3.6. Effect of metal ions and possible inhibitors on PPO activity

In order to determine the effect of metal ions and possible inhibitors on rcPPO activity, the rcPPO was incubated with 1 mM or 10 mM of different metal ions or some common PPO inhibitors (Table 2) for 30 min at 35 °C or pH 7.5, 45 °C, respectively, and then the residual activity was measured using standard protocol. The purified rcPPO activity in the absence of tested metal ions or inhibitors under optimal conditions (pH 7.5, 45 °C) was set as 100%.

As presented in Table 2, K^+ and Na^+, at 1 mM and 10 mM, had a positive effect, whilst divalent cations including Mg^{2+}, Ca^{2+}, Cu^{2+}, Mn^{2+}, Co^{2+} and Zn^{2+} generally had a negative one. Among the divalent cations tested, Cu^{2+} at 10 mM showed the strongest inhibitory effect, and 50% of the enzymatic activity was inhibited. This is not in agreement with what was reported by Aydemir in 2004 in artichoke heads.

Several common PPO inhibitors had an inhibitory effect on the rcPPO (Table 2). Purified rcPPO was extremely sensitive to sodium diethyldithiocarbamate (SDDC), a copper chelator, and more than 90% of its activity was inhibited by 1 mM of SDDC. However, the rcPPO was insensitive to EDTA and sodium azide, and more than 80% of its activity was retained even treated with higher concentration (10 mM). The tolerance of PPO to EDTA was also observed in the Barbados cherry (Anil Kumar, Kishor Mohan, & Murugan, 2008). Another metal ion chelator, citric acid, could inhibit the rcPPO activity by 25% and 35% at 1 mM and 10 mM, respectively. Strong reducing agents, sodium metabisulphite, sodium sulphite and ascorbic acid, inhibited completely rcPPO activity at the concentration of 10 mM. Sulphur containing compounds are known to be specific potent inhibitors of PPO by removing quinones and in turn preventing them from participating in melanizing reactions and/or reacting directly with the enzyme (Kong, Hong, Choi, & Kim, 2000). With regard to ascorbic acid, it may act more as an antioxidant than as an enzyme inhibitor, because it reduces the initial quinone formed by the enzyme to the original diphenol before it undergoes secondary reactions leading to browning (Gawlik-Dzik et al., 2008), although a irreversible inhibition of PPO was also observed (Golan-Goldhirsh & Whitaker, 1984). SH-blocking reagents, L-cysteine, β-mercaptoethanol and DTT, when used at 10 mM, resulted in a complete inhibition of rcPPO activity, suggesting that Cys residue(s) may be significant on the structure and conformation of the enzyme molecule. Thiourea had also a significantly inhibitory effect on rcPPO activity, and even at concentration of 1 mM, it inhibited more than 90% of the PPO activity (Table 2). These results suggest that cysteine, ascorbic acid, sodium sulphite and sodium metabisulphite may be used as inhibitor of enzymatic browning in red chard and its products.

3.7. Substrate specificity

The substrate specificity of purified rcPPO was studied by using 15 mM of monohydroxy-, dihydroxy- and trihydroxyphenol as substrates and at the optimal pH and temperature conditions, and results, presented as enzymatic activity relative to the oxidation of L-DOPA, are summarised in Table 3. The purified rcPPO showed enzymatic activity of monophenolase, diphenolase and even triphenolase, with the highest diphenolase activity detected with L-DOPA, followed by catechol, chlorogenic acid, *m*-dimethylphenol and *p*-dimethylphenol. The monophenolase activity of the

Table 3
Substrate specificity of purified red chard PPO.

Substrate	Wavelength	Relative activity[a] (%)
Diphenols		
L-DOPA	475	100
Catechol	420	86
p-Dimethylphenol	420	10.0
m-Dimethylphenol	420	11
Chlorogenic acid	400	80
Monophenols		
L-Tyrosine	400	2
4-Methoxyphenol	420	40
Trihydroxyphenols		
Gallic acid	420	73

[a] The relative activity is based on the enzymatic activity of rcPPO to substrate L-DOPA.

rcPPO was week when L-tyrosine and 4-methoxyphenol were used as monophenol substrates, and the relative activity was 5% and 40%, respectively. The triphenolase activity of the rcPPO indicated with gallic acid as substrate was moderate, between its monophenolase and diphenolase activity. These results revealed that the purified red chard PPO was a diphenolase with some low monophenolase activity, which is similar to PPOs purified from peppermint (Kavrayan & Aydemir, 2001), butter lettuce (Gawlik-Dziki et al., 2008) and dormant saffron PPO (Saiedian, Keyhani, & Keyhani, 2007).

Determined from Lineweaver–Burk plot, the K_m and V_{max} of rcPPO for L-DOPA, the most favourite substrate tested, were 3.17 mM and 1667 U/min/ml, respectively. Beet root PPO was reported to have the K_m of 6.16 mM (Gandía-Herrero et al., 2004), which is much higher than that of red chard PPO.

In summary, a polyphenol oxidase from red Swiss chard leaf was extracted, purified and characterised. The purified red Swiss chard PPO was as a monomeric protein of 41 kDa, with a specific conformation conserved in the Cu^{2+} combining region indicated by Western blot. It displayed as diphenolase with a weak monophenolase activity, and had much higher activity in the oxidation of L-DOPA than in hydroxylation of L-tyrosine. Its optimal active pH was at 7.5, and temperature at 45 °C. This enzyme was sensitive to some common PPO inhibitors, especially to sulphur-containing compounds, reducing agents and SH-blocking reagents. It could be activated by K^+, Na^+, SDS and laurouyl sarcosine, but inhibited by divalent cations, such as Mg^{2+}, Ca^{2+}, Cu^{2+}, Mn^{2+}, Co^{2+}, and Zn^{2+}. Purification and characterisation of the PPO provide a basis for understanding the enzyme in red Swiss chard, an excellent plant source for betacyanin pigment, bioactive compounds and nutritive ones. However, this is the first report on red Swiss chard PPO, and more studies are warranted to understand its isoenzymes if there are, its inhibition in relation to the browning reaction and its role in biosynthesis of betalain pigments.

Lipid oxidation
Irradiation
Rapeseed oil

ABSTRACT

The effect of α-, γ-, and δ-tocopherols (enrichment: 1000 ppm) on the peroxide formation in rapeseed oil triacylglycerols (RSOTG) was evaluated. The oxidation process was initiated by gamma-irradiation with doses of 4 and 10 kGy. Whereas a pronounced antioxidant effect was observed for γ- and δ-tocopherol (sequence: δ- > γ-tocopherol), the inhibition extent of α-tocopherol was insignificant.

1. Introduction

An increase in hydroperoxide formation with increasing radiation dose was found in various plant oils such as sunflower, soybean, palm and black cumin oils (Arici, Colak, & Gecgel, 2007; Zeb & Lutfullah, 2005; Lutfullah, Zeb, Ahmad, Atta, & Bangash, 2003). Tocopherols (TOH), especially α- and γ-TOH, naturally occur in a large number of mainly plant-derived tissues. Their antioxidative effect is based on an H-transfer from their hydroxyl group to lipid peroxyl radicals ($LOO^{\cdot}$), leading to the formation of lipid hydroperoxides (LOOH) and tocopheroxyl radicals ($TO^{\cdot}$). Although, the hydrogen-donating power is in the order α > γ > δ, a reverse order in antioxidant potency has been obtained in most experiments with fats, oils and lipoproteins (Kamal-Eldin & Appelquist, 1996; Yanishlieva, Kamal-Eldin, Marinova, & Toneva, 2002). Also prooxidant effects of tocopherols have been reported (Isnardy, Wagner, & Elmadfa, 2003). For α- and γ-TOH a concentration dependent antioxidant effectiveness in rapeseed oil triacylglyceroles was reported (Lampi, Kataja, Kamal-Eldin, & Vieno, 1999). At levels of 500 ppm a lower activity, combined with a faster disappearance, was found for α-TOH. However, both, α- and γ-TOH, showed a pronounced antioxidant activity.

The aim of this study was directed to the evaluation of the efficacy of α-, γ-, and δ-tocopherols to prevent radiation induced formation of peroxides in purified rapeseed oil triacylglycerols (RSOTG).

2. Materials and methods

2.1. Materials

Rapeseed oil was purchased at a local supermarket, the chemicals were from Sigma–Aldrich, Steinheim, Germany, and all gases were obtained from Air Liquide Austria GmbH, Schwechat, Austria.

Rapeseed oil purification was carried out by adsorption chromatography and it was verified by normal phase HPLC; no residual tocopherols could be detected (<1 ppm). The oil enrichment procedure (1000 ppm α-, γ- and δ-TOH) followed the method described by Isnardy et al. (2003). The irradiation treatment was performed immediately after oil purification and enrichment.

2.2. Irradiation and storage

Irradiation was carried out at room temperature in 15 ml glass bottles using a ^{60}Co gamma radiation source "Gammacell 220" (MDS Nordion International Inc., Kanata, ON, Canada) with doses of 4 and 10 kGy. The dose rate was 35.2 Gy/min. Irradiated and non irradiated oil samples were stored at −20 °C in closed plastic tubes containing approximately 2 ml each.

2.3. Tocopherol content

Tocopherol content was determined by normal phase high pressure liquid chromatography (HPLC) as described by Kamal-Eldin, Görgen, Pettersson, and Lampi (2000). HPLC system, Merck Hitachi, Vienna, Austria: L-7110 isocratic pump, L-7200 autosampler,

250 × 4.0 mm LiChrospher NH_2 100 5 μm column, and L-4250 UV–VIS detector, detection wavelength: 295 nm. The mobile phase consisted of 89% hexane, 9.9% tertiary-butylmethyl ether, 1% tetrahydrofuran, and 0.1% methanol.

2.4. Peroxide value (PV)

The lipid peroxides were measured using the PV-acetic acid/chloroform method (AOCS, 1998, Cd 8–53). The PV is expressed in milliequivalents peroxide per 1000 g of sample:

$$PV = [(S - B)\ N\ 1000]/m$$

with "*S*" and "*B*" being the volume (ml) of titrant used for the sample and blank, respectively, "*N*" being the normality of sodium thiosulphate solution and "*m*" the mass of sample (g).

3. Results and discussion

The major reactions immediately after radiation absorption in lipids (presence of oxygen and TOH) are summarised in Eqs. (1)–(12).

Initiation (ionisation, excitation):

$$LH \overset{gamma}{\rightarrow} [LH^{\bullet +}, e^-]\ (\text{geminate ions}) \rightarrow LH^* \quad (1a)$$

$$\overset{gamma}{\rightarrow} LH^* \quad (1b)$$

$$LH^* \rightarrow L^\bullet + H^\bullet,\ R_1^\bullet + R_2^\bullet\ (\text{C—C bond scission}) \quad (2)$$

Competition reactions:

$$L^\bullet + O_2 \rightarrow LOO^\bullet \quad (3)$$

$$L^\bullet + TOH \rightarrow LH + TO^\bullet\ (\text{repair}) \quad (4)$$

$$L^\bullet + LH \rightarrow LH + L^\bullet\ (\text{chain}) \quad (5)$$

$$H^\bullet + O_2 \rightarrow HO_2^\bullet \quad (6)$$

$$H^\bullet + TOH \rightarrow H_2 + TO^\bullet \quad (7)$$

$$H^\bullet + LH \rightarrow H_2 + L^\bullet\ (\text{chain}) \quad (8)$$

$$LOO^\bullet + TOH \rightarrow LOOH + TO^\bullet \quad (9)$$

$$LOO^\bullet + LH \rightarrow LOOH + L^\bullet\ (\text{autoxidation chain}) \quad (10)$$

$$HO_2^\bullet + TOH \rightarrow TO^\bullet + H_2O_2 \quad (11)$$

$$HO_2^\bullet + LH \rightarrow L^\bullet + H_2O_2\ (\text{chain}) \quad (12)$$

In the first step lipid radicals ($L^\cdot$) and $H^\cdot$ radicals are generated. The initial yield of free radicals in e.g. cyclohexane is (5–5.7) × 10^{-7} mol/L J^{-1}, the radical concentration per kGy is (5–5.7) × 10^{-4} mol/L (Swallow, 1987). The radicals originating from C–C bond scissions ($R_1^\bullet$, $R_1^\bullet$, etc.) are not discussed, but it should be mentioned that the formation of hydrocarbons is one method for detection of irradiated, fat containing food (Delincee, 2002). The radical-molecule reactions (Eqs. (3)–(12)) are competition reactions. Although, the reaction with oxygen (Eq. (3)) is very fast, at sufficient TOH concentration a repair of the lipid molecule (Eq. (4)) could take place. The solubility of O_2 in edible oils is high. For soybean oil a value of 55 mg/kg (1.7 × 10^{-3} mol/kg) was reported (Buchner, 1999). To possibly reduce an initial peroxyl radical formation (Eq. (3)) by scavenging of $L^\cdot$ radicals (Eq. (4)), scavenger concentrations comparable to that of oxygen are required. In this report 1000 ppm TOH, corresponding to 2.3 × 10^{-3} mol/kg α-TOH, 2.4 × 10^{-3} mol/kg γ-TOH, 2.45 × 10^{-3} mol/kg δ-TOH, were used. For δ-TOH this concentration is in the range of high effectiveness, whereas for α-TOH low antioxidant and even prooxidant effects might be expected. In general optimum concentrations for tocopherols were found to be for α-TOH ~ 100 ppm, for γ-TOH ~ 500 ppm and for δ-TOH an inhibition of hydroperoxide formation was observed up to 2000 ppm. For α-TOH also prooxidative activity were observed at high concentrations (Huang, Frankel, & German, 1994, 1995). Besides concentration the antioxidant action of TOHs is highly dependent on the lipid system, temperature and oxidation time. This study compared the antioxidant action of equal concentrations of TOHs using irradiation as oxidising system instead of storage and temperature.

RSOTG was chosen because of its high part of unsaturated fatty acids which are more sensitive to oxidation than saturated fatty acids. Since the oil samples were immediately frozen after irradiation to prevent autoxidation, no secondary oxidation products were to be expected. The experiments were focused on the determination of the primarily formed lipid peroxides.

For RSOTG and tocopherols the following investigations have been presented: In the range 5–500 μg/g α- and γ-TOH it was found that at concentrations above 100 mg/g γ-TOH was more effective than α-TOH (Lampi et al., 1999). Using 0.025–1.5 × 10^{-3} mol/kg α-TOH, the best effect was obtained up to 0.1 × 10^{-3} mol/kg (Ohm, Stöckmann, & Schwarz, 2005). At higher concentration a decrease of antioxidant efficiency was observed. Yet, both groups did not observe prooxidant effects. Authors from our group (Isnardy et al., 2003) applying α-, γ- and δ-TOH between 0.01% and 0.25% (100–2500 ppm) reported that at concentrations > 0.05% (500 ppm) especially α-TOH can act as prooxidant, whereas δ-TOH was practically not influenced in its activity, even at high concentrations.

The peroxide values (PVs) of the RSOTG with and without addition of 1000 ppm α-, γ-, and δ-TOH depending on dose are summarised in Table 1. For the non-enriched oil PVs showed a significant increase as a function of irradiation dose (correlation coefficient 0.898, $p < 0.01$). This is in accordance with the results from previous irradiation studies on various plant oils (Arici et al., 2007; Zeb & Lutfullah, 2005; Lutfullah et al., 2003). In presence of α-TOH there was no reduction of PVs, both, at 4 kGy and at 10 kGy. For γ- and δ-TOH a significant decrease of PVs was obtained, the reduction at 10 kGy was 35% and 44%, respectively (Table 1). The order of the antioxidant efficiency (δ > γ > α) is in conformity with literature data (Huang et al., 1995; Kamal-Eldin & Appelquist, 1996; Yanishlieva et al., 2002; Isnardy et al., 2003).

The results for the TOH-decrease are compiled in Table 2. The remaining concentrations are similar for all TOHs. At 4 kGy the degradation was 15–20% and at 10 kGy it was 22–28%. Since α-TOH did not show any peroxide inhibition effect, this compound must be consumed by other reactions, like Eqs. 7, 9, 11 and side reactions (e.g. reactions with peroxides, TOH + LOOH, and tocopherol mediated peroxidation, $TO^\cdot$ + LH). Side reactions of α-TOH have been extensively studied by various authors (Bowry & Ingold, 1995; Kamal-Eldin & Appelquist, 1996; Lampi et al., 1999; Yanishlieva et al., 2002). The consumption of γ-TOH at 4 kGy (20%)

Table 1
PVs ($n = 3$) of RSOTG (and their percentage decrease) without and with 0.1% (1000 ppm) α-, γ-, and δ-tocopherol depending on dose.

Dose	Mean PV [meq/kg]						
kGy	No TOH	α-TOH (0.1%)	Increase/decrease %	γ-TOH (0.1%)	Decrease %	δ-TOH (0.1%)	Decrease %
0	1.3 ± 0.3	1.3 ± 0.3		1.3 ± 0.3		1.3 ± 0.3	
4	6.5 ± 0.2	6.9 ± 0.2	+6	5.1 ± 0.3	−22	4.0 ± 0.2	−38
10	8.0 ± 0.1	7.9 ± 0.3	−1.25	5.2 ± 0.2	−35	4.5 ± 0.4	−44

Table 2
Remaining tocopherol concentration (%) in irradiated RSOTG (initial enrichment: 1000 ppm, corresponding to 100%).

Dose	Remaining tocopherol concentration in%		
kGy	α-tocopherol	γ-tocopherol	δ-tocopherol
4	85 ± 3	80 ± 2	82 ± 3
10	78 ± 3	78 ± 2	72 ± 10

equals the PV decrease, at 10 kGy (22%) it was less than the corresponding PV decrease. For δ-TOH the consumption at 4 kGy and 10 kGy (18% and 28%) was significant less than the PV decrease (38% and 44%). This might be referred to the formation of antioxidative products in the decay process of TO·, e.g. to the formation of δ-TOH-dimers (Eq. (13)), which have at least one free phenolic hydroxyl group for an antioxidant action.

$$TO^{\bullet} + TO^{\bullet} \rightarrow \text{products (dimerisation and disproportionation)} \quad (13)$$

Dimerisation was reported as preferred pathway for γ-TO· radicals (Choe & Min, 2006).

4. Conclusions

The radiation induced formation of peroxides/hydroperoxides in RSOTG was significantly reduced by δ- and γ-TOHs, whereas α-TOH did not affect the PV values. These findings demonstrate the different reaction pathways of the α-TOH/α-TO·, having two CH_3-groups vicinal to OH–/O·–, compared to γ-TOH and δ-TOH, having H–/CH_3– and H–/H–, respectively. Summarising it can be stated the main difference in using irradiation instead of temperature and storage time for oxidation of lipids is the time scale of initial radical production. It is fast and determined by the dose rate of the radiation source. Oxidation reactions (presence of O_2) and oxidation prevention (presence of TOH) showed a similar course as the conventional methods, with a sequence of antioxidant activity δ-TOH > γ-TOH > α-TOH.

Durian–alcohol reaction

ABSTRACT

The scientific basis of the adverse, or at times lethal, effect of ingesting durian (*Durio zibethinus* Murray) while imbibing alcohol has not been established. Symptoms are reminiscent of the disulfiram–ethanol reaction (DER) arising from the inhibition of aldehyde dehydrogenase (ALDH). Cognizant of the inhibitory effect of sulphur compounds like disulfiram on ALDH and the rich sulphur content of durian, the influence of durian fruit extract on the ALDH-mediated oxidative metabolism of acetaldehyde was investigated. We report a dose-dependent inhibition of yeast ALDH (yALDH), at most 70% at 0.33 ppm (mg extract/l assay mix), by dichloromethane:pentane extracts. Sulphur-rich TLC fruit extract fractions that eluted farthest from the origin effected the greatest inhibitory action. yALDH assay using diethyl disulfide as internal standard further supports the role of durian's sulfury constituents in the fruit's ALDH-inhibiting property. Insight into the etiology of DER-like symptoms felt upon simultaneous durian and alcohol consumption is hereby presented.

1. Introduction

Compelling scientific evidence support the beneficial effects of fruit and vegetable consumption (WHO, 2003), and moderate alcohol intake (Hines & Rimm, 2001) on cardiovascular health. Thus, dietary policies in countries like the US support the inclusion of these food items as part of disease preventive diets (USDA/HHS, 2005). However, risky interactions with ethanol were observed in some vegetables (Desager, Golnez, De Buck, & Horsmans, 2002; Lindros, Badger, Ronis, Ingelman-Sundberg, & Koivusalo, 1995).

Durian (*Durio zibethinus* Murray) is an important nutritional resource for Southeast Asian diets (FAO, 2003a). Its increasing popularity even in distant markets as the US and EC ensued the intensification of research to inform and familiarise consumers on the characteristics of the fruit (FAO, 2003b). Novel findings on its bioactive composition and health benefits (Charoensiri, Kongkachuichai, Suknicom, & Sungpuag, 2009; Mahattanatawee et al., 2006) point to its potential use in disease preventive diets (Leontowicz et al., 2008). However, anecdotal accounts on the interaction of durian with ethanol suggest an unsafe combination.

Reports on the adverse effects, which include cardiac episodes or deaths, in patients drinking alcohol with durian persists (Croft, 1981; Fuller, 2007; Singh, 1941). The symptoms have been described as being very unpleasant with clinical manifestations such as facial flushing, palpitation, drowsiness, vomiting and nausea. Similar effects have been associated with alcohol aversion therapy using disulfiram (tetraethylthiuram disulfide), a sulphur-containing drug (Lipsky, Shen, & Naylor, 2001; Veverka, Johnson, Mays, Lipsky, & Naylor, 1997). Disulfiram is known to inhibit aldehyde dehydrogenase (ALDH), causing the accumulation of alcohol-derived acetaldehyde. Although the possible contribution of alcohol itself to the unpleasant physiological effects has been discussed in several studies (Duranceaux et al., 2006; Jensen & Faiman, 1986), acetaldehyde appears to have a central role in mediating the adverse reactions referred to as the disulfiram–ethanol reaction or DER (Brien & Loomis, 1985; IARC, 1999; Inoue, Fukunaga, Kriyama, & Komura, 1984).

The inhibitory effects of sulphur-containing compounds from natural products on ALDH have been proposed by several groups (Brien & Loomis, 1985; Kitson & Weiner, 1996; Lindros et al., 1995; Veverka et al., 1997). Durian is rich in sulphur compounds (Baldry, Dougan, & Howard, 1972; Moser, Duvel, & Greve, 1980; Voon, Hamid, Rusul, Osman, & Quek, 2007a, 2007b; Weenen, Koolhaas, & Apriyantono, 1996; Wong & Tie, 1995), but there is yet no study demonstrating the inhibitory effects of durian or its sulphur constituents on ALDH. This study provides information on the possible link between some components of durian and DER-like effects.

Abbreviations: ALDH, aldehyde dehydrogenase; DE, durian extract; DER, disulfiram–ethanol reaction; K_m, Michaelis constant; β-NAD or NAD, nicotinamide–adenine dinucleotide; *Rf*, retardation factor; V_0, initial velocity; V_{max}, maximum velocity.

2. Materials and methods

2.1. Chemicals

Inhibition studies were conducted using potassium-activated ALDH enzyme from baker's yeast (*Saccharomyces cerevisiae*) in lyophilised powder form (Sigma–Aldrich, St. Louis, Missouri, USA) with β-NAD^+ (Oriental Yeast Corporation, Osaka, Japan) as cofactor. Dichloromethane, pentane, and authentic diethyl disulfide were procured from Wako Pure Chemical Industries, Ltd. (Osaka City, Japan). All chemicals and solvents used were of analytical grade and purity.

2.2. Durian fruit extract preparation

The pulp of table-ripe durian fruit (*Durio zibethinus* Murray *cv.* Monthong) purchased from a supermarket in Tsukuba City, Japan was mixed with dichloromethane:pentane (1:1 v/v) (Weenen, Koolhaas, & Apriyantono, 1996) in a 1:2 proportion (1 kg:2 L solvent mix) for 48 h at 4 °C. The clear liquid was decanted and the solvent was evaporated under vacuum (27.5 ± 2.5 in Hg) at 50 °C and 50 rpm in an RE52 Rotavaporator set-up (Yamamoto, Tokyo, Japan). The fruit extract (1.7 ml/kg pulp) was sealed in a glass container and kept at −20 °C.

2.3. Fractionation by TLC

TLC fractions of durian extract (DE) and durian extract spiked with authentic diethyl disulfide (55 mM) (DE + DD) were developed in 0.33 mm Chromato sheets (2 cm × 7 cm) (Wako Pure Chemical Industries, Ltd., Osaka, Japan) using water, 2-butanol and 28% ammonia (1:1:1) as solvent. Eight sheets each for DE and DE + DD were spotted with 10 μl sample (1 cm above the base) and developed in a chamber at 25 °C for 45 min until the solvent front reached 1 cm below the tip of the sheets. Chromatograms were dried in a fumehood at 25 °C, trimmed (0.5 cm base and top), cut into six equal parts (where *Rf* 0 encloses the spot; *Rf* 1 the solvent front). Each part was soaked with 150 μl 1 M Tris–HCl buffer, and centrifuged in Beckman GS-15R Centrifuge (Beckman Inst. Inc., Palo Alto, California) at 5000 rpm for 5 min, 10 °C. Fractions from the same *Rf* values of DE and DE + DD were pooled (≅1.2 ml/*Rf*), placed in ice bath and immediately used in inhibition assay.

2.4. yALDH assay

Enzymatic assay was monitored by following the rate of NADH accumulation indicated by the increase in A_{340} using a thermostat-equipped JASCO V-550 spectrophotometer (Tokyo, Japan) at 25 °C for 3 min (Sigma., 1996). A standard 3 ml final reaction mixture contained: 103 mM Tris–HCl buffer, pH 8.0; 0.67 mM β-NAD^+; 0.25–0.5 units yALDH solution (diluted in 100 mM Tris–HCl buffer with 0.02%(w/v) BSA); 100 mM-KCl; 10 mM 2-mercaptoethanol; 10 mM acetaldehyde; filled to volume with deionized water. Reactions were commenced by adding 0.10 ml β-NAD^+ to an otherwise complete reaction mixture.

Assay in test samples: authentic diethyl disulfide (1.1 ppm, final concentration); and filtered (PTFE 0.2 μm Millipore Millex-LG syringe-driven filter) durian extract (0.03, 0.07, 0.16, 0.33, 0.65, and 1.63 ppm, mg extract/l assay mix) and TLC fractions of DE and DE + DD (55 mM) followed the conditions described above except that reactions were commenced by adding a mix of the test sample and β-NAD^+.

Initial velocity studies in 0.33 ppm durian extract (mg/l assay mix) at 1, 2, 5, 10 and 50 mM acetaldehyde followed the reaction conditions described above. Computed kinetic parameters (i.e. K_m and V_{max}) were compared to that obtained without the extract at 2, 5, 7, 10, 30, and 50 mM acetaldehyde.

Determinations were done in triplicate *vis-à-vis* an almost identical solution (blank) that contains the enzyme diluent in *lieu* of the yALDH solution. Order of enzyme, substrate, cofactor and test sample addition was maintained in all enzymatic assay conducted. Results were subjected to a *t*-test ($P > 0.05$).

2.5. Sulphur test

Collected TLC fractions (300 μl) from the durian extract were mixed with 600 μl 20% (w/v) sodium formate solution and heated to liberate bound sulphur as hydrogen sulphide that manifests as dark discolorations in the lead acetate paper upon contact with tainted fumes (adopted from FAO (1996)).

3. Results and discussion

The durian–alcohol anecdote has been sheltered with over 250 years of belief. Few attempts to validate the interaction have vaguely disproved the alleged antagonism between durian and ethanol (Nilveses & Seangsirinavin, 1986; Ogle & Teh, 1969, 1971; Techapaitoon & Sim, 1973). None of these *in vivo* studies, however, considered the possible interference of some components in durian on the enzymatic system for detoxifying alcohol. To our knowledge, this is the first attempt to explore the molecular basis of the durian–alcohol anecdote and no other literature has yet linked a fruit to adverse reactions that may arise upon interaction with alcohol.

We used yALDH as a model protein because its active region is 95–100% homologous to that of the mammalian ALDHs (Saigal, Cunningham, Farres, & Weinar, 1991). Veverka et al. (1997) also used yALDH for studies on the mechanism of inhibition by disulfiram for the same reason.

yALDH significantly lost ($P < 0.05$) enzymatic activity in the presence of durian fruit extract at all concentrations used (Fig. 1, line graph). The intensity of inhibition increases with fruit extract concentration to a maximum of 70% at 0.33 ppm extract (final concentration). At higher concentrations (0.67 ppm and 1.67 ppm), the inhibitory effect weakened. Several studies reported the potent inhibitory action of sulphur compounds on ALDH (Brien & Loomis, 1985; Desager et al., 2002; Lindros et al., 1995; Park, Chung, Lee, Lee, & Kim, 2003). Similarly, the non-polar organic constituents (*Rf* 0.6, 0.8 and 1.0) of the durian fruit extract that also registered positive results in the sulphur-test elicited significant inhibitory effects on yALDH (Fig. 1, shaded bar graph). The degree of inhibition progressively declined from *Rf* 1.0 to *Rf* 0.4 with increasing polarity of these fractions. Veverka et al. (1997) reported a complete inhibition of yALDH activity upon treatment with 20 μM disulfiram by oxidising proximal cysteines in the active site to form a disulfide bridge. With this mechanism, they suggested that sterically suitable compounds containing a disulfide bridge may potentially inhibit ALDH. In durian, diethyl disulfide is the most abundant sulphur compound that contains a disulfide bridge (Laohakunjit, Kerdchoechuen, Matta, Silva, & Holmes, 2007; Voon et al., 2007a). Assay in 1.1 ppm authentic diethyl disulfide (final concentration) lowered the activity of yALDH by 81.5%. The contribution of diethyl disulfide to the durian extract-elicited inhibition of yALDH activity is hereby supported.

Authentic diethyl disulfide added to the durian fruit extract (55 mM) and subjected to planar TLC fractionation enhanced the inhibition elicited by the fraction with a calculated *Rf* value of 0.8 (Fig. 1, unshaded bar graph). The possible involvement of other non-polar sulfury constituents of durian to the observed inhibition, as our results imply, merits further investigation since the result-

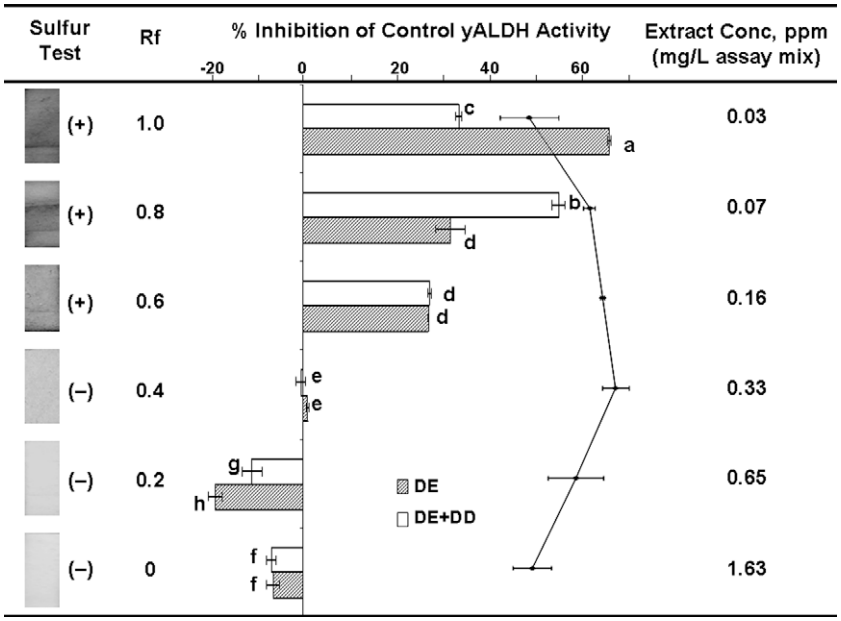

Fig. 1. yALDH inhibition by durian extracts (line graph), non-polar TLC fractions of durian extracts (DE, shaded bar graph) that yielded positive on the sulphur test (*Rf* 0.6, 0.8, and 1.0), and non-polar fractions of durian extract added with diethyl disulfide (DE + DD, unshaded bar graph). Values are reported as% inhibition of "control" yALDH activity, which was determined in the absence of any inhibitor. Data are means ± sd of three replicates. Graphs with similar letters indicate insignificant differences ($P > 0.05$).

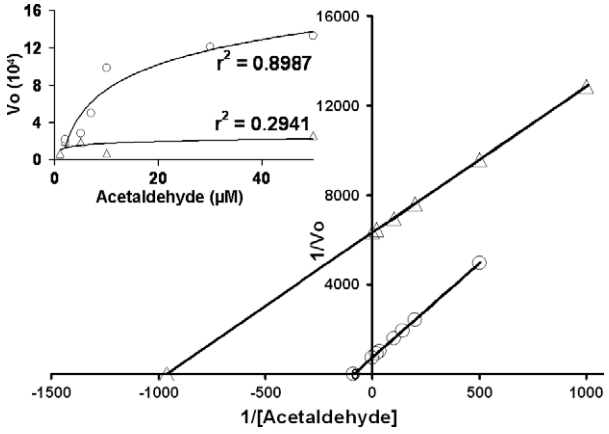

Fig. 2. Double reciprocal plot of V_0 vs. [Acetaldehyde] in 0.33 ppm durian fruit extract (Δ) and control (○) (regressed values). *Insert*, plot of V_0 as a function of [Acetaldehyde].

ing fractions from TLC may be broad and the contents of *Rf* 0.8 may have spread out to adjoining fractions.

Addition of the contents of *Rf* 0 and 0.2 enhanced yALDH activity (Fig. 1). Consistent with the fading inhibitory effect of durian extract at concentrations beyond 0.33 ppm earlier observed, enhanced yALDH activity in these polar fractions may have resulted from the increase in substrate concentration contributed by the endogenous aldehyde content of the durian fruit (Voon et al., 2007a). Fractions obtained from *Rf* 0.4 elicited insignificant alteration ($P > 0.05$) of the enzyme's activity.

Assay in 0.33 ppm crude extract lowered both the K_m and V_{max} values of yALDH (Fig. 2). Increasing the substrate concentration did not alter the activity of the enzyme as suggested by the low coefficient of determination ($r^2 = 0.2941$) (Fig. 2 insert). Based on the kinetic parameters, components of the durian fruit extract appear to elicit a mixed type of inhibitory action on yALDH. However, as this study involved the use of crude extract, further investigation of the inhibitory constituents is required to provide a conclusive characterisation of the mechanism of inhibition.

4. Conclusion

This study provides evidence that some component(s) of durian fruit inhibit(s) yALDH *in vitro*. Inhibitory action of the non-polar sulfury constituents of the fruit like diethyl disulfide on yALDH, with further investigation, offers a novel rationale to the etiology of the durian–alcohol anecdote. As such, work on this theme is currently undertaken to confirm the bioactive component(s) in the durian fruit, and validate the consistency of the findings hereby reported in mammalian models *in vivo*.

An important implication of studies along this line lies in strengthening science-based food safety precautions serving as impetus for issuing reliable toxicological disclaimer on the durian–alcohol interaction in a similar fashion to that of the watercress–alcohol. Such information should be useful to health care professionals or even the general consumer to avoid risky food–beverage interactions.

ABSTRACT

A reversed-phase high performance liquid chromatography (RP-HPLC) procedure was developed for simultaneous determination of five phenolic acids, two stilbenes and eight flavonoids in peanut skin extract. A C_{18} column fitted with diode array detection at 250 and 320, 280 and 370, and 306 nm for phenolic acids, flavonoids and stilbenes, respectively, with mobile phase consisting of 0.1% formic acid in water and 0.1% formic acid in 100% acetonitrile. Phenolic compounds were eluted with good resolution (Rs > 1.5) within 95 min as follows: gallic, protocatechuic, epigallocatechin, catechin, β-resorcylic (internal standard), caffeic, procyanidin B_2, epicatechin, epigallocatechin gallate, *p*-coumaric, ferulic, piceid, epicatechin gallate, catechin gallate, resveratrol and quercetin. The variation in recovery and reproducibility in peak area was <11 and <2.5%, respectively. The correlation coefficients, *r*, of calibration curves of the 15 compounds were >0.999. The method was used to quantify phenolic compounds in peanut skin extracts from Runner, Virginia and Spanish peanuts.

1. Introduction

A report identified peanut skins as one of the important sources of antioxidants with healthcare application that food manufacturer's can tap into (http://www.kaloramainformation.com/Healthcare-Opportunities-Food-1468551/). Peanut skins have a pink-red colour and an astringent mouth feel when consumed. They are typically removed before peanut consumption or inclusion in confectionary and snack products. In the early 1940's, these were initially thought to be toxic. But after a thorough examination by Dr. Jack Masquelier, then a doctoral candidate at the Faculty of Medicine and Pharmacy, University of Bordeaux, in France, peanut skin was found nontoxic, and protects and strengthens blood vessels (Louis, 1999). The colourless extract obtained was named OPC, oligomer proanthocyanidins. Peanut skins are rich in phenolic compounds and potentially other health-promoting compounds. Seventeen percent by weight of peanut skins are proanthocyanidins, consisting of low and high molecular weight oligomers (Karchesy & Hemingway, 1986). Lou et al. (1999) made a comprehensive analysis of the water-soluble phenolic extract from peanut skins, resulting in six A-type proanthocyanidins, including procyanidins A_1 and A_2, and three newly found epicatechin oligomers. They isolated ten compounds from the water-soluble fraction of peanut skins, including eight flavonoids and two novel indole alkaloids, reported for the first time from a natural source (Lou, Yuan, Yamazaki, Sasaki, & Oka, 2001). In 2004, they isolated five oligomeric proanthocyanidins, B_2, B_3 and B_4 from the water-soluble fraction and two new polyphenols, epicatechin-(2-β-*O*-7,4-β-6)-[epicatechin-(4-β-8)]-catechin and epicatechin-(2-β-*O*-7,4-β-8)-[epicatechin-(4-β-8)]-catechin-(4-α)-epicatechin, based on their spectral data (Lou et al., 2004). Huang, Yen, Chang, Yen, and Duh (2003) isolated and identified the ethanolic extract fraction from peanut seed testa that showed the highest yield and marked antioxidant activity. Thin layer chromatographic separation of this fraction allowed the isolation of the antioxidant component in peanut seed testa which was identified as ethyl protocatechuate (3,4-dihydroxybenzoic acid ethyl ester). Other types of compounds isolated and identified in peanut skins include phenolic acids, flavonoids and stilbenes (Yu, Ahmedna, & Goktepe, 2005). Yu, Ahmedna, Goktepe, and Dai (2006) identified and quantified catechins, procyanidin dimers, trimers and tetramers using reversed-phase high performance liquid chromatography (RP-HPLC). These compounds were detected in chemically purified peanut skin aqueous and ethanol extracts. Furthermore, higher concentrations of compounds mentioned were observed in raw peanut skins than roasted peanut skins. Caffeic acid, chlorogenic acid, ellagic acid and resveratrol were identified but not quantified due to very small

doi:10.1016/j.foodchem.2009.03.110

peaks, as a result of suppression by major procyanidin peaks. Resveratrol was found to be present at higher levels in the seedcoat than the peanut kernel. Seed coats from Runner and Virginia types contained approximately 0.65 μg/g of seed coat, which is equivalent to <0.04 μg/seed (Sanders, McMichael, & Hendrix, 2000). Ethanolic extract prepared from defatted peanut skins even showed higher resveratrol contents. The ethanolic extract contained 91.4 μg/g while the dry peanut skins contain 9.07 μg/g (Nepote, Grosso, & Guzman, 2004).

Reverse-phase chromatography is the most popular mode of analytical liquid chromatography for phenolic compounds. A RP-HPLC method for food phenolics requires optimising a wide variety of mobile-phase conditions (ionic strength, pH, ion pair, organic modifier, etc.) and column parameters (Lee, 2000). Columns range from 100 to 300 mm in length and usually with a 4.6 mm internal diameter. The most often used columns have been packed with C_{18} column material. Elution systems are usually binary with an aqueous acidified polar solvent such as aqueous acetic acid, perchloric acid, phosphoric acid, or formic acid (solvent A) and a less polar organic solvent such as methanol or acetonitrile, possibly acidified (solvent B). The greatest alteration observed in the mobile phase was the type of acid used as the modifier to minimise peak tailing (Merken & Beecher, 2000). The pH range most often used for RP-HPLC for phenolics is low, between 2 and 4. The pH and ionic strength of the mobile phase are known to influence the retention of phenolics on the column, depending on whether there is protonation, dissociation, or a partial dissociation (Lee, 2000). HPLC runs are generally an hour maximum, with equilibration between runs (Merken & Beecher, 2000).

Phenols absorb in the ultraviolet (UV) region. Most of the phenolic acids displayed their maxima at 246–262 nm with a shoulder at 290–315 nm (Lee, 2000). Flavonoids are benzo-γ-pyrone derivatives consisting of phenolic and pyrane rings A, B, and C. Two absorption bands are characteristic of flavonoids. Band II, with a maximum in the 240–285 nm range, is believed to arise from the A ring. Band I with a maximum in the 300–550 nm range, presumably arises from the B-ring (Merken & Beecher, 2000). Food phenolics are commonly detected using UV–vis and photodiode array (DAD) detectors.

Several hundred papers on the HPLC of phenolic compounds have been published in the past 20 years, yet HPLC of phenolic compounds can detect across one, two or perhaps three classes or subclasses in one analysis. Foods may contain several classes of phenolic compounds (Merken & Beecher, 2000). Phenolic extracts are always a mixture of different classes of phenolics that are soluble in the solvent system used (Naczk & Shahidi, 2004). Due to the large number, and the structural variations in closely related food phenolic compounds, analytical procedures for the analysis of individual phenolic compounds have been relatively difficult and complicated (Lee, 2000). The ideal profiling method should be as simple as possible, should detect all the compounds present, should provide as much information as possible for each peak in the chromatogram for the purpose of identification, structural evaluation, and quantification, and should accomplish all this in a single chromatographic run (Harnly, Bhagwat, & Lin, 2007). A review of some examples of profiling methods for the last 15 years is discussed by Harnly et al. (2007). With the increasing interest in peanut skins as a rich source of antioxidants, it is imperative to accurately determine and quantify as many phenolic compounds to answer the demand for timely information on health-promoting compounds present in peanut skins. The objective of this study was to develop a RP-HPLC method using DAD for the identification and quantification of phenolic compounds in peanut skin extracts.

2. Materials and methods

2.1. Chemicals and materials

Standards including gallic acid, quercetin, catechin, (−)-catechin gallate, (−)-epicatechin gallate, (−)-epigallocatechin, procyanidin B_2, and β-resorcylic acid (internal standard, IS) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Resveratrol, (−)-epigallocatechin gallate, caffeic acid, *p*-coumaric acid, protocatechuic acid, ferulic acid, and (−)-epicatechin were purchased from Fisher Scientific (Atlanta, GA, USA). Methanol, acetonitrile and formic acid were purchased from VWR (West Chester, PA, USA).

2.1.1. Standard solutions for quantifying phenolic compounds

Stock solutions of gallic acid (1000 ppm), quercetin (1000 ppm), catechin (1000 ppm), (−)-catechin gallate (2000 ppm), (−)-epicatechin gallate (2000 ppm), (−)-epigallocatechin (2000 ppm), procyanidin B_2 (2000 ppm), β-resorcylic acid (1000 ppm), resveratrol (1000 ppm), (−)-epigallocatechin gallate (1000 ppm), caffeic acid (1000 ppm), *p*-coumaric acid (1000 ppm), protocatechuic acid (1000 ppm), ferulic acid (1000 ppm) and (−)-epicatechin (1000 ppm) were prepared by dissolving the compounds separately in methanol, and stored in 2 oz. amber bottles (VWR West Chester, PA, USA) at −15 °C.

2.2. Preparation of peanut skin extract

Raw peanuts (2004 crop year) were purchased from Golden Peanut Company (GA). Runner medium (Georgia Green) were harvested in Dawson, GA; Virginia medium in Aulander, NC; and No. 1 Spanish in Anadarko, TX. All peanut bags were stored for 1 month under refrigerated storage in a cold room at 4 °C prior to analysis. Raw, peanuts were manually sorted to remove foreign material or damaged kernels. Kernels were manually peeled and skins were packaged in 12.7 × 16.5 cm polyethylene bags (Koch Supplies, N. Kansas City, MO, USA) flushed with nitrogen gas (medical grade, Air Products and Chemicals, Inc., Allentown, PA, USA), immediately heat-sealed (Thermal Impulse Heat Sealer, Model 14C/CAB, Vertrod Corp., USA) then stored in a walk-in freezer at −15 °C until used in HPLC analyses.

The extraction of phenolic compounds in peanut skin was carried out according to the method published by Nepote, Grosso, and Guzman (2005). Briefly, 20 mL of 70% ethanol was added to a flask containing 1 g of peanut skins. The flasks were shaken for 10 min using a Wrist Action Shaker (Model 75, Burrell Corp., PA, USA) at ambient temperature. The extract was filtered through a Whatman no. 1 filter paper and the residue was extracted again under the same conditions, for a total of three extractions.

All flasks were wrapped with aluminium foil to prevent light degradation during extraction as done by Yu et al. (2005). The combined filtrate was transferred into an evaporating flask and placed in a water bath (HB4 basic, IKA, Fisher Scientific Co., Fair Lawn, NJ, USA) set at 40 °C according to Duh and Yen (1997) for drying extracts from peanut hulls. The extract was evaporated under vacuum for 15 min in a rotary evaporator (RV05 Basic 1B, IKA, Fisher Scientific Co., Fair Lawn, NJ, USA) to a concentrated extract of about 5 mL. The extract was transferred to a plastic cup (No. P325, Solo Cup Co., Urbana, IL, USA) and the evaporating flask was washed with approximately 2 mL of deionised water which was combined with the extract in the cup. Sample cups were sealed with aluminium foil and frozen overnight in a walk-in freezer at −15 °C. The frozen mixture was then freeze-dried (Virtis Genesis 25ES, SP Industries Inc., Gardiner, NY, USA) at <100 mTorr vacuum for 24 h. Dried extracts were scraped from the cups and packaged in

8-mL vials wrapped with aluminium foil, and stored in a freezer at −15 °C until used.

2.3. HPLC analysis

Analysis was performed using a ProStar HPLC system (Varian Inc., Walnut Creek, CA, USA) comprised of a 210 Binary Pump, 410 AutoSampler and 335 DAD. The Star Work Station Software version 6.41 was used to control the autosampler, gradient settings, DAD and data acquisition. A C_{18} reverse-phase column, 4.6 × 250 mm, 5 μm particle size (Eclipse Plus, Agilent Technologies, Wilmington, DE, USA) was used. Preceding the analytical column was a C_{18} guard column (4.6 × 12.5 mm, 5 μm particle size, Eclipse Plus, Agilent Technologies, Wilmington, DE, USA), used to prevent any non-soluble residues from samples from contaminating the column. Peak areas were determined at 250 nm for the benzoic acid derivatives; 280 nm for the flavanols; 306 nm for stilbenes; 320 nm for the cinnamic acid derivatives; and 370 nm for flavonols.

2.3.1. Determination of solvent composition

The mobile phase consisted of 0.1% formic acid in filtered deionised water as solvent A and 0.1% formic acid in 100% acetonitrile as solvent B (Yu et al., 2006). To determine the gradient conditions the method of Snyder, Kirkland, and Glajch (1997) was used. Initial and final composition of A and B solvents were determined using exploratory gradient elution.

2.3.1.1. Exploratory gradient elution. The first phase involved increasing solvent B linearly from 5% to 100% over 60 min (gradient steepness, GS = 1.6%) with a flow rate of 2.0 mL/min, at room temperature (Snyder et al., 1997). Experimental peanut skin extracts from Runner, Virginia and Spanish skins were dissolved each in aqueous solvent at 300 ppm and injected at 20 μL. All analyses were conducted in duplicate. The retention times (t_R) of the first and last peaks observed in the chromatogram from the peanut skin samples were used to calculate the initial and final concentrations of solvent B using a tabular value on estimating the initial and final % B for gradient elution, based on retention time for first and last band in the initial gradient run, published by Snyder et al. (1997). In the second phase, the same conditions were used except for the initial and final gradient composition of solvent B which was adjusted to reflect the concentrations determined in the first phase. Total run time was 60 min with a flow rate of 1.5 mL/min.

2.3.1.2. Determination of the effect of gradient steepness and flow rate. The second experiment was carried out by examining the effect of different gradient steepness (GS) and flow rates on band spacing. A total of nine conditions, including three GS (1.6%, 1.3% and 1.0%) and three flow rates (1.5, 1.0 and 0.8 mL/min), using Runner skin extracts injected at 20 μL, were tested to determine the effect on resolution of peaks. Resulting chromatograms were evaluated for adequate resolution of peaks.

2.3.1.3. Improvement by segmentation of the gradient elution. The chromatograms from peanut skin extract obtained were rather complex in nature, thus a series of segmented gradients were conducted to enable the separation of the unresolved peaks. A solution of standards at 20 ppm was injected at 20 μL and resolutions and retention times were determined. Three segments were incorporated into the gradient elution to obtain a calculated resolution (Rs) >1.5 for all 16 compounds. When all compounds were eluted with sufficient resolution, a Runner peanut skin extract was spiked with the compounds to check that proper identification of the standards can be obtained. If standard peaks were being suppressed by peaks from peanut skins, adjustments were made in the gradient elution until all 16 compounds were resolved in the sample extract. Absorption spectra of the 16 standards were also obtained for reference when identifying phenolic compounds.

2.4. HPLC sample preparation

Preparation of peanut skin extracts was modified to remove sugar, protein and lipid from the matrix as suggested by Yu et al. (2005). The sample preparation of Nepote et al. (2004) employing liquid–liquid partitioning was used in the preparation of the purified extract. An internal standard, β-resorcylic acid, was used as recommended for HPLC samples requiring significant pretreatment or preparation before HPLC analysis (Snyder et al., 1997). This compound was not reported to be present in peanut skins. The freeze-dried peanut skin extract (20–25 mg) was weighed and 3 mL of dichloromethane (DCM), 2 mL of filtered deionised water and 1 mL of internal standard solution (20 ppm) were added. After mixing, partitioning and phase separation, the organic phase (DCM) was discarded. Water layer was then mixed with 5 mL ethyl acetate. After phase separation, the ethyl acetate layer was collected and evaporated in a rotary evaporator (RV05 Basic 1B, IKA, Fisher Scientific Co., Fair Lawn, NJ, USA) at 35 °C under reduced pressure. The dried phenolics were re-dissolved in 2 mL methanol and evaporated to dryness under nitrogen gas, re-dissolved in 1 mL 15% methanol before HPLC injection at 20 μL. The entire sample procedure was conducted under yellow light to prevent degradation.

2.5. HPLC method validation

After the RP-HPLC gradient conditions were determined, validation tests were performed for accuracy, precision, linearity, range and limit of detection and quantification.

2.5.1. Determination of accuracy

A stock standard solution containing 20 ppm of epigallocatechin, catechin and IS; 10 ppm of procyanidin B_2, epicatechin, epigallocatechin gallate, epicatechin gallate and catechin gallate; and 4 ppm of gallic acid, protocatechuic acid, caffeic acid, *p*-coumaric acid, ferulic acid, piceid, resveratrol and quercetin was prepared. Determination of accuracy was done by recovery method (Snyder et al., 1997), where peanut skin extracts (Runner type) were spiked by adding 50%, 75% and 100% of stock standard solution containing the 16 compounds, which where compared with peanut skin extracts without standards. Calculations were adjusted for protocatechuic acid, epigallocatechin, catechin, epicatechin, resveratrol, *p*-coumaric acid and quercetin, to account for its natural concentration, determined in peanut skin extracts not containing added phenolic compounds. Peak area was used for quantification purposes, using internal standard calibration using the equation of Macrae (1988)

$$\text{Amount of } i = \frac{\text{abs. RF}(i) \times A(i)}{\text{abs. RF(IS)} \times A(\text{IS})} \times M(\text{IS})$$

where abs. RF is the absolute response factor; *M* is the mass of component; *A* is the area under its peak; *i* is the phenolic compound; IS is the internal standard. Peanut skin extracts spiked with standards were injected at a volume of 20 μL in triplicate. Recovery of the 15 compounds was calculated using the equation

$$\text{Accuracy} = \% \text{ recovery} = \frac{\text{Actual concentration of analyte}}{\text{Theoretical concentration of analyte}} \times 100$$

For each level of concentration three replications were performed resulting in 12 analyses including control extract.

2.5.2. Determination of precision

To evaluate precision, a solution of the standards containing 20 ppm of epigallocatechin, catechin and IS; 10 ppm of procyanidin B_2, epicatechin, epigallocatechin gallate, epicatechin gallate and catechin gallate; and 4 ppm of gallic acid, protocatechuic acid, caffeic acid, *p*-coumaric acid, ferulic acid, piceid, resveratrol and quercetin was injected at 20 μL for a total of eight times. The precision of the method was expressed by coefficient of variation (% CV) of the data set. The mean peak area and t_R values for each compound were determined.

2.5.3. Determination of linearity and range

An intermediary mixed standard solution was prepared by dilution in filtered deionised water of the stock standard solution to give a concentration of 20 ppm for epigallocatechin, catechin and IS; 10 ppm for procyanidin B_2, epicatechin, epigallocatechin gallate, epicatechin gallate and catechin gallate; and 4 ppm for gallic acid, protocatechuic acid, caffeic acid, *p*-coumaric acid, ferulic acid, piceid, resveratrol and quercetin; from which a calibration working solutions with concentrations in the range of 4–20, 2–10 and 0.8–4 ppm, respectively, were prepared in triplicate and evaluated by injecting 20 μL. Calibration curve for each compound was constructed separately by plotting peak areas (*y*-axis) versus concentrations (*x*-axis). Using statistical analysis software (version 8.1, SAS Institute Inc., Cary, NC, USA) regression analysis (PROC REG) was used to relate each standard concentration as the dependent variable with peak area as the independent variable. Pearson's product correlation coefficients (*r*) between peak area and the concentration of each compound were calculated.

2.5.4. Determination of limit of detection and quantification

Limits of detection and quantification were calculated based on the standard deviation of the response and the slope (ICH, 1998). Calculated amounts per compound were prepared and standard mixture was injected in duplicate to verify the LOD and LOQ of each compound. The detection limit was expressed as

$$\mathrm{LOD} = \frac{3.3\sigma}{S}$$

where σ is the standard deviation of the response, S is the slope of the calibration curve.

The quantification limit was expressed as

$$\mathrm{LOQ} = \frac{10\sigma}{S}$$

2.6. Identification and quantification of phenolic compounds in peanut skin extracts

Phenolic compounds in Runner, Virginia and Spanish skins (raw) were identified on the basis of the retention times and UV–vis spectra of phenolic compounds analysed. Peak area was used for quantification purposes, using internal standard calibration. Peanut skin extracts were injected at a volume of 20 μL in duplicate. Values were reported as μg/g dry peanut skin.

3. Results and discussion

3.1. Determination of solvent composition

3.1.1. Exploratory gradient elution

From the five wavelengths monitored, the earliest and last peaks were observed at 280 nm as shown in Fig. 1a. The t_R of the first and last peaks observed in the chromatograms slightly differed for each peanut skin type as shown in Fig. 1a. For all peanut skin types, the t_R of the initial and final peaks were approximately

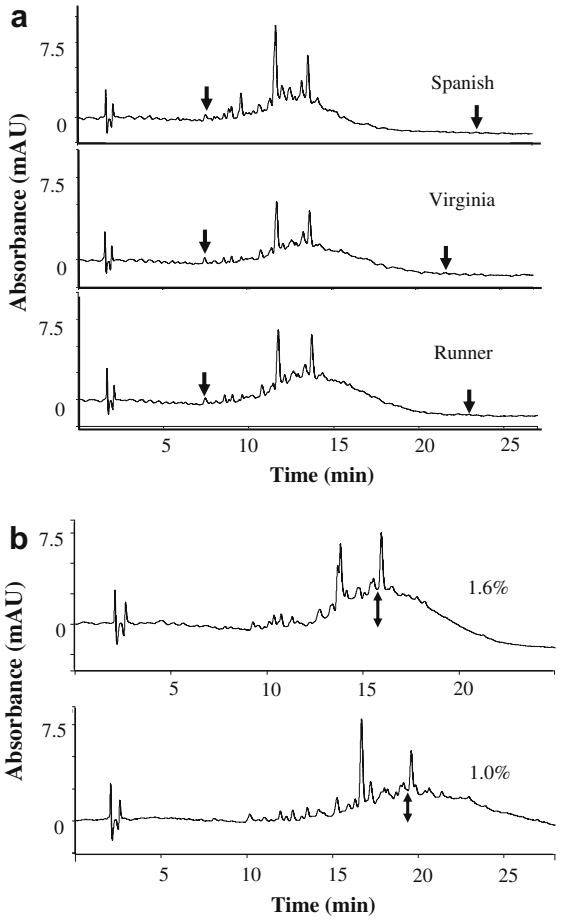

Fig. 1. (a) Determination of a gradient solvent composition for RP-HPLC analysis of phenolic compounds in peanut skin extract at 280 nm, with a linear gradient increasing solvent B (0.1% formic acid in acetonitrile) in solvent A (0.1% formic acid) at a flow rate of 2.0 mL/min, and analysis time of 60 min. Arrows show the first and last peak detected in Runner, Virginia and Spanish skin extracts. (b) Effect of RP-HPLC gradient steepness (GS) of 1.6% and 1%, on analysis of phenolic compounds in Runner peanut skin extract at 280 nm. Elution of peaks from analysis with a linear gradient increasing solvent B (0.1% formic acid in acetonitrile) from 5% to 43% at 1.5 mL/min. Arrows show the difference in baseline drifts from the unresolved 'hump' detected in the sample.

7 and 23 min, respectively. Between the first and last peaks, a non-separated 'hump' (detected as an elevation in the baseline) was present for all types. The 'hump' is a characteristic chromatogram of flavanoids, specifically procyanidins (Lazarus, Adamson, Hammerstone, & Schmitz, 1999). Peanut skins contain a complex series of procyanidin oligomers. Mass spectral data of peanut skins obtained by Lazarus et al. (1999) indicated presence of several singly and doubly-linked procyanidin oligomers through octamers in peanut skins. Lazarus et al. (1999) observed that although RP-HPLC has the ability to separate oligomers, analysis is not feasible due to retention time overlap of isomers from procyanidins causing the oligomers to co-elute as a large unresolved peak, as initially observed in this study. In other foods containing procyanidins, Adamson et al. (1999), Karonen et al. (2007), Salminen et al. (2005), and Ndhlala et al. (2007) obtained the typical unresolved peaks for procyanidin polymers, resulting in a recommendation to use normal phase HPLC to analyse these compounds.

Snyder et al. (1997) suggested that the initial composition of water (solvent A) should start at 95% or higher in order to minimise exposure of the column to high water conditions. Thus, the recommended initial solvent B composition was maintained at 5%. The fi-

nal composition of 43% solvent B was calculated from a t_R of 23 min, based on the tabular value of Snyder et al. (1997).

3.1.2. Determination of the effect of gradient steepness and flow rate

The unresolved 'hump' discussed previously was observed in all gradient steepness and flow rate combination tested. The 'hump' was observed to occur at solvent B composition of 7–17%, regardless of GS and flow rate conditions. Significant decrease in the elevation of the 'hump' was observed as GS decreased from 1.6% to 1% at a high flow rate of 1.5 mL/min as shown in Fig. 1b. Decrease in GS likewise resulted in increased resolution of peaks within the 'hump'. Adequate separation of peaks can therefore be obtained at reduced GS. Since the 'hump' occurs at a specific gradient range of 7–17% solvent B, use of nonlinear gradients as a means to improve the separation of peaks is suggested by Snyder et al. (1997).

3.1.3. Improvement by segmentation of the gradient elution

Table 1 lists the optimum instrumental parameter values for the chromatographic determination of phenolic acids, flavonoids and stilbenes. Three segments of the gradient elutions were incorporated into the final method to resolve the peaks. The first segment had a GS of 0.28%, with solvent B increasing from 5% to 7% in 7 min. This segment allowed the elution of the more polar compounds, the benzoic acid derivatives. The second segment, which were mostly flavanols had a 0.15% GS, with solvent B increasing from 7% to 17% in 68 min. At this GS, the peaks within the previously observed 'hump' were now adequately resolved and exhibited a normal baseline. The third segment had a GS of 0.86% to elute the less polar compounds. All compounds were eluted in 95 min. The use of the three segments allows quantification of polymeric procyanidins simultaneously with other phenolic compounds using RP-HPLC. Whereas previously, these compounds had to be run separately using normal HPLC.

During consecutive RP-HPLC runs, changes in retention time occurred after every sample. To minimise this, an additional run time of 7 min was added to the end of the analysis to flush the system by increasing solvent B to 100%. Another 7 min was incorporated to recondition the column and bring down solvent B to 5%. This new HPLC method enables detection of all phenolic compounds as distinct peaks with good resolution (Rs > 1.5). Fig. 2 shows the profile of 15 compounds and internal standard (IS) used for identifying and quantifying phenolic compounds in peanut skin extracts. Phenolic acids (compounds no. 1, gallic acid; no. 2, protocatechuic acid; no. 12, caffeic acid; no. 13, *p*-coumaric acid; no. 14, ferulic acid) were eluted with retention times between 4 and 45 min; flavonoids (compounds no. 3, epigallocatechin; no. 4, catechin; no. 5, procyanidin B2; no. 6, epicatechin; no. 7, epigallocatechin gallate; no. 8, epicatechin gallate; no. 9, catechin gallate) between 15 and 92 min; and stilbenes (compounds no. 10, piceid; no. 11, resveratrol) between 50 and 84 min. The specific retention times and the maximum UV band based on spectral data using diode array detector for the 16 compounds is shown in Table 2.

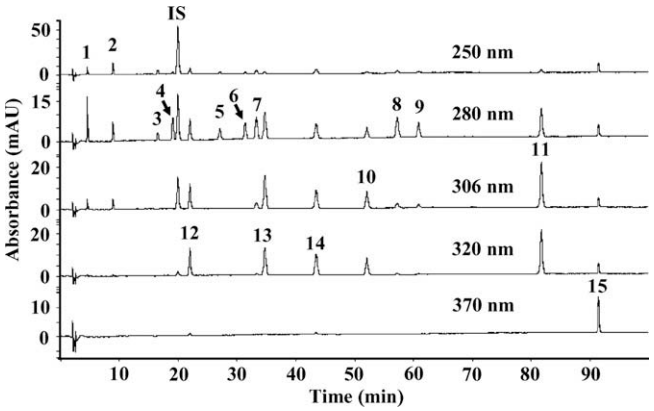

Fig. 2. HPLC profile for phenolic compounds (mAU vs. time) at different wavelengths. Number shows the following standard chemicals: 1 = gallic acid; 2 = protocatechuic acid; 3 = epigallocatechin; 4 = (+)-catechin; 5 = procyanidin B_2; 6 = (−)-epicatechin; 7 = (−)-epigallocatechin gallate; 8 = (−)-epicatechin gallate; 9 = (−)-catechin gallate; 10 = piceid; 11 = trans-resveratrol; 12 = caffeic acid; 13 = *p*-coumaric acid; 14 = ferulic acid; and 15 = quercetin.

3.2. HPLC method validation

3.2.1. Determination of accuracy

Recovery of peanut skin extracts containing all 15 compounds ranged from 58% to 119% as shown in Table 2. Recommended average recovery of an analyte for an active drug substance in a pharmaceutical formulation ranges from 99% to 101% (Snyder et al., 1997). Since the phenolic compounds were added to peanut skin extracts, other components in the sample matrix may have interfered with the accurate quantification of the analytes, thus, giving <99% recovery values for some of the compounds assayed in this

Table 1
Chromatographic conditions for the determination of phenolic compounds in peanut skin extracts.

Chromatographic conditions

study. The lowest recovery of 58% was obtained for gallic acid. This value was lower than those found by Sakakibara, Honda, Nakagawa, Ashida, and Kanazawa (2003) and Garcia-Falcon, Peres-Lamela, Marinez-Carballo, and Simal-Gandara (2007) of 87% and 79%, respectively, on the recovery of polyphenol standards in radish root and wines, respectively. The extraction procedure used in this study involved removal of lipids and lipid soluble compounds from the peanut skin extracts before extraction of polyphenolic compounds. Sakakibara et al. (2003) directly extracted the polyphenols in radish root using methanol as extracting solvent while Garcia-Falcon et al. (2007) employed acidic fractionation of wines to obtain hydroxybenzoic acids (including gallic acid). The differences in recovery values therefore may be attributed to the extraction procedures employed in these studies.

Resveratrol recovery in this study was 104% after accounting for its natural concentration in peanut skins. This value was higher than those found by Rudolf, Resurreccion, Saalia, and Phillips (2005) in peanuts, where a recovery range of 71–96% was obtained. Rudolf et al. (2005) used a clean-up column to remove interfering compounds that co-elute with resveratrol, which may have resulted in lower recovery. The obtained value in this study however, was comparable with those found by Sobolev and Cole (1999) where they obtained recoveries of 100–117% in fresh peanuts.

Recoveries for protocatechuic acid, quercetin and caffeic acid were 98%, 112% and 119% respectively. These values were higher than those found by Sakakibara et al. (2003) with obtained recoveries of 75%, 83% and 77% for these compounds using chalcone as internal standard. Their extraction procedure, as mentioned, was entirely different from those used in this study, thus, differences in values can be expected. The recovery calculation for catechin gallate was made at 306 nm instead of the recommended 280 nm (Sakakibara et al., 2003). Analysis of peak purity for catechin gallate when detected at 280 nm showed two different spectra, suggesting that another peak is partially co-eluting with it, resulting in an overestimated recovery value for this compound. But when measured throughout this study at 306 nm, only the peak for catechin gallate was detected.

3.2.2. Determination of precision

Calculated coefficient of variation (% CV) for the 15 compounds ($n = 8$) are presented in Table 2. Acceptable limits of 1–2% for compounds of low-level concentrations were suggested by Snyder et al. (1997). The low variance (0.68–2.14%) obtained in this study was considered to be sufficient to determine phenolic compounds in foods quantitatively. The CV range found for this paper was better compared to those reported in literature, 1.19–13.49% (Betes-Saura, Andres-Lacueva, & Lamuela-Raventos, 1996) and 1–9% (Garcia-Falcon et al., 2007) for simultaneous determination of 19 and 28 phenolic compounds, respectively, in wine.

3.2.3. Determination of linearity and range

Five-point standard curves were generated for each phenolic compound. The calibration plots of peak area vs. concentration of phenolic compound for each compound exhibited a straight line. Results of regression analysis are presented in Table 2. Calibration curves were linear over the concentration range studied. All Pearson's product correlation coefficients, r, were >0.999, indicating positive linear relationship between peak area and concentration. All r values reported were within the acceptable limits of $r > 0.999$ (Snyder et al., 1997).

3.2.4. Determination of limit of detection and quantification

Calculated limit of detection and limit of quantification are presented in Table 2. LOD ranged from 0.1 to 0.9, while LOQ varied from 0.2 to 2.6 ppm ratio. Values were comparable to the LOQs established for 28 phenolic compounds in wine ranging from 0.2 to 1 ppm, with LOD values of 3× lower than the LOQ (Garcia-Falcon et al., 2007).

3.3. Identification and quantification of phenolic compounds in peanut skin extracts

The developed RP-HPLC method was applied to raw peanut skin extracts and typical chromatograms showing compounds detected at 250, 280, 306, 320 and 370 nm are presented in Fig. 3. The three peanut types varied differently and significantly in terms of composition based on the compounds identified. Yu et al. (2005) identified three classes of phenolic compounds in raw peanut skins (type not identified): (1) phenolic acids including chlorogenic acid, caffeic acid and ferulic acid; (2) flavonoids including epigallocatechin, epicatechin, catechin gallate, epicatechin gallate; and (3) stilbenes (resveratrol). In their follow-up study, caffeic acid, chlor-

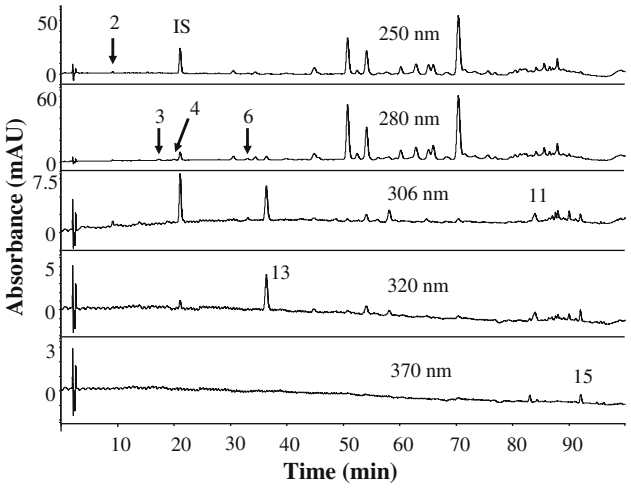

Fig. 3. HPLC profile of peanut skin extract from raw Runner peanuts (mAU vs. time) at different wavelengths. Peaks: 2 = protocatechuic acid; 3 = epigallocatechin; 4 = (+)-catechin; 6 = (−)-epicatechin; 11 = trans-resveratrol; 13 = *p*-coumaric acid; and 15 = quercetin.

ogenic acid, ellagic acid, resveratrol and its glycoside were identified but not quantified due to very low concentration and peaks were suppressed by major procyanidins.

3.3.1. Phenolic acids

Three phenolic acids namely: protocatechuic acid, caffeic acid and *p*-coumaric acid were identified and quantified from the peanut skin extracts (Table 3). Protocatechuic acid was significantly higher in Virginia (34.03 μg/g) followed by Spanish (15.45 μg/g) and Runner skins (7.62 μg/g). Previous studies showed that ethyl protocatechuate, a protocatechuic acid ethyl ester, was identified through fractionation in Spanish peanut skin ethanolic extracts (Huang et al., 2003; Yen, Chang, & Duh, 2005), but no amount was provided by the authors. Protocatechuic acid was identified and quantified using the HPLC method developed in this study with no further need for fractionation.

Caffeic acid was detected only in Spanish skins. This compound was detected by Yu et al. (2005) in peanut skins (peanut type not specified), but amount was not reported. *p*-Coumaric acid was highest in Runners (23.34 μg/g), followed by Spanish (12.31 μg/g) then Virginia (4.98 μg/g). *p*-Coumaric acid was not found by Yu et al. (2006) in peanut skins but it is predominantly present in peanut kernels as reported by Duncan, Gorbet, and Talcott (2006). One of the most prevalent antioxidant polyphenolics isolated from the water-soluble components of peanuts obtained by Duncan et al. (2006) was *p*-coumaric acid. Insignificant changes in *p*-coumaric concentration were observed after 8 weeks storage at 35 °C, but no amount was provided in their report.

Table 3
Mean values for phenolic compounds, calculated as μg/g dry skin, as measured by RP-HPLC, in raw peanut skin ethanol extracts.[A]

Compound	Runner	Virginia	Spanish
Protocatechuic acid	7.62c ± 1.34	34.03a ± 1.95	15.45b ± 0.87
Caffeic acid	nd	nd	3.49 ± 0.36
p-Coumaric acid	23.35a ± 0.91	4.98c ± 0.63	12.31b ± 1.42
Epigallocatechin	440.05b ± 16.70	1275.92a ± 77.10	1274.72a ± 67.50
Catechin	74.35c ± 13.14	535.03a ± 41.72	448.30b ± 36.47
Procyanidin B2	20.67b ± 5.63	17.69b ± 1.61	107.00a ± 18.99
Epicatechin	60.06c ± 11.44	144.75b ± 1.42	238.55a ± 9.20
Quercetin	20.14b ± 1.49	22.88b ± 2.92	27.99a ± 2.10
Resveratrol	4.30b ± 0.10	3.66b ± 0.44	15.04a ± 1.57

[A] Mean values for each compound in a row followed by the same letter are not significantly different ($\alpha = 0.05$) as determined by Fisher's least significant difference (LSD) mean separation test. Amounts were calculated as means of four analyses ± standard deviation. nd = not detected.

3.3.2. Flavonoids

Several peaks were observed at 280 nm (Fig. 3), indicating presence of flavanols, as shown by their spectral data (data not shown) having characteristic maximum wavelengths between 275 and 280 nm. Thirty to forty peaks were detected from the three peanut skin types at 280 nm. Similar findings were observed by Yu et al. (2006) where two monomer peaks and 39 other polymer peaks (dimers, trimers, tetramers) at 280 nm where detected by LC–MS. A small hump is still present at 75–90 min of runtime for all three peanut skin types. However, the compounds of interest are not found within this region.

Virginia and Spanish peanut skins had significantly more epigallocatechin than Runner skins (Table 3). In terms of total flavanol content (calculated as the sum of epigallocatechin, catechin and epicatechin), Spanish skins had 1962 μg/g; Virginia had 1956 μg/g and only 574 μg/g for Runners. All values were higher than those found by Yu et al. (2006) of 161 μg/g dry skin (peanut type not specified) for total procyanidin monomers. Differences in peanut skin type, sample extraction, preparation and analytical method may have contributed to the large discrepancy in values. Lazarus et al. (1999) also identified procyanidins (monomers to octamers) in peanut skin extracts, but these were not quantified. The dimer procyanidin B_2 was present at very low levels in Runner and Virginia skins compared to Spanish skins. As observed by Yu et al. (2006), directly peeled peanut skin contained mostly procyanidin trimers and tetramers. Higher forms of procyanidins may be present in raw peanut skins. As peanut skins were roasted, a considerable amount of trimers and tetramers were lost due to degradation (Yu et al., 2006).

The flavonol quercetin was highest in Spanish peanut skin. Other flavonols with peaks exhibiting characteristic absorption spectra similar to those of quercetin were also detected in Spanish skins. Quercetin was not found by Yu et al. (2006) in peanut skin extracts, while quercetin derivatives were identified by Daigle, Conkerton, Hammons, and Branch (1975) on selected white testa peanuts.

3.3.3. Stilbenes

Resveratrol but no piceid was detected in all peanut skin types. Resveratrol content was highest in Spanish skins (15.04 μg/g) followed by Runners and Virginia skins (4.30 and 3.66 μg/g, respectively). The amount present in Runners was lower compared to those reported by Nepote et al. (2004) of 9 μg/g peanut skins (Florunners), obtained from a blanching process and extracted with ethanol. The authors however had to fractionate the ethanol extract due to very low concentration of resveratrol. Sanders et al. (2000) also reported that seed coats from Runner and Virginia types (raw) contained ~0.65 μg/g of seed coat.

4. Conclusions

A RP-HPLC method for identification and quantification of 15 compounds, including phenolic acids, flavonoids and stilbenes from peanut skin extracts was developed and validated in this study. The gradient verified in this paper can be successfully applied to a reverse-phase HPLC system with a C_{18} column (4.6 × 250 i.d. mm, 5 μm particle size), with DAD detection and mobile phase consisting of 0.1% formic acid in water and 0.1% formic acid in acetonitrile. A maximum of nine of 15 phenolic compounds were identified and quantified in raw peanut skins. These were successfully quantified using β-resorcylic acid as an internal

standard using the HPLC reverse-phase gradient elution established in this study. The method detected the natural forms in peanut skin extracts directly without need for hydrolysis. Thus, the present method can determine quantitatively individual classes of flavonoids, phenolic acids and stilbenes.

Previous study by Francisco and Resurreccion (2009) showed that heat-treated peanut skins had higher total phenolics and antioxidant capacity than raw peanut skins. Similar observation was reported by Yu et al. (2005) when roasted peanut skins were compared to raw and water-blanched skins. An investigation on the quality and quantity of phenolic compounds in heat-treated skins is currently being conducted using this new method to determine and quantify health-promoting compounds present in peanut skins.

ABSTRACT

Chlorpyrifos-methyl hapten, *O*-methyl-*O*-(3,5,6-trichloro-2-pyridinyl)-*N*-(2-carboxyethyl)-phosphoramidothionte (H1), was synthesized and conjugated with bovine serum albumin (BSA) and ovalbumin (OVA) by the active ester method. Then H1–OVA conjugate was used as coating antigen, while H1–BSA conjugate was used as immunogen for producing monoclonal antibody. After optimisation, a monoclonal antibody-based effective competitive indirect enzyme-linked immunsorbent assay (ELISA) was developed and applied for determination of chlorpyrifos-methyl with a novel combination of antibody/antigen, I_{50} of which was 75.22 ng/ml, limit detection (LD) was 0.32 ng/ml, and there was relative high cross-reactivity (CR) only with chlorpyrifos (1.4%), and CRs with other tested pesticides were all below 1% and regarded as negligible. The recoveries obtained by standard chlorpyrifos-methyl addition to real samples, including grape, Chinese cabbages, water and soil were all from 82.4% to 110.2%. Therefore, the optimised ELISA might become a convenient and satisfied analytical tool for monitoring chlorpyrifos-methyl residues in agriculture ecosystem.

1. Introduction

There is increasing concern over food and environmental contamination caused by the widespread use of pesticides (Kim, Lee, Chung, & Lee, 2003). Among them, organophosphorous pesticides (OPs) are described as a group of highly toxic compounds (Costa, 1988; Zhang et al., 2007) and widely used in agriculture for protecting plants. It is reported that OP toxicants could elicit their effects by inhibition of acetylcholinesterase, which leads to the accumulation of the neurotransmitter acetylcholine (Ach) in synapses, over stimulates the post synaptic cholinergic receptors with consequent signs of neurotoxicity (Ecobichon, 1996; Gallo & Lawryk, 1991). Therefore, more and more non-target organisms, including human, fish and been are threatened by OPs.

Chlorpyrifos-methyl (*O*,*O*-dimethyl-*O*-(3,5,6-trichloro-2-pyridyl)phosphorthioate) is a widely used nonsystemic OP, which is effective against a wide range of insects. The most sensitive and toxicologically relevant effect after administration of chlorpyrifos-methyl is inhibition of acetylcholinesterase activity in erythrocytes and brain. Because of its toxicity and extensive application to crops and cattle, chlorpyrifos-methyl was classified as a restricted pesticide with a strict maximum residue limited (MRLs) standard for use in farming in many countries, including China Government.

Current analytical methods, such as gas chromatography (GC) and high-performance liquid chromatography (HPLC) are sensitive and reliable for the detection of pesticide residues (Kim, Lee, et al., 2003). However, they require a high cost and skilled analysts and involve time-consuming sample preparation steps. Therefore, there is a growing demand for more rapid and economical methods for determining pesticide residues. Immunoassays have recently emerged as an alternative to the traditional methods that can meet such demands. Immunochemical techniques that have been used extensively in clinical laboratories began recently to gain acceptance as a fast, sensitive and cost-effective tool for detecting trace amounts of chemicals such as pesticides (Hammock et al., 1982). It is reported that several monoclonal antibodies of pesticides, including parathion-methyl and fenitrothion were successfully prepared and applied for determination in samples (Kim, Kim, & Lee, 2007; Kolosova, Park, & Sergei, 2004). In our previous work, fenthion polyclonal antibody is prepared and applied for fenthion detection in fruit samples (Zhang et al., 2008). To date, several reports describe immunoassay for chlorpyrifos-methyl detection (Edward, Skerritt, Hill, & McAdam, 1983; Skoczenski, Fat, Matt, Pitts, & Zettler, 1996; Sullivan, Chen, & Goh, 2007). However, it is clearly that, on one hand, these reports as well as the commercial kit for chlorpyrifos (Strategic Diagnostics Inc.) described a

doi:10.1016/j.foodchem.2009.03.097

polyclonal antibody-based immunoassay for the detection of chlorpyrifos-methyl, on the other hand, the detection samples are limited to grain or water. To the best of our knowledge, chlorpyrifos-methyl is a widely used pesticide to control pest insects in farm as well as in storage grain. Therefore, it was necessary to detect chlorpyrifos-methyl from various samples, such as vegetables, fruits and soil. Together, the main objective of this work was to establish a monoclonal antibody-based ELISA assay for the detection of chlorpyrifos-methyl from vegetables, fruits, soil and water. In the present study, we reported that: (i) a specific monoclonal antibody of chlorpyrifos-methyl was prepared; (ii) a monoclonal antibody-based sensitive ELISA for chlorpyrifos-methyl detection was developed; and (iii) the chlorpyrifos-methyl from different real samples, including grape, Chinese cabbages, water and soil was detected by using the established ELISA protocol.

2. Materials and methods

2.1. Chemicals and instruments

Chemical reagents for hapten synthesis and pesticide standards used for cross-reactivity studies were supplied by Jiangsu Pesticide Research Institute (Nanjing, China). Analytical grade solvents were from Sinopharm Group Chemical Reagent Co., Ltd. (Shanghai, China). Dulbecco's Modified Eagle's Medium (DMEM), HAT medium (hypoxantin, aminopterin, thymidin), HT medium (hypoxantin, aminopterin) were purchased from Gibco (USA). Tween 20, *N*-hydroxysuccinimide (NHS), N,*N*-dicyclohexylcarbodiimide (DCC), bovine serum albumin (BSA), ovalbumin (OVA), complete or incomplete Freund's adjuvant and tetramethylbenzidine (TMB) were all purchased from Sigma (St. Louis, USA). Faetal bovine serum (FBS) was purchased from Hangzhou 'Sijiqing' Company (Hangzhou, China). Horseradish peroxidase (HRP)-labelled goat anti-mouse IgG was purchased from Sino-American Biotechnology Co. (Dalian, China). The Mouse Monoclonal Antibody Isotyping Kit was purchased from Roche Co. (Mannheim, Germany).

Thin-layer chromatography (TLC) was performed on 0.25 mm, precoated silica gel 60 F254 on aluminium sheets (Merck, Darmstat, Germany). Column chromatographic purifications were carried out with silica gel (60–230 mesh), from Qingdao Haiyang Chemical Co., Ltd. (Qingdao, China). UV–vis spectra were recorded on a Bechman 640 spectrophotometer. Polystyrene 96-well microtitre plates were from Costar (Corning, Massachusetts, USA). A microplate washer from Prolong New Technology Co. (Beijing, China) was used to wash enzyme-linked immunosorbent assay (ELISA) plates. Absorbance was measured using a microtitre plate reader (Thermo Electron Co., USA).

SP2/0 cells were stored in the Immunology and Quarantine Lab of Nanjing Agricultural University (Nanjing, China), and BALB/c mice were purchased from the Center of Comparative Medicine of Yangzhou University (Yangzhou, China). All animal studies were performed in accordance with institutional guidelines.

2.2. Synthesis of hapten

The hapten synthesis assay was performed as described previously, with some modifications (Brun, Garcés-García, Puchades, & Maquieira, 2004; Kim, Cho, Lee, & Lee, 2003; Kim et al., 2003; Zhang et al., 2007). The synthetic routes for hapten are illustrated in Fig. 1. In brief, a solution of 3,5,6-trichloro-2-pyridinol (4.17 g, 21.1 mmol) in acetonitrile was added dropwise to a stirred mixture of 3.83 g (23.2 mmol) of methyl dichlorothiphosphate, 8.7 g (63 mmol) of finely ground K_2CO_3 and 20 ml of acetonitrile. After stirring for 1 h at room temperature, the mixture was filtered through celite, and the solvent was removed under reduced pressure. The residue was subjected to column chromatography (silica gel, petroleum ether:methylenechloride (15:1)) to give 6.88 g (72.6%) of a straw yellow oil, named as product A (*O*-methyl-*O*-(3,5,6-trichloro-2-pyridinyl)-phosphorochloridothioate).

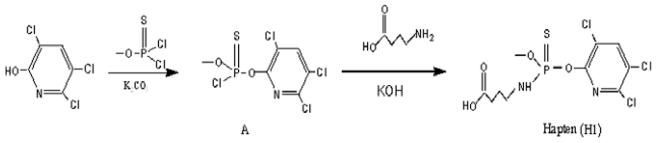

Fig. 1. Synthetic route for hapten (H1). A: *O*-methyl-*O*-(3,5,6-trichloro-2-pyridinyl)phosphorochloridothioate; hapten (H1): *O*-methyl-*O*-(3,5,6-trichloro-2-pyridinyl)-*N*-(2-carboxyethyl)phosphoramidothionte.

To a stirred solution of 1.37 g (4.2 mmol) of product A in 6 ml of methyl alcohol cooled in an ice-water bath was added dropwise a solution of 0.78 g (11.4 mmol) of KOH and 0.54 g (5.2 mmol) of 4-aminobutyic acid in 3.4 ml of methyl alcohol. After stirring for 5 min, the reaction mixture was filtered and adjusted pH to 4.0 with 1 mol/l (M) hydrochloric acid, then extracted with ethyl acetate and the solvent was evaporated, the residue gave 1.28 g (78%) of a straw yellow solid, termed as hapten H1 (*O*-methyl-*O*-(3,5,6-trichloro-2-pyridinyl)-*N*-(2-carboxyethyl)-phosphoramidothionte). The structure of H1 was confirmed by Mass Spectrometry (MS) and Proton Nuclear Magnetic Resonance (^{1}HNMR).

2.3. Preparation of hapten–protein conjugate

In order to generate immunogens and coating antigen, the hapten of chloropyrifos-methyl (H1) was coupled to protein BSA and OVA, respectively, according to the method as described previously (Langone & van Vunakis, 1982) The immunogen (H1–BSA) and coating antigen (H1–OVA) were purified by dialysis in phosphate buffer (PB: 0.02 M, pH 6.8). The structures of conjugates were confirmed by UV–vis spectral, and the final conjugates (H1–BSA and H1–OVA) were stored at −20 °C for further study. Assuming that the molar absorptivity of haptens was the same for the free and conjugated forms, the hapten densities (the number of hapten molecules per molecule of protein) of the conjugates were estimated directly by the mole absorbance: εHapten density = (εconjugation − εprotein)/εhapten as described previously (Kishiro, Kagawa, Naito, & Sado, 1995; Zhang et al., 2006).

2.4. Production of monoclonal antibody to chlorpyrifos-methyl

2.4.1. Immunisation and screening of sera

The immunisation of five BALB/c female mice was carried out according to the methods described (Kishiro et al., 1995; Zhu, Xu, Lou, Blake, & Liu, 2007). The immunogen (H1–BSA) was diluted into PBS (phosphate buffered saline), mixed with an equal volume of Freund's complete adjuvant, and stirred to prepare a water-in-oil emulsion. The emulsion (200 μg conjugate per mouse) was injected into the peritoneal cavity of 6-week-old BALB/c female mice. The same injection with incomplete Freund's adjuvant was repeated 3 weeks later, and at 3-weeks intervals thereafter. One week after the fifth immunisation, five antiserums for chlorpyrifos-methyl named Ab01, Ab02, Ab03, Ab04 and Ab05, respectively, were obtained from the tail vein of each mouse, and the sera were tested for antibody titres and for analyte recognition by indirect ELISA. The titres of the antisera from the different bleeds of mice were determined by measuring the binding of serial dilutions of the antisera to the corresponding coating antigen (H1–OVA) using noncompetitive ELISA protocol as described previously (Zhang et al., 2006). Flat-bottomed polystyrene microtitre plates were coated with H1–OVA (5 μg/ml, 50 μl per well) in 50 mM carbonate–bicarbonate buffer (pH 9.6) by overnight incubation at 4 °C. The following day, the coated plates were washed five times with

PBST (PBS containing 0.05% (vol/vol) Tween 20, pH 7.4) and blocked by incubation with 1% gelatin in PBS (100 μl per well) for 1.5 h at 37 °C. After another washing step, 50 μl per well of antiserum diluted with PBS (1:1600–1:512,000) were added to the plate, and the plates were incubated for 1 h at 37 °C. After another washing step, 50 μl of a GAM–HRP conjugate diluted 1:25,000 with PBST were added to each well and incubated for 1 h at 37 °C. Next, the plates were washed again, then, 50 μl of substrate solution (3.3 μl of 30% H_2O_2 and 400 μl of 0.6% TMB in DMSO (dimethyl sulfoxide) per 25 ml of acetate buffer, pH 5.5) were added to each well. Colour development was stopped after 15–30 min with 2 M H_2SO_4 (25 μl per well). The absorbance was measured by the single-wavelength mode at 450 nm.

2.4.2. Cell fusion and hybridoma selection

One mouse showing the highest serum reactivity was given peritoneal cavity injections of 200 μg H1–BSA conjugate in PBS at 1 week intervals. After four days of the last injection, the donor mouse was sacrificed. SP2/0 myeloma cells were cultured in high-glucose DMEM supplemented with 20% faetal bovine serum (referred to as s-DMEM). Cell fusion procedures were performed essentially as described previously (Nowinski, Lostrom, Tam, Stone, & Burnette, 1979). Mouse spleen lymphocytes were fused with SP2/0 myeloma cells at a 5:1 ratio, with PEG 1500 as the fusing agent. The fused cells were distributed in 96-well culture plates at an approximate density of 4×10^4 cells/μl of s-DMEM per well. Twenty-four hours after plating, 100 μl of HAT selection medium (s-DMEM supplemented with 100 μl hypoxanthine, 0.4 μM aminopterine, 16 μM thymidine) was added to each well. Half the medium of the wells was replaced with fresh HAT medium after cell fusion on forth and seventh day, respectively. Cells were grown in HAT medium for 2 weeks, then HAT was substituted by HT medium.

Eight to ten days after cell fusion, culture supernatants were screened for the presence of antibodies that recognised chlorpyrifos-methyl. Supernatants from these clones were collected and initially screened for antibodies by the indirect ELISA method as described above. Culture supernatants that passed the initial screen were subsequently tested for antibody specificity by competitive ELISA. Selected positive hybridoma cell lines were subsequently subcloned by limiting dilution.

2.4.3. Production, purification and isotyping of monoclonal antibodies

Ascites fluid was produced in BalB/c mice primed with incomplete Freund's adjuvant by intraperitoneal (Ip) injection of 2×10^7 hybridoma cells. Ascites fluid was harvested after 10–14 days of the hybridoma cell injection. Antibodies were purified on a small scale directly from ascites fluid by affinity chromatography on protein L-agarose as described previously (Schuler & Reinacher, 1991). The immunoglobulin subclass and light chain isotype of the antibodies were determined using a Mouse Monoclonal Antibody Isotyping kit.

2.5. Competitive indirect ELISA (CI-ELISA)

Microplates were coated overnight at 4 °C with 50 μl per well of the appropriate coating antigen concentration (3 μg/ml) in 0.05 M carbonate–bicarbonate buffer (pH 9.6). After washing with PBST (PBS containing Tween 20 (0.05%, vol/vol), pH 7.4), the wells were blocked with 100 μl of reagent in PBS (1% gelatin, or 1% OVA, or 1% polyvinyl alcohol, or 3% skimmed milk powder) for 1 h at 37 °C. After another washing step, 25 μl per well of culture supernatants diluted in PBS and 25 μl per well of analyte solution were added, and incubated for 1 h. Following a washing step, goat-anti-mouse–HRP conjugate (1:25,000 in PBST, 50 μl per well) was added and incubated for 1 h at 37 °C. The plates were washed again, and 50 μl per well of substrate solution was added. The colour development was stopped after 10–15 min with 2 M H_2SO_4 (25 μl per well). The absorbance was measured at 450 nm. Sigmoidal curves were fitted to a logistic equation (Raab, 1983) from which I_{50} values (concentration at which binding of the antibody to the coating antigen is inhibited by 50%) were determined.

2.6. Optimisation of a CI-ELISA

The screening of the variables to set up competitive ELISA procedures was performed in antibody- and conjugate-coated formats, following the protocols as described previously (Tijssen, 1987). Optimised assay was performed using chlorpyrifos-methyl as the competitor analyte. A set of experimental parameters, including ionic strength, pH and blocking agents were studied sequentially to improve the sensitivity of the immunoassay. The main criteria used to evaluate immunoassay performance were I_{50} and R^2 of their linear equation. In this work, the selection of optimised parameters of ELISA protocol was obtained according to two standards: "$R^2 > 0.9$" and "I_{50}/A_{max} was lowest" (described by Lee et al. (2006)). The effect of pH was evaluated using different PBS solutions, ranging from pH 5.0 to 8.0. To estimate the influence of salt (Na^+) concentration, PBS at 0, 0.2, 0.4, 0.8, 1.6 and 3.2 mg/ml was tested. Finally, the influence of blocking reagent (1% OVA, or 1% gelatin, or 1% polyvinyl alcohol, or 3% skimmed milk powder) was investigated.

2.7. Evaluation of the optimised CI-ELISA

2.7.1. Cross-reactivity (CR) studies

The specificity of the optimised ELISA procedures was determined against several organophosphorus insecticides, including chlopyrifos-methyl, chloryrifos, fenitrothion, prarthion-methyl, triazophos, 3,5,6-trichloro-2-pyridinol and dichlorvos. The CR was calculated as follows: CR (%) = (I_{50}(methyl-chlopyrifos)/I_{50}(interferent)) × 100. Here, CR (%) of chlopyrifos-methyl was defined as 100%.

2.7.2. Accuracy (analysis of spiked samples)

The accuracy was evaluated by spiked samples experiment. To study spike recovery, the materials, including grape, Chinese cabbages, water and soil were selected for study. Samples were spiked with different concentrations of chlopyrifos-methyl and analysed in a blind fashion by the ELISA protocol. The grape samples were purchased from a local supermarket, the Chinese cabbages and soil samples were taken from farm of Nanjing Agricultural University and water is tap water. For the spiked-and-recovery test, five solutions (0, 5, 10, 25 and 50 μg/ml) of chlopyrifos-methyl in methanol were prepared. Then, 1 ml of each solution was added to 1 g of the samples. Here, the samples were water (1 ml), soil, grape and Chinese cabbages (the peel of grape and the leaves of Chinese cabbages were chopped into fine pieces before the solution was added). In the following steps, all samples were shaken (60 rpm/min) for 2 h. After stability of several minutes (the pieces of grape peel or cabbage leaves, and soil were deposited), the sample supernatant was diluted with PBS–methanol buffer for 10-times (the final concentrations of chlopyrifos-methyl were 0, 0.5, 1, 2.5 and 5 μg/ml) and analysed by the optimised ELISA protocol.

3. Results

3.1. Verification of hapten (H1) and the coupled identification of artificial antigen

The hapten (H1) was synthesized with only two steps and the structure of H1 was clarified by MS and ^{1}HNMR. The results of

MS and ^{1}HNMR were described as follows: ^{1}HNMR (CD_3–CN) δ: 1.77 (m, 2H, CH_2CH_2COOH), 2.35 (m, 2H, CH_2COOH), 2.93 (t, 2H, CH_2NH), 3.12 (s, 3H, CH_3–OP), 7.76 (s, 1H, Ar). MS (EI^+) m/z (%): 167.1 (53.66), 102.1 (26.16), 86.1 (100), 84.1 (72.13). These results showed the structure of compound was in accordance with that of hapten (H1) designed.

In the UV–vis spectra obtained from continuous wavelength scanning, there were a lot of obvious changes between the spectra of the conjugate and that of its carrier protein. The conjugate of up taking peak shape is the result of lapping between the pristine carrier protein and hapten that have been coupled. The conjugation molar ratio of H1–BSA and H1–OVA is 22 and 21, respectively, which was assessed by spectrophotometric method. Finally, the conjugate H1–BSA was used as immunogen to produce monoclonal antibody, while H1–OVA was used as coating antigen.

3.2. Production and characterisation of monoclonal antibody

After fifth injection, the titres of Ab01, Ab02, Ab03, Ab04 and Ab05 were $1{:}1.28 \times 10^6$, $1{:}0.64 \times 10^6$, $1{:}2.56 \times 10^6$, $1{:}1.28 \times 10^6$ and $1{:}1.28 \times 10^6$, respectively. The titres of antisera from these five mice did not rise further after the sixth immunity. Therefore, the mouse, produced Ab03, was selected for subsequent hybridoma production because of its highest relative reactivity with H1–OVA. Hybridoma clones were initially screened by indirect ELISA for their reactivities with H1–OVA, and a total of 56 hybridoma cell lines were obtained. Then, one hybridoma cell line (3E12/B6) was further selected by competitive ELISA, and its produced stable monoclonal antibody (MAb) for chlopyrifos-methyl was used for further study.

The hybridoma cell line (3E12/B6) was found to secrete antibodies of the IgG1, kappa type. The MAb was ascites fluid in mouse (7.91 mg/ml), purified and stored at −20 °C for following characterisation studies.

3.3. Optimisation of a CI-ELISA

In order to get a optimised protocol for CI-ELISA, the effects of pH, blocking agents and ionic strength on ELISA performance were evaluated in this study. In the system MAb (3E12/B6)/H1–OVA, a lower salt concentration (<0.4 M) in the assay system resulted in higher I_{50}, whereas a higher salt concentration (3.2 M) in the assay system resulted in lower R^2 value of its linear equation owing to lower optical densities (OD). As shown in Table 1, 0.8 M of salt concentration was selected in CI-ELISA system because the $R^2 > 0.9$ and the I_{50}/A_{max} was lowest. Furthermore, when analyte was dissolved in buffer at different pH values ranging from 5.0 to 8.0, no significant effect on the I_{50} was detected, but, interestingly, both strong acid and alkali matrix resulted in low sensitivity, indicating that the assay could effectively detect chlorpyrifos-methyl at pH values ranging from 6.0 to 7.5. In addition, it was showed that ionic strength had a strong influence on ELISA performance. As for the effect of blocking reagents, the common blocking reagents, such as OVA, gelatin, polyvinyl alcohol and skimmed milk powder were tested. Finally, 1% polyvinyl alcohol was selected based on two strands (the lowest I_{50}/A_{max} and $R^2 > 0.9$). At last, the optimised parameters of ELISA procedure were determined as follows: concentration of coating antigen H1–OVA was 3 μg/ml, dilution of culture supernatants of MAb 3E12/B6 was 1:16, the blocking reagent was 1% polyvinyl alcohol, pH was 6–7.5, and ionic strength was 0.8 M.

Table 1
Effect of ionic strengths, pH values and blocking agents on the ELISA sensitivity (I_{50}).

Factors	I_{50}[d] (μg/ml)	A_{max}	R^2 of linear equation

3.4. Evaluation of the optimised CI-ELISA

3.4.1. Evaluation of sensitivity

Under the optimised conditions mentioned above, the indirect competitive ELISA procedures were conducted in quintuplicate with a series of standard concentration of chlorpyrifos-methyl at different times. Then a competitive curve representing the average was obtained (Fig. 2a). We used logit(B/B_0) as the lateral coordinates (y), logarithm of concentration of chlorpyrifos-methyl (ng/ml) as the longitudinal coordinates (x). After conversion of Fig. 2a, it was observed that in the range of 0.01–100 μg/ml, the

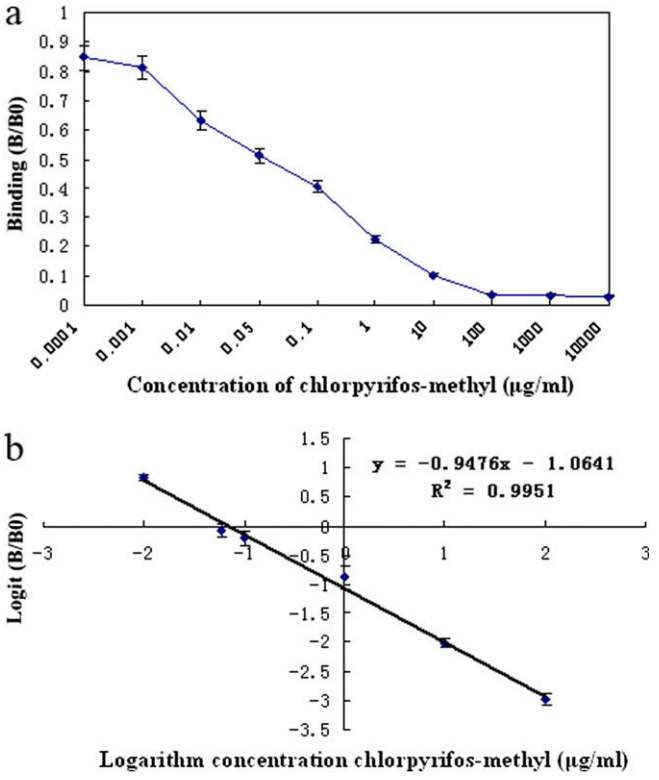

Fig. 2. Indirect competitive enzyme-linked immunsorbent assay (CI-ELISA) curve for chlorpyrifos-methyl. (a) Binding curve of the CI-ELISA, and "B/B_0" is binding ratio of antibody/coating antigen in wells; (b) the detection line conversed from (a), and "logit(B/B_0)"equals to logistic value of "B/B_0".

Table 2
Cross-reaction of monoclonal antibody 3E12/B6 with chlorpyrifos-methyl and its analogues.

Analogues	Structures	I_{50}[a] (μg/ml)	Cross-reactivity (%)
Chlopyrifos-methyl		0.075	100.0
Chloryrifos		5.2	1.4
Fenitrothion		11.52	0.64
Prarthion-methyl		300	<0.03
Triazophos		>300	<0.03
3,5,6-Trichloro-2-pyridinol		>300	<0.03
Dichloryos		>300	<0.03

[a] The concentration of chlorpyrifos-metyl that inhibited the colour development in the competitive immunoassay by 50%.

graph between logit(B/B_0) and logarithm of concentration of chlorpyrifos-methyl (μg/ml) was linear (Fig. 2b), and the regression equation was obtained ($y = -0.9476x - 1.0641$, $R^2 = 0.9951$). In this optimised ELISA, I_{50} value was 75.22 ng/ml and the limit detection (LD) was 0.32 ng/ml by the extrapolation of $B_0 - 3SD$ extrapolation.

3.4.2. Cross-reactivity

To determine the specificity of the optimised CI-ELISA, several organophosphorus pesticides were tested for cross-reactivity. As shown in Table 2, the highest cross-reactivity was 1.4%, obtained for chlorpyrifos. Meanwhile, the interferences of other tested similar compounds and organophosphorus pesticides were lower (<1%) and regarded as negligible. These results indicated that the optimised CI-ELISA had a high specificity and might be applied for determination of chlorpyrifos-methyl in samples.

3.4.3. Accuracy (analysis of spiked samples)

The spiked recoveries were used to confirm the accuracy of optimised CI-ELISA. As shown in Table 3, the average recoveries of spiked Chinese cabbages were from 88.5% to 92.6%, and those of spiked grape were from 82.4% to 94.6%, and those of spiked water were from 96.4% to 110.2%, those of spiked soil were from 82.2% to 87.2%. Overall, the CI-ELISA developed in this study could not only avoid complicated sample disposal protocol, but only accurately determine chlorpyrifos-methyl residues in samples of grape, Chinese cabbage, water and soil.

4. Discussion

The organophosphorous pesticides (OPs), including chlorpyrifos-methyl, have a thiophosphate group in common and differ only in the structure of their aromatic rings. Therefore, to achieve a high sensitivity ELISA for chlorpyrifos-methyl, it was desirable to synthesize hapten that has a bridge at the thiophosphate group in order to preserve the aromatic ring unique to chlorpyrifos-methyl. By this way, in this work, chlorpyrifos-methyl hapten (H1) was successfully synthesized. Compared to the previous works (Edward et al., 1983; Skoczenski et al., 1996; Sullivan et al., 2007), our work displayed three novelties: (i) a specific monoclonal antibody was prepared and applied for the detection of chlorpyrifos-methyl; (ii) various samples (especially for vegetables, fruits and soil) were selected to evaluate the efficiency of the optimised monoclonal antibody-based ELISA assay for chlorpyrifos-methyl; (iii) it was convenient to obtain stable and high-quality monoclonal antibodies from isolated positive hybridoma, whereas polyclonal antibody must be prepared each time by immunisation of rabbit. In this work, we have first developed an effective ELISA for chlorpyrifos-methyl based on specific monoclonal antibody using a novel combination of immunizing/coating hapten. Here, the "efficiency" of ELISA is mainly displayed on three aspects: (i) its high sensitivity. The limit detection (LD) of the optimised competitive indirect ELISA (CI-ELISA) was 0.32 μg/l, and its I_{50} was 75.22 μg/l, which made it possible to detect chlorpyrifos-methyl which are below the threshold level (0.1 mg/l) regulated by World Health Organization (WHO) for chlorpyrifos-methyl in vegetables. (ii) Its simplicity. Sample extraction is of great speediness and simplicity because of its high sensitivity mentioned above. In our work, it does not need to be concentrated after the pesticide (chlorpyrifos-methyl) in sample dissolves enough in organic solvent. Therefore, the ELISA could avoid the complicated former disposal procedure needed by chromatography (the sample extraction protocol of chromatography include sample dissolution, extraction and purification) (Arrebola, Martınez Vidal, Gonzaalez-Rodrıguez, Garrido-Frenich, &

Table 3
Recovery test of chlorpyrifos-methyl in real samples (soil, water, Chinese cabbages and grape).

Samples	Spiked (μg/ml)	Theoretical (μg/ml)	Found (μg/ml)	Average recovery ± SD (%)

	25	2.500	2.071 ± 0.013	82.8 ± 11.3
	50	5.000	4.168 ± 0.017	83.3 ± 6.0

Sanchez Morito, 2003; Zhang et al., 2006). (iii) Its utility. In our work, four independent samples, including fruit sample (grape), crop sample (Chinese cabbages), water and soil were chosen as the materials for studying spike recovery. As shown in Table 3, the recoveries obtained by standard chlorpyrifos-methyl addition to the four independent sample were all from 82.4% to 110.2%, indicating that optimised ELISA could detect chlorpyrifos-methyl in different samples with easy operation procedures. In addition, there was little or no cross-reactivity to similar compounds tested except for the insecticide chlorpyrifos, which showed a cross-reactivity of 1.4%. The high cross-reactivity of the antibody for chlorpyrifos is understandable, because it has the same thiophosphate structure as chlorpyrifos-methyl and its aromatic structure is very similar to chlorpyrifos-methyl. Together, the optimised ELISA might become a convenient and effective tool for monitoring chlorpyrifos-methyl in environment and agricultural samples.

Currently, work to amplify single chain variable fragment (scFv) from hybridoma cell line (3E12/B6) is in progress in our laboratory in order to produce recombinant antibody in *Escherichia coli*.

Purification

ABSTRACT

A monoclonal antibody (Mab) $6G_4$ against soybean β-conglycinin has been prepared using a conjugate of chicken ovalbumin and a synthetic peptide that corresponded to one of the epitope sequences of β-conglycinin as the immunogen. An ELISA method for the quantification of β-conglycinin has also been developed. In the present study, we report a novel method for the purification of β-conglycinin by Mab $6G_4$-based immuno-affinity chromatography. β-Conglycinin with a purity of 92.9% was successfully isolated from soybean proteins. Western blot assay was used to further identify its characteristics and the results demonstrated that the purified β-conglycinin maintains its biological activities. Therefore, the Mab-based immuno-affinity chromatography is an available method for purification of β-conglycinin. It also provides a new opportunity for future study on the mechanism of food allergy responses using high purity β-conglycinin as the experimental material.

1. Introduction

Soybean is widely used as food ingredients because of its nutritional and functional properties (Astadi, Astuti, Santoso, & Nugraheni, 2008; Friedman & Brandon, 2001; Liu et al., 2008; Saito, Kohno, Tsumura, Kugimiya, & Kito, 2001). However, soybean is also considered as a major source of food allergies especially in industrialised countries (Guo, Piao, Cao, Ou, & Li, 2008; Herman, Helm, Jung, & Kinney, 2003; Huisman & Jansman, 1991). Soybean allergies are prevalently becoming "health hacker" in the world recently (Chandra, 2002; Song, Frias, Martinez-Villaluenga, Vidal-Valdeverde, & de Mejia, 2008; Zeiger, 2000).

As a major soybean allergen, β-conglycinin with α, α′ and β subunits plays important roles in hypersensitive responses for children (Xiang, Beardslee, Zeece, Marwell, & Sarath, 2002) and young animals such as piglets (Li et al., 1990), calves (Lallès & Dreau, 1996) and mice (Guo et al., 2008). However, study on β-conglycinin has been limited due to the difficulty of separating β-conglycinin from other soybean proteins. Most previous studies have mainly used soybeans or their extracts as the experimental materials but not pure β-conglycinin because of the lack of an available isolation approach. Although some methods such as ammonium sulphate precipitation (Thanh & Shibasaki, 1976), pH adjustment isolation (Lovati et al., 1992), ultrafiltration membrane separation (Wu, Murphy, Reuber, & Fratzke, 2000) and phytase treatment (Saito et al., 2001) can be conducted to isolate β-conglycinin from soybean proteins, it is difficult to obtain enough pure β-conglycinin for research purposes. Since monoclonal antibodies (Mabs) are powerful tools for many molecular immunology investigations (Nelson et al., 2000), they have frequently been applied in practical studies on recognising antigens and identifying new cell surface molecules. These binding concepts of allergen and antibody also provide a possibility for us to prepare an immuno-affinity column mediated by Mab and develop a new approach for purification of β-conglycinin which can be used for future research purposes.

2. Materials and methods

2.1. Preparation of monoclonal antibody against soybean β-conglycinin

The preparation of a stable murine-derived hybridoma cell line, named as $6G_4$, has been described previously (You et al., 2008). The Mab against soybean β-conglycinin produced by $6G_4$ is an IgG1 isotype. It shows high affinity for β-conglycinin with an association constant of $6.9 \times 10^9\ M^{-1}$ and can specifically bind to the α and α′ subunits of β-conglycinin (You et al., 2008).

2.2. Production and purification of antibodies

A large amount of Mab was produced *in vivo*. The hybridoma cells from $6G_4$ (1×10^6 cells/mouse) were injected

intraperitoneally into BLAB/c mice pre-treated 7 days before with 0.5 mL mineral oil. About two weeks later, the ascitic fluids from mice inoculated by hybridoma cells were collected and centrifuged for 15 min at 10000×g to eliminate cells and dregs. The ascite supernatant was diluted with equal volume of 0.04 M barbital buffer (pH 7.0). An appropriate amount of SiO_2 powder was added into ascites dilution and gently stirred for 30 min. After centrifuging for 20 min at 2000×g, Mab $6G_4$ was primarily isolated from supernatant by ammonium sulphate, and a commercial Protein G Affinity Column (Amersham Biosciences, Uppsala, Sweden) chromatography was then performed to further purify IgG1 from ammonium sulfate precipitation.

2.3. Preparation of immuno-affinity column

The CNBr-activated Sepharose™ 4B (Amersham Biosciences, Uppsala, Sweden) medium was prepared according to its production instructions. Briefly, 2.3 g of CNBr-activated Sepharose™ 4B freeze-dried powder was suspended in 1 mM HCl (pH 2.5). After swelling, the medium was washed for 15 min with 1 mM HCl on a sintered glass filter to remove all additives.

Fifty-six mg of Mab $6G_4$ (IgG1) as ligand was dissolved in 8 mL of coupling buffer (0.1 M $NaHCO_3$, pH 8.3 containing 0.5 M NaCl) and mixed with prepared Sepharose 4B gel in a 10 mL test tube fitted with a stopper. Then, the tube was tied on the orbital shaker and the mixture was gently shaken for 1 h at 20–25°C. Excessive ligand was flushed away with at least five volumes of coupling buffer. Tris–HCl buffer (0.1 M, pH 8.0) was added to block any remaining active groups for 2 h. The gel was washed for at least three cycles of alternating pH using five volumes of each buffer. Each cycle consisted of a wash with 0.1 M acetate buffer (pH 4.0 containing 0.5 M NaCl) followed by a wash with 0.1 M Tris–HCl (pH 8.0 containing 0.5 M NaCl).

The gel coupled with IgG1 was loaded into a column (10 × 100 mm) which was washed with 20 mM sodium phosphate buffer (pH 7.0) at 4 °C. The residual space of the column was immediately filled with buffer, and the top of the column was connected to a pump. The pump was set to run at a flow rate of 1.3 mL/min. The elution was maintained for 10 bed volumes after a constant bed height was reached.

2.4. Extraction of total soybean proteins

Soybean seeds were ground with a Cyclotec Sample Mill (Model 1093, Tecator Inc., Herndon, VA, USA) to pass through a 60-mesh sieve. The soybean flour was defatted by *n*-hexane. The fat-free flour was then suspended in 0.03 M Tris–HCl buffer (pH 8.0 containing 0.01 M β-mercaptoethanol) (100 g flour per litre buffer). Proteins were extracted from the flour for 1.5 h by vortexing. Extracts were centrifuged at 12,000×g for 20 min at 4 °C using an Optima™ L-80 XP Ultracentrifuge (Beckman Coulter Inc, Palo Alto, CA, USA). After being filtered through a 0.45 μm Millex GP filter (Millipore, Cork, Ireland), the supernatant was used as test sample solution and stored at −20 °C until analysis.

2.5. Immuno-affinity chromatography of β-conglycinin

The total proteins was loaded onto the immuno-affinity column. The outlet tubing of the column was connected to an HD21-1 detector and a protein auto-collector (Huxi instrument Co., Shanghai, China). Flow rate was maintained for 1.0 mL/min. The medium was washed with binding buffer until the base line was stable. Glycine–HCl elution buffer (0.1 M, pH 2.7) was used to elute the sample and β-conglycinin was collected using the auto-collector according to absorbance profile. The pH of collection (β-conglycinin) was regulated immediately to neutral with 100 μL of 1 M Tris–HCl (pH 9.0).

2.6. Identification of β-conglycinin by Western blot

The proteins isolated from the immuno-affinity column were analysed by 12.5% sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS–PAGE) according to the standard procedure (Laemmli, 1970). The separated proteins were then transferred electrophoretically from gel to a 0.45 μm nitrocellulose membrane in a mini Trans-Blot Cell Apparatus (BioRad) for 1.5 h at 100 V. The membrane was incubated in 3% bovine serum albumin (BSA) for 2 h at 37 °C. After a stringent wash with Tris-buffered saline (TBS) containing 0.05% Tween-20 (TBST), the membrane was incubated with 0.1 μg/mL Mab $6G_4$ for 2 h at 37 °C. The unbound primary antibody was removed by washing with TBST. The horseradish peroxidase-conjugated secondary antibody (goat anti-mouse IgG-HRP) was then added and the substrate 3,3′-diaminobenzidine (DAB) was used to show the specific protein bands.

The concentration of isolated β-conglycinin was determined with a Mab-based competitive ELISA method described previously (You et al., 2008) and the concentration of total proteins was tested by Bicinchoninic Acid Kit for Protein Determination (BCA™ Kit, Pierce, Rockford, IL, USA). The purity of β-conglycinin is expressed as a percentage as the content of β-conglycinin compared with that of total proteins.

2.7. Evaluation of chromatography efficiency in the case of different Mab/gel ratio

There is a close relationship between the ligand (Mab)/gel ratio and the chromatography efficiency. In order to enhance the chromatography efficiency, it is necessary to obtain an optimal ligand (Mab)/gel ratio. In this study, five grade concentrations of Mab, 2.5, 5.0, 7.5, 10.0, 12.5 mg/mL gel, were conducted to prepare five immuno-affinity columns with the same size. The efficiency of the purification of β-conglycinin under identical conditions, including soybean protein extraction and isolation procedures, was then evaluated.

The concentrations and purities of isolated β-conglycinin were determined and the results are reported as mean ± SEM. All data were the average values from five replicate determinations. Statistical analysis was done using the Stat-View program (SAS Institute, Cary, NC, USA). Differences between the concentrations (or purities) of β-conglycinin obtained from five immuno-affinity columns were examined for statistical significance using the Dunnett test. A difference was considered as significant at $P < 0.05$.

3. Results and discussion

Fig. 1 shows the SDS–PAGE profile (Left) and Gary Density profile (Right) of β-conglycinin purified from soybean proteins. Lane b represents total soybean proteins before purification and lane c represents β-conglycinin purified from total proteins. The purified β-conglycinin fraction contained mainly α, α′, and β subunits of β-conglycinin. Lane d is a grey density profile obtained from track c of electrophoresis. Direct observation clearly indicated that β-conglycinin was successfully isolated from soybean proteins. A Mab-based competitive ELISA method was used to further test its content. The result indicated that the purity of β-conglycinin was 92.9% (Data not shown).

In previous reports, the purity of β-conglycinin acquired from soybeans were 68% by ultrafiltration membrane separation method (Wu et al., 2000) and no more than 79% by ethanol extraction method (Rickert, Johnson, & Murphy, 2004). In the present study,

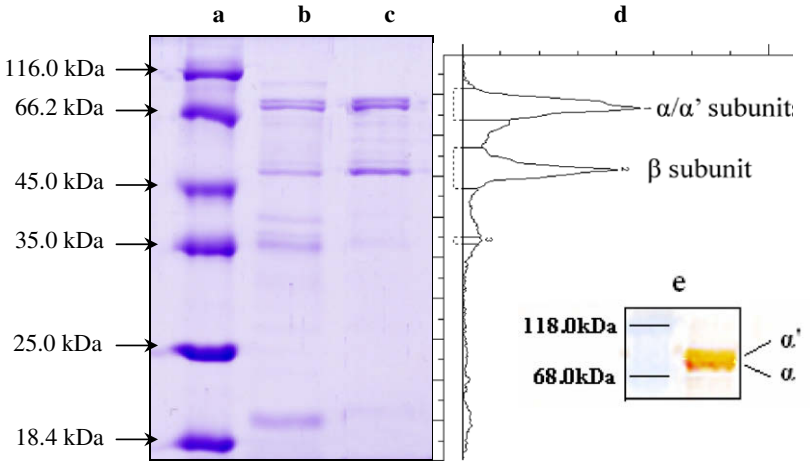

Fig. 1. SDS–PAGE profile (Left), grey density profile and Western blot assay (Right) of β-conglycinin purified by Mab-based immuno-affinity chromatography method. Proteins were separated by a 12.5% SDS–PAGE and stained with Coomassie Blue. Lane: a. Protein molecular weight markers; b. Total protein before purification; c. Goal protein (β-conglycinin) separated from soybean proteins through the immuno-affinity column; d. Gray density profile obtained from track c of electrophoresis using Syngene Analysis Solfware (Version 3.03.03); e. The proteins separated by SDS–PAGE were transferred electrophoretically to a 0.45 μm nitrocellulose membrane in a mini Trans-Blot Cell Apparatus. Wet blotting was performed at 100 V for 1.5 h. The blots were probed with 0.1 μg/mL of primary antibody (Mab). The goat anti-mouse IgG-HRP was used as the second antibody and KC™ General Western Blot Detection Kit (Roche Diagnostics Ltd., Lewes, UK) was used to detect the bound antibody.

a higher purity (92.9%) β-conglycinin was obtained by a Mab-based immuno-affinity chromatography method. We attribute the purity improvement to two factors. The first one is the use of immunochemical approach based on a highly specific Mab with moderate affinity. Using the prepared immuno-affinity column, the target protein was captured by the specific antibody molecule that immobilized on Sepharose 4B gel whilst other unwanted proteins were flushed from the column. The second factor is the convenient and rapid isolation procedure. It is well known that a complex and time consuming isolation procedure has an increased probability of degradation or denaturation of the target protein. Our purification procedure is very convenient and the time consumed per processing cycle is 5–10 min, which is less than about 30 min by methods of Thanh and Shibasaki (1976), Wu et al. (2000), and Rickert et al. (2004). The method developed by Thanh and Shibasaki (1976) and Wu et al. (2000) can separate two main soybean protein fractions, glycinin and β-conglycinin, by pH adjustment. However, it is difficult to avoid the present of an intermediate protein mixture (Wu et al., 2000). Also, other proteins of which the isoelectric point close to that of β-conglycinin are easy to precipitate in β-conglycinin samples. For the method described by Rickert et al. (2004), extraction environments (pH, ethanol concentration, temperature, and water-to-flake ratio) are each varied during bench-scale optimisation. Optimised conditions may yield more β-conglycinin with higher isoflavone and saponin concentrations, but fraction purity was diminished by glycinin contamination. Therefore, the probability that the target protein is degraded or denatured can be greatly reduced.

In addition to purity, the bioactivity of β-conglycinin is also an important index to evaluate the feasibility of the immuno-affinity column. The bioactivity of isolated β-conglycinin was assessed by the specific binding of β-conglycinin to Mab using Western blot assay. Fig. 1 (Lane e.) demonstrated that the Mab $6G_4$ could recognise the α′ and α subunits of the β-conglycinin molecule. This result indicated that the purified β-conglycinin maintained the natural bioactivity of protein molecule.

During the preparation of the immuno-affinity column, the coupling ratio of Mab and gel is one major factor impacting the isolation efficiency of β-conglycinin. The effects of Mab/gel ratio on isolation efficiency are presented in Table 1. No significant difference in terms of purity of isolated β-conglycinin was observed when the concentration of Mab coupled in Sepharose gel ranged from 2.5 to 12.5 mg/mL. However, different concentrations of Mab induced marked changes in yield of β-conglycinin. The concentrations of β-conglycinin in the 5.0, 7.5, and 10.0 mg/mL treatments were significantly higher than those in the 2.5 and 12.5 mg/mL treatments ($P < 0.05$). Interestedly, differences between 5.0, 7.5, and 10.0 mg/mL treatments were not significant ($P > 0.05$). Using this method, the yield of β-conglycinin separated from soybean proteins was 27.3–33.1 g/kg soybean. No differences were presented between 5.0, 7.5, and 10.0 mg/mL treatments ($P > 0.05$). Nevertheless, the yields in the 5.0, 7.5, and 10.0 mg/mL treatments were statistically superior to those in the 2.5 and 12.5 mg/mL treatments ($P < 0.05$). These results suggested that a low concentration of ligand (Mab) can reduce the isolation efficiency of β-conglycinin. Meanwhile, a very high concentration of ligand can have adverse effects on affinity chromatography. This may be because the less Mab couples in gel, the less likely goal protein in soybean solution binds to Mab. Namely, the more Mab couples in gel the more opportunity there is for goal protein to bind to Mab. However, too much Mab increases steric hindrance between the active sites and reduces the binding efficiency of the adsorbent. In

Table 1
Effects of Mab/gel ratio on efficiency of immuno-affinity chromatography for the isolation of soybean β-conglycinin.

	Concentration of Mab coupled in Sepharose 4B gel (mg/mL)				
	2.5	5.0	7.5	10.0	12.5
Concentration of isolated β-conglycinin (mg/mL)	0.48 ± 0.013^{b}	0.55 ± 0.010^{a}	0.56 ± 0.011^{a}	0.54 ± 0.008^{a}	0.50 ± 0.009^{b}
Yield in soybean (g/kg)	27.3 ± 1.9^{b}	31.6 ± 2.4^{a}	33.1 ± 2.1^{a}	32.4 ± 1.8^{a}	29.3 ± 1.5^{b}
Purity of isolated β-conglycinin (%)	93.2 ± 0.122	92.8 ± 0.292	93.1 ± 0.250	92.9 ± 0.203	92.7 ± 0.240

All data are means ± SEM ($n = 5$). Means within the same row that have no common superscript letters are significantly different ($P < 0.05$).

addition, substances bind more strongly to the immobilized ligand, which may result in difficult elution. On the other hands, the extent of non-specific binding increases at high ligand concentrations. For an efficient adsorbent, 5.0–10.0 mg ligand (Mab) per mL gel is suitable. In view of the above information, we considered that 92.7–93.2% purity of β-conglycinin can be successfully isolated from soybean proteins using the immuno-affinity column packed with 5.0–10.0 mg Mab per mL gel.

4. Conclusions

The Mab-based immuno-affinity chromatography developed in our study provides a novel method for the isolation of β-conglycinin. Under the optimized conditions, this technique can be used for collection of high purity β-conglycinin. In addition, the developed Mab-based immuno-affinity chromatography method also opens a new opportunity for the future study of the mechanism of food allergy responses using high purity β-conglycinin as an allergen protein material.

ABSTRACT

HSCCC technique in a semi-preparative scale was successfully applied in isolation and purification of nootkatone from the essential oil of fruits of *Alpinia oxyphylla* Miquel. Twelve kinds of two-phase solvent systems, consisting of seven non-aqueous and five organic-aqueous solvent systems, were selected with not only suitable partition coefficients of nootkatone but also suitable separation factors between nootkatone and valencene, the dominant impurity in the essential oil. Further on HSCCC, n-hexane–chloroform–acetonitrile (10:1:10, v/v) amongst the non-aqueous solvent systems and n-hexane–methanol–water (5:4:1, v/v) amongst the organic-aqueous solvent systems were separately screened out. However, n-hexane–methanol–water (5:4:1, v/v) was thought optimal due to quite shorter elution time and better HSCCC peak form. By eluting the lower phase of this solvent system in head–tail mode, 3.1 mg of nootkatone was obtained at a purity of 92.30% by GC–MS from 80 mg of crude essential oil in one step operation in less than 4 h. The chemical structure of nootkatone fraction was confirmed by EI-MS and ^{1}H NMR.

1. Introduction

Alpinia oxyphylla Miquel (Zingiberaceae), "Yizhi" in Chinese, cultivated widely in South China, has been used as a traditional medicine for intestinal and urethral disorders in Chinese pharmacopeia. The essential oil from fruits of *A. oxyphylla* Miq. mainly consists of various sesquiterpenoids (Liu, Guo, Xiao, Cai, & Han, 2006; Luo et al., 2001; Yi, Xiao, & Liang, 2004), amongst which the two eremophilanes, i.d., valencene and nootkatone (shown in Fig. 1), are often present in a considerable amount. Nootkatone is a flavorant (FEMA 3166) used for flavouring the food and tobacco (Chen, Xie, Liu, Kong, & Li, 2006). More importantly, it is an antiulcer agent (Yamahara, Yu, & Tamai, 1990) and has an insecticidal activity against *Drosophila melanogaster* (Miyazawa, Nakamura, & Ishikawa, 2000). However, due to its chiral stereostructure, the preparation of nootkatone via organic synthesis is difficult.

High-speed counter-current chromatography (HSCCC) has been widely applied for purification of functional components from traditional Chinese herbs and other natural products (Frighetto, Welendorf, Nigro, Frighetto, & Siani, 2008; Ma, Li, Zhang, Liu, & Fan, 2005; Shi, Zhang, Huang, Liu, & Zhao, 2008; Yan et al., 2005). It is a support-free liquid–liquid partition chromatography technique so that the irreversible adsorption onto the solid stationary phase and denaturation of the compounds can be eliminated. What is more, HSCCC offers many other advantages such as choice of a wide range of the solvent systems, short separation time, high-purity of fractions, quantitative sample recovery and ease of scaling up.

In this paper, HSCCC is applied in isolation and purification of nootkatone from the essential oil of *A. oxyphylla* fruits. The composition of the two-phase solvent system is optimised in terms of partition coefficients (K) of nootkatone and proper separation factors (α) between nootkatone and valencene by testing seven non-aqueous and five organic-aqueous solvent systems. Finally, the two-phase solvent system composed of n-hexane–methanol–water (5:4:1, v/v) was selected and utilised for the isolation and purification of nootkatone from the essential oil.

2. Experimental

2.1. Apparatus

The present study employed a model TBE 300A high-speed counter-current chromatograph (Shanghai Tauto Biotech, Shanghai, China) with three polytetrafluoroethylene coils (tubing I.D. 2.6 mm, total volume 300 ml) and a 20 ml manual injection sample loop. The evolution radius (R) is 5 cm, and the β values of the multilayer coil vary from 0.5 at the internal terminal to 0.8 at the

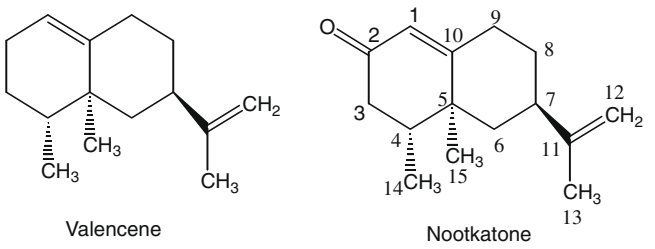

Fig. 1. Chemical structures of valencene and the target compound nootkatone.

external terminal ($\beta = r/R$, where r is the distance between the coil and the holder shaft). The rotary speed of the apparatus can be regulated at 700–1000 rpm with a speed controller. The elution of the solvent and the UV detection were performed by one ÄKTA prime system (Amersham Pharmacia Biotechnique Group, Sweden). The column temperature was controlled by an HX 1050 water-circulating constant temperature implement (Beijing Tianyou Science Development Co. Ltd., Beijing, China). The chromatogram was recorded by an N2010 workstation (Zhejiang University, Hangzhou, China).

An Agilent 6890N/5973i gas chromatograph and mass spectrometer (GC–MS) and an Agilent 6890 gas chromatograph coupled with a flame ionisation detector (GC-FID) (Agilent Technologies, USA) were used for analysis. ^{1}H NMR was performed on a Brucker Avance 400 MHz nuclear magnetic resonance (NMR) spectrometer.

2.2. Materials and reagents

The fruits of *A. oxyphylla* Miq. were purchased from Tongrentang drugstore (Qianmen, Beijing). Before use, they were ground into powder. The organic solvents, methanol, acetonitrile, ethyl acetate, ethanol, light petroleum (boiling point 30–60 °C), n-hexane, chloroform and dichloromethane, all in analytical grade, were from Beijing Chemical Reagent Company. The C_6–C_{23} n-alkanes used to analyse retention indices (RI) of the components in the essential oil, in chromatographic grade, were from Dikma Technologies in Beijing.

2.3. Preparation of essential oil by simultaneous distillation and solvent extraction (SDE)

Attached to a modified Likens-Nickerson apparatus were a 2000 ml round bottom flask and a 500 ml round bottom flask. In the 2000 ml round bottom flask, 500 g of pulverised sample was suspended in 1300 ml of water. In the 500 ml round bottom flask, 300 ml dichloromethane (purified in advance) was added. The sample and the solvent were heated by an oil bath and a water bath separately. After boiled and refluxed for 12 h, the dichloromethane fractions in both the solvent flask and the solvent loop were combined, dehydrated over anhydrous Na_2SO_4 and concentrated mildly by N_2 blowing. The essential oil obtained was pale yellow at a yield of 1.61%.

2.4. Determination of partition coefficients (K)

The partition coefficients (K) were determined as follows: a small amount of essential oil was dropped into a 10 ml test tube to which 2.0 ml of each phase of the equilibrated two-phase solvent system was added. The tube was shaken vigorously for 2 min to thoroughly equilibrate the sample between the two phases. Then an aliquot of each phase was analysed by GC. The K values were calculated by the peak areas in GC chromatograms.

2.5. Preparation of two-phase solvent systems and sample solutions

The solvents were mixed in a separatory funnel according to the selected volume ratios and thoroughly equilibrated by vigorous shaking at room temperature (ca. 22 °C). Prior to use, the upper phase and the lower phase were separated and degassed by sonication for 25 min.

For selection of two-phase solvent system the sample solution was prepared by dissolving 150 mg of essential oil into 18 ml two-phase solvent system, whilst for the isolation and purification of nootkatone the sample solution was prepared by dissolving 80 mg of essential oil into 15 ml two-phase solvent system.

2.6. HSCCC separation

Both head–tail and tail–head elution modes were carried out. When tail–head elution was used, the polytetrafluoroethylene tubes pertaining to entrance and exit on the injection loop were reversed. In each separation the multilayer-coiled column was first entirely filled with the stationary phase at a flow rate of 30 ml min^{-1}. Then the mobile phase was pumped through the column at a flow rate of 1.5 ml min^{-1} whilst the HSCCC apparatus was rotated at a speed of 850 rpm. After hydrodynamic equilibrium was established throughout the coil, the sample solution was injected into the separation column. During the separation the column temperature was controlled at 22 °C. The UV detector was set at 254 nm. The fractions were manually collected according to the chromatogram, and concentrated by N_2 blowing. The residue liquids were analysed by GC–MS. The purity of nootkatone fraction was expressed as the percentage of its peak area relative to the total peak area in GC–MS.

2.7. GC–MS and GC analysis

The DB-5 ms 30 m × 0.25 mm × 0.25 μm capillary column (Agilent Technologies, USA) was used in GC–MS analysis. The carrier gas was helium at 1 ml min^{-1}. The initial oven temperature was 100 °C held for 2 min; then raised to 165 °C at 10 °C min^{-1}; further raised to 170 °C at 1.5 °C min^{-1} kept for 2 min; and again raised to 183 °C at 1.5 °C min^{-1}. Finally it was raised to 280 °C at 30 °C min^{-1} and kept for 2 min. The sample of 2.0 μl was injected at 300 °C in a split mode (20:1). The mass detector was operated at 150 °C in an electron impact mode at 70 eV. The ion source temperature was kept at 230 °C whilst the transfer line temperature was at 250 °C. The chromatograms were recorded by monitoring the total ion currents in 40–450 mass range.

The HP-5 30 m × 0.32 mm × 0.25 μm capillary column (Agilent Technologies, USA) was used in GC analysis. The carrier gas was nitrogen at 1 ml min^{-1}. Other chromatographic conditions utilised were identical to those in GC–MS analysis above.

2.8. NMR analysis

In addition to GC–MS, the structure of nootkatone fraction was further confirmed by ^{1}H NMR. ^{1}H NMR spectra were recorded on a Brucker Avance 400 MHz spectrometer with TMS (tetramethylsilane) as internal standard and $CDCl_3$ as the solvent.

3. Results and discussion

3.1. Analysis of the essential oil

The total ion current chromatogram of the essential oil in GC–MS was shown in Fig. 2a. It could be seen that most of the peaks were distributed in the retention region over 8 min. According to NIST 02 mass spectra library as well as retention indices (RI), they

mainly belonged to sesquiterpenes (9.00–12.00 min) and oxygenous sesquiterpenes (12.31–24.00 min). Valencene (RI 1477) was the most abundant in the essential oil, representing 33.68% of the total peak areas, whereas nootkatone (RI 1834) was 7.64%.

3.2. Selection and optimisation of two-phase solvent systems

Successful separation by HSCCC mainly depends upon the selection of a suitable two-phase solvent system. Essentially, the non-aqueous solvent system is favourable for the isolation of non-polar target compounds like squalene (Lu, Jiang, & Chen, 2003), whereas the organic-aqueous solvent system is favourable for the polar compounds such as amygdalin (Yan, Tong, & Li, 2006) and inflacoumarin A (Wang, Lee, & Wang, 2004). Since nootkatone is an oxygenous sesquiterpene of weak polarity, both non-aqueous and organic-aqueous two-phase solvent systems were examined in the present work.

In order to find the solvent systems with suitable partition coefficients (*K*) (generally within the range of 0.5–2), the partition pat-

tern of nootkatone was investigated in a series of selected two-phase solvent systems, all of which satisfied the following requirements: nootkatone was stable and soluble in the solvent system; the solvent system could form two phases with acceptable volume ratios to avoid wastage; and the settling time was less than 20 s (Ito, 2005). In addition, the K value of valencene was also determined since it dominates in the essential oil and bears a chemical structure similar to nootkatone. To resolve nootkanone from valencene, which is a prerequisite to pure nootkatone from the essential oil, the ratio of K values between nootkatone and valencene or the separation factor ($\alpha = K_1/K_2$, where $K_1 > K_2$) ought to be greater than 1.5 in the semi-preparative multilayer separation column used in the present study (Ito, 2005). Otherwise, the α value could give an indication of resolving nootkanone from other sesquiterpene impurities of similar polarities to valencene in the essential oil.

In Table 1, the non-aqueous and organic-aqueous two-phase solvent systems examined in proper K values of nootkatone as well as proper α values between nootkatone and valencene were shown. Besides, several items involved in HSCCC separation for these two-phase solvent systems were listed in Table 1, which included purity of nootkatone fraction collected (percentage of total peak areas in GC–MS), % retention of the stationary phase, the elution time and the calculational retention time of nootkatone in both head–tail and tail–head elution modes. For head–tail elution in which the lower phase was used as the mobile phase, K was expressed as $K_{U/L} = A_U/A_L$, where A_U and A_L was the peak area of the compound in the upper phase and the lower phase by GC, respectively. Whilst for tail–head elution the upper phase was used as the mobile phase, K is the reciprocal of $K_{U/L}$, that is $1/K_{U/L}$.

As we know, when the K value enlarged, compound discrimination on HSCCC can be better whilst the elution time becomes longer. It could be seen from Table 1 that for the same two-phase solvent system employed, higher purity of nootkatone fraction mainly pertained to the elution mode whose K value of nootkatone was larger than its opposite elution. However, the extended hours in those larger K value elution modes were still acceptable. In Table 1, the highest purity (80.55%) of nootkatone fraction amongst the non-aqueous solvent systems and that (77.39%) amongst the organic-aqueous solvent systems were achieved by n-hexane–chloroform–acetonitrile (10:1:10, v/v) in tail–head elution and n-hexane–methanol–water (5:4:1, v/v) in head–tail elution, separately. The HSCCC chromatograms in these solvent systems were shown in Fig. 3a and b, whilst the resulting GC–MS chromatograms on nootkatone fractions collected by HSCCC were shown in Fig. 2b and c. In comparison, the organic-aqueous solvent system composed of n-hexane–methanol–water (5:4:1, v/v) in head–tail elution was more efficient than the non-aqueous solvent system composed of n-hexane–chloroform–acetonitrile (10:1:10, v/v) in tail–head elution since similar purity was achieved in rather shorter elution hours when the former used. Otherwise, it could be further seen from Fig. 3b and a that the HSCCC peak corresponding to nootkatone fraction given by n-hexane–methanol–water (5:4:1, v/v) in head–tail elution was suitable, whereas that by n-hexane–chloroform–acetonitrile (10:1:10, v/v) in tail–head elution was quite lower and relatively broader, which was unfavourable for the collection and recovery of nootkatone. In fact, the efficiency for n-hexane–methanol–water (5:4:1, v/v) probably originated from stronger hydrophobicity present for valencene as well as other sesquiterpene impurities in the organic-aqueous solvent system, which could render much higher α value shown in Table 1 and bring better resolution of nootkatone from the essential oil. Conclusively, to isolate nootkatone from the essential oil, the organic-aqueous solvent system composed of n-hexane–methanol–water (5:4:1, v/v) in head–tail elution was considered the most appropriate.

3.3. Isolation of nootkatone from the essential oil by HSCCC

In fact, the crude essential oil may be more complex than those samples reported on preparative separation by HSCCC (Cao et al., 2006; Lu et al., 2003; Yan et al., 2005, 2006), since various sesquiterpenoids having similar polarities to nootkatone are likely present in the essential oil and even the presence of the target nootkatone is not so prominent as shown in Fig. 2a. Thus, after the two-phase solvent system had been selected and optimised for the above work, the purity of nootkatone obtained was still unsatisfactory, as shown in Table 1 and Fig. 2. It is well known that sample size often affects the separation resolution (Wang et al., 2004). Therefore, in order to improve the purity of nootkatone in one step

[b] The partition coefficients (K): in head–tail elution using the lower phase as the mobile phase, the K value was expressed as $K_{U/L} = A_U/A_L$, where A_U and A_L was the peak area of the compound in the upper phase and the lower phase by GC, respectively; whilst in tail–head elution using the upper phase as the mobile phase, the K value is the reciprocal of $K_{U/L}$, that is $1/K_{U/L}$.
[c] α is the separation factor obtained by the ratio of K values between valencene and nootkatone, e.g. $\alpha = K_{U/L}$ (Valencene)/$K_{U/L}$ (Nootkatone).
[d] Percentage of peak areas of nootkatone analysed by GC–MS.
[e] S_f, retention of the stationary phase, $S_f = V_s/V_C$, where V_s is the volume of the retained stationary phase, V_C is the total column volume.
[f] The time range of nootakone fraction being eluted out.
[g] Head–tail elution mode, using the lower phase as the mobile phase.
[h] Tail–head elution mode, using the upper phase as the mobile phase.
[i] t_R, the theoretical retention time of nootkatone, calculated by $t_R = V_R/F$ and $V_R = V_C[1 + (K - 1)S_f]$, where V_R was the retention volume of nootkatone, F was the flow rate of the mobile phase and K was the partition coefficient of nootkatone.

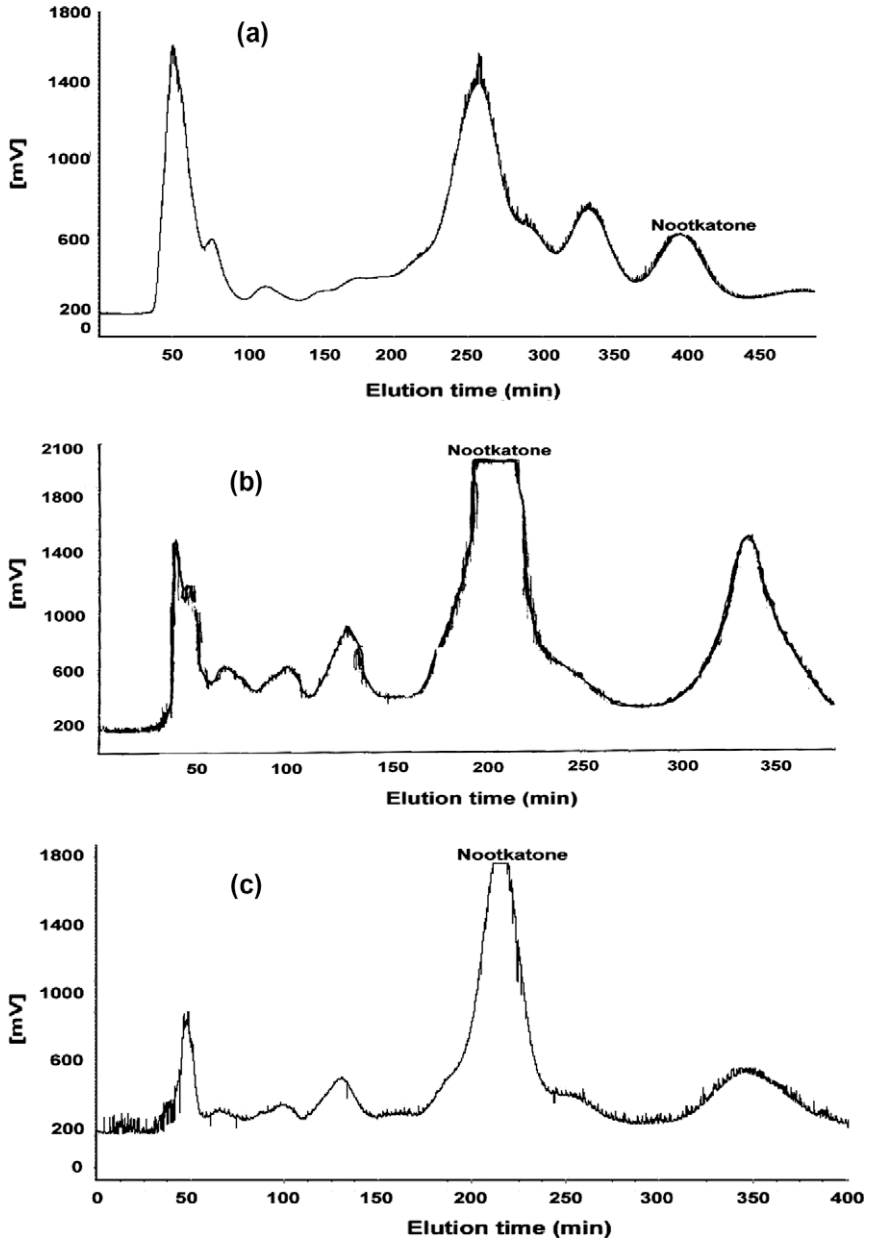

Fig. 3. HSCCC chromatograms on the separation of nootkatone from the crude essential oil of fruits of *Alpinia oxyphylla* Miquel. Revolution speed: 850 rpm; separation temperature: 22 °C, flow rate: 1.5 ml min^{-1}; and UV detection wavelength 254 nm. (a) Two-phase solvent system: hexane–chloroform–acetonitrile (10:1:10, v/v); mobile phase: the upper phase; sample size: 150 mg of essential oil dissolved into 18 ml two-phase solvent system. (b) Two-phase solvent system: n-hexane–methanol–water (5:4:1, v/v); mobile phase: the lower phase; sample size: 150 mg of essential oil dissolved into 18 ml two-phase solvent system. (c) Two-phase solvent system: n-hexane–methanol–water (5:4:1, v/v); mobile phase: the lower phase; sample size: 80 mg of essential oil dissolved into 15 ml two-phase solvent system.

HSCCC separation, the separation was similarly carried out with the solvent system composed of n-hexane–methanol–water (5:4:1, v/v) in head–tail elution mode by reducing the sample load (shown in Fig. 3c). It turned out that 3.1 mg of nootkatone, with a purity at 92.30% by GC–MS (shown in Fig. 2d), was obtained from 80 mg of crude essential oil.

However, when less sample loaded, separation on the non-aqueous solvent system composed of hexane–chloroform–acetonitrile (10:1:10,v/v) in tail–head elution mode was still not improved, and the HSCCC peak corresponding to nootkatone fraction often became too flat to be identified.

3.4. The structural identification

The nootkatone fraction obtained in purity of 92.30% was an pale oil with sweet, woody and orange-like odours. Its chemical structure was identified by EI-MS (in GC–MS) and ^{1}H NMR as follows:

MS (70 eV, *m*/*z*): 218 [M^+] (23); 147(100); 121(72); 91(69); 41(64). ^{1}H NMR ($CDCl_3$) δ(ppm): 5.80 (1H, s, H-1); 4.78 (2H, d, H-12); 1.77 (3H, s, H-13); 1.15 (3H, s, H-15); 0.99 (3H, d, H-14). The MS and ^{1}H NMR spectra data were in agreement with those reported (Luo et al., 2000; Miyazawa et al., 2000).

4. Conclusions

The HSCCC method in a semi-preparative scale was established and applied successfully in the isolation and purification of nootkatone from the essential oil of fruits of *A. oxyphylla* Miq. Five organic-aqueous and seven non-aqueous two-phase solvent systems were selected in terms of the partition coefficients of nootkatone

and also the separation factors between nootkatone and valencene. When subjected to HSCCC, the non-aqueous solvent system composed of n-hexane–chloroform–acetonitrile (10:1:10, v/v) in tail–head elution mode and the organic-aqueous solvent system composed of n-hexane–methanol–water (5:4:1, v/v) in head–tail elution mode proved potential to purify nootkatone from the essential oil. Nevertheless, because of rather less elution time and better HSCCC peak form of nootkatone, n-hexane–methanol–water (5:4:1, v/v) was determined optimal and finally employed in the preparative separation of nootkatone. By eluting the lower phase of n-hexane–methanol–water (5:4:1, v/v) at a flow rate of 1.5 ml min^{-1} under 850 rpm of revolution speed, 80 mg of crude essential oil was separated yielding 3.1 mg of nootkatone at a purity of 92.3% in less than 4 h. The chemical structure of nootkatone fraction obtained was confirmed by EI-MS and ^1H NMR.

Vitamin C esters
Mushroom tyrosinase
Inhibitory effect
Antioxidant activity

ABSTRACT

The inhibitory effects of vitamin C esters **1** and **2** on the diphenolase activity of mushroom tyrosinase have been studied. The results showed that compounds **1** and **2** inhibited tyrosinase with IC_{50} values of 0.58 and 0.16 mM, respectively. The dose–response curves demonstrated that compounds **1** and **2** not only lengthened the lag time, but also decreased the steady-state rate. The kinetic analyses showed that the inhibition by compound **2** was reversible and its mechanism was mixed type, which was different from compound **1** (irreversible inhibitor). Furthermore, the antioxidant activities of these compounds against hydroxyl radical scavenging, superoxide anion radical scavenging, and DPPH radical scavenging were also investigated. Compounds **1** and **2** exhibited potential antioxidant activities. In particular, compound **2** was found to be the most effective antioxidant, more potent than the well-known antioxidants vitamin C and TBHQ.

1. Introduction

Tyrosinase (EC 1.14.18.1; polyphenol oxidase, PPO), a multifunctional copper-containing enzyme, is widely distributed in fungi, plants and animals (Huang, Lin, Qiu, Shi, & Chen, 2006; Huang et al., 2006). It catalyses two distinct reactions of melanin synthesis, the hydroxylation of monophenols and the oxidation of *o*-diphenols to *o*-quinones, both depending on molecular oxygen (Khan et al., 2006; Martynez & Whitaker, 1995). The produced quinone is a highly reactive compound and can polymerise spontaneously to form melanin, which determines the colour of mammalian skin and hair. However, recently investigations demonstrated that some dermatological disorders, such as age spots and freckles, were caused by the accumulation of an excessive level of epidermal pigmentation (Mercedes & Francisco, 1997). Moreover, this highly active quinone can also react with amino acids and proteins in vegetables and fruits, and thus enhance the development of brown colour, which contributes to both quality loss and undesirable changes in colour, flavour and softening (Nerya, Musa, Khatib, Tamir, & Vaya, 2004; Shi, Chen, Wang, Song, & Qiu, 2005). In addition, tyrosinase is known to be involved in the moulting process of insects and adhesion of marine organisms (Liu, Yi, Wan, Ma, & Song, 2008).

The control of tyrosinase activity is of great importance in preventing the browning of vegetables and fruits and the accumulation of an excessive level of epidermal pigmentation in animals. So far, many efforts have been spent in the search for effective and safe tyrosinase inhibitors, and a large number of naturally-occurring and synthetic tyrosinase inhibitors have already been reported (Cho, Roh, Sun, Kim, & Park, 2006; Ley & Bertram, 2001; Um et al., 2003). However, some of them are either not potent enough to be considered of practical use or not compatible with safety regulations for food and cosmetic additives. So an urgent effort to discover and develop novel and potent tyrosinase inhibitors has become increasingly important in the food industry (Qiu et al., 2009) as well as in medicinal and cosmetic products (Maeda & Fukuda, 1991).

Vitamin C, also known as ascorbic acid, is widely distributed in plants, such as rose hips, blackcurrants and citrus fruits. It is well known that vitamin C has been considered by some scientists as a "universal panacea" due to its broad biochemical and pharmacological functions. For example, it could prevent the occurrence and development of some chronic diseases, such as cardiovascular disease, cancer and cataracts; acting as a highly effective antioxidant it can protect indispensable molecules in the body from damage by free radicals and reactive oxygen species. More recently, vitamin C as potent tyrosinase inhibitor has been studied in detail by Zeng, Zheng, and Chen (2005). The results suggested that it might act as a reducing agent in the reaction of the tyrosinase catalytic substance L-DOPA. In addition, some literature reported that 4-hydroxybenzoic acid and gallic acid had potent tyrosinase inhibitory effects (Huang, Lin et al., 2006; Varda, Noach, & Varda, 1997; Xue et al., 2007).

Inspired by these results, we supposed that the condensations of vitamin C and 4-hydroxybenzoic acid or gallic acid had potent

doi:10.1016/j.foodchem.2009.03.108

tyrosinase inhibitory activities with low side effects. In the present paper, therefore, compounds **1** and **2** (Fig. 1) were designed, synthesised and their inhibitory effects (inhibitory activity, inhibition mechanism, and inhibition kinetics) on mushroom tyrosinase were studied. Furthermore, the antioxidant activities of these compounds against hydroxyl radical scavenging, superoxide anion radical scavenging, and DPPH radical scavenging were also investigated. The aim of the present study was the discovery of feasible and efficient compounds as food additives or food preservatives, which can offer a clue to the design and synthesis of novel tyrosinase inhibitors with potent antioxidant activity.

2. Materials and methods

2.1. Chemicals and reagents

Melting points were determined on a WRS-1B digital instrument without correction. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Mercury-Plus 300 NMR instrument (^{1}H 300 MHz; ^{13}C 75 MHz) in DMSO-d_6. Mass spectra were recorded on a Thermo Finnigan LCQ DECAXP ion trap mass spectrometer. IR spectra were recorded as potassium bromide pellets on a Bruker Equinox 55 FT/IR spectrometer. Elemental analyses (C, H, N) were carried out on an Elementary Vario EL series elemental analyser and the results were within ± 0.4%.

Tyrosinase and L-3,4-dihydroxyphenylalanine (L-DOPA), 1,1-diphenyl-2-picrylhydrazyl (DPPH) phenanthroline, and tertiary-butyl-hydroquinone (TBHQ) were purchased from Sigma–Aldrich Chemical Co. (St. Louis, MO). Other chemicals were purchased from commercial suppliers and were dried and purified when necessary. The water used was re-distilled and ion-free. D-ascorbic acid-6-*p*-hydroxybenzoic acid ester (**1**) was available from our previous work (Wu et al., 2007).

2.2. Synthesis

A mixture of vitamin C (30 mmol), gallic acid (10 mmol) and H_2SO_4 (98%, 20 ml) was refluxed at 25 °C for 24 h. The residue was extracted with ethyl acetate several times and filtered. The filtrate was washed successively with saturated aqueous $NaHCO_3$ solution and ice-water, dried over $MgSO_4$, and evaporated. The obtained precipitate was recrystallised from water to afford compound **2** as a yellow solid. The structure of the synthesised compound **2** was established by IR, ^{1}H NMR, ^{13}C NMR, and ESI-MS, and the purity was confirmed by elemental analysis. The results were as follows: Melting point: 188.8–190.5 °C; IR (KBr, cm^{-1}): 3449, 3354, 1761, 1680, 1612, 1340, 1358, 1243, 1204, 1126, 1033, 1002; ^{1}H NMR (DMSO-d_6, 300 MHz) δ: 6.97 (s, 2H), 4.74 (s, 1H), 4.22 (m, 2H), 4.06 (m, 1H); ^{13}C NMR (DMSO-d_6, 75 MHz) δ: 172.5, 168.7, 154.4, 147.2 (2C), 139.3, 121.3, 119.1, 110.5 (2C), 76.3, 68.8, 66.2; ESI-MS: *m/z* 327 (M^{+-} 1, 100%); Anal Calcd for $C_{13}H_{12}O_{10}$: C, 47.57; H, 3.69; found: C, 47.33; H, 3.81.

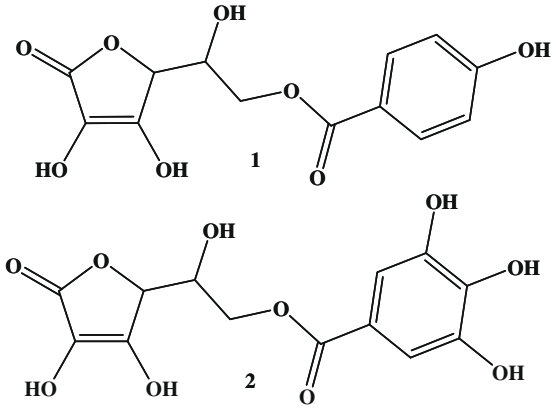

Fig. 1. Chemical structures of compounds **1** and **2**.

2.3. Assay of the diphenolase activity

The spectrophotometric assay for tyrosinase was performed according to the method reported by our groups (Liu et al., 2008; Yi et al., 2008) with some slight modifications. Both the synthesised compounds were screened for diphenolase inhibitory activity of tyrosinase, using L-DOPA as substrate. All the compounds were dissolved in dimethyl sulfoxide (DMSO). The final concentration of DMSO in the test solution was 2.0%. First, thirty units of mushroom tyrosinase (0.5 mg/ml) were pre-incubated with the sample in 50 mM phosphate buffer (pH 6.8) for 10 min at 25 °C. Then, the L-DOPA (0.5 mM) was added to the reaction mixture and the enzyme reaction was monitored for 1 min by measuring the change in absorbance at 475 nm, due to formation of the DOPAchrome. The measurement was performed in triplicate for each concentration and averaged before further calculation.

2.4. Assay of antioxidant activity of vitamin C esters 1 and 2

2.4.1. Assay of hydroxyl radical-scavenging activity

The hydroxyl radical-scavenging activity of samples was evaluated, according to a modified procedure from our previous report (Wu et al., 2007). First, 600 μl of 100 mM phosphate buffer (pH 5.5), 100 μl of aqueous solution of 7.5 mM $FeSO_4$, 100 μl of an ethanolic solution of 7.5 mM phenanthroline, and 100 μl of the sample solution (dissolved in ethanol) were put into a test tube. Then, 100 μl of H_2O_2 solution (dissolved in deionised water) were added to the tube and incubated at 37 °C in the dark for 1 h. The absorbance of the resulting solutions was measured at 536 nm. As a control, 100 μl of ethanol were added to the tube. Ascorbic acid and TBHQ were used as standard references. The extent of reduction by the addition of the sample was expressed as the percentage necessary for 50% reduction (EC_{50}).

2.4.2. Assay of superoxide anion radical-scavenging activity

The superoxide anion radical-scavenging activity of the samples was evaluated according to a modified procedure from our previous report (Wu et al., 2007). First, 100 μl of ethanolic solution of the sample was pre-incubated in 850 μl of 50 mM phosphate buffer (pH 8.2) at 25 °C for 10 min. Then, 50 μl of 3.0 mM pyrogallol solution (dissolved in 0.01 mM hydrochloric acid) were added to the reaction mixture and the oxidation reaction was monitored by measuring the rates at 320 nm for 100 s. As a control, 100 μl of ethanol were added to the tube. Ascorbic acid and TBHQ were used as standard references. The extent of reduction by the addition of the sample was expressed as the percentage necessary for 50% reduction (EC_{50}).

2.4.3. Assay of DPPH radical-scavenging activity

The DPPH radical-scavenging activity of the samples was evaluated according to a modified procedure from a previous report (Iwai, Kishimoto, Kakino, Mochida, & Fujita, 2004). First, 630 μl of 100 mM acetate buffer (pH 5.5) and 350 μl of an ethanolic solution of 0.3 mM DPPH were put into a test tube. Then, 20 μl of the sample solution (dissolved in DMSO) were added to the tube and incubated at 25 °C for 30 min. The absorbance of the

resulting solution was recorded at 517 nm. As a control, 20 μl of DMSO were added to the tube. Ascorbic acid and TBHQ were used as standard references. The extent of reduction by the addition of the sample was expressed as the percentage necessary for 50% reduction (EC_{50}).

3. Results

3.1. Effects of vitamin C esters 1 and 2 on the diphenolase activity of mushroom tyrosinase

Taking compound **1** and **2** (see Fig. 1 for structure) as the effectors, we proved their effect on the activity of mushroom tyrosinase for the oxidation of L-DOPA. The time courses of compound **1** were shown as curves **a** to **g** in Fig. 2A. For the first few minutes, absorptions increased slowly. After some time, the curve rose, mostly linearly, and gave a constant slope. The system reached a constant rate (the steady-state rate, V_{ss}) after the lag period, which was estimated by extrapolation of the curve to the abscissa (Xie, Chen, Huang, Liu, & Zhang, 2003). The kinetics course of the oxidation of the substrate in the presence of different concentrations of compounds **1** and **2** is shown in Fig. 2B and C, respectively. With increasing concentration of these compounds, the lag period increased exponentially. The result showed that compounds **1** and **2** could delay the lag time from 70 to 600 s at 0.75 mM and 10–410 s at 0.48 mM, respectively. On the other hand, the steady-state rate (V_{ss}) decreased with increasing concentration of compounds. The IC_{50} values of vitamin C, **1** and **2** were estimated to be 0.14, 0.58 and 0.16 mM, respectively. The results indicated that the inhibition strength followed the order: vitamin C ≈ compound **2** > compound **1**.

3.2. The inhibitory effects of compounds 1 (irreversible manner) and 2 (reversible manner) on the diphenolase activity of mushroom tyrosinase

The inhibition mechanism on mushroom tyrosinase by compounds **1** and **2** for the oxidation of L-DOPA was studied first. Fig. 3A shows the relationship between the enzyme activity and its concentration in the presence of compound **1**. The plots of the steady-state rate (V_{ss}) *versus* the concentrations of enzyme at different inhibitor concentrations gave a family of straight lines, which all ran parallel to each other. It indicated that compound **1** was an irreversible inhibitor of tyrosinase. However, for compound **2**, as shown in Fig. 3B, the plots gave a family of straight lines, which all passed through the origin. Increasing the inhibitor concentration resulted in a decrease in the slope of the line, indicating that compound **2** was a reversible inhibitor of tyrosinase.

3.3. Determination of the inhibitory types of the parent compound gallic acid and vitamin C esters 2 on mushroom tyrosinase

The inhibitory type of gallic acid on the diphenolase activity, during the oxidation of L-DOPA, was determined from Lineweaver–Burk plots. In the presence of gallic acid, the kinetics of the enzyme was shown in Fig. 4A. The plots of $1/V_{ss}$ *versus* $1/[S]$ gave a family of straight lines with different slopes but they intersected one another at the ordinate. The values of V_{max} remained the same and the values of K_m increased with increasing concentrations of the inhibitor, which indicated that gallic acid was a competitive inhibitor. The result showed that it could only bind with free enzyme. The inhibitory type of compound **2** on mushroom tyrosinase was determined by the same methods.

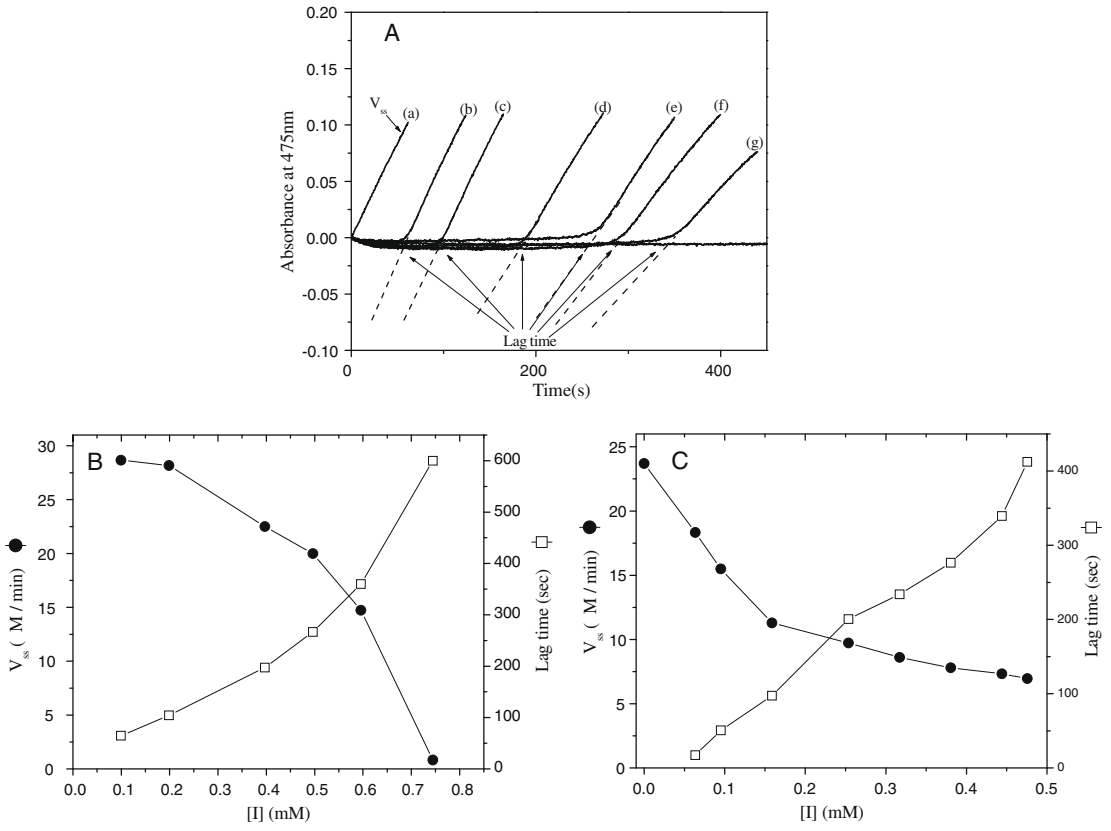

Fig. 2. Effects of vitamin C esters 1 and 2 on the diphenolase activity of mushroom tyrosinase. **A**: represents the progress curves for the inhibition of the diphenolase of mushroom tyrosinase by compound **1**. The concentrations of compound **1** for curves **a–h** were 0, 0.10, 0.20, 0.40, 0.50, 0.55, and 0.60 mM, respectively; **B** and **C** represent the effects of compounds **1** and **2** on the lag time and the steady-state-rate of the diphenolase of mushroom tyrosinase.

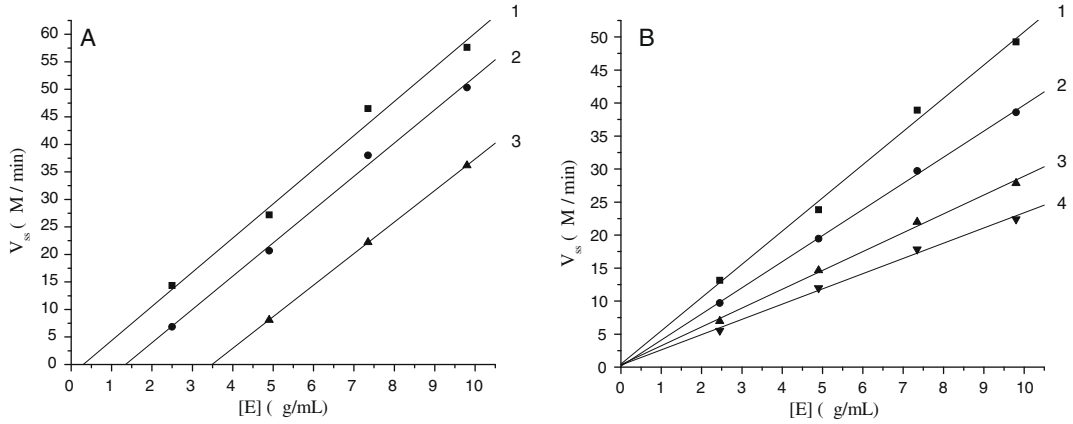

Fig. 3. Determination of the inhibitory effects of compound **1** and **2** on mushroom tyrosinase (**A** and **B**). The concentrations of compound **1** for curves 1–3 were 0.02, 0.13, and 0.34 mM, respectively. The concentrations of compound **2** for curves 1–4 were 0, 0.12, 0.24, and 0.36 mM, respectively.

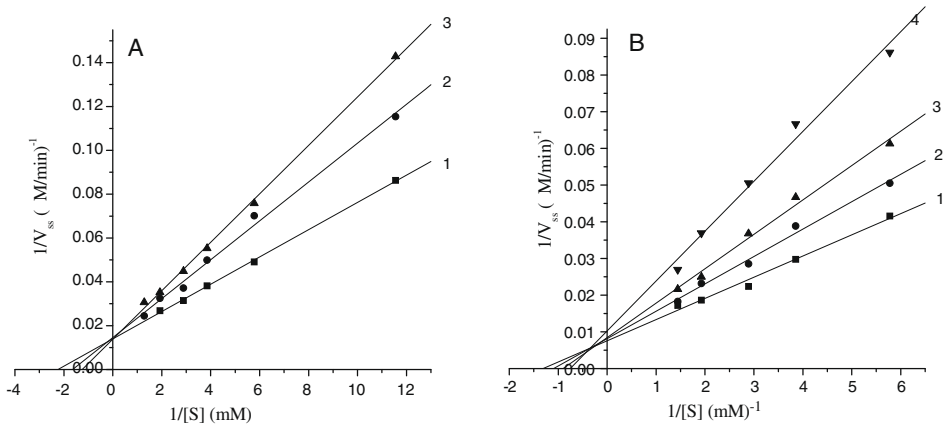

Fig. 4. Determination of the inhibitory types of gallic acid and compound **2** on mushroom tyrosinase (**A** and **B**). The concentrations of gallic acid for curves 1–3 were 0.03, 0.11, and 0.27 mM, respectively. The concentrations of compound **2** for curves 1–4 were 0, 0.03, 0.11, and 0.27 mM, respectively.

The results from Fig. 4B showed that compound **2** was a mixed-type inhibitor, since increasing its concentration resulted in a family of lines with different slopes, which intersected one another in the second quadrant. This result showed that compound **2** can bind, not only with free enzyme, but also with the enzyme–substrate complex (Huang, Lin et al., 2006; Huang, Chen et al., 2006).

3.4. Antioxidant activity of vitamin C esters 1 and 2

In the food industry, oxidation is one of the most important processes involved in food deterioration because it may affect food quality (colour, flavour and texture). Antioxidants may help preserve food quality by preventing the oxidative deterioration of lipids (Kinsella, Frankel, German, & Kanner, 1993). Furthermore, there is a considerable amount of evidence that points to an association between a diet rich in fresh fruits and vegetables and a decreased risk of cardiovascular disease and certain forms of cancer, and it is generally assumed that antioxidants (vitamins, carotenoids, sterols, polyphenols) are the active dietary constituents, which contribute to this protective effect.

Therefore, the antioxidant activities of compounds **1** and **2** against hydroxyl radical scavenging, superoxide anion radical scavenging and DPPH radical scavenging were also investigated. For the hydroxyl radical-scavenging activity, EC_{50} values of these compounds were determined and the results are shown in Fig. 5A. The scavenging strength follows the order: compound **2** > vitamin C > TBHQ > compound **1**. For the superoxide anion radical-scavenging activity, EC_{50} values of these compounds were determined and the results are shown in the Fig. 5B. The scavenging strength follows the order: compound **2** > compound **1** > vitamin C > TBHQ (EC_{50} = 5.1 mM, not shown). For the DPPH radical-scavenging activity, EC_{50} values of these compounds were determined and the results are shown in Fig. 5C. The scavenging strength follows the order: compound **2** > compound **1** > vitamin C ≈ TBHQ. These data showed that compounds **1** and **2** had potent antioxidant activities. In particular, compound **2** was found to be the most effective antioxidant, more potent than the well-known antioxidants vitamin C and TBHQ.

4. Discussion

Arbutin (4-hydroxybenzyl-*O*-β-D-glucoside) is an inhibitor of tyrosinase, which has been used widely in the cosmetic industry. Its IC_{50} value for diphenolase activity was measured as 7.30 mM (Yi et al., 2008). Our results in this paper showed that the IC_{50} values of compound **1** and its derivative **2** were 0.58 and 0.16 mM, respectively. This indicated that compound **1** and its derivative **2** could inhibit the diphenolase activity of tyrosinase at a lower concentration than that of arbutin, i.e., compound **1** and its derivative **2** were more effective inhibitors of diphenolase activity than arbutin. The results showed that these components might serve as new potent preservatives in the food industry or skin-whitening agents in cosmetics.

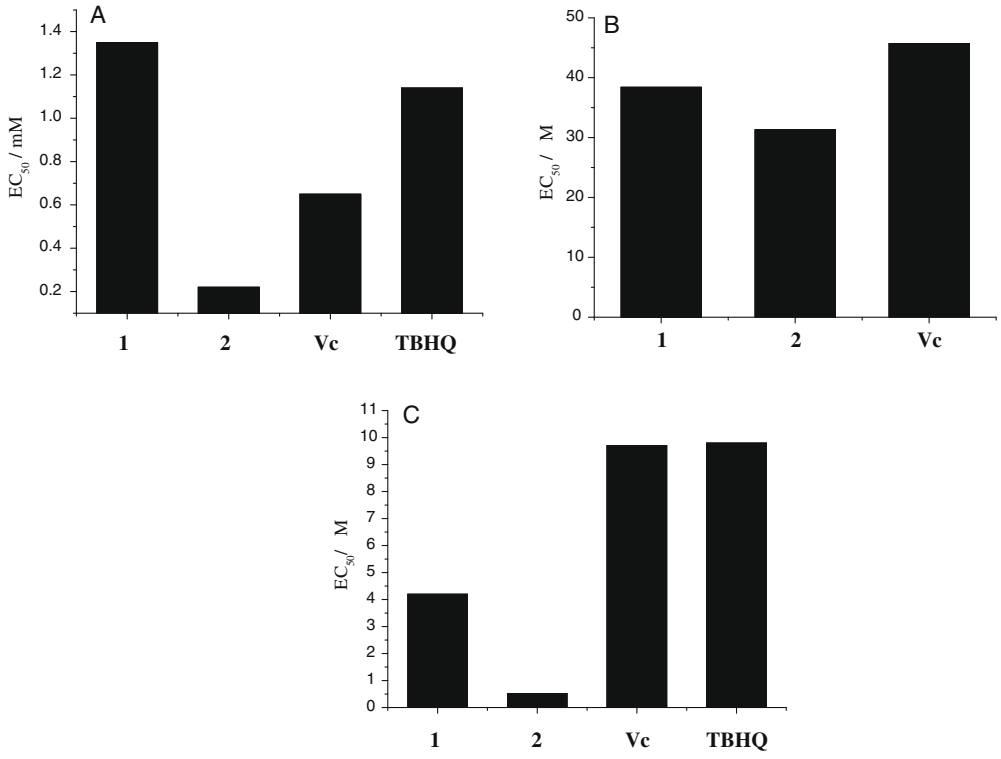

Fig. 5. EC_{50} values of compounds **1** and **2** on hydroxyl radical-scavenging activity (**A**), on superoxide anion radical-scavenging activity (**B**), and DPPH radical-scavenging activity (**C**). Here vitamin C (Vc) and TBHQ provide a comparison.

The dose–response curves demonstrated that compounds **1** and **2** not only lengthened the lag time, but also decreased the steady-state rate. Previous literature (Zeng et al., 2005) reported that the lag effect was caused by the reducing ability of vitamin C. On this basis, the action mechanism was concluded and summarised in Fig. 6. As shown in Fig. 6, the reason for the lag effects caused by vitamin C esters **1** and **2** might be that, the oxidation of L-DOPA to L-DOPAquinone occurred in the presence of tyrosinase and molecular oxygen. However, because of the existence of the vitamin C moiety, L-DOPAquinone was reduced to L-DOPA, and the redox reaction was repeated until the vitamin C moiety was completely transformed to the dehydrogenated vitamin C moiety. Undoubtedly, the greater the quantity of vitamin C existing in molecules, the longer the lag times as a result.

Recently, the crystallographic structure of tyrosinase has been reported, enabling a close look at its three-dimensional structure and a better understanding of its mechanism of action (Matoba, Kumagai, Yamamoto, Yoshitsu, & Sugiyama, 2006; Khatib et al., 2007) Within the structure, there are two copper ions in the active centre of tyrosinase and a lipophilic long-narrow gorge near to the active centre. Previous literature reported that vitamin C was defined as an irreversible inhibitor of tyrosinase, and suggested that

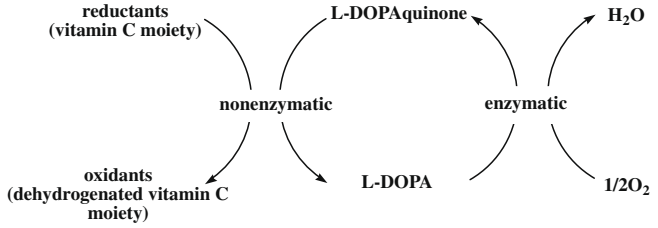

Fig. 6. The mechanism producing the lag effect in the inhibition of the diphenolase of mushroom tyrosinase by vitamin C esters.

it could exhibit strong affinity for copper ions in the active centre. Our report showed that the inhibitory effect of compound **1** was the same as vitamin C. However, its activity was four times lower than that of vitamin C. The result suggested that the introduction of 4-hydroxybenzoic acid into vitamin C might be detrimental to the tyrosinase inhibitory activity, which confirmed a previous report (Song et al., 2006) that the hydrophilic substituents, such as hydroxyl and carboxyl, might block the inhibitors that interact with the hydrophobic vicinity of the tyrosinase active centre. Interestingly, the inhibitory effect of compound **2** was obviously different from vitamin C and compound **1**. The kinetic analyses showed that the inhibition by compound **2** was reversible and its mechanism was mixed-type. From the result, it can be deduced that compound **2** might not combine with the binuclear copper ions of tyrosinase but with the hydrophobic pocket of the enzyme. Furthermore, it has been reported that hydrogen-bonding interactions could stabilise the *oxy*-form of *Streptomyces glaucescens* tyrosinase (Kubo & Kinst-Hori, 1999). Based on these observations, it could be supposed that an intermolecular hydrogen bond formed between the hydroxyl group of compound **2** and the sulfhydryl, amino, carboxyl or hydroxyl groups in the hydrophobic pocket of tyrosinase. Undoubtedly, the more hydrogen bonds formed between compound **2** and tyrosinase, the tighter and more stable the interaction between compound **2** and tyrosinase. In addition, the inhibition mechanism analysis showed that gallic acid was a competitive inhibitor of tyrosinase. By analogy with the chemical structures of gallic acid and compound **2**, the conclusion can be obtained that the introduction of a vitamin C moiety affected the binding mode of the substrate and the active site of tyrosinase.

Oxidation reactions, often radical initiated, are important processes in biological systems. A lot of pathophysiological conditions are considered to be initiated by radical reactions, and this oxidation can be protected by radical scavengers. Therefore, the present study also investigated the antioxidant activities of compounds **1** and **2**. The results showed that these compounds had potent

antioxidant activities. Comparison of compounds **1** and **2** indicated that the numbers of hydroxyl groups attached to the benzene ring might play a vital role in determining their antioxidant activities. The result further confirmed that the antioxidant activity depended on the number of donatable hydrogen atoms in the aromatic rings (Fagerlund, Sunnerheim, & Dimberg, 2009).

In summary, in the present paper, two novel vitamin C esters **1** and **2** were designed, synthesised and their inhibitory effects (inhibitory activity, inhibition mechanism, and inhibition kinetics) on mushroom tyrosinase were studied. Furthermore, their antioxidant activities against hydroxyl radical scavenging, superoxide anion radical scavenging, and DPPH radical scavenging were also investigated. All the data showed that compounds **1** and **2** might serve as new potent preservatives in the food industry or skin-whitening agents in cosmetics and suggested that further development of such compounds may be of interest.

In vitro ACE (angiotensin-I converting enzyme) inhibitory ability

ABSTRACT

The adsorption dynamics and thermodynamics of grass carp fish scale peptides (FSPs) onto non-polar macroporous resins (MARs), DA201-C, have been investigated. The adsorption of FSPs was affected by time, pH and peptide concentration. The adsorption process followed the Langmuir adsorption isotherm, and was endothermic ($\Delta H < 43$ kJ/mol). The predominant force in adsorption of FSPs onto DA201-C was hydrophobic. Depending on this force, the dynamic adsorption and gradient desorption results showed that DA201-C resins were good at desalting and enriching peptides with higher contents of hydrophobic amino acids, and these peptides had higher ACE inhibitory capabilities in vitro. The lowest concentration at which the eluted fraction possessed half of its original ACE activity (IC_{50}) was 0.13 mg/ml. The results indicated that fish scale peptides produced showed good ACE-inhibitory effect in vitro and fish scales are a good source of peptides with in vitro ACE inhibitory activity.

1. Introduction

The grass carp fish (*Ctenopharyngodon idella*) is one of the largest members of the minnow family, which inhabits fresh warm water. The body is covered with large and heavy scales. The global production of cultured grass carp fish was only 10.5 tons in 1950 (Vannuccini, 2004). By 2002 it reached 3.6 million tons and accounted for 15% of global fresh water aquaculture production. During the processing of fish, large amounts of waste resulting from filleting are either discarded or utilised for low value products. Fish scales are dermally derived, specifically in the mesoderm, and are comprised of highly ordered type I collagen fibres and hydroxyapatite $Ca_{10}(OH)_2(PO_4)_6$, (Ikoma, Kobayashi, Tanaka, Walsh, & Mann, 2003). However, fish scales are stiff, and most of them are discarded during processing. Due to increasing costs, animal protein supply is limited, as is the potential for increasing the supply through increased animal production. Therefore, there is a need for efficient utilisation of inexpensive and available food resources.

One of the approaches for improving and upgrading the functional and nutritional properties of proteins is enzymatic hydrolysis. Proteins can be hydrolysed to produce biologically active peptides. Protein hydrolysates are diverse in their functional and bioactive properties. Inhibition of angiotensin-I converting enzyme (ACE), which results in decreased blood pressure, is the bioactive property of interest in this study. Many food protein-derived enzymatic hydrolysates and peptides with in vitro ACE inhibitory activities have been well demonstrated having in vivo inhibitory activities on ACE and antihypertensive effects after oral or intravenous administration in animal experiments using spontaneously hypertensive rats (SHR) and in clinical trails. For example, Nakamura, Yamamoto, Sakai, and Takano (1995) reported that oral administration of ACE inhibitory peptides Val-Pro-Pro and Ile-Pro-Pro derived from sour milk shows antihypertensive effects in SHR, and a placebo-controlled study in hypertensive human subjects by Hata et al. (1996) demonstrated a significant reduction in blood pressure after daily ingestion of 95 ml of Calpis sour milk containing these two kinds ACE inhibitory peptides. Kawasaki et al. (2002) reported that the vegetable drink with peptides such as Val-Tyr derived from sardine protein hydrolysates exhibited the antihypertensive effect in the subjects with mild hypertension. Fujita, Yamagami, and Ohshima (2002) showed that the thermolysin digest of dried bonito, which contains ACE inhibitory peptide Leu-Lys-Pro-Asn-Met, showed long lasting antihypertensive activity without any problematic side effects in a placebo-controlled, double-blind, randomised, cross-over study in 61 borderline and mildly hypertensive subjects. Fish scales can also be enzymatically hydrolysed to produce functional peptides.

There have been many studies of peptide structure and function with respect to ACE inhibitory activity. Large numbers of ACE inhibitory peptide sequences have been determined, and dipeptides and tripeptides are particularly useful. ACE is a well-characterised Zn^{4+} metallopeptidase, and it cleaves dipeptides from the C-terminus of the substrate peptides. The C-terminus is important

doi:10.1016/j.foodchem.2009.04.015

for the binding of peptides to the ACE enzyme and for their inhibitory activity (Li, Le, Shi, & Shrestha, 2004; López-Fandiño, Otte, & Van Camp, 2006). The C-terminal catalytic site of the somatic form of ACE consists of three subsites, accommodating the three hydrophobic C-terminal residues of the substrate angiotensin I (Brew, 2003; Coates, 2003). Cheung, Wang, Ondetti, Sabo, and Cushman (1980) found that ACE has a higher affinity for substrates or competitive inhibitors that contain hydrophobic amino acid residues such as proline, phenylalanine and tyrosine at three positions from the C-terminus. Therefore, hydrophobic amino acids play an important role in ACE inhibitory peptides.

