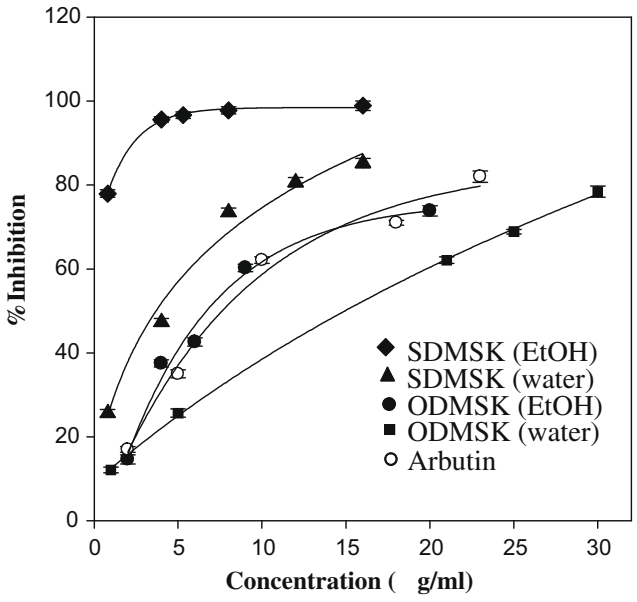

Fig. 2. Tyrosinase activities of MSK prepared with different drying conditions and extraction solvent compared to arbutin.

sample extracts were shown by SDMSK (EtOH). It is known that the solvent used in the extraction may affect the antioxidant activity of the extract, by its effect on the content and composition of the phenolic extract. The radical-scavenging activity of extracts is related to the content and structures of the phenolic components (such as gallic acid, ellagic acid, coumarin (Abdalla et al., 2007) and tannic acid (Arogba, 2000)), which differ in their electron transfer/hydrogen-donating abilities.

Fig. 2 shows the effect of concentration of MSK extracts, prepared by different drying and solvent extraction procedures, on inhibition of tyrosinase activity. This is the first report of the tyrosinase inhibitory activity of MSK. Tyrosinase catalyses two different reactions: the hydroxylation of monophenols to *o*-diphenols (monophenolase activity) and the oxidation of *o*-diphenols to o-quinones (diphenolase activity), both using molecular oxygen (Karioti et al., 2007). The tested compounds were assayed for the diphenolase inhibitory activity which demands L-DOPA as substrate. In comparison with arbutin, a naturally occurring cosmetic vehicle and whitening agent with tyrosinase inhibitory activity (Barsoom, Abdelsamad, & Adib, 2006), MSK extracts exhibited potent inhibitory activity (Fig. 2). Masuda, Kirikihira, and Takeda (2005) observed that seashore plant species, which are exposed to full sunlight, possess strong antioxidant activity and high tyrosinase inhibition ability. Findings from this study are consistent with this observation. In the comparison of extracts prepared with the different drying methods and extraction solvents at room temperature, SDMSK (EtOH) had the highest TP and AC values in the three methods, the DPPH·- and $ABTS^{\cdot+}$-scavenging activities and the emulsion method (Tables 1–3). SDMSK (EtOH) also showed a high metal-chelating activity. This extract thus has good tyrosinase inhibition ability, high antioxidant activity and good metal-chelating properties due to the content and structures of phenolic compounds present in the extract. This is consistent with previous reports that a good correlation exists between TP and tyrosinase inhibition ability (Madani, Kermasha, & Bisakowski, 1999).

The selected optimum drying and solvent extraction conditions for extraction of phenolics from raw material (MSK) were sun-drying for 3 days with ethanol extraction, which gave an extract with

the highest total phenolic content, chelating efficiency and antioxidant efficiency.

3.3. Effect of extraction and hydrolysis conditions on moisture content, yield, phenolic components, chelating activity, antioxidant activity and tyrosinase inhibition activity

Acid hydrolysis with heating was reported to give an extract with the highest antioxidant activity from mango kernel, and these conditions released free gallic acid and ellagic acid (Soong & Barlow, 2004). In order to achieve the best conditions, TP, CA, AC and TIA were evaluated for the SDMSK obtained using three different conditions (shaking, refluxing and acid hydrolysis). As expected, the TP and CA of MSK extracted after acid hydrolysis (AMSK) were higher than the values for samples of MSK extracted using shaking (SMSK) and refluxing (RMSK) conditions (Table 4). The TP of MSK extract in our study ranged from 90.0 mg of tannic acid equivalents per gramme (TAE/g) to 286 mg of TAE/g. The level of TP was slightly higher than that reported by Arogba (1997). This work showed that the extraction and hydrolysis procedure has a substantial effect on the content of phenolic compounds present in MSK. Acid hydrolysis released and degraded some phenolic compounds which is consistent with the work of Krygier, Sosulski, and Hogge (1982) and Chiang, Shih, and Chu (2001). Most phenolic