Generally, enzyme hydrolysates are purified first based on fractionation with respect to their molecular weight using ultrafiltration, size exclusion chromatography, or both (Kim, Whang, & Suh, 2004; López-Fandiño et al., 2006; Quirós et al., 2007; Vermeirssen, Van Camp, & Verstraete, 2005). Because of the lower capacity and film blocking problem, the purification process is limited. Although the hydrophobic amino acid content greatly affects the ACE inhibitory capabilities of these peptides, purification depends only on their molecular weight. Thus, these pre-purification methods result in reduced yields of ACE inhibitory peptides.

Recently, there has been a growing interest in employing macroporous resins (MARs) to separate bioactive components from crude extracts of herbal raw materials. MARs produce good recovery because of their unique adsorption properties and other advantages, including ideal pore structure and availability of various surface functional groups, low operational cost and easy regeneration (Tang, Zhou, & Duan, 2001; Zhang, Jiao, Liu, Wu, & Zhang, 2008). Generally, the main interactions between the absorbent and absorbate are known to be hydrophobic, electrostatic and hydrogen-bonding forces, but few reports have evaluated the adsorption mechanism between the peptides and MARs. In this paper, the adsorption behaviour and mechanism of water-soluble FSPs from aqueous solutions onto MARs have been studied. Specific MARs were chosen to desalt grass carp fish scale peptides (FSPs) and enrich the peptides with in vitro ACE inhibitory ability from the hydrolysates in order to provide purification information that may be useful for industry. We chose grass carp fish scales as the experimental material for production of peptides not only to ensure efficient exploitation of the by-products, but also to provide a potential value-added product to the market, thus solving the problem of waste disposal.

2. Materials and methods

2.1. Preparation of FSPs

Fresh grass carp fish scales were collected from market during the month of October, 2007 (Wuxi, Jiangsu province). The fish scales were washed twice in 1.5 mol/l NaCl solution to remove unnecessary proteins from the surface. Washes were performed by stirring the scales in the solution for 24 h. Demineralisation was achieved with 0.4 mol/l HCl solution (dry scales: solution = 1:15, w/v) for 90 min. The demineralised scales were washed thrice with distilled water and then dried. The dried fish scales were powdered using a crushing mill and a standard sample sieve with a particle diameter of about 0.42 mm, and then the powder was dispersed in water at a concentration of 50 g/l before hydrolysis. The neutral protease AS1398 (EC 3.4.24.28, Genencor, Wuxi, China) was used for hydrolysis of the protein at a ratio of 1:25 (w:w) enzyme:protein, respectively, at pH 7.0 and 50 °C (the optimal conditions for neutral protease AS1398).

The hydrolysis reaction was held at a constant pH value by continuous addition of 0.5 mol/l NaOH until a 16% degree of hydrolysis (DH) was achieved as determined using the pH stat method (Adler-Nissen, 1986). The hydrolysed mixtures were heated at 95 °C for 10 min after 16% DH had been reached. Mixtures were then filtered using Whatman 1 filter paper. The liquid was freeze-dried into FSP powder.

The nitrogen and ash contents of FSP powder were determined according to AOAC (1990) methods. The conversion factor for calculating the protein from nitrogen was 5.50. The content of carbohydrate was determined by phenol–sulfuric acid method (Dubois, Gilles, Hamilton, Rebers, & Smith, 1956).

2.2. Preparation of adsorbent

Macroporous resin DA201-C (Jiangyin chemical industry factory, Wuxi, China) was used as the adsorbent. The macroporous resins were extensively washed with plenty of distilled water to remove salts and impurities. Prior to the adsorption experiments, adsorbents were washed with ethanol, followed with distilled water, and then dried in a vacuum at a temperature of 60 °C.

2.3. Static adsorption experiments

The static adsorption tests of FSPs were performed as follows: 1.0 g pretreated dry adsorbent was introduced into a 250 ml Erlenmeyer flask. First, the dried resins were swelled by anhydrous ethanol and washed by distilled water until there was no ethanol and the water was blotted up. Then, 50 ml of 10 mg/ml aqueous solution of FSPs was added to each flask. The flasks were shaken (160 rpm) at 25 °C in an incubator shaker (SHZ-88, Taicang Experiment Equipment Co., Jiangsu, China). The adsorption capacities of the resins were evaluated by the following equation:

$$\text{Adsorption ratio}\ (\%) = (C_0 - C_m)/C_0 \times 100\%$$

$$\text{Adsorption capacity}\ (\text{mg/g}) = (C_0 - C_m)V_a/W$$

where C_0 and C_m are the initial and equilibrium adsorption solution peptide concentrations (mg/ml), respectively; V_a is the adsorption solution volume (ml) and W is the dry weight of the resins (g).

The experiments to study the effect of the pH on adsorption were done as described above with the samples dissolved in buffers of different pH at 25 °C.

2.4. Isotherm adsorption experiments

The adsorption isotherms of FSPs on the selected DA201-C resins at different temperatures were also studied by allowing 100 ml of FSP sample solutions at different concentrations (from 100 to 1100 mg/l, the interval was 200 mg/l) to come into contact with the resins (0.1 g) in shakers at 15, 30 and 45 °C, respectively.

2.5. Dynamic adsorption and desorption experiments

Dynamic adsorption and desorption experiments were carried out at room temperature in glass columns (2.6 × 30 cm) wet-packed with DA201-C resin. The bed volume (BV) of the resin was 100 ml. Sample solution (20 mg/ml) flow rate through the glass column was 1/2 BV/h. During adsorptive equilibration, the adsorbate-laden column was washed with distilled water with a flow rate of 1 BV/h until the eluate had the same conductivity as distilled water. Then, the adsorbate was gradient-eluted with ethanol–water (20%, 40%, 60%, 80%, v/v) solution at a flow rate of 1 BV/h. The eluting solvent was changed when the absorbance of eluate at 220 nm showed little alteration. The eluate was received in an auto-partial sampler (15 min per test tube). SFP fractions eluted by different concentrations of ethanol were pooled, concentrated by rotary evaporation, and freeze-dried. The conductivity was determined by a conductivity metre (DDS-11C, Shanghai Leici

Apparatus Co., China). The desorption ratio was calculated according to the following equation:

$$\text{Desorption ratio}(\%) = C_d \cdot V_d/(C_0 \cdot V_a - C_{water} \cdot V_{water}) \times 100\%$$

where C_d is the peptide concentration in the desorbed solution (mg/ml), V_d is the desorption solution volume (ml), C_0 is the initial peptide concentration in the adsorption solution (mg/ml); C_{water} is the peptide concentration (mg/ml) in the distilled water elution solution. V_a is the adsorption solution volume (ml); V_{water} is the distilled water elution volume (ml).

2.6. Amino acid analysis

FSP powder was dissolved in 6 mol/l HCl solution at 110 °C for 22 h, and the hydrolysates were analysed by an amino acid analyser (HP1100, Agilent).

2.7. Molecular weight determination

Hydrolysates were analysed for molecular weight distribution using a Waters™ 600E Advanced Protein Purification System (Waters Corporation, Milford, MA, USA). A TSK gel, 2000SWXL, (7.8 × 300 mm) column was used with 10% acetonitrile + 0.1% TFA in HPLC grade water as the mobile phase.

The calibration curve was obtained with bovine carbonic anhydrase (29,000 Da), horse heart cytochrome C (12,400 Da), bovine insulin (5800 kDa), bacitracin (1450 Da), Gly-Gly-Tyr-Arg (451 kDa) and Gly-Gly-Gly (189 Da). The results were obtained and processed with the aid of Millennium^{32} Version 3.05 software (Waters Corporation, Milford, MA 01757, USA).

2.8. Assay of in vitro ACE inhibitory activity

In vitro ACE inhibitory activity was measured using RP-HPLC in a Waters™ 600E Advanced Protein Purification System (Waters Corporation, Milford, MA 01757, USA). A peptide sample solution was dissolved in distilled water and diluted to make five different concentrations: 0.1, 0.25, 0.5, 1.5 and 2.5 mg/ml (three parallel samples for each concentration). Then, from each dilution, 10 μl was mixed with 40 μl of 0.5 mol/l sodium borate buffer (pH 8.3) containing 6.5 mmol/l Hip-His-Leu and 0.3 mol/l NaCl and incubated for 6 min at 37 °C. The reaction was initiated by the addition of 20 μl of ACE dissolved in 0.5 mol/l sodium borate buffer (pH 8.3, containing 0.3 mol/l NaCl) (0.1 U/ml) and further incubated for 30 min at 37 °C. The reaction was stopped by adding 80 μl of 1 mol/l HCl. The hippuric acid liberated by ACE was determined directly at 228 nm. The concentration of ACE inhibitors needed to reduce activity by 50% was defined as the IC_{50} value. Plots of the peptide concentrations against the % inhibition were plotted and from its regress equation the IC_{50} value was estimated.

The inhibition of ACE was calculated as following:

The inhibition of ACE (%) = $(A_0 - A_C)/A_0 \times 100\%$
A_0: the hippuric acid peak area of the blank
A_C: the hippuric acid peak area of sample

3. Results and discussion

3.1. Chemical composition and molecular distribution of the grass fish scale hydrolysates

Grass carp fish scale hydrolysates mainly contained protein and ash, and little carbohydrate, with contents of 87.23%, 10.35% and 0.22%, respectively. In this experiment, in order to maintain the highest enzyme activities to hydrolyse fish scales and calculate the DH, 0.5 mol/l NaOH was used to maintain the pH value; thus the ash content was higher in the hydrolysates. The molecular weight and number of peptide residues remaining in the peptide chains after hydrolysis is essential for producing protein hydrolysates with the desired functional properties. Peptides with two to five amino acids can be absorbed in the intestine directly (Webb, 1990).When the DH reached 16%, FSPs with molecular weights (MW) ranging between 145 and 650 Da occupied 71.7%; these were assumed to be di- to pentapeptides, which is consistent with the manufacturer's claims. However, the salt content was too high for use as an orally-administered product and MARs could be used for desalting biological samples (Zhong, Liu, Ma, & Shoemaker Charles, 2007).

3.2. Effect of adsorption time on the adsorption of FSPs onto DA201-C

Based on previous experiment (results not shown), DA201-C resins with a larger surface area, smaller pore diameter and non-polarity exhibited stronger adsorption abilities for FSPs. Adsorption time directly affected the adsorption efficiency and adsorption capacity of DA201-C. The adsorption capacity increased with increased adsorption time before adsorption equilibrium. After 10 h, the adsorption of FSPs reached 290 mg/g. Increasing the adsorption time had almost no effect on the adsorption capacity, indicating that the adsorption tended towards equilibrium at 10 h.

3.3. Effect of adsorption solution pH on the adsorption of FSPs onto DA201-C

The pH value of the solution affected the electric charges of the adsorbents in the solution, which can change the electrostatic attraction and hydrogen bonding, thus influencing the adsorption capacity of the resins. These results can be seen in Fig. 1. The equilibrium absorption capacity first increased with an increase in solution pH from 4 to 6, but decreased when the pH value was higher than six. The amino acid composition of the FSPs is shown in table 1 (crude). The FSPs contained more acidic amino acids (Asp and Glu) than alkaline amino acids (Arg and Lys); the MAR DA201-C resin is non-polar, so in acidic solutions, the resin can have good adsorption. However, in lower pH solutions, proteins tended to aggregate and deposit, which can decrease the adsorption capacity. At pH 6, the DA201-C resins had the highest adsorption capacity, about 300 mg/g. This also suggests that the force between resins and FSPs was hydrophobic.

3.4. Adsorption isotherm of FSPs onto DA201-C

The equilibrium adsorption isotherms of FSPs onto DA201-C resin at three different temperatures 15, 30 and 45 °C are shown in Fig. 2. It was clear that the equilibrium adsorption of FSPs onto

Ash content (%)	10.35	1.20	0.84	0.71	0.68

[a] Trp was not detected (g/100 g protein).
[b] Average hydrophobic value was calculated as Q (kJ/mol) = $\sum[A_iF_i/M_i/\sum(A_i/M_i)]$, where A_i (g) is the weight of each amino acid in 100 g protein, M_i (g/mol) is the molecular weight of the amino acid and F_i (kJ/mol) is the hydrophobic value of the amino acid.

DA201-C increased with increasing temperature and initial concentration of the FSPs. When the adsorption reached saturation, there were no further FSPs adsorbed onto the resins with additional initial concentrations. However, increasing the initial concentration did shorten the adsorption equilibrium time. Application of the Langmuir equation, which has been widely used in model adsorption processes to explain the absorption phenomenon, indicates that each site of the adsorbent can adsorb only one particle (Du, Yuan, Zhao, & Li, 2007). Hence, the Langmuir equation describes the adsorption behaviour of a monomolecular layer. In the following Langmuir equation:

$$C_s/C_s^{\max} = K \cdot C_m/(1 + K \cdot C_m)$$

C_s represents the equilibrium adsorption capacity (mg/g) and C_m is the equilibrium concentration in liquid phases (mg/l), C_s^{max} is the maximum adsorption capacity (the maximum surface coverage, formation of the monolayer, mg/g). K is the Langmuir constant. The Langmuir equation was converted to the linear form $1/C_s = 1/(KC_s^{max}C_m) + 1/C_s^{max}$, with $1/C_s$ and $1/C_m$ as dependent and independent variables (Y and X). The experimental data were statistically analysed and R^2 values were obtained. Table 2 gives the correlative parameters of Langmuir adsorption isotherm equations for the FSPs at different temperatures. The correlation coefficients of Langmuir equations on DA201-C resin at three temperatures were rather high, implying that the adsorption behaviour fit the Langmuir adsorption isotherm equations. The values of K and C_s^{max}, which according to the Langmuir theory are relative indicators of adsorption capacity, increased with increasing temperature, suggesting that increased temperature is advantageous for the adsorption process.

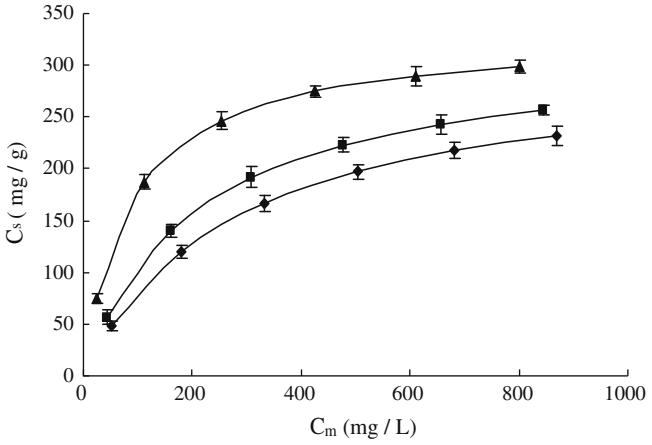

Fig. 2. Equilibrium adsorption isotherms for FSPs onto DA201-C at different temperatures. (♦) 15 °C; (■) 30 °C; (▲) 45 °C. C_s represents the equilibrium adsorption capacity (mg/g) and C_m is the equilibrium concentration in liquid phases (mg/l).

In general, adsorption involves the accumulation of molecules from a solution onto the exterior and interior surfaces of an adsorbent. These phenomena result from various interactions including those characterised by hydrophobic and electrostatic forces. Physical properties of resins (surface area, pore radius, pore distribution and porosity) can also play an important role in determining states and equilibria of adsorption (Koźlecki, Sokolowski, & Wilk, 1997). In this experiment, the resin with the larger surface area had a good adsorption capacity. Furthermore, the resin was non-polar and the FSPs were rich in hydrophobic amino acids. Therefore, the hydrophobic force was predominant in the adsorption of FSPs from the aqueous phase onto the non-polar adsorbent. Higher temperatures can strengthen the hydrophobic force (Pratt, 1985) and enhance the intraparticle diffusion rate of adsorbate into the pores; thus increasing the temperature can increase the amount of FSPs adsorbed onto the DA201-C resin.

Table 2
Langmuir adsorption parameters of FSPs on DA201-C resins at different temperatures.

Temperature (°C)	Langmuir equation	K	C_s^{max} (mg/g)	R^2
15	$Y = 0.9052X + 0.003272$	0.003615	305.6	0.9989
30	$Y = 0.6424X + 0.003138$	0.004884	318.7	0.9975
45	$Y = 0.2607X + 0.003028$	0.01162	330.3	0.9947

3.5. Isosteric enthalpies for FSPs adsorption

The isosteric adsorption enthalpy changes were calculated following a derivative of the Van't Hoff equation (Garcia-Delgado, Cotouelo-Minguez, & Rodriguez, 1992):

$$\mathrm{Ln}C_m = -\ln K_0 + \Delta H/R \cdot T$$

where C_m is the equilibrium concentration (mg/ml) at temperature T, ΔH is the isosteric enthalpy of adsorption, R is the gas constant (8.314 kJ/(mol K)), T is the absolute temperature (K) and K_0 is a constant. ΔH was calculated from the slope of the line plotted by ln C_m versus $1/T$, as shown in Table 3. The value of the enthalpy changes were positive, suggesting that the adsorption process was endothermic, and increasing temperature was favourable to adsorption. The value of the enthalpy change (<43 kJ/mol) also showed that the adsorption of FSPs on the DA201-C resins was physical (Huang & Cheng, 1997). The results were consistent with hydrophobic interaction. Therefore, the main force in the adsorption of FSPs on the surface of the DA201-C resins was hydrophobic.

3.6. Dynamic adsorption and desorption

The above static adsorption experiments showed that the force between adsorbates and resins was hydrophobic; thus peptides with different hydrophobic properties can be separated by gradient elution of the adsorbate resins with different concentrations of ethanol. In order to bring the separation to a larger scale and to shorten and control the desalting and gradient eluting process, dynamic adsorption of FSPs on DA201-C was used for the separation experiment. At a 1/2 BV loading rate, the loading volume at the penetration point (A_{220} = 0.05, at which peptides start to be overloaded and found in the eluate) was around 70 ml of FSP solution. The adsorbed resins were first eluted by distilled water. Due to the hydrophobic force between the resins and peptides, most of the salt was eluted with the distilled water, while only about 13% of the FSPs were eluted. When the conductivity ratio of the eluate was nearly equal to that of distilled water (about 8 BV), a gradient of ethanol solution was applied in order to elute the adsorbed resins, and about 90% of the adsorbates could be gradient-eluted. The yield and ash content of each eluted fraction are given in Table 1. The yield and ash content of fractions decreased with increased ethanol concentrations. The ash content in the crude dried FSPs was 10.35%, and it was lower than 1.5% after desalting by MAR. This suggests that using MAR adsorption is a good method to eliminate salt from peptides and to separate peptides with different hydrophobicities.

3.7. In vitro ACE inhibitory activity of different elution fractions

Fig. 3 shows the in vitro ACE inhibitory activities of different fractions. The crude hydrolysates without desalting had negative inhibitory activity at lower concentrations, indicating that the salt in the hydrolysates increases the activity of the ACE. ACE inhibition was found to increase with increased FSP concentrations, with IC_{50} values (in Table 1) of 1.66, 0.48, 0.39, 0.25 and 0.13 mg/ml. The IC_{50} values of different elution fractions became lower when fractions were eluted by higher concentrations of ethanol, suggesting that FSPs eluted by higher concentrations of ethanol had higher

Table 3
Thermodynamic values of FSP adsorption on DA201-C resins.

Adsorbent	C_s (mg/g)	ΔH (kJ/mol)
DA201-C	100	32.52
	150	33.34
	200	34.87

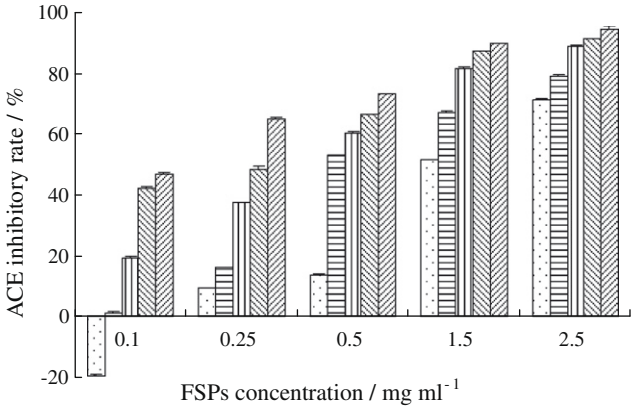

Fig. 3. In vitro ACE inhibitory abilities of different elution fractions. ⬚ Crude hydrolysates; ▭ fraction eluted by 20% ethanol solution; ▥ fraction eluted by 40% ethanol solution; ▧ fraction eluted by 60% ethanol solution; ▨ fraction eluted by 80% ethanol solution.

in vitro ACE inhibitory ability. The crude hydrolysates of grass carp fish scale protein had low ACE inhibitory activity (IC_{50} = 1.66 mg/ml) as compared to previously reported values for protein hydrolysates ranging from 0.021 to 1.73 mg/ml. However, when purified by MAR, hydrolysates had moderate ACE inhibitory activity (IC_{50} < 0.48 mg/ml). These results indicate that MAR DA201-C can separate peptides with different in vitro ACE inhibitory abilities by gradient ethanol elution in order to satisfy specific requirements of the consumer. Furthermore, the ethanol can also be recycled.

4. Amino composition of different fractions

In order to clarify the mechanism by which separation of peptides was achieved with gradient ethanol elution on MARs DA201-C, the amino acid composition of each peptide fraction was determined (Table 1). It was suggested that most naturally occurring ACE inhibitory peptides contain Pro, Lys or aromatic amino acid residues (Cheung et al., 1980; Kawakami & Kayahara, 1993; Suetsuna & Nakano, 2000), and that they are mostly hydrophobic. The present results showed that the content of hydrophobic amino acids (Ile, Tyr, Phe, Pro, Leu, Val and Lys) was greater in the fraction eluted with the higher ethanol concentration, and the contents of different fractions ranged from 30.79% to 37.67%, while the average hydrophobicity of each eluted fraction increased from 3.89 to 4.92 kJ/mol. These results suggest that the separation of FSPs with non-polar residues via ethanol gradient elution was based on hydrophobicity and that the in vitro ACE inhibitory ability of the FSPs was closely related to amino acid hydrophobic properties. In addition, the amino acids His, Thr and Arg were enriched. Suetsuna, Yamagami, and Kuwata (1988) studied the amino acid composition of ACE inhibitory peptides from 15 different types of fish and shellfish, and found that the ACE inhibitory peptides from fish were rich in Asp, Glu, Arg, Pro, Ile and Lys. As shown in Table 1 (crude), fish scale proteins were rich in these six amino acids, with a total percentage of 41.20%. This also indicates that grass carp fish scales are a good resource of ACE inhibitory peptides.

5. Molecular weight distribution of different fractions

Most food protein-derived peptides with ACE inhibitory abilities have relatively low molecular weight, generally ranging from dipeptides to pentapeptides with MW from 150 to 800 Da. However, ACE inhibitory peptides with six, seven or 11 amino acids have also been discovered (Haque & Chand, 2008; Otte, Shalaby Samah, Zakora, & Nielsen, 2007; Suetsuna & Nakano, 2000). Because

the FSPs separated by MAR DA201-C were distinguished based on hydrophobic force, the range in MW of the different fractions did not show great variability. However, peptides with MW from 750 to 330 Da were enriched from 25.68% to 45.12% as the ethanol concentration increased from 20% to 80%. Taking into account our previous findings that the fraction eluted by higher ethanol concentrations had the highest in vitro ACE inhibitory ability, the MW of most ACE inhibitory FSPs was deduced to be between 750 and 330 Da.

6. Conclusions

The non-polar MAR DA201-C with a larger surface area and smaller pore diameter proved to be efficient for separation of FSPs. The adsorption dynamics indicated that the DA201-C resins required about 10 h to reach equilibrium, and had a good adsorption capacity when the pH value of the adsorption solution was around 6. Higher temperatures favoured adsorption, indicating that the process was endothermic, and that hydrophobic forces were predominant in the adsorption of FSPs from the aqueous solution. Dynamic adsorption and desorption were used to study the process of desalting and gradient elution. The dynamic adsorption ratio of the FSPs reached 87%, and the dynamic desorption ratio of FSPs reached 90%. Most of the salt was removed from the FSPs. The in vitro ACE inhibitory ability was increased for fractions eluted using high ethanol concentration, and these fractions were mainly hydrophobic in nature. MAR DA201-C was thus a good material for desalting and enhancing peptides with in vitro ACE inhibitory properties. The results also indicate that fish scales are a good source for peptides with higher in vitro ACE inhibitory activity, which could be a potential value-added product in the market.

ABSTRACT

The effectiveness of increasing CLA in pork products through animal dietary supplementation or direct addition in the product formulation has been studied, and the effect of grilling on dry matter and fat contents and fatty acid composition has been analysed. Sausages made with meat and back fat from pigs with CLA dietary supplementation had the highest saturated fatty acid content. Sausages from dietary supplementation and direct addition had CLA levels between 6% and 7% of total fatty acids. Moisture and fat contents decreased and increased respectively after cooking for the three sausage types (control, dietary supplementation, direct addition). Grilling had little effect on fatty acid levels, especially for sausages with direct addition in the product formulation. In general, saturated fatty acids increased and poly-unsaturated fatty acids decreased due to the increase of C16:0 and to the decrease of C18:2 $n-6c$ and C18:3 $n-3$ fatty acids. Added CLA, both from animal dietary supplementation or direct addition, remained at similar levels in cooked sausages to those found in raw sausages.

1. Introduction

The relationship between diet, health and lifestyle is now a key focal point for consumers, researchers and policy makers alike as we witness an increase in obesity and the rise of diet-related chronic diseases (Swinburn, 2009). A key objective in the European Technology Platform on Food for Live focuses on ensuring that the healthy choice is an easy choice for consumers. The meat industry is addressing this demand by adopting strategies to produce meat products which have more beneficial ingredient profiles in a value-added manner. One such strategy includes the incorporation of functional lipids into existing meat products to provide a healthier version of an existing product.

Conjugated linoleic acid (CLA) is a collective term for a group of octadecenoic acids that are geometric and positional isomers of linoleic acid (C18:2) (Pariza, Park, & Cook, 2001). CLA has been shown to have a variety of biological effects (Hur, Park, & Joo, 2007). Several health benefits, such as anticancer, anti-oxidation, anti-atherosclerosis and improving immuno-responses (Belury, Nickel, Bird, & Wu, 1996; Lee, Kritchevsky, & Pariza, 1994; Miller, Stanton, & Devery, 2001; Pariza & Hargraves, 1985; Park et al., 1999) have been reported for CLA. These substances have been found in the meat and milk of ruminants, where they are mainly formed by biohydrogenation of grass derived fatty acids. Pork contains only small amounts of CLA because pig is a mono-gastric animal (Chin, Liu, Storkson, Pariza, & Ha, 1992).

Interest in dietary supplementation with CLA for pigs increased during the last decade due to its potential to improve productive, carcass and meat quality traits and, at the same time, for obtaining meat and meat products enriched in CLA (Marco et al., 2009; Martín, Antequera, Muriel, Andrés, & Ruiz, 2008a; Schmid, Collomb, Sieber, & Bee, 2006). A second approach for increasing CLA in meat products is its direct addition as an ingredient during the manufacturing process (Hah et al., 2006; Martín, Ruiz, Kivikari, & Puolanne, 2008b). In addition to the healthy benefits of CLA, its addition into products provides a strategy for partial replacement of saturated fatty acids in the diet by unsaturated fatty acids (Martín et al., 2008a).

While strategies can be enacted to improve the ingredient profile of foodstuffs the cooking method can have an impact on the levels of the beneficial ingredient in the product which is ready to consume. Some studies focused on the influence of processing and cooking on CLA content in meat products that naturally contain CLA such as beef (Ma, Wierzbicki, Field, & Clandinin, 1999; Shantha, Crum, & Decker, 1994) or lamb meat (Badiani et al., 2004). However, little work has been presented which assesses the impact of cooking on the fatty acid profiles of CLA supplemented meat products.

The aim of the present study was to study the effects of grilling on the chemical and fatty acid composition of pork products enriched in CLA through animal dietary supplementation or through direct addition in the product formulation. In addition this study

aims to compare the useful of CLA dietary supplementation or direct addition into breakfast sausages.

2. Material and methods

2.1. Treatments

Sausages were manufactured according to three different protocols (control, dietary supplementation and direct addition in the formulation) using Boston Butt (*Musculus infraspinatus*, *M. supraspinatus*, *M. subscapularis* and *M. serratus ventralis*) and back fat removed from the pigs 24 h after slaughter. The CLA supplement used for both, diet and formulation supplementation, was Luta-CLA 60 (BASF, Germany), which consists of 56% (w/w) of the two main CLA isomers (*t*9, *c*11 and *c*10, *t*12), dissolved in a base of linoleic acid.

Dietary supplementation with CLA was carried as reported in Marco et al. (2009). Ten female pigs of approximately 40 kg live weight were selected and their diet was supplemented with 2.0% of CLA (3.57% of total oil added per tonne of feeding). Pigs were fed *ad libitum* from hopper feeders. The feeding trial lasted for 8 weeks, after which the animals were slaughtered having reached live weights of approximately 95 kg.

Pork breakfast sausages with CLA added in the formulation were prepared with meat and back fat from pigs with non-CLA enriched diets and live weights of approximately 95 kg, where 2% Luta-CLA (1.12% of CLA), substituting the same weight of back fat, was added to the mixture during the manufacturing process.

As a control, another treatment was prepared using meat and back fat from pigs fed with a non-CLA enriched diet and with no added CLA.

2.2. Sausage manufacture

Sausages were manufactured with the following formulation (w/w), 44.2% of lean meat, 18.7% of back fat, 2.5% seasoning, 7.0% rusk and 27.5% water. Prior to manufacture, back fat was chopped whilst frozen for 1 min at chopping speed 2 and bowl speed 2 (2, 2) using a bowl chopper (Fatosa C-35-2Z, Fatosa S.A., Sabadell, Spain) and then refrigerated. Diced lean meat, seasoning, overnight-hydrated rusk and ⅓ of the ice water were introduced into the bowl chopper and blended at speed (1, 1) for 20 s. The chopped fat was then added to the bowl along with the remaining ice water. All ingredients were then chopped for 2 min at speed (1, 1) and the mix was stuffed into collagen casings of 16 to the lb. The process was made by triplicate with meat and back fat from each animal (batch). For each batch, the sausages were then vacuum packed in bags containing six sausages, and stored at −20 °C.

Prior to cooking, raw samples were taken from all the treatments for subsequent analysis. Sausages were grilled for 30 min at 200 °C using a domestic oven grill (B-AH51-7 SIEMENS-Electrogerate, GmbH Germany), minced (R301 Ultra Robot Coupe, Robot Coupe UK Ltd., Middlesex, UK), vacuum packed and frozen for subsequent analysis. All results are expressed as the mean of six replicates of each treatment.

2.3. Analysis of fat and dry matter contents

Fat and dry matter contents were analysed with Smart Trac (CEM SMART Trac™ Fat and Moisture Analyzer, CEM Corporation, Matthews, USA), using a combination of microwave drying technology and Nuclear Magnetic Resonance (NMR). Minced samples (two replicates of 3 g) were dried in the microwave to calculate their dry matter content using the difference of weight before and after drying. Dried samples were placed in the NMR analyzer to calculate their fat content.

2.4. Fatty acid analysis

The total fatty acids were extracted, methylated and analysed with an adaptation of the method described by Aldai, Osoro, Barron, and Nájera (2006), which has been reported to be highly effective for poly-unsaturated analysis (Juárez et al., 2008). Separation and quantification of the fatty acid methyl esters was carried out using a gas chromatograph (GC, Varian Star 3400CX, Varian Associates Inc., California, USA) equipped with a flame ionisation detector automatic sample injector, and using a BPX-70 capillary column (120 m, 0.25 mm i.d., 0.2 μm film thickness, SGE, Australia). Tricosanoic acid methyl ester (C23:0 ME) at 10 mg/ml was used as an internal standard. Individual fatty acid methyl esters were identified by comparing their retention times with those of authenticated standards from Sigma (Sigma Chemical Co. Ltd., Poole, UK). Fatty acids were expressed as a percentage of total fatty acids identified and grouped as follows: saturated (SFA), monounsaturated (MUFA) and poly-unsaturated (PUFA) fatty acids. PUFA/SFA ratio and total CLA and Δ9-desaturase activities were calculated.

2.5. Statistical analysis

Statistical analyses were performed using Statistica 7.0 for Windows (StatSoft Inc., 2006). The effects of the different treatments (control, CLA dietary supplementation and CLA addition in the formulation) and cooking process as well as the interaction between them were studied using analysis of variance (multifactor ANOVA).

3. Results and discussion

In general, heat is applied to meat products in different ways to improve its hygienic quality by inactivation of pathogenic microorganisms to enhance its flavour and taste, and increase shelf life (Bognàr, 1998; Pokorny', 1999). During cooking, physicochemical reactions modify the food nutritional value. Cooking induces water loss in the food, increasing its lipid content, while only some fat is lost (García-Arias, Álvarez Pontes, García-Linares, García-Fernández, & Sánchez-Muniz, 2003; Yarmand & Homayouni, 2009).

In all the types of sausages, fat ($P < 0.01$) and dry matter ($P < 0.001$) contents increased after cooking with no interaction ($P > 0.05$) between cooking and treatment observed (Table 1). If expressed on dry matter basis, fat content of control, diet and formulation sausages decreased ($P < 0.001$) from 55.7%, 57.2% and 54.3% to 49.9%, 52.2% and 50.0% respectively, due to cooking losses. However, this was accompanied, by higher decreases in moisture content in all treatments following cooking, resulting in an apparent increase of fat content. This has been reported by other authors: for example Baggio and Bragagnolo (2006) in sausages, meat balls and hamburgers and by Dreeling, Allen, and Butler (2000) in beefburgers. Sheard, Wood, Nute, and Ball (1998) noted a similar effect in pork loin chops.

Fatty acid profiles of the sausages (Tables 2 and 3) were in line with those profiles reported elsewhere for pork products (Baggio & Bragagnolo, 2006; Lauridsen, Mu, & Henckel, 2005; Lo Fiego, Macchioni, Santoro, Pastorelli, & Corino, 2005; Pereira, Tarley, Matsushita, & Souza, 2000). The interaction between the studied factors (cooking and treatment) was significant ($P < 0.05$) for SFA and PUFA indices and for PUFA/SFA ratio (Table 2), as well as for several individual fatty acids (Table 3). Therefore cooking impacted in different ways depending on the type of sausage.

When the fatty acid profiles of the different types of sausages are compared, the levels of SFA of sausages from pigs with CLA dietary supplementation showed higher levels ($P < 0.001$) in comparison to those from the other two types. In this context, Dugan,

^{a,b,c,d}Indicate significant differences ($P < 0.05$) between samples.

Aalhus, and Kramer (2004) observed how CLA dietary addition increased SFA in pig meat and fat, increasing marbling and fat firmness. The increase of SFA in this study was accompanied by a decrease of MUFA ($P < 0.001$) in sausages with dietary supplementation. Schöne et al. (2003) reported that same effect, particularly in the back fat of pigs fed with CLA. According to Schöne et al. (2003), the shift from the MUFA to the SFA could result from the diminution of the Δ9-desaturase activities by the CLA, as observed (Table 2) for sausages with CLA dietary addition ($P < 0.001$). No cooking effect ($P > 0.05$) was observed for Δ9-desaturase activities from any treatment. However, as expected, PUFA levels of the sausages with dietary supplementation and direct addition were much higher ($P < 0.001$) than those of the control sausages, as a result of the added CLA.

The PUFA/SFA ratio for all the treatments was over 0.45, the minimum recommended by the British Department of Health (1994), showing cooking had no negative effect on this parameter. The highest ratio ($P < 0.001$) was that from CLA direct addition. CLA dietary supplementation led to an increase of both PUFA and SFA levels as compared to meat and fat from pigs with regular diet. Nevertheless the final PUFA/SFA ratio was greater than that from the control sausages.

Sausages enriched with CLA (diet and formulation) had CLA levels between 6% and 7%, whereas CLA levels of control sausages were very low (0.1% of total fatty acids). Cooking had no impact on the percent CLA present in all products. As mentioned earlier pork may content low amounts CLA, depending on the diet, as reported by Dhiman, Olson, MacQueen, and Pariza (1999) and Raes, De Smet, and Demeyer (2004) and reviewed by Chilliard, Ferlay, and Doreau (2001). From a nutritional point of view, the increase in PUFA and CLA levels would be positive. Therefore, the simplest way to increase CLA levels in breakfast sausages is the direct addi-

tion during the manufacturing process, as this method would be cheaper and does not result in increased SFA. It is important to note though that an increase in PUFA could lead to variations in the texture and flavour of sausages as seen in other similar emulsion type products; Turkish sausages (Yildiz-Turp & Serdaroğlu, 2008), and emulsion type sausages (Hah et al., 2006). Nevertheless, other authors have increased the $n-3/n-6$ ratio of sausages without significant variations in texture or sensory evaluation (Cáceres, García, & Selgas, 2008). Finally, CLA dietary supplementation has been shown to be able to get high CLA levels in sausages, while increasing PUFA and SFA and decreasing MUFA levels. Also PUFA/SFA level was greater than the minimum recommended.

Cooked control sausages had higher SFA ($P < 0.05$) and lower PUFA ($P < 0.05$) contents, as well as lower PUFA/SFA ratio ($P < 0.05$) compared to raw ones (Table 2). The increase of SFA was related to the increase ($P < 0.001$) of C16:0 (Table 3). The decrease of PUFA was due to the decrease of C18:2 $n-6c$ ($P < 0.05$) and C18:3 $n-3$ ($P < 0.001$). In the literature reduced PUFA on cooking has been related to triglycerides unsaturated fatty acid drip losses (Cobos, Veiga, & Díaz, 2008; Scheeder et al., 2001). While the overall MUFA levels were not affected by cooking ($P > 0.05$), the levels of C16:1 were higher ($P < 0.05$) and those of C17:1 lower ($P < 0.05$) in cooked than in raw control sausages.

One fatty acid from each type (SFA, MUFA and PUFA) was affected by cooking in sausages made from pigs with CLA dietary supplementation. An increase was observed for C14:0 ($P < 0.05$) and C18-1 $n-6c$ ($P < 0.001$), while C18:2 $n-6t$ levels decreased ($P < 0.01$) after cooking. Therefore, cooked sausages showed again higher levels of SFA and MUFA ($P < 0.05$) than raw ones. Increases in PUFAs after cooking have been observed in other studies. Maranesi et al. (2005) observed an increase in PUFA for lamb rib-loins after broiling and microwaving followed by final grilling. Some authors (Gerber, Scheeder, & Wenk, 2008; Igene, Pearson, & Gray, 1981; Rodríguez-Estrada, Penazzi, Caboni, Bertacco, & Lercker, 1997) have found an increase in PUFA levels of meat and meat products after cooking due to the lipid losses, containing mainly triacylglycerols of adipose tissues with relatively more SFA than PUFA, as suggested by Ramamurti (1986). However, in those studies, PUFA levels were much lower (1–6%) than those found in the sausages of the present study (21–29%). It is interesting to note that in a recent study, Sarriés, Murray, Moloney, Troy, and Beriain (2009) found no changes in the relative distribution of fatty acids upon cooking (140 °C for 30 min) in beef from animals with diets designed to enhance the concentration of CLA in tissue.

Unlike the other two types of sausages, no cooking effect ($P > 0.05$) was observed between the levels of any measure of fatty acid content when CLA was added during manufacturing process. This suggests that the oil added during manufacturing might help stabilise the presence of fatty acids during cooking.

No significant differences were found in CLA levels (total CLA and CLA isomers) between raw and cooked sausages within each treatment ($P > 0.05$). Maranesi et al. (2005), also reported no differences in total CLA levels before and after microwaving and broiling lean meat from rib loins. Therefore, CLA addition, either by dietary supplementation or direct addition in the formulation, resulted in similar levels to that added to the raw sausages after grilling.

4. Conclusions

The results from this study show that pork products can be modified to provide a significant increase in a functional lipid, which can have positive influences on health. Moreover, grilling had no clear effect on fatty acid levels in sausages with CLA added during manufacturing process. Grilling has a small but significant effect in sausages made with meat and back fat from pigs with a dietary CLA addition. Total CLA levels were not affected by grilling. Therefore, since CLA levels have been found to be stable during cooking, texture and sensory properties of both types of sausages should be evaluated in future studies to clarify the optimal process to increase CLA levels in pork breakfast sausages.

ABSTRACT

The aerial parts of *Hypericum perforatum* L. were studied to assess their composition in basic categories of bioactive compounds and their antioxidant activity, employing commonly accepted assays. The results reveal that floral buds, during the development stage, bear the highest concentrations of hyperforin followed by the flowers of the plant and comparable concentrations of hypericin and pseudohypericin. Among the various plant fractions, shoots and branches show significant antioxidant activity, a fact which may be accounted for by the high phenolic content. The measurement of DPPH· antioxidant activity of extracts by an on-line HPLC-DPPH· antioxidant activity measurement set-up, delineated the pivotal contribution of hyperforin, adhyperforin and their analogues to this antioxidant property. The role of phenolic compounds on the total DPPH· scavenging activity was minor except chlorogenic acid and its derivatives. No encouraging results were obtained as regards the inhibition of the oxidative damage of proteins. All the extracts promote the damage of proteins exhibiting a functional pro-oxidant role.

1. Introduction

Oxidative damage of biological molecules in the human body is involved in degenerative or pathological processes such as aging, coronary heart disease, cancer, arteriosclerosis and rheumatism (Halliwell, 1999). In the past decade, lots of epidemiological studies have conformed that intake of exogenous antioxidants is effective in preventing or suppressing such diseases (Block, Patterson, & Subar, 1992; Singh & Downing, 1995). The use of naturally occurring antioxidants has attracted considerable attention and an increasing interest in natural antioxidants, mainly phenolic compounds, has appeared worldwide that might help prevent oxidative damage (Stalikas, 2007).

Plant species of the genus *Hypericum* are well known for their use in traditional medicine, due to the therapeutic efficacy of its many different species. One of the most important and recognised species of the genus is *Hypericum perforatum* L., St. John's wort, which has been used in herbal medicine, externally for the treatment of skin wounds, eczema and burns and, internally, for disorders of the central nervous system, the alimentary tract and other purposes (Barnes, Anderson, & Phillipson, 2001; Bombardelli & Morazzoni, 1995). Hypericum is the second most used antidepressant worldwide with more than two billion euros turnover annually in Europe. Several studies have revealed antidepressant, antiviral, wound healing, antioxidant and antimicrobial activity of various extracts of the flowers of *H. perforatum* (Barnes et al., 2001; Butterweck, Jürgenliemk, Nahrstedt, & Winterhoff, 2000; Sakar & Tamer, 1990). A survey of the recent literature showed that data on the antioxidant activity of all of the known varieties are rather scarce (Kirca & Arslan, 2008; Silva, Ferreres, Malva, & Dias, 2005; Silva, Malva, & Dias, 2008; Zou, Lu, & Wei, 2004).

Natural antioxidants are considered to be multifunctional and their activity depends on various parameters such as the multiplicity and heterogeneity of the matrix, the experimental conditions and mainly the reaction mechanism. In general, the effectiveness of an antioxidant relies on the interfacial phenomena and the distribution of the components between the lipophilic and hydrophilic phases. It is now known that the antioxidant properties of plant extracts cannot be evaluated by one single method due to the complex nature of phytochemicals. A thorough antioxidant assay of plant extracts should involve several activity studies.

Despite detailed studies on the flowers of *H. perforatum* L., information on the antioxidant activity and composition of different morphological parts of it has hitherto not been reported. Therefore, apart from the traditionally used flowers, it would be of interest to evaluate the antioxidant properties of extracts obtained from the different aerial parts of the plant, employing commonly accepted antioxidant activity assays. In this study, the aerial parts of *H. perforatum* were collected and subsequently extracted with organic and aqueous solvents. Their antioxidant activity was extensively evaluated using established protocols and their composition in

doi:10.1016/j.foodchem.2009.04.016

terms of basic constituents was considered. More specifically, the plant was divided into five parts: shoots with leaves, non flower-bearing branches, flower-bearing branches, floral buds and flowers. The extracts were then analysed for their total phenolic and chlorophyll content and their concentration in hypericin, pseudohypericin and hyperforin which are well established active substances of the plant (Gioti, Skalkos, Fiamegos, & Stalikas, 2005). The potential correlation between the content of the extracts and their antioxidant activity was investigated.

2. Materials and methods

2.1. Chemicals

Hypericin, pseudohypericin and hyperforin (99%) were purchased from Alexis Corp. (Lausen, Switzerland). L-α-Phosphatidylcholine (PC), bovine serum albumin (BSA), nitro blue tetrazolium chloride (NBT), 5-methylphenazinium methosulphate (PMS), quercetin, β-nicotinamide adenine dinucleotide (β-NADH), chlorogenic acid, and *n*-octanol were obtained from Sigma (St. Louis, MO, USA). Linoleic acid, malondialdehyde (MDA), 2,2-diphenyl-1-picrylhydrazyl radical (DPPH·), 2,6-di-*tert*-butyl-4-methyl phenol (BHT), vitamin E, ferrozine and gallic acid were from Aldrich (Steinheim, Germany). Trichloroacetic acid, EDTA, ferric chloride, citric acid (99.5%), potassium chloride (p.a.), sodium carbonate, hydrochloric acid (37%, p.a.) and *n*-butanol were from Merck (Darmstadt, Germany). Guanidine hydrochloride (⩾98%), Folin-Denis reagent, Tween-20, sodium thiocyanate, 2-thiobarbituric acid (TBA) (⩾98%) and catechin (⩾96%) were obtained from Fluka Chemie (Buchs SG, Switzerland). Sodium dihydrogen phosphate, sodium monohydrogen phosphate (p.a.), ferrous chloride, ascorbic acid, sodium chloride, hydrogen peroxide, orthophosphoric acid (85% p.a.) and ethanol were from Riedel-de-Haen (Seelze, Germany). Finally, methanol and acetonitrile were of HPLC-grade and obtained from Labscan Ltd. (Dublin, Ireland).

2.2. Sample collection and extraction

Samples of *H. perforatum* were collected during the summer of 2003, from Epirus, Northwestern Greece. Voucher specimens of the collected plants are kept at the Agricultural University of Athens (code n. 1022). The collected samples were divided into five parts: (a) shoots with leaves (Sh), (b) non flower-bearing branches (NFBB), (c) flower-bearing branches (FBB), (d) floral buds (FB) and flowers (Fl). Floral buds were collected during their development, before opening stage and flowers during maturation. Each part was dried in the dark over a period of 30 days, ground to pass through a 0.4 mm sieve and extracted with: (I) MeOH at room temperature followed by EtOH–water (60:40) at 80 °C (organic extract) and (II) water at room temperature (aqueous extract) (Poutaraud, Lobstein, Girardin, & Weniger, 2001).

The collected extracts were filtered and the filtrates were evaporated into a flash evaporator and finally lyophilised. The dry residues were weighed and stored at −18 °C in dark-walled glass vials.

2.3. Solutions

Standard solutions of hypericin 0.02 mg/ml, pseudohypericin 0.1 mg/ml and hyperforin 0.05 mg/ml were prepared in MeOH and stored at −18 °C. Plant extracts of various concentrations (~0.02–1.00 mg/ml) were prepared by successive dilutions of a stock solution of 10 mg of dry extracts dissolved in 10 ml of methanol. A stock solution of MDA 10^{-2} M was prepared by hydrolysis of 1,1,3,3-tetraethoxypropane (Stalikas & Konidari, 2001).

2.4. Instrumentation

Spectrophotometric measurements were performed on a UV 2100 UV–Vis Shimadzu, Spectrophotometer (Shimadzu, Kyoto, Japan). Lyophilised extracts were obtained by an Alpha 1-2LD Lyophilisation apparatus (Christ, Germany).

Liquid chromatographic analysis of hypericin and pseudohypericin was performed on a Shimadzu HPLC system Shimadzu (Duisburg, Germany), as described elsewhere (Gioti et al., 2005). Hyperforin was chromatographed on the same HPLC system furnished with a Shimadzu spectrophotometric detector SPD 10AV at 276 nm, connected in series with a fluorescence detection, as per conditions for hypericins. Class LC10 software Version 1.6 (Shimadzu) was used for data analysis and processing.

Mass spectra were measured on an Agilent 1100 Series LC-MSD-Trap-SL spectrometer (Palo Alto, CA, USA) equipped with an electrospray interface using the positive ionisation mode, and an autosampler with autoinjector. Operating conditions were: accumulation time, 300 ms; dry temperature, 350 °C; capillary voltage, 3500 V; nebuliser, 40 psi; dry gas, helium at 12 l/min. Ion trap full-scan analysis was conducted from *m*/*z* 50 to 700 with an upper fill time of 200 ms. A 10 μl sample volume was injected. System control and data evaluations were performed using the HP ChemStation for LC/MS. The analytical column and chromatographic program was the same used for the isocratic analysis of hypericins and hyperforin.

Liquid chromatographic analysis of the extracts was performed by the above mentioned HPLC systems by gradient elution using MeOH as solvent A and aqueous formic acid 0.1% as solvent B at a flow rate of 0.5 ml/min. The gradient program started with 20% solvent A, raised to 95% after 70 min, and remained at this percentage for 30 min. The overall analysis time was 100 min and the column was kept at 30 °C throughout analysis.

The on-line post-column radical scavenging measurements were carried out by a hyphenated DPPH· method based on a system first proposed by van Beek et al., 2000 (Koleva, Niederlander, & Van Beek, 2000). The separated analytes reacted post-column with the DPPH· and any reduction in the concentration of radicals was detected as a negative peak by the absorbance detector at 515 nm. The DPPH· solution (3×10^{-5} M) was inserted in the HPLC effluents with the use of a second HPLC pump at a flow rate of 0.4 ml/min and the reaction took place in a 5.0 m Teflon reaction coil of 0.25 mm internal diameter. The bleaching of the DPPH· solution was recorded by a second UV–Vis detector (Exarchou, Fiamegos, van Beek, Nanos, & Vervoort, 2006).

2.5. Methods of analysis and antioxidant measurements

The determination of total phenolic content was based on the Folin-Denis method. Total chlorophylls and chlorophylls *a* and *b* were determined by measuring the absorbance at 663 and 640 nm.

The free radical scavenging activity was evaluated by the DPPH· method. The percentage of the superoxide anion scavenging activity of the hypericum extracts was determined by the nitro blue tetrazolium chloride method. The metal chelating activity of hypericum extracts was evaluated by the ferrozine–Fe^{2+}complex formation method. The reducing power of the extracts was evaluated by the ferricyanate–Fe^{3+}method. The inhibition of lipid oxidation was determined by measuring the antioxidant activity using PC as the lipid matrix. Prevention of oxidative damage to proteins was based on the Fenton/BSA reaction. Linoleic acid antioxidant activity was based on the inhibition of linoleic acid oxidation.

More details on the above methods are provided in Supplementary material.

3. Results and discussion

3.1. Composition of extracts from Hypericum perforatum aerial parts

Phloroglucinols, naphthodianthrones, phenolic acids and flavonoids are the most prominent constituents of *H. perforatum*. Its pharmaceutical activity, however, is attributed mainly to hypericins and hyperforin (Butterweck, Petereit, Winterhoff, & Nahrstedt, 1998; Skalkos et al., 2005). Table 1 summarises the results from the quantitative determination of the three major components of the extracts and their respective total phenolic contents. The organic extracts, as opposed to the aqueous ones, are rich in all components because of the demonstrated low solubility of hypericin, pseudohypericin and hyperforin in water. Moreover, among the three constituents, hyperforin is the most abundant in all extracts. Highest was the concentration of hyperforin in the FB extracts. This is due to the fact that hyperforin is photosensitive and its highest concentrations appear just before the blossom period (Ang et al., 2004; Orth & Schmidt, 2000). From Table 1, it is also clear that in all extracts under study, phenolics are in abundance (expressed as mg of gallic acid/g dry extract) with the Sh extracts to exhibit the highest and the FB the lowest concentrations. Phenolic compounds have a wide range of polarity and thus, both organic and aqueous extracts show significant phenolic concentrations.

Ward's hierarchical clustering and principal component analysis based on standardised data of Table 1 can distinguish between tested samples. Visual diagrams summarising all ten samples are given in Fig. 1. Both diagrams reveal that the extracts fall into two major clusters-groups consisting of small sub-groups. In this way, the organic extracts of flowers and floral buds prove to belong to a distinct group because of their highest concentrations in hypericin, pseudohypericin and hyperforin. Two significant subgroups are comprised of NFBB and FBB for both extraction media, which are characterised by comparable phenolic content and concentrations of active constituents.

As for chlorophylls, highest total quantities were observed in the organic extracts as a consequence of their strong hydrophobicity. FB and Fl presented lower concentrations of total chlorophylls (see Supplementary material) most of which were attributed to chlorophyll α which are better extracted to polar organic solvents than chlorophylls *b*.

Furthermore, the LC–MS analysis of the extracts made it possible to identify the most prominent constituents of the extracts, in combination with the injection of reference compounds, where possible. As expected, the organic extracts are richer in constituents being in higher quantities, as compared to the aqueous counterparts. The identified constituents of the extracts are the following: chlorogenic acid, rutin, taxifolin ramnoside, hyperoside, isoquercitrin, quercetin, biapigenin, pseudohypericin, hypericin, hyperforin, adhyperforin together with two unidentified hyperforin and adhyperforin analogues. Chlorogenic acid is the dominant compound in all extracts while taxifolin ramnoside, routin, hyperoside and isoquercitrin were found to be equally distributed between the organic and aqueous extracts. The FB and Fl-organic extracts comparatively bear the highest quantities of hyperforin, adhyperforin and their analogues. Chromatographic and spectral data of the identified peaks are provided in Supplementary material.

3.2. Antioxidant activity of H. perforatum aerial parts

The antioxidant activity of an extract, especially when dealing with food and biological samples depends on several parameters such as the matrix effect, the oxidation parameters and the antioxidant reaction conditions. In order to evaluate the antioxidant activity of a natural product, it is crucial to implement more than one antioxidant methods, taking into consideration the various oxidation aspects in the systems under scrutiny. In this context, the antioxidant properties of the aqueous and organic extracts of the five aerial parts of *H. perforatum* were studied and compared with the activity of the well known antioxidants vitamin E, quercetin, gallic acid and BHT. Moreover, the EC_{50} values, which refer to the smallest concentration of antioxidants necessary for 50% of reactivity were calculated. The lower the EC_{50} value the more reactive the compound under study.

Various concentrations of the extracts were investigated for *their DPPH· radicals scavenging activity* and they were compared with that of BHT. Increased scavenging activities were recorded in all cases for extract concentrations higher than 0.27 mg/ml. Optimum behaviour was presented by organic and aqueous Sh and Fl extracts (~100% activity) which was comparable to BHT. The activities of the rest of the extracts ranged from 84.6% to 93.9%. Weakest reactivity was rendered by the organic FB extract approaching 73.7% of scavenging activity in this particular assay. It is worth mentioning that for concentrations lower than 0.27 mg/ml the extracts behaved better than BHT.

Radicals present in living organisms are short-lived. Thus, the study of the antioxidant activity of a natural product should inevitably be correlated with the required reaction time. EC_{50} values when combined with the respective time $T_{EC_{50}}$ (time required to achieve 50% of antioxidant reactivity) afford the antioxidant efficiency factor (*AE*), given by the equation $AE = 1/EC_{50}T_{EC_{50}}$ (Villano, Fernandez-Pachon, Moya, Troncoso, & Garcia-Parrilla, 2007). The higher the *AE* value the stronger the antioxidant activity of the

[a] Sh, shoots; NFBB, non-flower bearing branches; FBB, flower-bearing branches; FB, floral buds; Fl, flowers.

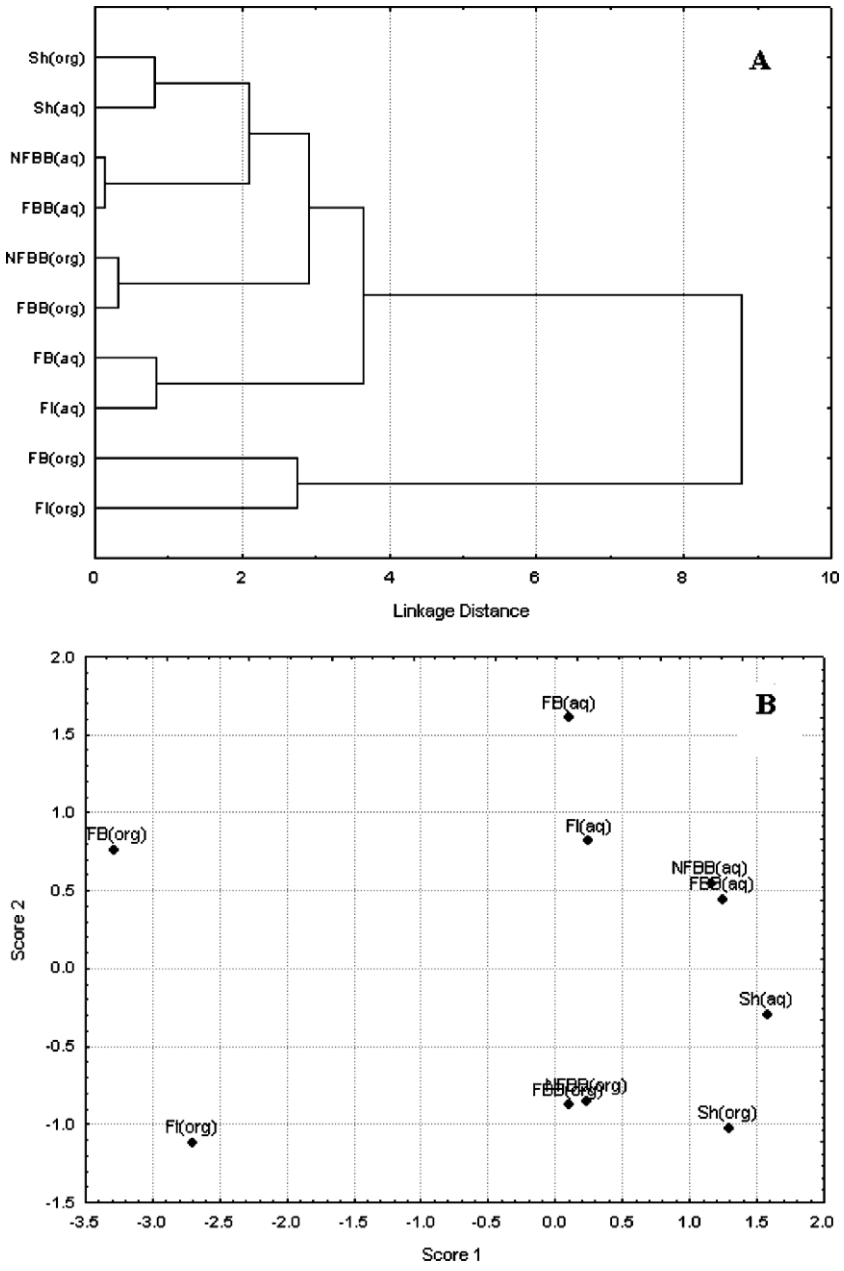

Figure 1. (A) Dendrogram indicating the grouping obtained by cluster analysis and (B) the scores plot obtained from principal component analysis of all plant extracts.

extract. If this approach is applied, the antioxidant potential of the different plant extracts is altered because of the different kinetic behaviour of the extracts. Resting on *AE* calculated values, the scavenging DPPH· activity decreases following the order: org-Sh > org-NFBB ∼ org-FBB > aq-Sh > aq-NFBB > aq-FBB > org-FB > org-Fl > aq-FB > aq-Fl.

On a subsequent step, a gradient elution program was applied to acquire on-line, post-column DPPH· scavenging measurements. Any reduction in the radical concentration was detected as a negative peak at 515 nm. Fig. 2 exhibits the chromatographic analysis of a methanol extract using the on-line DPPH· test. The negative peaks were observed with a time delay of 3.31 min which was attributed to the 5.0 m reaction coil. As expected, the negative peaks acquired exhibit low resolution and chromatographic peaks with close retention times are represented by a single broad peak. The contribution of each of the extracts components to the overall radical scavenging activity of the extract was correlated to the area of the respective negative peak. Since the reaction of 3.31 min is not adequate for the reactants to reach equilibrium, the overall procedure is a fixed-time method strongly depending on the kinetics of the reaction; thus, it is better described by the $T_{EC_{50}}$ value. Table 2 summarises the contribution of each of the main active ingredients, as a percentage of the overall activity of the extract.

Chlorogenic acid is the compound contributing the most to the DPPH· antioxidant activity; in the case of Sh, it accounts for ∼60% of the total activity. The antioxidant activity of chlorogenic acid, which appears in highest concentrations in both organic and aqueous extracts has been well established (Govindarajan et al., 2006). Worth mentioning is the high contribution of hyperforin, adhyperforin and their analogues which show up as main DPPH· antioxidants of the organic FE and Fl extracts. On the contrary, less significant is the contribution to the DPPH· scavenging activity of taxifolin ramnoside, rutin, hyperoside, isoquercitrin, quercetin and biapigenin.

The scavenging activity of the superoxide anion ($O_2^{\cdot-}$) of the extracts was evaluated against the activity of gallic acid. According to

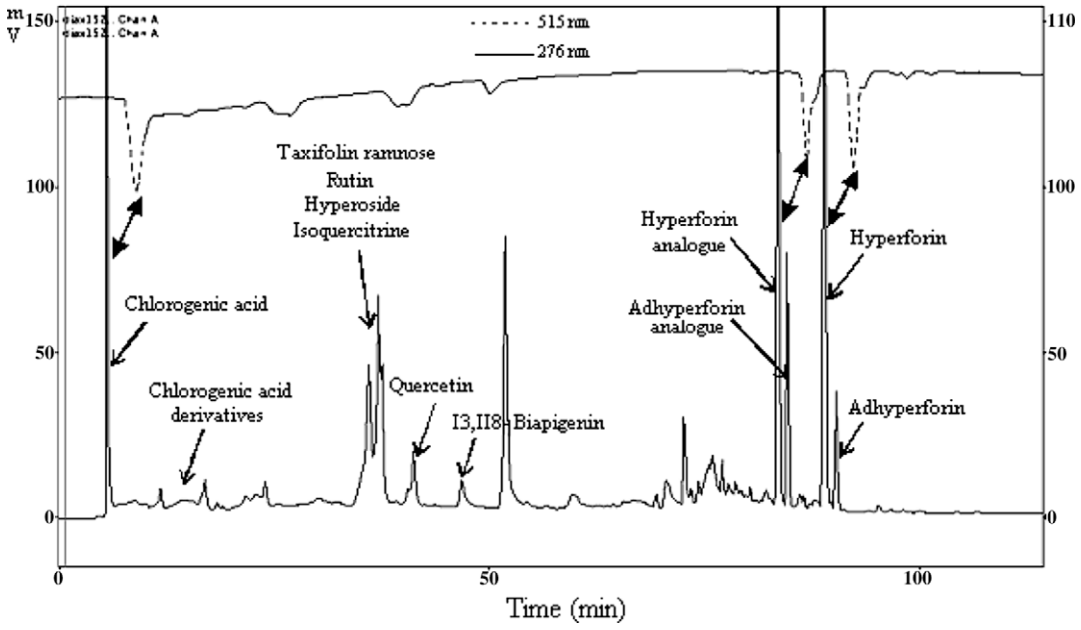

Figure 2. On-line, post-column radical scavenging chromatogram of the methanol extract of *Hypericum perforarum* L. flowers.

Table 2
Radical scavenging activity of the main constituents identified, presented as a percentage of the respective overall extract activity.

Sample	Extract constituents (%)

SDs of the values of the table are ranging between 0.3 and 0.8.

this study, the inhibition of the chromophor formation is directly correlated to the extract concentration, reaching 84% and 72% for the organic and aqueous extracts respectively. The activity of the extracts reaches the respective of gallic acid at concentrations above 1.0 mg/ml. This inhibitory effect for the aqueous extracts ranges from 68% to 72%, with the greatest activities corresponding to Sh and Fl. As regards the organic extracts, the respective percentages are 70–84% with the highest values corresponding to FBB and Fl. The EC_{50} values were between 0.18 and 0.23 mg/ml while the respective value for gallic acid was 0.020 mg/ml, indicating its superiority on superoxide anion scavenging activity. The scavenging activity of superoxide anion according to the calculated EC_{50} values follows the order: gallic acid > aq.-Sh > org.-FB > org.-Sh > aq.-FBB and aq.-Fl > org.-NFBB > aq.-NFBB and org.-Fl > aq.-FB > org.-FBB.

The occurrence of appropriate *chelating agents* into the extracts is substantial for the reduction of free transition metals which give rise to catalytic lipid peroxidation. These agents form σ-bonds with the metals stabilising their oxidised form (Elmastas, Gulcin, Beydemir, Kufrevioglu, & Aboul-Enein, 2006). It is known that Fe^{2+}generates lipid peroxidation through the Fenton reaction or by accelerating the dissociation of lipid hydroperoxides to the respective peroxy- and alkoxy-radicals. Thus, the ability of the extracts to bind with Fe^{2+}in the presence of ferrozine was compared with the respective of EDTA which is a strong chelating agent. If EDTA's chelating ability is taken as 100% then for a range of extract concentrations 0.17–1.00 mg/ml their chelating potential were determined. Organic and aqueous FE extracts exhibited best chelating behaviour, i.e. 34.1% and 45.5%, respectively. The corresponding EC_{50} values were between 0.242 and 1.411 mg/ml while for EDTA was 0.011 mg/ml. Although the chelating activity of the extracts was much lower than EDTA's, yet, values were not negligible for a natural product. The EC_{50} values of the chelating activity of the extracts is summarised as follows: EDTA > aq.-FB > org. FB > org.-NFBB > org.-Fl > aq.-Fl > aq.-FBB > org.-Sh and aq.-NFBB > aq.-Sh.

The *reducing power* of the extracts is directly associated to their antioxidant activity (Meir, Kanner, Akiri, & Philosoph-Hadas, 1995). A rise in the extract's concentration led to increase of the reducing power value. At extract concentrations between 0.01

and 0.12 mg/ml the highest reducing power values were acquired for Sh, NFBB and FBB extracts and lowest for the FB extracts, with the activity of BHT being by far the strongest.

Lipid phase antioxidant activity (TBARS method) was based on monitoring the behaviour of all the extracts under study after the induction of radical peroxidation in PC. Lipid peroxidation leads to the formation of MDA and other similar compounds which are characterised as thiobarbituric-reactive substances (TBARS). The inhibition of TBARS formation can directly be associated to the peroxidation inhibiting activity of extracts. BHT and quercetin, which is a well known natural antioxidant, were used as reference compounds. The activity of *H. perforatum* extracts was tested in the concentration range of 0.10–1.0 mg/ml. The synthetic BHT was the most active of the tested forms exhibiting lipid peroxidation protection of 89%. Quercetin presents behaviour closer to that of the extracts under study. Of the organic extracts, NFBB and Sh are more active, which accounts for 75.9% and 73.8% peroxidation inhibition, respectively. Less active are the aqueous extracts with aq.-Sh to demonstrate the inhibition of 65.4%. As for org.-FB, at concentrations higher than 0.50 mg/ml, its activity is reduced significantly and it acts as a pro-oxidant. The respective EC_{50} values shape the following decreasing order of activity: BHT (0.004) > quercetin (0.094) > org. extracts (0.101–0.203) > aq. extracts (0.192–0.330).

The inhibitory effect of quercetin against lipid peroxidation is attributed to its chelating properties. Quercetin forms complexes with Fe^{2+}which occurs in the PC oxidation solution and thus it is not possible for the hydroxyl radicals to be formed *via* the Fenton reaction. Moreover, quercetin promotes the oxidation of $Fe^{2+}$to Fe^{3+}rendering it less effective in the production of free radicals. Nonetheless, in metal-induced lipid peroxidation its antioxidant reaction dominates (Hajji, Nkhili, Tomao, & Dangles, 2006). On the other hand, BHT acts mainly as hydrogen donor, while its high lipophilicity facilitates its incorporation into the liposomes providing stronger protection against oxidation. This is probably the main activity mechanism of the extracts, as well. The antioxidant activity of all organic extracts against lipid phase oxidation may be attributed to a great number of compounds of different polarities and their protective orientation to the bilayer and polar surface of PC.

Oxidative damage of proteins is attributed to the presence of free radicals leading to the formation of carbonyl compounds. The ability of the extracts to *prevent protein oxidative damage* was evaluated based on the inhibition of carbonyls formation. This kind of oxidation is due to Fenton reaction, Fe^{2+}/H_2O_2 while H_2O_2 facilitates the production of free radicals. Here, BHT and quercetin were used as reference compounds at concentrations of 0.01–1.00 mg/ml. BHT is the only tested among compounds and extracts that showed an increase in the antioxidant activity with increasing concentrations. Quercetin, at concentrations of 0.01–0.20 mg/ml showed negative values of inhibition (−18.3%) manifesting itself as a pro-oxidant, in this concentration range. At concentrations greater than 0.20 mg/ml the pro-oxidative effect turns opposite with positive values of antioxidant activity (12.1% at 1.00 mg/ml). The plant extracts under study presented only increasing pro-oxidative activity. Thus, at concentrations of 1.00 mg/ml, pro-oxidative activities of 56.5 and 42.1% are produced by org. and aq.-Sh while org.- and aq.-FB extracts presented the lowest activity of 14.5 and 17.7%, respectively. This is not extraordinary since other researchers have noticed that several other plant extracts or pure antioxidants scarcely prevent metal-catalysed oxidation of proteins ((Makris & Rossiter, 2001; Moure et al., 2001). Unlike lipid-phase peroxidation, flavonoids in metal-catalysed protein oxidation may appear to have a pro-oxidative effect (Hajji et al., 2006). Besides, quercetin and other related phenolic substances are known to bind with proteins or amino acids, thus exhibiting reduced activity (Arts, Haenen, Voss, & Bast, 2001; Smith, Halliwell, & Aruoma, 1992). In addition to this phenomenon, the hydrophilicity of the proteinic system together with the occurrence of citric acid promotes the Fe^{2+}solubility which drives the elevated production of hydroxyl radicals. Although citric acid shows a tendency to form complexes with Fe^{2+}, this reaction is rather slow especially at neutral pH ambience. In addition, the pro-oxidation effect of the extracts may be attributed to the reduction of metal ions like $Fe^{3+}$to their considerably more active forms like Fe^{2+}(Moure et al., 2001). So, it is possible that the efficiency of the aqueous antioxidants may be negated by their pro-oxidant activity due to the occurrence of metal ions in their reduced form, which is more reactive.

Finally, the antioxidant activity of the extracts was tested with respect to the *prevention of oxidation of linoleic acid system*. The potential of the plant extracts under study to inhibit lipid peroxidation was measured in a time span of 1–72 h of incubation. In a previous work, we demonstrated that *H. perforatum* L. extracts inhibit the formation of pentanal and hexanal and work as antioxidants under induced oxidative conditions in oil-in-water systems (Gioti, Fiamegos, Skalkos, & Stalikas, 2007). The highest antioxidant activity was noticed at relatively low concentrations of extracts. From the experiments herein, it became evident that for 1 h incubation time the antioxidant activities of both types of extracts and the reference compounds were low ($\leqslant$37% for lipophilic BHT and vitamin E, $\leqslant$22% for org. extracts and $\leqslant$34% for aq. extracts). Increased incubation times led to an improvement in the activity with higher values to be observed in all cases in the concentration range 0.10–0.75 mg/ml and incubation time of 24 h (64–83% for org. extracts and 32–83% for aq. extracts). The extended antioxidant protection was achieved effectively at higher extract concentrations while aqueous extracts present lower antioxidant activity when lower extract concentrations were used in contrast to the respective organic extracts. The greater than 24 h the incubation period the higher the extract concentrations required in order to maintain enough antioxidant protection from lipid peroxidation. Vitamin E and BHT, as reference compounds, were superior for shorter incubation periods but their activities converged to the respective of the extracts for higher time periods (i.e. at concentrations higher than 0.50 for org. and 0.75 mg/ml for aq. extracts). For all the above antioxidant activity methods more data are provided in Supplementary material.

3.3. Correlation analysis of the measurements

It is widely accepted that the antioxidant activity of a plant extract is correlated to its phenolic content (Elmastas et al., 2006). However, the results of this study agree with researchers who question this possible correlation (Bocco, Cuvelier, Richard, & Berset, 1998; Oktay, Gulcin, & Kufrevioglu, 2003). In addition, experiments using pure compounds showed that the chemical structures of phenolic compounds have a decisive effect on their antioxidant properties. Thus, the antioxidant activity is stronger when a second hydroxyl or methyl group is present in *ortho* or *para* position (Tuberoso, Kowalczyk, Sarritzu, & Cabras, 2007). In order to elucidate the correlation between the phenol content of *H. perforatum* aerial parts and their antioxidant activity, linear regression analysis was performed, quoting the correlation coefficient (r) of each of the antioxidant tests performed. The significance test was based on the calculation of t_{exp} and its comparison with $t_{(0.05,8)}$ of the t-distribution, at 95% confidence (for $t_{exp} > t_{(0.05,8)}$ the correlation is statistically significant). It was obvious that the phenolic content in the extracts showed a strong correlation with $DPPH^{\cdot}$ scavenging activity ($r = 0.822$), reducing power ($r = 0.981$) and prevention of PC oxidation ($r = 0.946$). This implies that phenolics are undoubtedly responsible for such inhibition of *Hypericum perforatum* extracts. No significant correlation could be found between

phenolic content and superoxide anion scavenging activity and linoleic acid antioxidant activity.

The inhibition of protein oxidation is correlated negatively with phenolics, for reasons already mentioned. The same behaviour holds true for metal chelating activity. The pro-oxidant activity of metal chelating complexes is attributed to the capacity of the chelating agent to increase the solubility of the metal or to facilitating the participation of the metal on the redox cycle. In addition, the chelating ability highly depends on the pH of the solution. At pH values lower than the respective pK_a the active groups are protonated and their chelating power is substantially reduced. Moreover, the chelating ability is reduced in the presence of antagonistic chelating metals like Ca.

There are studies reporting that chlorophylls may present antioxidant activity while the pro-oxidant activity due to their light and heat instability is also supported (Tuberoso et al., 2007). In our case, a satisfactory correlation with DPPH· scavenging activity ($r = 0.660$) and reducing power ($r = 0.648$) exists, which entails stabilisation of the chlorophylls in the experimental conditions that allows their antioxidant activity to be expressed.

4. Conclusions

The *Hypericum perforarum* L. owes its widespread use in traditional and contemporary medicine to the high content of hypericins and hyperforins in its flowers. To reap the full benefits of the plant it was necessary to undertake a detailed antioxidant and compositional study of the entire aerial plant. Floral buds bear the highest concentrations of the foregoing constituents followed by the flowers; therefore, if extracts rich in bioactive substances is the case, floral buds should be extracted. Based on the antioxidant activity profile expressed through various assays, it can be concluded that, among the various plant fractions, shoots and branches show significant activity, which may be accounted for by the high phenolic content. Interestingly enough, the on-line HPLC-DPPH· antioxidant activity measurement of the extracts delineated the pivotal contribution of hyperforin, adhyperforin and their analogues to this antioxidant activity. The role of phenolic compounds on the total DPPH· scavenging activity was minor except chlorogenic acid and its derivatives. No encouraging results were obtained as regards the inhibition of the oxidative damage of proteins. All the extracts promote the damage of proteins exhibiting a functional pro-oxidant role. Finally, it is taken for granted that, the complex composition of plant extracts can lead to contradictory results if the antioxidant activity evaluation is carried out by a single method.

Cell viability

ABSTRACT

The health-promoting effects of natural phenolic compounds are attracting growing interest. In this study, we tested four plant extracts, namely basil, juniper, laurel and parsley, and two well-known pure phenolic compounds of natural origin, curcumin and resveratrol, for their possible cytotoxic effects *in vitro*. AraC was used as an apoptotic reference compound. The pure compounds were studied in two cell lines, SH-SY5Y neuroblastoma and CV1-P fibroblast cells, and the plant extracts in SH-SY5Y cells. Cytotoxicity was examined by MTT and LDH assays, and the molecular mechanisms by Western blot analysis of p53 protein in cells. Juniper extract decreased the cell viability and increased the amount of p53 in SH-SY5Y cells at lower concentrations than did other plant extracts, and its effects on the amount of p53 in cells were comparable to the treatment with 50 μM AraC. The actions of curcumin and resveratrol were dependent on the concentration and cell line. Curcumin decreased the cell viability and increased the amount of p53 in SH-SY5Y cells more effectively than in CV1-P cells. The comparison between the results of AraC and pure curcumin showed a similar effect on the amount of p53. Our results indicate a potential role of plant extracts and plant-derived compounds as health-promoting food constituents, as well as candidates for drug development.

1. Introduction

The role of cell death in health and disease has been intensively studied (Lockshin & Zakeri, 2007). Apoptosis is one form of programmed cell death and a closely regulated mechanism to control the removal of unwanted and/or harmful cells of an organism. Apoptosis is also needed for the maintenance and function of homoeostasis, differentiation, embryonic development and the immune system. Impairments in apoptosis can be associated with several diseases, e.g. cancer, autoimmune and neurodegenerative diseases and AIDS. An unregulated form of cell death is necrosis. It occurs due to various stress causes, e.g. toxins or physical damage, leading to uncontrolled death of a cell.

The p53 tumour suppressor protein is one of the key regulators of apoptosis and plays a pivotal role in mediating DNA damage-induced apoptosis. The role of p53 has also been widely studied in experimental models of apoptosis (Maňáková, Puttonen, Raasmaja, & Männistö, 2003; Roy, Baliga, Elmets, & Katiyar, 2005). Activation of p53 by a cellular stress, e.g. DNA damage and cytotoxic compounds, can lead the cells to apoptosis or cell cycle arrest by acting as a transcription factor and modulating the activity of other proteins related to apoptosis (Meulmeester & Jochemsen, 2008). The significance of p53 in cancer is, without dispute; thus an impaired p53 pathway is involved in most human cancers (Vogelstein, Lane, & Levine, 2000).

Natural phenolic compounds, abundant in fruits, berries and vegetables, have been shown to be capable of modulating cell signalling pathways related to cell death. Their role as chemopreventive agents is under intensive investigation and many promising compounds have been found (Pan, Ghai, & Ho, 2008). Indeed, the activities of two intensively studied plant phenolic compounds, resveratrol and curcumin, in the signalling mechanisms of a cell are indisputable. There is also strong evidence that natural phenolic compounds can alter cell signalling pathways related to tumour suppressor protein p53 in cancerous cell lines (Lin et al., 2008; Shukla & Gupta, 2008). Besides, there has been a growing interest in plant-derived extracts, instead of pure compounds. This is because the extracts have been used for therapy from past to present, and their health-promoting effects might involve several active compounds in the extracted material. A potential advantage of plant-derived compounds in healthcare is that their utilisation as food has a long history, and their use has been accepted as safe. The possible utilisation of plant-derived compounds and extracts as chemopreventive and health-promoting agents in the future has focussed increasing attention on the understanding of their molecular mechanisms and targets of action.

doi:10.1016/j.foodchem.2009.04.018

The aim of our study was to examine four plant extracts containing phenolic compounds (Hinneburg, Dorman, & Hiltunen, 2006), and two pure plant-originated phenolic compounds for their possible effects on cell viability and cell death. Therefore, we have tested the effects of water extracts from basil (*Ocimum basilicum* L.), juniper (*Juniperus communis* L.), laurel (*Laurus nobilis* L.) and parsley [*Petroselinum crispum* (Mill.) Nyman ex A.W. Hill] (Hinneburg et al., 2006) on the membrane integrity, metabolic activity and amount of protein p53 in SH-SY5Y neuroblastoma cells. Pure phenolic compounds, curcumin and resveratrol, were tested for their effects on the metabolic activity and amount of p53 in SH-SY5Y neuroblastoma and CV1-P fibroblast cells. In addition, the effects of plant extracts and pure compounds were compared with the effects of AraC, which was used as a positive control for apoptosis.

2. Materials and methods

2.1. Cell cultures and treatments

CV1-P fibroblast cells were cultured in Dulbecco's modified Eagle Medium (DMEM) containing L-glutamine, 1000 mg/l of D-glucose and sodium pyruvate (Gibco; Invitrogen, Carlsbad, CA) supplemented with 10% heat-inactivated foetal bovine serum (HyClone, Thermo Fisher Scientific, Waltham, MA), and penicillin (100 U/ml) and streptomycin (100 μg/ml) (Gibco). SH-SY5Y neuroblastoma cells were cultured in DMEM: nutrient mixture F-12 (1:1) containing 15 mM HEPES buffer and L-glutamine (Gibco) supplemented with 15% heat-inactivated foetal bovine serum (HyClone), penicillin (170 U/ml) and streptomycin (170 μg/ml) (Gibco) and 1% non-essential amino acids (Gibco). The cells were grown in 75 cm^2 cell culture flasks at 37 °C in a humidified atmosphere containing 5% CO_2 in air. CV1-P cells were seeded in 6-well plates and SH-SY5Y cells in 6-well plates or 60 mm culture dishes for Western blot analysis. Both cell lines were cultured in 96-well plates for cell viability assays. The cells were exposed to AraC, resveratrol, curcumin and, furthermore, SH-SY5Y cells to different plant extracts 18–24 h after plating. AraC was dissolved in milliQ H_2O, curcumin and resveratrol in DMSO: milliQ H_2O (1:1) and plant extracts in cell culture medium or milliQ H_2O. The final concentration of DMSO in all experiments was 0.1%. Control cells were exposed to the same amount of DMSO.

2.2. Preparation of plant extracts

Plant extracts from basil (*O. basilicum* L.), juniper berry (*J. communis* L.), laurel (*L. nobilis* L.) and parsley [*P. crispum* (Mill.) Nyman ex A.W. Hill] were prepared in our own laboratory (Hinneburg et al., 2006). Briefly, dried plant material was purchased from Paulig Oy, Finland. The extraction of plant material was performed by hot water under normal pressure and the volatile oils were removed by hydrodistillation. Plant extracts were freeze-dried, and stored at 4 °C.

2.3. MTT assay

An assay of MTT (methylthiazolyldiphenyl-tetrazolium bromide) reduction was used to examine the metabolic activity of the cells. The MTT assay is based on the reduction of the yellowish MTT to dark blue formazan by viable and metabolically active cells (Mosmann, 1983). The cells were incubated with different compounds for 12 or 24 h. Then, MTT (Sigma, Saint Louis, MO), dissolved in Hank's balanced salt solution, was added into each well to get the final concentration of MTT at 0.5 mg/ml. SH-SY5Y cells were incubated with MTT for 2.5 h and CV1-P cells for 3–4 h at 37 °C in 5% CO_2. The medium with MTT solution was removed and the formazan crystals were dissolved with DMSO. The absorbance was measured at 560 nm, subtracting the background at 655 nm, using a microplate reader (Bio Rad, model 550, Japan). The percentage metabolic activities were calculated using Eq. (1) from the values of 2–4 independent experiments.

$$\%\ \text{metabolic activity} = \left(\frac{\text{absorbance of treated cells}}{\text{absorbance of untreated cells}}\right) \times 100 \quad (1)$$

2.4. LDH assay

The membrane integrity of cells was measured using a commercial kit (CytoTox-ONE Homogeneous Membrane Integrity Assay; Promega, Madison, WI). The measurement is premised on the leakage of lactate dehydrogenase (LDH) from cells after different treatments, and the assay was performed according to the manufacturer's instructions. In brief, the cells were incubated with different extracts for 12 h and 50 μl of medium from treated cells were mixed with the 50 μl of CytoTox-ONE reagent. The plate was incubated for 30 min, shaking the first 10 min. The reaction was stopped adding 25 μl of CytoTox Stop Solution, and the fluorescence was determined with an excitation wavelength 560 nm and an emission wavelength 590 nm, using a fluorescence microplate reader (Varioskan, Thermo Scientific, Finland). The percentage membrane integrities were calculated using Eq. (2) from the values of 3–4 independent experiments.

$$\%\ \text{membrane integrity} = \left(\frac{\text{experimental-blank}}{\text{control-blank}}\right) \times 100 \quad (2)$$

2.5. Western blotting

Protein p53 is one of the key regulators of apoptosis. Therefore, we have measured the amount of p53 in cells after treatments using Western blotting. Both cell lines were incubated with different samples for 12 h and harvested into ice-cold PBS. The cells were spun down by centrifugation (SH-SY5Y: 5 min, 5000*g*, 4 °C and CV1-P: 5 min, 2000*g*, 4 °C) and the cell pellets were stored at −80 °C until the total protein was extracted. To extract the total protein from cells, the cell pellets were incubated with a lysis buffer (20 mM HEPES, 20% glycerol, 500 mM NaCl, 1.5 mM $MgCl_2$, 0.2 mM EDTA and 0.1% Triton X-100) supplemented with the cocktail of protease inhibitors (Complete Mini, Roche, Mannheim, Germany) for 30 min (SH-SY5Y) and 1 h (CV1-P) on ice. After incubation, the samples were sonicated 3 × 10 s and centrifuged (SH-SY5Y: 15 min, 16000*g*, 4 °C and CV1-P: 30 min, 13000*g*, 4 °C). The supernatants were collected and the amount of protein was determined by a colorimetric bicinchoninic (BCA) protein assay kit (Thermo Scientific, Rockford, IL). Protein samples were separated using 10–12% SDS–PAGE gel and transferred onto a nitrocellulose membrane. Nonspecific binding was blocked with 5% non-fat milk powder in Tris-buffered saline (TBS) supplemented with 0.05% Tween 20 for 2 h at room temperature. Proteins p53 and β-actin were identified using a mouse monoclonal p53 antibody (DO-7, Novocastra, UK) and a mouse monoclonal β-actin antibody (A1973, Sigma, Saint Louis, MO). Primary antibodies were incubated with the nitrocellulose membranes overnight at 4 °C in TBS with 0.5% non-fat milk powder with samples from SH-SY5Y cells and with 5% non-fat milk powder with samples from CV1-P cells. Then, the membranes were washed with TBS with 0.5% Tween 20, and exposed to a secondary antibody (Anti-mouse IgG-HRP, HAF007, R&D Systems, Minneapolis, MN) for 1 h at room temperature. The membranes were washed and the protein bands were

detected by a chemiluminescent reagent (SuperSignal West Pico, Thermo Scientific, Rockford, IL) according to the manufacturer's instructions. The protein bands were visualised by GeneSnap with GeneGnome (Syngene, Cambridge, UK). The results were analysed using the GeneTools (Syngene, Cambridge, UK) programme.

2.6. Statistical analysis

The results are shown as means ± SEM. Statistical significance was measured by one-way ANOVA, followed by Dunnett's multiple comparison test. $p < 0.05$ was defined significant.

3. Results

3.1. The effects of AraC, curcumin and resveratrol on the metabolic activity of SH-SY5Y and CV1-P cells

The effects of AraC, curcumin and resveratrol on the metabolic activity were measured by MTT reduction assay. Both cell lines were treated with various concentrations of compounds, and the metabolic activity of SH-SY5Y cells was determined after 12 h and that of CV1-P cells after 24 h. The reference compound, AraC, decreased the metabolic activity in CV1-P cells significantly at the concentrations of 200 and 400 μM, but it did not have any significant effect on SH-SY5Y cells (Fig. 1a). Curcumin significantly decreased the metabolic activity of SH-SY5Y cells at the concentrations of 25, 50 and 100 μM, but, in CV1-P cells, a significant decline was seen only upon treatment with 200 μM (Fig. 1b). Resveratrol significantly decreased the metabolic activity of CV1-P cells but had no significant effect on SH-SY5Y cells, although there was a slight decrease at 50 and 100 μM concentrations (Fig. 1c).

3.2. The effects of AraC, curcumin and resveratrol on the amounts of p53 in SH-SY5Y and CV1-P cells

The amount of p53 protein was determined from both cell lines by Western blotting after 12 h treatments with AraC, curcumin and resveratrol. AraC significantly increased the amount of p53 at all concentrations (5, 10, 25, 50 and 100 μM) in both cell lines (Fig. 2a). SH-SY5Y cells were more sensitive to AraC than were CV1-P cells, and the maximal increase of the amount of p53 was 250–300% in SH-SY5Y and 175–200% in CV1-P cells compared to the controls. Curcumin significantly increased the amount of p53 in SH-SY5Y but not in CV1-P cells (Fig. 2b). The maximal increase of the amount of p53 in SH-SY5Y cells exposed to 50 μM curcumin was 250% compared to the control cells. Resveratrol increased the amount of p53 in both cell lines, and CV1-P cells were slightly more sensitive to the effects of it than were SH-SY5Y cells. Resveratrol, at 100 μM, increased the amounts of p53, by 160% in SH-SY5Y and 200% in CV1-P cells. Other concentrations of resveratrol had no effects on the amount of p53 in cells.

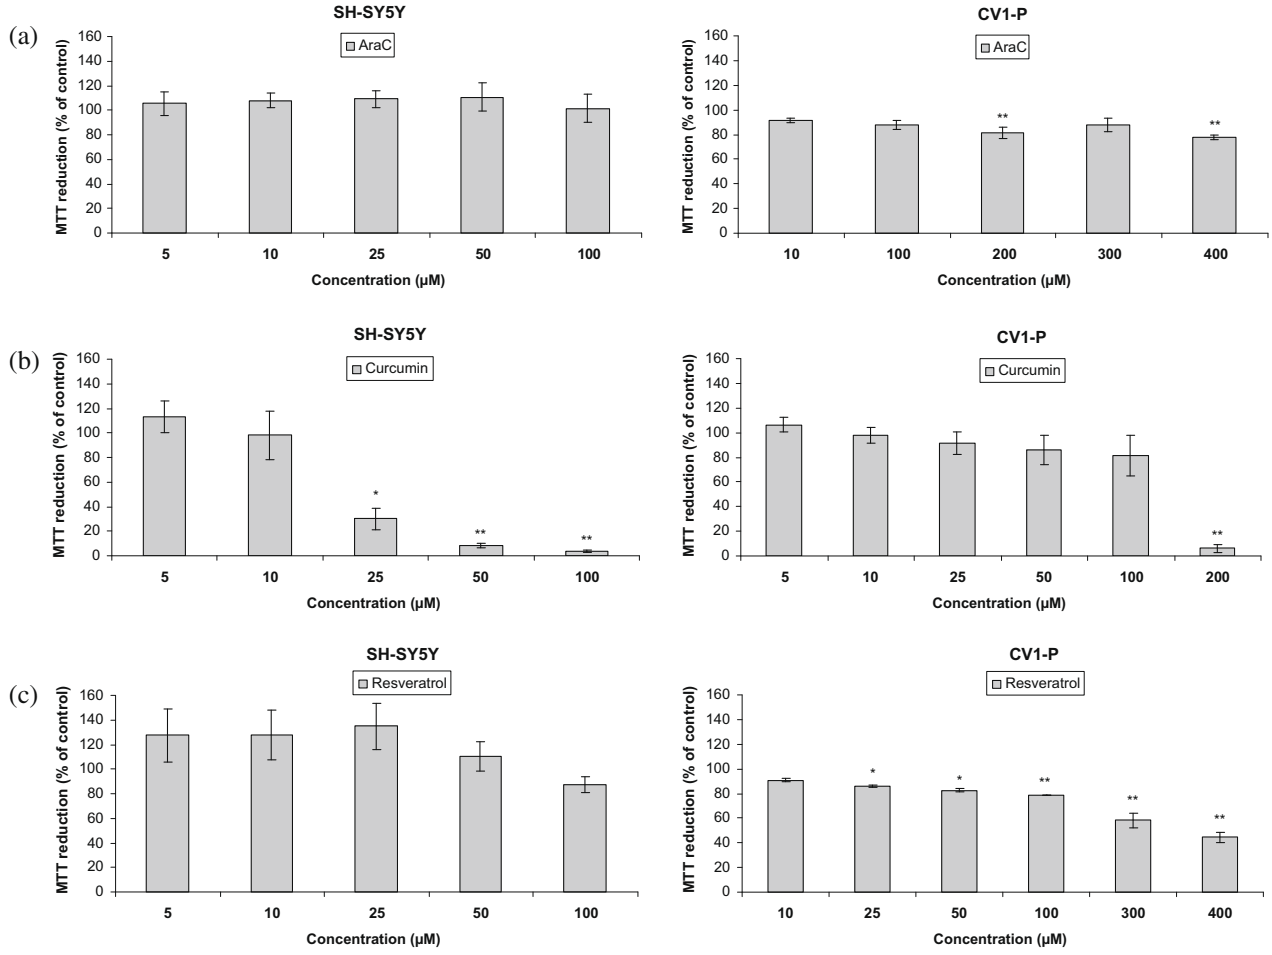

Fig. 1. Viability of SH-SY5Y and CV1-P cells after AraC (a), curcumin (b) and resveratrol (c) treatments, as measured by MTT reduction assay. The cells were exposed to the compounds for 12 h (SH-SY5Y) or 24 h (CV1-P) as indicated. The absorbance of MTT reduction was measured at the wavelength 550 nm and the background at 655 nm was subtracted. The values are expressed as means ± SEM from two independent experiments where the number of replications was 2x3 for SH-SY5Y and 2x6 for CV1-P cells. Statistical significance was determined by one-way ANOVA, followed by Dunnett's multiple comparison test; $^{*}p < 0.05$ and $^{**}p < 0.01$.

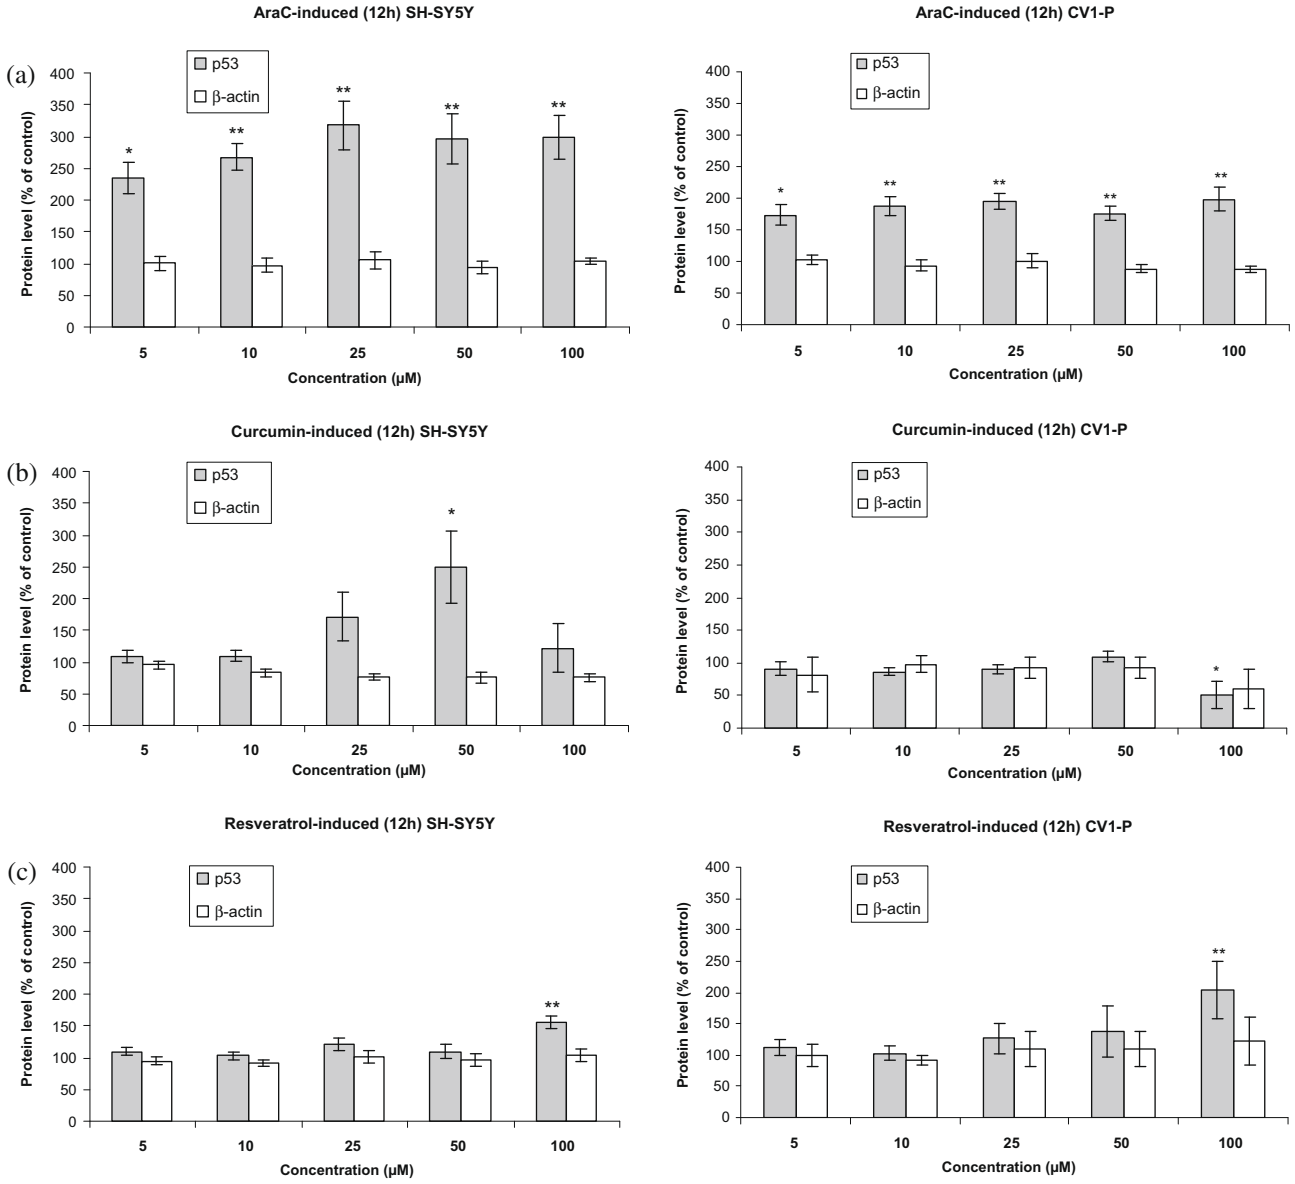

Fig. 2. Effects of AraC (a), curcumin (b) and resveratrol (c) on the amount of protein p53 in SH-SY5Y and CV1-P cells. The cells were treated for 12 h, and the levels of p53 and β-actin were examined by Western blot analysis. The values are means ± SEM from five independent experiments made in duplicate. Statistical significance was determined by one-way ANOVA, followed by Dunnett's multiple comparison test; $^{*}p < 0.05$ and $^{**}p < 0.01$.

3.3. The effects of plant extracts on the metabolic activity and membrane integrity in SH-SY5Y cells

Extracts from basil, juniper and laurel significantly decreased the metabolic activity of SH-SY5Y cells after 12 h of treatment (Fig. 3a). This effect was seen at all concentrations (0.01, 0.05, 0.1, 0.5 and 2.0 mg/ml) of juniper and laurel, but only at the highest concentration (2.0 mg/ml) of basil. The exposure of the cells to 2.0 mg/ml of basil, juniper and laurel decreased the metabolic activity by more than 50% compared to the control cells. A significant decrease in the integrity of cell membranes was observed after the exposure to 2.0 mg/ml of basil extract (Fig. 3b). However, evident increase of LDH leakage from cells is also observed after exposure to 2.0 mg/ml of juniper and laurel extracts, although the effects are not significant. Parsley extract had no effects on the metabolic activity or membrane integrity of cells. The exposure to 0.5 and 2.0 mg/ml of laurel extract produced a massive cell death which was not observed after treatments with the basil, juniper and parsley extracts.

3.4. The effects of plant extracts on the amounts of p53 in SH-SY5Y cells

The cells were treated with different concentrations of plant extracts for 12 h, as in the cell viability assays, and the amount of p53 was defined by Western blotting. Fig. 4 demonstrates that basil, juniper and laurel plant extracts increased the amount of p53 in SH-SY5Y cells. The exposure to 0.01 mg/ml juniper extract caused a significant rise of the amount of p53, although this effect was not observed at higher concentrations (Fig. 4b). The exposure of cells to the basil extract of 2.0 mg/ml significantly increased the amount of p53 in the cells (Fig. 4a). The laurel extract, at a concentration of 0.5 mg/ml, increased the amount of p53 up to 500% compared to the control cells in a single experiment, but there was also a considerable number of dead cells in this treatment (Fig. 4c). The laurel extract of 2.0 mg/ml caused remarkable cell death and therefore the amount of p53 was not possible to define. The parsley extract had no effect on the amount of p53 in SH-SY5Y cells (Fig. 4d).

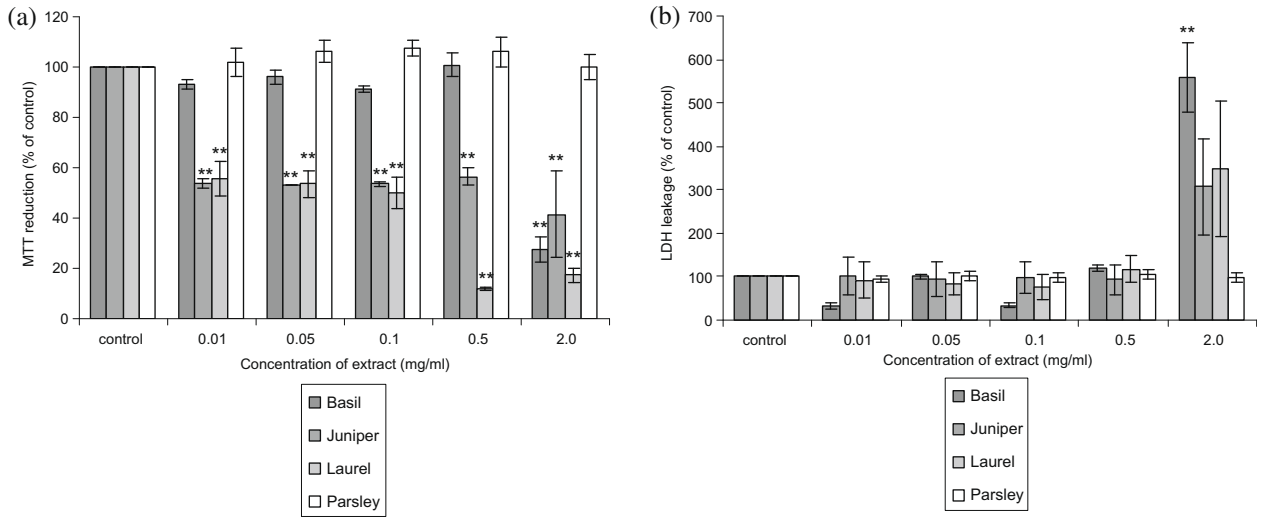

Fig. 3. The viability of SH-SY5Y cells after 12 h treatment with plant extracts from basil, juniper, laurel and parsley. The absorbance of MTT reduction was measured at 550 nm and the background at 655 nm was subtracted (a) and the leakage of LDH was determined using fluorescence with an excitation wavelength of 560 nm and an emission wavelength of 590 nm (b). The values of cell viability assays are means ± SEM of three or four independent experiments made with six replicates. Statistical significance was determined by one-way ANOVA, followed by Dunnett's multiple comparison test; $^{**}p < 0.01$.

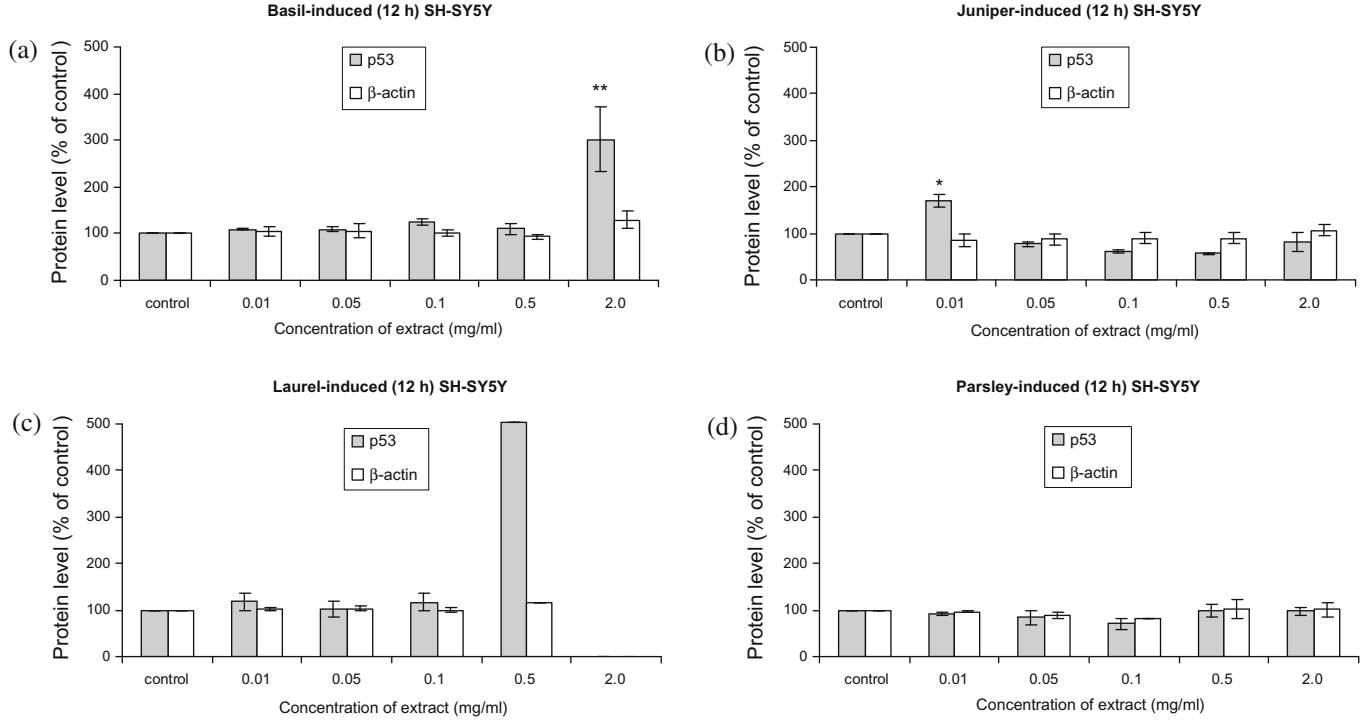

Fig. 4. The effects of basil (a), juniper (b), laurel (c) and parsley (d) extracts on the amounts of p53 protein in SH-SY5Y cells. The cells were treated for 12 h, and the amounts of proteins p53 and β-actin were examined by Western blot analysis. The values are means ± SEM from 2 to 3 independent experiments done in duplicate. Statistical significance was determined by one-way ANOVA, followed by Dunnett's multiple comparison test; $^{*}p < 0.05$ and $^{**}p < 0.01$.

3.5. The effects of juniper extract on the metabolic activity, membrane integrity and amount of p53 in SH-SY5Y cells

The effects of the juniper extract in SH-SY5Y cells were further defined with additional experiments. The cell viability decreased according to the MTT and LDH assays after the 12 h incubation, with concentrations between 1–30 μg/ml. The metabolic activity of cells decreased significantly at all concentrations (Fig. 5a), but the membrane integrity decreased significantly only after the exposure to the extract at concentrations between 20 and 30 μg/ml (Fig. 5b). Concentrations of 10, 12.5 and 15 μg/ml increased the amounts of p53 significantly (Fig. 5c), and the maximal increase of the amount of p53 (200% compared to the control cells) was observed after exposure to 12.5 μg/ml of juniper extract.

4. Discussion

There is growing evidence of the health-promoting effects of plant secondary metabolites, e.g. phenolic compounds. The beneficial connection between cancer and a diet rich in fruits and

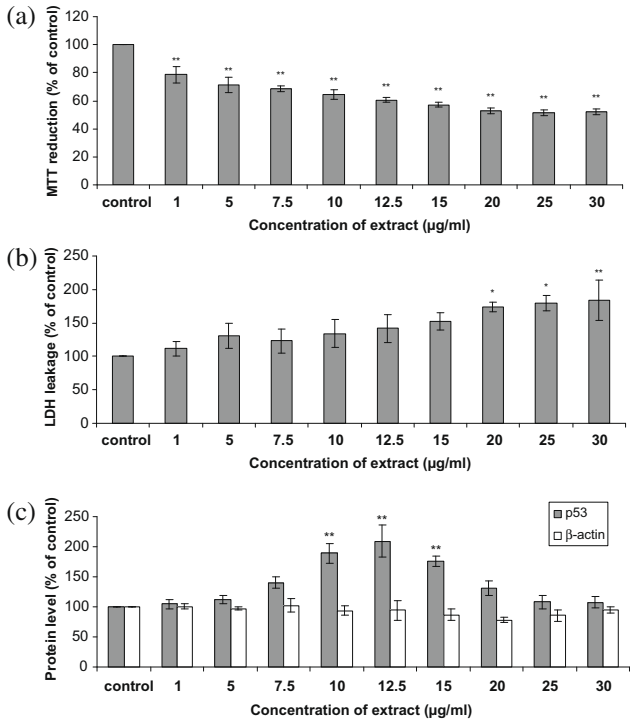

Fig. 5. The effects of juniper extract on the cell viability and the amount of p53 in SH-SY5Y cells. Cells were treated for 12 h, and the cell viability was determined by the MTT reduction in cells (a) and by the LDH leakage from cells (b). The amounts of proteins p53 and β-actin were examined by Western blot analysis (c). The values for the viability assays are means ± SEM from 4 to 5 independent experiments done with four replicates and for the Western blot from four independent experiments done in duplicate. Statistical significance was determined by one-way ANOVA, followed by Dunnett's multiple comparison test; $^{*}p < 0.05$ and $^{**}p < 0.01$.

vegetables is without dispute (Pan et al., 2008). In the present study, the roles of two phenolic compounds, namely curcumin and resveratrol, and four plant extracts from common spices, namely basil, juniper, laurel and parsley, were studied for their possible cytotoxic effects *in vitro*. Furthermore, their effects were also compared to those of AraC, a well known apoptotic compound. In earlier studies, AraC induced the apoptosis in SH-SY5Y cells and reduced the cell viability of SH-SY5Y and CV1-P cells (Maňáková et al., 2003; Puttonen, Lehtonen, Lampela, Männistö, & Raasmaja, 2008). The effects of AraC in this study are in agreement with those previous observations. Curcumin and resveratrol were chosen in our study as pure phenolic reference compounds for their proven effects on the apoptotic signalling and cell viability in several cell cultures and clinical trials (Francy-Guilford & Pezzuto, 2008). SH-SY5Y cells were used, in particular, because, in earlier studies, they have proved a good model to study cell death and have shown a high sensitivity to different toxins (Maňáková et al., 2003; Puttonen et al., 2008).

Curcumin and resveratrol decreased cell viability, measured by the metabolic activity of cells, more than did the reference compound AraC, and this decrease was markedly larger for curcumin than for resveratrol. Also, the toxic effect of curcumin was observed at lower concentrations, whilst that of resveratrol appeared only at higher ones. The sensitivity of cells to curcumin may also have some cell type-specificity since it was higher for SH-SY5Y than for CV1-P cells, whereas no clear difference was seen with resveratrol. Despite the less cytotoxic character of AraC, it was more potent at increasing the amount of p53 in both cell lines than were curcumin and resveratrol. Resveratrol caused a slight increase of the amount of p53 in both cell lines whilst the effect of curcumin occurred only in SH-SY5Y neuroblastoma cells and not in CV1-P fibroblast cells. In the literature, there are reports claiming the increased sensitivity of cancer cells compared to normal cells to the effects of natural phenolic compounds (Ahmad, Feyes, Nieminen, Agarwal, & Mukhtar, 1997; Widodo et al., 2007). Our results with curcumin support these reports. There is also evidence that the cancer cells prefer to take up curcumin more than do normal cells (Kunwar et al., 2008). That might explain the differences in toxicity to curcumin between used cell lines.

Plant extracts from basil, juniper, laurel and parsley have a long history in use as spices and herbal products, but the mechanisms of their possible actions on health are not fully understood. The extracts used in the present study were prepared using aqueous solvent and essential oils were removed by hydrodistillation (Hinneburg et al., 2006). The preparation process enables the elimination of organic solvents from cell experiments, and mimics the traditional and nutritional use of herbs mainly based on aqueous solvents. When the total phenols and antioxidant activity of extracts were defined by Hinneburg et al. (2006), the highest phenol contents were specified in the basil and laurel extracts. The juniper and parsley extracts contained from 12.5% to 32% of the amounts measured in extracts from basil and laurel. However, the juniper extract seemed to be the most efficient in increasing the amount of p53 amongst the tested plant extracts, and it also showed significant cytotoxic effects in SH-SY5Y cells. The concentrations of 10, 12.5 and 15 μg/ml significantly raised the amount of p53 in cells, and the cell viability decreased at all the concentrations. However, the reference compound AraC was more effective at increasing the amount of p53 compared to the control cells, raising it by 300% at the concentration of 50 μM whilst the juniper extract increased the amount of p53 by 200% at comparable concentrations (10, 12.5 and 15 μg/ml). The juniper extract has also shown cytotoxic effects in different cancer cell lines in a literature report (Bayazit, 2004).

The laurel extract decreased the cell viability at all concentrations whilst the basil extract had a significant effect on the cell viability and amount of p53 at the concentration of 2.0 mg/ml in SH-SY5Y cells. The amount of p53 was dramatically increased (500%) after the treatment with 0.5 mg/ml of laurel extract. Furthermore, massive cell death after treatments at concentrations of 0.5 and 2.0 mg/ml of the laurel extract, indicate that an unregulated form of cell death occurred. Also, in the study of Kaileh, Berghe, Boone, Essawi, and Haegeman (2007), a laurel extract had cytotoxic effects against fibrosarcoma cells but not against breast cancer cells.

In summary, the plant extracts from basil, juniper and laurel had an influence on the membrane integrity, metabolic activity and amount of p53 in SH-SY5Y cells. The juniper berry extract had effects at the lowest concentrations amongst other extracts studied found to be the most potent of our extracts. Our results do not clarify whether the effects are associated with apoptotic or necrotic cell death, and more profound experiments are needed to define the results. However, our results, and a long history of use of plants as herbal products, indicate that the plant extracts may be useful as health-promoting food constituents and for drug development. Since the juniper extract potently decreased the cell viability and increased the amount of p53, further studies are in progress to investigate the role of the juniper extract in the cell death.

ABSTRACT

The dependence of the extent of aqueous extraction of antioxidant compounds on particle size and contact time was studied for three important medicinal plants, that are commonly used in infusions: agrimony, sage and savoury. The effect of extraction time was dependent on the plant considered; however, ca. 5 min can be taken as the minimum period required to assure an acceptable degree of extraction of those compounds. As expected, a smaller particle size led to a higher extraction extents; a typical value of 0.2 mm is accordingly recommended. Chlorogenic acid was the dominant phenolic compound extracted from agrimony, whereas caffeic acid dominated in the case of sage or savoury. A mathematical model based on Fick's law was developed from first principles, and its two parameters were suitably fitted to the experimental data generated – in attempts to predict the evolution of antioxidant capacity extracted during contact time, for each plant and each particle size.

1. Introduction

Agrimony, sage and savoury (common English names for *Agrimonia eupatoria*, *Salvia* sp. and *Satureja montana*, respectively) are plants often used in traditional medicine in Portugal, and which grow in the poor soils of the Mediterranean basin. The former has been claimed to control uric acid, favour the respiratory system, function as an analgesic or a diuretic aid, treat wounds and provide a rich source of antioxidants (Venskutonis, Škėmaitė, & Ragažinskienė, 2007). Besides application as condiment, sage has been used as an anti-diarrhoea vector, and to help in digestion, contribute to heal wounds, play an anti-inflammatory role, fight insomnia and decrease blood pressure; some of these biological activities have been associated with its contents of rosmarinic acid (Petersen & Simmonds, 2003) and L-salvianolic acid (Lu & Foo, 2001), which are two antioxidant compounds. Finally, savoury is also used as condiment, and has been prescribed to combat diarrhoea, help digestion and heal wounds, as well as a disinfectant (Gião et al., 2007). Agrimony exhibits the highest antioxidant capacity and total phenolic content within the aforementioned three plants (Gião et al., 2007, 2008) – probably because of its rich contents of coumarins, flavonoids, tannins and terpenoids (Copland et al., 2003); savoury and sage come second (in this order) in those features.

Upstream of food (or beverage) production or formulation effective, harvesting antioxidants as nutraceuticals from the aforementioned plants depends on maximisation of their extraction. However, it is widely known that the efficiency of solid/liquid extraction processes is affected by critical processing parameters, such as temperature, nature of solvent, structure of solid matrix (mainly particle size) and extraction time (Franco, Pinelo, Sineiro, & Núñez, 2007). This means that each plant matrix/extraction solvent pair behaves in a unique way, so it should be studied as such. On the other hand, both the particle size of the plant matrix and the temperature of the extraction process are easily manipulated physical conditions. In general, a smaller size and a higher temperature facilitate mass transfer (Cacace & Mazza, 2003; Waterman & Sutton, 2003), but quantification of such heuristic rules for each plant source is required before optimisation efforts can be rationally developed.

The major goal of this research study was to model the influences of particle size and time of exposure on the efficiency of aqueous extraction of antioxidant power from solid dried material from given plants. A second goal was to characterise the chemical profiles of extracts in terms of phenolic compounds (which have been often associated with comparatively high antioxidant power).

2. Materials and methods

2.1. Sample preparation

Three plants were considered: agrimony, sage and savoury, all of which were a kind gift from ERVITAL (Castro Daire, Portugal). These plants had been cultivated as organic products, and were supplied in their commercial form of dried leaves: ca. 4 g was then

crushed (using a coffee mill) for 1 min, so as to obtain the corresponding powder. This powder was consecutively passed through bolters of 0.2, 0.25 and 0.3 mm mesh sizes (Haver and Boecker, Oeld, Germany), and the four different fractions thus collected were duly weighed.

Each fraction (ca. 1 g) was finally contacted, under uniform stirring, with 110 ml of boiling distilled water – so as to mimick ready-to-drink infusion preparations; samples were collected every minute up to 10 min, and an extra two samples by 12 and 15 min. All those samples were kept in ice, so as to quench the extraction process prior to analysis. Samples were assayed for their total antioxidant capacity, as described below. All experiments were run in duplicate.

For chromatographic analyses, samples were taken of aqueous infusions after 5 min, and were filtered through a 0.45 μm filter before injection.

2.2. Antioxidant capacity assessment

Determination of the antioxidant capacity was as detailed previously by Gião et al. (2007). The $ABTS^{\bullet+}$ stock solution was prepared via addition, at 1:1 (v/v), of 7 mM ABTS (2,2-azinobis (3-ethylbenzothiazoline-6-sulphonic) acid) diammonium salt (Sigma–Aldrich, St. Louis, MO, USA) to a solution of 2.45 mM potassium persulphate (Merck, Damstadt, Germany); the developing reaction took place in the dark, for 16 h. In order to obtain an absorbance of 0.700 ± 0.020 at 734 nm, measured with an UV 1203 spectrophotometer (Shimadzu, Tokyo, Japan), the aforementioned stock solution was diluted in as much ultra-pure water as necessary. A 10 μl-aliquot of the sample was assayed for inhibition percentage (between 20% and 80%, so as to guarantee a linear response of the analytical method), after 6 min of reaction with 1 ml of diluted $ABTS^{\bullet+}$ solution; triplicates of each sample were averaged to generate each datum point (which implies a total of six replicates per plant). The final result was expressed as equivalent concentration of ascorbic acid (in $g\,l^{-1}$), using a calibration curve previously prepared with such a reference compound.

2.3. Phenolic compound profiling

The chromatographic system consisted of a Prostar 210 LC pump (Varian, Walnut Creek, CA, USA), coupled with a 1200 triple quadrupole mass spectrometer (Varian) with electrospray ionisation (ESI) in both positive and negative modes. A 5 μm C_{18} column (4.6 mm × 100 mm, Merck) was used for separation, at a flow rate of eluant of 0.4 ml min^{-1}. The LC–MS/MS method was based on that followed by Politi, Rodrigues, Gião, Pintado, and Castro (2008). Chromatographic separation was performed within 33 min, using the following gradient pattern of eluant A (water with 0.1% (v/v) formic acid) and eluant B (methanol with 0.1% (v/v) formic acid): from 0 min with 90% A, to 12.05 min with 78% A, to 22.05 min with 50% A, to 27.05 min with 95% A, and to 30 min with 95% A. ESI–MS/MS detection used a capillary voltage of 55 V; for MS/MS fragmentation, Ar was used (under 1.20 mtorr, with a collision energy of 15 V). An in-house LC–MS/MS library was created in advance, by injecting 33 chromatographic standards of phenolic compounds, under similar analytical conditions. Identification of the phenolic compounds in the samples was by direct injection and comparison with the spectra of the in-house library; for simplicity, the results of quantification were presented as percent abundance.

2.4. Data treatment

Starting from mechanistic modelling based on Fick's law (Çengel, 2007), the balance of the antioxidant concentration throughout contact time is expected to be given by

$$V_L \frac{dC_{AL}}{dt} = kA_S(C^*_{AS} - C_{AL}) \qquad (1)$$
$$t = 0, \quad C_{AL} = C_{AL,0}$$

where V_L is the volume of the liquid phase, C_{AL} is the concentration of antioxidants in the liquid phase, t is the contact time, k is the mass transfer coefficient based on the liquid phase, A_S is the area of the solid phase, C^*_{AS} is the solubility of antioxidants in the liquid phase, and $C_{AL,0}$ is the initial value of C_{AL}. Defining a as the specific area of the powder, calculated as

$$a = \frac{A_S}{V_S} = \frac{6}{d} \qquad (2)$$

where d is the average particle diameter, and defining R as the volume ratio of the solid to the liquid phases, namely

$$R = \frac{V_S}{V_L} \qquad (3)$$

then Eq. (1) can be rewritten as

$$\frac{dC_{AL}}{dt} = kaR(C^*_{AS} - C_{AL}) \qquad (4)$$

Assuming that there is an excess of solute in the solid phase, then C^*_{AS} can be taken as essentially constant; consequently, integration of Eq. (4) from the initial condition set forth in Eq. (1) leads finally to

$$C_{AL}(t) = C^*_{AS}(1 - e^{-kaRt}) \qquad (5)$$

where (kaR) and C^*_{AS} accordingly become the only two adjustable parameters.

2.5. Statistical analyses

Non-parametric tests were applied to each set of experimental data, owing to their intrinsic heteroschedasticity. Friedman and Wilcoxon tests were thus chosen to check whether time influenced the observed results. Kruskal–Wallis tests were applied to check whether, at each time, plant source and particle size influenced the results produced. Mann–Whitney tests were, in turn, applied to unfold possible differences between plant source and particle size pairs. Principal component analysis for categorical data (PCA) was used to ascertain differences between fractional mass distributions. Finally, Tukey's tests were considered to quantify dif-

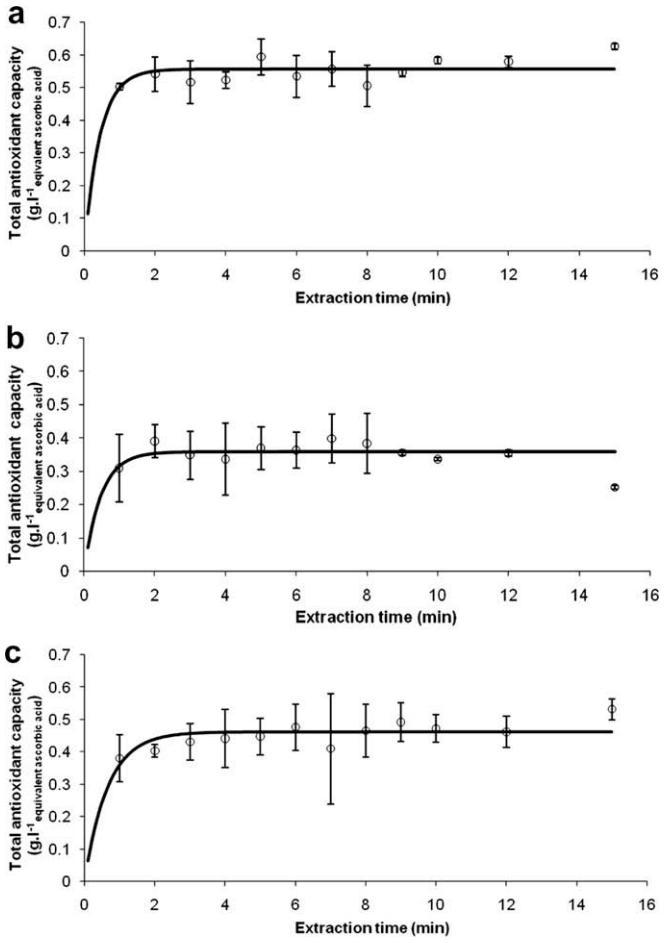

Fig. 1. Total antioxidant capacity, experimentally obtained (○, mean ± standard error) and theoretically predicted (—), of (a) agrimony, (b) sage and (c) savoury, as a function of extraction time, for particle sizes between 0.2 and 0.25 mm.

ferences between plants. All tests were used at a significance level of 0.05. The predictive model denoted as Eq. (5) was fitted by non-linear regression analysis to experimental data points, using the Levenberg–Marquardt estimation method. All statistical tests were performed using SPSS, v. 16.0.0 (Chicago, IL, USA).

3. Results and discussion

The total antioxidant capacities of the infusions obtained from the three plants, for various contact times and at particle sizes between 0.2 and 0.25 mm (for the sake of illustration), are depicted in Fig. 1. As expected (Waterman & Sutton, 2003), the antioxidant power increased with increasing extraction time and decreasing particle size; this means that an increase in the time and in the surface area available for molecular transport contribute to a more extensive mass transfer of solutes between phases – according to the general principles underlying Fick's law.

Non-linear regression analysis was sequentially applied to fit Eq. (5) to the data pertaining to each plant and to each particle size range; typical curves are depicted also in Fig. 1, whereas estimates of the associated model parameters (coupled with relevant statistical information) are comprehensively tabulated in Table 1.

The correlation coefficient between parameters C^*_{AS} and kaR was low, so the parameter estimates were relatively independent of each other – and thus no further uncoupling was required for efficient estimation. Inspection of Table 1, reveals that the range of equilibrium antioxidant power in the liquid phase is 0.3–0.7 g l^{-1} of equivalent ascorbic acid min^{-1}, whereas the characteristic time scale for mass transfer ranges from 0.14 to 0.33 min; extraction was accordingly efficient and fast. The maximum rate of extraction, observed when $t = 0$, ranged in turn from 0.3 to 1.6 g l^{-1} of equivalent ascorbic acid min^{-1}, and increased when the particle size decreased; it was also higher for agrimony and savoury than for sage. On the other hand, the likelihood associated with the model initially postulated and later fitted is high – as concluded from visual inspection of the goodness of fit illustrated in Fig. 1.

Following statistical analysis of our data, several conclusions can be drawn. When considering all three plants together, Friedman's test indicated that extraction time influenced total antioxidant capacity. On the other hand, Wilcoxon's test allowed definition of six time groups, the first group including only 1 min, the second only 2 min, the third, 3 and 4 min, the fourth, 5 until 9 min, the fifth, 10 and 12 min, and the sixth only 15 min. The initial minutes are thus particularly important regarding extraction – as extraction rate slows down considerably between 5 and 10 min (Fig. 1). These results are consistent with the choice of 5 min for extraction time, as proposed elsewhere (Gião et al., 2007, 2008).

The total antioxidant capacity extracted in the first 2 min, for each of the three plants studied, can be seen in Fig. 2 for the various particle size ranges. For particle sizes below 0.2 mm, agrimony showed significantly higher total antioxidant capacity; this difference decreased in magnitude with increasing particle size, and essentially vanished for particles larger than 0.3 mm. A strong decrease (ca. 0.1 g l^{-1} of equivalent ascorbic acid) of the total antioxidant capacity can also be observed as the particle size increases (see Fig. 2a–d). Upon calculation of average values among the different particle size ranges, a value similar to that obtained in previous studies (Gião et al., 2007) could be obtained.

In terms of particle size, Kruskal–Wallis' test unfolded differences at all extraction times. In an attempt to discriminate which sizes led to better performance at each extraction time, Mann–Whitney's test was applied; no influence of particle size was ob-

Table 1
Parameter values (estimate ± standard deviation) entertained by the mathematical model labelled as Eq. (5), for each plant and granulometry.

Plant	Granulometry (diameter: x)	C^*_{AS} (g l^{-1} equivalent ascorbic acid)	kaR (min^{-1})	Initial rate, $C^*_{AS} \cdot kaR$ (g l^{-1} equivalent ascorbic acid min^{-1})
Agrimony	$x < 0.2$ mm	0.694 ± 0.007	2.27 ± 0.31	1.58
	0.2 < x < 0.25 mm	0.557 ± 0.007	2.27 ± 0.38	1.26

	$x > 0.3$ mm	0.301 ± 0.014	0.99 ± 0.30	0.30

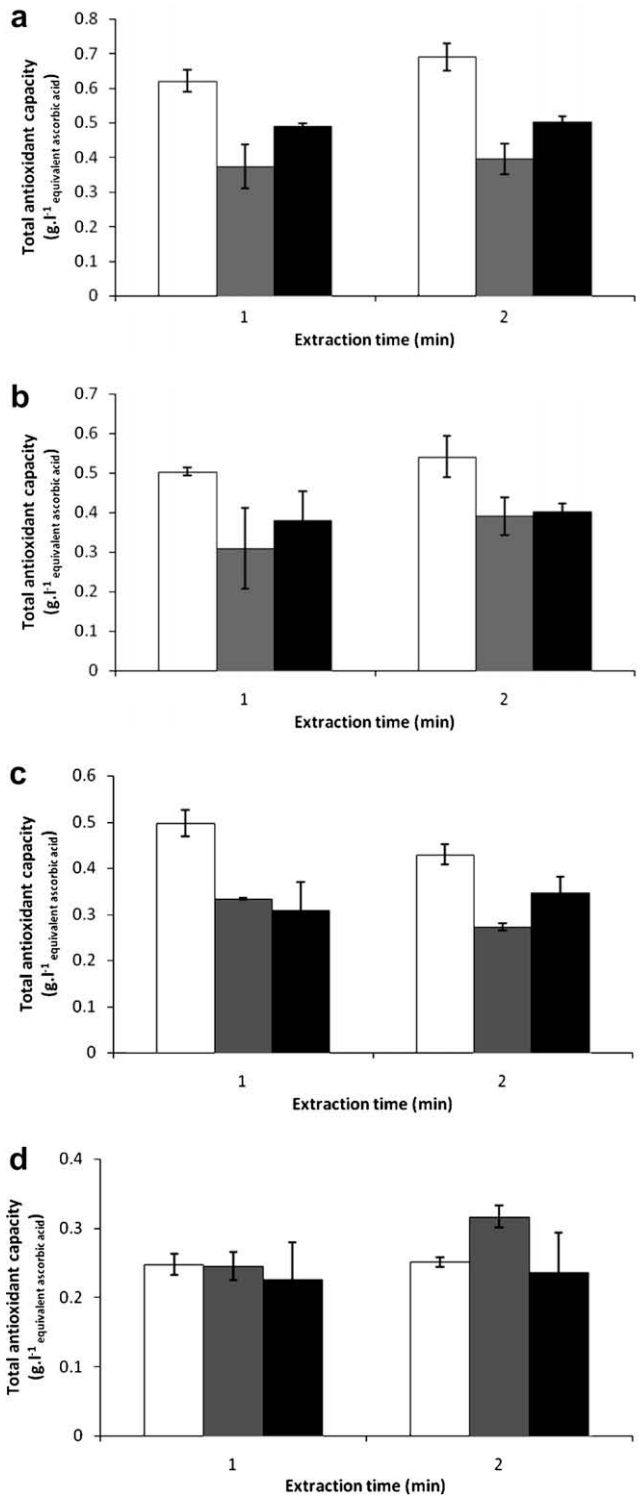

Fig. 2. Total antioxidant capacity, experimentally obtained by 1 and 2 min of extraction, of (□) agrimony, (▩) sage and (■) savoury, for particle sizes (a) below 0.2 mm, (b) between 0.2 and 0.25 mm, (c) between 0.25 and 0.3 mm, and (d) above 0.3 mm.

served only at 2 min (and this justifies the choice below of 2 min-extracted samples, for phenolic compound profiling). For 1 and 4 min, three different groups could in addition be pinpointed; one related to sizes below 0.2 mm, a second was associated with intermediate sizes (between 0.2 and 0.3 mm), and a third encompassed sizes above 0.3 mm; for 3 min, and from 5 to 15 min, only sizes above 0.3 mm appeared to be statistically different from the others.

Note: –, not detected.

Setting a given extraction time, a clear trend of particle size as a function of fractional mass distribution is apparent. PCA was accordingly applied, and indicated that a total variance of 79.9% was associated with the three major groups: one accounted for particles below 0.2 mm in diameter, a second was characterised by particles between 0.2 and 0.3 mm, and another included particles above 0.3 mm. These three groups could be pinpointed for all three plants – and a similar performance was associated with each plant, concerning the mass distribution.

When plants were considered separately, Kruskal–Wallis' test indicated differences arising throughout extraction time: agrimony appeared as different from either sage or savoury at all times, whereas the latter two were similar throughout extraction time. Meanwhile, Friedman's test unfolded significant differences between extraction times; this is why Wilcoxon's test was applied, so as to understand which times accounted for that difference for each plant separately. In the case of agrimony, the effect of extraction time allowed identification of three major groups: a first one associated with 1 and 2 min, a second with 3 to 9 min, and a third with 10 to 15 min. For sage, only 1 min stood out, and both 1 and 15 min appeared different in the case of savoury.

The phenolic compositions of the extracts, by 2 min of extraction and irrespective of particle size range, as obtained by LC–MS/MS, are depicted in Table 2. The identification of such compounds was achieved by comparison with chromatographic grade standards, injected previously using the same separation and detection conditions. Our in-house library of phenols contains 33 compounds – 13 of which could be found and identified in the extracts (Table 2); chlorogenic and caffeic acids were the most abundant, in agrimony and sage/savoury, respectively. Note that the majority of phenolic compounds are not highly soluble in water at room temperature, yet they were found in our extracts – because high temperature aqueous extraction was employed. The aforementioned compounds were already found in aqueous extracts of plants such as green tea (Bastos et al., 2007), yerba maté (Bastos et al., 2007) and *Mentha cervina* (Politi et al., 2008).

4. Conclusions

In general, statistically significant differences exist, in terms of total antioxidant capacity, among the three plants at each specific particle size range. Regarding extraction of antioxidants from the powdered plant material via boiling water, an exposure period of

5 min appears sufficient to assure that most antioxidant power is recovered. On the other hand, an indicative particle size of 0.2 mm, which is the smallest obtained via conventional coffee mill grinding, is sufficient to assure acceptable rates of extraction. The extraction phenomenon follows the typical asymptotic exponential behaviour predicted by Fick's law, with initial rates of extraction in the range of 0.3–1.6 g l^{-1} of equivalent ascorbic acid min^{-1}.

The data generated and the model proposed are innovative, and relevant to rational attempts to predict the antioxidant response of plant extracts, and how the degree of division of the plant material affects it.

Flow behaviour
Viscosity
Thixotropy
Viscoelastic

ABSTRACT

Rheological properties such as flow behaviour, viscosity, viscoelasticity, and thixotropy of solutions of β-glucan purified from barley fibre concentrate and twelve commonly used food gums, alone and in combinations, were characterised using an oscillatory rheometer. Pure gums and gum combinations were evaluated at 0.5% and 0.75% (w/w) total gum concentration in aqueous medium, whereas the β-glucan/gum ratios were kept at 90/10 or 80/20 (w/w). Viscosity synergism was observed for β-glucan solutions in combination with xanthan, *iota*-carageenan, and carboxymethyl cellulose. However, barley β-glucan blends with *lambda*-carageenan, Konjac, high- and low-methoxyl pectin, microcrystalline cellulose, alginate, and gum arabic showed marked lowering of the viscosity compared to β-glucan alone. In addition, β-glucan/xanthan gum blends demonstrated improved shear tolerance compared to xanthan dispersions alone, and soft gel transformation. Non-thixotropic behaviour was observed for 0.5 and 0.75% (w/w) β-glucan dispersions and its gum combinations. None of the gum combinations studied demonstrated thixotropy.

1. Introduction

β-Glucan, a soluble dietary fibre component present in the cell walls of barley and oat endosperm, possesses physiological functionalities, which confer a number of health benefits, including the reduction of heart disease risk as indicated in the health claims approved by the Food and Drug Administration of USA for oats (FDA, 1997) and barley (FDA, 2005). In spite of this, barley remains an underutilised crop. Only 5% of barley produced in Canada is currently being utilised for human consumption. There is potential to incorporate β-glucan into beverages and other food products thereby classifying β-glucan as an important functional food ingredient.

Due to functionality and cost considerations, blends of food gums are often used in food formulations (Le Gloahec, 1951; Nnanna & Dawkins, 1996; Schorsch, Garnier, & Doublier, 1997; Tako, Qi, Yoza, & Toyama, 1998; Casas, Mohedano, & Garcia-Ochoa, 2000; Hernandez, Dolz, Dolz, Delegido, & Pellicer, 2001). An important parameter that dictates the acceptability of gum blends in food and beverages is the stability of the blends throughout the product shelf life.

Studies directed towards understanding how barley β-glucan interacts with other food gums and its applications in common foods and beverages are limited. Factors such as the concentration and the type of gum (positively or negatively charged) may have a profound effect on the physicochemical properties of β-glucan in aqueous media (Bansema, 2000). Interactions between gums modify the rheological properties of gum mixtures and are important for new product development as well as improving the quality of the existing food products. For instance, the addition of *kappa*-carageenan to locust bean gum produces highly stable thermoreversible gels with important synergistic effects (Tako, Qi, Yoza, & Toyama, 1998). A mixture of gum arabic and carrageenan as an ice cream stabiliser has been patented (Le Gloahec, 1951) since it functions to retard both ice crystal formation and growth. The synergistic effect on viscosity due to blending two polysaccharides is the most studied interaction. It has much significance to the industry and it is quite an inexpensive method of manipulating rheology and texture of food products. Hence, establishing the fundamental rheological properties of gum blends and understanding the interactions of barley β-glucan with other food gums are of great importance.

This study was designed to provide insight into physical and functional properties of β-glucan in aqueous systems in combination with other food gums. The main objective of the present study was to investigate the rheological properties of aqueous dispersions of barley β-glucan (BBG) and binary gum blends consisting of BBG and commonly used food gums, namely sodium alginate

(ALG), carageenan (CAR) (*kappa*, *lambda*, and *iota*), carboxymethyl cellulose (CMC), gum arabic (GAR), guar gum (GUA), high-methoxyl pectin (HMP), Konjac gum (KOG), locust bean gum (LBG), low-methoxyl pectin (LMP), microcrystalline cellulose (MCC), and xanthan (XAN). Various rheological evaluations were performed, with a focus on flow behaviour, viscosity, viscoelasticity, and thixotropy of pure gums as well as blended gum systems.

2. Materials and methods

2.1. Materials

A barley β-glucan concentrate (60–65%, w/w, β-glucan) was obtained from Cevena Bioproducts Inc. (Edmonton, AB). XAN was provided by ADM Inc. (Decatur, IL), whereas CMC, GAR, GUA, HMP, LBG, and LMP were from TIC Gums Inc. (Belcamp, MD). ALG, CAR, KOG, and MCC were procured from FMC BioPolymer (Princeton NJ). Sodium carbonate, citric acid, and hydrochloric acid were procured from BDH Inc. (Toronto, ON) and Fisher Scientific Co. (Nepean, ON), respectively. Ethanol and Termamyl 120 LN, a thermostable α-amylase (E.C. 3.2.1.1) of *Bacillus licheniformis*, were procured from Commercial Alcohols Inc. (Brampton, ON) and Novozyme North America Inc. (Toronto, ON), respectively.

2.2. Extraction and purification of BBG from barley β-glucan concentrate

β-Glucan concentrate (50 g) was dissolved in 3.75 L deionized water at pH 10 by mixing the slurry continuously for 30 min at 50 °C. After adjusting the slurry pH to 6.5, thermostable α-amylase was stirred in at 90 °C for 1 h. The thermostable α-amylase was inactivated by adjusting the slurry pH to 4 and holding for 10 min. The slurry was then held for 10 min at pH 5.5 at room temperature to precipitate proteins followed by centrifugation at 13,000×*g* for 10 min. The supernatant was neutralised to pH 7 and then β-glucan was recovered by alcohol precipitation (i.e. adding absolute ethanol to the supernatant in order to bring the final ethanol concentration to 50% v/v and storing overnight at 4 °C) and centrifugation. The recovered purified β-glucan was washed once with 250 mL of absolute ethanol and then dried overnight at 40 °C.

2.3. Chemical analyses

Contents of moisture, BBG, starch, protein ($N \times 6.25$), and lipid of dried samples were determined in duplicate according to the methods of McCleary and Glennie-Holmes (1985), Megazyme assay kit (Megazyme International Ireland Ltd., Wicklow, Ireland), Holm, Bjorck, Drews, and Asp (1986), FP-428 Nitrogen Determinator (Leco Corp., St. Joseph, MI), and AACC (1982), respectively.

2.4. Determination of viscosity and thixotropy

Dispersions of BBG alone and its blends with common food gums (e.g. XAN, KOG, MCC, CAR, ALG, HMP, LMP, GUA, LBG, CMC, and GAR) were prepared at a total gum concentration of 0.5% and 0.75% (w/w) in ratios of 80/20 and 90/10 (w/w). For all binary blends, BBG was the major gum ingredient used. All gum dispersions were prepared separately, heated at 90 °C for 1 h and were allowed to cool down to room temperature. The gum blend dispersions were prepared by weighing and mixing at 80/20 and 90/10 (w/w) ratios of gum dispersions that were prepared individually. The samples were then mixed for 20 min at room temperature to ensure uniformity.

Viscosity tests were performed for BBG and binary blend dispersions. Viscosity was determined at consecutive fixed shear rates of 1.29–129 s^{-1} using a Paar Physica UDS 200 rheometer (Glenn, VA). The viscometer was equipped with a Peltier heating system that controlled the sample temperature. All viscosity tests were performed at 20 °C using DG 27 cup and bob geometry with a 7 ± 0.005 g sample. Shear rate was reported in s^{-1} after multiplying rpm by a conversion factor of 1.29 s^{-1} as specified by the manufacturer.

Thixotropy tests were also performed on both BBG and binary blend dispersions using DG 27 cup and bob geometry with a 7 ± 0.005 g sample at 20 °C. These tests were performed at a series of fixed shear rates that were consecutively increased from 1.29 to 3870 s^{-1} and then immediately decreased to the original shear rate of 1.29 s^{-1}. All analyses on gum blends were performed at least in duplicate.

2.5. Determination of viscous synergism index (I_v)

When blended gum dispersion exhibited greater viscosity than the sum of the viscosities of the individual gum dispersions determined separately, the situation was considered as synergism. These interactions were quantified using a "viscous synergism index", I_v, that was defined as:

$$I_v = \frac{\eta_{i+j}}{\eta_i + \eta_j} \quad (1)$$

where i and j represent the two gums forming the mixed system, $i + j$. The aqueous dispersions of the systems i, j, and $i + j$ were prepared at the same total gum concentration, i.e., $c_i = c_j = c_{i+j}$ (Hernandez et al., 2001). According to Eq. (1), I_v always has a positive value. If $0 < I_v < 0.5$, the viscosity of the mixed system will be less than the sum of the viscosities of its two component gums and also less than both of them individually, the situation is described as antagonistic interaction. However, if $I_v = 0.5$ and both gums are of equal viscosity (when considered separately at identical concentrations), so that $\eta_{i+j} = \eta_i = \eta_j$ then the situation is described as no interaction. On the other hand, if $0.5 < I_v < 1$, synergism occurs, provided η_{i+j} is more than η_i and η_j individually. If $I_v > 1$, indicating that the viscosity of the mixed system is greater than the sum of the viscosities of the two individual systems i.e., $\eta_{i+j} > \eta_i + \eta_j$, then synergism has also occurred (Hernandez et al., 2001; Pellicer et al., 2000). For economical and practical reasons, blending of two pure gums together to increase the viscosity is not necessary when the viscosity of one of the pure gums, η_i or η_j, is greater than η_{i+j} at identical gum concentrations (Hernandez et al., 2001).

2.6. Determination of viscoelastic properties of gum blends

All dispersions of individual and blended gums were prepared using a similar procedure to the one described under sample preparation for viscosity and thixotropy determinations. Since the viscoelastic properties are strongly dependent on time and temperature, all systems were allowed to equilibrate for 15 min at ambient temperature. Storage modulus (G') and loss modulus (G'') were obtained at 20 °C using a 7 ± 0.005 g sample placed in a DG 27 cup and bob geometry of a Paar Physica UDS 200 rheometer. The rheometer was set in amplitude sweep controlled shear displacement (CSD) mode with a constant frequency of 1 Hz and controlled strain of 0.25–20% and 0.75–120% for 0.5% and 0.75% total gum concentration, respectively.

3. Statistical analysis

Purification experiments were performed in duplicate. All chemical analyses were performed in duplicate for each β-glucan sample. Rheological measurements were performed for each of

the purified samples in duplicate. Viscosity tests for the gums or gum blends were also performed in duplicate for each of the purified samples. Means were reported for all parameters measured. Regression analysis used to determine the Power Law model parameters.

4. Results and discussion

4.1. Recovery and composition of purified BBG

Recovery is defined as the ratio between the amount of BBG in the purified sample and the amount of BBG present in the barley β-glucan concentrate. The recovery and purity of laboratory purified BBG were 82% and 94.7% (w/w, dry weight), respectively. Moisture, starch, and protein contents were 3.8%, 0.9%, and 1.7% (w/w), respectively. Lipid content was 0% (w/w) in the barley β-glucan concentrate used and hence it was assumed that the purified barley β-glucan contains no lipids.

4.2. Viscosity of gum blends

The viscosity of 0.5% and 0.75% (w/w) pure gums at 20 °C determined over a shear rate range of 1.29–129 s^{-1} is presented in Table 1. GAR, HMP, LMP, and MCC showed low viscosity at both concentrations of 0.5% and 0.75% (w/w). As expected, the viscosity of all gum dispersions increased when the concentration was increased from 0.5 to 0.75% (w/w). The flow curves of individual gums and blends showed shear thinning behaviour, while yield stress was observed only in dispersions containing XAN, CAR, and ALG. The concentration and shear rate effects on rheological properties were dependent upon the type of food gum used. The effect of concentration (0.5% and 0.75%, w/w) on viscosity enhancement was more pronounced in BBG, *iota*-CAR, and *kappa*-CAR dispersions as shown in Table 1. For XAN dispersions, however, the viscosity increased from 368 to 481 mPa s at shear rate of 12.9 s^{-1} upon increasing the gum concentration from 0.5% to 0.75% (w/w). This may be attributed to the near saturation of XAN dispersions at the concentrations tested.

In fluid flow behaviour studies, the Power Law model describes the pseudoplastic behaviour of gums (Marcotte, Hoshahili, & Ramaswamy, 2001). The following equation represents the Power Law model:

$$\tau = c\gamma^n \quad (2)$$

where τ is the shear stress (N/m^2), γ is the shear rate (s^{-1}), c is the consistency coefficient and n is the flow behaviour index or Power Law index. The flow behaviour index and consistency coefficient of 0.5% and 0.75% (w/w) pure gum dispersions are shown in Table 2. At 0.5% (w/w) concentration, ALG, *iota*-CAR, GAR, HMP, and LMP were almost Newtonian. Moreover, at 0.75% (w/w) gum concentration, HMP and LMP continued to behave almost like Newtonian with $n \sim 0.99$, over a shear rate range of 1.29–129 s^{-1}. BBG was highly pseudoplastic with a flow behaviour index of 0.74 and 0.59 at 0.5% and 0.75% (w/w) concentrations, respectively. In comparison to other gums at 0.5% (w/w) concentration, XAN demonstrated high pseudoplasticity with $n = 0.2$, followed by GUA with $n = 0.38$. In terms of the flow behaviour index, BBG at 0.5% (w/w) was comparable to CMC, KOG, and LBG.

Table 1
Viscosity (mPa s) of 0.5% and 0.75% (w/w) pure gum dispersions at shear rates of 1.29–129 s^{-1} and a temperature of 20 °C.

Pure gums systems	Shear rate (1/s)					
	1.29	6.46	12.9	25.8	64.6	129

MCC	0.840	0.011	1.000
XAN	0.210	3.580	0.999

Values are means of duplicate viscosity determinations; ALG = alginate; BBG = barley beta-glucan; CMC = carboxymethyl cellulose; GAR = gum Arabic; GUA = Guar gum; HMP = high-methoxyl pectin; *i*-CAR = *iota*-carageenan; KOG = Konjac; *k*-CAR = *kappa*-carageenan; LMP = low-methoxyl pectin; LBG = locust bean gum; *l*-CAR = *lambda*-carageenan; MCC = microcrystalline cellulose; XAN = xanthan.

Blending of gums resulted in changes in certain rheological properties such as viscosity, compared to the corresponding values for single components. The viscosities of gum blends having total gum concentrations of 0.5% and 0.75% (w/w), determined at shear rates of 1.29–129 s^{-1} at 20 °C, are presented in Table 3.

At total gum concentrations of 0.5% and 0.75% (w/w), dispersions of BBG blended with CMC and XAN showed marked enhancement in viscosity. Additionally, dispersions of BBG blended with *lambda*-CAR at 0.5% total concentration and BBG blended with *iota*-CAR at 0.75% total concentration exhibited viscosity enhancement. At total gum concentrations of both 0.5% and 0.75%, BBG blended with ALG, GAR, HMP, KOG, LMP, and MCC showed marked lowering of viscosity compared to BBG alone. At the 0.75% concentration, BBG blended with *lambda*-CAR also showed marked lowering of the viscosity.

As shown in Table 1, at a shear rate of 64.6 s^{-1}, 0.5% (w/w) BBG and XAN individually exhibited viscosities of 118 and 101 mPa s, respectively, whereas in Table 3 and 0.5% (w/w) BBG/XAN blended in 80/20 and 90/10 (w/w) ratios demonstrated viscosities of 158 and 174 mPa s, respectively. Thus, the BBG/XAN blend was more

Table 3
Viscosity (mPa s) of 0.5% and 0.75% (w/w) BBG/other gum blend dispersions at shear rates of 1.29–129 s^{-1} and a temperature of 20 °C.

n = Flow behaviour index; *c* = consistency coefficient; ALG = alginate; BBG = barley beta-glucan; CMC = carboxymethyl cellulose; GAR = gum Arabic; GUA = Guar gum; HMP = high-methoxyl pectin; *i*-CAR = *iota*-carageenan; KOG = Konjac; *k*-CAR = *kappa*-carageenan; LMP = low methoxyl pectin; LBG = locust bean gum; *l*-CAR = *lambda*-carageenan; MCC = microcrystalline cellulose; XAN = xanthan.

shear tolerant as evident by the higher flow behaviour index value (Table 3) than XAN alone.

The total gum concentration and ratio of gums in a blend affected the rate and the type of interaction (synergistic or antagonistic) as demonstrated by the viscosity measurements. These interactions were quantified using "viscous synergism index", I_v, as defined previously in Eq. (1).

Tables 4 and 5 show the I_v calculated for 0.5% and 0.75% (w/w) BBG/other gum blends, respectively, using the viscosity data determined at a shear rate of 6.46 s^{-1} (to mimic the approximate shear that exists in human mouth) at 20 °C. Synergistic interactions were observed in blends of BBG with CMC or *iota*-CAR under all studied conditions. Synergistic interactions were also observed between BBG and *lambda*-CAR at the 0.5% concentration level, and between BBG and XAN at the 0.75% concentration level, for both 80/20 or 90/10 blend ratios. All other gum blends and showed no interaction or antagonistic interactions.

Synergistic interactions between gums in a blend are governed by hydrogen bonding (Bresolin, Milas, Rinaudo, & Ganter, 1998). Increased intermolecular interactions between hydrocolloid polymers enhances the stability of the molecular entanglements, suppressing phase separation and improving shear tolerance, and the viscosity of the solution.

4.3. Thixotropy of gum blends

Thixotropy can be defined as a decrease in viscosity due to destruction of structure under a constant shear rate or a consecutively increasing shear rate that is fixed for a period of time at selected shear rates followed by the structural network redevelopment when shear is withdrawn (Muller, 1973; Schramn, 1994). The viscosity of non-thixotropic systems does not decrease with time when exposed to constant shear rates. Under consecutively increasing shear rates the viscosity decreases, but regains over time when shear is withdrawn.

In the present study, the thixotropy was examined, using consecutively increasing shear rates in the range of 1.29–3870 s^{-1} for fixed intervals of time and then decreasing it immediately to the original shear rate of 1.29 s^{-1}. Non-thixotropic behaviour was observed for BBG dispersions at 0.5% and 0.75% (w/w) gum concentration. Autio, Myllymaki, and Malkki (1987) also reported a similar behaviour for β-glucan dispersions. Table 6 summarises the thixotropy of pure BBG and gum blend dispersions at 20 °C at the total gum concentrations of 0.5% and 0.75% (w/w). None of the gum blends used in the study demonstrated thixotropy except BBG/MCC. Both 0.5% and 0.75% (w/w) BBG/MCC blends showed inability of viscosity redevelopment at 1.29 s^{-1} after being exposed to high shear (3870 s^{-1}), hence, showing thixotropy. BBG/XAN blended at a ratio of 80/20 (w/w) at 0.5% and 0.75% (w/w) total gum concentrations recovered its original viscosity in 10–15 s. For pure BBG dispersions, the time required for the viscosity to redevelop at 1.29 s^{-1} exceeded 4–6 min. Interestingly, during the thixotropy testing, 80/20 and 90/10 (w/w) BBG/XAN blends demonstrated an unusual increase in viscosity upon immediately decreasing the shear rate from 3870 to 1.29 s^{-1} compared to the original viscosity at the starting shear rate of 1.29 s^{-1}. This shear-induced thickening of the blend dispersion suggested typical "rheopectic" behaviour. Such rheopectic behaviour is possibly

Table 4
Viscous synergism index, I_v, of 0.5% (w/w) BBG/other gum blend dispersions at a shear rate of 6.46 s^{-1} and a temperature of 20 °C.

due to a change in polymer conformation. Changes in XAN conformations in aqueous media have been reported elsewhere, but the changes occurred due to heating (Bresolin et al., 1998; Kovacs & Kang, 1977). In the present study, the shear rate of 3870 s^{-1} employed during thixotropy testing might have resulted in unwinding of the ordered helical conformation of XAN into disordered random coil conformation, a cellulose-like conformation, thus increasing the hydrodynamic volume and hence the increased viscosity.

4.4. Elastic modulus of gum blends

Storage modulus (G') and loss modulus (G'') define the viscoelastic properties of gum solutions (Mandala & Palogou, 2003; Skendi, Biliaderis, Lazaridou, & Izydorczyk, 2003). G' and G'' at controlled strain and constant frequency (1 Hz) were recorded in order to locate the linear viscoelastic region (Dickinson & Merino, 2002; Mandala & Palogou, 2003). A typical curve of G' and G'' values versus strain defining a linear viscoleastic region has been discussed elsewhere (Mandala & Palogou, 2003). Deviations from linearity occur when the gel is strained to a point at which certain weak physical bonds of the aggregated network structure are destroyed. Formation of new bonds will also influence the linear viscoelastic region. In general, gels have much shorter linear regions than cross-linked polymer gels (Dickinson & Merino, 2002).

In the present study, an amplitude sweep was applied where stress and strain were increased linearly at a constant frequency of 1 Hz. Dependence of G' and G'' on frequency was not performed because it was beyond the scope of the present study. Frequency sweep is important to determine the time required for polymer entanglements to form or break within the variable periods of oscillations (Lazaridou, Biliaderis, & Izydorczyk, 2003). A constant frequency of 1 Hz was selected to allow sufficient time for network (polymer entanglements) to form and break because at higher frequencies, the molecular chains cannot disentangle during the short periods of oscillation (Lazaridou et al., 2003).

A gel-like material shows distinct behaviour that is different from liquid or concentrated solution when subjected to amplitude sweep in a rheometer at constant frequency. Freshly prepared BBG dispersions have been reported to behave like a viscoelastic liquid ($G'' > G'$) where the G' and G'' are highly dependent on frequency (Skendi et al., 2003). Formation of an elastic gel-like network ($G' > G''$) depends on the gum concentration as well as the induction time of gelation. Once the gel-like viscoleastic properties are gained, G' and G'' become less dependent on frequency (Lazaridou et al., 2003).

Comparison of G' and G'' for 0.5 and 0.75% (w/w) BBG dispersions was performed at linearly increasing strain of 0.25–20% and 0.75–120%, respectively, at a constant frequency of 1 Hz. For 0.5% (w/w) gum dispersions, the ramp of strain was carefully selected to ensure that the stress used would not exceed 1 Pa. A strain range of 0.25–20% was selected based on observations for preliminary experiments with 0.5% (w/w) gum dispersions and blends at different levels of strain sweep in order to prevent the destruction of physical bonds that contribute to the elastic properties. However, for 0.75% (w/w) gum and blend dispersions, strain sweep of 0.075–120% was selected to ensure the stress used would not exceed 10 Pa. The main reason for selecting a maximum stress of 1 Pa for 0.5% (w/w) and 10 Pa for 0.75% (w/w) gum and gum blend dispersions was to enable the comparison of linear viscoelastic regions of different BBG/other gum blends to that of pure BBG dispersions.

Figs. 1A and 2A show comparison of G' and G'' for 0.5% and 0.75% (w/w) BBG dispersions, respectively, determined at 20 °C. Both 0.5% and 0.75% (w/w) BBG dispersions demonstrated viscoelastic behaviour since $G'' > G'$. This finding is in agreement with other viscoelastic studies of oat and barley β-glucan dispersions at different concentrations (Lazaridou et al., 2003). Fig. 1B–G presents a comparison of G' and G'' for 0.5% BBG/other gum blends. Both gum ratios of 80/20 and 90/10 (w/w) of 0.5% (w/w) BBG/CAR, BBG/CMC,

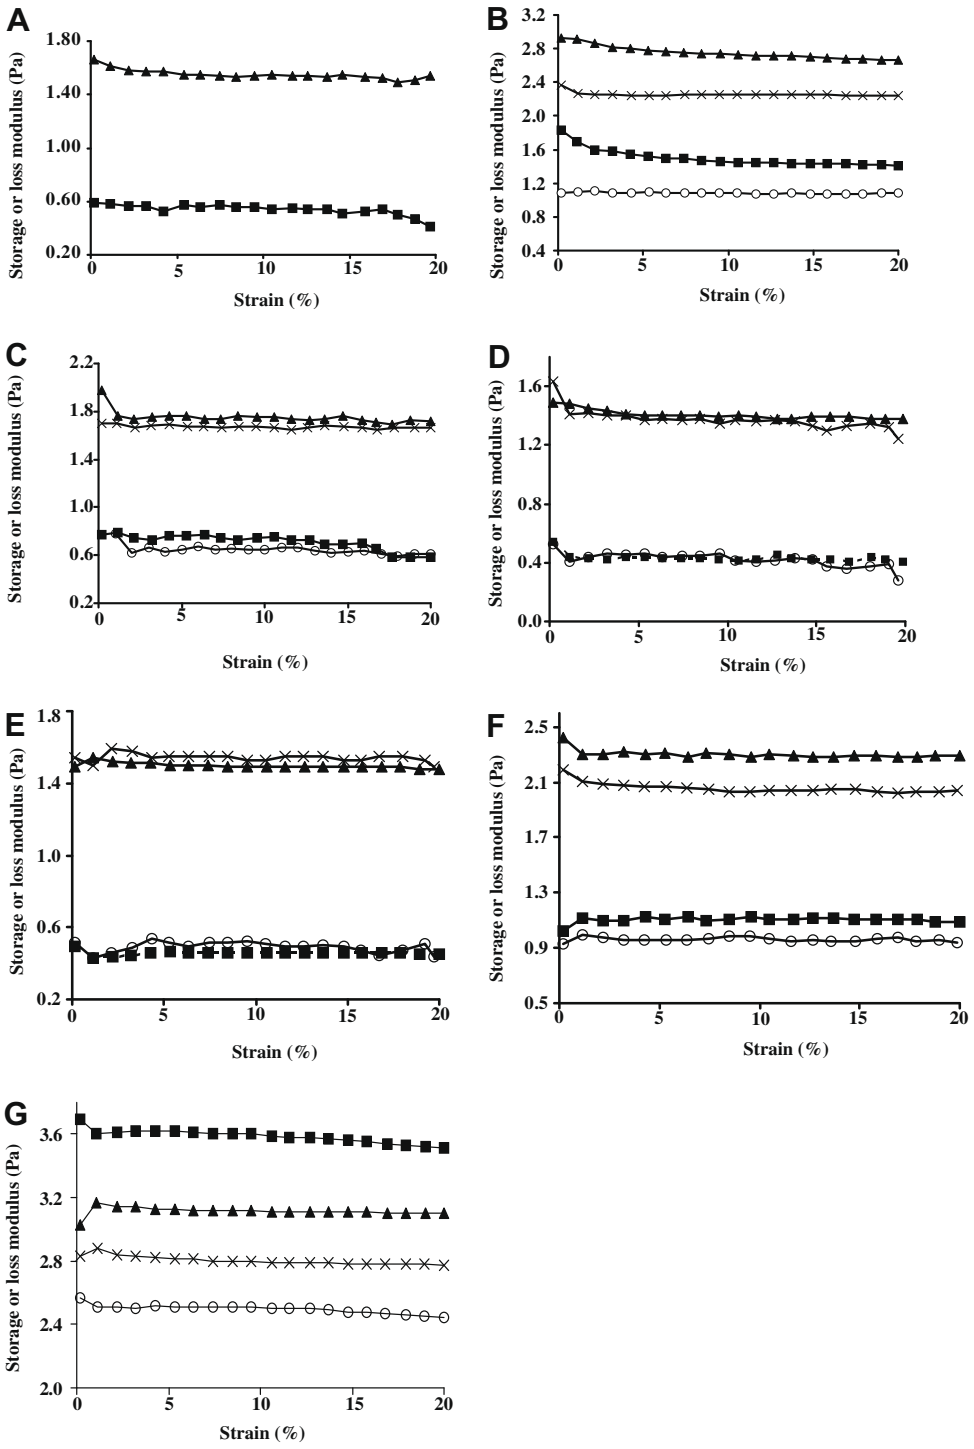

Fig. 1. Storage modulus (G') and loss modulus (G'') of 0.5% BBG alone and its blends (■) G' of 80/20, w/w, (▲) G'' of 80/20, w/w, (○) G' of 90/10, w/w, (×) G'' of 90/10, w/w. (A) 0.5%, w/w BBG alone, (B) BBG/CMC, (C) BBG/GUA, (D) BBG/KOG, (E) BBG/LBG, (F) BBG/*lambda*-CAR, (G) BBG/XAN.

BBG/GUA, BBG/KOG, and BBG/LBG blends exhibited viscoelastic behaviour with $G'' > G'$. However, 0.5% (w/w) BBG/XAN blend mixed at a ratio of 80/20 (w/w) became typical of an elastic gel network with $G' > G''$. Such an elastic gel-like behaviour was not exhibited by 90/10 (w/w) BBG/XAN blends at 0.5% (w/w) total gum concentration. Hence, BBG/XAN in a ratio of 80/20 (w/w) and mixed at 0.5% (w/w) total gum concentration is critical for the development of a gel-like network (Fig. 1G). Elastic network formation may be the reason for faster recovery time observed soon after the network destruction at 3870 s^{-1} during thixotropy testing. G' and G'' values decreased as the proportion of XAN increased from 10% to 20% (w/w) in 0.5% (w/w) BBG/XAN blend. Blends containing BBG and ALG, *iota*-CAR, GAR, HMP, LMP, and MCC having a total gum concentration of 0.5% (w/w), could not be measured using viscoelastic tests as the stress applied (1 Pa) during the amplitude sweep exceeded the strength of the network.

Fig. 2B–I shows the viscoelastic behaviour of 0.75% (w/w) BBG/other gum blends determined at 20 °C. For both gum ratios of 80/20 and 90/10 (w/w) of 0.75% (w/w) BBG/XAN blend, crossover of G' and G'' was observed. The crossover of G' and G'' defines a change from a viscoelastic fluid to a viscoelastic solid (Lazaridou et al., 2003). This indicated a soft gel formation when total gum blend

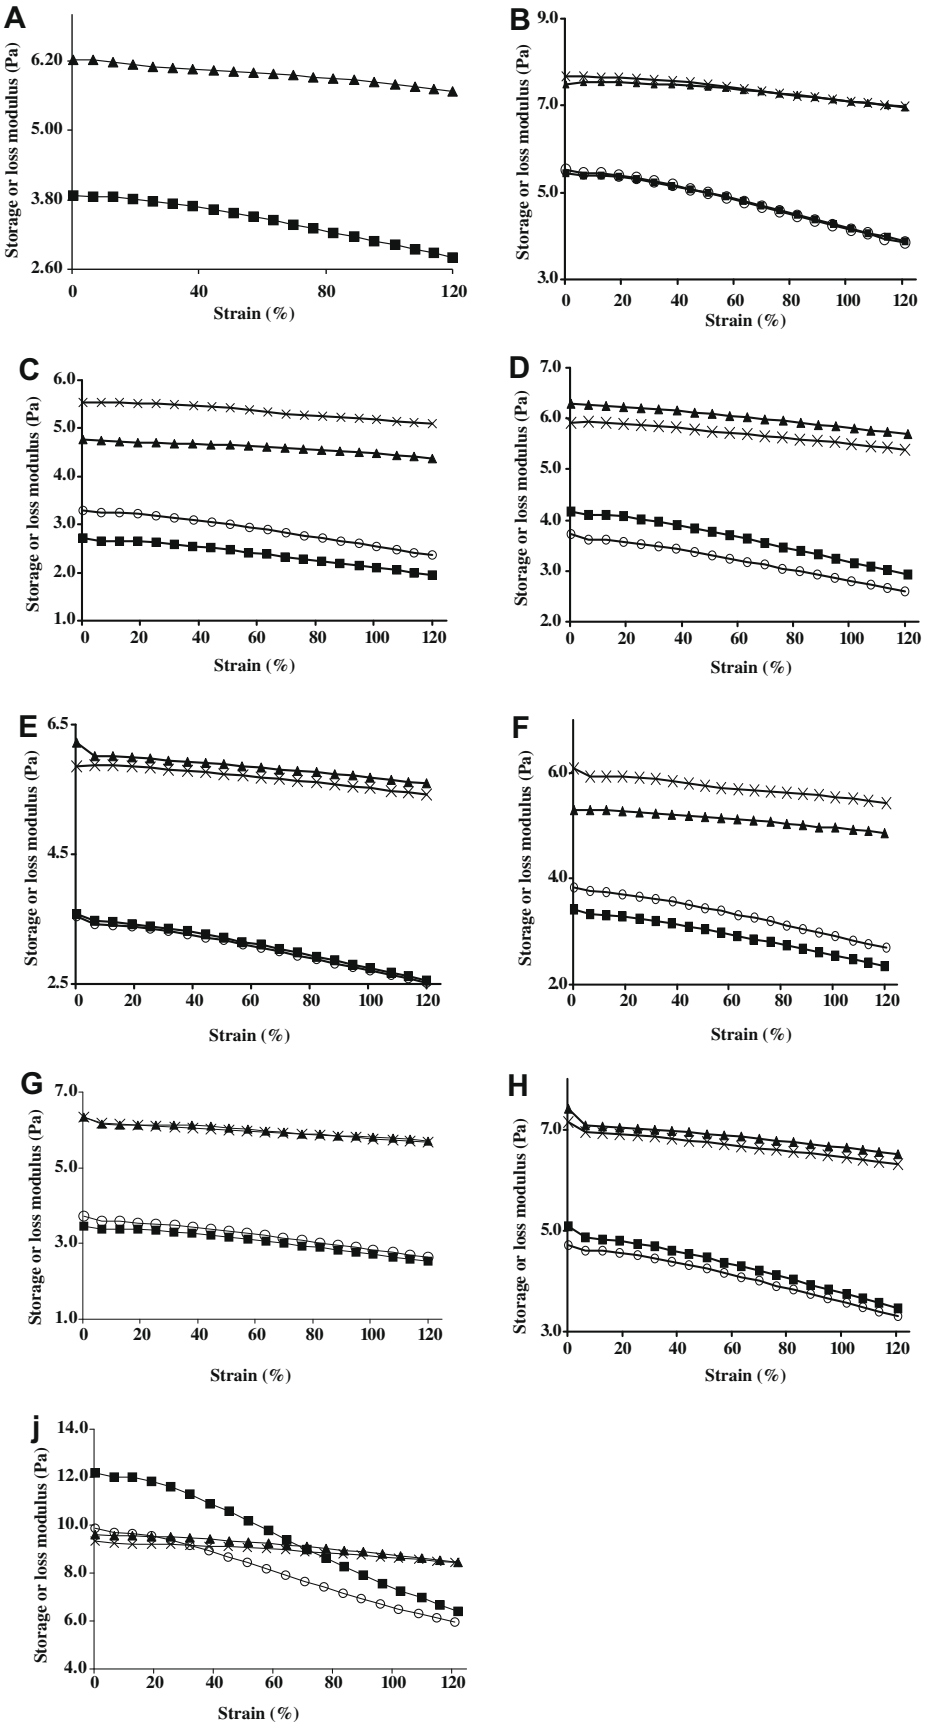

Fig. 2. Storage modulus (G') and loss modulus (G'') of 0.75% (w/w) BBG alone and its blends. (■) G' of 80/20, w/w, (▲) G'' of 80/20, w/w, (○) G' of 90/10, w/w, (×) G'' of 90/10, w/w. (A) 0.75%, w/w BBG alone, (B) BBG/CMC, (C) BBG/GUA, (D) BBG/*iota*-CAR, (E) BBG/KOG (F) BBG/*kappa*-CAR, (G) BBG/LBG, (H) BBG/*lamda*-CAR, (I) BBG/XAN.

concentration was increased from 0.5% to 0.75%, w/w. In addition to the gum concentration, the gel setting or gelation time has been reported to be affected by time and temperature of storage (Lazaridou et al., 2003). In the present study, critical time of G' and G'' crossover for the gum blends was not measured. Gum blends containing BBG and ALG, GAR, HMP, LMP, and MCC at a total gum concentration of 0.75% (w/w) were not subjected to viscoelastic tests as the stress applied (10 Pa) during the amplitude sweep exceeded the strength of the network.

5. Conclusions

BBG in binary systems exhibited synergistic interactions with XAN at 0.75%, *iota*-CAR, and CMC at both 0.5% and 0.75%, and *lambda*-CAR at 0.5% total gum concentration. Thus, the nature of the interactions depended on the blending ratios and the total gum concentrations. The improved shear tolerance (observed from flow behaviour index) of BBG/XAN blends may be beneficial in food applications where enhanced shear tolerance is required. The soft gel transformation (a change from viscoelastic fluid to viscoelastic solid) when BBG was blended with XAN may provide a unique consistency needed to achieve a "solids suspension property" much desired in products such as salad dressings or beverages with suspended particles. The addition of XAN or CMC to aqueous dispersions of BBG improved the solution viscosities at high shear rates as compared to BBG alone, meaning that at particular shear rates (e.g. intestinal shear rates), blends of BBG with XAN or CMC will maintain higher viscosities than BBG alone. The use of such blends could relate to an improved satiety effect of BBG within the human body and may be particularly useful in the creation of diet products intended to maintain a feeling of fullness. The evidence gathered from the present study also indicates potential applications for BBG in the functional beverage industry.

Postharvest
Vaccinium corymbosum

ABSTRACT

The levels of flavonoids in blueberries (*Vaccinium corymbosum* L.) were found to increase after illumination with UV-C. Phytochemicals affected included resveratrol, myricetin-3-arabinoside, quercetin-3-galactoside, quercetin-3-glucoside, kaempferol-3-glucuronide, delphinidin-3-galactoside, cyanidin-3-galactoside, delphinidin-3-arabinoside, petunidin-3-galactoside, petunidin-3-glucoside, petunidin-3-arabinoside, malvidin-3-galactoside, malvidin-3-arabinoside, and chlorogenic acid as analyzed by HPLC. Significantly higher antioxidant capacity was detected in fruit treated with 2.15, 4.30, or 6.45 kJ m^{-2} compared to the control fruit. UV-C dosage of 0.43 kJ m^{-2} also increased phenolics and anthocyanins, but to a lesser extent. The optimum doses of UV-C for enhancing phytochemical content in blueberries were 2.15 and 4.30 kJ m^{-2}. These data suggest that proper use of UV-C illumination is capable of modifying the phytochemical content of blueberries. Time course measurements of the effects of UV-C revealed that the strongest responses of fruit to UV-C treatment occurred instantly after the illumination and the effects diminished with time. Therefore, even though residual effects were evident following UV-C exposure, the best results were obtained immediately after the treatment.

1. Introduction

In recent years, increasing attention has been paid by consumers to the health and nutritional aspects of horticultural products (Scalzo, Politi, Pellegrini, Mezzetti, & Battino, 2005). Fruits and vegetables contain high levels of biologically active components that impart health benefits beyond basic nutritional value (Larson, 1988). Blueberries are one of the richest sources of natural antioxidants among fruits and have high antioxidant capacity against peroxyl radicals, superoxide radicals, hydrogen peroxide, and singlet oxygen (Heinonen, Meyer, & Frankel, 1998; Wang & Jiao, 2000). These antioxidants are capable of acting as free radical scavengers, peroxide decomposers, singlet oxygen quenchers, enzyme inhibitors and synergists (Larson, 1988).

UV-C illumination as a postharvest treatment has proven to be beneficial in delaying postharvest fruit senescence and reducing decay in various fruits and vegetables (Allende & Artes, 2003; Erkan, Wang, & Wang, 2008; Gonzalez-Aguilar, Wang, Buta, & Krizek, 2001). A previous study (Perkins-Veazie, Collins, & Howard, 2007) has indicated that postharvest application of UV-C might be effective in stimulating the antioxidant content of blueberries. However, no information is available on the effect of UV-C illumination on specific flavonols and flavonoids in blueberries. In addition, the residual effect of UV-C exposure has not been studied and little is known about what happens after UV-C treatment. The purpose of this study was to evaluate not only the changes in antioxidant capacity but also the response of individual flavonoid compounds in blueberries exposed to different UV-C illumination dosages, and the time course change of the responses of blueberries to the UV-C treatment.

2. Materials and methods

2.1. Chemicals

2,2′-Azobis(2-amidinopropane) dihydrochloride (AAPH) was obtained from Wako Chemicals USA Inc. (Richmond, VA, USA). Trolox, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid, 2,2-di-(4-*tert*-octylphenyl)-1-picrylhydrazyl (DPPH), and disodium fluorescein were obtained from Aldrich Chemical Co. (Milwaukee, WI, USA). Acetonitrile, methanol, acetone, and water were of HPLC grade and were purchased from Baxter (Muskegon, MI, USA). All anthocyanins and aglycons were obtained from Indofine Chemical Co. Inc. (Somerville, NJ, USA). Other authentic standards were obtained from Sigma Chemical Co. (St. Louis, MO, USA) and Fisher Scientific (Pittsburgh, PA, USA).

2.2. Fruit sample handling and illumination with UV-C

Blueberries (*Vaccinium corymbosum* L., cv. Duke) were hand-picked from Butler's Orchard in Maryland at a commercially mature stage. Approximately 2000 fruits were harvested and sorted to eliminate damaged, shriveled, and unripe fruit, and selected for uniform size and colour. Nine hundred and ninety fruits were selected, randomized, and used for this study. The UV-C illumination device consisted of two banks (upper and lower sides) of a 15 UV-C lamp (Model UVLMS-38: 3UV EL Series UV Lamp, 8W, LW/MR/SW, Upland, CA, USA) equipped with a filter (98-0016-02, Upland, CA, USA) to have only one wavelength at 254 nm. The intensity of the UV-C lamp was determined with a Blak-Ray J-225 photometer (Ultra-Violet Products Inc., San Gabriel, CA, USA). The UV-C lamps, reflectors, and treatment area were enclosed in a wooden box covered with aluminium foil and supported by a metal frame to provide protection for the operators. Fruit were placed on a polystyrene net and illuminated with UV-C from both the upper and lower sides. Four UV-C illumination durations and dosages were applied to blueberry fruit. These durations were 1, 5, 10, and 15 min which were equal to the dosages of 0.43, 2.15, 4.30, and 6.45 kJ m^{-2}, respectively, on each side of the berries. Non-illuminated blueberries were considered as controls. Experiments were carried out in triplicates with 30 fruits for each treatment. After UV-C illumination, control and illuminated fruit were frozen in liquid nitrogen and the samples were stored at −80 °C until analysis.

2.3. Measurement of residual effect after UV-C treatment

A separate batch of blueberries were illuminated with 4.30 kJ m^{-2} UV-C and then placed at 20 °C and samples were taken at 0, 60, 180, 300, 540, and 1440 min after UV-C illumination. Likewise, experiments were carried out in triplicates with 30 fruits for each timing in each replicate. The samples were then frozen in liquid nitrogen and stored at −80 °C until analysis.

2.4. Total anthocyanin and total phenolic content

Three 5-g composite samples from 30 berries were extracted twice with 25 mL 80% acetone containing 0.2% formic acid using a Polytron (Brinkmann Instruments Inc., Westbury, NY, USA). The homogenised samples from the acetone extracts were then centrifuged at 14,000 × *g* for 20 min at 4 °C. The supernatants were transferred to vials, then stored at −80 °C, and later used for total anthocyanin and total phenol analysis. Total anthocyanin content in fruit extracts was determined using the pH differential method (Cheng & Breen, 1991). Absorbance was measured using a Shimadzu Spectrophotometer UV-160 (Shimadzu Corp., Columbia, MD, USA) at 510 and 700 nm in buffers at pH 1.0 and 4.5, using $A = [(A_{510} - A_{700})_{pH\ 1.0} - (A_{510} - A_{700})_{pH\ 4.5}]$ with a molar extinction coefficient of cyanidin-3-glucoside (29,600). Results were expressed as milligrams of cyanidin-3-glucoside equivalent per gram of fresh weight (mg/g fw). Total soluble phenolics in the berry fruit extracts were determined with the Folin–Ciocalteu reagent by the method of Slinkard and Singleton (1977) using gallic acid as the standard. Results were expressed as mg gallic acid (GA) equivalents per gram fresh weight (mg GA/g fw).

2.5. Oxygen radical absorbance capacity (ORAC) assay

Three 5-g composite samples from 30 berries were extracted twice with 25 mL 80% acetone containing 0.2% formic acid. The ORAC assay was carried out according to Huang, Ou, Hampsch-Woodill, Flanagan, and Prior (2002) using a high-throughput instrument platform consisting of a robotic eight-channel liquid handling system. A FL800 microplate fluorescence reader (Bio-Tek Instruments Inc., Winooski, VT, USA) was used with fluorescence filters for an excitation wavelength of 485 ± 20 nm and an emission wavelength of 530 ± 25 nm. The plate reader was controlled by software KC4 3.0 (revision 29) (Bio-Tek Instruments Inc., Winooski, VT, USA). Sample dilution was accomplished by a Precision 2000 automatic pipetting system managed by precision power software (version 1.0) (Bio-Tek Instruments Inc., Winooski, VT, USA). The ORAC values were determined by calculating the net area under the curve (AUC) of the standards and samples (Huang et al., 2002). The standard curve was obtained by plotting Trolox concentrations against the average net AUC of the two measurements for each concentration. Final ORAC values were calculated using the regression equation between Trolox concentration (6.25–50 μM) and the net AUC and were expressed as micromole Trolox equivalents per gram of fresh weight (Huang et al., 2002).

2.6. Hydroxyl radical scavenging capacity (·OH; HOSC) assay

Three 5-g composite samples from 30 berries were extracted twice with 25 mL of 50% acetone. The ·OH in aqueous media is generated through the Fenton reaction. The HOSC assay was conducted with acetone solutions according to a previously published protocol (*21*) with some modifications. The assay was carried out using a high-throughput instrument platform consisting of a robotic eight-channel liquid handling system and a 96-well microplate with a FL800 microplate fluorescence reader (Bio-Tek Instruments Inc., Winooski, VT, USA). Fluorescence was measured every minute for 3 h with an excitation wavelength of 485 nm and emission wavelength of 535 nm. The plate reader was controlled by software KC4 3.0 (revision 29). Sample dilution was accomplished by a Precision 2000 automatic pipetting system managed by precision power software (version 1.0) (Bio-Tek Instruments Inc., Winooski, VT, USA). Reaction mixtures consisted of 115 μL of 3.352×10^{-6} M FL prepared in 75 mM sodium phosphate buffer, 20 μL of standard or sample or blank, 25 μL of 0.1990 M H_2O_2, and 41 μL of 3.43 mM $FeCl_3$. Trolox prepared in 50% acetone at concentrations of 12.5, 25, 50, and 100 μM was used to prepare the standard curve for HOSC quantification. The HOSC values were determined by calculating the net area under the curve (AUC) of the standards and samples. The standard curve was obtained by plotting Trolox concentrations against the average net AUC of the two measurements for each concentration. Final HOSC values were calculated using the regression equation between Trolox concentration and the net AUC and were expressed as micromole Trolox equivalents (TE) per gram of fresh weight.

2.7. 2,2-Di-(4-tert-octylphenyl)-1-picrylhydrazyl (DPPH) assay

To determine the antioxidant activity of different extracts, 2,2-di-(4-*tert*-octylphenyl)-1-picrylhydrazyl (DPPH) radicals were used. In the radical form, this molecule has an absorbance at 515 nm that disappears with acceptance of an electron from an antioxidant compound to become a stable diamagnetic molecule. The method described by Cheng, Moore, and Yu (2006) was used with some modifications. A high-throughput instrument platform consisting of a robotic eight-channel liquid handling system and a microplate with a FL800 microplate UV–visible spectrometer reader (Bio-Tek Instruments Inc., Winooski, VT, USA) was utilised for this assay. The automated sample preparation was performed using a Precision 2000 instrument with an automatic pipetting system managed by precision power software (version 1.0) (Bio-Tek Instruments Inc., Winooski, VT, USA). The plate reader was controlled by software KC4 3.0 (revision 29). Three 5-g composite samples from 30 berries were extracted twice with 25 mL of 50% acetone, and 50 μL of this extract was diluted with 150 μL of 50%

acetone. Then, 40 μL of this diluted extract was used for assay. An aliquot (160 μL) of the DPPH solution (3.3 mg/50 mL 100% ethanol) was added to each well. The mixtures were shaken gently and allowed to stand for 40 min in the dark. The decrease in absorbance was measured at 515 nm against a blank (50% acetone) without extract using a FL800 microplate UV–visible spectrometer reader (Bio-Tek Instruments Inc., Winooski, VT, USA). The DPPH values were determined by calculating the endpoint of the standards (gallic acid) and samples. Final DPPH values were calculated using the regression equation between standard gallic acid concentrations (6.25–50 μM) and were expressed as micromole gallic acid equivalents per gram of fresh weight (μmol GA/g fw).

2.8. HPLC analysis of blueberry fruit flavonoids

High performance liquid chromatography (HPLC) was used to separate and determine individual anthocyanins and phenolic compounds in blueberry fruit tissue. Three 5-g composite samples from 30 berries were extracted twice with 20 mL 80% acetone containing 0.2% formic acid using a Polytron homogenizer (Brinkmann Instruments Inc., Westbury, NY, USA) for 1 min. Extracts (40 mL) were combined and concentrated to 1 mL using a Buchler Evapomix (Fort Lee, NJ, USA) in a water bath at 35 °C. The concentrated sample was dissolved in 10 mL of acidified water (3% formic acid) and then passed through a C_{18} Sep-Pak cartridge (Waters Associated, Millipore, Milford, MA, USA), which was previously activated with methanol followed by water and then 3% aqueous formic acid. Anthocyanins and other phenolics were adsorbed onto the column while sugars, acids, and other water-soluble compounds were eluted. The anthocyanins and other phenolics were then recovered with 2 mL of acidified methanol containing 3% formic acid. The methanol extract was passed through a 0.45-μm membrane filter (Millipore, MSI, Westboro, MA, USA) and 20 μL was analyzed by HPLC. The samples were analyzed using a Waters (Waters Associated, Millipore, Milford, MA, USA) HPLC system equipped with two pumps (600 E system Controller) coupled with a photodiode array detector (Waters 990 Series). Samples were injected at ambient temperature (20 °C) onto a reverse phase NOVA-PAK C_{18} column (150 × 3.9 mm, particle size 4 μm) (Waters Associated, Millipore, Milford, MA, USA) with a guard column (NOVA-PAK C_{18}, 20 × 3.9 mm, particle size 4 μm) (Sentry guard holder universal). The mobile phase was acidified water containing 2.5% formic acid (A) and acetonitrile (B). The flow rate was 1 mL/min, with a gradient profile consisting of A with the following proportions (v/v) of B: 0 min, 3%, 1–10 min, 3–6% B; 10–15 min, 6% B; 15–35 min, 6–18% B; 35–40 min, 18–20% B; 40–45 min, 20–100% B; 45–50 min, 100% B. The phenolic compounds in fruit extracts were identified by their UV spectra, recorded with a diode-array detector and by chromatographic comparison with authentic markers. Individual flavonols and anthocyanins were quantified by comparison with an external standard of chlorogenic acid, resveratrol, myricetin, quercetin, kaempferol, or cyanidin-3-galactoside. Scanning between 250 and 550 nm was performed and data were collected by the Waters 990 3-D chromatography data system.

2.9. Statistical analysis

Data were subjected to analysis of variance using NCSS (NCSS 2007, Kaysville, UT, USA). ORAC and DPPH values, total phenolics, and total anthocyanin were evaluated by the Tukey–Kramer Multiple-Comparison test. Differences at $P \leqslant 0.05$ were considered significant. Correlation coefficients were calculated using the software, Microsoft Excel (Microsoft, 2003, Roselle, IL, USA).

3. Results

3.1. Instant effect of various doses of UV-C illumination

3.1.1. Effect on total phenols, anthocyanins, and antioxidant capacities

Different doses of UV-C illumination induced different degrees of response in blueberry fruit. Samples taken immediately after UV-C illumination showed that all UV-C doses used in this study including 0.43, 2.15, 4.30, and 6.45 kJ m^{-2} increased the levels of total phenols and anthocyanins compared to control (Table 1). The increases appeared to be dose-dependent for 0.43 and 2.15 kJ m^{-2}. However, UV-C doses higher than 4.3 kJ m^{-2} did not further enhance the levels of total phenols and anthocyanins. Instead, a slight decline in these levels were observed after blueberries were exposed to 6.45 kJ m^{-2}.

Antioxidant capacities measured by ORAC were also increased by the UV-C treatment. UV-C doses at 2.15 and 4.30 kJ m^{-2} were the most effective in promoting antioxidant capacities (Table 1). The DPPH and hydroxyl radical scavenging capacities had a similar response as the oxygen radical absorbance capacities to the UV-C exposure.

3.1.2. Effect on major phenolics and flavonoid content

Major phenolics and flavonoid components in blueberries include chlorogenic acid, resveratrol, myricetin-3-arabinoside, quercetin-3-galactoside, quercetin-3-glucoside, kaempferol-3-glucoside, and kaempferol-3-glucuronide with quercetin-3-galactoside as the predominant constituent and kaempferol-3-glucoside as a minor compound (Table 2). Resveratrol and myricetin-3-arabinoside were present at moderate amounts. Treatment with a UV-C dose at 0.43 kJ m^{-2} significantly increased the amounts of myricetin-3-arabinoside, quercetin-3-galactoside, and kaempferol-3-glucoside. Exposure to 2.15 or 4.30 kJ m^{-2} increased the levels of all the major phenolics and flavonoids detected including chlorogenic acid, resveratrol, and quercetin derivatives, in addition to myricetin-3-arabinoside, quercetin-3-galactoside, and kaempferol-3-glucoside. It appears that all individual phenolic compounds were affected similarly by the UV-C treatment. UV-C doses at 2.15 or

4.30 kJ m^{-2} induced comparable quantitative increases, but no qualitative changes.

3.1.3. Effect on major anthocyanin content

Malvidin-3-galactoside was found to be the main anthocyanin in blueberries followed by malvidin-3-arabinoside, petunidin-3-galactoside, petunidin-3-glucoside, petunidin-3-arabinoside, delphinidin-3-galactoside, cyanidin-3-galactoside, and delphinidin-3-arabinoside (Table 3). The levels of malvidin-3-galactoside, delphinidin-3-galactoside, delphindin-3-arabinoside, and petunidin-3-arabinoside were increased by the UV-C exposure at 0.43 kJ m^{-2}. The higher the UV-C doses up to 2.15 kJ m^{-2}, the higher the stimulation of the individual anthocyanins detected in this study. However, a decline in the levels of most of the individual anthocyanins was found when the UV-C dose increased to 4.3 or 6.45 kJ m^{-2}. UV-C illumination increased the concentrations of all individual anthocyanins, but did not influence the ratios of the flavonols and anthocyanins.

3.2. Residual effect of UV-C illumination

3.2.1. Changes of total phenols, anthocyanins, antioxidant capacities, and hydroxyl radical scavenging capacities in blueberries after UV-C illumination

Little information is available on the residual effect of UV-C illumination. In our study, we measured the changes of total phenols, anthocyanins, antioxidant capacities, and hydroxyl radical scavenging capacities in blueberry fruit at various time intervals after

the fruit had been exposed to 4.3 kJ m^{-2} UV-C. We found that the levels of these components and capacities were stimulated immediately after UV-C illumination as described in the previous sections. However, these levels gradually declined with time (Table 4). Samples taken at 1440 min after UV-C treatment contained much lower amounts of total phenols and anthocyanins than those taken immediately after the illumination. The decreases were not linear over time. The greatest decline occurred within the first 180 min following UV-C exposure and then gradually tapered off. After 1440 min, the concentrations of phenolic compounds were back to levels comparable to those of the initial samples (Table 1).

3.2.2. Changes of major phenolics and flavonoid content in blueberries after UV-C illumination

The main phenolics, chlorogenic acid, increased markedly immediately following UV-C illumination (Table 5). However, it declined steadily with time. After 1440 min following UV-C treatment, the amount of chlorogenic acid in treated samples decreased to a level comparable to those of the non-illuminated samples (Table 2). The major flavonoids such as quercetin-3-galactoside, myricetin-3-arabinoside, and resveratrol reacted to the UV-C treatment in a similar way. Residual effects of UV-C were evident from the change of levels of these flavonoids after the illumination, but the effects weakened with time.

3.2.3. Changes of major anthocyanins content in blueberries after UV-C illumination

Similar to phenolics and flavonoids, major anthocyanins increased substantially right after UV-C exposure (Table 6). Although there were obvious residual effects after UV-C treatment, these effects diminished with time. This phenomenon was especially noticeable in malvidin-3-galactoside, malvidin-3-arabinoside, petunidin-3-glucoside, petunidin-3-galactoside, delphindin-3-galactoside, and cyanidin-3-galactoside.

4. Discussion

Anthocyanins and phenolic compounds are largely responsible for the antioxidant capacity in plant tissues (Larson, 1988). Natural anthocyanins are glycosides which release aglycone forms (anthocyanidins) by hydrolysis. Anthocyanins have been reported to help reduce damage caused by free-radical activity such as low-density lipoprotein oxidation, platelet aggregation, and endothelium-dependent vasodilation of arteries (Heinonen et al., 1998). The increases of anthocyanins, phenolics, and antioxidant capacities in UV-C irradiated blueberries may allow for additional quenching of active oxygen species. Enhancement of anthocyanin levels by UV-C treatment also has been reported in strawberries and sweet cherries (Baka, Mercier, Corcuff, Castaigne, & Arul, 1999; Kataoka, Beppu, Sugiyama, & Taira, 1996). Fruit undergoing UV-C (9.2 kJ m^{-2}) and heat treatment (45 °C) retained better fruit quality and antioxidant activity than control fruit in boysenberries (Vicente et al., 2004). In grapes, accumulation of anthocyanin occurred in the skins when berry sections were exposed to UV irradiation (Kataoka, Sugiyama, & Beppu, 2003).

Stimulation of the biosynthesis of phenolic compounds in epicarp and mesocarp cells and biochemical reinforcement of the cell wall through lignification and suberization induced by UV-C treatment have been reported in tomatoes (Charles, Goulet, & Arul, 2008). These modifications have been implicated in the increased

disease resistance in UV-C treated tomato fruit. The beneficial effect of UV-C has also been linked to the activation of phenylalanine ammonia lyase (Nigro, Ippolito, Iattanzio, Di-Venere, & Salerno, 2000; Pan, Vicente, Martinez, Chaves, & Civello, 2004) and the accumulation of phytoalexins (Mercier, Arul, & Julien, 1993; Rodov, Ben-Yehoshua, Kim, Shapiro, & Ittah, 1992). In our study, we have found that UV-C illumination also enhanced levels of flavonoids and other antioxidant compounds.

UV-C exposure may act by inducing stress in plants. Increases in flavonoids and antioxidant capacities as described in this study might be part of the defense mechanism produced by blueberries in reacting to stress induced by UV-C illumination. The enrichment of stilbenes, such as resveratrol, in grapes in response to stress induced by postharvest UV-C irradiation has been described (Cantos, Espín, & Tomás-Barberán, 2002). The biological activity of resveratrol as an anticarcinogenic and an antioxidant has been reported (Jang et al., 1997). The increases of total phenols and anthocyanins in blueberries by UV-C illumination in our study appeared to be dose-dependent at lower doses (0.43–2.15 kJ m^{-2}). However, higher doses (4.30–6.45 kJ m^{-2}) tended to suppress these increases. This phenomenon has also been reported in strawberries where high doses of UV-C exposure was thought to cause too much stress and possibly resulted in injury (Baka et al., 1999).

Previous studies have showed that UV-C exposure retarded fungal growth in various commodities, and consequently reduced decay development in several fruits and vegetables after harvest (Stevens et al., 1996; Wilson et al., 1997). UV-C light has been considered as a germicidal agent and the use of this treatment has been demonstrated to directly inhibit microbial growth (Allende & Artes, 2003; Stevens et al., 1996). UV-C may also retard the mold development by enhancing the resistance of plant tissues against pathogenic attack (Droby et al., 1993). Thus, adequate UV-C treatment can be beneficial and have practical impact for commercial practices in terms of reducing the spoilage of fresh produce. Any other benefits obtained from UV-C treatment would be additive. Even though our study showed that the effect of UV-C on antioxidant capacities, phenolics, and anthocyanins might be short-term in blueberries, the responses of other commodities or the effect using different dosages could be different. Further investigations may also be warranted to explore if combining UV-C illumination with other postharvest techniques would have a long lasting effect in increasing the levels of antioxidant activity and potential health-promoting nutraceutical compounds.

ABSTRACT

In the food industry, the use of the oil is determined by the composition of fatty acids, and this is highly dependent on its natural origin. The fatty acid composition of whole corn kernel was determined in three varieties of corn (*Astro*, *GH*2547, and *Local*). Linoleic acid was the predominant fatty acid in the oil of *Astro* and *Local* at all collection dates, whereas it was the major fatty acid in the oil of *GH*2547 only between 40 and 60 days after pollination (DAP). The fatty acid accumulation in the endosperm, pericarp and germ fractions of the corn kernel during maturation was determined. The accumulation pattern of oil content was different in these three kernel fractions. The highest levels of oil content in the endosperm (2.2%), germ (34.3%) and pericarp (10.8%) fractions were detected at 20, 40 and 30 (DAP), respectively. The fatty acid accumulation patterns were different amongst the analysed kernel parts, indicating a numerous differences between the three corn kernel parts. Throughout the sampling periods, the endosperm fraction was distinguished by the highest and the lowest levels of oleic and linoleic acids, respectively. At all stages of kernel development, the pericarp fraction had the highest levels of total polyunsaturated fatty acids, which has numerous healthy applications. These results may be useful in the understanding of the potential source of the beneficial unsaturated fatty acids amongst the different fractions of the corn kernel during maturation.

1. Introduction

Plant oils and animal fats constitute one of the major classes of food product, for the provision of energy and essential fatty acids. Animal sources, such as butter and lard, are characterised by high concentrations of saturated fatty acids. It is well known that a diet rich in saturated fatty acids forms a risk factor for hypercholesterolemia, atherosclerosis and others diseases in humans. In order to reduce the saturated fat content of processed foods, the food industry in developed countries moves progressively from animal fat to vegetable fat sources (Ruiz-Jiménez, Priego-Capote, & Luque de Castro, 2004). The change in consumer preferences is mostly due to consumers demanding food products that combine a pleasant flavour with nutritional benefits. Vegetable oils have a high content of unsaturated fatty acids, which are heart-healthy. The nutritional value of *n*-3 polyunsaturated fatty acids (PUFA) in the human diet is well recognised, and increased consumption of these fatty acids has been recommended (Department of Health, 1994). The precursor of the *n*-3 series of long-chain PUFA is the essential fatty acid linolenic acid (C18:3), from which man can synthesise the longer chain PUFA such as eicosapentaenoic acid and docosahexaenoic acid (Elmore et al., 2005). Recently, interest in the PUFA, as health-promoting nutrients, has expanded dramatically.

The intensive research period up to the 1990s, focused on the modification of the fatty acid composition of oilseeds by biotechnology. Information on the fatty acid distribution in seed parts provides a possible way to produce vegetable oils with high additional value. Since, based on the understanding of composition, biosynthetic and metabolic pathways of fatty acids in seed parts it is practically applicable to genetically alter the lipid composition of cells through the alteration of the encoding genes of enzymes that are responsible for lipid synthesis or metabolism. Commercially exploited seeds such as soya and rape have been the subject of many years of breeding programmes to obtain oils with particular fatty acid patterns (Stenberg, Svensson, & Johansson, 2005). Successful advances in plant breeding, such as the elimination of erucic acid from rapeseed, have drastically improved the oil quality. The established limits of fatty acid contents could be used for the detection of fraud of the olive oil with corn oil, at levels of adulteration up to 5% (Christopoulou, Lazaraki, Komaitis, & Kaselimis, 2004). In industry, the use of the oil is determined by the composition of fatty acids, and this is highly dependent on its natural origin. The fatty acid composition of oils from vegetable sources varies depending on plant origin, genetic factors, ripening grade of fruits and specific climatic conditions (Davis & Poneleit, 1974; Velasco, Rojas-Barros, & Fernandez-Martinez, 2005). In exploring the role of lipids in cells and tissues, it is useful to know which lipids are present and in what proportions. Furthermore, one of the main objectives of industry is to identify plant matrices rich in

some compounds, which have large industrial applications. Thus, Bruni et al. (2002) analysed Ecuadorian *Theobroma subincanum* seed parts to determine quali-quantitative tocopherol, fatty acids and sterols distributions. A number of studies have been reported concerning the developmental changes in the fatty acid composition of the whole corn kernel (Poneleit & Davis, 1972; Weber, 1969). However, there is limited information on the fatty acid distribution within corn kernel during maturation. The objective of the present research was to monitor the accumulation pattern of fatty acids in the endosperm, germ and pericarp fractions of the corn kernel during maturation. This study seems to be very useful in understanding the source of nutritionally and industrially fatty acids in the corn kernel fractions and for many aspect of vegetable oil production.

2. Experimental

2.1. Reagents and standard

Methanol, chloroform acetone and pentane, solvents of HPLC grade, were purchased from Panreac Quimica SA. (Barcelona, Spain). Triflorure Bore (BF_3) was from Fisher Scientific SA (Loughborough, Spain). Fatty acid standards were acquired from Sigma Aldrich (Madrid, Spain).

2.2. Samples

Sweet corn (variety *GH*2547*)* was obtained from USA. The sweet corn (*Zea mays saccharata*) differs from dent corn (*Zea mays indentata*) by a single recessive gene which prevents some of the sugar to being converted to starch (Bland, 1971). *GH*2547 variety was grown in restricted zones (15 × 3 m) on the Agronomy farm of the INRAT (Institut National Recherche Agronomie Tunis, North of Tunisia) from the middle of April until the end of August 2005. Ear samples were collected at intervals after the date of hand-pollination. Corn kernels were steeped for 3 h in 0.1% sodium metabisulfite solution at 50 °C before dissection.

2.3. Lipid extraction

The total lipids were extracted by the method of Folch, Lees, and Sloane Stanley (1957) modified by Bligh and Dyer (1959). Seeds (2.5 g) were washed with boiling water for 5 min to denature the phospholipases and then crushed in a mortar with a mixture of $CHCl_3$–MeOH (2:1, V/V). The water of fixation was added and the homogenate was centrifuged at 3000*g* for 15 min. The lower chloroformic phase containing the total lipids was kept and dried in a rotary evaporator at 40 °C.

2.4. Fatty acid analyses

The fatty acid composition of the seed oil was determined by gas chromatography of fatty acid methyl esters. Fatty acid methyl esters were prepared by simultaneous extraction and methylation following the procedure described by Mectalfe, Schmitz, and Pellka (1966) modified by Lechvallier (1966). Fatty acid methyl esters were analysed by gas chromatography (GC) using a HP 4890 chromatograph equipped with a flame ionisation detector (FID) on a capillary column coated with supelcowaxTM 10 (30 m length, 0.25 mm id, 0.2 μm film thickness). Column temperature was programmed from 150 to 200 °C (4 °C min^{-1}. Temperatures of detector and injector were 250 and 230 °C, respectively. The fatty acids were identified by comparison of their retention times with those of standards. The quantitative evaluation was carried out on the base of gas chromatography peak areas of the different methyl esters. The response factor for fatty acids, calculated by using heptadecanoic methyl ester, was 0.95.

2.5. Statistical analysis

Statistical analysis was performed by using the Proc ANOVA in SAS (Software version 8). Duncan's Multiple Range Test was used. For each oil sample, three determinations have been done.

3. Results and discussion

3.1. Oil content

Numerous studies reported the developmental changes in the oil content of the maturing whole corn kernel (Harrabi et al., 2007; Weber, 1969). The distribution of the total lipid in the different fractions of mature corn kernel has been examined (Harrabi et al., 2008). In this study, the maturing corn kernels were divided into three parts: germ, endosperm and pericarp. At 20 days after pollination (DAP), the corn kernel was made up mainly of the pericarp (37.1%) and endosperm (52.7%) fractions; however the proportion of the germ part was 10.2%. From 20 to 30 DAP, the percentages of the endosperm and germ parts rapidly increased, whilst those of the pericarp fraction decreased (Fig. 1). This result suggested that the biosynthesis of organic matter such as lipids, carbohydrates and protein was more important in the endosperm and germ fractions than that in the pericarp part. The endosperm development was divided into phases: the first was characterised by a rapid accumulation of soluble constituents, and the second

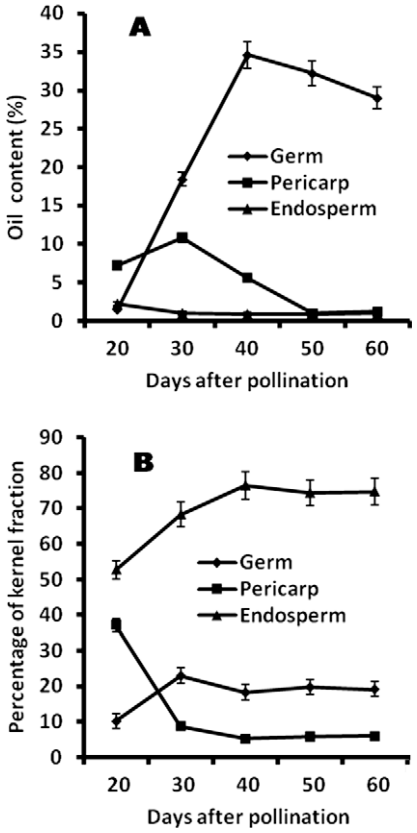

Fig. 1. Changes in the oil content (percentage dry weight (A)) and proportions of corn kernel fractions (B) during maturation of *GH*2547 variety. Pericarp fraction is presented by (■), germ part is presented by (♦) and endosperm part is presented by (▲).

by the utilisation of those soluble constituents to cause an increase in the protein content (Davis & Poneleit, 1974).

During the corn kernel development, the total lipid content decreased gradually from 2.2% at 20 DAP to about 0.9% at 40 DAP in the endosperm fraction (Fig. 1). Conversely, the oil content in the pericarp fraction increased to a maximum (10.8%) at 30 DAP, and then decreased gradually to reach a constant value of 1.2% at 40 DAP. The oil which was accumulated early in the pericarp fraction was apparently metabolised later. The greatest increase of oil content was observed in the germ part, resulting in much higher final oil content (29.0%) in this kernel fraction. The final oil content in the three corn kernel parts was influenced by the duration and rate of oil synthesis. This result suggested numerous differences between the corn kernel parts, such as the amounts and activities of enzymes catalysing the various lipid synthetic processes. The oil is presumably synthesised and stored by the germ fraction for eventual use as energy during germination and other processes. During the corn kernel development, the endosperm and germ fractions stores primarily starch and lipids, respectively.

3.2. Fatty acid profiles of the whole corn kernel and its parts at maturity

The fatty acid profiles of the mature whole corn kernel were compared amongst the three varieties (Table 1). For all the three corn varieties, linoleic acid (49.7–62.7%) was the predominant fatty acid components, followed by oleic (23.5–34.9%) and palmitic (9.5–11.5%) acids. This contrasts with the composition of olive oil where oleic acid was the most abundant fatty acid (78.1%), followed by palmitic (10.2%) and linoleic (7.1%) acids (Rezanka & Rezankova, 1999). *Astro* was distinguished by the highest level of linoleic acid (62.7%) and the lowest for oleic acid (23.5%), whilst *GH*2547 showed the highest value for oleic acid (34.9%) and the lowest for linoleic acid (49.7%). The percentage of linolenic acid was nearly the same for the three corn varieties (1.7–2.1%). Considering the fact that the three varieties were grown in the same experimental conditions, we suggested that the variability in fatty acid composition was mainly due to genetic effects.

The fatty acid profile of the principal parts of the mature corn kernel was also investigated. A comparison between the three corn kernel parts demonstrated that there was a significant difference ($p < 0.05$) in their fatty acid percentages (Table 1). In the endosperm fraction, the percentage of oleic acid was higher than that of linoleic acid, whilst the reverse is true in the germ and pericarp fractions. *GH*2547 endosperm had significantly ($p < 0.05$) higher oleic acid percentage (66.3%) than had *Astro* endosperm (52.7%) and *Local* endosperm (48.5%). Oleic acid was converted to linoleic acid by Δ12 desaturase, which is a membrane bound enzyme; thus we suggested that this desaturation step was less important in the endosperm part. In addition, this result could be linked to the activity of phosphatidyl choline oleoyl desaturase, enzyme which catalyses the desaturation of oleic acid to linoleic acid (Velasco et al., 2005).

Amongst the three corn kernel parts, germ part had the most levels of palmitic acid (11.4–15.6%), whilst pericarp part had the lowest levels (5.3–7.6%) of this fatty acid. Tan and Morrison (1979) reported that the levels of this fatty acid in the pericarp, germ and endosperm fractions were: 19.4–24.7%, 10.6–12.0% and 24.7–27.5%, respectively. However, Moreau, Singh, Nuñez, and Hicks (2000) reported that the germ, fibre and aleurone fractions had similar proportions of palmitic acid. Abundance of this fatty acid might be linked to the abundances and activities of 3-ketoacyl-ACP (Acyl Carrier Protein) synthase II and thioesterase specific for saturated acyl-ACP. In fact, the palmotyl-ACP synthesised in plastid could be hydrolysed by thioesterases or converted to stearoyl-ACP by 3-ketoacyl-ACP synthase II (Ohlrogge & Jaworski, 1997).

The oil extracted from the pericarp fraction had significantly ($p < 0.05$) higher amount of linolenic acid than had the endosperm and germ fractions. This result suggested that Δ15-desaturase, enzyme which converted linoleic acid to linolenic acid, was more abundant and active in the germ fraction than that in the endosperm and pericarp fractions. The percentage of stearic acid (0.5–2.2%) was very lower in all of the corn kernel fractions, as it was in the whole corn kernels of the three varieties. According to Bruni et al. (2002), the seed parts of sterculiaceae (*T. subincanum*) had high amounts of stearic acid (24.3–40.7%). That result underlines the differentiation between the seed parts of sterculiaceae and those of corn. The abundance of various fatty acids in the different seed parts might be considered as characteristic of the vegetal species.

3.3. Fatty acid accumulation in the whole corn kernel

Differences in the percentages of the various fatty acids over the course of maturation of the three corn varieties are evident in Fig. 2. As the corn kernel developed, the percentage of palmitic acid decreased rapidly between 20 and 30 DAP and then remained nearly stable until maturity, in agreement with the results of Poneleit and Davis (1972) and Weber (1969). Oleic acid and linoleic acid exhibited contrasting accumulation patterns in the maturing whole corn kernel; the percentage of linoleic acid increased whilst the oleic acid percentage decreased. The patterns of fatty acid accumulation were different amongst the vegetable seeds. In fact, the

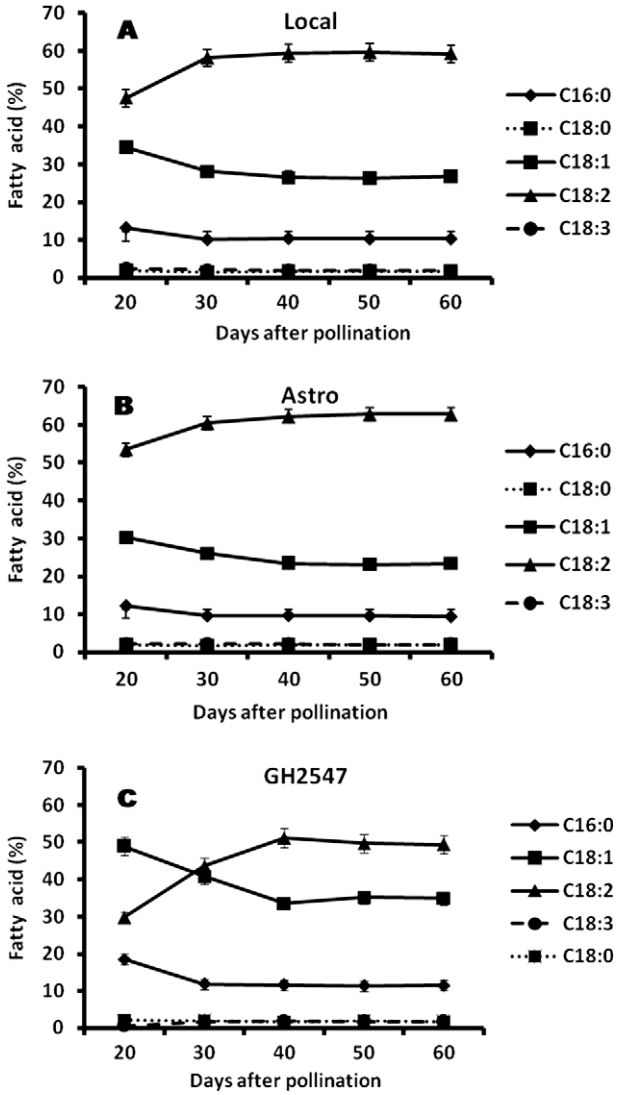

Fig. 2. Fatty acid composition (percentage of the total fatty acids) of the whole kernel during maturation of three corn varieties: (A) *Local*, (B) *Astro*, (C) *GH*2547. Palmitic acid (♦), linoleic acid (▲), oleic acid (■), stearic acid (...■...), linolenic acid (●).

percentage of linoleic acid decreased in the developing seeds of castor (Velasco et al., 2005). Linoleic acid was the predominant fatty acid in the oil of *Astro* and *Local* at all collection dates, whereas it was the major fatty acid in the oil of *GH*2547 only between 40 and 60 DAP. Although *GH*2547 accumulated linoleic acid at faster rate than did *Astro* and *Local*, *GH*2547 had the lowest levels of this unsaturated fatty acid at all collection dates. This result suggested that the percentage of linoleic acid should be influenced by the highly efficient of Δ12 desaturase in the early development period before 20 DAP. The increase in the amount of linoleic acid was not accompanied by a concomitant raise of linolenic acid percentage, which suggested that the very low level of linolenic acid could be the result of a lower efficiency of the desaturation of linoleic acid in the maturing corn kernel.

3.4. Fatty acid accumulation in the endosperm, pericarp and germ fractions

The patterns of fatty acid accumulation were different amongst the three corn kernel parts (Fig. 3). In the germ and pericarp fractions, oleic and linoleic acids exhibited contrasting accumulation patterns, as it was in the whole corn kernel. However, these two fatty acids followed a similar accumulation pattern in the endosperm fraction, where their percentages increased slightly from 20 to 30 DAP and then remained unchanged. As the corn kernel developed, the highest levels of oleic acid (62.4–67.5%) and the lowest for linoleic acid (14.2–21.3%) were detected in the endosperm fraction. This result suggested a lower efficiency of the desaturation of oleic to linoleic acid and indicated that this desaturation step was not favoured by the accumulation of the substrate. At all collection dates, the percentages of stearic acid was very small (0.9–4.3%) in the three corn kernel parts. Stearic acid was converted to oleic acid by Δ9 desaturase, a reaction that occurs in plastids. Therefore, it can be thought that this desaturation step occurred mainly before 20 DAP. The interplay between the fatty acid synthase, Δ9 desaturase, and thioesterases determines the levels of palmitic and stearic acids. Considering the facts that cell membranes are constituted mainly by phospholipids and that the early period of seed development are characterised by an intense cell divisions (Cresti, Blackmore, & Went, 1992), we suggested that the highest rate of the biosynthesis of C18:1 and C18:2 was required by cells for the synthesis of phospholipids to regulate membrane permeability and fluidity. Ohlrogge and Jaworski (1997) reported that the rate of fatty

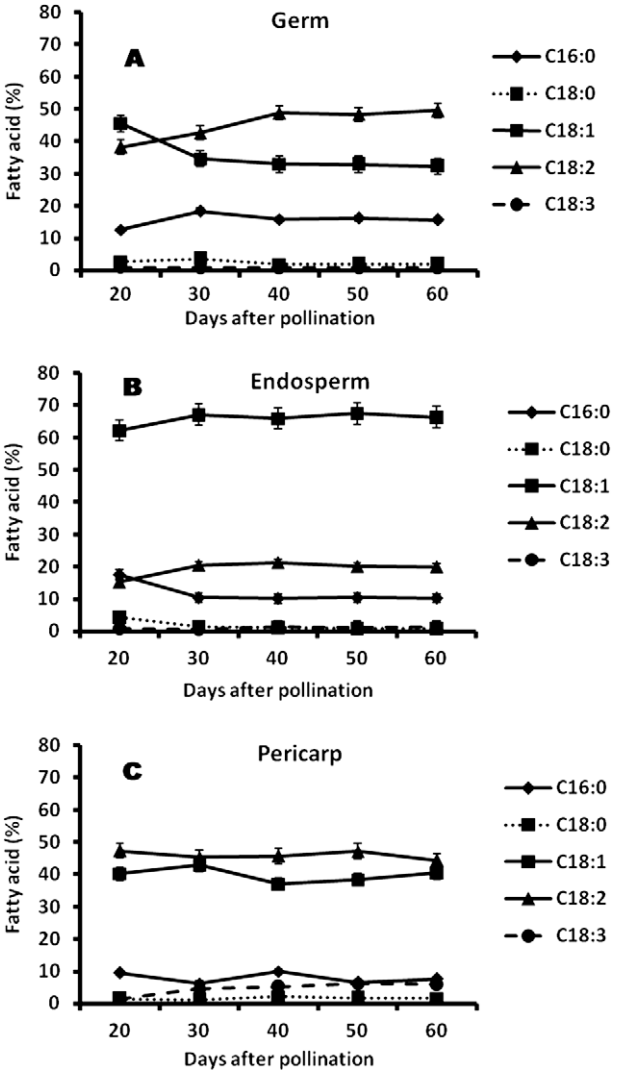

Fig. 3. Fatty acid composition (% of the total fatty acids) of the germ (A), endosperm (B), and pericarp (C) fractions, during maturation of *GH*2547 variety. Palmitic acid (♦), linoleic acid (▲), oleic acid (■), stearic acid (...■...), linolenic acid (●).

acid synthesis can apparently be regulated by the demand for fatty acids, which were needed for membranes synthesis. This could explained why the increase in the amounts of oleic and linoleic acids occurred during the most rapid rate of endosperm mitosis, in fact it has been reported that cell divisions in the endosperm part of corn kernel (variety Wf9) was essentially completed within 28 DAP (Ingle, Beitz, & Hageman, 1965).

The pattern of palmitic acid accumulation varied amongst the three corn kernel parts. In the endosperm fraction, palmitic acid exhibited the same trend observed for the whole corn kernel. Whereas in the germ fraction, the percentage of palmitic acid increased from 12.6% at 20 to 18.3% at 30 DAP, and then decreased to reach a constant value about 15.5% at 40 DAP. This result is in contrast with the result of Jellum (1970), which indicated that palmitic acid proportion decreased in the germ fraction. Differences in variety were likely the reason for the observed result. In fact, Goffman and Böhme (2001) reported that variation for fatty acid composition of corn oils was principally due to genetic differences amongst the hybrids. In the pericarp fraction, the amount of palmitic acid fluctuated and no definite trend was evident; although the highest level (9.9%) was observed at 40 DAP. Arachidic acid amount in the germ and pericarp fractions (0.1–0.2%) was relatively constant during corn kernel development; however it increased slightly in the endosperm fraction from 0.1% at 40 to 0.4% 60 DAP. As the corn kernel developed, the amount of linolenic acid in the pericarp oil rapidly increased from 1.3% at 20 to 4.5% at 30 DAP, whereas it was nearly the same in the endosperm and germ fractions. Fatty acid synthesis increases in response to the high demand for acyl chain for the synthesis of glycerolipids in the endoplasmic reticulum. At all stages of kernel development, the pericarp fraction was richer in linolenic acid than the endosperm and germ fractions. Considering the fat that Δ15 desaturase catalyses the conversion of linoleic to linolenic, we suggested that this enzyme was more abundant and active in the pericarp part than in the endosperm and germ parts. The highest amounts of total polyunsaturated fatty acids were detected in the pericarp fraction, at all stage of corn kernel development (Fig. 4). This result suggested the high healthy nutritional value of the pericarp oil. In fact, polyunsaturated fatty acids have been suggested to be beneficial in reducing the risk of certain chronic diseases, such as cardiovascular, inflammatory and atherosclerosis diseases (Finley & Shahidi, 2001; Riemersma, 2001).

Ricinoleic acid, which synthesised by the hydroxylation of oleic acid, was not detected in the three corn kernel fractions. This result suggested the absence of Δ12 hydroxylase, a microsomal enzyme which convert oleic acid to ricinoleic acid (Bafor, Smith, Jonsson, Stobart, & Stymne, 1991) in the different parts of corn kernel. In contrast, this fatty acid was detected in the seeds of castor (Velasco et al., 2005).

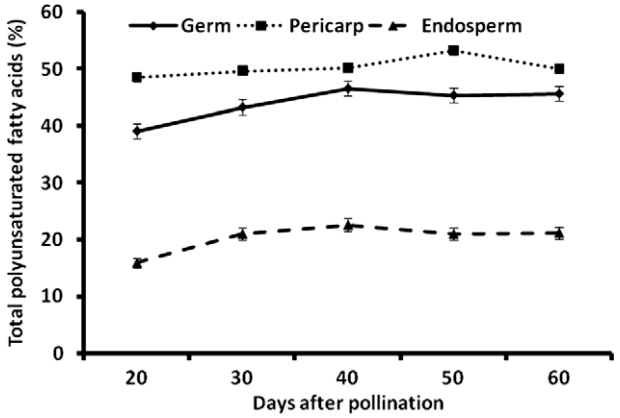

Fig. 4. Pattern of variation in polyunsaturated fatty acid composition (percentage of the total fatty acids) for the three fractions of the corn kernel during maturation (variety *GH*2547). Pericarp fraction is presented by (■), germ part is presented by (♦) and endosperm part is presented by (▲).

4. Conclusion

The fatty acid composition showed a different pattern in endosperm, germ and pericarp fractions of the maturing corn kernel. In the endosperm fraction, the early accumulation of oleic acid did not promote its desaturation to linoleic acid, which remained unchanged during corn kernel development. The pericarp fraction accumulated linolenic acid for a longer period and at faster rate than did the germ and endosperm fractions. As a result, at all collection dates the highest levels of linolenic acid were detected in the pericarp fraction. The highest amounts of polyunsaturated fatty acids detected in the pericarp fraction, at all stage of corn kernel development, suggested its high healthy nutritional value.

ABSTRACT

Three microbial proteases, validase (Val) from *Aspergillus oryze*, alkaline protease (AP) from *Bacillus licheniformis*, and neutral protease (NP) from *Bacillus subtilis*, were investigated for producing antioxidant hydrolysates/peptides from milk protein isolate. The hydrolysates were fractionated by sequential ultrafiltration and their antioxidant properties examined. The oxygen radical absorbance capacity (ORAC) of the twelve hydrolysate fractions varied significantly ranging from 62.9 to 246.6 μmol Trolox equivalents (TE) per gram with Val-F3 fraction possessing the highest value. The 1,1-diphenyl-2-picrylhydrazyl radical (DPPH·) scavenging activities of the hydrolysate fractions also varied significantly ranging from 3.1 to 35.4 μmol TE/g. The results revealed that most hydrolysate fractions exerted weak chelating activities of ranging from 0.1 to 0.9 mg ethylenediaminetetraacetic acid (EDTA) equivalents/g. However, the NP-F2 fraction exerted an exceptionally higher activity of 4.7 mg EDTA equivalents/g. Val-F3, Val-F2, and NP-F2 were incorporated into ground beef to determine their impact on lipid peroxidation. Only the Val-F3 fraction (200 μg/g in the meat) significantly reduced meat lipid peroxidation. Increasing the dosage of VAL-F3 (800 μg/g) did not enhance the inhibition on meat lipid oxidation.

1. Introduction

Lipid oxidation is a key process that occurs in food products which correlates to the deterioration of food quality. Incorporating antioxidant compounds into food products have proved to be an effective measure for inhibiting lipid oxidation which extends shelf-life and improves food quality by preserving flavour and nutritional value (Laguerre, Lecomte, & Villeneuve, 2007; Rojas & Brewer, 2007). The identification and development of food-derived peptides with antioxidant properties has attracted increased attention due to heightened safety concerns over the use of synthetic antioxidants and the consumer's preference for naturally derived products (Sakai, Miyata, & Takahashi, 1997; Shahidi & Zhong, 2008). Once proven safe and effective naturally derived antioxidant peptides could have beneficial utility/application in the food industry as of result of their incorporation into fat-rich meat products replacing synthetic antioxidants such as BHA to inhibit lipid oxidation and improve shelf life. Interest in the development of peptides as an alternative antioxidant stems from studies in which a variety of food proteins, such as milk, soy, zein, canola, capelin, and porcine collagen, were found to inhibit lipid oxidation in commonly consumed foods and in *in vitro* models (Amarowicz & Shahidi, 1997; Cervato, Cazzola, & Cestaro, 1999; Chen, Muramoto, Yamauchi, & Nokihara, 1996; Cumby, Zhong, Naczk, & Shahidi, 2008; Li, Chen, Wang, Ji, & Wu, 2007). These antioxidant properties are believed to be attributed to unique sequences inherent in the protein macromolecular structure (Giovanna, Roberta, & Benvenuto, 1999; Wang, Fujimoto, Miyazawa, & Endo, 1991). For example, clear evidence of the antioxidant activities associated with specific peptides were demonstrated in oil-in-water emulsions, beef homogenates, liposomal suspensions, and β-carotene/linoleate model system (Diaz, Dunn, McClements, & Decker, 2003; Kong & Xiong, 2006; Sakanaka, Tachibana, Ishihara, & Juneja, 2005; Shahidi & Amarowicz, 1996). Certain hydroxyl- or sulphate-bearing amino acids such as Tyr, Met, His, Lys, and Trp have been shown to possess some degree of antioxidant properties (Chen et al., 1996; Saito et al., 2003). Furthermore, specific peptides have been reported to have enhanced antioxidant activities when compared to constituent amino acid mixtures (Guo, Kouzuma, & Yonekura, 2009). Consequently, it has been suggested that the synergistic effect of specific amino acid sequences in peptides, molecular structures, and functional groups are all major factor that contribute to the antioxidant potential of peptides.

A variety of methods have been employed with the purpose of generating potentially functional peptides. For example, food-derived peptides with biological activities are primarily produced through enzymatic hydrolysis, fermentation, and chemical or enzymatic synthesis (Gill, Lopez-Fandino, Jorba, & Vulfson, 1996;

Hernandez-Ledesma, Davalos, Bartolome, & Amigo, 2005; Robert, Razaname, Mutter, & Juillerat, 2004; Shahidi & Zhong, 2008). Amongst these processes, enzymatic hydrolysis is often the method of choice in which common digestive enzymes are exploited, such as trypsin and pepsin, to generate peptides with potential antioxidant properties (Jiang, Chen, Ren, Luo, & Zeng, 2007; Kanda, Hisayasu, Abe, Katsura, & Mashimo, 2007). During hydrolysis the protease specificity is essential because it dictates the amino acid sequence of the resultant peptides and their biofunctional properties (Murray & FitzGerald, 2007). Use of commercial proteases of microbial or plant-origin has gained increased popularity due to their unique functions and cost-effectiveness. For instance, a commercially developed and marketed *Bacillus* protease enzyme, Protamex® by Novozyme, was used to generate catfish protein hydrolysates with notable antioxidant activities (Theodore, Raghavan, & Kristinsson, 2008). Furthermore, the plant derived papain enzyme has been attributed to utility in the production of a variety of protein hydrolysates with different functions in food science (Hicks, Onuorah, & Surjawan, 2000; Kong & Xiong, 2006). Additional enzyme hydrolysis research is merited due to the fact that there is a general recognition that the type of enzyme used in the hydrolysis process will impact the potency of bioactive properties such as antioxidant capacity.

In this study, three commercial microbial proteases, validase from *Aspergillus oryze*, alkaline protease from *Bacillus licheniformis*, and neutral protease from *Bacillus subtilis*, were utilised for the generation of functional peptides. The three selected proteases are commonly used for digesting food proteins but with considerably different substrate specification and reacting characteristics. The purpose of this study was to determine whether these commercial microbial proteases can, through hydrolysis of milk protein, generate functional antioxidant peptides as a strategy to improve food quality and extend shelf-life by inhibiting lipid oxidation. The milk protein hydrolysates were fractionated by sequential ultra-filtration. The acquired fractions were assessed for their antioxidant properties by various methods such as oxygen radical absorption capacity (ORAC), 1,1-diphenyl-2-picrylhydrazyl radical ($DPPH^{\cdot}$) scavenging ability, and metal ion chelating activities. To test for a potential inhibitory effect on the lipid peroxidation process associated with the development of rancidity, off flavours, and shorter shelf life, fractions identified to have potent antioxidant activities were selected for further antioxidant assessment against lipid peroxidation in cooked ground beef by the thiobarbituric acid reactive substances (TBARS) method.

2. Material and methods

2.1. Materials

The milk protein isolate (MPI 5003) was obtained from Protient Inc. (St. Paul, MN, USA) with 90% purity on a dry basis. Protease Validase® FP concentrate (Val) and alkaline protease concentrate (AP) was kindly provided by Valley Research Corporate (South Bend, IN). Neutral protease (NP) was provided by Bio-CAT Inc (Troy, VA). Val is a fungal peptidase complex produced by submerged fermentation of a selected strain of *A. oryzae* and contains both endoprotease and exopeptidase activities. The AP is a serine alkaline protease prepared from *B. licheniformis* which contains endopeptidase activity. The NP is an extracellular endopeptidases produced from *B. subtilis*, these enzymes are active in the neutral pH range. These proteases were selected because they have been commonly used in industrial processes with high-quality thermostability. Fluorescein, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox™), and 1,1-diphenyl-2-picrylhydrazyl (DPPH) were purchased from Sigma–Aldrich Chemical Co. (St. Louis, MO, USA). 2,2′-azobis(2-amino-propane) dihydrochloride (AAPH) was purchased from Wako Chemicals (Richmond, VA). All other chemicals and solvents were of analytical or HPLC-grade. The ultra-filtration system (Model No. 8050) and cellulose membranes for the preparation of protein hydrolysates were purchased from Millipore Co. (Billerica, MA).

2.2. Preparation of milk protein hydrolysates

For digestion of the milk protein isolate, three microbial proteases, Val, AP, and NP, were used according to the peptide guidelines from the manufacturer with slight modification. An amount of 50 g of the milk protein was homogenised in 500 mL water and hydrolysed by the individual proteases at a concentration of 2% (m/m, enzyme/substrate). The enzymatic hydrolysis was conducted for 6 h in a water bath at 55 °C under shaking. For Val, the reaction mixture was adjusted to pH 7.0 using 0.5 M NaOH or 0.6 M HCl during hydrolysis. For AP, the solution was adjusted to the optimum pH 10. The enzymatic reactions were terminated by boiling the mixtures for 5 min. Each mixture was centrifuged at 15,000*g* and the soluble fraction was then filtered using filtration paper (Whatman 4) for further fractionation.

2.3. Determination of the degree of hydrolysis (DH)

The DH of milk protein isolate by the three different proteases (AP, NP, and Val) was calculated by determining free amino groups after reacting with the trinitrobenzenesulphonic acid (TNBS) according to a previously reported protocol with modification (Adler-Nissen, 1979). The sample solution was mixed with 0.2 M sodium phosphate buffer (pH 8.2) and 0.1% TNBS, followed by incubation in the dark for 60 min at 50 °C. The reaction was quenched by adding 4.0 mL of 0.1 M HCl, and the absorbance was read at 340 nm. A 1.5 mM L-leucine solution was used as the standard. The DH was calculated by comparing the results to the standard curve for each particular protein substrate.

2.4. Fractionation of protein hydrolysates by ultrafiltration

The collected protein hydrolysates were ultra-filtered sequentially using a Millipore 8050 ultra-filtration unit through cellulose membranes with different molecular weight (MW) limits. Briefly, the hydrolysates were diluted with water and then ultra-filtered through a membrane with 10 kDa nominal molecular weight limit (NMWL) under 40 psi nitrogen gas. This process yielded two fractions: retentate (fraction 1, F1, represented hydrolysates > 10 kDa) and permeate (MW < 10 kDa). The permeate was further ultra-filtered through a 3 kDa NMWL membrane to obtain the second retentate (fraction 2, F2, represented hydrolysates between 3 and 10 kDa) and permeate. The second permeate was ultra-filtered through a 1 kDa NMWL membrane to yield the third retentate (fraction 3, F3, represented hydrolysates between 1 and 3 kDa) and permeate (fraction 4, F4, represented hydrolysates < 1 kDa). All retentates and permeates were lyophilised and stored at −20 °C until further analysis.

2.5. Measurement of oxygen radical absorbance capacity (ORAC)

The ORAC assay was conducted to kinetically measure the peroxyl radical scavenging activity of peptides with Trolox™ as the antioxidant standard according to the method reported previously (Moore et al., 2005). The Fluorescein was used as the fluorescent probe and the peroxyl radicals were generated from AAPH in 75 mM phosphate buffer (pH 7.4). The Trolox™ standards and samples were plated in duplicate to the inside wells of a black 96-well flat bottom plate. The fluorescence of the reaction mixture was

monitored and recorded every minute (λ_{ex} = 485 nm and λ_{em} = 535 nm) maintained at 37 °C until the reading had declined to less than 5% of the initial reading by a Victor^3 multilabel plate reader (Perkin–Elmer, Turku, Finland). Results for ORAC were determined by using a regression equation relating Trolox™ concentrations and the net area under the kinetic fluorescein decay curve. The ORAC value was expressed in micromoles of Trolox equivalents per gram dry weight milk protein (μmol TE/g).

2.6. Measurement of DPPH· scavenging activity

To test the DPPH· scavenging ability of milk samples a reaction mixture containing 100 μL of each sample and 100 μL of 0.208 mM DPPH solution were prepared. The initial absorption at 515 nm was determined immediately when the reaction was initiated by gentle shaking using a Victor^3 multilabel plate reader (Perkin–Elmer, Turku, Finland). For this kinetic assay each standard and sample were measured once every minute for 1.5 h in duplicate on a 96-well plate. The relative DPPH· scavenging ability for each sample was expressed as μmol of Trolox equivalents per gram of dry weight milk protein (μmol TE/g).

2.7. Measurement of metal chelating activity

The 2,2′-bipyridyl competition assay was conducted to measure the Fe^{2+} chelating activity of each fraction (Zhou, Yin, & Yu, 2005). The reaction mixture contained 0.1 mL of 1 mM $FeSO_4$ solution, 50 μL of fraction sample, 0.3 mL of 10% hydroxylamine-HCl, 0.4 mL of 2,2′-bipyridyl solution (0.1% in 0.2 M HCl), and 0.8 mL of Tris–HCl buffer (pH 7.4). The absorbance at 522 nm was measured and used to determine Fe^{2+} chelating activity using EDTA as the reference standard. The Fe^{2+} chelating activity was expressed as mg of EDTA equivalents per gram of dry weight milk protein (mg EDTA/g) in duplicate.

2.8. Preparation of ground beef with protein hydrolysates and cooked meat samples

The milk protein hydrolysate fractions with strong ORAC or DPPH· scavenging activities were further assessed for their antioxidant activity against lipid oxidation in ground beef. To accomplish this part of the study, beef trims were obtained from the Virginia Tech Meat Laboratory, ground through a 3.175 mm plate twice and mixed for 2 min at 4 °C. The ground beef sample was vacuum-packed and stored at −20 °C until further analysis.

To determine the impact of each milk hydrolysate fraction on lipid oxidation, 250 g of the prepared ground beef was homogenised with 25 mL of diluted solution for 2 min by a macro-ultrafine generator (Virtishear 225318, The Virtis Company Inc., Gardiner, NY). The homogenised samples were placed into 50 mL centrifuge tubes, weighed, and centrifuged at 100g for 10 min to remove trapped air. Next, the beef mixtures were cooked to an internal temperature of 71 °C in a water bath (Model 10l, Fisher Scientific, Pittsburgh, PA). The internal temperature was monitored by a needle-size thermocouple inserted into the thermal centre of the tubes during cooking. The cooked meat samples incorporated with protein hydrolysate fractions were re-weighed and the weight loss was calculated. After cooling to room temperature, the cooked meat samples homogenised with select hydrolysate fractions were placed in trays, covered with PVC film, and stored at 4 °C. The extent of lipid peroxidation in each meat sample was determined by the TBARS assay on days 1, 8, and 15 post cooking.

2.9. Lipid peroxidation determination by TBARS

The thiobarbituric acid reactive substances (TBARS) assay was used for screening and monitoring lipid peroxidation of the beef samples using a previously reported protocol with slight modification (O'Keefe & Wang, 2006; Shahidi & Hong, 1991). In brief, the 6-tetramethoxypropane (TMP) standard solutions were prepared at 0.0 (blank), 2.5, 5.0, 7.5, and 10.0 μM. An amount of 5 g of each meat sample, in triplicate, were homogenised with 50 mL of distilled water, 0.1 mL of 10% sodium dodecyl sulphate (SDS), and 10 mL of solution III (0.01% propyl gallate and 0.02% ethylenediaminetetraacetic acid, EDTA). Each homogenate was thoroughly stirred and 1.0 mL of homogenate was immediately transferred into a 15 mL centrifuge tube. The homogenate or the standard solution was further mixed with 4.0 mL of a solution containing 0.4% TBA, 0.5% SDS, and 9.3% acetic acid. The mixtures were heated in 95 °C in a water bath for 60 min under shaking. After cooling, 5.0 mL of pyridine/*n*-butanol (1:15) solution was added and mixed. Following centrifugation at 10 °C, the upper organic layer was collected and measured at 532 nm on a spectrophotometer (Model 21D Spectronic, Milton Roy Co., Rochester, NY). The final unit of TBARS value was calculated with the standard curve and expressed as mg of malonaldehyde (MDA) equivalents per kilogram of sample (mg MDA equivalent/kg).

2.10. Statistical analysis

The mean values within each test were compared by a two-sample *t*-test. Data is presented as mean ± SD (standard deviation). Difference was considered statistically significant when the *P* value was < 0.05 (SPSS for Windows, version 10.0.5., 1999). A two-tailed Pearson correlation test was conducted to determine the correlations amongst means.

3. Results and discussion

3.1. Generation and fractionation of milk protein hydrolysates and degree of hydrolysis

Protease digestion of milk protein isolate was conducted under the same conditions except using different optimum pH for each enzyme which included validase (Val) from *A. oryze*, neutral protease (NP) from *B. subtilis*, and alkaline protease (AP) from *B. licheniformis*. The degrees of hydrolysis (DH) value of the milk protein isolate were 27.9%, 35.5%, and 30.7% for NP, Val, and AP, respectively (Table 1). The result suggested that all three selected micro-

Table 1
The degree of hydrolysis (DH) by three microbial proteases and the resulting protein hydrolysate fractions after sequential ultrafiltration.

Proteases	DH (%)	F1 (g) (NMWL > 10 K)	F2 (g) (NMWL: 3–10 K)	F3 (g) (NMWL: 1–3 K)	F4 (g) (NMWL < 1 K)	Total (g)
NP	27.9	3.392	4.399	2.692	1.588	12.071
Val	35.5	4.59	2.326	4.827	5.206	16.949
AP	30.7	14.346	3.602	1.913	3.002	22.863

The digestive proteases included: validase from *Aspergillus oryze* (Hernandez-Ledesma et al., 2005), neutral protease from *Bacillus subtilis* (NP), and alkaline protease from *Bacillus licheniformis* (AP). NMWL refers to the nominal molecular weight limit.

bial proteases have notable affinity and digesting efficiency for milk protein with Val resulting in the highest activity. The DH values are remarkably higher when compared to biologically relevant digestive enzymes such pepsin and trypsin (data not shown). These findings indicate that commercial microbial proteases may provide a practical option for producing potentially functional peptides from milk protein. To accomplish the experiments, the soluble protein hydrolysates from each protease were fractionated into four fractions by sequential ultra-filtration with 10, 3, and 1 kDa NMWL membranes. This ultra-filtration technique has been used for separations of food protein hydrolysates because it is both cost-effective and can be readily scaled-up; however, it is acknowledged that the membrane separation based on molecular weight is not as precise as that of gel-filtration chromatography. For NP, a total of 12.1 g of water-soluble protein hydrolysates were recovered from 50 g milk protein isolate, of which, 4.3 g penetrated the 3 kDa NMWL membrane which was designated as small peptides (F3 and F4) with F4 containing free amino acids. These small peptide fractions accounted for 35.5% of total protein hydrolysates. The Val enzyme generated approximately 16.9 g soluble protein hydrolysates in which 59.2% of the hydrolysates were small peptides. Amongst the three microbial proteases investigated, the AP generated the largest amount of the protein hydrolysates (22.9 g). The majority of AP-derived hydrolysates were the retentates after filtration with 10 kDa NMWL membrane. In particular, amongst the three tested proteases, Val exhibited the highest degree of hydrolysis on milk protein and also produced the largest amount of small peptides under similar digestive conditions. However, this does not conclusively indicate that Val is superior compared to the other proteases for hydrolysing milk protein because the digesting conditions for each individual proteases were not optimised but rather conducted under the same conditions except in regards to the optimal pH of each enzyme. It is recognised that the hydrolysing conditions, including reaction temperature, incubation time, and substrate concentration, can significantly affect the efficiency of an individual protease for specific protein substrates.

3.2. ORAC activity of milk protein hydrolysates

The ORAC assay was used to assess the capacity of the twelve obtained protein hydrolysate fractions to quench the generated peroxyl radicals; the fractions with strong activity were then identified as potential antioxidant candidates for ensuing beef-model testing of lipid peroxidation. The ORAC values of each of the protein hydrolysate fractions varied significantly ranging from 62.9 to 246.6 μmol Trolox equivalents (TE) per gram dried weight, with the majority of hydrolysate fractions ranging from 95 to 145 μmol TE/g (Fig. 1). On average, the ORAC values of the protein hydrolysates with molecular weights between 1 and 10 kDa (i.e. F2 and F3 with 159.0 and 164.6 μmol TE/g, respectively) were higher than the hydrolysates greater than 10 k Dalton (F1) with 93.6 μmol TE/g and less than 1 kDa (F4) with 98.5 μmol TE/g. The F3 fraction prepared from Val provided the highest ORAC value of 246.6 μmol TE/g which was distinctly higher than the other protein hydrolysates. Interestingly, the F4 fraction prepared from the same protease Val had the lowest ORAC value (62.9 μmol TE/g) which was 74.5% lower than that of the Val-F3 fraction. These findings are similar with previous research which demonstrated that a variety of peptides, albeit primarily produced from pepsin and pancreatin, exhibited antioxidant potential in regards to their ORAC activities (Theodore et al., 2008). Overall, the ORAC results suggest a strong potential to generate specific peptides with potent antioxidant activity by using commercial microbial proteases.

3.3. DPPH· scavenging activity

DPPH· scavenging experiments were used as a second measure for assessing the antioxidant ability of the different milk hydrolysate fractions. Similar to the ORAC results, the DPPH· scavenging activities of the hydrolysate fractions varied significantly ranging between 3.1 and 35.4 μmol TE/g (Fig. 2). The Val-F2 fraction had the strongest activity against DPPH· followed by Val-F3 and NP-F3 with 32.6 and 28.6 μmol TE/g, respectively. The AP-F1 fraction had the lowest activity (3.1 μmol TE/g). Consistent with the ORAC results, the F2 and F3 fractions, on average, had the highest antiox-

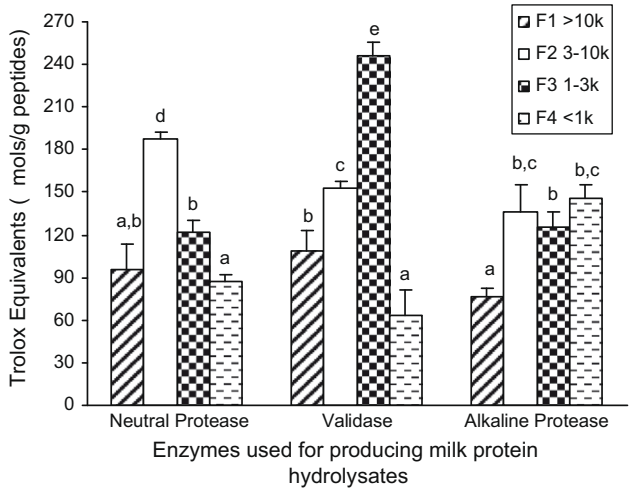

Fig. 1. Oxygen radical absorbance capacity (ORAC) values for milk hydrolysate fractions hydrolysed with three different microbial proteases. The digestion enzymes included: neutral protease (NP), validase (Val), and alkaline protease (AP). Each milk fraction of different molecular weights (F1, F2, F3, and F4 correspond to samples > 10, 3–10, 1–3, or <1 kDa, respectively) was tested in duplicate with ORAC values expressed in Trolox equivalents per gram of dry weight of milk hydrolysates (μmol TE/g). For each measurement, the data marked by different letters are significantly different ($P < 0.05$).

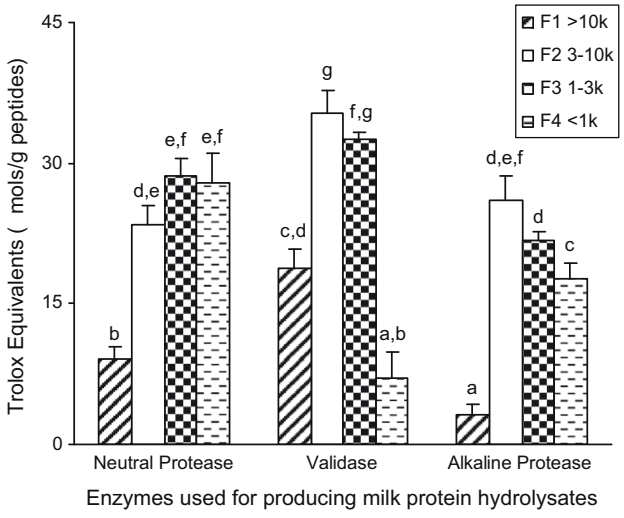

Fig. 2. DPPH· scavenging capacity for milk protein hydrolysate fractions hydrolysed with three different microbial proteases. The digestion enzymes included: neutral protease (NP), validase (Val), and alkaline protease (AP). Each milk fraction of different molecular weights (F1, F2, F3, and F4 correspond to samples > 10, 3–10, 1–3, or < 1 kDa, respectively) was tested in triplicate with the DPPH· scavenging ability expressed in Trolox equivalents per gram of dry weight of milk protein (μmol TE/g). For each measurement, the data marked by different letters are significantly different ($P < 0.05$).

idant activity as compared to the F1 and F4 milk hydrolysate fractions. However, there was no significant correlation detected between the ORAC and the DPPH· scavenging activities. This may be due to the possibility that the peptides were involved in separate redox scavenging mechanisms such as electron transfer (ET) whilst interacting with DPPH· radicals, whilst the ORAC assay was conducted based on hydrogen atom transfer (HAT) reactions. As such, a report of higher ORAC activity does not necessarily suggest a stronger DPPH· scavenging ability. The type of enzyme employed in protein hydrolysis has been reported to influence antioxidant potential. For example, Cumby and colleagues prepared canola protein hydrolysates using commercial enzymes (i.e. Alcalase and Flavourzyme) and reported that the hydrolysates exhibited notable antioxidant activity as determined by the DPPH radical scavenging capacity and reducing power assays (Cumby et al., 2008). The hydrolysate prepared using Flavourzyme exhibited higher antioxidant activity than those prepared using a combination of the two enzymes, or Alcalase alone. The authors suggested that the enzyme used for protein hydrolysis will impact antioxidant potential due in part to the mechanism of action of enzyme and subsequent presence or absence of functional groups such as hydroxyl groups on phenolic compounds (Cumby et al., 2008). Taken as a whole, our results and others indicate that the type of enzyme employed in the hydrolysis process will impact the antioxidant capacity of the hydrolysates.

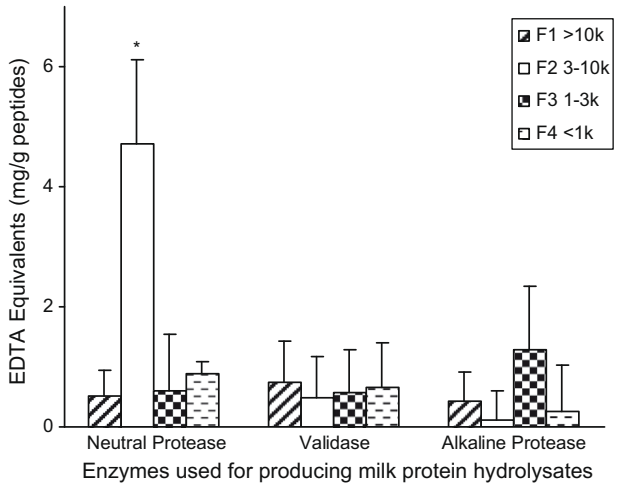

Fig. 3. Metal chelating activity for milk protein hydrolysate fractions hydrolysed with three different microbial proteases. neutral protease (NP), validase (Val), and alkaline protease (AP). Each milk fraction of different molecular weights (F1, F2, F3, and F4 correspond to samples > 10, 3–10, 1–3, or < 1 kDa, respectively) was tested in triplicate were the Fe^{2+} metal chelating activity was expressed as mg EDTA equivalents per gram of dry weight (mg EDTA/g). For each measurement, the data marked by different letters are significantly different ($P < 0.05$).

3.4. Metal chelating activity

Transitional metals are well-known promoters of lipid oxidation and their chelation facilitates in the delay of peroxidation and subsequently prevent food rancidity. Thus the assessment of metal chelating activity is an important measure of antioxidant properties. The ability of the protein hydrolysates to chelate transition metal ions was tested by assessing Fe^{2+} ion chelation with ethylenediaminetetraacetic acid (EDTA) as a positive control. The results showed that most hydrolysate fractions exerted weak chelating activities of 0.1–0.9 mg EDTA equivalents/g and there was no significant difference detected amongst these fractions except for the NP-F2 sample (Fig. 3). Under our experimental conditions, the NP-F2 was the only milk protein hydrolysate fraction that exerted a remarkably higher chelating activity (4.7 mg EDTA equivalents/g). Similar to these findings, previous studies have demonstrated that certain food-derived peptides such as caseinophospho peptides (CPP) and protein hydrolysates possess weak to moderate chelating activities (Diaz et al., 2003; Theodore et al., 2008). For example, the sunflower protein hydrolysates, after Alcalase and Flavourzyme digestion, were shown to inhibit beta-carotene oxidation induced by copper (Megias et al., 2007). Canola protein hydrolysates prepared using Alcalase and Flavourzyme also possessed significant DPPH· scavenging activities (Cumby et al., 2008). These results suggest that the NP-F2 sample warrants further investigation into the characterisation of its potentially active constituents involved in Fe^{2+} chelating activities. Once identified and analysed these particular peptides may have functional utility in emulsions and other lipid food applications in the food industry.

3.5. Lipid peroxidation in cooked beef

Lipid-rich products such as meat have been widely used as food models to evaluate the potential of functional agents in preventing or reducing lipid oxidation. For our study, cooked ground beef was prepared in order to determine whether peptides with notable antioxidant properties (as determined by ORAC, DPPH·, and Fe^{2+} chelating activities) can effectively inhibit lipid peroxidation in lipid-rich meat samples. After analysing the antioxidant and metal chelating data, three protein hydrolysate fractions, Val-F2, Val-F3, and NP-2, were selected for additional evaluation of their inhibitory activity on lipid oxidation in ground beef. The effects of the selected peptides on the lipid oxidation of the ground beef at different storage times are presented in Table 2. As reflected by the TBARS results, there was clear indication of lipid peroxidation in the beef samples which progressively increased as a function of storage time. For instance, at day 1, all the meat samples had experienced some degree of lipid peroxidation with the TBARS concentration varying from 7.6 to 11.4 mg MDA equivalents/kg of beef. Amongst the treatments with the selected hydrolysate mix-

Table 2
Lipid peroxidation determined by TBARS assay in cooked beef after treatments with the selected protein hydrolysate fractions at three different storage times post cooking.

Selected Fractions	Concentration in the meat (μg/g)	TBARS (mg/kg) at different storage time		
		Day 1	Day 8	Day 15
Control	0	11.35 ± 1.14	32.66 ± 1.74	44.49 ± 2.16
Val-F3	200	7.64* ± 1.24	21.71* ± 1.04	28.69* ± 1.03
Val-F3	800	9.57* ± 1.03	33.87 ± 1.67	41.82 ± 1.92
Val-F2	200	10.60 ± 0.47	31.29 ± 3.41	41.47 ± 1.35
Val-F2	800	10.79 ± 1.24	35.04 ± 0.48	40.54 ± 0.75
NP-F2	200	10.46 ± 0.86	32.55 ± 1.47	43.12 ± 1.83
NP-F2	800	11.01 ± 0.94	33.41 ± 1.24	41.13 ± 1.51

The final unit of TBARS value was calculated with the standard curve and expressed as mg of malonaldehyde equivalent per kilogram of sample (mg MDA equivalent/kg). The data marked by an asterisk is significantly different as compared to the control meat sample ($P < 0.05$).

tures, the treatment doses of 200 and 800 μg/g with the Val-F3 significantly ($P < 0.05$) reduced the meat lipid peroxidation at day 1. For the same measurements at day 1, the Val-F2 and NP-2 samples revealed a slight tendency to reduce lipid peroxidation in the meat but the effects did not achieve statistical significance. Interestingly, Val-F3 at a concentration of 200 μg/g appeared more effective in inhibiting oxidation than at a higher concentration of 800 μg/g. At days 8 and 15, the treatment doses of 200 μg/g with the Val-F3 sample continued to have a pronounced inhibitory effect on lipid oxidation in the meat in which the TBARS concentrations were significantly reduced by 33.5% and 35.6% compared to the control, respectively. However, at the storage day 8 and 15 under the 800 μg/g treatment condition, the Val-F3 sample did not enhance but rather reduced the inhibition on lipid oxidation of the meat. This result was reflected by a significantly higher TBARS values associated with the 800 μg/g treatment compared to 200 μg/g treatment condition. These observations indicate that Val-F3 was a more effective antioxidant at lower concentration. It is known that some antioxidants at high concentration may promote or may accelerate the rate of autoxidation (Pratt, 1996). For instance, previous studies have shown that vitamin E in the presence of transitional metals (Maiorino, Zamburlini, Roveri, & Ursini, 1993) and some phenolic compounds at higher concentration exerted pro-oxidant effects (Laughton, Halliwell, Evans, & Hoult, 1989; Sakihama, Cohen, Grace, & Yamasaki, 2002). Therefore, further experiments are needed in order to clarify and determine the appropriate dose of Val-F3 needed for improving the quality of meat-based products in regards to antioxidant activity without initiating an pro-oxidant scenario. In summary, the results demonstrate the usefulness of specific microbial proteases such as validase from *A. oryze* for generating potentially useful functional peptides with antioxidant application. Continued enzyme hydrolysis research efforts are warranted in order to development natural antioxidant peptides for utility in improving the quality and shelf-life of food products.

Mediators of inflammation
Mice

ABSTRACT

The anti-inflammatory effects of the crude extract (CE) of *Lotus corniculatus* var. São Gabriel and its derived hexane (HEX), ethyl acetate (AcOEt), *n*-butanol (BuOH) and aqueous (Aq) fractions and isolated compounds kaempferitrin, oleanolic acid and β-sitosterol, in a mouse model of pleurisy induced by carrageenan were investigated. Swiss mice were used in the *in vivo* experiments. The crude extract of *L. corniculatus* and its derived fractions, and also its isolated compounds, inhibited leukocytes, exudation, and myeloperoxidase (MPO) and adenosine-deaminase (ADA) activities, as well as nitrite/nitrate concentration and interleukin-1 beta (IL-1β) level ($p < 0.05$). *L. corniculatus* showed important anti-inflammatory activity by inhibition not only of leukocytes and/or exudation, but also of pro-inflammatory enzymes and mediators such as MPO, ADA, and IL-1β. The constituent's kaempferitrin, oleanolic acid and β-sitosterol may well account for it.

1. Introduction

Plants are a good source of useful anti-inflammatory agents. The continuing search for novel anti-inflammatory substances especially from plants with historically documented or pharmacological properties holds considerable nutraceutical and/or pharmaceutical promise (Kaplan et al., 2007). *Lotus corniculatus* var. São Gabriel (Fabaceae), also known as "Cornichão" in Brazil, is a plant used as a ruminant feed since it promotes an important increase in essential amino acid absorption (Waghorn, Ulyatt, John, & Fisher, 1987), ovulation rate, and production of milk protein and lactose (Wang, Douglas, Waghorn, Barry, & Foote, 1996). This herb is also used as an important anti-helmintic substance in these animals (Aerts, Barry, & McNabb, 1999).

Studies had demonstrated that these effects are due to the presence of secondary metabolites named proanthocyanidins, or condensed tannins (Xie & Dixon, 2005). The proanthocynidins also have important antioxidant (Kandil et al., 2002), immunomodulatory (Lin, Kuo, & Chou, 2002), analgesic and anti-inflammatory effects (Subarnas & Wagner, 2000).

Previous investigations into the chemical composition of this herb have identified the following compounds: flavonoids (kaempferol and quercetin) (Reynaud & Lussignol, 2005), oleanolic acid and saponins (Walter, 1961). Studies have also reported that kaempferol and quercetin modulate the inducible nitric oxide synthase (iNOS), cyclooxygenase-2 (COX-2), reactive C-protein (CRP), and nuclear factor kappa B (NF-κB) (García-Mediavilla et al., 2007). Other studies have shown that oleanolic acid and saponins possess anti-inflammatory, (Giner-Larza et al., 2001; Wang, Gao, Kou, Zhu, & Yu, 2008) and antitumoral properties (Chen et al., 2008; Wang, Zhang et al., 2008).

Motivated by rare studies of the anti-inflammatory properties of *L. corniculatus*, the crude extract and derived fractions of this herb was studied by analyzing its effects upon leukocyte migration, exudation concentration and myeloperoxidase/adenosine-deaminase activities, as well as nitrite/nitrate concentration and interleukin-1 beta levels, in the inflammation induced by carrageenan in the mouse model of pleurisy. We also isolated and identified the components from *L. corniculatus* that were responsible for the anti-inflammatory activity.

2. Material and methods

2.1. Plant material

L. corniculatus L. var. São Gabriel was collected in November 2006 in Lages, Santa Catarina State, Brazil. The material was identified by the botanist Prof. Dr. Daniel de Barcelos Falkenberg at the Department of Botany of the Federal University of Santa Catarina, Florianópolis, SC, Brazil. A voucher specimen was deposited in the Herbarium at the same university (FLOR 18.770).

2.2. Preparation of plant extracts

The aerial parts of *L. corniculatus* var. São Gabriel were air-dried and protected from light at room temperature (25 °C) for one week. Subsequently the dried aerial parts (620 g) were grounded into particles (1.5 mm) using a knife mill (Mill TE-651, Tecnal, Piracicaba, SP, Brazil). The ground material was extracted with 5 L of ethanol 96% (plant 1:8, w/v) at room temperature. After two days, the extract obtained was filtered (Watmann, no. 1) and the ethanol was removed by rotavapor (Fisatom-802, São Paulo, SP, Brazil) at 55 °C under reduced pressure (460 mm Hg) (Vacuum Q-355A2, Quimis, Diadema, SP, Brazil). This procedure was repeated fifteen times in a period of one month to obtain the maximal yield of the crude extract (78 g).

The CE was fractionated by liquid–liquid extraction using solvents in growing order of polarity, resulting in hexane (HEX: 7.82 g), ethyl acetate (AcOEt: 11.4 g), *n*-butanol (BuOH: 5.24 g) and aqueous (Aq: 30.8 g) fractions.

2.3. Preliminary phytochemical analysis

A preliminary phytochemical screening of the crude extract of *L.* corniculatus was carried out according to Harborne (1998) to detect the presence of phenols, tannins, anthocyanins, anthocyanidins, flavonoids, xanthones, steroids, triterpenes and saponins. In these protocols we used the following reactions: the cyanidin test or Shinoda's test for flavonoids, anthocyanins and anthocyanidins; the Lieberman-Burchard reactions for sterols and triterpene; Stanishy's reaction to characterize the presence of condensed tannins and hydrolyzed tannins; the foam formation test to detect the presence of saponnins and finally for xanthones using chloridic acid and metallic magnesium, in which the appearance of red colour indicates the presence of xanthones (Harborne, 1998).

2.4. Isolation and identification of the compounds

The hexane fraction was subjected to silica gel column chromatography and eluted with a gradient of HEX/EtOAc, resulting in the isolation of two terpenoids: β-sitosterol as colourless crystals, m.p 137–139 °C, 76 mg, from fraction eluted with HEX/EtOAc (90:10, v/v), and oleanolic acid, as a white powder, m.p. 279–282 °C, 25 mg, from HEX/EtOAc (70:30, v/v). The chromatographic fractionation on silica gel of the EtOAc fraction afforded a crude flavonoid from EtOAc/EtOH (50:50, v/v) eluate that was further purified by flash chromatography using ethyl acetate/water/formic acid/acetic acid (70:20:3:2, v/v/v/v) as eluent, yielding 45 mg of kaempferitrin as a yellow needle crystals, m.p. 198.5–201.3 °C. The structures of the known compounds were identified by their spectroscopic data (^{1}H NMR, ^{13}C NMR (Varian AS-400 – Palo-Alto, CA, USA), and IR – Perkin Elmer FTIR 16 PC, Beaconsfield, England) measurement, comparison with spectral data obtained from the literature (Hung & Yen, 2001; Uurgoankar & Shaw, 2007), and co-TLC with authentic samples.

2.5. Structure elucidation of the compounds

The chemical structure of each isolated compound was determined on the basis of its physical characteristics, spectral data produced by infrared analysis (Perkin Elmer FTIR 16 PC, Beaconsfield, England) and nuclear magnetic resonance (^{1}H and ^{13}C NMR) recorded on a Varian AS-400 (Palo-Alto, CA, USA) spectrometer operating at 400 and 100 MHz, respectively. Thin Layer Chromatography (TLC) was carried out on silica gel 60 F_{254} plates (Macherey-Nagel, Düren, Germany). Finally, the structures of the compounds isolated were confirmed by comparing with reference data previously reported from available reliable sources.

2.6. Animals

Swiss mice, weighing 18–25 g, were housed under standardized conditions (room at constant temperature (22 ± 2 °C) with alternating 12 h periods of light and darkness), humidity 50–60%, and they were fed on a standard mouse diet with water *ad libitum* before use. This study was approved by the Committee for Ethics in Animal Research of the Federal University of Santa Catarina (Protocol number – PP00180), and experiments were performed in accordance with the norms of the Brazilian College of Animal Experimentation.

2.7. Experimental protocol

Initially, for analysis of the dose–response curve, different groups of animals were treated with different doses of crude extract (CE: 100–400 mg/kg) of *L. corniculatus* var. São Gabriel or its derived fractions or isolated compounds: hexane fraction (HEX: 50–200 mg/kg), ethyl acetate fraction (AcOEt: 100–400 mg/kg), *n*-butanol fraction (BuOH: 50–200 mg/kg), aqueous fraction (Aq: 25–200 mg/kg), kaempferitrin (50 and 100 mg/kg), oleanolic acid (10–100 mg/kg) or β-sitosterol (10–100 mg/kg) administered by intraperitoneal route (i.p.) 0.5 h before pleurisy induction by carrageenan (Cg 1%) that was administered by intrapleural route (i.pl.). In parallel, some animals received an injection of either sterile saline (NaCl, 0.9%) (negative – control group) or carrageenan (positive – control group) administered by intrapleural (i.pl.) route. After 4 h the animals were killed with an overdose of ether, the thorax was opened, and the pleural cavity was washed with 1.0 mL of sterile phosphate buffered saline (PBS) (pH 7.6), composition: NaCl (130 mmol), Na_2HPO_4 (5 mmol), KH_2PO_4 (1 mmol) and distillated water (1000 ml) containing heparin (20 IU/mL). Leukocytes and exudation were then evaluated.

In another set of experiments employed to establish the time course profile, different groups of animals were pre-treated with a single dose of CE (200 mg/kg), HEX (100 mg/kg), AcOEt (200 mg/kg), BuOH (100 mg/kg), Aq (100 mg/kg), kaempferitrim (100 mg/kg), oleanolic acid (50 mg/kg) or β-sitosterol (50 mg/kg) administered at different time points (0.5–4 h) and the same inflammatory parameters were evaluated 4 h after carrageenan administration.

After choosing the best dose and period of pre-treatment required for the crude extract of *L. corniculatus* and its derived fractions, as well as its isolated compounds, that inhibit leukocytes and/or exudation, different groups of animals were treated with CE (200 or 400 mg/kg), HEX (100 or 200 mg/kg), AcOEt (200 or 800 mg/kg), BuOH (100 mg/kg), Aq (50 or 400 mg/kg), kaempferitrin (100 mg/kg), oleanolic acid (50 mg/kg) or β-sitosterol (50 mg/kg) administered 0.5 h prior to pleurisy induction to analyze their effects upon myeloperoxidase (MPO) and adenosine-deaminase (ADA) activities, as well as nitrite/nitrate concentration (NO^x) and interleukin-1 beta (IL-1β) levels.

Dexamethasone (potent inhibitor of phospholipase A_2, of the expression of both induced NOS and of COX-2, among others, 0.5 mg/kg) and indomethacin (cyclooxygenase inhibitors, 5 mg/kg, i.p.) administered by intraperitoneal route (i.p.) 0.5 h before pleurisy induction, were used as anti-inflammatory drugs.

2.8. Quantification of leukocyte migration and exudation

After killing the animals, samples of the fluid leakage of the pleural cavity were collected to determine the total and differential leukocyte contents, and exudation. Total leukocyte counts were determined in a Newbauer chamber, and cytospin preparations of fluid leakage were stained with May-Grünwald-Giemsa for the differential count (Saleh, Calixto, & Medeiros, 1996). The degree

of exudation was determined by measuring the amount of Evans blue dye extravasation. Thus, in each experimental group, animals were challenged 0.5 h before the inflammation induction with a solution of Evans blue dye (25 mg/kg) administered by intravenous route (i.v.) in order to evaluate the exudation in the pleural cavity. On the day of the experiment, a batch of stored samples was thawed at room temperature and the amount of dye was estimated by colorimetric using an ELISA plate reader (Organon Teknika, Roseland, NJ, USA) at 620 nm, by interpolation from a standard curve of Evans blue dye in the range of 0.01–50 μg/mL.

2.9. Quantification of nitrite/nitrate concentration

Nitric oxide and its breakdown products nitrite (NO_2^-) and nitrate (NO_3^-) were measured using the Griess method (Green et al., 1982). Samples of exudates from the pleural cavity were collected, separated and stored at −20 °C. Nitrite/nitrate concentration was determined and the concentrations were estimated by means of colorimetric measurement at 450 nm on an ELISA plate reader (Organon, Teknika, Roseland, NY, USA) by interpolation from a standard curve (0–150 μM). The results were expressed as μM.

2.10. Quantification of myeloperoxidase activity

Standard samples with different concentrations of myeloperoxidase (from human neutrophils, Sigma: M6908, St. Louis, MO, USA) were prepared in order to obtain a standard curve in the range of 0.07–140 mU/mL. Pleural cavity fluid samples (40 μL) and standards were transferred to cuvettes and the reaction was initiated with the addition of 360 μL of assay buffer (0.167 mg/mL of *o*-dianisidine (3,3′-dimethoxybenzidine; fast blue B) dihydrochloride and 0.0005% H_2O_2). The reaction was stopped with sodium azide 1%. Afterwards, the samples were centrifuged at 50*g* for 5 min, the supernatants were separated, and the rates of changes in absorbance at 520 nm were determined. The mieloperoxidase activity was estimated by interpolation from the standard curve by means of colorimetric measurements on an ELISA plate reader (Organon Teknika, Roseland, NJ, USA) (Rao, Curie, Shaffer, & Isakson, 1993). The results were expressed as mU/mL.

2.11. Quantification of adenosine deaminase activity

Initially, standard samples (final volume of 500 μL) with different volume concentrations of $NaH_2PO_4{\cdot}H_20$ (35 mM), $Na_2HPO_4{\cdot}H_2O$ (15 mM) and NH_3SO_4 (15 mM) were prepared in order to obtain a standard curve in the range of 10–50 U/L. Pleural cavity fluid samples (20 μL) were transferred to cuvettes and the reaction was initiated by the addition of adenosine phosphate buffered solution (pH 6.5, 500 μL, composition: $NaH_2PO_4{\cdot}H_2O$ (35 mM), $Na_2HPO_4{\cdot}12H_2O$ (15 mM) and adenosine (0.5 mM)). After incubation for 1 h at 37 °C, the reaction was halted with the addition of a solution (1000 μL) of phenol (1 mM) and nitroprussiate (0.17 mM), plus alkaline buffer (1000 μL: NaCl: 11 mM). This solution (final volume 2000 μL) was also added to the cuvettes with the different standard samples. Afterwards, the rate of change in absorbance at 620 nm was determined. ADA activity was estimated by interpolation from the standard curve by means of colorimetric measurements on an ELISA plate reader (Organon Teknika, Roseland, NJ, USA) (Giusti & Galanti, 1984). The results were expressed as U/L.

2.12. Quantification of IL-1β levels

For analysis of IL-1β levels, samples of exudates were collected and immediately prepared for the analysis of cytokine levels. In this protocol, commercially available kits were used with monoclonal-specific antibodies for each cytokine. The cytokine level was measured by enzyme-linked immunosorbent assay (ELISA), using the kits according to the manufacturers' instructions. The range of values detected by this assay was: IL-1β (100–6400 pg/mL). The intra- and inter-assay coefficients of variation (CV) for IL-1β were: intra CV: IL-1β = 6.2 ± 0.4%; inter CV: IL-1β = 5.1 ± 0.6%, with a sensitivity value of IL-1β = 1.7 pg/mL. The cytokine concentration was estimated by means of colorimetric measurements at 450 nm on an ELISA plate reader (Organon Teknika, Roseland, NJ, USA) by interpolation from a standard curve.

2.13. Drugs

The following drugs and reagents were used: carrageenan (degree IV), human neutrophil myeloperoxidase, indomethacin, (Sigma Chemical Co., St. Louis, MO, USA), dexamethasone, (Ache pharmaceutical laboratories S.A., São Paulo, SP, Brazil), and Enzyme-linked immunosorbent assay (ELISA) for quantitative determination of rat IL-1β. Organic solvents: acetone, chloroform, *n*-hexane, ethyl acetate, *n*-butanol, methanol, and ethanol, all analytical grade, were purchased from Synth (Diadema, SP, Brazil). Other reagents used were also of analytical grade and were obtained from different commercial sources.

2.14. Statistical analysis

The data is reported as the mean ± SEM. Significant differences between groups were determined by two-way analysis of variance (ANOVA) followed by Student's-Newman-Keuls post-hoc tests, and the significant difference was set at $p < 0.05$.

3. Results

3.1. Phytochemical analysis

In this study, preliminary phytochemical analysis showed that the crude extract of *L. corniculatus* var. São Gabriel contained a significant amount of flavonoids, steroids and terpenoids. Representing the steroids and terpenoids classes, we isolated the β-sitosterol (compound **1**) (Fig. 1) and the oleanolic acid (compound **2**) (Fig. 2) from hexane fraction. In the ethyl acetate fraction, the flavonoid *O*-heteroside kaempferitrin (compound **3**) (Fig. 3) as representative of flavonoids was isolated. These compounds isolated from the specie *L. corniculatus* not reported previously to this variety. β-Sitosterol represented 2.08% and the oleanolic acid 0.67% of the hexane fraction. Further, the kaempferitrin represented 0.51% of the ethyl acetate fraction.

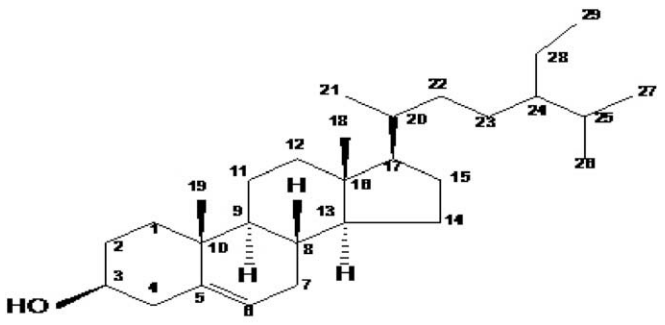

Fig. 1. The chemical structure of compound **1** (β-sitosterol) isolated from *n*-hexane fraction of *Lotus corniculatus* var. São Gabriel (Fabaceae) aerial parts.

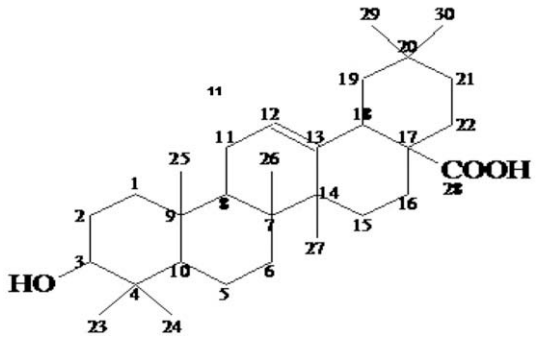

Fig. 2. The chemical structure of compound **2** (oleanolic acid) isolated from *n*-hexane fraction of *Lotus corniculatus* var. São Gabriel (Fabaceae) aerial parts.

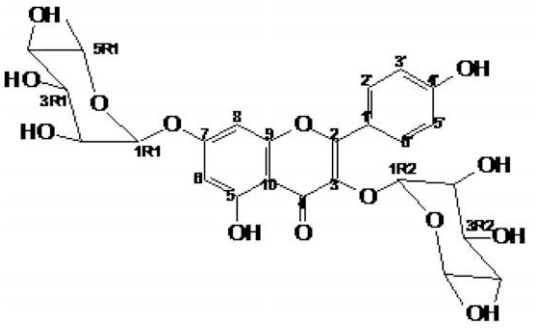

Fig. 3. The chemical structures of compound **3** (kaempferitrin) isolated from ethyl acetate fraction of *Lotus corniculatus* var. São Gabriel (Fabaceae) aerial parts.

3.2. Effects of crude the extract of L. corniculatus var. São Gabriel, its derived fractions and isolated compounds upon leukocyte migration and exudation

The crude extract of *L. corniculatus* (CE: 200 and 400 mg/kg) significantly decreased leukocyte migration from 38.7 ± 5.8% to 48.0 ± 7.7% ($p < 0.01$), neutrophils from 37.7 ± 5.2% to 46.4 ± 8.4% ($p < 0.01$), mononuclears from 44.2 ± 9.4% to 57.3 ± 11.6% ($p < 0.05$), and exudation from 25.4 ± 5.3% to 50.5 ± 2.2% ($p < 0.05$). CE (100 mg/kg) did not modify the studied inflammatory parameters ($p > 0.05$) (Table 1).

The hexane fraction (HEX: 100 and 200 mg/kg) significantly suppressed leukocytes from 26.1 ± 5.0% to 53.2 ± 12.5% ($p < 0.01$) and neutrophils from 21.8 ± 6.7% to 68.3 ± 17.3% ($p < 0.05$). HEX (100 mg/kg) also inhibited mononuclears by 45.5 ± 12.2% ($p < 0.05$) and at the dose of 200 mg/kg, HEX also inhibited exudation by 51.7 ± 12.0% ($p < 0.05$). The HEX fraction (50 mg/kg) did not alter any of the studied inflammatory parameters ($p > 0.05$) (Table 1).

The ethyl acetate fraction (AcOEt: 200 and 400 mg/kg) produced a significant inhibition of leukocyte migration from 21.0 ± 6.5% to 41.9 ± 8.7% ($p < 0.05$), neutrophils from 20.9 ± 7.4% to 56.1 ± 5.8% ($p < 0.05$) and exudation from 33.6 ± 6.6% to 34.8 ± 10.9% ($p < 0.05$). Nevertheless, the AcOEt fraction (100 mg/kg) did not inhibit these inflammatory parameters ($p > 0.05$). Mononuclears also were not inhibited by the AcOEt fraction ($p > 0.05$) (Table 1).

The *n*-butanol fraction (BuOH: 100 and 200 mg/kg) produced a significant decrease of leukocytes from 34.9 ± 9.1% to 39.2 ± 4.9% ($p < 0.01$) and neutrophils from 36.0 ± 5.8% to 36.3 ± 8.8% ($p < 0.01$). The BuOH fraction (200 mg/kg) also decreased mononuclears by 54.8 ± 6.2% ($p < 0.05$), and the dose of 50 mg/kg did not vary the leukocyte content ($p > 0.05$), but caused a significant enhancement of exudation by 50.7 ± 16.0% ($p < 0.05$) (Table 1).

The aqueous fraction (Aq: 50–200 mg/kg) caused a significant inhibition of leukocytes from 31.6 ± 8.1% to 43.0 ± 5.8% ($p < 0.05$), and neutrophils from 30.7 ± 8.5% to 44.2 ± 6.7% ($p < 0.01$), but failed to reduce mononuclears ($p > 0.05$). The Aq fraction (200 mg/kg) was also effective in inhibiting exudation by 44.7 ± 3.8% ($p < 0.05$). The doses of 25 and 50 mg/kg of this fraction increased exudation from 31.4 ± 12.3% to 38.2 ± 5.9% ($p < 0.05$). The Aq fraction (25 mg/kg) also did not inhibit total and differential leukocytes ($p > 0.05$) (Table 1).

The study of the effect of the isolated compounds showed that kaempferitrin, at the dose of 100 mg/kg, was also effective in sig-

β-Sitosterol 100[b]	4.10 ± 0.60**	3.22 ± 0.60**	0.88 ± 0.30	9.38 ± 1.70
Dex 0.5[b]	1.75 ± 0.30**	1.33 ± 0.20**	0.44 ± 0.10**	6.51 ± 0.50**
Indo 5[b]	2.26 ± 0.30**	1.78 ± 0.20**	0.48 ± 0.20*	7.93 ± 0.50*

Kaempferitrin (50 and 100 mg/kg), oleanolic acid (10–100 mg/kg) and β-sitosterol (10–100 mg/kg) isolated from *Lotus corniculatus* administered 0.5 h before the pleurisy induction by carrageenan (1%). C = response in animals treated only with carrageenan. Dex = response in animals pre-treated with dexamethasone (0.5 mg/kg). Indo = r-esponse in animals pre-treated with indomethacin (5.0 mg/kg). $^{*}p < 0.05$ and $^{**}p < 0.01$. The data is reported as the mean ± SEM. a = administered by intrapleural route, b = administered by intraperitoneal route. $n = 5$ animals.

nificantly inhibiting leukocytes by 35.5 ± 8.0% and neutrophils by 33.7 ± 8.8% ($p < 0.05$) (Table 2).This compound (50 and 100 mg/kg) also inhibited mononuclears by 65.2 ± 20.9% and 43.5 ± 5.7%, and exudation by 33.3 ± 9.8% and 37.0 ± 3.3% ($p < 0.05$) (Table 2).

The oleanolic acid (25–100 mg/kg) significantly suppressed leukocytes from 21.2 ± 5.8% to 52.4 ± 11.2% ($p < 0.05$) and neutrophils from 27.9 ± 7.5% to 71.6 ± 2.8% ($p < 0.05$). This compound failed to change mononuclears ($p > 0.05$). The dose of 10 mg/kg of this compound did not inhibit the inflammation caused by carrageenan ($p > 0.05$). Under the same conditions, oleanolic acid (25 and 50 mg/kg) reduced exudation levels from 35.3 ± 1.9% to 42.6 ± 3.9% ($p < 0.05$) (Table 2).

The β-sitosterol (25–100 mg/kg) significantly decreased leukocytes from 15.1 ± 1.9% to 33.9 ± 9.4% ($p < 0.05$) and neutrophils from 19.1 ± 2.9% to 36.7 ± 12.6% ($p < 0.05$). This compound did not modify mononuclears ($p > 0.05$), but at doses of 25 and 50 mg/kg it significantly inhibited the exudation from 28.2 ± 10.0% to 33.1 ± 2.3% ($p < 0.05$). The dose of 10 mg/kg did not vary the inflammatory parameters ($p > 0.05$) (Table 2).

The time course profile for the crude extract of *L. corniculatus* and its derived fractions, as well as its isolated compounds, showed that they were effective in inhibiting the studied inflammatory parameters when they were administered 0.5 h before carrageenan. It is important to note that the BuOH fraction (100 mg/kg), as well as the AcOEt fraction (200 mg/kg), had a long-lasting anti-inflammatory effect, since they were able to decrease the inflammation caused by carrageenan for up to 2 h of pre-treatment (results not shown).

As expected, dexamethasone (0.5 mg/kg, i.p.) and indomethacin (5.0 mg/kg, i.p.) significantly inhibited leukocytes by 71.7 ± 5.0% and 63.5 ± 5.0% ($p < 0.01$), neutrophils by 73.8 ± 4.2% and 64.9 ± 5.0% ($p < 0.01$), mononuclears by 60.7 ± 2.0% and 57.1 ± 1.0% ($p < 0.05$), and exudation by 43.3 ± 7.8% and 31.0 ± 5.0% ($p < 0.05$), in the inflammation response induced by carrageenan, respectively (Tables 1 and 2).

3.3. Effects of the crude extract of L. corniculatus var. São Gabriel, its derived fractions and isolated compounds upon myeloperoxidase and adenosine-deaminase activities

The pre-treatment (0.5 h) of animals with crude extract of *L. corniculatus* and its derived fractions, and also its isolated compounds, caused a significant decrease in myeloperoxidase (% of inhibition: CE (200 mg/kg): 63.7 ± 6.0, HEX (100 mg/kg):

Table 3
Effects of crude extract of *Lotus corniculatus*, its derived fractions and isolated compounds upon myeloperoxidase and adenosine-deaminase activities, and IL-1β levels in the inflammation induced by carrageenan in the mouse model of pleurisy.

Groups/doses (mg/kg)	MPO (mU/mL)	ADA (U/L)	IL-1β (pg/mL)

Oleanolic acid 50[b]	182.00 ± 72.20**	8.23 ± 3.70	1870.00 ± 229.00*
β-Sitosterol 50[b]	85.80 ± 56.30**	3.06 ± 0.60**	1040.00 ± 213.00
Dex 0.5[b]	135.80 ± 14.60**	2.80 ± 0.70**	516.00 ± 47.30*
Indo 5[b]	120.10 ± 13.70**	3.48 ± 0.10**	586.00 ± 20.00*

The crude extract (CE: 200 mg/kg) of *Lotus corniculatus* and its derived fractions, hexane fraction (HEX: 100 mg/kg), ethyl acetate fraction (AcOEt: 200 mg/kg), *n*-butanol fraction (BuOH: 100 mg/kg) or aqueous fraction (Aq: 50 or 100 mg/kg), and isolated compounds, kaempferitrin (100 mg/kg), oleanolic acid (50 mg/kg) and β-sitosterol (50 mg/kg) administered 0.5 h before the inflammation induction by carrageenan (1%). C = response in animals treated only with carrageenan. Dex = response in animals pre-treated with dexamethasone (0.5 mg/kg). Indo = response in animals pre-treated with indomethacin (5.0 mg/kg). $^{*}p < 0.05$ and $^{**}p < 0.01$. The data is reported as the mean ± SEM. a = administered by intrapleural route, b = administered by intraperitoneal route. $n = 5$ animals.

47.4 ± 11.6, AcOEt (200 mg/kg): 57.9 ± 4.4, Aq (100 mg/kg): 34.3 ± 12.6, kaempferitrin (100 mg/kg): 90.6 ± 3.4, oleanolic acid (50 mg/kg): 45.5 ± 21.6 and β-sitosterol (50 mg/kg): 73.0 ± 13.1) ($p < 0.05$), and adenosine-deaminase activities (% of inhibition: CE (200 mg/kg): 67.5 ± 6.8, HEX (100 mg/kg): 54.4 ± 15.0, AcOEt (200 mg/kg): 94.0 ± 1.4, BuOH (100 mg/kg): 67.1 ± 9.0, Aq (50 mg/kg): 64.5 ± 8.8, kaempferitrin (100 mg/kg): 77.1 ± 7.9, β-sitosterol (50 mg/kg): 68.7 ± 6.0) ($p < 0.01$), except for the BuOH fraction that did not inhibit MPO, and oleanolic acid that did not decrease ADA activities ($p > 0.05$) (Table 3).

Dexamethasone and indomethacin were effective in inhibiting myeloperoxidase by 59.4 ± 7.0% and 64.4 ± 7.0% ($p < 0.01$), and adenosine-deaminase activities by 71.4 ± 6.0% and 64.4 ± 6.0%, respectively ($p < 0.05$) (Table 3).

3.4. Effects of the crude extract of L. corniculatus var. São Gabriel, its derived fractions and isolated compounds upon IL-1 levels

The crude extract of *L. corniculatus* and its derived fractions, as well as its isolated compounds, caused a significant decrease of IL-1β (% of inhibition: CE (200 mg/kg): 24.9 ± 6.9, HEX (100 mg/kg): 43.2 ± 8.6, AcOEt (200 mg/kg): 36.9 ± 24.0, BuOH (100 mg/kg): 38.1 ± 17.2, Aq (100 mg/kg): 35.9 ± 2.6, and kaempferitrim (100 mg/kg): 61.1 ± 13.8) ($p < 0.05$). The oleanolic acid (50 mg/kg) caused a significant increase of the IL-1β levels by 61.4 ± 19.7% ($p < 0.05$), and β-sitosterol (50 mg/kg) did not alter the IL-1β level ($p > 0.05$) (Table 3).

Dexamethasone and indomethacin also significantly inhibited the IL-1β level by 55.5 ± 6.0% and 49.8 ± 6.0%, respectively ($p < 0.05$) (Table 3).

3.5. Effects of the crude extract of L. corniculatus var. São Gabriel, and its derived fractions and isolated compounds upon nitrite/nitrate concentration

Although the best dose of the crude extract of *L. corniculatus* and its derived fractions was determined, only higher doses caused a significant decrease of nitrite/nitrate concentration (% of inhibition: CE (400 mg/kg): 30.4 ± 5.6, HEX (200 mg/kg): 34.3 ± 9.9, AcOEt (800 mg/kg): 38.4 ± 5.4 and Aq (400 mg/kg): 44.1 ± 4.2) ($p < 0.05$). The isolated compounds also inhibited this inflammatory parameter (% of inhibition: kaempferitrin (100 mg/kg): 32.9 ± 4.2, oleanolic acid (50 mg/kg): 35.9 ± 5.6 and β-sitosterol (50 mg/kg): 35.2 ± 3.2) ($p < 0.05$). Dexamethasone and indomethacin pre-treatment of animals presented an inhibitory effect on nitrite/nitrate concentration by 75.6 ± 2.6% and 50.0 ± 1.3%, respectively ($p < 0.01$) (Table 4).

Table 4
Effects of the crude extract of *Lotus corniculatus*, its derived fractions and isolated compounds upon nitrite/nitrate concentration in the inflammation induced by carrageenan in the mouse model of pleurisy.

Groups/doses (mg/kg)	NO_x (μM)
C[a]	16.40 ± 1.50
CE 400[b]	11.40 ± 0.90*
HEX 200[b]	10.80 ± 1.60*
AcOEt 800[b]	10.10 ± 0.90**
BuOH 100[b]	14.90 ± 0.60
Aq 400[b]	9.16 ± 0.70**
Kaempferitrin 100[b]	11.0 ± 0.70*
Oleanolic acid 50[b]	10.5 ± 0.90*
β-Sitosterol 50[b]	10.6 ± 0.50*
Dex 0.5[b]	4.00 ± 0.76**
Indo 5[b]	8.21 ± 1.48**

The crude extract (CE: 400 mg/kg) of *Lotus corniculatus* and its derived fractions, hexane fraction (HEX: 200 mg/kg), ethyl acetate fraction (AcOEt: 800 mg/kg), *n*-butanol fraction (BuOH: 100 mg/kg), aqueous fraction (Aq: 400 mg/kg), and isolated compounds, kaempferitrin (100 mg/kg), oleanolic acid (50 mg/kg) and β-sitosterol (50 mg/kg) administered 0.5 h before the pleurisy induction by carrageenan (1%). C = response in animals treated only with carrageenan. Dex = response in animals pre-treated with dexamethasone (0.5 mg/kg). Indo = response in animals pre-treated with indomethacin (5.0 mg/k). * $p < 0.05$ and ** $p < 0.01$. The data is reported as the mean ± SEM. a = administered by intrapleural route, b = administered by intraperitoneal route. $n = 5$ animals.

4. Discussion

Data from this study indicates that the crude extract of *L. corniculatus* and its derived fractions had an important anti-inflammatory effect in a murine model of pleurisy. Although, different doses of *L. corniculatus* and its derived fractions were necessary to inhibits this inflammatory reaction. The results show that this herb exhibits a distinct inhibitory profile when compared to conventional drugs, such as indomethacin and dexamethasone.

The anti-inflammatory effect of *L. corniculatus* was more pronounced in relation to the inhibition of leukocytes and exudation. To understand the modulation of leukocytes by this herb, we also studied its effect upon MPO and ADA activities, which are known to be markers of activated neutrophils and mononuclears, respectively (Fröde & Medeiros, 2001). Our results demonstrated that the crude extract of *L. corniculatus* and its derived fractions significantly attenuated both MPO and ADA activities. These results reveled that *L. corniculatus* not only inhibited the leukocyte influx to the site of the inflammatory response, but also the activated leukocytes (Fröde & Medeiros, 2001).

The role of IL-1β in the inflammatory response is well known. The effect of *L. corniculatus* upon IL-1-β levels was also analyzed. In this experiment we observed a significant inhibition of this important mediator by *L. corniculatus* and its derived fractions.

Nitric oxide (NO) is another important pro-inflammatory substance that is released in the acute and chronic inflammatory response and is related to the exudation and cellular chemotaxis (Tripathi, Tripathi, Kashyap, & Singh, 2007). Once again, *L. corniculatus* showed an anti-inflammatory response, since the crude extract of this herb and its derived fractions, except for BuOH, caused a significant decrease of nitrite/nitrate concentration.

All the studied fractions isolated from *L. corniculatus* presented an important anti-inflammatory effect. The distinct biological effect may be linked to differences among chemical structures. This fact is observed mainly in the HEX and AcOEt fractions, which revealed a more pronounced anti-inflammatory response than the other fractions, since they were able to inhibit all the studied inflammatory parameters. On the contrary, BuOH did not inhibit either MPO activity or nitrite/nitrate concentration.

In an attempt to evaluate the anti-inflammatory potential of the isolated compounds from these fractions, first we isolated kaempferitrin from the AcOEt fraction, and β-sitosterol and oleanolic acid from the HEX fraction.

Likewise, we tested the effects of these compounds upon the same studied pro-inflammatory parameters. Our results revealed that all compounds inhibited leukocytes, neutrophils, exsudation, and MPO activity, as well as NO levels.

Although, β-sitosterol was a main compound isolated from *L. corniculatus*, kaempferitrin demonstrated a better anti-inflammatory effect since it was 3.8-fold, 1.5-fold and 1.3-fold more effective in inhibiting MPO, ADA and IL-1β levels, respectively, than indomethacin, and 4.3-fold and 1.2-fold more effective in inhibiting MPO and ADA activities than dexamethasone.

Similar results have also been observed with kaempferitrin that inhibits nitric oxide levels, as well as pro-inflammatory cytokines such as TNF-α and IL-12, in murine macrophages stimulated by LPS/IFN-γ (Fang, Rao, & Tzeng, 2005).

In relation to oleanolic acid, studies from literature have demonstrated the anti-inflammatory effect of this substance by reducing the paw edema induced by dextran, and also inhibiting the nitric oxide release via down-regulation of NF-κB in murine macrophage cells induced by LPS (Singh, Singh, Bani, Gupta, & Banerjee, 1992; Suh et al., 2007).

For β-sitosterol, studies have demonstrated important anti-inflammatory activity not only by inhibiting IL-12 from human Jukart T cells stimulated by concanavalin (ConA) or by phorbol-12-myristate-13-acetate plus ionomycin (PMA + IoM) (Aherne & O'Brien, 2008), but also by decreasing the eosinophil influx, mucus secretion, and IL-4/ IL-5 expression in a murine model of asthma induced by ovalbumin (Yuk et al., 2007), and the ear oedema induced by acetone in mice (Mavar-Manga et al., 2008).

In conclusion, *L. corniculatus* showed an important anti-inflammatory property, and its constituent's kaempferitrin, oleanolic acid and β-sitosterol may well account for it. These compounds have potential as novel lead compounds for the future development of therapeutic intervention in the treatment of patients with inflammatory disorders.

Acknowledgements

The authors thank MSc researcher MSc Ulisses de Arruda Córdova of EPAGRI (Empresa de Pesquisa Agropecuária e Extensão Rural de Santa Catarina S.A, Pesquisa, Estação Experimental de Lages) for the kind donation of *Lotus corniculatus* var. São Gabriel. We would also like to thank the Coordenação de Aperfeiçoamento Docente CAPES, Brazil, for financial support.

3-Alkylphenols

ABSTRACT

Pistachio kernels were extracted with *n*-hexane and the oil obtained was saponified with methanolic KOH. The extracted unsaponifiable matter was fractionated on Thin Layer Chromatography (TLC) plates. The band with $R_f = 0.47$, analysed by Gas Chromatography–Mass Spectrometry (GC–MS), showed the presence of long-chain alkylphenols: this is the first time that alkylphenols are reported in pistachio kernels. To elucidate the structures, Nuclear Magnetic Resonance (NMR) and GC–MS analyses (on the trimethylsilyl derivatives) were used. Sixteen different 3-alkylphenols (cardanols) with a saturated, monounsaturated and diunsaturated chain were detected. A reaction with dimethyl disulphide was successfully used to determine the double bond position in the monounsaturated compounds. Three phenols were new natural compounds. The most abundant cardanols were 3-(8-pentadecenyl)-phenol, 3-(10-pentadecenyl)-phenol, 3-pentadecyl-phenol and 3-(10-eptadecenyl)-phenol. Total amount of cardanols in the oils (mean of five samples) was roughly evaluated as 440 ± 95 mg kg^{-1}.

1. Introduction

Pistachio (*Pistacia vera* L.) is a plant from the Anacardiaceae family. The pistachio nut is mainly cultivated in Iran, Turkey, USA, Greece and Syria; in Italy it is almost exclusively cultivated in Sicily, near the volcano Etna, in the area of Bronte (FAO, 2005). Pistachio seeds are usually used as ingredients in the food industry or roasted and consumed as snack food.

Chemical studies on pistachio kernels mainly regarded the fatty acids and sterols content (Arena, Campisi, Fallico, & Maccarone, 2007; Chahed et al., 2006; Chahed et al., 2008; Daneshared & Aynehchi, 1980; Okay, 2002; Phillips, Ruggio, & Ashraf-Khorassani, 2005; Ryan, Galvin, O'Connor, Maguire, & O'Brien, 2006; Satil, Azcan, & Baser, 2003; Venkatachalam & Sathe, 2006; Yildiz, Turcan Gurcan, & Ozdemir, 1998); other studies concern the kernel pigments characterisation (Bellomo & Fallico, 2007; Giuffrida, Saitta, La Torre, Bombaci, & Dugo, 2006; Wu & Prior, 2005), the resveratrol recovery in seeds (Gentile et al., 2007; Grippi et al., 2008; Tokusoglu, Unal, & Yemis, 2005) and the presence of anacardic acids in the outer green shell (Yalpani & Tyman, 1983).

Several reports, conducted on other Anarcadiaceae, especially on the cashew (*Anacardium occidentale* L.) demonstrated that phenolic compounds such as anacardic acids (6-alkylsalicylic acids), cardols (5-alkylresorcinols) and cardanols (3-alkylphenols) with 15 carbon atoms in the side chain, saturated and unsaturated, were found on the external part of the hull (Paramashivappa, Phani Kumar, Vithayathil, & Srinavasa Rao, 2001; Phani Kumar, Paramashivappa, Vithayathil, Subba Rao, & Srinivasa Rao, 2002; Strocchi & Lercker, 1979; Trevisan et al., 2006; Tyman, Tychopoulos, & Colenutt 1981). The cardanols were also found in other vegetable species (Alen et al., 2000; Du, 1990; Franke, Masaoud, & Schmidt, 2001; Pramono, Gleye, Moulis, Debray, & Stanislas, 1985; Tan, Shen, Wang, & Yu, 2001).

Members of the Anacardiaceae characteristically produce a series of compounds based on unsaturated fatty acid precursors. Biosynthetically, usually the CoA ester of palmitoleic acid serves as a precursor of this group of compounds by chain elongation with three acetate groups; the side chain structure of active compounds can be mono-, di-, or triunsaturated, suggesting that a number of unsaturated acyl-CoA starter units can also be employed (Dewick, 1997). Some pure compounds are very active human allergens (Dewick, 1997).

Natural phenols are compounds with high antioxidant activity (Moure et al., 2001); this activity was studied on the phenolic compounds of pistachio hull extracts (Goli, Barzegar, & Sahari, 2005) and on the alkyl phenols of the cashew (Trevisan et al., 2006). Other studies about the Anacardiaceae phenols regarded the cytotoxic activity of anacardic acids and cardols against both BT-20 breast and HeLa epithelioid cervix carcinoma cells (Kubo, Ochi, Vieira, & Komatsu, 1993) and the antinematodal properties of some cardanols respect to the pine wood nematodes *Bursaphelenchus xylophilus* (Alen et al., 2000).

To the best of our knowledge, in the literature, studies about the identification of alkylphenols in pistachio kernels are not present; during our research on the composition of the unsaponifiable matter of pistachio oils, we found the presence of long-chain alkylphenols: in this paper we report the recovery of 3-alkylphenols (cardanols) and their characterisation.

2. Materials and methods

2.1. Pistachio seeds

Five fresh commercial samples of shelled pistachio (50–100 g each) were used. Two samples were from Bronte (Italy), while other labels did not specify the provenience.

2.2. Reference compounds

Solvents and reagents were purchased from Sigma–Aldrich (St. Louis, Missouri, USA). Bis(trimethylsilyl)trifluoroacetamide and trimetylchlorosilane (BSTFA:TMCS 99:1) were purchased from Supelco (Bellefonte, Pennsylvania, USA).

2.3. Extraction of pistachio oils

Pistachio seeds were accurately ground with a homogenizer and then 30 g were weighed and extracted with 150 mL of *n*-hexane in a screw-cap flask, in the dark with magnetic stirring, at room temperature for 2 h. Hexane was separated by settling and the residue was extracted again with 150 mL of fresh *n*-hexane. A total of five extractions were carried out; to the combined solvent 5 g of anhydrous Na_2SO_4 were added and then *n*-hexane was filtered. The solvent was removed under vacuum at room temperature; the oil obtained was flushed with a stream of dry nitrogen to volatilise the solvent residues and then was weighed. All the oil samples were stored at −5 °C before the analysis. The oils yields obtained were in the range 46.2–52% (the mean of the five samples was 48.5 ± 2.3%).

2.4. Extraction of 3-alkylphenols

Five grams of pistachio oil were saponified with 50 mL of 2 N KOH in methanol, refluxing for 60 min. After cooling, 100 mL of distilled water were then added and the unsaponifiable matter was extracted three times in a separatory funnel with diethyl ether (75 + 50 + 50 mL). The combined organic layers were washed with distilled water (50 mL) and the obtained ethereal extract was filtered on anhydrous Na_2SO_4. Then the solvent was removed under vacuum at room temperature. The obtained unsaponifiable matter was fractionated by using Thin Layer Chromatography (TLC). The plates (20 × 20 cm) were layered with a slurry of 12 g of silica gel G in 25 mL of 2 N NaOH and then activated by heating at 110 °C for 90 min. Diethyl ether solutions of the unsaponifiable were put on the plates using a 100 μl syringe. Elution was performed with 100 mL of *n*-hexane:diethyl ether (60:40) in a glass developing chamber (27.0 x 26.5 x 7.0 cm), using two plates at a time. Elution time was about 45 min. Plates were then sprayed with a 0.2% (w/v) ethanolic solution of 2,7-dichlorofluorescein to highlight the bands under an UV source (366 nm). The band with R_f = 0.47 was separated and extracted from the silica gel with hot chloroform (3 + 2 + 2 mL). After removing the chloroform under vacuum, the residue was dissolved in 0.2 mL of *n*-hexane and then analysed by GC–MS.

2.5. Derivatization of 3-alkylphenols

The residues were also analyzed after derivatization by using 0.2 mL of bis(trimethylsilyl)trifluoroacetamide and trimethylchlorosilane (BSTFA–TMCS 99:1) at room temperature, for 30 min. Trimethylsilyl derivatives were analyzed by GC–MS.

For double bond location, dimethyldisulphide derivatives (Christie, 1997) were prepared as follows: to 2 mg of cardanols, 0.5 mL of dimethyldisulphide and 0.1 mL of iodine solution (60 mg/mL in diethyl ether) were added; the reaction mixture was stirred at room temperature for 24 h and then 5 mL of *n*-hexane were added and two washings with 5 mL of $Na_2S_2O_3$ 0.01 N were done. The organic phase was separated, filtered on anhydrous Na_2SO_4 and the solvent was removed under vacuum at room temperature. Hydroxyl groups were then silylated with BSTFA–TMCS as previously reported and the dimethyldisulphide–trimethylsilyl derivatives were analyzed by GC–MS.

2.6. GC analysis

Analysis was carried out using a Finnigan MAT GCQ GC–MS system equipped with a splitless-split injector and a Restek RTX-5MS column (30 m, 0.25 mm i. d., 0.25 μm film thickness).

Underivatized samples were analyzed in the following oven conditions: initial temperature 60 °C (2 min isothermal), from 60 to 275 °C at 21.5 °C/min and then isothermal for 33 min.

For the trimethylsilyl derivatives analysis, the oven temperature was programmed as follows: initial temperature 60 °C, from 60 to 150 °C at 15 °C/min, from 150 to 275 at 5 °C/min and then isothermal for 24 min.

Injector was set at 250 °C, transfer line at 275 °C and ion source at 200 °C. Injections were performed with a 60 s splitless with He as carrier gas, at 40 cm/s constant rate. The mass spectrometer was used in full scan EI mode (70 eV), from 40 to 800 amu, 1 spec/s.

2.7. NMR analysis

^{1}H NMR spectra were taken on a Varian Gemini 300 (300 MHz) in $CDCl_3$ using tetramethylsilane (TMS) as an internal standard. All the signal were referenced to TMS to within ± 0.01 ppm.

3. Results and discussion

The analyses carried out on the hexanic solution of the band with R_f = 0.47 showed chromatograms with a tailing peak (main compound) and some very little ones (Fig. 1). The mass spectrum of the main compound had base peak at *m/z* 108 and hypotethic molecular ion at *m/z* 302 (Fig. 2). The ions at *m/z* 77, 91 and 108 suggested the presence of a benzene ring with a phenolic hydroxyl and the ions at *m/z* 133, 147, 161, 175 and 206, 220, 234 suggested the presence of an alkyl chain. The molecular weight of 302 could be compatible with the structure of a phenol with a monounsaturated C-15 chain.

To evaluate this hypothesis, 25 mg of the band were collected and analyzed by ^{1}H NMR spectroscopy. The regiochemistry for

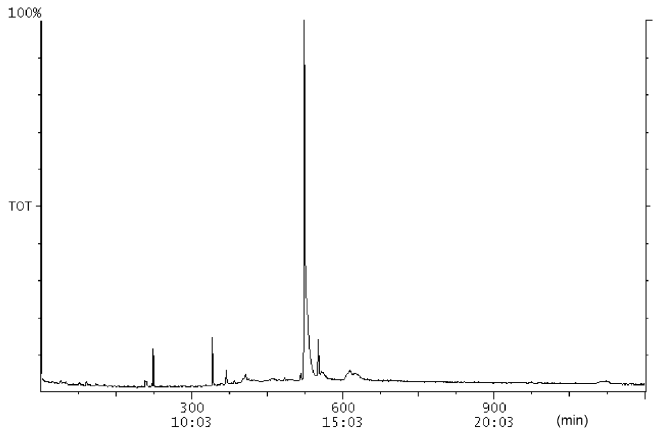

Fig. 1. Chromatogram of the extract of the band with R_f = 0.47.

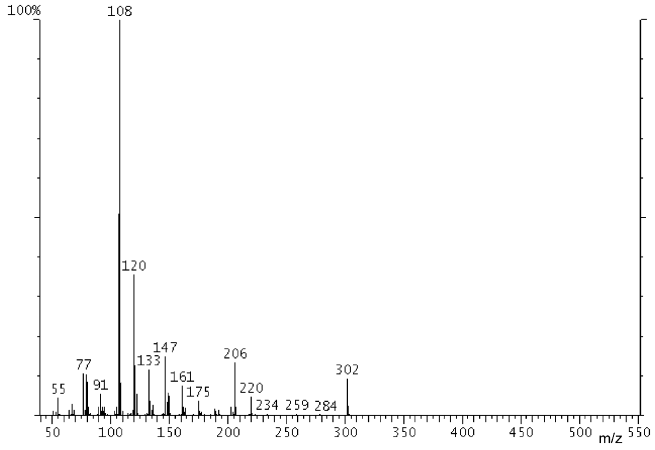

Fig. 2. Mass spectrum of the main compound.

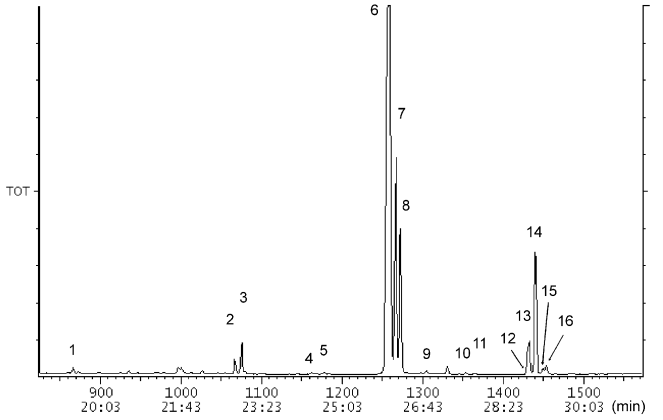

Fig. 3. Chromatogram of the alkylphenols (trimethylsilyl derivatives) of a pistachio sample. Peaks identification as in Table 3.

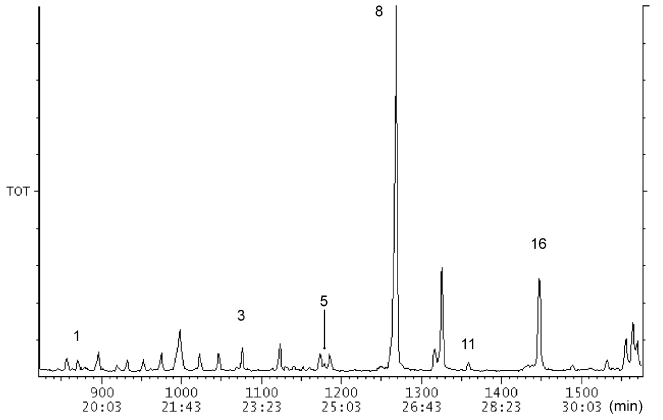

Fig. 4. Chromatogram of the alkylphenols (dimethyldisulphide–trimethylsilyl derivatives) of a pistachio sample (Part 1). Peaks identification as in Table 3.

the main compound was evident from its ^{1}H NMR spectrum which contained an aromatic pattern (4H, s, t and two d, all of equal intensity between 7.26 and 7.83 δ) distinctive of 1,3 substitution. The configuration of the double bond along the aliphatic chain was deduced from the coupling of the double bond protons; in fact, the characteristic resonance for these protons (2H, *m*, δ 5.96–5.92, J_{HH} = 10.4 Hz) points out a Z configuration of the double bond along the aliphatic chain. All the other ^{1}H NMR peaks [δ 3.18 (2H, *t*, –CH_2Ar), 2.47–2.68 (6H, *m*, –CH_2–), 2.12–2.26 (6H, *m*, –CH_2–), 1.80–2.01 (10H, *m*, –CH_2–), 1.44 (3H, *t*, –CH_3)], are consistent with the presence of a long aliphatic chain. Additionally, a characteristic feature of ^{1}H NMR spectrum was the appearance of the signal indicating the presence of a hydroxyl group [δ 5.29 (1H, br, OH)], just evidenced through the mass spectroscopy.

Literature data agree that long-chain alkylphenols recovered in plant materials are 3-alkylphenols and that the configuration of the double bond of the unsaturated compounds is Z (Alen et al., 2000; Paramashivappa et al., 2001; Phani Kumar et al., 2002; Tan et al., 2001).

Then, a GC–MS analysis on the trimethylsilyl derivatives was carried out to improve the separation; thus, the tailing peak of Fig. 1 was splitted in three narrow peaks (Fig. 3, peaks 6, 7 and 8) and the chromatograms obtained showed the presence of sixteen different alkylphenols. In Table 1 is reported a summary of the mass spectrometric characteristics of these compounds.

Molecular weights suggested the presence of alkylic chains from C11 to C17, mainly odd and monounsaturated; some compounds had the same molecular weight (peaks 6–7 and peaks 13–14–15), but the spectral characteristics did not allow a characterisation because there were not evident differences (Table 1). Fragmentation did not permit to determine the double bond positions, so the analysis of the dimethyldisulphide–trimethylsilyl derivatives was attempted. The dimethyldisulphide derivatives were chosen because they are easy to prepare, the increase in the molecular weights is smaller than the classic hydroxylation–trimethylsilylation, the reaction involves simple addition of dimethyl disulphide across the double bond and several applications have been described for the structural elucidation of fatty acids by

mass spectrometry, in particular for monoenoic ones (Christie, 1997).

Fig. 4 reports the first part of a chromatogram of the dimethyldisulphide–trimethylsilyl derivatives. In this figure, the peaks 1, 3, 5, 8, 11 and 16 were saturated compounds, and no differences in retention times and spectra (as reported in Table 1) were observed, respect to the trimethylsilyl derivatives. In Fig. 5, the second part of the chromatogram showed the dimethyldisulphide–trimethylsilyl derivatives of the monounsaturated compounds (peaks 2, 4, 6, 7, 10, 13, 14 and 15); the addition of the dimethyldisulphide group on the double bond introduces characteristic features on the mass spectra: fragmentations occur where the former unsaturation existed (Christie, 1997). Thus, differences can now be observed in the spectra of peaks 6 and 7 (Fig. 6): the first had base peak at *m/z* 323 and an intense ion at *m/z* 145, corresponding to the structures $[(CH_3)_3SiO–C_6H_4–(CH_2)_7–CHSCH_3]^+$ and $[CH_3–(CH_2)_5–CHSCH_3]^+$, respectively; the second had base peak at *m/z* 351 and an intense ion at *m/z* 117, corresponding to the structures $[(CH_3)_3SiO–C_6H_4–(CH_2)_9–CHSCH_3]^+$ and $[CH_3–(CH_2)_3–CHSCH_3]^+$, respectively. Compound **6** was then 3-(8-pentadecenyl)-phenol and compound **7** was 3-(10-pentadecenyl)-phenol. The same considerations could be done for the peaks 2, 4, 10 and the three isomers 13, 14 and 15 (Table 2): spectra permitted to localise the former double bond position and the compounds were 3-(8-tridecenyl)-phenol, 3-(8-tetradecenyl)-phenol, 3-(10-hexadecenyl)-phenol, 3-(8-heptadecenyl)-phenol, 3-(10-heptadecenyl)-phenol and 3-(12-heptadecenyl)-phenol, respectively. Thus, all monounsaturated alkylphenols were characterised (Table 3); these compounds presumably have the same configuration (Z) of the principal component, 3-(8-pentadecenyl)-phenol: this hypothesis was supported by the literature data (Alen et al., 2000; Paramashivappa et al., 2001 ; Phani Kumar et al., 2002; Tan et al., 2001) and also by our chromatograms, in which only one geometric isomer for each different unsaturated compound was visible.

Unfortunately, no informations were available for the double bond positions of the two diunsaturated compounds; it is possible

to hypothesize that peak 9 could be 3-(8,11-pentadecadienyl) phenol (Paramashivappa et al., 2001; Phani Kumar et al., 2002; Strocchi & Lercker, 1979) and peak 12 could be 3-(10,14-heptadecadienyl) phenol.

The composition of the pistachio cardanols is very different from other plant species: usually, only four compounds are found in cashew, all with a C-15 alkyl chain (Paramashivappa et al., 2001; Phani Kumar et al., 2002; Strocchi & Lercker, 1979; Tyman et al., 1981); two C-15 cardanols are reported in *Semecarpus vitiensis* (Pramono et al., 1985), C-15 and C-17 in *Rhus vernicifera,* an Anacardiacea (Du, 1990), a C-11 and a C-13 in *Knema hookeriana* (Alen et al., 2000), a C-15 and two C-17 in *Ginkgo biloba* (Tan et al., 2001) and nine different compounds in another Anacardiacea, *Rhus thyrsiflora* (Franke et al., 2001).

To our knowledge, 3-(8-tetradecenyl) phenol (peak 4), 3-tetradecyl phenol (peak 5) and 3-(10-hexadecenyl) phenol (peak 10) are new natural compounds.

Total cardanols content was roughly estimated from the weight of the purified TLC bands: the mean amount calculated on the five oil samples was 440 ± 95 mg kg^{-1}.

Quantitative data for each compound were calculated with the internal normalisation method (Table 3). The most abundant compounds were the C-15 cardanols (about 87% of total cardanols); monounsaturated compounds were predominant (87.89%) respect to saturated ones (10.95%). The double bond was in the position 8 in the C-13 and C-14 phenols and in 8 (prevalent isomer) and 10 in the C-15 cardanols; from the C-16 alkyl chain, the predominant isomer had the double bond in the position 10. Cardanols with an even alkyl chain were below 0.1%.

4. Conclusions

Sixteen different 3-alkylphenols from pistachio kernels, mainly monounsaturated, were recovered; fourteen were characterised with the aim of Nuclear Magnetic Resonance and Gas Chromatography–Mass Spectrometry. Dimethyldisulphide–trimethylsilyl derivatives were very useful to determine the double bond position of the monounsaturated alkylphenols. This is the first time that 3-alkylphenols are reported in pistachio kernels.

Short communication

Rapid screening of volatile compounds in edible plants by direct chromatographic analysis

On-line coupling PTV–PTV

ABSTRACT

A method based on the use of the on-line coupling of two programmed temperature vaporizers (PTVs) is proposed to perform the concentration step required prior to the gas chromatographic determination of volatile compounds in edible plants. The reported procedure does not demand a previous sample handling stage whilst allowing the rapid and reliable screening of plant materials to be performed. The matrix to be analysed is directly introduced into the PTV of a gas chromatograph, thus avoiding the risk of losses and contamination typically observed when external concentration techniques are applied. The analytes in the vapour phase are swept from the matrix and then retained onto a suitable adsorbent material placed inside the second PTV injector. The described set-up allows the simple and rapid performance of the experimental work as the overall analysis of naturally occurring compounds with potential application as food ingredients can be performed in less than 1 h.

1. Introduction

The reliable determination of volatile components is of special relevance with respect to flavour and fragrance studies and, in general, to foodstuffs. As the aroma is considered to be a key issue to evaluate the consumer acceptance or rejection of a product, the volatile profile is often used to assess a number of valuable properties namely purity, quality and origin (Maarse & Belz, 1985; Marsili, 1997, 2002; Schreier, 1984; Surburg & Panten, 2006; Teranishi, Wick, & Hornstein, 1999).

On the other hand, the use of bioactive compounds extracted from natural sources has been lately considered as an interesting alternative in either the design of new functional foods or in the development of food additives. In this way, natural occurring compounds can be eventually used as substitutes of synthetic antioxidants and antimicrobial agents which might have negative effects on human health. As a consequence, further research on rapid and reliable screening of plant materials is highly demanded not only to identify new compounds but also to select the natural source most adequate for the isolation of the compounds of importance for specific applications.

Conventional sample preparation usually starts with an extraction step. A concentration procedure is then normally required to allow the detection of compounds by the chosen analytical method. Sample preparation comprises from conventional extraction technologies (e.g., liquid–liquid extraction, steam distillation, as well as static and dynamic headspace sampling) to modern techniques (e.g., high pressure solvent extraction methods, supercritical fluid extraction, as well as solvent-free and fast techniques, namely solid phase microextraction and stir bar sorptive extraction) (David & Sandra, 2007; Durán, Natera, Castro, & García-Barroso, 2006; Díaz-Maroto, Pérez-Coello, & Cabezudo, 2002; Salinas, Zalacain, Pardo, & Alonso, 2004). Advantages and disadvantages of the above mentioned procedures have also been described and the convenience of new developments to overcome their limits and, consequently, to enlarge their field of application has been emphasised very recently (Bicchi, Cordero, Liberto, Sgorbini, & Rubiolo, 2008).

In this context, the usefulness of a programmed temperature vaporizer (PTV) (Vogt, Jacob, Ohnesorge, & Obwexer, 1979) for the determination of volatile compounds in complex mixtures has already been demonstrated. Most methods previously reported have mainly focussed on large volume sampling introduction into the injector and the retention of the target compounds in a suitable material placed inside. The elimination of the solvent and the gas chromatographic analysis of the thermally desorbed compounds is subsequently performed. Specifically, the optimisation of a number of variables involved in the retention of the target solutes in an adsorbent kept inside the PTV injector body has allowed the determination of trace compounds in very different matrices (Mol, Janssen, Cramers, Vreuls, & Brinkman, 1995; Staniewski, Janssen, Cramers, & Rijks, 1992; Villén, Señoráns, Reglero, & Herraiz, 1995, 1996).

An interesting feasibility of the PTV injector involves its use for thermal desorption of volatiles from a solid sample material

doi:10.1016/j.foodchem.2009.04.046

directly introduced into the glass liner of the injector body (Reglero, Herraiz, Herraiz, & Sanz, 1989) although the risk of column overloading limits this application. There has also been reported the use of adsorbent materials to trap the compounds of interest (Tabera, Reglero, Herraiz, & Blanch, 1991), but in this case a concentration step must be performed externally to the chromatographic analysis itself. Results obtained with both procedures showed a potential which suggests the interest of combining their advantages, whilst overcoming their respective drawbacks, to integrate, in a unique analysis, both the extraction and concentration of the target compounds, as well as its subsequent sampling into a gas-chromatographic system.

The goal of this work was to evaluate the possibility of using the on-line coupling of two PTVs to achieve the internal concentration of the volatiles present in a solid sample material directly placed into the system. A further aim was to significantly reduce sample handling thus avoiding the risk of artefacts formation, as well as that of decomposition of thermally labile components which may distort the volatile profile of the sample to be analysed.

As an example of the performance of the proposed sampling-assembly for the determination of naturally occurring bioactive compounds in plant materials, in the present work we report the direct analysis of *Mentha piperita* because of its extensive use in foods and beverages. This specie is commonly employed in the liquor and confectionery industries, as well as in herbal teas or as ingredients of commercial spice mixtures used for many foods.

2. Materials and methods

2.1. Samples and materials

A standard solution containing α-phellandrene, limonene, menthone, dihydrocarvone and pulegone (1 mg/L of each compound in diethyl ether) was used to establish the experimental conditions more convenient for the analysis of plant material using the set-up proposed in this work. All standards were obtained from Sigma–Aldrich (Dorset, UK) whilst diethyl ether was supplied by Scharlau (Barcelona, Spain). *M. piperita* was acquired in the commercial market and was placed into the PTV-1 (see Fig. 1) without any kind of pre-treatment. After grinding the dried plant material, it was directly introduced into the silylated glass liner (54 × 3.4 mm i.d. × 5 mm o.d.) of the injector. A 4-cm length plug of Tenax TA (80–100 mesh Chrompack, Middelburg, The Netherlands) was used as packing material in the silylated glass liner (54 × 3.4 mm i.d. × 5 mm o.d.) of the PTV-2 (see Fig. 1). Tenax TA was kept in place at both ends with silanized glass wool (Phase Separations, Norwalk, CT, USA). Prior to its use, Tenax TA was conditioned under a stream of helium for 120 min at 300 °C. Although it was intended to analyse the standard solution and the plant material under the same conditions, its different nature eventually demanded the use of different conditions for specific variables (i.e., the amount of sample introduced into the system, the time interval during which helium is passed through the injector and the split ratio).

2.2. On-line coupling PTV–PTV

Sampling introduction and volatile concentration were accomplished using two Varian (Palo Alto, CA, USA) PTV injectors, Model 1079 (PTV-1 and PTV-2 in Fig. 1) linked through a fused-silica tube. In all cases the sample (i.e., a 0.4-μL volume of the standard solution or a 5.5-mg weight of the plant material) was introduced into the PTV-1 operated in the splitless mode and maintained at 50 °C under a helium stream (1.4 bars). Subsequently, a dynamic headspace was performed by stripping the target analytes from the sample in the vapour phase, 20 and 10 min being the times applied depending upon whether the standard solution or the plant material, respectively, was analysed. Finally, the volatile compounds were concentrated into the adsorbent material placed into the PTV-2 (kept at 10 °C) which was also operated in the splitless mode.

During the sweeping procedure, the chromatographic column was disconnected from the injector to concentrate the sample (Fig. 1). The PTV-2 was maintained at 10 °C to transfer solutes whilst avoiding their possible loss. Upon completion of this step, the column was connected again and the solutes retained in the packing material placed inside the glass liner of the PTV-2 were then transferred to the GC column by increasing the PTV temperature from 10 to 250 °C at 200 °C/min. The final temperature was kept for 10 min. The subsequent GC analysis was accomplished under the experimental conditions detailed below.

2.3. GC-analysis

GC-analysis was carried out using a CP-3800 Varian chromatograph and a 30 m × 0.25 mm i.d. fused-silica column coated with a 0.25-μm layer of poly (5% phenyl: 95% dimethylsiloxane) (VF-5 ms, Varian) using helium (2 mL/min) as the carrier gas. The oven temperature was increased from 60 °C (10 min) up to 100 °C (10 min) at 5 °C/min and up to 220 °C at 5 °C/min and the final temperature

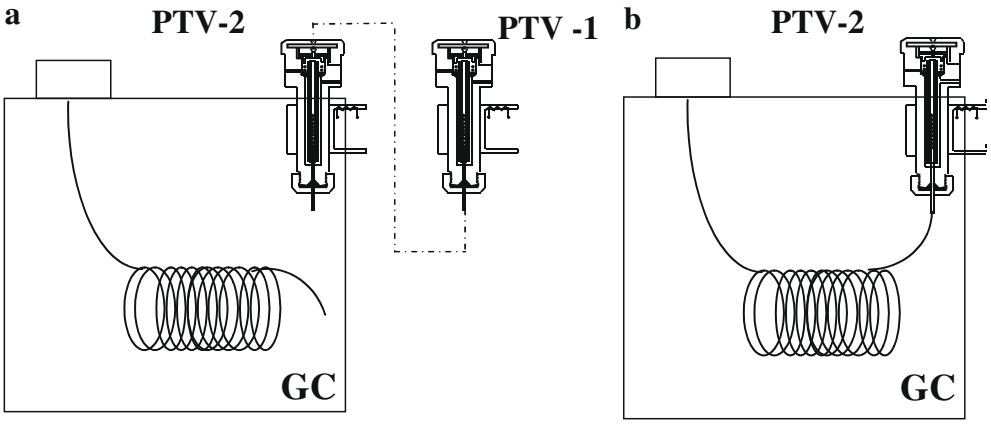

Fig. 1. Experimental set-up showing the on-line coupling of two programmed temperature vaporizers (PTV-1 and PTV-2). The analysis is performed in two steps which include the sample introduction into the PTV-1 whilst applying an helium flow to strip the volatile compounds which are retained inside the PTV-2 (a) and the thermal desorption of the solutes retained in the PTV-2 and its subsequent transfer to the chromatographic column (b). (See text for further details).

was maintained for 10 min. The split mode (split ratio; 20:1 and 60:1 for the standard solution and the plant material, respectively) was used in all cases. The flame ionisation detector (FID) used in the chromatographic analysis was set at 250 °C throughout the experimentation. Data acquisition was performed using a Star Toolbar system (Varian). Under the experimental conditions applied in the overall analysis, satisfactory blanks between consecutive runs were obtained for the complete procedure.

Compounds were identified by matching their GC retention times with those obtained from authentic standards analysed under the same experimental conditions. Moreover, for identification purposes, compounds retained on Tenax TA were thermally desorbed on the above mentioned GC column coupled to a Saturn 2000 ion-trap Varian mass spectrometer (MS). The recorded mass spectra were then compared with those of the US National Institute of Standards and Technology (NIST) library. For the MS, ionisation was accomplished by electron impact (EI). The transfer line temperature was set at 280 °C whilst 200 and 60 °C were the temperatures used for the trap and the manifold, respectively.

3. Results and discussion

A starting point of our research was the generally admitted statement that the less sample manipulation (and, therefore, the fewer variables affecting the experiment) the more likely the finally obtained results will be reliable. For that reason, we decided to reduce drastically the usually laborious and time consuming handling of the sample prior to the chromatographic analysis in such an extension that, in the method reported in the present work, it is actually limited to the simple introduction of the milled sample into the chromatographic system (i.e., an external fractionation step is not required prior to the chromatographic analysis).

Due to the relatively low concentrations in which several relevant volatile compounds may occur in plant material, it is evident that an effective concentration step is always convenient, or even essential, to produce a chromatographic profile that can be considered as truly representative of the investigated sample. Consequently, a method to concentrate the sample should minimize, or even prevent, possible sources of errors such as the generation of unknown peaks or the decomposition of thermally labile components in heated zones close to the column in which the chromatographic separation will be performed. Thus, with this specific objective, we formulated the hypothesis that the isolation of the part of the system in which the sample is placed, and also the dynamic headspace is performed, (step a in Fig. 1) from the part in which the stripped volatiles are retained in an adsorbent material, and subsequently are directly transferred onto the head of the chromatographic column (step b in Fig. 1), would result in a higher reliability of the overall on-line procedure investigated. When performing the experimentation under the conditions detailed in Section 2, the flow of helium passing through PTV-1, as well as the initial temperature of this injector, were established to facilitate the extraction of the volatile compounds from the sample. It should be underlined that the initial temperature of PTV-2 was fixed at a value substantially lower than that of PTV-1 (in this case 10 *vs.* 50 °C) to achieve the focusing of the analytes at the head of the column for improving chromatographic peak shape. Then, direct thermal desorption was applied to remove the volatiles from the adsorbent material in which they had been previously retained. This was achieved by increasing the PTV-2 temperature up to 250 °C.

Figs. 2 and 3 depict the chromatograms resulting from the PTV–PTV–GC-analysis of the standard solution and the *M. piperita*, respectively, under the experimental conditions detailed above. Table 1 gives the RSD values (calculated from a minimum of three replicates) and the recovery values obtained for all the compounds included in the mentioned standard solution. As can be seen, RSD values ranging from 3.7% to 14.4% were observed whilst recovery values close to 80% were estimated for some compounds (specifically for dihydrocarvone and pulegone).

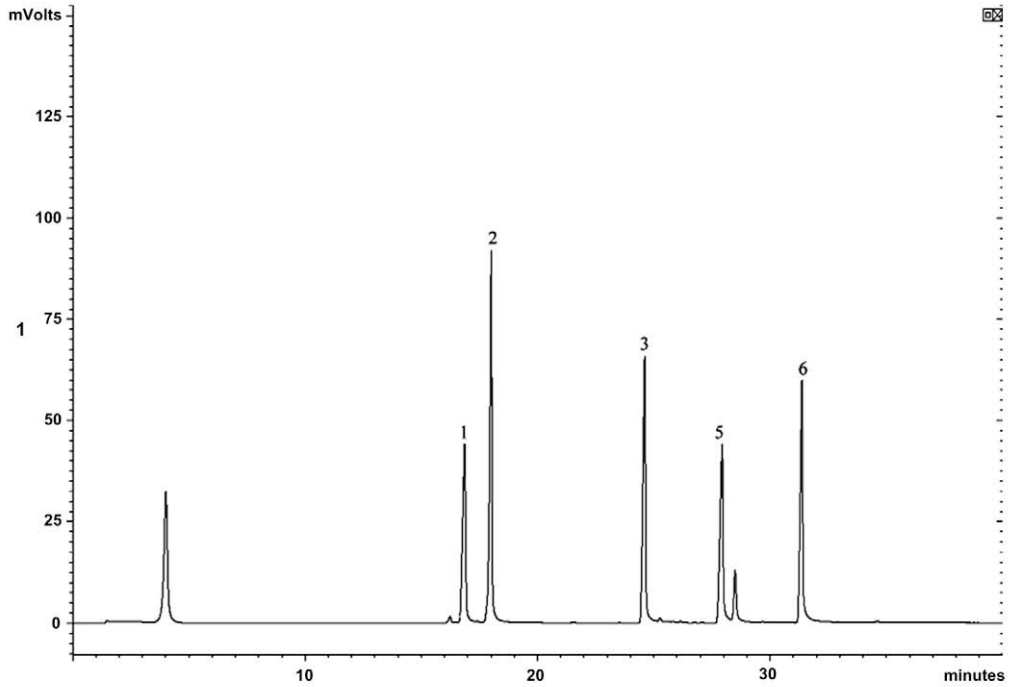

Fig. 2. PTV–PTV–GC-analysis (split ratio, 20:1) of the standard solution using the experimental set-up shown in Fig. 1 under the experimental conditions detailed in the text. Peak identification: 1. α-phellandrene, 2. limonene, 3. menthone, 5. dihydrocarvone, 6. pulegone.

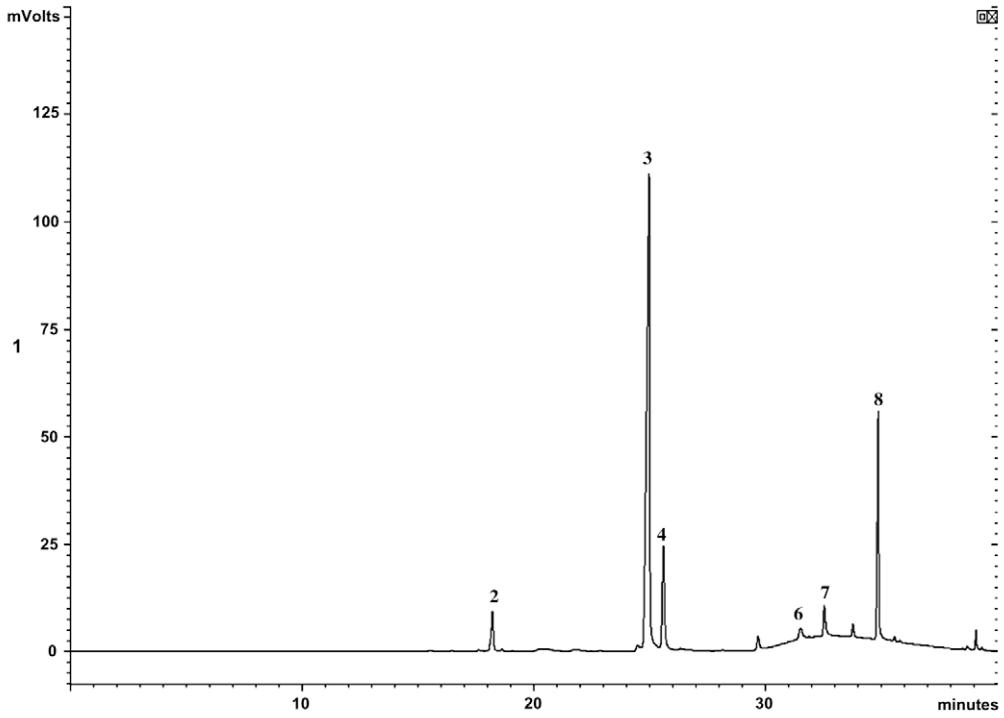

Fig. 3. PTV–PTV–GC-analysis (split ratio, 60:1) of a commercial sample of *M. piperita* using the experimental set-up shown in Fig. 1 under the experimental conditions detailed in the text. Peak identification: 2. limonene, 3. menthone, 4. isomenthone, 6. pulegone, 7. piperitone, 8. menthyl acetate.

Table 1
Relative standard deviation (RSD, $n = 3$) and recoveries obtained from the PTV–PTV–GC-analysis of the standard solution using the experimental set-up shown in Fig. 1.

Compounds	RSD (%)	Recovery (%)
α-Phellandrene	14.4	56.2
Limonene	9.7	44.7
Menthone	11.5	33.9
Dihydrocarvone	5.9	79.5
Pulegone	3.7	79.9

Interestingly, the PTV–PTV–GC-analysis of *M. piperita* demonstrated the feasibility of the proposed method for the analysis of real-life samples as the occurrence of characteristic compounds (i.e., menthone and isomenthone) could be reliably identified is less than 1 h. Moreover, the presence of other compounds, like limonene, pulegone, and piperitone occurring at quite lower concentrations with respect to that of menthone could also be determined (see Fig. 3). The RSD ($n = 3$) calculated for the compounds identified in the *M. piperita* sample, namely limonene, menthone, isomenthone, pulegone, piperitone and menthyl acetate resulted to be 11%, 16%, 14%, 14%, 11% and 11%, respectively.

It should be emphasised that although regarding the sensitivity achievable in the overall analysis it would have been more convenient to operate in the splitless mode during the GC separation of the *M. piperita* sample, we decided to use less favourable conditions (i.e., split ratio of 60:1). In this way, we intended to evaluate the performance of the experimental set-up in those cases in which the target analytes may occur in very different concentrations and, consequently, a split ratio must be applied to separate, with acceptable chromatographic resolutions, minor compounds eluting next to major compounds. Generally speaking, when analysing different plant materials the concentration range of specific sample components will determine the split ratio to be applied in each particular case.

The reported procedure involves a type of internal sample fractionation because the experimental values of the purge flow, the purge time and the temperature under which the sampling is performed obviously determine the amount of the different volatiles stripped from the sample. Thus, exclusively these compounds are transferred to the second PTV and, subsequently, are thermally desorbed onto the column. As a result, clean chromatograms can be eventually obtained which facilitates the optimization of chromatographic resolutions and, at last, the reliable determination of compounds occurring at both high and low levels.

On the contrary, the earlier reported one-step analysis by thermal desorption of a plant material directly introduced into a PTV injector does not include the previous stripping of the target compounds from the sample (Reglero et al., 1989). Consequently, rather complex chromatograms are usually obtained in which column overloading and overlapped peaks, as well as non-volatiles or other disturbing matrix components, ultimately may avoid the reliable identification and quantification of specific target compounds.

It is interesting to point out that in the present work the sampling step can be performed whilst keeping during transfer the GC column either connected or disconnected depending upon the chemical nature of the sample and the concentration range in which the target compounds occur. Likewise the split ratio must be optimised in each particular case either to avoid column overloading due to compounds present at high concentrations or to increase the sensitivity achievable in the analysis of compounds in minor quantities.

A further aspect of special interest concerning the potential field of application of the proposed design is the possibility of using the detailed PTV–PTV procedure to perform a multidimensional separation in the chromatographic analysis. To this aim, the only modification required with respect to the design depicted in Fig. 1 is the employment of an additional separation column just to make it possible the transfer, from one column into another, of different selected cuts. An important practical consequence of this fact will be

the use of this method for especially difficult separations in which both a pre-column and a main column are required to avoid overlapping of otherwise unresolved compounds in a GC-unidimensional system.

4. Conclusions

The preliminary results obtained with the proposed procedure (i.e., the on-line coupling PTV–PTV–GC) show its usefulness for the extraction and concentration of substances occurring in edible plants. The GC-analysis of volatile compounds using the mentioned sampling assembly offers clear advantages over other analytical techniques as its performance allows the use of mild conditions whilst stripping the target compounds from the sample matrix. Consequently, the risk of artefacts generation, with respect to conventional sample preparation methods, is basically avoided whereby volatile fraction profiles truly representative of the plant material can be performed in just one step, the overall analysis time being less than 1 h. A further interesting feature is the fact that the use of two PTV injectors allows the transfer to the chromatographic column of only those compounds previously purged off from the plant in the first PTV. Then, clean chromatograms can be obtained in which the identification of naturally occurring bioactive compounds with potential application as food ingredients can be easily and reliably accomplished.

ABSTRACT

A sensitive and rapid kinetic method for trace determination of Cu(II) was developed and validated, based on its catalytic effect on the oxidation of disodium-6-hydroxy-5-[(4-sulphophenyl)azo]-2-naphtalenesulphonic acid (wide used, food colour "Sunset Yellow FCF", E110, in text selected as SY) by hydrogen peroxide in borate buffer at pH 10.5. The reaction was monitored spectrophotometrically by measuring the decrease in the absorbance of SY at 478.4 nm. The optimum operating conditions regarding concentration of reagents, pH and temperature were established. The calibration curve was linear up to 318 ng mL^{-1} of Cu(II) and the limit of detection ($3\sigma/S$) is 5.0 ng mL^{-1}, and limit of quantification ($10\sigma/S$) is 16.67 ng mL^{-1}. The proposed kinetic procedure was successfully applied to monitoring of the concentration of Cu(II) in fruit, wine and milk samples from different areas. The results obtained by the proposed kinetic procedure were compared by those obtained by ICP-OES method, and shown good agreement. The proposed kinetic method could be used for monitoring of quality of drinks or fruit depending on Cu(II) concentration, because of its important role as nutritional element.

1. Introduction

Since copper occurs at low concentration in many real samples, such as natural, tap, waste waters, food, wine, drinks and soil, a sensitive, cost-effective, selective and rapid method is required for its determination in those samples. Copper is essential to human health, but only in limited amounts (Prasad & Halafihi, 2003).

In many food samples and drinks (fruit, juices, milk and wines) copper and iron are widely present. The high concentration of Cu, Fe, Mn and Zn may cause instability and turbidity of wine (Liskovskii & Skurikhin, 1976). Typical wines contain average copper levels at about 0.1–0.3 mg L^{-1} (Li, Guo, & Wang, 2008). In wines, the main sources of copper are equipments used in the wine production, addition of copper salts ($CuSO_4$) and pesticides employed during growth.

Hydrogen peroxide may be formed during the oxidation of phenols in wine, which has been widely accepted (Li et al., 2008). H_2O_2 in association with iron and copper tends to generate reactive oxygen species such as hydroxyl radical (·OH), which is known as the Fenton reaction (Li et al., 2008). In that way, most of the ·OH radicals generated in wine and fruit juice samples come from the metal-catalysed decomposition of hydrogen peroxide according to the Fenton-type reaction.

In recently reported references, Cu(II) was determined in different samples by using graphite furnace atomic absorption spectrometry (GF-AAS), (Ajtony et al., 2008; Karadjova, Izgi, & Gucer, 2002), inductively coupled plasma optical emission spectrometry (ICP-OES), (Lara, Cerutti, Sajonia, Olsina, & Martinez, 2005; Moreno et al., 2008). High performance liquid chromatography (Bermejo et al., 2001; Katerina, Christian, Ilse, Gregory, & Josef, 1999), and anodic stripping voltammetry (Cesar, Joanna, Jon, & Richard, 1999; Zeng, Liu, Tan, Zhang, & Gao, 2002) have also been used for the determination of copper with high sensitivity and selectivity, but suffer from more or less time consuming procedures and complicated instrumentation.

Despite of the instrumental improvements of the last decades, spectrophotometric techniques (Reddy, Reddy, Narayana, & Reddy, 2008) are still attractive from an analytical point of view since they are cheap, sensitive and simple to implement in laboratories. Among them, the kinetic-catalytic methods give high sensitivity and accuracy without the need for expensive and special equipment, by using different masking reagents or extraction to improve their selectivity (Crespo, Andrade, Inon, & Tudino, 2005; Crouch, Cullen, Schelline, & Kirkor, 1998; Crouch, Schelline, & Kirkor, 2000; Ghasemi, Kiaee, Abdolmaleki, & Semnani, 2008; Mitic, Miletic, & Obradovic, 2004; Mottola & Perez-Bendito, 1996; Prasad & Halafihi, 2003; Tomiyasu, Aikou, Anazawa, & Sakamoto, 2005; Tosic, Mitic, Obradovic, & Sunaric, 2004). Their sensitivity is at least 2–3 orders of magnitude higher than that of the ordinary

doi:10.1016/j.foodchem.2009.04.042

spectrophotometric methods. Catalytic-kinetic methods have been widely used in determining many species at traces levels.

Some of them have low sensitivity (Ghasemi et al., 2008; Tosic et al., 2004), or poor selectivity, which makes difficulties in their application in complex samples. Compared to other kinetic methods for the determination of Cu(II), the kinetic method developed in this work falls to order of more sensitive methods (nanogram levels). Among its high sensitivity, the method has also advantage in view of its simple and rapid applicability to different real samples, using easy available masking agents for elimination main interfering effects (Fe^{3+}, Mn^{2+}, Ni^{2+} and Co^{2+}), without complicated pretreatments, with satisfactory accuracy which was confirmed by ICP-OES method.

In this study, we found that food dye SY is oxidised by hydrogen peroxide in borate buffer; this oxidation reaction is significantly catalysed by trace amounts of Cu(II). Consequently, the main aim of this study was the development of a new sensitive kinetic-spectrophotometric method for the determination of Cu(II), based on its catalytic effect, and optimisation of the procedure for its simple and direct application in the presence of other species in real samples. Since this element is usually present at low levels in many environmental (natural and waste waters, soil and air), food, wines, drinks or biologically samples (blood, serum, urine), sensitive and selective analytical techniques are required for its determination. The developed kinetic procedure is sensitive, rapid, low-cost and applicable. The method was successfully applied to determination of traces amounts of Cu(II) in fruit, wine and milk samples. An ICP-OES method was also used for determination of Cu(II) in these samples, in order to validate the proposed kinetic-spectrophotometric method. The obtained results have shown good agreement. Also, based on the results of this work it can be seen that oxidation of Sunset Yellow, as widely used artificial dye for food and drinks, is catalysed by traces of metal ions, in presence of oxidative compounds (such as H_2O_2) in alkaline media, at about 25 °C, which is followed by decolourisation of such a kind of food and drink samples.

2. Materials and methods

2.1. Apparatus

Spectrophotometric measurements were performed on Perkin–Elmer Lambda 15 UV–vis spectrophotometer (Perkin–Elmer Instruments, Shelton, USA) using cylindrical cell thermostated at about 25.0 °C. For the pH measurements, Radiometer PHM 29Bb pH metre, (MeterLab, USA) and a combined glass–calomel electrode, GK2311C were used. All solutions were kept in a thermostatic water-bath at 25.0 ± 0.1 °C before the beginning of the reaction. ICP-OES measurements were done by means of an atomic-emission spectrometer SPECTRO CIROS^{CCD} (Spectro Analytical Instruments, Kleve, Germany). High precision measuring for laboratory applications was performed by using an analytical balance METTLER TOLEDO, AB204-S, Switzerland.

2.2. Reagents and solutions

Analytical grade chemicals and deionised water (MicroMed high purity water system, TKA Wasseraufbereitungssysteme GmbH) were used for the preparation of all solutions.

All the stock solutions were stored in polyethylene containers. All the polyethylene containers and the glassware used were cleaned in aqueous HCl (1:1) and then thoroughly rinsed with deionised water. A 1.000 g L^{-1} Cu(II) (nitrate salt, Merck®, KGaA, Darmstadt, Germany) was used as a stock solution. Cu(II) working solutions were made by suitable dilutions of the stock solution. A solution of SY (disodium-6-hydroxy-5-[(4-sulphophenyl)azo]-2-naphtalenesulphonic acid), Fluka (Bushs, Switzerland) of 1×10^{-3} mol L^{-1} was prepared by weighing 0.0226 g of substance of analytical grade, using an analytical balance, and dissolving with deionised water in a calibrated volumetric flask of 50 mL. A 2 mol L^{-1} solution of hydrogen peroxide (Merck®) was prepared by appropriate dilution of 30% of reagent in volumetric flask of 50 mL with deionised water. The solution of borate buffer was prepared by appropriate mixing a solution of $Na_2B_4O_7{\cdot}10H_2O$ (Merck®) of (0.05 mol L^{-1}) and 0.1 mol L^{-1} solution of NaOH. Sigma buffers, pH of 7.00 ± 0.01 and pH of 4.00 ± 0.01, were used to calibrate the pH metre.

2.3. Kinetic-spectrophotometric procedure

A suitable aliquot of Cu(II) solution, specified below for each sample, was transferred into a 10 mL standard flask with a glass stopper. Then, 0.2 mL of 10^{-3} mol L^{-1} solution of SY, and 2 mL borate buffer pH of 10.5 were added and the solution was diluted up to 4 mL with deionised water. The solution was kept at 25.0 ± 0.1 °C in the thermostated bath. After the temperature of the solution had reached 25.0 ± 0.1 °C, 1 mL of hydrogen peroxide solution of 2 mol L^{-1} was added in reaction mixture to initiate the reaction. The reaction mixture was transferred immediately into the spectrophotometric cell and the absorbance at 478.4 nm was measured every 30 s during the first period of 6 min from the beginning of the reaction. The method of tangents was used and the slope of the absorbance–time curve, $dA/dt = tg\alpha$, was used as a measure of the reaction rate.

2.4. ICP-OES conditions

The following ICP-OES conditions were applied: plasma power 1400 W, coolant flow 14.00 L/min, auxiliary flow 1.00 L/min and nebuliser flow 0.90 L/min. It is simultaneous spectrometer with radial viewed plasma, Paschen–Runge mount optical system and 22 linear CCDs placed detectors arranged on a Rowland's circle, enabling a spectral range 125–770 nm, and with a Scott-type spray chamber. Energy for the plasma was achieved with a free-running 27.12 MHz generator. Emission intensities were axially measured at 324.754 nm, as these conditions provided the highest sensitivity. Working parameters were controlled and altered using software package Smart Analyser Vision®. Calibration was performed using external standard prepared from 1000 g L^{-1} stock of Cu(II), made up as appropriate with 2% nitric acid.

2.5. Sampling plan and preparation of samples

The proposed kinetic method was applied for comparative determination of traces amounts of Cu(II) in samples of wine, grapes and milk, at different locations in South Serbia (Porecje, Vucje) and Kosovo (Mitrovica, Novo Brdo), in order to monitor the influence of different environmental and geo-morphological conditions on its contain in mentioned samples. The proposed kinetic method was also applied for determination of traces amounts of Cu(II) in fruit samples (lemon and orange – Tivat, Montenegro) and vineyard leaf.

The grape, wine (white, red) and milk samples (randomly selected, during 2007 autumn season) are collected at the same time from following area: (grape, red and white wine, vineyard leaf) – Porecje, Serbia; (red grape) – Mitrovica, Kosovo; (cow milk) – Porecje, Serbia and Novo Brdo, Kosovo; (lemon, orange) – Tivat, Montenegro. For the determination of trace levels of elements, contamination or loss are of prime consideration. Examined samples (lemon, orange and grape) are collected in plastic containers, and maintained at 4 °C during transport, protecting them from

all sources of mineral contamination. Fresh milk and wine samples are taken in polyethylene bottles, that are pre-washed with detergent, followed by 10% HNO_3 and deionised water. Samples are maintained at 4 °C during transport to the laboratory and stored at 4 °C. Samples prepared by this way have been analysed immediately under procedure mentioned below, for each type of samples.

A 1 g of samples red grapes were accurately weighed and carefully heated with 10 mL nitric acid (65%) followed by gentle heating with the addition of 8 mL perchloric acid (70%) until colourless. After cooling 30 mL deionised water was added and heating resumed for 10 min. Finally, the solutions were cooled, then made up to 50 mL with deionised water. A 100 mL of wine samples and fresh squeesed juice of orange and lemon using a water bath was boiled dry and the residue was burned at a temperature of 450–500 °C for 12 h. After that, 5 mL of concentrated HNO_3 was added and the sample was boiled dry again. The residue was kept for about 2–3 h at the same temperature. After that the residue was dissolved in five drops of concentrated HNO_3 and diluted up to 50 mL with deionised water. In 10 mL of milk, three drops of CH_3COOH were added. Using a water bath the samples were boiled dry and the residue was burned at a temperature of 400–450 °C for 12 h. After that 1 mL of concentrated HNO_3 was added and the sample was boiled dry again. The residue was kept about 2–3 h at the same temperature as before. After that the residue was dissolved in two drops of concentrated HNO_3 and diluted up to 25 mL with deionised water.

For kinetic application in that way prepared samples of fruit, wine and milk are treated as following: to 0.2 mL of prepared sample solution was added 0.8 mL of 2 mol L^{-1} NaOH in order to adjust of working pH. After that, 1 mL of prepared sample was used for the recommended procedure for kinetic measurements.

In order to eliminate the main interference effects from the presence of Fe^{3+}, Mn^{2+}, a volume of 0.1 mL of 0.01 mol L^{-1} of F^- was added and of Co^{2+}, Ni^{2+} a volume of 0.5 mL of 0.01 mol L^{-1} of citrate solution, and recommended kinetic procedure was successfully applied on these prepared samples (Piatnickii & Suhan, 1990).

3. Results and discussion

3.1. Optimisation of chemical variables

The catalytic effect of Cu(II) on the oxidation reaction of 6-hydroxy-5-[(4-sulphophenyl)azo]-2-naphtalenesulphonic acid (SY), by hydrogen peroxide in borate buffer was observed (Fig. 1). Absorbance measurements have been performed at the wavelength of the absorption maximum of SY at 478.4 nm, at pH of 10.5 and at 25 ± 0.1 °C. In order to establish the optimum conditions for the trace analysis of Cu(II), the influence of the reaction variables were studied for both, non-catalytic and catalytic reactions.

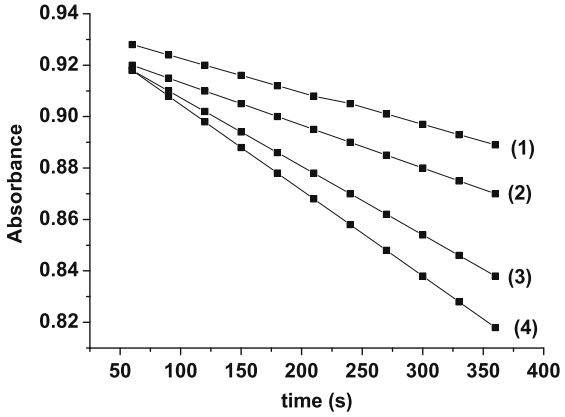

Fig. 1. Dependence of the reaction rate on the Cu(II) concentration. Experimental conditions: $C_{SY} = 4 \times 10^{-5}$ mol L^{-1}; $C_{H_2O_2} = 0.4$ mol L^{-1}; pH 10.5; $t = 25.0 \pm 0.1$ °C, $\lambda_{max} = 478.4$ nm; (1) $C_{Cu(II)} = 0$ ng mL^{-1}; (2) $C_{Cu(II)} = 32$ ng mL^{-1}; (3) $C_{Cu(II)} = 127$ ng mL^{-1}; (4) $C_{Cu(II)} = 254$ ng mL^{-1}.

3.2. Effect of pH

Keeping all other experimental parameter constant, the effect of pH was studied the first, to obtain information about the highest difference between the rate of the reactions. The dependence of the reaction rate on pH in borate buffer in the range of 9.2–11.5 has been studied. The optimal difference between the rates of non-catalytic and catalytic reactions has occurred at pH 10.5 and for further work a pH of 10.5 has been selected, because at higher value of pH rate of both reactions significantly increased and thus, enlarged errors during measurements. The dependence of the reaction rate on the volume of borate buffer was investigated. The maximum difference between the rate of the non-catalytic and catalytic reactions occurred for volume of 2.0 mL. For further work, a volume of 2.0 mL of borate buffer pH of 10.5 has selected as the optimal.

3.3. Effect of reagent concentration and temperature

The dependence of reaction rate on the concentration of SY was investigated over the range from 2×10^{-5} to 6×10^{-5} mol L^{-1}. For further work, a concentration of SY of 4.0×10^{-5} mol L^{-1} was selected as the optimal value, because at higher concentrations absorbance significantly increases ($A > 1$), which also increases the error of the spectrophotometric determination.

The dependence of the reaction rate on the concentration of H_2O_2 was investigated in the range 0.1–0.8 mol L^{-1}. The order for both reactions, catalytic and non-catalytic is zero, with respect to the concentration of H_2O_2 in the investigated interval. For further work, a concentration of H_2O_2 of 0.4 mol L^{-1} was selected as the suitable value.

The influence of temperature on the reaction rate was studied in the range 22–34 °C. The reaction rate increased as the temperature increased. However, although higher sensitivity could be obtained at the higher reaction temperature, it was troublesome to control the temperature precisely at the evaluated temperature; hence, a reaction temperature of 25 °C was chosen.

3.4. Validation of the proposed method

The calibration graph has been constructed under the following working conditions: $C_{SY} = 4 \times 10^{-5}$ mol L^{-1}; $C_{H_2O_2} = 0.4$ mol L^{-1}, pH 10.5; $t = 25.0 \pm 0.1$ °C, $\lambda = 478.4$ nm.

Under these conditions the change of the reaction rate was quite reproductive providing additional quality of the method in routine laboratory applications. The calibration curve was linear up to 318 ng mL^{-1} of Cu(II). The equation of the calibration curve was found to be:

Table 1
Effect of other ions on the determination of 191 ng mL^{-1} of Cu(II).

Tolerance limit Foreign ion/Cu(II)	Ion added
1000	Na^+, K^+, NH_4^+, Li^+, W^{6+}, Ca^{2+}, Cl^-, I^- CH_3COO^-
100	Zn^{2+}, Al^{3+}, Mg^{2+}, Cd^{2+}, V^{5+}, As^{3+}, As^{5+}, F^- NO_3^-, SO_4^{2-}, SO_3^{2-}, NH_4^+
10	Mo^{6+}, Hg^{2+}, Sn^{2+}, Sr^{2+}, Cr^{6+}, Ba^{2+}, $C_2O_4^{2-}$

Milk (Porecje, Serbia)	72.1 ± 1.10	1.525	100.3	70.8 ± 0.94	1.328	99.0

[a] Mean value ± standard deviation (ng mL^{-1}) (number of replicate measurements, n = 5).
[b] ng/g.
[c] Relative standard deviation.
[d] Recovery was calculated as: 100 − [(added value − found value) × 100]/added value.

$$tg\alpha \times 10^2 = 0.00262c + 0.8188,$$

where c is concentration of Cu(II) in ng mL^{-1}.

The limit of detection was determined as the signal-to-noise ratio ($3\sigma/S$) and it was 5 ng mL^{-1} and limit of quantification ($10\sigma/S$) was 16.67 ng mL^{-1}, where σ is the standard deviation of the blank, and S is the slope of the calibration curve.

In order to estimate the precision and accuracy of the proposed kinetic method, reaction rates were determined in five replicate determinations at each of three different Cu(II) concentrations 25, 191 and 318 ng mL^{-1} with RSD (%), respectively, 8.80%, 6.12% and 2.22%.

The method ruggedness was evaluated by five replicate determinations at different concentrations of Cu(II) (25, 191 and 318 ng mL^{-1}) over a period of 5 days. The low values of between-day RSD for different concentration of Cu(II) (less than 5%) indicate that solutions of SY, hydrogen peroxide and borate buffer have a very good stability.

The robustness of proposed method is a measure of its capacity to remain unaffected by small, but deliberate variations in the method parameters and provides an indication of its reliability during usage. The most significant variables of the system (temperature and the concentration of SY and hydrogen peroxide) were modified in the range ±10% (excluding pH, which was modified in the range ±5%) from their optimum values. Errors lower than 5% were observed in all cases. Thus, the proposed method was found to be robust for routine determination of Cu(II) in different real samples.

To access the selectivity of the method, the influence of some foreign ions on the catalytic reaction rate was studied, under the reaction conditions mentioned above, at a constant Cu(II) concentration of 191 ng mL^{-1}. The results are summarised in Table 1.

4. Application of the developed method

To evaluate the proposed kinetic method, the amounts of Cu(II) in wine, fruit and milk samples were determined. The results of proposed kinetic method have shown good agreement with results obtained by ICP-OES measurements (Table 2).

The obtained results confirm that the spectrophotometric kinetic method presented in this paper, under established working conditions, was successfully applied for Cu(II) determination in fruit, wine and milk samples, from different locations. The values of Cu(II) in milk, wine and grape samples from this area are also higher in comparing to values of Cu(II) in samples taken from other location without mines or plants (Porecje, Vucje, Serbia).

5. Conclusion

This work presents development and application of a rapid, simple, low-cost and sensitive kinetic method for the determination of trace amounts of Cu(II). The proposed method was applied in fruit, wine and milk samples. Validation of the method was made by determination of Cu(II) in these samples by using ICP-OES method, and results obtained using both methods have shown good agreement. The method has advantage in view of its sensitivity, low-cost, easy available chemicals and instrumentation, simple and direct application to many real samples.

ABSTRACT

The nutritional characteristics of seed proteins of Spanish wild populations of *Lupinus angustifolius*, *L. cosentinii*, *L. gredensis*, *L. hispanicus*, *L. luteus* and *L. micranthus* have been studied. Protein contents in this genus ranged from 23.8% in *L. gredensis* to 33.6% in *L. luteus*. On the one hand, *L. cosentinii* showed the most balanced amino acid composition, being only deficient in lysine. On the other hand, *L. gredensis* showed the worst amino acid composition. The *in vitro* protein digestibility (IVPD) was high in all species examined, ranging from 82.3% in *L. gredensis* to 89.0% in *L. cosentinii*. In addition to the amino acid composition and IVPD, other nutritional parameters, such as amino acid score, calculated biological value, predicted protein efficiency ratio or protein digestibility corrected amino acid score, were studied. These data yielded *L. luteus*, *L. hispanicus* and *L. cosentinii* as the species with seed proteins with the best nutritional properties, similar to those observed in other legumes with recognised high quality proteins, such as soybean. Results confirm the importance of studying wild populations of cultivated and non-cultivated *Lupinus* species as sources of seeds with good nutritional characteristics.

1. Introduction

Legumes represent, together with cereals, the main plant source of proteins in human diet. Beans are generally rich in high quality proteins, dietary fibre and carbohydrates and have a low content of saturated fats. For these reasons, beneficial health effects derived from legume consumption have been recognised and related to legume components, such as fibre or proteins and other minor compounds, such as certain lipids, polyphenols or bioactive peptides (Rochfort & Panozzo, 2007). These health promoting effects have been related to the prevention of diseases like diabetes mellitus, coronary heart diseases, or colon cancer (Duranti, 2006). However, legume consumption has decreased in recent decades in many Western countries, although the chemical and nutritional composition of beans show that they could play a much more important role in human nutrition. The genus *Lupinus* is not an exception and many of the cultivated species have seen their areas of cultivation reduced in the last century. However, the conservation of biodiversity may be, especially in developing countries, an important factor for their development. In order to recover and maintain this biodiversity the diversification of crops is necessary and this can be achieved by increasing our knowledge of local plants. Legume seeds are one of the most promising alternative sources of protein for human and animal nutrition. Among the main cultivated legumes, soybean is by far the most important. Other legumes, such as lupins, are being studied as potential alternative sources of protein in order to reduce the need to import soybean. *Lupinus* is an ancient crop belonging to the tribe *Genisteae* that was widely cultivated in the Mediterranean Region and South American Andes. The major cultivated species of lupins are *L. albus* (white lupin), *L. angustifolius* (blue lupin), *L. luteus* (yellow lupin) and *L. mutabilis* (pearl lupin). On average, lupin seeds have total protein content similar to soybean and acceptable amounts of essential amino acids. The chemical, functional and nutritional properties of lupin proteins mean that lupin seeds can be considered as a source of high quality protein (Lampart-Szczapa, Obuchowski, Czaczyk, Pastuszewska, & Buraczewska, 1997), with the protein content of cultivated lupin seeds ranging from 33.8% in *L. angustifolius* (Lqari, Vioque, Pedroche, & Millán, 2002) to 44% in *L. albus* (Duranti, Restani, Poniatowska, & Cerletti, 1981). Another interesting aspect of lupins as a new source of protein is that they can be grown in soils and in climates where soybean cannot grow. It has been suggested that lupin proteins supplemented with methionine could replace soy concentrate in countries where soybean must be imported (Ruiz & Hove, 1976). Moreover, lupin seeds have a lower content of the main anti-nutritional components often contained in legumes, such as phytates, oligosaccharides, trypsin inhibitors and lectins (El-Adawy, Rahma, El-Bedawey, & Gafar, 2001). Furthermore, *Lupinus* seed flours have been used for the production of

doi:10.1016/j.foodchem.2009.04.039

protein isolates with good functional and nutritional properties (Lqari et al., 2002). The aims of this study were to evaluate the nutritional characteristics of seed proteins of six lupins species which grow in Southern Spain.

2. Materials and methods

2.1. Materials

Trypsin, chymotrypsin and peptidase were acquired from Sigma (Tres Cantos, Madrid, Spain). Diethyl ethoxymethylenemanolate was purchased from Fluka. All other chemicals were of analytical grade. The samples of *Lupinus* seeds were collected from wild populations in Spain.

2.2. Amino acid analysis

Duplicate samples (10 mg) were hydrolysed with 4 ml of 6 N HCl. The solutions were sealed in tubes under nitrogen and incubated in an oven at 110 °C for 24 h. Amino acids were determined after derivatisation with diethyl ethoxymethylenemalonate by high-performance liquid chromatography (HPLC), according to the method of Alaiz, Navarro, Giron, and Vioque (1992), using D,L-α-aminobutyric acid as an internal standard. Tryptophan was analysed by HPLC after basic hydrolysis according to Yust et al. (2004).

2.3. In vitro protein digestibility (IVPD)

In vitro protein digestibility was determined according to the method of Hsu, Vavak, Satterlee, and Miller (1977).

2.4. Determination of nutritional parameters

The amino acid composition of studied lupins was used for the determination of several nutritional parameters of lupin seed proteins:

- Amino acid score (chemical score) was calculated as:
  % sample essential amino acids contents/% recommended essential amino acids (FAO/WHO/UNU, 1985).
- Protein efficiency ratio values (PER) were calculated from the amino acid composition of lupin seeds based on the following three equations (Alsmeyer, Cunningham, & Happich, 1974):

$$\mathrm{PER}_1 = -0.684 + 0.456 \times \mathrm{Leu} - 0.047 \times \mathrm{Pro}$$

$$\mathrm{PER}_2 = -0.468 + 0.454 \times \mathrm{Leu} - 0.105 \times \mathrm{Tyr}$$

$$\mathrm{PER}_3 = -1.816 + 0.435 \times \mathrm{Met} + 0.78 \times \mathrm{Leu} + 0.211 \times \mathrm{His} - 0.944 \times \mathrm{Tyr}$$

- Protein digestibility corrected amino acid score (PDCAAS) (FAO/WHO, 1989) was calculated as:
  The lowest individual amino acid score × IVPD.
- Predicted biological value (BV) was calculated according to Morup and Olesen (1976) using the following equation:

$$\mathrm{BV} = 10^{2.15} \times \mathrm{Lys}^{0.41} \times (\mathrm{Phe} + \mathrm{Tyr})^{0.60} \times (\mathrm{Met} + \mathrm{Cys})^{0.77} \times \mathrm{Thr}^{2.4} \times \mathrm{Trp}^{0.21}$$

where each amino acid symbol represents:

% amino acid/% amino acid FAO pattern (1985), if % amino acid ⩽ % amino acid FAO pattern or:
% amino acid FAO pattern (1985)/% amino acid, if % amino acid ⩾ % amino acid FAO pattern.

2.5. Cluster analysis

Cluster analysis of different taxa was performed using PRIMER-pc program, employing the Bray–Curtis index of dissimilarity (Bray & Curtis, 1957). The dissimilarity index was transformed to the index of similarity (1 − dissimilarity index × 100).

3. Results and discussion

Seed protein contents in studied lupins ranged from 23.8% in *L. gredensis* to 33.6% in *L. luteus* (Table 1). The percentages observed in wild populations are lower than those observed in seeds belonging to cultivated samples from the same species. Hence, *L. angustifolius* samples studied contained as an average 26.6% protein in contrast to 33.8% in commercial samples (Lqari et al., 2002). However, protein contents of the studied lupins were higher than those observed in other commercial legumes such as chickpea (24.7%) (Sánchez-Vioque, Clemente, Vioque, Bautista, & Millán, 1999).