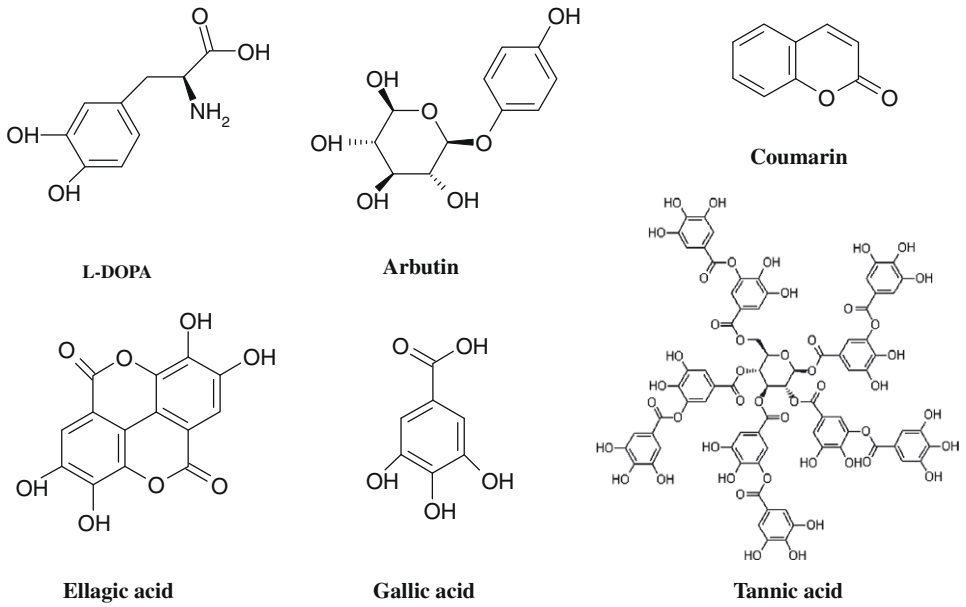

Fig. 4. Chemical structures of studied compounds.

compounds in plant seeds primarily occur in the bound form as conjugates with sugars, fatty acids, or proteins (Krygier et al., 1982). Therefore, it is important that a hydrolysis process is adopted in order to obtain maximum yield of the phenolic content of mango seed kernel. Moreover, the yield from the acid hydrolysis method was greater than that from the extraction methods without hydrolysis. The result was consistent with that of Troszynska and Ciska (2002). They found that acid hydrolysis released a greater concentration of phenolic compounds, such as protocatechuic acid, from the seed. The colour and moisture content of the extracts varied, depending on the extraction conditions (Table 4). The colour of MSK extracts from acid hydrolysis (method 3) was darker than that of both methods (methods 1 and 2). The moisture contents of all extracts from the different procedures was not sig-