The amino acid composition of studied wild lupin populations is shown in Table 1. All species show an amino acid pattern characteristic of legumes. Thus, except *L. cosentinii*, all taxa are deficient in sulphur amino acids and tryptophan according to FAO recommendations (FAO/WHO/UNU, 1985). Also, some species were deficient in aromatic amino acids and valine. Besides, all taxa, except *L. hispanicus*, were deficient in lysine, while in legumes the lysine content is usually above that suggested by FAO (1985). On the one hand, from the amino acid composition point of view, the most equilibrated species are *L. cosentinii* which is only deficient in lysine, and *L. hispanicus* which is also deficient in sulphur amino acids and tryptophan. On the other hand, *L. angustifolius* and *L. luteus* appear as the species which have the worst amino acid composition. This deficiency of lysine, tryptophan and valine has also been reported for commercial samples of *L. luteus, L. angustifolius* and *L. albus* (Sujak, Kotlarz, & Strobel, 2006).

The importance of protein composition in the diet has been well known for many years. Less clear is how to determine the nutritional quality of protein intake, which depends mainly on the amino acid contents. The first step is to determine the amino acid composition of proteins. To make use of these amino acids proteins must be digested in order to release them. Many different factors may impair digestibility, which would result in lower protein quality. Hence, in addition to amino acid composition, protein digestibility has been proposed as another protein characteristic which determines the protein quality. *In vitro* protein digestibility (IVPD) in studied *Lupinus* ranged from 82.3% in *L. gredensis* to 89.0% in *L. cosentinii.* This is a high IVPD, similar to those observed in other lupins, such as *L. albus* (86.9–88.8%) (El-Adawy et al., 2001), or to soybean (85.8%), rice (84.8%), or wheat (83.7%) (Wolzak, Elias, & Bressani, 1981). Moreover, it is higher than those observed in other legumes, such as chickpea (76.2%) (Sánchez-Vioque et al., 1999).

The highest predicted biological value was in *L. cosentinii* and *L. luteus* with values of 85.9 and 90.2, respectively (Table 2). The lowest predicted biological values were observed in *L. hispanicus* with 42.3. The best predicted biological values observed in studied *Lupinus* were lower than those described for lactoalbumin, with 97%, but higher than those reported for other crops, such as triticale (65.3) or wheat (61.6) (Friedman, 1996).

All *Lupinus* species studied here showed PER theoretical values over 2 and many even close to 3, corresponding to proteins of high nutritional value. Better calculated PER values were observed in *L. luteus* with indexes around 3. The lowest values were calculated for *L. gredensis* and *L. angustifolius*. Calculated PER values in wild populations of *L. Luteus* studied (Table 2) were higher than those previously observed in cultivated *L. luteus* (between 2.17 and 2.67) (Sujak et al., 2006), and those in many meat-containing foods

Table 1
Seed protein amino acids composition of studied lupins. Data expressed as g/100 g protein are the average ± standard deviation of indicated number of populations studied.

(Alsmeyer et al., 1974). The *Lupinus angustifolius* calculated PER reported here were similar to those calculated for cultivated samples (between 2.10 and 2.77) (Sujak et al., 2006). Similar values to those reported here for *Lupinus* have been described for other legumes, such as soybean (2.57) (Wolzak et al., 1981) or chickpea (2.8) (Newman, Roth, Newman, & Lockerman, 1987). Lower PER values were observed in other legumes such as peanut (between 1.45 and 1.76) (Ghuman, Mann, & Hira, 1990), or *Vigna radiata* (between 1.6 and 2.1) (Savage & Deo, 1989).

The use of amino acid scores has been proposed as a more accurate alternative to PER parameters (Sarwar et al., 1984). The amino acids score was the highest in *L. hispanicus* and *L. cosentinii* with average values of 107.7 and 104.1, respectively (Table 2). The lowest value was observed in *L. gredensis* with average values of 86.4. Similarly, the% essential amino acids / total amino acids ratio was the highest in *L. hispanicus* and *L. cosentinii* with average values of 36.5 and 35.3, respectively.

The PDCAAS is nowadays the most recommended theoretical parameter for evaluating the nutritional quality of food proteins. It is based on FAO recommendations of amino acid requirements (FAO/WHO/UNU, 1985) and *in vitro* protein digestibility. The highest PDCAAS value for a given protein is 1.0. The lowest PDCAAS was observed in *L. micranthus* with 0.4, while the highest PDCAAS was observed in *L. cosentinii* with 0.80. This index was higher than that observed in other legumes, such as peas (0.69), beans (0.68) or lentils (0.52).

The analysis of similarity based on a profile of seed protein amino acid composition shows two major groups (A and B, Fig. 1) with 91.7% affinity. The first includes only *L. gredensis,* while the remaining species studied form the other group (group B). Within group B, two groups (C and D) are distinguished with 95.8% similarity. Group C includes only *L. cosentinii*, while the remaining species form group D. In the latter group two other groups are recognised (E and F) with 96% affinity. Not considering *L. gredensis*, the separation of *L. cosentinii* (group C) from the other species (group D) supports the delimitation of the *Lupinus* species on the basis of the seed coat texture into two distinct groups: the rough-seeded (*L. cosentinii*) and the smooth-seeded species (the remaining species) (Naganowska, Wolko, Sliwinska, & Kaczmarek, 2003; Przybylska & Zimmniak-Przybylska, 1995). With respect to group D the subdivision (with 96% affinity) in group E (*L. micranthus*) and group F is in accordance with molecular data (Naganowska et al., 2003). According to the amino acid composition *L. gredensis* is the most divergent specie. In conclusion, the analysis of similarity of studied *Lupinus* based on the amino acid composition shows some discrepancy with the established interspecific taxonomical

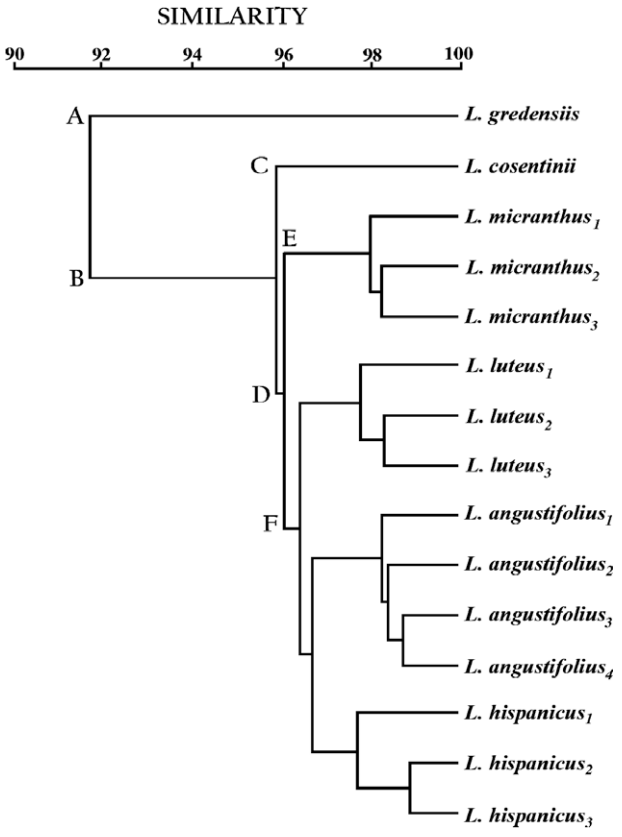

Fig. 1. Clustering based on the amino acid composition of studied *Lupinus* species, according to the Bray–Curtis similarity index (1 − dissimilarity index × 100).

relationships. However, amino acid composition was useful to group in single clusters populations belonging to the same specie.

From the studied species *L. cosentinii* appears as the one with the most equilibrated amino acid composition. It was only deficient in lysine. It is used for livestock feeding and soil fertilisation and has been used in breeding programmes in Australia since 1954 (Weder, Salmanowicz, & Köhler, 1997) due to its successful adaptation to alkaline soils.

With respect to the nutritional parameters, *L. luteus, L. hispanicus* and *L. cosentinii* showed the best results. On the contrary, *L. gredensis* showed the worst nutritional characteristics.

Results confirm the interest in studying wild populations of cultivated and non-cultivated *Lupinus* species as a source of seeds with good nutritional characteristics. This may help in the domestication of new species or the use of wild populations in breeding programmes, favouring the bio-conservation of *Lupinus*.

ABSTRACT

A rapid simple and economical method was described for the determination of ochratoxin A produced by *Aspergillus ochraceus* ITEM 5117 grown in a biofermenter in submerged culture. The ochratoxin A was determinate with RP-HPLC-FLD (reverse phase high performance liquid chromatography) with direct injection in the HPLC apparatus using a C18 column. The mycotoxin was completely resolved by using the mixture acetonitrile, water and acetic acid (49:49:2 v/v) as the mobile phase with a flow rate of 1.0 mL/min. Mean recoveries of ochratoxin A ranged from 95.36% to 103.15%. The limit of detection for ochratoxin A in medium was found to be 1 $\mu g\,L^{-1}$.

1. Introduction

Mycotoxins, a structurally diverse group of mostly small molecular weight compounds produced by the secondary metabolism of fungi, are ubiquitous in a broad range of commodities and feeds (Steyn, 1995). They may cause a toxic response, known as mycotoxicosis, when ingested by higher vertebrates and other animals. The mycotoxigenic fungi involved with the human food chain belong mainly to three genera: *Aspergillus*, *Fusarium* and *Penicillium* (Sweeney & Dobson, 1998).

Among the mycotoxins that have a substantial importance in the medical field and in foods, further at the aflatoxins and trichotecenes, there are OTA, beauvericin and the enniatins belonging to classes A and B (Sweeney & Dobson, 1998).

The mycotoxin OTA derives its name from *Aspergillus ochraceus*, the first mould from which it was isolated. It is the main toxic component in cultures of this mould, but it is also produced by other ubiquitous moulds such as various other strains of *Aspergillus* and *Penicillium*. OTA consists of a dihydroisocoumarin moiety linked through its 7-carboxy group by an amide bond to L-phenylalanine, as showed in Fig. 1 (Rohr, Dietrich, Schlatter, & Schlatter, 1995).

Several toxic effect of OTA have been described, such as inhibition of protein synthesis, impairment of calcium homeostasis, induction of lipid peroxidation, oxidative stress and DNA damage, with species and tissue specific differences (Almela et al., 2007). Furthermore, this mycotoxin is known/considered to be nephrotoxic, cytotoxic (Rinaldi, Mancini, Ferruzza, Sambuy, & Peruzzi, 2007), carcinogenic, teratogenic and immunosuppressive. It may also induce gene mutation, although the mechanism of genotoxicity is not clear (Rinaldi et al., 2007).

Human exposure to OTA has been related to Balkan Endemic Nephropathy (BEN) syndrome, but available clinical and epidemiological data do not confirm this hypothesis because similar concentrations of this mycotoxin do not cause the disease in other European areas (Abouzied et al., 2002; Blank et al., 2003; Creppy, Baudrimont, & Betleder, 1998; Jimmer, Lopez de Cerain, Gonzales-Penas, & Bello, 1999). On the other hand, BEN syndrome has been associated with other nephrotoxic agents (Pfohl-Leszkowicz, Petkova-Bocharoma, Chernozensky, & Castegnaro, 2002).

The underlying mechanism of OTA-mediated pathologies has not been fully elucidated (O'Brien & Dietrich, 2006; Ringot, Chango, Schneider, & Larondelle, 2006).

Various analytical methods have been developed to evaluate OTA, in different matrix such as foods and biological fluids with HPLC or thin-layer chromatography (TLC) (Assaf, Betbeder, Creppy, Pallardy, & Azouri, 2004; Munoz, Vega, Rios, Munoz, & Madariaga, 2006; Pittet & Royer, 2002; Santos & Vargas, 2002). We propose a new HPLC method for the evaluation of OTA produced by *A. ochraceus* ITEM 5117 in submerged culture with a biofermenter without any sample preparation. The HPLC analysis was performed by a direct injection in a C18 monolithic column, which allows to directly analyse liquid matrix with any previous treatment.

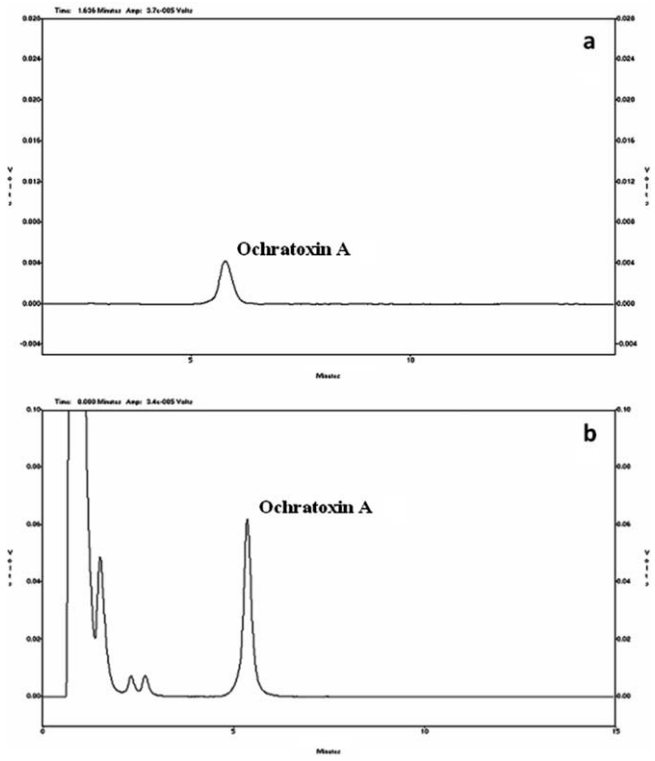

Fig. 1. (a) Chromatogram related to the ochratoxin A standard (10 μg L^{-1}) analysed with monolithic C18 column and (b) separation of ochratoxin A detected in PDB inoculated with *Aspergillus ochraceus* ITEM 5117 at ninth fermentation day, on the monolithic C18 column.

2. Materials and methods

2.1. Microorganism and inoculum preparation

A commercial cultural broth, potato dextrose broth (PDB), was used for this study, obtained from Oxoid (Basingstoke, UK). A suspension of conidia in concentration of 10^6 conidia mL^{-1} of *A. ochraceus* ITEM 5137 was used for inoculation. Conidial concentration was measured by optical density at 600 nm and adjusted to 10^6 conidia mL^{-1} in the biofermenter (Kelly, Grimm, Bendig, Hempel, & Krull, 2006). The strain used is deposited in culture collections at the Istituto delle scienze delle Produzioni Alimentari del Consiglio Nazionale delle Ricerche (ISPA-CNR) (Bari, Italy), in sterile 18% glycerol.

2.2. Cultivation system

The cultivations are accomplished by triplicate in 5 L bioreactors Inforce (Bottmingen, Switzerland) with a working volume of 4 L. For agitation, two rushton turbines (Ø 45 mm) are used and aeration related to the working volume is set to a constant value of 2 L min^{-1}.

The agitation rate was set at 180 rpm. Temperature and pH are maintained at 30 °C and 7.0, respectively. The pH is controlled by the addition of sodium hydroxide (0.5 M).

The biofermenter was inoculated with conidia produced in preculture for 24 h at low agitation rate of 50 rpm.

In order to evaluate OTA production during the mould growth, a volume of 2 mL of the broth containing *A. ochraceus* ITEM 5117 was sampled every three days during one month, it was filtered through 0.22 μm regenerated cellulose membrane and injected in triplicate directly in the HPLC for OTA determination.

2.3. Apparatus and column

Direct HPLC analysis of OTA was performed using a Shimadzu HPLC system (Shimadzu, Kyoto, Japan) equipped with two binary pumps (mod. LC-10ACvp), a fluorometre detector (mod. RF-10Axl), a system controller (mod. SCL-10Avp) and a valve inject mod. 7725 Rheodyne (Park Court Rohnert Park, USA). The fluorometre detector was set up at λ_{ex} of 333 nm and λ_{em} of 460 nm. The instrument was fitted with a 20 μL peek loop and a 100 μL precision syringe Hamilton (Reno, USA) was used for this injection. The chromatograms were stored and processed with a Shimadzu software Class-VP v.4.3 (Shimadzu, Kyoto, Japan). The mobile phase was a mixture of acetonitrile, water and acetic acid (49:49:2 v/v/v, respectively) at a constant flow of 1 mL min^{-1} under/using isocratic conditions and an Onyx Monolithic C18 100 × 3 mm ID 5 μm, Phenomenex (Torrance, USA) analytical column was used. The OTA retention time was 5.8 min (Fig. 1) with a retention factor of $k' \cong 6.56$.

2.4. Chemicals

A stock standard solution of OTA Sigma–Aldrich (St. Louis, USA) was prepared by dissolving 1 mg of standard in 1 mL of pure methanol, obtaining a stock solution of 1000 mg L^{-1}. This stock solution was used to prepare the work solutions (from 1 to 100 μg L^{-1}) by preparing appropriate dilutions with pure methanol. Acetonitrile, methanol, water (all HPLC grade) and acetic acid were purchased from Merck (Whitehouse Station, USA). The 0.2 μm filter used were the type RC25 Phenomenex (Torrance, USA).

2.5. Calculation of results

The amount of OTA, in the mediums, analysed by HPLC was determined by using a calibration graph of concentration with a linear range from 1 to 100 μg L^{-1}. The linear fit was: $y \cong 8500.7 \cdot x$ (with a $r^2 \cong 0.9998$). The limit of quantification (LOQ) was 1 μg L^{-1} and the limit of detection (LOD) was 0.1 μg L^{-1}, calculated as 3 and 10 times the height of the noise level, respectively.

2.6. Recovery

The mediums without amounts of OTA were supplemented with different levels of ochratoxin A, in particular in the concentration of 1, 5, 10, 50 and 100 μg L^{-1} to determine the recovery of the procedure analysis.

3. Results and discussion

3.1. Recovery analysis

The recovery analysis showed very satisfying values (Table 1). The recovery of the ochratoxin A was 95.36% or higher for added levels of 1, 5, 10 and 100 μg L^{-1}. The % SD ranged from 0.35% in the medium containing 50 μg L^{-1}, and 2.02% in the medium containing 5 μg L^{-1} of the toxin.

Table 1
Recovery of ochratoxin A from medium supplemented with different toxin's concentration.

Spiking level (μg L^{-1})	Recovered (μg L^{-1})	Recovery (%)	Standard deviation (%) (n = 3)
1	0.99	99.00	0.56
5	5.15	103.15	2.02
10	10.17	101.70	1.05
50	47.68	95.36	0.35
100	98.62	98.62	2.48

Table 2
Monitoring of ochratoxin A concentration produced by *Aspergillus ochraceus* in PDB during 30 days of fermentation.

Days	Ochratoxin A produced by *Aspergillus ochraceus* ITEM 5117 in PDB ($\mu g\ L^{-1}$)
0	20.05
3	22.26
6	19.02
9	121.89
12	147.33
15	161.53
18	162.96
21	146.57
24	144.71
27	126.94
30	122.30

3.2. Separation efficiency

The standard of ochratoxin A was subjected to a series of chromatographic runs in order to establish optimum condition for separation in C18 monolithic column (Fig. 1). The water used alone as the mobile phase was not found sufficient to resolve the ochratoxin A. Including acetonitrile in the mobile phase mixture 50% resulted a better separation owing to faster elution. Fig. 1 illustrates the separation of pure ochratoxin A on a monolithic C18 column using a mixture acetonitrile, water and acetic acid (49:49:2 v/v/v) as the mobile phase at a flow rate of 1.0 mL/min.

Fig. 1 also illustrates the medium chromatogram in which all co-extractives were resolved from each other under the same chromatographic condition. Retention time of ochratoxin A was approximately 6.0 min. RSDs was 0.74%, indicating good retention time reproducibility.

3.3. Applicability

The method was used to evaluate the amount of ochratoxin A produced by *A. ochraceus* ITEM 5117 in submerged culture, using PDB as growth medium, in biofermenter during 30 days. Results are shown in the Table 2. The initial OTA concentration detected when the *Aspergillus* was inoculated in PDB was 20 $\mu g\ L^{-1}$, because the mould had already activated its secondary metabolism in the preinocul culture.

However, OTA's amount experienced a great increment at the nine fermentation's day, rising from 19 to 121 $\mu g\ L^{-1}$. The biggest OTA concentration was reached at the 18th day of growth, corresponding to 162 $\mu g\ L^{-1}$ of the toxin (Harris & Mantle, 2001).

Between the 21st and the 30th day the toxin's concentration decreased from 146 to 122 $\mu g\ L^{-1}$, because in this phase the microbial death starts occurring, and the microorganism use the toxin as a carbon source (Munoz et al., 2006).

4. Conclusion

The OTA is one of most studied mycotoxins because results to be involved in different toxicological and medical fields. Considering that the study of secondary metabolism products in submerged culture is fundamental for understanding the secondary moulds metabolism, a method to analyse OTA in the medium would be rapid, accurately and possibly economic. In this study, a simple, a precise and a sensitive HPLC method which requires less chemicals and time for the determination of ochratoxin A is described.

The method passed a series of validation tests including separation efficiency, reproducibility and applicability and found useful for routine control of ochratoxin A production in submerged culture fermentation which involved many ochratoxigenic moulds.

Odour activity value
Factorial design
Gas chromatography–electron trap mass spectrometry

ABSTRACT

This study focus on the development of a headspace solid-phase microextraction (HS-SPME) method coupled to gas chromatography–ion trap mass spectrometry (GC–ITMS) to identify and quantify simultaneously 32 characteristic volatile compounds. A mixed level factorial 3×2^3 design was performed to asses the influence of several factors and their interactions (extraction temperature, fibre coating, salt addition and sample volume) on the extraction efficiency. The evaluation of the design showed that temperature and fibre coating were the most significant variables. The method showed good linearity ($r^2 > 0.990$) and repeatability (RSD $\leqslant$ 16%) for all compounds, with detection limits ranging from 0.0024 μg/L for limonene to 238 μg/L for ethyl 3-hydroxybutyrate, in general below their odour threshold limits. Matrix effects were thoroughly studied. The method was after applied to the first aroma characterisation of the monovarietal young red wine Mencía from the Galician (NW Spain) designation of origin "Valdeorras DO". To achieve the identification of the major would-be impact odourants, the odour activity value (OAV) was also calculated.

1. Introduction

The wine is a complex matrix which contains volatile compounds, as minor basic components, which play an important role in the organoleptic quality to their account for wine flavour, basically. These odourants are produced through metabolic pathways during ripening and harvest of grapes (primary or pre-fermentative aroma), during their fermentation (secondary or fermentative aroma) and/or also during the storage of wines (post-fermentative aroma or bouquet) (Etiévant, 1991); then, factors such as grape variety, environmental conditions (climate and soils), fermentation conditions (yeast flora, pH and temperatures), wine-making process and ageing conditions are primordial in the final composition of these odourants. As a final result, wine aroma contains over 1000 compounds that belong to heterogeneous chemical groups such as acids, alcohols, aldehydes, esters, ethers, hydrocarbons, ketones, lactones, nitrogen compounds, sulphur compounds and/or terpene alcohols (Bonino et al., 2003; Cabredo-Pinillos, Cedrón-Fernández, & Sáenz-Barrio, 2008; Martí, Mestres, Sala, Busto, & Guasch, 2003; Tao, Li, Wang, & Zhang, 2008).

The concentration levels of the volatile odourants are variable, ranging from several mg/L to a few ng/L. Due to this complexity and these low levels, the use of extraction/concentration techniques are essential. There are several extraction techniques for the gas chromatographic (GC) analysis of volatile aroma components of wine. Liquid–liquid extraction (LLE) technique was the most widely used to extract volatile compounds in wine samples; however, LLE requires large volumes of organic solvents, it is time-consuming and low recoveries are registered (Cutzach, Chatonnet, & Dubourdieu, 2000; Lee & Noble, 2003; Silva Ferreira & Guedes de Pinho, 2003). Headspace techniques (static and dynamic) require specific instrumentation coupled with the GC instrument (Aznar & Arroyo, 2007). Other alternative extraction techniques include simultaneous extraction, distillation and solid-phase extraction (Campo, Cacho, & Ferreira, 2007; Castro, Natera, Durán, & García-Barroso, 2008; Hernanz, Gallo, Recamales, Meléndez-Martínez, & Heredia 2008), supercritical fluid extraction (Carro, García, & Cela, 1996; Karásek et al., 2003), liquid–liquid microextraction (Farina, Boido, Carrau, & Dellacassa, 2007; Ferreira, Escudero, López, & Cacho, 1998), and stir-bar sorptive extraction (Alves, Nascimento, & Nogueira, 2005; Díez, Dominguez, Guillén, Veas, & Barroso, 2004; Zalacaín, Marín, Alonso, & Salinas, 2007); they offer specified advantages but also they can present some drawbacks such as the possibility of contamination with solvents, artefact formation and insufficient selectivity.

Solid-phase microextraction (SPME) appears like an excellent alternative to conventional extraction techniques due to their advantages: simple, fast, inexpensive, sensitive and no-solvent required, among others. Headspace SPME (HS-SPME) has been widely applied in wine analysis to identify key primary, secondary and bouquet aroma compounds (Alves et al., 2005; Bonino et al.,

2003; Bosch-Fusté et al., 2007; De la Calle García et al., 1997; Martí et al., 2003; Perestrelo, Caldeira, Rodrigues, & Câmara, 2008; Tat, Comuzzo, Stolfo, & Battistutta, 2005; Torrens, Riu-Aumatell, López-Tamames, & Buxaderas, 2004); to identify the geographical origin of the product, the authenticity preventing product adulteration (Cabredo-Pinillos et al., 2008; Jurado et al., 2008) and/or to determine fungicide residues coming from the phytosanitary treatments of the grapes (Rial-Otero, Yagüe-Ruiz, Cancho-Grande, & Simal-Gándara, 2002).

This work is focussed on primary and secondary odourants of Mencía red wine. Mencía wine is a monovarietal young red wine produced under the Galician designations of origin "Valdeorras DO", "Ribeira Sacra DO" and "Monterrei DO" (Ourense, NW Spain). Only a previous work was published to establish an aroma pattern for Mencía variety from "Monterrei DO" and "Ribeira Sacra DO" using time-consuming LLE with different extraction solvents depending of the chemical family (Calleja & Falqué, 2005), but it is known that new trace aroma compounds are not detectable by conventional LLE technique (Bonino et al., 2003). The main purposes of this work were basically two:

1. To present a unique method based on HS-SPME, sampling with DVB-CAR-PDMS fibre, and subsequent GC–ITMS for the identification and determination of the most representative odourants of Mencía wines from the "Valdeorras DO".
2. To define the first profile of the major volatile compounds and impact odourants in Mencía wines from this region.

2. Experimental

2.1. Volatile standards

Volatile compounds tested in Mencía red wines were purchased from Fluka (St. Louis, MO, USA), Sigma–Aldrich (St. Louis, MO, USA) and Safc (St. Louis, MO, USA).

2.2. Standard and working solutions

Individual standard solutions for the volatile compounds were prepared in EtOH. Secondary standard solutions were also prepared by dilution in EtOH of the individual standard solutions. All the standards were stored in the darkness at 4 °C.

Working solutions, containing target analytes, were prepared by mixing and diluting different amounts of secondary standard solutions in a synthetic wine solution previously prepared by dissolving 130 mL of EtOH, 7.2 mL of glycerol, 3 g of tartaric acid, 0.7 g of citric acid, 0.9 mL of lactic acid, 0.5 mL of acetic acid, 1.5 g of glucose:fructose (1:1), 35 μL of HSO_3^- (5% in water) and a suitable amount of sodium hydroxide in deionised water (1 L of total volume); the percent of EtOH and pH value of the synthetic model wine was 13% (v/v) and 3.3, respectively, to reproduce the properties of the young Mencía wine studied. 2-octanol and methyl nonanoate were employed in working solutions as internal standards because of their chemical structure (belonging to alcohol and ester families, respectively) and their absence as natural components in wine.

2.3. Wine samples

Red wines of the 2007 vintage, originating from Mencía grape variety from the "Valdeorras DO" (Ourense, NW Spain) were elaborated in the winery of the Regulatory Council of the Valdeorras DO. All samples were taken from bottled wine (750 mL) ready for sale and were stored at 4 °C until analysis.

2.4. SPME coating

The commercially available SPME device and fibres were purchased from Supelco (Bellefonte, PA, USA). An 85 μm polyacrylate (PA) and 50/30 μm divinylbenzene-carboxen-polydimethylsiloxane (DVB-CAR-PDMS) fibres were initially conditioned according to the instructions of the manufacturer in order to remove contaminants and to stabilize the phase. Conditioning was carried out in an extra split/splitless port (split open) with helium carrier gas prior to each extraction. This procedure prevents the passive extraction of interfering analytes from room air.

2.5. Experimental design

The influence of the main variables potentially affecting the efficiency of SPME was evaluated by using an experimental design approach, which allowed the simultaneous variation of all variables selected and the detection of probable interactions among them that could not be found in classical one-at-a-time optimisation. Factors included in the factorial design were: temperature (A) at three levels (25, 42.5 and 60 °C); fibre coating (B) at two levels (PA, DVB-CAR-PDMS); salt addition (NaCl) (C) at two levels (0% and 30%) and sample volume (D) at two levels (15 and 30 mL).

A mixed level factorial 3×2^3 design, which involved 24 experiments, was selected. The design had resolution *V*, which means that it was capable of evaluating all main effects and all two-factor interactions, allowing 12 degrees of freedom to estimate the experimental error.

Experiments were performed in headspace mode with aliquots of synthetic wine spiked at 1 mg/L of 2-methyl-1-propanol (**9**), 1-butanol (**10**), 3-methyl-1-butanol (**11**) and ethyl 3-hydroxybutyrate (**24**); 500 μg/L of terpineol (**3**), *trans*-3-hexen-1-ol (**13**), benzyl alcohol (**16**), *cis*-3-hexen-1-ol (**14**), *trans*-2-hexen-1-ol (**15**), 2-phenylethyl acetate (**19**), ethyl 2-methylpropanoate (**20**), ethyl butanoate (**21**), 4-ethyl-2-methoxyphenol (**28**), 4-ethyl-phenol (**29**) and 2-methoxy-4-vinyl phenol (**30**); 150 μg/L of linalool (**2**), citronellol (**4**), nerol (**5**), β-damascone (**6**), α-ionone (**7**), β-ionone (**8**), 1-hexanol (**12**), 3-methyl-1-butyl acetate (**17**), diethyl succinate (**26**), 2-furfuraldehyde (**31**) and benzaldehyde (**32**); 30 μg/L of limonene (**1**), hexyl acetate (**18**), ethyl hexanoate (**22**), ethyl octanoate (**23**), ethyl decanoate (**25**) and ethyl dodecanoate (**27**). Samples were magnetically stirred and the sampling time was set at 30 min.

The experimental design matrix and data analysis resulting from the experimental design were performed with the statistical software package Statgraphics Plus 5.1 (Manugistics, Rockville, MD, USA).

2.6. Final analytical procedure

2.6.1. HS-SPME

Wine samples (30 mL) were placed in a 40 mL glass sample vial. To each sample, 2-octanol and methyl nonanoate were used as internal standards (50 μL of a mix solution of 30 mg/L) and 9.0 g of Nacl was added. The vial was sealed with a Teflon-faced septum cap. Pre-conditioning of the sample at the extraction temperature was established between 10 and 15 min; some authors found this could be an important factor in the yield of the flavour extraction (Carrillo, Garrido-López, & Tena, 2006). After pre-conditioning, the SPME fibre was exposed to the headspace for 45 min. The sample was shaken with a magnetic stirring bar at 1100 rpm at controlled temperature (25 °C) during the extraction process and immediately the fibre was inserted during 10 min into the GC injector port (at 250 °C) for thermal desorption of the analytes.

2.6.2. GC-ITMS

GC analyses were carried out on a Trace GC Thermo Finnigan gas chromatograph (Rodano, Italy) equipped with a PolarisQ ion trap mass selective detector (ITMS), interfaced to a PC computer running the software XCalibur 1.4, from Thermo Electron Corporation (Italy). Chromatographic separations were done by using a Supelcowax fused-silica capillary column (60 m × 0.25 mm ID, 0.25 μm film thickness) from Supelco. The carrier gas, helium, operated at 1 mL/min in constant flow mode. Splitless mode was selected for 10 min. The oven temperature was programmed as follows: 40 °C for 2 min; 2 °C/min ramp to 225 °C where it was held for 15 min. The transfer line temperature was 260 °C, and the ion-trap manifold temperature was 250 °C. The ion energy for electron impact (EI) was always 70 eV. Mass detection was performed in the single ion range (SIR) mode; selected ions (m/z) used for qualitative and quantitative purposes are shown in Table 2.

3. Results and discussion

3.1. Chromatographic analysis

The first step consisted of developing experiments conducted to optimize the chromatographic separation of the 32 target analytes. Under the finally selected conditions, described in Section 2.6, an adequate separation of the compounds was achieved in 82 min, only 2-phenylethyl acetate (peak 19) and β-damascone (peak 6) were not completely resolved. Terpineol (peak 3) gave peak clusters corresponding to their α, β and γ isomers; in this study, the area of the α-isomer (the most abundant) was taken into account for determination.

3.2. Evaluation of the SPME process: factorial design

Extraction temperature is one of the most relevant parameters to evaluate in SPME since it affects both thermodynamics and kinetics of the extraction; temperature may enhance or worsen the extraction process depending on the volatility, vapour pressures and Henry's law constant values of the compounds (Pawliszyn, 1997). Two types of fibres (PA and DVB-CAR-PDMS), among those used most routinely for assaying wine volatiles, were also tested taking account of the physico-chemical characteristics of the target compounds under consideration. In agreement with published results, PA fibre showed an effective extraction for polar compounds such as alcohols of low molecular weight (Begala, Corda, Podda, Fedrigo, & Traldi, 2002; Martí et al., 2003; Rocha, Ramalheira, Barros, Delgadillo, & Coimbra, 2001; Vaz Freire, Costa Freitas, & Relva, 2001), higher alcohols, fatty acids (Perestrelo et al., 2008) and terpenes (De la Calle García et al., 1997; Rocha et al., 2001; Vaz Freire et al., 2001); on the other hand, previous works confirmed that DVB-CAR-PDMS is a versatile fibre, as it is highly sensitive for different chemical classes of analytes (esters, fatty acids, alcohols) (Carrillo et al., 2006; Howard, Mike, & Riesen, 2005; Martí et al., 2003; Setkova, Risticevic, & Pawliszyn, 2007; Tat et al., 2005; Torrens et al., 2004). The effect of ionic strength – no-addition and addition of 30% of NaCl (saturated condition) – was considered in the experimental design. Generally, the presence of electrolyte in an adsorption system could influence the adsorption in two ways: changing the properties of the phase boundary and decreasing the solubility of hydrophobic compounds (Yang & Peppard, 1994). Since the amount adsorbed in the SPME fibre is dependent on the sample volume, different volumes (15 and 30 mL) of the sample (subsequently different headspace volumes) were also tested. Although the presence of a gas phase should not change the distribution of an analyte between the liquid phase and the adsorption phase at equilibrium, the volume of the gas phase also influence the actual amount adsorbed on the fibre (Yang & Peppard, 1994).

The selection of some factors such as sampling mode and magnetic stirring were kept constant during the experimental design following the considerations cited in the bibliography (De la Calle García et al., 1997; Selli et al., 2004) in this way, HS-SPME mode should be more appropriated than direct sampling mode (D-SPME) for the analysis of aroma components of wines due to headspace mode showed better performance and higher sensitivity than direct immersion, since avoid the occurrence of interferences (Alves et al., 2005) and the direct contact of the coating with the relative high content of EtOH present in wine (De la Calle García et al., 1997). A magnetic stirring could be useful to accelerate the transfer of the analytes from the sample to the fibre coating; stirring facilitates the release of volatile compounds by increasing the surface of the liquid–vapour interface (Rocha et al., 2001).

Due to the selected design (3×2^3 mixed level factorial design) allowed 12 degrees of freedom, some statistic tests and graphic tools were evaluated in order to determine which factors had a statistically significant effect on the extraction process of each odourant, as well as which were the significant interactions between factors. The analysis of variance (ANOVA) was performed to evaluate and to asses the significance of the selected model. The most relevant graphical results of the design – Pareto charts and main effects plots – are showed in Fig. 1, respectively. One representative compound of each family is selected instead of the 32 aroma compounds studied. Pareto charts are useful graphs to illustrate the effect of the variables and their interactions. The bar length is proportional to the influence of each investigated variable or their interactions on the response. These charts include a vertical line corresponding to the 95% confidence interval; the main effects or interactions that exceed this reference line may be considered statistically significant (Fernández-Álvarez et al., 2008). The main effect plots are other graphical valuable tools for the interpretation of experimental design outcomes. This kind of plots shows the main effects with a line drawn between the low and the high level of the corresponding factors. The slope and the length of the depicted curves represent the variation in the response measured for each compound when the associated factor changes from the low to the high level considered in the domain of the design. The sign (+ or −) of the slope is related to the positive or negative exerted influence (Carpinteiro, Rodríguez, Cela, & Ramil, 2009).

Table 1 summarises the most favourable conditions evaluated for the extraction of the target compounds, including the significant interaction effects. As can be seen, the fibre coating (B) was the most important factor with a significant effect for 26 of the 32 studied compounds (Fig. 1, Table 1); the DVB-CAR-PDMS fibre exhibited the maxima responses in all cases, including those aromas where the fibre coating is not statistically significant (linalool, citronellol, nerol, 2-methyl-1-propanol, 1-butanol and ethyl hexanoate). The second important factor on the aroma response was the extraction temperature (A), presenting statistically significance for 18 compounds. Main effects plots of one of these 18 flavours (2-phenylethyl acetate) showed a slightly improvement at 42.5 °C (medium level), for four compounds the response is indistinct at 25 °C or 42.5 °C (benzyl alcohol, 4-ethylphenol, 2-furfuraldehyde and benzaldehyde) and the remaining compounds registered higher peak areas at room temperature (25 °C). Just in the case of citronellol, β-damascone, α-ionone, β-ionone, 1-butanol, ethyl hexanoate, ethyl decanoate, ethyl dodecanoate, 4-ethyl-2-methoxyphenol and 2-methoxy-4-vinyl phenol, 42.5 °C led also to higher chromatographic responses, but, for these compounds, the extraction temperature was not a significant variable. Salt addition was a significant factor for the extraction of only three of the investigated flavours (limo-

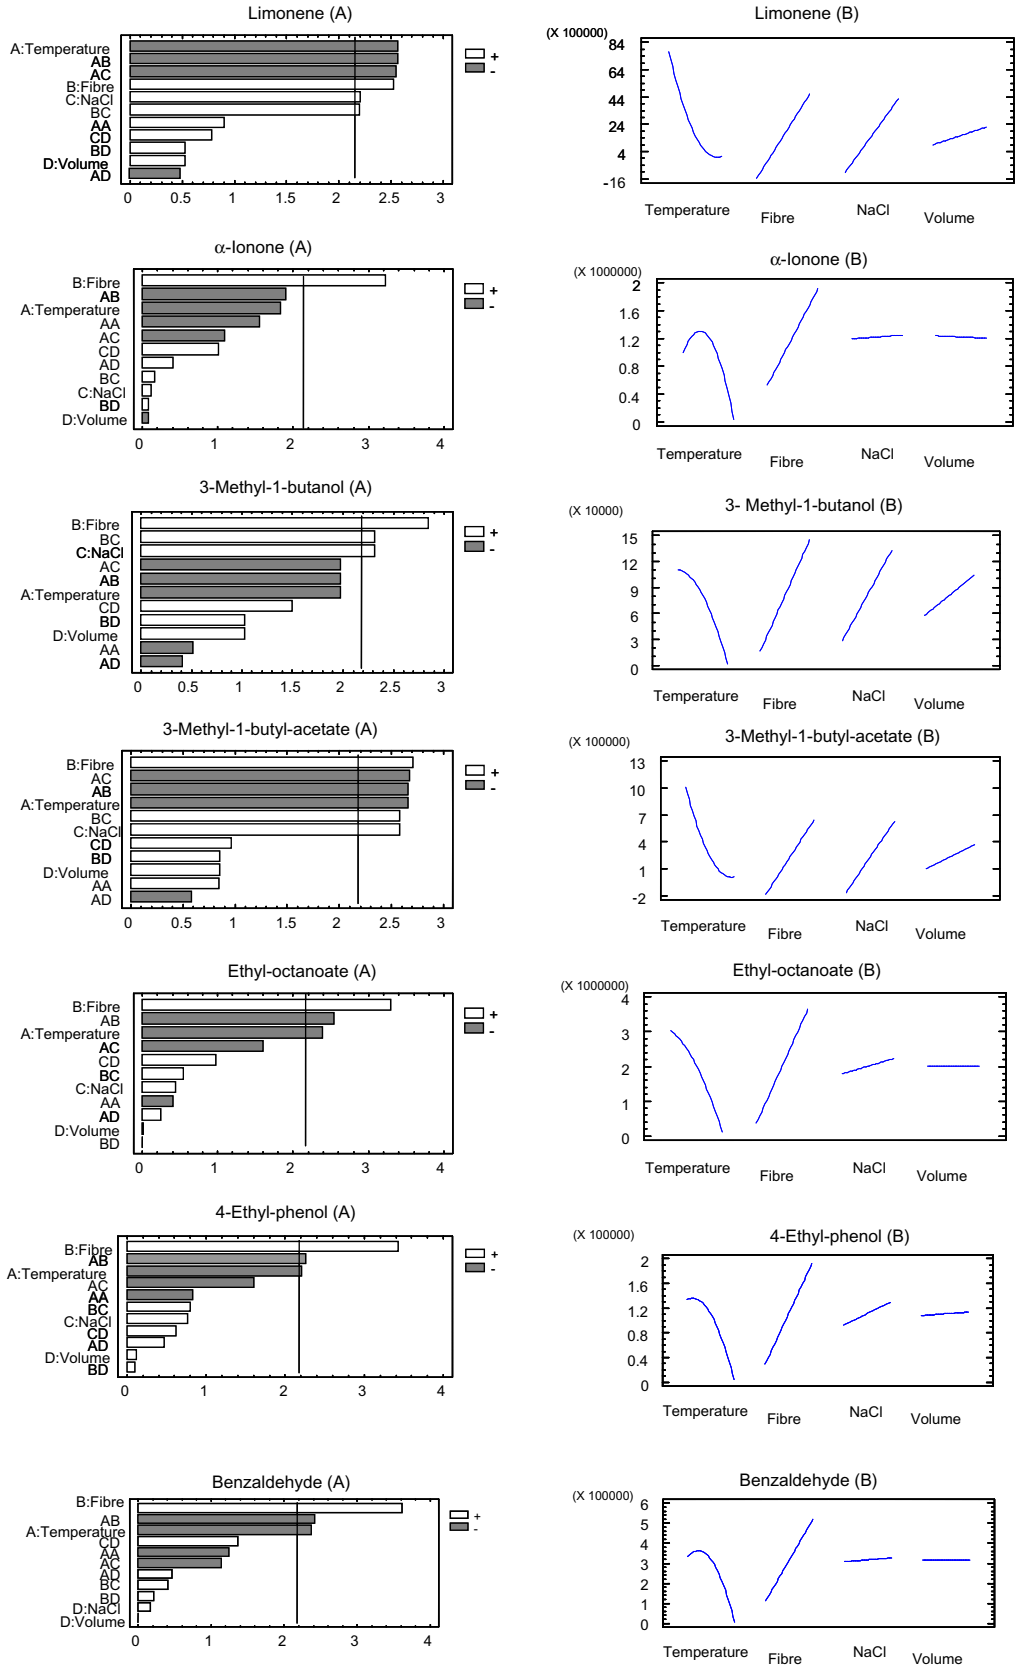

Fig. 1. Pareto charts (A), main effects plot (B) and interaction plots (C) for some selected aroma compounds.

nene, 3-methyl-1-butanol and 3-methyl-1-butyl acetate). For most of the remaining compounds, according to the interpretation of the main effects charts, the "salting-out" effect was shown to enhance the extraction. Finally, the volume was not

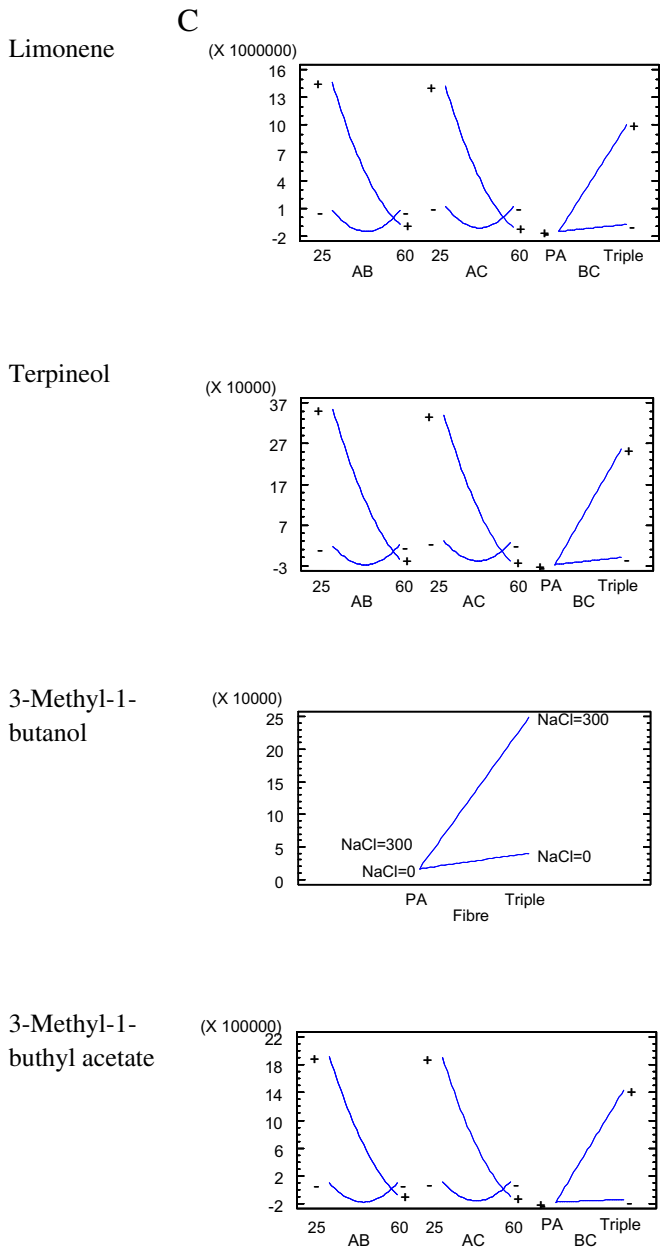

Fig. 1 *(continued)*

statistically significant for any of the studied compounds; nevertheless, in many cases the response achieved was higher with 30 mL of sample volume.

Other important graphical tool in experimental design analysis is the interaction plots, where the effect of two factors is simultaneously analyzed. Several interaction effects were significant for various analytes and some of them are depicted in Fig. 1. The interaction temperature-fibre coating (AB) was significant for 17 compounds. Working with triple fibre at 25 °C led to better responses than working at 60 °C with both fibres. Another significant interaction was found between temperature and salt addition (AC) for limonene, terpineol and 3-methyl-1-butyl acetate (Fig. 1). In this case, slight differences between no-addition and addition of 30% of NaCl were observed at 60 °C, however, at 25 °C, these differences were important and better results were obtained with salt addition. The combined effect between fibre coating and salt addition (interaction BC) is statistically significant in the case of limonene, 3-methyl-1-butanol and 3-methyl-1-butyl acetate (Fig. 1). The influence of the salt addition is much higher for triple fibre than PA fibre.

Taking into account both main and second order effects, the final proposed method for the simultaneous extraction of the 32 investigated wine volatile compounds was as follows: DVB-CAR-PDMS fibre coating, 30% NaCl, 30 mL of sample and 25 °C (Table 1).

3.3. HS-SPME adsorption and desorption processes

The extraction of volatile compounds with the DVB-CAR-PDMS fibre using HS-SPME is basically an adsorption process due to the presence of the DVB and CAR sorbents immobilized on the fibre by using PDMS. Optimum sorption time is defined as the time after which the amount of extracted analyte remains constant. Duplicate synthetic wine samples, fortified at the same levels described in the Section 2.5, were analyzed under the experimental conditions obtained by means of the experimental design. The influence of EtOH content during the extraction process was not previously checked (the final EtOH percentage in the samples was 15%) due to their concentration in wine has only a small influence on the peak intensities of aroma compounds in HS-SPME (De la Calle García et al., 1997); in the same sense, Jurado et al. (2008) did not observed significant differences in the responses with the variation of the EtOH content between 9.5% and 16.5%.

In general, longer sampling time than 45 min did not increase the total amount of volatile compounds. Of more detailed form, three different behaviours were registered. For a first group of volatile compounds (e.g. linalool, limonene 1-butanol, 3-methylbutanol, 1-hexanol, *trans*-2-hexen-1-ol *cis*-3-hexen-1-ol, *trans*-3-hexen-1-ol, isopentyl acetate, hexyl acetate, ethyl hexanoate or benzaldehyde), the most volatile ones (boiling points lower than 200 °C), a decrease in the corresponding area to 90 min was registered respect to 45 min. For a second group of volatile compounds (e.g. citronellol, nerol, terpineol, β-damascone, α-ionone, benzyl alcohol, 2-phenylethyl acetate, ethyl octanoate, ethyl decanoate, 4-ethylguaiacol or 4-vinylguaiacol), with a intermediate volatility (boiling points between 200 and 260 °C), no significant differences were observed in ITMS areas registered at 45 and 90 min which indicates that the equilibrium process has been reached. For the third minority group (e.g. β-ionone), with a low volatility, it was observed that 45 min was not enough to reach the equilibrium; according to Ai (1997), SPME determination is feasible at non-equilibrium conditions and then, sorption time can be shortened. As a conclusion, 45 min was considered as the optimized exposure time for all the volatile compounds studied.

The GC injector temperature was optimized to ensure that all the volatile compounds are completely desorbed from the fibre and to avoid carryover. For the DVB-CAR-PDMS fibre, three temperatures (230, 250 and 270 °C) were tested. Finally, 250 °C was selected as the optimum value. Desorption profiles showed that 8 min was enough to ensure total desorption for the majority of the compounds, except to some norisoprenoids (β-ionone), higher alcohols (benzyl alcohol) or volatile phenols (4-ethylguaiacol or 4 ethyl-phenol); moreover, carryover on SPME fibres due to incomplete desorption of analytes during the desorption process was attributed to strong adsorption in the coating. This fact was resolved with a desorption time of 10 min; then, no aromas or aromas lower than limits of detection (LODs) appeared in the chromatogram corresponding to the analysis of the fibre prior to re-exposure.

3.4. Quality parameters in synthetic wine

With the selected conditions for the SPME procedure, analytical quality parameters were evaluated in order to asses the performance of the HS-SPME/GC–ITMS method.

Table 1
Optimal experimental conditions and significant interactions given for each compound by the mixed level factorial 3×2^3 design (significant factors are emphasised in bold and italics).

[a] *x*: Denotes a significant second-order interaction.
[b] When two values appear, it means that this factor did not affect the response, it does not matter which.

The repeatability (intra-day) and reproducibility (inter-day) of the method were calculated by analyzing five spiked synthetic wine samples in the same day and in two different not consecutive days, respectively. Results are reported in Table 2. As can be seen, the relative standard deviation (RSD) for repeatability was about 10% for all compounds; and for reproducibility, RSD% values increased around 2% but they continued being lower than 15%, except for ethyl butanoate (22.9%). These values allow confirming the good precision of the method and they agree with values contributed by other authors for the same fibre (Tat et al., 2005; Torrens et al., 2004).

Linearity of the method was evaluated by plotting 5-point calibration curves of the analyte area relative to that of the internal standard (internal standard selected for each compound is specified in Table 2). Linear ranges and determination coefficients (r^2) obtained for each volatile compound are given in Table 2. The method exhibited good linearity in the examined concentration range for all compounds with correlation coefficients (r^2) higher than 0.99.

Finally, limits of detection (LODs) and quantification (LOQs) were evaluated on the basis of the signal background obtained with the analysis of unfortified synthetic wine samples ($n = 7$) (Table 2). The LOD and LOQ were defined as the concentrations of analyte that provide signal-to-noise ratios of 3 and 10, respectively. The LODs, which ranged from 0.0024 μg/L for limonene to 238 for ethyl 3-hydroxybutyrate, were below the odour threshold limits reported in the literature for the studied compounds (Ferreira, López, & Cacho, 2000).

3.5. Matrix effects study

Wine is a very complex matrix; besides EtOH content there are others wine compounds, such as protein, amino acids, sugar and polyphenols, that make each wine different from the others (Pizarro, Pérez-del-Notario, & González-Sáiz, 2007). In HS-SPME, the distribution constants between the liquid phase, the headspace and the coating are strongly dependent on the matrix. In this respect, Dufour and Bayonove (1999) have suggested that wine polyphenols may interact with aroma compounds, reducing vapour pressure in some cases; Rocha et al. (2001) revealed the extent of the changes in the concentration of one matrix component in the SPME absorption of the other liquid matrix components, in general the change in the concentration of one matrix component affects the GC peak areas of all the others. For this reason, it is imperative in aroma analyses to check the matrix interferences in detail to avoid fatal quantification errors.

Table 2
Quality parameters of the optimized HS-SPME/GC-ITMS method using the DVB-CAR-PDMS fibre.

Table 3 shows relative percentage of peak areas of volatile compounds in a real wine with regard to synthetic wine. Both wines were spiked at the same concentration level and analyzed twice. Results from the table revealed that peak areas of analytes decreased significantly, demonstrating a remarkably matrix effect, that means some kind of competition between interfering substances and analytes occurred. This phenomenon, in spite of its importance, has not been commonly studied (Begala et al., 2002; Bonino et al., 2003; Cabredo-Pinillos et al., 2008; Perestrelo et al., 2008; Tao et al., 2008; Torrens et al., 2004) which has not guaranteed appropriate quantification and consequently reliable results.

Different actions could be taken to overcome such problems: (1) the use of isotopically-labelled analytes as IS in isotope dilution based methods; (2) the use of multiple headspace SPME (MHS-SPME) procedure, which leads to a complete extraction of the analytes performing several consecutive extractions (Martínez-Uruñuela, González-Saiz, & Pizarro, 2005); (3) the use of appropriate ISs, which are affected by the matrix effect in the same way as the analytes (structurally similar); (4) a dilution of

[a] Matrix effect (%) = 100 × (peak area obtained in a spiked Mencía wine sample − peak area obtained in a Mencía wine sample)/peak area obtained in synthetic wine at the same spiked level.

[b] Negative values due to high response of these aromas in Mencía wines, the addition is not noticeable.

the sample; (5) the generation of a matrix similar to the real wine but free of volatiles, a "non-flavour" wine. The non-volatile components remain unchanged and the concentration of the ethanol and pH value of the "non-flavour" wine was equal to that of the real wine (13% (v/v) EtOH, pH 3.3) (Liu, Zeng, & Tian, 2005); and (6) quantification by standard addition into each sample and with each analyte investigated.

In this work two of these different strategies (4 and 5) were tested for their ability to compensate or minimize the influence of matrix effects in wine analysis. They were evaluated by comparison with those results obtained by strategy number 6 (standard addition; four concentration levels performed in duplicate), assuming that the standard addition approach provides the true analyte concentrations. The main conclusions of these evaluations are as follows:

1. For aroma compounds with high analytical responses, a 15-fold dilution of the sample with synthetic wine and internal calibration in synthetic wine with appropriate ISs was considered. The criterion followed to optimize wine dilution was the maximum dilution at which was possible to obtain a quantifiable response of those analytes that overloaded the fibre in Mencía wine (i.e. 3-methylbutanol, 2-methyl-1-propanol, benzyl alcohol, 1-hexanol, diethyl succinate, ethyl butanoate, 2-furfuraldehyde, 3-methyl-1-butyl acetate, 2-phenylethyl acetate, benzaldehyde, ethyl hexanoate, ethyl octanoate, ethyl decanoate, hexyl acetate, ethyl dodecanoate). As can be seen in Table 4, standards prepared in synthetic wine could be used for most of the fibre overloading compounds. Only for 2-phenylethyl acetate, diethyl succinate and ethyl dodecanoate, significant differences (Students *t*-test, at a 95% confidence level) were observed between concentrations calculated by standard addition and IS calibration. In this case, quantification of analytes must be performed by matrix-matched standards.
2. For minor aroma compounds quantification was performed using internal standard method preparing the calibration standards in "non-flavour" wine. Previously, quality parameters were calculated as it was described for synthetic wine (Table 2), the degree of agreement between the real amount added and that determined by interpolation (relative recovery %) was satisfactory, close to 100%. IS calibration with 'non-flavour' wine was possible for 8 of the 13 remaining compounds. From the statistical data analysis (Students *t*-test, at a 95% confidence level), no significant

differences between both calibration methods (standard addition and IS calibration) could be concluded. The quantification process (Table 4) confirmed that for α-ionone, β-ionone, *trans*-3-hexen-1-ol, *cis*-3-hexen-1-ol and *trans*-2-hexen-1-ol, matrix effects can not be compensated for by using IS method and selecting the "non-flavour" wine as working standard matrix.

3.6. Quantitative composition and odour active values

The first characterisation of the main odourants of Mencía red wines from the "Valdeorras DO" is given in Table 5. Concentration data indicated that 28 out of the 32 studied compounds could be found in the volatile fraction of the wine; higher alcohols were quantitatively the largest group of the volatiles in Mencía wine followed by acetates from higher alcohols. To evaluate the contribution of a volatile compound to the aroma of a wine, the odour activity value (OAV), known also as aroma index, was calculated as the ratio between the concentration of the compound and the odour threshold found in the literature (Ferreira, Rapp, Cacho, Hastrich, & Yavas, 1993; Ferreira et al., 2000; Guth (1997); Perestrelo, Fernandes, Albuquerque, Marques, & Câmara, 2006). This value constitutes a preliminary step to achieve the identification of the potentially most important wine odourants in a wine.

3.6.1. Terpenes

Terpenes play a significant role in the varietal odourants of wines; they are located in grape skin and linked to sugars,

[c] n.d.: Not determined.

constituting an important part of the grape bouquet. Terpenes are not changed by the metabolism of yeast during fermentation (Mateo & Jiménez, 2000).

Four terpenes were detected al low concentrations in the sample wine: linalool, citronellol, terpineol and limonene (6.4, 6.3, 4.7 and 0.1 μg/L, respectively). They made up of 0.006% of the total volatile analyzed compounds. In all cases, the OAVs were lower than 1. It seems that these terpenoid compounds could not contribute substantially to the aroma of the Mencía wines.

3.6.2. Norisoprenoids

The presence of norisoprenoids is considered to be a quality factor and typical from each grape variety. α-Ionone and β-ionone were detected at concentrations of 0.1 and 0.5 μg/L, respectively. The content of β-ionone is higher than its odour threshold with an OAV of 5. This compound supplies a characteristic aroma of "violets" to the Mencía wine.

3.6.3. Higher alcohols

This volatile fraction is composed mainly by *n*-alcohols of C_6 chain length and aroma compounds such as benzyl alcohol. The higher alcohols could be synthesized by yeast through either the anabolic pathway from glucose, or the catabolic pathway from their corresponding amino acids (valine, leucine, *iso*-leucine and phenylalanine). Consequently, they are released to the medium as secondary products of metabolism of yeasts being responsible for the secondary or 'fermentative' aroma of wines.

The higher alcohols are quantitatively the largest group of the volatile compounds found in Mencía wines (96.4% of the total volatiles analyzed). This volatile fraction was mainly composed of 2-methyl-1-propanol (or isobutanol) (25,950 μg/L), 1-butanol (1520 μg/L), 3-methyl-1-butanol (or isoamyl alcohol) (249,750 μg/L), 1-hexanol (1790 μg/L) and benzyl alcohol (545 μg/L).

3-Methyl-1-butanol was markedly the most abundant higher alcohol, being present at levels higher than its odour threshold (30,000 μg/L), thus its sensorial contribution with "alcohol, fusel" odour was expected. The next higher alcohol with a significant role in the aroma of Mencía wine was 1-hexanol that contributed with "herbaceous" and "vegetal" odour. Benzyl alcohol, with an OAV very close to unity, supplied an agreeable scent of "blackberry fruits".

3.6.4. Acetate esters

Acetate esters were the result of the reaction of acetyl-CoA with higher alcohols formed by degradation of amino acids or carbohydrates (Perestrelo et al., 2006). 3-Methyl-1-butyl acetate with a fruity odour of "banana" was found in a concentration of 930 μg/L, 31 times over its odour threshold.

3.6.5. Ethyl esters

The ethyl esters of the fatty acids are one of the most relevant groups of compounds in the wine aroma. They are produced enzymatically during yeast fermentation and from ethanolysis of acyl-CoA that is formed during fatty acids synthesis or degradation. Their concentration is dependent on several factors mainly: yeast strain, fermentation temperature, aeration degree and sugar contents (Perestrelo et al., 2006). The nuances of ethyl esters coincide with the fruity and floral descriptors of the wines and play a modulating role in the quality (Ferreira, Fernández, Peña, Escudero, & Cacho, 1995).

The ethyl ester concentration was 5991 μg/L, being 2.1% of the total volatiles analyzed. The contribution of some of them to wine flavour and aroma was clearly important, thus ethyl octanoate ("pineapple, pear") and ethyl hexanoate ("green apple") showed the highest OAVs of the studied volatile compounds (80 and 22, respectively), consequently the strongest odour impact. Ethyl butanoate ("strawberry") with an OAV of 13.7, ethyl 2-methylpropanoate ("banana") with 1.3 and diethyl succinate ("wine") with an OAV near unity (0.8) also contributed to a great extent to the aroma of Mencía wines.

3.6.6. Volatile phenols

These compounds could originate from *p*-coumaric and ferulic acids by decarboxylation (Perestrelo et al., 2006). Within the family of volatile phenols only 4-ethyl-phenol was found at a low concentration of 3.1 μg/L. No contribution of this compound could be appreciated in the aroma of the wine because of its low OAV value (0.007).

3.6.7. Aldehydes

Aldehydes are formed from unsaturated fatty acids, such as linoleic and linolenic acids. Also, they can be considered as products of lipoxygenase catalysis (Perestrelo et al., 2006). The contents of the two aldehydes analyzed, 2-furfuraldehyde and benzaldehyde, although high (3111 and 226 μg/L, respectively), showed values lower than their odour thresholds (OAVs: 0.2 and 0.1, respectively).

4. Conclusions

A mixed level factorial design was performed to obtain the appropriated extraction conditions for the determination of primary and secondary aroma compounds in Mencía red wine by HS-SPME. The proposal analytical procedure was: 30 mL of sample with addition of 30% of NaCl, DVB-CAR-PDMS fibre, 25 °C of extraction temperature, 45 min of extraction time with agitation, 250 °C of desorption temperature and 10 min of desorption time. A marked matrix effect was registered; to overcome this negative phenomenon two suitable approaches were considered for 24 aroma compounds: a 15-fold dilution of the sample and IS calibration in synthetic wine for determining major aroma compounds and IS calibration in "non-flavour" wine for minor compounds. The remaining 8 analytes – 2-phenylethyl acetate, diethyl succinate, ethyl dodecanoate, α-ionone, β-ionone, *trans*-3-hexen-1-ol, *cis*-3-hexen-1-ol and *trans*-2-hexen-1-ol – were easily quantified by standard addition quantification to guarantee reliable results.

With regard to aroma profile of Mencía wine from "Valdeorras DO", this wine is characterized by the presence of high levels of higher alcohols (96.4%). Considering all the odourants detected with OAVs > 1, ethyl esters and acetates provided "banana", "strawberry", "green apple", "pineapple" and "pear" nuances to the aroma; higher alcohols conferred "fused alcohol" and "vegetative" nuances; and, finally, β-ionone gave a pleasant odour of "violet" to the wine, the typical aroma distinctive of this red young wines.

Analytical Methods

Determination of three dyes in commercial soft drinks using HLA/GO and liquid chromatography

Yahya S. Al-Degs

Chemistry Department, The Hashemite University, P.O. Box 150459, Zarqa, Jordan

HLA/GO
HPLC

ABSTRACT

Allura Red, Sunset Yellow, and Tartrazine usually present in commercial soft drinks were accurately quantified using HLA/GO method, a net analyte signal-based method, without the need for solutes separation. The obtained percent recoveries (R.S.D.) of dyes were 99.8 (2.8), 102 (3.3), and 100 (4.5) for Allura Red, Sunset Yellow, and Tartrazine, respectively. The calibration method was applied for analysis of food dyes in powdered soft drinks with minimum sample preparation measures. The proposed HLA/GO method was validated against a standard HPLC method. Statistical analyses showed insignificant differences between the results of two methods. The developed HLA/GO method offers a simple and rapid procedure for determination of food dyes in powdered soft drinks in comparison with HPLC methodology.

1. Introduction

Allura Red (E-129), Sunset Yellow (E-110), and Tartrazine (E-102) are three highly used synthetic dyes which are added to many food products (López-de-Alba, Wróbel-Kaczmarczyk, Wróbel, López-Martínez, & Hernández, 1996; Nevado, Cabanillas, & Salcedo 1995). Allura Red, Sunset Yellow, and Tartrazine are used as additives in pharmaceuticals and cosmetics because they can be easily mixed to give favourable shades and because of their low price compared with natural colourants (López-de-Alba, López-Martínez, Cerdá, & De-León-Rodríguez, 2001). Generally, synthetic dyes contain azo (N=N) functional groups and aromatic ring structures, so they are harmful to human health (López-de-Alba et al., 2001). An extensive review on the genotoxicity of food, drug, and cosmetic azo dyes and other dyes had been presented in the literature (Combes & Haveland-Smith, 1982). Accordingly, monitoring of synthetic food dyes in high consumption products such as beverages becomes an essential task. The European Union (Directive 94/36//EC, 1994) has issued comprehensive schemes that regulating the use of food colours and their allowed levels in all food products. Such regulations will guide the analytical chemists for monitoring synthetic dyes in food products. Allura Red, Sunset Yellow, and Tartrazine are probably the most common dyes that applied (individually or together) to colour soft drink powders. According to the legislations of the European Union for food dyes (which is the same legislations adopted by the official food control laboratories in Jordan), the maximum level of Allura Red, Sunset Yellow, and Tartrazine dyes should not be more than 100 μg ml^{-1} (individually or in combination) in non-alcoholic beverages with added juices and/or flavours (Directive 94/36//EC, 1994). The task of monitoring synthetic dyes in food products should be the responsibility of official food control laboratories and the food manufacturers to ensure safety for the consumers.

In fact, many analytical methods were provided for analysis of synthetic colours in beverages. The direct determination of food dyes is generally impossible. The colours must be separated from foodstuffs and purified, as co-extractives interfere with analysis of the colours. Moreover, the extract must be also concentrated because many food colours are used at low concentrations. The common analytical techniques that frequently used for determination of colours include visible spectrophotometry (Berzas, Rodríguez Flores, Villaseñor Llerena, & Rodríguez Fariñas, 1999), thin-layer chromatography (Oka et al., 1987), and mostly high performance liquid chromatography (Alves, Brum, de Andrade, & Netto, 2008; Chen, Mou, Hou, Riviello, & Ni, 1998). A typical example on using liquid chromatography for food dyes determination is the work of (García-Falcón & Simal-Gándara 2005), the authors provided a simple chromatographic method for analysing five synthetic food dyes in commercial soft drinks within minimal sample clean-up. A recommendation to adopt the earlier method for a serious control of dyes in food products was suggested by the authors.

Recently, multivariate calibration techniques have been employed for simultaneous determination of several analytes in a given sample without the need for analytes separation or even matrix clean-up in some instances (Adams, 2004; Martens & Naes,

E-mail address: yahyaaldeqs@yahoo.com

0308-8146/$ - see front matter © 2009 Elsevier Ltd. All rights reserved.
doi:10.1016/j.foodchem.2009.04.097

1992; Otto, 1999). Classical least squares (CLS), principal component regression (PCR), and partial least squares (PLS) are three multivariate calibration methods that have received considerable attention in the chemometric literature (Adams, 2004; Geladi & Kowalski, 1986; Martens & Naes, 1992; Otto, 1999). Beside the mentioned multivariate calibration methods, newly developed calibration methods based hybrid linear analysis (HLA) were applied in chemical analysis with satisfactory results (Goicoechea & Olivieri, 1999).

The aim of this work is to apply HLA/GO calibration method, for the first time, for simultaneous determination of Allura Red, Sunset Yellow, and Tartrazine in four powdered soft drinks without running expensive chromatographic separation for the samples. The figures of merit of the proposed HLA/GO method for dyes determination are reported. The proposed method is validated against a standard liquid chromatographic method.

2. Materials and Methods

2.1. Instruments and software

A Cary 3E UV–Vis double beam spectrophotometer (Varian company, Australia) connected to a PC for data acquisition was used for all spectral measurements. A PerkinElmer instrument (Series 200 Pump, Germany) with UV/Vis detector was used for chromatographic analysis of food dyes. The pH measurements were carried out using a WTW-Inolab (Germany) pH-meter using a companied glass electrode. Data treatment and numerical calculations were carried using MATLAB® (version 6.1). All programs were run on a PC (Pentium IV 3.00 GHZ) with Microsoft windows XP operating system.

2.2. Materials, reagents, and solutions

The dyes of purity higher than 99% were purchased from the Aldrich Company (USA). The employed dyes were Allura Red (E-129 and colour index: 16035), Sunset Yellow (E-110 and colour index: 15985), and Tartrazine (E-102 and colour index: 19140). Throughout the text, Allura Red, Sunset Yellow, and Tartrazine were referred to as AR, SY, and T, respectively. All other chemicals were obtained from Riedel-de Haën (Germany) and were of analytical reagent grade. Standard solutions (1000 μg ml^{-1}) of dyes were prepared using pure water. Acetic acid/sodium acetate (0.1 M, pH = 5.0) was used as buffer solution. The solutions employed in chromatographic analyses were: methanol (HPLC grade) and NaH_2PO_4/Na_2HPO_4 buffer (0.10 M, pH = 7.0). Dyes standard solutions (100 μg ml^{-1}) and food solutions were prepared with dilution with methanol–water mixture (v/v, 50/50) for HPLC method.

2.3. Preparation of soft drink solutions

Four types of powdered soft drinks of mango and orange flavours were collected from different local stores: TANG®/Mango & TANG®/Orange (Kraft Foods Incorporation, USA) and SQUEEZE®/Mango & SQUEEZE®/Orange (Confectionary Development Industrial Company, Syria) were selected for this study. Solutions of powdered drinks were prepared by dissolving 2.0 g in 100 ml water with good mixing. The mixture was heated on a water bath for 10 min. The obtained mixture was centrifuged for 30 min at 3500 rpm and filtered. Different aliquots of the filtrate were diluted with acetate buffer for chemometric analysis or with methanol–water mixture for HPLC analysis. Qualitative assays were done for the detection of food dyes in commercial samples by paper chromatography. Water-dissolved samples and standard dyes were applied to normal-phase chromatographic papers and developed in the mobile phase of *n*-butyl alcohol–ethyl alcohol–water (1:1:1). R_f values, the ratio between the distance travelled by the dye and the distance travelled by the solvent, were estimated for the samples and the standards.

2.4. Procedures

2.4.1. HLA/GO method

In 25 ml volumetric flasks, aliquots of the stock dyes solutions were added to get concentration range between 0–10 for AR and T and 0–7 μg ml^{-1} for SY. Before final dilution with water, 5.0 ml of acetate buffer solution (pH 5) was added. The spectral measurements for all solutions were carried out over the spectral range 200–800 nm against a blank. The design of the calibration and validation sets is presented as 3D plot (Fig. 1). The design of calibration set was based on four-level fractional factorial design according to Brereton's procedure (Brereton, 1997). The validity of HLA/GO method was further tested on an independent validation set. Prior analysis of dyes by HLA/GO method, the optimum number of wavelengths was carefully selected as will be shown later. Analysis of dyes in standard solutions and food samples was carried out separately for each dye as following: (a) an average spectrum of all calibration samples (37 spectra) was obtained, (b) A_k matrix was obtained for the dye of interest, (c) NAS projection matrix of this dye was obtained as $\mathbf{P}_{NAS,k} = [\mathbf{I} - \mathbf{A}_k^T(\mathbf{A}_k^T)^+]$, (d) $\mathbf{s}_k^*$, the net sensitivity vector, was then estimated using HLA/GO algorithm, and (e) the prediction of dye concentration in validation or food samples was obtained from the corresponding sample spectrum ($\mathbf{r}$) as: $c_{un,k} = \frac{(\mathbf{s}_k^*)^T \mathbf{r}_k^*}{\|\mathbf{s}_k^*\|^2}$, where $\mathbf{r}_k^*$ was estimated as: $[\mathbf{I} - \mathbf{A}_k^T(\mathbf{A}_k^T)^+]\mathbf{r}$. In the earlier formulae, **T**, || ||, and + are stand for matrix or vector transpose, Euclidean norm, and pseudoinverse, respectively. **I** is the unity matrix of $n \times n$ order. The adopted algorithm is outlined in the literature (Goicoechea & Olivieri, 1999, 2000).

2.4.2. Chromatographic procedure

Analytical separation and quantification of dyes was achieved at 1.3 ml min^{-1} and 22.6 °C with a 0.1 M phosphate buffer (pH 7) – methanol gradient. Solvent programme was started with 14% methanol, held for 0.5 min, followed by a linear gradient to 25% methanol in 7.0 min, and another linear gradient to 31% methanol in 10 min. Dyes eluting from the column were detected by UV-spectrophotometer set at 475 nm. A 10 μl sample volume was injected in all experiments.

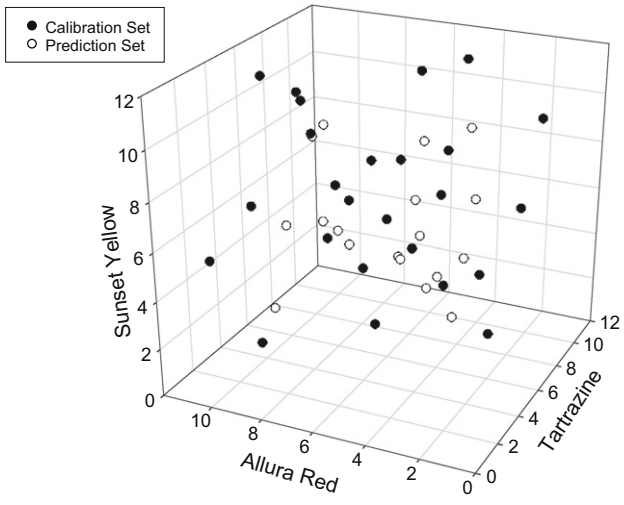

Fig. 1. A 3D graphical presentation of calibration and prediction sets.

2.4.3. One-component calibration

A series of standard dye solutions in the concentration range from 1 to 40 ppm was prepared for one-component calibration. An adequate volume of the stock dye solution and 5.0 ml of buffer solution were placed in a 25 ml volumetric flask and the flask was filled with pure water. The absorbance was recorded at the wavelength corresponding to maximum of the absorption band of each dye. The calibration equations and the linear dynamic ranges were calculated for each dye.

3. Results and discussion

3.1. Spectral overlap and application of HLA/GO calibration for dyes determination

The absorption spectra of dyes recorded at pH 5.0 are presented in Fig. 2. As indicated in Fig. 2, the three dyes were active in ultraviolet and visible regions and this is attributed to their chemical structure which contains many active functional groups. Generally speaking, the spectral overlap between dyes is high over the entire spectral range. Within the spectral region 350–650 nm, the spectra of AR and SY were highly overlapped, while, a low extent of spectral overlap between T and other dyes in that region was observed. The estimated degrees of spectral overlap between dyes, as obtained from Goicoechea and Olivieri method (Goicoechea & Olivieri, 1998), were 65%, 75%, and 95% between T–SY, T–AR, and SY–AR, respectively. The presence of such high overlapping (particularly between SY and AR) limits the analysis of these dyes in food products by conventional univariate calibration methods. Accordingly, the spectral resolution of food dyes is necessary and this could be established either by: (a) using chromatographic methods like HPLC or TLC or (b) applying multivariate calibration methods.

Recently, many applications of multivariate calibration methods have been reported in chemical (Galeano Diaz, Guiberteau Cabanillas, Alexandre Franco, Salinas, & Viré, 1998), food (López-de-Alba et al., 2001), and pharmaceutical (Goicoechea & Olivieri, 1998; Ni, Wang, & Kokot, 2001) analysis.

López-de-Alba and co-workers were effectively applied PLS (1 and 2 types) and PCR for analysis of R40, Y6, and Y5 in commercial soft drinks and compared their results with a standard HPLC method (López-de-Alba et al., 2001). Nevado, Flores, & Llerena, 1998 have proposed a simple, accurate and rapid PLS calibration method for analysis of Tartrazine, sunset Yellow, and Ponceau in three commercial soft drinks without the need for solutes separation or sample clean-up due to the simple nature of soft drink matrix (Nevado et al., 1998).

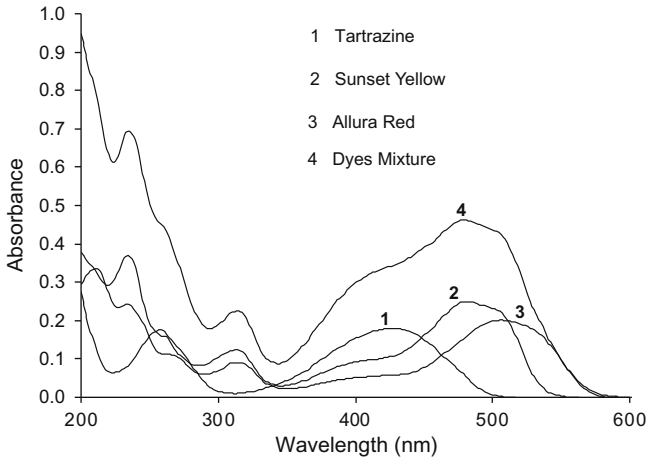

Fig. 2. UV–Vis spectra of pure and mixture of dyes recorded at pH 5.0. Dyes content: Allura Red and Sunset Yellow 5.0 μg ml^{-1}, and Tartrazine 6.0 μg ml^{-1}.

Lorber had proposed the common net analyte signal (NAS) concept that permits estimation figures of merit for multivariate data (Lorber, 1986). The estimation of those figures of merit was initially restricted to the CLS model (when pure spectra and concentrations of all components are known (Lorber, 1986)). After that, NAS concept was extended to inverse calibration methods that only need the concentration of the target analyte in the calibration set (Lorber, Faber, & Kowalski, 1997). Recently, new families of multivariate calibration methods have been proposed based on the concept of NAS which are know as NAS-based calibration methods (Berger, Koo, Itzkan, & Feld, 1998; Espinosa-Mansilla, Merás, Rodríguez Gómez, Muñoz de la Peña, & Salinas, 2002; Ferré & Faber, 2003; Goicoechea & Olivieri, 2000; Mirmohseni, Abdollahi, & Rostamizadeh, 2007; Moore, Cogdill, Short, Hair, & Wildfong, 2008; Xu & Schechter, 1997).

These NAS-based calibration methods used suitable scaling procedures for eliminating the information of the analyte of interest during the calibration step. Removing the spectrum of the pure component from calibration data is the basic step in hybrid linear analysis (HLA) method (Berger et al., 1998). A number of calibration methods have been proposed based on earlier HLA method like HLA/XS (Xu & Schechter, 1997), HLA/GO (Goicoechea & Olivieri, 2000), and HLA/AS (Ferré & Faber, 2003). In fact, the earlier NAS-based methods have been applied for determination of many analytes in complex matrices. HLA method was used for determination of tetracycline in human serum using fluorescence data (Goicoechea & Olivieri, 1999). A good review on NAS-based calibration methods was provided by Ferré and Faber (2003). Beside their simplicity and ease of implementation, the HLA-based calibration methods can be applied for determination of an analyte in a complex matrix without the need for including the effect of other interferences in the calibration stage (Ferré & Faber, 2003). Particularly, in HLA/GO calibration method, there is no need to have the pure spectrum of analyte of interest like the case in CLS, HLA, and HLA/XS calibration methods (Ferré & Faber, 2003; Goicoechea & Olivieri, 2000; Lorber et al., 1997).

In this work, and for the first time, the application HLA/GO method is applied for determination of AR, SY, and T in their mixtures and in food containing these dyes. For sake of validation of HLA/GO method, an independent HPLC method is applied.

3.2. Effect of solution pH on dyes absorption and optimisation of calibration samples

One of most experimental variables that highly affect dyes absorption is solution pH. Therefore, dyes solutions should be maintained at certain pH so that high absorption intensities (for all dyes) should be observed at that pH. The influence of pH on the absorption intensity of food dyes was investigated over a wide pH range: 2–12. Dyes solutions of variable pH were prepared using buffer solutions. Generally speaking, the absorbance values of dyes (at their corresponding λ_{max}) were not changed over the pH range 2–8, after which a considerable reduction in absorbance readings was observed for all dyes. It is highly possible that dyes have been completely ionised at higher pH values and this will affect their light absorption. Based on that, pH 5 was selected as an optimum pH for measuring dyes absorbances. Moreover, dyes solutions were found stable over 30 days when placed in a cold dark place (5.0 °C).

3.3. Designing of calibration mixtures, outlier(s) detection and wavelength selection

The efficiency of multivariate calibration methods is highly dependant on the design of standard mixtures in the calibration

and validation sets and the presence or absence of outliers. Four important issues should be addressed when building calibration and validation sets: (a) the concentration of individual solute should be within its linear range obtained from univariate calibration, (b) calibration set should be orthogonally deigned to reduce the collinearity in calibration matrix and to ensure high prediction power for the method, (c) the absorbances of calibration and validation mixtures should not be higher than the maximum response of the instrument. Usually, in spectrophotometric measurements absorbances higher than 1.0 were not considered and dilution for these mixtures is suggested, and (d) the concentration of solutes in validation set should be within the range used in calibration set. These issues were taken into consideration when building calibration and validation sets for the current dyes system. The obtained dynamic ranges were: 0.3–32, 0.3–35, and 0.4–25 μg ml^{-1} for AR, SY, and T, respectively. To avoid high absorption intensities for standard mixtures (i.e., absorption values > 1.0), the concentration ranges of dyes were adjusted in away to achieve that aim.

Elimination of outlier(s) from calibration or validation samples is essential prior multivariate calibration. Usually, the detection of outlier(s) can be simply carried out using Mahalanobis distance method (López-de-Alba, López-Martínez, Cerdá, & Amador-Hernández, 2006) or principal component analysis (Adams, 2004; Hemmateenejad, Akhond, & Samari, 2007). Cluster plots (derived from principal component analysis PCA) represent a more systematic way to detect outlier(s). Usually, cluster plots obtained by plotting the first principal component (PC1) against the next component (PC2). In the absence of outliers, all samples should form a clear cluster of the data. PCA was carried out for spectral data of calibration and validation sets. For both sets, the variances (94%) in absorption data can be effectively presented using the first two principal factors. PC1–PC2 plot (not shown) clearly indicated that both sets were fall within the same domain and form one homogenous cluster. If an outlier sample is there, then it will be much away from the cluster of samples. Furthermore, cluster analysis indicated the high homogeneity between two sets and this ensures a high prediction power of HLA/GO multivariate calibration method for future samples.

Most of multivariate calibration methods, in fact, are considered as full-spectrum methods because, in some instances, the entire data in a given spectrum would be included in numerical analysis. Including all spectral data points is not necessary to improve the quality of analysis, moreover, it has been shown for many multicomponent systems that reduction of data points could improve the accuracy and precision of numerical analysis (Brown, 1992). Hence, various criteria have been developed to allow for effect wavelength selection prior multivariate calibration (Al-Degs, El-Sheikh, Al-Ghouti, Hemmateenejad, & Walker, 2008). In this work, the method proposed by López-de-Alba and co-workers is employed to select the optimum wavelength region(s) for HLA/GO calibration (López-de-Alba, López-Martínez, & De-León-Rodríguez, 2002). For each dye, the correlation coefficients between dye concentration (in calibration set) and the corresponding absorbance at each wavelength were estimated.

The correlation coefficient–wavelength plot of dyes (not presented) indicated that T and AR showed good correlation over the wavelength range 362–455 and 450–550 nm, respectively. On the other hand, SY dye exhibited a poor correlation with the entire spectral range. For HLA/GO calibration, six spectral regions (with 1.0 nm interval) were selected based on the correlation coefficient – wavelength plot: 200–800, 200–600, 200–350, 300–600, 350–550, and 350–800 nm. HLA/GO calibration was carried out separately for each dye for each selected wavelength range. The quality of calibration was assessed by calculating relative error of prediction (REP%) for dyes concentrations (Goicoechea & Olivieri, 1999 and Hemmateenejad et al., 2007).

The prediction power of HLA/GO was satisfactory (total REP < 1%) when the analysis was limited to 350–550 nm spectral range. However, the spectral range 300–600 nm was also useful for HLA/GO calibration where the total REP% value for dyes determination was about 2.0%. It is interesting to notice that including the entire spectral range (200–800 nm, 601 points/spectrum) has decreased the method's efficiency for prediction as inferred from the high total REP% value (7.32%). The spectral domain 200–350 nm is not recommended for calibration where the maximum values of REP% were reported for that range (13.61%). The modest prediction power of HLA/GO method over 200–350 nm range could be attributed to the high spectral overlap between dyes in that region (Fig. 2).

After checking out outliers and setting the suitable spectral range, HLA/GO calibration method is ready for dyes determination in validation set and food samples and this subject will be investigated next.

3.4. Determination of food dyes in synthetic mixtures by HLA/GO calibration

In this section, HLA/GO method is employed for prediction of dyes contents in calibration and validation sets at the optimum calibration factors (pH 5 and wavelength range 350–550 nm). This goal was achieved by estimating the net sensitivity vectors ($\mathbf{s}_k^*$) for dyes (separately) and then use these vectors for estimating dyes concentrations in calibration/validation sets and food samples. For each dye in both sets, PRESS (prediction error sum of squares), relative error of prediction (REP%), and square of correlation coefficients (r^2) were calculated and the results were summarised in Table 1.

As clearly indicated in Table 1, the HLA/GO method gave satisfactory results for dyes determination. In all cases, r^2 values were approached to unity which reflects the high closeness between real and predicted values. The average recoveries and R.S.D. values were also satisfactory. In both sets, the average recoveries were within the range: 99.5–102.3% and R.S.D. values were <5.0% in all cases. In summary, the proposed HLA/GO method offers a simple and rapid procedure for dyes determination in water with high precision and accuracy without the need for any previous separation step.

Figures of merit (like accuracy, precision, repeatability, and detection limits) were evaluated for the proposed calibration method as outlined in the literature (Lorber et al., 1997). Analytical intraday precision was determined by analysing a standard mixture of dyes (containing 5, 5, and 6 μg ml^{-1} of AR, SY, and T, respectively) in six replicates in one day. Interday precision was determined by measuring the same control mixture in duplicate for three days. The concentration of each dye in the control mixture was determined using HLA/GO method on the first day of the study. The standard solution of dyes was prepared and analysed six times within the same day to measure the repeatability of the method. The obtained accuracy and R.S.D. values were

Table 1
Assessment of HLA/GO method for dyes quantification in water.

Dye	Internal Validation[a]			External Validation[a]		
	PRESS	REP%	r^2	PRESS	REP%	r^2
Allura Red	0.24	0.62	0.9996	0.31	0.91	0.9995
Sunset yellow	0.17	0.84	0.9991	0.28	0.63	0.9992
Tartrazine	0.36	0.92	0.9998	0.18	0.75	0.9994

[a] PRESS, REP%, and r^2 values were all estimated for non-zero dye concentrations. The proposed method predicts a very close value to zero when no dye had been added (data not given).

99.2–101.2% and 1.13–2.51 for intraday analysis and 99.1–101.4% and 1.41–1.76 for interday analysis.

The earlier values were satisfactory and reflecting the high accuracy and precision of HLA/GO method for both intraday and interday analysis. The repeatability was also high with a random error of <3%. The obtained detection limits for AR, SY, and T were 0.66, 0.52, and 0.43 μg ml^{-1}, respectively.

3.5. Determination of food dyes in food drinks using HLA/GO method

There are a number of studies that discussed the application of multivariate calibration for food dyes analysis. For example, Nevado and co-workers have applied PLS-1, PLS-2, and PCR for determination of four food dyes in different commercial beverages (Nevado et al., 1995). López-de-Alba and co-workers have successfully applied PLS-1 and PLS-2 on zero and first order spectral data for sake of determination of three common food dyes in soft drinks (López-de-Alba et al., 2001). Moreover, the pervious authors have validated the proposed chemometric methods against independent chromatographic methods. According to our literature survey, HLA/GO calibration method has not been applied for food dyes analysis in any food type. The HLA/GO method was applied for determination of AR, SY, and T in four commercial soft drinks. The solutions of food samples were prepared as described earlier and scanned using the spectrophotometer. The spectral data were then subjected to HLA/GO calibration to find dyes contents in each sample. The results of analysis were provided in Table 2. The results obtained by HPLC method were given in the same table for sake of comparison.

As indicated in Table 2, food dyes were simultaneously quantified in commercial samples with a reasonable precision using HLA/GO method. For more validation to HLA/GO method, the same food samples were analysed using an independent analytical method. In such cases, one has two options to go through. The first option is to carry out standard addition techniques and the second one is to apply an independent standard method (like HPLC) for dyes determination in food samples. The second option was adopted here because of the high validity of HPLC method in food dyes analysis (Alves et al., 2008).

Under the conditions already outlined earlier for HPLC method, calibration graphs (peak area vs. dye content) were obtained from triplicate determination using five standard solutions of dyes. Table 3 summarised the chromatographic results for dyes separation. The results obtained for dyes determination by an independent HPLC method was also provided in Table 2. To decide whether the results of HLA/GO and HPLC methods are comparable or not, *t* and *F* statistical tests were carried out. For all cases, *t*-calculated values were lower than *t*-table values which indicated that no significant difference between HPLC and the proposed method for determination of dyes in food samples. Moreover, *F*-calculated values were also lower than *F*-table values which confirmed that both methods are of similar precision. The results in Table 2 indicated that HLA/GO method was able for dyes quantification in four commercial soft drinks without the need for running chromatographic separation. Relatively speaking, the proposed HPLC method has better precision than HLA/GO method as indicated from S.D. values and this was expected because dyes were totally separated before their quantification, while, in HLA/GO method the dyes were quantified directly in the sample matrix. Compare to HPLC method, HLA/GO method was rapid, easy to implement, and of low running cost for dyes quantification. The HLA/GO method could be used for food dyes quantification in cases where the chromatographic ones cannot be implemented owing to cost limitations or lack of analytical instrumentation. It is worth to mention that the levels of AR, SY, and T in soft drinks were below the limit set by European legislations (Directive 94/36//EC, 1994).

The results of HLA/GO and liquid chromatography were, qualitatively, confirmed by simple paper chromatography. The paper chromatographic tests indicated the absence of AR in TANG/Mango, TANG/Orange, and SQUEEZE/Orange and confirmed the existence of all dyes in SQUEEZE/Mango. The separated dyes from food samples were have well-resolved bands and identical R_f values to those obtained from the standards, 0.71, 0.45, and 0.37 for AR, SY, and T, respectively.

It is worth to mention here that the excipients that present in soft drink samples (like citric acid, sucrose, and synthetic flavouring materials) have a low interference with dyes determination. This conclusion was drawn when the spectrum of pure dyes mixture was matched with the spectra of food samples. Fig. 3 showed the spectra of dyes in water and in SQUEEZE/Mango sample. SQUEEZE/Mango sample was selected because of the presence of the three dyes in high amounts (see Table 2).

The similarity between the spectra depicted in Fig. 3 indicated that other food excipients do not interfere in dyes determination by HLA/GO or even HPLC method. It seems that other food excipients are active within the spectral range (250–305 nm) as indi-

Table 2
Determination of Allura Red, Sunset Yellow, and Tartrazine in four commercial soft drinks using HLA/GO and HPLC methods.[a]

Sample	Allura Red		Sunset Yellow		Tartrazine

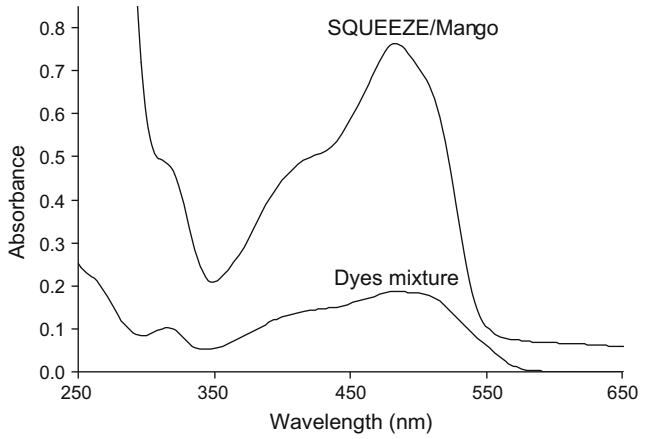

Fig. 3. Absorbance spectra of SQUEEZE/Mango solution (2.0 sample in 100 ml pure water) and synthetic dyes mixture (10.0 μg ml^{-1} for Tartrazine and Sunset yellow and 7.0 μg ml^{-1} for Allura Red) pH = 5.0.

cated from their high absorbance and, fortunately, this region was excluded from the chemometric analysis. In case where a high interference is present with target dyes, a suitable extraction and clean-up procedures are necessary to extract dyes prior applying HLA/GO or HPLC methods.

4. Conclusions

HLA/GO method, as a multivariate calibration method, was found useful method for simultaneous determination of AR, SY, and T dyes in pure solutions and in four soft drink samples. The percent recoveries and R.S.D. values for dyes determination in solution were 99.3(4.2), 101.3(3.8), and 102.4(4.6) for AR, SY, and T, respectively. The results obtained by HLA/GO method for determination of dyes were fairly comparable to those obtained by HPLC method which reflects the effectiveness of the former method. Fortunately, the components of soft drinks did not strongly interfere with dyes analysis. In case of presence a strong interference, dyes should be extracted and preconcentrated prior their analysis. HLA/GO calibration method is a reasonable substitute for expensive HPLC method for quantification of dyes in soft drinks.

ABSTRACT

This study demonstrates the use of front face fluorescence spectroscopy and multivariate data analysis for differentiating brandies from wine distillates. Owing to the low price of the wine distillates, they are sometimes used for the counterfeiting brandies. For this reason, there is a need for a rapid method for drink authentication to reassure consumers and protect regional designations. Total luminescence and synchronous scanning fluorescence spectra were recorded followed by a classification of samples using principal component analysis (PCA) and hierarchical cluster analysis (HCA). Both PCA and HCA carried out on the emission spectra (360–650 nm) recorded at excitation wavelength 350 nm and synchronous fluorescence spectra (200–700 nm) collected at wavelength interval 90 nm provide very good differentiation between the two spirit classes. Less good classification was obtained using excitation spectra (225–425 nm) obtained at emission wavelength 440 nm. These results indicate that the front face fluorescence spectroscopy offers a promising approach for the authentication of brandies.

1. Introduction

Brandy is a spirit drink produced from wine spirit, whether or not blended with a wine distillate distilled at <94.8 vol.%, provided that that distillate does not exceed a maximum of 50% by volume of the finished product. This spirit is aged for at least one year in oak receptacles or for at least six months in oak casks. Wine spirit is a spirit drink produced by the distillation at <86 vol.% of wine or wine fortified for distillation or by the redistillation of a wine distillate at <86 vol.%. Wine spirit shall not contain added ethanol of agricultural origin (Regulation (EC) No 110/2008).

In Slovak Republic there are two types of these spirits: "wine distillates" are less expensive, and can be legally produced using wine distillates diluted with ethanol from other sources, whereas "brandy" is more expensive and should contain ethanol from grape. Brandy has to be aged for a certain period in oak casks to obtain characteristic taste, flavour and colour. Traditional techniques utilised to analysis of brandy, such as gas chromatography–mass spectrometry (Caldeira, Pereira, Climaco, Belchior, & Bruno de Sousa, 2004), high-performance liquid chromatography (Canas, Belchior, Spranger, & Bruno-de-Sousa, 2003) and capillary electrophoresis (Panossian, Mamikonyan, Torosyan, Gabrielyan, & Mkhitaryan, 2001), focus on the determination of a certain marker compounds in a test product followed by a comparison of the values obtained with those previously documented for authentic product. This approach is often time-consuming, expensive, requires highly trained staffs and the range of compounds, which must be quantified to ensure authenticity, is continuously increasing. In the last few years, there has been an increasing need to develop rapid, inexpensive and effective analytical methods, as well as requiring low sample manipulation. These demands lead to an approach based on food matrix characterisation as a whole and spectroscopic methods combined with chemometric techniques have been studied for this purpose.

While there has been a notable growth for near-infrared (Barboza & Poppi, 2003; Pontes et al., 2006) and Fourier transform infrared (Lachenmeier, 2007; Palma & Barroso, 2002) spectroscopy, there has been little research carried out using either UV–VIS absorption or fluorescence spectroscopy in spirit drink authentication applications. Recent work using UV–VIS absorption spectroscopy dealt with discriminating 100% agave tequilas from other types of tequila (Barbosa-García et al., 2007).

A review (Christensen, Norgaard, Bro, & Engelsen, 2006) has revealed that the application of fluorescence spectroscopy for direct analysis of food has increased during the last decade, probably due to the wide-spread use of multivariate data analysis tools.

Front face fluorescence spectroscopy has demonstrated its feasibility to classify Swiss honeys from seven different floral sources (Karoui, Dufour, Bosset, & De Baerdemaeker, 2007). This method has also been used for the determination of the geographical origin of milk (Karoui, Martin, & Dufour, 2005) and cheeses (Karoui, Bosset, Mazerolles, Kulmyrzaev, & Dufour, 2005; Karoui, Dufour, et al., 2005). Within the area of cheese ripening, the studies concluded

doi:10.1016/j.foodchem.2009.04.053

that fluorescence spectroscopy is suitable to discriminate each ripening stage (Karoui & De Baerdemaeker, 2007).

The potential of front face fluorescence spectroscopy combined with principal component analysis (PCA) and factorial discriminant analysis (FDA) has been investigated for discriminating different wines according to variety, typicality and vintage. PCA performed on the whole collection of excitation spectra allowed a good discrimination between French and German wines. Using FDA, correct classification of typical and non-typical Beaujolais amounting to 95% was observed for the emission fluorescence data set (Dufour, Letort, Laguet, Lebecque, & Serra, 2006).

Synchronous scanning fluorescence spectra and multivariate data analysis (nearest neighbour method and linear discriminant analysis) have been used for classification of differently stored beer samples (Sikorska, Górecki, Khmelinskii, Sikorski, & De Keukeleire, 2006) and of different beers from different breweries (Sikorska, Górecki, Khmelinskii, Sikorski, & De Keukeleire 2004). Synchronous scanning fluorescence spectra are also useful for detection of adulteration of virgin olive oil (Poulli, Mousdis, & Georgiou, 2007).

The aim of this paper is to show that front face fluorescence spectroscopy and multivariate statistical methods (principal component analysis and hierarchical cluster analysis, HCA) can be used for distinguishing between commercial samples of brandies and wine distillates. It appears that front fluorescence spectroscopy may give a quick and non-destructive answer to the product authenticity as spectra can be recorded directly on samples.

2. Materials and methods

2.1. Samples

The studies were performed on 16 brandies (B) from three different producers (B_1, $n = 8$; B_2, $n = 4$; B_3, $n = 4$) and 30 wine distillates (D) from five different producers (D_1, $n = 12$; D_2, $n = 10$; D_4, $n = 4$; D_5, $n = 2$; D_6, $n = 2$). Four brandies were acquired directly from the manufacturers; other samples were purchased from the local supermarkets. Brandy B_1, a traditional Slovak product from the Small Carpathian viticultural region, is made of the grape using a classic method of ageing wine spirit in small 300 l oak barrels for a minimum 5 years. The wine spirit then goes to 20,000 l barrels for next 3 years. Brandy B_2 is made of the pure high quality foreign wine spirit matured by natural way in oak barrels. B_3 is made of the wine spirit from the East Slovak viticulture region matured by natural way in oak barrels.

Wine distillates are produced using wine spirits diluted with ethanol from other sources. They are frequently mixed with sugar, brandy aroma and caramel. Wine distillates D_1 contain honey and colourants (E 102, E 110, E 120, E 122, E 132 and E 151).

Samples were stored in the dark at room temperature until the day of analysis.

2.2. Fluorescence spectroscopy

Fluorescence spectra were recorded using a Perkin–Elmer LS 50 Luminescence spectrometer equipped with a Xenon lamp and a variable angle front-surface accessory. The incidence angle of the excitation radiation was set at 56°. Samples were placed in 10 mm × 10 mm × 45 mm quartz cell. Excitation and emission slits were both set at 5 nm.

Fluorescence excitation spectra were recorded between 200 and 500 nm (increment 0.5 nm), repeatedly, at emission wavelengths from 300 to 600 nm, spaced by 5 nm interval in the emission domain.

Fluorescence emission spectra were recorded from 250 to 700 nm (increment 0.5 nm), repeatedly, at excitation wavelengths from 200 to 500 nm, spaced by 5 nm interval in the excitation domain.

Synchronous fluorescence spectra were collected by simultaneously scanning the excitation and emission monochromator in the excitation wavelength range 200–700 nm, with constant wavelength differences $\Delta\lambda$ between them. Spectra were recorded for $\Delta\lambda$ interval from 10 to 100 nm, in steps of 5 nm. Fluorescence intensities were plotted as a function of the excitation wavelength.

Fluorescence measurements were done in triplicate for each sample.

The spectrometer was interfaced to a computer supplied with FL Data Manager Software (Perkin–Elmer) for spectral acquisition and data processing.

Contour maps of total luminescence and synchronous scan fluorescence spectra were plotted using Windows-based software OriginPro 7.5 (OriginLab, USA, 2002).

2.3. Mathematical analysis of data

PCA and HCA were applied to the fluorescence spectra to investigate differences between the samples. PCA is an unsupervised (we have no prior knowledge of the groups to be expected) pattern recognition method that reduces the dimensionality of the original data matrix while retaining the maximum amount of variability as well as recognising the data structure. PCA decomposes a data matrix with n rows (samples) and p columns (variables) into the product of a scores matrix, with n rows (samples) and $d < p$ columns (principal components, PCs), and a loadings matrix, with $d < p$ rows (PCs) and p columns (variables). The scores are the positions of the samples in the space of the principal components and the loadings are contributions of the original variables to the PCs. All PCs are mutually orthogonal, and each successive PC contains less of the total variability of the initial data set. Usually, only a limited number $d < p$ of PCs are retained, as the variability in the others is due to noise. This reduces the dimensionality of the data considerably, enabling effective visualisation, classification, and regression of multivariate data (Geladi, 2003).

HCA is an unsupervised pattern recognition method detecting natural grouping in data. Objects are grouped in clusters in terms of their similarity. The initial assumption is that the nearness of objects in the space defined by the variables reflects the similarity of their properties. There are diverse possibilities and rules used to measure distances (in various metrics in multidimensional space), form and linkages among individual clusters. We used hierarchical (agglomerative) cluster analysis, where similarity extent was measured by Manhattan (city-block) distances and cluster aggregation was based on Ward's method (Otto, 1999).

Microsoft Excel 2000 and Statistica software version 6.0 (StatSoft, USA, 2001) were used for statistical analysis.

3. Results and discussion

3.1. Total luminescence spectra

Recently, total luminescence spectroscopy (TLS) has been applied to obtain emission spectra over a range of excitation wavelengths in the form of Excitation–Emission matrices (EEM contour maps), which allowed to obtain more detailed information than that obtained using conventional mono dimensional fluorescence (Poulli, Mousdis, & Georgiou, 2005; Sikorska et al., 2006).

Total luminescence spectra of the brandy and wine distillate are shown in Fig. 1 as contour maps. In general, spectral features and fluorescence intensity values of all brandies are typical of brandies of similar origin and nature. Brandy total luminescence contour

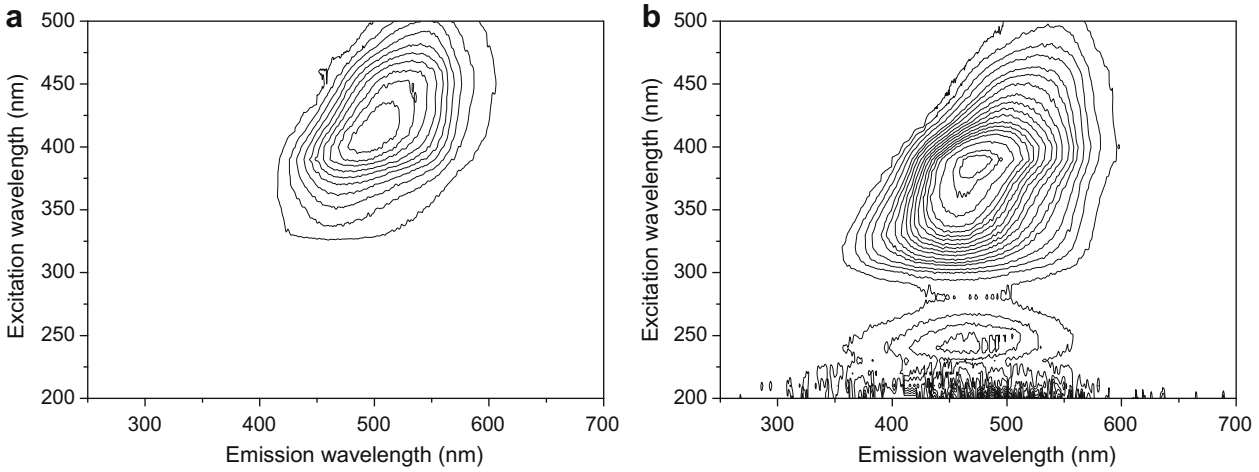

Fig. 1. Contour plots of total luminescence spectra of brandy (a) and wine distillate (b) samples. Contours join the points of equal fluorescence intensity.

map spreads in the excitation wavelength range higher than 320 nm, in contrast to wine distillate that spreads in the full excitation wavelength range. The contours for brandy are concentrated in the emission wavelength region 470–520 nm and excitation wavelength region 390–430 nm, while the contours for wine distillates are concentrated in the emission wavelength region 450–500 and 440–490 nm and the excitation wavelength region 360–390 and 230–250 nm, respectively.

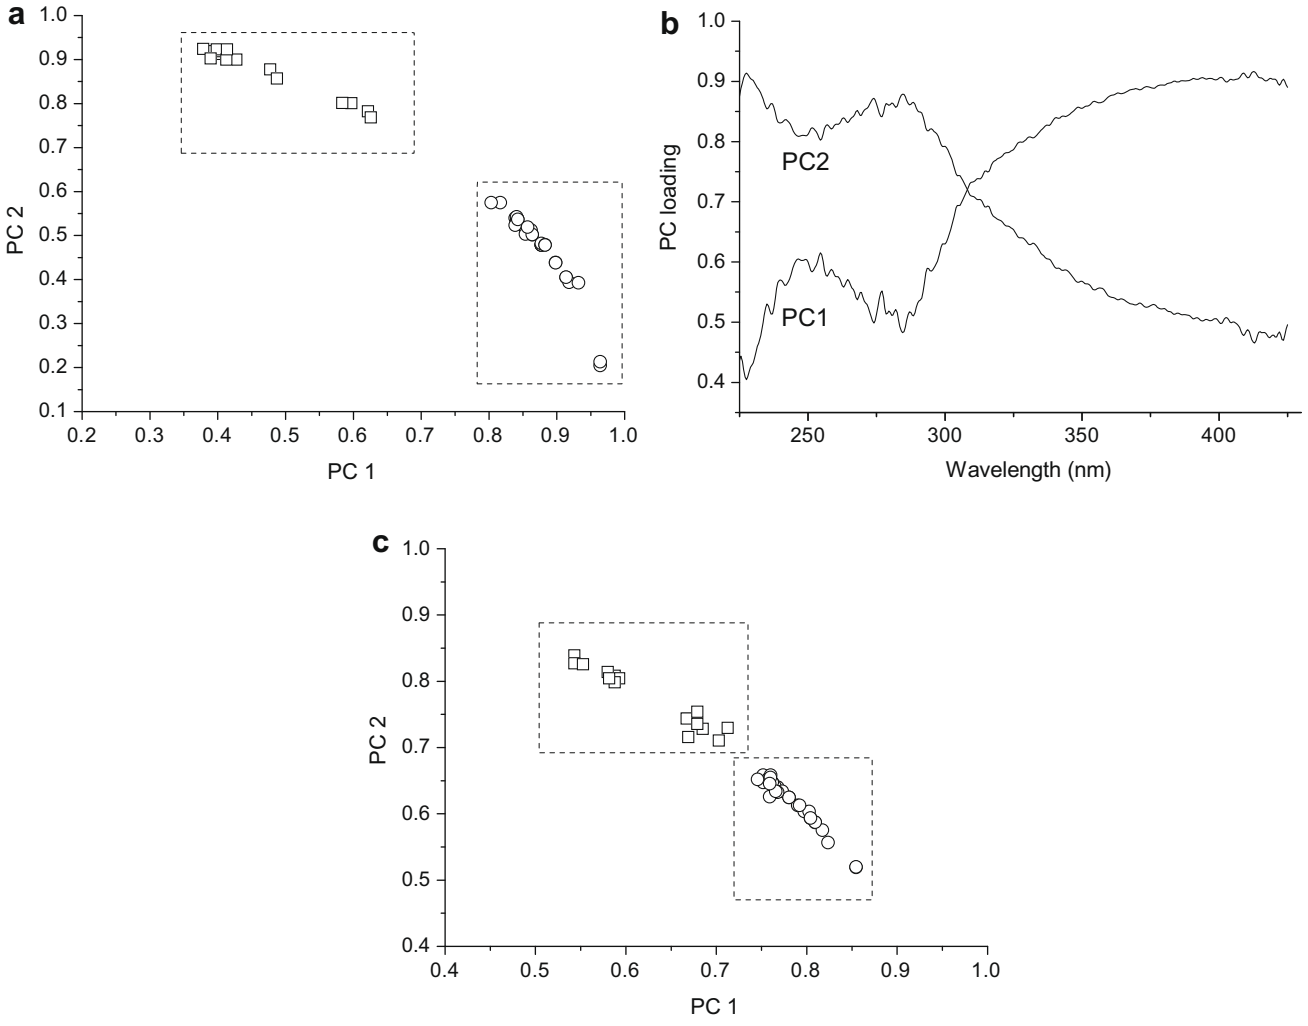

Fig. 2. Principal component analysis similarity map (score plot) determined by principal component 1 (PC1) and principal component 2 (PC2) (a) and spectral pattern (loading) corresponding to PC1 and PC2 (b) for excitation fluorescence spectra recorded at emission wavelength 440 nm (a and b) and principal component analysis similarity map determined by PC1 and PC2 for emission spectra recorded after excitation at 350 nm (c) on brandy (□) and wine distillate (○) samples.

The fluorescence spectra of brandies B_1 are characterised by the main fluorophores centred at an excitation/emission wavelength pair of 410/500 nm. The other brandies have the following excitation/emission maxima: B_2 – 396/485 nm, B_3 – 396/485 nm. However, the excitation/emission wavelength values of the major peaks of the brandies are generally longer than those usually measured for wine distillates, e.g., D_1 – 390/475 nm, D_2 – 388/472 nm. The spectra of the wine distillates reveal the presence of an additional band at 240–250 nm in excitation and 440–460 nm in emission. The shape and intensity of these intermediate emissions varies from one distillate to another. Further, another excitation band was observed for the distillates with excitation maxima at 330 and 395 and an emission region above 520 nm. Moreover, wine distillates show stronger fluorescence than brandies.

As it is clearly shown in Fig. 1 the shape and the fluorescence intensities are different between the two classes of beverages. Consequently, total luminescence spectroscopy can be used to characterise brandy and wine distillate samples using suitable wavelength regions.

3.2. Multivariate analysis of excitation and emission spectra

The PCA was applied separately on the excitation and emission spectra to investigate differences between samples. The best classification was achieved using emission spectra (360–650 nm) recorded at excitation wavelength 350 nm or excitation spectra (225–425 nm) recorded at emission wavelength 440 nm. The fluorescence spectra showed different shapes. The width of excitation spectra was larger for wine distillates than those for brandies. Wine distillates had higher fluorescence intensity regardless of wavelength but they were also more heterogeneous in this respect.

The similarity map defined by the PC1 and PC2 of the PCA performed on excitation spectra accounted for 99.6% of the total variance with PC1 accounting for 91.2% and allowed a good discrimination of beverages (Fig. 2a). Spectral pattern associated with the PCs provide the characteristic wavelengths that may be used to discriminate between spectra (Fig. 2b). The spectral pattern associated with the PC1 exhibited a positive peak around 250 nm and a broad positive peak between 320–420 nm corresponding to caramel. The spectral pattern associated with the PC2 exhibited positive peaks at 230 and 290 nm.

While a discrimination of the brandy and wine distillate samples was achieved with excitation data collection, a different trend was observed with emission spectra. Although the PCA similarity map defined by the PC1 and PC2 (98.5% and 1.3% of the total variance, respectively) did not lead to a clear discrimination of beverages, a general trend pointing out the brandies and wine distillates was observed on the map (Fig. 2c).

In a second step, HCA was carried out separately on the excitation and emission spectra in order to evaluate the number of subsets of similar samples appearing in the complete data set. For the sake of simplicity, a reduced number of samples were included in the figures, but from them we can clearly recognise the clustering common to all the samples. The evaluation of the above mentioned excitation spectral region provided two main clusters (Fig. 3a). All wine distillates are linked together in the first main cluster. This main cluster is heterogeneous enough but consists of various small groups of very similar products. For instance, most of the wine distillates from producer 1 (D_1) is found as such in one subgroup with 95% of similarity among them. All brandies are linked together in the second main cluster. One subcluster is constituted of B_2 (brandy from producer 2) with 98% of similarity. Another subcluster is constituted of B_1 and B_3 with 96% of similarity among them and 87% in relation to B_2.

Fig. 3b shows the results from HCA concerning the emission spectra. The first main cluster contains wine distillate samples, while the second one contains brandy samples. Wine distillates

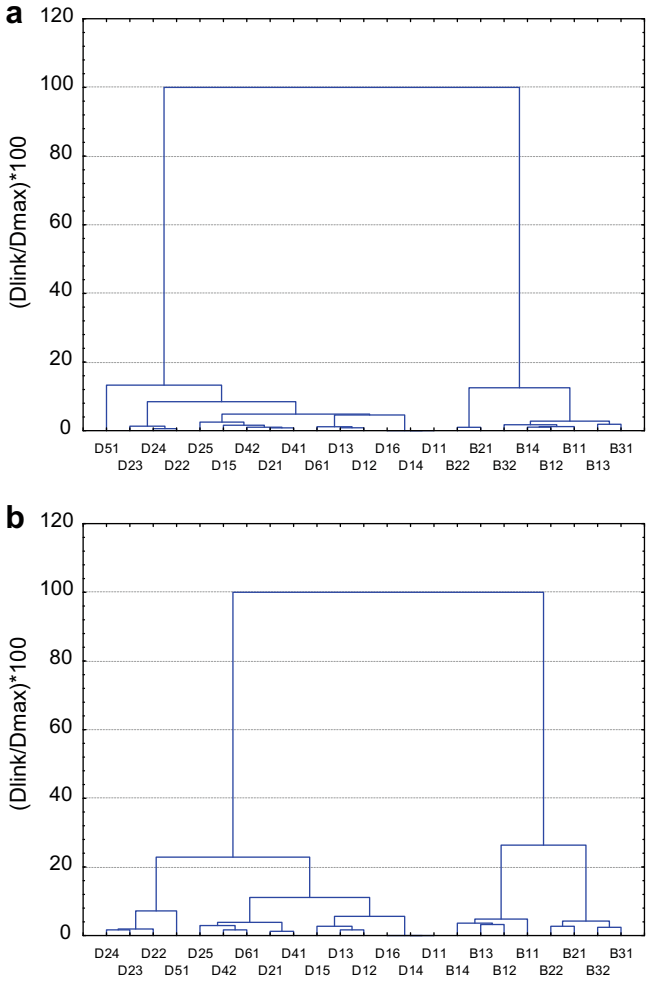

Fig. 3. Hierarchical cluster analysis dendrogram using Manhattan distance for excitation fluorescence spectra recorded at emission wavelength 440 nm (a) and emission spectra recorded after excitation at 350 nm (b) on brandies (*B*) and wine distillates (*D*).

form three smaller groups. One small group is constituted of samples D_2 with 98% of similarity among them and by sample D_5 with 92% of similarity with the samples D_2 of this group. Another group is constituted of D_2, D_4 and D_6 with 96% of similarity among them and 90% in relation to the group of D_1. Samples D_1 show a similarity of 94% to each other. Brandy samples form three small subclusters of the second main cluster corresponding to three different producers. One subcluster is constituted of B_1 with 96% of similarity. Another subcluster is constituted of B_2 and B_3 with 96 % of similarity among them and 74% in relation to B_1.

3.3. Total synchronous fluorescence spectra

The contour plots of total synchronous fluorescence (TSF) spectra were obtained by plotting the fluorescence intensity (z-axis) as a function of excitation wavelength (x-axis) and wavelength interval $\Delta\lambda$ (y-axis). The TSF spectra of a brandy sample are given in Fig. 4a. It shows that the TSF contour map spreads in the excitation wavelength 330–530 nm and in the wavelength interval 10–100 nm. The contours are concentrated in the excitation wavelength region 390–440 nm and wavelength interval 70–100 nm. The plot shows one fluorescence maximum only. For example, the maximum fluorescence intensity was observed at excitation wavelength 410 nm ($\Delta\lambda$ = 90 nm), 396 nm ($\Delta\lambda$ = 90) and 396 nm ($\Delta\lambda$ = 90 nm) for brandy B_1, B_2 and B_3, respectively.

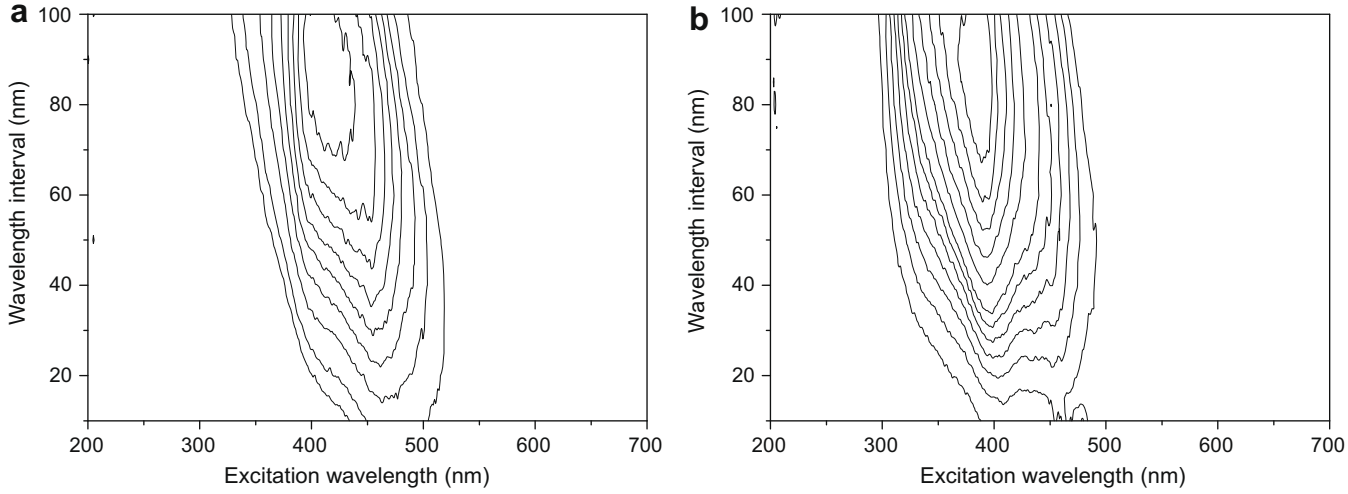

Fig. 4. Contour plots of total synchronous fluorescence spectra of brandy (a) and wine distillate (b) samples. Contours join the points of equal fluorescence intensity.

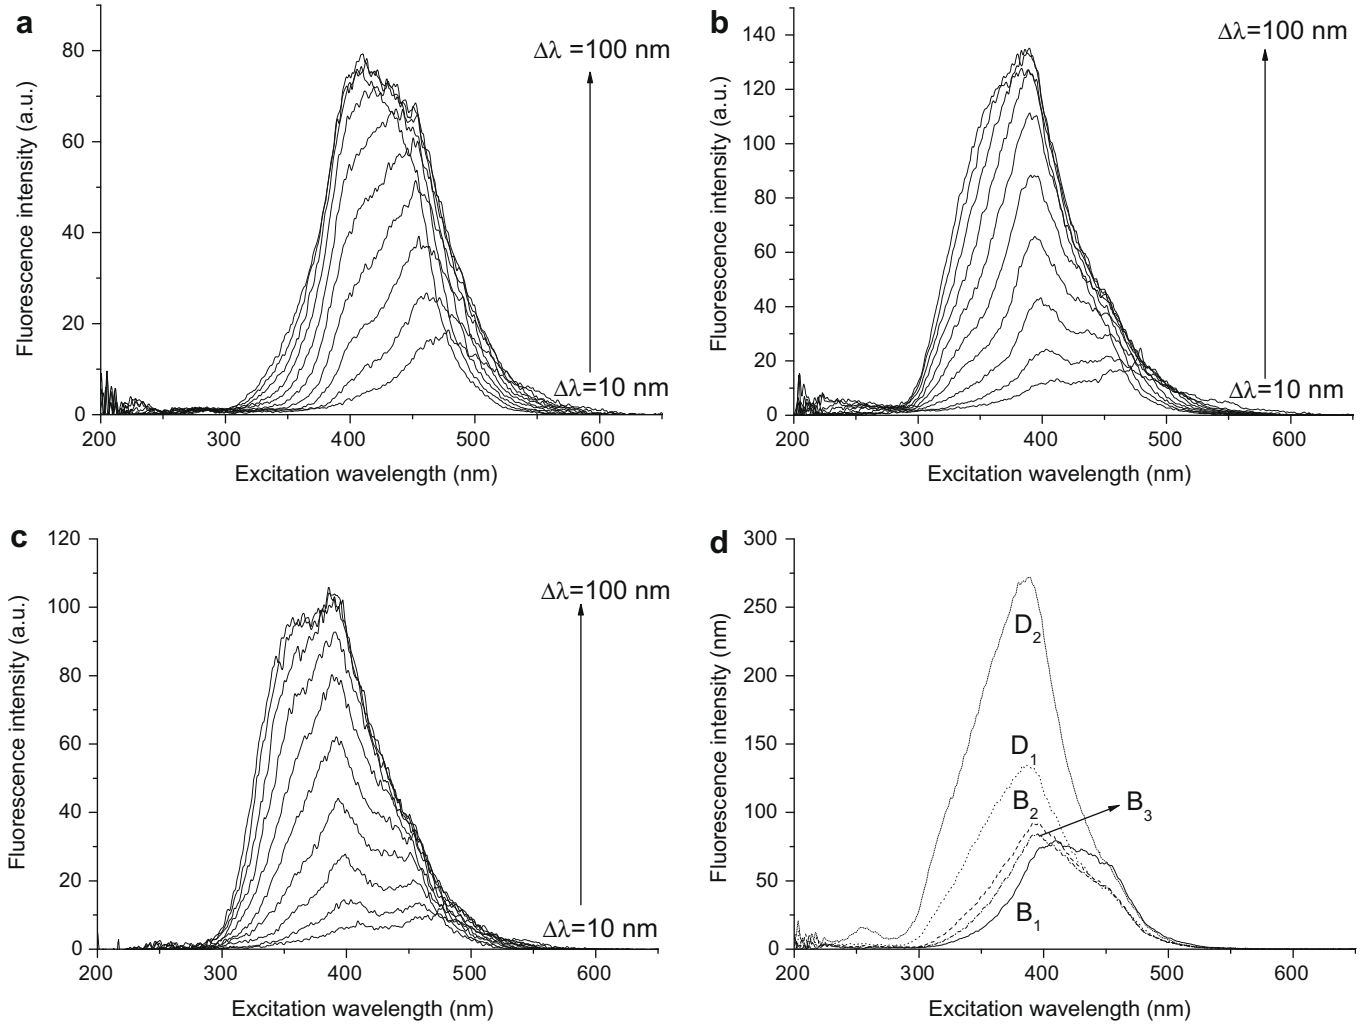

Fig. 5. Synchronous fluorescence spectra of brandy (a), wine distillate (b) and caramel (E 150a) (c) recorded at wavelength interval from 10 to 100 nm in steps of 10 nm. Synchronous fluorescence spectra of brandy (*B*) and wine distillate (*D*) samples from various producers (1–3) obtained at wavelength interval 90 nm (d).

The TSF spectra of a wine distillate sample are given in Fig. 4b. The contour map spreads in the excitation wavelength 300–510 nm and $\Delta\lambda$ 10–100 nm. The contours are concentrated in the excitation wavelength 370–410 nm and $\Delta\lambda$ 70–100 nm. The spec-

tra of wine distillates are characterised by two fluorescence maxima, one at ~390 nm and the other at ~440 nm, and a shoulder at about 330 nm. The maximum fluorescence intensity for distillate D_1 and D_2 was observed at excitation wavelength 390 nm ($\Delta\lambda$ = 85 nm) and 388 nm ($\Delta\lambda$ = 85), respectively.

Generally, the fluorescence maxima shift to shorter wavelengths with increasing $\Delta\lambda$ for both brandy and wine distillates. Wine distillates give a shorter wavelength high intensive fluorescence band and brandies give a longer less intensive band.

Fig. 5 shows the shift, simplification and amplification of synchronous fluorescence spectra of brandy, wine distillate sample and caramel (E 150a) using different wavelength intervals. For brandy, the plot shows one fluorescence maximum only blue-shifted from 480 to 400 nm with increasing $\Delta\lambda$ (Fig. 5a). For wine distillate, three overlapping bands with maxima at 412, 433 and 478 nm are apparent for λ = 10 nm (Fig. 5b). For $\Delta\lambda$ = 30 nm, the fluorescence intensity of bands increased, changes in their relative intensities were noted, and maxima were blue-shifted to 396, 435 and 453 nm, respectively. For $\Delta\lambda$ = 40 nm, one band with maxima at 395 and shoulder at 439 nm are observed. In addition, a short-wavelength shoulder appeared with a maximum at about 340 nm. The further increase of intensity and band broadening was apparent for $\Delta\lambda$ = 50 nm, resulting in only one band with maxima at 391 nm and shoulder at 336 nm. At higher $\Delta\lambda$ values, the maximum of the synchronous spectrum is shifted to the blue and broadened, with additional fluorescence intensity changes. The shape and intensity of the fluorescence maxima varied from one wine distillate to another. Moreover, the shape of the spectra changed with distillate samples, varying in the shoulder intensity and/or $\Delta\lambda$ where shoulder appear (30–50 nm)/disappear (60–80 nm).

An alcoholic beverage is a complex mixture consisting of a large variety of substances with different spectroscopic characteristics. Due to this complexity, an intrinsic fluorescence of the beverage is result of the overlapping numerous fluorescence bands. Although complete assignment of the fluorescence bands is beyond the scope of our work, some preliminary assignments could be made, based on comparison of the fluorescence spectra with the fluorescent characteristics of particular beverage constituents. The short-wavelength fluorescence, with excitation at 280 nm and emission maxima located at 370 and 450 nm, was clearly observed in diluted brandy samples, along with the longer-wavelength fluorescence, with excitation at 340 nm and emission at 450 nm (data not shown). The former band was preliminary attributed to the aromatic amino acids. Since phenolic acids exhibited emission between 360 and 420 nm after excitation set between 250 and 280 nm, they can also modify the shape of the fluorescence spectra after excitation at 280 nm. The latter band could be

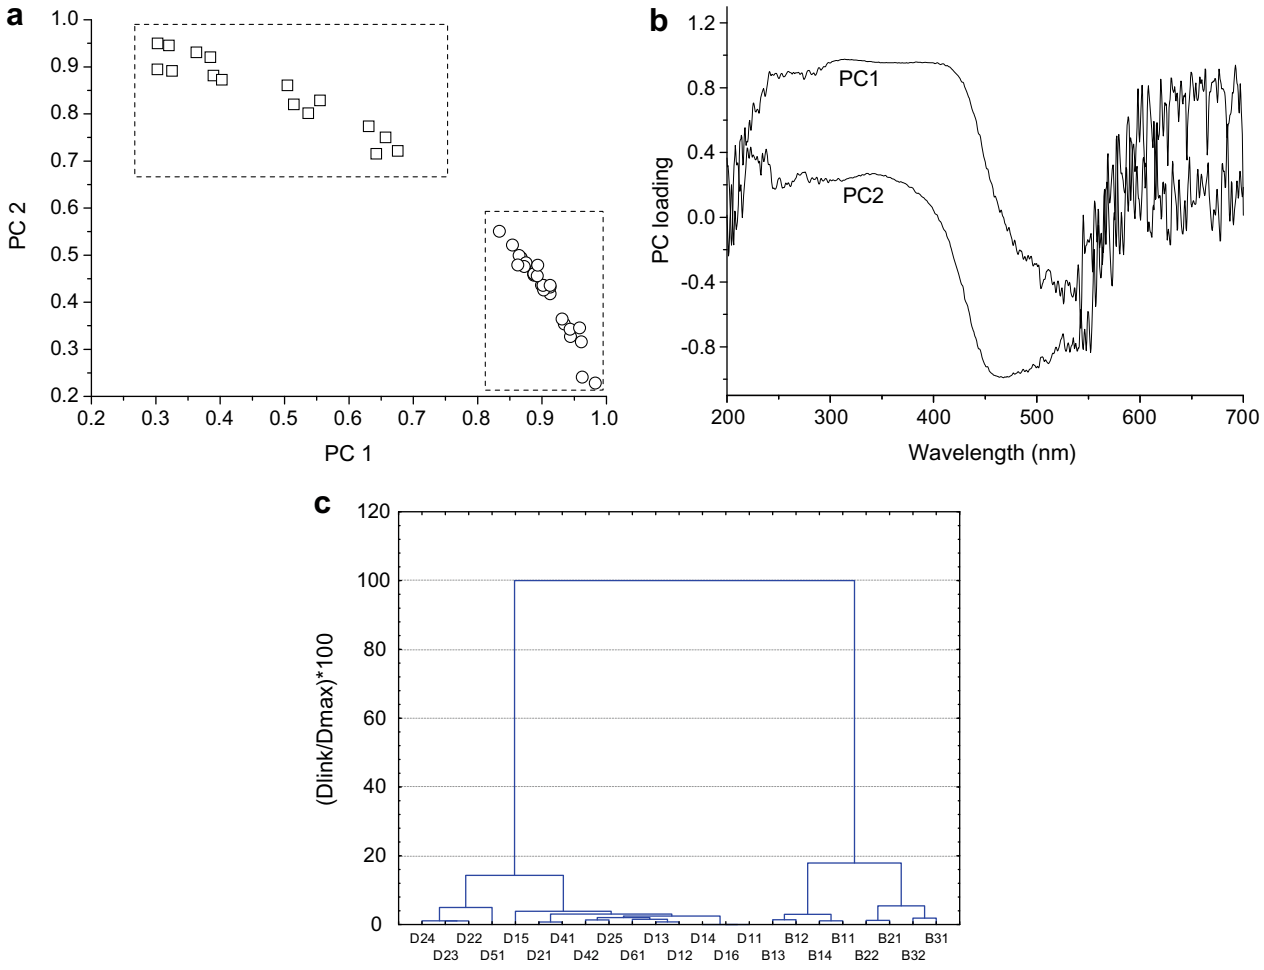

Fig. 6. Principal component analysis similarity map (score plot) determined by principal components 1 (PC1) and principal component 2 (PC2) (a) and spectral pattern (loading) corresponding to PC1 and PC2 (b) for synchronous fluorescence spectra recorded at wavelength interval 90 nm on brandy (□) and wine distillate (○) samples. Hierarchical cluster analysis dendrogram (c) using Manhattan distance for synchronous fluorescence spectra recorded at wavelength interval 90 nm on brandy (*B*) and wine distillate (*D*) samples.

due to the presence of fluorescent cinnamic acids, coumarins – namely scopoletin, Maillard reaction products, tannins and other unknown fluorescent compounds present in brandies.

The short-wavelength band could not be observed in the bulk brandy samples, while the longer-wavelength band was fairly intense. On the contrary, these two bands were clearly observed in the bulk wine distillate samples, showing higher intensity.

As mentioned, the wine distillates are frequently coloured with caramel (E 150a) to imitate the effect of long ageing in wooden casks. Therefore we assumed that the longer-wavelength bands originate from this colourant. To support this assumption, spectra of caramel in water were recorded. Emission spectra recorded after excitation at 390 nm showed a maximum located around 482 nm. The shape and intensity of the synchronous fluorescence spectra depend on the difference between excitation and emission wavelengths $\Delta\lambda$ (Fig. 5c). For $\Delta\lambda = 10$ nm, two bands with maxima at 411 and 477 nm are observed. At increased $\Delta\lambda$, the first band was shifted to 398 and 393 nm and the second one to 453 and 440 nm for $\Delta\lambda = 30$ and 40 nm, respectively. For $\Delta\lambda = 50$ nm, only one band with maxima at 391 nm was recorded. Comparison shows that the maxima observed for caramel at different $\Delta\lambda$-values are consistent with the respective maxima in wine distillates, so confirming a correct assignment of the longer-wavelength band to caramel.

3.4. Multivariate analysis of synchronous fluorescence spectra

PCA was applied separately on synchronous spectra measured at $\Delta\lambda$ 10–100 nm. The best classification was achieved using fluorescence spectra recorded at $\Delta\lambda = 90$ nm. The synchronous fluorescence spectra showed different shapes. The width of synchronous spectra was larger for wine distillates than those for brandies. Wine distillates had higher fluorescence intensity regardless of wavelength but they were also more heterogeneous in this respect. Fig. 5d illustrates differences in the synchronous fluorescence spectra of brandy and wine distillates from various producers obtained at $\Delta\lambda = 90$ nm.

Fig. 6a shows that the plot of the first two PCs leads to a good discrimination of beverages according to origin. PC1 and PC2 describe 90.2% and 9.5%, respectively, of the total variance. The spectral pattern associated with the PC1 presented a broad positive peak between 300–400 nm and a negative peak at 520 nm (Fig. 6b). The spectral pattern associated with the PC2 exhibited a narrow positive peak at 230 nm, a broad positive peak around 350 nm and a negative peak at 460 nm.

Applying HCA to fluorescence spectra recorded at $\Delta\lambda = 90$ nm, the dendrogram shows that the wine distillates are well separated from brandies (Fig. 6c). The first main cluster contains wine distillate samples only, while the second one contains brandy samples. Wine distillates cluster consists of various small groups of very similar products. One small group is constituted of samples D_2 with 99% of similarity among them and by sample D_5 with 95% of similarity with the samples D_2 of this group. Another group is constituted of D_1, D_4 and D_6 with 96% of similarity among them and 85% in relation to the previous group. Brandy samples form three small subclusters of the second main cluster corresponding to three different producers. One subcluster is constituted of B_1 with 97% of similarity. Another subcluster is constituted of B_2 and B_3 with 95% of similarity among them and 82% in relation to B_1.

4. Conclusion

This preliminary study shows that brandies and wine distillates can be discriminated using differences in their front face fluorescence spectra. Although differentiation between samples was possible by visual inspection of the spectra, it was accomplished by multivariate data analysis methods more easy. Front face fluorescence spectroscopy offers a promising approach for the authentication of brandies as neither sample preparation nor special qualification of the personnel are required, and data acquisition and analysis are relatively simple.

Synchronous fluorescence spectroscopy

ABSTRACT

Synchronous fluorescence (SyF) spectra combined with principal component analysis (PCA) is proven to be a useful tool for monitoring olive oil deterioration under UV irradiation at 80 °C. Spectra acquired in the range 300–500 nm during 12 h accelerated oxidation stress using a surface per volume ratio of 0.95 cm^2 ml^{-1} reveal five different classes after PCA. Parallel monitoring of lipid oxidation parameters peroxide value (PV), anisidine value (AV) shows that after 12 h, TOTOX value increases 10-fold, 19-fold and almost 38-fold for extra virgin olive, olive and olive-pomace oil, respectively.

Linear correlations between parameter values versus exposure time were observed during extra virgin olive oil deterioration under UV at different temperatures: ambient (~20 °C), 40, 60 and 80 °C. The rate of increase was found to be 6.3, 18.7, 37 and 56 TOTOX h^{-1}, 2.8, 8.3, 16.5 and 25.6 meq peroxides kg^{-1} h^{-1} and 0.84, 2.0, 3.6 and 4.9 AV h^{-1}, respectively. The rates of parameter change increase linearly with temperature, the slopes being 0.84 ± 0.06 TOTOX h^{-1} °C^{-1}, 0.38 ± 0.03 meq peroxides kg^{-1} h^{-1} °C^{-1} and 0.07 ± 0.003 AV h^{-1} °C^{-1}.

1. Introduction

Oxidation results in deterioration of edible oils reducing shelf life and nutritional value, while at the same time toxic compounds are produced. Primarily oxidation products are hydroperoxides that subsequently decompose to secondary products such as aldehydes, alcohols, ketones and hydrocarbons. These compounds are responsible for the off-flavour characterising degraded edible oils. Oxidation is depended on light (Caponio, Bilancia, Pasqualone, Sikorska, & Gomes, 2005; Grigoriadou & Tsimidou, 2006; Nakajima & Hidaka, 1993) heat (Choe & Min, 2006; Naz, Siddiqi, Sheikh, & Sayeed, 2005) and endogenous metals, pigments, phospholipids and antioxidants (Baldioli, Servili, Perretti, & Montedoro, 1996; Hamilton, 1994; Velasco & Dobarganes, 2002). Moreover, the fatty acid composition i.e. saturated versus mono- and poly- unsaturated fatty acids, strongly affects the oxidative process.

Classical analytical methods are used for monitoring the oxidation state of edible oils: peroxide value (PV), anisidine value (AV), 2-thiobarbituric acid value, carbonyl value and total polar materials (Fritsch, 1981). Useful indices are also spectrophotometric absorption at 232 and 270 nm (Vieira & Regitano-d'Arce, 1999). Chromatographic methods that have been used to identify and quantify individual oxidation products are cumbersome and time consuming (Bilancia, Caponio, Sikorska, Pasqualone, & Summo, 2007). Recently, nuclear magnetic resonance (Guillen & Ruiz, 2006) and vibrational techniques (Muik, Lendl, Molina-Diaz, Valcarcel, & Ayora-Canada, 2007; Sinelli, Cosio, Gigliotti, & Casiraghi, 2007) which are rapid and easy to use have been used to monitor edible oil deterioration. Fluorescence spectroscopy has been recently used for monitoring deterioration of extra virgin olive oil during heating (Cheikhousman et al., 2005).

One of the modes of fluorescence spectroscopy is synchronous fluorescence (SyF). In SyF both the excitation and emission monochromators are scanned simultaneously in such a manner that a constant wavelength interval ($\Delta\lambda$) is kept between emission and excitation wavelengths. SyF enhances fluorescence spectroscopy in the analysis of complex multi-component samples such as olive oil, since it reduces spectral overlaps by narrowing spectral bands and simplifies spectra using a suitable wavelength interval (Patra & Mishra, 2002a; Poulli, Mousdis, & Georgiou, 2007). Total synchronous fluorescence (TSyF) spectra are obtained by plotting fluorescence intensity as a combined function of the excitation wavelength and the wavelength interval. In this way, spectra selectivity is increased and multi-component samples are better characterised (Patra & Mishra, 2002b).

This work presents an accelerated oxidation setup using a high surface per volume ratio, UV and thermal stress. SyF spectra are assessed as a tool for monitoring olive oil deterioration and differentiation of olive oils according to stress time by multi-dimensional chemometrics. Furthermore, the rate of PV, AV and TOTOX

value changes for extra virgin olive oil during oxidation under UV irradiation at ambient temperature (~20 °C), 40, 60 and 80 °C is studied.

2. Materials and methods

2.1. Samples and reagents

Olive oils by Minerva S.A. (Athens, Greece) were purchased from a local shopping centre. Isooctane and glacial acetic acid of analytical reagent grade were purchased from Merck. Chloroform of analytical reagent grade was purchased from SDS. Potassium iodide 99.5%, sodium thiosulphate standard solution 0.1 M, starch and p-anisidine 99% were purchased from Ferak Berlin, Merck, Riedel-de Haën and Aldrich, respectively.

2.2. Analytical methods

PV of the samples was determined according to the official EC method (European Union Commission Regulation, 1991). AV was determined according to the International Union of Pure and Applied Chemistry standard method (IUPAC, 1979). Total oxidation value (TOTOX) is calculated as $2 \times PV + AV$ (Rossell, 1994).

2.3. Instruments

Fluorescence spectra were acquired by the Jobin Yvon fluorolog-3 spectrofluorometer which is a fully computer controlled instrument using a double-grating excitation and a single-grating emission monochromator. The spectrofluorometer uses a 950 W xenon lamp for excitation. Excitation and emission slit widths were set at 2 nm. A quartz cell from Hellma 104F-QS with an optical length of 4 mm was used. Right-angle geometry was used for spectral acquisition.

For SyF spectra, samples were used as received without any pretreatment to avoid noxious solvents reducing manipulation steps.

SyF spectra were collected in the excitation wavelength range 250–720 nm. TSyF spectra were obtained by measuring the excitation wavelength in the same spectral region and varying the wavelength interval from 20 to 120 nm in 20 nm intervals. The spectra were corrected for the excitation lamp, the photomultiplier detector spectral response and emission and excitation gratings.

A Perkin Elmer Lambda 19 UV/Vis/NIR spectrometer was used for p-anisidine value measurements. Quartz cells from Hellma 100-QX with 10 mm optical lengths were used.

Contour plots of TSyF spectra were plotted using the Origin Software Version 7.0 (OriginLab, USA, 2002).

2.4. Data analysis

Data analysis was performed using the Statistica Software Version 6.0 (StatSoft, USA, 2001). Principal component analysis (PCA) is an unsupervised classification procedure. The main aim of PCA is to reduce a large number of variables to a much smaller number of principal components (PCs) that capture the vast majority of variance in the data. This reduces the dimensionality of the original data considerably, enabling effective visualisation, regression and classification of multivariate data (Brereton, 1992).

2.5. Procedure

100 mL of olive oil were placed in a Petri dish of 11 cm diameter thermostated at 80 °C over a Heidolph hot plate. This setup provides a surface per volume ratio of 0.95 cm^2 ml^{-1}. A Hanovia UV lamp (200 Volt, 125 Watts) placed 21.5 cm above the dish was used for sample irradiation. Samples of approximately 5 g were withdrawn every 2 h. PV was measured immediately and the sample was stored at −40 °C for subsequent AV analysis and SyF spectra acquisition.

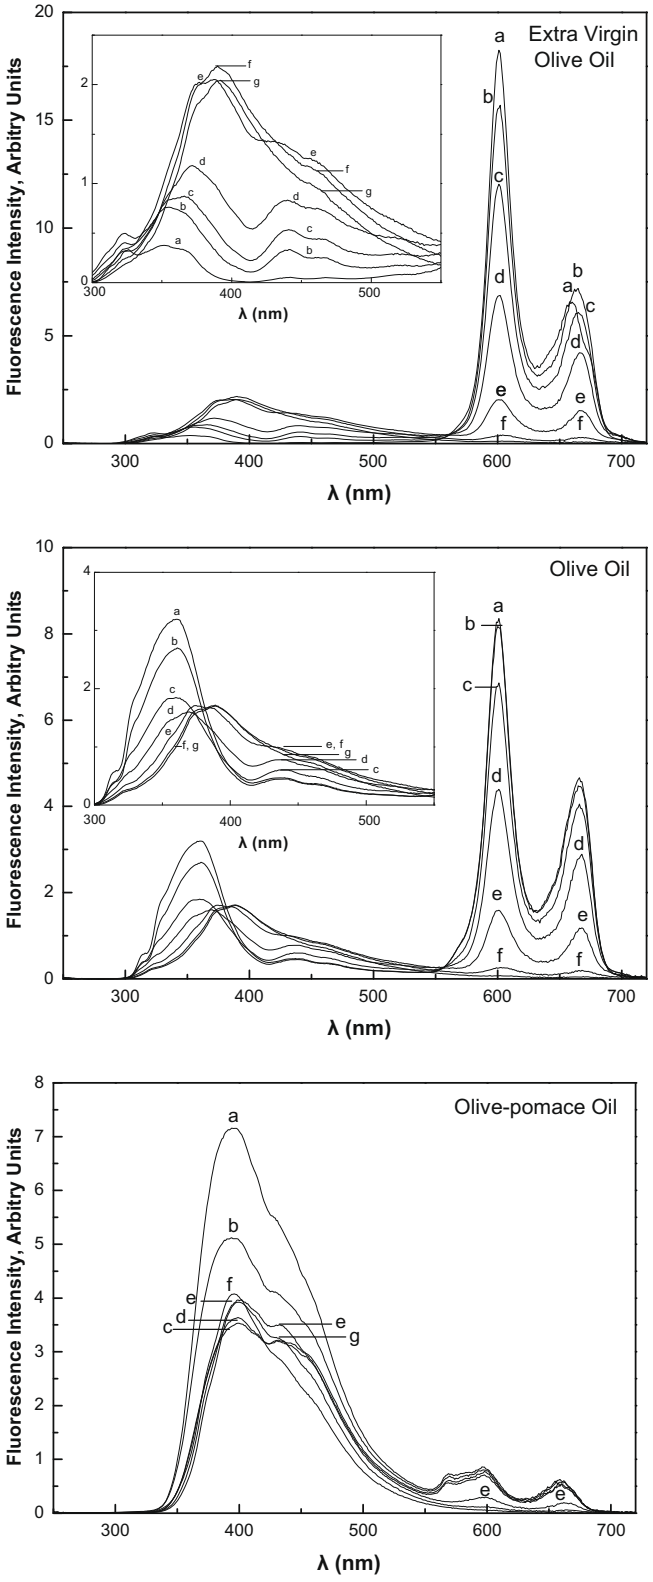

Fig. 1. Synchronous fluorescence spectra of extra virgin olive, olive and olive-pomace oil after 0 (a), 2 (b), 4 (c), 6 (d), 8 (e), 10 (f) and 12 h (g) under UV irradiation at 80 °C using 80 nm wavelength interval.

Extra virgin olive oil was used as a study case for a detailed investigation at different temperatures: ambient (~20 °C), 40, 60 and 80 °C. Samples, around 2 g, were withdrawn every few hours for PV, AV and TOTOX value analyses. The experiment was terminated when the peroxide value reached ~400 meq kg^{-1}.

For comparison, 100 ml extra virgin olive oil was placed in a Petri dish and stored in the dark for 6 months. A sample was withdrawn every 2 weeks for PV analysis.

3. Results and discussion

3.1. Synchronous fluorescence spectroscopy

Fig. 1 shows the evolution of SyF spectra of extra virgin olive, olive and olive-pomace oil during the time course of the experiment. All olive oils show fluorescence bands in the range of 550–700 nm which are attributed to chlorophyll pigments (Kyriakidis & Skarkalis, 2000). These bands are stronger for extra virgin olive oil and minimal for olive-pomace oil due to the different extraction procedure that involves organics solvents. During the time course of the experiment, these fluorescence bands decrease significantly due to deterioration of chlorophyll pigments that are involved in photo-oxidation (Choe & Min, 2006).

Extra virgin olive oil gives signals in the region 300–330 nm that decrease during oxidation and the region 350–550 nm that increase during the initial 8 h and then remain almost constant for up to 12 h.

Olive oil gives signals in the region 300–550 nm. The fluorescence bands in the region 300–370 nm decrease during oxidation whereas fluorescence bands in the region 370–550 nm increase during the initial 8 h and remain almost constant afterwards.

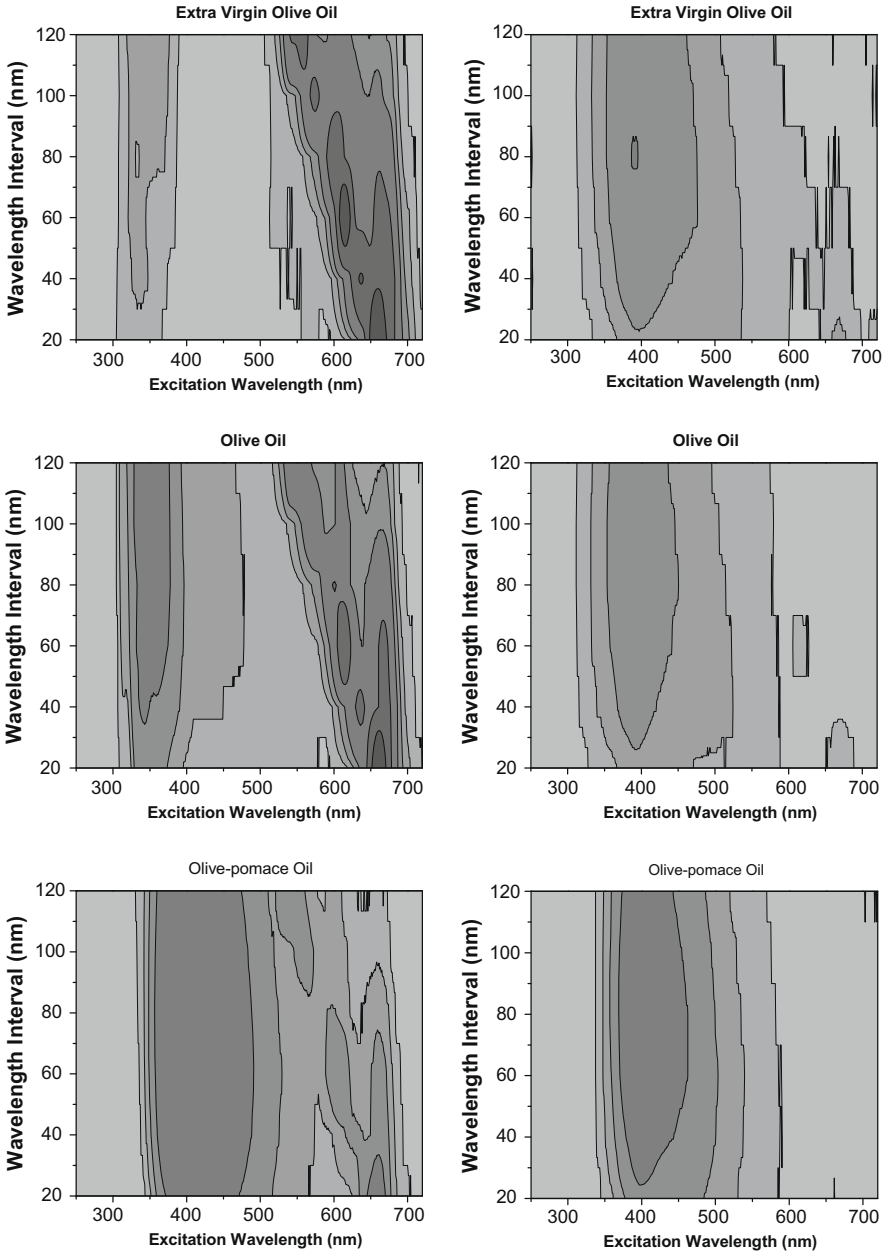

Fig. 2. Total synchronous fluorescence spectra contour plots of olive oils before (left) and after 12 h (right) exposure to UV light at 80 °C. Grayscale indicates fluorescence intensities.

Olive-pomace oil gives fluorescence bands in the region of 350–550 nm that decrease during the initial 6 h and then a small increase is observed.

As shown above, fluorescence spectra change even after just 2 h stress. This indicates that the combination of UV light and thermal stress using surface to volume ratio of 0.95 cm^2 ml^{-1} is sufficient for accelerated oxidation studies.

Initial TSyF contour plots change significantly after 12 h (Fig. 2). TSyF contour plot of extra virgin olive oil spreads in the excitation wavelength region 302–390 nm and 510–720 nm. After 12 h exposure to UV light at 80 °C, the fluorescence bands in the region 510–720 nm diminish and the region 302–320 nm disappear while fluorescence bands in the region 390–510 nm appear.

TSyF contour plot of olive oil spreads in the excitation wavelength region 305–480 nm and 515–720 nm. After 12 h under UV light at 80 °C, fluorescence in the wavelength region higher than 590 nm is almost suppressed whereas fluorescence bands in the wavelength region 480–515 nm appear.

Olive-pomace oil TSyF contour plot spreads in the excitation wavelength region 340–705 nm. After 12 h exposure to UV light at 80 °C the TSyF contour plot spreads in the excitation wavelength region 340–590 nm while the fluorescence bands in the region 590–705 nm disappear.

According to the results presented in the contour plots, the spectral characteristics of extra virgin olive, olive and olive-pomace oil change dramatically during the procedure. Fluorescence signals in the region 600–720 nm, attributed to chlorophyll, decrease significantly after 12 h while fluorescence bands in the low wavelength region expand up to 590 nm.

3.2. Principal component analysis

The spectra range selected was 300–500 nm using 80 nm wavelength interval after normalisation. The score for olive oil samples in the first two principal components that explain 95.1% of the data matrix variance is depicted in Fig. 3. Five different classes are well separated. Class A includes the initial olive-pomace oil spectrum and that acquired at 2 h stress. Olive-pomace oil spectra obtained after 2 h up to 12 h form class B. Extra virgin olive and olive oil spectra acquired after 4 h up to 12 h form class C. Classes D and E refer to extra virgin olive and olive oil, respectively. They include the initial spectrum and spectra at 2 and 4 h stress.

Extra virgin olive and olive oil (classes C, D and E) have positive scores in the first principal component (PC1) in contrast to olive-pomace oil (classes A and B). Furthermore, extra virgin olive (class D), in contrast to olive oil (class E) has positive scores in the second principal component (PC2). The results show that SyF spectra combined with PCA could be used for monitoring olive oils during stress under UV light at 80 °C if the surface to volume ratio is 0.95 cm^2 ml^{-1}.

3.3. Classical methods

As shown above, olive oil SyF spectra change substantially during oil oxidation. This could be attributed to evolution of primary and secondary oxidation products that are followed using PV, AV and TOTOX values.

Fig. 4 shows TOTOX value increase of extra virgin olive, olive and olive-pomace oil during the procedure. As shown, the TOTOX value increases 10-fold after 12 h for extra virgin olive oil while the same end point is reached after just 8 h for olive oil. Olive oil TOTOX value increases almost 19-fold after 12 h. The TOTOX value of olive-pomace oil increases 20-fold after 8 h and almost 38-fold after 12 h. It is clearly shown that extra virgin olive oil shows the lowest rate of deterioration while olive-pomace oil shows the highest.

Extra virgin olive oil was further used as a study case for a detailed investigation of olive oil deterioration.

Fig. 5 shows the change of extra virgin olive oil TOTOX value versus exposure time under UV light at different temperatures. TOTOX value increases linearly during oil deterioration. The increase of PV and AV with time is also linear. Rates of parameters increase are given in Table 1. In comparison to stress under UV light at ambient temperature (~20 °C), the rates for TOTOX and PV value are almost three times higher when the temperature increases to 40 °C, almost six times higher at 60 °C and nine times higher at 80 °C. The rate of AV change at 40 °C is almost two times higher than that at 20 °C, four times at 60 °C and six times at 80 °C. It is interesting to note the linear correlation between the rates and temperature, the slopes being 0.84 ± 0.06 TOTOX h^{-1} $°C^{-1}$, 0.38 ± 0.03 meq peroxides kg^{-1} h^{-1} $°C^{-1}$ and 0.07 ± 0.003 AV h^{-1} $°C^{-1}$ with correlation coefficients of 0.996, 0.995 and 0.998, respectively.

In contrast to the above results, the control sample that was stored in the dark for 6 months shows just a slight increase of PV from 12 to 23 meq kg^{-1}.

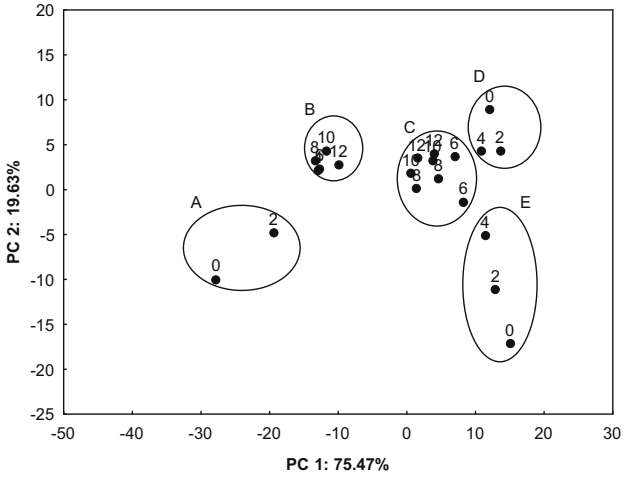

Fig. 3. PCA based on fluorescence spectra of extra virgin olive, olive and olive-pomace oil acquired in the range 300–500 nm during the time course of exposure to UV light at 80 °C: Classes A and B contain olive pomace oil, class C extra virgin olive and olive oil, class D extra virgin olive oil and class E olive oil. Numbers are the exposure time (h).

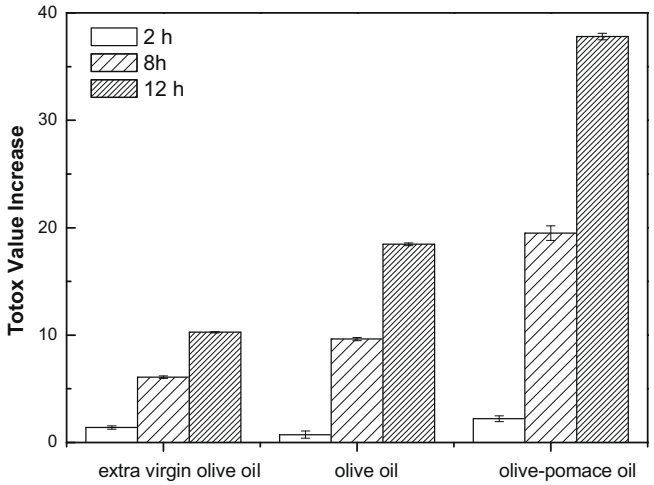

Fig. 4. TOTOX value increases during extra virgin olive, olive and olive-pomace oil deterioration under UV light at 80 °C. Values are means of three replicate measurements accompanied by standard deviations.

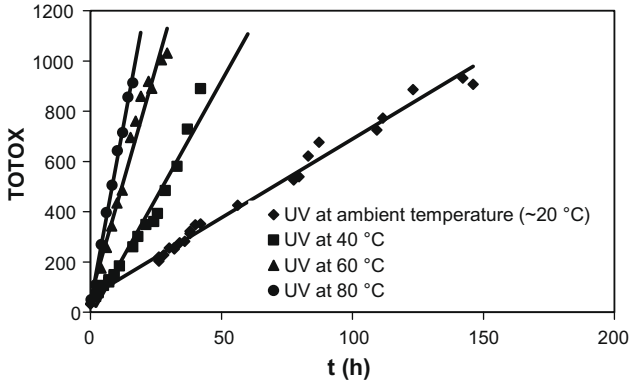

Fig. 5. Change of TOTOX value during extra virgin olive oil deterioration under different treatments.

Table 1
Rate of parameter changes during extra virgin olive oil oxidation under different treatments.

Parameter	Treatment	Correlation coefficient (r)	Rate ± SD
TOTOX			TOTOX × h^{-1}
	UV	0.994	6.3 ± 0.2
	UV at 40 °C	0.98	18.7 ± 0.9
	UV at 60 °C	0.99	37 ± 2
	UV at 80 °C	0.997	56 ± 2
PV			meq × Kg^{-1} × h^{-1}
	UV	0.992	2.8 ± 0.05
	UV at 40 °C	0.98	8.3 ± 0.4
	UV at 60 °C	0.98	16.5 ± 0.8
	UV at 80 °C	0.997	25.6 ± 0.6
AV			AV × h^{-1}
	UV	0.997	0.84 ± 0.01
	UV at 40 °C	0.97	2.0 ± 0.1
	UV at 60 °C	0.991	3.6 ± 0.1
	UV at 80 °C	0.997	4.9 ± 0.2

As shown above, extra virgin olive oil is very stable in the dark whereas it is susceptible to oxidation under UV light. Studying the combined effect of thermal stress and UV light is important for Mediterranean countries producing olive oil as the temperature could exceed 40 °C during summer rendering olive oil packed in transparent bottles prone to oxidation.

4. Conclusion

Synchronous fluorescence spectroscopy is a useful tool for monitoring olive oil deterioration under thermal and UV stress. Olive oils can be categorised according to stress time through synchronous fluorescence spectra combined with multi-dimensional chemometrics. Surface to volume ratio of 0.95 cm^2 ml^{-1} was found sufficient for accelerated oxidation tests. The experimental setup used proved to be appropriate for monitoring extra virgin olive oil deterioration under thermal and UV stress through classical methods such as peroxide, anisidine and TOTOX value. Linear correlations between parameters values versus exposure time as well as the rate of parameter changes versus temperature were observed.

ABSTRACT

A novel supercritical fluid extraction (SFE) method has been developed for extracting essential oil from the aerial part of *Coriandrum sativum*. Various experimental conditions were investigated to optimise the SFE. It suggested that the extraction of 35 °C, 8 MPa, 2 h might be the optimisation to get the maximum of coriander essential oil. Then, high-speed counter-current chromatography (HSCCC) was successfully used in one step for the isolation and purification of coriandrone B, coriandrin, dihydrocoriandrin and coriandrone A from the coriander oil with a two-phase system composed of *n*-hexane–ethyl acetate–methanol–water (3:7:5:5, v/v/v/v) for the first time. High-performance liquid chromatography (HPLC) was employed to analyse the HSCCC fractions and revealed that the purities of the isocoumarins were all above 90%, and the chemical structures were identified by spectroscopic analysis including ESIMS, ^{1}H NMR and UV.

1. Introduction

Coriandrum sativum L. (family Umbelliferae) is a culinary and medicinal plant originating from the Mediterranean region, and is nowadays grown widely all over the world. The leaves are variously referred to as coriander leaves in Britain; cilantro in the United States, and "yanshui" in China. It is featured in the cuisines of China, Southeast Asia, India, and South and Central America. As a medicinal plant, *C. sativum* has been credited with a long list of medicinal uses in traditional Chinese medicine to treat indigestion and abdominal distention. The effect of letting out skin eruptions and invigorating stomach by coriander was also recorded.

The essential oil and various extracts from coriander have also shown the activities of antibacterial (Kubo, Fujita, Kubo, Nihei, & Ogura, 2004), anticancerous and antimutagenic (Chithra & Leelamma, 2000), antioxidant (Madsen & Bertelsen, 1995; Ramadan, Kroh, & Morsel, 2003; Wangensteen, Samuelsen, & Malterud, 2004), antidiabetic (Gallagher, Flatt, Duffy, & Abdel-Wahab, 2003).

Research on the secondary metabolites has focused on the analysis of the essential oil from *C. sativum* from different origins and stages of maturity (Anitescu, Doneanu, & Radulescu, 1997; Bandoni, Mizrahi, & Juarez, 1998; Carrubba, la Torre, Di Prima, Saiano, & Alonzo, 2002; Msaada et al., 2007). However, none of studies has examined in detail on the preparative separation of coriander essential oil composition. As this plant exhibits an ample range of biological activity and is widely used in folk medicine and the human diet, it is important to extend the study to preparative scale.

The essential oil of aromatic herbs is traditionally obtained by hydrodistillation, steam-distillation or solvent extraction. As an alternative, supercritical fluid extraction (SFE) is a particularly suitable method. Carbon dioxide is an ideal solvent because it is non-toxic, non-explosive, readily available and easy to remove from extracted products. SFE has the ability to use low temperatures, leading to less deterioration of the thermally labile components in the extract with comparable or better recovery, and minimal alteration of the active ingredients; thus the curative properties can be preserved. So SFE is widely used to extract and separate active compounds in food, pharmaceutical and cosmetic industries (Mostafa, Yadollah, Fatemeh, & Naader, 2004).

High-speed counter-current chromatography (HSCCC) is a kind of support-free all-liquid partition chromatography that was first invented by Ito (1981). As no solid stationary phase is used, it eliminates irreversible adsorption of sample on the solid support, which is a common drawback in conventional chromatographic column. What is more, it can avoid the devitalisation of active components. As an advanced separation technique, HSCCC has been widely used for the separation of active components in traditional Chinese herbs and other natural products in recent years. Successful application of HSCCC has also been reported for the separation and purification of alkaloids (Liu, Chu, Sun, & Kong, 2005), quinines (Du, Li, & Ito, 2001), flavonoids (Chen, Song, Lan, Games, & Sutherland, 2005), coumarins (Wei, Zhang, & Ito, 2004) and other

natural products (Yao, Li, & Kong, 2006; Yao, Liu, Huang, & Kong, 2007).

The preparative separation and purification of isocoumarins from the aerial parts of *C. sativum* by classical methods are tedious and usually require multiple chromatographic steps on silica gel and large amounts of organic environmentally unfriendly solvents. In the present work, the extraction condition was optimised first with a preparative-scale SFE system by an orthogonal test. The crude extract (contain essential oil and oleoresin) obtained was then purified by high-speed counter-current chromatography (HSCCC). There have no reports of using SFE to extract and HSCCC to isolate chemical compounds from coriander. The aim of this paper is to extract and separate the coriander essential oil rapidly, and to develop a new mode of the isolation of low polar compounds from essential oils.

2. Materials and methods

2.1. Plant material

Coriander herbs were collected from suburbs of Xuzhou, Jiangsu Province, China. Xuzhou was located in the southeast of North China Plain. The elevation was 30–50 m. Its coordinate of longitude and latitude was 34°16′N, 117°10′E. The average temperature during the year was 15.1 °C. On average it rains about 100 days of the year, and the mean annual rainfall is 881.1 mm.

For collection at the initial stage of maturity, only full green fruits were picked up in October, 2006. The aroma of the coriander was natural and pleasant.

The coriander roots were removed and the aerial parts were cleaned, cut into pieces and dried in a ventilated drying oven and stored in plastic bags at ambient temperature and protected from light.

2.2. Reagents

Carbon dioxide, 99.9% purity, was obtained from Topgrand Petrifaction Industry Gas Co., Jiangsu, China. All other solvents were of analytical grade.

2.3. Supercritical fluid extraction (SFE)

HA-130-50-05 supercritical extraction apparatus (Hua'an Supercritical Extraction Limited Company, Jiangsu, China) was used for all the extractions. The SFE system was equipped with 500 mL stainless steel vessel. In order to determine a suitable extraction condition in a wide range with a minimum number of trials, an orthogonal test design was employed where temperature, pressure and time were considered to be three major factors for effective extraction. Combinations of the two different levels of each factor are listed in Table 1. In each test, 500 g of the coriander was placed into an extraction vessel. Carbon dioxide with a purity of 99.9% was used as a solvent. After 10 min of static extraction (no liquid flow), the sample was then subjected to dynamic extraction by flowing gaseous carbon dioxide at a rate of 2 L/min. The coriander oil (contain essential oil and oleoresin) was trapped into a collection vessel and transferred into brown glass bottle and stored in a freezer until being subjected to HSCCC purification.

Table 1
Orthogonal test design in coriander SFE process.

No.	Temperature (°C)	Pressure (MPa)	Time (h)	Yield of coriander oil (% w/w)
1	25	5	1	0.189
2	25	8	2	0.306
3	35	5	2	0.332
4	35	8	1	0.237

All the experiments were done in three times and yields were averaged (n = 3).

2.4. Preparation of two-phase solvent and sample solution

Each component of the selected solvent system was added to a separatory funnel and thoroughly equilibrated at room temperature for 12 h. The upper phase and lower phase were separated and degassed by sonication for 30 min shortly before use. For HSCCC separation of coriander essential oil, the sample solution was prepared by dissolving 300 μL of essential oil in 5 mL of the upper phase and 5 mL of the lower phase of the solvent system for isolation, and then was filtered with micropore membrane filters (Φ = 0.45 μm).

2.5. HSCCC separation

The HSCCC separation was performed with a TBE-300 high-speed counter-current chromatography system manufactured by Tauto Biotech Co., Shanghai, China. The apparatus was equipped with three preparative coils (diameter of tube, 1.5 mm, total volume, 300 mL) and a 20 mL sample loop. The revolution radius was 5 cm, and the values β ($\beta = r/R$, where r is the rotation radius or the distance from the coil to the holder shaft, and R is the revolution radius or the distance between the holder axis and central axis of the centrifuge) of the multilayer coil varied from 0.5 at internal terminal to 0.8 at the external terminal. The revolution speed of the apparatus can be regulated with a speed controller in the range between 0 and 1000 rpm. The system was also equipped with one S-1007 constant flow pump (Shenyitong Tech. and Exploitation, Beijing, China) and a Model 8823B-UV monitor (Bingdayingchuang Sci. and Tech., Beijing, China). The data were collected with the model N2000 chromatography workstation (Zhejiang University, Hangzhou, China).

In each separation, the coiled column was first entirely filled with the upper phase (stationary phase), then the apparatus was rotated at 850 rpm, while the lower phase (mobile phase) was pumped into the column at a flow rate of 1.2 mL/min. After the mobile phase front emerged from the tail outlet and the system established hydrodynamic equilibrium, the sample solution was injected into the column through the injection valve. The effluent from the tail end of the column was continuously monitored with a UV detector at 254 nm. The whole process of separation was carried out under room temperature. Each peak fraction was manually collected

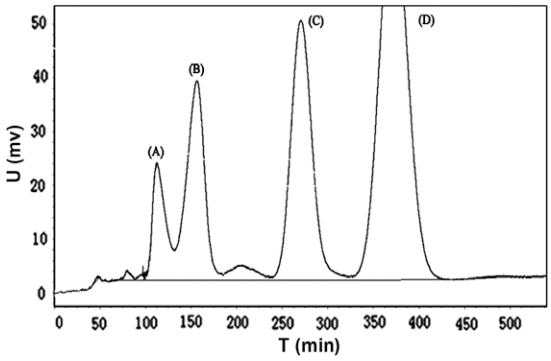

Fig. 1. HSCCC chromatogram of coriander essential oil from *Coriandrum sativum* L. *Conditions:* two-phase solvent system: *n*-hexane–ethyl acetate–ethanol–water 3:7:5:5 (v/v/v/v); stationary phase: upper phase; mobile phase: lower phase; flow rate: 1.2 mL/min; revolution speed: 850 rpm; sample size: 300 μL of essential oil dissolved in 5 mL of the upper phase and 5 mL of lower phase; retention of the stationary phase: 59%.

according to the chromatogram (Fig. 1) and then evaporated under reduced pressure for later analysis. The retention of the stationary phase was calculated from the volume of the stationary phase collected from the column after the separation was completed.

2.6. HPLC analysis and identification of HSCCC fractions

The crude sample and peak fractions obtained by HSCCC were analysed by HPLC at room temperature. The HPLC equipment used was Agilent 1100 series system and Agilent HPLC workstation (Agilent, USA). The column used was a Shim-pack VP-ODS column (150 mm × 4.6 mm, 5 μm), with a gradient elution from 50% to 80% methanol in 40 min. The effluent was monitored at 254 nm and the flow rate was set at 1.0 mL/min constantly. Identification of HSCCC fractions was carried out by ESIMS (Agilent 1100 Series LC–MS Trap SL), ^{1}H NMR spectra (Bruker ACF-300), UV (Agilent 1100 with G1315B DAD).

3. Results and discussion

3.1. Optimisation of the SFE conditions

Since various parameters potentially affect the extraction process, the optimisation of the experimental conditions represents a critical step in the development of a SFE method. Pressures and temperatures of the fluid, and the extraction times are generally considered as the most important factors. In the present study, all selected factors were examined using an orthogonal test design. Reverchon (1997) suggested performing SFE of essential oils at 40–50 °C and pressure below 10 MPa would suppress co-extraction of higher molecular weight compounds. So the extractions were carried out at temperatures of 25 and 35 °C, pressures of 5 and 10 MPa, durations of 1 and 2 h.

For the experimental results of orthogonal test, the range of the extraction yields were 0.189–0.332%, the condition of 35 °C, 5 MPa, 2 h got the maximum extract yield. It suggested that the extracted time was the most important factor. It also meant that it could not achieve complete extraction at 2 h. However, the content of essential oil in the extract was higher. It suggested that the long extraction time, higher temperatures and higher pressure would get higher extract yield when the SFE performed at temperature below 40 °C and pressure below 10 MPa. The influence of different parameters on the extract yield of coriander SFE process was also confirmed by Illés in their study (Illés, Daood, Perneczki, Szokonya, & Then, 2000). Although the extract yield was high, the essential oil content of the extracts could possibly decrease and fatty acid composition would increase remarkably. The high temperature and low pressure could lead to the increase of the selectivity of the extraction. Although propane might increase the yield of extraction, considering the solvent residual, it was not chosen as the entrainer.

Reverchon (1997) suggested irrespective of pressure and temperature, the essential oil content of the extract rapidly decreased in accord with the increased quantity of the recovered oil. This means that essential oils are first solubilised by SC–CO_2. Therefore, in order to get as much amount of the coriander essential oil as possible and suppress co-extraction of higher molecular weight substances to simplify the procedure of purification, the optimal conditions for the extraction of coriander essential oil by SFE were at pressure of 5 MPa, temperature of 35 °C and extract time of 2 h.

3.2. Selection of two-phase solvent system

The selection of the two-phase solvent system for the target compounds is an important step in HSCCC. Optimal solvent system should satisfy two requirements. Firstly, the value of the partition coefficient (K) of the solvent system should be in the range of 0.5–2.0. The partition coefficient (K) reflects the solute distribution between the two mutually equilibrated solvent phases. Secondly, the higher retention of the stationary phase, the better peak resolution because the retention of the stationary phase is accomplished by a combination of coiled column configuration and the planetary motion of the column holder (Ito, 2005).

In the present study, the two-phase solvent systems composed of light petroleum (b.p. 60–90 °C)–methanol–water 5:4:1 (v/v/v), chloroform–methanol–water 5:4:1 (v/v/v), *n*-hexane–ethyl acetate–methanol–water 3:7:5:5 (v/v/v/v) and *n*-hexane–ethyl acetate–methanol–water 6:4:5:5 (v/v/v/v) were tested for the two parameters.

After the measuring of the K values and settling time of the above solvent systems, the target substances in the solvent system of *n*-hexane–ethyl acetate–methanol–water 3:7:5:5 (v/v/v/v) got suitable K values in the range of 0.5–1 and the settling time was 15 s. Therefore it was chosen for the HSCCC separation finally.

3.3. HSCCC purification and HPLC identification

The crude extract coriander oil (contain essential oil and oleoresin) (300 μL) was separated and purified by HSCCC. The retention of the stationary phase was 59%, and the separation time was about 600 min in each separation run. Separation of the coriander oil by the preparative HSCCC with *n*-hexane–ethyl acetate–methanol–water 3:7:5:5 (v/v/v/v) as a solvent system is shown in Fig. 1. Based on the HPLC analysis and the elution curve of the preparative HSCCC, all collected fractions were combined into different pooled fractions, yielding 3.3 mg of coriandrone B (fraction A, the purity is 90.21%), 12.0 mg of coriandrin (fraction B, 99.15%), 10.5 mg of dihydrocoriandrin (fraction C, 96.25%) and 5.7 mg of coriandrone A (fraction D, 90.98%) in only one-step separation. These results demonstrate the high resolving power of HSCCC. The chromatograms of HPLC and UV spectra of these compounds are shown in Fig. 2.

Fractions A–D were identified as coriandrone B, coriandrin, dihydrocoriandrin and coriandrone A, respectively (Fig. 3) based on the comparison of the ESI-MS and NMR spectroscopic data with the literature data (Ceska et al., 1988; Baba, Xiao, Taniguchi, Ohishi, & Kozawa, 1991).

HSCCC fraction A in Fig. 1: ESI-MS (m/z): 293 $[M+H]^+$; ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.31, 1.44 (each 3H, s), 1.45 (d, J = 6.2 Hz), 2.65 (dd, J = 16.1, 4.5 Hz), 2.77 (2H, d, J = 5.1 Hz), 2.85 (dd, J = 16.1, 11.0 Hz), 3.80 (1H, t, J = 5.1 Hz), 3.87 (s), 4.51 (1H, m, J = 6.2, 11.0, 4.5 Hz), 6.25 (1H, s); UV λ_{max} (MeOH) nm: 223, 266, 300.

HSCCC fraction B in Fig. 1: ESI-MS (m/z): 230 $[M+H]^+$; ^{1}H NMR (500 MHz, $CDCl_3$): δ 2.25 (3H, d, J = 1.0 Hz), 4.23 (3H, s), 6.23 (lH, q, J = 1.0 Hz), 7.06 (lH, dd, J = 2.4, 1.0 Hz), 7.10 (lH, d, J = l.0 Hz), 7.61 (lH, d, J = 2.4 Hz); UV λ_{max} (MeOH) nm: 250, 285, 298, 340.

HSCCC fraction C in Fig. 1: ESI-MS (m/z): 487 $[2M+Na]^+$, 233 $[M+H]^+$; ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.50 (3H, d, J = 6.4 Hz), 2.94 (1H, dd, J = 16.1, 5.0 Hz), 3.00 (1H, dd, J = 16.1, 9.2 Hz), 4.19 (3H, s), 4.57 (1H, m, J = 6.4, 9.2, 5.0 Hz), 7.00 (1H, dd, J = 2.3, 1.0 Hz), 7.04 (1H, d, J = 1.0 Hz), 7.57 (1H, d, J = 2.3 Hz); UV λ_{max} (MeOH) nm: 231, 259, 309.

HSCCC fraction D in Fig. 1: ESI-MS (m/z): 585 $[2M+H]^+$, 293 $[M+H]^+$; ^{1}H NMR(500 MHz, $CDCl_3$): δ 1.21 (3H, s), 1.37 (3H, s), 1.46 (3H, d, J = 6.3 Hz), 2.81 (1H, dd, J = 16.1, 4.8 Hz), 2.85 (1H, dd, J = 16.1, 10.6 Hz), 3.03 (2H, d, J = 9.2 Hz), 3.87 (3H, s), 4.54 (1H, m, J = 6.3, 10.6, 4.8 Hz), 4.79 (1H, t, J = 9.2 Hz), 6.22 (1H, s); UV λ_{max} (MeOH) nm: 227, 267, 306.

Of the four isocoumarins, coriadrin was found to be a potent inhibitor and inactivator of purified human P450 1A1. It could inactivate hepatic EROD activity and also possess anticarcinogenic

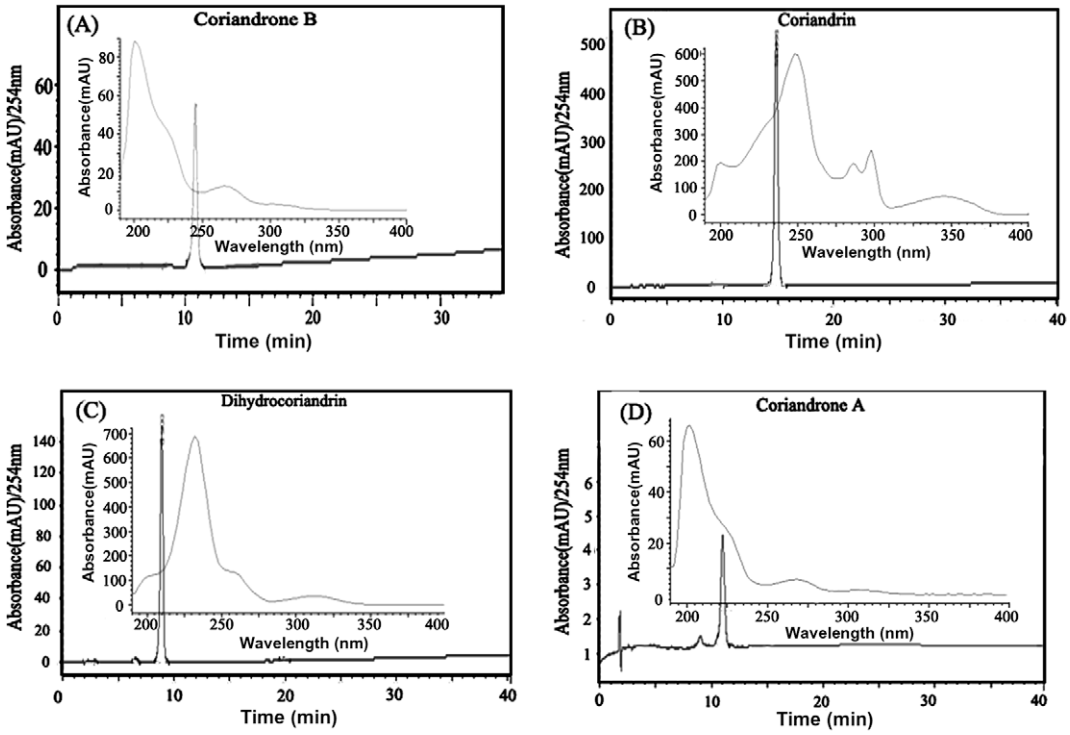

Fig. 2. HPLC chromatogram of the HSCCC peak fractions A–D. *Conditions:* column: Shim-pack VP-ODS column (150 mm × 4.6 mm, 5 μm). Mobile phase: a gradient elution from 50% to 80% methanol in 40 min. Detection wavelength: 254 nm.