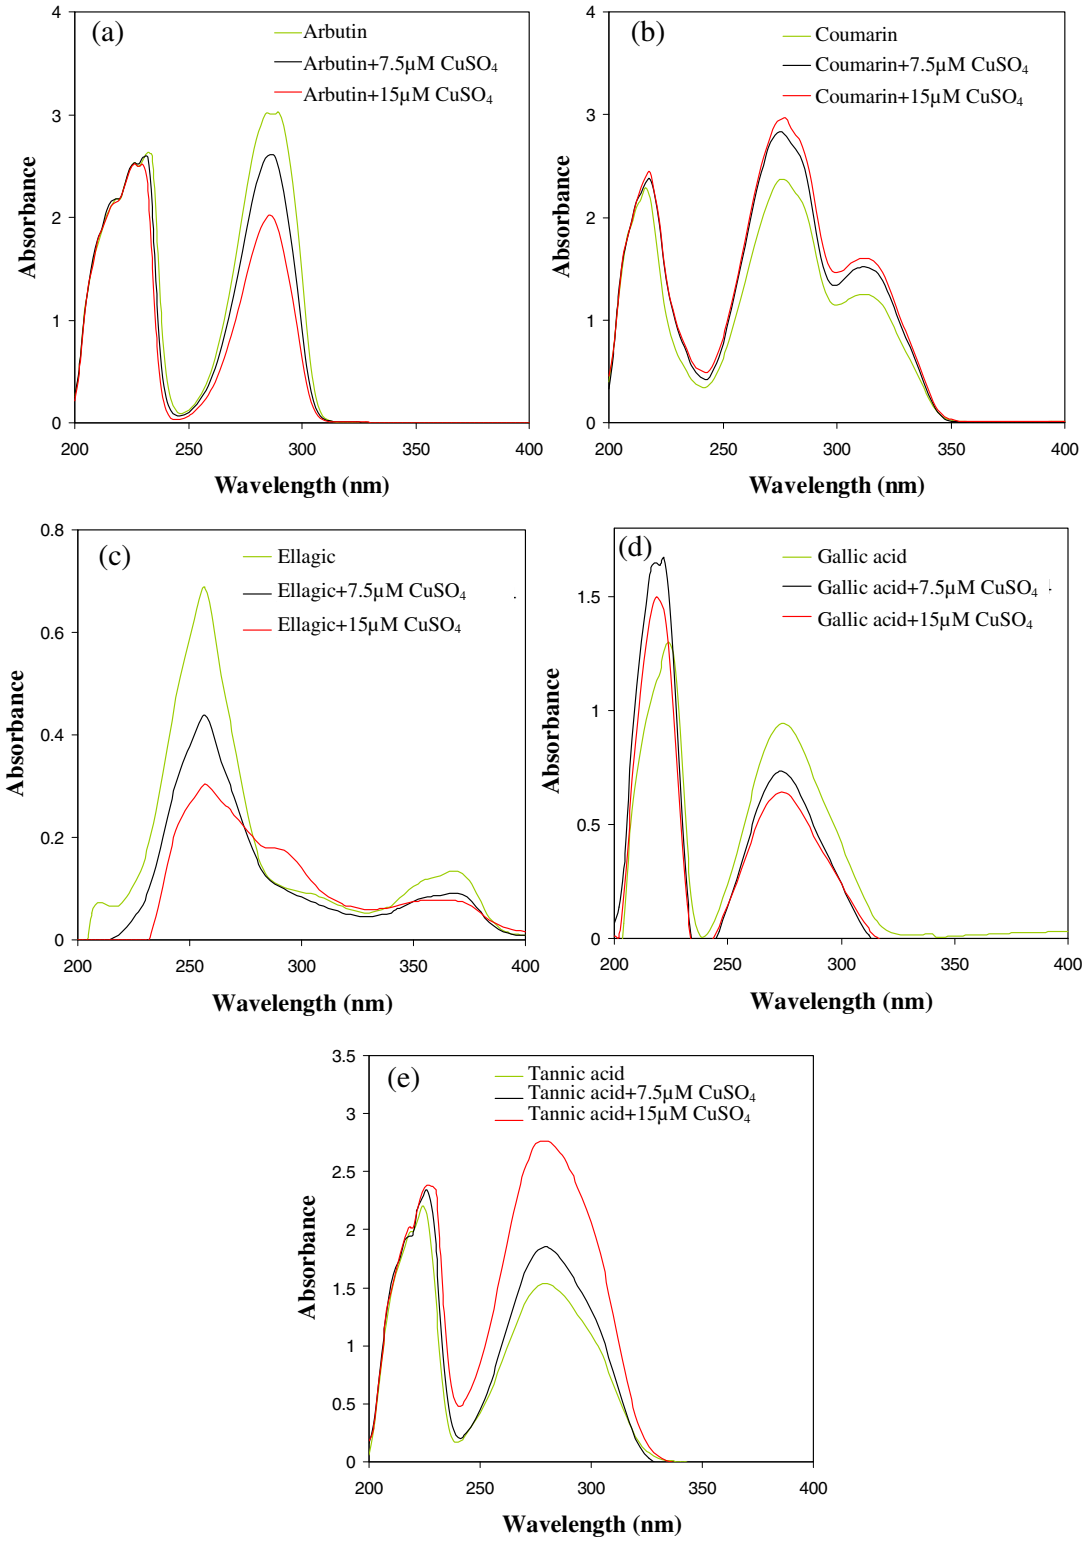

Fig. 6. Spectra of the complex formed between (a) arbutin, (b) coumarin, (c) ellagic acid, (d) gallic acid, and (e) tannic acid and several concentrations of Cu (II) ion.

nificantly different ($P \geqslant 0.05$) and ranged from 4.03 to 4.12% (dry weight basis).

There are few studies comparing the antioxidant properties of MSK extracts prepared with different extraction and hydrolysis conditions. According to the results shown in Table 4, The amount of TP showed the same order as the metal-chelating efficiency (Table 4) and the antioxidant capacity (Table 5). The DPPH radical-scavenging activity of SMSK, RMSK and AMSK extracts was strong, since the average EC_{50} values were 0.57 ± 0.05, 0.39 ± 0.04 and 0.24 ± 0.03 μg/ml, respectively, and these values were similar to those of gallic acid and ellagic acid. A similar order of radical-scavenging activity was seen in the ABTS radical cation assay. It can be seen that AMSK showed the highest antioxidant activity of the isolated extracts. This can be attributed to the higher phenolic content in AMSK (286 mg TAE/g) compared to that in the other extracts (212 and 90.0 mg TAE/g, respectively). The results suggested that some phenolic conjugates might be released by acid hydrolysis and the free form might provide more potent antioxidant activity. The good correlation between antioxidant activity and phenolic content of extracts obtained from various natural sources has been demonstrated by many workers (Jung, Heo, & Wang, 2008; Liu et al., 2008). Pérez-Jiménez and Saura-Calixto (2006) found that some compounds which have $ABTS^{\cdot+}$-scavenging activity did not show DPPH radical-scavenging activity. This is not the case in this study, as the plant extracts were able to quench both radicals. This showed the ability of the extracts to scavenge free radicals in different systems, indicating that they could be investigated as possible therapeutic agents for reducing radical-related pathological damage. All MSK samples obtained from methods 1–3, exhibited antioxidant activity, using the ferric thiocyanate method (FTC), similar to the DPPH and ABTS assays (Table 5). These findings showed that the phenolic compounds found in MSK were capable of both radical-scavenging activity inhibition of lipid oxidation.

The tyrosinase inhibitory activity (ID_{50}) of the MSK extracts was established using tyrosine as a substrate. The ID_{50} value for the most active MSK extract (AMSK) was lower than that of arbutin, and several components of the extract, including ellagic acid, gallic acid and tannic acid, contributed to the tyrosinase inhibitory activity, since they were more active than was the reference inhibitor used (arbutin) with a lower ID_{50} value (Table 6). Coumarin, however, was not an active component. Currently available tyrosinase inhibitors, such as arbutin, suffer from toxicity and/or a lack of efficacy. For these reasons, this is a good opportunity to use MSK as an alternative tyrosinase inhibitor.

To get an insight into the mode of inhibition of tyrosinase by MSK extracts, the effect of increased L-DOPA concentration on the kinetics of inhibition of mushroom tyrosinase by the studied compounds was further investigated by a Lineweaver–Burk plot. The results (Fig. 3) show that the plots of $1/V_o$ versus $1/[S]$ give a family of straight lines with different slopes that intersect one another in the Y-axis. The value of V_{max} remained the same (Table 6) and the value of km differed with different extraction procedures used for isolation of the MSK. The same value of V_{max} indicates that MSK extract is a competitive inhibitor of the enzyme. These inhibitors bind at the same site as the substrate and bind only to the free enzyme. As stated earlier, most competitive inhibitors closely resemble the molecular structure of the substrate. The phenolic compounds present in the MSK extract (including ellagic acid, gallic acid and tannic acid) are ortho-dihydroxyphenols, and they share this structural feature with L-DOPA (Fig. 4). Gallic acid also acted as a competitive inhibitor (Table 6). The km value of AMSK was the lowest one. A competitive inhibitor increases the apparent km value for a particular substrate, as shown by the three MSK extracts. Typically, the stronger the inhibitory activity, the higher the km value obtained. This indicates that the tyrosinase inhibitory effect of AMSK was stronger than that of RMSK and SMSK (Table 6).