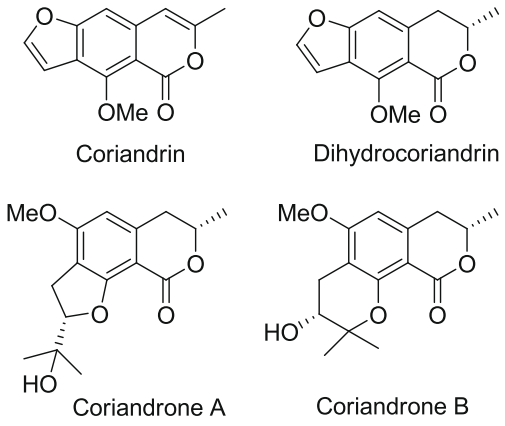

Fig. 3. The four isocoumarins isolated from the *Coriandrum sativum* L. by HSCCC.

effect towards chemical carcinogens such as polycyclic aromatic hydrocarbons by inhibition of DNA adduct formation (Cai, Baer-Dubowska, Ashwood-Smith, & DiGiovanni, 1997; Cai et al., 1996, 1997). Moreover, in contrast to other antiviral furocoumarins, such as 8-methoxypsoralen (MOP), the RNA-virus and the DNA-virus murine cytomegalovirus were substantially more sensitive to coriandrin. Human immunodeficiency virus, HIV-1, was also susceptible to coriandrin + UVA (Hudson, Graham, Harris, & Ashwood-Smith, 1993). Certainly additional work on other isocoumarins would be valuable. For example, the further study of all aspects, such as pharmacology and structural modification could be done for the other isocoumarins except coriandrin from coriander.

A few studies were carried out using GC–MS on the chemical compositions of the essential oil from *Coriandrum sativum* L. at different stage of maturity (Msaada et al., 2007). Isocoumarins have not been reported in these investigations. Therefore, the combinatorial application of SFE and HSCCC may be a good complemental method to the conventional GC–MS.

4. Conclusion

Four isocoumarins including coriandrone B, coriandrin, dihydrocoriandrin and coriandrone A were extracted, separated and purified by SFE and HSCCC from coriander. The SFE condition was optimised to be 35 °C, 8 MPa, 2 h. At last, high purities of isocoumarins were obtained by HSCCC in one step with a two-phase solvent system composed of *n*-hexane–ethyl acetate–methanol–water at a volume ratio of 3:7:5:5 (v/v/v/v). The purity was assessed by analytical HPLC and the confirmation of chemical structures was performed by ESIMS, NMR and UV spectroscopy. The present method is suitable for preparing available quantities of pure isocoumarins and the quantification of coriandrone B, coriandrin, dihydrocoriandrin and coriandrone A in coriander.

ABSTRACT

A fast, direct, small-sample measurement method of ethanol determination in alcoholic drinks was established by the application of attractive characteristics of a eukaryote double-mediator (EDM) system, as previously reported. The EDM system, which consists of yeast as well as both hydrophilic and hydrophobic mediators, demonstrates superior sensitivity to organic substances. For high performance, the EDM system was reoptimised for ethanol determination with a small sample volume of only 3 μL and a short incubation time of 5 min. Under optimal conditions, a practical calibration curve for ethanol determination in alcoholic beverages was obtained between 0.5 and 50 v/v% (r = 0.997, 9 points, n = 3, average of relative standard deviation, RSD_{av} = 2.75%), with a detection limit of 0.5 v/v%. To characterise our ethanol determination method, the effects of pH, organic substances, carbon dioxide gas, or sodium sulphite on EDM responses were studied in detail. No notable effects of pH on EDM responses were observed; however, glucose and ascorbic acid strongly increased the EDM response to ethanol. Real sample applications were mainly performed using distilled alcoholic drinks (shochu, brandy, vodka, gin, and whisky) and several kinds of beer and similar beverages (lager, draft, low-malt, non-malt, and sugar-free). When the results with sugar-free beverages were compared with those obtained by the available enzymatic-spectrophotometric (ES) method, an excellent correlation was obtained (r = 0.990, 7 points, n = 3, RSD_{av} of the EDM method = 7.90%), with an excellent slope of 1.05. Finally, a yeast suspension stored at 4 °C was stable for at least 7 days, with a response reduction of 88% (RSD_{av} for five testing days = 4.8%).

1. Introduction

In recent years, a need for ethanol determination has arisen in the fields of food, diagnostic, and environmental analyses. Of the various methods which have been developed, a refractive index method using an available refractometer is widely utilised for liquid samples; however, the influences of colour in the sample are not negligible. High-performance liquid chromatography (HPLC) methods are used to determine the ethanol concentration accurately but are expensive in terms of both equipment and measurement. In addition, enzymatic-spectrophotometric (ES) methods using alcohol dehydrogenase (ALDH), though widely used in experiments, involve costly measurements and are affected by the sample colour, gaseous ethanols such as breath ethanol, carbon dioxide gas, and so on. In addition, in the ES methods, the direct measurement of an alcohol beverage is not possible, and the samples must be diluted (~10,000 times).

For simple and rapid measurement, enzyme biosensors for ethanol have been developed using ALDH (Kitagawa et al., 1991; Niculescu, Mieliauskiene, Laurinavicius, & Csoregi, 2003) or alcohol oxidase (Azevedo, Prazeres, Cabral, & Fonseca, 2005; Huseyin & Levent, 2006; Lapa, Lima, & Pinto, 2003). However, both enzymes lack stability, and purification is expensive. In addition, these enzymatic methods require dilution of the sample, which requires precision and careful avoidance of contamination.

On the other hand, cost-effective microbial biosensing methods have been widely studied (Lei, Chen, & Mulchandani, 2006; Nakamura & Karube, 2003, 2005; Nakamura, Shimomura-Shimizu, & Karube, 2008). In recent years, we have actively developed many types of microbial biosensors for use in such environmental fields as soil diagnosis (Hashimoto, Nakamura, Asaga, & Karube, 2008), biological oxygen demand (BOD) measurements (Nakamura et al., 2007a, 2007b, 2007c, 2008a, 2008b; Yoshida, McNiven, Morita, Nakamura, & Karube, 2002; Yoshida et al., 2000; Yoshida et al., 2001a, 2001b), toxicity measurements (Ikebukuro, Nakamura, & Karube, 2000, chap. 19; Nakamura & Suzuki, 2007a, 2007b;

Nakamura et al., 2007d), and composting monitoring (Yoshida et al., 2001c). Recently, microbial biosensors for use in food analyses have been developed. For example, to enhance koji quality control in the sake brewing process, Chiyo, Matsui, Murakami, Yokoyama, and Tamiya (2001) developed a microbial biosensor using a surface photovoltage (SPV) device. For ethanol measurement, *Gluconobacter oxydans* (Tkac, Vostiar, Gemeiner, & Sturdik, 2002; Tkac, Vostiar, Gorton, Gemeiner, & Sturdik, 2003) as a prokaryote or yeast strains (Rotariu, Bala, & Magearu, 2004) as eukaryotes have recently been used as bio-recognition elements.

Yeast is one of the most attractive microbes used for the fast, stable, low-cost determination of ethanol concentrations in alcoholic beverages. Thus, we have used yeast to investigate the possibility of a microbial biosensing method to ethanol determination utilising a eukaryote double-mediator (EDM) system which consists of yeast, potassium hexacyanoferrate(III) [HCF(III)] as a hydrophilic mediator, and menadione as a hydrophobic and lipophilic mediator (Nakamura et al., 2007a, 2008a). In the previous study, BOD measurements in real samples were performed by obtaining an electrical signal from a batch-type, carbon-paste electrode chip equipped with a micro-stir system. Characteristics of uniformly sustainable yeast in the incubation mixture of the sensor chip made it possible to obtain reproducible results. In this study, Baker's yeast was applied to the EDM system for ethanol determination as a readily available, safe, and easily handled microbe. The EDM system was optimised, and the measurement conditions for the direct measurement of ethanol in small samples of alcoholic beverages were characterised for real sample application. Finally, the stability test of a yeast storage suspension was performed for practical use.

2. Experimental

2.1. Reagents and solution

Potassium HCF(III), ethanol (99.5 v/v%; top grade according to Japanese Industrial Standards), and dimethyl sulfoxide (DMSO) were purchased from Wako Pure Chemicals (Osaka, Japan). Menadione (2-methyl-1,4-naphthoquinone) was purchased from MP Biochemicals, LLC (Germany). Triton X-100™ (Triton™) was purchased from Sigma Chemicals (USA). The other chemicals used in this study were of reagent grade and were obtained from various distributors. Water was used after deionization.

A 100-mM sodium phosphate buffer (PB) solution was prepared (pH 7.0) and used after autoclaving. A 400-mM potassium HCF(III) solution was prepared using the PB solution. In addition, menadione was freshly prepared using DMSO to give a 20-mM solution, and a 0.05-v/v% Triton™ solution was prepared using sterilized water. A standard solution of ethanol was also prepared before use.

2.2. Preparation of yeast cells

Baker's yeast (Super Camellia) was purchased from Nisshin Foods, Inc. The procedures for the yeast cell preparation were performed according to the method described in the previous study ***(Nakamura et al., 2008a). Yeast cells were grown in a two-step process in a sterilized YPD medium (10 g yeast extract, 20 g glucose, and 20 g Polypeptone™ in 1 L; pH 6.5–6.6). The cells were grown at 180 rpm and 28 °C for 8 h in 2 mL of the YPD medium using a test tube for the pre-culture step. Of the pre-cultured medium, 0.5 mL was inoculated to 200 mL fresh YPD medium and incubated at 120 rpm for 15 h using a Sakaguchi flask.

After growth, the yeast cells were harvested by centrifugation (3 min and 3000 rpm) and washed three times with a 0.9% NaCl solution at room temperature. The yeast cells were resuspended in 35 mL of the NaCl solution in a centrifugation tube (50 mL) and starved by shaking at 120 rpm and 28 °C for 2 h. After starvation, the yeast cells were cooled in crushed ice for 10 min and washed three times using the Nacl solution (4 °C). For experimental use, the yeast cells were resuspended in the NaCl solution to an optical density (OD_{600}) of 20 and put on crushed ice. For storage, the yeast cell suspension was diluted 20 times using the NaCl solution and was stored at 4 °C.

2.3. Experimental procedure

The same measurement system of an electrochemical analyser (CHI-1202, BAS, USA) and a batch-wise carbon paste electrode chip (inner volume, 563 μL) equipped with the micro-stir system used in the previous study was employed (Nakamura et al., 2008a). Chronoamperometry was performed by poising the carbon-working electrode + 900 mV relative to the carbon reference/counter electrode for 3 s. The output obtained by the measurement system of the chronoamperometry was taken as the EDM response. All experiments were performed three times ($n = 3$) at room temperature and with a reaction volume of 400 μL.

The EDM sensor chip was preconditioned for each measurement using diluted bleach and stirring at ca. 300 rpm for 3 min. After adequate washing, the current response of the EDM sensor chip to 10 mM of a standard potassium HCF(II)-HCF(III) solution, which was prepared by dissolving equimolar amounts of both potassium HCF(II) and potassium HCF(III), was confirmed between 150 and 170 μA without stirring.

In the experiments using the EDM system, 40 μL of 400 mM HCF(III) solution, 4 μL of 20 mM menadione, 4 μL of 0.05% Triton™, 120 μL of a yeast suspension ($OD_{600} = 20$), 3 μL of the sample solution, and 229 μL of water were added to the sensor cuvette to give a final volume of 400 μL. The reaction in the sensor cuvette was started by the final addition of the yeast suspension under stirring at ca. 300 rpm. One electrochemical measurement was performed after 5-min incubation.

3. Results and discussion

3.1. Optimization

In Japan, beverages containing more than 0.5 v/v% ethanol are defined as alcoholic. In the present study, we investigated measurement conditions which did not require the dilution of alcoholic beverage samples containing between 0.5 and 50 v/v% of ethanol. As a result, the constituents of the incubation mixture were optimised to contain 10 mM PB solution (pH 7.0), 40 mM HCF(III), 0.2 mM menadione, 5 mg L^{-1} Triton™, and $OD_{600} = 6$ of yeast cells. A sample solution of 3 μL was added to the incubation mixture, and the final volume of the incubation mixture was fixed at 400 μL. The stirring condition was then adjusted to ca. 300 rpm, and the incubation time was defined as 5 min.

3.2. Calibration curves

In order to identify the fundamental condition of the EDM system, we made a calibration curve for HCF(II) using HCF(II)–HCF(III) mixtures prepared with a total of 40 mM HCF and containing 10 mM PB solution (pH 7.0). Under stirring at 300 rpm, the calibration curve was obtained at 0.03, 0.1, 0.3, 1.0, and 3.0 mM HCF(II) (sensitivity, 68.0 μA mM^{-1}, $r = 0.9997$, 5 points, $n = 3$, average of relative standard deviation, $RSD_{av} = 2.38\%$), with a detection limit of 30 μM HCF(II) and an upper limit of 20 mM HCF(II).

Next, a calibration curve for ethanol was investigated under optimum conditions. The results are shown in Fig. 1. The calibra-

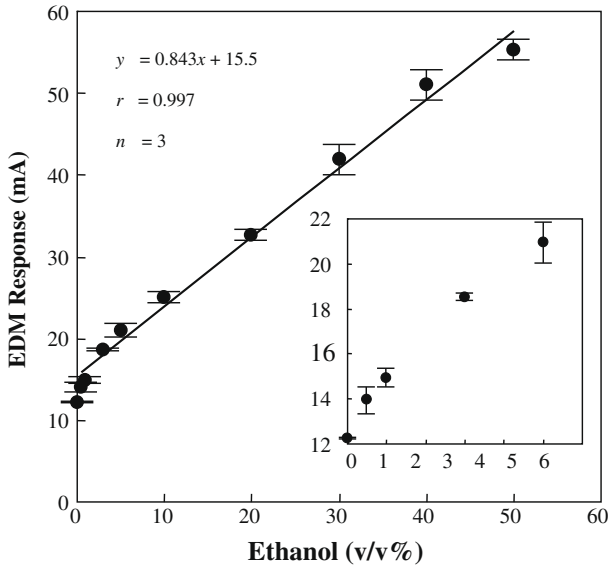

Fig. 1. Calibration curve for ethanol.

tion curve was obtained at 0.5, 1.0, 3.0, 5.0, 10, 20, 30, 40, and 50 v/v% ethanol ($r = 0.997$, 9 points, $n = 3$, $RSD_{av} = 2.75\%$) with a detection limit of 0.5 v/v% ethanol. Thus, the EDM system met the measurement conditions without dilution of the available alcoholic beverage samples.

3.3. Characterisation

The effects of pH on the EDM responses were investigated. Each pH value of a 100 mM PB solution was prepared, and 40 μL of the PB solution was added to the incubation mixture as a substitute for the 100 mM PB solution (pH 7.0). The results are shown in Fig. 2. The EDM responses to 25 v/v% ethanol were slightly increased by increasing the pH; however, as shown at pH 8.0, the relatively large error bar might be negligible due to the effects of pH. In addition, the RSD_{av} obtained between pH 5.0 and 9.0 was 3.98%. Because the sample volume was only 3 μL, the effects of pH on the EDM responses were ignored.

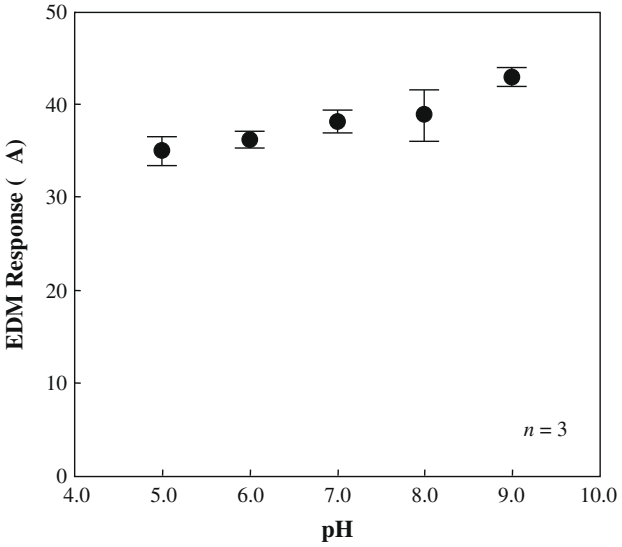

Fig. 2. Effects of pH.

Next, influences of organic substances in the EDM method were investigated. The EDM response to 5 M ethanol was measured as a control, and the EDM response to 5 M ethanol containing 50 mM of an organic substance was measured as a sample. In this examination, we chose glucose, fructose, sucrose, and maltose as sugars, ascorbic acid and citric acid as organic acids, glutamic acid as an amino acid, and methanol and 2-propanol (isopropyl alcohol) as other alcohols. The results are shown in Table 1. Except for the results obtained by maltose and 2-propanol, the EDM responses to organic substances were strongly increased (more than 110% as the relative value). The results obtained by the addition of glucose or ascorbic acid were remarkable, probably because yeast metabolic activity was strongly enhanced by two nutrients (ethanol or glucose). In addition, strong influences on the electrochemical signal were observed by the addition of ascorbic acid as a reducing substance. These results showed the necessity of some elimination methods of such organic substances or selective ethanol detection methods, for example, the use of membrane techniques (Rotariu & Bala, 2003; Tkac et al., 2002, 2003).

In addition, influences of inorganic substances in the EDM method were also examined using carbon dioxide gas or sodium sulphite. Sparkling water (SODA, 500 mL, Suntory Limited, Osaka, Japan) was used as the water containing carbon dioxide gas. Up to 350 mg L^{-1} sodium sulphite was used as the oxygen scavenger agent or antioxidant for alcoholic beverages. No notable influences were observed, although the EDM responses to 25 v/v% ethanol containing 350 mg L^{-1} sodium sulphite were slightly increased compared with the EDM responses to 25 v/v% ethanol (control) (Table 2).

Based on these results, we concluded that the present EDM method influenced coexisting substances in the alcohol beverages. Therefore, we tried to determine the ethanol concentrations in distilled alcohol beverages.

3.4. Real sample application and comparison with conventional method

As real samples, distilled alcoholic beverages and beers were used for the determination of ethanol concentrations utilising the present EDM method. In general, distilled beverages are defined as spirits that are low in sugars and contain at least 35 v/v% of ethanol by volume. The distilled beverages we chose were gin (375 mL, Gilbey's Special Dry Gin, W. & A. Gilbey Co., London, UK), vodka (375 mL, Gilbey's Imported Vodka), whisky made from malt and grain (180 mL, Finest Old Whisky, Suntory, Ltd.), brandy

Influences of inorganic substances on the EDM response to 25 v/v% ethanol[a].

Inorganic substance	Relative value (%)	SD (±)	RSD (%)
Control	100.0		
Sparkling water[b]	104.3	5.6	5.3
Sodium sulphite[c]	109.2	5.2	4.8

[a] Each control and sample was measured with three replications ($n = 3$).
[b] The sample contained sparkling water and 50 v/v% ethanol with 1:1.
[c] The sample contained sodium sulphite at 350 mg L^{-1}.

made from grapes (640 mL, VO, Suntory, Ltd.), and shochu, a traditional Japanese alcoholic beverage (200 mL, Takara-Cup 35°, Takara Shuzo Co. Ltd., Kyoto, Japan). In Japan, beers are categorised into three groups: beer (normal), low-malt beer ("Happo-Shu"), and non-malt beer ("Daisan-no-Beer"). For normal beers, we chose lager (135 mL, Lager Beer, Kirin Brewery Co., Ltd., Tokyo, Japan), draft (135 mL, Super Dry, Asahi Breweries, Ltd., Tokyo, Japan), and black draft (350 mL, Yebis The Black, Sapporo Breweries, Ltd.). For low-malt beers, we used diet draft (350 mL, Diet 77 kcal, Suntory, Ltd.), carbohydrate-free (250 mL, Style Free, Asahi Breweries, Ltd.), and draft (135 mL, Tanrei, Kirin Brewery Co., Ltd.) beers. As the non-malt beer, a draft (350 mL, Draft One, Sapporo Breweries, Ltd.) was used.

In the EDM method, calibration was performed with 0 and 50 v/v% ethanol before the determination of ethanol. The sample volume was then fixed at 3 μL, and the sample was measured without any pretreatment such as dilution. For comparison, ethanol determination in alcoholic beverages was performed using an available enzymatic-spectrophotometric (ES) method (F-kit ethanol, Cat. No. 176290, J. K. International, Inc., Tokyo, Japan). In the ES method, an ADH reaction was employed, and the amount of NADH produced by the ADH reaction was measured. A spectrophotometer (Model DU-800, Beckman Coulter, Inc., Fullerton, CA, USA) was used, and absorbance at 340 nm was fixed and measured for the determination of ethanol. In the ES method, the ethanol content in the sample solution must be between 5 and 60 mg/L; therefore, all of the alcohol beverages used in this study were diluted several times.

Table 3 shows the results obtained by both methods. In our EDM method, the ethanol concentrations were relatively higher than those obtained through the ES method. One possible reason is that other nutrients contained in beers or spirits raised the

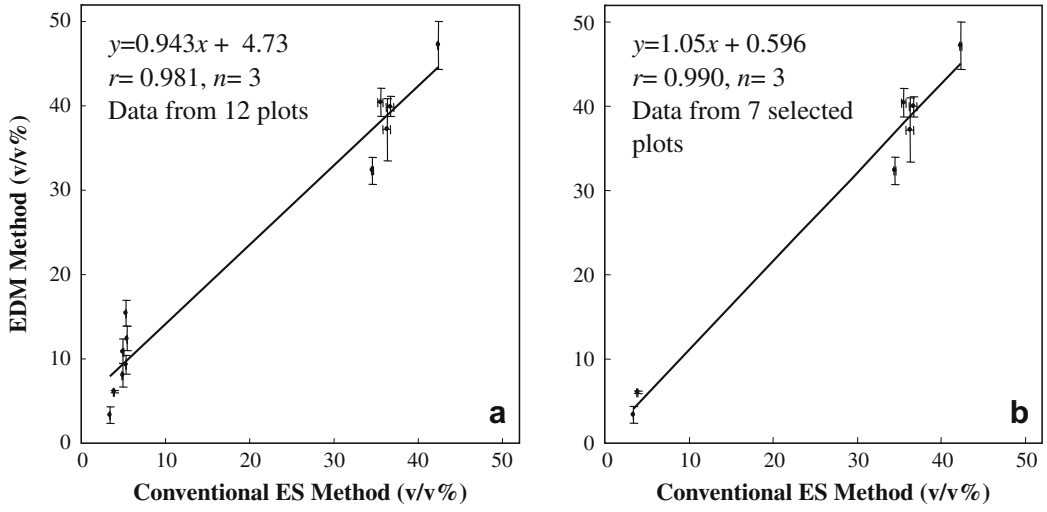

Fig. 3. Correlation of the ethanol concentration calculated from the response of the MDM method with the SE method for alcoholic beverage samples.

EDM values. The correlations between the two methods are shown in Fig. 3. All the data obtained by both methods are shown in Fig. 3a. In this figure, the slope is at a slightly low value of 0.943, which was induced by the relatively high values of beers evaluated by the EDM method. Thus, we next made a correlation between the two methods without the results from beers which contained other nutrients. As shown in Fig. 3b, the correlation was improved, with a slope of 1.05, and the correlation coefficient for these results was also improved from 0.981 to 0.990. The average RSD values (RSD_{av}) obtained at 7 points were around 7.90% for the EDM method and 0.855% for the ES method. However, in general, the reproducibility of microbial biosensor methods is around 10%; therefore, the RSD_{av} value obtained by our method can be considered a standard value. These results indicate that it is possible to determine ethanol concentrations by our EDM method, although several problems related to the influences of other nutrients need to be solved.

3.5. Storage stability

In the present study, the yeast cell suspension was diluted 20 times using a 0.9% NaCl solution after experimental use and stored at 4 °C. Before experimental use, the stored yeast cell suspension was centrifuged for 3 min at 3000 rpm, and the restrictive volume of the supernatant was removed. By adding a dilution procedure, we examined the effects of low-OD suspension and washing. The stability of the yeast suspension stored at 4 °C was examined for 25 days by estimation of the EDM response to 100 v/v% ethanol. The response reduction of 88% was observed during the first 7 days (RSD_{av} for five testing days, 4.8%), and the response reduction of 24% was observed during the first 25 days (RSD_{av} for seven testing days, 5.5%). Based on these results, we believe that the yeast suspension can be used for at least 7 days for ethanol measurements using the EDM system.

4. Conclusions

We have demonstrated the potential of the present EDM method as a direct ethanol determination method and have applied it to real samples of spirits and beers. In the present study, the problem of poor selectivity in the EDM method remained. Therefore, experiments to enhance the selectivity will be performed in the future.

Amplicon size
DNA degradation
Food processing
Genetically modified organisms
Polymerase chain reaction

ABSTRACT

The analysis of processed foods entails a number of complications, which negatively affect the performance of DNA based detection methods. Heat-processing methods viz. autoclaving and micro-waving, that mimic processing and manufacturing, as model unit operation systems were used to study their effect on the detection of genetically modified organisms (GMOs). This study confirms the premise that high temperature and/or pressure significantly reduce the level of detectable DNA. PCR methods were developed and adapted to target varying amplicon sizes of the trait, construct and event specific gene sequences that occur in MON-810 maize and Roundup Ready® soybean. Integrity of DNA, recovery and PCR amplicon size (<200 bp) are major factors that direct the successful detection of GMOs in processed foods. The model systems used provide a platform to devise better strategies in developing detection protocols, especially for processed foods containing GMOs.

1. Introduction

A tremendous and rapid increase in the global area dedicated to transgenic crops has occurred in recent years. Herbicide tolerant soybean is the principal genetically modified (GM) crop occupying 71% of global biotech area. USA, Argentina, Brazil, Canada and China currently share 98% of the worldwide area planted with GM crops whereas India accounts for 1% of the total global area (James, 2005). Since the approval of *Bt* cotton in 2002, to date 62 *Bt* cotton hybrids have been granted market authorisation in India. Consumer's awareness and concerns of the potential risks associated with GM crops on environment, biological diversity, human health and safety have burgeoned. A number of countries have therefore adopted, or are in the process of developing legislation related to the approval of GM-products. Regulatory provisions for labelling of products derived from genetically modified organisms (GMOs) have been introduced in the European Union, Japan, Korea and other countries with different threshold levels (EC 1829/2003; Notification No. 1775, 2000; Notification No. 2000-31, 2000). India too has a robust regulatory framework and an elaborate review process, which is backed by well-developed bio-safety guidelines (Warrier, 2006). Rule 37E and 48F of the recently enacted Food and Safety Standards Act (Food Safety and Standards Act, 2006) states that all imports of GMOs for the purpose of food, feed, industrial processing, research and development for environment release or commercialisation will be governed by and allowed only with the certification of the Genetic Engineering Approval Committee (GEAC). Moreover, imported consignments containing genetically modified products must carry a declaration stating that the product is genetically modified (Notification No. 2 RE-2006/2004–209, 2006). A process-based rather than a product-based labelling approach is under consideration so that any product derived from gene technology must be compulsorily labelled, even if the novel DNA and/or protein are absent (Draft notification on labelling of GM food, 2006).

Polymerase chain reaction (PCR) is a widely used technique considered as the method of first choice in GMO detection to comply with a robust labelling system. Several DNA based screening methods have been developed to detect GMOs in raw food materials (James, Schmidt, Wall, Green, & Marsi, 2003; Lau, Collins, Yiu, Xing, & Yu, 2004; Lipp et al., 2001). Food manufacturing entails a number of complex processing steps that are harsh and might negatively influence detection of GMOs. These include cooking, heating (dry as well as in presence of moisture), high pressure, pH treatments, physically shearing, extrusion at high temperatures and high torque settings. Each food and each food-processing step contribute to a unique environment in which, DNA undergoes deterioration and proteins are denatured. Hupfer, Hotzel, Sachse, and Engel (1998) reported that temperature and pH influenced degradation of a *cry*1A(b) sequence in *Bt*-maize during preparation of polenta. Thermal stress in combination with pH affects DNA integrity (Bauer, Weller, Hammes, & Hertel, 2003). Murray, Butler, Hardacre, and Vaughan (2007) demonstrate a substantial degradation of endogenous maize DNA at high temperature and torque settings. The degree of DNA degradation adversely affects the limit of detection by qualitative PCR, which is dependent on the effective concentrations of amplifiable DNA sequences (Terry, Harris, & Parkes, 2002).

Heat transfer, an operation that occurs repeatedly in food manufacture namely cooking, baking, drying, sterilizing or freezing is part of the processing of almost every food. It is therefore important to understand the effect of heat transfer on the target molecules viz. DNA and protein. The investigations on how various food-processing parameters affect the level and quality of DNA are limited.

MON-810 maize and Roundup Ready® soybean (RR-soy) are currently the major GM crops. The qualitative detection of these two transgenic events are based on PCR amplification using primers that recognise regulatory regions of the promoter derived from Cauliflower mosaic virus (CaMV35S) and *Agrobacterium tumefaciens* nopaline synthase (TNOS) terminator, both of which have a significant risk of obtaining false positives. These two elements are natural DNA sequences occurring in the growing environment (Brodmann et al., 1997). Furthermore, the trait specific transgenic gene, the enoyl pyruvyl shikimate phosphate synthase (EPSPS) or *cry*1A(b) can be incorporated in various independent transformation events of various species. The detection of the transgene cannot distinguish between an authorised and unauthorised GMO. In the present study, PCR methods were developed to detect the event: the junction between the newly introduced genes and the integration into the host genome, referred to as event specific methods (Burns, Shanahan, Valdivia, & Harris, 2003). In addition, PCR methods to amplify the cross border sequence of the transgenic construct were also developed. The specific genetic elements of RR-soy and MON-810 maize were targeted and their capability to direct PCR in unit heat operations (a) microwave treatment (MWO) at 540 W and 900 W, (b) autoclaving, (c) baking (180 °C) and (d) freezing (−80 °C) were evaluated. Microwave treatment simulates dry heating, a common method of processing used in post-baking, drying and moisture control of biscuits, crackers, bread and other bakery products. Autoclaving simulates moist heating under pressure, used to manufacture soy drink, textured vegetable protein, soybean meal, maize instant tortilla, etc. The key questions to be answered were: (1) can the DNA be detected when GMO containing grain/seed is subjected to heat processing and (2) what are the implications on PCR based detection of such GMOs? The PCR detection methods described are based on amplifying much smaller segments (200 bp) of the target DNA in processed foods.

2. Materials and methods

2.1. Materials

Standard flours (Certified reference materials, IRMM-410S 5% Roundup Ready® soy and IRMM-413 5% MON-810) containing defined percentages of GMO material prepared and certified by the Institute of Reference Materials and Measurements (Geel, Belgium) were purchased from Fluka, (Riedel-deHaën, Germany). Crushed seed powder of Roundup Ready® (RR) soybeans and Yieldgard® (MON-810) were a gift from Monsanto Co. (St Louis, MO, USA) obtained with the approval of the Research Committee for Genetic Manipulation, Department of Biotechnology, Government of India (India). For simplicity sake, the term RR-soy and MON-810 will be used hereafter to refer Roundup Ready® soy and MON-810 maize, respectively. A conventional non-GM-soy and maize were procured from the pilot plant, Department of Protein Chemistry and Technology, Central Food Technological Research Institute (Mysore, Karnataka, India). Wizard™ magnetic DNA purification kits for food were purchased from Promega Corporation (Madison, USA). *Taq* PCR core kit was obtained from Qiagen Gmbh (Hilden, Germany). Agarose was from Amresco (Solon, Ohio, USA). Ethidium bromide was purchased from Sigma–Aldrich Chemicals Private Limited (Bangalore, India). Mass loading dye (6×) and 100 bp ladder size marker were obtained from Fermentas Inc., (Maryland, USA).

2.2. Oligonucleotide primers

Oligonucleotide primers EPSPS-101F (5′-AAGTCGATCTCCCACCGGTC-3′), EPSPS-101R (5′-TTGCCCGTATTGATGACGTC-3′), EPSPS-210F (5′-ATCGAACTCTCCGATACGAAG-3′), NOS-210R (5′-CCCATCTCATAAATAACGTCAT-3′), GTS-181F (5′-GCATGCTTTAATTTGTTTCTAT-3′), GTS-181R (5′-ATCTTGAACGATAGCCTTTCCT-3′), GTS-121F (5′-TAGCGCGCAAACTAGGATAAA-3′), GTS-121R (5′-CGGTGATGCGCGTTTCA-3′), hsp-95F (5′-AGCACCTCGACCTCAGGGTT-3′) and cry1A(b)-95R (5′-TTGTAATGCAGATACCAAGCG-3′) employed in this study were designed using Primer Express™ 2.0 software (Applied Biosystems, Foster City, CA, USA), to amplify distinctly different sized products of the host genome-junction and cross border junction DNA sequences unique to either RR-soy or MON-810. The primers chosen from literature, target gene, primer sequence and expected amplicon lengths are listed in Table S1 (Supplementary data). The single-copy lectin gene (*Le*1) of soy and zein (*Ze*1) of maize were selected as internal controls. The primers synthesised by Sigma–Genosys (Sigma–Aldrich Chemical Private Limited, Bangalore, India) were diluted to a final concentration of 1 nmol μL^{-1} with nuclease free water and stored at −20 °C.

2.3. Preparation of raw material

The RR-soy and MON-810 crushed seed powders were further ground to a fine powder and sieved (Aperture size of 450 μm). One% RR-soy and MON-810 flour were prepared in-house by spiking the defatted conventional soy or maize flour with an appropriate quantity of RR-soy or MON-810 flour, respectively. Adequate care was taken to avoid contamination during spiking and the subsequent sieving step. The proportion of GM-ingredient in the spiked samples was deliberately set at 1% (w/w) to assess the degree of the expected effects at a level that would be of practical interest for threshold labelling.

2.4. Heat processing operations

All of these experiments were bench top experiments. Utmost care was taken to avoid the intermixing of transgenic samples during heat processing. All the processing steps were carried out individually and in triplicate.

2.4.1. Autoclaving

One gram of flour was directly autoclaved using an automated high-pressure steam steriliser (HA-240MIV/300 mV, Hirayama Manufacturing Corporation, Japan) at 121 °C and 15 lbs pressure for 20 min. The time did not include raising and lowering of the temperature.

2.4.2. Microwave treatment

One gram of flour was spread uniformly and heated in a microwave oven [(MWO) LG, India] at 540 and 900 W for 2 min. The MWO exposure was restricted to 2 min as charring occurred when subjected to 3 min.

2.4.3. Baking

Biscuits containing 0.67 wt.% level of RR-soy and MON-810 were prepared by conventional baking. The dough containing GMOs was sheeted to about 3.5 mm thickness and cut into biscuit shapes and placed on a tray. Biscuits were baked at 180 °C for 15 min and cooled to room temperature.

2.4.4. Freezing

One gram of the flour in an air tight container was kept at −80 °C for 48 h.

2.5. Extraction of genomic DNA

DNA was extracted from finely ground individual powders (0.2–0.5 g) using Wizard™ Magnetic DNA purification kits following the manufacturers protocol, with some modifications. The RNase (10 mg ml^{-1}) added to the autoclaved and MWO flours suspended in lysis buffer was increased from 10 to 25 μL and incubated at 25 ± 2 °C for 10 min. The suspensions were centrifuged at 13,000*g* for 10 min. Fifty microlitres of paramagnetic particle (PMP) solution were added to the supernatant, washed thoroughly with 70% ethanol and air dried. Bound DNA was eluted in 100 μL of nuclease free water and PMPs removed by magnetic separation. The DNA concentration was checked by spectrophotometry (UV-601, Shimadzu, Japan) after dilution. The DNA concentration and impurity factor (A_{260}/A_{280} ratio) were recorded. DNA integrity was evaluated by 1% agarose gel electrophoresis in 0.5× TBE (5× TBE: 450 mM Tris–Borate, 10 mM EDTA) at 100 V. The Gel Doc 2000™ documentation system with Quantity One software (Bio-Rad Laboratories Inc., CA, USA) was used to visualise the ethidium bromide stained DNA.

2.6. Qualitative PCR for detection of RR-soy and MON-810 DNA fragments

The PCR reactions performed in a total volume of 50 μL contained 1× PCR buffer containing 1.5 mM $MgCl_2$, 20 pmol of each primer, 200 μM dNTP and 1.5 U of *Taq* polymerase. The concentration of template DNA was varied depending on the percentage of GMO and the degree of heat processing (unprocessed: 80 ng; autoclaved: 1000 ng; MWO: 500 ng and baking: 850 ng). The PCR thermal profile included an initial 10 min denaturation step at 95 °C, followed by 40 cycles of denaturation at 94 °C (20 s), annealing at either 60 °C (lectin inner, lectin outer, CaMV35S-CTP, EPSPS-TNOS) or 61 °C (TNOS-soy genome, EPSPS, *hsp*70 intron1-*cry*1A(b)-95) or 59 °C (soy genome-CaMV35S) (60 s) and extension at 72 °C (30 s). A final extension step was performed at 72 °C for 3 min. The thermal cycling program used for Zein (*Ze*1) (Hohne, Santisi, & Meyer, 2002), CaMV35S promoter-*hsp*70 intron1 and *hsp*70 exon1 (Zimmermann, Hemmer, Liniger, Luthy, & Pauli, 1998), maize genome-CaMV35S promoter (ISO/FDIS 21569: 2005) and *hsp*70–*cry*1A(b) (Yamaguchi, Sasaki, Umetsu, & Kamada, 2003) were as reported. The PCR was carried out using a Gene Amp® PCR system 9700 (Applied Biosystems, Foster City, CA, USA). The amplified DNA fragments were separated by electrophoresis in a 2% agarose gel (supplemented with 0.5 μg ml^{-1} ethidium bromide) in 0.5× TBE buffer at 150 V and visualised using The Gel Doc 2000™ documentation system (Bio-Rad Laboratories Inc., CA, USA). Samples were analysed in triplicate.

2.7. Direct sequencing analysis of PCR products

The PCR products were purified using a PCR product purification kit (Promega, Madison, USA) following the manufacturer's instructions and subjected to direct dideoxy sequencing on an automated DNA sequencer (ABI 310, Applied Biosystems, Foster City, CA, USA).

3. Results

3.1. Influence of processing on DNA quantity and integrity

The DNA extracted from 200 mg of MWO and baked products were quantifiable. In contrast, the extracted DNA from autoclaved flours was not quantifiable. Increasing the initial sample size to 500 mg yielded sufficient DNA (30 ng/mg flour). The quantity of extractable DNA is therefore affected by heat-processing (Fig. 1). Yoshimura et al. (2005a) reported that increasing the initial weight of cornstarch from 2 to 5 g resulted in the extraction of sufficient DNA. Statistical analyses performed for DNA extracted reveals a significant impact of the processing method applied (Fig. 1). The quantity of extracted DNA varied with the severity of the processing method used. The highest yields were obtained with unprocessed flours, followed by baking, MWO and autoclaved. Within the MWO model system, flours microwaved at 900 W yielded less DNA than the 540 W. The most notable effects occurred during autoclaving, wherein the yield of DNA was <70% of unprocessed

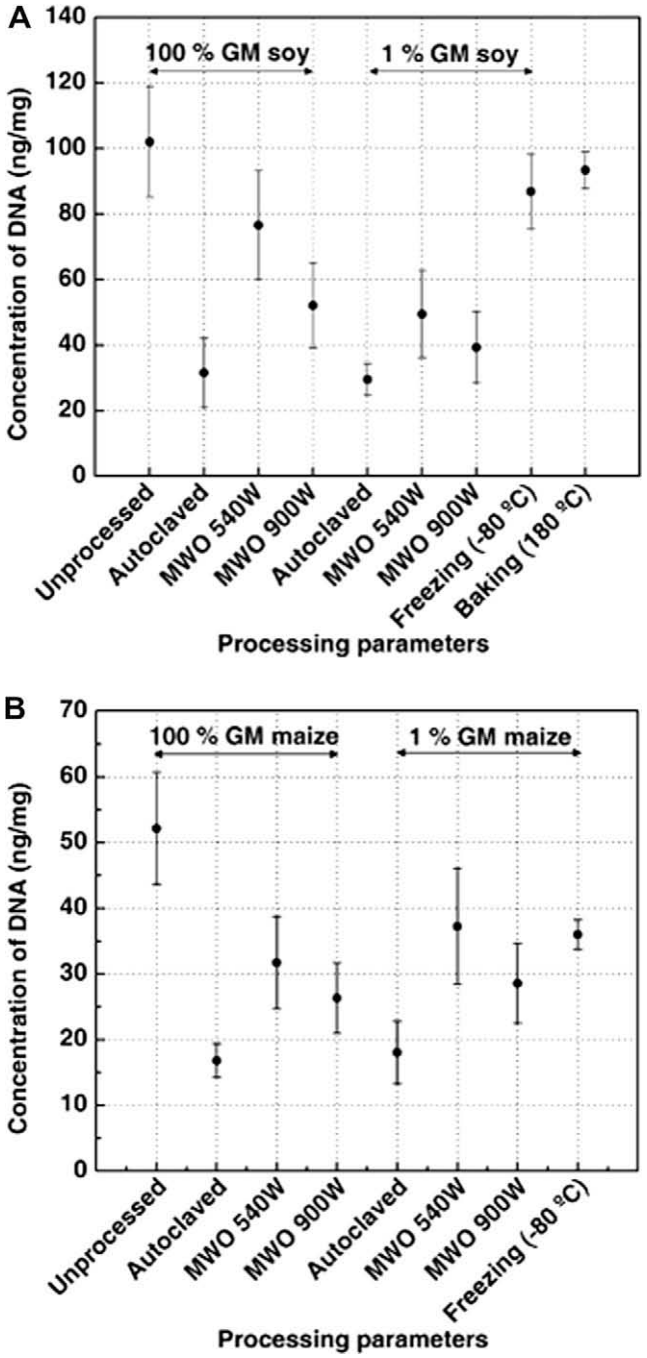

Fig. 1. Concentration of DNA extracted from model heat processed samples. (A) RR-soy and (B) MON-810. Vertical bars denote 95% confidence intervals. The mean values are derived from five extractions for each model system.

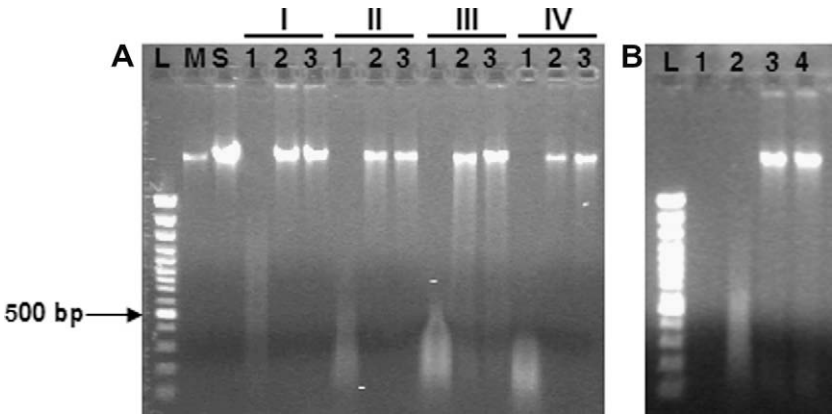

Fig. 2. Degradation of DNA induced by (A) autoclaving and microwave treatment. I: 100% RR-soy; II: 1% RR-soy; III: 100% MON-810; IV: 1% MON-810. Lane L, 100 bp ladder size marker; Lane M, unprocessed MON-810; Lane S, unprocessed RR-soy; Lane 1, autoclaved; Lane 2, MWO 540 W; Lane 3, MWO 900 W, (B) baking and freezing. Lane 1, control biscuit; Lane 2, 0.67 wt.% GM-biscuit; Lane 3, 1% MON-810 and Lane 4, 1% RR-soy. DNA loaded was 250 ng for all samples except autoclaved and baking where 1000 ng was loaded.

flours. Freezing at −80 °C also yielded less DNA. In addition, it is also evident that the DNA yield from soy was higher when compared to maize, either unprocessed or heat processed (Fig. 1). This lower yield in maize can be ascribed to the albuminous nature of the grain. Differences in the DNA size, a parameter of DNA integrity is dependent on the degree of processing the sample has been subjected to. DNA extracted from unprocessed RR-soy and MON-810 appear as clear distinct bands of high intensity >3000 bp (the highest band of the DNA marker 3000 bp) (Fig. 2). The DNA from autoclaved flours shows the complete absence of the longer DNA with the concomitant appearance of a smear smaller in size indicating DNA deterioration (Fig. 2). In contrast, a major portion of the DNA from the MWO treated is still intact with minimal smearing (<500 bp) when compared with DNA ladder accounting for some sheared DNA. These results reckon that the shearing of DNA during MWO though not severe, yet occurs. The fragmentation of DNA was most extensive in the autoclaved flours with the long DNA fragment being totally absent (Fig. 2, Lane 1). This is probably because of the intensity of the heat and the presence of moisture during autoclaving. Exposure of DNA to high temperature and pressure is known to cause fragmentation of DNA and breaks in strands thus reducing the average fragment size. Nevertheless DNA fragments <500 bp are present reckoning that amplification of DNA through PCR is still possible. The quantity of DNA loaded for detection was approximately five times greater for the autoclaved in comparison to the MWO. These results reckon that heat processing not only affects the yield of DNA but also has a significant impact on DNA deterioration. Low temperatures (−80 °C) had no effect on the DNA. The impurity factor defined by the A_{260}/A_{280} ratio showed values ranging from 1.6 to 1.8, which indicate that the DNA extracts are sufficiently pure for PCR amplification.

3.2. Specificity of the oligonucleotide primers

On the basis of published recombinant DNA sequences of RR-soy and MON-810 maize and data obtained by sequencing, primer pairs were designed to distinctly amplify specific DNA sequences for RR-soy and MON-810 (Table S1 (Supplementary data)). DNA degradation and amplicon length are crucial factors in the success of a PCR designed to identify GMOs in highly processed foods (Van Hoef, Kok, Bouw, Kuiper, & Keijer, 1998). The primers used in this study were designed to generate shorter amplicons, ~200 bp, targeting the trait (EPSPS gene), construct (EPSPS-NOS) and event (integration site: soy genome-CaMV35S promoter and NOS-soy genome) specific gene sequences of RR-soy. The primer pair *hsp*–95F/*cry*1A(b)-95R amplifies a 95 bp fragment unique to MON-810, which incidentally has a high GC content. Specificities of the primers designed were individually assessed and validated using DNA extracts of IRMM-410S (5% RR-soy) and IRMM-413 (5% MON-810). Compact and distinct bands of the expected length are visible (Fig. 3). These amplicons are visibly absent in the non-GM-soy and -maize (Fig. 3A and B). Specificity of the PCR, was

Lane L, 100 bp ladder size marker; Lane C, premise control; Lane N, non-GM-soy; Lane 1, EPSPS (101 bp); Lane 2, TNOS-soy genome (121 bp); Lane 3, Soy genome-CaMV35S promoter (181 bp); Lane 4, EPSPS-TNOS (210 bp) and (B) MON-810 (IRMM-413). Lane N, non-GM maize; Lane 5, *hsp*70 intron1–*cry*1A(b) (95 bp).

further evidenced when DNA isolated from rice (*Oryza sativa*), wheat (*Triticum aestivum*) and barley (*Hordeum vulgare*) showed no amplification when used as template (data not shown).

3.3. Effect of microwave treatment and autoclaving on detection

The detection of a species-specific single copy gene is often used to assess the amplifiability of DNA from soybean-derived products. The primer pairs GMO1/GMO2 and GMO3/GMO4 directed to amplify a 413 bp and an internal 118 bp fragment, respectively, specific for soy lectin *Le*1 gene (Meyer & Jaccaud, 1997) were used. The 413 bp amplicon was discernable in the MWO but absent in the autoclaved flours (Fig. 4A). This result is not unexpected considering the highly fragmented DNA of <500 bp in the autoclaved samples (Fig. 2). In contrast, a smaller internal fragment (118 bp) was amplifiable in all the heat processed samples (Fig. 4B). This result emphasises the suitability of primers that generate shorter PCR products when analysing processed foods. This observation was the premise for designing the other primers listed in Table S1 (Supplementary data).

The primer pair EPSPS-101F/EPSPS-101R was designed to amplify a 101 bp region of EPSPS gene. The amplicon size was minimised to obtain the highest possible sensitivity without the interferences of primer–dimer formation. A 101 bp fragment was observed in both the autoclaved and MWO processed RR-soy (Fig. 4C). The EPSPS gene of *A. tumefaciens* has been used in developing several herbicide tolerant GMOs, therefore the specificity is restricted to this trait and not the GM-crop. Construct specific primer pair EPSPS-210F/NOS-210R attaches to the EPSPS sequence and the adjacent nopaline synthase gene which is used to end the expression of EPSPS in RR-soy. Positive amplification of the 210 bp fragment was observed in both the MWO samples (Fig. 4D). The 210 bp fragment was amplified in the autoclaved 100% but not in 1% RR-soy (Fig. 4D). The primer pair 35SF-2/petuR-1 amplifies a 172 bp junction sequence between the CaMV35S promoter and the petunia hybrid chloroplast transit signal sequence (ISO/FDIS 21569: 2005). The 172 bp product is observed in both the autoclaved and MWO processed flours (Fig. 4E). It is feasible that this construct is present in several GMOs; therefore two independent GMO events cannot be distinguished by this method. Ultimate specificity for GMO detection is achieved by the use of an event- or line-primers that identifies a DNA sequence that spans the junction between the newly introduced genes and the host plant DNA. This site of integration in the plant genome will be unique to a GMO and therefore will specifically identify only the GMO in question. For RR-soy event specific detection, primer pairs GTS-181F/GTS-181R and GTS-121F/GTS-121R that encompass the sequence of the integration site of the transgene and soy plant genome were designed to amplify 181 and 121 bp, respectively. The pair GTS-181F/GTS-181R amplifies a 181 bp region between the soy plant genome and CaMV35S promoter whereas GTS-121F/GTS-121R pair detects the NOS terminator and soy plant genome integration site at the other end. A 181 bp product was visible in both autoclaved and MWO samples (Fig. 4F). A 121 bp fragment was amplified in the autoclaved and MWO RR-soy flours (Fig. 4G). The results reckon that these intergenic DNA sequences were stable to the processing deterioration. The lower limit of detection for the amplification of these RR-soy line-specific genes under this simulated model study was 1% (Fig. 4F and G).

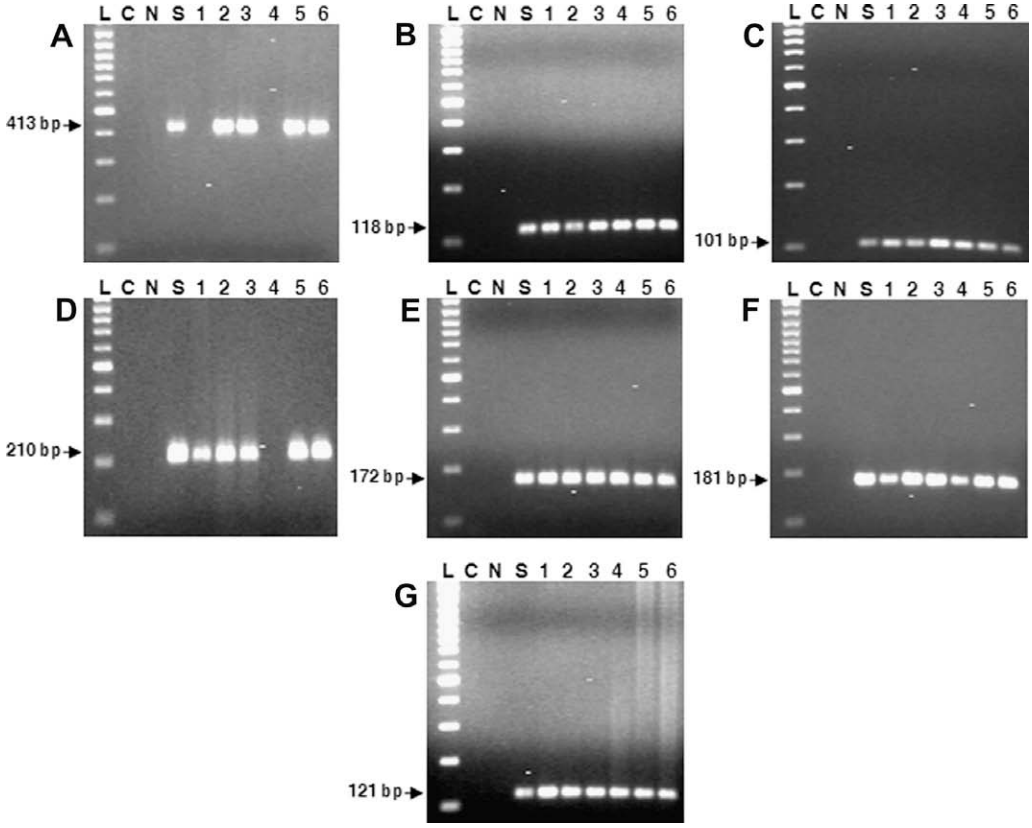

Fig. 4. Agarose gel electrophoresis of PCR products amplified from genomic DNA of heat processed RR-soy. The arrows indicate the expected PCR amplification products. Primer pairs (Table S1 in the Supplementary data section) were used for the detection of lectin outer (A), lectin inner (B), EPSPS (C), EPSPS-TNOS cross border (D), CaMV35S promoter-Petunia-CTP cross border (E), soy genome-CaMV35S promoter junction region (F) and TNOS-soy genome junction region (G). Lane L, 100 bp ladder size marker; Lane C, premise control; Lane N, non-GM-maize in (A) and (B) non-GM-soy in (C)–(G); Lane S, unprocessed 100% RR-soy; Lane 1, autoclaved (100% RR-soy); Lane 2, MWO 540 W (100% RR-soy); Lane 3, MWO 900 W (100% RR-soy); Lane 4, autoclaved (1% RR-soy); Lane 5, MWO 540 W (1% RR-soy) and Lane 6, MWO 900 W (1% RR-soy).

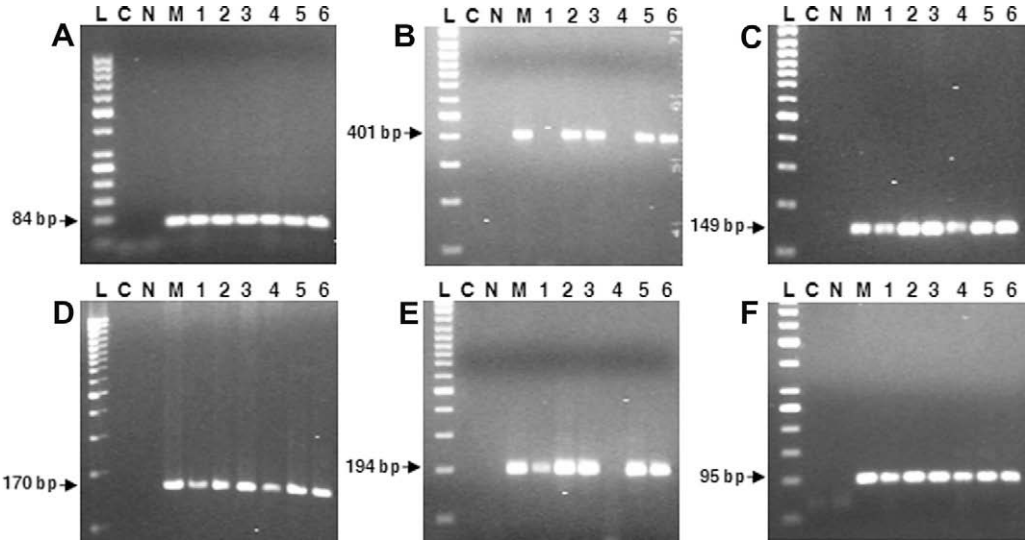

Fig. 5. Agarose gel electrophoresis of PCR products amplified from genomic DNA of heat processed MON-810. The arrows indicate the expected PCR amplification products. Primer pairs (Table S1 in the Supplementary data section) were used for the detection of Zein gene (A), CaMV35S promoter–*hsp*70 intron1 cross border (B), CaMV35S promoter-*hsp*70 exon1 cross border (C), maize genome-CaMV35S promoter junction region (D), *hsp*70 intron1–*cry*1A(b) cross border (E) and *hsp*70 intron1–*cry*1A(b) smaller fragment (F). Lane L, 100 bp ladder size marker; Lane C, premise control; Lane N, non-GM-soy in (A) non-GM-maize in (B)–(F); Lane M, Unprocessed 100% MON-810; Lane 1, Autoclaved (100% GM); Lane 2, MWO 540 W (100% GM); Lane 3, MWO 900 W (100% GM); Lane 4, Autoclaved (1% GM); Lane 5, MWO 540 W (1% GM) and Lane 6, MWO 900 W (1% GM). A 50 bp ladder size marker was used for A and F.

The amplifiability of DNA extracted from the processed GM-maize (MON-810) was confirmed using a primer pair ZeinF/ZeinR for the endogenous reference gene Zein (*Ze*1) (Hohne et al., 2002). An 84 bp amplicon was detected in both the MWO and autoclaved MON-810 flours (Fig. 5A). The gene stretch of CaMV35S promoter, followed *hsp*70 intron1 and the *hsp*70 exon1 is unique and specific to only MON-810. The primer pairs mg1/mg2 and mg3/mg4, which amplify parts of the CaMV35S promoter, *hsp*70 intron1 and *hsp*70 exon1 have been previously used for the specific detection of MON-810 (Zimmermann et al., 1998). The outer primers (mg1 and mg2) yield an amplicon of 401 bp spanning the sequence between the CaMV35S promoter and *hsp*70 intron1 whereas the inner primers (mg3/mg4) amplify a 149 bp fragment comprising the CaMV35S promoter and *hsp*70 exon1. When the primer pair mg1/mg2 was used positive amplification was observed only with the MWO processed samples. The signal for 401 bp was not discernable in the autoclaved flours (Fig. 5B). In contrast, the smaller 149 bp inner fragment was observed in both MWO and autoclaved maize samples (Fig. 5C), clearly demonstrating that primers targeting shorter fragments are more effective in detection of GMOs in processed foods.

The primer pair VW01F/VW03R (ISO/FDIS 21569: 2005) is MON-810 specific detecting the integration site between the maize genome and CaMV35S promoter. Using this primer pair a 170 bp fragment was observed for both autoclaved and MWO samples. The fluorescence intensity for autoclaved samples was visibly lower than that observed for the MWO (Fig. 5D). These PCR results are concurrent with the observed extensive fragmentation of the extracted DNA following autoclaving (Fig. 2). The primer pair MonF/MonR has often been used to amplify a 194 bp fragment, by hybridizing with the cross border region between *hsp*70 and *cry*1A(b) of MON-810 maize (Yamaguchi et al., 2003). Though the signal for the 194 bp amplicon was visible in the autoclaved 100% MON-810, it was not discernable in the 1% MON-810 (Fig. 5E). This can be explained by the fact that the copy number of the inserted sequence is much lower. Moreover, with increased processing, the size of the genomic DNA fragments available for detection also decreases. In consequence a primer pair hsp-95F/

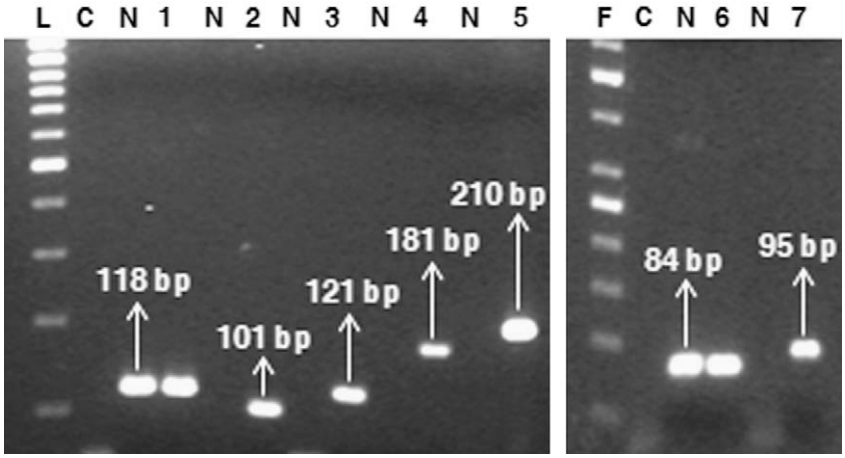

Fig. 6. Agarose gel electrophoresis of PCR products amplified from genomic DNA of baked product. Lane L, 100 bp ladder size marker; Lane C, premise control; Lane N, control biscuit; Lane 1, lectin inner (118 bp); Lane 2, EPSPS (101 bp); Lane 3, TNOS-soy genome (121 bp); Lane 4, Soy genome-CaMV35S promoter (181 bp); Lane 5, EPSPS-TNOS (210 bp); Lane F, 50 bp ladder size marker; Lane 6, Zein (84 bp) and Lane 7, *hsp*70 intron1–*cry*1A(b) (95 bp).

cry1A(b)-95 R was designed to amplify a much smaller inner fragment of the 194 bp sequence. A 95 bp fragment was amplified in both the autoclaved and MWO treated flours (Fig. 5F). These results further advocate that amplification of smaller fragments facilitate detection of GMOs in highly processed foods. The sequences of all the PCR products shown in Figs. 3–5 were verified by direct sequencing.

In the present study, the concentration of template DNA was varied (80–1000 ng) depending on the percentage of GMO and the degree of heat processing. The DNA required for amplification of the transgenes from MWO heated 100% MON-810 and RR-soy was ~4–5 folds greater than that of the unprocessed flours. MON-810 and RR-soy flours subjected to autoclaving required more template DNA as compared to MWO treated. A 9–13 fold increase of the autoclaved processed GMO-DNA was required for positive amplification over that of the raw material. It is clearly evident that the PCR assays of heat processed samples require a higher concentration of template DNA. It is reckoned that as the defined percentage of GMO decreases, a higher amount of template DNA is required.

In all the above PCR assays, appropriate controls were used. PCR set up without template DNA served as premise control labelled as Lane 'C' (Figs. 3–5). PCR set up with template DNA from the conventional non-GM-soy or non-GM-maize served as a negative control (Figs. 3–6, Lane N). PCR set up with unprocessed 100% RR-soy and MON-810, served as positive controls (Lanes S and M, respectively). The absence of any amplification product in the premise control indicates the absence of contaminating DNA from the environment, buffers or reagents used.

3.4. Detection of RR-soy and MON-810 under practical conditions: effect of baking

Baking was chosen as a practical food processing method for monitoring DNA degradation and detection of GMOs. Biscuits containing 0.67 wt.% each of RR-soy and MON-810 were prepared. Control biscuits contained exactly the same amount of conventional soya and maize flours. The DNA of longer length (>3000 bp) was visibly absent in the baked products (Fig. 2B). The extracted DNA showed a smear of short DNA fragments <500 bp with a total loss of the long DNA fragment as observed in the processed flours (Fig. 2B). These results are in close agreement with the DNA smearing reported for bread and cookies (Gryson, Dewettinck, & Messens, 2007; Straub, Hertel, & Hammes, 1999). Although the extracted DNA was fragmented this difference was not observed in the impurity factor (A_{260}/A_{280} = 1.7). The quantity of DNA extracted was greater than that extracted from the same amount of autoclaved or MWO processed flours. Although the extracted DNA was <500 bp in length, the sequences required for the construct and line specific event detection were intact as evidenced by the positive PCR amplification of these sequences (Fig. 6). These results further affirm that the newly designed PCR systems dovetailed to detect RR-soya and MON-810 specific sequences exhibit sufficient specificity for qualitative PCR analyses of a practical unit operation of food processing. The near to identical signal intensity for both the plant specific (lectin/zein) and line-specific sequences of RR-soy/MON-810 (Fig. 6A and B) suggest the usefulness of these assays in the quantitation of GMOs in processed foods.

4. Discussion

It is generally considered difficult to accurately determine the GMO content of processed foods. The suitability of isolated DNA as an analyte for PCR based detection or characterisation technique depends on the concentration, purity, and integrity, each of which, may be influenced by the sample matrix and extraction technique (Terry et al., 2002). Although several factors are important in achieving successful amplification, the template DNA concentration that is often overlooked was also found to be a critical factor in the present study. Despite the genomic DNA of autoclaved RR-soy and MON-810, not being visible by agarose gel electrophoresis (Fig. 2), the PCR detection of smaller fragments suggests that the extracted DNA was capable of directing amplification in the subsequent PCR (Figs. 4 and 5). The copy number of the transgene decreases with considerable physical damage and fragmentation as a result of high temperature and pressure associated with food processing. It can be raised above the detection limit by increasing the amount of template DNA used in PCR (Yoshimura et al. 2005a, 2005b). The results of this study reconfirm that the amount of the DNA present in autoclaved GM-foods is several orders of magnitude lower than the DNA found in the corresponding unprocessed samples (Fig. 1). The difficulty in recovering amplifiable DNA target sequences increases proportionately to the severity of processing. The higher the temperature and/or pressure, and longer the processing time, greater the damage to DNA (Fig. 2). Degradation of genomic DNA is primarily linked to processes carried out at low pH and increases dramatically with thermal stress. DNA fragmentation has been observed as a result of enzymatic hydrolysis (Klein, Altenbuchner, & Mattes, 1998) and to a certain extent on milling and grinding owing to the impact of both shear forces and mechanical stress (Moreano, Busch, & Engel, 2005). The quantity of DNA and DNA degradation in complex matrices, differences in DNA recovery and presence of PCR inhibitors are factors that direct a successful amplification. Baking served not only as a practical food processing condition, but also the effect of the food matrix could be evaluated. In the baking process although a significant deterioration of intact DNA was visible, amplifiable sequences still existed. These results indicate that the complex food matrix is not a protective factor. A pH-dependent fragmentation of DNA has also been reported during baking (Straub et al., 1999). Degradation of both transgene and endogenous reference gene sequences during the processing of soybean to soy powder, tofu and soymilk have been reported by Chen, Wang, Ge, and Xu (2005). Murray et al. (2007) using maize nuclear sequences encoding chloroplast glyceraldehyde-3-phosphate dehydrogenase and cell wall invertase show that maize DNA was degraded by a number of heat processing procedures including extrusion at high temperatures and/or high torque settings.

Sufficient amounts of DNA may be extractable following heat processing, yet it is the extent of degradation, which is a critical factor in determining whether a specific sequence can be amplified or not. Our results also demonstrate that amplification of <200 bp fragments are most suited for the detection of GMOs in highly processed foods. Our results are in agreement with those of Lin, Wei, Lin, and Shih (2006) who showed that the effect of DNA degradation from heating could be reduced by targeting shorter genes. Hupfer et al. (1998) showed that DNA fragments of 1914 bp were no longer detectable after boiling *Bt*-176 maize flour for 5 min at pH 2 whereas boiling for 60 min at pH 8.5–9.5 a shorter 211 bp fragments remained detectable. Therefore, it was recommended that the primers used in PCR detection of GMOs in processed foods, yield amplification products of 150–300 bp (Hupfer, Hotzel, Sachse, & Engel, 1999). This is further validated from this study as all the primers designed by us amplify fragments of ~200 bp. It is also likely that the degradability of the PCR target sequences also depends on the GC content. DNA regions containing high GC content are generally considered to be more heat stable. As observed all the target sequences with 40% GC content or higher were amplifiable (Table S1 (Supplementary data)). Yoshimura et al. (2005b) demonstrated that the construct specific region of MON-

810 and CaMV35S was more strongly degraded than the SSIIb1–4 as the GC content was lower.

Yoshimura et al. (2005) based on their heat processing studies conclude that the amplification regions used to quantitate recombinant and taxon-specific DNA should be closely similar in terms of size. To this end the primers designed in this study to amplify 101 bp (EPSPS-101F/EPSPS-101R) and 121 bp (GTS-121F/GTS-121R) meet this criterion and therefore would be very useful to quantify RR-soy in processed foods owing to their closeness in size to the 118 bp *Le*1 taxon specific gene of soya. In addition, the primer pair hsp-95F/cry1A(b)-95R amplifies a 95 bp fragment of MON-810, which once again in similar in size to the 84 bp product of *Ze*1 the maize taxon specific product.

5. Conclusion

The models of simulated food processes revealed a strong correlation between the degree of processing and the recovery of target DNA. Such simulation studies can be used to predict the availability of target DNA sequences for GMO detection. We believe that they provide an appropriate and a reliable basis that can be extrapolated to commonly used food technological processes such as retorting and rendering, which combine heat and high pressure to sterilise, and cook food and animal feed, respectively. When analysing products that have undergone processing, one can expect the DNA to be highly fragmented and hence can choose an appropriate method to meet the testing requirement, preferably one which targets smaller fragments. The effects of processing steps on DNA degradation must be clearly understood for each processed food on a case to case basis before any DNA based method can be applied to detect GMOs. The present study therefore contributes to the accumulation of basic data necessary to consider the impact food processing has on DNA based detection.

GC–MS

ABSTRACT

A method applying solid-phase microextraction followed by gas chromatography–mass spectrometric determination was in-house validated and used to study furan concentrations in baby-food samples purchased from the Finnish markets. The validation parameters showed that the method was well applicable for the reliable analysis of furan. Furan was analysed in 21 different baby-food samples as three independent replicates. The mean levels of furan varied between 4.7 and 90.3 μg kg^{-1} being well in accordance with the levels reported in other studies. The mean concentrations of similar product formulas based on their ingredients were 9.2, 37.0 and 49.6 μg kg^{-1} for fruit-, vegetables- and meat-containing baby-foods, respectively. According to the statistical analyses, fruit-based baby-food samples had significantly lower concentrations of furan as compared to other formulas. Based on our exercise, it seems that a low margin of safety exists between the extreme worst case infant exposures and the deduced NOAEL of furan on experimental animals, particularly for a clear rodent carcinogen.

1. Introduction

Chemical food safety is a topic with an increasing concern within the respective community, although due to the present risk management procedures the acute threat posed by harmful chemicals is very uncommon. Instead, more interest has been focused on the minute concentrations and consequent potential chronic symptoms. It has been postulated, that chemical contaminants found in foods (and feeds) might be aetiological factors behind several diseases (e.g. cancer), the causes of which are still greatly unknown. In addition to the environmental and agrochemical residues as well as natural toxins, contaminants produced during the food processing or storage, such as acrylamide, polycyclic aromatic hydrocarbons (PAH compounds), benzene and furan, are becoming an issue.

Furan is a lipophilic contaminant, which is formed during heating process used for the manufacture of foods. Furan is an aromatic heterocyclic compound (Fig. 1) which is highly volatile with a boiling point of 31.36 °C (The Merck Index, 2006). Furan has been detected in hot-air dried, baked, fried and roasted food items, such as cereal products and coffee as well as canned or jarred prepared foods (EFSA, 2005; US FDA, 2004a; Zoller, Sager, & Reinhard, 2007). Using experimental models it has been proposed that there exist multiple precursors and alternative routes for the formation of furan in foods rather that a single mechanism. Non-enzymatic browning involving reducing sugars only (Strecker degradation) or together with amino acids (Maillard reactions) has shown to produce furan and furan derivatives, the latter being important aroma compounds (Beliz, Grosch, & Schieberle, 2004). Ascorbic acid has proved to form furan through the same pyrolytic pathway than sugars even in less harsh conditions (Becalski & Seaman 2005; Limacher, Kerler, Conde-Petit, & Blank, 2007). Secondly, amino acids serine and cysteine can rearrange to form both molecular moieties needed for aldol condensation and subsequent furan formation (Perez Locas & Yaylayan, 2004). The third alternative, especially potent in prepared foods, is the formation of furan from oxidised polyunsaturated lipids, either produced via radical attack or lipoxygenase activity (Becalski & Seaman, 2005; Perez Locas & Yaylayan, 2004). However, most studies have been conducted using simple mixtures, and only few recent papers try to resolve which reactions prevail in more complicated or food systems (Limacher, Kerler, Davidek, Schmalzried, & Blank, 2008; Märk, Pollien, Lindinger, Blank, & Märk, 2006).

Acute exposure effects of furan are poorly studied but can be considered of low priority as far as the food contamination is concerned. Instead, the chronic low level exposure seems to be more relevant with cancer as an endpoint. In a two-year bioassay conducted by the National Toxicology Program, furan administered by gavage to rats induced for example hepatic cholangiocarcinoma

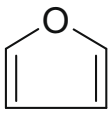

Fig. 1. The chemical structure of furan.

and hepatocellular adenoma and carcinoma (NTP, 1993). A preliminary report from a second two-year bioassay in female mice found increased incidence and multiplicity of hepatic tumours at exposure level of 4 mg/kg bw/day exposure level (Goldsworthy et al., 2001). Furan is regarded as a possible human carcinogen (Group IIB) by the International Agency for Research on Cancer (IARC, 1995). The mode of action in furan induced carcinogenesis has two schools of thoughts: a genotoxic mode of action is supported for example by the data that metabolic activation by cytochrome P450 enzyme (CYP2E1) generates *cis*-2-butene-1,4-dial which has been found to irreversibly bind to proteins (Burka, Washburn, & Irwin, 1991) and nucleosides (Byrns, Predecke, & Peterson, 2002). However, genotoxic mechanism is not supported by a recently conducted in vitro and *in vivo* micronucleus assays (Durling, Svensson, & Abramsson-Zetterberg, 2007). Alternative hypothesises are metabolite induced cell proliferation and uncoupling of mitochondrial oxidative phosphorylation (Kedderis & Ploch, 1999; NTP, 2002).

The determination of furan is very challenging due to its highly volatile nature. The most used analytical technique used to date is (automated) head-space extraction combined with gas chromatography–mass spectrometric (GC–MS) determination (e.g. Becalski et al., 2005; Hasnip, Crews, & Castle, 2006; US FDA, 2004b). Later, however, sample extraction based on solid-phase microextraction (SPME) followed by GC–MS has been developed (e.g. Bianchi, Careri, Mangia, & Musci, 2006; Goldmann, Périsset, Scanlan, & Stadler, 2005). Both approaches are very convenient sample preparation techniques for head-space analyses of volatiles, as they are very simple and demand no expensive equipment for sample extraction/concentration. Both techniques also give satisfactory results, if applied correctly (Wenzl, 2008). Instead, attention should be paid to the sample storage and preparation, careful standard preparation, calibration using internal standard as well as proper quality control procedures (Wenzl, 2008). In 2007 the European Commission put out the recommendation for the monitoring of furan in different foods that have undergone heat treatment during processing. To provide competent analytical data for risk assessment, a reliable determination method is, certainly needed.

The aims of this study were (i) to develop and validate an in-house SPME–GC–MS – method for the determination of furan in baby-foods, (ii) to apply the developed method to study the concentration levels of furan in different kind of baby-food samples (fruit purées, vegetable purées and meat-containing foods) purchased from the Finnish markets, and (iii) to estimate the exposure of Finnish infants to furan based on the levels detected.

2. Materials and methods

2.1. Standards

Furan (0.94 g/ml, ⩾99%) was purchased from Fluka Chemie (Buchs, Switzerland) and deuterated furan d_4 (0.99 g/ml, internal standard) was purchased from Isotec (Miamisburg, Ohio, USA). Standard solutions of 0.94 mg/ml, 0.94 and 0.094 μg/ml for furan and 1.19 mg/ml and 1.55 μg/ml for deuterated furan were prepared in methanol and stored at +4 °C.

2.2. Chemicals

Methanol was of HPLC-grade and purchased from J.T. Baker (Deventer, The Netherlands). De-ionised water was purified with a Millipore Milli-Q Plus system (Millipore, Espoo, Finland). Sodium chloride (NaCl) was of p.a (proanalysis) – grade and purchased from Merck (Darmstadt, Germany).

2.3. Samples

Twenty-one different baby-food samples were purchased from the local markets in February–March 2008. The samples represented all the brands available on the markets. All brands were represented by three different product categories (if available): (i) a fruit-based, (ii) a vegetable-based and (iii) a meat–vegetable based purée packed in a glass-jar. Unfortunately, exactly corresponding samples were not available for all of the brands. The main ingredients of the baby-food samples analysed are presented in Table 1. All samples were analysed as three independent replicates originating from the same batch. The sample jars were stored unopened at +4 °C before the analysis.

2.4. Sample preparation

The method used was a modification of the method of Goldmann et al. (2005). In brief, the sample was homogenised in an ice-bath, after which 2.5 g of homogenous sample was weighed into a 40 ml headspace vial (Supelco, Bellefonte, PA, USA) with a PTFE/silicone-septum. 2.5 g of ice-cold 20% NaCl was added followed by the blending of the mixture with a Polytron 1200 rod-homogenisator (Kinematica Ag, Lucerne, Switzerland). About 250 μl of MeOH and 50 μl of internal standard (deuterated furan, 1.55 μg/ml in MeOH) were added. Furan was statically extracted from the sample using SPME (CAR/PDMS-fibre, 75 μm, Supelco) at +45 °C using a magnetic stirring for 20 min.

2.5. GC–MS analysis

Furan was analysed using an Agilent 6890 GC and an Agilent 5973N MS (Agilent Technologies, Palo Alto, CA, USA). The capillary column used was a 30 m × 0.32 mm × 20 μm HP-PLOT/Q (J&W Scientific, Folsom, CA, USA). The injection port temperature was 290 °C with injection in the splitless mode. The hold time of the injector was 1 min. Helium was used as a carrier gas with a flow rate of 2.0 ml/min. The initial GC temperature was 40 °C with a hold time of 8 min, after which the temperature was increased to 220 °C at 40 °C/min and then held for 1 min. Selected ion monitoring (SIM) was used for the detection of furan and internal standard. The ions monitored were *m/z* 68 and 39 and *m/z* 72 and 42 for furan and deuterated furan, respectively. After the extraction, the holder was removed from the head-space of the vial and the fibre immediately inserted into the injector of the GC–MS-system. The retention time of furan and deuterated furan was approximately 12.28 min. The extracted ion chromatograms for a spiked carrot-purée and a baby-food sample are presented in Fig. 2.

Furan was quantified using the internal standard method. The calibration points were prepared as follows: 2.5 g of MQ-water and 2.5 g of 20% NaCl was weighed into a headspace vial. Different volumes (50–250 μl) of furan working standard solutions and a constant volume (50 μl) of internal standard working solution were added. Finally, MeOH was added to ensure that corresponding volume of solvent was added to all vials. The calibration curve covered the concentration range of 1.9–93.6 μg kg^{-1} furan in baby-food.

Table 1
The different baby-food samples analysed with the ingredients and nutritional values reported by the manufacturers. All samples were analysed as three independent replicates (see text).

Sample number	Manufacturer	Product	Ingredients	Protein (g/100 g)	Carbohydrates (g/100 g)/sugars (g/100 g)	Fat (g/100 g)
1	A	Carrot and potato purée	Carrot, water, potato	0.7	5.4/3.4	0.1
2	A	Banana and peach purée	Banana, peach, water, rice flours, citron juice, vitamin C	1.1	15.2/12.1	0.01
3	A	Vegetables and bovine meat	Carrot, potato, water, bovine meat, maize oil	2.2	6.3/2.4	2.3
4	B	Apricot purée	Water, apricot, fructose, tapioca starch, vitamin C	<0.5	15/11	<0.5
5	B	Carrot and potato purée	Carrot, water, potato, rice starch, rape seed oil	0.5	7.5/2.5	1.0
6	B	Vegetables and meat	Water, potato, pork meat, Apple purée, rice starch, bovine meat, onion, peas, tomato purée, wheat flours, salt	3.0	9.0/1.0	3.5
7	C	Fruit purée	Apricot, apple juice, water, mango, pineapple, tapioca starch, vitamin C	0.5	12/7	<0.5
8	C	Vegetable purée	Carrot, water, potato, maize, rice starch, rapeseed oil	1	10/2	1.5
9	C	Meat casserole	Water, potato, pork meat, carrot, peas, maize starch, onion, rapeseed oil, salt, bay, allspice	3	8.5/1	3.3
10	D	Apple and apricot purée	Apple juice, water, apple, apricot, rice starch, vitamin C, iron	0.2	12/6.5	0.1
11	D	Carrot purée	Carrot, water, rapeseed oil	0.5	7	2.4
12	D	Vegetables and pork meat	Water, potato, ham, carrot, peas, orange juice, rice starch, skimmed milk powder, rapeseed oil, white pepper, rosemary	4	10	3.5
13	E	Fruit purée	Apple purée, peach purée, apple juice, rice flours, vitamin C	0.6	14/9.8	0.04
14	E	Carrot purée	Carrot, water, rice flours	0.8	5.6	0.2
15	E	Vegetables, rice and pork meat	Zucchini, apple juice, rice, tomato, carrot, pork meat, wheat starch, maize oil, parsley, yeast extract	3.2	10.9	1.7
16	F	Organic carrot and veal meat	Water, maize, potato, carrot, veal meat, vegetable oil	2.5	9.5/1.5	2.5
17	G	Organic peach purée	Peach, apple	0.7	11.1/8.5	0
18	G	Organic carrot purée	Carrot, maize	1.1	6.2/2.2	0.7
19	G	Organic vegetables and meat stew	Potato, peas, carrot, onion, water, low-fat ham, parsley	3.9	7.1/1.2	0.5
20	H	Apple and banana purée	Apple, banana, water, rice flours	1.0	18.6/13.1	0.2
21	H	Vegetables purée	Carrot, water, potato, spinach, parsnip, leek	0.6	5.1/2.0	0.3

2.6. Validation

The following validation parameters were determined for the method used: specificity, recovery percent, repeatability, reproducibility, linearity, limit of detection (LOD) and limit of quantification (LOQ).

2.7. Quality control procedures

The quality control practices included the daily determination of furan concentration in a positive control sample (commercial baby-food sample) and the recovery of furan from spiked samples (self-made carrot purée). The ion ratio (*m/z* 68/39) of the samples was compared to that of standards and used for further confirmation of a positive identification of furan (data not shown).

2.8. Measurement uncertainty

The measurement uncertainty of the method was determined according to EURACHEM/CITAC Guidelines (2000).

2.9. Statistical analyses

The results from furan analyses were subjected to statistical analyses (two-sided *t*-test and one-way analysis of variance (ANOVA)) using Statistix for Windows, version 7.0 (Analytical Software, Tallahassee, FL, USA). The *p*-values <0.05 were considered statistically significant.

3. Results

3.1. Method validation

The specificity of the method was determined by analysing 12 blank samples (self-made carrot purée). The analyses showed, that a signal (both at *m/z* 68 and 39) was recorded at the retention time of furan. Hence, the method can not be concerned as absolutely specific with respect to the common validation guidelines. The signal of blank samples was, however, taken into consideration with the calculation of LOD and LOQ (see later). According to the observations it was concluded that the method is specific for the determination of furan only when all identification parameters (detection of both ions, ion ratio corresponding to standard, correct retention time) are compatible.

The repeatability was tested by analysing six replicates of spiked blank samples at three different spiking levels (Table 2). The experiment was repeated to test the in-house reproducibility. The repeatability (as well as the reproducibility) of the method was good, as the relative standard deviations (RSD) for the determinations varied between 6.3–14.3% depending on the spiking level (Table 2). The same samples were also used to determine the recovery of furan. The mean recovery was excellent, varying between 97.5% and 115.8% (depending on the spiking level). It must be noted, however, that the signal observed in the blank matrix was not taken into consideration in the calculations of recovery, which caused the mean recovery of >100% at the lowest spiking level (4.7 μg kg^{-1}).

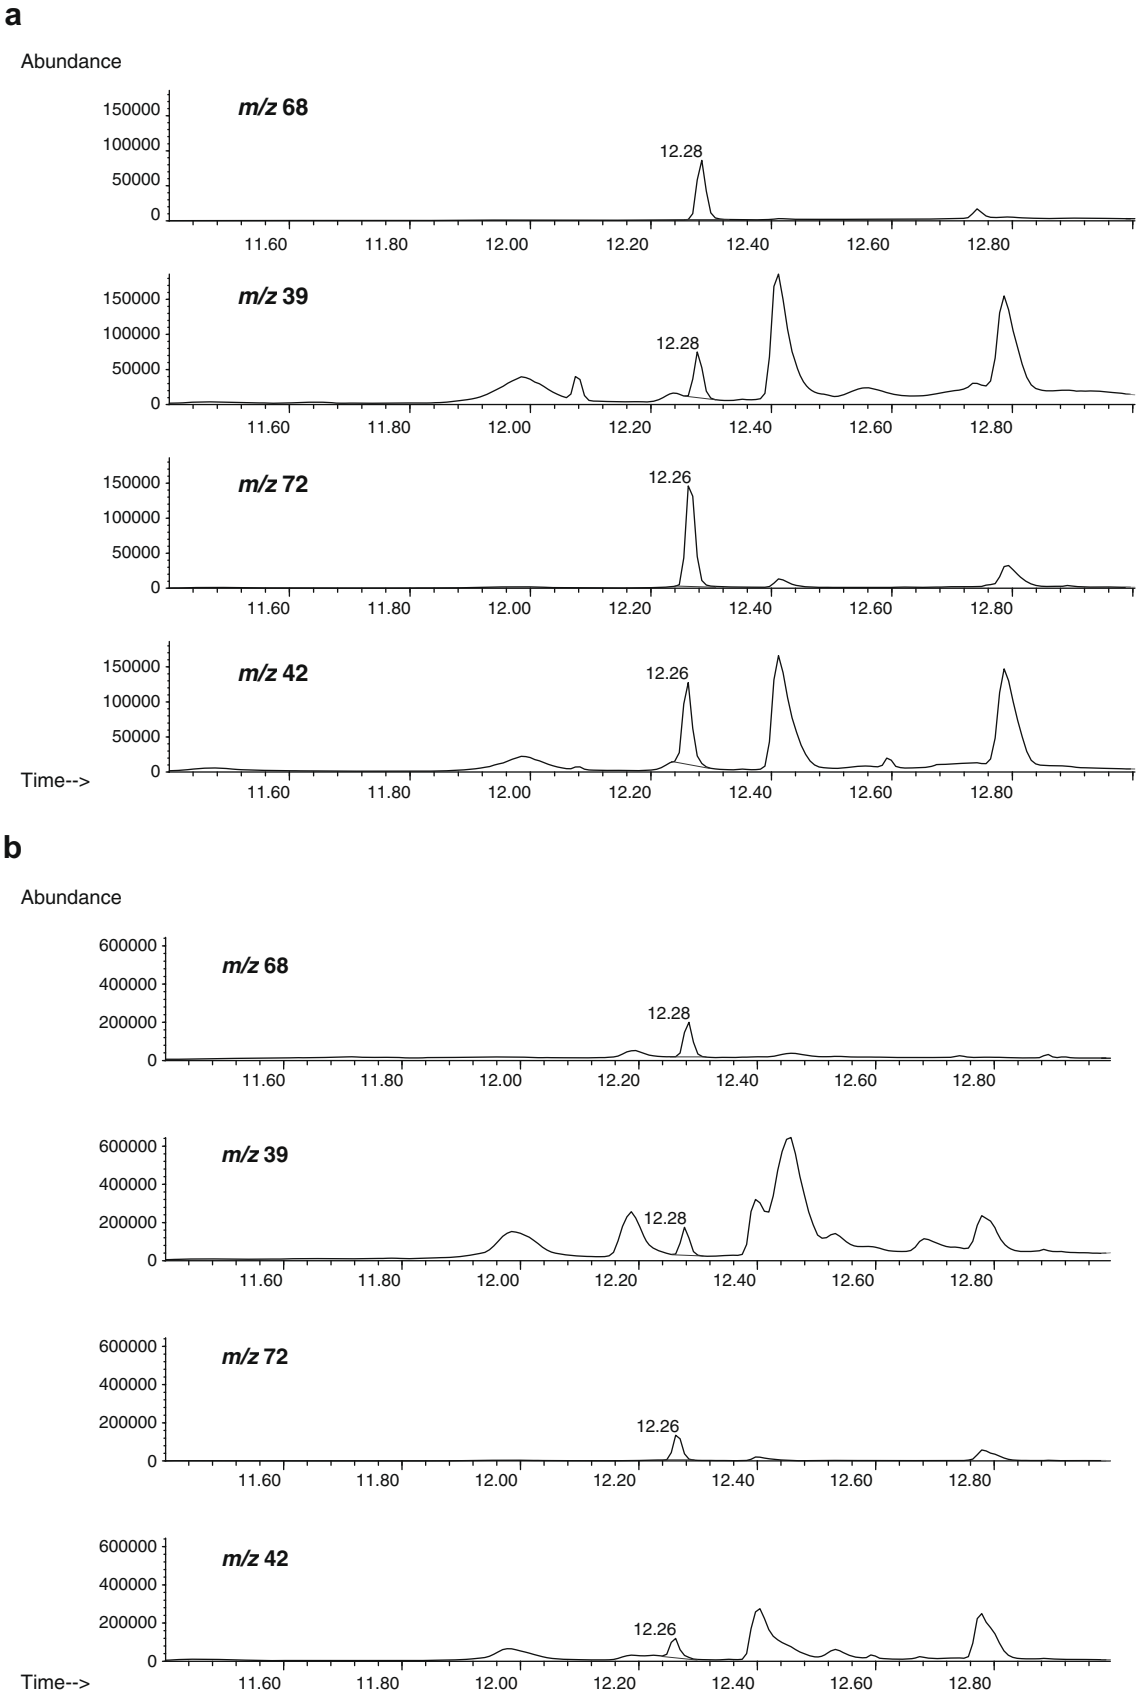

Fig. 2. The extracted ion chromatograms for (a) a spiked carrot purée sample (28.1 μg kg^{-1}) and (b) a baby-food sample (58.5 μg kg^{-1}).

The acceptable linearity of each point of the calibration curves was tested with the method of van Trijp and Roos (1991). A tolerance of 100 ± 10% was accepted for the separate calibration points for good linearity. On that basis, the method can be considered as

Table 2
The mean recoveries and relative standard deviations of furan determinations at three different spiking levels used. Each spiking level is represented by 12 replicates.

	Spiking level 4.7 μg kg^{-1}	Spiking level 28.1 μg kg^{-1}	Spiking level 74.9 μg kg^{-1}
Mean recovery (%)	115.8	97.5	104.7
RSD (%)	13.2	14.3	6.3

being linear for the determination of furan in the range tested (1.9–93.6 μg kg^{-1}) (data not shown).

LOD and LOQ for furan were calculated from the responses of the SIM signal for the "blank" matrix (n = 12). The calculated LOD (blank matrix mean response +3 × standard deviation) was 1.9 μg kg^{-1} and the calculated LOQ (blank matrix mean response +10 × standard deviation) was 4.0 μg kg^{-1}.

3.2. Measurement uncertainty

The measurement uncertainty calculated based on the systematic error (spiked samples) and random error (positive control samples) of the method is 29% (at the level of 5 μg kg^{-1}), 23% (at the level of 25 μg kg^{-1}) and 20% (at the level of 75 μg kg^{-1}).

3.3. Furan in the baby-food samples

All samples analysed had quantifiable amounts of furan (Table 3). The highest mean concentration (90.3 μg kg^{-1}) was determined in sample 15 (vegetables, rice and pork meat), whereas the lowest mean concentration (4.7 μg kg^{-1}) was observed in sample 2 (banana and peach purée). The three replicates gave very comparable results, the relative standard deviations (RSD) of the three independent measurements ranging between 1.7–31.4%. In previous studies, it has been claimed that reproducibility of the quantitative analysis of food volatiles is greatly affected by the changes in individual CAR–PDMS fibres (Mestres, Sala, Mart, Busto, & Guasch, 1999; Natera Marín, Castro Mejians, Garcia Moreno, Garcia Rowe, & Garcia Barroso, 2002), but based on our data this does not apply. The statistical analyses (two-sided t-test) showed that the concentration levels measured from a positive control sample (n = 20) did not differ significantly (t-test), although two different fibres were used in parallel. However, variation may arise when using fibres originating from different batches. This kind of problems will, however, be overcome by careful quality assurance procedures used in the analytical laboratory. The use of two fibres was practical, as this increased the laboratory efficiency remarkably, when manual injections were applied.

The mean concentrations of similar product formulas based on their ingredients were 9.2, 37.0 and 49.6 μg kg^{-1} for fruit-, vegetables- and meat-containing baby-foods, respectively.

Table 3
The concentration of furan in the baby-food samples analysed.

Sample	Jar 1 (μg kg^{-1})	Jar 2 (μg kg^{-1})	Jar 3 (μg kg^{-1})	Mean concentration (μg kg^{-1})	RSD (%)
1	29.3	30.0	30.3	29.9	1.65
2	4.4	4.6	5.1	4.7	7.6
3	52.2	53.1	58.5	54.6	6.2
4	13.4	10.0	18.8	14.1	31.4
5	19.2	25.6	23.1	22.6	14.2
6	28.1	32.4	30.3	30.3	7.2
7	12.9	14.4	14.9	14.1	7.5
8	39.8	37.9	40.4	39.4	3.3
9	13.7	12.3	12.3	12.8	6.2
10	8.2	8.6	7.6	8.1	6.2
11	18.1	26.0	24.6	22.9	18.4
12	41.2	37.3	37.3	38.6	5.8
13	7.7	9.9	8.1	8.6	13.6

17	5.3	5.9	5.4	5.5	5.7
18	35.6	41.0	34.5	37.0	9.4
19	49.9	45.9	41.0	45.6	9.8
20	9.0	8.9	10.3	9.4	8.5
21	82.8	67.8	69.7	73.4	11.2

4. Discussion

The method performance parameters determined during the in-house validation showed that the analytical method is well applicable for the reliable determination of furan in baby-foods with limit of detection and limit of quantification suitable for the purpose. The sample analyses showed RSD of less than 20% for all other samples except sample 4, although three independent replicates were analysed. This further demonstrates that the method is repeatable for the determination of furan in baby-foods, although two different fibres from the same batch were used in parallel. In addition, the low RSD values emphasise, that only minor difference in the furan concentrations occurs in the jars prepared in the same batch.

We used calibration curve prepared in water in contrary to the recommendations of Wenzl (2008). This was because the standard addition method was not found suitable as the determination was accomplished manually and therefore the suggested method would have restricted the laboratory efficiency dramatically. In addition, as the recovery of furan from the spiked samples was around 100% at all spiking levels, it is unlikely, that the matrix would affect the quantitative result. Crews, Hasnip, Roberts, and Castle (2007) compared these two different quantification methods (standard addition and calibrants prepared in solvent) and found that they both provide nearly identical results and suggested that the relative partitioning of furan and deuterated furan is not significantly affected by the nature of the sample matrix. Additionally, Limacher et al. (2007) used calibrants diluted to water to perform a reliable quantitative analysis of furan in vegetable purée.

The furan concentrations in baby-food samples from the Finnish markets of our study are well in accordance with the levels determined in other studies (Becalski et al., 2005; Bianchi et al., 2006; Morehouse, Nyman, McNeal, DiNovi, & Perfetti, 2008; US FDA, 2004a; Zoller et al., 2007). Lowest concentrations have typically been found in fruit-based purées and juices, and highest in meat-containing baby-foods. However, Zoller et al. (2007) reported low concentrations of furan (3–6 μg kg^{-1}) in the meat-containing baby-foods, but it is noteworthy that these samples did not contain vegetables. US FDA (2004a) internet database is rather extensive, and data from years 2004–05 shows furan concentrations in fruit-based baby-foods below 8 μg kg^{-1}, vegetables and mixed vegetables up to 112 μg kg^{-1} and meat containing mixed baby and toddler foods up to 90 μg kg^{-1}. It must be noted, however, that all samples in our study represent baby-foods prepared by autoclaving in glass jars, which has been suggested to favour furan formation over other technologies used for commercial baby-food preparation and domestic practises (Roberts, Crews, Grundy, Mills, & Matthews, 2008; US FDA, 2004a; Zoller et al., 2007).

Statistical analyses (ANOVA) showed that furan concentrations in baby-food samples were not significantly affected by the agricultural practise (organic/conventional) or the manufacturer whereas a significant difference was found between the recipes: the fruit-based products had significantly lower concentrations of furan as compared to vegetable- or meat-based products. As dis-

cussed above, same tendency has been obtained in other studies. It must be noticed that the fruit-based products with added ascorbic acid contain also organic acids. It has been reported that the formation of furan from sugars or ascorbic acid is less likely at low pH (Becalski & Seaman, 2005; Limacher et al. 2008), although Fan, Huang, and Sokorai (2008) have recently reported completely opposite findings. So it seems that the effect of pH on the formation of furan is much more complex than what has been previously suggested. Apparently preparation of autoclaved baby-food does not include process conditions of low water activity at high temperatures typical for non-enzymatic browning reactions to occur, thus more likely furan is formed through other mechanisms than Strecker degradation or Maillard reaction. Although not directly confirmed in our study, it is possible to speculate, that most potential precursors for furan in such baby-foods are polyunsaturated lipids such as polyunsaturated fatty acids and carotenoids (Becalski & Seaman, 2005; Perez Locas & Yaylayan, 2004). This is also supported by the findings of Limacher et al. (2008) and Fan et al. (2008).

Based on the EFSA database on the occurrence of furan in baby-foods the concentration levels ranged from nondetectable to 112 μg kg^{-1} (EFSA, 2005). In our exercise the levels are well in agreement with those figures ranging from 4.7 to 90.3 μg kg^{-1}. A consumption of 195 g/day of baby-foods (ready-to-eat or -drink) in Germany is reported (Kersting, Alexy, Sichhert-Hellert, Manz, & Schöch, 1998) which is somewhat higher than the corresponding Finnish value of 172 g/day for industrial baby-foods (Tapanainen & Virtanen, unpublished data). By using the EFSA database the German consumption level result to the exposure which range from less than 0.03 μg kg^{-1} bw/day to 2.9 μg kg^{-1} bw/day (EFSA, 2005) assuming a body weight of 7.5 kg for a 6 months old baby (Scientific Committee for Food, 1993). If we apply the mean Finnish consumption figure (172 g/day) to our data, the furan intakes in Finnish infants range from 0.8 to 15.5 μg/day resulting to exposures of 0.1 μg kg^{-1} bw/day and 2.1 μg kg^{-1} bw/day, respectively. Two extreme worst case scenarios can, however, be deduced from our data: (i) the maximum value in consumption of canned baby-foods (883 g/day) (Tapanainen & Virtanen, unpublished data) and the maximum concentration of furan detected (90.3 μg kg^{-1}) and (ii) 95 percentile consumption of canned baby-foods (384 g/day) (Tapanainen & Virtanen, unpublished data) and the maximum concentration of furan detected (90.3 μg kg^{-1}). These two extreme worst case scenarios gave intakes of 79.7 and 34.7 μg, respectively. National Research Council deduced as a compromise value for no observable adverse effect level (NOAEL) of furan 0.08 mg kg^{-1} bw/day from the lowest observed adverse effect level (LOAEL) in gavaged rats of 2 mg kg^{-1} bw/day by applying the benchmark dose rate as well as safety-factor approaches (NRC, 2000). If the margin of safety (MOS) is calculated by using the deduced NOAEL of 0.08 mg kg^{-1} bw/day (600 μg/day for 7.5 kg baby) and the extreme worst case exposure scenarios of Finnish infants, the MOS values of 7.5 and 17.3 can be derived. In the case of low exposure scenario (mean consumption of 172 g/day and furan concentration of 4.7 μg kg^{-1}) the MOS value is 750, respectively. Based on our exercise, it seems that a low margin of safety exists between the extreme worst case infant exposures and the deduced NOAEL on experimental animals, particularly for a clear rodent carcinogen. That conclusion is in line with the conclusion EFSA (2005) derived. However, a significant reduction to the exposure scenarios is provided by the fact that at least in Finland the use of fruit-based baby-foods with low furan content (as observed in our study) is comprising a substantial proportion (mean consumption 78 g/day, maximum consumption 488 g/day and 95 percentile consumption 197 g/day) (Tapanainen & Virtanen, unpublished data) of the consumption of total industrial baby-foods. Additionally, although a rising cancer trend among children in various organs/tissues in 15 European countries is reported due to the changes in lifestyle and exposure to a variety of cancer causing agents (Kaatsch et al., 2006), the authors did not observe any changes in the incidence of hepatic tumours, the clear target organ (cholangiocarcinoma, hepatocellular adenoma and carcinoma) of furan caused cancers in experimental animals (NTP, 1993). If additional safety precautions are hoped to avoid furan exposure, heating in an open can and applying occasional stirring is reported to considerably lower furan concentration in baby-food (Bianchi et al., 2006; Roberts et al., 2008; Zoller et al., 2007).

Acknowledgements

The authors want to thank Milla Rantala, Sanna Ylikarjula and Goran Šarić for their excellent technical assistance during the method development and Tiina Ritvanen for her assistance with the statistical analyses.

ABSTRACT

The removal of tebuconazole residues during the winemaking process, applied initially to red must elaborated from Mencía variety grapes from A.O.C. Valdeorrras (Ourense, N.W. Spain), was studied. Analytical determination of tebuconazole residues in grapes, musts and wines were perfomed by gas chromatography equipped with an ion trap mass spectrometry detector (GC–ITMS). Tebuconazole is retained on the solid matter (cakes and lees) and clarification agent. The eliminated percentage of tebuconazole in the final wine is 86%. The influence of this fungicide on the fermentative activity of *Saccharomyces cerevisiae* yeast and the *Oenococcus oeni* was also studied through *in vitro* assays. Liquid chromatography equipped with triple quadrupole mass spectrometer (LC–MS/MS) was used to determine tebuconazole residues in synthetic must and wine used for *in vitro* assays. No effect on the alcoholic or malolactic fermentation was observed; and no degradation of tebuconazole originated by these microorganisms was registered.

1. Introduction

Grey mold (*Botrytis cinerea*), powdery mildew (*Uncicula necator*) and downy mildew (*Plasmopara viticola*) are the most common fungi encountered in vineyards control (Sala et al., 1996). Fungicides are widely used in the treatment of diseases of grapes for vinification. Tebuconazole is a fungicide widely used in Galicia (N.W. Spain), an important vineyard area which produces white and red wines protected by five Appellation d'Origine (A.O.C) – Rías Baixas, Ribeiro, Valdeorras, Monterrei and Ribeira Sacra.

Although the correct use of fungicides does not cause problems of public concern in health and environmental areas, if inappropriate abusive treatments are applied without respecting safety recommendations, undesirable residues can remain on grapes after harvest and they can be transferred to the wine. Luckily, the winemaking process and the oenological steps carried out contribute to their reduction (Cabras & Angioni, 2000; Cabras et al., 1997, 1999; De Melo et al., 2006; Jiménez, Bernal, del Nozal, Bernal, & Toribio, 2007; Navarro, Barba, Oliva, Navarro, & Pardo, 1999; Navarro et al., 2000; Oliva, Payá, Cámara, & Barba, 2007; Sala et al., 1996). However, several studies are focused on the connection between fungicide residues and stuck and sluggish alcoholic and malolactic fermentations (Cabras & Angioni, 2000; Cabras et al., 1999, 2000; Ruediger, Pardon, Sas, Godden, & Pollnitz, 2005) and therefore the negative effect on the aromatic composition of wines (García et al., 2004; Oliva, Navarro, Barba, Navarro, & Salinas, 1999). As a conclusion, to decrease the risk to the consumer's health and to increase the quality of wine is necessary to know the evolution of fungicide residues and their degradation products during the winemaking process.

No studies have reported the fate of fungicides in Galicia. The first aim of this study is to report the tebuconazole residues through the winemaking process considering red grapes, *Vitis vinifera* var. Mencía, produced in A.O.C Valdeorras (Ourense, N.W. Spain). The second aim is to evaluate, through *in vitro* experiments, the effect of tebuconazole on the behaviour of alcoholic fermentation by *Saccharomyces cerevisiae* yeast and malolactic fermentation by *Oenococcus oeni* lactic bacteria, as well as to determine if yeast and/or bacteria could produce a decrease on tebuconazole pesticide residues in wine.

2. Materials and methods

2.1. Vinification experiments

Red grapes, *Vitis vinifera* var. Mencía, produced in A.O.C. Valdeorras were harvested in September 2007. Two vinification experiments (A and B), by duplicate, were performed at the experimental cellar belonging to Consejo Regulador from A.O.C. Valdeorras. Experiment A, used as a vinification control, consisted of performing the vinification processing with uncontaminated

doi:10.1016/j.foodchem.2009.04.030

crushed and destemmed Mencía grapes. For experiment B, crushed and destemmed grapes were spiked with a pure standard of tebuconazole at level of 3.3 mg/kg. The winemaking process with maceration was identical for all experiments. The selected contamination level is corresponding to around 1.5 maximum residue limit (MRL, 2.0 mg/kg) from tebuconazole established by European legislation to control pesticide levels in grapes from vinification (Commission Regulation, 2008).

2.1.1. Winemaking process

Intact bunches of freshly harvested grapes were weighed into four replicates of 40 kg. Winemaking process, itemised in Fig. 1, was identical for all vinification experiments, as it was commented above. Briefly, each grape sample were crushed and destemmed, introduced into independent metallic vessels of fermentation and supplied with SO_2 (40 mg/L) and the fungicide (only for experiment B). After 24 h, commercial yeast (*S. cerevisiae*) was added. During alcoholic fermentation-maceration (conducted at temperatures below 18–20 °C during 10–11 days), the mixture was re-pressed two times a day, and the temperature and density values were measured in all containers. At the end of the process the wine was strained off, grapes were pressed and the wine-must mixture transferred again to metallic vessels for the malolactic fermentation where commercial lactic bacteria (*O. oeni*) was added). At the end of malolactic fermentation, the wine was racked, supplied with SO_2 and clarified with fresh egg albumin. Finally, wine was bottled.

2.1.2. Sampling

For studying the effect of the different winemaking steps in elimination of tebuconazole, the following samplings (summarized in Fig. 1) were carried out for each vessel such it follows: (1) (crashed grape samples before to start alcoholic fermentation); (2) (wine and pomace samples collected at the end of alcoholic fermentation); (3) (wine samples at the end of malolactic fermentation after racking); and finally, (4) (bottled wine samples after clarification process).

2.2. Chemicals

2.2.1. Tebuconazole extraction and analysis

Tebuconazole [(RS)-1-p-chlorophenyl-4,4-dimethyl-3-(1H-1,2,4-triazol-1-ylmethyl)pentan-3-ol], of certified purity > 98%, was obtained from Riedel-de-Haën (Seelze, Germany). Tebuconazole D6 (100 mg/L, in acetone) from Dr. Ehrenstorfer, was used as internal standard (IS) to correct for variability in chromatographic injection and mass spectrometric detection response. The 3-ethoxy-1,2-propanediol (98%), D-sorbitol (>99%) and L-gulonic acid γ-lactone (>98%), used as analyte protectants, were obtained from Aldrich (Steinheim, Germany). Solvents (residue analysis grade) were acetone, acetonitrile, formic acid (85%), ultra-pure water (Panreac, Barcelona, Spain), dichloromethane (Merck, Darmstadt, Germany), methanol and toluene (Scharlau, Barcelona, Spain). Sodium chloride, anhydrous sodium sulfate and ammonium formiate were purchased from Panreac. Standard solutions of fungicides and analyte protectants were prepared according to a previous work (González-Rodríguez, Rial-Otero, Cancho-Grande, & Simal-Gándara, 2008a).

2.2.2. Assays of in vitro fermentations

Ingredients and culture media (peptone, yeast extract, agar and MRS broth) were obtained from Cultimed (Barcelona, Spain). Glucose PA–ACS, ethanol 96% PA–ACS, glycerol PA–ACS–ISO, malic acid PRS–CODEX, NaCl PRS–CODEX, $CaCl_2$ PA–ACS, H_2SO_4 95–98% PRS–CODEX, NaOH PA–ACS–ISO, 3,5-dinitrosalicylic acid PB and Na–K-tartrate PA–ACS–ISO were obtained from Panreac (Barcelona, Spain).

2.3. Materials and small apparatus

The sorbent material used for solid-phase extraction was Supelclean Envi-Carb II/PSA, 6 mL size (Supelco Corp., Bellefonte, PA, USA). For solid–liquid and liquid–liquid extractions, samples were placed in 50 mL polypropylene screw-capped centrifuge tubes (Sterilin, Staffordshire, UK). Samples initially were vigorously homogenised in an ultrasounds bath (Ultrasons-H, J.P. Selecta, Barcelona, Spain). Centrifugation was performed in a Rotina 35R centrifuge (Hettich Zentrifugen, Tuttlingen, Germany). Organic extracts were evaporated under a stream of nitrogen in Turbo Vap LV evaporator (Caliper Life Sciences, Hopkinton, MA, USA). *In vitro* fermentation assays without agitation were performed in a refrigerated incubator FOC 225E (Velp Scientifica, Milano, Italy). Agitated incubations were done in a thermostatized orbital shaker (Unitron incubator, Infors, Bottmingen, Switzerland). For absorbance measurements a 6505 UV/VIS spectrophotometer (Jenway, Essex, England) was used.

2.4. Extraction procedure

For the extraction of tebuconazole residues in grapes, musts, pomaces and wines, a fungicide multiresidue method, previously developed in our laboratory, was used (Rial-Otero, Cancho-Grande, & Simal-Gándara, 2003); some modifications were performed to improve the purification process and to reduce the matrix contribution (González-Rodríguez et al., 2008a). Briefly, crushed grapes (5 g), must and wine (5 mL) samples were weighed inside a 50 mL polypropylene screw-capped centrifuge tubes. A volume (25 mL) of dichloromethane–acetone (75:25, v/v) was added and the container was vigorously homogenised in an ultrasounds bath for 10 min. Sodium chloride (3 g) and anhydrous sodium sulphate (12 g) were added followed by vigorous shaking for 5 min. After phase partitioning (10 min, 4000 rpm) in a centrifuge, an aliquot of 15 mL of the organic layer was transferred to a 40 mL glass vial and evaporated to dryness under a stream of nitrogen in Turbo Vap LV evaporator and the residue was redissolved in acetonitrile (2 mL). For clean-up, a multi-layer Supelclean Envi Carb-II/PSA SPE cartridge was conditioned with 5 ml of acetonitrile:toluene (3:1, v/v). Acetonitrile extract was loaded and the retained pesticide was eluted weakly, in a 40 mL glass vial, with a volume of 20 ml of acetonitrile:toluene (3:1, v/v). The eluate was evaporated till dryness under a stream of nitrogen and filled up to a final volume of 2 mL with acetone containing the three analyte protectants (3-ethoxy-1,2-propanediol at 10 g/L; and D-sorbitol and L-gulonic acid γ-lactone at 1 g/L; respectively). Use of analyte protectants mixture provided the best results in terms of effective compensation for matrix-induced enhancement effect. Tebuconazole D6 (0.1 mg/L) as internal standard was also added and the acetone extract was finally homogenised by vortex shaking. An aliquot of the final acetone extract was placed via 350 μL glass inserts into 2 mL vials prior to chromatographic analysis.

2.5. Tebuconazole analysis

Residues of this fungicide were determined by gas chromatography-ion trap mass spectrometry (GC–ITMS) in grapes, musts and wines. Liquid chromatography equipped with triple quadrupole mass spectrometer (LC–MS/MS) was instead used to determine tebuconazole residues in synthetic must and wine used for *in vitro* assays.

2.5.1. GC–ITMS analysis

GC analyses were carried out on a Trace GC Thermo Finnigan gas chromatograph (Rodano, Italy) equipped with a PolarisQ ion trap mass selective detector (ITMS), interfaced to a PC computer running the software Xcalibur 1.4, from Thermo Electron Corpora-

tion (Italy). Chromatographic separations were done by using a SPB-5 fused-silica capillary column (30 m × 0.25 mm ID, 0.25 μm film thickness) from Supelco. PTV was used for the 2 μL injection volume into a silcosteel liner (120 × 2 mm id). The temperature programming of the PTV was 85 °C for 0.3 min; 600 °C/min to 270 °C and hold for 2 min; 840 °C/min to 300 °C for 5 min. The carrier gas, helium, operates at 100 kPa in constant pressure mode. Splitless mode was selected for 45 s. The oven temperature was programmed as follows: 80 °C for 3 min; 15 °C/min ramp to 270 °C for 5 min. The transfer line temperature was 270 °C, and the ion-trap manifold temperature was 250 °C. The ion energy for electron impact (EI) was always 70 eV. Mass detection was performed in full scan mode to identify possible degradation products of tebuconazole and in single ion monitoring (SIM) mode to measured tebuconazole residues in samples. The selected ions (m/z) were 163 and 250 for tebuconazole, and 256 for internal standard (tebuconazole D6).

2.5.2. LC–MS/MS analysis

LC analyses were performed with a Thermo Separation Products system equipped with a vacuum membrane degasser, a Spectra Series P200 quaternary pump, an AS1000 autosampler, a column heater and a SN4000 system controller. The LC system was coupled on-line to a TSQ Quantum Access triple quadrupole mass spectrometer (TQMS) (Thermo Fisher Scientific) equipped with an electrospray ionisation (ESI) source and operated in the positive ion mode. The analytical column was a Luna C_8 (150 × 2 mm ID, 5 μm particle size), coupled with a C_8 Security Guard cartridge system (4 × 2 mm ID, 5 μm particle size), both from Phenomenex (Torrance, CA, USA). An aliquot (5 μL) was injected into the column and eluted at 45 °C, with a constant flow-rate of 0.25 mL/min, using as solvents 5 mM ammonium formiate in water (solvent A), 5 mM ammonium formiate in methanol (solvent B) and 0.5% formic acid (solvent C). Elution was performed with a gradient of 35% B (0–2 min), 35–95% B (2–4 min), 95% B (4–9 min), 95–35% B (9–9.1 min) and 35% B (9.1–22 min), using a constant 5% C along all gradient program. A divert valve was placed between the analytical column outlet and the mass spectrometer inlet, and the flow was diverted to waste during the first 5.9 min and the last 8.5 min of the chromatographic run. The MS conditions were as follows: spray voltage 4000 V; capillary temperature 350 °C; sheath gas pressure (N_2) 20 units; auxiliary gas pressure (N_2) 5 units; collision gas (Ar) 1.5 mTorr; and scan time 0.5 s. The mass spectrometer was operated in full scan mode to identify possible degradation products of tebuconazole and in selected reaction monitoring (SRM) mode to quantify tebuconazole residues. The parent mass, the product mass and the collision energy selected were 308 and 314, 70 and 72, and 22 and 30, for tebuconazole and for internal standard, respectively. For instrument control, data acquisition and processing, Xcalibur software version 2.1.0 (Thermo Electron Corporation) was used.

2.6. In vitro assays. Inoculation and fermentation

2.6.1. Microorganisms

2.6.1.1. (A) Yeast inoculation. The commercial dry yeast used was Fermol Arôme Plus (*S. cerevisiae* var. *cerevisiae*) from AEB Group (Brescia, Italy). Before using it as inoculum, the yeast was purified to eliminate unknown coadyuvants that could make difficult the analysis of possible tebuconazole degradation products. It was done by rehydrating the commercial powder as described by the manufacturer, and inoculating it on YPD-agar plates, which were incubated without agitation at 30 °C for 24 h and kept at 5 °C until use. Inoculum was prepared by transferring cells from a sole colony in the plates to YPD liquid broth placed in an Erlenmeyer flask, and incubating it in an orbital shaker (150 rpm, 30 °C). The exponentially growing cells were separated from the supernatant by centrifugation (5,000 rpm/15 min), and washed twice and suspended in an enough volume of sterile water to reach a cell concentration of 2.5 g/L (measured as turbidity in a spectrophotometer at 750 nm).

2.6.1.2. (B) Bacteria inoculation. The commercial freeze dried lactic bacteria used was Uvaferm Alpha (*O. oeni*) from Lallemand S.A. (Saint Simon, France). The bacterium was also purified in the same way as the yeast substituting YPD by MRS (Liofilchem, Roseto degli Abruzzi, Italy) media. Precultures were prepared inoculating MRS liquid broth with a sole colony form the MRS-agar plates, and incubating it without agitation (30 °C) in consecutive batches with increasing ethanol concentrations (0, 10, 40 and 80 g/L) to adapt the microorganism to the alcohol. Cells from exponential cultures with 80 g/L ethanol were then washed twice and suspended in 0.8% of NaCl. The determination of biomass concentration in concentrated inoculum for *in vitro* malolactic fermentation experiments was carried out by optical density measurement at 600 nm ($1x10^9$ cells/mL) (Guilloux-Benatier, Remize, Gal, Guzzo, & Alexandre, 2006).

2.6.2. Alcoholic fermentation assays

Three series of experiments were carried out: in series A′ *S. cerevisiae* was cultured in presence of tebuconazole, in series B′ the yeast grew without the pesticide, and series C′ was a control of the tebuconazole stability in the culture medium. A simple culture medium reproducing the main must characteristics was elaborated with 200 g/L glucose, 7 g/L peptone and 3.5 g/L yeast extract, and sterilized by filtration through 0.22 μm membrane filters (Millipore, Bedford, MA, USA). Part of the culture medium (experiments A′ and C′) was supplemented with a tebuconazole concentrated standard solution in ethanol (400 ppm) to give a final concentration of 2 mg/L in the medium, and the rest (for experiment B′) was supplemented with an equivalent volume of ethanol (which corresponded to a 0.5% of the total volume). These liquid culture media were distributed into 49 mL replications in 100 mL erlenmeyer flasks (12 replications for each experiment A′, B′ and C′). Erlenmeyer flasks of experiments A′ and B′ were inoculated with 1 mL of the yeast suspension, and 1 mL of sterile water was added to the flasks of experiment C′. All flasks were incubated for 13 days in an orbital shaker at 20 °C and 75 rpm. Two samplings of each experiment consisting in the whole culture of a flask were carried out at 0, 3, 4, 6, 9 and 13 days after inoculation. The following analyses were made: biomass, reducing sugars, fermentation metabolites (ethanol and glycerol) and tebuconazole (free and adsorbed to yeast cells). A 15 mL aliquot of the culture medium (in experiments A′ and B′) was centrifuged at 4000 rpm for 20 min. The supernatants were stored at -20 °C for reducing sugars and fermentation metabolites analysis, and the biomass was washed twice to measure the biomass concentration by dry weight. Reducing sugars were assayed by the 3,5-dinitrosalicylic acid (DNS) method (Bernfeld, 1951) with glucose as standard, and ethanol and glycerol were measured by a high-performance liquid chromatograph equipped with a RI-150 Spectra System refractive index detector (Thermo Separation Products) and a column model ION-300 (Transgenomic, San Jose, CA) eluted with 0.0085 M H_2SO_4 at 35 °C and a flow rate of 0.4 mL/min during 40 min. On the other hand, a 30 mL aliquot of the culture medium (experiments A′ and C′) was centrifuged to quantify free tebuconazole and tebuconazole degradation products in the supernatant, while the biomass was washed twice with water, re-suspended in 0.5 M $CaCl_2$, incubated in an orbital shaker for 60 min at 200 rpm to extract the fungicide residues adsorbed on yeast cells, and centrifuged to obtain the supernatant for quantifying the adsorbed fungicide, according to Zadra and co-workers (Zadra, Cardinali, Corte, Fatichenti, &

Marucchini, 2006). Free and adsorbed tebuconazole was directly analysed in LC–TQMS following the instrumental conditions described before. Quantification was performed by external calibration using standards made in their correspondent matrix ($CaCl_2$ and YPD broth medium).

2.6.3. Malolactic fermentation assays

Three series (A″, B″ and C″) were again performed as for *Saccharomyces* fermentation assays, just substituting the yeast by the bacterium in series A″ and B″, reducing the concentration of tebuconazole from 2 to 0.4 mg/L in series A″ and C″, and changing the medium, which consisted on a synthetic wine (pH = 4.9) containing 1 g/L glucose, 7 g/L peptone, 3.5 g/L yeast extract, 5 g/L malic acid and 80 g/L ethanol, sterilized by filtration through 0.22 μm membrane filters and supplemented with tebuconazole as described. These liquid culture media were distributed into 245 mL replications in 500 mL glass bottles (2 replications for each experiment A″ and B″, and 1 replication for experiment C″). Bottles of experiments A″ and B″ were inoculated with 5 mL of the bacteria inoculum, and 5 mL of sterile 0.8% NaCl was added to the bottle of experiment C″. All bottles were closed and incubated without agitation at 25 °C under anaerobic conditions for 31 days. An aliquot of 5 mL from each bottle was taken each 2–3 days. Firstly, biomass was measured by absorbance readings at 600 nm (using the synthetic wine as a blank). The samples were then centrifuged at 4000 rpm for 20 min, and the supernatants were stored at −20 °C for fermentation metabolites (malic and lactic acids) and free tebuconazole and tebuconazole degradation products analysis. Malic and lactic acids were measured by HPLC-RI following the same analytical conditions of ethanol and glycerol analysis described above, and free tebuconazole was directly analysed in LC–TQMS (synthetic wine was used as matrix to make the calibration standards).

3. Results and discussion

3.1. Analytical performance

Determination of pesticide residues in food matrices may be adversely affected by a phenomenon commonly known as the "matrix-induced chromatographic response enhancement effect", contracted to matrix-induced response enhancement, which was first described by Erney and co-workers (Erney, Guillespie, Gilvydis, & Poole, 1993). When pesticides are in absence of matrix during the injection step, poor peaks with low response resulted for analytes susceptible to be degraded and/or absorbed on the GC injector; however, peak intensity and shape of affected compounds improved when they are injected in the presence of a complex matrix (carbohydrates, proteins and/or lipids). This effect is presumably the most discussed matrix effect negatively impacting quantitation accuracy of certain analytes in GC (Hajšlová & Zrostlíková, 2003). The use of analyte protectants, which are compounds that interact with active sites in the GC system, decreases degradation and/or adsorption of co-injected analytes (Anastassiades, Maštovská, & Lehotay, 2003; Maštovská, Lehotay, & Anastassiades, 2005). The mixture of these three analyte protectants (3-ethoxy-1,2-propanediol at 10 g/L; D-sorbitol and L-gulonic acid γ-lactone at 1 g/L; respectively) was previously adopted in the determination of pesticides in leafy vegetables (González-Rodríguez et al., 2008a; González-Rodríguez, Rial-Otero, Cancho-Grande, & Simal-Gándara, 2008b) and the use of fortified blank samples as calibration standards was avoided. In this case, the use of this mixture was also adopted to evaluate the compensation of this effect in the determination of tebuconazole residues in grapes, musts and wines samples.

The performance of the SLE/SPE/GC–ITMS and SLE/SPE/LC–TQMS methods for determining tebuconazole in grapes, musts and wines was assessed by evaluating quality parameters (such as linearity range, precision, limits of detection and quantitation), which experimental values are summarized in Table 1, such it was described as follows. Uncontaminated Mencía crushed grapes, musts and red wine previously fortified for tebuconazole at different levels (ranging from 0.1 to 1.0 mg/kg or mg/L for GC–ITMS/ranging from 0.01 to 0.1 mg/kg or mg/L for LC–TQMS) were treated following the experimental conditions described above. Linearity of each method was established by plotting the relative area of tebuconazole to the tebuconazole D6 (A/A_{is}), versus the concentration of the fungicide (C_i). Acceptable linearity was obtained for each matrix evaluated with a correlation coefficient > 0.99 (Table 1). Absolute recovery value for the whole calibration line was obtained from the ratio between the slope of the calibration line corresponding to the spiked sample and the slope of the calibration line corresponding to the fungicide standards injected directly onto the analytical column (standards ranging from 0.15 to 1.5 mg/L for GC–ITMS and ranging from 0.015 to 0.15 mg/L for LC–TQMS, in acetone, containing the same concentration of internal standard and analyte protectants). Absolute recovery values ranged from 77 to 92%. One-way analysis of variance between mean recovery values obtained with both chromatographic techniques (GC–ITMS and LC–TQMS) for each type of sample (grapes, musts and wines) were performed. The p-values of the F-test (95% probability) in the ANOVA was greater than 0.05 for each type of sample evaluated; then, there is not a statistically significant difference between the mean recoveries for each type of sample obtained with both techniques at the 95.0% confidence level. Moreover, the use of analyte protectants for both chromatographic techniques eliminated practically the differences between calibrations obtained in different samples versus matrix-free solutions. Another aspect to comment is that recoveries in must and wine samples were higher than values obtained in grapes; this fact could be due to the presence of solid particles in grapes (as skins or nuggets), where tebuconazole could be adsorbed and then, the extraction efficiency reduced. Precision of the SLE-SPE procedure, were calculated by analysing, on the same day, five replicates of each type of sample (grape, must and wine) fortified at concentration of 0.4 mg/kg or mg/L for GC–ITMS and 0.05 mg/kg or mg/L for LC–TQMS; precision was expressed as relative standard deviation (RSD%), which was lower than 7% for the three samples evaluated and injected with both chromatographic techniques. Limits of detection (LOD) and quantitation (LOQ) were evaluated following the recommendations of the American Chemical Society (American Chemical Society, 1980); they were calculated from the signal-to-noise ratios obtained by analysing unspiked samples ($n = 7$); thus LOD and LOQ were taken to be the concentrations of tebuconazole resulting in a signal-to-noise ratio of three and ten, respectively. Under these conditions, LOD and LOQ obtained by LC–TQMS were eight times lower than LOD and LOQ obtained by GC–ITMS. For both cases, the SLE/SPE procedure followed of the chromatographic techniques allowed to determine residue levels 40 (for GC–ITMS) and 250 times (for LC–TQMS) than those established in European legislation (Commission Regulation, 2008).

3.2. Decrease of tebuconazole residues during Mencía winemaking process

Red grapes, *Vitis vinifera* var. Mencía, were previously analysed to guarantee the absence of tebuconazole before beginning the vinification experiments. When red grapes were crushed and destemmed, a pure standard of tebuconazole was added at 3.3 mg/kg only in vessels corresponding to experiments B; this contamination level is 1.6 times higher than European maximum residue level (2.0 mg/kg) established to control pesticide levels in grapes for

Table 1
Performance of the optimised method for the determination of tebuconazole in grape, must and wine.

Sample	GC–ITMS					LC–TQMS				
	Linearity[a] (r^2)	Recovery (%)	RSD[b] (%)	LOD[c]	LOQ[c]	Linearity[d] (r^2)	Recovery (%)	RSD[b] (%)	LOD[c]	LOQ[c]
Grape	0.991	83	5	0.028	0.050	0.993	77	2	0.004	0.008
Must	0.991	88	7	0.023	0.041	0.990	83	6	0.003	0.006
Wine	0.991	87	6	0.024	0.042	0.994	92	7	0.003	0.006

[a] Linear range: 0.1–1.0 mg/kg or mg/L ($n = 7$).
[b] Precision, expressed as relative standard deviation (RSD), $n = 5$.
[c] LOD and LOQ, expressed as mg/kg for grape and as mg/L for must and wine, $n = 7$.
[d] Linear range: 0.01–0.1 mg/kg or mg/L ($n = 7$).

vinification (Commission Regulation, 2008). We opted for this contamination level to identify possible new compounds originated by degradation of the initial tebuconazole; moreover, we opted for addition of tebuconazole as pure standard instead of a commercial formulation to eliminate interferences associated to other substances such as additives and/or excipients.

One day after the addition of tebuconazole standard, necessary to provide the liquid–solid partitioning in experiment B, the winemaking process started. Sampling followed in experiments A and B are described in Fig. 1. Residual concentrations of tebuconazole found in the different control stages of vinification experiment B, by duplicate, are shown in Table 2. No tebuconazole residues were detected in the duplicates of vinification experiment A.

Comparing the alcoholic fermentation course in experiments A and B, followed by the evolution of must density, it can be concluded that both fermentation had a regular course (10–15 days). This seems to indicate that this yeast is not negatively affected by tebuconazole in the vinification conditions here assayed, as also reported by other authors with this microorganism and other fungicides like iprodione and fludioxonil (Ochiai et al., 2002) and fenhexamid (Cabras et al., 2001). On the contrary, the maceration-alcoholic fermentation stage was the most influential one in the

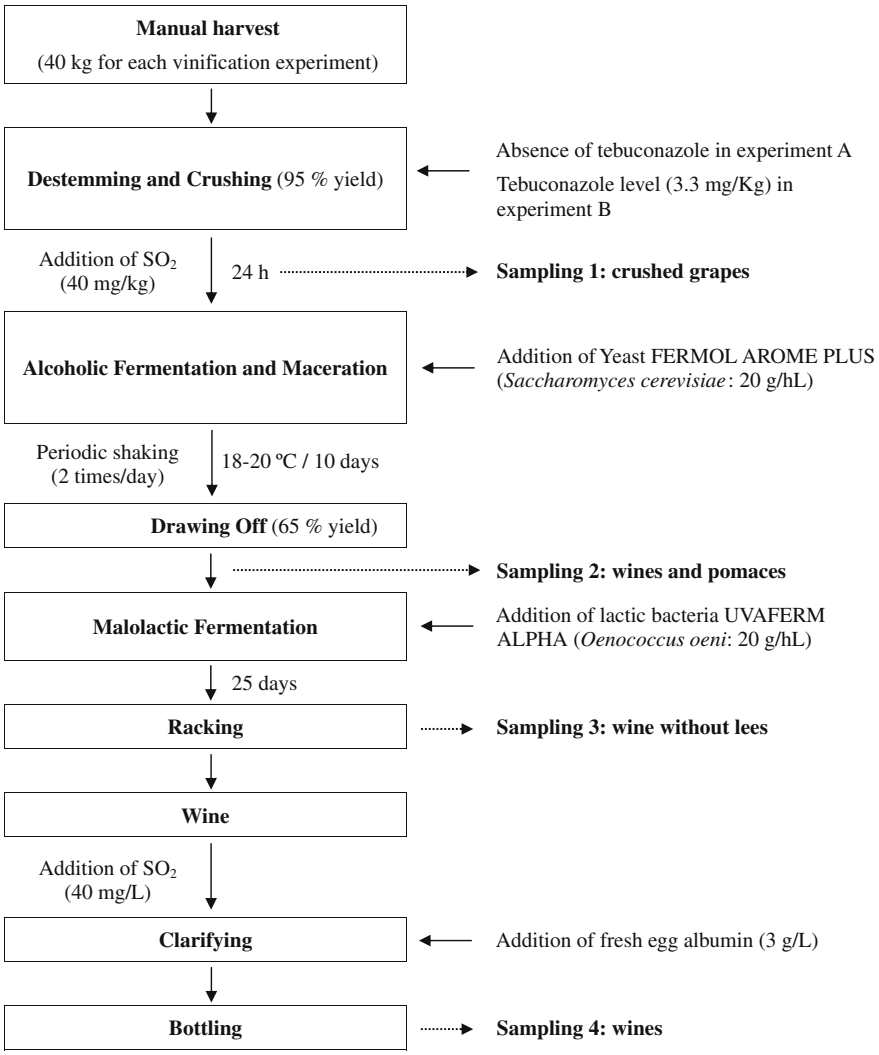

Fig. 1. Flowsheet and sampling for Mencía wine vinification.

Table 2
Average (experiment A) of residual concentrations of tebuconazole ($n = 2$) found in the different control stages of vinification (mg/kg or mg/L ± SD) by GC–ITMS.

Sample 1	Sample 2		Sample 3	Sample 4
Crashed grapes	Must (65%)	Pomace (35%)	Racked wine	Clarified wine
3.49 ± 0.57	0.64 ± 0.15	6.12 ± 0.49	0.59 ± 0.03	0.45 ± 0.01

levels of tebuconazole present in the wine and the pomace. From the initial enrichment of the must to the end of the alcoholic fermentation-maceration, the fungicide was distributed between the fermenting must (the liquid phase) and the pomace (the solid phase). Tebuconazole did not remained completely dissolved in the liquid phase due to its low water solubility (0.032 g/L), unlike other fungicides studied by other authors like metalaxyl (7 g/L) which 64% remains dissolved (Navarro et al., 2000). The remaining amount in the wine was only around 12% of the total amount in comparison to the 88% present in pomace samples (see Table 2); it shows the high affinity of this compound to be adsorbed on the suspended solid matter. For other fungicides, such as quinoxyfen, myclobutanil and tetraconazole (another fungicide of the triazole family), no determinable residues were found at the end of the alcoholic fermentation (Cabras & Angioni, 2000; Cabras et al., 2000).

Malolactic fermentation, followed by thin layer chromatography, had a regular course in all vessels too, also showing the resistance of the bacteria used to the tebuconazole concentration remaining in the wine after the first stage of alcoholic fermentation (0.6 mg/L). Although studies on lactic acidic bacteria inhibition by pesticides (Bordons, Masqué, & Vidal, 1998; Cabras et al., 1994; Haag, Kreiger, & Hammes, 1988) report minimum inhibitory concentrations for various pesticides ranging from as low as 1 to > 30 mg/L, in most cases pesticide residues were found to have little or no effect on malolactic fermentation. Recently, Ruediger and co-workers (Ruediger et al., 2005) evaluated the effect of red wine malolactic fermentation on the fate of seven fungicides (carbendazim, chlorothalonil, fenarimol, metalaxyl, oxadixyl, procymidone and triadimenol); only dicofol has an inhibitory effect on the catabolism of malic acid. On the other hand, the malolactic fermentation stage resulted in no significant reduction on tebuconazole levels (around 0.6 mg/L). Published studies showed that a minimum number of pesticides were degraded or adsorbed by the bacteria during this process (Cabras et al., 1999, 2000; Navarro et al., 2000; Ruediger et al., 2005).

Clarification was performed with fresh egg albumin; it is a clarifying agent used in high prestige red wines. It removes a large number of phenols and mellows wines with a high content in astringent tannins. Compared to other clarifying agents, it offers the advantage of not modifying the sensory qualities (Oliva et al., 2007). Clarification as well as filtration allows achieving the clearness demanded of wines but they also lead to remove other exogenous substances such as pesticide residues. In this case, tebuconazole residues decreased around 25% in this stage with regard to racked wine due to this fungicide was also adsorbed in lees formed along the clarification (see Table 2). Similar results were obtained by Oliva and co-workers (Fernández, Oliva, Barba, & Cámara, 2005; Oliva et al., 2007) who studied the effects of clarification and filtration processes on the removal of other fungicides in the winemaking process of red wine elaborated from Monastrell variety grapes. Fresh egg albumin presented the highest elimination, in the clarified wine, for famoxadone, flunquiconazole and trifloxystrobin (50% for the three target fungicides) (Oliva et al., 2007); and for the blood albumin was observed highest elimination for cyprodinil, pyrimethanil (70%) and fludioxonil, quinoxyfen (30–40%).

At the end of the winemaking process, the residue remaining in the final wine was lower than in grapes, presenting a mean transfer factor from grape to wine of 0.14. These results are in accordance with those published for other fungicides of the triazole family in red grapes winemaking process. As example, penconazole and propiconazole decreased by as much as 90% of the initial value in red wines (Navarro et al., 1999); levels of tetraconazole fell by 100% of the initial value found in grapes (Cabras et al., 1998) and the loss of tebuconazole in the final red wine ranged from 50% to 73% (Cabras et al., 1997; Jiménez, Bernal, del Nozal, Toribio, & Bernal, 2004). For white and rosé wines, the reduction of the contamination levels for tebuconazole is lower as a consequence of the absence of the malolactic fermentation and the minor presence of the matter in suspension that can adsorb the tebuconazole; Cabras et al. (1997) established that tebuconazole residues in wine were ca. 50% that levels found in grapes.

Some fungicides, which are unstable in an acid environment, started to degrade after pressing, and at the end of fermentation new related compounds were present in wines. The results here presented also appear to show the absence of tebuconazole degradation processes in this system since no degradation products could be detected. Jiménez and co-workers (Jiménez et al., 2004) determined the degradation products of bromopropylate, trichlorphon, parathion-methyl and tebuconazole, formed during the winemaking process; degradation products were only identified for the three initial fungicides meanwhile tebuconazole, remained intact. It is necessary to make *in vitro* assays to confirm if tebuconazole is degraded and/or their degradation products were also adsorbed on solid matter.

As a conclusion, tebuconazole showed a continuous decrease through the red winemaking process. Nowadays any European legislation to control maximum residue levels of pesticides in wine exists. In future, according these results, MRL for tebuconazole in red wines could be established as a eight times lower (0.25 mg/L) than MRL established in wine grapes (2 mg/kg).

3.3. Evaluation of in vitro assays

Although the previous winemaking experiments allowed to discard negative effects of tebuconazole on the alcoholic and malolactic fermentation at the concentration assayed, the presence in the must of the solids coming from the grapes during the maceration–alcoholic fermentation stage makes difficult to analyse the real effect of the fungicide on yeast grown and fermenting activity since solids reduce the concentration of soluble tebuconazole by adsorption and interfere in yeast biomass determination. On the other hand, the complex composition of must and wine makes also difficult to detect, identify and quantify possible tebuconazole degradation products produced by the yeast and the bacteria.

Consequently, *in vitro* alcoholic and malolactic fermentation assays were carried out employing liquid synthetic media with a simpler composition than must and wine, but reproducing their main characteristics (sugars, ethanol and malic acid concentration, and pH) and enriched in tebuconazole to evaluate the effect of the fungicide on the main fermentation parameters.

3.3.1. Effect of tebuconazole on alcoholic fermentation

To evaluate whether the presence of tebuconazole can negatively affect yeast growth and alcoholic fermentation of the must by *S. cerevisiae*, experiments in the synthetic medium described in Materials and Methods were carried out using the maximum residue limit of tebuconazole in grapes for vinification (MRL, 2.0 mg/kg). Evolution of sugars consumption, yeast growth and ethanol production, with and without presence of tebuconazole residues, is shown in Fig. 2.

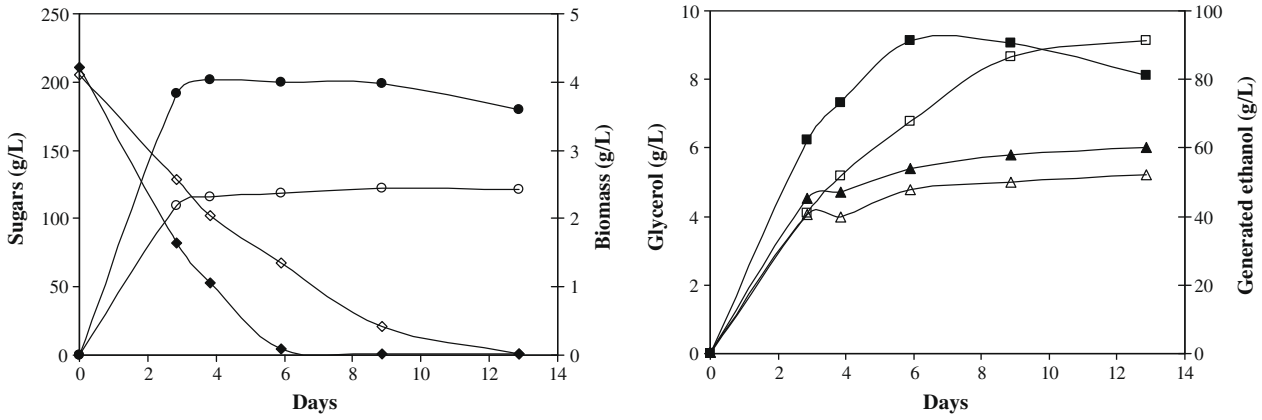

Fig. 2. Time course of sugars consumption (◇, ♦) and biomass (○, ●), glycerol (△, ▲), and ethanol (□, ■) production during alcoholic fermentation of a synthetic medium with *Saccharomyces cerevisiae*, in presence and absence of tebuconazole residues, respectively.

The presence of tebuconazole in the culture medium at a concentration of 2 mg/L caused a decrease of the sugar consumption rate and, consequently, a slower growth and ethanol production rate. Moreover, the maximum biomass reached was clearly lower in the series incubated with tebuconazole, all of that showing the toxic effect of this fungicide for the yeast. These results are in accordance with the general inhibitory effect of azole compounds on the transformation of lanosterol into ergosterol in the cell membranes of the yeasts (Ji et al., 2000). Glycerol production was not affected, while ethanol production was slower than in the control but reached a maximum concentration 4–5 days later that was comparable to the series without the fungicide. Although the final ethanol concentration was lower in the control, this can be explained by the earlier sugars depletion in this series, what causes the stop of the ethanol production and, consequently, a more evident effect of ethanol evaporation as well as the beginning of ethanol consumption as a new substrate.

According to these results the presence of tebuconazole at the concentration assayed has a toxic effect for *S. cerevisiae*, reducing the biomass and slowing the fermentation. Nevertheless, and for practical purposes, it is expected that during red winemaking the levels of soluble tebuconazole in the must are reduced by adsorption on grape solids to a concentration low enough to make these effects irrelevant, as it happened in this work.

There are some works showing the ability of *S. cerevisiae* cells to adsorb inorganic and organic contaminants as fungicides (Aksu & Dönmez, 2003; Gomes, Fragoso, Riger, Panek, & Eleutherio, 2002; Goyal, Jain, & Banerjee, 2003: Martín-Esteban, Fernández, & Cámara, 1997; Razmkhab et al., 2002), which is attributed to the cell wall polysaccharides (Ballou, 1988). To investigate if the tebuconazole concentration in the must during red winemaking is reduced not only by adsorption on grape solids but also by the yeast, pesticide residues were determined both in the fermentation medium (free tebuconazole) and in the yeasts (adsorbed tebuconazole) during the fermentative process (Table 3). In this case the levels of soluble tebuconazole were not modified during the fermentation and the amount of tebuconazole extracted from the cells was not significant. Moreover, degradation products of tebuconazole were not identified. These results indicate that yeast activity during fermentation did not induce any degradation of the pesticide during must fermentation.

3.3.2. Effect on malolactic fermentation

Several studies have directly or indirectly investigated the effect of pesticide residues on the rate of malolactic fermentation. In most cases, pesticide residues were found to have little or no effect on malolactic fermentation, and very few pesticides were degraded or adsorbed by the bacteria during this process (Bordons et al., 1998; Haag et al., 1988). In other cases, the fermentation activity of *O. oeni* was affected by the presence of certain pesticides, azoxystrobin, cyprodinil, fludioxonil, pyrimethanil, (Cabras et al., 1994; Oliva et al., 2007) and dicofol (Ruediger et al., 2005) with a lower degradation of malic acid; however, the amount of these pesticides was not affected significantly during MLF, except in the case of dicofol. For quinoxyfen (Cabras et al., 2000), mepanipyrim (Cabras et al., 1999), carbaryl, carbendazim, chlorothalonil, fenarimol, metalaxyl, oxadixyl, procymidone and triadimenol (Ruediger et al., 2005) no effect on the MLF was observed, and, as before, bacteria do not have any degradative effect on them.

To evaluate whether tebuconazole can negatively affect the malolactic fermentation of wine by *O. oeni* and be adsorbed or degraded by the microorganism, *in vitro* experiments with the wine synthetic medium described in Materials and Methods were carried out using a concentration of 0.6 mg/L of tebuconazole, 80% lower than the maximum residue limit in grapes according to the tebuconazole reduction after alcoholic fermentation in our field experiments. The evolution of malic and lactic acid, as well as tebuconazole residues were analysed during the incubation.

The results in Fig. 3 show that this concentration of tebuconazole did not affect significantly the conversion rate of malic to lactic acid, as well as the final concentration of both acids at the end of the fermentation with respect to the control. As reported by other

Table 3

n.d.: not detected.

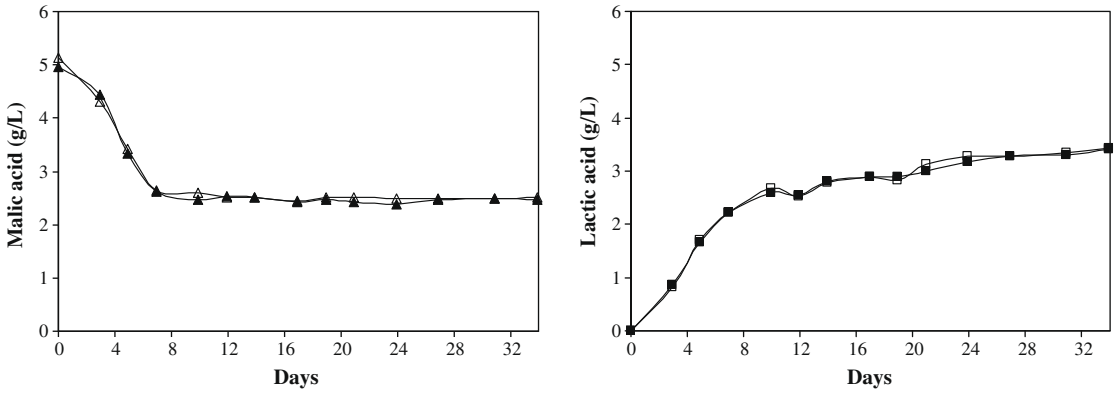

Fig. 3. Time course of malic acid (△, ▲) and generated lactic acid (□, ■) during malolactic fermentation of *Oenococcus oeni* bacteria, in presence and no presence of tebuconazole residues, respectively.

authors (Cabras et al., 1999), there is a remnant malic acid concentration that was not degraded, what is probably due to the lost of cell viability after a long period of exposure to ethanol and lactic acid. Finally, the levels of tebuconazole remained constant during the MLF and no degradation products were detected, what allows concluding that this bacterium does not have any adsorptive or degradative effect on it at the fungicide concentration assayed.

4. Conclusions

The winemaking process followed in A.O.C. Valdeorras for producing red wines allowed to decrease the tebuconazole residues of the initial musts. Tebuconazole presented high affinity to be adsorbed on the suspended solid matter. The eliminated percentage of tebuconazole in the final wine is 86%. In future, according these results, MRL for tebuconazole in red wines could be established as a eight times lower (0.25 mg/L) than MRL established in wine grapes (2 mg/kg). Results of *in vitro* assays showed that the presence of tebuconazole did not affect alcoholic nor malolactic fermentations. At the same time, these two fermentative processes did not affect the amount of tebuconazole either by degradation or by adsorption.

ABSTRACT

The yield, major phytochemicals (oryzanols, tocopherols (T), and tocotrienols (T3)) and antioxidant properties of *Japonica* rice bran extracts were investigated, for illustrating the major effects from solvent property. Generally, the extract yield varied with the solvent used in the order of methanol (MeOH) > ethyl acetate (EtOAc) > hexane. In contrast to hexane extracts, both MeOH and EtOAc extracts exhibited a higher total content in phenolic compounds (~2.5 g gallic acid equivalent/kg bran), oryzanols (1.6–1.8 g/kg bran), or tocols (126–130 mg/kg bran), and a higher T3% in tocols (24–26%). The MeOH extract (at 1 mg/ml) showed the greatest capability in inhibiting linoleic acid peroxidation (57%), scavenging DPPH radicals (93%), reducing power (78%), and Fe^{2+} chelating activity (~1300 μg EDTA equivalent/g) than the other two extracts, partly attributed to its high antioxidant contents. It is newly found that the yield, total content in phenolic compounds, oryzanols, and tocols, and T3% in tocols of the extracts increased with increasing Synder's polarity value in a quite good linear manner (R^2 = 0.923–1.000), associated with an increased solvent viscosity. This clearly suggests the potential of using Synder's polarity value as an index in isolation of desired rice bran phytochemical extracts.

1. Introduction

Rice bran contains a significant amount of natural phytochemicals such as oryzanols, tocopherols and tocotrienols that have been reported as the strongest antioxidants in rice bran (Godber & Juliano, 2004; Godber & Wells, 1994; Orthoefer & Eastman, 2004). The tocopherols and tocotrienols can be used as radical scavengers, terminating the propagation of radical chain reactions by reacting with peroxyl radicals and generating unreactive phenoxyl radicals as well as hydroperoxide products (Kitts, 1997). Another research discovered that rice bran contains a phenolic content (2.51–3.59 mg/g) higher than wheat bran (Iqbal, Bhanger, & Anwar, 2005). The phenolic compounds show higher antioxidant activities, in contrast to tocopherols (Chen & Ho, 1997; Ohnishi et al., 1994). In addition to lipophilic antioxidant activity, tocotrienols have shown peculiar physiological potential including antitumor properties toward mammary cancer (Guthrie, Gapor, Chambers, & Carroll, 1997; Nasaretnam, 2005), reducing serum cholesterol effects (Qureshi, Mo, Packer, & Peterson, 2000), and anti-inflammation (Akihisa et al., 2000).

Recent studies on the phytochemicals and antioxidant properties of rice bran involve using various solvents such as hexane (Chen & Bergman, 2005; Hu, Wells, Shin, & Godber, 1996; Kim, 2005; Lloyd, Siebenmorgen, & Beers, 2000; Rohrer & Siebenmorgen, 2004), methanol (Aguilar-Garcia, Gavino, Baragaño-Mosqueda, Hevia, & Gavino, 2007; Chotimarkorn, Benjakul, & Silalai, 2008; Renuka Devi & Arumughan, 2007), acidic 80% methanol (Iqbal et al., 2005; Shen, Jin, Xiao, Lu, & Bao, 2009), isopropanol (Hu et al., 1996), and ethyl acetate (Renuka Devi & Arumughan, 2007). However, there have been few investigations clarifying the dependence of rice bran antioxidant compositions on solvent property during extraction. Accordingly, this study was to elucidate the influence of solvent property on the extract yield, total phenolic content, oryzanol content and tocol compositions of the extracts with methanol, ethyl acetate and hexane. The antioxidant activity of each extract was also analyzed, in relation to the phytochemical compositions.

2. Materials and methods

2.1. Rice material

Rice bran of TaiKung 9 (TK9), a *Japonica* rice cultivar hybrid from Japanese Koshihikari cultivar and popular as cooked rice in Taiwan, was collected during milling brown rice to polished rice with a degree of milling of 88% in Hung-Chang Rice Mill Factory, Tainan, Taiwan.

2.2. Stabilisation of rice bran

Rice bran stabilisation was carried out in a microwave oven, following the method of Malekian et al. (2000). Rice bran (100 g) packed in a polyethylene microwave-safe bag was heated in a preheated (120 °C, 3 min) microwave oven (2450 MHz, output power 550 W), followed by cooling at room temperature overnight. The heating–cooling process was repeated twice to ensure complete inactivation of endogenous lipase. The free fatty acid content of the stabilised rice bran was low (3.1–3.6% on dry bran basis), in contrast to the unstabilised bran (3.8% increasing to 18.4%), during 6-week storage at room temperature, as detected with the *m*-cresol purple titration method (Hoffpauir, Petty, & Guthrie, 1947). The stabilised bran was immediately used for solvent extraction.

2.3. Extraction of rice bran phytocompounds

Ten grams of stabilised rice bran were extracted with 100 ml of methanol (MeOH), ethyl acetate (EtOAc) or *n*-hexane at room temperature for 3 h under gentle stirring, followed by filtering through Whatman No.1 filter paper. The residue was re-extracted twice. The filtrates were then collected, vacuum dried in a rotary evaporator (50 °C), and weighed immediately. The extraction procedure was done in three replications for each of the extracts. The extraction yield was expressed as the weight percentage on dry rice bran basis. All extracts were stored in a sealed container at 4 °C for further analysis.

2.4. Total phenolic content measurement

The total phenolic content of the extract was measured with the Folin–Ciocalteau method as described by Taga, Miller, and Pratt (1984), using gallic acid as a standard. A 0.1 ml of the extract solution (1.0 mg/ml DMSO) was sampled into 2 ml of 2% Na_2CO_3 and mixed for 3 min. After adding 0.1 ml of 50% Folin–Ciocalteau reagent, the final mixture was left for 30 min before reading the absorbance at 750 nm (Hitachi U-2000, Tokyo, Japan). All measurements were conducted in triplicate and the data were expressed as g gallic acid equivalent (GAE) per kg of the extract, based on the calibration curve of gallic acid.

2.5. Oryzanol content determination

The content of oryzanols was detected on a reverse-phase HPLC system consisting of a Hitachi L-7100 pump, Hitachi L-7200 autosampler, Hitachi L-7420 UV detector, Hitachi D-7500 integrator (Tokyo, Japan), and C18 column (Nova Pak C18, 150 × 3.9 mm, Waters, Alliance Milford, MA). The mobile phase was the mixture of methanol, acetonitrile, dichloromethane and acetic acid (50:44:3:3 by volume) and eluted at a flow rate of 1.4 ml/min at ambient temperature (McBride & Evans, 1973). The detector wavelength was set at 330 nm. The injection volume for the sample was 50 μl. The data were produced in three replicates and in reference to the peak area-concentration calibration curve of oryzanol standards (Wako Pure Chemical Industries Ltd., Osaka, Japan).

2.6. Tocopherol and tocotrienol quantification

The reverse-phase HPLC conditions for quantifying tocopherols and tocotrienols were similar to those for the oryzanol content mentioned above, except that a Hitachi L-7480 fluorescence detector (Ex = 298 nm; Em = 328 nm), gradient mobile phase, and flow rate of 0.8 ml/min were applied instead. According to Rogers et al. (1993), the mobile phase acetonitrile–methanol–isopropanol–water mixture was initiated at 45:45:5:5 (by volume), programmed linearly to 50:45:5:0 for the first 10 min, and then maintained for a further 15 min before being returning to the initial condition. Total tocopherol or tocotrienol content was determined as the summation of their isomers (α, β, γ and δ) quantified from the peak area-concentration calibration curves of corresponding tocopherol or tocotrienol standards (Sigma Chemical Co., St Louis, MO and ChromaDex , Santa Ana, CA, USA, respectively), where β and γ isomers coeluted on a C18 column.

2.7. Inhibition on linoleic acid peroxidation

Following the suggestions of Mitsuda, Yasumoto, and Iwami (1966), rice bran extract (0.5 mg) dissolved in 0.5 ml of DMSO was mixed with linoleic acid (LA) emulsion (2.5 ml, 0.02 M, pH 7.0) and phosphate buffer (2.0 ml, 0.2 M, pH 7.0) in a test tube. The mixed solution was then incubated at 37 °C for 72 h for completing colour development rising from $FeCl_2$–thiocyanate interaction. The absorbance at 500 nm ($A_{500\ nm}$), an index of the peroxide value, of the resultant solution was then checked (Hitachi U-2000, Tokyo, Japan). Butylated hydroxyl anisole (BHA) was examined for reference. All data were means of triplicate analyses. The percentage of LA peroxidation inhibition was calculated as Eq. (1):

$$\text{Inhibition on LA peroxidation } (\%) = \left[1 - \left(A_{500\ nm,sample}/A_{500\ nm,control}\right)\right] \times 100 \quad (1)$$

2.8. Scavenging effect on DPPH radical

DPPH radical scavenging activity was determined using the method originally developed by Blois (1958). A portion (0.1 ml) of the extract solution (1.0 mg/ml DMSO) in a test tube was well mixed with 3.9 ml of methanol and 1.0 ml of α,α-diphenyl-β-picrylhydrazyl (DPPH) solution (1.0 mM in methanol). The mixture was kept at ambient temperature for 30 min prior to measurement of the absorbance at 517 nm ($A_{517\ nm}$). BHA was used as the reference. All measurements were done in triplicate. The scavenging effect was derived following Eq. (2):

$$\text{DPPH scavenging effect } (\%) = \left[1 - \left(A_{517\ nm,sample}/A_{517\ nm,control}\right)\right] \times 100 \quad (2)$$

2.9. Reducing power determination

According to the method of Oyaizu (1986), 5.0 ml of the extract solution (1.0 mg/ml DMSO) was mixed with 5.0 ml of phosphate buffer (0.2 M, pH 6.6) and 5.0 ml of 1.0% potassium ferricyanide. The mixture was incubated at 50 °C for 20 min, followed by adding 5.0 ml 10% trichloroacetic acid and centrifugation. A portion of the supernatant (5.0 ml) was mixed with 5.0 ml water and 1.0 ml 1% ferric chloride. The absorbance at 700 nm ($A_{700\ nm}$), indicative of the reducing power, was recorded on the final mixture. All data were run in triplicate and compared with BHA reference.

2.10. Metal chelating activity

The method of Decker and Welch (1990) was applied with modifications in preparation of the sample solution. A portion of the extract solution (1 mg/ml DMSO, 0.2 ml) was added to a solution of 2 mM $FeCl_2$ (0.1 ml), followed by adding 5 mM ferrozine (0.2 ml). The mixture was stirred vigorously and left standing at room temperature for 10 min for equilibrium, and finally measured its absorbance at 562 nm ($A_{562\ nm}$) indicating the level of ferrozine–Fe^{2+} complex. All tests were run in triplicate. The metal chelating activity was calculated according to Eq. (3), using disodium ethylenediaminetetracetate (Na_2EDTA) as standard and expressing as EDTA equivalent (EDTAE, ug/g).

$$\text{Metal chelating activity } (\%) = \left[1 - \left(A_{562\ nm,sample}/A_{562\ nm,control}\right)\right] \times 100 \quad (3)$$

2.11. Statistical analyses

Analysis of variance (ANOVA) and Duncan's multiple range tests among data were carried out using the Statistical Analysis System software (v 8.2, SAS Institute Inc., Cary, NC).

3. Results and discussion

3.1. Yield and phytochemical profile of rice bran extracts

Table 1 indicates that the yield of the rice bran extracts significantly varied with the solvents applied, in the order of MeOH (16.3%) > EtOAc (12.9%) > hexane (7.85%). For the extract compositions, the total phenolic content was significantly greater for the EtOAc extract (~20 g GAE/kg extract) than for the MeOH and hexane (~15 g GAE/kg extract). The oryzanol content was similar for both EtOAc and hexane extracts (13–14 g/kg extract), higher than the MeOH (9.8 g/kg extract). Both total tocopherol (T) and tocotrienol (T3) contents in the extracts were EtOAc > MeOH >> hexane and predominated with β + γ-isomers rather than α- and δ-isomers, regardless of the solvents used. However, if the extraction efficiency on a rice bran weight basis (data in parenthesis) was concerned, both MeOH and EtOAc exhibited comparably high extraction efficiencies in total phenolic substances (~2.5 g GAE/kg bran), oryzanols (1.6–1.8 g/kg bran), and tocols (126–130 mg/kg bran; 93–99 and 31–33 mg/kg bran for T and T3, respectively), in contrast to hexane.

Generally, the yield of MeOH extract in this study was similar to the reported values (~16%) for the MeOH extract at RT for 3 days (Akihisa et al., 2000) and Drew rice bran hexane extract using an accelerated solvent extractor (10.3 MPa, 50 °C, 30 min) (Rohrer & Siebenmorgen, 2004). It was 2-folds of the hexane extract at ambient temperature (this study) but is lower than those (17–21%) of hexane or isopropanol extracts at an elevated temperature (40–60 °C) (Hu et al., 1996; Kim, 2005; Shin & Godber, 1996). These results are higher by 12–17% than those for defatted rice bran (Renuka Devi & Arumughan, 2007).

The total phenolic contents for TK9 rice bran extracts (1.2–2.5 g GAE/kg bran) are close to that reported for Thailand long-grain (LG) rice bran with MeOH at RT for 12 h (2.2–3.2 g GAE/kg bran) (Chotimarkorn et al., 2008) and the rice flour extracts from 481 China rice cultivars with acidic MeOH at RT for 24 h (1.1–2.5 g GAE/kg flour) (Shen et al., 2009). They are in the range between those reported for Pakistan rice bran extract with acidic 80% MeOH at RT for 3 h (2.5–3.6 g GAE/kg bran) (Iqbal et al., 2005) and Venezuelan rice bran extract with MeOH at RT for 3 min (1.1–1.2 g GAE/kg bran) (Aguilar-Garcia et al., 2007). These results are certainly lower than the pigment rice bran extracts with MeOH at RT for 17 h (8–45 g GAE/kg bran) (Goffman & Bergman, 2004).

3.2. Antioxidant activity of rice bran extracts

Fig. 1 demonstrates that, at the concentration examined (1.0 mg/ml), a general tendency of MeOH extract > EtOAc extract > hexane extract was found for inhibition on linoleic acid (LA) peroxidation (Fig. 1A), DPPH scavenging activity (Fig. 1B), reducing power (Fig. 1C), and metal (Fe^{2+}) chelating activity (Fig. 1D), where the MeOH and EtOAc extracts displayed statistically similar inhibition capability on LA peroxidation. The antioxidant activity of the MeOH extract was the most promising among the extracts examined, accounting for ~57%, 93%, and 78% of BHA in inhibition on LA peroxidation, DPPH scavenging activity, and reducing power, respectively.

The reason for that MeOH extract had superior antioxidant activities to the EtOAc, which exhibited a comparatively greater amount of the antioxidant compositions, may be explained by the possibility of more polar phenolic compounds and lipids in the MeOH extract than in the EtOAc. Chlorogenic acid (Ohnishi et al., 1994), caffeic acid, hydroxycinnamic acid (Chen & Ho, 1997), and anthocyanes (Iqbal et al., 2005) may also contribute to the total polyphenol content and antioxidant activities. Besides, α-tocopherol has been found to show a DPPH radical scavenging

Table 1
Yields and antioxidant compositions of the extracts from TK9 rice bran with various solvents.

Composition[A]	Type (unit)	MeOH	EtOAc	Hexane
Extract yield	(%, w/w)	$16.27 \pm 1.55^{a,B}$	12.91 ± 1.33^{b}	7.85 ± 0.88^{c}
Total phenolic content	(g GAE/kg)	15.7 ± 0.6^{b} (2.55 ± 0.10^{a})[C]	19.7 ± 0.8^{a} (2.54 ± 0.10^{a})	14.7 ± 1.2^{b} (1.15 ± 0.09^{b})
Oryzanol	(g/kg)	9.8 ± 0.4^{b} (1.60 ± 0.07^{a})	13.8 ± 0.9^{a} (1.78 ± 0.11^{a})	13.1 ± 0.5^{a} (1.03 ± 0.04^{b})
Tocopherol (T)	α (mg/kg)	46 ± 9^{a}	48 ± 4^{a}	18 ± 6^{b}
	β + γ (mg/kg)	509 ± 10^{b}	662 ± 24^{a}	115 ± 23^{c}
	δ (mg/kg)	18 ± 0^{b}	60 ± 2^{a}	63 ± 5^{a}
	Total T (mg/kg)[D]	573 ± 13^{b} (93 ± 9^{a})	770 ± 24^{a} (99 ± 10^{a})	196 ± 24^{c} (15 ± 2^{b})
Tocotrienol (T3)	α (mg/kg)	26 ± 4^{b}	83 ± 4^{a}	ND[E]
	β + γ (mg/kg)	151 ± 3^{a}	136 ± 5^{b}	16 ± 1^{c}
	δ (mg/kg)	25 ± 1^{a}	18 ± 1^{b}	1 ± 0^{c}
	Total T3 (mg/kg)[D]	202 ± 5^{b} (33 ± 3^{a})	237 ± 6^{a} (31 ± 3^{a})	17 ± 1^{c} (1 ± 0^{b})
Total tocols (T + T3)	(mg/kg)	775 ± 14^{b} (126 ± 9^{a})	1007 ± 25^{a} (130 ± 10^{a})	213 ± 24^{c} (16 ± 2^{b})

[A] Extract yields are on a dry weight basis of rice bran; all chemical compositions except in parenthesis are on a dry weight basis of the extract.
[B] Means ± standard deviations ($n = 3$); means followed by different letters in the same row differ significantly ($P < 0.05$).
[C] Data in parentheses are on a dry weight basis of rice bran.
[D] Sum of α, β, γ, and δ-isomer contents.
[E] Not detectable.

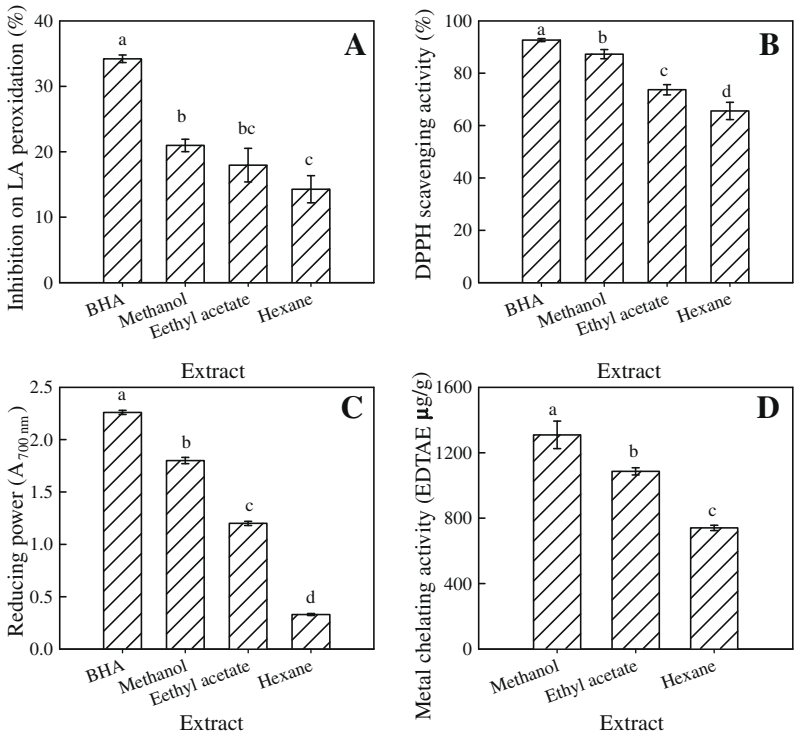

Fig. 1. Antioxidant activities of rice bran extracts (A: inhibition on linoleic acid peroxidation; B: DPPH radical scavenging activity; C: reducing power; D: metal chelating activity). Values are expressed as means of three replicates ± standard deviations; means indicated with different letters differ significantly.

capability high up to ~7-folds of those does γ-oryzanol (Juliano, Cossu, Alamanni, & Piu, 2005). However, a great antioxidant activity for oryzanol as 10-folds of tocopherols in different biological systems is also reported (Abdel-Aal & Hucl, 1999). Comparatively, the DPPH radical scavenging ability of the MeOH in this study is higher than the MeOH extract from oat groat (Sun, Xu, Godber, & Prinyawiwatkul, 2006). The Fe^{2+} chelating abilities (0.06–0.21 EDTAE mg/g bran) of all extracts in this study are less than those of Pakistan rice bran extract with 80% MeOH (0.61–0.72 EDTAE mg/g bran) (Iqbal et al., 2005).

Table 2
Antioxidant compositions of rice bran extracts with respect to the rice source and extraction conditions reported.

No	Rice bran source[a]	Extractioncondition	Oryzanol	Tocol composition				Reference
			Content (g/kg bran)	Total (mg/kg bran)	T%	T isomer α:(β+γ):δ	T3 isomer α:(β+γ):δ

3.3. Factors influencing the phytochemical compositions of rice bran extracts

For the oryzanol and tocol compositions of rice bran, the data in this study and that reported for rice bran extracts are compared in Table 2, in order to understand the variations with rice source, extraction condition, and other factors to the extent as great as possible. Briefly, the MeOH extracts from rice cultivars of Taiwan (#1), Venezuelan (#2), Pakistan (#3) and Thailand (#5) showed a lower oryzanol content in rice bran than those of US rice (#4). This implies that the cultivation environment is important for the oryzanol content, as reported for southern US rice (Bergman & Xu, 2003), since many diverse rice cultivars (including MG and LG rice) and a wide extraction period (3 min–12 h) have been studied in these reports. Besides, the MeOH extracts possessed a diverse tocol content in the order of Pakistan MG rice (#3) and Thailand LG rice (#5) (756–1230 mg/kg bran) > US LG and MG rice (#4) > Venezuelan rice (#2) > Taiwan rice (#1) and T% in tocols varying from 21% to 28% (#2) to >70% (#1 and parts of #5).

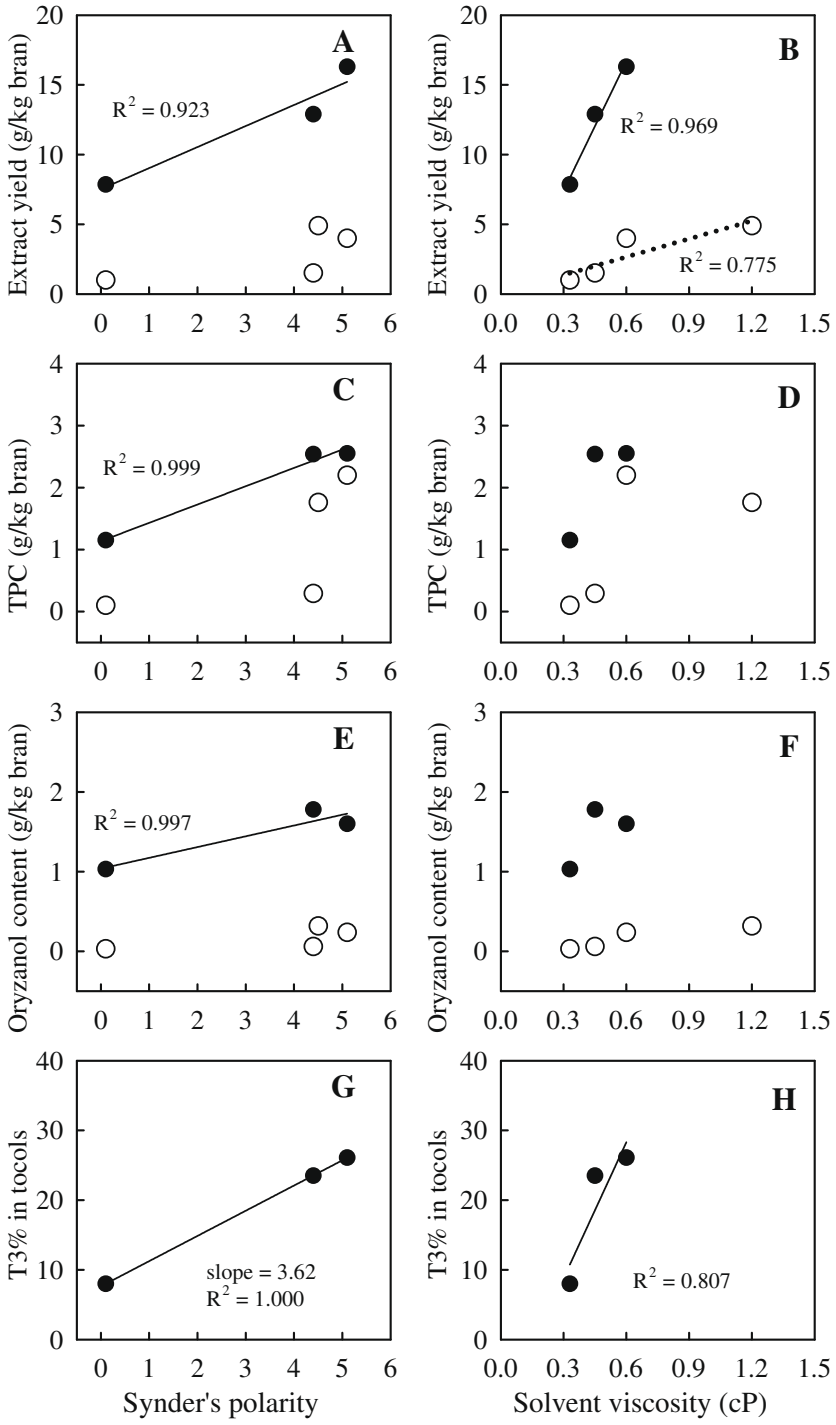

Fig. 2. Effects of solvent polarity and viscosity on the yield, total phenolic content (TPC), oryzanol content and tocotrienol (T3) percentage in tocols of TK9 rice bran extracts (filled circle), in comparison to defatted rice bran extracts (Renuka Devi and Arumughan, 2007) (open circle). R^2 values are the regression coefficients by the least-squared fits.

In contrast to the MeOH extract at RT (#1) (Table 2), applying hexane instead (#6) resulted in a noticeably reduced content in oryzanol and total tocols, lower (β + γ)-T% in T, but greater T% in total tocols and (β + γ)-T3 isomer% in T3. These differences between MeOH and hexane are hardly perceivable for the US rice (#7, #8 vs. #4) including the same rice cultivars (e.g. Cypress, Bengal, and La-Grue) since warm hexane (60 °C) was employed. Nonetheless, comparison of #9 with #8 and #4 (based on the same rice cultivar Cypress) reveals that pressurised extraction (#9) promotes the yield of oryzanols and total tocols by about 2–4 and 3–5-folds, respectively, of the traditional hexane extraction (#4 and #8).

Regarding the T and T3 isomer distribution, it is conclusive from Table 2 that those extracts that predominated with α-T isomer in T composition are those from US rice with either MeOH (#4) or hexane (#8), the partial refined oil of South Korea rice bran (#10), and that reported by Shin and Godber (1996) (#11). The extracts from Taiwan *Japonica* rice with MeOH (#1) or hexane (#6), most of Thailand LG rice cultivars (#5), and parts of Venezuelan rice (#2) are mainly with γ- or β-T isomers in T composition. As to T3 isomer distribution, γ-, or β-T3 isomers are generally the majority for most of the extracts studied, except some of Thailand LG rice (#5) and US rice (#8).

For taking insight into the effects of solvent property on the yields and phytochemical compositions of rice bran extracts, three kinds of solvent polarity scales defined by Synder, Hildebrand and Reichardt, dielectric constants (Berthod, 1994), and solvent viscosity (Seidel, 2006) were evaluated. Synder's polarity values resemble those reported by Seidel (2006) and are developed based on both the solubility parameter and the eluting power of the solvent in thin-layer chromatography (Berthod, 1994). It is encouraging to find that the yield and major phytocompound compositions of rice bran extracts related very closely with Synder's polarity value, partly associated with solvent viscosity (Fig. 2), where hexane, EtOAc, MeOH, and ethanol possess a Synder's polarity value of 0.1, 4.4, 5.1, and 4.5 (Berthod, 1994) and viscosity of 0.33, 0.45, 0.60, and 1.2 cP (Seidel, 2006), respectively. Ethanol was compared herein for the reported defatted rice bran extracts using four solvents including ethanol (Renuka Devi & Arumughan, 2007). When on a rice bran basis, the extract yield (Fig. 2A), total phenolic content (TPC) (Fig. 2C), oryzanol content (Fig. 2E), and T3% in tocols (Fig. 2G) of the rice bran extracts in this study increased with increasing Synder's polarity value in a very good linearity (R^2 = 0.923–1.000), accompanying with a positive dependence on solvent viscosity especially for the yield and T3% in tocols (R^2 = 0.969 and 0.807, respectively). The variations for total tocol content (data not shown) were similar to those of oryzanol. The yield, TPC and oryzanol content for the extracts from defatted rice bran (Renuka Devi & Arumughan, 2007) also tended to increase with increasing Synder's polarity value and solvents viscosity, even that rice bran has been previously defatted and subject to Soxhlet extraction at an elevated temperature.

Generally, hexane is traditionally preferred for rice bran oil extraction for cost consideration (Orthoefer & Eastman, 2004). However, it is a worse solvent than MeOH, EtOAc, ethanol (in this study; Renuka Devi & Arumughan, 2007) and isopropanol (Chen & Bergman, 2005; Hu et al., 1996) for extracting antioxidative phytocompounds from rice bran. This can be attributed to the amphipathic characteristics of tocopherols, tocotrienols, or oryzanols, involving the methyl groups on a chroman ring and the hydroxyl groups on an aromatic ring of vitamin E homologs, or the carboxylic group on a ferulated moiety, long side chain, and methyl groups on a hydropyrano moiety and sterol of oryzanols (Chen & Bergman, 2005; Godber & Juliano, 2004). In addition to the extraction solvent, the other factors influencing the product composition and antioxidant activity may include stabilisation temperature for raw rice bran (Shin & Godber, 1996), oil refining treatment (Orthoefer & Eastman, 2004; Rogers et al., 1993), rice cultivars and milling time (Chen & Bergman, 2005; Godber & Juliano, 2004; Lloyd et al., 2000), and cultivated environment for rice (Bergman & Xu, 2003).

4. Conclusions

Extraction of antioxidant phytocompounds from non-defatted rice bran with MeOH and EtOAc produced the extracts of a significantly greater yield and total content in phenolic compounds, oryzanols, or tocols (either tocopherols or tocotrienols) than did those with hexane. The composition variations in the extracts could partly account for the high antioxidant activities of both MeOH and EtOAc extracts in inhibiting linoleic acid peroxidation, DPPH radical scavenging ability, reducing power, and metal chelating activity. Comparison with the data of rice bran antioxidant extracts from TK9 and the reported diverse rice cultivars illustrated some phytochemical differences between rice sources or cultivation environments, in addition to the effects of extraction conditions concerned. It is newly discovered that either extraction yield or the antioxidant compositions examined were basically interpretable by a linear function of Synder's polarity value of the solvents used. Further studies on the synergism of phenolic compounds or oryzanol and tocols are needed in the future, for developing rice bran phytocompounds with preferred antioxidant and physiological potential.

Analytical Methods

Multiresidue determination of tetracyclines, sulphonamides and chloramphenicol in bovine milk using HPLC-DAD

ABSTRACT

A high-performance liquid chromatographic method for the simultaneous determination of tetracycline, oxytetracycline, chlortetracycline, sulfamethazine, sulfaquinoxaline, sulfamethoxazole and chloramphenicol in milk has been developed. The determination of these antimicrobials was carried out using HPLC-DAD with a C_{18} hybrid column and gradient elution with a mobile phase composed of an aqueous phase of 0.075 mol L^{-1} sodium acetate, 0.035 mol L^{-1} calcium chloride and 0.025 mol L^{-1}sodium EDTA, pH 7 and an organic phase of methanol:acetonitrile, 75:25 v/v. Sample preparation involved protein precipitation followed by solid-phase extraction using a polymeric cartridge. The method was validated and applied for the analysis of pasteurised milk samples commercialised in Brazil. The limits of quantitation for all antimicrobials, with the exception of choramphenicol, were below the maximum residue limit, which indicates that the method is appropriate for the determination of these antimicrobials in milk.

1. Introduction

Antimicrobial agents are widely used in food of animal origin for therapy to treat diseases, to control and prevent infection and for growth promotion and production efficiency.

The presence of residues of antimicrobial agents in food of animal origin in excess of the established maximum residue limits (MRLs) indicates that good veterinary practices were not respected and may contribute to the generation of resistance to bacteria in humans; nevertheless, current evidence suggests that the risk is low. In milk, however, their presence may cause allergic reactions in sensitive individuals and may interfere with starter cultures for cheese and other dairy products (Schenk & Callery, 1998).

The sulphonamides, among them, sulfamethazine (SMZ), sulfaquinoxaline (SQX) and sulfamethoxazole (SMX) play an important role as effective chemotherapeutics of bacterial and protozoal diseases in veterinary medicine. The Committee for Veterinary Medicinal Products considers that a tissue MRL of 100 μg kg^{-1} of the original drug substance should be applied to all substances of the sulphonamide group. In addition, the combined residues of all sulphonamides in bovine milk should not exceed 100 μg kg^{-1} (EMEA, 2007).

The Joint FAO/WHO Expert Committee of Food Additives and Contaminants (JECFA), at its 50th Meeting in 1998, established a group acceptable daily intake (ADI) of 0–0.03 mg kg^{-1} body weight for the tetracyclines (oxytetracycline (OTC), tetracycline (TC) and chlortetracycline (CTC)), alone or in combination. The committee also recommended MRLs in milk of 100 μg L^{-1}. Tetracyclines, in particular chlortetracycline, have been routinely employed to prevent and treat mastitis in lactating dairy cows (JECFA, 1998).

Chloramphenicol (CLP) is a broad-spectrum antibiotic that is an effective therapeutic agent for the treatment of mastitis in cattle. Historically, epidemiological data suggested that the treatment of humans with chloramphenicol was associated with induction of blood dyscrasias. Due to the potential risk to human health posed by its residues in food the use of CLP is prohibited in food-producing animals destined for the human consumption in many countries, among them, the USA, Australia, Europe and Brazil. Due to the lack of toxicological data available, no ADI was established for CLP and, in consequence, no MRL could be attributed (JECFA, 2004).

In many regions of the world antimicrobial drug residues are known to be present in food (Ekuttan, Kang'ethe, Kimani, & Randolph, 2007; Helena, Zdenka, Ksenija, Andrej, & Vesna, 2007; Husam et al., 2007). Lack of a control can be attributed to the costs of analyses. In many instances this is beyond the reach of most low income countries. Helena et al. (2007), reported the presence of CLP in some samples of raw milk taken in the autumn of 2002 in Slovenia. Studies conducted in Kenya showed samples of milk to contain tetracyclines at levels exceeding the established MRL (Ekuttan, Kang'ethe, Kimani, & Randolph, 2007).

The governmental institution responsible for public health in Brazil (ANVISA, National Agency of Sanitary Surveillance) reported for the period 2004/2005 that 7% of the milk samples analyzed (312) showed to be positive in the screening test for the presence of tetracyclines, however none of them was confirmed by a chromatographic method. In addition, 7% of 306 milk samples analyzed indicated the presence of CLP, however the confirmatory test was not implemented at this time (ANVISA, 2006).

Thus, there is a need for countries to establish surveillance systems that allow for obtaining reliable data on veterinary antimicrobial usage. Therefore, it is necessary to establish simple, sensible and reliable analytical methods for the determination of multiresidues of different classes of antimicrobials in food and, in particular in milk.

The structures of the sulphonamides, tetracyclines and chloramphenicol used in veterinary medicine and evaluated in this work are shown in Fig. 1.

While rapid screening methods (immunological or microbial inhibition assays) are commonly used to detect the presence of antimicrobials in food, more accurate chromatographic methods are required by the governmental regulatory agencies to identify and confirm the presence of these compounds. Milk is consumed all over the world and its quality control is important to guarantee food safety.

Chromatographic methods require elaborate sample preparation procedures before quantitation in order to eliminate interferents from the food matrix and concentrate the analyte. The extent of sample preparation depends on the detection device of the chromatographic system. Conventional sample treatment protocols involve protein precipitation, centrifugation and analyte extraction, followed by clean-up of the extract over solid-phase cartridges and eluate concentration under a nitrogen flow. Alternatively, liquid–liquid extraction, combined or not with solid-phase extraction and matrix solid-phase extraction has been employed (Andersen et al., 2005; Bogialli et al., 2005; Furusawa, 2003; Schenk & Callery, 1998).

Many liquid chromatographic methods have been published for the determination of tetracyclines (Oka, Ito, & Matsumoto, 2000; Andersen et al., 2005), sulphonamides (Furusawa, 2000; Van Rhijn, Lasaroms, Berendsen, & Brinkman, 2002) and chloramphenicol (Long et al., 1999; Perez et al., 2002) in milk. However, almost all of them aim at the determination of antimicrobials of a single group. Simultaneous determination of multiresidues of antimicrobials of different groups has been carried out using liquid chromatography coupled to tandem mass spectrometry (Koesukwiwat, Jayanta, & Leepipatpiboon, 2007). Samanidou and Nisyriou (2008) presented a review of the state of the art in the analytical strategies concerning the multiresidue analysis of antibiotics in milk.

This paper focuses on the development and validation of a simple HPLC-DAD method for the simultaneous multiresidue determination of TC, CTC, OTC and SMZ, SQX, SMX and CLP in milk which could be applied to quality control in the routine analysis.

2. Materials and methods

2.1. Equipment

The HPLC-DAD measurements were carried out using a binary gradient chromatographic system from Waters (USA), model 1525, coupled to a Waters photodiode array detector (PDA) model 2996 and a Rheodyne injector, model 7725 (sample loop of 50 μL). Data acquisitions were performed by the Millenium^{32} 4.0 software.

For the solid-phase extraction procedures a 12 port vacuum manifold from Alltech (USA) was employed.

Measurements of pH were made with a DM-20 pH-meter from Digimed (Brazil), using a combined glass electrode.

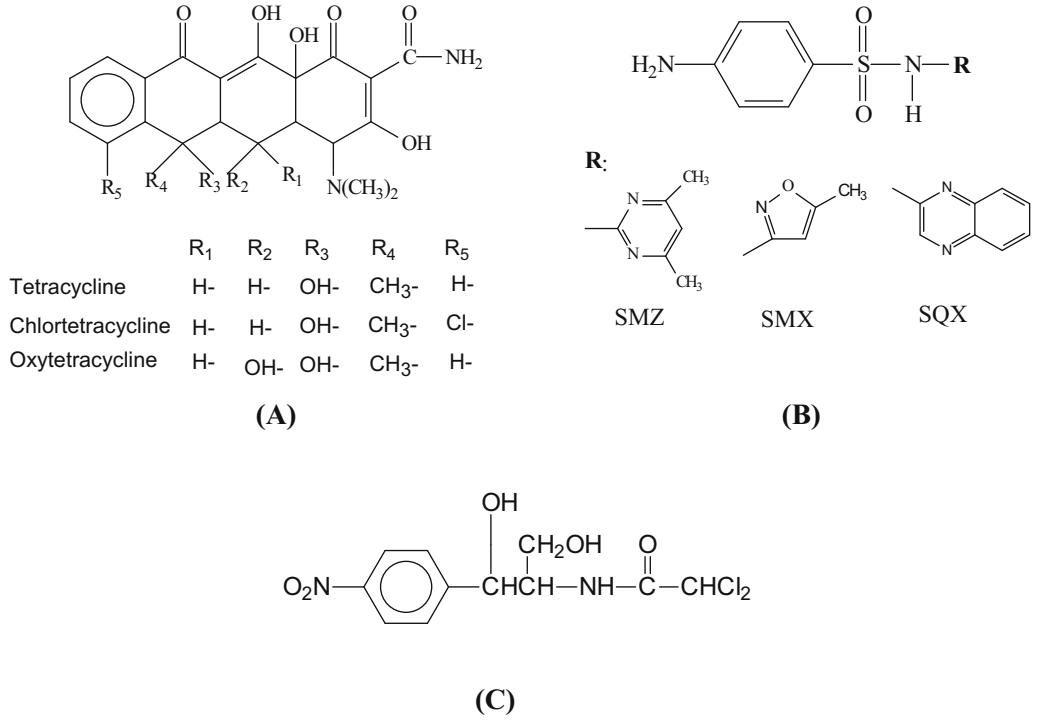

Fig. 1. Structures of (A) tetracyclines, (B) sulphonamides and (C) chloramphenicol.

2.2. Chromatographic columns and solid-phase extraction cartridges

The separation of the antimicrobials by HPLC was evaluated on the following chromatographic columns: (i) LiChrocart®, 125 x 4.6 mm, containing 5 μm LiChrospher® from Merck (Germany) with a guard column (6.0 x 4.0 mm, 5 μm) of the same stationary phase; (ii) X-Terra® C_{18} hybrid silica column (250 mm × 4.6 mm, 5 μm) from Waters (USA) with a guard column (4.0 x 4.6 mm, 5 μm) of the same stationary phase.

The solid-phase extraction procedures were carried out using endcapped octadecyl silica cartridges (500 mg, 3 mL, Waters, EUA) and polymeric cartridges (200 mg, 6 mL, OASIS HLB, Waters, EUA).

2.3. Standards and reagents

Tetracycline hydrochloride (92.6%) was purchased from Sigma (USA), while oxytetracycline dihydrate and chlortetracycline hydrochloride (99.8%) were purchased from ICN Biomedical Inc. (USA). Sulfamethazine (99%), sulfaquinoxaline (95%) and sulfamethoxazole (99.7%) were purchased from Sigma (USA) and chloramphenicol (99%) was purchased from ICN Biomedical Inc. (USA). Enrofloxacin (99.7%) was purchased from Fluka (Switzerland).

Analytical grade disodium hydrogenphosphate (sodium $HPO_4{\cdot}7H_2O$), sodium hydroxide, calcium chloride, sodium ethylenediaminetetraacetate (sodium EDTA), hydrochloride acid and phosphoric acid were purchased from Merck (Germany). Methanol and dimethylformamide, HPLC-grade solvents, were purchased from Tedia (USA). Citric acid was purchased from Nuclear (Brazil). Trichloroacetic acid (TCA) and sodium acetate were purchased from Sigma (USA) and J.T. Baker (USA), respectively.

Throughout the study, water was obtained from a Milli-Q system from Millipore (USA). Before the HPLC analysis, all the solutions were filtered through 0.45 μm membrane filters from Millipore (Brazil).

The mobile phase was composed of an aqueous phase (AP) (0.075 mol L^{-1} sodium acetate, 0.035 mol L^{-1} calcium chloride and 0.025 mol L^{-1} sodium EDTA, pH 7) and an organic phase (methanol:acetonitrile, 75:25 v/v), with gradient elution. The pH of the aqueous phase was adjusted with 3 mol L^{-1} ammonium hydroxide or 3 mol L^{-1} hydrochloric acid.

2.4. Standard solutions

Standard stock solutions of TC, OTC, CTC, SMZ. SMX, SQX and CLP were prepared by dilution of appropriate volumes of the standards in methanol to a final concentration of 1.0 mg mL^{-1}. These solutions were stored under refrigeration (−18 °C) until use. Working solutions in the concentration range of 50 μg mL^{-1} were prepared daily by dilution of aliquots of the standard stock solution in water. The working solution was used directly for sample fortification to produce calibration standards of 50, 100, 200, 300 and 500 ng mL^{-1} concentrations. The sodium EDTA-McIlvaine buffer was prepared as previously described (Pena, Lino, & Silveira, 1999) and stored at 4 °C. All the stock solutions were stable for a period of at least 90 days.

2.5. Milk samples

Sixteen samples of pasteurised whole bovine milk types A, B and C were purchased at retail markets in Campinas, São Paulo State, Brazil. All samples were acquired in 2006.

2.6. Sample preparation

A volume of 5 mL of the milk sample (blank sample or fortified sample) was apportioned into 50 mL polypropylene centrifuge tubes. The sample was added to 2.5 mL 30% TCA in methanol, sonicated for about 10 min and centrifuged for 10 min at 1000*g* at room temperature. The upper phase was transferred to another sample tube and the remaining solid was re-extracted with a second portion of 10 mL McIlvaine buffer, pH 4. Sample was again sonicated for 10 min and centrifuged at 1000*g* for 20 min. The extracts were combined and cleaned up over hydrophobic–lipophilic-balanced SPE cartridges (OASIS HLB, Waters USA) using a 12 port manifold under atmospheric pressure. The SPE cartridges were previously conditioned with 5 mL methanol, 10 mL acetonitrile and 5 mL McIlvaine buffer, pH 4. The sample extracts were applied and the cartridges were washed with 10 mL of a mixture of methanol, acetonitrile and McIlvaine buffer (6:7.5:86.5, v/v/v). The retained antimicrobials were eluted with 5 mL of methanol. The milk extracts obtained were concentrated to dryness at 35 °C under a nitrogen flow and the residue was dissolved in 500 μL of the aqueous phase of the chromatographic mobile phase which composed of 0.075 mol L^{-1} sodium acetate, 0.035 mol L^{-1} calcium chloride and 0.025 mol L^{-1} sodium EDTA, pH 7. After filtration through a 0.45 μm membrane filter (Millipore, Brazil) a volume of 50 μL was injected into the HPLC system.

2.7. HPLC analysis

Chromatographic separation of the antimicrobials on the octadecyl X Terra® column was achieved using a mobile phase containing an aqueous phase (AP) of 0.075 mol L^{-1} $CaCl_2$, 0.035 sodium acetate and sodium EDTA, pH 7.0 and an organic phase (OP) of methanol:acetonitrile (75:25, v/v). Gradient elution of 90:10 AP:OP v/v to 50:50 AP:OP v/v (0–30 min) then to 90:10 AP:OP v/v (30–37 min) was used. The flow rate was 0.7 mL min^{-1}.

Quantitation was performed through internal standardization at 265 nm (SMZ, SMX, SQX), 311 nm (ENRO and CLP) and 385 nm (TC, CTC, OTC). For this purpose blank milk samples were fortified at five concentration levels (50, 100, 200, 300 and 500 ng mL^{-1}), using 300 ng mL^{-1} ENRO as an internal standard.

2.8. Method validation

The method was validated using the following performance criteria: linearity and linear range, sensitivity, selectivity, intra-assay and inter-assay precision, accuracy, limit of detection (LOD) and limit of quantitation (LOQ). The linearity, linear range, sensitivity and LOD were established through the calibration curve obtained by triplicate analysis of SMZ, SMX, SQX, TC, CTC, OTC and CLP at five concentration levels (50, 100, 200, 300 and 500 ng mL^{-1}) in the milk matrix. The sensitivity is the slope of the calibration graph.

The selectivity of the method was evaluated by exposing SMZ, SMX, SQX, TC, CTC, OTC and CLP, at a concentration level of 1000 ng mL^{-1}, to the following stress conditions for 1 h: 0.1 mol L^{-1} HCl, 0.1 mol L^{-1} NaOH, 3% v/v H_2O_2 and temperature (55 °C). The solutions were analyzed considering the resolution between the analyte and other substances formed during the experiment and the analytical signal before and after the exposure of the analyte to the stress conditions, expressed as recovery.

The intra-assay precision of the method, expressed as the relative standard deviation (RSD) of peak area measurements ($n = 5$), was evaluated through the results obtained with the method operating over 1 day under the same conditions, using a blank milk sample fortified at a single concentration level of 200 ng mL^{-1}. The inter-assay precision was determined at two concentration levels, 100 and 200 ng mL^{-1}, and the analyses were performed for 5 days. According to the European Commission, Regulation 2002/657/EC, the RSD should be lower than 15%.

The accuracy of the method was determined through the recovery at three fortification levels (100, 200 and 300 ng mL^{-1}) in triplicate analyses. Enrofloxacin at a concentration of 300 ng $mL^{-1}$was used as internal standard. The European Communities guidelines recommend a recovery in the range of 80–110% of the target concentration (European Commission, Regulation 2002/657/EC).

The limit of detection (LOD) and limit of quantitation (LOQ) were determined at the signal-to-noise ratios of 3 and 10, respectively, measured at the approximate retention time of the corresponding analyte peak.

3. Results and discussion

3.1. HPLC-DAD method development

Initially, a silica-based octadecyl column (LiChrocart®) was employed for optimisation method and the mobile phase was prepared according to Houglum and Larson (1997), for the quantitation of chlortetracycline in animal feeds by HPLC with fluorescence detection.

The main aim was the separation of the seven antimicrobials from three different classes in a single run, using a photodiode array detector and measuring each analyte in its best detection condition, i.e. maximum absorption wavelength. The optimum wavelengths are: 260 nm (SMZ, SQX and SMX), 311 nm (CLP) and 385 nm (OTC, TC and CTC). Minocycline (MC) was initially evaluated as internal standard, however enrofloxacin (ENRO) was later employed for this purpose due to the fact that this antimicrobial did not elute at the same time as other components did from the milk matrix and it is not recommended for application to dairy animals.

When the silica-based octadecyl stationary phase column was employed with a mobile phase containing an aqueous phase (AP): 0.075 mol L^{-1} sodium acetate, 0.035 mol L^{-1} $CaCl_2$, 0.025 mol L^{-1} sodium EDTA, pH 7 and an organic phase (OP): MeOH:ACN 65:35 v/v, it was possible to separate SMZ, SQX, SMX, TC, CTC and CLP with adequate resolution. However, the tetracyclines, especially OTC, showed broad peaks with inadequate asymmetry factors. The poor peak shape of the tetracyclines could be explained due to the residual acidic silanols in the stationary phase of the silica-based octadecyl column.

To overcome this limitation a hybrid octadecyl column (X Terra®) and different organic phases (MeOH:ACN 65:35, 75:25 and 80:20 v/v) were evaluated. The aqueous phase was the same as described before and the separation was conducted using gradient elution. The use of the hybrid octadecyl column and 75:25 v/v MeOH:ACN in the organic phase of the mobile phase resulted in adequate efficiency and selectivity for the separation of the antimicrobials under study (Fig. 2).

Co-elution of SMZ with TC was observed using 65:35 and 80:20 v/v MeOH:ACN as organic phase. At pH 7 the sulphonamides ($pK_a \approx 5.5$) are in their anionic form, which is the reason for their lower retention times due to their lesser interaction with the apolar stationary phase in comparison with tetracyclines, which will be mainly in their zwitterionic form. CLP is the last compound eluted from the chromatographic column. This is attributed to its non-ionic form at pH 7 (pK_a 11) and to their lipophilic property. The system suitability parameters are in the acceptable range: retention factor ($1 < k$), plates ($N > 2000$) and resolution ($Rs > 2.0$) (EC, 2002).

3.2. Extraction of the antibiotics from milk

Due to the different chemical structures and physicochemical properties of the antimicrobials under study the establishment of a unique sample preparation procedure is a difficult task and therefore all steps must be carefully evaluated. The main experimental steps evaluated were: protein precipitation, extraction, clean-up using solid-phase cartridges and concentration of the eluate.

For protein precipitation different solutions have been recommended in the literature for the determination of tetracyclines in milk: succinic acid (Andersen et al., 2005), ACN (Fletouris, Psomas, & Botsoglou, 1990), 1 mol L^{-1} hydrochloric acid (Moats & Harik-Kahn, 1995; Zhao, Zhang, & Gan, 2004) and McIlvaine buffer/EDTA (Abete, Genta, & Squadrone, 1997; Brandsteterova et al., 1997) and for sulphonamides: ACN (Van Rhijn et al., 2002) and 20% TCA (Furusawa, 1999). The procedures have not been harmonised for the same antimicrobial group and considering that compounds from three different groups would be evaluated in this work, protein precipitation conditions were studied. The solutions evaluated were: McIlvaine buffer/EDTA, 1 mol L^{-1} hydrochloric acid, ACN and 20% and 30% TCA in MeOH. For these studies fortified blank milk samples (1000 ng mL^{-1}) were employed. Before HPLC quantitation, the extracts obtained after protein precipitation were cleaned up using octadecyl silica-based cartridges. As wash solution 10 mL of 97:3 v/v McIlvaine buffer, pH 4:MeOH was employed. The analytes were eluted with 5 mL MeOH and concentrated under N_2 flow. The residues were reconstituted in 1.0 mL of mobile phase before injecting into the HPLC system.

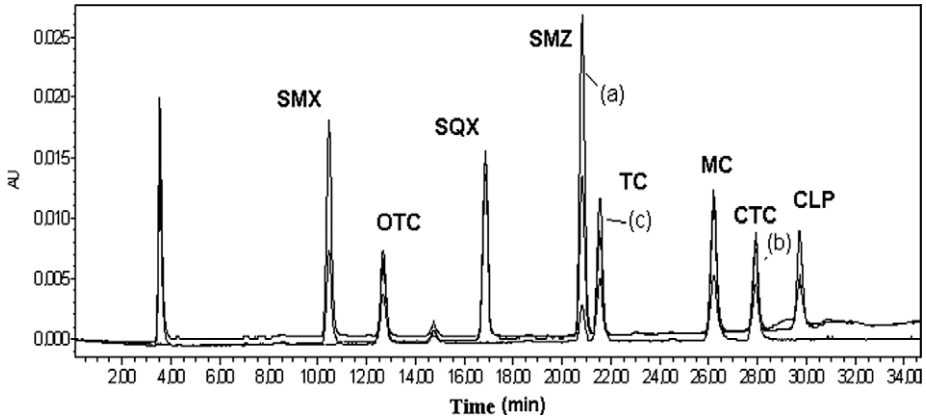

Fig. 2. Chromatogram of SMX = sulfametoxazole, OTC = oxytetracycline, SQX = sulfaquinoxaline, SMZ = sulfamethazine, TC = tetracycline, MC = minocycline, CLP = chloramphenicol and CTC = chlortetracycline (1000 ng mL^{-1}) on a hybrid-polymeric column. Mobile phase, aqueous phase (AP): sodium acetate 0.075 mol L^{-1}, $CaCl_2$ 0.035 mol L^{-1}, Na_2EDTA 0.025 mol L^{-1}, pH 7 and organic phase (OP): MeOH:ACN 75:25 v/v. Gradient elution: AP:OP 90:10 v/v – 50:50 AP:OP v/v (0–30 min); AP:OP 90:10 v/v (30–37 min). Flow rate: 0.7 mL min^{-1}. λ: 250 nm (a), 278 nm (b) and 385 nm (c).

All solutions, with exception of the TCA, did not result in complete protein precipitation and the chromatograms obtained with the fortified blank milk samples showed a large number of interferents and/or low recoveries of the analytes. Using McIlvaine buffer/EDTA a suspension was obtained even after centrifugation indicating an incomplete protein precipitation. Among all protein precipitation solutions evaluated the best results for all compounds under study were obtained with TCA in MeOH. Even then, 20% TCA in MeOH gave low recoveries of the antimicrobials. The use of 30% TCA in MeOH provides adequate protein precipitation with better recoveries than those obtained with 20% TCA. However, some interferents were not eliminated and some compounds were co-eluted with SMZ and CLP. To overcome these problems, different SPE-cartridges (octadecyl silica-based, endcapped octadecyl silica and copolymer OASIS HLB) were evaluated for clean-up. In addition, a liquid–liquid extraction (LLE) with n-hexane after protein precipitation and before SPE clean-up with octadecyl silica-based cartridges, in order to eliminate some interferents, was also evaluated. The results are summarised in Table 1. The LLE with hexane, before clean-up on the silica-based octadecyl sorbent, showed an increase in the extraction efficiency for all antimicrobials, with the exception of OTC, which was not recovered. It is well known that basic compounds (e.g. OTC) interact with the acidic residual silanols from silica-based octadecyl sorbents. Due to this fact, octadecyl endcapped and copolymer OASIS HLB were evaluated and the results are also presented at Table 1. It was verified that the OASIS HLB allowed higher recovery values and lower interferences near the retention time of each analyte.

Table 1
Average ($n = 2$) extraction efficiency (%) using different SPE sorbents.

Compound	Extraction efficiency[a] (%)			
	C_{18}	LLE[b]+C_{18}	C_{18} endcapped	OASIS HLB
SMX	67	64	52	59
SQX	54	52	10	60
SMZ	45	47	26	21

CLP	70	72	66	80

[a] The extraction efficiency was calculated from the recovery of the analyte in the fortified blank milk sample (100 ng mL^{-1}) in relation to the same concentration of the standard in the solvent (analytical curve with internal standard).
[b] LLE with n-hexane.

Table 2
Average ($n = 2$) extraction efficiency (%) using OASIS HLB cartridges and different washing solutions.

Antimicrobial	Extraction efficiency[a] (%)	
	MeOH:ACN:buffer[b]	ACN:buffer
	3:7:90 v/v/v	8:92 v/v
SMX	64	22
SQX	48	52
SMZ	19	25
OTC	80	63
TC	64	62
CTC	61	58
ENRO	90	88
CLP	89	85

[a] The extraction efficiency was calculated from the recovery of the analyte in the fortified blank milk sample (100 ng mL^{-1}) in relation to the same concentration of the standard in the solvent (analytical curve with internal standard).
[b] McIlvaine buffer, pH 4.0.

In order to increase the recovery of the antimicrobial residues and to diminish the interference the washing step of the cartridge was evaluated. SMZ showed to be the compound most susceptible to the effect of the organic solvent in the washing step (Table 2).

The use of the ACN in the elution step decreases the recoveries of the sulphonamides, because this solvent is less polar than methanol. A mixture of MeOH and ACN in the proportion MeOH:ACN:-buffer 6:7.5:86.5 v/v/v, was adequate for antimicrobial recoveries.

The results indicated that it was not possible to establish a single condition that allowed high recoveries for all the antimicrobials, using one SPE cartridge for extraction in the clean-up step. Thus, the best compromise between recovery and time of analysis was reached using the procedure described in Section 2.6.

3.3. Method validation

The HPLC-DAD method was *in-house* validated for the determination of the tetracyclines, sulphonamides and chloramphenicol by evaluating the following parameters: selectivity, linear range, linearity, sensitivity, intra- and inter-assay precision, accuracy, limit of detection and limit of quantitation. The results are summarised in Table 3.

Selectivity indicates the ability of the method to accurately measure the analyte response in the presence of potentially interfering sample components or degradation products. In this study selectivity was evaluated by exposing the analytes to stress conditions, such as 0.1 mol L^{-1} HCl, 0.1 mol L^{-1} NaOH and 3% v/v H_2O_2. The solutions were analyzed considering the resolution between the analyte and other substances formed during the experiment and the analytical signal before and after the exposure of the analyte to the stress conditions. Co-migration of degradation products

Table 3
Validation parameters for the HPLC-DAD method developed for the determination of SMX, SQX, SMZ, CLP, OTC, TC and CTC in milk.

Parameter	SMX	SQX	SMZ	CLP	OTC	TC	CTC
Linear range (ng mL^{-1})	60–500	60–500	60–500	60–500	60–500	60–500	60–500
Sensitivity (ua mL ng^{-1})	0.0058	0.0072	0.0020	0.0012	0.0027	0.0034	0.0019
Linearity (r)	0.998	0.996	0.995	0.998	0.996	0.995	0.992
Linear coefficient	−0.019	−0.174	−0.067	−0.014	0.090	0.053	0.022
Intra-assay precision ($n = 5$) (RSD%) 200 ng mL^{-1}	6.5	3.9	3.1	2.6	3.9	4.9	2.7
Inter-assay precision ($n = 5$) (RSD%)							
100 ng mL^{-1}	8.1	5.4	13.2	7.4	15.8	6.4	6.0
200 ng mL^{-1}	4.8	9.0	7.1	7.3	14.6	10.0	7.1
300 ng mL^{-1}	12.5	7.6	15.6	8.3	5.4	10.0	12.7
LOD (ng mL^{-1})	20	20	20	20	20	20	20
LOQ (ng mL^{-1})	60	60	60	60	60	60	60
Accuracy, ($n = 5$) recovery/s (%)							
100 ng mL^{-1}	108/8	104/4	103/10	109/7	92/14	112/6	103/6
200 ng mL^{-1}	99/4	110/8	101/7	102/10	100/2	106/7	107/6
300 ng mL^{-1}	104/11	106/7	107/14	101/7	93/5	83/8	100/12

RSD: relative standard deviation, LOD: limit of detection, LOQ: limit of quantitation, s: estimated standard deviation.

was not observed due to the fact that peak purity for each analyte was confirmed by the overlay of the spectra before and after degradation process. It was verified that the stability of the tetracyclines depends on their chemical structure. Under the three stressing conditions, CTC and CLP were the least stable compounds to alkaline treatment and OTC was the least stable to acid and oxi-

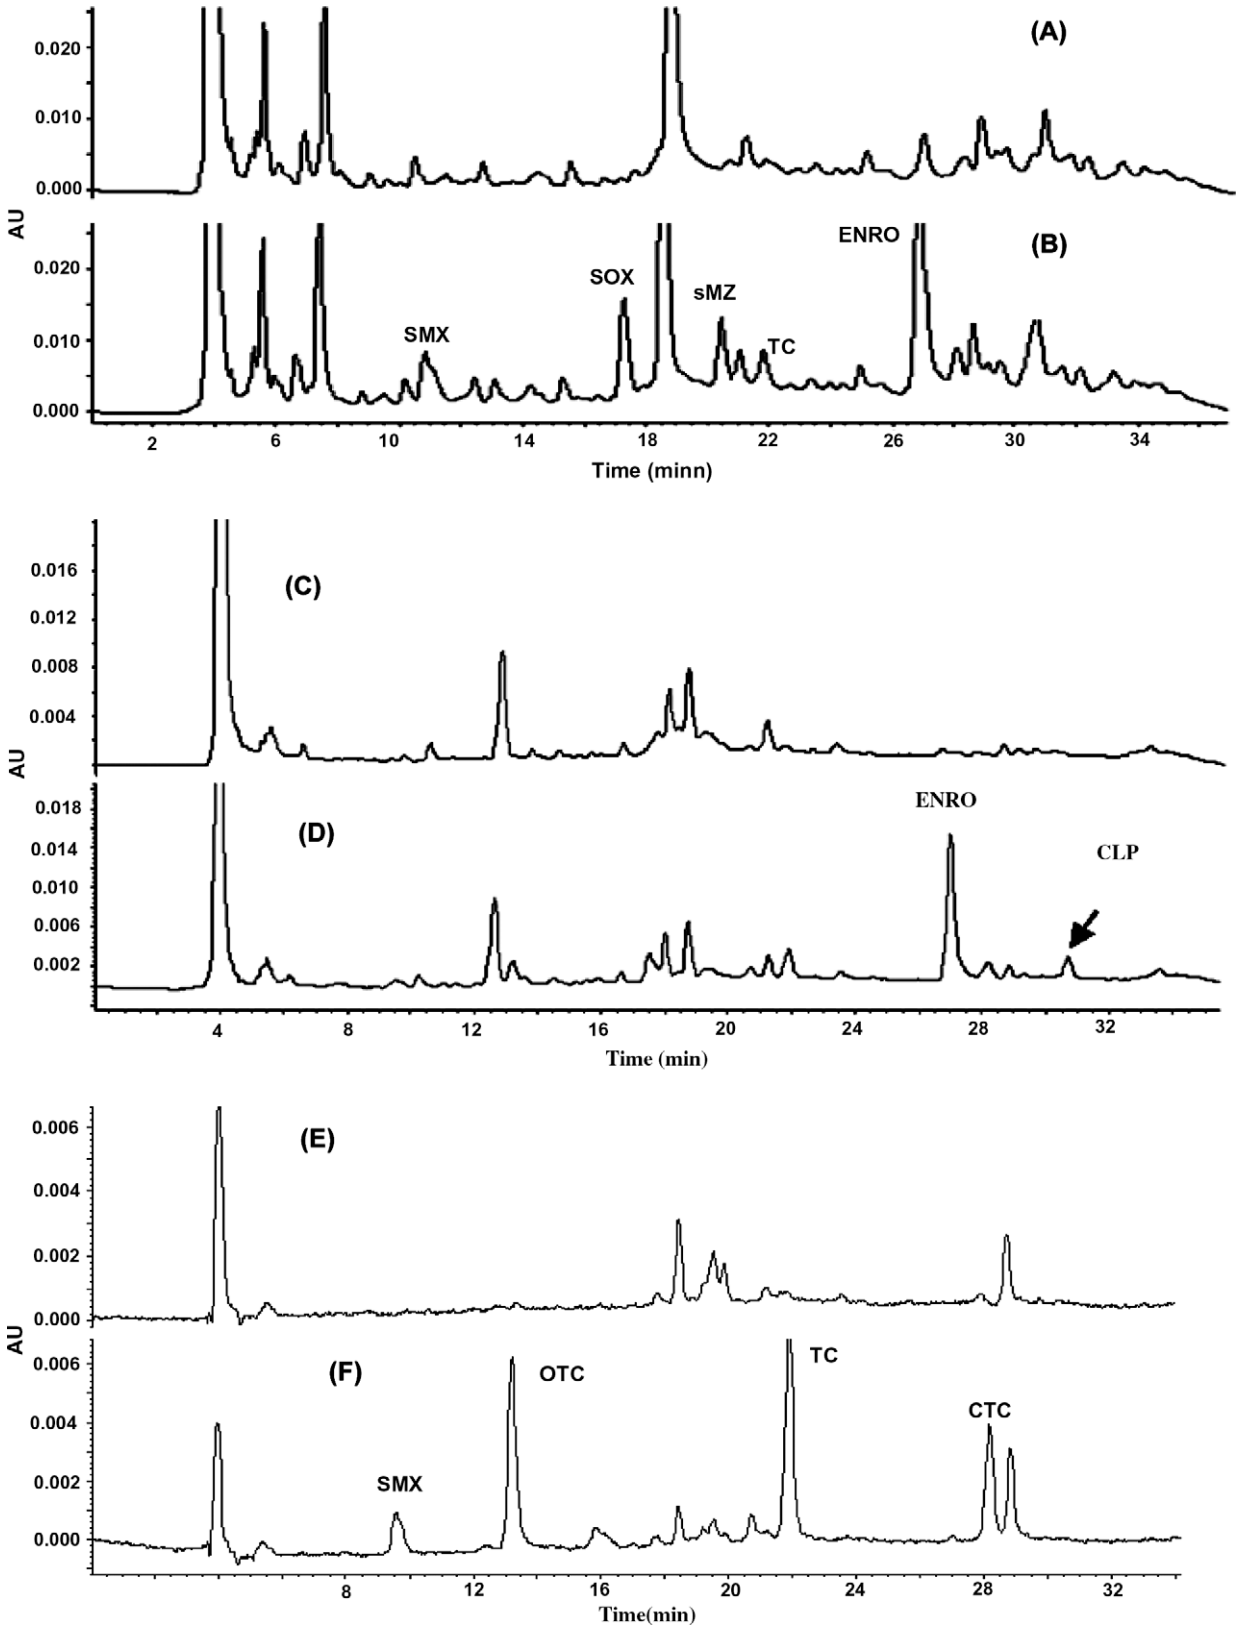

Fig. 3. Chromatograms: (A) blank milk sample, detection λ: 265 nm; (B) blank milk sample fortified, detection λ: 265 nm; (C) blank milk sample, detection λ: 311 nm; (D) blank milk sample fortified, detection λ: 311 nm; (E) blank milk sample, detection λ: 385 nm; (F) blank milk sample fortified, detection λ: 385 nm. Fortification level: 100 ng mL^{-1} of SMX, SQX, SMZ, CLP, OTC, TC, CTC and 300 ng mL^{-1} of ENRO (internal standard).

dant media. The sulphonamides were more stable under the evaluated stress conditions. Even though some degradation products under the evaluated stress conditions are formed, they present retention times different from the analytes and, in consequence, they do not affect the selectivity method.

Endogenous interferences were also appraised. For this purpose five blank milk samples were analyzed. Characteristic chromatograms from blank milk samples registered at the three different wavelengths (265 nm, 311 nm and 385 nm) are presented in Fig. 3A–F. The chromatogram shown in Fig. 3A, obtained at 265 nm, shows the presence of peaks near to the retention times of SMX (t_R 10.8 min), SQX (t_R 17.3 min) and SMZ (t_R 20.5 min). However, none of them have any effect on the accuracy of the method, since the recoveries were in the range of 96–108%.

At 311 nm, no potential interference was observed for the signal of ENRO (internal standard) and CLP, since all the compounds from the milk matrix eluted at lower retention times (Fig. 3C and D). At 385 nm, even though some compounds eluted in the range of 18–20 min and 29 min, these compounds did not interfere in the tetracycline determinations (Fig. 3E and F).

Due to the fact that no potential interference was detected in the blank samples at the retention time of each analyte, it could be concluded that the method developed presents adequate selectivity for the determination of the antimicrobials.

The linearity, linear range and sensitivity were obtained from calibration graphs using an internal standard (ENRO, 300 ng mL^{-1}) and fortifying blank milk samples at five concentration levels (60, 100, 200, 300 and 500 ng mL^{-1}) for each analyte under study, with triplicate analyses. The linearity was tested using a pure error lack of fit test with simple regression, which was not significant at the 5% level.

The precision of the method was evaluated using the results obtained over 1 day of operation under the same conditions (intra-assay) and during 5 days (inter-assay precision). The intra-assay precision was evaluated by means of analysis in one single day with five blank milk samples fortified at 200 ng mL^{-1}. The RSD for all the antimicrobials studied (TC, CTC, OTC, SMZ, SQX, SMX and CLP) was in the range of 2.6–6.5%. The inter-assay precision was evaluated through the analysis, during five different days, of fortified blank milk samples at three concentration levels (100, 200 and 300 ng mL^{-1}). The inter-assay precision (RSD) was in the range of 4.8–15.8% (Table 3). Considering that the European Commission Decision 2002/657/EC, 2002 (European Commission, 2002) recommends that the inter-assay precision should be lower than 23%, the values obtained by the proposed HPLC method are adequate.

The accuracy of the method was assessed by recovery tests, analyzing fortified blank milk samples at three concentration levels (100, 200 and 300 ng mL^{-1}) over 5 days. The results are presented at Table 3. The recovery varied from 83% to 112% and is in accordance with the EU guidelines, which established a range of 80–120% for these concentration levels (EC, 2002).

The limit of detection (LOD) and limit of quantitation (LOQ) were determined at a signal-to-noise ratio of 3 and 10, respectively, measured at the approximate retention times of the corresponding analyte peaks. These values were validated by the analyses of fortified samples with these values. The LOD for all antimicrobials was similar, i.e. 20 ng mL^{-1}. The quantification limit (LOQ) is the lowest concentration of an analyte in a sample that can be determined with acceptable precision and accuracy under the stated operational condition of the method. The LOQ was established at 60 ng mL^{-1} for all the antimicrobials and fulfils the requirement that this value must be lower than the MRL, with the exception of CLP. In the case of CLP residues in milk, as well as meat, eggs, aquaculture products and honey, the European Commission established a minimum required performance limit (MRPL) of 0.30 ng g^{-1} to ensure the same level of consumer protection throughout the community (EC, 2002). Considering this MRPL, the CLP LOQ value of the developed method (60 ng mL^{-1}) does not fulfil adequate detectability for the quality control. However, the required EC detectability might be possible using a LC–MS–MS system.

3.4. Analysis of commercial samples

In Brazil, fluid pasteurised bovine milk that is available to the consumers at the retail market is commercialised in three different categories (A, B and C). These categories differ in terms of total quality of the product (control of the milk origin, veterinary control of the cows and chemical, physical–chemical and microbiological quality). The pasteurised bovine milk types A and C belong to the highest and lowest categories of quality, respectively.

To evaluate the antimicrobial presence in milk the three types of pasteurised (A, B and C type) milk were considered. Analyses of the selected milk samples show that all the antimicrobials were below the LOD of the method (20 ng mL^{-1}) and therefore below the established MRL values (EC, 2002). It is worth emphasising that the aim of this work is not to conduct a quality control program, but to verify the performance of the method in the different milk matrices.

4. Conclusions

The method developed using high-performance liquid chromatography associated with photodiode array detection was shown to be adequate for the simultaneous determination of multiresidues of SMX, SQX, SMZ, OTC, TC and CTC in milk. Considering the maximum residue limits established for those antimicrobials (100 ng mL^{-1}), the LOQ value, as well as the other parameters of validation of the method, is adequate for the monitoring of their residues in milk. In the case of CLP, which has a LMPR of 0.3 ng mL^{-1}, the proposed method does not have adequate detectability for the quality control of this antimicrobial in milk.

ABSTRACT

The research presented here describes the assessment of a number of physiological and xenobiotic metal concentrations occurring throughout the enological production processes of two native wines from Irpinia, *Aglianico* and *Fiano of Avellino*. In order to evaluate the wines' metal content throughout the entire wine-making process, samples of grapes and musts from both wines were taken at time intervals during the fermentation and maturation phases. Copper, chromium, nickel, iron, zinc, lead and cadmium levels were analysed by atomic absorption spectrophotometry. The concentration of metals obtained were compared to the limits fixed by the Organization Internationale de la Vigne et du Vin (O.I.V.) and in the Italian ad European legislation.

1. Introduction

Wine contains hundreds of different substances (more than 600 known substances), the organoleptic properties (Maarse, Slump, Tas, & Schaefer, 1987) of which are not only influenced by its major components, such as water and ethanol, but also by traces of minor components like the 2,4,6-trichloroanisole which gives to certain wines an unpleasant cork taste.

Due to the wide range of wine-making techniques, it is difficult to define the average composition of wine. However the following components are always present: water; alcohols: ethanol, methanol, super alcohols, glycerin; organic acid: tartaric, malic, citric, lactic, acetic (Maarse et al., 1987); sugars: glucose, fructose; rubber and pectin; polyphenols (Singleton, 1988): anthocyanins (Mazza & Miniati, 1993; Ribèreau-Gayon, 1982), tannins; mineral substances: anions and cations; volatile substances (Maarse et al., 1987; Moret, Scarponi, & Cescon, 1984; Noble, Flath, & Forrey, 1980; Rapp, Guenter, & Ullmeyer, 1985; Rapp & Gunter, 1985; Rapp, Suckrau, & Versini, 1993; Rapp, Volkmann, & Niebergall, 1993; Schreier, Drawert, Junker, & Reiner, 1976): volatile acids, esters, aldehydes, terpenes; vitamins; dissolved gases: carbon dioxide, sulphur dioxide, oxygen.

The organoleptic characteristics of this beverage are a function of the interactions which occur between these elements and the chemical balance during wine-making and ageing.

As for many other foods, wine analysis may be broken down into a number of measurements: normative, nutritional and qualitative.

The normative aspects are linked to the analytical parameters that each enological product must have in order to be marketed, including alcoholic grade, total acidity, partial and fixed dry extract, etc., although the production techniques are not as restrictive from this point of view.

The nutritional aspect of wine relate to the beneficial properties (within certain limits of consumption) that it may bring to one's health, in particular, through the intake of antioxidant substances such as polyphenolic compounds (Minussi et al., 2003).

Finally, qualitative assessment of a wine refers to its aroma and bouquet, and therefore to the hundreds of volatile substances contained within a wine, many of which are yet to be identified and/or quantified.

At the European Community level, EC Regulation No. 2676/90 dictates the methods of analysis which must be used by wineries or wine companies. This law describes all of the important parameters relating to the nutritional safety of wine. Subsequent updates resulting from the developments within our understanding of wine chemistry have allowed significant new improvements to be made brought through the introduction of new methodologies.

Like those in other European countries, Italian wine-making laws relating to analytical methodologies refer to those set out by the EU.

With regards to the upper limit of the concentration of undesired substances in wine, there are still no laws set out by the EU. Mean-

while, industrial waste, gas emissions and the use of pesticides have all contributed to a significant increase in the concentrations of toxic metals which occur in the environment – unlike natural organic and synthetic substances, once absorbed into the soil, these seldom degrade due to their more extensive latency period. Metal toxicity varies according to chemical form, as well as concentration and modality of exposure. Pollution caused by non-physiological metals is one of the most important fields of study in the epidemiological investigations relating to the health of living systems. The analytical determination of metals in wines is still used frequently not only to assess the wine's origin, but also to certify its quality and to show that the tolerable limits established by law have been respected throughout the production process (Azenha & Vasconcelos, 2000; Gennaro, Mentasti, Sarzanini, & Pesticcio, 1986; Jaganathan, Reisig, & Dugar, 1997; Lapa, Lima, & Santos, 1996; Maarse et al., 1987; Moret et al., 1984; Thiel, Bauer, Danzer, & Eschnauer, 1998).

Moreover, it is important to consider the different factors that determine the content of elements in wine such as: the soil on which the vines grow; the capacity of the grapes to absorb mineral substances from the soil, preliminary treatment of the grape harvest, the fermentation reaction, the addition of composts possessing different functions, preservation and bottling.

The final content is therefore the result of a number of different variables, such as the chemical and physical characteristics of the soil in which the vines have grown, as well as other factors that cannot be controlled or are non-discriminating.

The so-called 'natural' elements are those of which the concentration in wine is not influenced by the productive cycle, but is instead determined by the degree to which the mineral is present within the soil and the capacity of the vine to assimilate it. These elements include mineral substances such as aluminum, boron, barium, lithium, magnesium, molybdenum, silicon, strontium, and titanium. Other elements are Lanthanides and metals of the second and third transition series which are present in trace quantities.

Furthermore there are elements that occur both naturally and from 'artificial' sources, the concentration of which is determined by a number of different factors; these include elements such as calcium and magnesium; also copper and zinc are also taken up naturally from the soil and are also derived from fungicidal treatment (Bordeaux mixture, zinc thiocarbamates) or from wine-making equipment.

The concentration of iron is due in part to natural (e.g. presence of residual earth particles in the must), and in part to artificial sources (wine-making equipment, steel containers); potassium is the predominant cation in grapes, but it is also added as metabisulphite or carbonate during wine making. Sodium comes from the soil or is added illicitly like chloride, when salting; phosphorous is naturally present as both organic and non-organic phosphites, but it is also added to wine as a calcium or ammonium salt. There are also elements of which the concentration is almost exclusively influenced by artificial sources.

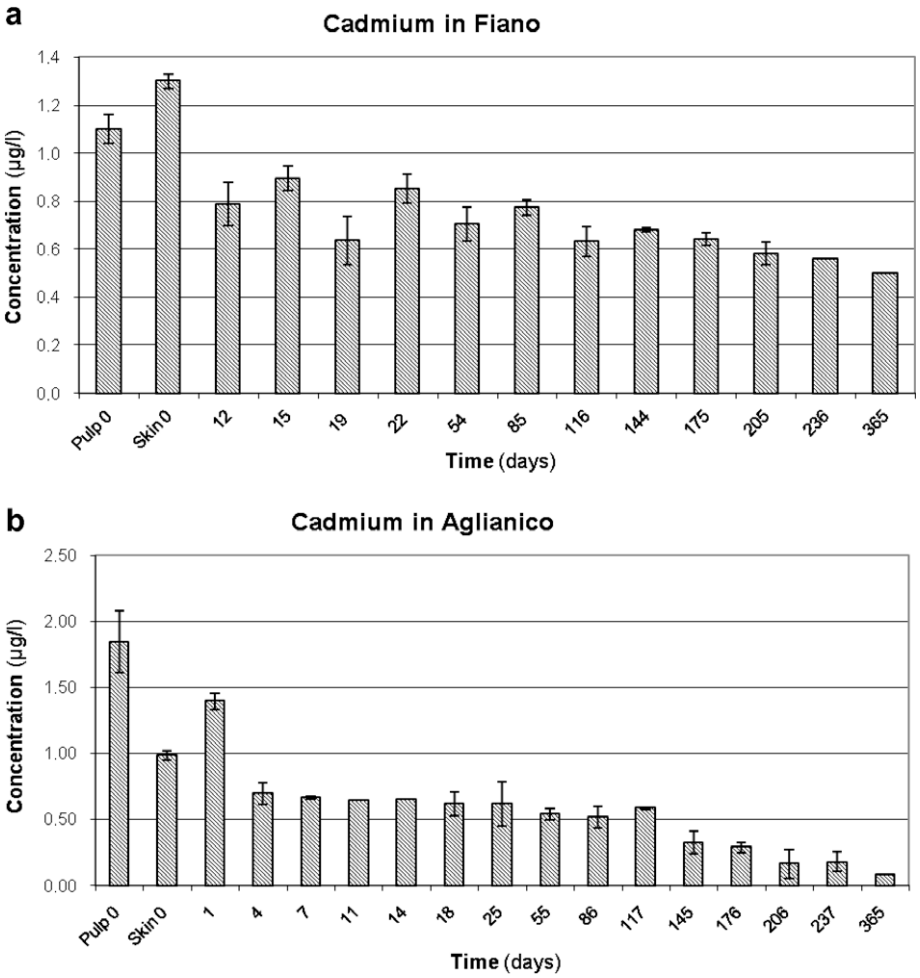

Fig. 1. Cadmium concentration, expressed in µg/l, along the production process of *Fiano of Avellino* (a) and *Aglianico* (b) wines.

Lead comes predominately from fungicides treatment, sealed containers or pollution of the atmosphere (for example, vines located near roads subjected to heavy traffic) and in small quantities from the soil.

Cobalt, chromium, nickel and vanadium, normally present in wine at low concentrations, are most probably derived from the interaction of the must and wine with the metal containers, rather than from natural sources. However, it is thought that cadmium originates exclusively from atmospheric pollution and it has the remarkable capacity to accumulate in the ground.

Heavy metals, in particular cadmium, mercury and lead are those that are the most toxic to man. The accumulation of these elements in the organism leads to a number of diverse and deleterious effects, both in the long and the short term, and varies according to the type of metal. They can cause damage to the kidneys, to the nervous and immune systems, and in some cases they can have cancerous effects. The classic symptom of heavy metal intoxication include irritability, mood changes, depression, headaches, tremor, loss of memory and reduced capacity of sight (Järup, 2003).

In contrast, metals such as copper, zinc and iron are essential for man. For example copper is important in respiration because it is necessary for synthesis of hemoglobin, the protein that transports oxygen in the blood stream. Moreover, it participates in the synthesis of collagen and the neurotransmitter noradrenalin, as well as being one of the most important blood antioxidants and helping to prevent breakdown of polyunsaturated fatty acids which help to keep the cell membrane healthy. Iron is also necessary for the synthesis of collagen and is present in the brain as a co-factor in the synthesis of the serotonin, dopamine and noradrenalin neurotransmitters. Its principle function is through its interaction with proteins and copper in the formation of hemoglobin. Zinc performs various functions: it plays a part in the normal absorption, it interacts with vitamins, pertaining in particular to the B complex, and is present as a component of over 200 enzymes required for digestion and metabolism (e.g. carbonic anhydrase necessary for tissue oxygenation) (Vallee & Falchuk, 1993).

Furthermore, when zinc is present at good levels, it competes for uptake with cadmium, reducing absorption of the latter and minimising its detrimental effects.

Numerous studies have proven that moderate consumption of wine, especially red wine, is considered to be beneficial to health when combined with a balanced diet (Doll, Peto, Holl, Wheatlag, & Gray, 1994; Gronbaek et al., 1995; Klatsky, Armostrong, & Friedman, 1992). It does, in fact, contribute significantly to the demands for essential elements including potassium, calcium, magnesium, chromium, cobalt, iron, fluorine, iodine, copper, manganese, molybdenum, nickel, selenium and zinc (Eschnauer & Neeb, 1988).

On the other hand many metals like lead, cadmium and arsenic, are known for being potentially toxic, like copper (Scheinberg, 1991), aluminum, iron and zinc when present in high concentration (Gennaro et al., 1986). Many elements, amongst them copper, iron, aluminum, zinc and nickel, also contribute to the formation of opacity and sometimes to the colour, aroma and taste of the wine.

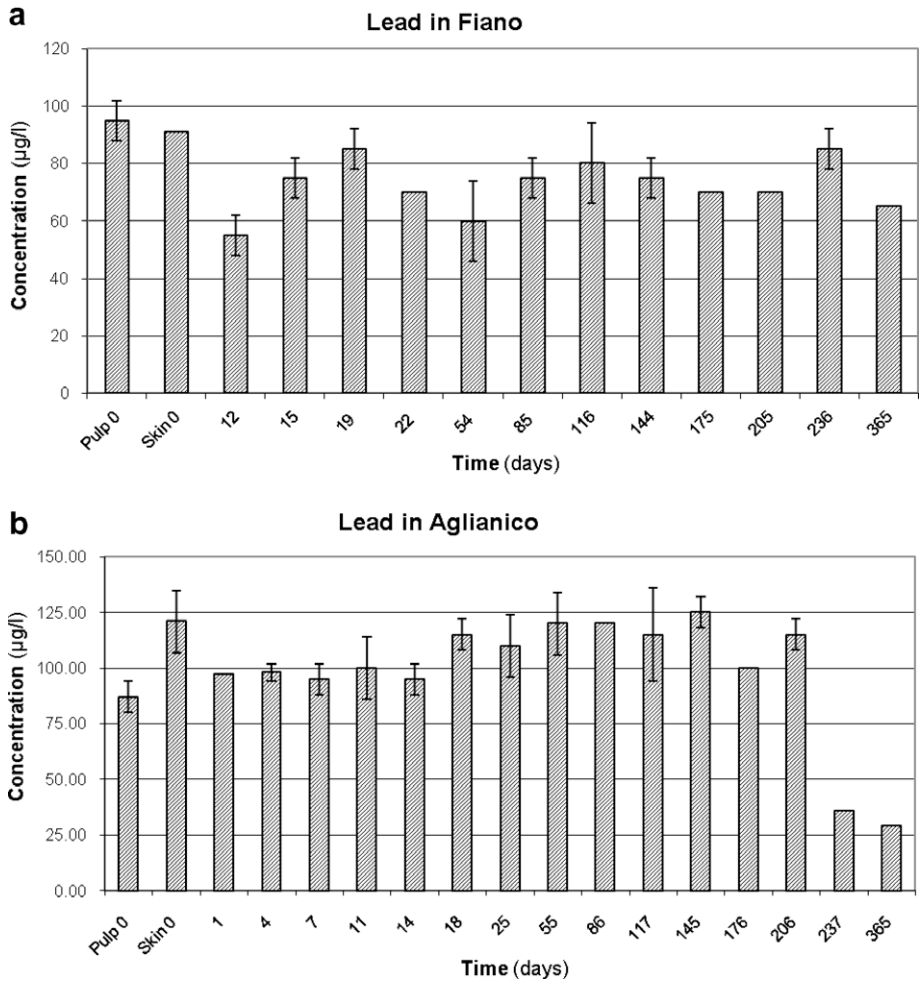

Fig. 2. Lead concentration, expressed in µg/l, along the production process of *Fiano of Avellino* (a) and *Aglianico* (b) wines.

Analysis of the specific metal content of wines can be useful in the identification of its geographic area of origin (Almeida, Bastos, Cardoso, Ferreira, & Lima, 1992; Almeida, Cardoso, & Lima, 1994). The determination of lead in grapes has previously been investigated by Teissedre, Cabanis, Champagnol, and Cabanis (1994) who showed that this metal is present at significant but varying levels in several parts of a grape: seed concentration was found to be 352 μg/kg, in the skin 90 μg/kg and in the pulp it was only 3 μg/kg. Other researchers have analysed the concentration of iron and cadmium in local wines and musts (Lazos & Alexakis, 1989).

On this basis, it is necessary to determine a wine's metal content not only to verify its authenticity, but also in order to confirm that levels are within legal limits, and to obtain knowledge pertaining to the wine's components to set the conditions necessary to proceed, prior to packaging, to the corrective treatments suggested by modern enological techniques. It is important to stress that although existing laws (both EU and national rules) describe the minimum or maximum limits for some parameters, in most cases, accurate estimation of an authenticity can only be derived from final examination of the specific analytical data.

The main objective of this work will be to monitor the concentration (μg and mg/l) levels, through the use of Atomic Absorption Spectrophotometry, of iron, copper, nickel, chromium, zinc, lead and cadmium which occur throughout the production process of two typical Irpinia vines, *Aglianico* (red) and *Fiano of Avellino* (white) from grape-harvesting up to wine bottling.

The concentration of physiological (iron, copper, zinc, chromium, nickel) and toxic metals (lead and cadmium) will be compared to the limits described by the Organization International de la Vigne et du Vin (O.I.V.), bearing in mind the recent decision ENO 13/2006 which fixed a new maximum permitted lead concentration of 0.15 mg/l. The analytical methodology used has been according to CEE Regulation No. 2676/90, the European Community's Official Journal L. 272 dated 03/10/1990. The only Italian law on the subject, specific for the elements copper, iron, manganese and zinc, is the D.M. 29/09/1976.

2. Materials and methods

2.1. Samples collection

Grape samples of *Aglianico* and *Fiano of Avellino* were collected from the Institute of Agrarian Technology of Avellino vines in correspondence to their harvesting dates and stored at −20 °C. The same thing was done with samples of wine withdrawn at several time intervals.

2.2. Sample treatment

For each type of grape, pulp and skin were manually separated, samples were then coarsely crushed in a mortar with rough and pestled walls. Samples were processed using a simple strainer to

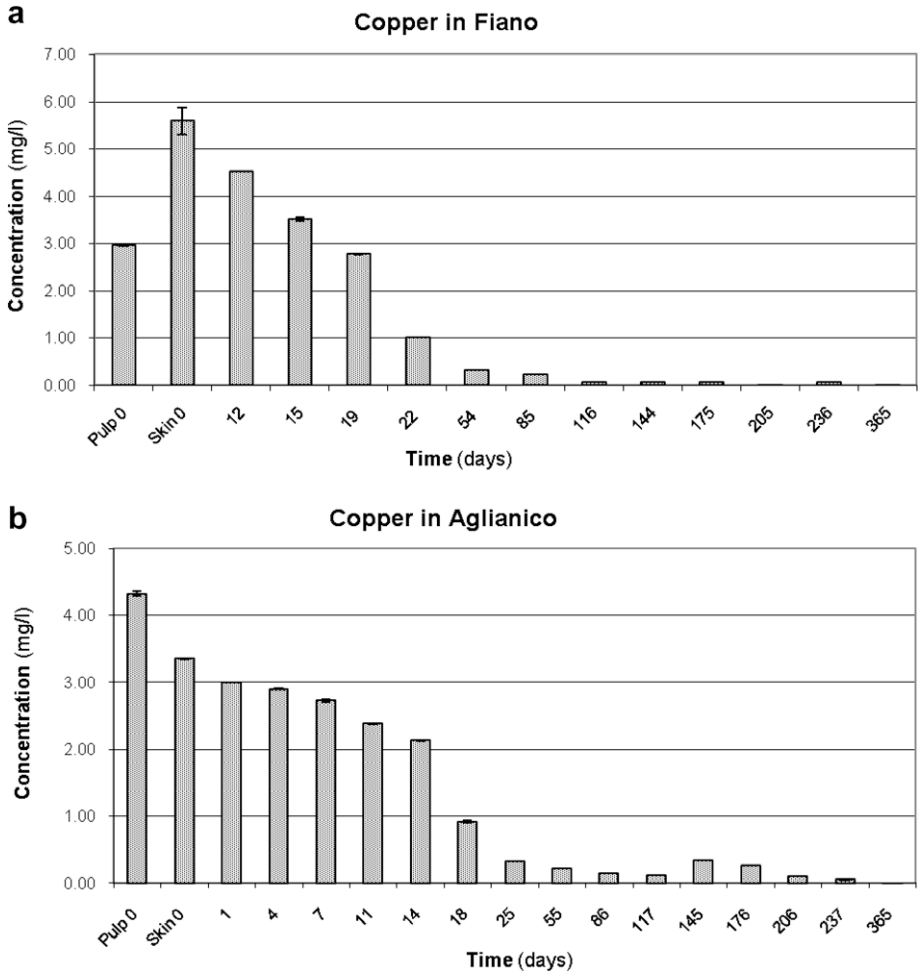

Fig. 3. Copper concentration, expressed in mg/l, along the production process of *Fiano of Avellino* (a) and *Aglianico* (b) wines.

roughly filter the contents in order to remove the suspended deposits, followed by a finer progressive filtration on a sterile Millex-HA (Millipore, 0.45 μm filters).

The samples of must and wine, withdrawn at regular intervals, were centrifuged directly at 4.500 rpm for 15 s; the floating supernatant was gathered and then placed in a RotoVapor at 30 °C, in order to remove the alcoholic component. The watery solution obtained was acidified with 1% HNO_3 in order to resuspend the metals, and the concentration subsequently optimised for atomic absorption spectrophotometry analysis.

2.3. Atomic absorption spectrophotometry analysis

In the present work, we have evaluated the concentration of five physiological metals; copper, chromium, nickel, iron and zinc, and two xenobiotic metals, lead and cadmium. To determine the metal concentrations, a Varian-SpectrAA 200 spectrophotometer (Mulgrave – Victoria, Australia) equipped with an optical bench with a double beam and a monochromator (Czerny-Turner type) was used. Two methods were used for analysis: flame (for quantitation of cadmium and lead) and graphite furnace (mod. GTA 100) (for Co, Cr, Ni, Fe and Zn), completely controlled by the SpectrAA computer. The oven's temperature was set between 40 °C and 3000 °C, with a maximum ramp of 2000 °C/s.

Real temperature controls was achieved through sensors that indicating the resistance to the electrode heads and the temperature of the cooling water. The gas flow used for the flame analysis was programmed at 3 l/min. The standard solutions used for the calibration lines, useful for the determination of each metal (1000 ppm concentration), were as follows.

Cadmium and lead standard solutions diluted in HNO_3 ($Cd(NO_3)_2{\cdot}4H_2O$ and $Pb(NO_3)_2$, respectively); nickel, copper and zinc standard solutions diluted in HCl ($NiCl_2{\cdot}6H_2O$, $CuCl_2{\cdot}2H_2O$ and $ZnCl_2$, respectively); all "Carlo Erba" reagents.

The iron standard consisted of a solution of Fe in 3% HNO_3 (Solutions *Plus Inc.*), and the chromium (III) standard from $Cr(NO_3)_3$ in 3% HCl (Spectro Pure).

The wavelengths used to determine the absorbance of the metals were: lead – 217.0 nm, chromium – 425.4 nm, nickel – 232.2 nm, zinc – 213.9 nm, copper – 324.8 nm, iron – 248.3 nm and cadmium – 228.8 nm.

The measurement of absorbance detected alongside the concentrations, expressed in mg/l and in μg/l, were characterised by standard deviations of less than 1%, for measurements taken with a flame, and less than 5%, for measurements taken with a graphite furnace. For each measured standard and for each sample of grapes, must and wine analysed, the readings were performed in duplicate and each result was the average value of three subsequent replicates (Lara, Cerutti, Salonia, Olsina, & Martinez, 2005).

3. Results and discussion

Out of the metals tested, the results for chromium are not reported, as this was not detected to be present at any point throughout the wine production procedure, Figs. 1–6 show the concentration of the following elements: cadmium and lead (expressed in μg/l), copper, iron, zinc and nickel (expressed in mg/l) occurring throughout the production of the *Fiano of Avellino* (a) and *Aglianico* (b) wines.

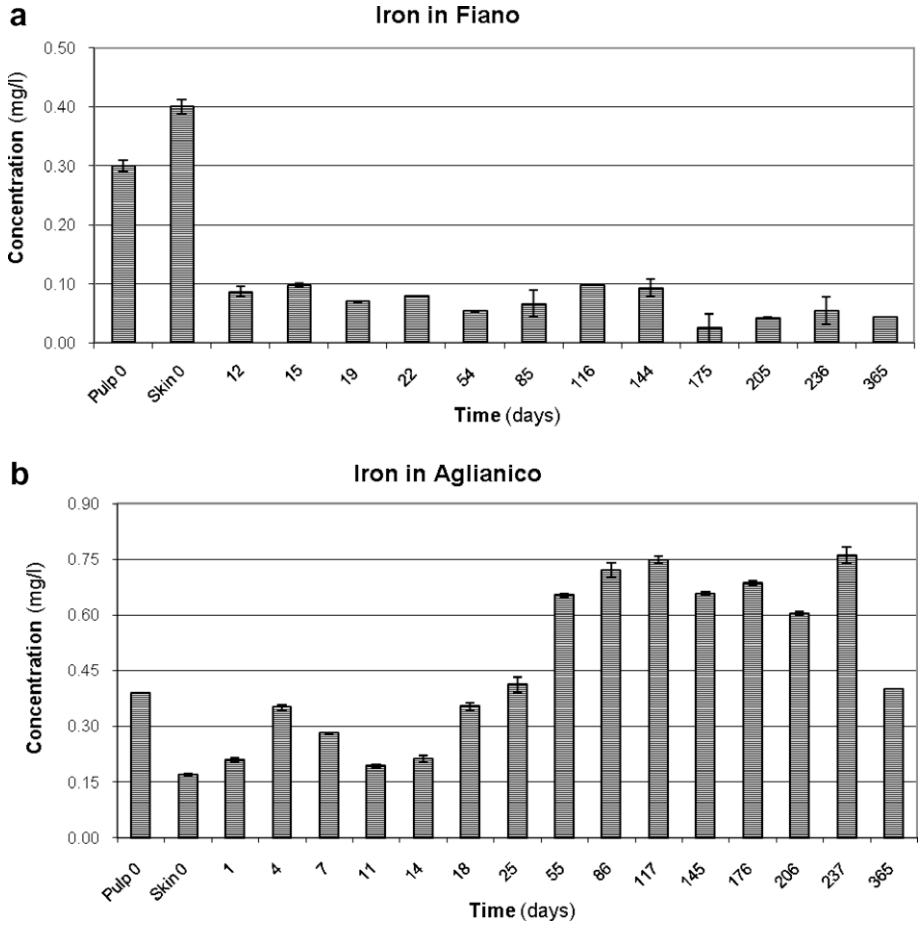

Fig. 4. Iron concentration, expressed in mg/l, along the production process of *Fiano of Avellino* (a) and *Aglianico* (b) wines.

3.1. Cadmium

The maximum limit set by the O.I.V. for the concentration of cadmium in wines is 10 μg/l. Relative to *Fiano* wine, this element was found to decrease both constantly and progressively; in fact the pulp and skin cadmium concentration was found to be more than 1.0 μg/l, and was found to gradually decrease from 12 days to one year (0.5 μg/l) (see Fig. 1a).

The pulp of the *Aglianico* showed higher values compared to the *Fiano* wine, whereas an opposite trend was observed in the skin. After four days, a gradual decrease in metal concentration was observed (see Fig. 1b). Whilst both red and white wines showed a similar trend, i.e. a decrease in cadmium concentration, after one year, cadmium concentration in *Aglianico* was lower than that in *Fiano* wine.

3.2. Lead

The O.I.V. states that 150 μg/l is the maximum lead concentration permitted in wine. In both the *Fiano* and *Aglianico* wines, the monitored values were always under the limit and each showed a regular trend (see Fig. 2a and b). Whilst, after one year, there appeared to be little change in the values for Fiano wine, with the values remaining almost constant, the *Aglianico* wine showed a significant decrease in lead concentration.

3.3. Copper

The copper concentration limit set by the O.I.V. and the Italian norm D.M. 29/09/1976 in wines equal to 1 mg/l; Fig. 3a and b show the copper concentrations for *Fiano* and *Aglianico* wines respectively, revealing that pulp and skin of both wines possess a concentration value higher than the O.I.V. limit allowed. This is most probably due to the cupric treatment that both wines are subjected to during the production process. In fact copper sulphate in particular is used to prevent parasitic infection during growth of the grapes. However, throughout the whole fermentation process, there is a constant decrease in copper levels, down to extremely low values and, after one year, the copper concentrations for both wines reach a level which is well below the legally permitted limit.

3.4. Iron

O.I.V. rules define no limit stated relating to the concentration of iron in wines, while the old Italian law establishes the standard limits at 2.5 mg/l (in the case of soils rich in iron the concentration can reach 10–12 mg/l).

As shown in Fig. 4a, the pulp and skin of *Fiano* grapes contain iron concentrations ranging from 0.3 to 0.4 mg/l, significantly higher than the level seen from the 12th day onwards (around 0.08 mg/l). In red wine however, the iron content remains uniform (ranging from 0.4 to 0.8 mg/l) throughout the production process (Fig. 4b).

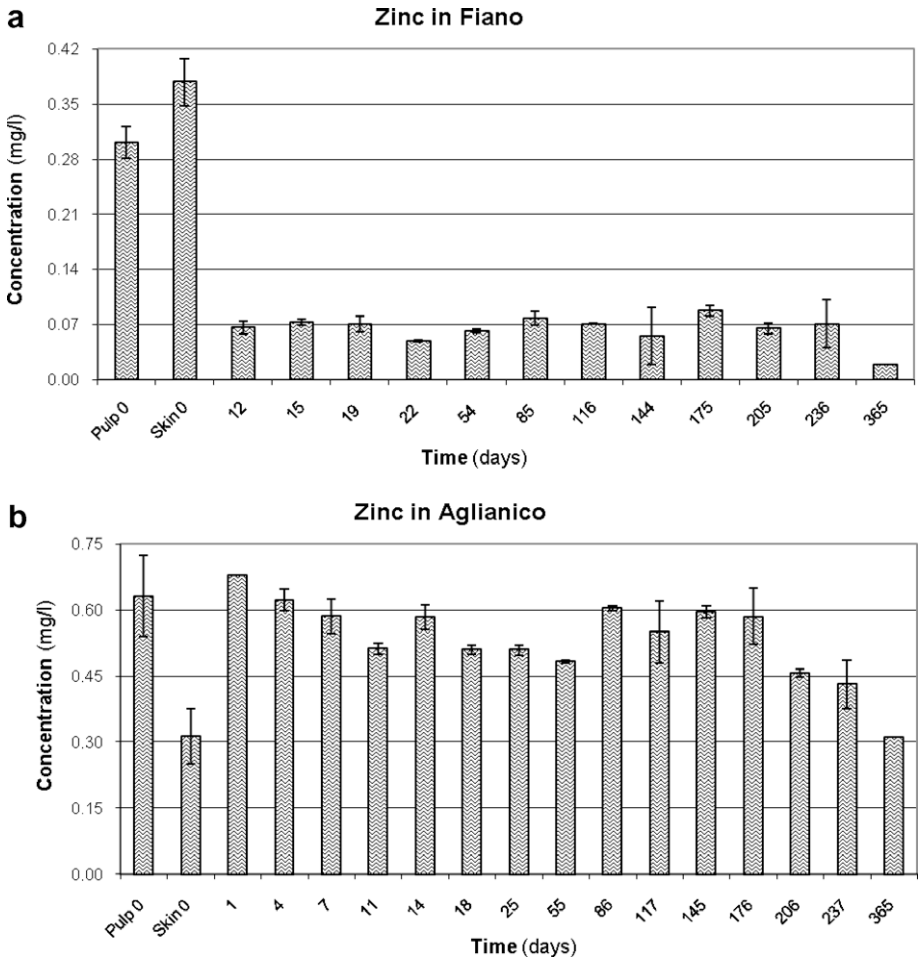

Fig. 5. Zinc concentration, expressed in mg/l, along the production process of *Fiano of Avellino* (a) and *Aglianico* (b) wines.

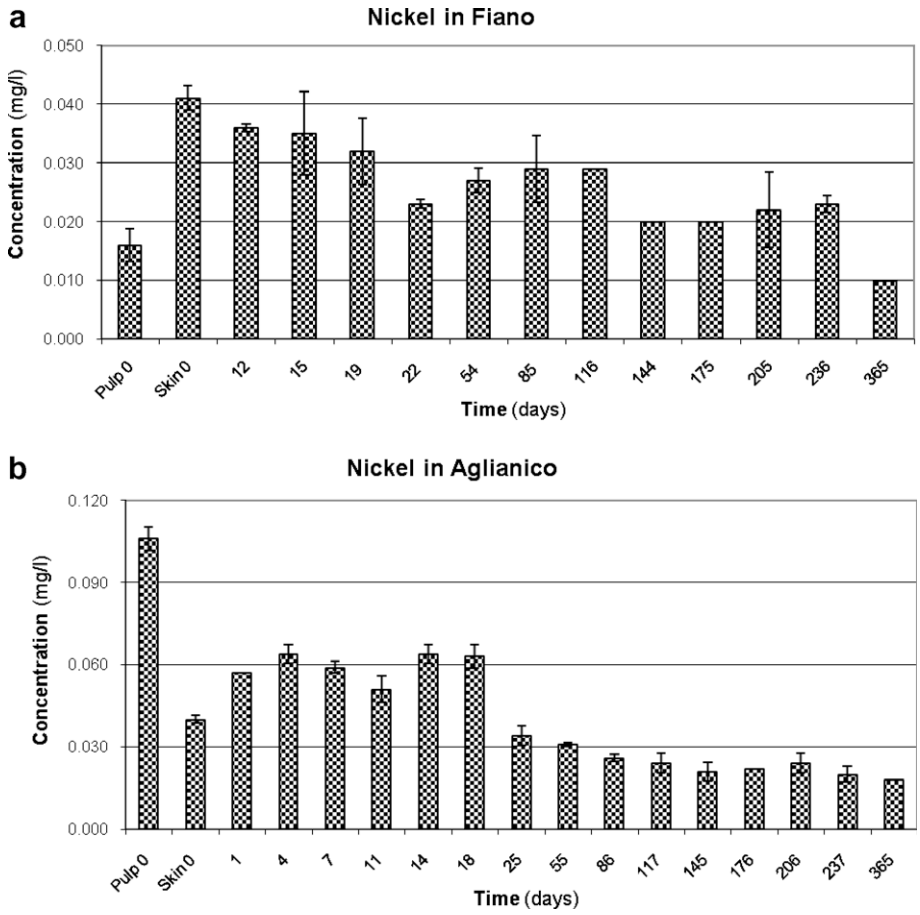

Fig. 6. Nickel concentration, expressed in mg/l, along the production process of *Fiano of Avellino* (a) and *Aglianico* (b) wines.

In both cases, this may be due to the soil being particularly poor in iron.

3.5. Zinc

The presence of this type of metal in wines is usually linked to the plan's capacity of absorbing it from the soil. With regards to its concentration, both the O.I.V. and the Italian law agree on an upper concentration limit of 5 mg/l in the enological production chain.

For zinc, the white wine shows a trend similar to that seen for iron (see Fig. 5a): in fact, pulp and skin values are about 3–4 times higher than wine. In general, red wine contains zinc values are higher in red wine than in white, the trend being in the range of 0.40–0.60 mg/l (Fig. 5b).

3.6. Nickel

Enological containers are made of stainless steel; generally referred to as 18/10, they contain 18% chromium plus 10% Nickel and are internationally classified, according to American abbreviation as AISI 304 or, according to European abbreviation, as X5CrNi1810 (or W. 1.4301) from the norm EN 10088/3 (in Italy as UNI EN 10088/3). Italian and European law do not describe limits relating to nickel concentration in wine, whereas the O.I.V. sets the limit at 0.01 mg/kg. The average nickel content in plants varies between 0.05 and 8.00 μg/g dry weight. Whilst this concentration very rarely exceeds 5 μg/g in normal growth conditions, it may reach up to 50 μg/g (100 μg/g) in ultrabasic substrates. Furthermore, the pH regulates mobility and therefore nickel can be assimilated from the ground to the plant. The effects of pH on nickel's chemical mechanisms have been demonstrated by way of various studies relating to the application of mud purifiers to soil, on plant nutrition, on the re-utilisation of serpentinitic soil and a study on ionic retention in soil. The studies collectively show that the quantity of nickel held by soil increases concomitantly with an increase in pH. In areas that receive mud depurates containing a high load of toxic minerals, or in which soils have a pH higher than 6.5, nickel and other metals should not cause toxicity to crops or damage the food chain. The critical concentration of nickel is much lower in acidic soils compared to calcareous or alkaline soils.

The data presented here show that throughout the production process of both *Aglianico* and the *Fiano* nickel levels are extremely low, and show a more or less constant level over time, with mg/l values around the second decimal place (see Fig. 6a and b); in some cases, particularly for *Aglianico*, the value is significant on the third decimal place.

4. Conclusions

Few statistical studies exist pertaining to the metal content of Italian wines. Recently Marengo and Aceto (2003) characterised the metal content of five classes of wines derived from the *Nebbiolo* grapes of northern Italy. Comparison of the data reported here with that of Marengo and Aceto highlights some interesting differences which exist between northern Italian wines and the *Fiano* and *Aglianico* wines of Southern Italy.

In particular, the initial copper concentration of both the *Aglianico* and *Fiano* is higher than that reported for *Nebbiolo* wines, though the values observed at the end of production process are

very low. Lead, cadmium and zinc concentrations of *Aglianico* and *Fiano* are in the same values range of *Nebbiolo* wines, while nickel is significantly inferior. Moreover, due to the scarcity of iron in the soils in which the Irpinia vines are grown, the iron concentration interval determined in our study is somewhat inferior to that observed for the *Nebbiolo* wines.

With regards to white wine (*Fiano*), and with the exception of lead and cadmium, the concentration of physiological and xenobiotic metals is almost always lower than in red wine; this is primarily due to the production process of the former, in which fermentation proceeds without grapes skin, the latter containing higher metal concentrations than pulp.

In conclusion, by way of an extremely rigorous control procedure characterised by ongoing monitoring of physiological and xenobiotic metal concentrations, the data presented confirms that both the wine production processes described here are well within the toxicological safety limits. With the exception of copper and zinc (whose concentration is unusually high for both wines due to antiparasitic treatments and plant zinc uptake, respectively), the concentration of the metals monitored throughout the production process of both wines fall well within the limits stated by both the Italian and O.I.V norms. The acceptable concentration limit of nickel is yet to be legally defined, and therefore remains difficult to compare to a standard reference.

During wine storage, it is very important to use a container that guarantees non-contamination with the liquid that it holds: being unassailable by wines or musts, 18/10 stainless steel described above certainly represents the best currently available option for this purpose. It is important to remember that for wine makers of coastal zones, i.e. those with vineyards in proximity to the sea and therefore in an area with a salty atmosphere, not only is the use of austenitic stainless steel advisable, but also those containing chromium and nickel with 2% of molybdenum, the latter being particularly effective in preventing corrosion caused by both the mixtures and reactions occurring during the productive cycle and wine maturation and that caused by the saline nature of the external atmosphere. Apart form this, an infinitesimal quantity of nickel will normally be present throughout a wine's enological production process, the cause of which is difficult to assign. Finally, treatments should be sought which will increase the concentration of iron that is particularly low in both wines.

GC-ECD

ABSTRACT

Headspace solid-phase microextraction (HS-SPME) was evaluated for the determination of pesticide residues in fruits and vegetables by gas chromatography with an electron capture detector (GC-ECD). The fibre used was coated with polydimethylsiloxane (100 μm thickness) and the analytical conditions employed have been developed and optimised in a previous work [Chai, M. K., Tan, G. H., & Asha, L. (2008). Optimisation of headspace solid-phase microextraction for the determination of pesticide residues in vegetables and fruits. *Analytical Sciences, 24* (2), 273–276]. The results show that the HS-SPME procedure gave a better linear range, accuracy, precision, detection and quantification limits and is adequate for analysing pesticide residues in fruits and vegetables. The average recoveries obtained for each pesticide ranged between 71% and 98% at three fortification levels with the relative standard deviation of less than 5%. Repeatability (0.3–3.7%) and intermediate precision (0.8–2.5%) were shown to be satisfactory. The limits of detection (0.01–1 μg L^{-1}) and the limits of quantification (0.05–5 μg L^{-1}) of these pesticides were much lower than the maximum residue levels (MRL), allowed for fruits and vegetables in Malaysia.

1. Introduction

The public awareness pertaining to the health hazards posed by pesticide residues in fruits and vegetables have led to the development of many analytical methods (Stajnbaher & Zupancic-Kralj, 2003) for measuring these residues. The main focus is on simplification, miniaturisation, and improvement of sample extraction and cleanup methods with universal microextraction procedures, namely supercritical fluid extraction (SFE) (Lehotay & Garcia, 1997; Nerin, Batlle, & Cacho, 1998; Stefani, Buzzi, & Grazzi, 1997), matrix solid-phase dispersion (MSPD) (Blasco, Font, & Pico, 2004; Bogialli, Curini, Corcia, Nazzari, & Tamburro, 2004; Kristenson, Haverkate, Slooten, & Ramos, 2001), solid-phase extraction (SPE) (Abhilash, Jamil, & Singh, 2007; Juan-Garcia, Pico, & Font, 2007; Sharif, Man, Hamid, & Chin, 2006; Stajnbaher & Zupancic-Kralj, 2003) on cartridges to replace liquid–liquid extraction (LLE), enzyme-linked immunosorbent assay (ELISA) (Bushway, Savage, & Ferguson, 1990; Watanabe, Yoshimura, Yuasa, & Nakazawa, 2001) and solid-phase microextraction (SPME) (Beltran, Peruga, Pitarch, Lopez, & Hernandez, 2003; Cai, Gong, Chen, & Wu, 2006; Chen, Su, & Jen, 2002; Zambonin, Cilenti, & Palmisano, 2002). Among these extraction and cleanup methods, SPME has become a popular technique in recent years. It is an inexpensive, environment-friendly and solvent-free technique with reliable and excellent sensitivity as well as good selectivity.

SPME was developed by Pawliszyn and co-workers in 1990 in an attempt to redress the limitations inherent in the SPE and LLE techniques (Kataoka, Lord, & Pawliszyn, 2000). It is a sample preparation technique using a fused-silica fibre which is coated on the outside with an appropriate stationary phase and is then employed to extract the analytes from a variety of matrices, which are subsequently transferred into the injector of a GC system for analysis. This sample preparation prior to the GC analysis can be carried out by direct immersion of the fibre into the sample (DI-SPME) or via the exposure of the fibre in the headspace above a liquid or solid sample (HS-SPME).

In a previous paper (Chai, Tan, & Asha, 2008), the optimisation of a HS-SPME extraction and thermal desorption procedure coupled to gas chromatography with electron capture detection for the determination of 8 pesticide residues in fruits and vegetables was carried out. A 100 μm polydimethylsiloxane (PDMS) coated fibre was found to be the most efficient in extracting the investigated pesticide residues. Parameters such as the effects of extraction time

and temperature, salting-out effect, stirring speed, pH, desorption time and temperature, the effects of dilution and types of organic solvent were developed and optimised.

The purpose of the work reported here is to perform the validation of the optimised HS-SPME analytical method for the analysis of eight organochlorine (OC) and organophosphorous (OP) pesticide residues. The method, after validation, has been applied to various types of samples of fruits and vegetables found in Malaysia.

2. Materials and methods

2.1. Chemicals and standard solutions

All the solvents used were HPLC grade. Acetone and methanol were purchased from Fisher Scientific, Longhborough, UK. Eight pesticides standards >95% pure (diazinon, chlorothalonil, malathion, chlorpyrifos, quinalphos, profenofos, α-endosulfan and β-endosulfan) which are commonly used by local farmers in fruit and vegetable cultivation (Suzuki, 2003) were purchased from AccuStandard Inc., New Haven CT, USA. A range of standard mixture stock solutions containing 0.5–50 mg L^{-1} were prepared in methanol and stored at 4 °C. Preparation of different concentration levels of the stock solutions is carried out to correspond to the sensitivity of the ECD detector towards different compounds. Working standard solutions of a mixture of pesticides were freshly prepared daily by volume dilution in distilled water. 1-Chloro-4-fluorobenzene (98.0%), purchased from AccuStandard Inc. was used as the internal standard to compensate for sample and injection volume changes and was added to the vial prior to the GC-ECD analysis.

2.2. Sample preparation

In the multiclass and multiresidue analysis of pesticides in fruits and vegetables, three types of fruits namely strawberry (*Fragaria ananassa*), star fruit (*Averrhoa carambola*) and guava (*Psidium guajava*) and three types of vegetables namely cucumber (*Cucumis sativus*), tomato (*Lycopersicon esculentum*) and pakchoi (*Brassica parachinensis*) were obtained from a pesticide-free farm in the Malaysian Agricultural Research and Development Institute (MARDI), Selangor, Malaysia. For the HS-SPME analysis, 100 g of the individual fruit or vegetable sample was weighed and finely chopped. A 30 g subsample was accurately weighed and placed in a 150 mL beaker. Three concentration levels – low, medium and high, were spiked into the sample to provide the spiked control sample. After being kept at room temperature for 1 h, 30 g of distilled water was added to the spiked sample which was then blended and homogenised in a food processor. The sample was then placed in separate vials.

2.3. HS-SPME analysis

A homogenised spiked sample was added with 2% (vol/weight) of methanol/acetone (1:1) and optimum dilution was made with distilled water containing 10% NaCl until the total sample in the vial was equal to 5.00 g. Then, the internal standard was added. The sample was extracted via the headspace SPME method using a 100 μm PDMS coated fibre mounted in a manual syringe holder (obtained from Supelco, Bellefonte, PA, USA) at 60 °C for 30 min; with sample agitation at 800 rpm without any pH adjustment. Desorption was done at 240 °C for 10 min.

2.4. Gas chromatography-electron capture detector (GC-ECD)

A Shimadzu GC 17A version 2.21 gas chromatograph coupled with an electron capture detector (ECD) which was purchased form Kyoto, Japan was used. A SGE BPX5, 30 m × 0.32 mm i.d. capillary column with a 0.25 μm film was used in combination with the following oven temperature program: initial temperature 120 °C, then heated at 7 °C min^{-1} to a final temperature of 250 °C, and then held for 4.5 min. The total run time was 23.07 min. A silanised narrow-bore injector liner (0.75 mm i.d.) for the SPME injections was installed and the fibre was inserted into this injector using the splitless mode. The injector temperature was held at 240 °C and the detector temperature was maintained at 300 °C. Nitrogen (99.999%) was used as the carrier gas with a gas flow at 24.4 cm s^{-1} linear velocity and the pressure maintained at 94 kPa.

2.5. Validation studies

The calibration graph of each pesticide was constructed using samples spiked with six different concentrations of the standard mixture solutions. The calibration standard mixture solutions over the concentration range of interest were prepared by serial dilution of the mixed standard stock solution with methanol and then spiked to the fruit and vegetable samples. The analyte peaks obtained were integrated and plotted as functions of the concentration. The standard mixture solutions were analysed in triplicate by GC-ECD at each concentration level.

Samples spiked at three different concentrations and three replicates for each concentration were analysed on three different occasions together with a calibration curve were performed to establish the repeatability (intra-day precision), intermediate precision (inter-day precision) and accuracy of the method. The accuracy was determined as the mean of the measured value relative to the theoretical spiked values and is reported in percentage (%). The precision is represented by the intra- and inter-day relative standard deviation (RSD).

The selectivity of the method was assessed by comparing the chromatograms obtained with and without the analytes in the blank samples. Each analyte was injected separately to ensure that no interfering peaks with the same retention times were present.

The limits of detection (LOD) and the limits of quantification (LOQ) were evaluated as the signal-to-noise ratios of 3:1 and 10:1, respectively. The LOD and LOQ in distilled water were evaluated for each pesticide as follows:

(a) Retention times were determined by running the chromatogram of a standard solution.
(b) The average noise levels were measured by running the chromatogram of a blank sample.
(c) The concentration that led to a signal of three or 10 times the noise level was evaluated using the average of the peak areas of the spiked samples in triplicate and taking into account the values of the noise level.

Recovery tests were based on the addition of known amounts of pesticides to the fruit and vegetable samples. Since the SPME technique is a non-exhaustive extraction procedure, the relative recovery, which is defined as the ratio of the concentration found in the samples and working solution, spiked with the same amount of analytes was used instead of the absolute recovery associated with an exhaustive extraction procedure. The recoveries and linearity of the method was examined on pesticide-free fruit and vegetable samples. All recoveries were determined in triplicates at three concentration levels. The different spiking levels were carried out to reflect the sensitivity of the ECD detector towards different compounds.

3. Results and discussion

The development of the HS-SPME technique for trace analysis of multiresidue pesticides in fruits and vegetables without any pre-

treatment of the samples has been demonstrated in the previous paper (Chai et al., 2008). The developed HS-SPME method has resulted in a drastic reduction of the analysis time and organic solvent consumption. The use of the 100 μm PDMS fibre is most suitable for the analytes in this study which consist of non-polar to semi-polar compounds. The extraction time of 30 min was selected after taking into consideration factors such as sample preparation time, loss of analyte during extraction and the sensitivity of the method. The extraction temperature of 60 °C was found to be the optimum temperature. This is due to the fact that the extraction efficiency decreases when the extraction temperature exceeds 60 °C as a result of the degradation of the pesticides with increasing water vapour pressure in a gas tight vial and the formation of air bubbles. The use of 10% NaCl to increase the extraction efficiency is due to the salting-out effect. The extraction efficiency decreases when the percentage of NaCl exceeds 10% because of the predominant salt interaction with the analyte in the solution. The addition of water and 2% (vol/weight) of methanol/acetone (1:1) is necessary to enhance the release of the analytes from complex matrices such as fruits and vegetables.

When a method has been developed, it is important to validate it to confirm that it is suitable for its intended purpose. In this study, the analytical performance characteristics of the optimised HS-SPME method were validated.

3.1. Calibration curve (linearity)

The linearity of an analytical method is its ability to produce test results that correspond directly to the concentration of the analyte in the samples within a given range. For the linearity studies, a minimum of five different concentrations are recommended. It is also recommended that a specific range, normally from 80% to 120% of the expected concentration range (Shah, 2001) be employed.

Usually, spiked solutions are made with a known amount of a mixture of the analytes and the calibration curves are plotted by relating the peak areas obtained when desorption occurs at the concentrations used for spiking the samples. However, in real samples, the number of analytes and their concentrations are unknown, and some matrix effects which exist can affect the calibration curves. In order to ensure that no competition occurs between the analytes during the partition process, the calibration curves of the analytical method in this study were determined under three conditions: (a) with only one pesticide spiked in the sam-

Table 1
Comparison of the linearity range, r^2 and RSD (%) values of investigated pesticides in distilled water and in cucumber sample.

Pesticide	In distilled water			In cucumber sample		
	Range (μg L^{-1})	r^2	RSD (%)	Range (μg L^{-1})	r^2	RSD (%)

ples (cucumber), (b) a mixture of eight pesticides spiked in the samples (cucumber), and (c) a mixture of eight pesticides spiked in distilled water.

The method of internal standard quantification was carried out at six levels of concentrations using three different conditions in triplicate. The peak area ratio (peak area of analytes/peak area of internal standard) was used for each compound.

The results show that the three calibration curves are almost similar with the r^2 value >0.9950 for all the calibration curves. These results are significant and imply that, the partition process is reproducible using these conditions, thus indicating that the method is quantitative for these pesticides.

Table 1 shows the comparison of the linearity range, with the r^2 and RSD values of investigated pesticides in distilled water and in the cucumber sample. The linearity range, from the r^2 and RSD values are slightly better in distilled water when compared to the cucumber sample, showing that the vegetable sample has a small matrix effect in the analysis of the investigated pesticides. Overall, the linearity using these two conditions is acceptable and the r^2 values are better than 0.9950 in all cases with the RSD value of less than 7% for all the investigated pesticides.

3.2. Precision

The precision of an analytical method is the closeness of a series of individual measurements of an analyte concentration when the analytical procedure is applied repeatedly to multiple samplings of a homogeneous sample. The precision is usually expressed as the relative standard deviation (RSD). The measured RSD can be subdivided into three categories: repeatability (intra-day precision), intermediate precision (inter-day precision) and reproducibility (inter-laboratory precision as in a collaborative study). In this study, we have measured the repeatability and intermediate precision.

The accuracy of an analytical method is a measure of the degree of closeness between the true value of the analytes in the sample and the value as determined by the method and is sometimes called "*trueness*" (Shah, 2001). Accuracy can be measured by analysing samples with known concentrations and comparing the measured values with the true values.

(a) Repeatability

The repeatability of an analytical method refers to the use of the procedure within a laboratory over a short period of time, carried out by the same analyst with the same equipment. According to the International Conference on Harmonisation (ICH), it is recommended

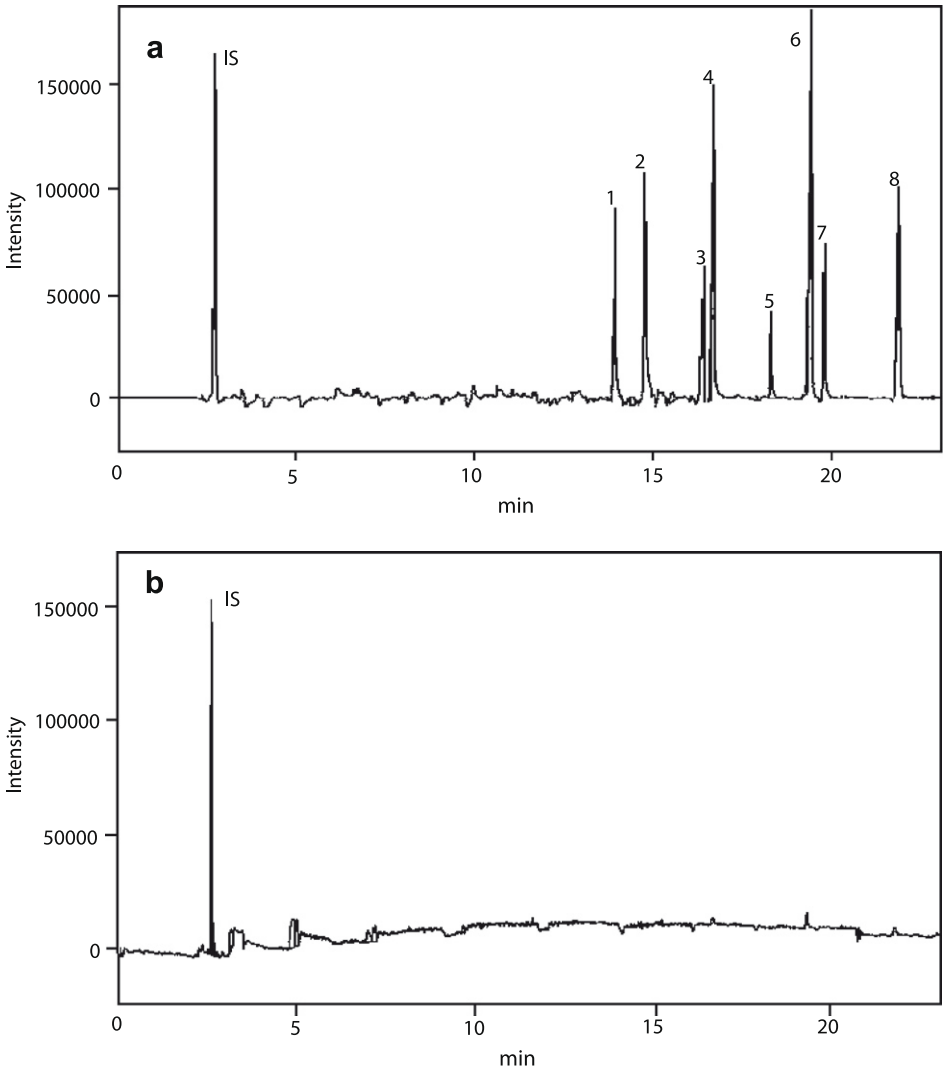

Fig. 1. Selectivity chromatograms (a) spiked cucumber sample (b) blank cucumber sample. IS (internal standard), 2.68 min; 1. Diazinon, 13.58 min; 2. Chlorothalonil, 14.74 min; 3. Malathion, 16.42 min; 4. Chlorpyrifos, 16.65 min; 5. Quinalphos, 18.30 min; 6. α-Endosulfan, 19.37 min; 7. Profenofos, 19.76 min; 8. β-endosulfan, 21.83 min.

that repeatability be assessed using a minimum of nine determinations covering the specified range (i.e., three concentrations and three replicates for each concentration) or a minimum of six determinations of 100% of the test concentration (ICH-Topic Q2b, 1996).

The intra-day accuracy and repeatability was assessed, at three concentration levels and with three replicates for each concentration on the same day. Table 2 shows the repeatability of the method for the investigated compounds in the spiked cucumber and strawberry samples.

The results show that the intra-day accuracies ranged between 71.4% and 81.9% with the RSD values between 0.4% and 3.7% for the cucumber samples. For the strawberry samples, the intra-day accuracies ranged from 70.0% to 83.5% with the RSD values from 0.3% to 2.5%. For the analysis of pesticide residues at the ppb or ppm levels, accuracy and recovery of 70% to 120% are considered as acceptable (Herdman, Pahrham, & Shen, 1988). Hence, the results obtained above can be considered to be acceptable for the concentration levels being investigated.

(b) Intermediate precision

The intermediate precision in this study is based on the mean repeatability values of a set of spiked samples at three concentration levels and analysed daily for a period of 4 days. The inter-day accuracies ranged from 70.7% to 83.9% with the RSD values from 0.8% to 2.5% for both samples indicating that the proposed HS-SPME method produces acceptable intermediate precision.

With the use of the internal standard and the relative recovery method, the RSD values of less than 4% are obtained. The internal standard and relative recovery method can overcome the common problems of the SPME technique such as inconsistency of the fibre quality and poor repeatability.

3.3. Selectivity/specificity

According to the ICH classification, specificity is defined as the ability to assess unequivocally the analyte in the presence of other components, which may be expected to be present such as impurities, degradation products and matrix components. Other authoritative international organisations such as IUPAC and AOAC have preferred the term selectivity, reserving specificity for those procedures that are completely selective (Soh & Abdullah, 2005).

The selectivity of the analytical method in this study was determined by comparing the chromatograms of a blank matrix solution with another spiked matrix solution. Fig. 1 shows the chromatograms of the spiked cucumber sample and the blank cucumber sample by GC-ECD. The analytes of interest were well-separated from the other components present in the samples. SPME is an equilibrium method which is more selective when compared to other exhaustive methods as it takes full advantage of the differences in the extracting phase/matrix distribution constants to separate the mixture of pesticides from the interferences. This SPME technique has demonstrated its selectivity since it does not require an additional cleanup step to remove any interference prior to GC analysis.

3.4. Limits of detection (LOD) and limits of quantification (LOQ)

The LOD is the lowest concentration of the analyte in a sample which can be detected but not necessarily quantified. The LOQ is the lowest concentration of the analyte in a sample which can be quantified with an acceptable degree of accuracy and precision. The LOQ should have an accuracy of 80–120% and the RSD value not exceeding 20% for its precision (Shah, 2001).

The LOD values obtained (Table 3) are below the first calibration level. These values are lower than the Maximum Residue Levels as stipulated in the Codex Alimentarius (EU, 2004) for fruits and vegetables. α-Endosulfan showed the lowest LOD values for all the samples because it is the most sensitive analyte measured by the ECD detector compared to the other analytes in this study.

Table 3
Limit of detection (LOD), limit of quantification (LOQ) and Codex Alimentarius maximum residue limits (MRL) of the investigated pesticide using the optimised HS-SPME method.

Pesticide	Pesticide level ($\mu g\ L^{-1}$)	Pesticide Level ($\mu g\ L^{-1}$)					
		Cucumber	Tomato	Pakchoi	Guava	Starfruit	Straw berry

	MRL	50	500	50	50	50	50
Range	LOD	0.01–1					
	LOQ	0.05–5					

3.5. Recovery

The mean recovery data and its RSD values obtained in the analysis of fortified fruit and vegetable samples are as listed in Table 4. Acceptable relative recoveries were obtained, ranging between 71% and 97% for the vegetable samples with the RSD values ranging from 0.1% to 4.7%, and the relative recoveries of 76–98% for the fruit samples with the RSD values ranging from 0.5–4.7%. The percentage relative recoveries and the RSD values obtained for the fruit samples were slightly better than those obtained for the vegetable samples. This is probably due to the presence of higher total suspended solids in the vegetable samples. When all the fruit and vegetable samples are compared, the relative recoveries obtained in "*pakchoi*" are lower than those obtained from the other samples. This could be due to the water content of the "*pakchoi*" being the lowest among all the samples. From the results, it can be seen that the matrix has little effect on the developed HS-SPME method.

3.6. Real sample analysis

The developed HS-SPME method has been applied to the analysis of 10 fruits and vegetables purchased from a local market. Table 5 shows the pesticide levels detected in the selected fruit and vegetable samples. The residue levels of the pesticides determined were found to be lower than the MRLs specified by the EU (2004).

To ensure the validity of the results when the proposed method is applied for routine analysis, the following internal quality control criteria were applied in order to check if the system is under control:

A blank extract was carried out daily to eliminate any false positive via contamination in the extraction process, instrument or reagents used.

A blank extract spiked at the intermediate concentration level was run prior to the analysis of the real sample in order to assess the extraction efficiency. Recoveries between 70% and 120% are considered as acceptable in any method development.

Calibration curves are prepared daily to check for both, sensitivity and linearity in the working concentration range in order to avoid errors in quantitation caused by possible matrix effects or instrumental fluctuation ($r^2 > 0.99$ are required).

4. Conclusions

The developed HS-SPME method offers significant advantages and can overcome the common problems of SPME. The use of the

internal standard and relative recovery test can compensate for any inconsistency in the quality of the fibre to give high precision (<4%) and good recoveries (71–98%). The use of the headspace method can prolong the lifetime of the fibre until 120 extractions. By using optimum dilution and 2% organic solvents, the recoveries can be further improved. The validation results for the developed HS-SPME method in this study are comparable or even better when compared with the results reported by Berrada, Font, and Molto (2004), Zambonin, Quinto, Vietra, and Palmisano (2004), Dong, Zeng, and Li (2005), Cai et al. (2006) and Fytianos, Raikos, Theodoridis, Velinova, and Tsoukali (2006) for various food matrices.

The developed HS-SPME method is fast, cheap and environment-friendly because it employs a very simple sample preparation procedure with very minimal organic solvent consumption.

ABSTRACT

The influence of different treatments, i.e., crushing, high temperature short time (90 °C/4 min) (HTST) and low temperature long time (60 °C/40 min) (LTLT) blanching, acidification (pH 4.3), and sequences of these treatments on the folate poly-γ-glutamate profile and stability were investigated. In this study, broccoli was used as a case study. Regarding the folate poly-γ-glutamate profile, endogenous folate poly-γ-glutamates in broccoli florets were found predominantly as hepta- and hexa-γ-glutamates. Crushing raw broccoli, acidification and LTLT blanching enhanced folate deconjugation resulting in monoglutamate, di- and tri-γ-glutamates. Compared to other treatments, HTST blanching preformed prior to crushing resulted in the highest concentration of long chain poly-γ-glutamates. Regarding folate poly-γ-glutamates stability, acidification combined with LTLT blanching decreased folate stability whereas HTST blanching combined with different sequences of blanching and crushing did not affect folate poly-γ-glutamates stability. It was concluded that crushing (prior to heating), acidification and blanching could be strategically applied to increase the folate monoglutamate content of broccoli.

1. Introduction

Folates have been attracting a lot of attention due to their association with reduction in the occurrence of neural tube defects, certain types of cancer and diseases, e.g., cardiovascular disease by lowering homocysteine levels (Lucock, 2002; McKillop et al., 2002; Stranger, 2002). Man cannot synthesize folates and therefore has to obtain them from the diet. Dietary sources rich in folates include yeast extracts, liver, eggs, kidney, green leafy vegetables, legumes and citrus fruits (Scott, Rébeillé, & Fletcher, 2000).

The bioavailability of folates from plant based foods has been reported to vary from 50% to 98% in comparison with that of synthetic folic acid (Brouwer et al., 1999; Hannon-Fletcher et al., 2004; Sauberlich, Kretsch, Skala, Johnson, & Taylor, 1987; Seyoum & Selhub, 1998). Low folate bioavailability could be attributed to various factors such as folate instability and existence of dietary folates as poly-γ-glutamates (Seyoum & Selhub, 1998). Due to their state of reduction at the 5–8 positions of the pteridine moiety, dietary folates are quite unstable during processing, and can easily undergo oxidation (McKillop et al., 2002; Murphy, Boyle, Weir, & Scott, 1976; Murphy, Keating, Boyle, Weir, & Scott, 1978). The stability of folates during processing is influenced by temperature, pressure, pH, oxygen, light, metal ions, antioxidants and duration of heating (Gregory, 1989; Hawkes & Villota, 1989; Indrawati et al., 2004; McKillop et al., 2002; Verlinde, Oey, Hendrickx, & Van Loey, 2008).

In fruits and vegetables, folates mainly occur as poly-γ-glutamates with typically 2–11 γ-glutamic acid residues (Eitenmiller & Landen, 1999; Gregory, 1989; Lucock, 2002; Melse-Boonstra et al., 2002; Scott et al., 2000; Seyoum & Selhub, 1998). Before absorption in the intestines, folate poly-γ-glutamates must first be deconjugated to monoglutamate by the intestinal γ-glutamyl hydrolase (GGH, EC 3.4.19.9). However, the activity of intestinal GGH is said to be susceptible to inhibition by constituents found in some foods (Bhandari & Gregory, 1990), and such inhibition may further jeopardize the bioavailability of dietary folates. Therefore, increasing folate monoglutamate concentration in foods prior to ingestion could increase the bioavailability of dietary folates. Plant GGH, the enzyme that catalyses the hydrolysis (deconjugation) of folate poly-γ-glutamates to shorter chain poly-γ-glutamates and monoglutamates (Orsomando et al., 2005), has been reported to occur in the cytosol, extracellularly and in the vacuole (Huangpu, Pak, Graham, Rickle, & Graham, 1996; Lin, Rogiers, & Cossins, 1993; Orsomando et al., 2005). Therefore, matrix disruption (e.g., cutting, crushing, processing) facilitate the GGH catalyzed hydrolysis of native folate poly-γ-glutamates to shorter poly-γ-glutamates and monoglutamate (Leichter, Landymore, & Krumdieck, 1979; Melse-Boonstra et al., 2002).

doi:10.1016/j.foodchem.2009.04.036

Despite the potential of exploiting processing techniques to increase the bioavailability of dietary folates (by enhancing poly-γ-glutamate deconjugation), only limited data on the folate poly-γ-glutamate profile and the influence of processing on the poly-γ-glutamate profile of fruits and vegetables is available (Ndaw, Bergaentzlé, Aoudé-Werner, Lahély, & Hasselmann, 2001; Verlinde et al., 2008; Zheng, Lin, Lin, & Cossins, 1992). Hereto, the objectives of this research were to evaluate the native profile of folate poly-γ-glutamates; the effects of different treatments namely blanching, crushing and acidification on stability and deconjugation of folate poly-γ-glutamates and the effect of different sequences of performing these treatments on the stability and deconjugation of folate poly-γ-glutamates. In this study, broccoli was used as a case study since it is rich in folate poly-γ-glutamates.

2. Materials and methods

2.1. Reagents and folate standards

All chemicals used were of analytical or HPLC grade. Unless otherwise stated, all reagents were prepared using double demineralized water (18 MΩ cm at 25 °C) produced with a water purification system (Simplicity 185, Millipore Massachusetts, USA). The following folate poly-γ-glutamate standards were obtained from Schircks Laboratories (Switzerland); (6R,S)-5-methyl-5,6,7,8-tetrahydrofolic acid poly-γ-glutamates (5-CH_3–H_4PteGlu$_{2-5}$) trihydrochloride salts, pteroylhexa-γ-L-glutamic acid (PteGluγ$_6$) and pteroylhepta-γ-L-glutamic acid (PteGluγ$_7$). 5-CH_3–H_4PteGluγ$_6$ and 5-CH_3–H_4PteGluγ$_7$ were obtained by chemical conversion of PteGluγ$_6$ and PteGluγ$_7$ as outlined by Ndaw et al. (2001). (6S)-5-Methyl-5,6,7,8-tetrahydrofolic acid calcium salt (5-CH_3–H_4PteGlu$_1$) was obtained as a gift from Merck Eprova AG (Schaffhausen, Switzerland).

2.2. Sample preparation

To determine the native folate poly-γ-glutamate profile, one batch of each of two broccoli varieties (Belstar (BS) from Belgium, and unknown variety from Holland (HK)) was purchased from a local greengrocer. The broccoli was stored at 4 °C for maximum five days before use. For each of the two varieties the florets (including 1 cm of stalk) were cut from the broccoli heads, mixed to obtain a homogenous sample and then divided into two portions. One portion of intact florets was vacuum-packed in plastic bags (50 g per bag) and given a heat shock treatment by boiling in water for 10 min to inactivate endogenous GGH and other enzymes. The heat shocked florets were then cooled in ice water, frozen in liquid nitrogen and stored at −80 °C until folate extraction. The other portion of intact florets was vacuum-packed and directly frozen in liquid nitrogen without heat shock treatment (no inactivation of GGH and other enzymes) and stored at −80 °C until extraction. Prior to folate extraction, the frozen samples were ground (Grindomix, GM 200, Germany) to a frozen powder.

To determine the influence of different treatments on the stability and profile of folate poly-γ-glutamates, one batch of broccoli (20 kg, variety Grammel, Spain) was purchased from a local supplier. During the study, the broccoli was stored at 4 °C for a period not longer than 5 days. Both the florets and the stalks were used for the treatments. Broccoli heads were obtained by cutting the main stalk at the point slightly below the emergence of the smaller stalks. The florets, together with about 1 cm of stalk, were cut off from the rest of the stalk and these were used as broccoli floret samples. The rest of the stalk was cut into pieces of about 1 cm and used as broccoli stalk samples. The bottom main stalk was discarded.

2.3. Treatments

Two different crushing-blanching sequences were carried out as illustrated in Fig. 1. Mechanical (i.e., crushing) and thermal (blanching) treatments were conducted at the natural pH of broccoli around 6.5 and at acidic pH of 4.3. To obtain pH 6.5 and 4.3, broccoli florets or stalks were crushed (Buchi mixer, B-400, Switzerland) in the presence of distilled water or acetate buffer (0.2 M, pH 3.7) respectively, at a ratio of 1:1 (w/v). A crushing time of 20 s was standardized.

For thermal treatments, the samples were vacuum-packed (Multivac A300/16, Wolfertschwenden, Germany) in plastic bags (50 g per bag) and heated in a water bath (Memmert, WBU 45, Germany) either before or after crushing. High temperature short time (HTST) blanching was carried out at 90 °C for 4 min and low temperature long time (LTLT) blanching at 60 °C for 40 min. For the samples crushed before blanching, a 30 min period (including the time for vacuum-packing) after crushing and before blanching was standardized. For the samples crushed after the thermal treatment, a 15 min period after crushing (including the time for vacuum-packing) was standardized. After the various treatments, samples were cooled in ice water, frozen in liquid nitrogen and then freeze dried. The samples were then packed in opaque plastic containers and stored in a desiccator containing phosphorous pentoxide (P_2O_5) at room temperature for maximum 21 days.

2.4. Folate analysis

Folate analysis including extraction, chemical conversion of broccoli folates to 5-CH_3–H_4PteGlu$_n$, purification, and quantification was performed according to the method of Ndaw et al. (2001) optimized for broccoli (Verlinde et al., 2008) with a few modifications. Regarding folate extraction, 20 g heat shocked or 20 g non-heat shocked samples was respectively mixed with 50 ml cold or 50 ml boiling extraction buffer (phosphate buffer (0.1 M, pH 7, containing ascorbic acid)). Afterwards, the mixtures were homogenized (Ultra Turrax T25, IKA Labortechnik, Staufen, Germany) for 30 s. The non-heat shocked samples were hot extracted by immersion of the sample-containing tubes in boiling water for 10 min and subsequently cooled in ice water. The heat shocked samples did not receive a hot extraction to avoid folate degradation due to excessive heating and so that both categories of samples received approximately the same total heating intensity.

To extract folates from treated samples, 2 g freeze-dried broccoli was mixed with 50 ml boiling extraction buffer (phosphate buffer (0.1 M, pH 7, containing ascorbic acid) and 17.8 ml of double distilled water. The subsequent extraction steps were performed as described by Verlinde et al. (2008). The heat shocked and non-heat shocked samples were analyzed in triplicate while the treated samples were analyzed in duplicate. The dry matter content of broccoli folate and stalks was determined by oven drying broccoli at 105 °C for 16 h.

Quantification of the folates from broccoli was done using an external calibration with folate standards (5-CH_3–H_4PteGlu$_{1-7}$) and was based on peak height. The detection limit for the various poly-γ-glutamates and monoglutamates ranged from 0.015 to 0.100 pmol on column. The recovery of different folate derivatives as determined by spiking broccoli with standard (5-CH_3–H_4PteGlu$_{1-7}$) was taken into account in the quantification.

2.5. Method validation and recovery determination

The efficiency of the chemical conversion used in the current study had been previously demonstrated to be high (Verlinde et al., 2008). However, since the quality of the folate binding proteins (in the affinity chromatography columns) degrade with

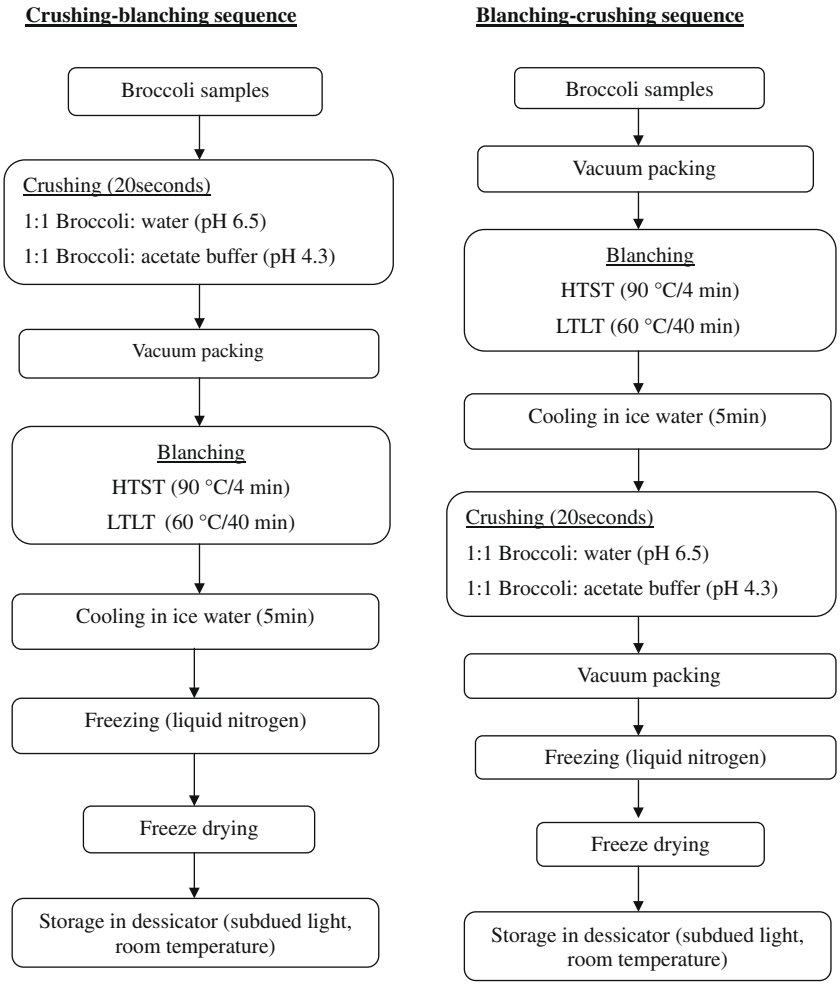

Fig. 1. Schematic representation of the different treatments applied to broccoli florets and stalks.

time, freshly made affinity chromatography columns were used in the current study. To ensure maximum folate recovery from samples, the maximum binding capacity of the affinity chromatography columns was checked using an excess of 5-CH_3–H_4PteGlu$_1$ (4.02 nmol). During folate purification, only 5 ml of chemically converted samples (with folate content less than 25% of the maximum binding) was applied on the columns.

The entire method of folate analysis was validated by analyzing a certified reference material consisting of lyophilized mixed vegetables (CRM 485, BCR, Geel-Belgium) and by spiking heat shocked broccoli with folate standards. Six grams of the CRM 485 was analyzed in triplicate. The dry matter content of the reference material was determined by oven drying the samples for 2 h at 105 °C.

Heat shocked broccoli was used during the spiking experiment to avoid enzymatic interconversion of folate poly-γ-glutamates which might interfere with the quantification of the different folates. Ten grams of the heat shocked broccoli was spiked with a mixture of 5-CH_3–H_4PteGlu$_{1-7}$ (total 29.4 nmol) in the beginning of the extraction procedure. The 5 ml chemically converted (spiked) sample applied on the affinity columns contained 0.32 nmol folates (approximately 10% of the maximum binding capacity). The folate content in the spiked broccoli ($n = 3$) was compared with the folate content in non spiked broccoli ($n = 3$).

2.6. Data analysis

Significance of differences for the mean of total folate contents and percent distribution of various folate derivatives in differently treated samples were analyzed by one way ANOVA using Tukey method (S-Plus 6.1.2, Release 1 for Microsoft Windows: 2002). The mean of total folate contents and percent distribution of various derivatives in all treated samples were compared with that of unblanched crushed (pH 6.5) samples.

3. Results and discussion

3.1. Method validation and recovery of folates

The recovery of folates during the chemical conversion step had been previously demonstrated to be close to 100% (Verlinde et al., 2008). The maximum binding capacity of the affinity columns as determined with 5-CH_3–H_4PteGlu$_1$ ranged from 2.24 to 3.15 nmol for the five columns used in the current study. The entire method of folate analysis was validated by analyzing a certified reference material (CRM 485). Using the current method, 2.87 ± 0.22 μg PteGlu1/g DM (6.50 ± 0.50 nmol/g DM) was found in CRM 485. This value was based on a dry matter content of 98.5% for CRM 485 and was in the range of 3.15 ± 0.28 μg PteGlu/g DM (7.15 ± 0.63 nmol/g DM) stated in the certification for this material. The predominant folate derivative in CRM 485 was monoglutamate (2.19 ± 0.23 μg PteGlu/g DM).

The average recovery of the folates spiked into broccoli was 91%. The recovery for individual folates is summarized in Table 1. These recoveries were taken into account in quantifying the folate content in broccoli samples.

Table 1
Individual folate derivative recovery from heat shocked broccoli spiked with 5-CH_3–$H_4PteGlu_{1-7}$ standards.

Folate derivative	Percent recovery
Hepta-γ-glutamate	90 ± 12[a]
Hexa-γ-glutamate	90 ± 15
Penta-γ-glutamate	96 ± 16
Tetra-γ-glutamate	88 ± 18
Tri-γ-glutamate	99 ± 6
Di-γ-glutamate	89 ± 11
Monoglutamate	91 ± 12

[a] Mean ± SD (n = 3).

3.2. Native folate poly-γ-glutamates profile of broccoli

To determine the native profile of broccoli folates, intact broccoli florets were first subjected to a heat shock treatment in order to inactivate endogenous broccoli GGH. The folate profile of the heat shocked broccoli was compared with that of non heat shocked (raw) broccoli. Although differently substituted folate derivatives (10-formyldihydrofolate (10-HCO–$H_2PteGlu_{1)}$, 5-formyltetrahydrofolate (5-HCO–$H_4PteGlu_1$), tetrahydrofolate ($H_4PteGlu_1$)) have been isolated from broccoli, results from several authors show that broccoli folates are mainly 5-CH_3 substituted (Konings et al., 2001; Stea, Johansson, Jägerstad, & Frølich, 2006; Zheng et al., 1992).

Table 2 shows the poly-γ-glutamate profile of both heat shocked and raw broccoli florets. Folates with 1–7 glutamate residues were found in broccoli. The folates in heat shocked broccoli predominantly occurred as hexa- and hepta-γ-glutamates. However, in comparison to the heat shocked broccoli, raw broccoli contained lower concentration of hexa- and hepta-γ-glutamates and higher concentration of tri-, di-γ-glutamate and monoglutamate. Results from the current study indicate that the native profile of broccoli folates consist mainly of hepta- (>50%) and hexa-γ-glutamates (>20%) and very little of folate monoglutamates. However, upon matrix disruption in the presence of active endogenous GGH the hepta- and hexa-γ-glutamates are deconjugated to shorter chain folate poly-γ-glutamates and monoglutamates. From these observations it was concluded that endogenous broccoli GGH was active in the raw samples and was responsible for the deconjugation of hepta- and hexa-γ-glutamates to shorter folate poly-γ-glutamates and folate monoglutamates. Since the raw broccoli was frozen with liquid nitrogen in the intact form and stored at −80 °C before extraction, not much enzymatic reaction due to GGH activity occurred in the frozen state. However, it is likely that most of the deconjugation took place during thawing and during the early stages of the hot extraction before the broccoli samples reached temperatures sufficient to inactivate GGH.

The native profile of broccoli folate poly-γ-glutamates observed in the current study is different from that reported in literature. Verlinde et al. (2008) reported that two broccoli varieties predominantly contained tri-γ-glutamates (>50%) while Zheng et al. (1992) reported that broccoli consisted of 80% di-γ-glutamates. Zheng et al. (1992) sliced the raw vegetables prior to hot extraction while Verlinde et al. (2008) extracted folates from frozen but raw broccoli. The high percentage of tri-γ-glutamate (Verlinde et al., 2008) and di-γ-glutamates (Zheng et al., 1992) could be the result of deconjugation of longer chain poly-γ-glutamates to the shorter chain poly-γ-glutamates during extraction of raw samples containing active endogenous GGH.

Regarding the poly-γ-glutamate profile of other vegetables, Zheng et al. (1992) reported folates with 2–8 γ-glutamyl residues for cauliflower, lettuce, cabbage pea leaves and carrot while Ndaw et al. (2001) found folates with 1–6 γ-glutamyl residues in spinach and peas. The latter authors reported relatively high percentage of monoglutamate (24%) in peas and spinach, an indication of GGH activity during sample handling and/or extraction.

Based on the findings of the current study, it was concluded that endogenous GGH activity can influence the poly-γ-glutamate profile of vegetables. In order to accurately determine the native folate poly-γ-glutamate profile of a vegetable, it is important to first inactivate the endogenous GGH prior to matrix disruption.

3.3. Effect of treatments on the native folate poly-γ-glutamate profile of broccoli

The different treatments investigated in the current study influenced the profile of broccoli poly-γ-glutamates in different ways. The percentage distribution of the various folate poly-γ-glutamates and monoglutamate in all the investigated treatments is presented in Fig. 2. A similar trend regarding the changes in the poly-γ-glutamate profile was observed in both florets and stalks.

Crushing unblanched broccoli resulted in deconjugation of the predominantly occurring hepta- and hexa-γ-glutamates into shorter folate poly-γ-glutamates (mainly tri-γ-glutamates) and monoglutamate. The poly-γ-glutamate profile of the unblanched crushed (pH 6.5) floret and stalk samples was similar to that of raw samples discussed in the previous section.

Regarding the influence of different crushing-blanching sequences, crushing broccoli prior to blanching led to deconjugation of folate poly-γ-glutamates as indicated by a higher percentage of monoglutamate, di- and tri-γ-glutamates and a lower percentage of longer poly-γ-glutamates. However, changes in the poly-γ-glutamate profile of broccoli blanched in the intact form (prior to crushing) were dependent on the temperature of the blanching process. HTST-crushed florets samples had a higher percentage of hepta- and hexa-γ-glutamates but lower percentage of shorter chain poly-γ-glutamates and monoglutamates, a profile similar to that of heat shocked samples discussed above. In comparison to HTST-crushed samples, LTLT-crushed samples contained lower concentration of hepta- and hexa-γ-glutamates but higher concentration monoglutamate di- and tri-γ-glutamates indicating

Table 2
The native folate poly-γ-glutamate profile (percentage distribution) and total folate content (nmol/g DM) of heat shocked (95 °C/10 min, HTST) and non-heat shocked (raw) broccoli.

	HK HTST (%)	HK raw (%)	BS HTST (%)	BS raw (%)
Hepta-γ-glutamate	56.5 ± 6.0[a]	20.1 ± 6.0	52.9 ± 10.7	7. ± 0.9
Hexa-γ-glutamate	20.4 ± 1.7	10.6 ± 2.6	23.7 ± 6.0	3.1 ± 0.6
Penta-γ-glutamate	6.8 ± 1.8	4.4 ± 0.9	6.8 ± 2.9	3.1 ± 0.2
Tetra-γ-glutamate	2.4 ± 0.5	13.7 ± 3.8	3.7 ± 1.6	13.7 ± 3.5
Tri-γ-glutamate	7.7 ± 2.9	27.8 ± 7.1	9.1 ± 3.3	47.0 ± 12
Di-γ-glutamate	4.2 ± 2.0	13.4 ± 3.2	2.9 ± 0.8	16.2 ± 7.6
Monoglutamate	1.8 ± 0.5	10.0 ± 3.9	1.0 ± 0.3	9.4 ± 2.6
Total folate (nmol/g DM)	49.9 ± 3.4	48.1 ± 7.8	67.9 ± 27.4	58.7 ± 7.5

[a] Mean ± SD (n = 3).

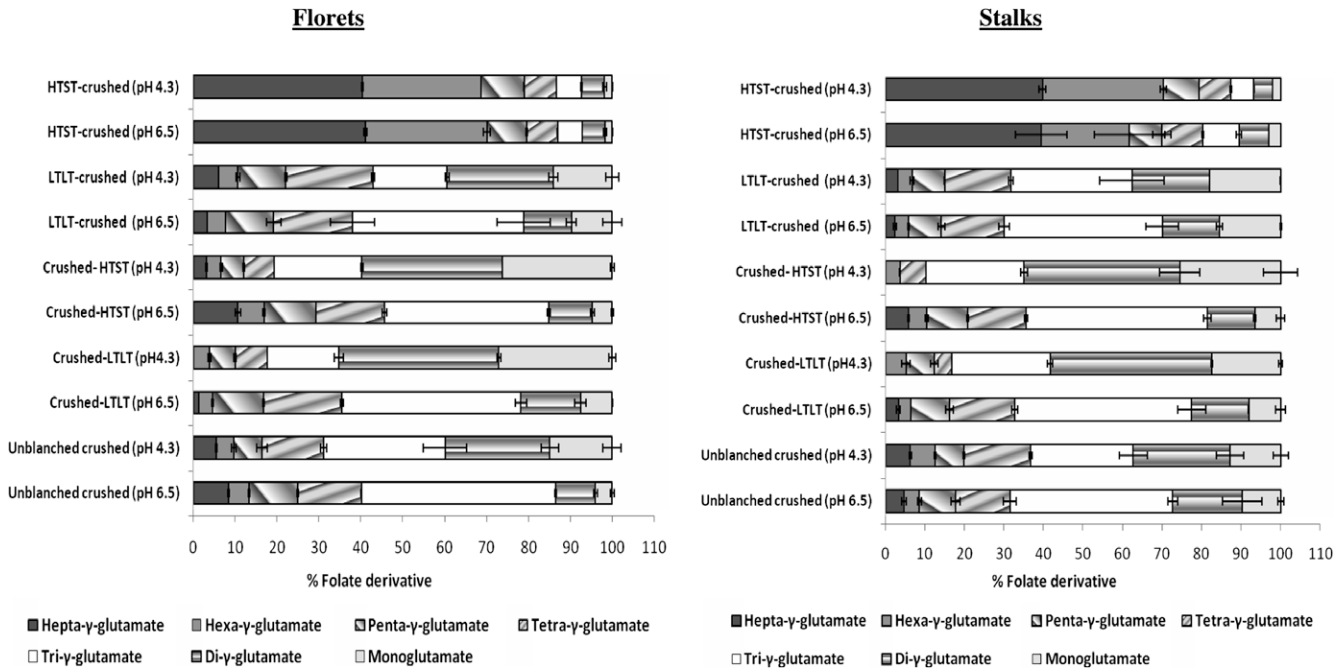

Fig. 2. The influence of crushing, acidification and blanching on the percent distribution of different folate derivatives in broccoli florets and stalks. Error bars indicate the standard deviation ($n = 2$).

that there was deconjugation during LTLT blanching of intact broccoli.

Regarding the influence of blanching temperature, the changes in the polyglutamate profile were identical for LTLT blanched and HTST blanched samples when broccoli was crushed prior to blanching. However, when broccoli was blanched prior to crushing, LTLT blanching resulted in deconjugation of polyglutamates, while HTST blanching maintained the native profile of poly-γ-glutamates.

Acidification had a significant influence on the folate poly-γ-glutamate profile. In general, crushing broccoli at pH 4.3 prior to blanching resulted in a higher percentage of monoglutamate and di-γ-glutamate in comparison to crushing at pH 6.5. The highest concentrations of monoglutamate and di-γ-glutamates were observed in crushed (pH 4.3)-LTLT and crushed (pH 4.3)-HTST samples. In samples crushed at pH 4.3 with subsequent blanching, hepta-γ-glutamate was almost completely deconjugated to shorter poly-γ-glutamates and monoglutamate. The obtained results indicated that GGH was responsible for the deconjugation and that pH 4.3 favored the activity of endogenous broccoli GGH compared to pH 6.5. Lowering the pH of broccoli in samples where the GGH was inactivated (e.g., HTST-crushed (pH 4.3)) did not result in deconjugation. This observation is in agreement with results of Verlinde et al. (2008) who observed that non-enzymatic folate poly-γ-glutamates deconjugation did not occur during thermal and combined thermal-high pressure treatments of 5-CH_3–H_4PteGluγ_5.

Several isozymes of GGH were reported to occur in plant materials, but the number of isozymes may vary depending on the plant species. It was recently demonstrated that two of these isozymes (AtGGH1 and AtGGH2 proteins from *Arabidopsis* but expressed in *Escherichia coli*) could cleave $PteGlu_5$ in different ways. AtGGH1 resulted mainly in $PteGlu_1$, $PteGlu_2$ and $PteGlu_3$ while AtGGH2 resulted mainly in $PteGlu_1$ (Orsomando et al., 2005). Results from the current study indicated that conditions favoring the activity of endogenous broccoli GGH resulted mainly in monoglutamate, di- and tri-γ-glutamates. Leichter et al. (1979) made a similar observation whereby they noted that the free folate content of vegetables increased when vegetables were homogenized before boiling. Similarly, Melse-Boonstra et al. (2002) observed that processing conditions leading to plant cell damage (freezing (−18 and −80 °C) and high pressure treatments) without prior heat treatment contributed to higher folate monoglutamate content in leeks, cauliflower and green beans while blanching and steaming resulted in high amounts of folate poly-γ-glutamates. However, Leichter et al. (1979) and Melse-Boonstra et al. (2002) did not show the folate profile of the vegetables. Verlinde et al. (2008) reported that broccoli predominantly contained tri-γ-glutamates but also noted that the proportion of hepta- and hexa-γ-glutamates was greater in broccoli treated at 70–90 °C for 30 min compared to the untreated samples and samples treated at lower temperatures. The current study has proved that hepta- and hexa-γ-glutamates are the predominant folate poly-γ-glutamates in broccoli. However, hepta- and hexa-γ-glutamates can be enzymatically deconjugated by active GGH to give mainly tri-γ-glutamates.

Literature on the properties of endogenous plant GGHs is limited. A few earlier studies showed that GGH from green leaves of soybean and pollen has an optimum pH of 4.5 (Iwai, 1957; Nielson & Holmström, 1957). However, other authors reported higher pH values for optimum GGH activity. Zheng et al. (1992) reported that broccoli leaves GGH optimally converted $PteGlu_3$ and $PteGlu_6$ to $PteGlu_1$ at pH 5.0. Orsomando et al. (2005) reported an optimum pH between 6.5 and 7.0 for AtGGH1 and pH 6.5 for AtGGH2. Results from the current study indicate that the optimum pH for broccoli GGH could be located below pH 6.5 since the rate of deconjugation was higher at pH 4.3 than at pH 6.5. However, further investigations need to be carried out to confirm the optimal pH of endogenous broccoli GGH. Finding the optimal pH of broccoli GGH might be useful in processing broccoli to products with higher monoglutamate content with the aim of increasing folate bioavailability.

Most vegetables are thermally treated prior to consumption. A survey carried out by McKillop et al. (2002) in the UK showed that 49% of people boil vegetables while 45% steam them. Observations

made in the current study indicate that the most abundant folate forms in thermally treated broccoli (and probably in other thermally treated vegetables) are poly-γ-glutamates. However, acidification, mild heating and crushing of vegetables prior to thermal treatments can be useful strategies of increasing folate monoglutamates without significantly decreasing stability.

3.4. Effect of treatments on stability of folates in broccoli

A total folate content of 690 ± 29 and 303 ± 30 nmol/100 g FW, respectively, was found in unblanched crushed (pH 6.5) florets and stalks in the current study. The values were calculated based on a dry matter content of 11% and 7% for florets and stalks, respectively. The folate content found for florets in the current study was higher than values (231, 258, 261, 401 and 315 nmol/100 g FW) reported by DeSouza and Eitenmiller (1986), Vahteristo, Lehikoinen, Ollilainen, and Varo (1997), McKillop et al. (2002), Stea et al. (2006) and Verlinde et al. (2008), respectively. The higher values reported in this study could be attributed to seasonal and varietal differences. The folate content in broccoli stalks is not widely investigated. In this study, broccoli stalks were found to contain 56% less folates compared to florets.

The influence of different treatments on the stability of folates is shown in Tables 3 and 4. The unblanched crushed (pH 6.5) sample was used as a reference to compare the effect of different treatments on folate stability. In this study, crushing resulted in a limited effect on folate stability in florets since, for example, there was no significant difference in crushed-HTST and HTST-crushed florets. However, stalks crushed prior to blanching (except crushed (pH 6.5)-LTLT) seemed to retain less folates compared to stalks blanched prior to crushing. This apparent difference in folate stability in florets and stalks crushed prior to blanching could be due to lower antioxidants (e.g., ascorbic acid) content in stalks (Nishikawa et al., 2003) than in florets.

Concerning the effect of blanching temperature on folate stability, HTST-blanched samples retained more folates compared to LTLT-blanched samples. The lower folate stability during LTLT blanching could be due to slower and probably incomplete oxidative enzymes (such as ascorbate oxidase, phenol oxidase and peroxidase) inactivation and longer heating time. Slower and probably incomplete oxidative enzyme inactivation during LTLT could have lowered the antioxidant status in LTLT blanched samples leaving folates exposed to oxidation. On the other hand higher temperature during HTST blanching could have resulted in faster oxidative enzyme inactivation thus rendering the folates more protected against oxidation.

The stability of folates was found to be lower at pH 4.3 than at pH 6.5. The lowest stability was observed in treatments involving both pH 4.3 and LTLT blanching. For example, crushed (pH 4.3)-LTLT florets samples showed the highest folate loss (36%) among all treatments investigated. The lower folate stability during treatments involving LTLT blanching and pH 4.3 could be attributed to higher heating intensity and acidic pH. Except for the low folate stability observed in treatments involving LTLT blanching and pH 4.3, lower folate losses compared to losses reported in literature were probably due to exclusion of leaching effects. Most folate losses reported in literature during thermal processing of vegetables were attributed to leaching in the cooking water. DeSouza and Eitenmiller (1986) reported losses of 70% for water blanched (4 min) and only a loss of 9% for steam blanched (4 min) broccoli. In another study by McKillop et al. (2002), boiling broccoli for 10 min caused 51% folate loss compared to raw broccoli while steaming for 10 min caused non-significant folate losses. Stea et al. (2006) observed 27% folate losses after water blanching broccoli in comparison to steaming. Although there is not much data on the effect of pH on folate stability during vegetable processing, low

Table 3
Effect of crushing, acidification and blanching on individual and total folate content in broccoli florets. Letters in parenthesis indicate which treatment resulted in significantly different concentration of each derivative compared to the unblanched crushed (pH 6.5).

pH has been reported to reduce folate stability during folate extraction from vegetables (Vahteristo et al., 1997; Zhang, Storozhenko, Van Der Straeten, & Lambert, 2005) and in model systems (Indrawati et al., 2004).

4. Conclusion

Acidification and thermal treatment (depending on the heating intensity) result in different impacts on the stability and the poly-γ-glutamate profile of folates in broccoli. Lowering pH resulted in lower folate stability but enhanced the activity of endogenous GGH. In addition, the sequence of conducting crushing and thermal treatments also played an important role in facilitating enzymatic and chemical reactions resulting in differences in the stability and poly-γ-glutamate profile of folates.

These observations imply that different process strategies of crushing, acidification and thermal treatment could result in fruit and vegetable based products with similar folate content but different folate poly-γ-glutamate profiles which could eventually affect the bioavailability. This study has demonstrated for example that crushing (pH 6.5) followed by HTST blanching resulted in a folate content similar to that of HTST blanching followed by crushing (pH 6.5) but in a totally different folate poly-γ-glutamates profile. Therefore, it is clear that different sequences of processes could be intelligently designed and controlled to achieve a specific targeted profile of poly-γ-glutamate folate while maintaining folate stability. With regard to process optimization, it should be taken into consideration that the activity and the stability of undesired enzymes, e.g., ascorbate oxidase should also be controlled in parallel with enhancing the activity and the stability of desired enzymes such as endogenous GGH during processing.

So far, information on the processing effect on the stability and the activity of undesired enzymes affecting folate stability, e.g., ascorbate oxidase in food matrix and on the effect of folate poly-γ-glutamate profile on bioavailability is still limited in literature. Hereto, further research addressing these issues is still needed.

Acknowledgements

We acknowledge and appreciate the support of the following organizations in accomplishment of this work: Interfaculty Council for Development Co-operation (IRO-Doctoral scholarship, K.U. Leuven), Specific Targeted Research Project (EU Project, Healthy Structuring 2006-023115), Institute for the Promotion of Innovation through Science and Technology in Flanders (Doctoral Grant, IWT-Vlaanderen) and Research Foundation Flanders (Postdoctoral Grant, FWO-Vlaanderen) The kind donation of (6S)-5-methyl-5,6,7,8-tetrahydrofolic acid calcium salt by Merck Eprova AG was also appreciated.

Zinc dialysability

ABSTRACT

The investigation aimed at studying the influence of soya proteins on *in vitro* dialysability of exogenous iron and zinc. Soyabean was processed into various components like soya flour (SF), concentrate (SC) and isolate (SI) and two peptides (<30 kDa and >30 kDa). The protein contents of SF, SC and SI were 51, 62 and 78 g/100 g, respectively. Their iron contents ranged between 9.7 and 15.8 mg/100 g and zinc contents from 3.3 to 6.7 mg/100 g. Phytic acid contents (mg/100 g) of the soya components were SF 339, SC 226, SI 186 and peptides 18–20. In SF, percent dialysable iron and zinc were 12.6 and 50, respectively, this reduced to one-third and one-fifth in SC and SI. Dialysability of exogenously added minerals was found to be significantly lower in all soya protein components. However, the inhibitory effect was less pronounced in peptides. The protein component/matrix effect needs to be investigated to counteract the inhibitory effect of soya on iron dialysability.

1. Introduction

Soyabeans are the richest sources of protein among the plant foods. Good quality and functionality of its proteins, hypoallergenicity, low cost and surplus availability are other added features that motivated the researchers to explore its utility in a wide range of foods including the complementary foods. With these attributes, soyabeans have been considered as an ideal food for meeting the protein needs of the population. Soyabeans in the form of full fat flour, concentrate, isolate and texturised proteins have been used in a wide range of food products. However, the impact of soya based formulas on the growth and development of infants were shown to be contradictory. Some studies have shown that infants fed with soya based formula achieved a similar growth to their peers who received cow's milk (Fomon, 1993), while others have shown that infants fed with soya based formulas showed poor growth rates (Golden & Golden, 1981). The presence of phytic acid at different levels in soya based products has been shown to inhibit trace mineral absorption (Davidson, Zeigler, Kastenmayer, Dael, & Barclay, 2004; Derman et al., 1987; Sandstorm, Cederblad, & Lonnerdal, 1983).

Iron deficiency anaemia is one of the major nutritional problems at global level with a major thrust from the developing world, zinc deficiency is another emerging nutritional problem that needs immediate attention. The main aetiology in these micronutrient deficiencies was found to be low intake accompanied by poor bioavailability (Charlton & Bothwell, 1983; Layrisse et al., 1990). Bioavailability of the minerals in any food is influenced by the proportion of inhibitors and enhancers present in it. Since phytic acid in soyabean was found to be the major inhibitor of both iron and zinc absorption, attempts were made to use dephytinised soya in products. The extent of improvement in enhancing the mineral bioavailability was found to be proportional to the degree of dephytinisation (Davidson, Almgren, Sandstorm, & Hurrell, 1995; Davidson et al., 2004; Hurrell et al., 1992; Lonnerdal, Jayawickrama, & Lien, 1999; Zeigler, Janghorbani, Nelson, & Edwards, 1990). In addition, protein in soyabeans was also reported to be inhibitory for iron absorption (Lynch, Dassenko, Cook, Luillerat, & Hurrell, 1994). The inhibition of absorption of one mineral on the absorption of another has been studied by many investigators, but the results are quite conflicting as each study has used a different food matrix and different ratios of minerals (Sandstorm, 2001).

Food fortification has been considered as one of the effective strategies for combating both macro and micronutrient deficiencies that are co-existent in the developing countries. A recent comprehensive review by Parada and Aguilera (2007) has clearly brought out the fact that food microstructure has a major role to play in affecting the bioavailability of minerals (Moretti et al., 2006). Hence it becomes essential to study the effect of food matrix on the bioavailability of both endogenous and exogenously added micronutrients. The investigation was undertaken to study the effect of soya proteins on the dialysability of endogenous and exogenous iron and zinc.

2. Materials and methods

2.1. Materials

Ferrous sulphate and zinc oxide were procured from Sigma–Aldrich Ltd. The enzymes used for the study were Pepsin (Hi media, Batch no.; 06-1315) and Pancreatin (Hi media, Batch no.; 5-1497). All the chemicals used for the study were of analytical grade. The dialysis tubing of 10 kDa was procured from Spectrum, USA. Triple distilled water was used for the entire analysis. All the analysis was done in triplicates. Soyabeans [*Glycine hispida* (Moench) maxim] was procured from the local market. The soya protein components namely flour, concentrate and isolate processed at the pilot scale in the laboratory (in a single large-scale batch) were used for the entire analyses cited below.

2.2. Preparation of soya flour components

(i) *Defatted soya flour*: Soyabean seeds were cleaned, dehulled and flaked. The flakes were defatted with n-hexane and the fat content was determined by soxhlet method. Defatting was continued until the fat content was less than 1%. The defatted flakes were dried and powdered in a Quadrumat mill (Buisberg, Germany). The fractions were obtained using sieves, defatted flour was the component having a pore size below 100 μ.

(ii) *Soya protein concentrate: Soya* protein concentrate was prepared by eliminating soluble carbohydrate fractions and some flavour compounds from defatted meal. The process involved acid leaching at isoelectric pH wherein the proteins were insolubilised (a small portion of the carbohydrates remained soluble), and were separated by centrifugation. Solids containing mainly proteins and insoluble carbohydrate were then dispersed in water, neutralised to pH 7 and were spray dried.

(iii) *Soya protein isolate: Soya* protein isolate was prepared from defatted soya meal using mild alkali extraction (pH 8–10) of proteins. The insoluble residue (mostly carbohydrate) was removed by centrifugation, followed by precipitation of soya protein at its isoelectric point. The precipitated protein was separated by mechanical decanting, washed, and neutralised to a pH of 7.0 and then spray-dried.

(iv) *Peptides:* Two peptides of different molecular weight; one of <30 kDa and the other >30 kDa was prepared by ultrafilteration. In brief, the defatted flour was hydrolysed using the enzyme fungal protease for 2 h. The hydrolysates were clarified by tangential flow and the filtrate was fractionated by tangential flow through a Satacon Slice Cassette, which had a cut off of 30,000. The ultra filtrate (concentrate) composed of soya peptides of <30 kDa and retentate composed of fraction having a molecular weight of >30 kDa. The two fractions with different molecular weight were spray dried and desiccated until further use.

Molecular weight of the prepared peptides was determined using 12% sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS–PAGE) (Laemmili, 1970). The molecular weight markers used were, bovine serum albumin (BSA), 66 kDa; ovalbumin chicken egg, 45 kDa; glyceraldehyde 3-P dehydrogenase, 36 kDa; carbonic anhydrase, 29 kDa; trypsinogen bovine, 24 kDa; trypsin inhibitor soya, 20 kDa; α-lactalbumin bovine, 14.2 kDa; aprotinin bovine lung, 6.5 kDa.

Molecular weight was further confirmed by fast protein liquid chromatography (FPLC) using a superdex-75 HR column from Amersham Pharmacia (Uversky, 1993). Sample was prepared in 0.02 mM phosphate buffer with a pH of 7.9, 200 μl was loaded and eluted with the same buffer at a flow rate of 0.5 ml/min, elution was monitored at 280 nm.

2.3. Analysis

Moisture: The moisture content of soya flour and its components was estimated by AOAC method (AOAC, 1999).

Protein: The estimation of nitrogen was done by micro Kjeldhal method using automated nitrogen distiller. The protein content was determined by multiplying the nitrogen value with 6.25 (Raghuramulu, Nair, & Kalyanasundram, 2003).

Total ash: The greyish white residue formed after charring and incineration in a muffle furnace at 600 °C for 6–8 h comprised of the total mineral content. Iron and zinc content of the soya protein components were analysed by atomic absorption spectroscopy (AAS) (Raghuramulu et al., 2003).

Dialysable iron and zinc: The dialysable fraction of iron and zinc contents was estimated by the method of equilibrium dialysis (Luten et al., 1996). Iron present in the dialysate predicts non-heme absorption *in vivo,* it contains other minerals that are in the absorbable form. It is expressed as dialysable minerals (iron and zinc).

Phytin phosphorus: Phytic acid was extracted and determined according to the supernatant difference method (Thompson & Erdman, 1982).

The effect of protein on the availability of exogenous iron and zinc was studied by adding ferrous sulphate and zinc oxide for the respective minerals. The ratios of protein and minerals were based on the recommended dietary allowances for adults given by Indian Council of Medical Research (ICMR) (Gopalan, Sastri, & Balasubramanian, 2000). RDA of protein for adults is 55 g/day, iron is 29 mg/day and zinc is 15 mg/day (zinc values are taken from US RDA). Based on protein content of soya products exogenous minerals were added. It was 27 mg iron and 19 mg zinc for 100 g flour, 32.9 mg iron and 17 mg zinc for concentrate and 41.2 mg iron and 21.3 mg zinc for isolate and peptides.

Statistical analysis: the analysed data were subjected to statistical analysis using the statistical package OriginPro, version 7.0, the probability level was set to $P < 0.05$. Analysis of variance (ANOVA) was adopted to study the differences in the dialysable iron and zinc contents between different soya protein products and also on the externally added minerals in the same protein products.

3. Results and discussion

The soya protein products namely flour, concentrate and isolate were prepared as described under methodology. Short peptides with characteristic amino acid composition and defined molecular weight are highly desirable in nutrition and food science for both functional and nutritional purposes. Based on the molecular weight two peptides, one <30 kDa and the other >30 kDa were fractionated by ultra filtration. The molecular weights of the peptides were determined by electrophoresis. Fig. 1 shows the SDS–PAGE gel electrophoretic pattern of control and ultra filtered soya protein in 12% acrylamide gel. The control protein showed twelve bands, ultra filtered protein <30 kDa had two bands below 20 kDa and the filtrate protein >30 kDa had eight bands. The purity of isolated peptides were further confirmed by FPLC given in Fig. 1a and b. The fraction >30 kDa contained seven peaks and peptide fraction <30 kDa had four peaks.

The related chemical components of the soya protein fractions are presented in Table 1. Defatted soya flour comprised of 50 g protein/100 g flour, preparation of the concentrate and isolate further enhanced the protein content by 11 and 27 g/100 g of products, respectively (Table 1). The protein content in the flour and concentrate was found to be similar to those reported by other investigators (Gopalan et al., 2000; Sandstorm, Kivisto, & Cederblad, 1987). However, in the isolate it was found to be slightly lower than that cited in the literature. This could be attributed to the processing

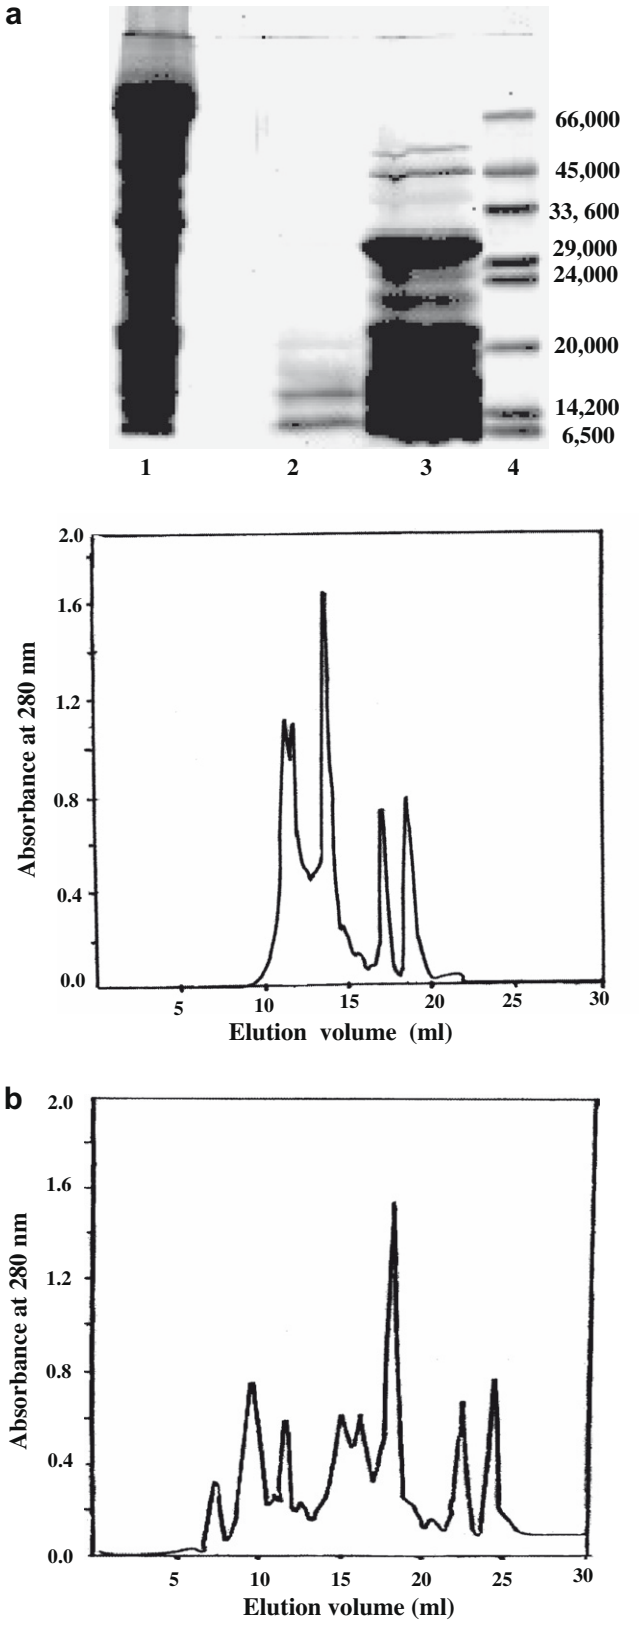

Fig. 1. Sodium dodecyl sulphate poly acrylamide gel electrophoresis (SDS–PAGE) of soya protein peptides. Lane 1: Total soya proteins; Lane 2: Soya protein fractionless than 30 kDa; Lane 3: Soya protein fractiongreater than 30 kDa; Lane 4: Molecular markers. (a) FPLC pattern of soya peptides below 30 kDa. Superdex-75 HR column equilibrated with 0.02 mM phosphate buffer pH 7.9 and eluted with the same buffer at 0.5 ml/min and monitored at 280 nm. (b) FPLC pattern of soya peptides above 30 kDa. Superdex-75 HR column equilibrated with 0.02 mM phosphate buffer pH 7.9 and eluted with the same buffer at 0.5 ml/min and monitored at 280 nm.

variables. The mineral content of the flour was 8 g/100 g and this was found to reduce by almost 44% on concentration and isolation of the protein. Soya flour apart from being a rich source of protein also contains fairly good amount of iron and zinc. With increase in the concentration of the protein content, a 62–63% increase in iron and 81–106% increase in zinc contents was evident. The extent of differences in the iron and zinc contents among the flour components was found to be extremely significant ($F = 115.14^{***}$ for iron and $F = 188.02^{***}$ for zinc). The estimated iron content for soya flour and soya concentrate of the present study matched well with an earlier report (Sandstorm et al., 1987). The iron content in the isolate was found to be lower in comparison with values reported in the literature which could be attributed to the differences in the processing techniques and the extent of extraction. The estimated zinc of soya flour was found to be half of what was reported earlier (Sandstorm et al., 1987). However, it was two and three times higher in the concentrate and the isolate respectively than that reported by the other researchers. Phytic acid content of different soya products ranged 399–186 mg/100 g, it decreased with increasing concentration of protein from flour to isolate. Phytic acid content was 17.7 mg/100 g and 20.3 mg/100 g in <30 kDa and >30 kDa peptides, respectively, which was ten times lower than that present in isolate.

The proportion of the minerals that is biologically available is more important from the nutritional point of view. As evident from Table 1, around 13% of the iron present in the soya flour was dialysable. In concentrate and isolate the dialysability of the mineral ranged between 4 and 5% of the total content. Though the total iron content was higher by 50% in the concentrate and isolate compared to the flour its dialysability reduced to around 1/3rd of its concentration. The differences in the dialysable iron content of the soya flour components was found to be extremely significant as per ANOVA ($F = 87.36^{***}$). Dialysable zinc of soya flour was found to be 50%, it reduced by almost fivefolds and more in concentrate and isolate. The differences in the dialysability of the element among the soya protein products were found to be extremely significant ($F = 184.8656^{***}$). However, the dialysability of zinc was measurably higher compared to iron in the soya protein products. It is well established that phytic acid negatively affects the dialysability of the minerals in any food matrix. When the dialysable iron and zinc contents were associated with the phytic acid content in different soya protein products, a high negative correlation was observed for both iron ($r = -0.97$) and zinc ($r = -0.99$). Though a linear reduction was evident in the phytic acid content from flour to isolate no positive (rather a negative) impact was evident in the iron or zinc dialysabilities. Our results confirm the reports of other investigators that factors other than phytic acid in soya protein components affect the dialysability of the minerals. Research has shown that dephytinisation partially improved iron dialysability only when the phytic acid content was below 30 mg/100 g in the flour and <1 mg/100 g in the isolate (Hurrell et al., 1992).

3.1. Protein mineral interaction and percent dialysability of iron and zinc

Among the absorption promotive components, the amino acid cysteine is also shown to enhance non-heme iron absorption in humans. In human subjects all sources of proteins do not have an equivalent effect on non-heme iron absorption; the effect may be different in different matrices having varied composition. The present study investigates the effect of soya proteins on exogenous iron and zinc. A model system comprising of anhydrous ferrous sulphate (as source of iron), zinc oxide (as source of zinc) and both in combination with different soya protein products was used.

Table 1
Chemical composition of soya protein components per 100 g.

Soya flour components	Moisture (%)	Protein (g)	Mineral content (g)	Iron (mg)	Dialysable iron* (mg)	Zinc (mg)	Dialysable zinc* (mg)	Phytin phosphorus (mg)
Soya flour	5.33	51.4 ± 0.04	8.0 ± 0.94	9.74 ± 1.05	1.23 ± 0.04 (12.6)	3.27 ± 0.16	1.64 ± 0.03 (50.1)	399.4 ± 5.5
Soya concentrate	7.00	62.3 ± 0.03	4.5 ± 0.15	15.84 ± 1.07	0.65 ± 0.01 (4.1)	5.92 ± 0.46	0.57 ± 0.04 (9.6)	226.3 ± 6.8
Soya isolate	7.00	78.2 ± 0.04	4.5 ± 0.23	15.21 ± 0.56	0.74 ± 0.05 (4.8)	6.74 ± 0.28	0.56 ± 0.02 (8.3)	186.4 ± 4.3

* Figures in parenthesis indicate percent dialysability.

3.1.1. Addition of $FeSO_4$ to soya protein products

Percent dialysability of exogenous iron was found to be very low in all soya protein products, it ranged from around 2.4–0.9% (Table 2). A twofold decrease in the dialysable iron was observed from flour to isolate. The differences between the three protein components analysed were found to be highly significant ($F = 23.019^{**}$), a similar pattern was observed in the dialysability of endogenous iron in all soya protein components wherein iron dialysability was inversely proportional to protein content. Evidences suggest that addition of soya flour to test/semi synthetic meals reduced bioavailable iron and extent of reduction was proportional to concentration of protein (Bodwell, 1983; Schricker, Miller, & Campen, 1982). In the fraction <30 kDa, 9.7% of the iron was dialysable. This was 4–10 times higher than that observed for flour and isolate matrices. The percent dialysable iron for the high molecular weight fraction was found to be 3.1% lower than the low molecular weight fraction. However, it was comparatively higher than flour, concentrate and isolate.

On addition of iron to the soya matrices, zinc dialysability was higher than the endogenous or native zinc in three components of soya. The extent of inhibition decreased with increase in concentration of the protein. In peptides 32–56% inhibition in zinc dialysability was observed in presence of iron. The process of preparation of the peptides reduced the phytic acid content by 9–15 times compared to flour, concentrate, and isolate. This is very well reflected in corresponding increase in iron and zinc dialysability. This confirms the earlier findings wherein the researchers have reported that phytic acid content <30 mg/100 g was less inhibitory to the dialysability of minerals (Lynch et al., 1994). The results of present study show that reducing the phytic acid content is sufficient for enhancing zinc dialysability and protein has no role to play in modifying the zinc dialysability.

3.1.2. Addition of ZnO to soya protein products

Addition of exogenous zinc to the soya protein products resulted in a varied level of zinc dialysability (Table 3). Percent dialysability was found to be 19% for the flour and 5.5% for the concentrate and isolate which was 3.5 folds lower than that of the soya flour. The difference in the dialysability of zinc in the three components was found to be extremely significant ($F = 188.02^{***}$). An inverse relationship was evident between the concentration of the protein and the dialysability of zinc. The percent dialysability of exogenous zinc was lower than that of endogenous zinc, it was lower by 2.6 times in flour, and 1.5–1.7 times in concentrate and isolate. This confirms the findings of several other investigators who studied the dialysability of zinc from zinc carbonate in presence of full fat soya flour, freeze dried soya beverage and soya concentrate. The dialysable fraction in presence of soya products was reported to range between 20% and 40% compared to egg protein (77–94%). The authors indicated that the intrinsic zinc in soya proteins and the zinc in the exogenous form did not form a common absorptive pool (Forbes & Parker, 1997; Whittaker, 1996). The dialysability of the exogenous mineral is influenced by the food matrix used and hence a varied dialysability is observed with different protein fractions of soya flour. In case of peptides the dialysability of zinc was 75–87% which was comparatively higher than other soya protein products. Among the peptides the one with high molecular weight showed higher dialysability. On addition of zinc to the soya flour components, a drastic reduction was observed in the dialysability of iron in all three components analysed. The extent of inhibition was found to increase from flour to isolate (without exogenous minerals). Apart from protein in soya products zinc also interfered in iron dialysability. However the difference in the extent of inhibition was not statistically significant ($F = 0.4747^{ns}$). The fraction <30 kDa showed the least dialysability compared to all the three soya protein fractions. In case of high molecular weight fraction, the dialysability was comparable to soya isolate. On the whole it can be said that zinc in isolation showed an inhibitory effect on iron dialysability.

3.1.3. Addition of $FeSO_4$ and ZnO in combination to soya protein products

Foods/medicinal supplements contain zinc and iron in different proportions, the interaction between the two decides the dialysability of the minerals. The interaction between the trace elements is primarily antagonistic. It is expected that when two chemically similar ions are present in the intestinal lumen the one having molar excess will tend to exclude the other. In terms of recommendations the quantity of zinc is half of iron. The percent dialysability of iron on addition of both minerals in combination was lower in all the three soya protein components (Table 4). The extent of dialysability was lower by 8% in flour and by 2–4% in concentrate and isolate compared to that of endogenous dialysability. The extent of inhibition posed by the combination of minerals was of a lesser magnitude compared to that added in isolation in same protein matrices. The differences in the dialysability of the mineral among the soya protein components was found to be insignificant ($F = 0.4748^{ns}$). Among the peptides the lower molecular weight fraction exhibited around 2% dialysability whereas the higher molecular weight fraction showed four times higher dialysability.

Table 2
Dialysable iron and zinc of soya protein products on addition of ferrous sulphate – mg/100 g soya product.

Soya protein products	Exogenous iron added (mg/100 g)	Dialysable iron	Dialysable zinc
Soya flour	27.1	0.66 ± 0.05 (2.4)	0.53 ± 0.02 (16.4)
Soya concentrate	32.9	0.73 ± 0.03 (2.2)	0.23 ± 0.01 (3.91)
Soya isolate	41.2	0.38 ± 0.02 (0.9)	0.36 ± 0.02 (5.34)
Peptides <30 kDa	41.2	3.98 ± 0.03 (9.7)	4.60 ± 0.56 (68.5)
Peptides >30 kDa	41.2	2.62 ± 0.03 (6.4)	2.95 ± 0.32 (43.8)

Figures in parenthesis indicate percent dialysability.

Table 3
Dialysable zinc and iron of soya protein products on addition of zinc oxide – mg/100 g soya product.

Soya protein products	Exogenous zinc added (mg/100 g)	Dialysable zinc (mg/100 g)	Dialysable iron
Soya flour	14.1	3.46 ± 0.83 (19.0)	0.10 ± 0.00 (0.66)
Soya concentrate	17.0	1.20 ± 0.15 (5.5)	0.12 ± 0.04 (0.73)
Soya isolate	21.3	1.46 ± 0.19 (5.6)	0.10 ± 0.00 (0.38)
Peptides <30 kDa	21.3	16.03 ± 1.05 (75.3)	0.10 ± 0.01(0.04)
Peptides >30 kDa	21.3	18.63 ± 1.53 (87.5)	0.12 ± 0.03 (0.77)

Figures in parenthesis indicate percent dialysability.

Table 4
Dialysable iron and zinc of soya protein products on combined addition of ferrous sulphate and zinc oxide – mg/100 g soya product.

Soya protein products	Exogenously added		Dialysable iron (mg/100 g)	Dialysable zinc (mg/100 g)
	Iron (mg/100 g)	Zinc (mg/100 g)		
Soya flour	27.1	14.1	1.04 ± 0.04 (3.8)	4.35 ± 0.91 (30.9)
Soya concentrate	32.9	17.0	0.50 ± 0.02 (1.5)	1.67 ± 0.25 (9.8)
Soya isolate	41.2	21.3	0.32 ± 0.02 (0.8)	2.60 ± 0.15 (12.2)
Peptides <30 kDa	41.2	21.3	0.67 ± 0.13 (1.6)	14.95 ± 1.05 (70.0)
Peptides >30 kDa	41.2	21.3	3.28 ± 0.33 (7.9)	15.00 ± 1.53 (70.4)

The presence of zinc in both the fractions showed a contradictory effect wherein it inhibited the iron dialysability to a larger extent in the low molecular weight fraction than in the high molecular weight fraction. Research has shown that high concentration of iron (iron:zinc in a ratio of 1:1 in water) can have a negative effect on zinc absorption (Boccio et al., 2002; Whittaker, 1996). However, in foods such as corn tortillas, weaning cereals, white wheat flour and infant formula there was no effect of iron on zinc absorption (Davidson et al., 2005). The dialysability of exogenous zinc was lowered in presence of iron in the soya flour and concentrate but not in isolate (compared to the endogenous zinc). In the isolate the inhibition was reversed to enhancement (though marginal) in combination. In the peptide matrices 70% of the exogenous fraction of zinc was dialysable irrespective of the molecular weight showing the non-interference of iron. Literature suggests that iron reduces zinc absorption in water and in model systems. Contrasting to this our results suggest iron to have a beneficial effect on zinc dialysability when present in combination with zinc in the soya protein fractions.

Soya flour as a whole comprising of protein by half of its weight is a good source of iron and moderate source of zinc. The process of concentrating the protein enhanced the iron and zinc contents between 60% and 100% with a corresponding decrease in the phytic acid content, but dialysability of the minerals decreased by one-third to one-fifth. The dialysability of the exogenous minerals added in the soya protein matrices was negligible. The addition of zinc in isolation significantly lowered the dialysability of iron but it was beneficial for zinc dialysability on addition of iron. The inhibitory effect lowered when both the minerals were added in combination. The dialysability of the minerals was comparatively higher in the peptide matrix, which can be attributed to low phytate content and hydrolysis of protein. As concentrate and isolate are much extensively used in food formulations, the matrix needs to be researched to achieve optimum dialysability of the essential minerals for combating the highly prevalent devastating micronutrient deficiencies.

Angiotensin converting enzyme inhibition
Tilapia
Ultrafiltration
Cryotin
Flavourzyme

ABSTRACT

Fish processing wastes can be used for preparing bioactive peptides with various functionalities. Our objective was to evaluate the in vitro angiotensin converting enzyme (ACE) inhibitory activity of tilapia protein hydrolysates and its corresponding fractionates. Tilapia protein was alkali-solubilised at pH 11.0 and recovered at pH 5.5 to obtain a stable substrate. This substrate was hydrolysed using two enzymes, Cryotin-F or Flavourzyme, to 7.5% and 25% degree of hydrolysis (DH). The hydrolysates were ultra-filtered into three fractions: >30 kDa fraction, 10–30 kDa fraction, and <10 kDa fractions. Both hydrolysates and fractionates were tested for ACE inhibition. Results showed that both Cryotin and Flavourzyme hydrolysates with 25% DH gave maximum ACE inhibitory activity. Low MW peptides showed higher ACE inhibition than high MW peptides. The inhibitory activity of fractionates was lower than that of the corresponding hydrolysates, possibly due to separation and removal of synergistic peptides by ultrafiltration. Amongst fractionates, all the 7.5% DH Cryotin fractions and 25% DH Flavourzyme fractions exhibited optimum % ACE inhibition. The results of this research could be used for optimising enzyme parameters to obtain peptides from tilapia with optimum in vitro ACE inhibitory activity.

1. Introduction

Angiotensin-I converting enzyme (ACE) plays an important role in the regulation of blood pressure and hypertension (Pfeffer, 1993). ACE catalyzes the conversion of inactive angiotensin-I into a potent vasoconstrictor, angiotensin-II (Goodfriend, Elliott, & Catt, 1996). ACE also inactivates the vasodilator, bradykinin (Kon, Fogo, Ichikawa, Hellings, & Bills, 1993; Witherow, Helmy, Webb, Fox, & Newby, 2001). Inhibitors of ACE are often used to treat myocardial infraction (Flather et al., 2000), hypertension (Pahor et al., 2000), and other cardio-related diseases. Studies have shown that several food derived proteins and related peptides may have potent ACE inhibitory activities (Ariyoshi, 1993). These peptides are derived from casein hydrolysates (Miguel, Manso, Lopez-Fandino, Alonso, & Salaices, 2007), whey proteins (FitzGerald & Meisel, 1999; Vermeirssen, Van Camp, & Verstraete, 2005), soy proteins (Wu & Ding, 2001), seed proteins (Aluko & Monu, 2003), and fish proteins (Bougatef et al., 2008; Fujita & Yoshikawa, 1999).

Over the last decade, an increase in the consumption of aquatic food products has resulted in an increase in fish processing wastes. Several research groups around the world have been working on converting these wastes into useful food and bioactive ingredients (Kitts & Weiler, 2003; Raghavan & Kristinsson, 2008; Raghavan, Kristinsson, & Leeuwenburgh, 2008; Theodore & Kristinsson, 2007). Some of these groups have been doing research on the ACE inhibitory activities of fish derived proteins and on fish processing wastes (Bougatef et al., 2008; Theodore & Kristinsson, 2007; Tsai, Lin, Chen, & Pan, 2006). Researchers have identified and reported specific peptides from animal and fish proteins responsible for ACE inhibition (Vercruysse, Van Camp, & Smagghe, 2005). However, preparation of cheap and high quality ACE inhibiting protein hydrolysates on a commercial scale poses several challenges including (a) the quality of raw material, and (b) the economy of separation and fractionation to obtain specific peptides.

The nature of fish species and the quality of the raw material are some of the many factors which would affect the bioactive potential of fish protein hydrolysates (Kristinsson, 2005). Hydrolysates from muscle protein sources can have several pro-oxidants such as heme and unstable oxidised lipid substrates. Contamination with these pro-oxidants may not only decrease the stability of protein hydrolysates but may affect their bioactivity as well. An isoelectric precipitation method developed by Hultin and Kelleher (2000) has often been used to prepare protein isolates with improved functional properties (Kristinsson & Hultin, 2003) and a low amount of unstable lipid substrates (Undeland, Kelleher, & Hultin, 2002). In brief, this method involves solubilising myofibrillar proteins at high (alkaline) pH and then recovering the solubilised proteins by isoelectric precipitation at pH 5.5. Utilisation of isoelectric

Abbreviations: DH, degree of hydrolysis; MW, molecular weight; ACE, angiotensin converting enzyme.

doi:10.1016/j.foodchem.2009.04.058

precipitation will hence be a new and cheap method for preparing high quality bioactive hydrolysates from fish by-products and wastes. In our current study, we used tilapia (*Oreochromis niloticus*) protein isolates prepared using the above mentioned alkali process as a substrate for enzyme hydrolysis. We chose tilapia, a commercially important aquatic species, since large quantities of processed wastes are generated every year. Utilisation of the tilapia waste will not only add value to the fish industry, but would also provide a new source of bioactive compounds. Two commercial enzymes, (a) Cryotin-F, a mixture of trypsin, chymotrypsin and elastase, and (b) Flavourzyme, a mixture of endoproteases and exopeptidases from *Aspergillus oryzae*, were used to hydrolyse tilapia protein to different degrees of hydrolysis. These two enzymes were chosen, as our previous studies showed that hydrolysates prepared using these enzymes have significantly high antioxidant activity (Raghavan & Kristinsson, 2008) and a high ability to quench stimulated mononuclear cells (Raghavan et al., 2008).

The second challenge for the utilisation and commercialisation of fish wastes and by-products is the process of separation and fractionation. Although researchers have identified specific peptides responsible for ACE activity (Vercruysse et al., 2005), commercialisation of these specific peptides would involve either discarding the remaining hydrolysate and peptides or synthetically preparing the ACE inhibiting peptides. Both these methods do not solve the problem of fish waste utilisation. Also, separation and purification using column chromatography on a large-scale poses scale-up problems. Ultrafiltration is a technique used commonly both on laboratory and on commercial scale to fractionate, purify and concentrate proteins (Ghosh, 2003). Although it is possible to obtain very pure protein fractions using suitable columns as in column chromatography, ultrafiltration is a low cost and easy to scale-up method used widely in food industries for quick separation and concentration of food proteins. In our current research we used ultrafiltration to fractionate tilapia hydrolysate into a range of molecular weight fractions.

To summarise, the first objective of our current work is to use alkali-solubilisation technique for preparing fish protein hydrolysates and test their ACE inhibition activity. The second objective is to use ultrafiltration for separating and isolating hydrolysate fractions and compare the ACE inhibition potential of these fractionates with the whole hydrolysates.

2. Materials and methods

2.1. Materials

Tilapia fillets were purchased locally in Gainesville, FL and transported to the laboratory on ice. Chemicals were purchased from Fisher Scientific (Fair Lawn, NJ). All reagents were of ACS grade. Flavourzyme enzyme was given by Novozymes A/S Denmark. Cryotin-F was a gift from North Ltd. (Reykjavik, Iceland). Lyophilized powder of rabbit lung angiotensin converting enzyme, and substrate for ACE (FAPGG or *N*-[3-(2-Furyl) acryloyl]-L-phenylalanyl-glycyl-glycine) were purchased from Sigma–Aldrich (St. Louis, MO).

2.2. Methods

2.2.1. Preparation of protein isolates using alkali solubilisation method

The white muscle from tilapia was separated and used for preparing protein isolates. The protein isolates were prepared by alkali solubilisation method as described in Hultin and Kelleher (2000). According to this method, the white muscle was first minced using a Waring PRO professional meat grinder (Model MG800, Waring Products, East Windsor, NJ) through a 3/16-in diameter sieve. The minced muscle was homogenised with 9 parts of cold deionized water using a Biohomogenizer (M133/1281-0, Bio Spec Products Inc., Bartlesville, OK) at high speed for 1 min. Myofibrillar proteins present in the homogenised sample were solubilised by adjusting the pH to 11.0 using 2 N sodium hydroxide. The pH adjusted sample was incubated at 4 °C for 30 min after which the mixture was centrifuged at 10,000*g* for 20 min at 4 °C in a Sorvall RC-5B Superspeed Refrigerated centrifuge (DuPont Instruments-Sorvall, DuPont Co. Newtown, CT). The supernatant was separated and filtered through a double layered cheese cloth. The pH of this supernatant was adjusted to 5.5 using 2 N HCl for precipitating the myofibrillar proteins. The pH adjusted mixture was again centrifuged at 10,000*g* for 2 min at 4 °C for recovering the myofibrillar proteins as sediment. Protein isolate obtained as sediment was used as a substrate for enzyme hydrolysis. The amount of protein in the isolates was determined using Kjeldahl method (AOAC Official Method 991.20).

2.2.2. Enzymatic hydrolysis of protein isolates

Enzymatic hydrolysis of tilapia protein isolates were performed using two different enzymes, Flavourzyme and Cryotin-F. The optimum hydrolysis conditions used for these enzymes were as follows: Flavourzyme (50 °C, pH 7.0), and Cryotin (45 °C, pH 8.0). The protein isolate was added to deionized water and homogenised for 1 min at maximum speed using a Biohomogenizer. The concentration of the homogenate was then adjusted to 2% w/v. The homogenate was equilibrated to the optimum pH and temperature conditions corresponding to the enzyme used for hydrolysis. The enzyme preparation was then added to the homogenate at 1% (w/v) level, and the degree of hydrolysis (DH) was calculated using the following equation (Adler-Nissen, 1986):

$$\%\ \text{Degree of hydrolysis (DH)} = \frac{B \times N_{\text{base}}}{\alpha \times h_{\text{tot}} \times \text{MW}} \times 100$$

where, B = volume of base used, N_{base} = normality of base used, α = degree of dissociation, MW = amount of protein used, h_{tot} = total number of peptide bonds per mass unit. The degree of dissociation (α) was determined by the following equation:

$$\alpha = \frac{10^{\text{pH}-\text{p}K_a}}{1 + 10^{\text{pH}-\text{p}K_a}}$$

where, pH is the value at which enzyme hydrolysis was performed. The pK_a values were calculated using the equation (Steinhardt & Beychok, 1964):

$$\text{p}K_a = 7.8 + \frac{(298 - T)}{298 \times T} \times 2400$$

where, T is the temperature of enzyme hydrolysis in Kelvin degrees. Using each of the two enzymes, tilapia protein isolates were hydrolysed to achieve 7.5% and 25% DH. Once the desired % DH was achieved, the homogenate was heated to 90 °C for 10 min to inactivate the enzymes, followed by cooling on ice. Hydrolysed samples were stored at −20 °C until further use.

Tilapia protein hydrolysates were also fractionated using ultrafiltration (Amicon Model 202 stirred ultrafiltration cell, Amicon Corp., Danvers, MA) into three different fractions (Fig. 1). A 30 kDa pore-sized membrane was used first to separate the hydrolysate into >30 kDa retentate and <30 kDa filtrate. The >30 kDa retentate was the first fraction used for ACE inhibition studies. The <30 kDa filtrate was again ultra-filtered using a 10 kDa pore-sized membrane to obtain a 10–30 kDa retentate and <10 kDa filtrate. These two 10–30 kDa and <10 kDa fractions were used for ACE inhibition studies. The three fractions, >30 kDa, 10–30 kDa and <10 kDa peptides, were stored at −20 °C until further use.

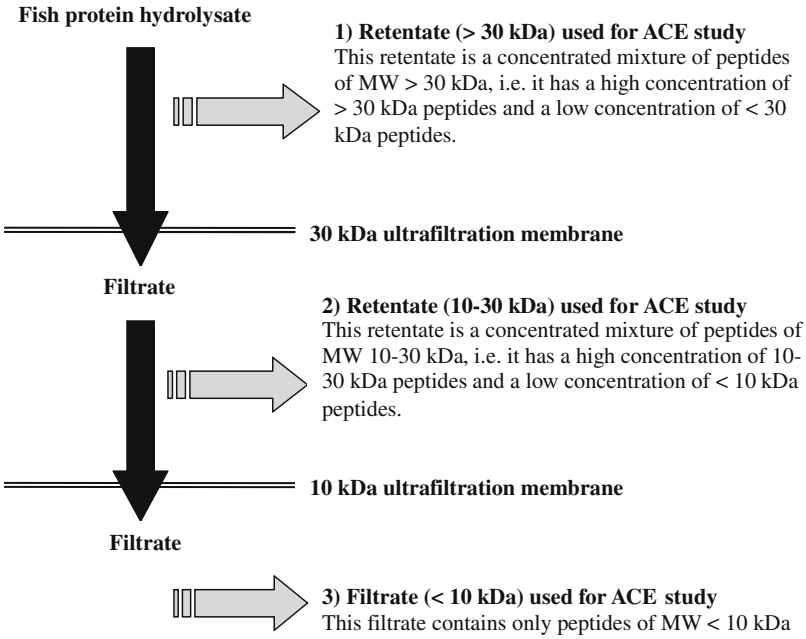

Fig. 1. Flow diagram for ultrafiltration of protein hydrolysates into different molecular weight fractionates. Fractionates used for ACE studies were (1) >30 kDa fraction which is a concentrated mixture of peptides of MW >30 kDa, (2) 10–30 kDa fraction, which is a concentrated mixture of peptides of MW 10–30 kDa, and (3) <10 kDa fraction which contains peptides of MW <10 kDa.

2.2.3. ACE inhibitory activity of tilapia protein hydrolysates

Both Flavourzyme and Cryotin hydrolysed tilapia protein isolates, as well as the three fractions from each hydrolysate, were tested for ACE inhibitory activity using FAPGG as the synthetic substrate for ACE and using a combination of methods of Murray, Walsh, and FitzGerald (2004) and Theodore and Kristinsson (2007) as mentioned below. Samples (100 μL of 0.2% w/v protein concentration), enzyme (50 μL of 15 mU enzyme) and substrate (1 mL of 0.5 mM FAPGG substrate) were mixed and incubated for 60 min at 25 °C. At the end of 60 min incubation period, absorbance at 340 nm was measured using an UV–Vis spectrophotometer. Hydrolysis of FAPGG by ACE will result in a decrease in absorbance at 340 nm. ACE inhibitory activity was measured by the ability of tilapia protein hydrolysates to decrease the hydrolysis of FAPGG as mentioned in Theodore and Kristinsson (2007). A sample containing FAPGG substrate and the ACE enzyme was used as a control. A 100% ACE inhibitory activity would indicate complete inhibition of the enzyme and no decrease in absorbance. All experiments were done in duplicates:

$$\%\ \text{ACE inhibition} = \frac{(\text{Abs}_{\text{no sample}} - \text{Abs}_{\text{sample}})}{\text{Abs}_{\text{no sample}}} \times 100$$

where, $\text{Abs}_{\text{no sample}}$ is the absorbance of the enzyme-substrate mixture in the absence of tilapia protein hydrolysates, and $\text{Abs}_{\text{sample}}$ is the absorbance of the enzyme-substrate mixture in the presence of protein hydrolysates.

2.2.4. SDS–PAGE

Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS–PAGE) was performed on the protein hydrolysates using a 10–20 % tris–tricine gel (Schagger & von Jagow, 1987) to characterise the hydrolysates based on their molecular weights (MW). The MW of the hydrolysates was calculated with reference to the migration of SDS–PAGE wide range molecular weight standard. After electrophoresis, the gels were stained using Sigma Brilliant Blue perchloric acid staining solution. Once the desired staining was achieved, gels were scanned using an Epson Stylus CX5400 scanner. Images were analysed using Scion Image 4.0.2 (Scion Co., Frederick, MD) software. The bands in the samples were compared with known bands of protein standards.

2.2.5. Statistical analysis

Experiments were performed in duplicates and repeated at least 2 times. Statistical analyses on the samples were performed using JMP™ Statistical Discovery Software (version 5.0). Tukey's multiple-comparison tests were used to compare the differences amongst the means. Dunnet's multiple-comparison test was used for comparing the effect of different treatments to the control. Analysis of variance was employed to examine the difference amongst treatments at $p < 0.05$ level.

3. Results and discussion

3.1. Characterisation of tilapia hydrolysates using SDS–PAGE

SDS–PAGE was used to characterise the molecular weight of both tilapia protein hydrolysates (Fig. 2). At 7.5% DH, both Cryotin and Flavourzyme yielded hydrolysates with MW ranging from 3.5 kDa up to 110 kDa (Fig. 2). These may represent various intact and hydrolysed myofibrillar proteins. Increasing hydrolysis to 25% significantly ($p < 0.05$) increased the amount of low molecular weight peptides. At 25% DH, both Cryotin and Flavourzyme hydrolysates showed some light bands near 40 and 60 kDa, but a majority of the peptide bands were less than 40 kDa. The ability of various enzymes such as Protamex, Neutrase and Alcalase to yield low molecular weight peptides at high % DH in species such as catfish, cod and salmon has been well documented (Lalasidis, Bostrom, & Sjoberg, 1978; Liaset, Lied, & Espe, 2000; Panyam & Kilara, 1996; Theodore, 2005).

3.2. Characterisation of tilapia fractionates using SDS–PAGE

The hydrolysates were ultra-filtered using 10 and 30 kDa membranes and were characterised using SDS–PAGE (Fig. 3). When a

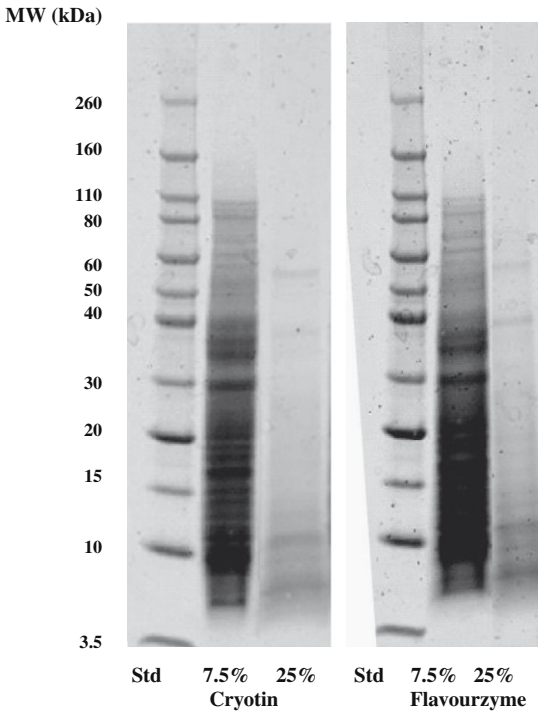

Fig. 2. SDS–PAGE of tilapia protein hydrolysates performed using 10–20% tris–tricine gels. Two enzymes, Cryotin and Flavourzyme were used for hydrolysing the tilapia isolate to 7.5% and 25% DH (degree of hydrolysis). The lane indicated as Std was the molecular weight (MW) marker with its corresponding molecular weights indicated as a column to its left. The wells adjacent to the marker from the left are Cryotin 7.5% DH, Cryotin 25% DH, Flavourzyme 7.5% DH and Flavourzyme 25% DH.

30 kDa membrane was used, >30 kDa retentate fraction and <30 kDa filtrate were obtained. Although ultrafiltration is a fast and easy technique for separating peptides based on their MW, it would require numerous washings and prolonged separation times to completely get rid of low MW fractions (i.e. <30 kDa fractions) from the >30 kDa retentate. However, as the majority of <30 kDa fractions are removed during ultrafiltration, the >30 kDa retentate will be concentrated in high MW fractions rather than with low MW fractions. In the SDS gel, this was indicated by strong bands of MW greater than 30 kDa (Fig. 3). Also, 25% DH hydrolysates obtained before ultrafiltration (Fig. 2) showed weak bands of MW >30 kDa, while the corresponding fractionates obtained after ultrafiltration (Fig. 3) showed strong bands of high MW indicative of the ability of ultra-filtration to concentrate the retentate samples. Between the 7.5% and 25% ultra-filtered samples, 7.5% ultra-filtered samples showed significantly higher number of strong bands between 30 kDa and 110 kDa than 25% DH samples. This could be due to the breakdown of high MW peptides at 25% DH. The filtrate obtained using the 30 kDa membrane had MW <30 kDa. This <30 kDa filtrate was again ultra-filtered as mentioned in the methods section, using a 10 kDa membrane filter to yield two fractions, a retentate fraction of MW 10–30 kDa, and a filtrate fraction of MW <10 kDa. An analysis of 10–30 kDa fractionates showed higher amount of peptides in 10–30 kDa region for 7.5% DH samples compared to 25% DH samples. This could be again due to the break down of proteins by 25% DH resulting in small peptides which could not be characterised in the gel. The <10 kDa fractions show a light band just below the 10 kDa range. Otherwise no band was visible indicating the presence of low MW peptides which could not be detected using SDS–PAGE.