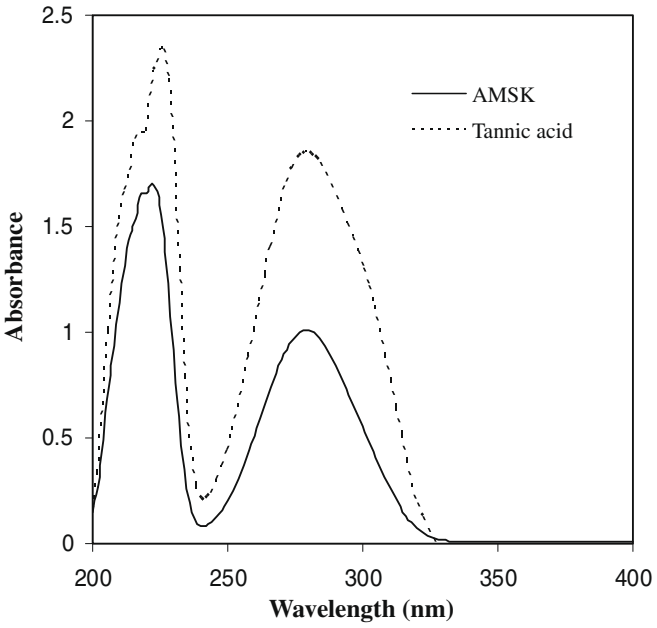

Fig. 7. Spectra of AMSK and tannic acid.

The inhibitory effects of MSK and studied reference compounds might be due to binding with copper, which is the metal at the centre of the active site of tyrosinase. The copper-chelating properties of the MSK extract and its component phenolics were investigated. Spectrophotometric analyses were conducted to establish the ability of polyphenols to bind copper. The UV–Vis spectra of polyphenol mixtures extracted from SMSK, RMSK and AMSK were not different (data not shown). As shown in Fig. 5, the $_{max}$ value was 220 nm with a shoulder at 212 nm for the AMSK sample. The increase in ratio of Cu (II) to AMSK caused increased absorbance at 224 and 280 nm, with the disappearance of the absorbance at 220 nm, showing that binding to Cu (II) occurred. The reference compounds, coumarin and tannic acid, showed similar binding to Cu (II) (Fig. 6b, d and e). Coumarin showed increasing absorbance at 217, 276 and 312 nm with increasing Cu (II) concentration. The UV–Vis spectrum of gallic acid increased in absorbance at 220 nm with increasing Cu (II) concentration, but the absorbance at 280 nm was reduced. Tannic acid showed changes in the absorbance pattern similar to AMSK. Interestingly, the UV–Vis spectrum of the AMSK extract was similar to that of tannic acid (Fig. 7). However, arbutin showed a decrease in the maximum absorbance at 288 nm (Fig. 6a) after the addition of Cu (II) ion, while ellagic acid showed a characteristic shift in $_{max}$ to shorter wavelength (Fig. 6c). There are few reports on changes in the UV–Vis spectra of plant extracts with Cu (II) addition. Wu, Chen, Ho, and Yang (2003) reported that adding Cu (II) ion to red koji extract caused an increase in absorbance at 250 nm.

Safety is a primary consideration for tyrosinase inhibitors, especially for cosmetic products. Therefore, the acute skin irritation values of SDMSK (EtOH) and AMSK were investigated. The results showed that all treated rabbits did not exhibit dermal irritation when treated with either extract.

4. Conclusions

It can be concluded that sun-drying, followed by ethanol extraction, is suitable for the preparation of an MSK extract. The optimum extract prepared by sun-drying and ethanol extraction contained a higher phenolic content, and its antioxidant capacity,

metal-chelating activity and ability to inhibit tyrosinase were higher than those of extracts prepared with oven-drying or water extraction. Acid hydrolysis of MSK extracts gave an increased yield of total phenolics and the extract had higher activity in terms of CA with Fe^{2+}, AC and TIA, compared to shaking and heating solvent extraction conditions. The kinetics of inhibition of mushroom tyrosinase showed that the MSK extracts acted as a competitive inhibitor of the enzyme. MSK extracts were also shown to be good chelators of copper.

ABSTRACT

We report purification and characterisation of a polyphenol oxidase from red Swiss chard (rcPPO). Our purification procedure resulted in a 39-fold enrichment in specific activity and 17% recovery of total enzyme activity. The purified rcPPO appeared as a monomeric protein of 41 kDa, with a specific conformation conserved in the Cu^{2+} combining region. It was optimally active at pH 7.5 and 45 °C. It had a diphenolase substrate preference towards L-DOPA, catechol and chlorogenic acid, but also exhibited weak monophenolase one toward 4-methoxyphenol and L-tyrosine. We also found that the enzyme was activated by K^+, Na^+, SDS and laurouyl sarcosine, but inhibited by divalent cations including Ca^{2+}, Cu^{2+}. Its activity was completely inhibited by ascorbic acid, cysteine, 1,4-dithiothreitol, β-mercaptoethanol, sodium diethyldithiocarbamate, sodium metabisulphite, sodium sulphite and thiourea. This first report on the purification and characterisation of red Swiss chard PPO provides a basis for understanding and use of this enzyme.

1. Introduction

Polyphenol oxidase (PPO) is a copper-containing enzyme that is capable of catalysing both molecular oxygen-dependent hydroxylation of monophenols to their corresponding *o*-diphenols (hydroxylation or monophenolase activity, E.C. 1.14.18.1) exemplified by the oxidation of tyrosine to L-(3,4-dihydroxyphenyl)-alanine (L-DOPA), and oxidation of *o*-diphenols such as L-DOPA to their cognate *o*-quinones, dopaquinone (diphenolase activity, E.C. 1.10.3.1) (Sánchez-Ferrer, Rodríguez-López, García-Cánovas, & García-Carmona, 1995). This enzyme is widely distributed in microorganisms, animals and higher plants. In plants, a significant body of literature on the catalytic properties of PPO has been reported. Research to date is mainly focused on the following three aspects: (1) its antiviral and antioxidant properties, as well as the protective effect against damage from ultraviolet radiation (Mayer, 2006), (2) its roles in darkening damaged tissue and in fruit and vegetable browning during storage and processing (Friedman, 1996), (3) its potential involvement in the betalain biosynthetic pathway (Steiner, Schliemann, Böhm, & Strack1, 1999; Gandía-Herrero, Escribano, & Garcia-Carmona, 2005), in which the PPO catalyses two different reactions: hydroxylation of tyrosine to form L-DOPA and oxidation of the DOPA to produce dopaquinone.