3.3. ACE inhibitory activity of tilapia protein hydrolysates

The hydrolysates samples obtained after enzyme hydrolysis were tested for ACE inhibitory activity (Fig. 4). Both Cryotin and Flavourzyme hydrolysates exhibited ACE inhibition. For Cryotin hydrolysates, the ACE inhibitory activity was around 62% and 71% for 7.5% DH and 25% DH, respectively. Cryotin, as mentioned earlier, is a mixture of trypsin, chymotrypsin and elastase. It has already been shown that hydrolysis of yellowfin sole frame proteins (Jung et al., 2006) and whey proteins (Mullally, Meisel,

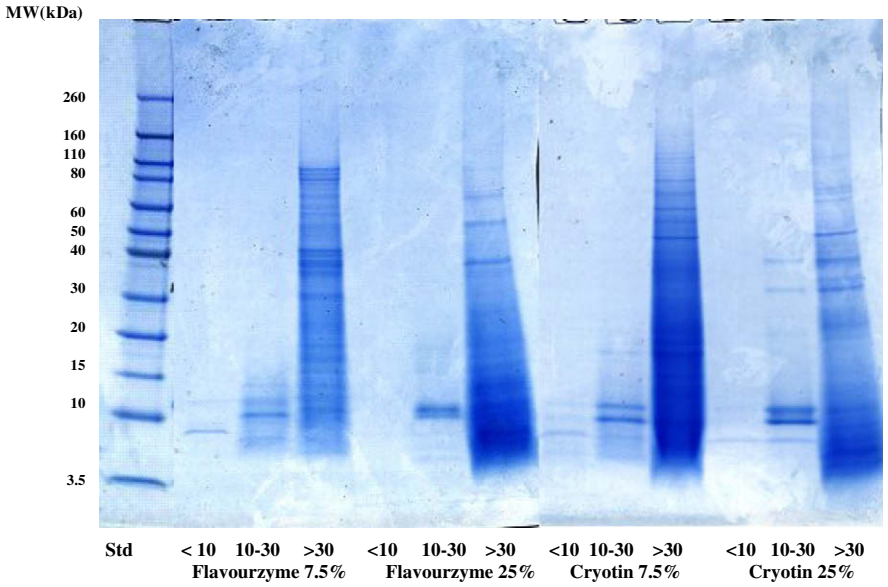

Fig. 3. SDS–PAGE of tilapia protein fractionates performed using 10–20% tris–tricine gels. Two enzymes, Cryotin and Flavourzyme were used for hydrolysing the tilapia isolate to 7.5% and 25% DH (degree of hydrolysis). Both these hydrolysates were first fractionated using 30 kDa membranes to obtain two samples: >30 kDa and <30 kDa. The latter sample was fractionated using 10 kDa membrane to obtain a third, <10 kDa sample. The lane indicated as Std was the molecular weight (MW) marker with its corresponding molecular weights indicated as a column to its left. The wells adjacent to the marker from the left are Flavourzyme 7.5% DH fractionates <10 kDa, 10–30 kDa and >30 kDa, Flavourzyme 25% DH fractionates <10 kDa, 10–30 kDa and >30 kDa, Cryotin 7.5% DH fractionates <10 kDa, 10–30 kDa and >30 kDa and Cryotin 25% DH fractionates <10 kDa, 10–30 kDa and >30 kDa.

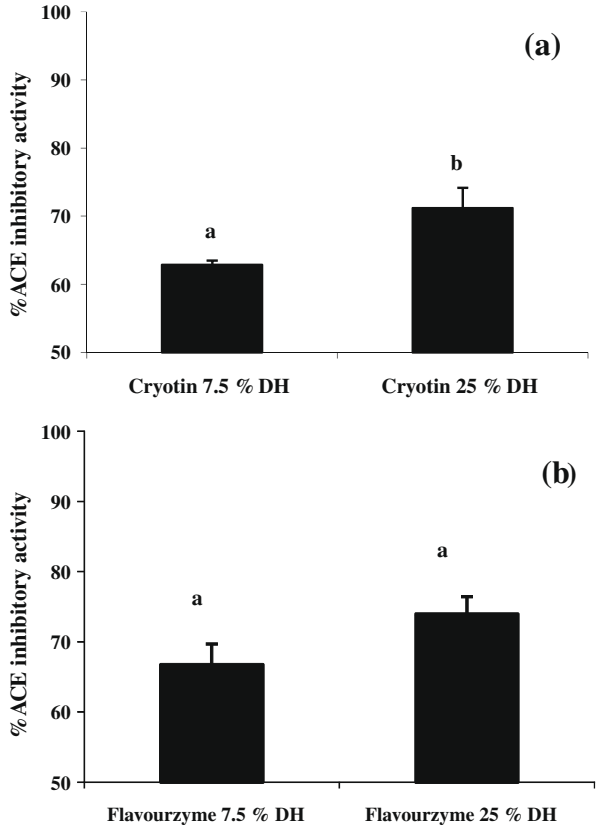

Fig. 4. ACE inhibitory activity of tilapia protein hydrolysates. Two enzymes, Cryotin and Flavourzyme were used for hydrolysis. (a) Cryotin hydrolysates with 7.5% and 25% DH. (b) Flavourzyme hydrolysates with 7.5% and 25% DH. DH is the degree of hydrolysis. Different letters in each figure represent a significant difference amongst the treatments ($p < 0.05$).

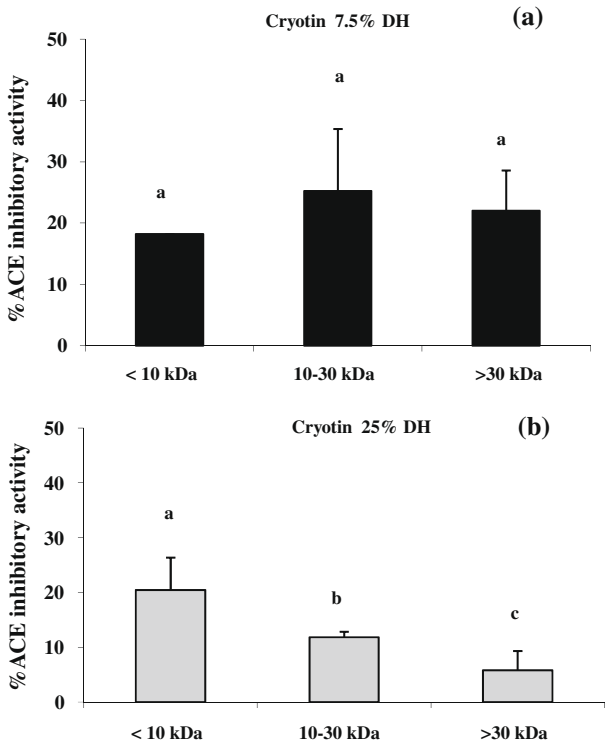

Fig. 5. ACE inhibitory activity of fractionates obtained from Cryotin-hydrolysed tilapia protein. Fractionates with molecular weights <10 kDa, 10–30 kDa and >30 kDa were obtained by ultrafiltration of tilapia hydrolysates. (a) Cryotin-hydrolysed sample with 7.5% DH. (b) Cryotin-hydrolysed sample with 25% DH. DH is the degree of hydrolysis. Different letters in each figure represent a significant difference amongst the treatments ($p < 0.05$).

& FitzGerald, 1997) using pancreatic enzymes yield peptides with high ACE inhibitory activity. For Flavourzyme hydrolysates, the ACE inhibitory activity was 66% and 73% for 7.5% DH and 25% DH, respectively. Flavourzyme is a complex mixture of fungal proteases and peptidases with un-specific peptide cleavage activity. The results from Fig. 4 indicate that the type of enzymes did not significantly ($p > 0.05$) affect ACE inhibitory activity. Also, in general, 25% DH hydrolysates showed higher ACE inhibition compared to 7.5% DH hydrolysates indicating that low MW peptides are better ACE inhibitors than high MW peptides. The ability of low MW peptides to inhibit ACE activity has also been reported for peptides derived from a variety of fish species such as bonito (Masaaki et al., 2000), yellowfin sole (Jung et al., 2006), Alaska pollock (Je, Park, Kwon, & Kim, 2004) and sea bream (Fahmi et al., 2004).

3.4. ACE inhibitory activity of tilapia protein fractionates

The three fractions obtained using ultrafiltration was tested for their ACE inhibitory activity. In general, ultrafiltration significantly decreased ($p < 0.05$) the ACE inhibitory activity of fractionates (Figs. 5 and 6) compared to the whole hydrolysates (Fig. 4). For example, Cryotin and Flavourzyme hydrolysates with 25% DH showed more than 70% inhibition compared to their corresponding ultra-filtered fractionates which showed less than 25% inhibition. The lower activity of fractionates compared to whole hydrolysate indicates a possible synergistic action amongst all the peptides when present together in the whole hydrolysate. Amongst the different samples, the inhibitory activity of >30 kDa fractionates (for both enzymes) was significantly lower ($p < 0.05$) than that of whole hydrolysates,

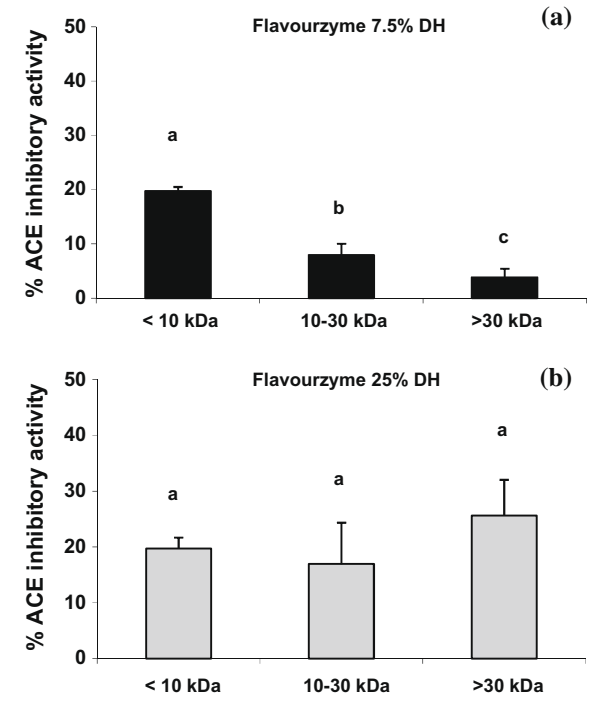

Fig. 6. ACE inhibitory activity of fractionates obtained from Flavourzyme-hydrolysed tilapia protein. Fractionates with molecular weights <10 kDa, 10–30 kDa and >30 kDa were obtained by ultrafiltration of tilapia hydrolysates. (a) Flavourzyme-hydrolysed sample with 7.5% DH. (b) Flavourzyme-hydrolysed sample with 25% DH. DH is the degree of hydrolysis. Different letters in each figure represent a significant difference amongst the treatments ($p < 0.05$).

although both hydrolysates and fractionates had peptides in the MW range 3.5–110 kDa (Figs. 2 and 3). The >30 kDa fractionates obtained from Cryotin 7.5% DH and Flavourzyme 25% DH showed ~25% ACE inhibition while their corresponding whole hydrolysates showed around 65% and 75% ACE inhibition. As explained in the previous section under 'characterisation of tilapia fractionates using SDS–PAGE', the whole hydrolysate contain peptides of all molecular weights, while the >30 kDa fractionates are concentrated with >30 kDa fractions with a small amount of <30 kDa peptides. Hence, the difference in ACE inhibition between >30 kDa fractionates and the whole hydrolysates could be either due to the high concentration of large MW peptides and the absence of low MW peptides in the >30 kDa fraction.

At 7.5% DH, Cryotin fractionates showed no significant ($p > 0.05$) variation in ACE inhibitory activity (Fig. 5a), but Flavourzyme fractionates (Fig. 6a) showed a significant decrease in inhibitory activity with an increase in MW of fractions. The ACE inhibition of Cryotin fractionates was around 20%, and for Flavourzyme fractionates the inhibitory activity decreased from 20% for <10 kDa fraction to less than 5% for >30 kDa fraction. At 25% DH, Cryotin fractionates showed a decrease in % ACE inhibitory activity with an increase in MW of the fractions (Fig. 5b), while Flavourzyme fractionates showed no significant difference ($p > 0.05$) in their inhibitory activity (Fig. 6b). For Flavourzyme, the % ACE inhibition for various fractions was around 20–25%, while the inhibitory activity for Cryotin fractionates was around 10% for a >30 kDa fraction and the % inhibition increased to 20% for <10 kDa fractions. A similar increase in the ACE inhibitory activity of ultra filtered low MW fractions was also reported for whey protein digests (Pihlanto-Leppala, Koskinen, Piilola, Tupasela, & Korhonen, 2000) and for hydrolysates prepared from the protein of yellowfin sole frames (Jung et al., 2006).

These results show that tilapia hydrolysed using Cryotin or Flavourzyme achieved its optimum ACE inhibitory activity at 25% DH (Fig. 4). Ultrafiltration of 25% DH Cryotin hydrolysate into various fractions did not improve the ACE inhibition efficacy of fractionates compared to the whole hydrolysates. When Cryotin hydrolysates were hydrolysed to 25% DH, the inhibition activity of the low MW (<10 kDa) fractions increased while that of high MW (>30 kDa) fractions decreased. However, the inhibition activity of the low MW (<10 kDa) fraction was not significantly ($p > 0.05$) different from Cryotin 7.5% DH fractionates. When Flavourzyme was used at 7.5% DH, the low MW fraction (<10 kDa) showed optimum ACE inhibitory activity while the high MW (10–30 kDa and >30 kDa) fractions showed lower activity. Increasing hydrolysis to 25% DH increased the activity of high MW (10–30 kDa and >30 kDa) fractions, but all the fractions at 25% DH had similar efficacy as Flavourzyme 7.5% DH, <10 kDa fraction.

4. Conclusion

Hydrolysates prepared from alkali solubilised tilapia white muscle exhibited significant ACE inhibitory activity. The inhibitory activity did not differ significantly between the types of enzymes used for hydrolysis, i.e. Cryotin and Flavourzyme, but increased with the % DH. Our results indicate the potential for converting the wastes from tilapia industry by enzyme hydrolysis into useful bioactive food ingredients. Fractionating whole tilapia hydrolysates using ultrafiltration into various molecular weight fractions did not improve the ACE inhibitory activity of fractionates compared to the whole hydrolysates. Hence, it would be economical to enzyme hydrolyse and utilise whole tilapia protein hydrolysates for their bioactive potential (without fractionation).

ABSTRACT

Phenylpropanoids are the main class of compounds from lemon verbena which have shown a wide biological activity, verbascoside being the most abundant one. In this work, the composition of a lemon verbena extract was elucidated by HPLC-ESI-MS/MS and one flavone and one methoxylated phenylpropanoid were found in this source for the first time. The antioxidant activity of the lemon verbena extract was fully characterised by several methodologies. Unexpectedly, the extract was especially active in lipophilic environments and lipid peroxidation inhibition assay, as it was found for pure verbascoside. The lemon verbena extract, containing verbascoside as its major bioactive compound, was acutely administered to rats and verbascoside was the only metabolite detected in plasma samples as measured by HPLC mass spectrometry. The correlation between the highest verbascoside concentration in plasma and maximum plasma antioxidant capacity was observed at 20 min as measured by different techniques, i.e. minimum malondialdehyde (MDA) generation, highest ferric-reducing ability of plasma (FRAP value) and maximum superoxide dismutase activity (SOD). Therefore, the *in vitro* measurements of the antioxidant activity of lemon verbena extract may significantly support the antioxidant activity observed *in vivo* in this work. Moreover, neither evidence of acute oral toxicity nor adverse effects were observed in mice when the lemon verbena extract containing 25% verbascoside was used at a dosage of 2000 mg/kg.

1. Introduction

Lemon verbena (*Aloysia triphylla* or *Lippia citriodora*) is an herb mainly used as a spice and a medicinal plant. It grows spontaneously in South America and is cultivated in North Africa and Southern Europe. Lemon verbena leaves are used to add a lemony flavour in many culinary purposes such as fish and poultry dishes, vegetable marinades, salad dressings, jams, puddings, and beverages. It is also used to make herbal teas and refreshing sorbets. Therefore, lemon verbena products and their compounds can be considered into the food category.

The leaves of these species are reported to possess digestive, antispasmodic, antipyretic, sedative and stomachic properties. It has traditionally been used in infusions for the treatment of asthma, cold, fever, flatulence, colic, diarrhoea and indigestion (Newall, Anderson, & Phillipson, 1996). Phenylpropanoids represent the main class of compounds of this plant as verbascoside being the most abundant one (Fig. 1) (Bilia, Giomi, Innocenti, Gallori, & Vincieri, 2008; Laporta et al., 2004). Several properties have been described for this compound like anti-inflammatory (Deepak & Handa, 2000; Diaz et al., 2004; Hausmann et al., 2007), antimicrobial (Avila et al., 1999) and antitumor (Ohno, Inoue, Ogihara, & Saracoglu, 2002). Among several factors, verbascoside antioxidant activity may suppose a significant contribution to its protective effects (Liu et al., 2003; Siciliano et al., 2005; Valentao et al., 2002; Wong, He, Huang, & Chen, 2001).

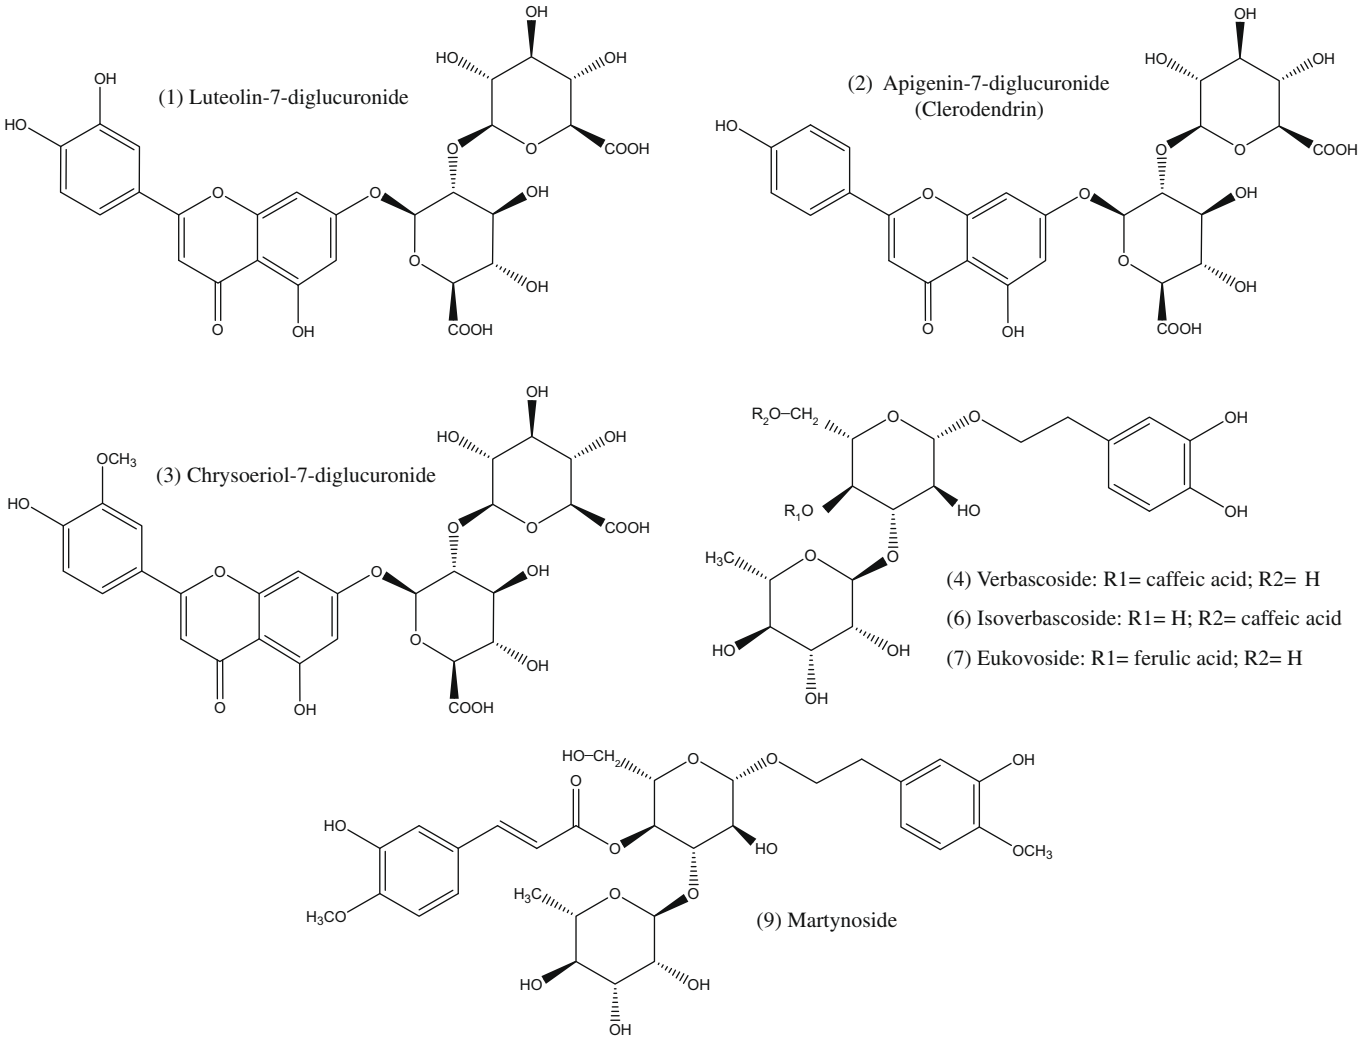

Fig. 1. Chemical structures of the major compounds found in lemon verbena leaves extract.

Due to the presence of lemon verbena in food products, it may be necessary to know its pharmacokinetics and its possible antioxidant effects *in vivo*. So far, most of the previous results on lemon verbena derive from *in vitro* assays. Till now, detailed information about the pharmacokinetics of verbascoside is very limited and derives from plants which are different from lemon verbena (Wu, Lin, Sung, & Tsai, 2006; Wu, Tsai, Lin, & Tsai, 2007). Only one report has shown pharmacokinetics of this compound after oral administration and its bioavailability was found to be very low (Wu et al., 2006).

In this work, the composition and *in vitro* antioxidant activity of an extract from lemon verbena standardised in 25% verbascoside (w/w) was determined. Moreover the pharmacokinetics of this compound in rats after oral administration of the above mentioned extract was studied. Significant amounts of verbascoside were found in plasma of rats which was readily available 20 min after oral administration. In addition, a correlation of the plasma antioxidant status in rats, as measured by different antioxidant methods, and the concentration of verbascoside is shown for the first time. Finally the toxicity of the extract in mice was also studied.

2. Materials and methods

2.1. Reagent and chemicals

Sulphatase and glucuronidase (EC 232-772-1) from *Helix pomatia* type H-1, butylated hydroxytoluene (BHT); trichloroacetic acid (TCA); thiobarbituric acid (TBA); 1,1,3,3-tetraethoxypropane (TEP); 2,4,6, tripyridyl-S-triazine (TPTZ); ferric chloride ($FeCl_3$); Trolox (6-hydroxy-2,5,7,8 tetramethylchroman-2-carboxylic acid); 2,2′-azino-bis(3-ethylbenzothiazoline-6 sulphonic acid) (ABTS); 2, 2′-azobis (2-methyl-propionamine) dihydrochloride (AAPH); fluorescein (FL), xanthine; xanthine oxidase and cytochrome *c* were purchased from Sigma–Aldrich Corp. (St. Louis, MO, USA). Natural lipid egg yolk phosphatidylcholine (EYPC) was obtained from Avanti Polar Lipids (Birmingham, AL, USA), dissolved in chloroform/methanol (1:1, v/v) and stored at −20 °C. Lemon verbena extract (25% verbascoside, w/w), *Citrus aurantium* peel extract (25% naringin, 25% neohesperidin, w/w) and olive leaf extract (25% oleuropein, w/w) were kindly provided by Monteloeder, S.L. (Elche, Spain). All other compounds were of analytical, spectroscopic or chromatographic reagent grade and were obtained from Merck KGaA (Darmstadt, Germany). Double-distilled and deionized water was used throughout this work.

2.2. Animals

Twenty-eight male Wistar rats (280–380 g) were housed in standard cages at room temperature with free access to food and water for two weeks. Throughout the experiments, animals were processed according to the suggested ethical guidelines for the care of laboratory animals (Morton et al., 2001).

2.3. Treatment of animals

Rats were orally treated with lemon verbena extract (2180 mg/kg, corresponding to 545 mg/kg of verbascoside) via gastric gavage. For the administration, the extract was suspended in saline serum (3 mL). The control group received only saline serum. Rats were subjected to ketamine/xylazine anesthesia and the blood samples were withdrawn via cardiac puncture into heparinized tubes at 20, 40, 55, 75, and 100 min post dosing. All blood samples were centrifuged at 1000*g* for 15 min at 4 °C, and then plasma was stored at −80 °C.

2.4. Measurement of the Trolox equivalent antioxidant capacity (TEAC)

The Trolox equivalent antioxidant capacity (TEAC) assay, which measures the reduction of the radical cation of ABTS by antioxidants, was performed as previously described (Laporta, Pérez-Fons, Mallavia, Caturla, & Micol, 2007). Compounds were assayed at five different concentrations determined within the linear range of the dose–response curve. A calibration curve was prepared with different concentrations of Trolox (0–20 μM). Results were expressed in mM of Trolox per mM pure compound or g of extract.

2.5. Radical-scavenging capacity by measurement of inhibition of malondialdehyde (MDA) generation

The quantitative evaluation of the antioxidant capacity of the compounds/extracts against lipid peroxidation was determined through the measurement of the inhibition of MDA generation by using small unilamellar vesicles formed by sonication of multilamellar vesicles of egg yolk phosphatidylcholine (EYPC). Oxidation conditions, extraction and quantitation of TBA–MDA chromogen were performed as previously described (Laporta et al., 2007). Briefly, the chromogen was determined using HPLC coupled to fluorescence detection. The analysis were conducted by injecting 20 μL of sample into a reverse phase column LiChrospher® 100 RP-18 (5 μm, 250 x 4 mm i.d.) from Merck KGaA (Darmstadt, Germany) using isocratic mode with methanol-50 mM potassium phosphate buffer, pH 6.8 (40:60, v/v), and a flow rate of 1 mL/min. The TBA–MDA product was monitored by fluorescence detection with excitation at 515 nm and emission at 553 nm. Results were expressed in mg/L for extracts or μM of pure compound which were able to inhibit 50% of the generation of MDA (nmol MDA/mg EYPC).

2.6. Assay of the oxygen radical absorbance capacity (ORAC)

To assay the capacity of the compounds/extracts to scavenge peroxyl radicals a validated ORAC method, which uses fluorescein (FL) as the fluorescent probe ($ORAC_{FL}$), was utilised (Ou, Hampsch-Woodill, & Prior, 2001) with minor modifications (Laporta et al., 2007). ORAC values were expressed as micromole Trolox equivalents per gram of antioxidant substance.

2.7. Enzymatic hydrolysis and determination of verbascoside in plasma

Plasma (50 μL) was mixed with 50 μL of enzyme mixture in 100 mM acetate buffer (pH 5.0) containing 12.5 units of sulphatase and 270 units of β-glucuronidase activity. The mixture was incubated at 37 °C for 45 min. Soon after 200 μL of 0.83 M acetic acid in methanol were added. The mixture was vortexed, sonicated, and centrifuged (7400*g* for 5 min at 4 °C), and the supernatant was analysed by HPLC-DAD-MS/MS system. The LC/MS system consisted of an Agilent LC 1100 series (Agilent Technologies Inc., Palo Alto, CA, USA) controlled by the Chemstation software. The HPLC instrument was coupled to an Esquire 3000 + (Bruker Daltonics, GmbH, Germany) mass spectrometer equipped with an ESI source and ion trap mass analyser, and controlled by Esquire control and data analysis software. A Merck LiChrospher 100 RP-18, 5 μm, 250 × 4 mm (i.d.) column was used for analytical purposes. For the analysis of verbascoside, a 20 min linear gradient from 5% to 30% acetonitrile in 1% formic acid in water was used. For the accurate performance of the LC–MS pump, 10% of organic solvent was premixed in the water phase. The flow rate was 0.5 mL/min (Maatta, Kamal-Eldin, & Torronen, 2003). Diode-array detection was set at 280 and 330 nm. Mass spectrometry operating conditions were optimised in order to achieve maximum sensitivity values. The ESI source was operated in negative mode to generate $[M-H]^-$ ions using the following conditions: desolvation temperature at 350 °C and vapourizer temperature at 400 °C; dry gas (nitrogen) and nebulizer were set at 5 L min^{-1} and 65 psi, respectively. The MS data were acquired as full scan mass spectra at 150–1000 m/z by using 50 ms for collection of the ions in the trap.

2.8. Peaks identification and validation of the verbascoside assay method

Identification of all constituents was performed by HPLC-DAD- and –MS/MS analysis, comparing the retention time, UV and MS spectra of the peaks in the samples with those authentic reference samples or data reported in the literature. The purity of peaks was checked comparing the UV spectra of each peak with those of authentic reference samples and by examination of the MS and MS/MS spectra.

The accuracy of the method for the determination of verbascoside in plasma was further assessed with recovery studies by spiking verbascoside into blank plasma and water in triplicates. The linearity range of the responses was determined on eight concentration levels with three injections for each level. Calibration graphs for HPLC were recorded with sample amount ranging from 0.25 μg/mL to 0.25 mg/mL ($r^2 > 0.9999$). Quantitative evaluation of verbascoside was performed by means of a six-point regression curve ($r^2 > 0.996$) in a concentration range between 0.25 μg/mL and 0.1 mg/mL, using verbascoside as reference external standard and evaluated at 330 nm. LOD (Limit of Detection) was 0.10 μg/mL and Limit of Quantification (LOQ) was 0.25 μg/mL.

2.9. HPLC analysis of plasma MDA

Briefly, 50 μL of plasma were mixed with 50 μL of 0.05% BHT in ethanol and 50 μL of TCA 20% in HCl 0.6 M. The samples were incubated 15 min on ice and then were centrifuged at 5000*g* during 15 min at 4 °C. Then 100 μL of TBA 0.6% in water were added to 100 μL of supernatant. At follow, the mixture was incubated at 97 °C for 1 h, let to cool down and extracted with 300 μL of n-butanol through vigorous shaking, and then samples were centrifuged at 10000*g* for 3 min. The TBA–MDA chromogen was determined using an HPLC and fluorescence detection system as previously described in paragraph 2.5 of this section.

2.10. Ferric-reducing ability of plasma

To assess plasma antioxidant capacity, the ferric-reducing ability of plasma (FRAP) was measured as previously described (Benzie & Strain, 1996). Briefly, 40 μL of diluted plasma samples (1:2) were mixed on a 96-well plate with 250 μL of freshly prepared FRAP reagent. Samples were incubated for 10 min at 37 °C and then absorbance at 593 nm was recorded during 4 min on a microplate reader (SPECTROstar Omega, BMG LabTech GmbH, Offenburg, Germany). FRAP values were calculated using $FeSO_4 \cdot 7H_2O$ as standard.

2.11. Superoxide dismutase (SOD) activity in plasma

SOD activity was measured through an adaptation of the method of McCord and Fridovich (1969). The xanthine/xanthine oxidase system was used to generate the superoxide anion. This anion produced the reduction of cytochrome *c*, which was monitored at 550 nm. The SOD activity in the sample removed the superoxide anion and produced an inhibition of the cytochrome *c* reduction. The activity was determined with a SPECTROstar Omega microplate reader at 37 °C.

2.12. Acute oral toxicity assessment

Ten-week-old male and female ICR strain mice were used for the study. The animals were housed in cages in a temperature-controlled animal room (23 ± 1 °C) with a relative humidity of 55 ± 5% and were fed a standard diet. The animal care and handling was done according to the regulations of Council Directive 86/609/EEC about Good Laboratory Practice (GLP) on animal experimentation. The animals were allowed to fast by withdrawing the food and water for 18 h and divided into four groups of eight individuals each (two groups for the control and two groups for the test substance) before the administration. Briefly, the powder (lemon verbena extract, 25% verbascoside) was dissolved in 0.9% NaCl sterile solution, pH 7.4 at a concentration of 80 mg/ml and centrifuged to eliminate insoluble particles. The test substance was administered by oral gavage in a total volume of 0.5 mL at a single dose of 2000 mg/kg. Weight control and observations were continued for 14 days. On day 14, the mice were anesthetized, killed by exsanguinations, and examined by necropsy. The assay was performed following the recommend regulations (OECD Test Guideline 420; Fixed Dose Procedure).

2.13. Statistical analysis

Statistical analysis was performed using the statistical package SPSS 13.0 for Windows. The effects of lemon verbena extract consumption on the investigated parameters were evaluated by comparing the values obtained at different time intervals with the control (0 time) using one way ANOVA test. Depending on the results, significance values of $p < 0.01$, $p < 0.05$ and $p < 0.10$ were considered statistically significant.

3. Results and discussion

3.1. Composition of lemon verbena extract by HPLC–MS/MS

The composition of the lemon verbena extract utilised in this work was determined by means of HPLC-DAD-ESI-MS/MS. The identification of the peaks was based on the analysis of their retention time, UV spectra and MS/MS data as mentioned in the Materials section. Fig. 2 shows the high-performance liquid chroma- tography profile at 330 nm of lemon verbena extract (Fig. 2A) and its corresponding base peak chromatogram (BPC) (Fig. 2B), which is indicative of peak purity detection in data generated with LC–MS.

We were able to identify seven major phenolic compounds in the extract (see Fig. 1 and Table 1), namely four phenylpropanoids, and three glycosylated flavones. Nevertheless, no iridoid derivatives were identified in the extract although other authors have found them in lab-scale ethanolic extractions from lemon verbena leaves (Bilia et al., 2008). Among the phenylpropanoids, verbascoside was clearly the most abundant compound (around 25%, w/w). In contrast to previously reported (Bilia et al., 2008), its positional isomer, isoverbascoside, was found in very low amounts (Fig. 2). It has been reported that isoverbascoside can be obtained from the deacetylation and caffeoyl migration of verbascoside under hydrolytic environment, so it might derive from drastic extraction conditions (Kawada, Asano, Makino, & Sakuno, 2002). The methoxylated phenylpropanoid eukovoside was also present in the lemon verbena extract, as previously reported (Bilia et al., 2008; Shuya, Shengda, Xingguo, & Zhide, 2004; Sticher, Salama, Chaudhuri, & Winkler, 1982). Martynoside, another methoxylated phenylpropanoid (Kirmizibekmez et al., 2005) was indentified for the first time in the lemon verbena extract.

Three flavones were also identified in minor quantities in the lemon verbena extract (Fig. 1), all of them in their diglucuronide form, luteolin-7-diglucuronide (Carnat et al., 1995) and apigenin-7-diglucuronide (Bilia et al., 2008; Ragone, Sella, Conforti, Volonte, & Consolini, 2007), both previously reported in ethanolic extracts of lemon verbena. Moreover, one methoxylated flavone, chrysoeriol-7-diglucuronide is reported for the first time in lemon verbena. Total mass data and fragmentation patterns of these flavones were identical to those ones reported in other plant sources (Wang et al., 2008).

3.2. Antioxidant activity of lemon verbena extract

The antioxidant activity of lemon verbena extract was fully characterised *in vitro* by using several antioxidant measurements. First, the antioxidant activity by means of the Trolox equivalent antioxidant capacity (TEAC) assay was studied and compared to other antioxidant extracts and pure compounds. Quercetin, one of the most potent compounds under this type of assay, was used as a reference, which showed TEAC values that agreed to those found by other authors (Miller & Begoña Ruiz-Larrea, 2002; Rice-Evans, Miller, & Paganga, 1996; Soobrattee, Neergheen, Luximon-Ramma, Aruoma, & Bahorun, 2005) (Table 2). Lipophilic TEAC value obtained for lemon verbena extract was considerably high, i.e., 1.15 ± 0.07 (mM Trolox/g). Pure verbascoside showed a lipophilic TEAC value of 1.28 ± 0.11 mM Trolox/mM (i.e., 1.28 mmol Trolox/mmol or 2.05 mmol Trolox/g), which was consistent with the value previously found by other authors (Siciliano et al., 2005). In spite of the extract only contained 25% verbascoside and minor quantities of other phenylpropanoids and flavones (Fig. 2), TEAC value found for lemon verbena extract accounted for more than the half of the value determined for pure verbascoside per gram. The theoretical TEAC value of the extract due to verbascoside contribution would have been 0.51 mM Trolox/g but unexpectedly more than double of this value was obtained. From this result it could be postulated that other minor components of the extract such as the flavones could contribute to enhance the antioxidant capacity of the extract probably in a synergistic manner. Furthermore, lemon verbena extract showed stronger TEAC values than other strong antioxidant extracts such as olive leaf extract (25% oleuropein) or orange flavonoid extract (25% naringin, 25% neohesperidin).

Surprisingly, lemon verbena extract showed a higher TEAC value in a lipophilic environment than in water, which has been shown for other hydrophilic and glycosylated phenolic antioxidants such as hypoxoside (Laporta et al., 2007). As it has been previously reported, this fact may be related to its stronger capacity to scavenge free radicals in a lipophilic environment. This behaviour was also observed for the orange flavonoid extract, which also contains minor quantities of flavones that could contribute to this antioxidant behaviour. In contrast, olive leaf extract showed similar TEAC value in a lipophilic environment (ethanol) than in a hydrophilic medium (water).

In order to determine the contribution of the radical scavenging activity of the single compounds which are part of the verbascoside molecule, i.e., caffeic acid and hydroxytyrosol, TEAC and MDA inhibition values of these compounds were also evaluated in comparison to verbascoside. Lipophilic and hydrophilic TEAC and MDA

Table 1
List of the main phenolic compounds in the lemon verbena extract identified by HPLC-DAD-ESI-MS/MS.

Retention time (min)	Peak no. Lemon verbena extract	Compound	UV_{Max} (nm)	Mol. ion $[M-H]^-$	Primary fragment (MS/MS)
12.1	1	Luteolin-7-diglucuronide	348	637	351, 285
14.0	2	Apigenin-7-diglucuronide (Clerodendrin)	340	621	351
17.3	3	Chrysoeriol-7-diglucuronide	340	651	351
18.0	4	Verbascoside	330	623	461
19.0	5	Not identified	350	566	–
20.2	6	Iso-verbascoside	330	623	461
22.3	7	Eukovoside	330	637	351
26.7	8	Not identified	340	711	–
27.7	9	Martynoside	330	651	475

Table 2
Lipophilic and hydrophilic TEAC values and IC_{50} values for MDA generation inhibition of several extracts and pure compounds. Quercetin is shown as reference value.

Extract or compound	Antioxidant capacity		
	TEAC mM (H_2O)[a]	TEAC mM (EtOH)[b]	MDA inhibition (IC_{50}[c])
Lemon verbena	0.81 ± 0.04[d]	1.15 ± 0.07	6.91 ± 0.21[f]
Olive leaf	0.92 ± 0.12	0.94 ± 0.11	7.00 ± 1.20
Orange flavonoid	0.51 ± 0.01	0.71 ± 0.08	15.6 ± 1.64
Verbascoside	1.03 ± 0.15[e]	1.28 ± 0.11	3.82 ± 0.5[g]
Caffeic acid	0.59 ± 0.03	0.73 ± 0.14	7.41 ± 1.10
Hydroxytyrosol	0.66 ± 0.12	0.80 ± 0.10	15.42 ± 2.70
Quercetin	3.00 ± 0.30	2.26 ± 0.07	3.66 ± 0.20

[a] mM Trolox equivalent antioxidant capacity determined in H_2O ($n = 3$).
[b] mM Trolox equivalent antioxidant capacity determined in EtOH ($n = 3$).
[c] Concentration corresponding to the 50% inhibition of lipid peroxidation determined by HPLC–MDA measurement ($n = 3$).
[d] mM Trolox/g of extract.
[e] mM Trolox/mM of pure compound.
[f] mg/L of extract.
[g] μM of pure compound which were able to inhibit the 50% of the production of MDA (nmol MDA/mg lipid).

inhibition values of hydroxytyrosol were in agreement to previously reported (Laporta et al., 2007). Among the tested pure compounds, verbascoside showed higher TEAC values than caffeic acid or hydroxytyrosol, but it was less potent than quercetin. Verbascoside exhibited the same behaviour shown before, i.e., a higher TEAC value in EtOH than in water, what was consistent with the behaviour observed for the lemon verbena extract. Caffeic acid and hydroxytyrosol also showed a similar behaviour, but it was less pronounced. This fact might reveal the efficacy of verbascoside to scavenge free radicals within a hydrophobic environment. In contrast, quercetin evidenced a lower TEAC value in a lipophilic environment (ethanol) than in a hydrophilic medium (water).

The capacity of the lemon verbena extract to inhibit lipid peroxidation was also determined by HPLC determination of MDA generation (Table 2). Lemon verbena extract showed an IC_{50} value of 6.91 ± 0.21 mg/L, which revealed stronger antioxidant activity than other antioxidant extracts, such as olive leaf and tea catechins, determined in the same conditions (Laporta et al., 2007), and similar potency to the previously reported African potato extract, i.e., 7.5 mg/L (*Hypoxis hemerocallidea*). This fact may also be in relation to the stronger capacity showed by this extract in the lipophilic TEAC assay, what may also reveal the capability of lemon verbena extract (and therefore verbascoside) to scavenge free radicals under a specific environment such as the biological membranes. Some apparently hydrophilic antioxidants such as hypoxoside (Laporta et al., 2007), have shown to be effective antioxidants in lipophilic environments and exerted strong effects in biological membranes (Laporta, Funes, Garzón, Villalaín, & Micol, 2007). When the capacity to inhibit lipid peroxidation was measured by MDA inhibition assay, verbascoside was much stronger than hydroxytyrosol or caffeic acid, and as potent as quercetin (Table 2). This result reveals that even though verbascoside is a water-soluble compound, it seems to be quite efficient to avoid lipid peroxidation, probably establishing some kind of molecular interactions with the lipid membrane surface, as it has been proposed for other hydrophilic antioxidants (Laporta et al., 2007).

The antioxidant capacity of the lemon verbena extract was also determined by using the well-known ORAC-FL assay (Ou et al., 2001), which accounts for the scavenging of peroxyl radicals. The antioxidant dose–response behaviour of this extract was determined through the measurement of the area under the fluorescence decay curve (AUC) of the sample as compared to that in the absence of antioxidant. Lemon verbena extract showed an $ORAC_{FL}$ value of 4075 ± 234 TE/g dw, which is a significant antioxidant value compared to other antioxidant powdered extracts measured in the same conditions (Ou et al., 2001) and similar to the values previously reported for green tea extract (70% catechins) and olive leaf extract (25% oleuropein), and performed in identical conditions (Laporta et al., 2007).

Since verbascoside was the major compound present in lemon verbena extract, we might assume that the *in vitro* antioxidant capacity of the extract shown in the previous assays was mainly due to this compound, although synergistic effects of verbascoside with the rest of minor compounds (other phenylpropanoids and flavones) cannot be discarded.

3.3. Pharmacokinetic study of verbascoside from lemon verbena in rats

A pharmacokinetic study after oral administration of lemon verbena extract was performed in order to determine the presence of the compounds from the extract in the plasma of rats. Verbascoside was detected in rat plasma using LC–MS/MS with electrospray ionisation. Fig. 3 shows the HPLC-DAD-MS profile of a rat plasma sample 20 min after the oral administration of lemon verbena extract and the product ion scan spectrum using electrospray negative-ion mode. Retention time of verbascoside in plasma samples was 17.3 min. The mass spectrum revealed a base peak at *m*/*z* 623 corresponding to $[M-H]^-$, which was corroborated with the use of a commercially available verbascoside standard (Fig. 3B). Moreover, a fragment ion at *m*/*z* 461 ($[M-H-163]^-$) was consistent with the loss of the rhamnosyl moiety.

The pharmacokinetic study was performed using five individuals for each of five times data collection plus controls (Table 3). The pharmacokinetic parameters revealed an AUC of 3085 ± 1400 ng min/mL for an oral administration of total extract corresponding to a verbascoside dose of 545 mg/kg. The maximum verbascoside concentration found in plasma after oral administration was reached within the first 20 min, meaning that this compound was quickly absorbed from the gastrointestinal tract. In this study, the maximum verbascoside concentration found in plasma samples was 1431 ± 300 ng/mL (around 2.3 μM), which means 15 times more than that one previously reported by another study which used a different plant source containing verbascoside (Wu et al., 2006). Nevertheless, it can be concluded that oral bioavailability of verbascoside in rats is still rather low. However, the presence of other metabolites deriving from verbascoside or flavones and still non-determined in plasma could contribute to the *in vivo* biological activity of the lemon verbena extract.

Absorption and pharmacokinetics of verbascoside have been proposed to be similar to other phenolic compounds such as rosmarinic acid or some tea catechins (Wu et al., 2006). The plasma concentration of these and other polyphenolic compounds such as phenolic acids, flavonoids, stilbenes and lignans in plasma, as determined in different mice and human studies have been estimated to be in the low micromolar range (Manach, Scalbert, Morand, Remesy, & Jimenez, 2004; Manach, Williamson, Morand, Scalbert, & Remesy, 2005; Rice-Evans, Miller, & Paganga, 1997; Yang, Sang, Lambert, & Lee, 2008). Nevertheless, a large body of evidences has demonstrated the biological activity of several phenylpropanoids at the low micromolar range (Korkina, 2007). The antiinflammatory activity of several phenylpropanoids has been proven in several cellular models at low micromolar values (Diaz et al., 2004; Matsuda, Morikawa, Managi, & Yoshikawa, 2003; Matsuda, Pongpiriyadacha, Morikawa, Ochi, & Yoshikawa, 2003). In addition, several phenylpropanoids, verbascoside among them, have shown strong antioxidant capacity at low micromolar concentrations in microsomal and LDL lipid peroxidation assays (Cos et al., 2002; Wong et al., 2001). Moreover the antitumour activity of phenylpropanoids has been shown in the micromolar range in cultured cells (Chen et al., 2005; Inoue, Sakuma, Ogihara, & Saracoglu, 1998; Zhang et al., 2002) and some phenylpropanoids have been able to suppress the growth and metastasis of tumour xenografts in nude mice *in vivo* (Chung et al., 2004). Moreover, the *in vivo* hepatoprotective effect of verbascoside against CCl_4 in mice and the antioxidant effects in rats were achieved at relatively low dosages, i.e., 30 and 3 mg/kg, respectively (Lee et al., 2004). Therefore it seems reasonable to postulate that low verbascoside concentrations, i.e., within the low micromolar range, maintained for a long term in plasma might be able to exert some effects at their cellular targets.

3.4. Plasma antioxidant capacity in rats after lemon verbena oral administration

The antioxidant activity of verbascoside has been previously documented in several *in vitro* and *ex vivo* systems (Liu et al., 2003; Seidel et al., 2000; Siciliano et al., 2005; Valentao et al., 2002; Wang et al., 1996; Wong et al., 2001). Therefore, in this work, the *ex vivo* antioxidant activity of plasma samples of rats previously fed with lemon verbena extract was determined. Several measurements were performed in the same samples in which the pharmacokinetic study was done: determination of the level

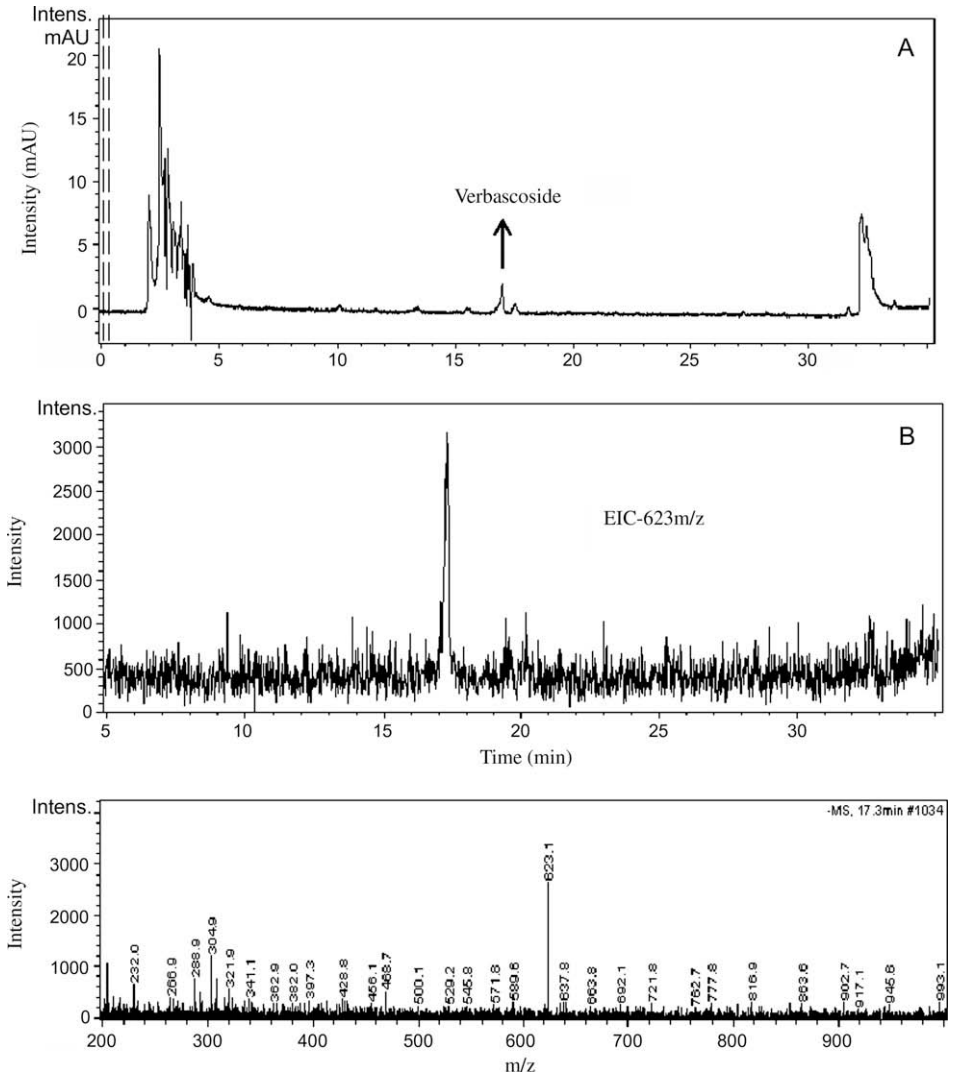

Fig. 3. HPLC-DAD-ESI-MS profile of rat plasma sample containing verbascoside collected 20 min after oral administration of lemon verbena (A) at 330 nm and (B) extracted-ion chromatogram (EIC) at 623 m/z and MS spectra of the peak corresponding to the same sample.

of plasma malondialdehyde (MDA) by HPLC, the ferric-reducing ability of plasma (FRAP value) and the superoxide dismutase activity (SOD).

Fig. 4A shows the level of MDA determined by HPLC with fluorescence detection in rat plasma samples corresponding to the different time data points of the pharmacokinetic study (bars). The figure also shows the concentration of verbascoside determined in the same samples as measured by HPLC-DAD-ESI-MS/MS. The figure shows a clear correlation between the maximum peak of verbascoside concentration at 20 min (1431 ± 300 ng/mL) and the minimum MDA value. The differences of MDA values determined at 20 and 40 min were statistically significant compared to the control.

Table 3
Pharmacokinetic data of verbascoside after oral administration of lemon verbena extract in rats.

Parameter	545 mg/kg, p.o.
T_{max} (min)	20
C_{max} (ng/mL)	1431 ± 300
AUC_{0-100} (ng min/mL)	3085 ± 1400
K_{el} (ng min/mL)	0.016 ± 0.005

T_{max} and C_{max} were obtained from experimental observation. The AUC_{0-t} was calculated using trapezoidal rule to the last point, and elimination rate constant (K_{el}) was calculated by the residual method.

To further characterise the antioxidant activity of the plasma samples of rats subjected to a single oral dose of lemon verbena extract, the ferric-reducing ability of plasma, FRAP, was determined *in vitro* (Fig. 4B). In this case, maximum antioxidant activity was observed for samples corresponding to 20 and 40 min extractions, with a significance of $p < 0.01$ compared to control. In addition, the capability of rat plasma samples to scavenge superoxide radicals was determined by using the xanthine/xanthine oxidase system coupled to superoxide dismutase (Fig. 4C). The results showed that the maximum capacity to inhibit the formation of the superoxide anion radical, i.e., SOD activity, also correlated to the rat plasma sample obtained at 20 min after the oral ingestion of lemon verbena extract, at which it was also observed the highest verbascoside concentration by LC–MS/MS.

Therefore, all these results obtained using three different complementary antioxidant measurements lead to the assumption that the antioxidant activity shown in the plasma samples of rats subjected to oral ingestion of lemon verbena extract must be mainly due to the presence of verbascoside or its derivatives, which may also exert other biological effects after reaching the appropriate

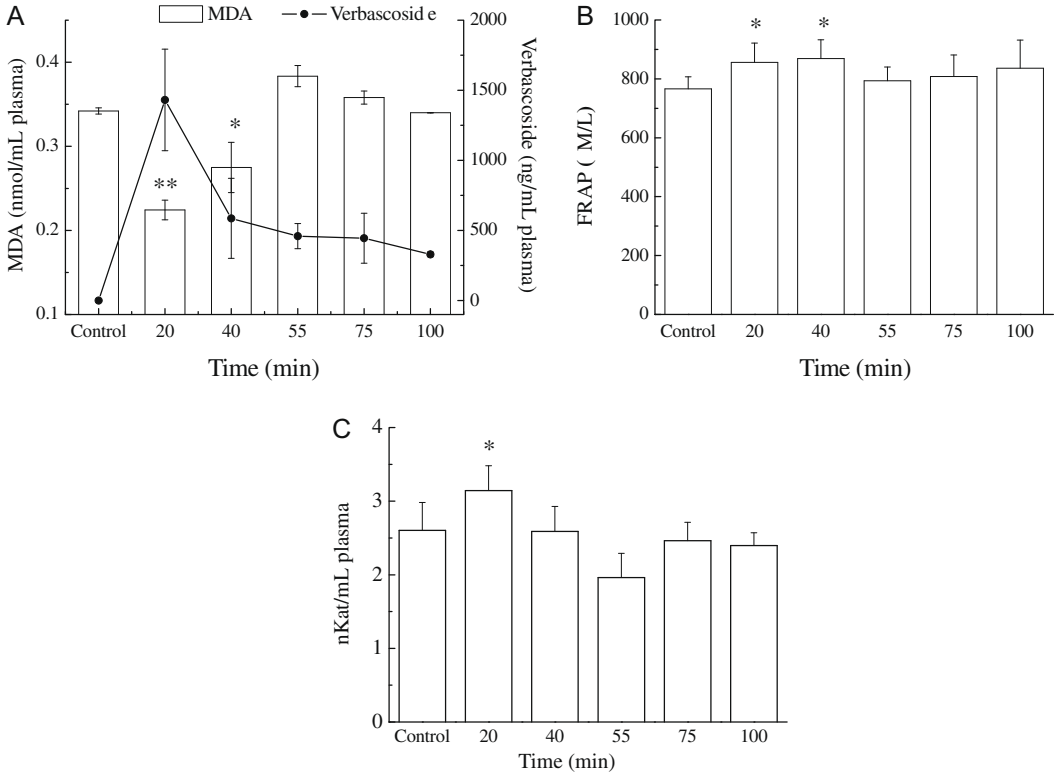

Fig. 4. (A) Inverse correlation between MDA values determined by HPLC-fluorescence (bars) and plasmatic levels of verbascoside determined by HPLC-DAD-ESI-MS/MS (filled circles) in the same rat plasma samples. Each bar represents the mean ± SD ($n = 8$); ** ($p < 0.05$) and * ($p < 0.1$) indicate statistically significant differences compared to control. (B) Ferric-reducing capacity of plasma (FRAP) in rats at 20, 40, 55, 75 and 100 min after being orally treated with lemon verbena extract. Each bar represents the mean ± SD ($n = 12$); * ($p < 0.01$) indicates statistically significant differences compared to control. (C) Superoxide dismutase activity in plasma of rats at the same time intervals than those in B after the oral ingestion of lemon verbena extract. Each bar represents the mean ± SD ($n = 8$); * ($p < 0.05$) indicates statistically significant differences compared to control.

cellular targets. As deduced from the *in vitro* antioxidant measurements, verbascoside might be also able to reach targets on lipophilic environments. It could also be postulated that the presence of verbascoside, or other related but non-detected metabolites, could increase the activity of antioxidant enzymes such as catalase, superoxide dismutase or glutathione peroxidase at post-translational level. Moreover, any change at the level of gene expression regulation must be discarded due to the short time of the observed effect. However, further research is needed in order to find any possible cellular metabolites from phenylpropanoids and to determine the presence of the metabolites deriving from lemon verbena in humans.

3.5. Oral Acute Toxicity of lemon verbena extract

Although lemon verbena is an edible plant and is commonly used to prepare infusions and spices, the oral acute toxicity of an extract containing a high content of verbascoside was performed in mice in order to establish the approximate oral LD_{50}. A single dose of 2000 mg/kg b.wt. of lemon verbena extract (25% verbascoside) was utilised and mice were observed through a 2-week period. No deaths occurred in either the control or the lemon verbena groups during treatment. No significant alterations in the body weight of the lemon verbena-treated groups (male and female) compared with their respective controls were observed (not shown).

Once the assay was completed, two individuals (one from each sex) treated with the extract were sacrificed and compared with their respective controls through postmortem and pathological examinations. Observation comprised examination of the external surface of the body (skin), all orifices, mucous membranes and the cranial, thoracic and abdominal cavities and their contents. The postmortem analysis of either male or female individuals subjected to treatment did not show abnormalities on vital organs such as brain, heart, lungs, liver, spleen, kidneys or intestines. Digestive system (stomach, duodenum, ileum, etc.) was also completely normal compared to controls. In addition, no particular gender-related effects were observed since no toxicity was noticed in male or female groups. A complete absence of toxicity at a concentration as high as 2000 mg/kg b.wt. was observed meaning that the substance may be classified either as a very low toxicity substance, i.e., GHS Category 5 (Globally Harmonized System) or unclassified. Considering that the lemon verbena extract used contained 25% verbascoside, an LD_{50} value for the pure compound, verbascoside, of $\geqslant$500 mg/kg b.wt. might be extrapolated.

4. Conclusions

To conclude, lemon verbena extract containing 25% verbascoside showed strong antioxidant capacity, especially in a lipophilic environment, which was higher than expected as concluded from the antioxidant capacity of pure verbascoside, probably due to synergistic effects. The capacity of verbascoside to act as an effective radical scavenger in lipophilic environments was also shown.

Moreover, verbascoside was found as the only metabolite identified by HPLC-ESI-MS/MS in the plasma samples deriving from rats fed with the lemon verbena extract, obtaining a C_{max} at 20 min of 2.3 μM. Verbascoside peak correlated to maximum plasma antioxidant activity as measured by malondialdehyde (MDA)

determination, ferric-reducing ability of plasma (FRAP value) and superoxide dismutase (SOD) measurements. In addition, no signs of toxicity were observed in mice at a verbascoside dosage of 500 mg/kg. Therefore, lemon verbena extract may suppose a non-toxic source of verbascoside.

Verbascoside or acteoside is present in many vegetable materials and by-products. For instance, recent work has found verbascoside to be the most potent antioxidant compound in olive mill waste extract (Obied, Prenzler, & Robards, 2008), then verbascoside-enriched extracts, such as lemon verbena extract, might have interesting applications in cosmetic, nutraceuticals or functional food.

Germination
Polyphenols
Flavonoids
Antioxidant activity

ABSTRACT

In this work, the effect of germination of lupin seeds (*Lupinus angustifolius* L., c.v. Zapatón) on bioactive phenolic compounds as well as on the antioxidant activity was studied. Phenolic compounds were analysed by HPLC-PAD-ESI/MS. The antioxidant activity was determined by spectrophotometry, evaluating the free radical scavenging activity of the samples. Germination produced significant changes in flavonoids and non-flavonoid phenolic compounds. In the analysed samples, isoflavones, flavones and dihydroflavonols in free and conjugated forms were identified. The results obtained indicate that germination modifies the quantitative and qualitative polyphenolic composition of lupin (*Lupinus angustifolius* L.) seeds during the different days of the process, with a significant increase of flavonoids. An increase in the antioxidant activity was also observed as a consequence of the process. Germination was shown to be a good process to increase the phenolic content of lupin seeds as well as their antioxidant activity.

1. Introduction

Germination of seed legumes is conducted extensively in many countries in which legume sprouts have great appeal to consumers. During germination, some of the seed reserve materials are degraded and used for respiration and synthesis of new cell constituents of the developing embryo, thus causing significant changes in the biochemical characteristics. Germination of legume seeds to produce sprouts is one of the processing methods with the potential to increase nutritive value and health qualities of the seeds (Urbano et al., 2005; Zanabria, Katarzyna, De Jong, Birgit, & Robert, 2006). This process also raises the levels of free amino acids, available carbohydrates, dietary fibre and other components and augments also the functionality of the seeds due to the subsequent increase in the bioactive compounds (Frías, Miranda-Zárate, & Vidal-Valverde, 2005; Fernández-Orozco et al., 2006; López-Amorós, Hernández, & Estrella, 2006).

It has been reported that germination processes caused a significant increase in the antioxidant capacity of lupin seeds due to the enhancement of vitamin C, E and tocopherols' content (Fernández-Orozco et al., 2006; Frías et al., 2005). In germinated pea and bean flours, the changes of phenolic compounds seem to be associated with an increase in the free radical scavenging capacity (López-Amorós et al., 2006).

Lupin (*Lupinus*) is a legume valued primarily for its high protein content, similar to that of soybean, and for its full range of essential amino acids, and important dietary minerals. In contrast to soy, lupin can be grown in more temperate to cool climates and it can be considered as the strongest potential competitor of soybean (*Glycine max*). In addition the sweet lupin varieties *Lupinus albus* and *Lupinus angustifolius* present low content in fats, and high content of dietary fibre (Górecka, Lampart-Szczapa, Janitz, & Sokolowska, 2000) and are more palatable (Vilariño, Mareggiani, Grass, Leicach, & Ravetta, 2005). Germination, among other processes, has been widely used for its ability to decrease levels of antinutritional factors present in legume seeds, at the same time improving the concentration and bioavailability of their nutrients. Other studies have demonstrated that the germination of lupin seeds modifies the composition of the protein fraction, and minimises the presence of alkaloids, improving the nutritional quality of legume and obtaining more palatable seeds (Gulewicz et al., 2008; Sanchez et al., 2005).

One of the most abundant groups of secondary metabolites in legumes are phenolic compounds (Dueñas, Estrella, & Hernández, 2004; Dueñas, Fernández, Hernández, Estrella, & Muñoz, 2005; Dueñas, Hernández, & Estrella, 2002; López-Amorós et al. 2006; Amarowicz, Estrella, Hernández, & Toroszynska, 2008; Amarowicz & Pegg, 2008), which are considered to be natural antioxidants, representing an important group of bioactive compounds in foods, which may prevent the development of many diseases such as arteriosclerosis, cancer, etc.

The protection against disease of phenolics may be associated with the powerful antioxidant and free radical scavenging properties of these compounds (Dueñas, Hernández, & Estrella, 2006; Amarowicz & Pegg, 2008). This property affects the auto-immune system of the consumer organism (Nakagami, Nanaumi-Tamura, Toyomura, & Shgehisa, 1995). The content of phenolics depends not only on the species and variety but also on the degree of ripeness, processes, etc. (López-Amorós et al., 2006; Dueñas, Hernández, & Estrella, 2007a, 2007b). The different phenolic compounds found in lupin seeds can influence the taste and colour (Oomah, Tiger, Olson, & Balasubramanian 2006) and they can also act as fungicides, bacteriostats, etc.

Phenolics such as flavones and isoflavones are present in several parts of lupin, including the seeds (García-López, Kachlicki, Zamora-Natera, Ruiz-Moreno, & Stobiecki, 2006; Tsaliki, Lagouri, & Doxastakis, 1999), which are related to high antioxidant activity, although the presence of some amino acids and peptides can also contribute to this activity (Frías et al., 2005).

The greatest therapeutic effect of phenolics, such as antioxidant activity, depends on their structure, including the number of hydroxyl groups and their position. In general the flavonoid compounds present a stronger antioxidant activity than non-flavonoids (Jovanovic, Steenken, Simic, & Hara, 1998) and the combined forms, such as glycosides, have lower activity than free forms (Rice-Evans, Miller, & Paganga, 1996).

The aim of the present study was to identify the phenolic compounds in the extracts of raw and germinated lupin (*Lupinus angustifolius* L., c.v. Zapaton) and to know the effect of different germination periods on the phenolic composition. The antioxidant activity of raw and germinated seeds' flours was also evaluated in order to determine the optimal conditions of germination for attaining flours with higher functionality.

2. Materials and methods

2.1. Samples

Sweet lupin seeds (*Lupinus angustifolius* L., c.v. Zapatón) were provided by the Agrarian Research and Technology Development Service from the Agriculture and Commerce Council of the Junta de Extremadura (Spain). Seeds were cleaned and stored in polyethylene containers at 4 °C in a cool room until use.

2.2. Germination process

Two hundred grams of lupin seeds were treated for 30 min with 1000 ml of 0.07% sodium hypochlorite. Then, the seeds were washed with distilled water until the pH was neutral. Afterwards, seeds were soaked with 1000 ml of distilled water for 5 h and 30 min and shaken every 30 min. The hydrated seeds were placed on a germination tray, where a wet laboratory paper was extended and they were then covered with the same wet paper. The tray was introduced into the germination machine (G-120 Snijders International S.L., Holland) and the wet paper was in contact with the circulating water of the germinator; therefore the seeds were maintained wet by capillarity (Frías et al., 2005). The seeds were germinated in darkness at 20 °C for 2, 3, 4, 5, 6 and 9 days. The germination process was evaluated by percentage of germinated seeds and the sprouts were freeze-dried, ground and passed through a sieve of 0.5 mm. The flours obtained were stored in darkness, under vacuum conditions in desiccators at 4 °C until further analysis.

2.3. Preparation of samples and extraction of phenolic compounds

The lupin samples (10 g) were macerated with 3 × 80 ml of a solution of methanol-HCl ($1^0/_{00}$)/water (80:20 v/v) using an orbital shaker at room temperature, separating the supernatants by centrifuging. The three combined supernatants were taken to a fixed volume (240 ml) of the methanol solution, yielding a methanol extract whose total phenolic content was evaluated by Folin–Ciocalteu reaction (Singlenton & Rossi, 1965).

An aliquot of the methanolic solutions (100 ml) was extracted three times with 3 × 30 ml of diethyl ether and 3 × 30 ml of ethyl acetate and evaporated to dryness under vacuum at 30 °C. The residue was dissolved in methanol/water (1:1 v/v), and filtered through a 0.45 μm cellulose acetate filter (Millipore) and kept at 4 °C until HPLC analysis. The samples were prepared and extracted in duplicate.

2.4. HPLC–PAD and HPLC–MS analysis

The chromatographic system was comprised of an auto-injector, a quaternary pump, a photodiode-array detector 2001 and Millennium 32 chromatography manager software (Waters, Milford, Mass, USA). Separation of phenolic compounds was achieved on a reverse phase C_{18} column (Nova-Pak, 300 × 3.9 mm, particle size 4 μm). The mobile phase was comprised of two solvents, A: water/acetic acid (98:2, v/v) and B: water/acetonitrile/acetic acid (78:20:2, v/v/v). The gradient profile was 0–55 min, 100–20% A; 55–70 min, 20–10% A; 70–80 min, 10–5% A; 80–110 min, 100% B. The flow rate was 1 ml/min from the beginning to 55 min and 1.2 ml/min from this point to the end. The column was re-equilibrated between injections with 10 ml of acetonitrile and 25 ml of the initial mobile phase. Detection was performed by scanning from 210 to 400 nm with an acquisition speed of 1s. A volume of 25 μl was injected. The samples were analysed in duplicate.

Mass spectra were obtained using a Hewlett Packard 1100MS (Palo Alto, CA) chromatograph equipped with an API source, using an ESI interface. The solvent gradient and column used were the same as for HPLC–PAD but with a flow rate of 0.7 ml/min. ESI conditions were as follows: negative mode, nitrogen was used as the 40 psi nebulizing pressure drying gas, 10 l/min at 340° C; voltage at capillary entrance, 4000 V; and variable fragmentation voltage, 100 V (m/z < 200), 200 V (m/z 200–1000), 250 V (m/z 1000–2500). Mass spectra were recorded from m/z 100 to m/z 2500.

Chromatographic peaks were identified by comparison of the retention times, UV spectra and data of UV spectral parameters with those of standards and confirmed by HPLC–MS. The standards, protocatechuic, *p*-hydroxybenzoic, *trans p*-coumaric, *p*-hydroxyphenyl acetic and *trans*-ferulic acids, flavones apigenin 7-*O*-glucoside, luteolin 7-*O*-glucoside, diosmetin 7-*O*-rutinoside, diosmetin 7-*O*-neohesperidoside, isoflavones genistein and genistein 7-*O*-glucoside and the flavanone eriodictyol, were obtained from Extrasynthèse (France). Other compounds, for which no standards were available, were identified based on the study of data of UV spectral parameters and by HPLC–MS (ESI) (Dueñas et al., 2002, 2004).

Quantification was carried out using the external standard method with commercial standards. The calibration curves were made by injection of different volumes from the stock solutions over the range of concentration observed for each of the compounds, using a linear regression for the relationship of area sum versus concentration under the same conditions as for the samples analysed. The unknown non-flavonoid and flavonoid derivatives were quantified with the calibration curves of the most similar compounds.

2.5. Antioxidant activity

Antioxidant activity (EC_{50}) of the methanol extracts was determined by the Brand-William, Cuvelier, & Berset (1995) method with 2,2′diphenyl-1-picrylhydrazyl (DPPH) radical, adapted to the

legume samples by López-Amorós et al. (2006). The reaction was carried out with 2 ml of a methanol solution of DPPH$^{\cdot}$ (0.025 g/l) and solutions of different concentrations from the different samples. The absorbance was measured at 1 min intervals at 515 nm until the reaction reached a plateau (time at the steady state). The percentage of remaining DPPH against the sample concentration was plotted to obtain the amount of antioxidant (mg of legume flours) necessary to decrease DPPH by 50%. The antioxidant capacity was expressed as Trolox units. The samples were prepared and measured separately in duplicate.

2.6. Statistical treatment

Analyses were performed in duplicate and the data are presented as mean ± SD. Analysis of variance and comparison of treatment means (LSD, 5% level) and principal components were performed using Statgraphics Plus 5.0 (Statistical Graphics Software System, Rockville, MD, USA).

3. Results and discussion

Values of total phenols, in which a general increase was found, of raw and germinated seeds (expressed as mg of gallic acid) are shown in Table 1. An individualised knowledge of the different phenolic compounds is necessary to reach a more specific conclusion.

3.1. Identification of phenolic compounds in lupin flours

The UV spectra provided a complete overview of the main flavonoids in all samples studied. Thus, for structural elucidation of different phenolic compounds, the UV spectra were considered (Fig. 1) in accordance with the data from Markham (1982). Dihydroflavonols (Fig. 1A) presented a maximum at 289 nm and a shoulder at 310 nm; flavones showed a UV spectrum (Fig. 1B) with two maxima at 254 and 348 nm, the latter more pronounced. The UV spectrum of isoflavones (Fig. 1C) had a maximum at 260 and a shoulder at 320 nm. Most structural information was obtained from HPLC–MS analysis in negative mode.

Among the analysed sample extracts several phenolic compounds, non-flavonoids hydroxybenzoics, hydroxycinnamics and flavonoids, such as flavones, isoflavones and dihydroflavonols, were identified.

Figs. 2 and 3 show the chromatograms of the raw and germinated lupin at 9 days, respectively and Tables 2 and 3 present the wavelength of maximum UV absorption and the molecular ions of identified compounds from HPLC–MS, grouped in accordance with similarity in phenolic structure. Analysis of MS spectra recorded for each peak together with comparison of MS^2, UV spectra and retention times led to identification of some of the compounds from the chromatographic conditions.

3.1.1. Hydroxybenzoic and hydroxycinnamic compounds

Peaks 1, 2, 3, 4, 5, 8, 9 and 11 presented UV spectra which correspond to hydroxybenzoic acids and aldehydes. Some of them, peaks 2, 3, 8, 9 and 11 were identified by comparison of retention times and UV spectra with those of corresponding standards (Table 2).

Peak 1 showed a UV spectrum similar to that of protocatechuic acid and it presented an $[M-H]^-$ at *m/z* 315 (Table 2) corresponding to protocatechuic acid linked to a hexose and one fragment ion $[M-H]^-$ at *m/z* 153.1 from protocatechuic acid. This compound was identified as protocatechuic acid glycoside, an infrequent form found in legumes. This compound was described in pea seeds by the same authors (Dueñas et al. 2004). Protocatechuic acid in esterified form was also identified in cowpeas by Cai, Hettiarachchy, and Jalaluddin (2003).

Peak 4 and 5 presented UV spectra similar to hydroxybenzoic acid, but with different retention times, therefore these compounds were identified as hydroxybenzoic derivatives, since data of their MS spectra could not be obtained.

The UV spectra presented by peaks 7, 10, 14, 16, 21 and 26 were characteristic of hydroxycinnamic compounds and they are, therefore, considered as derivatives of these compounds. Peaks 16 and 21 were identified by comparison of retention times and UV spectra with those of standards (Table 2).

The UV spectrum of peak 7 was similar to that of *trans p*-coumaric acid. In the HPLC–MS (ESI) analysis it presented an $[M-H]^-$ at *m/z* 295.0 which corresponds to *p*-coumaric acid linked to a glutaric acid and a fragment $[M-H]^-$ at *m/z* 163 from *p*-coumaric acid. This compound was identified as *trans p*-coumaroyl-glutaric acid and is reported for the first time in lupin. It was also reported in cowpea seeds by Cai et al. (2003) and Dueñas et al. (2005).

Peak 10 showed a UV spectrum similar to that of ferulic acid, with an $[M-H]^-$ at *m/z* 355 (Table 2) from ferulic acid linked to a hexose and one fragment ion: $[M-H]^-$ at *m/z* 193.1 from ferulic acid. It was identified as a ferulic acid glycoside. Peak 14 was identified by the UV spectrum as a ferulic acid derivative; it presented a molecular ion $[M-H]^-$ at *m/z* 308 from the ferulic acid linked to malic acid. This peak corresponding to a feruloyl malic acid was also identified in the pea seed coat (Dueñas et al., 2004). Peak 26 showed a molecular ion $[M-H]^-$ at *m/z* 178, corresponding to coniferylaldehyde.

3.1.2. Dihydroflavonols

Peaks 6, 15, 23 and 43 presented UV spectra corresponding to dihydroflavonols (Fig. 1A). Peaks 6 and 43 had a fragment ion $[M-H]^-$ at *m/z* 303 from dihydroquercetin and were identified as dihydroquercetin derivatives.

Peak 15 had a molecular ion $[M-H]^-$ at *m/z* 507 which is associated with dihydroquercetin linked to an acetyl glucoside, and a fragment ion $[M-H]^-$ at *m/z* 303 from dihydroquercetin. It was identified as dihydroquercetin acetyl glucoside. Peak 23 generated a molecular ion $[M-H]^-$ at *m/z* 491 corresponding to dihydrokaempferol acetyl glucose.

3.1.3. Flavones

The UV spectra of peaks 17, 18, 28, 29, 32, 33, 34, 39, 41, 42, 44, 47, 48, 49, 50, 51, 52 and 53 corresponded to those of flavones (Fig. 1B).

Peaks 17 and 39 were identified as apigenin apioglucoside and apigenin neohesperidoside, respectively, by comparison of retention times and UV spectra with those of standards (Table 2). Some others, 18, 28, 29 and 50 were identified as apigenin derivatives due to the fragment of molecular ion $[M-H]^-$ at *m/z* 269, corresponding to apigenin.

Table 1
Total phenols* (mg/g dry matter) of raw lupin and lupin sprouts.

Raw	2 days	3 days	4 days	5 days	6 days	9 days
8.56 ± 0.85	10.60 ± 1.02	13.67 ± 1.01	15.46 ± 1.25	11.22 ± 0.97	16.61 ± 1.13	24.37 ± 1.31

* Expressed as gallic acid.

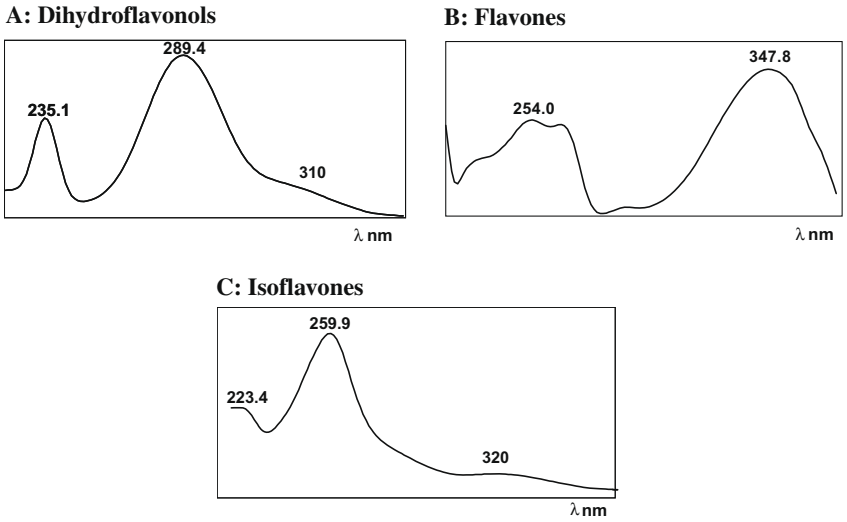

Fig. 1. UV spectra of dihydroflavonols, flavones and isoflavones.

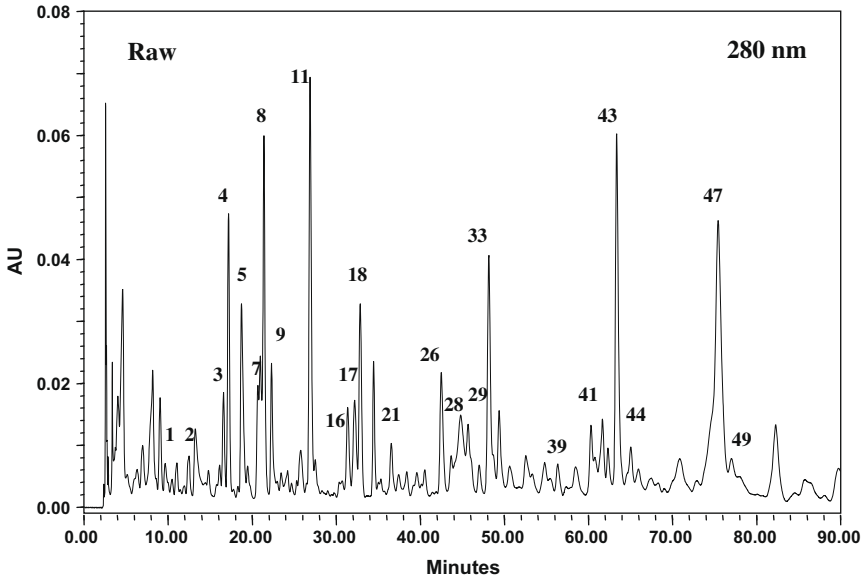

Fig. 2. HPLC chromatogram of raw lupin.

Peaks 33, 34, 41, 48 and 49 presented a fragment ion $[M-H]^-$ at *m/z* 285 which corresponded to luteolin, therefore they were designated luteolin derivatives. Peak 32 was identified as luteolin 7-glucoside by comparison with the standard.

Peak 42 showed a λ_{max} at 347.0 characteristic of luteolin derivatives. This compound presented hypsochromic shifts of their absorption spectra with regard to the luteolin glucoside due to the acetyl moiety. It showed a negative molecular ion $[M-H]^-$ at *m/z* 489, which corresponds to the luteolin glycoside acetylate and two fragments ions $[M-H]^-$ at *m/z* 456 ($[M-42]^-$, loss of acetyl residue) and at *m/z* 285 ($[M-204]^-$, loss of acetyl glycoside residue). It was identified as luteolin glucopyranosyl acetate.

Peaks 44 and 47 were identified as diosmetin 7-rutinoside and diosmetin 7-neohesperidoside, respectively, by comparison with the standards. Peak 52 presented a UV spectrum (252–346 nm) of diosmetin. In the analysis MS showed a negative molecular ion $[M-H]^-$ at *m/z* 635 and two fragments ions $[M-H]^-$ at *m/z* 461 ($[M-174]^-$, (loss of acetyl pentose residue) and at *m/z* 299 $[M-336]^-$, corresponding to diosmetin aglycone. It was identified as diosmetin apiofuranosyl acetyl glycoside. Peaks 51 and 53 presented an $[M-H]^-$ at *m/z* 299 from diosmetin and they were identified as diosmetin derivatives.

Peak 35 presented a UV spectrum (λ_{max} at 285 nm) corresponding to the flavanone eriodictyol with a fragment ion at *m/z* 287 from free eriodictyol; it was identified as an eriodictyol derivative.

3.1.4. Isoflavones

Peaks 12, 13, 19, 20, 22, 24, 25, 27, 30, 31, 36, 37, 38, 40, 45, 46 and 54 were considered isoflavones taking into account their UV characteristics (Fig. 1C).

The following compounds, genistein 7-glucoside (peak 30) and genistein (peak 54) were identified by comparison of retention times and UV spectra to those of standards and confirmed by HPLC–MS (ESI) analysis (Table 3).

Peaks 12, 24, 27, 31 and 46 showed a λ_{max} at 259.0 nm characteristic of genistein; they were considered genistein derivatives based on the fragment ion $[M-H]^-$ at *m/z* 269 in the analysis by HPLC–MS. Peak 22 together with the fragment ion from genistein

molecular ion $[M-H]^-$ at *m/z* 563, which corresponded to the genistein linked to pentose and hexose and two fragment ions $[M-H]^-$ at *m/z* 431 ($[M-132]^-$, loss of a pentose moiety) and at *m/z* 269 ($[M-294]^-$, loss of pentose-hexose moiety). It was identified as genistein diglycoside.

Peak 25, 36 and 45 showed a λ_{max} at 259.0 nm characteristic of genistein derivatives. These compounds showed a negative molecular ion $[M-H]^-$ at *m/z* 473, which corresponded to the genistein glycoside acetylate and two fragments ions $[M-H]^-$ at *m/z* 431 ($[M-42]^-$, loss of acetyl residue) and at *m/z* 269 ($[M-204]^-$, loss of acetyl glycoside residue). They were identified as genistein acetyl glycosides in different positions.

Peaks 37 and 40 showed a negative molecular ion $[M-H]^-$ at *m/z* 575, which corresponded to the genistein linked to acetyl and pentose and hexose and two fragments ions $[M-H]^-$ at *m/z* 431 ($[M-132]^-$, loss of pentose residue) and at *m/z* 269 ($[M-204]^-$) corresponding to genistein. These compounds were identified as genistein acetyl diglycosides.

Peaks 19 and 20 corresponded to isoflavones, and they presented a fragment ion at *m/z* 285 assigned to hydroxygenistein (Bednarek et al., 2003). These compounds were identified as hydroxygenistein 7-*O*-glucoside and hydroxygenistein 7-*O*-acetyl glucoside, respectively.

3.2. Changes occurring during the germination process

From the results obtained in the evaluation of total phenols (Table 1) it can be deduced that germination caused an increase of total phenols (expressed as mg of gallic acid) in sprouts of *Lupinus angostifolius* var. Zapatón. An increase was observed at four days and a more pronounced one at nine days, where a rise of up to 63% was found. These results agree with those reported by Fernández-Orozco et al. (2006) who also found an increase of 53% of total phenols (expressed as mg of catechin) in lupin sprouts after nine days. A rise in total phenols of chickpea was also reported after five days of germination (Khattak, Zeb, Bibi, Khalil, & Khattak, 2007).

Moreover, greater qualitative and quantitative differences in the identified phenolic compounds were observed between the raw and germinated lupin seeds (Tables 2 and 3). Due to the high number of identified phenolic compounds in the samples, Table 4 shows the total concentration of the compounds grouped in different families (hydroxybenzoics, hydroxycinnamics, flavones, dihydroflavonols and isoflavones) in order to achieve a better clarification of the results.

The hydroxybenzoic compounds represented 18% of the identified phenolics in raw lupin seeds. In general, there was a loss of these compounds, corresponding to a reduction of 65% at 9 days. Several variations were observed during the different days of germination with the maximum value at day 4 and the minimum being produced on day 6 (Table 4).

The hydroxycinnamic compounds in raw lupin seeds represented 1.2% of the identified phenolic compounds. During germination this group increased its content considerably, with two maxima at 4 and 9 days, augmenting by 91% at the end of the process (Table 4). This group included hydroxycinnamic compounds in free forms (*trans p*-coumaric and *trans*-ferulic acid) and those linked to other compounds (hydroxyacids and sugars) (Table 2). In general, *p*-coumaric and ferulic acids increased their contents, as well as other derivatives from these acids, some of them not being identified in raw lupin. Other authors also observed that with germination there was the novo synthesis of hydroxycinnamic acids such as *p*-coumaric and ferulic acids (Diaz-Batalla, Widholm, Fahey, Castaño-Tostado, & Paredes-López, 2006; López-Amorós et al., 2006).

The flavones group presented the highest percentage in all samples (Table 4), in raw (76%) and germinated lupin seeds (68–84%). During germination, variations in the behaviour of this group were observed with minimum values at 2, 4 and 5 days. Two increases were observed, one at 3 days and from day 6 until day 9 of germination where an increase of 86% with respect to raw seeds was observed (Table 4). The flavones mainly identified were glycosides of luteolin, apigenin and diosmetin (Table 2). Germination for 9 days gave rise to an increase in the number of identified compounds from luteolin and diosmetin derivatives, in contrast to apigenin derivatives. This could be attributed to the biochemical changes of seeds during germination, which might produce some secondary plant metabolites, such as flavonoids or release aglycones from conjugated glycosides due to enzymatic activation (Ribeiro et al., 2006).

The flavanone identified as an eriodictyol derivative was only found in germinated lupin seeds (Table 2). The dihydroflavonols represented the lowest percentage (0.4%) in raw lupin seeds and, in the germinated samples at different times, ranged from 0.6–1.5%, which means an increase during the time of germination. It was at 9 days when lupin showed the highest rise (93%) (Table 4).

The content of isoflavones in the raw lupin seeds represented 4% of identified phenolics (Table 4). The isoflavones significantly increased during the germination from 2 days, with a high value at 3 days, but it was at 9 days when lupin sprouts attained the highest increase (95%).

Table 4
Concentrations (μg/g) in raw and germinated lupin, of identified phenolic compounds, grouped in hydroxybenzoics, hydroxycinnamics, flavones, dihydroflavonols and isoflavones.

Compounds	Raw	2 days	3 days	4 days	5 days	6 days	9 days
Hydroxybenzoics	4.60 ± 0.51^{d}	1.90 ± 0.08^{b}	1.40 ± 0.05^{ab}	2.70 ± 0.11^{c}	1.30 ± 0.03^{ab}	0.80 ± 0.02^{a}	1.60 ± 0.05^{b}
Hydroxycinnamics	0.30 ± 0.01^{a}	0.80 ± 0.02^{b}	1.20 ± 0.03^{b}	4.20 ± 0.21^{e}	0.90 ± 0.02^{b}	2.20 ± 0.11^{c}	3.60 ± 0.09^{d}
Flavones	19.10 ± 1.95^{b}	10.20 ± 0.98^{a}	31.50 ± 1.12^{c}	13.20 ± 0.85^{ab}	12.40 ± 0.91^{ab}	42.60 ± 2.10^{d}	135.30 ± 5.21^{e}
Dihydroflavonols	0.10 ± 0.01^{a}	0.09 ± 0.02^{a}	0.40 ± 0.03^{c}	0.20 ± 0.05^{b}	0.30 ± 0.04^{b}	0.50 ± 0.04^{c}	1.60 ± 0.09^{d}
Isoflavones	0.90 ± 0. 03^{a}	2.10 ± 0.07^{ab}	8.60 ± 1.01^{c}	3.10 ± 0.21^{b}	2.50 ± 0.12^{ab}	9.30 ± 0.54^{c}	18.20 ± 0.91^{d}

Values are mean ± SD (n = 2); means followed by the superscript letters in a row are not significantly different (LSD, 5%).

The elevated number of isoflavones identified as genistein derivatives in the sprouts is remarkable in comparison to raw lupin (Table 3). Several authors have also observed in other legumes, such as soybean or beans that the isoflavones content increased, during the process of germination (Lin & Lai, 2006; Diaz-Batalla et al., 2006). After germination for 72 h an increase of isoflavones in the cotyledon of soybeans was also found which was accompanied by a rise of β-glucosidase activity (Ribeiro et al., 2006).

It is important to point out the presence of the aglycon genistein in the germinated lupin, considering its antioxidant capacity. It is important to note that the isoflavones, such as genistein, are known as phytoestrogens that have been related to a risk reduction of cardiovascular disease and cancer, particularly breast and prostate cancer (Mathers, 2002). This would make the germinated common lupin an alternative source of phytoestrogens.

Genistein aglycone showed a considerable increase (data not shown) after 9 days of germination. It is well known that during germination, enzymatic activity increases, such as that of glucosidases (Ribeiro et al., 2006); therefore, if glucosidase activity increased, it would increase the content of aglycones during the germination. At the beginning of germination not only aglycones are released from glucosides through the catalysis of activated glucosidase in seeds, but also isoflavones are produced through the biosynthesis in the malonate and phenylpropanoid pathways (Hahlbrock & Scheel, 1989). Genistein derivatives were the most prominent compounds found in lupin sprouts after 9 days.

During the germination of *Lupinus angustifolius* studied in this work, different behaviours of flavonoids and non-flavonoid phenolic compounds was observed. Flavonoids presented two maximum concentrations at 3 and 9 days of germination, showing the biggest increase at 9 days. Differences were observed in non-flavonoids compounds, such as hydroxycinnamics and hydroxybenzoics. These compounds presented a maximum at 4 days. Hydroxybenzoic compounds decreased at the end of the process.

Previous studies carried out by our research group in legumes after different processes, such as fermentation, addition of enzymes and germination reported similar behaviour to that found in this work, with increases and decreases being observed through the study period. This great variation of these compounds could be explained by the complex biochemical metabolism of seeds during treatment.

At the end of the germination (9 days) a considerable increase (84%), with respect to raw lupin, in the total concentration of identified phenolic compounds was observed. However, there were few differences between the groups, hydroxycinnamics (92%), flavones (86%), isoflavones (95%) and dihydroflavonols (94%).

3.3. Antioxidant activity of raw lupin and lupin sprouts

The increase of phenolic compounds with the germination process could have an influence on the free radical scavenging capacity. For this reason, the evaluation of antioxidant activity in the methanolic extracts of all samples was carried out to discover the changes in relation to the days of germination, in order to know the influence of germination on the antioxidant activity, taking into account the correlation of phenolic compounds with the free radical scavenging activity.

Table 5 shows the antioxidant activity values determined as mg Trolox/g sample. It was observed that at 3, 6 and 9 days of germination antioxidant activity increased considerably with respect to raw lupin (59%, 61%, and 63%, respectively) and a lesser increase was observed in samples of 4 and 5 days.

Comparing the content in total phenolics (Table 1) with the values of antioxidant activity (Table 5) for the different samples, we can observe no coincidence among them. A low correlation between the total phenolics and antioxidant activity was obtained (R^2 = 0.7195), which suggests that other compounds different than phenolics, which also react with the Folin–Ciocalteu reagent. However, an increase in total phenolics did not always bring about a corresponding increase in antioxidant activity as seen for example, from day 3 to day 4.

The improvement of antioxidant activity during the germination process has also been observed by other authors. Fernández-Orozco et al. (2006) observed that TEAC values changed slightly up to 5 days of germination but after 6 and 9 days significant increases (25% and 28%, respectively) were found in lupin seeds. Frías et al. (2005) also observed that germination of lupin (*Lupinus albus*) after 9 days produced an enhancement in the antioxidant activity that corresponded to an increase in content of vitamins E and C.

The variations in the antioxidant activity could be better explained in relation to the changes in the different identified phenolics. In both cases (antioxidant activity and levels of identified phenolics) there was an increase at 9 days of germination in the groups of the identified compounds, with the exception of hydroxybenzoic compounds.

López-Amorós et al. (2006) reported an increase in the antioxidant activity of beans and peas germinated for 6 days, but an opposite behaviour was observed for lentils. The changes observed in these legumes were related to the increase of phenolics in peas and beans as a consequence of germination and the decrease in the case of lentils. An increase of antioxidant activity after germination was also observed in soybean, azuki bean and mung bean (Lin & Lai, 2006), attributed to the biochemical metabolism of seeds during germination.

The antioxidant activity of phenolic compounds is related to their chemical structure, thus in order to relate antioxidant activity to the identified polyphenolic compounds in the lupin samples on the different days of germination an analysis of principal components was carried out. Principal component analysis was performed on the values of the antioxidant activity (Table 5) and the concentrations of the groups of identified compounds (Table 4).

Table 5
Antioxidant activity (mg trolox/g sample) of raw and germinated lupin.

Raw	2 days	3 days	4 days	5 days	6 days	9 days
7.1 ± 0.3	8.3 ± 0.2	17.5 ± 3	12.3 ± 0.2	11.4 ± 0.2	18.2 ± 3	19.1 ± 0.2

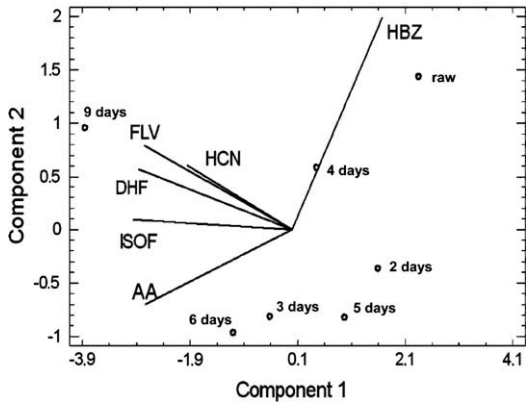

Fig. 4. Plot of the principal components of the polyphenolic compounds and antioxidant activity (Trolox) of raw and germinated lupin seeds during 2, 3, 4, 5, 6 and 9 days. HBZ, hydroxybenzoics; HCN, hydroxycinnamics; FLV, flavones; DHF, dihydroflavonols; ISOF, isoflavones; AA, antioxidant activity.

Six components were obtained of which the first two accounted for 86.51% of the total variance. Fig. 4 shows the graphic representation of the first two components. Four groups of compounds, hydroxycinnamics, isoflavones, flavones and dihydroflavonols were more positively related to the antioxidant activity and at the same time (9 days of germination), which means that these compounds produced an increase in this activity when compared to raw lupin. Hydroxybenzoics were the only phenolics that had a high relation with raw lupin and they are not related to antioxidant activity.

It is well known that non-flavonoid compounds present less antioxidant activity than flavonoids (Baderschneider & Winterhalter, 2001). However, hydroxycinnamic compounds show a relationship with the antioxidant activity; thus, in previous work carried out by our group with lentils and peas, these also showed a relationship between the hydroxycinnamic compounds and the antioxidant activity (Dueñas et al., 2006; López-Amorós et al., 2006).It has also been reported that compounds such as ferulic and *p*-coumaric acids are correlated with antioxidant activity in cooked soybeans (Kim et al., 2006). Isoflavones are the phenolic compounds present in lupin which most influence the antioxidant activity, especially considering the presence of the aglycone genistein in lupin seeds at the end of the germination process, with a more potent antioxidant activity than the conjugated forms (Arora, Nair, & Strasburg, 1998).

4. Conclusions

Germination caused significant changes in the phenolic composition of lupin, due mainly to endogenous enzymes' activation and the complex biochemical metabolism of seeds during this process. During germination non-flavonoids presented a maximum of concentration at four days. This differs from flavonoids, whose maximum appeared at three days of germination, which demonstrates different behaviours for the two types of compounds during this process. Germination during nine days gave rise, in general, to an increase in the content of the majority of phenolic compounds mainly flavonoids, such as flavones, isoflavones and dihydroflavonols with respect to raw lupin.

Therefore, germination may be a good process to obtain a functional food with a high antioxidant capacity.

Virgin olive oil

ABSTRACT

An electronic nose based on an array of six metal oxide semiconductor sensors was used to monitor the oxidative status of virgin olive oils (VOO) during storage. VOO samples, with and without phenolic compounds, were stored at 60 °C for 7 weeks. Once a week, absorbance at 232 and 270 nm, oxidized stability index, electronic nose, and sensory analysis were evaluated. Linear discriminant analysis models were constructed in order to classify samples according to oxidative levels. Based on these models, VOO samples with and without phenolic compounds at different storage times, divided in eight categories, were correctly classified also achieving a good correlation for sensory analysis. The method is a fast and economical tool for on-line monitoring of VOO oxidation status.

1. Introduction

Among edible oils, virgin olive oil (VOO) is a basic component of the Mediterranean diet and has several characteristics that render it unique (Bendini et al., 2007a). The importance of VOO is mainly attributed to its high oxidative stability and its characteristic sensory and nutritional properties (Aparicio, Roda, Albi, & Gutiérrez, 1999; Bendini et al., 2007a; Cerretani, Salvador, Bendini, & Fregapane, 2008). The high oxidative stability of VOO with respect to other vegetable oils is mainly due to its fatty acid composition, and in particular to the high monounsaturated-to-polyunsaturated ratio and the presence of minor compounds, that play a major role in preventing oxidation. However, in spite of its high stability, VOO is also susceptible to suffer oxidative processes such as enzymatic oxidation (which occurs when the oil is in the fruit and during the technological extraction process), photo-oxidation (which occurs when the oil is exposed to light) and auto-oxidation (mainly produced during processing and storage when the oil is in contact with oxygen) (Bendini, Cerretani, Salvador, Fregapane, & Lercker, submitted for publication; Frankel, 1985). In these latter cases, the presence of antioxidant compounds can modify the oxidation process. A classification of the antioxidants based on their mechanism of action includes primary antioxidants, synergistic, and secondary antioxidants (Rajalakhmi & Narasimham, 1996). Phenolic compounds are one of the major groups in the polar fraction and act as primary antioxidants (AxH) to inhibit oxidation in VOO. These compounds act as chain breakers by donating a radical hydrogen to the alkylperoxyl radicals ($ROO^{\cdot}$) formed during the initiation step of lipid oxidation, and subsequently form a radical ($Ax^{\cdot}$) that is stabilized by resonance forms during the reaction (Carrasco-Pancorbo et al., 2005):

$$ROO^{\cdot} + AxH \rightarrow ROOH + Ax^{\cdot}$$

The polar extracts of VOO contain phenolic compounds that belong to different classes comprising phenolic acids, phenyl ethyl alcohols, hydroxy-isochromans, flavonoids, lignans, and secoiridoids. The secoiridoid family is characteristic of Oleaceae plants, being the main compounds of the phenolic fraction of VOO (Bendini et al., 2007a). The shelf-life of VOO is longer than other vegetable oils, mainly due to the presence of phenolic molecules possessing a catechol group, such as hydroxytyrosol and its secoiridoid derivatives. Three different assays (antiradical test, electrochemical method and a forced oxidation model system) have been used to establish the antioxidant activity of these phenolic compounds (Carrasco-Pancorbo et al., 2005).

VOO is also a unique, edible vegetable oil with characteristic sensory properties. The sensory attributes of VOO mainly depend on the content of minor components such as phenolics and volatile compounds. The individual components contribute to different sensory perceptions (Cerretani et al., 2008). Approximately 180

compounds belonging to several chemical classes such as aldehydes, alcohols, esters, ketones, acids, ethers, hydrocarbons and terpens have been separated from the volatile fractions of VOO (Angerosa et al., 2004). The oxidation process leads to the production of several products of varying volatility. These compounds, mainly saturated and unsaturated aldehydes generated by autoxidation, are the major cause of the sensory perception of the rancid defect in vegetable oils (Vichi, Pizzale, Conte, Buxaderas, & López-Tamames, 2003). Concerning gustatory perceptions, it is well established that phenolic compounds are responsible for bitterness (Beltrán, Ruano, Jiménez, Uceda, & Aguilera, 2007; Cerretani et al., 2008; Esti, Contini, Moneta, & Sinesio, 2009; Gutierrez-González, Albi, Palma, Rios, & Olias, 1989; Gutierrez-Rosales, Rios, & Gomez-Rey, 2003) and pungency in VOO (Andrewes, Busch, De Joode, Groenewegen, & Alexandre, 2003; Cerretani et al., 2008; Esti et al., 2009; Tovar, Motilva, & Romero, 2001). In particular, Andrewes et al. (2003) found that decarboxymethyl-ligstroside aglycon, also called oleocanthal (Beauchamp et al., 2005), is the major phenolic molecule responsible for the burning pungent sensation of VOO. Recently, Beauchamp et al. (2005) found that oleocanthal inhibits enzymes related to inflammation and also shows ibuprofen-like activity. Moreover, the phenolic content has been associated with protection against several chronic and degenerative diseases (Menendez et al., 2007).

For commercial classification of VOO, the European Union Commission has provided 26 chemical–physical and organoleptic parameters (EC Reg. 1989/03; EC Reg. 640/08; EEC Reg. 2568/91). The latter are important for quality analysis in order to identify sensory defects (mainly winey, fusty, mouldy, muddy, and rancid) present in VOO. Among these defects, only rancidity is linked with aging of VOO.

The official and/or routine chemical and sensory methods used for these determinations are expensive, time-consuming, labor intensive, and require large amounts of solvent and reagents (Bendini et al., 2007c). The use of spectroscopic techniques together with multivariate analysis (Bendini et al., 2007b,c; Maggio et al., 2009; Sinelli, Cosio, Gigliotti, & Casiraghi, 2007) can minimize these disadvantages and offer potentially rapid methods that can screen large numbers of samples. More recently, metal oxide semiconductor (MOS) sensors have been shown to be valid instruments that are applicable in many fields of food control; these sensors have a low cost and can work on-line without sample pretreatment (Escuderos, Uceda, Sánchez, & Jiménez, 2007; Esposto et al., 2009). Regarding control of aroma in VOO, electronic noses have been used to detect a variety of sensory defects (Aparicio, Rocha, Delgadillo, & Morales, 2000; Camurati, Tagliabue, Bresciani, Sberveglieri, & Zaganelli, 2006; García-González & Aparicio, 2002; García-González & Aparicio, 2003) and to authenticate VOOs according to varietal or geographical origin of olives (Tena, Lazzez, Aparicio-Ruiz, & García-González, 2007). In this regard, the oxidation level of VOO has been recently studied (Buratti, Benedetti, & Cosio, 2005; Cosio, Ballabio, Benedetti, & Gigliotti, 2007).

To date, only limited research has been carried out using MOS sensors coupled with linear discriminant analysis (LDA) to detect the oxidation level of VOO (Cosio et al., 2007). In this study, only three oxidation levels were identified.

The aim of the present investigation was to establish a non-destructive method based on MOS sensors, in combination with LDA, for the classification of the oxidative level of VOO. The application of this system allowed the classification of VOOs with and without phenolic compounds sampled at different storage times in eight oxidation levels. This approach is a fast and economical tool for on-line monitoring of the oxidation status of VOO.

2. Materials and methods

2.1. Reagents and sample preparation

The following reagents were used: sodium hydroxide (NaOH), sodium chloride (NaCl), potassium hydroxide (Carlo Erba, Milan, Italy), hexane, methanol, diethyl ether (Sigma–Aldrich, St. Louis, MO, USA), chloroform, acetonitrile, hydrochloric acid (HCl), anhydrous sodium sulfate, formic acid, ethanol, phenolphthalein, sodium thiosulfate (Merck, Darmstadt, Germany), iso-octane, potassium iodide, 3,4-dihydroxy phenyl acetic acid (3,4-DHPAA) and acetic acid (3, and acetic acid (Fluka, Buchs, Switzerland).

An extra-virgin olive oil (EVOO) sample from the olive fruit variety Brugnola produced at San Marino (picked on October 03, 2008) was used. The olives were processed using an Oliomio 150 extraction machine (Tem, Tavernelle Val di Pesa, Florence, Italy) in order to obtain EVOO. For evaluation of EVOO oxidation, the oil sample was divided in two aliquots: EVOO and EVOO without phenols (EVOOP). Phenolic compounds were removed from EVOO according to the procedure described by Bonoli-Carbognin, Cerretani, Bendini, Almajano, and Gordon (2008). Briefly, 35 g EVOO were washed with several aliquots of 0.5 M NaOH (4 × 15 mL). To eliminate the aqueous phase, the mixture was centrifuged (1000*g*, 5 min) after each washing. Combined olive oil fractions were then washed with 0.5 M HCl (2 × 10 mL) and saturated NaCl solution (5 × 10 mL), centrifuged at 1000*g* for 5 min, dried with anhydrous sodium sulfate and finally filtered under vacuum. Dried olive oil free of phenolic compounds (EVOOP) was obtained.

According to Bendini, Cerretani, Vecchi, Carrasco-Pancorbo, and Lercker (2006) and Bonoli-Carbognin et al. (2008), both samples, EVOO and EVOOP, were divided in eight aliquots each, stored in glass bottles and kept in the dark at 60 °C for 7 weeks. Every week an aliquot of each sample was analyzed for diene and triene, oxidized stability index, electronic nose, and sensory analysis.

Moreover, an additional 25 VOO samples were used to evaluate the model. To assure the robustness of the model, samples from different geographical origins and genetic varieties, collected during different years, were also analyzed.

2.2. Instrumentation

2.2.1. MOS sensor array

An electronic olfactory system (EOS 507, Sacmi Imola S.C., Imola, Bologna, Italy) composed of a measuring chamber with six MOS sensors and a personal computer was used for the acquisition and analysis of the data generated by the EOS 507. The sensors used were: sensor 1 (SnO_2), sensor 2 (SnO_2 + SiO_2), sensor 3, 4 and 5 (catalyzed SnO_2 with three different metals) and sensor 6 (WO_3). During the analysis, sensors were maintained at a temperature range of 350–450 °C. The EOS 507 was controlled by an integrated PDA equipped with proprietary software, and was connected to an automatic sampling apparatus (Model HT500H) which had a carousel of 10 sites for loading samples. Samples were kept at controlled temperature (37 °C) and placed in a chamber provided by a system that removes humidity from the surrounding environment.

2.2.2. Experimental procedure

After samples were removed from the oven, 15 g were placed in 100 mL Pyrex vials equipped with a pierceable silicon/Teflon cap. Samples were incubated at 37 °C for 7 min before injection. The oil headspace, sampled with an automatic syringe, was then pumped over the sensor surfaces for 2 min during which the sensor signals were recorded. The sensors were then exposed to filtered air at a constant flow rate of 50 sccm (standard cubic cm per min) to obtain the baseline. After this, another 7 min period was

then applied to restore the original MOS conditions. Ambient air filtered with activated silica and charcoal was used as a reference gas during the recovery phase of the measurement cycle. The previous conditions ensured that the baseline reading had indeed been recovered before the next analysis was performed.

The experimental conditions adapted from Camurati et al. (2006) were used, and each sample was evaluated in duplicate.

2.2.3. Oxidized stability instrument

An eight-channel oxidative stability instrument (OSI) (Omnion, Decatur, IL, USA) was used. The instrument was set at 110 °C with an air flow rate of 120 mL min^{-1}. The OSI index was determined twice for each sample and the mean value was expressed as OSI time in hours.

2.3. Qualitative parameters

The chemical parameters measured were: acidity, which is indicative of the free fatty acid content of the oil expressed as the percentage of oleic acid; peroxide value (PV), which is a measure of the amount of hydroperoxides expressed as meq O_2 kg^{-1}; UV absorbance at 232 and 270 nm (k_{232}, k_{270}), which provide a measurement of the state of oxidation of the oils and fatty acid (FA) composition, expressed as percentage of saturated, monounsaturated, and polyunsaturated FAs (as methyl esters). The ratio of oleic/linoleic acids was also calculated. All chemical analyses were performed according to the official methods of the European Commission (EEC Reg. 2568/91). The content in total phenols expressed as mg of 3,4-DHPAA kg^{-1} oil was measured, and the extraction procedure, high performance liquid chromatography (HPLC) with diode array detector (DAD) analysis and quantification were adapted from Carrasco-Pancorbo et al. (2007). The oxidative stability index of the samples was also monitored according to Bendini et al. (2007a).

2.4. Sensory analysis

Sensory analysis was performed according to the European normative reported in Annex XII of EEC Reg. 2568/91. Ten trained assessors working as a professional panel from the Dipartimento di Scienze degli Alimenti (panel recognized by Italian Ministry-Mipaaf on 20 July 2006) used a scorecard to provide a quantitative-descriptive analysis (Cerretani, Biasini, Bonoli-Carbognin, & Bendini, 2007) of orthonasal perceptions. A set of positive (green or ripe fruity and other pleasant attributes such as leaf, grass, artichoke, tomato, almond, apple, others) and negative (winey-vinegary, fusty, mouldy, muddy, rancid, others) sensory attributes were evaluated. Oil samples were graded for each positive and negative attribute using a numerical scale from 0 to 5 related to the perception of flavor stimuli, according to the judgement of assessors. The median, mean, and robust standard deviation (EC Reg. 640/08) were calculated for each attribute. If the value of the robust standard deviation was higher than 20%, the analysis was repeated. All samples were subjected to a panel test.

2.5. Data treatment and statistical analysis

The data from the electronic nose was extracted and analyzed with the statistical package "Nose Pattern Editor" (Sacmi Imola S.C.). A feature extraction algorithm called "classical feature" was applied to the data before other statistical treatments. The response extracted by each sensor was defined by:

$$X = R/R_0$$

where R_0 was the initial resistance of the sensor balanced in the air, R was the resistance of a sensor in the presence of the volatile compounds emitted from the VOO headspace (which decreased respect to R_0), and X was the response of each sensor recorded. This algorithm defined several conditions for evaluation of R_0 and R reported in the software package.

Successive statistical analyses were performed using SPSS (v. 11.0, Statistical Package for the Social Sciences, Chicago, IL, USA).

3. Results and discussion

3.1. Evaluation of VOOs during storage

The chemical composition and oxidative parameters of the EVOO and EVOOP from the Brugnola variety are reported in Table 1. The free acidity percentage of EVOO and EVOOP ranged from 0.24% to 0.18%, while the PV varied from 11.96 to 12.44 meq O_2 kg^{-1} oil (Table 1). These values (free acidity and PV) were below the limits set by the EC Regulation for extra-VOO (EC Reg. 1989/03).

The main groups of FA of samples at storage time zero (t_0) are reported in Table 1. EVOO and EVOOP showed very similar values in terms of FA composition, which demonstrate that the phenol-removing procedure does not affect this fraction. The oils were characterized by high values in terms of MUFA and the oleic/linoleic acid ratio, confirming the contribution of FA composition of these oils towards oxidative stability (Aparicio et al., 1999). On the contrary, a significant variation in total tocopherols was observed, and EVOOP showed a slight decrease with respect to EVOO.

EVOO and EVOOP were also analyzed by HPLC-DAD to quantify individual phenols. Considering the sum of all identified and quantified phenolic compounds, their total concentration in EVOO was high with a value of 162 mg DHPAA kg^{-1} oil. The stripping of phenolic compounds from the oil by alkaline washing reduced the concentration of these minor compounds to a very low level; in fact, the decrease was higher than 99.5% (Table 1). A similar effect has been previously observed by Bonoli-Carbognin et al. (2008). The oxidative status of oils was assessed by OSI time values, which underlined that phenols have a major contribution to the oxidative stability of VOO (Aparicio et al., 1999). In fact, as shown in Table 1, EVOOP showed a 73.4% reduction in terms of oxidative stability compared to EVOO.

The changes in the oxidative status of EVOO and EVOOP stored at 60 °C are shown in Fig. 1 as conjugated dienes (A) and trienes (B). The two samples at t_0 showed k_{232} and k_{270} values that were below the limits established by the EC Regulation for extra-VOO category (EC Reg. 1989/03), which corresponded to 2.50 and 0.22, respectively. However, after 1 week of storage (t_1), EVOO and EVOOP exceeded the limit for k_{232}, reaching values of 9 and

Table 1
Chemical parameters of EVOO and EVOOP samples at storage time zero.

Parameter	EVOO	EVOOP
Acidity (%)	0.24	0.18
PV (meq O_2 kg^{-1})	11.96	12.44
C18:1/C18:2[a]	7.87	7.85

[c] Polyunsaturated fatty acids.
[d] Saturated fatty acids.

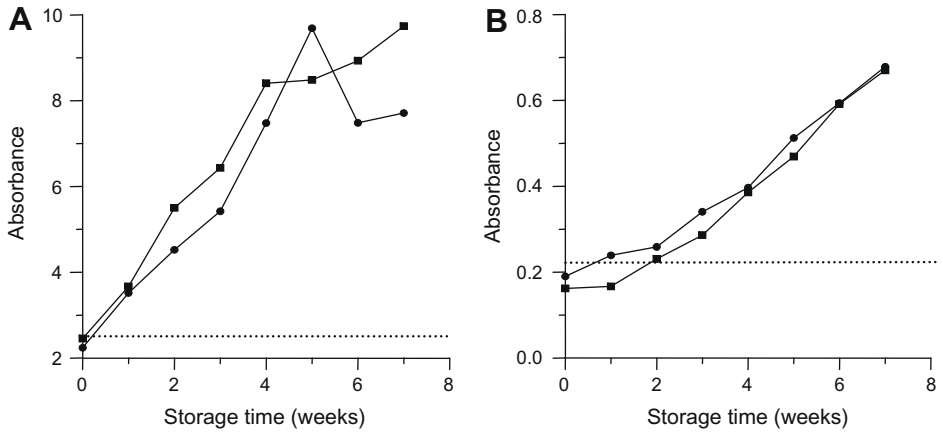

Fig. 1. Changes in conjugated diene at 232 nm (A) and triene at 270 nm (B) contents of the extra-VOO (●) and EVOOP (■) samples during storage at 60 °C. The horizontal line indicated the legal limit established by the EC Regulation for extra-VOO category.

7 for EVOOP and EVOO, respectively, after 7 weeks (t_7) of storage (Fig. 1). Concerning k_{270}, after 1 week of storage (t_1) only EVOO exceeded the EC limit, but 7 days later EVOOP also surpassed the legal value. k_{270} showed a similar trend respect to k_{232} and after 7 weeks (t_7) of storage final values of 0.7 for both types of samples were seen (Fig. 1). Similar trends were also found by Bendini et al. under comparable experimental conditions (Bendini et al., 2006).

Starting from t_0 to the end of the storage time (t_7), both EVOO and EVOOP samples showed a substantial decrease in terms of OSI time that was more evident for EVOO, also if this oil was characterized by a higher OSI time at t_0 (Fig. 2). This difference in terms of oxidative stability between EVOO and EVOOP, especially at the beginning of storage time, could be explained by the different amounts of phenolic compounds. For EVOOP, the OSI value at t_0 close to 10 h could only be attributed to the high oleic acid content, the low amounts of polyunsaturated FA, and thus to the high oleic/linoleic acid ratio.

3.2. Construction of the data matrices and LDA models

LDA, a supervised classificatory technique, is widely recognized as an excellent tool to obtain vectors showing the maximal resolution between a set of previously defined categories. In LDA, vectors minimizing the Wilks' lambda, λ_w, are obtained (Vandeginste et al., 1998). This parameter is calculated as the sum of squares of the distances between points belonging to the same category divided by the total sum of squares. Values of λ_w approaching zero are obtained with well resolved categories, whereas overlapped categories approach a λ_w of one. Up to N-1 discriminant vectors are constructed by LDA, and N has the lowest value for either the number of predictors or the number of categories.

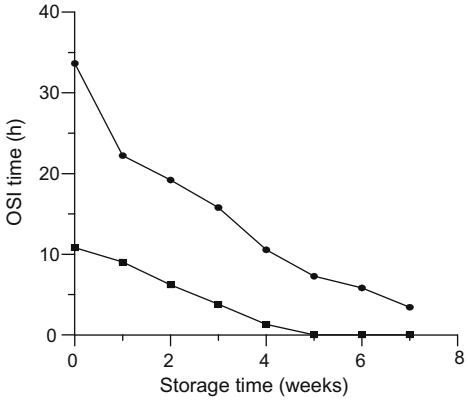

Fig. 2. Oxidized stability index of EVOO (●) and EVOOP (■) samples.

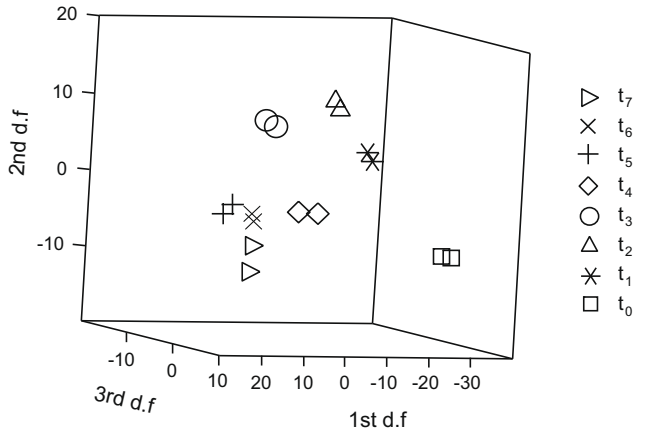

Fig. 3. Score plot on an oblique plane of the 3-D space defined by the three first discriminant functions of the LDA model constructed with EVOO samples. d.f., discriminant function.

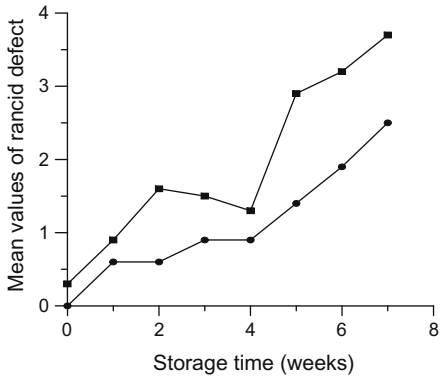

Fig. 5. Evolution of the rancid defect expressed as the mean of the sensory analysis values as a function of storage time for EVOO (●) and EVOOP (■) samples.

Using the 6 MOS sensors as predictors, LDA models capable of classifying the oil samples according to storage time were constructed. Three matrices containing the six predictors were constructed: one containing EVOO samples (8×2 replicates), another containing EVOOP samples (8×2 replicates), and the third containing both types of samples (16×2 replicates). A response column containing the eight categories corresponding to the different storage times was added to the matrices. To construct the LDA models, the SPSS stepwise algorithm was used. According to this algorithm, a predictor is selected when the reduction of λ_w produced after its inclusion in the model exceeds F_{in}, the entrance threshold of a test of comparison of variances or *F*-test. However, the entrance of a new predictor modifies the significance of those predictors which are already present in the model. For this reason, after the inclusion of a new predictor, a rejection threshold, F_{out}, is used to decide if one of the other predictors should be removed from the model. The process terminates when there are no predictors entering or being eliminated from the model. Probability values of F_{in} and F_{out}, 0.05 and 0.10, respectively, were adopted.

First, an LDA model was constructed using the matrix containing the EVOO samples, and excellent resolution between the category pairs was obtained (Fig. 3, $\lambda_w = 0.049$). This value was very low taking into account that a large number of categories were simultaneously distinguished. Next, another LDA model was constructed using the matrix constructed with the EVOOP samples. With this model, resolution between the category pairs was also excellent (Fig. 4, $\lambda_w = 0.068$). Finally, another LDA model was constructed using all the samples, and good resolution between all the category pairs was achieved ($\lambda_w = 0.892$). In this case, for the same category, two different groups were observed, one for EVOO and the other for EVOOP samples (data not shown). This dispersion within the same category could explain the high λ_w value achieved. With this LDA model, it is possible to conclude that electronic nose data discriminated between samples with and without phenolic compounds. The variables selected by the SPSS stepwise algorithm, and the corresponding standardized coefficients of the three

models, showing the predictors with large discriminant capabilities, are shown in Table 2. As can be deduced, the LDA model constructed with the EVOO samples was the only one which uses sensor 4 as a predictor. For this reason, this sensor was surmised to have a response due to volatile compounds formed after oxidation in the presence of phenolic compounds. For the three models, and using the leave-one-out validation, all points were correctly classified (the degree of classification is 100%).

3.3. Sensory analysis and evaluation of the LDA model

EVOO and EVOOP samples were evaluated by the panel of testers. Only the EVOO sample at t_0 was characterized by a green fruity and leaf and grass attributes, while all other samples had a ripe fruity and any pleasant attributes. Only the EVOO sample at t_1 showed a winey defect, probably masked at t_0 by the green fruity aspect, while rancidity was the only defect noted in all samples during the 7 week period. The evolution of the rancid defect is shown in Fig. 5 (mean values were used instead of median to better demonstrate inter-sample variations). As can be observed, rancidity was more pronounced for the EVOOP samples, which could be indirectly attributed to the absence of phenolic compounds. Therefore, the model clearly responded to the rancid defect.

An additional 25 VOOs were also subjected to the panel test assessment, being also used to evaluate the model in order to verify if they were well assigned according to sensory data. The most important sensory attributes of these samples and the predicted category for the model are shown in Table 3. As is evident, the model distinguished all the samples without defects from the others, assigning them to the t_0 category. Moreover, Table 3 shows that the model was able to correctly identify 13 defective samples, with the exception of N16 and N17, which were characterized by a winey defect and fruity absence. In particular, the model responded linearly for the four samples characterized by the rancid defect, quite well for N11, N20, and N21, which presented different intensities of fusty, but less for oils with other defects (mouldy, muddy).

It is interesting to note that slight differences were observed for the real defected samples (from N13 to N15) and those provided by IOC to recognize the rancid defect (N18 and N19). This could be linked to the differences in total volatile compounds between the profile of VOO and the rancid standard (Aparicio et al., 2000). In this respect, the near total absence of volatile components responsible for pleasant fruity note (from the LOX pathway) and the high presence of several saturated and unsaturated aldehydes in the IOC samples could have influenced the MOS response.

4. Conclusions

The possibility of classifying VOOs according to their oxidative level by using MOS sensor data has been demonstrated. In fact, for samples with and without phenols (EVOO and EVOOP) characterized by different storage times under forced oxidation (7 weeks at 60 °C), excellent resolution was achieved by LDA which divided oils into eight categories. Moreover, good correlation was obtained between the model and sensory analysis. In particular, the model distinguished all VOOs without defects from the others, and responded linearly for the four samples characterized by a rancid defect. The method is a fast and economical tool for on-line monitoring of VOO oxidation status, and could be also used to study the oxidative level of other vegetable oils during processing (i.e. refining steps) and distribution phases in addition to industrial uses (i.e. frying).

Acknowledgements

The authors gratefully acknowledge Sacmi Imola S.C. who kindly allowed us to use the MOS system (EOS 507), and Ibanez Riccò for technical assistance. Project CTQ2007-61445 (MEC and FEDER funds) are acknowledged. MJL-G thanks the Generalitat Valenciana for an FPI grant for PhD studies and for a grant to study in a foreign institution.

TEAC

ABSTRACT

Phenolic constituents of six barley varieties, namely Falcon, AC Metcalfe, Tyto, Tercel, Phoenix and Peregrine were separated into free, soluble conjugate and insoluble-bound fractions. Soluble conjugates and insoluble-bound phenolics were extracted into diethyl ether after consecutive alkaline hydrolysis for 4 h. Total phenolic content of each of the three fractions was determined by using Folin–Ciocalteau method. Total antioxidant capacity of the phenolic fractions was determined by trolox equivalent antioxidant capacity (TEAC) assay. The extracts were evaluated for their efficacy in scavenging of 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical. Oxygen radical scavenging capacity ($ORAC_{FL}$) of the extracts was determined using a fluorometric assay. Effectiveness of phenolic extracts in inhibiting oxidation of human LDL cholesterol and radical-induced supercoiled DNA breakage was also evaluated. The contribution of insoluble-bound phenolics toward total phenolic content was significantly ($p < 0.05$) higher than the soluble phenolics for all barley extracts tested. The ratio of soluble to insoluble phenolics ranged from 1:27 to 1:35. TEAC and ORAC values and DPPH radical scavenging capacity of the insoluble phenolic fraction were significantly ($p < 0.05$) higher than those of their insoluble counterparts. A similar trend was observed against inhibition of LDL cholesterol oxidation and radical-induced DNA breakage.

1. Introduction

Cereals contain a myriad of phenolic compounds including benzoic acid and cinnamic acid derivatives, anthocyanins, quinones, flavanols, chalcones, flavones, lignans, proanthocyanidins, and amino-phenolic compounds (Goupy, Hugues, Boivin, & Amoit, 1999; Shahidi & Naczk, 2004). Polyphenols identified in barley include anthocyanins, flavonols, phenolic acids, catechins and proanthocyanidins (Goupy et al., 1999). There are more than 50 proanthocyanidins reported in barley. Proanthocyanidins in barley include oligomeric and polymeric flavan-3-ol, catechin (c), and gallocatechin (gc). The most abundant proanthocyanidin in barley are dimeric proanthocyanin B3 and procyanidin B3. Major trimers include T1 (gc–gc–c), T2 (gc–c–c), T3 (c–gc–c), and T4 or procyanidins C2 (c–c–c) (Friedrich, Eberhardt, & Galensa, 2000).

Cereals contain a wide range of phenolic acids, mainly those belonging to the benzoic acid and cinnamic acid groups. Phenolic acids are different from other phenolic compounds bearing acidic properties due to the presence of a carboxylic acid group. Ferulic acid and *p*-coumaric acid are the major phenolic acids found in many cereals, including barley. A significant proportion of these phenolic acids is known to be linked to lignans and arabinoxylans (Nordkvist, Salomonsson, & Amna, 1984). Ferulic acid is highly concentrated in the cell walls of aleurone layer that is rich in arabinoxylan (McNeil, Albersheim, Taiz, & Jones, 1975; Maillard & Berset, 1999).

Phenolic compounds in cereal grains exist in the free, soluble esters or conjugates and insoluble-bound forms. It is reported that 74% and 69% of total phenolics present in rice and corn, respectively, are in the insoluble-bound form (Adom & Liu, 2002). Most of the studies reported in the literature have ignored insoluble-bound phenolic compounds, hence underestimating the content of phenolic compounds present.

Having both carboxylic acid and hydroxyl groups in their structures, phenolic acids are capable of forming both ester and ether bonds with other compounds leading to the formation of linkages with cell wall polysaccharides. Phenolic acids can be esterified with small molecules such as alcohols, other phenolic acids, phenols, and alkaloids, among others (Yu, Vasnathan, & Temelli, 2001). Non-starch polysaccharides such as xylose, and arabinose units may easily esterify with phenolic acids. Phenolic acids with carboxyl and hydroxyl groups can bind either starch or other polysaccharides through hydrogen bonds, chelation, or covalent bonds (Yu et al., 2001).

Phenolic esters can be hydrolyzed to release phenolic acids by different means. Alkaline, acidic or enzymatic hydrolysis methods are adopted in order to release insoluble-bound phenolics from

doi:10.1016/j.foodchem.2009.04.055

the cereal matrix (Yu et al., 2001). Generally, alkaline hydrolysis is the method mostly used for extracting esterified or bound phenolics at room temperature. Alkaline hydrolysis was used in this study to release phenolic acids present in the insoluble-bound form.

The objectives of this study were to extract free, esterified, and insoluble-bound phenolic compounds from six barley cultivars using alkaline hydrolysis and to determine antioxidative, and anti-radical efficacies of the phenolic fractions so obtained.

2. Materials and methods

2.1. Chemical reagents

Sodium carbonate, Trisma base, methanol and hexane were purchased from Fischer Scientific (Nepean, ON, Canada). Compounds 2,2′-azobis (2-methylpropionamidine) dihydrochloride (AAPH), 1,1-diphenyl-2-picrylhydrazyl (DPPH), ferulic acid, Folin–Ciocalteu reagent, mono- and dibasic sodium and potassium phosphates, trolox, deoxyribonucleic acid (DNA) of pBR 322 (*Escherichia coli* strain RRI), sodium chloride, agarose, ethidium bromide, bromophenol, xylene cyanol, sucrose, human low density lipoprotein (hLDL), copper chloride, ferric chloride, luminol, and fluorescein were purchased from Sigma–Aldrich Canada Ltd. (Oakville, ON, Canada).

2.2. Samples

Grains of six barley cultivars from 2002 crop year, namely Falcon, AC Metcalfe, Tyto, Tercel, Phoenix and Peregrine (grown under the same conditions) were obtained from Field Crop Development Centre, Lacombe, Alberta, Canada. All cultivars examined were grown under the same climatic and agronomic conditions, in well-drained fertile loam soil under relatively cool temperatures and under full sunlight conditions.

2.3. Separation of phenolic fractions using alkaline hydrolysis

The free phenolics, soluble conjugates and insoluble-bound phenolic acids from AC Metcalfe, Falcon, Phoenix, Tercel, Tyto and Peregrine barley samples were isolated using the procedure explained by Krygier, Sosulski, and Hogge (1982) and Naczk and Shahidi (1989). Barley meals (2 g) were extracted six times with a 40 mL mixture of methanol-acetone-water (7:7:6, v/v/v) using a Polytron homogenizer at 10,000 rpm for 4 min. The resulting mixture was centrifuged at 4000*g* for 5 min and the supernatants were collected and combined. The solvent mixture was evaporated at 30 °C *in vacuo* to approximately 40 mL, followed by extracting six times with diethyl ether at 1:1 (v/v) solvent to supernatant ratio. The combined extracts were evaporated to dryness *in vacuo* at 30 °C in order to obtain free phenolic acid fraction which was subsequently dissolved in methanol. The supernatant containing soluble conjugates was subsequently hydrolyzed with 30 mL of 4 M NaOH under N_2 for 4 h at room temperature. The resultant hydrolysate was acidified to pH 2 using 6 M HCl followed by extraction with diethyl ether. The ether extracts were combined and evaporated to dryness *in vacuo* at 30 °C and subsequently dissolved in methanol to obtain soluble esters. The leftover meal was treated with 20 mL of 4 M NaOH and hydrolyzed for 4 h at room temperature under a stream of N_2 and acidified to pH 2 with 6 M HCl and centrifuged at 4000*g* for 5 min. The supernatant was extracted with diethyl ether six times. The combined extracts were evaporated to dryness at 30 °C *in vacuo* and subsequently dissolved in methanol to obtain insoluble-bound phenolic fraction.

2.4. Determination of total phenolic content

The total content of phenolics was determined according to the procedure explained by Singleton and Rossi (1965) and the results were expressed as mg of ferulic acid equivalents per gram of defatted material.

2.5. Total Antioxidant Capacity by trolox Equivalent Antioxidant Capacity (TEAC) assay

The TEAC assay is based on scavenging of 2,2′-azinobis-(3-ethylbenzothiazoline-6-sulphonate) radical anion ($ABTS^{\cdot-}$). A solution of $ABTS^{\cdot-}$ was prepared in 100 mM saline phosphate buffer (pH 7.4, 0.15 M sodium chloride) (PBS) by mixing 2.5 mM 2,2'-azobis-(2-methylpropionamidine) dihydrochloride (AAPH) with 2.0 mM $ABTS^{2-}$. The solution was heated for 16 min at 60 °C, protected from light by covering in a tin foil, and stored at ambient temperature until used. The $ABTS^{\cdot-}$ solution was used within 2 h as the absorbance of the radical itself depletes with time. Barley extracts were dissolved in PBS at a concentration of 3 mg/mL and diluted accordingly to have them fit in the range of values in the standard curve (drop of 0–0.3 optical density unit). For measuring antioxidant capacity, 40 μL of the sample were mixed with 1.96 mL of $ABTS^{\cdot-}$ solution. Absorbance of the above mixture was read at 734 nm after 6-min as the extracts needed a minimum of 6 min for completion of the reaction. The decrease in absorbance at 734 nm after 6 min of addition of a test compound was used for calculating TEAC values. A standard curve was prepared by measuring the reduction in absorbance of $ABTS^{\cdot-}$ solution at different concentrations of trolox. Appropriate blank measurements (decrease in absorbance at 734 nm due to solvent without any compound added) were carried out and the values recorded (van den Berg, Haenen, van den Berg, & Bast, 1999). TEAC values were expressed as μmol trolox equivalents per gram of defatted material.

2.6. DPPH radical scavenging assay

The effect of extracts on DPPH radical was monitored according to the method of Hatano, Kagawa, Yasuhara, and Okuda (1988). The extracts (100 μL at a concentration of 3 mg/mL) were added to a methanolic solution (1.9 mL) of DPPH radical (final concentration of DPPH radical was 5.7 μM). The mixture was shaken vigorously and left standing at room temperature for 20 min; the absorbance was measured spectrophotometrically at 517 nm. DPPH radical scavenging capacity was expressed as μmol ferulic acid equivalents per gram of defatted material based on the depletion of absorbance after 20 min of the assay.

2.7. Determination of oxygen radical absorbance capacity ($ORAC_{FL}$)

The determination of $ORAC_{FL}$ was carried out using a Fluostar Optima plate reader (BMG Labtech, Durham, NC) equipped with an incubator and two injector pumps with fluorecsein as the probe and AAPH as the radical generator. Fluorescein was dissolved in phosphate buffer (0.75 M, pH 7.0) to obtain a final concentration of 32 nM and injected into the wells containing 20 μL of extract or standards using the first pump in the first cycle. The mixture was incubated for 20 min at 37 °C in the built-in incubator and subsequently 60 μL of APPH solution were injected into the wells using the second pump. The plate was shaken for 4 s after each addition at 4 mm shaking width. To optimize signal amplification in order to obtain maximum sensitivity, a gain adjustment was performed at the beginning by manually pipetting 200 μL of fluorescein into a designated well. No more than 35 wells of the 96-well plate (Costar 2650 black plate) were used due to increased

cycle time. Fluorescence was determined and recorded every minute for 60 min and the antioxidant activity of the extracts was calculated as trolox equivalents using a standard curve prepared with 1–10 μM (final concentration) trolox. Fluorescein filters with an excitation wavelength of 485 nm and an emission wavelength of 520 nm were used (Huang, Ou, Hampsch-Woodill, Flanagan, & Prior, 2002).

2.8. Determination of metal chelation activity

The Fe^{2+} chelation activity of the barley extracts was measured by using a 2,2′-bipyridyl competition assay explained by Yu, Haley, Perret, and Harris (2002) and Yamaguchi, Ariga, Yoshimura, and Nakazawa (2000). The reaction mixture contained 0.2 mL of 1 mM $FeSO_4$, 1 mL of Tris–HCl buffer (pH 7.4), 0.2 mL of extract (6 mg/mL whole seed extract; 2 mg/mL, pearling fractions) or ethylenediaminetetracetic acid (EDTA) standard, 0.4 mL of 10% hydroxylamine HCl, 1 mL of bipyridyl solution (0.1% in 0.2 M HCl), and 2.5 mL of ethanol. The reaction mixture was mixed well and the intensity of the colour developed was measured at 522 nm. Metal chelation activity was expressed as EDTA equivalents using a standard curve prepared with 75–675 μM EDTA.

2.9. Measurement of cupric ion-induced human low density lipoprotein (LDL) peroxidation

The method explained by Andreason, Landbo, Christensen, Hansen, and Meyer (2001) and Hu and Kitts (2000) was used to measure LDL cholesterol oxidation. Human LDL in saline phosphate buffer solution (PBS) containing 0.01% EDTA was dialyzed against 10 mM saline PBS (pH 7.4, 0.15 M NaCl) for 12 h under nitrogen at 4 °C and EDTA-free LDL was subsequently diluted to obtain a standard protein concentration of 0.2 mg/mL with PBS. The diluted LDL solution (200 μL) was mixed with 1000 μL of PBS and 10 μL of extract (2 mg/mL) in a test tube. Oxidation of LDL was initiated by adding 5.1 mM cupric sulphate solution resulting in a 4 μM copper concentration in the reaction mixture. The mixture was incubated at 37 °C for 100 min and conjugated dienes (CD) of the mixture were measured (at 232 nm) at 5 min intervals over 100 min. Inhibition percentage was calculated based on the CD values at 100 min of incubation.

2.10. Supercoiled strand DNA scission by peroxyl and hydroxyl radicals

Plasmid supercoiled DNA (pBR 322) was dissolved in 10 mM PBS (pH 7.4, 0.15 mM sodium chloride). DNA (25 ng/ μL) was mixed with ferulic acid and barley extracts dissolved in the same PBS. Peroxyl radical was generated using AAPH (dissolved in PBS; pH 7.4, 0.15 mM sodium chloride) to obtain a final concentration of 1 mM and mixed with the DNA and the extract mixture at a total volume of 12 μL. The reactants were incubated at 37 °C for 1 h in the dark (Hu, Zhang, & Kitts, 2000).

The hydroxyl radical generating system consisted of 100 μM ferric chloride, 100 μM ascorbic acid, 100 μM hydrogen peroxide and 100 μM EDTA for non site-specific hydroxyl radical generation (Halliwell et al., 1987). The total volume was adjusted to 12 μL with PBS and the reaction mixture was incubated at 37 °C for 1 h in the dark. Upon completion of incubation, the loading dye (3 μL) (consisting 0.25% bromophenol blue, 0.25% xylene cyanol and 40% sucrose in distilled water) was added to the sample and loaded to a 0.7% (w/v) agarose gel prepared in Tris–acetic acid–EDTA buffer (40 mM Tris acetate, 2 mM EDTA, pH 8.5). Horizontal gel electrophoresis was performed at 32v for 8 h. DNA strands were stained with 0.5 μg/mL ethidium bromide and visualized under ultraviolet light. Images were analyzed using AlphaEase™ stand alone software (Alpha Innotech Co., San Leandro, CA). The protective effect of extracts and catechin was calculated based on the following equation.

$$\text{DNA retention},\% = \left\{\frac{\text{Intensity of supercoiled DNA in sample}}{\text{Intensity of supercoiled DNA in control}}\right\} \times 100$$

3. Results and discussion

3.1. Total phenolic content

The contents of free, soluble conjugate, and insoluble-bound phenolics of barley extracts are listed in Table 1. The content of insoluble-bound phenolics was significantly higher than those of soluble conjugate and free phenolic fractions among all barley extracts tested. Free phenolic content ranged from 0.18 to 0.42 mg ferulic acid equivalents per gram defatted material with the highest content in Peregrine extracts while soluble conjugates ranged from 0.42 to 0.81 mg ferulic acid equivalents per gram of defatted material. Insoluble-bound fraction ranged from 2.03 for Tercel to 3.36 mg ferulic acid equivalents per gram of defatted Peregrine. The ratio of soluble phenolics (the sum of free and soluble conjugate fractions) to insoluble-bound phenolics ranged from 1:2.74 to 1:3.92 for barley extracts.

Adom and Liu (2002) analyzed a number of cereals, namely corn, wheat, oat and rice and reported that corn had the highest free phenolic content (0.411 mg/g of grain), followed by rice (0.407 mg/g of grain), then wheat (0.368 mg/g of grain), and finally oat (0.343 mg/g of grain). The content of insoluble-bound phenolic was significantly higher among all cereals tested (Adom & Liu, 2002). It is evident that a significantly high proportion of phenolic content is present in the bound form in cereals. Similar results were found for canola seeds by Naczk and Shahidi (1989). Insoluble-bound phenolic compounds are associated with cell wall materials, especially complex carbohydrates such as arabinoxylan. Gastrointestinal enzymes usually are not capable of releasing phenolics from the complexes of phenolic compounds and complex carbohydrates, hence they pass the upper intestinal tract intact.

3.2. Total antioxidant capacity (TAC) as measured by trolox equivalent antioxidant capacity (TEAC)

Total antioxidant activity of free, soluble conjugates and insoluble-bound phenolic fractions is listed in Table 2. It is evident that TAC follows a similar trend to that of TPC among all barley extracts tested. Total antioxidant activity of free, soluble conjugate and insoluble-bound phenolic fractions ranged from 1.89 to 3.11, 1.77 to 3.98, and 7.44 to 9.88 μmol trolox/g defatted material, respectively. The highest TAC was rendered by Peregrine extract while the lowest efficacy was due to Tyto extract.

TEAC value of a compound represents the concentration of trolox (a water soluble vitamin E analogue without the side chain moiety) that has the same antioxidant capacity as the compound or a mixture of compounds of interest (van den Berg et al., 1999). Thus, TEAC value may be considered as a stoichiometric number related to TEAC, for trolox value of 1. Insoluble-bound phenolic fraction contributed the highest proportion towards TAC, followed by soluble conjugate and free phenolics.

3.3. DPPH radical scavenging capacity of phenolic fractions of barley

DPPH radical scavenging capacity of free, soluble conjugate and insoluble-bound phenolic fractions from six barley cultivars is listed in Table 3. DPPH radical scavenging capacity of free phenolic

Table 1
Contents of free, soluble conjugate, and insoluble-bound phenolics of barley cultivars[A].

Barley cultivar	Free phenolics	Soluble conjugate phenolics	Insoluble-bound phenolics	Total phenolic content[B]	Soluble to insoluble-bound phenolics[C] ratio
Falcon	0.34 ± 0.02^{c}	0.63 ± 0.00^{c}	2.66 ± 0.06^{c}	3.63	1:2.74
AC Metcalfe	0.31 ± 0.01^{c}	0.81 ± 0.01^{d}	3.34 ± 0.01^{e}	4.46	1:2.98
Tyto	0.26 ± 0.02^{b}	0.52 ± 0.02^{b}	2.78 ± 0.03^{d}	3.56	1:3.56
Tercel	0.22 ± 0.00^{ab}	0.49 ± 0.01^{ab}	2.16 ± 0.00^{b}	2.64	1:3.04
Phoenix	0.18 ± 0.00^{a}	0.42 ± 0.00^{a}	2.03 ± 0.01^{a}	2.63	1:3.38
Peregrine	0.42 ± 0.02^{d}	0.73 ± 0.04^{d}	3.36 ± 0.02^{e}	4.51	1:3.92

Results are means of three determinations ± standard deviation.

[B] The sum of free, soluble conjugate and insoluble-bound phenolics; expressed as mg ferulic acid equivalents/g defatted material.
[C] Soluble phenolics represent the sum of free and soluble conjugate phenolic fractions.

Table 2
Total antioxidant capacity (TAC) of free, soluble conjugate, and insoluble-bound phenolic fractions of barley cultivars as measured by trolox equivalent antioxidant capacity (TEAC)[1].

Barley cultivar	Free phenolics	Soluble conjugate phenolics	Insoluble-bound phenolics
Falcon	3.11 ± 0.02^{e}	3.46 ± 0.05^{c}	8.98 ± 0.06^{c}
AC Metcalfe	2.67 ± 0.31^{cd}	3.87 ± 0.16^{d}	9.45 ± 0.17^{cd}
Tyto	2.45 ± 0.02^{bc}	2.37 ± 0.22^{b}	7.44 ± 0.23^{a}
Tercel	1.89 ± 0.05^{a}	1.77 ± 0.08^{a}	7.53 ± 0.19^{a}
Phoenix	2.16 ± 0.09^{ab}	2.66 ± 0.04^{b}	8.23 ± 0.06^{b}
Peregrine	3.02 ± 0.02^{de}	3.98 ± 0.09^{d}	9.88 ± 0.26^{d}

Results are means of three determinations ± standard deviation.
Values in each column having the same superscript are not significantly different ($p > 0.05$).
[1] TEAC values are expressed as mg μmol trolox/g defatted material.

Table 3
DPPH radical scavenging capacity of free, soluble conjugate, and insoluble-bound phenolics fractions of barley cultivars[A].

Barley cultivar	Free phenolics	Soluble conjugate phenolics	Insoluble-bound phenolics
Falcon	2.20 ± 0.02^{e}	2.76 ± 0.00^{e}	4.56 ± 0.06^{d}
AC Metcalfe	1.89 ± 0.01^{b}	2.23 ± 0.01^{c}	3.95 ± 0.01^{a}
Tyto	2.11 ± 0.02^{d}	1.99 ± 0.02^{a}	4.76 ± 0.03^{c}
Tercel	1.76 ± 0.00^{a}	2.10 ± 0.01^{b}	4.12 ± 0.00^{b}
Phoenix	2.56 ± 0.00^{f}	2.44 ± 0.00^{d}	4.22 ± 0.01^{b}
Peregrine	1.98 ± 0.02^{c}	2.98 ± 0.04^{f}	5.62 ± 0.02^{e}

Results are means of three determinations ± standard deviation.
Values in each column having the same superscript are not significantly different ($p > 0.05$).
[A] DPPH radical scavenging capacity values are expressed as μmol trolox equivalents/g defatted material.

fraction ranged from 1.76 to 2.56 μmol ferulic acid equivalents per gram defatted material with the highest efficacy rendered by Phoenix extract. The corresponding values for soluble conjugate and insoluble-bound fractions were 1.99–2.98 and 3.95–5.62 μmol ferulic acid equivalents per gram defatted material. In the DPPH assay, antioxidants reduce DPPH·, one of the few stable organic nitrogen radicals that has an absorption maximum at 515 nm. DPPH assay is based on the measurement of reducing ability of antioxidants toward DPPH·, which can be monitored by measuring the decrease in absorbance spectrophotometrically or by electron paramagnetic resonance (EPR) spectrometry (Prior, Wu, & Schaich, 2005).

3.4. Oxygen radical absorbance capacity ($ORAC_{FL}$) of phenolic fractions from barley

Oxygen radical absorbance capacity of free, soluble conjugate, and insoluble-bound phenolic fractions is listed in Table 4. $ORAC_{FL}$ values of free, soluble conjugate, and insoluble-bound phenolic fractions were in the range of 5.99–8.45, 11.78–18.88, and 22.13–34.67, respectively. As observed with TAC and DPPH radical scavenging data, the contribution of insoluble-bound fraction towards the total $ORAC_{FL}$ was significantly higher than free and soluble ester conjugates. Peregrine exhibited the highest total $ORAC_{FL}$ followed by Tyto, Falcon, AC Metcalfe, Phoenix, and Tercel. $ORAC_{FL}$ value is based on the inhibition of the peroxyl radical-induced oxidation initiated by thermal decomposition of azo compounds such as 2,2'-azinobis [3-ethylbenzthiazoline-6-sulphonic acid] (APPH). $ORAC_{FL}$ is the only assay that combines both inhibition time and degree of inhibition into a single quantity (Prior et al., 2005), that is μmol trolox equivalents/g defatted material.

3.5. Inhibition of LDL cholesterol oxidation by phenolic fractions from barley

Percentage inhibition of oxidation of LDL cholesterol by free, soluble conjugate, and insoluble-bound phenolic fractions at a final concentration of 16 μg/mL is listed in Table 5. Percentage inhibition of oxidation of LDL cholesterol was in the range of 5.33–12.32, 14.33–29.87, and 42.99–72.32 for free, soluble conjugate and insoluble-bound phenolic fractions, respectively. As expected, insoluble-bound phenolic fraction rendered the highest antioxidant activity towards inhibition of LDL cholesterol oxidation followed by soluble conjugates. Conjugated dienes (CD) are often used as indicators of the level of peroxidation of LDL in antioxidant studies. Inhibition of LDL cholesterol oxidation of the extracts was

Table 4

Table 6
Percentage inhibition of peroxyl radical-induced supercoiled strand scission of PBR322 DNA by free, soluble conjugated, and insoluble-bound phenolic fractions from barley.

Barley cultivar	Free phenolics	Soluble conjugated phenolics	Insoluble-bound phenolics
Falcon	11.89 ± 1.32^{bc}	22.33 ± 1.61^{cd}	87.95 ± 3.45^{abc}
AC Metcalfe	9.22 ± 0.99^{ab}	17.78 ± 2.22^{ab}	96.66 ± 5.76^{c}
Tyto	8.87 ± 0.87^{a}	15.97 ± 0.01^{a}	82.34 ± 3.12^{ab}
Tercel	12.33 ± 1.21^{c}	19.94 ± 0.65^{bc}	84.34 ± 2.80^{ab}
Phoenix	10.00 ± 1.11^{abc}	24.45 ± 1.40^{d}	78.98 ± 2.55^{a}
Peregrine	12.56 ± 0.67^{c}	25.32 ± 0.09^{d}	92.23 ± 4.88^{bc}

Results are means of three determinations ± standard deviation.
Values in each column having the same superscript are not significantly different ($p > 0.05$).

expressed as percentage inhibition based on the CD value after 100 min of incubation.

3.6. Inhibition of peroxyl radical-induced supercoiled plasmid DNA scission by phenolic fractions

The percentage inhibition offered by free, soluble conjugate, and insoluble-bound phenolic fractions of barley extracts at 1 mg/mL concentration were in the range of 8.87–12.56%, 15.97–25.32%, and 82.34–96.66%, respectively. The inhibitory effect was tested at 0.4–1.2 mg/mL, however, 1 mg/mL concentration was used for calculating the inhibitory effect. Peregrine exhibited the highest inhibition against DNA scission while Phoenix exhibited the lowest inhibition of 78.2% at 4 mg/mL. It is important to note that no pro-oxidant activity was observed at any level for all the extracts tested. All extracts showed a similar pattern of concentration dependence in protecting supercoiled plasmid DNA (see Table 6).

4. Conclusions

A major proportion of phenolic compounds present in balrey kernels existed in the insoluble-bound form. Insoluble-bound phenolic compounds contributed most to the TPC of barley, followed by soluble conjugates, the least contribution was due to the free phenolics. This finding lends support to those in the existing literature for barley and other cereals such as wheat and rye. The antioxidant and antiradical activities of insoluble-bound phenolic fraction, in general, was higher than those of soluble conjugates and free phenolic fractions.

Acknowledgements

We thank Mr. Mike Oro, Field crop specialist, Field crop development center, Lacombe, AB, Canada for providing barley samples. Financial support from the Natural Science and Engineering Research Council (NSERC) of Canada in the form of a discovery grant to FS is acknowledged.

ABSTRACT

The effect of *Rhodotorula glutinis* treatment alone or in combination with methyl jasmonate (MeJA) in controlling blue mold decay, the natural fungal decay of pears and the postharvest quality parameters including fruit firmness, total soluble solids, titratable acidity, and ascorbic acid were investigated. The combination of methyl jasmonate (200 μM) and *R. glutinis* (1×10^8 CFU/ml) was a more effective approach to reduce the disease incidence and lesion diameter of blue mold decay of pears than the application of MeJA or *R. glutinis* alone after incubation for 7 d at 20 °C. The natural fungal decay of pears treated with the application of *R. glutinis* combined with MeJA resulted in reduced average decay incidence of 10.42% or 4.16%, respectively, compared with 27.17% or 20.83% in the control fruits following storage at 20 °C for 15 d or 4 °C for 60 d followed by 20 °C for 15 d. The combined treatment did not impair quality parameters of fruits under both conditions.

1. Introduction

Blue mold decay caused by *Penicillium expansum* is one of the important postharvest diseases of pears (Spotts & Chen, 1987; Zhang, Zheng, & Su, 2006) and can be controlled effectively by synthetic chemical fungicides. However, the development of fungicide resistance by pathogens and increasing international concern over fungicidal residues in fruits and vegetables has stimulated a search for alternative measures for disease control (Droby et al., 2002; Fan & Tian 2001; Mlikota Gabler & Smilanick 2001). Microbial biocontrol agents have shown a great potential as an alternative to synthetic fungicides for the control of postharvest decay of fruits and vegetables (Wilson et al., 1991). Recently, an antagonistic yeast strain of *Rhodotorula glutinis* have been reported as an effective biocontrol agent against postharvest decay of apples (Qin, Tian, Liu, & Xu, 2003), pears (Zhang, Wang, Huang, Dong, & Zheng, 2008), strawberries (Zhang et al., 2007), sweet cherries (Tian, Qin, & Xu, 2004) and oranges (Zheng, Zhang, & Sun, 2005). It has been reported that biological control is only effective with high concentrations of antagonistic yeasts (Fan & Tian, 2001). However, higher concentrations of antagonists would increase production costs and make biological control methods less attractive. Moreover, biological control as the alternative to chemical control is not as broad spectrum and is usually not as effective as chemical fungicides; therefore, it is important to find effective methods that could increase the antagonistic activity of yeasts and inhibit pathogenic infections. Enhancement of the biocontrol activity of antagonists could be obtained by many approaches. Combining organic and inorganic additives with antagonistic yeasts is a very effective method for enhancing the biocontrol efficacy of yeasts (Jackson, Whipps, Lynch, & Bazin, 1991).

The use of exogenous substances to potentiate the natural defence of plants represents another alternative, potentially promising approach to disease control (Kessmann et al., 1994). Jasmonic acid (JA) and its methyl ester, methyl jasmonate (MeJA), exist naturally in a wide range of higher plants. MeJA is a potential plant defence activator that has been shown to reduce postharvest disease on a number of horticultural crops (Creelman & Mullet, 1997). Exogenous application of methyl jasmonate (MeJA) has been considered as effective at inducing secondary metabolites in plant cell cultures, resulting in the expression of a set of defence genes and inducing resistance of host against pathogens (Epple, Apel, & Bohlmann, 1997; Kozlowski, Buchala, & Métraux, 1999). Recently, MeJA had shown promise in preventing postharvest disease and disorders in horticultural crops, application of MeJA has been reported to effectively suppress gray mold rot caused by *Botrytis cinerea* in strawberry (Moline, Buta, Saftner, & Maas, 1997), to decrease green mold decay caused by *Penicillium digitatum* in grapefruit (Droby et al., 1999), to reduce microbial contamination of freshcut celery

doi:10.1016/j.foodchem.2009.04.054

and peppers (Buta & Moline, 1998), to decreased fruit decay infected by *Colletotrichum gleosporioides* and *Alternaria alternata* on papaya fruit (González-Aguilar, Buta, & Wang, 2003), to suppress anthracnose rot caused by *Colletotrichum coccodes* in tomato fruit (Tzortzakis, 2007), to reduce anthracnose rot caused by *Colletotrichum acutatum* infection in loquat fruit (Cao et al., 2008), and to inhibit brown rot caused by *Monilinia fructicola* in sweet cherry fruit (Yao & Tian, 2005a). Furthermore, exogenous application of MeJA has been found to enhance the efficacy of the antagonistic yeast *Cryptococcus laurentii* to control brown rot and blue mould caused by *Monilinia fructicola* and *Penicillium expansum* in peach fruit (Yao & Tian, 2005b). However, to the best of our knowledge, there is little information concerning the effect of a combination of *R. glutinis* and MeJA on the control of the postharvest blue mold decay of pear fruits.

The objective of this study were to evaluate (a) the effects of MeJA and the antagonistic yeast *R. glutinis*, used separately or in combination, on controlling postharvest blue mold decay of pear fruits caused by *P. expansum*; (b) the effects of MeJA on spore germination of *P. expansum* in vitro; (c) the effect of MeJA on population dynamics of the *R. glutinis* on fruits; (d) the efficacy of MeJA and *R. glutinis*, separately or in combination, in controlling of natural decay development of pears and its effects on quality of pears after storage, including firmness, total soluble solids, ascorbic acid and titratable acidity.

2. Materials and methods

2.1. Pathogen inoculum

Penicillium expansum Link was isolated from infected pear fruits. The culture was maintained on potato-dextrose agar medium (PDA: extract of boiled potatoes, 200 ml; dextrose, 20 g; agar, 20 g and distilled water, 800 ml) at 4 °C, and fresh cultures were grown on PDA plates before use, respectively. Spore suspensions were prepared by removing the spores from the sporulating edges of a 7 d old culture with a bacteriological loop, and suspending them in sterile distilled water. Spore concentrations were determined with a hemocytometer, and adjusted as required with sterile distilled water.

2.2. Antagonist

The yeast antagonist *R. glutinis* (Fresenins) Harrison was isolated from the surfaces of strawberries harvested in unsprayed orchards and identified by VITEK 32 Automicrobic system (bioMérieux Company, Marcy l'Etoile, France). *R. glutinis* isolates were maintained at 4 °C on nutrient yeast dextrose agar (NYDA) medium containing 8 g nutrient broth, 5 g yeast extract, 10 g glucose and 20 g agar, in 1 l of distilled water. Liquid cultures of the yeast were grown in 250-ml Erlenmeyer flasks containing 50 ml of NYD broth (NYDB) which had been inoculated with a loop of the culture. Flasks were incubated on a rotary shaker at 28 °C for 20 h. Following incubation, cells were centrifuged at 5000*g* for 10 min and washed twice with sterile distilled water in order to remove the growth medium. Cell pellets were re-suspended in sterile distilled water and adjusted to the concentrations required.

2.3. Fruits

Pear fruits (*Pyrus pyrifolia* Nakai.) cultivar "Shuijing" were harvested at commercial maturity from Zhenjiang of Jiangsu province. Fruits were used immediately after harvest, and selected for uniformity of size, ripeness and removed any fruit with apparent injuries or infections. Fruits were disinfected with 1% sodium hypochlorite for 2 min, washed with tap water, air dried prior to wounding.

2.4. Efficacy of MeJA at various concentrations in controlling of blue mold decay of pears

The pear fruit samples were wounded (3 mm diameter and approximately 5 mm deep) using a sterile borer. Each wound was treated with 30 μl of MeJA at 0, 10, 100, 200 and 500 μM, respectively. Two hours later, 20 μl of suspension of *P. expansum* (5×10^4 spores/ml) was inoculated to each wound. After air drying, the pears were stored in enclosed plastic trays to maintain a high relative humidity (above 95%) and incubated at 20 °C. The number of the infected fruit wounds and the average lesion diameters of the overall treated fruits were examined after storage at 20 °C for 7 d post-inoculation. There were three replicates of 10 fruits for each treatment, and the experiment was conducted three times.

2.5. Efficacy of R. glutinis treatment alone or in combination with MeJA in controlling of blue mold decay of pears

The pear fruit samples were wounded (3 mm diameter and approximately 5 mm deep) using a sterile borer. Each wound was treated with 30 μl of: (1) the cell suspensions of *R. glutinis* (1×10^8 cells ml^{-1}); (2) a solution of MeJA (200 μM); (3) *R. glutinis* suspensions (1×10^8 cells ml^{-1}) amended by MeJA (200 μM); and (4) sterile distilled water as the control. Two hours later, 20 μl of a suspension of *P. expansum* (5×10^4 spores/ml) was inoculated to each wound respectively. After air drying, the pears were stored in enclosed plastic trays to maintain a high relative humidity (above 95%) and incubated at 20 °C. The number of the infected fruit wounds and the average lesion diameters of the overall treated fruits were examined after storage at 20 °C for 7 d post-inoculation. There were three replicates of 10 fruits for each treatment, and the experiment was conducted three times.

2.6. Effects of MeJA on spore germination of P. expansum in vitro

The effects of MeJA on spore germination of pathogen were tested in potato dextrose broth (PDB). Aliquots of 100 μl of *P. expansum* suspension were added into 10 ml glass tube containing 5 ml of PDB to obtain a final concentration of 1×10^6 fungal spores ml^{-1}. The PDB contained different concentrations of MeJA (0, 1, 10, 100, 200 and 500 μM). All tubes were put on a rotary shaker at 100 rpm at 25 °C and incubated for 18 h. Approximately 100 spores of each pathogen were measured for germination rate per treatment within each replicate. Each treatment was replicated three times and the experiment was conducted three times (Zhang et al., 2007).

2.7. Effects of MeJA on population growth of R. glutinis in pear wounds

Pears were rinsed in fresh water, and air dried. A uniform 3 mm wide by 5 mm deep wound was made at the equator of each fruit (put on its side) using the tip of a sterile dissecting needle. Thirty microlitres of a suspension of *R. glutinis* at 1×10^8 CFU/ml alone or in combination with MeJA at 200 μM was applied to wounds on the fruit. Fruits were incubated at 20 °C (90% relative humidity) or at 4 °C (98% relative humidity). *R. glutinis* was recovered from the wounds after incubation at 20 °C for 0 (1 h after treatment), 1, 2, 3, 4, 5, 6 and 7 d, and at 4 °C, for 0 (1 h after treatment), 5, 10, 15, 20, 25 and 30 d, respectively. Wounded tissue was removed with an ethanol-flamed, 7 mm (internal diameter) cork borer and ground with a autoclaved mortar and pestle in 50 ml of sterile 0.85% sodium chloride solution. Serial tenfold dilutions were made and 0.1 ml of each dilution was spread in NYDA. The plates were incubated at 28 °C for 2 d and the colonies were counted. Population densities of *R. glutinis* were expressed as $\log_{10}$ CFU per wound.

There were three single fruit replicates per treatment, and the experiments were repeated twice (Zhang et al., 2007).

2.8. Efficacy of R. glutinis treatment alone or in combination with MeJA on natural infections and postharvest quality of pears

Intact fruits were inoculated by dipping them in the suspension of (1) the cell suspensions of *R. glutinis* (1×10^8 cells ml^{-1}); (2) a solution of MeJA (200 μM); (3) *R. glutinis* suspensions (1×10^8 cells ml^{-1}) amended by MeJA (200 μM); (4) sterile distilled water as the control respectively for 30 s, and air-dried. The treated fruits were sealed in polyethylene-lined plastic boxes to retain high humidity. Fruits were stored at 20 °C for 15 d or 4 °C for 60 d followed by 20 °C for 15 d in order to determine disease development under normal shelf-life conditions. Infection rate was recorded afterwards. There were three replicate trials of 10 fruits with a complete randomisation in each test and experiment was repeated three times.

To evaluate the effect of *R. glutinis* treatment alone or in combination with MeJA on postharvest quality of pears, freshly harvested fruits were treated, and stored as described above to evaluate the effect of *R. glutinis* treatment alone or in combination with MeJA on reducing natural decay development. Quality parameters were measured after storage, on three replicates of five fruits each, and performed at ambient temperature (about 20 °C). The testing methods are described below.

Firmness values of each individual pear were measured at three points of the equatorial region by using the TA-XT2i Texture Analyser (Microstable Instruments, UK) with a 5 mm diameter flat probe. The probe descended toward the sample at 1.0 mm s^{-1}, and the distance that the probe travelled through the sample is 10 mm. The maximum force (N) was defined as firmness (Zhang et al., 2008).

Total soluble solids (TSS) were determined by measuring the refractive index of the same juice with a hand refractometer and the results expressed as percentages (g per 100 g fruit weight) (Manganaris, Vasilakakis, Diamantidis, & Mignani, 2007).

The 2,6-dichloroindophenol titrimetric method was used to determine the ascorbic acid content of pressed fruit juice. Results were expressed as milligrams of ascorbic acid per 100 g sample (Özden & Bayindirli, 2002).

Acidity was measured by titration with 0.1 N NaOH to pH 8.1; 4 g of juice diluted with 20 ml of distilled water was evaluated for each replicate. Titratable acidity was calculated as percent malic acid (Wright & Kader, 1997).

2.9. Statistical analysis

The data were analysed by the analysis of variance (ANOVA) in the statistical program SPSS/PC version II.x, (SPSS Inc. Chicago, Illinois, USA). When the number of means in each group is three or above, the analysis of variance (ANOVA) was performed and Duncan's multiple range test was used for means separation. The statistical significance in this experiment was all applied at the level $P < 0.05$.

3. Results

3.1. Efficacy of MeJA at various concentrations in controlling of blue mold decay of pears

The results showed that MeJA at various concentrations had no effect on the disease incidence of blue mold caused by *P. expansum* (Table 1). Similarly, MeJA at concentrations of 1, 10, and 500 μM had no effect on the lesion diameter of blue mold decay, whereas MeJA at concentrations of 100–200 μM significantly decreased the lesion diameter of blue mold decay after 7 d incubation at 20 °C ($P < 0.05$).

Table 1
Effects of MeJA at various concentrations in control of blue mold decay of pears.

MeJA concentration (μM)	Disease incidence (%)[A]	Lesion diameter (cm)
0	100 ± 0a	1.78 ± 0.16a
1	100 ± 0a	1.63 ± 0.11a
10	100 ± 0a	1.52 ± 0.13a
100	100 ± 0a	1.30 ± 0.13b
200	100 ± 0a	1.17 ± 0.12c
500	100 ± 0a	1.59 ± 0.11a

[A] Means are averaged values of three replications ± the standard error. Values followed by the same letter within column are not significantly different at $P = 0.05$ according to Duncan's multiple range test.

3.2. Efficacy of R. glutinis treatment alone or in combination with MeJA in controlling of blue mold decay of pears

MeJA, as a stand-alone treatment, could not reduce the percentage of blue mold infected wounds (Fig. 1). However, it significantly reduced lesion diameters of blue mold decay. *R. glutinis*, as a stand-alone treatment, significantly reduced the disease incidence and

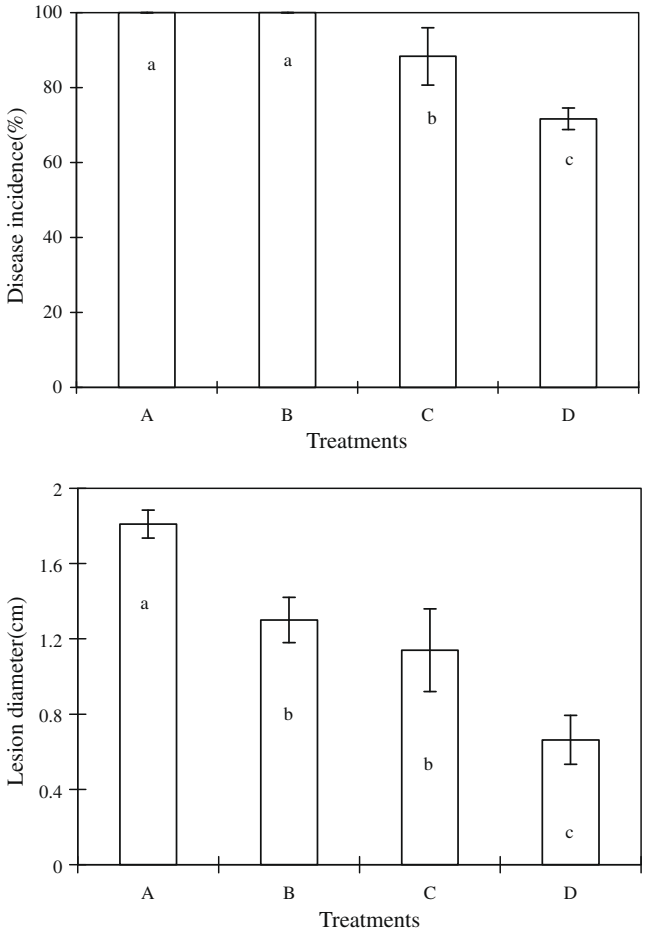

Fig. 1. Effect of *R. glutinis* treatment alone or in combination with MeJA on blue mold rots incidence and lesion diameter in pear wounds. Treatments are as follow: A = Control, B = MeJA (200 μM), C = *R. glutinis* (1×10^8 CFU ml^{-1}), D = *R. glutinis* (1×10^8 CFU ml^{-1}) + MeJA (200 μM). Each value represents the mean of three experiments. Bars represent the standard error of the mean. Data in columns with different letters are statistically different according to Duncan's multiple range test at $P = 0.05$.

lesion diameter of blue mold decay in pears (Fig. 1). The combination of *R. glutinis* with MeJA was a more effective approach to reduce the disease incidence and lesion diameter of blue mold decay of pears than the applications of *R. glutinis* alone. The disease incidence and the lesion diameter of blue mold infected wounds treated with *R. glutinis* combined with MeJA were 71.66% and 0.66 cm, respectively, compared with the 100% and 1.81 cm of the control, respectively.

3.3. Effects of MeJA on spore germination of P. expansum in vitro

Our experiments evaluated the effects of MeJA at various concentrations on spore germination of *P. expansum* in PDB. The result presented in Fig. 2 indicated that MeJA at the concentrations of 1–500 μg ml^{-1} had no significant effect on the spore germination of *P. expansum* compared with the control ($P < 0.05$).

3.4. Population studies of R. glutinis in fruit wounds

Rapid growth of *R. glutinis* in wounds was observed during the first 2 d at 20 °C when *R. glutinis* was applied to wounds in combination with MeJA at 200 μM. However, when *R. glutinis* was applied to wounds alone, rapid growth of *R. glutinis* in wounds was observed during the first 3 d (Fig. 3). At the first 2 d at 20 °C, the population of *R. glutinis* in the fruits treated with MeJA was higher than that of the control. Similarly, on pear wounds kept at 4 °C, rapid growth of the yeast in wounds was observed during the first 5 d after being applied either alone or in combination with MeJA (200 μM), and then the populations stabilised for the remaining storage period. However, the population of *R. glutinis* in the fruits treated with MeJA was higher than that of the no MeJA control for the entire duration of the experiment (Fig. 3).

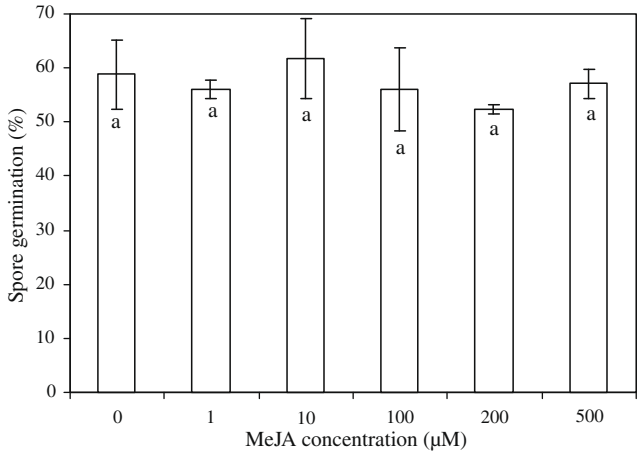

Fig. 2. Effect of MeJA at various concentrations on spore germination of *P. expansum* in potato-dextrose broth medium. Germination rate was measured by electronic microscope after 18 h incubation at 25 °C. Each value is the mean of three experiments. Bars represent the standard error of the mean. Data in columns with different letters are statistically different according to Duncan's multiple range test at $P = 0.05$.

3.5. Efficacy of R. glutinis treatment alone or in combination with MeJA on natural infections and postharvest quality of intact fruits

Our experiments evaluated the efficacy of yeast antagonist and MeJA, as stand-alone treatments or in combination, in reducing the natural infections after storage at 20 °C for 15 d or 4 °C for 60 d followed by 20 °C for 15 d. The result presented in Table 2 indicated that, the application of *R. glutinis* alone significantly reduced the average decay incidence on fruit after storage compared with the control under both storage conditions. Similarly, MeJA (200 μM), as a stand-alone treatment, could reduce the natural fungal decay after storage under both conditions (Table 2). The natural disease incidence of pears treated with the application of *R. glutinis* combined with MeJA resulted in low average decay incidence in 10.42% or 4.16%, respectively, compared with 27.17% or 20.83% in the water-treated control fruit following storage at 20 °C for 15 d or 4 °C for 60 d followed by 20 °C for 15 d.

After 15 d storage at 20 °C, *R. glutinis*, MeJA as a stand-alone treatment or in combination, had no significant effect on total soluble solids, titratable acidity or ascorbic acid (Table 2). Similarly, *R. glutinis* and MeJA as stand-alone treatments had no significant effect on the firmness, however the firmness of pears treated with the combination of *R. glutinis* with MeJA was significantly higher than that of the control. After storage at 4 °C for 60 d followed by 20 °C for 15 d, the firmness, titratable acidity and ascorbic acid of the pears treated with *R. glutinis*, MeJA as stand-alone treatments or in combination were equal or higher than that of the control. The total soluble solids of the pears treated with *R. glutinis* and MeJA as stand-alone treatments or in combination were equal or lower than that of the control.

4. Discussion

In this study, we found that MeJA treatment at 100 or 200 μM could significantly reduce blue mold rot lesion diameter of pear fruits. However, MeJA at various concentrations had no effect on the disease incidence of blue mold. These results suggest that MeJA may have the ability to control postharvest blue mold decay, but the ability is limited, and must be used with other control measures to obtain an improved treatment. The combination treatment of MeJA

[A] Means are averaged values of three trials ± the standard error. Values followed by the same letter are not significantly different at $P = 0.05$ according to analysis by Duncan's multiple range test.

at 200 μM with *R. glutinis* significantly reduced the disease incidence and lesion diameter of blue mold rot of pear fruits, and the control efficacy was better than *R. glutinis* alone at 20 °C. These results suggested that combining MeJA with *R. glutinis* significantly enhanced the biocontrol activity of *R. glutinis* against blue mold decay of pears.

To understand the direct effect of MeJA on the growth of this pathogen, we investigated the effects of MeJA on spore germination of *P. expansum* in vitro. Our results showed that MeJA at all tested concentrations could not suppress the spore germination of *P. expansum*. This is similar with other research results which indicated that MeJA could not directly influence the growth of some fungal pathogens such as *B. cinerea*, *P. digitatum* and *M. fructicola* (Darras, Terry, & Joyce, 2005; Droby et al., 1999; Tsao & Zhou, 2000; Yao & Tian, 2005a). These results suggest that MeJA controls the postharvest blue mold decay and enhances the biocontrol efficacy of *R. glutinis* by mechanisms other than directly effecting pathogen growth/germination. Yao and Tian (2005b) have suggested that the mechanism by which MeJA enhanced the biocontrol efficacy of the antagonistic yeast may be related to its ability to induce resistance in peach fruit by MeJA and antagonistic yeast. However, this mechanism should be further studied.

Our results showed that the populations of *R. glutinis* were greatly increased by the presence of MeJA in the wounded sites at 4 °C and 20 °C. The result was consistent with the result obtained by Yao and Tian (2005b), who observed that MeJA stimulated growth of *C. laurentii* in the wounds of peach fruit at both 25 and 0 °C. This may be because MeJA induces resistance to pathogens in fruits, and pathogens cannot utilise the nutrients of fruits well, so that antagonistic yeast can rapidly colonise the fruit tissues. The biocontrol yeasts have been selected mainly for their capacity to rapidly colonise and multiply in surface wounds, and subsequently to compete with the pathogen for nutrients and space (Droby et al., 2002). The nutritional environment at the wound site may be favourable to *R. glutinis,* which rapidly colonises the fruit tissues and will be competing with the pathogen for nutrients. When MeJA was used with *R. glutinis* in fruits, *R. glutinis* multiplied rapidly in wounds and consumed available nutrients, which may facilitate biocontrol by nutrient competition. These results suggest that MeJA enhances the biocontrol efficacy of *R. glutinis* to postharvest blue mold decay of pears by facilitating the growth of *R. glutinis* in pears and enhancing nutrient competition. The mechanism by which MeJA enhances the biocontrol efficacy of yeast is complex and may be attributed to the influence of MeJA on antagonist, pathogen, and fruits.

Examination of the effects of *R. glutinis* in combination with MeJA on natural infections and postharvest quality parameters of pear fruits revealed that the combined treatments significantly reduced the average decay incidence and did not impair quality parameters of fruits including firmness, total soluble solids, titratable acidity and ascorbic acid under commercial conditions after 15 d storage at 20 °C or 4 °C for 60 d followed by 20 °C for 15 d. There was however minimal difference between *R. glutinis* treatment alone and the *R. glutinis* and MeJA combination treatment in preventing natural fungal decay. These suggest that the combination of *R. glutinis* and MeJA has potential for commercialisation.

In conclusion, the results of this experiment showed that combination of *R. glutinis* with MeJA provided a more effective control for blue mold decay than the application of *R. glutinis* or MeJA alone, which should be considered to be a useful and promising measure for controlling postharvest decay on a commercial scale. We infer that MeJA could enhance the biocontrol activity of *R. glutinis* against blue mold decay in pears by facilitating the growth of *R. glutinis* in fruits thereby reducing nutrient availability, but this mechanism should be further studied. Future research will be aimed at developing the technology to be used under large-scale operations and investigating the mode of action of the induction of resistance and the delay of senescence in pear fruits by these treatments.

ABSTRACT

The effect of partial replacement of NaCl by KCl in the dry-curing of loins has been evaluated by biochemical and sensory analysis of the final products. Endoproteolytic enzymes like cathpesins B and B + L appeared to be more active when more KCl and less NaCl were present in the curing salt while cathepsin H remained unaffected. Proteolysis was reflected by SDS–PAGE in the higher density of the sarcoplasmic proteins bands within the range 55.0–28.0 kDa. Alanyl aminopeptidase (AAP) was unaffected while arginyl and leucyl aminopeptidases were more activated by KCl. On the other hand, methionyl aminopeptidase and dipeptidylpeptidase I and III were more inhibited as KCl increased in the curing salt blends. The sensory analysis revealed no significant differences between control loins with 100% NaCl and those with up to 50% of KCl substitution. Furthermore, loins elaborated with 50% of each salt obtained the highest scores.

1. Introduction

During the last decades, several studies have linked high levels of sodium chloride (NaCl) intake with raised blood pressure, also known as hypertension (He & MacGregor, 2003; Obarzanek et al., 2003). This fact has promoted the current tendency to reduce sodium intake, in order to proportionally lower blood pressure levels and confer significant health benefits by contributing to a decreased risk of cardiovascular disease (Matthews & Strong, 2005). For these reasons, consumer demand for a variety of low-salt products, especially meat products has increased considerably (Russunen & Puolanne, 2005).

NaCl is an essential ingredient in processed meat products for its contribution to the water-holding capacity, prevention of microbial growth, reduction of water activity, facilitating the solubilisation of certain proteins and conferring a typical salty taste by enhancing the flavour of such food products. Moreover, salt affects some chemical and biochemical phenomena such as proteolysis, lipolysis and lipid oxidation which contribute to the development of texture and typical flavour in meat products (Andrés, Cava, Ventanas, Muriel, & Ruiz, 2004; Guàrdia, Guerrero, Gelabert, Gou, & Arnau, 2006; Toldrá, 2006a). Nevertheless, consumers are demanding lower sodium chloride content in meat products (Gou, Guerrero, Gelabert, & Arnau, 1996; Guàrdia et al., 2006; Russunen & Puolanne, 2005). However, sodium chloride must be reduced without altering the curing process. In this sense, main approaches are focused towards the reduction of the NaCl added or substitution with other salts like KCl, but these actions may require an alteration of the processing techniques. The reduction of the level of NaCl added has led to some problems such as an excess of proteolysis due to the intense action of endopeptidase enzymes resulting in defective textures like softness, and also exopeptidase enzymes which could overact on polypeptides and proteins generating excessive content of low molecular weight nitrogen compounds (peptides and free amino acids), which could lead to unpleasant flavour by enhancing the bitter and metallic tastes (Martín, Córdoba, Antequera, Timón, & Ventanas, 1998; Toldrá 1998; Toldrá, Aristoy, & Flores, 2000). Further, the decrease of salt content in meat products also seems to have a slight promoting effect on the lipolysis phenomena (Andrés, Cava, Martín, Ventanas, & Ruiz, 2005).

The partial substitution of NaCl by KCl appears to be the best alternative to reduce sodium content in meat products. Indeed both salts have similar properties and potassium intake has not been linked to the development of hypertension and cardiovascular diseases (Buemi et al., 2002; Geleijnse et al., 2007; Kimura et al., 2004), although its addition to meat products is mainly limited by its bitter and astringent taste (Reddy & Marth, 1991).

In this sense, numerous attempts have been made during the last decades by several researchers to develop acceptable low salt meat products using NaCl/KCl mixtures. Thus, curing salts with up

doi:10.1016/j.foodchem.2009.04.056

to 75% of KCl, in fresh pork sausages (Pasin et al., 1989) or 50% in frankfurters (Whiting & Jenkins, 1981) were used with no negative effect on their sensory properties. Similar results were obtained in cured products like dry-cured ham (Hand, Terrel, & Smith, 1982; Keeton, 1984), dry-cured loin (Gou et al., 1996) and fermented sausages (Gelabert, Gou, Guerrero, & Arnau, 2003). These results indicate that the substitution up to 50% of NaCl with KCl is adequate to obtain an acceptable meat product without affecting its texture, flavour, colour and also microbiological characteristics. Recently, the effect of different chloride salts, including KCl, on porcine muscle proteases has been evaluated (Armenteros, Aristoy, & Toldrá, 2009). However, there is no available information about the effect of a partial or total replacement of NaCl by KCl on the proteolytic and lypolitic phenomena taking place during the dry-curing process. Consequently, the basic aim of this study was to evaluate the effect of the partial NaCl substitution by KCl on the biochemical and sensory characteristics at the end of the ripening stage in dry-cured loins. This meat product may be considered as a model system because of its homogeneous shape and structure and the short time required for ageing.

2. Materials and methods

2.1. Samples

Fifteen fresh loins (2.6 ± 0.8 kg) from *Landrace x Large White* pigs were obtained from a local slaughterhouse. Loins were vacuum-packed and immediately frozen at −40 °C and stored for a minimum of 5 days at −20 °C. Then, the frozen loins were thawed in a cold chamber at 3–4 °C for 5 days, similarly to the industrial process. Three of the loins were used as a control of the raw material. The remaining 12 loins were divided into four groups with three loins each. Loins from one group (batch I) were salted by rubbing and kneading with the traditional NaCl content (100% NaCl, treatment I). The other groups were salted using the same processing conditions, but with a partial substitution of NaCl by KCl. So, the second batch (batch II) was salted with 65% NaCl and 35% KCl (treatment II), the third batch (batch III) was salted with 50% of both salts (treatment III) and finally the fourth batch (batch IV) with 30% NaCl and 70% KCl (treatment IV). All the salting experiments were carried out at 3 ± 1 °C and 90% of air relative humidity (RH) for 6 days and each loin was weighed every day. The amount of the salt mixture was about 2% the weight of the loin and also 150 ppm of KNO_3 and 150 ppm of $NaNO_2$ were added to the mixture as curing agents (Toldrá, 2006b).

After the salting stage, the loins were stuffed into artificial casings and immediately hung in a chamber for ripening at 3 °C and 90% RH for 5 days. Subsequently, the loins were transferred to a drying chamber at 10 °C and 85% RH for 7 days and afterwards at 12 °C and 75% RH until the loins reached 47% of commercial humidity. Dry-cured loins were immediately vacuum-packed and frozen at −20 °C until analysis.