Red Swiss chard (*Beta vulgaris* subspecies *cicla*) is a herbaceous biennial leafy vegetable cultivated in many parts of the world for its year round availability, low cost and wide use in many traditional dishes. Different from its sister variety garden beet, red chard is rich in red–violet betacyanins in its leaf (Kugler, Stintzing, & Carle, 2004), not the root. The betacyanins in garden beet have been investigated widely for its physiological functions, such as scavenging powerful radical (Pavlov, Kovatcheva, Georgiev, Koleva, & Ilieva, 2002), inhibiting the proliferation of tumour cells in vitro (Reddy, Alexander-Lindo, & Nair, 2005), antimicrobial properties (Abdou, Abou-Zeid, & El-Sherberny, 1972), protective UV-filter and fungal resistance (Sepúlveda-Jiméneza, Rueda-Beníteza, Portaa, & Rocha-Sosa, 2004). The same physiological functions were demonstrated for the betacyanins of red chard. In addition to betacyanins, red chard contains in the leaf also a substantial amount of phenolic acids with antioxidant activity (Pyo, Lee, Logendra, & Rosen, 2004) and flavonoids with antimitotic activity on human breast cancer cells (Ninfali et al., 2007). Red chard has been used as an ingredient in folk medicine for hypoglycaemia (Bolkent, Yanardag, Tabakoglu-Oguz, & Özsoy-Sacan, 2000), inflammatory and haemorrhage. All of these physiological effects make red chard very valuable in field of medicine, in addition to a good alternative plant material for betacyanin pigment production. As leaf vegetables, red chard not only has a vivid colour in the leaf vein and petiole but also has some unique nutritional properties, for example, rich in vitamins A, C and B, calcium, iron, and phosphorus (Pyo et al., 2004). The attractive appearance of red chard it was even explored as a decoration item in many occasions. However, the appearance, flavour, taste and nutritional value of the red chard can be significantly reduced by enzymatic blackening or browning during harvest, processing or prolonged cold storage. The browning also interferes with extraction of betalain pigments and other

doi:10.1016/j.foodchem.2009.04.013

beneficial bioactive compounds, leading to a destructive colour change from bright charming red to dark-brown red, especially in the production of the red chard vegetable juice. Understanding red chard PPO characteristics is therefore needed to control enzymatic browning of red chard plant and its products.

To the best of our knowledge, red chard PPO has not been investigated although PPOs from garden beet (Gandía-Herrero, Garcia-Carmona, & Escribano, 2004) and a number of other plant species have been characterised. In this study, red Swiss chard PPO was purified and characterised, and its substrate specificity, pH and thermal stability of the PPO and the influence of surfactants, metal ions and inhibitors on the PPO's activity were determined. The information reported here provides a basis for understanding and potential use or inhibition of red chard PPO.

2. Materials and methods

2.1. Plant materials

Red chard plants were grown in a greenhouse with natural light and temperature fluctuated from 20–25 °C during the day to 15–20 °C at night. Plants were watered every 5 d. Fresh leaves harvested from the plants were washed, cut and processed for enzyme extraction immediately.

2.2. Reagents and chemicals

DEAE-Sepharose and Sephadex G-75 were purchased from Amersham Pharmacia Biotech (Uppsala, Sweden), substrates and molecular weight markers from Sigma Chemical Co. (St. Louis, MO, USA), the Bradford protein assay reagent, bovine serum albumin and electrophoresis reagents from Bio-Rad (Bio-Rad Laboratories, Hercules, CA). Other reagents were of analytical grade.

2.3. Enzyme extraction and purification

Fresh red chard leaves were homogenised with ice-cold 20 mM Tris–HCl (pH 7.5). The crude extract samples were filtered through four layers of cheesecloth and then centrifuged at 12,000*g* for 20 min. After centrifugation, several precipitations with solid ammonium sulphate, between 0–20%, 20–40%, 40–60%, 60–70%, and 70–80%, were examined to find the proper saturation point. The precipitate was dissolved in a small quantity of 20 mM Tris–HCl buffer (pH 7.5) and dialysed at 4 °C in the same buffer.

For further purification of PPO, the dialysed enzyme solution was loaded onto a Sephadex G-75 column (1.2 × 90 cm) equilibrated with 20 mM Tris–HCl buffer (pH 7.5). The dialysed enzyme solution was passed through the column, washed with the same buffer containing 25 mM NaCl. The elution rate was adjusted to 15–20 ml/h. Fractions (3 ml, each) were collected and the active fractions were pooled.

The final purification was done by DEAE-Sepharose Fast Flow ion-exchange column chromatography. The column was equilibrated with 20 mM Tris–HCl buffer (pH 7.5). The enzyme solution from the gel filtration was applied to the column and washed with the same buffer without any NaCl. Then the proteins bound to the column were eluted with a linear gradient of 0–1.0 M NaCl in Tris–HCl buffer (pH 7.5) at the same flow rate. Fractions were collected with 1.0 ml/min and were monitored at 280 nm. The enzymatic activities of the fractions were detected using 15 mM L-DOPA as substrate and the fractions with higher enzymatic activity were collected and pooled together for further characterisation studies.

In the elution processes of the column chromatograph, PPO activity was measured in the eluates showing absorbance at 280 nm. Thus, values obtained were plotted against the tube number. The final active elute was used for bioassay, sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS–PAGE) and other biochemical studies. Protein content was determined by the dye-binding method of Bradford (1976) with bovine serum protein as the standard.

2.4. Electrophoretic procedures

To determine the homogeneity and apparent molecular mass of the purified PPO, SDS–PAGE was performed on 12% acrylamide gels according to Laemmli (1970). In-gel staining of PPO activity was carried out using the reported procedures (Wang & Constabel, 2003).

2.5. Western blot

Immunodetection by Western blot was performed following the method described by Bollag and Edelstein (1991). Polyclonal anti-PPO antiserum was raised against recombinant 31-kDa polypeptide of *Amaranthus* sp. PPO protein, which was produced in our lab (Han et al., unpublished data). The purified red chard PPO was subjected to denaturing SDS–PAGE or Non-denaturing SDS–PAGE, transferred to nitrocellulose membrane and probed with anti-*Amaranthus* PPO polyclonal antibodies. Antibody binding was visualised using goat anti-rabbit IgG (H + L) alkaline phosphatase conjugate in a dilution of 1:4000 and alkaline phosphatase colour development reagents 5-bromo-4-chloro-3-indoyl phosphate (BCIP) and nitroblue tetrazolium chloride (NBT).

2.6. Enzyme assays and analysis of protein

PPO activity was determined by measuring the initial rate of quinone formation, as indicated by an increase in absorbance at 475 nm using L-DOPA as a substrate. Increment of 0.001 min^{-1} in absorbance was taken as one unit of enzyme activity (Ho, 1999). The increase in absorbance was linear with time for the first 120 s. The sample cuvette contained 2.95 ml of substrate solution in 20 mM Tris–HCl (pH 8.0) and 0.05 ml of the enzyme solution. The blank sample contained 2.95 ml of substrate solution and 0.05 ml of Tris–HCl buffer. Unless otherwise stated, experiments were repeated in triplicate. The results were expressed as absorbance increment/min.

2.7. Effect of pH and temperature

Optimum pH for rcPPO activity was estimated by monitoring its activity at pH range of 3.0–10.0 with buffers at concentration of 20 mM. The buffer systems used were citrate buffer for pH 2.0–3.5; acetate buffer for pH 4.0–5.5; phosphate buffer for pH 6.0–7.5; Tris–HCl buffer for pH 7.5–9.0; carbonate–bicarbonate buffer for pH 9.5–10.0. For determining its pH stability, the enzyme solution was incubated for 1 h at the given pH at 35 °C and then, its residual PPO activity was determined under the standard assay conditions.

For determining the optimum temperature of PPO reaction, the enzyme activity was measured at temperature ranging from 10 to 70 °C. The effect of temperature on PPO stability was determined by analysing PPO residual activity after the enzyme was incubated in a 20 mM Tris–HCl buffer (pH 7.5) for pre-determined time periods (10–60 min) at temperatures ranging from 30 to 80 °C.

2.8. Effect of inhibitors on enzyme activity

The effects of several potential inhibitors were evaluated, using L-DOPA as substrate. The reaction mixture was incubated at 35 °C and the change in absorbance was measured spectrophotometri-

cally at 475 nm. A control test was run in parallel in the absence of the inhibitor.

For determining the effect of metal ions on enzyme activity, reactions were performed by incubating the reaction mixture containing 1 ml of enzyme and 1 or 10 mM of metal ion, such as Na^+, K^+, Zn^{2+}, Co^{2+}, Ca^{2+}, Mg^{2+}, Mn^{2+} or Cu^{2+}. After incubation for 30 min at 35 °C, the remaining enzyme activity was assayed.

2.9. Substrate specificity

The oxidation of substrates by rcPPO was determined spectrophotometrically at the specific wavelength of each substrate in a 20 mM Tris–HCl buffer (pH 7.5). The PPO concentration used for the oxidation of each substrate was the same. Substrate specificity was examined by using 10 mM L-DOPA, catechol, *p*-dimethylphenol, *m*-dimethylphenol, chlorogenic acid, L-tyrosine, 4-methoxyphenol or gallic acid.

3. Results and discussion

3.1. Purification of red chard PPO

The purification steps and results were summarised in Table 1. Purification of rcPPO began with the extraction of PPO from fresh leaves of red chard in 20 mM Tris–HCl (pH 7.5) buffer containing ascorbic acid, which was used to reduce quinones to phenolic substrates during extraction. The precipitate obtained with 40–80% of $(NH_4)_2SO_4$ displayed maximum enzymatic activity on a protein content basis. This active fraction was dialysed using 10 kDa cut-off range dialysis membrane and applied to Sephadex G-75 column. Peak fractions with high enzymatic activities on 15 mM L-DOPA were collected in fractions 64–80 (Fig. 1a) and three protein peaks were eluted. This chromatography step removed most unwanted proteins of high and low molecular weight (Fig. 1a) but with a loss of only 30–40% of the total enzyme activity. The most active fractions (65–75) were combined for further purification. Up to this step, the betalain pigments influencing the measurement of PPO activity were completely removed. The last step of purification was performed with DEAE-Sepharose anion exchange chromatography. The enzyme was finally eluted at a salt concentration of 0.35 M NaCl along with a protein peak, corresponding to fractions of 35–60 (Fig. 1b).

Our purification steps resulted in a 39-fold purification. The overall activity yield of the purified PPO was 17%, with specific PPO activity of 18,084 U/mg. The obtained enzyme was used for further studies.

3.2. Molecular weight and purity

The molecular weight of the purified enzyme, as determined by SDS–PAGE under reducing conditions, was 41 kDa in average (Fig. 2a), which was lower than that of butter lettuce PPO (60 kDa; Gawlik-Dziki, Złotek, & Świeca, 2008), potato PPO (57–60 kDa), tomato PPO (57–62 kDa) and broccoli florets PPO (53.1 kDa) (Gawlik-Dziki, Szymanowska, & Baraniak, 2007), but higher than that of *Hevea brasiliensis* PPO (32 kDa and 34 kDa; Wititsuwannakul, Chareonthiphakornb, Pacec, & Wititsuwannakul, 2002). It was also much less than that of the PPO from beet root (54 kDa), a sister variety of red chard (Gandía-Herrero et al., 2004). Under non-denaturing SDS–PAGE, a single protein band was detected for PPO activity (Fig. 2b). On the same gel, a single protein band was also visualised and the band was at the same migration distance as that of the active staining, which confirmed that the purified homogeneous protein was PPO and suggested that the red chard PPO was a monomer.

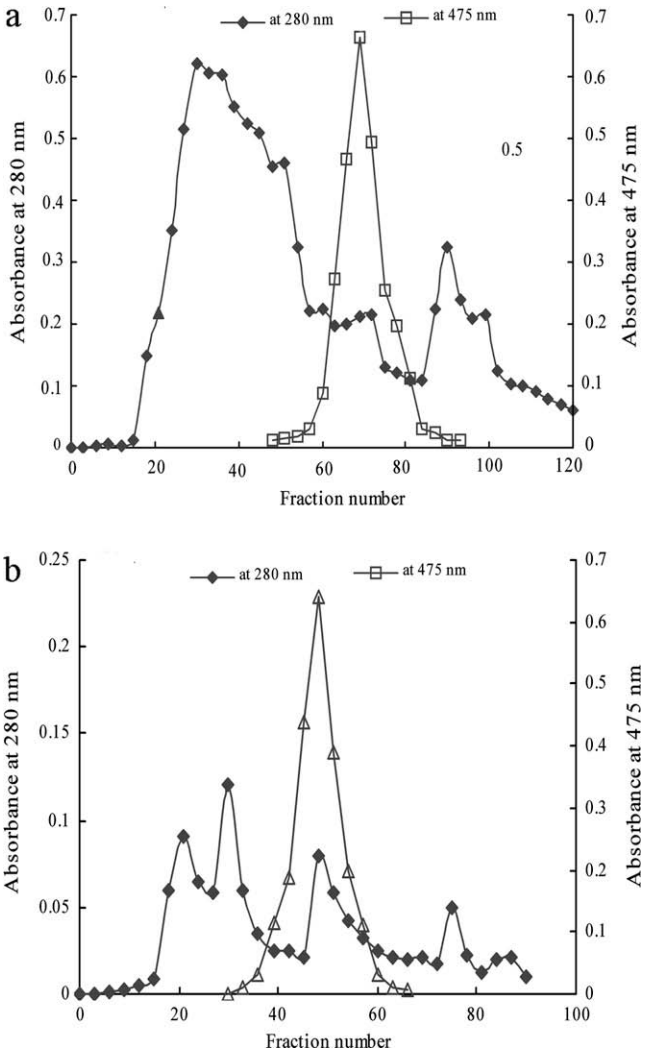

Fig. 1. Chromatographic elution profiles of PPO from red Swiss chard (a) Sephadex G-75 gel filtration chromatography. (b) Separation on DEAE-Sepharose Fast Flow anion exchange chromatography. Protein was monitored by UV absorbance at $\lambda = 280$ nm and the PPO activity, at $\lambda = 475$ nm as described in Section 2.

3.3. Western blot

To study the structural features of purified rcPPO, Western blotting was conducted following fully and non-denaturing SDS–PAGE

Table 1
Purification procedure of PPO from red Swiss chard leaves.

Purification steps	Total activity (U)	Total protein (mg)	Specific activity (U/mg protein)	Yield (%)	Purification (*n*-fold)
Crude extract	57216.75	124.00	461.42	100.00	1.00
Ammonium sulphate precipitation	38675.26	41.96	921.81	67.59	2.00
Sephadex G-75	19251.12	5.80	3318.75	33.65	7.19
Sepharose FF	9567.48	0.53	18084.21	16.72	39.19

with Anti-*Amaranthus* PPO antiserum. The purified rcPPO cross-reacted with the antiserum, and showed a single immunoreactive band corresponding to the single protein band visualised with Coomassie brilliant blue under fully and non denaturing conditions (Fig. 2). These features suggested that the purified rcPPO share the specific conformation conserved in the Cu^{2+} combining region of PPOs from many sources.

3.4. Effects of pH and temperature on PPO activity

Activity profiles of rcPPO were investigated at 45 °C between pH 3.0 and 10.0. As shown in Fig. 3a, the PPO was rapidly inactivated by the pH below 5.0. The activity of rcPPO gradually increased with pH value in the range of 5–7. Below and above pH 7.5, the activity decreased rapidly. Hence, the optimum pH value of rcPPO was 7.5. Furthermore, the enzyme appeared to prefer alkaline conditions since more than 70% of its optimal activity was kept between pH 7.5 and 10.0. The optimal pH of rcPPO is similar to that of *Allium* PPO (Arslan, Temur, & Tozlu, 1997), but higher than that of *Ferula* sp. (6.0) (Erat, Sakiroglu, & Kufrevioglu, 2006), and medlar fruit (6.5) (Dincer, Colak, Aydin, Kadioglu, & Güner, 2002).

For assessment on pH stability of the purified rcPPO, the enzyme was preincubated for 1 h at 35 °C using citrate buffer (pH range from 2 to 3.5), acetate buffer (pH 4.0–5.5), phosphate buffer (pH 6.0–7.5), Tris–HCl buffer (pH 7.5–9.0) or carbonate–bicarbonate buffer (pH 9.5–11). The enzyme was stable within pH 4–10 (Fig. 3b), retaining more than 80% of its activity in the pH range of 5–9, and the maximum in the pH 7.0–8.0. In general, the rcPPO showed more stable under the alkaline conditions. After incubating at pH 11.0 for 1 h the rcPPO still retained 74% of its activity whereas at pH 3.0, it was left with only 39.4% (Fig. 3b).

To determine temperature effect on enzyme activity, the standard reaction mixture was incubated at different temperatures

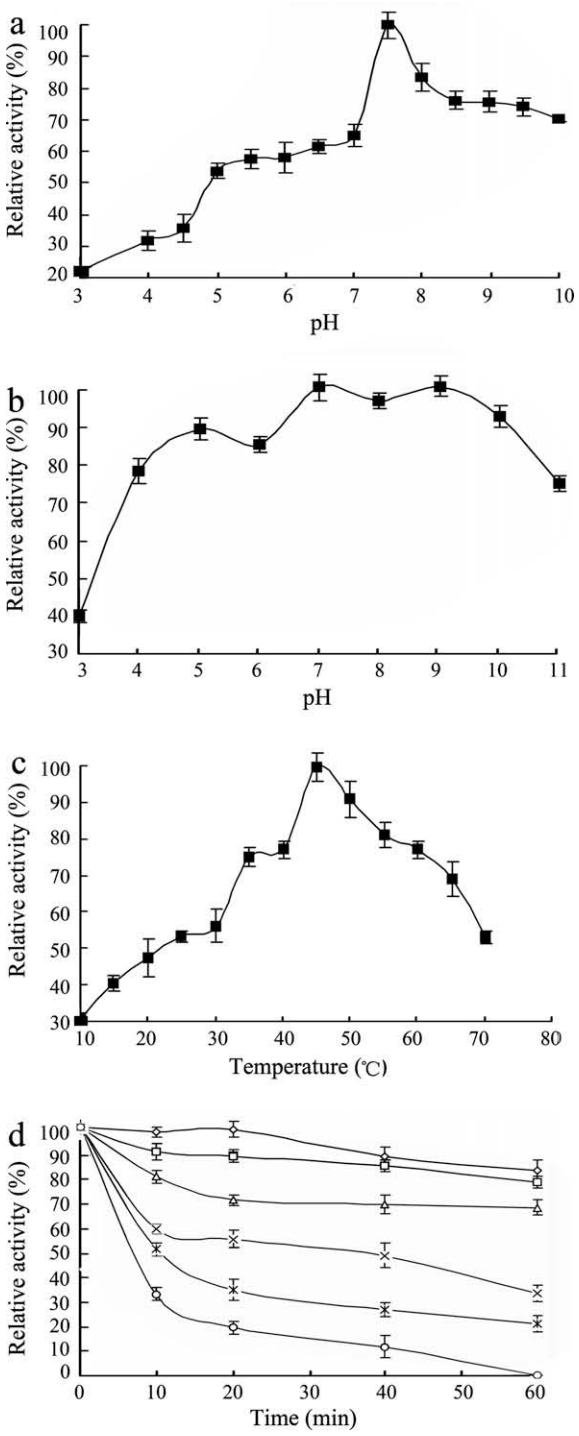

Fig. 3. Effect of pH and temperature on the activity of purified red Swiss chard PPO. (a) Optimal pH of rcPPO activity. (b) pH stability of rcPPO. (c) Optimal temperature of rcPPO activity. (d) Thermal stability of rcPPO. The rcPPO activity was measured with L-DOPA as substrate. For determination of the optimal temperature, the purified rcPPO was preincubated for 2 min at different temperatures, and then its activity was assayed at 45 °C. For determination of the thermal stability, the activity of purified rcPPO was tested after preincubation for 80 min at a given time at different temperatures: 30 °C (◇), 40 °C (□), 50 °C (Δ), and 60 °C (×), 70 °C (+) and 80 °C (○). The experiment was performed in triplicate and each value is expressed as the mean value ± standard deviation.

(10–70 °C). As shown in Fig. 3c, the activity of rcPPO gradually increased with temperature ranging from 10 to 45 °C, but followed by a decrease at higher temperatures. Thus, the temperature for the maximum PPO activity was estimated to be 45 °C for L-DOPA,

which was consistent with that of the mulberry PPO (Arslan, Erzengin, Sinan, & Ozensoy, 2004), but higher than that of some reported plant PPOs, such as peach, grape, plum, thymus and aubergine (Dincer et al., 2002; Dogan, Arslan, & Dogan, 2002; Dogan & Dogan, 2004).

The effect of temperature on rcPPO stability was also investigated by incubating the sample at 30–80 °C at definite intervals for a total of 80 min. The residual soluble PPO activity (Fig. 3d) remained above 60% after 40 min at 30, 40 and 50 °C and then decreased significantly when temperature reached at 60 °C, with only 55% activity in just 10 min. When the temperature was raised to 80 °C, the enzyme retained less than 18% of its original activity after 20 min and even less after prolonged incubation. A number of PPOs purified from different plants were stable in the 10–50 °C range. For example, butter lettuce PPO was stable at 40 °C for 60 min (Gawlik-Dziki et al., 2008), *Allium* sp. PPO at 40 °C (Arslan et al., 1997) and peppermint PPO at 30 °C for 30 min (Kavrayan & Aydemir, 2001).

3.5. Effects of surfactants on PPO activity

For determining the effect of different surfactants on the rcPPO activity, the purified rcPPO was incubated with surfactants at 35 °C for 1 h and the enzymatic activity was determined under normal assaying conditions. The PPO activity without any surfactants (control) was taken as 100%. As displayed in Table 2, the enzyme activity was drastically inhibited by CTAB (cationic), slightly by Tween-20 (nonionic), but not by Triton X-100, with 51%, 16% and 0% enzyme activity lost, respectively. In contrast to cationic (CTAB), anionic surfactants activated rcPPO, and the enzyme activity with 0.2% Laurouyl Sarcosine or SDS treatment was 124% and 133% of the control, respectively. The activation effect of SDS on the rcPPO was also reported in beet root (Gandía-Herreroi et al., 2004). SDS activation of PPO is a well-known phenomenon for many plants PPO (Moore & Flurkey, 1990), and this effect was attributed to the SDS-causing alterations of the enzymatic and physical characteristics, and a limited conformational change due to binding of small amounts of SDS (Moore & Flurkey, 1990).

Table 2
Effects of metal ions, common PPO inhibitors and surfactants on purified red chard PPO activity.