2.2. Sodium and potassium analysis

Briefly, 5 g of minced dry-cured loin was homogenised 1:10 (*p*/*v*) with 50 ml Milli®-Q water in a stomacher (IUL Instruments, Barcelona, Spain) for 10 min at 4 °C, and then centrifuged at 10.000*g* for 20 min at 4 °C. Supernatant was filtered through glass wool and immediately frozen at −20 °C until used. Previous to the analysis, thawed samples were filtered through nylon membrane filters (0.45 μm) and injected using the Metrohm 838 Advanced Sample Processor (Metrohm Ltd., Switzerland). Subsequently, an Advanced Compact IC 861 (Metrohm® Ltd., Herisau, Switzerland) ion chromatograph (IC) was used to determinate sodium (Na^+) and potassium (K^+) cations in sample solutions. Guard column S-Guard and analytical column Metrosep C3–250A (4.0 × 250 mm) were from Metrohm® Ltd. (Herisau, Switzerland). The mobile phase consisted of 3 mM/l nitric acid with 50 ml/l acetone. The separation was monitored using a conductivity detector and a software IC Net 2.3 (Metrohm® Ltd., Herisau, Switzerland) was used for data collecting and processing. The concentration of each cation was determined by interpolation in the corresponding calibration curve. The calibration for the assay was established using a triplicate set of standard solutions of Na^+ and K^+ (Fluka, Switzerland, Sigma, St. Louis, MO). The results were means of three determinations and were expressed in mg/g of sample.

2.3. Sensory analysis

After the drying stage (~2 months), the dry-cured loins from batches I, II, III and IV were subjected to sensory analysis, in order to evaluate the influence of the partial replacement of NaCl by KCl on sensory characteristics. Batch I (100% NaCl, treatment I) was used as a control. The dry-cured loin casing was removed and the loin cut in approximately 5 mm thick slices, using a commercial slice machine. Slices were left to rest for 30 min on white plastic plates at room temperature (20–23 °C) before serving. A glass with about 100 ml of water at 12 °C and a toast of bread without salt were provided for each assessor after each sample. All sessions were held in a sensory panel booth room at 22 °C equipped with white fluorescent lighting (220–230 V, 35 W) and a personal computer (Hewlett–Packard). The samples were assessed by a non-trained panel consisting of 48 members in two different sessions. A preference test (ISO-5495, 1983) was carried out, in which assessors were asked to indicate their preference within each pair consisting of the control and the respective batch (II, III and IV), regarding colour, aroma, texture, taste and overall quality. Sensory evaluations were recorded by computer software using the Compusense® *five* release 4.6 (Compusense Inc., Guelph, ON, Canada).

2.4. Preparation of enzyme extracts for cathepsin/peptidases assays

Minced dry-cured loin (2.5 g sample) was homogenised in 25 ml of 50 mM sodium citrate buffer, pH 5.0, containing 1 mM EDTA and 2% (*v*/*v*) Triton X-100 (for cathepsins) or 4.0 g of sample was homogenised in 20 ml of 50 mM phosphate buffer, containing 5 mM EGTA, pH 7.5 (for peptidases). In both cases, the homogenisation was achieved by 3 × 10 s at 27.000 rpm in ice using a polytron homogenizer (Kinematica AG, Switzerland) and the obtained extracts were centrifuged at 10.000*g* for 20 min at 4 °C. The resulting supernatants were filtered through glass wool and used for the enzyme assays.

2.5. Assay of enzyme activities

Muscles enzyme activities were measured by fluorometric assays using aminoacyl-7-amido-4-methyl coumarin (AMC) as substrate. Cathepsin activities were assayed as previously described by Rico, Toldrá, and Flores (1991) using N-CBZ-Arg-Arg-AMC, N-CBZ-Phe-Arg-AMC and L-Arg-AMC (Sigma, St. Louis, MO) as substrates for cathepsin B, B + L and H, respectively, which were added to the reaction buffers (40 mM sodium phosphate buffer, at pH 6.0 for cathepsin B and B + L or pH 6.8 for cathepsin H, containing 0.4 mM EDTA, 10 mM cysteine, and 0.05 mM substrate).

Aminopeptidases were analyzed by following the method described by Flores, Aristoy, and Toldrá (1997a). Thus, alanyl aminopeptidase (AAP) activity was assayed in 100 mM phosphate buffer, pH 6.5, containing 2 mM β-mercaptoethanol and 0.1 mM Ala-AMC as substrate. Arginyl aminopeptidase (RAP) was assayed in 50 mM phosphate buffer, pH 6.5, containing 200 mM NaCl, 0.25 mM puromicyn and 0.1 mM Arg-AMC as substrate. Leucyl aminopeptidase

(LAP) activity was assayed in 50 mM borate–NaOH buffer, pH 9.5, containing 5 mM magnesium chloride and 0.25 mM Leu-AMC as substrate. Methionyl aminopeptidase (MAP) activity was analyzed as described by Flores, Marina, and Toldrá (2000) in 100 mM phosphate buffer, pH 7.5, containing 10 mM dithiothreitol (DTT), 0.05 mM bestatin and 0.15 mM Ala-AMC as substrate.

Dipeptidyl peptidase activities (DPP) I, II, III and IV were assayed as previously described by Sentandreu and Toldrá (2001). DPP I activity was assayed in 50 mM sodium acetate buffer, pH 5.5, containing 5 mM DTT and 0.5 mM Gly-Arg-AMC as substrate; whereas DPP II was assayed in the same buffer containing 0.032 mM bestatin and 0.5 mM Lys-Ala-AMC as substrate. DPP III activity was assayed in 50 mM sodium tetraborate buffer, pH 8.0, containing 0.05 mM cobalt chloride and 0.5 mM H-Arg-Arg-AMC as substrate and DPP IV was assayed in 50 mM tris-base buffer, pH 8.0, containing 5 mM DTT and 0.25 mM Gly-Pro-AMC as substrate.

In all cases, 50 μl of extract was diluted with 250 μl of the corresponding reaction buffer containing the substrate, and incubated in a multiple plate at 37 °C for 15 min. The fluorescence was determined using excitation and emission wavelengths of 355 and 460 nm, respectively by using a multiscan fluorometer (Fluoroskan Ascent FL, Labsystems, Helsinki, Finland). Four replicates were performed for each enzyme assay, except when determining dipeptidyl peptidase activity, where three replicates were done. One unit of enzyme activity (U) was defined as the amount of enzyme which hydrolyses 1 μmol of substrate per min at 37 °C.

2.6. Proteolysis analysis

The extractions of the sarcoplasmic and myofibrillar proteins were performed as described by Molina and Toldrá (1992). The samples were ground, homogenised 1:10 (*w*/*v*) with 30 mM phosphate buffer, pH 7.4 in a stomacher for 3 min at 4 °C and centrifuged at 10.000*g* for 20 min at 4 °C. The supernatant containing the sarcoplasmic proteins was filtered through glass wool and kept at 4 °C. This operation was repeated with the pellets up to three times to recover all sarcoplasmic proteins by pooling the supernatants which were stored at 4 °C until use. The resulting pellet was finally homogenised with nine volumes of 100 mM phosphate buffer at pH 7.4, containing 0.7 M potassium iodide and 0.02% sodium azide using a stomacher for 8 min and then centrifuged at 10.000*g*, for 20 min at 4 °C. The supernatant containing myofibrillar proteins was collected. The protein concentration of both, sarcoplasmic and myofibrillar proteins extracts, was determined by the method of Smith et al. (1985), using bicinchoninic acid as a reagent and the bovine serum albumin as a standard (Sigma, St. Louis, MO).

The study of the proteolysis was done by sodium dodecyl sulphate-polyacrylamine gel electrophoresis (SDS–PAGE) as described by Toldrá, Miralles, and Flores (1992). Proteins from the sarcoplasmic and myofibrillar extracts were denaturalised by mixing in the ratio 1:1 (*v*/*v*) with 50 mM Tris buffer, pH 6.8, containing 8 M urea, 2 M thiourea, 75 mM DTT, 3% (*w*/*v*) SDS and 0.05% bromophenol blue (sample buffer). The mixture was heated at 100 °C for 4 min and stored at −20 °C until use. Thawed samples were diluted with the sample buffer up to 1 mg/ml protein concentration and then, 12 μl of these samples were injected, respectively, in each line into the gels. SDS–PAGE was carried out using 12% polyacrylamide gels and stained with coomassie brilliant blue R-250. Standard proteins from BioRad (Hercules, CA, USA) were simultaneously run for molecular mass estimation. Finally, the gels were scanned with Fujifilm Las 1000 Intelligent Dark Box II (Fujifilm, SA, Spain).

2.7. Free amino acids analysis

Samples for free amino acid analysis were extracted and deproteinised following the method described by Aristoy and Toldrá (1991). Dry-cured loin samples were cut, minced and 5 g subsequently homogenised with 0.01 M HCl 1:5 (*v*/*v*) in a stomacher for 8 min at 4 °C and then centrifuged at 10.000*g* during 20 min at 4 °C. The supernatant was filtered through glass wool and stored at −20 °C until required. Next, 200 μl of thawed samples plus 50 μl of an internal standard solution (1 mM norleucine in 0.01 M HCl), were deproteinised with 600 μl of acetonitrile. Free amino acids in the supernatant were derivatised to their phenylthiocarbamyl derivates according to the method of Bidlingmeyer, Cohen, Tavoin, and Frost (1987) and analyzed by reversed-phase HPLC (1100 Agilent, Palo Alto, CA, USA) in a waters Nova Pack® C18 column (3.9 × 300mn) (Waters Corporation, Milford, MA, USA) and ultraviolet detection (254 nm), as described by Flores, Aristoy, Spanier, and Toldrá (1997b).

2.8. Free fatty acids analysis

Total lipids were extracted from dry-cured loin samples according to the method of Folch, Lees, and Sloane Stanlye (1957), using dichloromethane:methanol 2:1 (*v*/*v*) instead of chloroform:methanol 2:1 (*v*/*v*) as solvent. Free fatty acids were purified from the total lipids as described by Countron-Gambotti and Gandemer (1999) using an anion exchange resin (Amberlyst A26, Rohm & Haas, Delf, Nederland) and determined by means of gas chromatography of the corresponding methyl esters (Needs, Ford, Owen, & Tuckley, 1983). The derivatives were obtained according to the method of Berry, Cevallos, and Wade (1965) and the analysis of the fatty acid methyl esters (FAME) was carried out as described by Navarro, Nadal, Nieto, and Flores (2001) using a Fison 816 gas chromatograph (Fisons Instruments, San Carlos, CA, US) equipped with a flame ionisation detector. The split ratio used was 1:50. The capillary column was a DB-225 (J&W Scientific, Barcelona, Spain; 30 m long, 0.25 mm i.d., 0.25 μm film thickness) and the detector and injector temperatures were both set to 240 °C. The individual fatty acids were identified by comparing their retention times with those of standard fatty acids using the araquidonic acid as internal standard for quantification.

2.9. Statistical analysis

The effect of the partial replacement of NaCl by KCl on the studied variables (enzyme activities, free amino acids, free fatty acids and sodium and potassium content) was done by analysis of variance using the STATHGRAPHICS Plus 5.1 version software (Manugistics Inc., Rockville, MD, USA). In those cases where the effects were significant, the means were compared using Fisher's least significant difference (LSD) procedure.

3. Results and discussion

3.1. Sodium and potassium content

The residual content of sodium and potassium cations was determined in the dry-cured loins at the end of the ripening stage. As expected (Table 1), the dry-cured loin salted with a mixture of NaCl and KCl (treatments II, III and IV) showed an enhanced amount of residual K^+ which increased proportionally to the added KCl (taking into account the naturally content of this cation in muscle (0.16 mEq in treatment I). This confirms the correct penetration of this chloride salt. Furthermore, as observed in Table 1 the use of NaCl/KCl mixtures effectively reduced the Na^+mEq:K^+mEq ratio in dry-cured loins from 7.62 to 0.79 for 0 to 70% of substitution, respectively.

Table 1
Sodium and potassium content in dry-cured loins submitted to four types of salting treatments: I: Control, 100% NaCl; II: 65% NaCl–35% KCl; III: 50% NaCl–50% KCl and IV: 30% NaCl–70% KCl.

Parameter	I	II	III	IV
Na^+ (mg g^{-1})	27.82	24.54	15.55	12.30
K^+ (mg g^{-1})	6.21	17.07	18.59	26.31
Na^+:K^+ ratio	4.48	1.44	0.84	0.47
mEq Na^+	1.21	1.07	0.68	0.53
mEq K^+	0.16	0.44	0.48	0.67
Na^+mEq:K^+ ratio	7.62	2.44	1.42	0.79

mEq Na = mg g^{-1} Na^+/23.
mEq K = mg g^{-1} K^+/39.

3.2. Effect of the salting treatments on sensory analysis

The results of the sensory analysis of the dry-cured loin submitted to the four types of salting treatments are shown in Table 2. Non significant differences ($p < 0.05$) were found with respect to aroma, texture and taste attributes between the control (batch I, 100% NaCl) and batches II and III salted with substitutions up to 50% of NaCl by KCl. Furthermore, the dry-cured loins salted with the treatments II and III were preferred by assessors with respect to the colour and overall quality. Whereas, the dry-cured loins salted with 70% of KCl (treatment IV) received lower scores than the control respect to all attributes, except colour, which did not show significant differences ($p < 0.05$). These results are in agreement with those reported by Gelabert et al. (2003) and Gou et al. (1996) for fermented sausages and dry-cured loins and indicated that substitutions up to 50% of NaCl by KCl did not affect the texture or colour and also provided an acceptable flavour without a noticeable bitter taste. In fact, the best scores in our study corresponded to the dry-cured loin salted with 50% of NaCl substitution by KCl (treatment III).

3.3. Effect of the salting treatments on enzyme activities

The cathepsin activity in the dry-cured loins submitted to different salting treatments was studied for its relevance among the proteolytic changes taking place during the processing of these products. Previous studies had demonstrated that salt (NaCl) induces an inhibitory effect on cathepsins B and B + L activities (Rico et al., 1991; Toldrá, Rico, & Flores, 1993). Nevertheless, the presence of 50–70% KCl (treatment III and IV) in the mixture of curing salts favoured a higher cathepsin B and B + L activities ($p < 0.05$) in comparison to that with 100% NaCl (treatment I) as shown in Table 3, while significant differences ($p < 0.05$) were not found between the activity of these enzymes in the dry-cured loin salted with the treatments I and II. The cathepsin H activity was not seriously affected by any of the experimental salting treatments (II, III and IV). These results suggested that the partial replacement of 50% NaCl by KCl or higher could led to a higher cathepsin B and B + L activities and consequently it may have resulted in a prolongation of proteolysis.

The activity of dipeptidyl peptidases in dry-cured loins was different depending on the type of salted treatments used (Table 3). The exception was DPPII, that was not influenced by the type of treatment employed ($p < 0.05$). DPPI activity was significantly higher ($p < 0.05$) in the dry-cured loin salted with 100% NaCl (treatment I) in comparison to the other. However, DPPIII activity decreased ($p < 0.05$) when the substitution of KCl increased. Finally, DPPIV activity was not affected by the salting treatment except by the treatment II, which exerted a slight inhibitory effect ($p < 0.05$).

Finally, the aminopeptidase activities were affected by the salting treatments employed as follows (Table 3). RAP showed higher activity in treatments III and IV and LAP in treatment IV. On the contrary, MAP was more inhibited in the presence of any concentration of potassium salt. The effect of potassium substitution on AAP activity was variable and no clear relationships between experimental salting treatments (II, IIII and IV) and traditional treatment could be found.

3.4. Effect of the salting treatments on proteolysis

Sarcoplasmic and myofibrillar proteins were extracted from the dry-cured loins salted with four different salt formulations. As shown in Figs. 1 and 2, the most relevant differences were observed in the sarcoplasmic proteins while the myofibrillar proteins patterns were very similar. Indeed, the electropherograms of myofibrillar proteins (Fig. 1) in all samples showed an intense degradation of the myosin and actin bands throughout the ripening stage, as already observed in dry-cured ham (Toldrá et al., 1993).

On the other hand, the electrophoretic profile of sarcoplasmic proteins showed more density of the bands in the dry-cured loin salted with partial replacement of NaCl (treatments II, III and IV) than in those salted traditionally (treatment I), as shown in

Table 2
Sensory analysis (preference test) of the dry-cured loins at the end of the ripening stage.

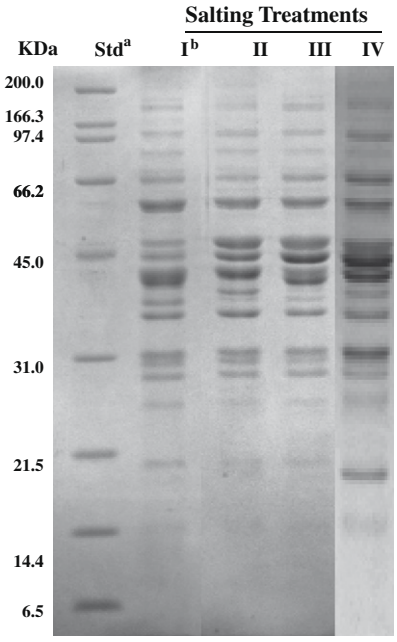

Fig. 2. Twelve percent SDS–PAGE gel of sarcoplasmic proteins in the dry-cured loin salted with the four types of treatments. [a]Std: BioRad molecular weight standards. [b]Treatment I: 100% NaCl, treatment II: 65% NaCl–35% KCl, treatment III: 50% NaCl–50% KCl and treatment IV: 30% NaCl–70% KCl.

Fig. 2. More concretely, the dry-cured loins salted with the treatments II, III and IV showed a progressive increase in the intensity of bands between 55 kDa and 28 kDa. This is also related to the higher cathepsin B and B + L activity in those loins with larger amount of potassium. The exception was the 36 kDa band corresponding to glyceraldehydes-3-phosphate dehydrogenase, which remained in all samples with a similar density.

Free amino acids which are final products of proteolysis, are of great importance not only for their attribution to specific taste but also for their involvement in degradation reactions that generate volatile compounds which contribute to the flavour in meat products (Toldrá et al., 2000). The results of the free amino acids concentrations in the dry-cured loins submitted to the different treatments are presented in Table 4. There was no statistically significant effect of the salting treatment on the release of total free amino acids ($p < 0.05$), which indicated a similar aminopeptidase activity. Similar results were found in fermented fish sauce (Sanceda, Suzuki, & Kuruta, 2003) and Feta cheese (Katsiari, Alichanidis,

Total FFA	508.72	498.82	496.73	589.36

Results are expressed as means of three replicates.
Means in the same line with different letters are significantly different ($p < 0.05$).
[A] SFA: total saturated fatty acids amount.
[B] MUFA: total monounsaturated fatty acids amount.
[C] PUFA: total polyunsaturated fatty acids amount.

Voutsinas, & Roussis, 2000), in which the proteolysis was not influenced by the type of the salting treatment employed during their manufacture.

On the other hand, the concentrations of some amino acids, like Glu, Pro and Val in the loins salted with the treatment III, were significantly different ($p < 0.05$). The good taste found by sensory analysis in the dry-cured loins submitted to treatment III could be due in part to the contribution of these amino acids (Kato, Rhue, & Nishimura, 1989; Nishimira & Kato, 1988).

3.5. Effect of the salting treatments on free fatty acids content

Free fatty acids (FFA) were analyzed at the end of the ripening stage as indicators of the lipolysis process in the dry-cured loins (Table 5). The treatments did not promote significant differences ($p < 0.05$) in either total amounts of saturated (SFA), monounsaturated (MUFA) or polyunsaturated (PUFA) fatty acids content in the dry-cured loins. These results are consistent with those reported by other authors in cheese (Katsiari, Voutsinas, Alichanidis, & Roussis 2001; Lindsay, Hargett, & Bush, 1982), where the replacement up to 50% of NaCl by KCl did not affect the lipolysis phenomena or in dry-cured ham (Countron-Gambotti, Gandemer, Rousset, Maestrini, & Casabianca, 1999) where salt content did not affect the fatty acid compositions.

4. Conclusions

These results indicate that the replacement of up to 50% NaCl by KCl in the salting stage of the processing of dry-cured loins did not significantly affect the proteolysis and lipolysis phenomena taking place. Also, the sensory analysis of the final products did not reveal marked differences among loins with up to 50% of substitution and even those with 50% KCl were the most valued. These results may be useful as a starting point for the study of NaCl reduction in other dry-cured meat products such as dry-cured ham.

Liquid chromatography–tandem mass spectrometry

ABSTRACT

Pesticides applied to grape vines before harvest may concentrate in the grape seed due to their high oil solubility. Twenty-four samples of grape marc, representing a range of red and white wine grape varieties, were collected and analysed for selected fungicides and insecticides. Fifteen of the 24 samples were matched with insecticide and fungicide application diaries. Residue concentrations of the fungicides, procymidone, iprodione, cyprodinil, fenhexamid, fludioxinil, pyrimethanil and trifloxystrobin, and the insecticides, indoxacarb and tebufenozide, were higher in grape seed oil and grape seed meal than in the fruit and the marc. The relative concentrations were approximately proportional to the octanol to water partition coefficients, log K_{ow}. A range of other fungicides and insecticides were detected but were not significantly concentrated in the oil and seed meal relative to fruit and marc. The presence of pesticide residues in grape seed oil and grape seed meal will impact on the possibility of producing these wine by-products.

1. Introduction

Large quantities of grape marc (solids remaining after juice extraction) are produced by regional wineries in Victoria, Australia (Jordan, 2002). Currently, the marc is either fed to livestock or consigned to land fill as the costs for transport and reprocessing into distilled alcohol, tartaric acid or polyphenolic supplements make these options uneconomic. Alternatively, grape seed oil (for human consumption) and seed meal (for animal feed), could be produced from the marc. However, previous work (Cabras & Angioni, 2000; Navarro, Barba, Oliva, Navarro, & Pardo, 1999; Teixeira, Aguiar, Afonso, Alves, & Bastos, 2004; Tsiropolous, Aplada-Sarlis, & Miliadis, 1999) suggests that the grape seed oil and the seed meal may contain unacceptable levels of systemic pesticide residues that were applied to the vines prior to harvest. Residue levels of five out of six pesticides (penconazole, chlorpyrifos, vinclozolin, fenarimol and metalaxyl) applied to grape vines prior to harvest were higher in grape marc than in the crushed grapes during elaboration of red wines. Also, the residue levels in must, 4 days after vinification, were significantly lower than in crushed grapes for the six pesticides (including mancozeb) (Navarro et al., 1999). Residue levels of 10 out of 12 fungicides applied to vines prior to harvest were lower in must and wine than in the grapes. Six out of eight of these fungicides had reduced levels in clarified must, suggesting that the residues tend to be retained in the solid portion of the must (seeds, skins and stalks). Similarly, the levels of six out of nine organophosphate insecticides were lower in the wine than in the grapes and the levels of five of these organophosphate insecticides were lower in clarified must (after solids removal) than in the must. However, dimethoate and methidathion, the compounds with lowest log K_{ow} (more soluble in water and ethanol), were at higher concentrations in the must and wine than in the marc (Cabras & Angioni, 2000). Another study by Tsiropolous et al. (1999) showed significantly lower levels of the insecticide teflubenzuron in wine than in the grapes. Clarified must residue levels were also significantly lower than in must suggesting that teflubenzuron residues were associated with the solid portion of seed, skins and stalks rather than the juice of the grape. It was suggested by Teixeira et al. (2004) that systemic pesticides, such as oxydixyl, were preferentially found in the grape pulp, whilst contact pesticides, such as folpet, were present only in the skin. The relationship between the levels in different parts of the grape was also thought to be dependent on the time between application and sampling.

This study investigates the potential concentration of applied fungicides and insecticides in grape seed produced from grape marc collected from selected wineries in Victoria, Australia. Additionally, the relationship between the octanol to water coefficient (log K_{ow}) and the concentration of each fungicide/ insecticide in grape seed was explored.

2. Materials and methods

2.1. Reagents

Pesticide hexanes (nanograde 95% n-hexane), nanograde dichloromethane (DCM), and HPLC grade methanol, were all purchased from Mallinkrodt, Kentucky, USA. Acetone was redistilled from AR grade solvent (BDH/Merck, Kilsyth, Australia). HPLC grade acetonitrile was purchased from OmniSolv, EM Science NJ, USA. Labchem grade Florisil was purchased from Ajax Fine Chemicals, Sydney Australia, and activated by placing in a muffle furnace at 550 °C for 2 h prior to use. Anhydrous AR grade sodium sulphate and anhydrous AR grade ammonium acetate were purchased from Ajax Fine Chemicals, Sydney Australia. Water was Type 1 (18 Megohm resistivity).

2.2. Certified standards

Cyprodinil (98.5% purity), fenhexamid (99.5%), fludioxinil (98.0%), metalaxyl (99.5%), pyraclostrobin (99.7%), trifloxystrobin (99.0%), quinoxyfen (99.0%), spinosad A + D (95%), spiroxamine (97.5%), captan (99.5%), chlorothalonil (98.5%), procymidone (98.0%) and iprodione (99.0%) were purchased from Dr. Ehrenstorfer-Schafers, Augsburg, Germany. Indoxacarb (99.3%), pyrimethanil (99.6%), triadimenol (97.7%) and tebufenozide (99.9%) were purchased from the National Measurement Institute, Pymble, Australia. Penconazole (99%) and myclobutanil (99.9%) were purchased from Riedel de Haan, Hanover, Germany and tributyl phosphate (TBP) was purchased from Chem Service, PA, USA.

2.3. Sampling and sample preparation

2.3.1. Fruit and by-product samples

Grape marc and, where possible, matching fruit samples were collected from regional Victorian wineries during the autumn, 2004 vintage. Of a total of 24 samples of marc, 15 samples were matched with application diaries. A target list of fungicides and insecticides was developed from examination of the available diaries. Fungicides represented the highest proportion of chemicals applied to the vines prior to harvest. There was no record of organophosphate or synthetic pyrethroid insecticide usage. Central Victorian marc samples were collected fresh and transferred to Stoney Creek Oils (SCO) located at Talbot in central Victoria. The seed was wet-separated immediately at SCO and the seed dried on forced air drying screens, sieved and stored for pressing. Yarra Valley marc samples were collected and immediately frozen prior to transfer to SCO. The frozen marc samples were thawed and the seed wet-separated, dried, sieved and stored for pressing. Where possible, matching fruit samples were collected from harvest fruit bins at the wineries. However, due to harvesting patterns, there is no guarantee that the fruit samples were representative of chemical usage throughout harvest blocks. A standard linseed oil press was used to cold-press the seed. Residue free seed oil was used to clean the oil press between samples. Seed meal samples were also collected from each seed batch processed and analysed for organic residue content.

2.3.2. Fruit and marc extraction

Fifty grammes of marc or homogenised grape berry were extracted with 200 ml of acetone using a probe homogeniser. The sample was vacuum-filtered, the filtrate mixed with 650 ml of saturated aqueous sodium sulphate and extracted with 1×100 ml and 2×50 ml volumes of DCM. The extracts were combined, passed through an anhydrous sodium sulphate drying column and inverted into 10 ml of hexane.

2.3.3. Seed oil extraction

Two grammes of oil were diluted with 25 ml of hexane and extracted with 1×50 ml and a further 2×25 ml of hexane saturated acetonitrile. The acetonitrile layers were combined, dried, and inverted into 2 ml of dichloromethane (DCM).

2.3.4. Seed meal extraction

Approximately 25 g of meal were mixed with 200 ml of 35% water/65% acetone and shaken for 30 min. The sample was vacuum-filtered, the filtrate mixed with 650 ml of saturated aqueous sodium sulphate and extracted with 1×100 ml and 2×50 ml volumes of DCM. The DCM volumes were combined, dried through an anhydrous sodium sulphate drying column and inverted into 10 ml of hexane.

2.4. Apparatus

2.4.1. Gas chromatography–nitrogen phosphorus detection (GC–NPD)

The fungicides, chlorothalonil, penconazole, procymidone, iprodione, triadimenol and myclobutanil were determined using a Varian 3400 CX capillary gas chromatograph fitted with nitrogen–phosphorus detector (Varian, Mulgrave, Australia). An aliquot (2 μl) of hexane (derived for each sample as described above) was simultaneously injected onto parallel columns (15 m, 0.32 ID dimethyl-polysiloxane stationary phase, J&W® DB-1) and a 15 m, 0.32 ID 50% diphenyl-dimethyl-polysiloxane stationary phase (J&W® DB-17) via a split/splitless injector with a split ratio of 1:20. The GC oven was temperature-programmed (120 °C 0–2 min, 120–300 °C at 20 °C/min, held 300 °C for 1 min) for optimum separation efficiency. The injector and detector temperatures were set at 280 and 320 °C, respectively. Helium was used as carrier gas. Varian Star software (V6.0) was used to manage the chromatographic data. The organic residues were quantified by comparison with external standards.

2.4.2. Gas chromatography–electron capture detection (GC–ECD)

The fungicide captan was determined using a Varian 3800 capillary gas chromatograph fitted with an electron capture detector (Varian, Mulgrave, Australia). The hexane extract obtained from sample processing, as described above, was further purified by adding 0.5 ml of the extract to 3.0 g of activated florisil, followed by elution with 25 ml of 1% acetonitrile/49% hexane/50% DCM. This was inverted to 2 ml of hexane. An aliquot (2 μl) of hexane was injected simultaneously onto parallel capillary columns (15 m, 0.32 ID 14% cyanopropyl-phenyl on dimethyl-polysiloxane stationary phase, J&W® DB-1701) and a 15 m, 0.32 ID, 25% cyanopropyl, 25% diphenyl, 50% dimethyl-polysiloxane stationary phase (Restek®, RTX-225) via a split/splitless injector with a split ratio of 1:20. The GC oven temperature was set at 200 °C. The injector and detector temperatures were set at 280 and 350 °C, respectively. Helium was used as carrier gas. Varian Star software (V6.0) was used to manage the chromatographic data. The organic residues were quantified by comparison with external standards.

2.4.3. Liquid chromatography–tandem mass spectrometry (LC–MS/MS)

The fungicides, cyprodinil, fenhexamid, metalaxyl, fludioxinil, pyraclostrobin, quinoxyfen, trifloxystrobin and pyrimethanil, and the insecticides, spinosad, spiroxamine, indoxacarb and tebufenozide, were determined using a Waters 2975 separation module interfaced with a Waters Micromass Quattro Micro tandem mass spectrometer operating in the positive ion electrospray mode (Waters Micromass, Manchester, UK). An aliquot (0.2 ml) of the hexane extract, obtained as described above, was inverted into methanol (4 ml) containing 0.06 μg/ml of tributylphosphate (TBP) as internal standard. The compounds were separated with

a 150 mm × 2.0 mm Luna® 5 μm C18(2) analytical HPLC column fitted with a C18 guard column. The HPLC column was maintained at 25 °C. The mobile phase consisted of (A) 20% methanol in 5 mM ammonium acetate and (B) 90% methanol in 5 mM ammonium acetate with the following gradient: 100% A–100% B (0–15 min), 100% B (15–28 min), 100% B–100% A (28–30 min) with a flow rate of 0.2 ml/min. Masslynx Software (V4.0) was used for data processing. Residues were quantified using external standards and each standard set was assayed a minimum of three times during each sample batch run. Each standard also contained TBP (0.06 μg/ml) as the internal standard. Sample and recovery concentrations were calculated from a linear regression of the standards. Samples and standards were corrected for internal standard (IS) response. The tandem mass spectrometer was operated in the multiple reaction monitoring (MRM) mode. The precursor ions, product ions, confirmatory product ions and retention times for each compound are listed in Table 1.

2.5. Quality control

Spiked recoveries for each residue were included in every sample extraction batch and the recoveries determined as described for samples. Samples were spiked in the range of 0.05–1.2 mg/kg. Mean recoveries for GC residues were; 79% in fruit, 92% in marc, 89% in seed oil and 85% in seed meal. Mean recoveries for LC–MS/MS residues were: 65% in fruit, 91% in marc, 69% in seed oil and 51% in seed meal. The reported data were not corrected for batch recoveries. The lower recovery of LC–MS/MS analytes in grapes is related to the matrix suppression of mass spectrum ion response routinely observed in extracts from fruit high in moisture and soluble sugars, such as grapes and pome fruit. This effect was also observed in LC–MS/MS in the extracts of seed oil and seed meal. Matrix enhancement of the LC.MS/MS response was observed for pyrimethanil, and the strobilurin fungicides, pyraclostrobin and trifloxystrobin.

3. Results and discussion

3.1. General

Table 2 shows the residue levels present in fruit, marc, seed oil and seed meal for fungicides that are routinely used in Victoria, Australia. At the time of the study, the maximum residue limit (MRL) for grapes was taken from the Food Standards Australia and New Zealand (FSANZ) Code (Food Standards Australia New Zealand, 2006). FSANZ MRLs for agricultural produce are applied to derived foods, such as seed oils, where there is no separate MRL listed.

3.2. Cyprodinil and fludioxinil

The anilinopyrimidine systemic fungicide cyprodinil and the phenylpyrrole non-systemic fungicide fludioxinil are applied in a mixture formulated to control grey mould, *Botrytis cinerea* (Australian Pesticide and Veterinary Medicine Authority (APVMA), 2008). The formulated mixture has a withholding period of four weeks and a restriction of a maximum of two applications per season. No samples contained either fungicide above the Australian MRL; however, the residues in the seed oil from sample CH10 may have been above the MRL at the withholding period. Label instructions limit applications prior to grape veraison at the latest, so it is unlikely that any crop would be harvested at the minimum withholding period. The relative concentrations of the fungicides in the samples reflect the composition of the formulation (37.5% cyprodinil and 25% fludioxinil).

3.3. Procymidone

The systemic dicarboximide fungicide procymidone is registered for control of grey mould in wine grapes and has a withholding period of 7 days (APVMA, 2008). Seven out of nine seed oil samples contained residues above the Australian MRL of 2 mg/kg (Food Standards Australia New Zealand (FSANZ), 2006). Four out of nine marc samples also contained residues above the MRL. The residues for grape sample CH4 was more than twice the MRL for grapes, indicating that the withholding period may be too short, especially where multiple applications have been made prior to harvest. There were no application diary records for samples CH8, CH14 and Ref#14. The data suggest that it is likely that sample CH15 had an unrecorded application close to the withholding period. Sample CH15 also reported a grape sample above the MRL, supporting the previous observation that the withholding period was too short for the listed MRL. Results show that procymidone is a high-risk fungicide for seed oil, marc, seed meal and grapes in these samples. In 2005, following numerous international reports of its toxicity, additional application and usage controls for procymidone, to control grey mould in wine grapes, were implemented by the Australian Pesticide and Veterinary Medicine Authority. The revised controls have resulted in the phase-out of procymidone use on wine grapes in Australia.

[a] C = chardonnay, P = pinot, M = merlot, S = shiraz, R = Riesling, CS = cabernet sauvignon.

3.4. Fenhexamid

Fenhexamid is a contact (non-systemic) hydroxyanilide fungicide, used for controlling grey mould. Fenhexamid is registered for a 21-day withholding period on grapes (APVMA, 2008). There is a label restriction with a maximum of two applications per season. Application diary records show one application 3–4 months prior to harvest. Seed oil samples showed the highest level of residues but these were less than 10% of the Australian MRL. Given the existing usage patterns, fenhexamid is a low risk fungicide.

3.5. Pyrimethanil

Pyrimethanil is a contact anilinopyrimidine fungicide used for control of grey mould. The withholding period for pyrimethanil application on grapes is 7 days (APVMA, 2008). All samples were reported at less than 25% of the Australian MRL. Three of the six reported samples had application diary records which indicated application four months prior to harvest. It is likely that the three samples without application diary records were also treated 3–4 months prior to harvest. Following this usage pattern, pyrimethanil is a low risk fungicide for residues in seed oil and marc.

3.6. Captan

Captan is a contact multi-site phthalimide fungicide. The registered product has a withholding period of 7 days on grapes and is used for control of grey mould, black spot (*Elsinoe ampelina*), downy mildew (*Plasmopara viticola*) and phomopsis leaf blight (*Phomopsis viticola*) (APVMA, 2008). Up to five applications are allowed per season. Three of the seven samples showed captan use more than once in the season. All applications were at a minimum of 45 days withholding period and reported residues were all less than 20% of the Australian MRL. As expected, the sample with the highest residue level (1.6 mg/kg in seed oil) was the sample with the shortest actual withholding period. Captan is a low risk fungicide in the samples tested with the reported usage patterns.

3.7. Iprodione

Iprodione is a contact dicarboximide fungicide used for controlling grey mould (*B. cinerea*). The withholding period is 7 days with a recommendation to limit application to a maximum of two sprays per season (APVMA, 2008). None of the available application diaries showed applications of iprodione; however, iprodione residues were detected in samples for which application diaries were not available. Two of the reported seed oil samples contained 16 mg/kg of iprodione, or 75% of the Australian MRL. It is likely that iprodione was used with an application pattern similar to procymidone. Results show that iprodione is a high-risk fungicide for seed oil, marc, seed meal and grapes in these samples.

3.8. Trifloxystrobin

Trifloxystrobin is a strobilurin type fungicide, used for controlling powdery mildew (*Uncinula necator*) and suppression of downy mildew. This fungicide is mesostemic in action and it also has translaminar activity and can be redistributed by superficial vapour movement (Tomlin, 2003). The label withholding period is 35 days. Label instructions limit usage prior to grape bunch closure (APVMA, 2008), thus it is unlikely that application would be made three months prior to harvest. This would include the samples for which no application diary records were available. Five samples had application diary records indicating application had actual withholding periods of more than one hundred days prior to harvest. With these application patterns, it is unlikely that grape, marc, seed oil or meal would be at 50% of the Australian MRL, so trifloxystrobin is a low risk fungicide for the production of grape seed oil and seed meal for commercial purposes. The reported levels are lower than for most fungicides, due to the exceptional sensitivity of the LC–MS/MS instrument for the determination of trifloxystrobin.

3.9. Pyraclostrobin ($\log K_{ow} = 4.0$)

Pyraclostrobin is used for controlling powdery mildew and downy mildew. The label withholding period is 21 days. The label stipulates a maximum of three applications at 10–14 day intervals, commencing at flowering (APVMA, 2008), therefore it is unlikely to be applied within three months of harvest. Two samples of seed oil contained pyraclostrobin residues at 10% of the Australian MRL. Pyraclostrobin is a low risk fungicide providing label usage is followed. Pyraclostrobin is considered to be a lower risk fungicide than trifloxystrobin, as the MRL for this similar fungicide is four times lower (0.5 mg/kg).

3.10. Metalaxyl ($\log K_{ow} = 1.75$)

Metalaxyl is a phenylamide–acylalanine systemic fungicide with protective and curative properties with a label withholding period of 7 days (APVMA, 2008). It is registered for use in controlling downy mildew and is absorbed through leaves, stems and roots. Label instructions limit application to a maximum of four per season. Application diary records for three samples showed one application at two months minimum prior to harvest. Residues were less than 10% of the Australian MRL for grapes and by-products. Metalaxyl is low risk given current usage patterns.

3.11. Quinoxyfen ($\log K_{ow} = 4.7$)

Quinoxyfen is registered for protective (not curative) action against powdery mildew and has a withholding period of 14 days (APVMA, 2008). Label advice limits applications to three per season. Reported levels are less than 10% of the Australian MRL. Quinoxyfen is low risk given the current usage pattern.

3.12. Chlorothalonil ($\log K_{ow} = 2.9$)

Chlorothalonil is a multi site-chloronitrile non-systemic foliar fungicide registered for protective action against downy mildew, black spot and grey mould. The label withholding period is 14 days (APVMA, 2008). Application diaries indicate that it was applied to at least seven samples and records show that the minimal actual withholding period was 100 days. It was detected in three of the grape samples at low levels but not detected in seed oil, marc or seed meal samples. It is extremely unlikely that the Australian MRL of 10 mg/kg would be contravened in grapes or grape by-products under these application conditions.

3.13. Penconazole ($\log K_{ow} = 3.7$)

Penconazole is a DMI:triazole systemic fungicide registered for control of powdery mildew. The label withholding period is 14 days. Application is permitted up to three times per season (APVMA, 2008). The Australian MRL is 0.1 mg/kg. It was applied to a minimum of four samples but not detected in any of the samples analysed. Records showed that the minimum actual withholding period was 84 days with no repeat applications. Due to the low MRL, penconazole would represent a risk of contravening MRL residue levels in grape and grape by-products; however, for this reason, growers probably use the chemical with a maximum possible withholding period.

3.14. Triadimenol (log K_{ow} = 3.2)

Triadimenol is a systemic DMI:triazole fungicide with protective, curative and eradicant action used for control of powdery mildew. Its label withholding period is 7 days (APVMA, 2008) and the Australian MRL is 0.5 mg/kg. Application is listed on the label for the period until the fruit is set, so it is unlikely that residues would be reported at harvest. Application diaries indicated that triadimenol was applied to two samples with withholding periods listed as 125 and 146 days, however, triadimenol was not detected in any of the samples analysed.

3.15. Myclobutanil (log K_{ow} = 2.9)

Myclobutanil is a systemic DMI:triazole fungicide with protective and curative action, used to control powdery mildew. The label withholding period is 14 days (APVMA, 2008) and the Australian MRL 1 mg/kg. Applications are restricted to three per season; however, it is unlikely that more than one application was made. Application diaries indicate that myclobutanil was applied to one sample; however, it was not detected in any of the samples analysed.

3.16. Spiroxamine

Spiroxamine is a morpholine:spiroketalamine systemic fungicide with protective, curative and eradicant action, used to control powdery mildew. It is composed of two isomers, A and B, with a log K_{ow} = 2.8 and log K_{ow} = 2.9, respectively. The label withholding period is 28 days (APVMA, 2008) and application was listed in three application diaries at actual withholding periods of 119, 161 and 168 days. Spiroxamine was not detected in any samples.

Table 3 shows data for the diacylhydrazine insecticide, tebufenozide, and the oxydiazine insecticide, indoxacarb. These compounds are used to control light brown apple moth. Withholding periods are 21 days and 8 weeks, respectively.

3.17. Tebufenozide

This was listed in two application diaries (100 and 115 days prior to harvest) and residues were detected in six samples. For the samples with application diaries, the residues were detected in the seed oil up to 10% of the MRL. However, for sample CH14, where the application was not recorded, the residue level in the seed oil is 30% of MRL. It is possible that tebufenozide residues in seed oil for this sample would be at the MRL at the minimum withholding period.

3.18. Indoxacarb

This was listed in four sample application diaries and was reported in these samples in addition to three other samples. The actual withholding periods are listed as 81–140 days, in excess of the minimum label withholding period of 56 days. Two samples of seed oil without application diary records show residues at 40% of the MRL. It is possible that MRL levels of indoxacarb would occur at the minimum withholding period in the seed oil.

3.19. Spinosad

Spinosad is a biopesticide used for controlling light brown apple moth, comprising a mixture of two isomers, A and D. The log K_{ow} is 4.0 for the A isomer and 4.5 for the D isomer at pH 7 (Tomlin, 2003). The log K_{ow} for both isomers decreases with decreasing pH. The Australian MRL is 0.5 mg/kg. Spinosad was identified in two application diaries but was not detected in any of the samples. Applications were at 84 and 105 days prior to harvest.

The data in Table 4 show that residue concentrations, for eight of the listed pesticides with acceptable sample sets, are significantly higher in seed oil than in fruit. The residues are also higher in marc than in fruit and by calculation, higher in seed oil than marc. A similar pattern of residue levels for the fungicides, fludioxinil, quinoxyfen and pyraclostrobin, was also evident for a smaller number of samples. The two systemic fungicides (procymidone and cyprodinil) have the highest concentration factor in seed oil relative to fruit and marc. This suggests that there is a partitioning of the highly oil-soluble (log K_{ow} > 2.5) fungicides into the oily components of the

Table 4
Mean concentration ratios of pesticides in oil/fruit and marc/fruit.

Pesticide	log K_{ow}	Number of samples	Oil/fruit	Marc/fruit

grape vine, and that systemic activity facilitates transfer to the seed oil. This supports the hypothesis that oil-soluble pesticides, removed from must by clarification, are present in the seed oil. Alternatively, polar (water-soluble) pesticides are more likely to be retained in the wine and metabolised by fermentation.

For cyprodinil (Table 2), the increase in residue levels from fruit to seed oil ranged from 8 (CH9, CH10) to 64 (CH8). Similarly, for procymidone (Table 2), the increase in residue levels from fruit to seed oil ranged from 4 (CH4) to 40 (CH8, CH14).

4. Conclusion

This study confirms that oil-soluble ($\log K_{ow} > 2.5$) fungicides and insecticides applied to wine grapevines are concentrated in the grape seed oil. The concentrations of the pesticide residues in the seed oil relative to marc and fruit were highest for the systemic fungicides, procymidone and cyprodinil. Thus oil-solubility and systemic action are confirmed as key risk factors for residue contamination in grape marc and seed oil. Thus the pattern of minimal applied pesticide residues in wine reported in the literature is logical, as these mainly oil-soluble pesticides are concentrated in the seeds, a major component of marc.

Acknowledgements

The authors would like to thank Greg Jarratt, Jamie Hewett, Andrew Fleming and Richard Shenfield, of Fosters Ltd., Fred Davies of Stoney Creek Oil Products P/L for supplying samples, Dr. Jun Du, Pei Zhang and Colin Cook of DPI-Werribee for technical support and Dr. Craige Trenerry for assistance in preparing the manuscript. This project was funded by the Department of Primary Industries (Victoria) through the Naturally Victorian Initiative.

Radical scavenging

ABSTRACT

An exopolysaccharide (EPS) fraction isolated from mycelial culture of a *Cordyceps sinensis* fungus, designated EPS-1 with an average molecular weight (MW) of 38 kDa, was hydrolysed in dilute sulphuric acid solution at pH 1 and 90 °C, yielding two major MW fractions, 3.0 kDa and 30 kDa, respectively. While the proportion of lower MW fraction increased with the hydrolysis period (18% in 0.5 h and 92% in 10 h), the polydispersity (M_w/M_n) of EPS decreased steadily (from 1.47 initially to 1.10 in 10 h). The IR spectra of hydrolysed EPS fractions showed changes only in the C–O–C and C–O–H band peaks from that of EPS-1. These results suggest that the hydrolysis of EPS in the acidic solution caused the EPS degradation mainly by cleaving the glycosidic linkage but no change in the primary molecular structure. The hydrolysed EPS fractions had much higher (30–80%) antioxidant and radical-scavenging activities.

1. Introduction

Cordyceps sinensis (Berk.) Sacc., generally called Cordyceps or Dong-Chong-Xia-Cao (winter worm–summer grass) in Chinese, is a precious and famous medicinal fungus in China which has been used as a general tonic and therapeutic herb by the Chinese over hundreds of years. Cordyceps has shown a broad range of health effects on the immune, kidney, liver and cardiovascular functions, and antitumor and antioxidation activities (Li & Tsim, 2004; Russell & Paterson, 2008; Zhu, Halpern, & Jones, 1998). Natural Cordyceps is a rare and endangered species insufficient to meet the demand, and mycelial fermentation is a more economical and sustainable process for production of *Cordyceps* mycelial biomass and polysaccharides. Polysaccharides represent a major class of bioactive compounds in Cordyceps and many other medicinal mushrooms which have anticancer and immunomodulation activities, and other notable health effects such as antioxidation and hypoglycemic activity (Li & Tsim, 2004).

Since oxidative stress evoked by reactive oxygen species (ROS) is harmful to human health and a potential cause of many human diseases (Halliwell & Gutteridge, 1998), the antioxidant properties of functional foods and herbal products are important for health protection and disease prevention. Numerous previous studies have examined the antioxidant and radical-scavenging activities of water extracts of natural Cordyceps and cultivated fungal mycelia (Dong & Yao, 2008; Li, Dong, & Tsim, 2001; Yamaguchi, Kagota, Nakamura, Shinozuka, & Kunitomo, 2000). As the major constituents of water extracts, polysaccharides are attributable to their antioxidant activities. A few studies have also shown the antioxidant activities of purified polysaccharide fractions isolated from *Cordyceps* species, such as the one isolated from *C. sinnesis* mycelia protecting against hydrogen peroxide-induced damage of PC12 cells in culture (Li et al., 2003), and the one from cultivated *C. militaris* fruit bodies scavenging hydroxyl radicals (Yu et al., 2007).

The application and efficacy of polysaccharides for health care is dependent not only on the chemical structure but also on the molecular size or molecular weight (MW), which has a direct influence on solubility and viscosity in solution, and usually also on the bioactivity (Shahidi, Arachchi, & Jeon, 1999). Most of the polysaccharides isolated from various *Cordyceps* species are of high average MW over 10 kDa, usually from 50 to 1000 kDa (Leung, Zhao, Ho, & Wu, 2009). Moderate degradation of the high-MW polysaccharides may increase the water solubility and decrease the viscosity in solution, thus improving the medicinal properties. Moderate degradation has also been shown to improve the antioxidant activities of natural and modified polysaccharides, such as ulvan (from seaweeds, Chorophyta) (Qi, Zhao, Zhang, & Zhao, 2005) and chitosans (Xing, Liu, Guo, & Yu, 2005). While the polymer degradation can usually be accomplished through chemical, enzymatic and

thermal processes, the hydrolysis by dilute acids is a simple and effective method, and not destructive to the primary chemical structures of biopolymers (Soldi, 2005).

Cs-HK1 is a fungal species isolated from natural Cordyceps fruiting body in our lab, and is a high producer of exopolysaccharides (EPS) in mycelial liquid culture (Leung, Zhang, & Wu, 2006). The EPS from the Cs-HK1 mycelial culture had a wide range of MW from 5 to over 200 kDa and showed moderate antioxidant activities (Leung et al., 2009). The present study was to examine the degradation of a high-MW EPS fraction isolated from Cs-HK1 mycelial culture by hydrolysis in dilute sulphuric acid. The molecular weight profiles of hydrolysed EPS fractions were analysed, and their antioxidant activities were measured by different assays.

2. Materials and methods

2.1. Chemicals

ABTS (2,2′-azinobis (3-ethylbenzothiazoline-6-sulphonic acid) and Trolox were purchased from Calbiochem/EMD (Gibbstown, NJ, USA), vitamin C (Vc, ascorbic acid) and assay kits for lipid peroxidation, hydroxyl and superoxide anion radicals from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). All reagents were of analytical grade. Aqueous media and reagent solutions were all prepared with distilled de-ionised water. Dry EPS fractions were stored in a desiccator at room temperature, and EPS solutions stored at 4 °C before use.

2.2. Preparation of EPS-1 fraction from Cs-HK1 mycelial culture

Cs-HK1 mycelial liquid culture was maintained in a stirred fermentor for 6–7 days; at the end of fermentation, the culture broth was spun down and the liquid medium was collected. Exopolysaccharide (EPS) was isolated from the liquid medium by ethanol precipitation. Details of the Cs-HK1 mycelial culture conditions and fermentation process, and the EPS isolation procedure can be found in Leung et al. (2006, 2009). The crude EPS isolated from the Cs-HK1 fermentation broth by ethanol precipitation contained about 70% carbohydrate and 20–25% protein, and the carbohydrate content was mainly composed of β-glucans.

The crude EPS fraction (ethanol precipitate) from the Cs-HK1 mycelial culture was purified through the following steps. It was first deproteinised with enzyme and Sevag reagent as described by Staub (1956). For enzyme deproteinisation, papain (lyophilised powder, from Sigma–Aldrich Chemical Co.) was applied at 1.5–2 U/mg EPS to the EPS solution at pH 6.4 and incubated at 60 °C for 3 h. The solution was then centrifuged and the supernatant was mixed with Sevag reagent (1-butanol/chloroform at 1:4 v/v) at 25 °C with constant stirring for 2 h. The deproteinised EPS solution (1 g/l) was then mixed with 1.5% (w/v) powdered activated carbon at 80 °C for 40 min and three times to remove the brown pigments. After removal of the activated carbon (by filtration), the EPS solution was dialysed (using 12–14 kDa membrane) against water for 48 h. The purified EPS solution was concentrated by vacuum evaporation and then lyophilised, which was designated as EPS-1 and used as the starting EPS material in the following acid hydrolysis experiments. The total carbohydrate content of EPS was determined by the phenol–sulphuric acid method using glucose as a standard (Dubois, Gilles, Hamilton, Rebers, & Smith, 1956).

2.3. Acidic hydrolysis of EPS

Acidic hydrolysis of EPS-1 was performed according to the procedure as described by Xu, Andrey, and Lari (2008) with slight modifications. EPS-1 was first dissolved in water at 0.1% (w/v) with constant stirring at 80 °C for 2 h, and then at room temperature overnight. For acid hydrolysis, each 20 ml of the EPS-1 solution was filled in a 50 ml centrifuge tube and the solution pH was adjusted to 1.0 by adding 1 M H_2SO_4. The tubes were capped and immersed in a water bath at 90 °C or other selected temperatures for 0.5–10 h. After the hydrolysis period, the acidic EPS solution was cooled down immediately in an ice-water bath and adjusted to neutral pH with 1 M NaOH solution.

2.4. Determination of intrinsic viscosity

The EPS samples were dissolved in water at a series of dilute concentrations, and the solution viscosity was measured with an Ubbelohde viscometer at 25 °C. The intrinsic viscosity $[\eta]$ of a sample was taken from the intercept of $\ln(\eta_r/C)$ versus C line, where η_r is the relative viscosity and C the concentration of sample solution (Chinese Pharmacopoeia Committee, 2002).

2.5. Measurement of molecular weight and IR spectra

The molecular weights (MW) of EPS samples were analysed by high-pressure gel permeation chromatography (HPGPC). The HPGPC system consisted of a Waters 1525 binary pump and a 2414 RI detector (Waters Co., Milford, MA, USA), and a series of two GPC columns, a TSK-GEL G-5000 PW xL column and a TSK-GEL G-3000 PW xL column (both of 7.8 mm × 300 mm dimension) (TOSOH Co., Japan). A solution of 0.02 M KH_2PO_4 was used as the elution solvent flowing at 0.6 ml/min. The samples were dissolved in the elution solvent at 2 mg/ml and filtered through 0.45 μm membrane before the injection. The MW calibration curve was generated with six linear dextran MW standards of molar masses ranging from 5.2 to 668 kDa (Sigma). The GPC spectra were analysed with the Breeze V3.3 software (Waters Co.) to derive the weight- and number-average MW, M_w and M_n of EPS samples.

The infrared (IR) spectrometry of EPS samples was performed in the 4000–800 cm^{-1} wave number region on a Vector 33 FTIR instrument (Bruker Co., Germany).

2.6. Antioxidant activity tests

The antioxidant properties of EPS fractions were measured with four different assays as described below for more comprehensive evaluation of their activities against lipid peroxidation and various free radicals (Halliwell & Gutteridge, 1998; Oyanagui, 1984). In these assays the EPS samples were predissolved in water and tested at various concentrations in parallel with water as the blank and vitamin C (Vc) as an antioxidant reference (positive control) (or Trolox as a reference in the TEAC assay).

The assays for inhibition of lipid peroxidation, and scavenging hydroxyl and superoxide anion radicals were performed using the commercial kits from Jiancheng Bioengineering Institute (Nanjing) according to the supplier's manuals. The lipid peroxidation assay kit was based on the peroxidation of linoleic acid and formation of malondialdehyde (MDA) with a peak absorbance at 520 nm. The hydroxyl radicals ($OH^{\cdot}$) in the assay kit were generated by the Fenton reaction (exhibiting a red colour with a peak absorbance at 550 nm); the assay reaction was performed at 37 °C in a water bath for 20 min. The superoxide anion radicals ($O_2^{\cdot-}$) in the assay kit were generated by the xanthine/xanthine oxidase reaction with 2,4-iodiphenyl-3,4-nitrophenyl-5-phenyl-tetrazolium chloride to form formazan, a coloured compound with a peak absorbance at 530 nm. After the assay reactions, the absorbance of assay solutions was measured and the inhibition or scavenging activity (in %) was represented by the percentage of absorbance decrease with the sample relative to the blank. TEAC (Trolox equivalent antioxi-

dant capacity) is the activity of a sample equivalent to Trolox in scavenging $ABTS^{\cdot+}$, a stable free radical (Rice-Evans, Miller, & Paganga, 1996), and was measured of the EPS fractions as described in Leung et al. (2009).

2.7. Statistical analysis

All hydrolysis experiments and antioxidant tests were performed in triplicate and the results were represented by mean ± standard deviation (SD). Statistical significance of the antioxidant tests was determined by Duncan's multiple-range test at $p < 0.05$.

3. Results

3.1. Molecular weights of EPS-1 and its hydrolysates

After a series of purification steps (deproteinisation, decolorisation and dialysis) of the crude EPS from the Cs-HK1 mycelial culture, a white, filamentous and water soluble solid was yielded, designated EPS-1 which had a total carbohydrate content of 90% and negligible protein, and an average MW of 38 kDa (M_w). As in our previous study (Leung et al., 2009), the total carbohydrate content (plus protein content) measured of the EPS was lower than 100% which was due probably to the incomplete acid hydrolysis of the EPS in the analytical procedure. Table 1 shows the weight- and number-average molecular weights and MW distribution of EPS-1 before and after the acid hydrolysis at a fixed temperature of 90 °C for various periods of time. The acidic hydrolysis of EPS-1 resulted in two major MW peaks of a higher M_w ranging from 26 to 36 kDa and a lower M_w about 3.0 kDa. The relative proportion (based on the GPC peak area) of lower MW fraction increased with the hydrolysis period, from 0% to 18% in 30 min (EPS-1A), and to 92% in 10 h (EPS-1D), indicating the increasing degree of EPS degradation in the acidic solution.

The polydispersity index M_w/M_n of EPS-1 fraction (Table 1, corresponding to the higher MW peak) decreased steadily and almost linearly with the hydrolysis time; the polydispersity indexes of all hydrolysed fractions were close to 1.0 at the lower MW peaks. This implies that acidic degradation led to a narrower or more uniform MW distribution of EPS fraction.

3.2. Decrease of EPS intrinsic viscosity by hydrolysis

Fig. 1 shows the time course of intrinsic viscosity [η] of EPS-1 undergoing hydrolysis in dilute sulphuric acid at three different temperatures from 25 to 90 °C. The intrinsic viscosity of EPS-1 decreased with time at all temperatures but more rapidly at a higher temperature, e.g., from the initial value of 4.83–1.55 dl/g at 90 °C in 10 h. The decrease in intrinsic viscosity is indicative of an increase in the degree of EPS degradation and the reduction of the average MW by acidic hydrolysis. The degradation rate increased with the hydrolysis temperature.

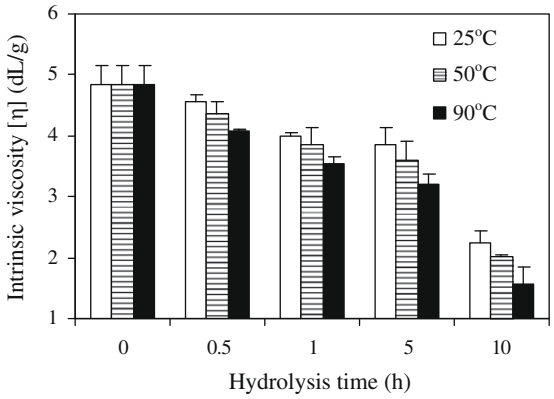

Fig. 1. Intrinsic viscosity time courses of EPS-1 in acidic solution (pH 1) at two different temperatures (significant difference between intrinsic viscosities at 25 °C and 90 °C at $p < 0.05$; error bars for SD, $n = 3$).

3.3. IR spectra of EPS-1 and its hydrolysates

Fig. 2 presents the IR spectra of the original EPS-1 and two hydrolysed fractions. The two EPS-1 hydrolysates (one collected at 0.5 h and the other at 10 h of hydrolysis time) had virtually an identical spectrum, indicating their identical molecular composition. In comparison with the EPS-1 spectrum, the spectra of hydrolysed EPS fractions show a close match in the higher wave number region over 1200 cm^{-1}, but some notable changes in the lower wave number region. In particular, an absorption spike appeared at 1000 cm^{-1} which represents the first order δO–H bond; the band peak at 1144 cm^{-1} which represents the C–O stretching vibration and the second order δO–H in C–O–H was significantly enhanced, due probably to the cleavage of a γC–O–C bond. These spectral data suggest that the major change in the EPS molecule during acid hydrolysis was an alteration of the C–O bond. On the other hand, none of the two characteristic absorption bands associated with a $C–O–SO_3$ group (at 1258 cm^{-1} for the asymmetrical S=O stretching vibration and at 810 cm^{-1} for the symmetrical C–O–S vibration) is present in the spectra of EPS-1 hydrolysates, indicating that no sulphation occurred in the dilute sulphuric acid solution. Overall the IR data (Fig. 2) suggest that the depolymerisation of EPS-1 in the acidic solution mainly caused the breakage of the glycosidic linkages but no significant change of the basic chemical structure of the EPS molecules.

3.4. Enhanced antioxidant activities of EPS-1 by acid hydrolysis

Fig. 3A–C shows the three antioxidant activity indexes of the original and the hydrolysed EPS-1 fractions, inhibition of lipid

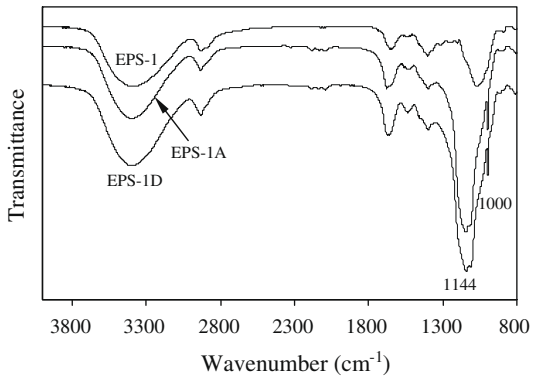

Fig. 2. IR spectra of EPS-1 and two hydrolysed fractions, EPS-1A (0.5 h hydrolysis) and EPS-1D (10 h hydrolysis).

peroxidation (Fig. 3A), scavenging of hydroxyl radicals (Fig. 3B) and superoxide anion radicals (Fig. 3C), which all increased with the concentration from 10 to 120 μg/ml. The three activity indexes exhibited a unanimous and consistent trend of increasing activity with the increasing degree of EPS degradation from EPS-1A to EPS-1D. Similarly, the Trolox equivalent antioxidant capacity (TEAC) of the EPS-1 fractions (Fig. 3D) also showed a steady increase with the degree of EPS degradation, from 18.5 μmol of the original EPS-1 to 30 μmol of EPS-1A and finally to 43.4 μmol Trolox/g of EPS-1D.

Table 2 presents the IC_{50} values derived from the four antioxidant activity assays of the EPS fractions and the antioxidant references. In all assays the hydrolysed EPS fraction EPS-1D has a much lower IC_{50} value and is thus a more potent antioxidant than the original EPS-1. Based on the IC_{50} values, the hydrolysed EPS-1D fraction had more potent activity for scavenging the superoxide anion and $ABTS^{\cdot+}$ radicals, but less potent activity on lipid peroxidation and hydroxyl radicals. The IC_{50} values on superoxide and $ABTS^{\cdot+}$ radicals are close to those of the respective antioxidant references vitamin C and Trolox, suggestive of a great potential of the degraded low-MW EPS fraction as an effective antioxidant for dietary and therapeutic applications.

4. Discussion

The generation of a single low-MW peak from the acidic degradation of EPS-1 is an indication of specific and non-random chain scission in the EPS molecules (Table 1). Such a mode of degradation is favourable for producing a uniform MW polysaccharide fraction. In addition, the change of M_w/M_n during polymer degradation is dependent upon the chain scission mechanisms, of which the central-point scission usually causes a lowering of the polydispersity M_w/M_n but the random chain scission does not change the M_w/M_n (Emsley & Heywood, 1995). According to these rules of thumb, central-point scission is assumed as the chief mode of chain cleavage for the degradation of EPS-1 in the acidic solution.

Because of the relatively mild condition in the weak acid, the degradation only occurred to the most vulnerable points of the polymer chain. The susceptibility of the glycosidic bond to acidic degradation may be attributable to its acetal structure with the glycoside oxygen atom accepting H^+ to form a protonated glycosidic bond, weakening the C–OR bond. Accordingly, we propose the major reaction steps as shown in Fig. 4 for the EPS-1 hydrolysis in the acidic solution. The reaction starts with the cleavage of the reductive C–O bond in the glycosidic linkages, and the resultant fragment is protonated to form a cationic intermediate, which is neutralised by OH^- to form a neutral polysaccharide. After the acidic degradation, more reductive terminals (–O–H) in the PS molecule are exposed which can form hydrogen bonds with other active groups in the solution.

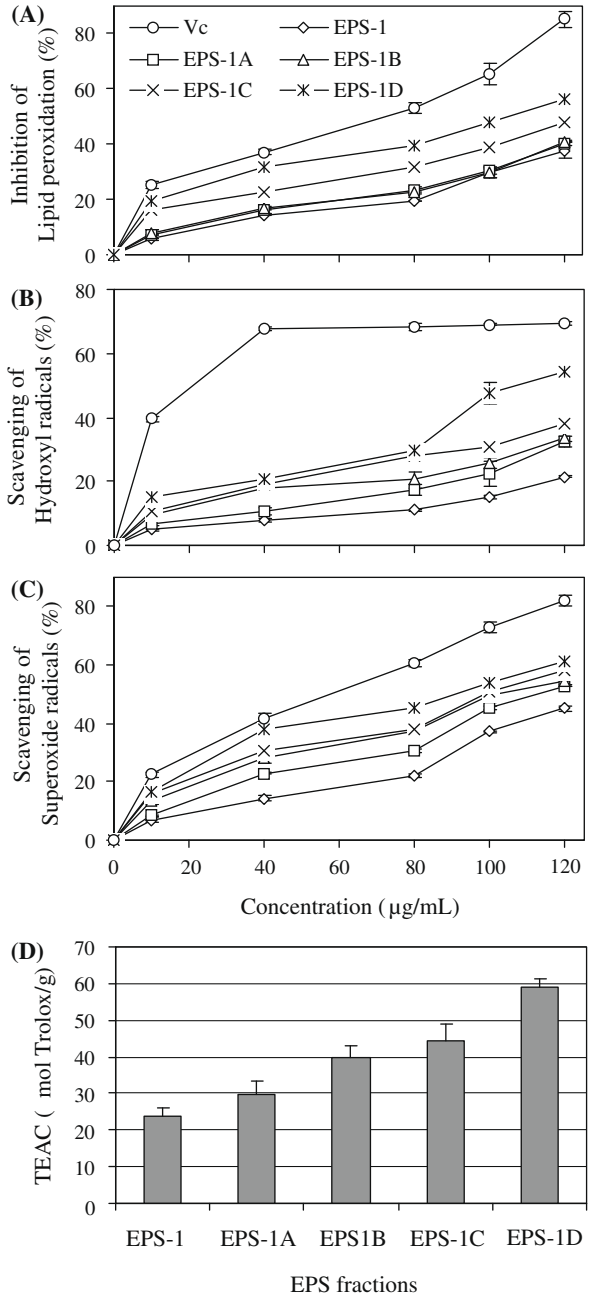

Fig. 3. Antioxidant activity indexes of EPS-1 and hydrolysed fractions: (A) inhibition of linoleic acid peroxidation; (B) scavenging of hydroxyl radicals; (C) scavenging of superoxide anion radicals; (D) Trolox equivalent antioxidant capacity of EPS-1 and its hydrolysed fractions (error bars representing SD, $n = 3$).

It is widely believed that reactive oxygen species (ROS) are involved in the pathogenesis of various diseases (Halliwell & Gutteridge, 1998). Therefore antioxidant activity is of broad significance for the therapeutic and health-promoting functions of many natural and medicinal products. In particular, lipid peroxidation caused by ROS is the culprit of several human diseases such as coronary arteriosclerosis, diabetes mellitus, aging and carcinogenesis (Negre-Salvayre, Coatrieux, Ingueneau, & Salvayre, 2008). Lipid peroxidation in the cell membrane involves the formation and propagation of lipid radicals, the uptake of oxygen, and rearrangement of the double bonds in unsaturated lipids, eventually leading to the destruction of membrane lipids and the production of

peroxides such as MDA. Antioxidants can prevent or slow down the lipid peroxidation by accepting or reacting with the ROS. Hydroxyl radical ($OH^{\cdot}$) is the most reactive ROS able to induce severe damage to biomolecules; superoxide anion (O_2^{-}) radicals are also harmful to cellular components directly or as a precursor for more active ROS (Chance, Sies, & Boveris, 1979; Halliwell & Gutteridge, 1998).

A variety of assay methods and activity indexes is available for measuring different materials in different systems (Oyanagui, 1984; Schlesier, Harwat, Böhm, & Bitsch, 2002). Because of the multiplicity and complexity of oxidation and antioxidation processes, several assays are needed for a comprehensive and unequivocal evaluation of the antioxidant activity of a sample. In our present study, we employed four different in vitro assays to evaluate and compare the antioxidant activities of the EPS fractions, all of which showed consistently a dramatic enhancement of the antioxidant activities by acidic degradation of the high-MW EPS to lower MW fractions. Similarly, Li et al. (2001) have also found that lower MW polysaccharides fractions isolated from Cordyceps fungi had stronger scavenging effects on superoxide anion radicals. Xing et al. (2005) reported that the hydroxyl radical-scavenging activity of lower MW chitosan fractions (9 kDa) was much higher than that of high-MW fractions (760 kDa) Although the antioxidant properties of natural polysaccharides from various sources such as medicinal fungi and mushrooms have been widely evaluated, the antioxidant activity to molecular structure relationship is still not well understood. Among the functional groups of a polysaccharide molecule, the hydroxyl group is the most possible player in the antioxidation action by donating electrons to reduce the radicals to more stable forms and/or by directly reacts with the free radicals to terminate the radical chain reaction (Lindsay, 1996). In this sense, the lower MW polysaccharide molecules have more reductive –OH terminals (on per unit mass basis) to accept and eliminate the free radicals.

In conclusion, an exopolysaccharide (EPS) about 38 kDa MW isolated from *C. sinensis* Cs-HK1 mycelial culture was hydrolysed in an acidic solution to 3.0 kDa MW. The hydrolysed EPS fraction had a lower polydispersity or narrower MW distribution. The low-MW EPS fraction had much higher antioxidant and radical-scavenging activities due perhaps to an increase in the number of hydroxyl groups available for reacting with the radical species. Further investigation is worthwhile on the degradation mechanism, and the structure to activity relationships. In addition, the antioxidant activity of hydrolysed EPS fractions must be examined in biological systems such as cell cultures and animals to prove and understand their health effects and potential value.

Vitamin C

ABSTRACT

Red pepper has been recognised as an excellent source of antioxidants, being rich in ascorbic acid and other phytochemicals. Drying conditions, particularly temperature, leads to pepper modifications that can cause quality degradation. In this work, the effects of process temperatures between 50 and 90 °C on physico-chemical properties, rehydration, colour, texture, vitamin C, antioxidant capacity and total phenolics during the drying of red pepper were studied. The rehydration ratio decreased with temperature and the maximum water holding capacity was achieved at 50 °C. Both vitamin C content and the total phenolic content decreased as air-drying temperature decreased. The radical scavenging activity showed higher antioxidant activity at high temperatures (i.e. 80 and 90 °C) rather than at low temperatures (i.e. 50, 60 and 70 °C). Chromatic parameters (L^*, a^*, b^*, C^* and $H°$), non-enzymatic browning compounds and extractable colour were affected by drying temperature, which contributed to the discolouring of pepper during this process.

1. Introduction

The pepper (*Capsicum annuum*, L.), indigenous to South and Central America, has been introduced worldwide. In particular, red pepper var. Hungarian, also known as Sweet Banana, is a very important product in the manufacture of paprika in different regions of the word. This pepper is highly appreciated for its flavour and colour, being the latter the main quality attribute that determines its overall quality and consequently its final market price (Krajayklang, Klieber, & Dry, 2000). Carotenoids are responsible for the colour of pepper and their contents are related to variety, ripeness and technological factors (Deepa, Kaura, George, Singh, & Kapoor, 2007; Gnayfeed, Daood, Biacs, & Alcaraz, 2001). Carotenoids are natural pigments responsible for the diverse colours in fruits and vegetables and are abundant in peppers. The main pigments in peppers are β-carotene, lutein and capsanthin and they are predominantly provitamin A (Howard, 2001; Rodriguez-Amaya, Kimura, Godoy, & Amaya-Farfan, 2008; Topuz & Ozdemir, 2007). Furthermore, red pepper is an excellent source of vitamin C (Guil-Guerrero, Martinez-Guirado, Rebolloso-Fuentes, & Carrique-Pérez, 2006; Topuz & Ozdemir, 2007) and polyphenols, particularly flavonoids, quercetin and luteolin (Chuah et al., 2008; Materska & Perucka, 2005). The antioxidant activity of phenolics is mainly due to their redox properties which allow them to act as reducing agents, hydrogen donors, single oxygen quenchers and metal chelators (Deepa et al., 2007). Thus, all the mentioned compounds show antioxidant activity as potential action against certain cancers, stimulate the immune system, prevent cardiovascular diseases and delay the aging process, amongst other biological activities (Chuah et al., 2008; Podsedek, 2007).

Dehydration is one of the most widely used methods for fruits and vegetables preservation. Its main objective is the removal of water to the level at which microbial spoilage and deterioration reactions are minimised. However, it is well known that during hot-air drying, vegetables undergo physical, structural, chemical and nutritional changes that can affect quality attributes like texture, colour, flavour, and nutritional value (Di Scala & Crapiste, 2008).

Amongst others, the acceptability of dried products depends mainly on their structural properties, like texture, which is one of the attributes used by consumers in judging their quality. Destruction of the cellular system is one of the most important physical and structural changes that occur during drying (Crapiste,

doi:10.1016/j.foodchem.2009.04.066

2000; Yadollahinia, Latifi, & Mahdavi, 2009). Moreover, dehydrated pepper must be rehydrated for consumption of prepared foods like soups, sauces, pizzas and other foodstuffs. Rehydration behaviour has been considered as a measure of the induced damage in the material during drying, such as integrity loss and reduction of hydrophilic properties, which decrease the rehydration ability (Marques, Prado, & Freire, 2009). Theoretically, if there are no adverse effects on the integrity of the tissue structure, it should absorb water to the same moisture content as the initial product before drying (Senadeera, Bhandari, Young, & Wijesinghe, 2000, chap. 6). Rapid and complete rehydration is very important for dried products. Rehydration capacity is affected significantly by drying conditions, pretreatments prior to drying and textural characteristics of dried products. Likewise, drying can diminish the osmotic properties of cell walls; as a result, an increase in water absorption and volume occurs due to the swelling of hydrophilic materials such as starch, cellulose, and pectic materials (Kaymak-Ertekin, 2002). Rehydration is maximised when structural disruption at the cellular level is minimized (Crapiste, 2000).

The basic requirements for a vegetable dryer are that it must achieve the required amount of drying in a reasonable time, obtain a product of acceptable quality, minimising operative costs (Kiranoudis, Maroulis, Marinos-Kouris, & Tsamparlis, 1997). Besides, the increasing demand for high-quality shelf-stable dried products requires the optimisation of the drying process conditions, especially temperature, with the purpose of accomplishing not only the efficiency of the process but also the final quality of the dried product (Banga, Balsa-Canto, Moles, & Alonso, 2003). Thus, from an engineering point of view, the control of this variable is a challenging problem that demands the evaluation of many interconnected non-linear mass and heat transport phenomena in a system with variable properties, shrinkage and modifications of quality attributes (Crapiste, 2000).

Therefore, the aim of this work was to study the effect of air-drying temperature on physico-chemical properties, rehydration ability (rehydration ratio (RR) and water holding capacity), colour development, texture (firmness) and antioxidant capacity (phenolic and ascorbic acid content) that occurred during the drying process of red pepper var. Hungarian.

2. Materials and methods

2.1. Sample preparation and drying process

Red peppers were grown and harvested in Salamanca, Chile, and stored at 4 °C before processing for a maximum time period of five days. The samples were selected visually by colour, size and freshness, and with no sign of mechanical damage. Then, they were cut into slabs of 4.0 ± 0.2 mm in thickness. The samples were dried in a pilot-scale convective dryer at five inlet temperatures 50, 60, 70, 80 and 90 °C (Vega-Gálvez, Lemus-Mondaca, Bilbao-Sainz, Yagnam, & Rojas, 2008a). The air flow rate was 2.0 ± 0.1 m/s. Each experiment was carried out in triplicate.

2.2. Physico-chemical analysis

The crude protein content was determined using the Kjeldahl method with a conversion factor of 6.25 (AOAC No. 960.52). The lipid content was analysed gravimetrically following Soxhlet extraction (AOAC No. 960.39). The crude fibre was estimated by acid/alkaline hydrolysis of insoluble residues (AOAC No. 962.09). The crude ash content was estimated by incineration in a muffle furnace at 550 °C (AOAC No. 923.03). The available carbohydrate was estimated by difference. The equilibrium moisture content was determined by means of AOAC method No. 934.06. All methodologies followed the recommendations of the Association of Official Analytical Chemists (AOAC (1990)). The pH was measured using an EXTECH Instruments microcomputer pH-vision 246072 (Waltham, Massachusetts, USA); the level of titratable acidity was expressed as malic acid. The water activity (a_w) was measured at 25 °C by means of a water activity instrument (Novasina, model TH-500, Pfäffikon, Lachen, Switzerland). Soluble solids were measured using a refractometer (ABBE, 1T, Tokio, Japan) which measures refraction indices both of solid and liquid samples in a fast and accurate way and its scale ranges from 0.0 to 95 °Brix. All measurements were done in triplicate.

2.3. Rehydration analysis

The dried pepper slabs were placed in distiled water at 40 °C for 6 h, using a solid to liquid ratio of 1:50. The samples were then removed, drained for 30 s, and weighed. All measures were done in triplicate. The rehydration ratio (RR) was calculated according to Eq. (1) and expressed as grams of water absorbed per gram dry matter. The water holding capacity (WHC) was determined by centrifuging the rehydrated samples at 3500×g for 15 min at 20 °C in tubes fitted with a centrally placed plastic mesh which allowed water to drain freely from the sample during centrifugation. The water holding capacity was calculated from the amount of water removed following Eq. (2), according to Vega-Gálvez, Lemus Mondaca, Bilbao-Sáinz, Fito, and Andrés (2008b):

$$\mathrm{RR} = \frac{W_{\mathrm{reh}} * X_{\mathrm{reh}} - W_{\mathrm{dried}} * X_{\mathrm{dried}}}{W_{\mathrm{dried}} * (1 - X_{\mathrm{dried}})} \quad (1)$$

$$\mathrm{WHC} = \frac{W_{\mathrm{reh}} * X_{\mathrm{reh}} - W_l}{W_{\mathrm{reh}} * X_{\mathrm{reh}}} * 100 \quad (2)$$

where W_{reh} is the weight of the sample after the rehydration process, X_{reh} is the corresponding moisture content on a wet basis, W_{dried} is the weight of the sample after the drying process, X_{dried} is the corresponding moisture content on a wet matter and W_l is the weight of the drained liquid after centrifugation.

3. Quality parameters

3.1. Surface colour measurement

Surface colour of the samples was measured using a colorimeter (HunterLab, model MiniScan™ XE Plus, Reston, VA, USA). Colour was expressed in CIE L^* (whiteness or brightness), a^* (redness/greenness) and b^* (yellowness/blueness) coordinates, standard illuminant D_{65} and observer 10° (Vega-Gálvez et al., 2008b). Five replicate measurements were performed and results were averaged. In addition, colour intensity (Chroma), total colour difference (ΔE) and hue angle were calculated using the following Eqs. (3)–(5), where L_o, a_o and b_o are the control values for peppers (Sigge, Hansmanw, & Joubert, 2001).

$$\mathrm{Chroma} = (a^{*2} + b^{*2})^{0.5} \quad (3)$$

$$\Delta E = \left[(a^* - a_0)^2 + (b^* - b_0)^2 + (L^* - L_0)^2\right]^{0.5} \quad (4)$$

$$\mathrm{Hue\ angle} = tg^{-1}(b^*/a^*) \quad (5)$$

3.2. Extractable colour

The determination was carried out according to the methodology proposed by the American Spice Trade Association (ASTA (1995)). Rehydrated red pepper slabs (0.5 g) were kept in about 50 ml acetone (Sigma Chemical CO., St. Louis, MO, USA) in 100 ml screw-cap jars maintained in the dark for 16 h at ambient temperature. An aliquot of this solution was used for the

spectrophotometric measurement (Spectronic® 20 Genesys™, Illinois, USA) at 460 nm. ASTA units were calculated as follows:

$$\mathrm{Cv} = \frac{A * 16,4 * I_F}{W_{\mathrm{reh}}} \quad (6)$$

where A is the absorbance of the acetone extract; I_F is the instrument correction factor calculated from a pattern solution of potassium dichromate and W_{reh} is the sample weight.

The colour loss value (%) was calculated according to the following equation:

$$(\%)\text{Colour loss value} = \frac{Cv_o - Cv_T}{Cv_o} \times 100 \quad (7)$$

Cv_o is the ASTA colour value of the fresh pepper and Cv_T is the ASTA colour value of the rehydrated peppers dried at different temperatures.

3.3. Determination of non-enzymatic browning index

The methodology applied for determination of non-enzymatic browning compounds (NEB) solubilised in the rehydration water was that proposed by Vega-Gálvez et al. (2008b). The rehydration water was first clarified by centrifugation at 3200×g for 10 min. The supernatant was diluted with an equal volume of ethanol (Sigma Chemical CO., St. Louis, MO, USA) at 95% and centrifuged again at 3200×g for 10 min. The browning index (absorbance at 420 nm) of the clear extracts was determined in quartz cuvettes using a spectrophotometer (Spectronic® 20 Genesys™, Illinois, USA). All measurements were done in triplicate.

3.4. Determination of vitamin C

Vitamin C (AA) was determined based upon the quantitative discolouration of 2,6-dichlorophenol indophenol (Merck KgaA, Darmstadt, Germany) titrimetric method as described in AOAC methodology No. 967.21 (AOAC, 2000). Comparative evaluations of vitamin C stability in fresh and rehydrated pepper were carried out, where 5.0 ± 0.1 g of each sample was weighed, crushed and diluted in 1 l distiled water. The vitamin C content was expressed as mg AA retained/100 g dry matter. All measurements were done in triplicate.

3.5. Determination of total phenolic content

Total phenolic content (TPC) was estimated as gallic acid equivalents (GAE) as described by Folin–Ciocalteau's (FC) method with modifications (Chuah et al., 2008). An aliquot (0.5 ml) of the pepper extract solution is transferred to a glass tube; 0.5 ml of reactive FC is added after 5 min; 2 ml of Na_2CO_3 (200 g/l) are added and shaken. After 15 min of incubation at ambient temperature, 10 ml of ultra-pure water was added and the formed precipitate was removed by centrifugation during 5 min at 4000×g. Finally, the absorbance was measured in an spectrophotometer (Spectronic® 20 Genesys™, Illinois, USA) at 725 nm and compared to a GA calibration curve. Results were expressed as mg acid gallic/100 g dry matter. All reagents were purchased from Merck (Merck KGaA, Darmstadt, Germany), and all measurements were done in triplicate.

3.6. Determination of DPPH radical scavenging activity

Free radical scavenging activity of the samples was determined using the 2,2,-diphenyl-2-picryl-hydrazyl (DPPH) method (Turkmen, Sari, & Velioglu, 2005) with some modifications. Different dilutions of the extracts were prepared in triplicate. An aliquot of 2 ml of 0.15 mM DPPH radical in ethanol was added to a test tube with 1 ml of the sample extract. The reaction mixture was vortex-mixed for 30 s and left to stand at room temperature in the dark for 20 min. The absorbance was measured at 517 nm, using a spectrophotometer (Spectronic® 20 Genesys™, Illinois, USA). The spectrophotometer was equilibrated with 80% (v/v) ethanol. Control sample was prepared without adding extract. All solvents and reagents were purchased from Sigma (Sigma Chemical CO., St. Louis, MO, USA). Total antioxidant activity (TAA) was expressed as the percentage inhibition of the DPPH radical and was determined by the following equation:

$$(\%)\ \mathrm{TAA} = \left(1 - \frac{\mathrm{Abs}_{\mathrm{sample}}}{\mathrm{Abs}_{\mathrm{control}}}\right) \times 100 \quad (8)$$

where TAA is the total antioxidant activity and Abs is the absorbance.

IC_{50}, which is the concentration required to obtain a 50% antioxidant capacity, is typically employed to express the antioxidant activity and to compare the antioxidant capacity of various samples. IC_{50} was determined from a graph of antioxidant capacity (%) against amount of extract (mg).

3.7. Determination of firmness

The property firmness, i.e. the maximum force applied to puncture the pepper tissue, was measured as an indicator of texture. Firmness of samples was measured using a Texture Analyzer (Texture Technologies Corp., TA, XT2, Scardale, NY, USA). The puncture diameter was 2 mm, with a travel distance of 20 mm and 1.7 mm/s test speed. The maximum force was measured by making one puncture in each rehydrated pepper sample, using 10 slabs per treatment. The mean value of maximum firmness for each treatment was then calculated and the results were expressed as N/mm.

3.8. Statistical analysis

The effect of air-drying temperature on each quality parameter was estimated using Statgraphics® Plus 5 (Statistical Graphics Corp., Herndon, VA, USA). The results were analysed by an analysis of variance (ANOVA). Differences amongst the media were analysed using the least significant difference (LSD) test with a significance level of $\alpha = 0.05$ and a confidence interval of 95% ($p < 0.05$). In addition, the multiple range test (MRT) included in the statistical program was used to demonstrate the existence of homogeneous groups within each of the parameters.

4. Results and discussion

4.1. Effect on physico-chemical properties

Proximate analysis of red pepper (on 100 g of fresh weight) presented an initial moisture content of 89.40 ± 1.40 g; crude protein (nitrogen x 6.25) of 1.20 ± 0.10 g; total lipids of 0.53 ± 0.04 g; crude fibre of 1.20 ± 0.10; crude ash of 2.07 ± 0.16 g; available carbohydrates (by difference) of 4.82 ± 0.44 g.

Table 1 shows the mean values and standard deviations of the moisture content, water activity, soluble solids, % acidity and pH of both fresh and dry-rehydrated samples. Significant differences were found between temperature and the properties mentioned ($p < 0.05$). A maximum value of moisture content of 10.63 ± 0.16 g water/g dry matter was observed at 70 °C; however, products with lower moisture contents were obtained at 50 and 60 °C as well as at 80 and 90 °C due to long drying times and high temperatures, respectively. Values of water activity, which is an indicator of water availability, were high for all the samples, as expected for rehydrated samples. Soluble solids and % acidity exhibited a

Table 1
Physico-chemical properties of fresh and dry-rehydrated red pepper as function of air-drying temperature.

Sample Condition	Water content (g water/g dry matter)	a_w	Soluble solids (°Brix)	Acidity (%)	pH
Fresh	4.52 ± 0.28[a]	0.975 ± 0.002	11.33 ± 0.29[a]	0.358 ± 0.004[a]	4.72 ± 0.01[a]
50 °C	8.75 ± 0.75[b]	0.975 ± 0.001	4.2 ± 0.30[b]	0.113 ± 0.009[b,c]	5.29 ± 0.04[b]

70 °C	10.63 ± 0.16[c]	0.979 ± 0.002	2.7 ± 0.30[c]	0.108 ± 0.009[b]	5.13 ± 0.06[d]
80 °C	8.72 ± 0.21[b]	0.981 ± 0.001	2.8 ± 0.30[c]	0.128 ± 0.009[d,e]	4.96 ± 0.04[c]
90 °C	8.88 ± 0.66[b]	0.982 ± 0.003	2.5 ± 0.50[c]	0.123 ± 0.009[c,d]	4.96 ± 0.11[c]

Different letters in the same column indicate that the values are significantly different ($p < 0.05$).

decreasing tendency in all the different treatments respect to the fresh sample. In the same table, pH increased slightly from its original value, showing the same tendency of acidity. Similar results were found by Miranda, Maureira, Rodriguez, and Vega-Gálvez (2009), working with dehydrated Aloe Vera.

4.2. Effect on water holding capacity and rehydration ratio

Rehydration process depends on structural changes in vegetal tissues and cells of food material during drying, which produces shrinkage and collapse (Kaymak-Ertekin, 2002). Fig. 1 presents the behaviour of the rehydration ratio (RR) as well as the water holding capacity (WHC) for each air-drying temperature studied. The WHC decreased as the air temperature increased ($p < 0.05$). The maximum WHC was 47.4 ± 2.8 (g retained water/100 g water) at 50 °C which implies that this drying temperature causes tissue structure damage; thus, the pepper dehydrated at this temperature retained a great amount of water. On the other hand, samples dried at 80 and 90 °C have reduced their WHC, thereby preventing the complete rehydration of the dried product. Similar investigations reported that drying temperature is the main factor affecting the WHC (Vega-Gálvez et al., 2008b). In the same figure, RR was affected by the drying temperatures, since absorbed water decreased with temperature. However, RR showed no significant differences ($p > 0.05$). The lowest RR value was 4.24 ± 0.12 (g absorbed water/g d.m.) at 90 °C, this could be explained due to cellular structure damage resulting in modifications of osmotic properties of the cell as well as lower diffusion of water through the surface during rehydration (Kaymak-Ertekin, 2002). Moreover, pretreatments with saline or sweet solutions such as $CaCl_2$ or saccharose allow to maintain the initial texture, leading to cellular structure stability (Lewicki, 2006; Papageorge, McFeeters, & Fleming, 2003).

4.3. Antioxidant activity

Fig. 2 shows the vitamin C as well as the total phenolic content (TPC) for the fresh and dry-rehydrated samples during the five drying experiments. The initial content of vitamin C in peppers was 188.2 ± 4.5 mg ascorbic acid/100 g fresh sample, which is within the ranges found in other studies for red peppers (75–277 mg/100 g fresh weight; Castro et al., 2008). It can be seen that an increase in drying temperature has an important effect on vitamin C ($p < 0.05$), thus, a maximum loss of 98.2% vitamin C in samples dried at 90 °C is observed. This could be explained due to irreversible oxidative processes either during drying or rehydration water lixiviation of this water-soluble vitamin (Sigge et al., 2001; Vega-Gálvez et al., 2008b). In addition, vitamin C is considered as an indicator of the quality of food processing due to its low stability during thermal processes (Podsedek, 2007). Similar results were obtained by other authors working with peppers (Di Scala & Crapiste, 2008; Sigge et al., 2001). Pretreatments like blanching or additives like SO_2 and $CaCl_2$ can improve the retention of this vitamin (Vega-Gálvez et al., 2008b). Besides vitamin C, foods of plant origin also supply our diet with other antioxidants in large amounts: carotenoids and phenolic compounds which constitute one of the major groups of compounds acting as primary antioxidants or free radical terminators (Tabart, Kevers, Pincemail, Defraigne, & Dommes, 2009). The initial phenolic content was 1359 ± 148 g galic acid/g fresh sample. Sweet peppers contain numerous phenolic compounds, and not all of the genotypes may contain a similar profile or relative proportions of these compounds within the profile. Differences in these profiles may subsequently result in complex changes in antioxidant activity or other bioactivities (Deepa et al., 2007). It can be observed (Fig. 2) that an increase in drying temperature has an important effect on the total phenolic content ($p < 0.05$). The formation of phenolic compounds at high temperatures (i.e. 90 °C) might be because of the availability of precursors of phenolic molecules by non-enzymatic interconversion between phenolic molecules (Que, Mao, Fang, & Wu, 2008).

The radical scavenging activity was investigated based on air-drying temperature ($p < 0.05$) as observed in Fig. 3, where dehydration at high temperatures (i.e. 80 and 90 °C) shows higher antioxidant activity rather than at low temperatures (i.e. 50, 60 and

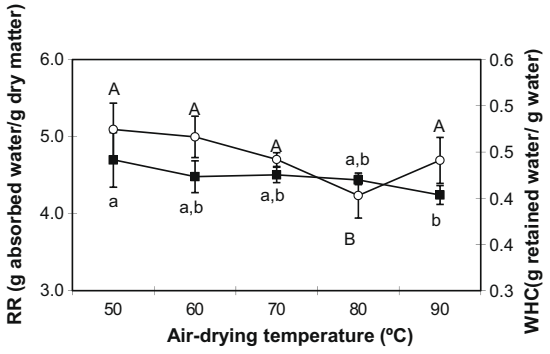

Fig. 1. Effect of air-drying temperature on the rehydration ratio (RR) and the water holding capacity (WHC) for dry-rehydrated pepper samples. Identical letters above the bars indicate no significant difference.

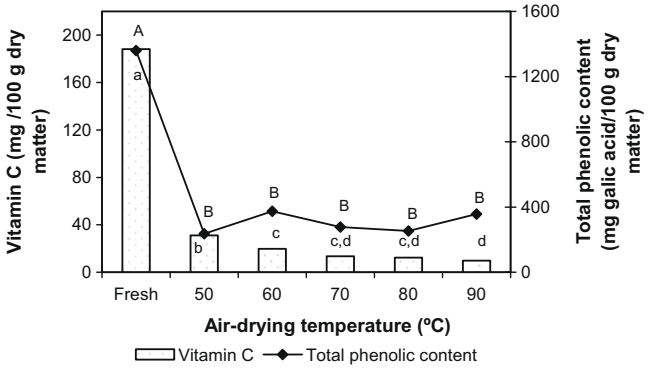

Fig. 2. Effect of air-drying temperature on vitamin C and total phenolic content of fresh and dry-rehydrated pepper samples. Identical letters above the bars indicate no significant difference.

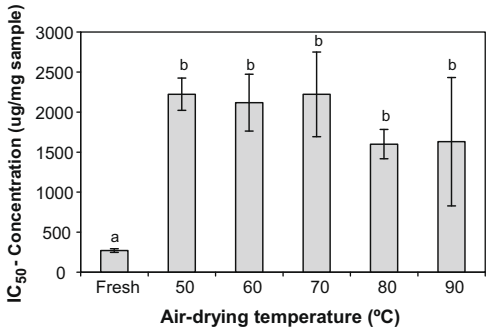

Fig. 3. Effect of air-drying temperature on DPPH free radical scavenging activity of fresh and dry-rehydrated pepper samples. Identical letters above the bars indicate no significant difference.

70 °C). This behaviour could be related to drying process at low temperatures, which implies long drying times that may promote a decrease of antioxidant capacity (Garau, Simal, Roselló, & Femenia, 2007). Furthermore, generation and accumulation of Maillard-derived melanoidins having a varying degree of antioxidant activity could also enhance antioxidant properties at high temperatures (i.e. 80 and 90 °C) (Miranda, Maureira, Rodriguez, & Vega-Gálvez, 2009; Que et al., 2008). Increasing correlation between antioxidant activity and total phenolic content has been reported during food dehydration (Deepa et al., 2007). However, data on the effects of drying on TPC and antioxidant activity of vegetables are conflicting due to several factors, like drying method, type of extraction solvent, antioxidant assays used as well as interactions of several antioxidant reactions (Manzocco, Calligaris, Mastrocola, Nicoli, & Lerici, 2001; Que et al., 2008).

4.4. Effect on colour

Fig. 4 presents the colour changes of pepper related to both non-enzymatic browning (NEB) and the ASTA colour value. It can be observed that an increase in temperature led to an important formation of brown products. This could be explained due to an increase in the kinetic reaction rate that shows a maximum NEB value of 0.19 ± 0.01 Abs/g dry matter at 90 °C. Furthermore, it is well known the effect of water on chemical reactions, via a_w or by plasticising amorphous systems (dehydrated systems) since the inhibitory effect of water seems to be a decisive factor in the NEB reaction rate (Acevedo, Schebor, & Buera, 2008). In addition, the development of the Maillard reaction frequently occurs in concomitance with other events, which can contribute to change both colour and the overall antioxidant capacity of pretreated foods (Manzocco et al., 2001). For example, addition of SO_2 can be applied during drying as an inhibitor of browning due to its capacity of both disinfectant and antioxidant on essential compounds (Miranda, Berna, Salazar, & Mulet, 2009).

Moreover, Fig. 4 shows the profiles of the ASTA colour for the different drying temperatures. The ASTA colour for the fresh samples was 222.83 ± 3.06 ASTA units/ g dry matter. When the results were compared, it could be observed that the highest air-drying temperature (90 °C, 380.90 ± 2.60 ASTA units/g dry matter) presented the lowest value of colour showing a maximum at 70 °C (568.90 ± 6.90 ASTA units/g dry matter). ASTA colour content is mainly attributable to endogenous carotenoids such as capxantine, capsorubin, β-carotene and others (Vega-Gálvez et al., 2008b). In consequence, the behaviour of this parameter is directly related to deterioration in these pigments due to high drying temperatures (Ergunes & Tarhan, 2006). Furthermore, discolouration of carotenoids during processing might occur through enzymatic or non-enzymatic oxidation (Rodriguez-Amaya et al., 2008). Both NEB and ASTA colour presented significant differences ($p < 0.05$).

Fig. 5 shows the average values of the chromatic coordinates L^*, a^* and b^*, for the fresh and dry-rehydrated samples of pepper. It can be observed that coordinate L^* presents the lowest values 27.70 ± 2.65 at high temperatures (90 °C) indicating that fresh peppers presented a darker colour compared to the dry-rehydrated samples. For drying temperatures from 50 to 80 °C, the differences in lightness are not so evident ($p < 0.05$). Although there is a hypothesis related to rehydrated products with high water content having high L^* values, in this case it was not confirmed. Rehydrated peppers become darker probably due to a larger extension of the Maillard reaction, especially at higher drying temperatures (Acevedo et al., 2008; Manzocco et al., 2001). Pretreatments, like addition of different compounds, can enhance the chromatic coordinates (Garau et al., 2007; Sigge et al., 2001).

Modifications in coordinate a^* (greenness–redness) for fresh and dry-rehydrated samples are also presented in Fig. 5, where there was a decrease of this coordinate (13% at 90 °C) respect to fresh samples ($p > 0.05$). This could be explained due to the presence of carotenoids as well as other components (vitamins, carbohydrates, aminoacids, etc.) in the pepper affecting the final product colour (Miranda, Maureira, Rodriguez, & Vega-Gálvez, 2009).

Coordinate b^* (blueness–yellowness) showed a slight increase in its value (15% at 90 °C) as temperature increased (Fig. 5) as a result of generation of brown products due to non-enzymatic reactions ($p > 0.05$). Since total colour difference (ΔE) is a function of the three CIE L^* a* b* coordinates (Eq. (3)), changes from

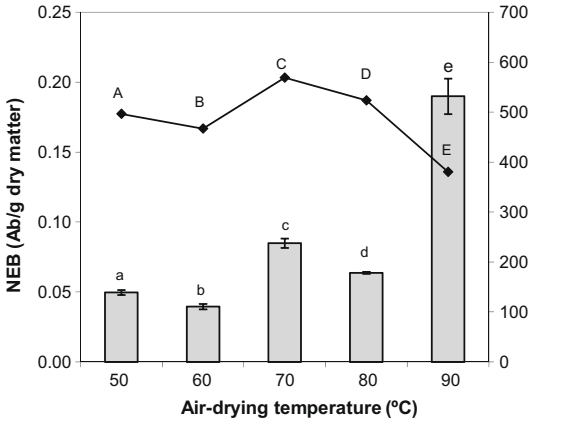

Fig. 4. Effect of air-drying temperature on non-enzymatic browning and ASTA color for dry-rehydrated pepper samples. Identical letters above the bars indicate no significant difference.

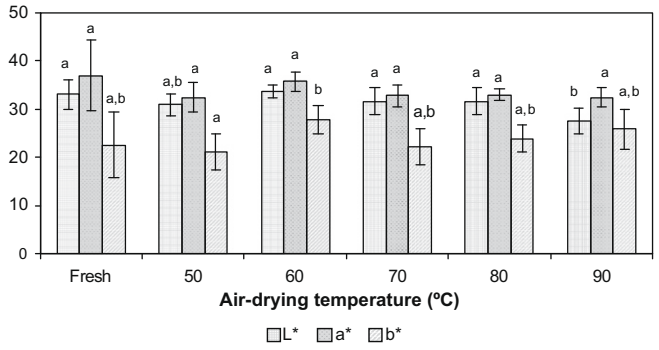

Fig. 5. Effect of air-drying temperature on the chromatics coordinates (L^*, a^* and b^*) of fresh and dry-rehydrated pepper samples. Identical letters above the bars indicate no significant difference.

5.78 ± 2.91 to 7.79 ± 2.16 were estimated for 50 and 90 °C, respectively. Similar results were obtained by Miranda, Maureira, Rodriguez, and Vega-Gálvez (2009), where high ΔE values were found at high drying temperatures due to the effect of high temperatures on heat-sensitive components like proteins and carbohydrates, amongst others.

The saturation index or chroma (C^*) and the hue angle (H^o), as shown in Fig. 6, provide more information about the spatial distribution of colours than direct values of tristimulus measurements (Sigge et al., 2001). The values of C^* and H^o are shown in Fig. 6, where it is observed that both indices are affected by temperature in opposite ways ($p > 0.05$) for both fresh and dry-rehydrated samples. Estimated chroma values retained the 96% of the fresh pepper, the hue angle showed an increase of 23% compared to fresh sample indicating discolouration of the original pepper colour.

4.5. Effect on firmness

Firmness is one of the most desirable attributes in fresh as well as rehydrated peppers (Castro et al., 2008). The behaviour of this physical property affected by drying temperature is illustrated in Fig. 7. It can be observed that air-drying temperature has a negative effect on this textural property presenting a maximum decrease of 50% respect to the fresh sample at 70 °C ($p < 0.05$). This tissue firmness reduction could be explained due to changes in the plant cell wall that occurred during processing at high temperatures (Papageorge, et al., 2003; Castro et al., 2008; Vega-Gálvez et al., 2008b). This behaviour can be minimized adding calcium which has been reported to maintain firmness by crosslinking cell wall and middle lamella pectins, stabilizing cell membranes, and/or affecting cell turgor potential (Castelló, Igual, Fito, & Chiralt, 2009; Vega-Gálvez et al., 2008b).

5. Conclusions

The effect of air-drying temperature on physico-chemical properties, firmness, rehydration, colour and antioxidant activity due to total phenolic content and ascorbic acid of red pepper during hot air-drying between 50 and 90 °C was investigated. The rehydration ratio (RR) decreased with temperature showing a lower RR of 4.24 ± 0.12 (g absorbed water/ g d.m.) at 90 °C. The maximum water holding capacity was 47.4 ± 2.8 (g retained water/100 g water) at 50 °C. Moreover, both vitamin C content and total phenolic content decreased as air-drying temperature increased. A maximum loss of 98.2% in vitamin C was observed in samples dried at 90 °C. The radical scavenging activity showed higher antioxidant activity at high temperatures (80–90 °C) respect to low temperatures (50–70 °C). Non-enzymatic compounds increased with temperature. ASTA colour was affected by temperature and presented the lowest colour value at 90 °C. All chromatic parameters (L^*, a^*, b^*, C^* and H°) were affected by temperature. In addition, the development of the Maillard reaction, which occurs in concomitance with other events, could contribute to change both colour and the overall antioxidant capacity of the pepper. A tissue firmness reduction was observed at high temperatures.

In consequence, the results obtained in this work are essential for the processing of dehydrated pepper in order to obtain the optimum benefits of bioactive compounds present in this food product during drying.

Yeast extract

ABSTRACT

The induction of α- and β-galactosidases in six strains of *Lactobacillus reuteri* (*L. reuteri*) by six carbohydrate sources and four protein sources was studied. *L. reuteri* grown on raffinose had the highest α-galactosidase activity (10.55 Gal U/ml), while lactose exhibited the highest β-galactosidase activity (43.82 Gal U/ml) when compared to other carbohydrate sources. *L. reuteri* grown on yeast extract exhibited the highest α- and β-galactosidases activity (15.27 and 12.88 Gal U/ml, respectively) when compared to other protein sources. MF14C and SD2112 grown on raffinose had the highest α-galactosidase activity (14.75 and 14.18 Gal U/ml, respectively) followed by CF2-7F (13.38 Gal U/ml). CF2-7F grown on lactose had the highest β-galactosidase activity (82.01 Gal U/ml). SD2112, MM2-3 and CF2-7F grown on yeast extract (20.96, 19.67, 19.67 Gal U/ml, respectively) showed the highest α-galactosidase activity. MM2-3 and CF2-7F grown on yeast extract showed the highest β-galactosidase activity (18.1 and 17.59 Gal U/ml, respectively). Raffinose and lactose were the best carbohydrate sources to produce α- and β-galactosidases, respectively. Yeast extract was the best protein source to produce both enzymes and CF2-7F strain was the best producing strain on all tested conditions.

1. Introduction

α-Galactosidase (EC 3.2.1.22) and β-galactosidase (EC 3.2.1.23) are functional enzymes that catalyse the hydrolysis of oligo- and polysaccharides containing terminal α-galactosyl groups or β-D-galactopyranosides, respectively. Both enzymes have health benefits and industrial applications. α-Galactosidase hydrolyses raffinose and stachyose in leguminous foods and feeds, as these oligosaccharides tend to cause intestinal discomfort, flatulence and low feed utilisation in monogastrites (Ulezlo & Zaprometova, 1982). β-Galactosidase can alleviate the problems associated with whey disposal, lactose crystallisation in frozen concentrated desserts and milk consumption by lactose-intolerant individuals (Kim & Rajagopal, 2000). On the other hand, α- and β-galactosidases are effective for galactooligosaccharides (GOS) synthesis by transglycosylation or reverse hydrolysis reactions (Donkor, Henriksson, Vasiljevic, & Shah, 2007; Hsu, Yu, & Chou, 2005). The formation of GOS can be used as prebiotic functional food ingredients to contribute to human health (Splechtna et al., 2006).

The investigation of the production of α-galactosidase or β-galactosidase from microorganisms is not new (e.g. Donkor et al., 2007; Garro, de Giori, de Valdez, & Oliver, 1994; Hsu et al., 2005; Ibrahim & O'Sullivan, 2000). However, most of the α- and β-galactosidases used in these studies were not approved for food use, because they were not obtained from food grade microorganisms. In addition, production of α- and β-galactosidases from the previously studied microorganisms is low, which hinders its commercial use. To address this need, identification of source microorganisms which are safe for human use and capable of producing high levels of α- and β-galactosidase becomes critically important.

Several studies have shown that Lactic Acid Bacteria (LAB) could be a good source of both enzymes (Akolkar, Sajgure, & Lele, 2005; Alazzeh, Ibrahim, Song, Shahbazi, & AbuGhazaleh, 2009; Bury, Geciova, & Jelen, 2001; Donkor et al., 2007; Garro et al., 1994; Ibrahim & O'Sullivan, 2000) Lactobacilli is part of LAB, which reside normally in the gastrointestinal tract of humans and animals (Xanthopoulos, Litopoulou-Tzanetaki, & Tzanetakis, 2000) meet the Generally Recognized as Safe (GRAS) standard for food processing (Speck, Dobrogosz, & Casas, 1993). *Lactobacillus reuteri* (*L. reuteri*) has a good clinical record and good probiotic characteristics, such as the ability to produce antimicrobial products like reuterin (Gänzle, Hältzel, Walter, Jung, & Kammes, 2000), the ability to prevent and reduce hypercholesterolaemia in mice (Taranto, Medici, Perdigon, Ruiz Holgado, & Valdez, 1998), and the ability to survive gastrointestinal pH (Rodriguez, Arques, Rodriguez, Nunez, & Medina, 2003). Most studies that have investigated LAB for the production of galactosidases have concentrated on *Lactobacillus acidophilus*, *Lactobacillus delbrueckii* and *Lactobacillus fermentum* (Bury et al., 2001; LeBlanc, Garro, & Savoy de Giori, 2004; Sasaki,

doi:10.1016/j.foodchem.2009.04.065

Samant, Suzuki, Toba, & Itoh, 1993). These studies and others show that the production of α- and β-galactosidases from microorganisms is affected by various culture conditions such as the sources of carbohydrates and proteins and the occurrence of ion metals. For example, α-galactosidase activity with raffinose and melibiose as carbohydrate sources has been demonstrated to be up to 30 folds higher than when glucose is used (Tzortzis, Jay, Baillon, Gibson, & Rastall, 2003; Xiao, Tanaka, Qian, Yamamoto, & Kumagai, 2000). Hsu et al. (2005) found that lactose as a carbohydrate source and yeast culture as a protein source were the best culture conditions to produce β-galactosidase in bifidobacteria. Bury et al. (2001) showed that α-galactosidase activity in *L. delbrueckii* subsp. *Blugaricus* increased threefold when yeast extract was added to a whey media. A few studies have investigated the production of galactosidases from *L. reuteri* and have found that *L. reuteri* could be a good source of galactosidases (Alazzeh et al., 2009; Nguyen, Splechtna, Yamabhai, Haltrich, & Peterbauer, 2007). However, more work is needed to optimise the culture growth conditions of *L. reuteri* to enhance the activities of α- and β-galactosidases. In this study we are trying to establish strains of *L. reuteri* with enhanced α- and β-galactosidases activities. These strains could be added as a food grade additive to achieve added health benefits to food products mainly to those that have indigestible sugars. Our objectives were to optimise the culture conditions of carbohydrate and protein sources of six strains of *L. reuteri* to obtain strains with enhanced α- and β-galactosidases activities that could be good candidates as a food additive or a food supplement.

2. Materials and methods

2.1. Microorganisms

Six strains of *L. reuteri* (CF2-7F, DSM20016, MF14-C, MM2-3, MM7 and SD2112) were used. These strains were obtained from a commercial source (BioGaia, Raleigh, NC). The sources of the strains were child faecal isolate (CF2-7F), mother faecal isolate (MF14C) and mother's milk (DSM20016, MM2-3, MM7 and SD2112).

2.2. Culture conditions

L. reuteri strains were maintained on *Lactobacillus* MRS agar (Difco Laboratories, Becton Dickinson, Sparks, MD) petri dishes at 4 °C. Before use, the strains were activated by taking one bacterial colony of each strain and separately inoculating the colony into *Lactobacillus* MRS broth (Difco Laboratories, Becton Dickinson, Sparks, MD) in anaerobic culture tubes at 37 °C for18 h.

2.2.1. Carbohydrate enzyme induction

The activated strains were harvested by centrifugation (10,000*g* for 10 min at 4 °C) and washed twice with 0.1% sterilised peptone water. To examine the effect of carbohydrate source on induction of α- and β-galactosidases, a modified M17 media (Ibrahim, Ahmed, & Song, 2009) was prepared in 950 ml distilled water comprised of: 37.25 g M17 (Difco Laboratories, Becton Dickinson, Sparks, MD), 5.00 g beef extract, 2.50 g yeast extract and 5.00 g phyto-peptone. This preparation was then sterilised at 121 °C for 15 min and 50 ml of different sterile sugars (dextrose, galactose, lactose, melibiose, raffinose and sucrose solutions (40%) were added separately. The control group consisted of the modified M17 media without added carbohydrate source.

2.2.2. Protein enzyme induction

To test the induction of α- and β-galactosidases activity by different protein sources, the activated strains were harvested by centrifugation (10,000*g* for 10 min at 4 °C) and washed twice with 0.1% sterilised saline water. Fermentation of strains with different protein sources was carried out by transferring 0.1 ml of inoculum into 10 ml culture media samples consisting of 1% g lactose, 1% g raffinose, 0.5% $NaCH_3COO$, 0.05% $MgSO_4{\cdot}7H_2O$, 0.005% $MnSO_4{\cdot}4H_2O$, 0.3% K_2HPO_4, 0.1% KH_2PO_4, 0.05% L-cysteine (Sigma, St. Louis, MO, USA) and 0.1% Tween 80. Different protein source samples were created by adding either 2% either of beef extract, tryptic soy, tryptone, or of yeast extract. For negative control, the same media was prepared with no added protein source. *Lactobacillus* MRS broth with L-cysteine samples (described earlier) served as a positive control. After 18 h incubation at 37 °C, cultures were harvested for testing for enzymes activities.

2.3. Determination of α- and β-galactosidases activity

Strain samples were prepared as described by Hsu et al. (2005) with slight modification. Overnight cultures were first harvested by centrifugation (10,000*g* for 10 min at 4 °C). After washing twice with phosphate buffer (pH 6.8), the bacteria cells were resuspended in 1 ml of phosphate buffer in Eppendorf tubes containing 0.1 mm glass beads (BioSpec Products Inc., Bartlesville, OK, USA) and maintained in an ice bath. All samples were treated with a bead beater (MiniBead Beater-8, BioSpec Products Inc., Bartlesville, OK, USA) for total of 3 min. After every minute, the samples were rested for 15 s in an ice bath. Samples were then centrifuged (12,000*g*, 30 min) to obtain the supernatant which was preserved at −80 °C until enzyme activity was assayed. The supernatant served as the enzyme source.

2.3.1. α-Galactosidase assay

α-Galactosidase activity was assayed according to the Food Chemicals Codex (2003) protocol. α-Galactopyranoside activity was tested by adding 1 ml of *p*-nitrophenyl-α-D-galactopyranoside substrate to 0.5 ml of each sample and transferring the samples into water bath at 37 ± 0.2 °C for 15 min. All reactions were stopped by adding 2.5 ml of Borax buffer. A blank for each sample was prepared by sequentially adding 0.5 ml sample, 2.5 ml Borax buffer and 1 ml of substrate solution. Absorbance was measured at 405 nm by spectrophotometer (Model Genesys 10Vis, Thermospectronic, Rochester, NY, USA).

2.3.2. β-Galactosidase assay

β-Galactosidase activity was assayed according to the method described by Nagy, Kiss, Szentirmai, and Biró (2001). The reaction mixture was composed of 0.5 ml of enzyme source and 0.5 ml of 15 mM *o*-nitrophenyl-β-D-galactopyranoside in 0.03 M sodium phosphate buffer (pH 6.8). Reactions were maintained on a water bath at 37 ± 0.2 °C with automatic shaking for 10 min, and then 2.0 ml of 0.1 M sodium carbonate was added to stop the reaction. The optical density (OD) for each of the samples was measured at 420 nm with spectrophotometer (Model Genesys 10Vis, Thermospectronic, Rochester, NY, USA). The unit of enzyme activity was defined as the amount of enzyme catalyzing the formation of 1 μmol of *o*-nitrophenyl per minute under the assay condition.

2.4. Protein assay

Protein in strain samples was measured by Bradford method with bovine serum albumin as the standard (Bradford, 1976). To calculate α- and β-galactosidases specific activity, activity of each enzyme was divided by its protein content.

2.5. Statistical analysis

Statistical analysis of data was performed using the SAS general linear model (GLM) program (1999). Duplicate samples of each of

the strains under every growth condition were assayed for α- and β-galactosidases activity. Least square means of the duplicate samples were calculated and Duncan's Multiple Range Test was used to determine significant ($P < 0.01$) differences.

3. Results and discussion

3.1. Induction of α- and β-galactosidases by different carbohydrate sources

3.1.1. Effect of carbohydrate source on α-galactosidase activity

Data of each carbohydrate/protein source were averaged to test the effect of single sugar/protein source on the induction of α- and β-galactosidases activity. Results of carbohydrate sources showed that *L. reuteri* grown on raffinose had a significantly higher ($P < 0.01$) α-galactosidase activity (10.55 Gal U/ml) than the control and other carbohydrate (sugar) sources. The next highest producer was melibiose (6.15 Gal U/ml) which was significantly higher ($P < 0.01$) than the remaining carbohydrate sources. Lactose, dextrose, galactose and sucrose induction of α-galactosidase activity was not increased significantly ($P > 0.05$) (Table 1). α-Galactosidase specific activity was also significantly higher ($P < 0.01$) in *L. reuteri* grown on raffinose (11.75 Gal U/mg) than the control and the other carbohydrate sources (Table 1).

The highest levels of α-galactosidase activity being associated with raffinose may be due to its ability to induce the gal operon responsible for LAB production of α-galactosidase (Semsey, Virnik, & Adhya, 2006). Raffinose and melibiose, which are saccharides with an α-galactosyl group linkage between their subunits, might activate genes responsible for the over production of α-galactosidase. The other saccharides used in this study do not have an α-gal linkage, which might explain the lower α-galactosidase production in the media containing these sugars. Our results are in agreement with Xiao et al. (2000) who showed that raffinose followed by melibiose were the most effective sugars to induce α-galactosidase in *Bifidobacterium breve*. Li, Yang, Yan, Zuo, and Jin (1997) found that melibiose followed by raffinose were the best carbohydrate sources for α-galactosidase activity in *Bacillus* sp.

3.1.2. Effect of carbohydrate source on β-galactosidase activity

β-Galactosidase activity (43.82 Gal U/ml) in *L. reuteri* grown on lactose was significantly higher ($P < 0.01$) than for the other carbohydrate sources. Specific activity of β-galactosidase followed the same trend as activity with *L. reuteri* grown on lactose; it had a significantly higher ($P < 0.01$) specific activity (48.25 Gal U/mg) than the other carbohydrate sources (Table 1). The presence of lactose in the media probably triggered β-galactosidase activity by the lac operon mechanism (Miller & Reznikoff, 1978). This interpretation is in agreement with the findings of Akolkar et al. (2005) and Hsu et al. (2005), who showed that the presence of lactose in the media led to an enhancement of β-galactosidase activity for bifidobacteria and *L. acidophilus*, respectively. On the other hand, Kim and Rajagopal (2000) found that galactose is better than lactose as an inducer of β-galactosidase activity in *Lactobacillus crispatus*. In our experiment, the activity of β-galactosidase was minimally higher than lactose only in one strain (MF14C). However, the differences were not significant ($P > 0.05$), and the discrepancies between the two studies could be attributed to the use of different *Lactobacillus* sp.

3.1.3. Between strain comparisons of α-galactosidase activity due to different carbohydrate sources

L. reuteri strains had different responses, in terms of enzyme activity, to the presence of carbohydrate sources in the media. α-Galactosidase activity in MF14C grown on raffinose (14.75 Gal U/ml) was significantly higher ($P < 0.01$) than that in other *L. reuteri* strains, followed by SD2112 (14.18 Gal U/ml) and CF2-7F (13.38 Gal U/ml) both grown on raffinose, which were significantly higher ($P < 0.01$) than the remaining strains (Fig. 1). Among strain enzyme activity was significantly higher ($P < 0.01$) in *L. reuteri* grown on raffinose followed by melibiose (Fig. 1).

3.1.4. Between strain comparisons of β-galactosidase activity due to different carbohydrate sources

CF2-7F grown on lactose showed significantly higher ($P < 0.01$) β-galactosidase activity (82.01 Gal U/ml) than other strains, followed by DSM20016 grown on lactose (73.75 Gal U/ml), which was significantly ($P < 0.01$) higher than the remaining strains (Fig. 2). Results for both enzymes suggest that CF2-7F and DSM20016 strains showed the highest levels. Other strains showed high activity only in one enzyme (MF14C and SD2112 also showed high activity for α-galactosidase).

3.2. Induction of α- and β-galactosidases by different protein sources

3.2.1. Effect of protein source on α-galactosidase activity

L. reuteri grown on yeast extract showed a significantly higher ($P < 0.01$) α-galactosidase activity (15.27 Gal U/ml) than other protein sources (Table 2) followed by tryptone and tryptic soy (11.35 and 9.27 Gal U/ml, respectively), which were significantly higher ($P < 0.01$) than the remaining protein sources. Media containing yeast extract showed also a higher ($P < 0.01$) α-galactosidase specific activity (41.13 Gal U/mg) than other protein sources followed by tryptic soy, tryptone and beef extract (26.7, 22.05 and 18.72 Gal U/mg, respectively) which were significantly higher ($P < 0.01$) than the remaining protein sources. These findings are consistent with Gote, Umalkar, Khan, and Khire (2004) who found that yeast extract was the best protein source for α-galactosidase activity in *Bacillus stearothermophilus*.

3.2.2. Effect of protein source on β-galactosidase activity

β-Galactosidase activity in *L. reuteri* due to different protein sources followed the same trend of α-galactosidase. Yeast extract media showed a higher ($P < 0.01$) β-galactosidase activity (12.88

Means ± standard error of means in the same column with different superscripts are significantly ($P < 0.01$) different.

Gal U/ml) than other protein sources, followed by tryptic soy and tryptone (7.91 and 7.87 Gal U/ml, respectively), which were significantly higher ($P < 0.01$) than the remaining protein sources. In addition, yeast extract media produced significantly higher ($P < 0.01$) β-galactosidase specific activity (35.43 Gal U/mg) than the other protein sources followed by tryptic soy and beef extract and peptone (23.99, 21.43 and 15.74 Gal U/mg, respectively. Both Bury et al. (2001) and Hsu et al. (2005) showed that yeast extract was effective in enhancing β-galactosidase activity in *L. delbrueckii* subsp. *bulgaricus* and bifidobacteria, respectively.

3.2.3. Between strain comparisons of α-galactosidase activity due to different protein sources

Between strains comparisons showed that generally, strains grown on yeast extract had the best α-galactosidase activity. SD2112, MM2-3 and CF2-7F grown on yeast extract (20.96, 19.67, 19.67 Gal U/ml, respectively) and SD2112 grown on peptone

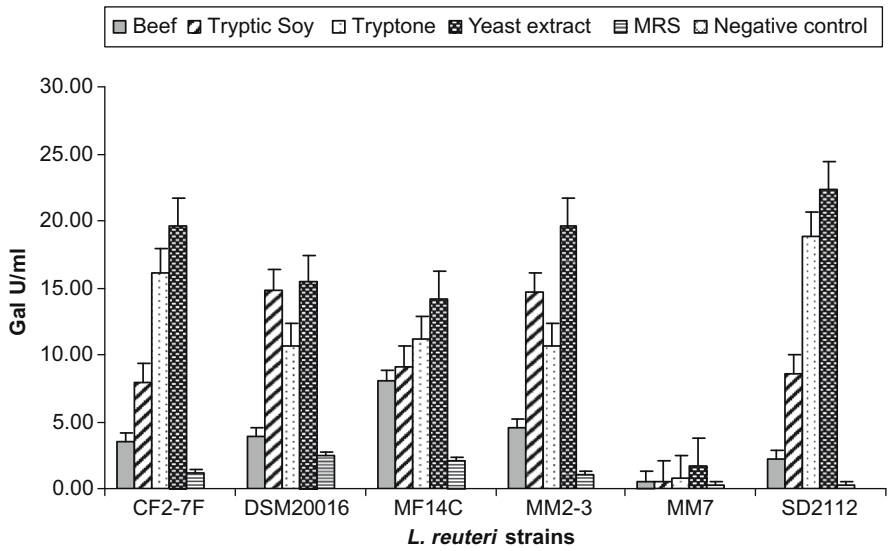

Fig. 3. α-Galactosidase activity (Gal U/ml) of six strains of *L. reuteri* grown on different protein sources. (Error bars represent a pooled standard error of the means for each protein source.)

(18.87 Gal U/ml) were associated with significantly higher ($P < 0.01$) α-galactosidase activity than other tested strains (Fig. 3).

3.2.4. Between strain comparisons of β-galactosidase activity due to different protein sources

β-Galactosidase activity in the six *L. reuteri* strains in response to the different protein sources is shown in Fig. 4. From the figure it can be seen that MM2-3 and CF2-7F strains grown on yeast extract media had significantly higher ($P < 0.01$) activity of the enzyme (18.1 and 17.59 Gal U/ml, respectively). Results from the protein enzyme induction experiment showed that yeast extract lead to a significantly higher ($P < 0.01$) activity and specific activity of both enzymes than the other protein sources. Therefore, this suggests that yeast extract could be a possible protein source in traditional LAB media to enhance the activity of both enzymes. CF2-7F, DSM20016 and SD2112 strains grown on yeast extract showed good results for the activity of both enzymes as a response of different protein sources (Figs. 1 and 2). However, only CF2-7F strain showed high activity of both enzymes either in carbohydrate or protein source experiments.

4. Conclusion

In this study we tried to optimise the growth conditions of *L. reuteri* by testing different carbohydrate and protein sources in the growth media to obtain enhanced activities of α- and β-galactosidases. *L. reuteri* grown on raffinose exhibited the best activity and specific activity of α-galactosidases. MF14C, SD2112 and CF2-7F showed the best α-galactosidase activity when grown on raffinose. *L. reuteri* grown on lactose showed the best activity and specific activity of β-galactosidase. CF2-7F and DSM2112 were the best strains with enhanced activities of this enzyme when grown on lactose. Yeast extract performed as the best protein source in terms of enhanced activity and specific activity of α- and β-galactosidases. SD2112, MM2-3 and CF2-7F grown on yeast extract and SD2112 grown on peptone were the best strains

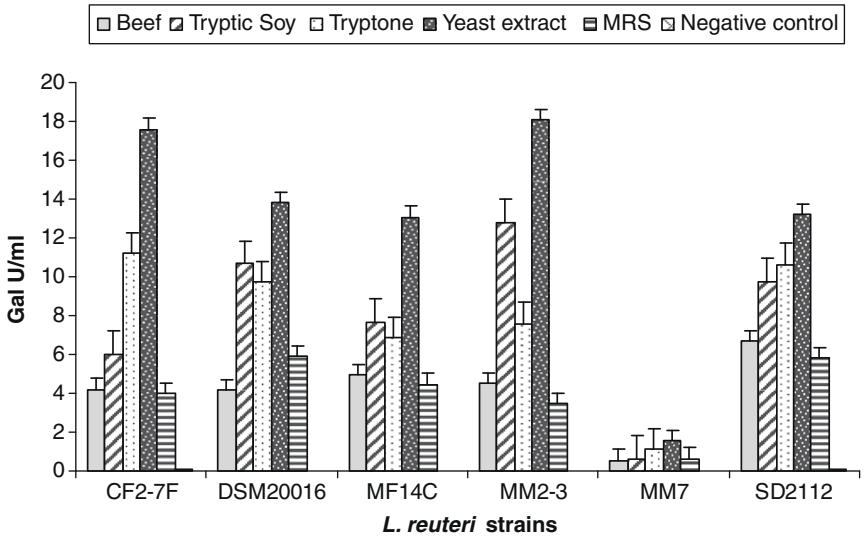

Fig. 4. β-Galactosidase activity (Gal U/ml) of six strains of *L. reuteri* grown on different protein sources. (Error bars represent a pooled standard error of the means for each protein source.)

with enhanced activities of α-galactosidase. MM2-3 and CF2-7F strains grown on yeast extract were the best strains with enhanced activities of β-galactosidase. Yeast extract was the best protein source to enhanced the activities of both enzymes and CF2-7F strain was the only strain with enhanced activities of both enzymes on all tested conditions. Our results showed that CF2-7F grown in a growth medium with raffinose and lactose as carbohydrate sources and with yeast extract as a protein source could provide conditions as a good probiotic candidate. For this reason, *L. reuteri* strain CF2-7F should receive further attention as potentially beneficial food additive or food supplement. With the increasing attention of the role of LAB bacteria in the production of probiotic products for health and nutritional benefits, the use of *L. reuteri* strain CF2-7F with high α- and β-galactosidases activities should be addressed.

Acknowledgments

We like to express our gratitude to Dr. C.S. Turner and Dr. Keith Schimmel (Energy and Environmental Interdisciplinary Studies at NC A&T) for their support and to and Dr. K.J. Gruber from the Agricultural Research Program at North Carolina A&T State University for his review and comments on this manuscript. We would like also to thank Ms. Elizabeth Fitzpatrick for her technical help.

SPPARγMs
PPARγ-antagonists

ABSTRACT

Obesity and the related disorders, diabetes, hypertension and hyperlipidemia have reached epidemic proportions world-wide. The influence of 70 plants, herbs and spices on peroxisome proliferators-activated receptor (PPAR)γ activation or antagonism, a drug target for metabolic syndrome, was investigated. Approximately 50 different plant extracts bound PPARγ in competitive ligand binding assay, including pomegranate, apple, clove, cinnamon, thyme, green coffee, bilberry and bay leaves. Five plant extracts transactivated PPARγ in chimeric GAL4-PPARγ-LBD system: nutmeg, licorice, black pepper, holy basil and sage. Interestingly, nearly all plant extracts antagonized rosiglitazone-mediated coactivator recruitment in time resolved fluorescence resonance energy transfer coactivator assay. The five transactivating extracts may function as selective PPARγ modulators (SPPARγMs), and the other extracts seem to be moderate antagonists or undetectable/weak SPPARγMs. As SPPARγMs improve insulin resistance without weight gain and PPARγ antagonists exert antiobesity action, a combination of these plants in diet could reduce obesity and the incidence of metabolic syndrome.

1. Introduction

The prevalence of obesity has increased rapidly over the last decade. According to the World Health Organization (WHO), in 2005 approximately 1.6 billion adults were overweight and at least 400 million adults were obese (WHO, 2006). Obesity is associated with insulin resistance, a key factor of the metabolic syndrome which is defined as the coexistence of hyperglycaemia, hypertension, hyper- and dyslipidemia and central obesity. Cardiovascular diseases such as coronary heart diseases and stroke are more prevalent amongst patients with this syndrome (Alberti, Zimmet, Shaw, & Grundy, 2006).

Diabetes has historically been treated with plants or plant-derived formulations in different cultures (Grover, Yadav, & Vats, 2002; Shapiro & Gong, 2002). Scientific investigations have reported the efficiency of several plants and plant preparations including red clover (*Trifolium pratense*) (Mueller & Jungbauer, 2008), pomegranate (*Punica granatum*) (Huang et al., 2005), garlic (*Allium sativum*), onion (*Allium cepa*), turmeric (*Curcuma longa*), coriander (*Coriandum sativum*) (Grover et al., 2002; Srinivasan, 2005), cinnamon (*Cinnamonum verum*) (Verspohl, Bauer, & Neddermann, 2005), green and black teas (*Camellia sinensis*), allspice (*Pimenta officinalis*), bay leaves (*Laurus nobilis*), nutmeg (*Myristica fragrans*), clove (*Syzygium aromaticum*) (Broadhurst, Polansky, & Anderson, 2000), licorice (*Glycyrrhiza uralensis*) (Mae et al., 2003). The most prominent representatives of plant extracts currently used for treatment of diabetes are cinnamon powder, bitter melon (*Momordica charantia*) and fenugreek. Different mechanisms for the antidiabetic effect of plants have been proposed: increased release of insulin, reduction of intestinal glucose absorption, enhancement of glycogen synthesis (Grover et al., 2002) and PPARγ-activation (Huang et al., 2005; Mae et al., 2003).

One of the drug targets for diabetes is the peroxisome proliferators-activated receptor (PPAR)γ (Guo & Tabrizchi, 2006). Full PPARγ activators increase insulin sensitivity, but simultaneously induce adipocyte differentiation and lipid storage, subsequently causing weight gain. In contrast, selective PPARγ modulators (SPPARγMs) show antidiabetic action without promoting weight gain. These substances function as PPARγ ligands that cause selective cofactor recruitment, meaning that adipogenic cofactors are not recruited (Zhang, Lavan, & Gregoire, 2007). PPARγ antagonists were shown to exert antiobesity and antidiabetic action by the inhibition of adipocyte differentiation, inhibition of adipose tissue accumulation and thus decrease of adipokine secretion (Rieusset et al., 2002).

In this study, a number of edible plants and plant extracts were screened for their PPARγ binding affinity, and PPARγ agonistic and antagonistic activity.

2. Materials and methods

2.1. Materials

Various chemicals were procured from Sigma–Aldrich (St. Louis, MO, USA/ Darmstadt, Germany) and Cayman Chemicals (Ann Arbor, MI, USA).

Table lists the tested plant extracts, ratio of extraction, standardization according to manufacturer's specifications, the IC_{50} values determined by competitive PPARγ ligand binding assay (= LBA), the equivalent rosiglitazone concentration calculated from ligand binding data, the IC_{50} values (determined by TR-FRET antagonist screening) and the EC_{50} value and efficiency of transactivation (determined by a chimeric GAL4- PPARγ assay). Ligand binding results of $IC_{50} \geqslant 500$ μg/ml were described as "ligands". If no EC_{50} value could be determined in the transactivation assay, compounds were described as "active". Only the most potent ligands were tested by transactivational assay and only one extract per species.

Polar Screen PPAR Competitive Assay and Lantha Screen TR-FRET (time resolved fluorescence resonance energy transfer) PPARγ coactivator assay were purchased from Invitrogen Corporation (Carlsbad, CA, USA). Black U96 microwell plates were obtained from Nunc (Roskilde, Denmark). Fluorescence polarisation was measured with the Genios Pro plate reader from Tecan (Crailsheim, Germany). Dulbecco's minimum essential medium (DMEM) used for cell culture was obtained from Biochrom (Berlin, Germany), foetal calf serum (FCS) was purchased from HyClone (Logan, Utah, USA), SuperFect was obtained from Quiagen (Germantown, Maryland, USA), and the Dual Glo Luciferase Assay System from Promega (Madison, Wisconsin, USA).

2.2. Preparation of plants extracts/powders

Dry powder (100 mg) of plants, herbs or spices was extracted with 1 ml DMSO for 24 h at room temperature. The extract was clarified by centrifugation for 1 h at 13,000 rpm. The clear supernatant was further diluted by DMSO, and used for analysis in the PPARγ ligand binding and transfection assays.

2.3. Polar screen PPAR competitive assay

The PPAR ligand-binding competitive assay was performed with PolarScreen™ PPAR Competitor Assay Green according to the manufacturer's protocol. In brief, the PPARγ ligand-binding domain (LBD) and the fluorescent PPARγ ligand form a complex with a high polarisation value. Displacement of the fluorescent ligand by PPARγ ligands frees the fluoromone in solution to tumble rapidly during its fluorescence lifetime, causing a low polarisation value. The change in polarisation value was used to determine the relative affinity of test compounds for the PPARγ-LBD. Fluorescence polarisation was measured using a Genios Pro plate reader (Tecan, Crailsheim, Germany) at an excitation wavelength of 485 nm and an emission wavelength of 535 nm. Rosiglitazone, a substance with high PPARγ affinity, was used as a standard, and maximal polarisation value of rosiglitazone was defined as 100%.

2.4. Plasmids

The pGAL4-hPPARγ-LBD expression plasmid that expresses the chimeric GAL4 DNA binding domain fused to the human PPAR-LBD (Staels et al., 1998) was provided by Prof. Staels. The luciferase reporter plasmid pFR-Luc containing a firefly luciferase gene controlled by GAL4-binding elements was purchased from Stratagene (La Jolla, California, USA). The Renilla control plasmid pRL-tk coding for *Renilla* luciferase gene and was obtained from Promega (Madison, Wisconsin, USA).

2.5. Transactivation assay

NIH-3T3 cells (German Collection of Microorganisms and Cell Cultures (GSMZ), Ac. No. 59) were seeded at a density of 1×10^4 cells per well. After 24 h of incubation, cells were co-transfected with 30 ng pGAL4-hPPARγ-LBD, 300 ng pFR-Luc reporter plasmid, and 15 ng pRL-TK using SuperFect transfection reagent according to the manufacturer's protocol. After transfection, cells were incubated with standard and test substances dissolved in DMSO solution in DMEM for 24 h; DMSO concentration did not exceed 0.1%. Luciferase assays were performed using the Dual Glo Luciferase Assay System according to the manufacturer's protocol. Renilla and firefly luminescence were measured with the Genios Pro plate reader. The firefly to Renilla ratio was calculated by dividing the firefly luciferase activity by the Renilla luciferase activity, which normalises for transfection efficiency. Rosiglitazone, a strong PPARγ activator, was used as a positive control, and the efficiency of rosiglitazone was defined as 100%.

2.6. TR-FRET coactivator assay

Antagonist screening was performed with the Lantha Screen TR-FRET PPARγ coactivator assay in antagonist mode according to the manufacturer's protocol. In brief, binding of an agonist (in this case rosiglitazone) to PPARγ results in a conformational change to recruit the coactivator peptide TRAP220/DRIP-2. The close proximity of the fluorescently labelled coactivator peptide and the terbium-labelled anti-GST antibody bound to the PPARγ GST fusion protein results in energy transfer from the terbium label to the fluorescein label, which is detected as an emission at 520 nm. Antagonists displace rosiglitazone from PPARγ and the emission signal at 520 nm decreases. Fluorescence intensity was measured using a Genios Pro plate reader at an excitation wavelength of 340 nm and an emission wavelength of 520 and 495 nm with a delay time of 100 μs and an integration time of

200 μs. The emission ratio of 520:495 indicates the extent of coactivator displacement.

2.7. Calculation of concentrations and statistics

Binding affinity, transactivational activity and antagonistic activity were determined by plotting polarisation values, transactivational efficiencies and emission ratio against the concentration of the test compound. Curve fitting was performed using a logistic dose–response model (Eq. (1)) of the Table Curve 2D software (Jandel Scientific, Erkrath, Germany). This non-linear equation uses a Levenburg–Marquard algorithm (Jungbauer & Graumann, 2001)

$$y = a + \frac{b}{1 + (c/x)^d}, \quad (1)$$

where a equals the baseline, b is the difference between the plateau of the curve and the baseline, c is the transition centre of the curve, which is the concentration that causes 50% efficiency (ligand potency), and d is the transition zone and is a measure of positive or negative cooperativity.

The concentration of the test compounds that results in a half-maximal decrease of polarisation value, half-maximal transactivational efficiency, or half-maximal decrease of emission ratio is the IC_{50}/EC_{50} value of the test compound. This value indicates PPARγ binding affinity, transactivational activity or antagonistic activity.

The competitive assay was performed in duplicate, the transactivation assay was performed in quadruplicate and the TR-FRET PPARγ coactivator assay was performed in triplicate. Each assay was performed on independent days, and intervariation was in the same range as intravariation.

The equivalent rosiglitazone concentration corresponds to the theoretical concentration of rosiglitazone in the extract producing the same binding affinity. Rosiglitazone was used as reference substance. The equivalent IC_{50} value was calculated by dividing the IC_{50} value of rosiglitazone by the IC_{50} value of the plant extracts or isoflavones (Eq. (2)):

$$IC_{50}\ (\text{nmol/g}) = \frac{IC_{50(\text{rosiglitazone})}\ (\text{nmol/L})}{IC_{50(\text{extract})}\ (\text{g/L})}. \quad (2)$$

3. Results

The PPARγ binding affinity of various plant extracts was determined by a competitive assay, transactivational activity by a chimeric GAL4-PPARγ-LBD assay system, and antagonistic activity by TR-FRET coactivator assay in antagonist mode. Potencies of the competitive ligand binding assay, the transactivation assay and the TR-FRET coactivator assay were determined by a logistic dose–response curve with the polarisation values, transactivation efficiency or emission ratio (compared to rosiglitazone or GW9662) plotted against the concentration of the test compounds. The potency indicates the concentration necessary to reach half-maximal binding affinity, transactivational efficiency or antagonistic activity.

3.1. Polar screen PPAR competitive assay

Pomegranate fruit extract (*P. granatum*) standardised on 40% ellagic acid exerted the highest binding affinity of the tested extracts, with an IC_{50} value of 0.35 μg/ml (Table 1, Fig. 1). Several extracts showed moderate binding affinity, including, amongst others, apple extract (*Malus domestica*), a 200:1 extract containing 5% quercetin and 30% phloridzin, with an IC_{50} value of 0.49 μg/ml, clove (*S. aromaticum*) (IC_{50} = 0.89 μg/ml), cinnamon (*Cinnamomum zeilanicum*) 10:1 extract (IC_{50} = 1.9 μg/ml), thyme 7:1 extract (*Thymus vulgaris*) (IC_{50} = 2.4 μg/ml), green coffee (*Coffea arabica*)

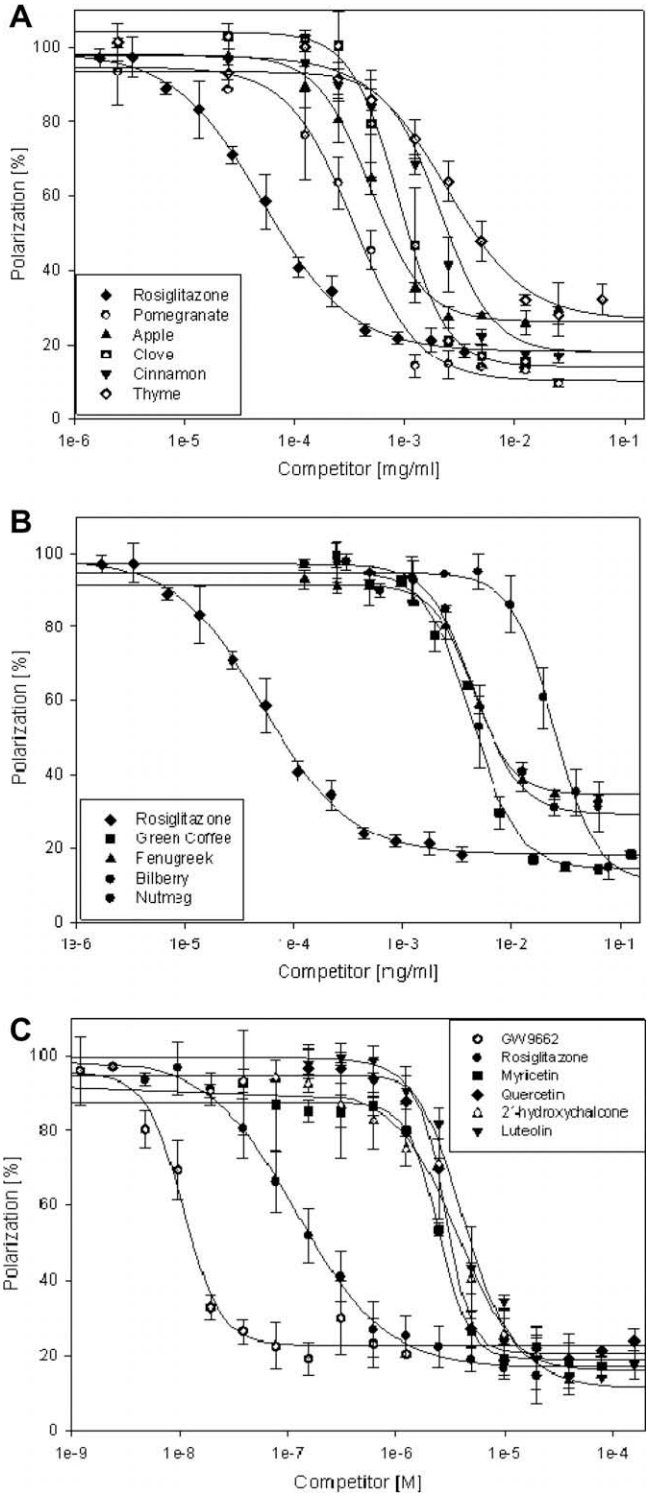

Fig. 1. (A) Logistic dose response curves of rosiglitazone, pomegranate fruit extract (standardised to 40% ellagic acid), apple extract (200-fold concentration and standardised to 5% quercetin and 30% phloridzin), clove, cinnamon extract (10-fold concentration), thyme extract (7-fold concentration) determined by competitive PPARγ ligand binding assay. (B) Logistic dose response curves of rosiglitazone, green coffee extract, fenugreek extract, bilberry extract (standardised to 35% phenols and 10% anthocyanins), nutmeg determined by competitive PPARγ ligand binding assay. (C) Logistic dose response curves of GW9662, rosiglitazone, myricetin, quercetin, 2′-hydroxychalcone, luteolin determined by competitive PPARγ ligand binding assay.

Table 2
Various substances occurring in the tested plant extracts were tested with a PPARγ competitive ligand binding assay (IC_{50}) and a chimeric GAL4-PPARγ assay system (EC_{50}).

Substance	CAS no.	Ligand binding IC_{50} (μM)	Transactivation EC_{50} (μM)	Efficiency (%)	Examples for occurrence (according to literature)

Compounds with an IC50 of ⩾ 500 μM were described as "ligand". If transactivation was observed but no EC50 value could be determined, compounds were described as "active". The efficiency describes the maximal induction using chimeric GAL4-PPAR assay and rosiglitazone as the standard. For some substances no binding and transactivation was observed (nd, not determined) when assayed up to a concentration of 2.5 mM (ligand binding assay) or 0.3 mM (transactivation assay).

(IC_{50} = 4.3 μg/ml), fenugreek (IC_{50} = 4.4 μg/ml), bilberry standardised on 35% phenols and 10% anthocyanines (IC_{50} = 4.5 μg/ml), rooibos tea (IC_{50} = 6.4 μg/ml), bay leaves (IC_{50} = 9.3 μg/ml) and holy basil, a 5:1 extract with high tannin content (IC_{50} = 16.2 μg/ml). Overall, approximately 50 plant extracts demonstrated PPARγ binding activity (Table 1, Fig. 1).

Isolated compounds that potentially represented the active substances of different plant extracts were also tested, along with glitazones for comparison (Table 2, Fig. 1). Quercetin showed the highest PPARγ binding affinity (IC_{50} = 2.8 μM), 2-hydroxychalcone and 2′-hydroxychalcone exerted moderate PPARγ binding affinity with IC_{50} values of 3.8 and 2.9 μM, luteolin bound with an IC_{50} value of 3.9 μM, rosmarinic acid bound with an IC_{50} value of 15.7 μM, cinnamaldehyde bound with an IC_{50} value of 10.3 μM and coumestrol moderately bound PPARγ (IC_{50} = 10.5).

3.2. Transactivation assay

Twenty-two plant extracts and several compounds were tested for their induction of PPARγ transactivational activity using a chimeric GAL4- PPARγ assay system. Five plant extracts, nutmeg, holy basil, licorice, sage and black pepper, were moderate PPARγ transactivators (Table 1, Fig. 2). An EC_{50} value could only be determined for nutmeg extract (106.1 μg/ml) as the logistic dose response curve of the other extracts could not be established due to a lack of saturation of receptor activation. Transactivation efficiency compared to rosiglitazone ranged from 10.3% for licorice extract to 15.3% for nutmeg extract.

The 2-hydroxychalcone, 2′-hydroxychalcone, coumestrol, phloretin, resveratrol, and apigenin compounds stimulated PPARγ transactivation (Fig. 2). The EC_{50} values ranged from 21.3

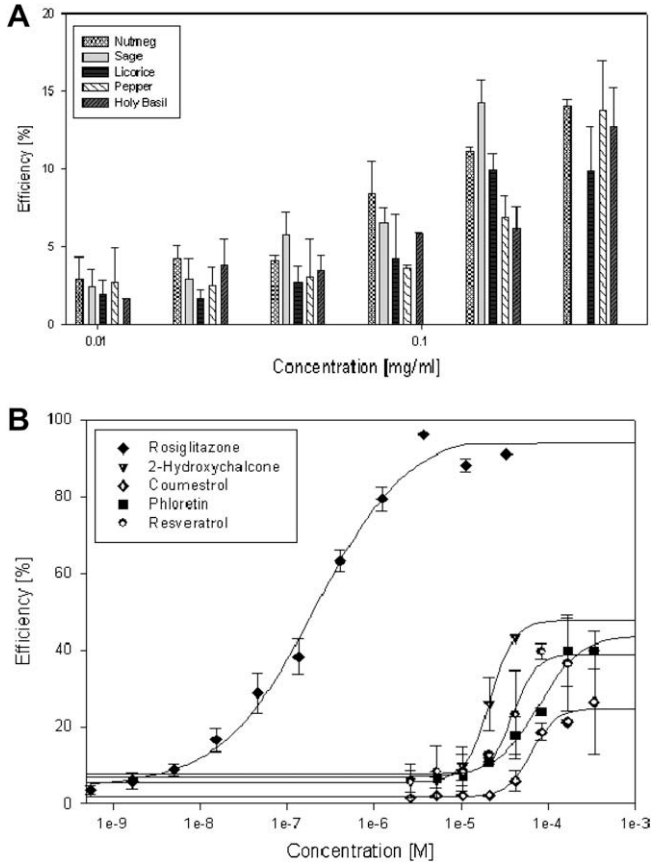

Fig. 2. (A) Nutmeg, licorice, sage, black pepper and holy basil transactivate PPARγ as determined by chimeric Gal4-PPARγ assay system. (B) Logistic dose response curves of rosiglitazone, 2-hydroxychalcone coumestrol, phloretin and resveratrol determined by chimeric Gal4-PPARγ assay system.

(2-hydroxychalcone) to 76.0 (phloretin) and the efficiencies from 15.7% (apigenin) to 47.9% (2-hydroxycachalcone). The strong ligands quercetin, luteolin and rosmarinic acid showed no transactivational activity. Cinnamaldehyde was highly cytotoxic, thus could not be assessed with this assay.

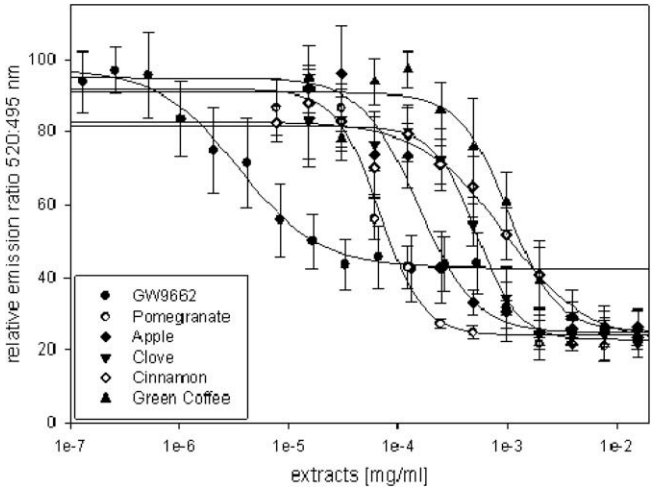

Fig. 3. Logistic dose response curves of GW9662, pomegranate fruit extract (standardised to 40% ellagic acid), apple extract (200-fold concentration and standardised to 5% quercetin and 30% phloridzin), clove, cinnamon extract (10-fold concentration), green coffee extract determined by TR-FRET coactivator assay in antagonist mode.

3.3. TR-FRET coactivator assay

The 22 plant extracts were next assessed with the TR-FRET coactivator assay system, as was the antagonist GW9662 (Table 1, Fig. 3). GW9662 showed strong antagonistic activity, with an IC_{50} value of approximately 0.003 μg/ml. With the exception of ginseng, stevia tea and curry powder, all plant extracts antagonized coactivator recruitment to PPARγ mediated by rosiglitazone. The strongest antagonists were pomegranate fruit extract (IC_{50} = 0.07 μg/ml), apple extract (IC_{50} = 0.15 μg/ml), clove (IC_{50} = 0.5 μg/ml), cinnamon extract (IC_{50} = 0.9 μg/ml), green coffee extract (IC_{50} = 1.0 μg/ml), bay leaves (IC_{50} = 3.0 μg/ml), crimson clover flower (IC_{50} = 3.3 μg/ml), bilberry (IC_{50} = 3.5 μg/ml) and rooibos tea (IC_{50} = 3.6 μg/ml). Interestingly, the extracts with transactivational activity, nutmeg, sage, licorice, holy basil and black pepper, also antagonized PPARγ coactivator recruitment.

4. Discussion

Obesity is a serious world wide health problem reaching nearly epidemic proportions. The health consequences of obesity include hypertension, diabetes, hyper- and dyslipidemia, and consequently an increased risk for cardiovascular morbidity and mortality (Alberti et al., 2006). Treatment of diabetes type 2, a key factor of the metabolic syndrome, with plants has been used a traditional remedy in many cultures (Grover et al., 2002; Shapiro & Gong, 2002), and accordingly, scientific studies have reported many medicinal and culinary plants with anti-diabetic potential (Broadhurst et al., 2000; Grover et al., 2002; Huang et al., 2005; Mae et al., 2003; Mueller & Jungbauer, 2008; Srinivasan, 2005; Verspohl et al., 2005). In this study, we identified many culinary herbs, plants and spices that function as PPARγ antagonists or SPPARγMs, suggesting their possible use in reducing the incidence of obesity and the risk of developing the metabolic syndrome. The main causes for obesity are high calorie intake, high fat intake and a sedentary lifestyle, but PPARγ active compounds may also play an important role in this process.

Approximately 50 different extracts from plants, herbs and spices, surprisingly almost all edible plants, with PPARγ binding affinity were identified. Five extracts (nutmeg, holy basil, licorice, sage and black pepper) showed moderate PPARγ transactivational activity. Our findings are consistent with the previously reported antidiabetic potential of nutmeg, sage and licorice extract via PPARγ agonism (Han et al., 2007; Mae et al., 2003; Rau, Wurglics, Dingermann, Abdel-Tawab, & Schubert-Zsilavecz, 2006).

The binding affinity of several plant extracts can be explained by the affinity of their compounds p. ex. quercetin which is found in pomegranate fruit (Naz, Siddiqi, Ahmad, Rasool, & Sayeed, 2007), apple (Kahle et al., 2007), tarragon, dill, bay leaf, parsley, chive, lovage (Justesen & Knuthsen, 2001), bilberry (Ehala, Vaher, & Kaljurand, 2005), and onion, 2-hydroxychalcone, 2́-hydroxychalcone and cinnamaldehyde which are found in cinnamon (Marongiu et al., 2007), luteolin which occurs in various plants such as sage, rosemary, thyme (Proestos, Chorianopoulos, Nychas, & Komaitis, 2005), tarragon, parsley (Justesen & Knuthsen, 2001), and alfalfa (Seguin & Zheng, 2006), rosmarinic acid, a component of sage, rosemary, lavender (Wang, Provan, & Helliwell, 2004), and thyme (Proestos et al., 2005), or coumestrol, which occurs in alfalfa extract.

Nearly all the tested extracts antagonized rosiglitazone-mediated DRIP205/TRAP220 coactivator recruitment, including the five transactivating extracts. Likely these extracts could function as selective PPARγ modulators (SPPARγMs), which transactivate PPARγ but do not recruit all coactivators.

The extracts that bind PPARγ and antagonize the DRIP205/TRAP220 coactivator recruitment, such as pomegranate, apple, cinnamon, clove or thyme, are moderate antagonists or undetectable

or weak SPPARγMs. We found that compounds of these extracts function as agonists, such as resveratrol and coumestrol, or antagonists, such as quercetin, luteolin and rosmarinic acid. Interestingly, the antagonistic activity exceeds the agonistic activity. Apple extract with a high amount of phloridzin is a putative PPARγ agonist in vivo, as phloridzin was previously shown to be metabolized into aglycone phloretin (Kahle et al., 2007), a moderate PPARγ binder and activator. Although ginseng, stevia and curry powder are PPARγ ligands and did not function as transactivators, they did not antagonize DRIP205/TRAP220 coactivator recruitment. These extracts may have extremely weak and undetectable transactivator activity. According to reports in the literature, ginseng and stevia extract exert antihyperglycemic activity (Jeppesen, Gregersen, Alstrup, & Hermansen, 2002; Vuksan et al., 2008).

Full PPARγ agonists, such as glitazones, are used for treating diabetes type 2; these function by recruiting a specific spectrum of coactivators, and are associated with side effects such as weight gain. Amongst other coactivators, the PPARγ coactivator DRIP205/TRAP220 was classified as a so called "adipogenic factor", indicating that it promotes adipogenesis and adipocyte differentiation in cell culture and weight gain in humans (Rieusset et al., 2002; Zhang et al., 2007). In this study, 19 of 22 tested plant extracts were identified to antagonize DRIP205/TRAP220 coactivator recruitment, and we presume that they may therefore support weight reduction.

Interestingly, this study identified not only herbs and spices, which are consumed in small amounts, as PPARγ activators, but also many edible plants that are consumed in high amounts, such as apple, bilberry, cacao, onion, kale and white cabbage.

There are uncertain parameters in the calculation of a daily effective dose for antiobesity or antidiabetic activity. One challenge is in standardising the plant extracts. Due to the influence of climatic circumstances and growth area, extracts of one species from different suppliers differed significantly in their PPARγ activity. Furthermore, metabolism of compounds can result in more active or less active PPARγ ligand activity, absorption rate of different compounds varies considerably, and the influence of the food matrix must be considered.

A vegetarian or vegetable rich diet is known to reduce the incidence of obesity and other cardiovascular risk factors (Bazzano, Serdula, & Liu, 2003). In addition to exercise, the major factor of weight reduction is still reduction of calorie intake (Bazzano, Serdula, & Liu, 2005). Furthermore a diet rich in herbs and spices may provide pharmacological active compounds that may prevent weight gain (Lee et al., 2008).

With a diet including the above-mentioned culinary plants, a certain amount of PPARγ antagonists and SPPARγMs is simultaneously consumed. Improvement or prevention of insulin resistance and obesity, the main cause of insulin resistance, could be achieved simultaneously. A diet rich in these plants for obese and/or diabetic patients could reduce the dose of hypoglycaemic agents and support weight reduction. Obese patients without manifest diabetes could possibly even avoid those drugs. Obese patients without insulin resistance could prevent developing diabetes.

5. Conclusion

In conclusion, our study identified a wide variety of culinary herbs, plants and spices with PPARγ binding activity, including pomegranate extract, apple extract, clove, cinnamon, thyme, green coffee, fenugreek, bilberry, nutmeg, rooibos tea and bay leaves. The five plant extracts, nutmeg, black pepper, licorice, holy basil and sage, likely function SPPARγMs. Nearly all extracts antagonized DRIP205/TRAP220 coactivator recruitment, which may result in the antagonism of adipocyte differentiation and thus support weight reduction. Inclusion of a combination of these plants in the diet could reduce the incidence of obesity and attenuate developing metabolic syndrome.

Acknowledgements

We thank Prof. Staels (Institut Pasteur, University of Lille, France) for providing the pGAL4-hPPARγ-LBD expression plasmid.

emulsified shortenings are more suitable for icings, cakes, etc. where the incorporation of air into the shortening system is desired. In terms of emulsifiers, mono- and diacylglycerols possess marked surface activity because of their lipophilic and hydrophilic groups. Improvement in aeration is observed by the addition of mono- and diacylglycerols (2–4% (w/w) of the shortening) (Chrysam, 1985).

The preparation of a shortening through chemical interesterification of high oleic sunflower oil and fully hydrogenated fat is reported here. The functionality of the finished product was related to the chemical composition, polymorphism, morphology, and rheological properties of the fat. Finally, the functionality of the product was compared to that of a widely used commercial shortening in cookie manufacture.

2. Materials and methods

2.1. Raw materials

Blends of fully hydrogenated canola oil (FHCO), fully hydrogenated soybean oil (FHSO) and high oleic sunflower oil (HOSO) in a weight ratio of 17:13:70 were chemically interesterified. Fully hydrogenated canola oil (FHCO) and high oleic sunflower oil (HOSO) were generously provided by Bunge Canada (Toronto, ON, Canada) and Nealanders (Toronto, ON, Canada), respectively. All chemicals and organic solvents were purchased from Fisher Scientific (Ottawa, ON, Canada) and Sigma–Aldrich (Oakville,ON, Canada). Anhydrous citric acid and monoglyceride Dimodan-P-TK-A were generously donated by ADM (Decatur, IL, USA) and Danisco (New Century, KS, USA) Inc., respectively.

2.2. Chemical interesterification

Chemical interesterification was carried out using 0.3% (w/w) sodium methoxide (Sigma–Aldrich, Oakville, ON, Canada) as a catalyst. A 20 kg mixture FHCO, FHSO and HOSO (17:13:70, w/w/w) were melted in a container at 85 °C, under a nitrogen blanket to limit the presence of moisture and air. The chemical reaction was started by the addition of catalyst. The blends were interesterified under agitation and under a blanket of nitrogen for 60 min at 88 ± 2 °C. The start of the reaction was associated with the appearance of a red–brown colour. The addition of 4% acidic water (20% citric acid, w/v) was used to stop the reaction. The product was washed with eight parts hot water (1:8, v/v) to remove soaps, excess citric acid, sodium methoxide and some of the free fatty acids. Residual water and any remaining impurities were then removed by adding bleaching clay (1.5 wt%) and the sample heated again at 88 ± 2 °C for 20 min under nitrogen gas. The interesterified blend was then filtered. The fat was poured into a bucket and stored at 5 °C prior to use.

2.3. Crystallizer equipment

Samples of the interesterified blends were prepared in a Gerstenberg and Agger crystallizer (Copenhagen, Denmark). The unit consists of a melting container, chilling system (three separate chilling units) and pin worker. The CI-sample was heated to 55 °C and mixed with 2% emulsifier (monoacylglyceol, Dimodan-P-TK-A). The homogenous blend at 55 °C was fed at 910 g/min through the chilling unit. A film of solidified, partially crystallized fat was removed from the tube walls by scraper blades. The material exiting from the chilling unit at 10.7 °C was then allowed to enter the pin machine at a speed rate of 350 rpm. The finished product was stored at room temperature in a closed container. For comparison, a commercial all purpose shortening was purchased from a local store.

2.4. Triacylglycerol (TAG) composition

The TAG composition was determined using a high-performance liquid chromatography system (model 1100; Agilent Tech. Palo Alto, CA) equipped with a quaternary pump (C1311A), auto sampler (G1313A), and a Hewlett–Packard Chem Station software system (Version A.10). TAGs were detected with an evaporative light scattering detector (Alltech, MK III, Deerfield, IL, USA) using nitrogen at 50 PSI with neubulization conducted at 50 °C. Solutions of each blend in chloroform (2.5% (w/w)) were filtered (Osmonics magma nylon membrane filter, 0.45 μm pore size, Fisher Scientific, Ottawa, ON, Canada). A 20 μL sample was passed through an Econosil column (C18, 250 × 4.6 mm) (Alltech Associates, Deerfield, IL, USA) in isocratic mode at a flow rate of 1.0 mL/min. The mobile phase was acetonitrile–chloroform (70:30, v/v). TAG species were identified by comparison with standards (Sigma–Aldrich, Oakville, ON, Canada) and they were quantified based on a relative peak area basis.

2.5. Fatty acid composition

Fatty acid composition was determined by gas liquid chromatography (GLC) after preparation of fatty acid methyl esters. Anhydrous 5% HCl/methanol (by weight) for 1 h at 80 °C was used for the methylation reaction. In each case, the resultant fatty acid methyl esters (FAME) were extracted using hexane after the addition of water. Hexane was removed and the FAMEs were purified by TLC on silica gel G plates (Fisher Scientific, Ottawa, ON, Canada) using the developing solvent hexane/diethylether/acetic acid (85:15:1, v/v/v). The FAME band were identified on plate after spraying the plate with 2′,7′-dichlorofluorescein in methanol and the band was visualised under ultraviolet light. The FAME band scrapped off and transferred into a Pasteur pipette and the FAME eluted with hexane (Azizian, Kramer, & Winsborough, 2007). An appropriate concentration of prepared samples were analysed by GC (Hewlett–Packard Model 5890 Series II, Palo Alto, CA, USA) equipped with a flame ionisation detector and an autosampler (Hewlett–Packard, Model 7673). A CP-Sil 88 fused capillary column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; Varian Inc., Mississauge, ON, Canada) and a Hewlett–Packard Chem Station software program (Version A.10) were used. The operating conditions were: injector and detector temperature both at 250 °C, H_2 as carrier gas (1 mL/min) and for the FID detector (30 mL/min), N_2 make up gas (30 ml/min) and air (300 mL/min). The column temperature program was: initial temperature of 45 °C and held for 4 min, then programmed at 13 °C/min to 175 °C and held for 27 min, then temperature was increased to 215 °C at 4 °C/min and held for 35 min. Individual components were identified by comparison with a GC reference FAME standard (#463, Nu-Chek Prep, Inc., Elysian, MN, USA). Fatty acids were quantified based on relative peak area.

2.6. Physical measurements

Melting profile, storage modulus, Solid fat content, crystal size, texture analysis and polymorphism were performed as described by Ahmadi, Wright, and Marangoni (2008a, 2008b).

2.7. Cone penetrometry

Penetration depth was determined by allowing a metal cone (aluminium) to penetrate into a sample for 5 s. The cone is clamped into an apparatus with which the penetration depth can be measured. Five replicate analyses were performed for each sample and the mean ± SEM is reported. The cone used for determination of the yield values was 15 g cone with an angle = 15°. The yield value [g/cm^2] was calculated as

$$\text{Yield Value} = K\frac{\text{mass of cone(g)}}{(\text{depth of penetration}, 0.1\text{mm})^{1.6}} \quad (1)$$

where K for a cone with an angle of 15° is tabulated as 30700 (Haighton, 1959).

2.8. Use of the shortening in a baking application

To demonstrate the functionality of the CI-shortening, the following formulation was used to make chewy brownie cookies and compared to cookies made with commercial shortening (Table 1).

2.9. Preparation of the cookies and evaluation

Shortening (20.6%), sugar (15.5%), brown sugar (12.6%), and vanilla (0.4%) were mixed in a Kitchen Aid professional HD mixer for 2 min at speed 2 with a flat beater. Beaten egg (9.8%) was added on low speed for 1 min and 30 s until mixture is just combined. Flour (19%), cocoa (5.7%), baking soda (0.3%), and salt (0.3%) were combined and added to the mixture with milk (5%) and beaten on speed 2 for 1 min and 30 s. Finally, chocolate chips (13%) were added and mixed. A 50 g portion of dough was placed on a baking sheet and baked at 350°F for 10 min. Width and thickness of cookies were measured with a caliper and the spread ratio was obtained by dividing width (mm)/thickness (mm). The breaking strength was measured using an SMS Materials Tester model MT-LQ (Stable Micro Systems Ltd., Surrey, England) equipped with a blade cutting probe, 1.4 cm long and 0.4 mm thick. A force–displacement diagram was taken for each sample. The force (N) required to break a cookie was recorded and the average value of 10 replicates was reported (Zoulias, Oreopoulou, & Tzia, 2002).

2.10. Sensory evaluation

The sensory analysis of cookies was carried out by 37 untrained consumer panellists. The selected method was a triangle test. In the triangle test, three coded samples are given to the panellist. In the questionnaire form it is stated that two of the samples are identical and the panellist is asked to identify the odd sample. The sensory evaluation test and analysis of cookies was carried out a day after preparing them (Larmond, 1970).

3. Results and discussion

The fatty acid and triacylglycerol composition of the two samples (CI-sample and commercial sample) are presented in Tables 2 and 3.

The CI-shortening contained high amounts of unsaturated fatty acids (59.7%) in which the major fatty acid was oleic acid (51.5%).

Table 1
Ingredients used for preparation cookies.

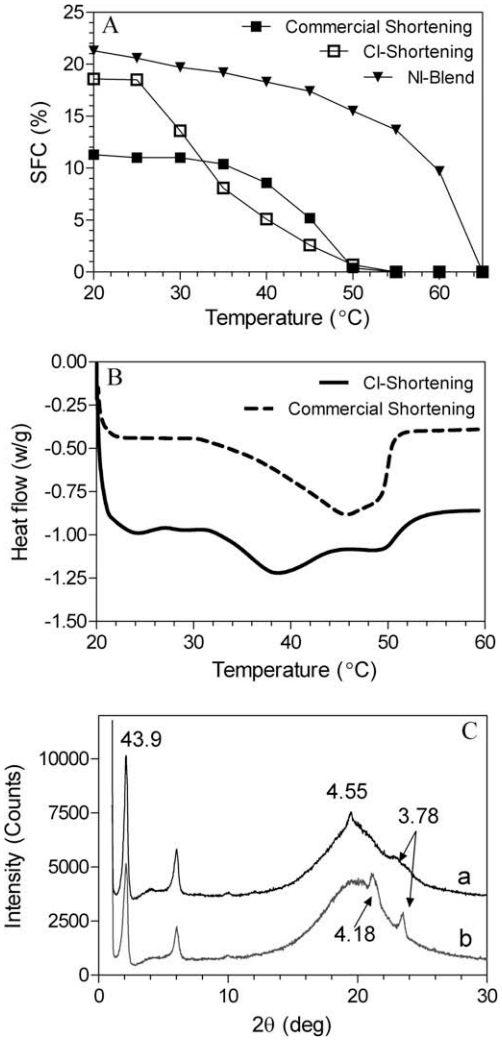

Fig. 1. (A): SFC as a function of temperature in 30%-NI-blend, 30% CI-shortening and commercial shortening, and (B) Differential scanning calorimetery melting thermograms of 30% CI-shortening and commercial shortening. C: Powder X-ray diffraction pattern for commercial and CI-shortening crystallized at room temperature for 24 h; (a) CI-shortening and (b) commercial shortening.

The total amount of unsaturated molecules in the commercial shortening was 63.9% and linoleic acid (41.5%) was in the highest amounts. Due to the high oxidative susceptibility of linoleic acid, replacing it with oleic acid should improve the oxidative stability of the product. The major saturated fatty acids in the CI-shortening and commercial shortening were stearic acid (29.9% and 12.9%, respectively) and palmitic acid (6.8% and 14.7%, respectively). Trans fatty acids were identified in the CI-samples (0.9%) and shortening (4.2%) (Table 2). The presence of trans fatty acid indicated that the commercial shortening contained partially hydrogenated fat, even though the product was labelled as trans-fat free. GLC analysis revealed that the majority of trans fatty acids were elaidic acid (18:1t).

Table 3 shows the TAG composition of the two shortenings. In the commercial shortening, TAGs contained linoleic acid such as LLL, LLO, LOS, and LLP which constituted 73.1% of the total TAGs. In the CI-shortening, TAGs containing oleic acid and stearic acid, such as OSO, SOS and POS were the main species present. Polymorphic behaviour is influenced by TAG and fatty acid composition (Takeuchi, Ueno, & Sato, 2002). In some cases the presence of a specific TAG has a beneficial effect on the polymorphic form and its stability (deMan & deMan, 2001). For example, 1-palmitoyl, 2-ste-

TAG shown constitutes the major species present (i.e. >0.1%).
Values represent the mean value of two replicates with standard deviation.

aroyl, 3-palmitate (PSP) exists in a β′ form, whereas 1-stearoyl, 2,3-dipalmitate (SPP) and 1-palmitoyl, 2,3-distearate (PSS) crystallize in both β and β′ forms (Lutton, 1950). PSP in the tested commercial shortening was probably a factor affecting β′ polymorphism. In addition, a higher amount of palmitic acid in the commercial shortening can lead to increases in β′ polymorphism. D'Souza et al. (1991) concluded that the difference between β and β′ in margarines could be related to the C16 fatty acid. In the β-tending margarines the C16 fatty acid content was below 11%, but it was above 17% in the β′-tending margarines. deMan, deMan, and Blackman (1989) showed that the shortening containing partially hydrogenated fat was in β′ form compared to shortening without partially hydrogenated fat in the β form.

SFC: The SFC profiles of the experimental CI and commercial shortenings are shown in Fig. 1A. The SFC of the physical blend (NI-Blend, i.e. non-interesterified) was changed dramatically after chemical interesterification. The SFC of the interesterified blends was consistently lower than those of the NI blends. This is due to the randomization of fatty acids in the TAG molecules during the interesterification and creation of TAG species with melting points below that of trisaturated molecules (Chu et al., 2001). Lee, Akoh, and Lee (2008) found the same results for an interesterified sample produced with fully hydrogenated soybean oil, rapeseed oil and palm stearin in three different ratios. The observed changes in the slope of the CI-shortening curve were attributed to the presence of intermediate TAGs created after the interesterification process (Litwinenko, Rojas, Gerschenson, & Marangoni, 2002; Metzroth, 2005). The CI-sample showed an SFC profile close to that of the commercial shortening and the SFC of both samples decreased sharply with increases in temperature. Products with the type of profile are referred to as high stability shortenings (Metzroth, 2005). Overall, the CI-shortening had plasticity curves in the range of the commercial shortening.

Even though the CI-sample had a higher SFC at 20 °C than the commercial shortening, both samples melted completely at 50 °C. DSC results showed the same end point melting temperature for both samples (52 °C) (Fig. 1B). The physical characteristics of this shortening make it a suitable choice to use as a deep fat frying, as ingredient in cookies, crackers and some other confectionary products. Because these type of products need a fat with high SFC at low temperature and low SFC around 45 °C (Metzroth, 2005).

Crystal structure and crystal morphology: Polymorphism, crystal size and crystal shape were studied using polarised light microscopy and X-ray diffraction on samples stored for 24 h at room temperature. The polymorphic form of the crystals can affect the shape and size of the crystals and crystal aggregation (Hoerr & Waugh, 1955; Kellens, Meeussen, & Reynaers, 1992). Powder X-ray diffraction (Fig. 1C) indicated that the β′ polymorph was predominant in the commercial shortening, with short spacings observed at 4.2 and 3.8 Å. The CI-sample was mostly in the β form with a short spacing of 4.55 Å. Storage of the sample at room temperature gave enough time for crystals to convert to a stable polymorphic form. The level of softness or graininess of the shortening product may be associated, in part, with the polymorphic form. However the same polymorphic forms could have different crystal sizes and dif-

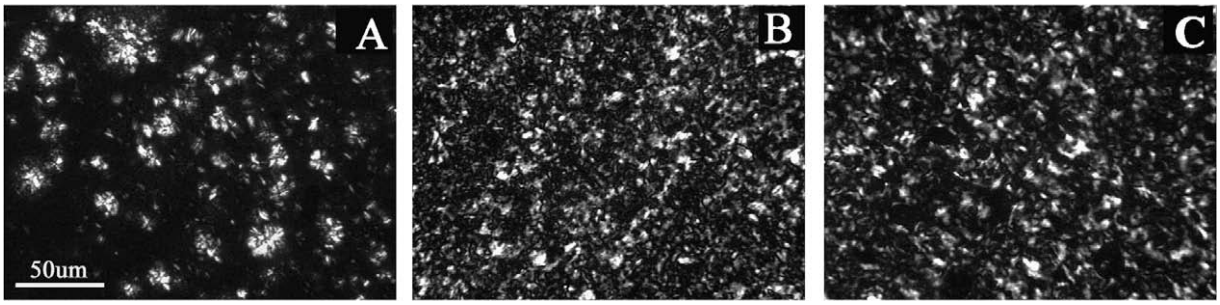

Fig. 2. Polarized light micrograph of (A) CI-shortening (static), (B) CI-shortening (under shear), and (C) commercial shortening stored at 25 °C/24 h.

ferent crystal shapes which in turn could lead to a greater or lesser graininess of the product (Kellens et al., 1992).

The β′ polymorph is usually believed to be the most functional polymorphic form in shortenings because of its small size and needle-like shape (Ghotra et al., 2002). Observing the crystal morphology of the CI-samples by PLM (Fig. 2) clearly demonstrates that even though the polymorphic form is different in the two samples, their morphology was the same. Crystal size and shape are the key factors influencing fat functionality and rheological properties of plastic fat (Tang & Marangoni, 2006). Large crystals impart a sandy mouth feel, whereas smaller crystals lead to firmer products (Rodriguez, Castro, Salinas, Lopez, & Miranda, 2001).

Polarized light images of the CI-sample before and after shearing were taken in order to understand how the appearance and morphology of crystals was affected by the thermal and mechanical treatment. Fig. 2A shows larger crystals (10.2 ± 3.42 μm), more aggregation and a more heterogeneous distribution of crystals for crystallization under static conditions compared to the sheared samples. After shearing and crystallization, images showed a smaller crystal size (3.5 ± 1.28 μm), less aggregation, and a more homogenous distribution of the crystals (less void space) (Fig. 2B). Shear induces more nucleation and less crystal growth and crystal breakage which resulted in a smaller crystals size. Therefore, products become more firm, more stable and possess a greater plastic range as the crystal size decreases. Decreasing crystal size induces a greater combined surface area and provides a strong network (Metzroth, 2005).

Rheological properties: At the same storage temperature (25 °C/24 h), the commercial sample of shortening had a higher storage elastic modulus than the CI-sample ($P < 0.05$) (Table 4), even though the CI-sample had a higher SFC. Small differences in the storage modulus value could be attributed to different chemical composition or different processing and tempering between the two samples. The measurement of G′ in the CI-sample before crystallization and shearing was not possible because the sample was too soft. Measuring the hardness of the shortenings by cone penetrometry revealed that the commercial shortening had a firmer texture relative to the CI-shortening. Penetration depth (0.1 mm) values of both of the shortenings were within the range of those reported for a soft shortening (50–300 g/cm^2) (Haighton, 1959).

Physical characteristics of cookies: The physical characteristics of cookies made using the different fats are shown in Table 5. Cookies made with the commercial shortening had a relatively lower spread ratio than cookies made with 30% FHCO and FHSO ($P < 0.05$). In contrast, the hardness of cookies was unaffected by the kind of shortening, and both samples had the same hardness index ($P > 0.05$). Jacob and Leelavathi (2007) reported the cookies made with sunflower oil had a higher spread value than cookies containing non-emulsified hydrogenated fat, but cookies made using sunflower oil were harder than cookies made using hydrogenated fat. There were no significant differences in the measured hardness between the two samples ($P > 0.05$).

Sensory evaluation test: A triangle test was carried out using 37 panellists. The results showed that 21 of the 37 tasters could not distinguish between cookies made using the CI-shortening and the commercial shortening ($P < 0.01$). Therefore, despite the differences in spread ratio of the cookies, they showed the same hardness and the same sensory attributes.

In conclusion, a chemically randomized blend of a 30% stearic acid-rich (FHCO and FHSO) and oleic acid-rich (HOSO) can be used as a zero trans shortening. Comparable plasticity was achieved by chemical interesterification of the mixture and then crystallization and shearing of the fat. This high stability shortening can find application in deep fat frying and many all-purpose bakery applications. This product had a comparable plasticity and melting characteristics as a commercial shortening, but with the added health benefits of high stearic and oleic acids.

Table 4
Rheological properties of CI-shortening and commercial shortening stored at 25 °C for 48 h.

Physical properties	CI-shortening	Commercial shortening
Storage modulus (G′) (Pa)	$1.25 \times 10^5 \pm 0.342 \times 10^5$	$2.02 \times 10^5 \pm 0.505 \times 10^5$
Penetration depth (0.1 mm)	212 ± 7.0	126 ± 8.2
Yield value (g/cm^2)	88.65	199.7

Values represent means and standard deviation of 10 replicates.

Table 5
Effect of shortening type on the physical specifications of cookies.

Shortening type	Width (mm)	Thickness (mm)	Spread ratio (mm)	Yield force (N)
30% CI-blend	70.55 ± 0.25^a	9.69 ± 0.09^a	7.38 ± 0.28^a	16.63 ± 3.97^a
Commercial	67.62 ± 0.11^b	10.38 ± 0.05^a	6.54 ± 0.15^b	17.99 ± 5.05^a

Values represent means and standard deviation of 10 replicates.
Different superscript letters indicate significant differences ($P < 0.05$) of values within each column.

Acknowledgments

The authors acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada and the Ontario Ministry of Agriculture, Food and Rural Affairs. The authors are thankful to Prof. John Kramer in Agriculture and Agri-Food Canada for his assistance in determining the fatty acids and triacylglycerols content of the fats. We are grateful to Dr. Gary List for providing the samples of fully hydrogenated soybean and canola oil.

25, 50, and 75 mW/cm^3 and exposure times (PT) of 2, 5, and 8 min; and both treatments were incubated (IC) at 25 °C for 24, 36, and 48 h. Untreated raw peanuts served as controls. Two replications of the 27 UV and US treatments, and one control were prepared, a total of 110 samples analysed for *trans*-RES and *trans*-piceid in duplicate. When large coefficient of variation (COV) > 35% occurred between two replicates, a third duplicate analysis was conducted to decrease COV to <35%. Outlying results were dropped from the data set if COV remained >35%.

2.2. Sample preparation

Raw peanuts, (*Arachis hypogaea* cv Georgia green medium runners, 2005 crop year; Golden Peanut Co., Alpharetta, GA) stored for 2 months at 4 °C were used. All processing implements and surfaces were washed and sanitised with 200 ppm chlorine solution prior to use. About 1.8 kg peanuts were washed twice in 4 kg tap water, drained, surface sanitised in 2 kg of 150 ppm chlorine solution for 15 min, and rinsed with sterilised deionised water, prepared by passing through a 0.2 μm nylon filter (Millipore Corp., Bedford, MA). Peanuts were fully imbibed in 2 kg sterilised water for 16 h, drained, and manually sliced to about 7 mm.

UV treatment: Sliced peanuts, three batches of about 900 g each, were spread 1 cm layer deep on a plastic tray (56L × 30.5W × 60H cm, HDPE, Gage Industries Inc., Lake Oswego, OR). Three trays were positioned side by side along their length, a total of 91.5 cm, to allow equal exposure to 122 cm UV light (UPV XX-40S, 40 W, 254 nm, UltraViolet Products, Upland, CA) at a specific distance, and trays were removed after specific time according to experimental design. Peanuts were mixed after half of exposure time for equal exposure of surfaces to UV.

US treatment: Sliced peanuts, approximately 900 g/batch, were placed in a 2.5 L stainless steel cylindrical container (20 cm, i.d.) then filled with deionised water to 1.5 L. US at 20 kHz was applied through a 25 mm diameter probe of an ultrasonic processor with temperature controller (750W, 115 VAC, 50/60 Hz, Cole Parmer, Vernon Hills, IL) operating continuously at 25 °C and positioned at the centre of peanuts. The amplitude to achieve the desired power delivered to the probe was calculated using the formula, power (J or W-s) = PD (mW/cm^3) × volume of water (cm^3) × time (s) × 1 W/1000 mW, and empirically determined from preliminary sonication of peanuts immersed in water resulting in 21%, 48% and 68% amplitudes to achieve PD of 25, 50 and 75 mW/cm^3, respectively. Peanuts were sonicated and then drained, 15 min, to remove excess water.

Treated peanuts were packed in half gallon glass mason jars (Ball Corp., Muncie, IN), sealed with two-piece lids (Alltrista Corp., Muncie, IN), wrapped with foil and incubated at 25 °C (Environmental Growth Chamber, Chagrin Falls, OH) for 24, 36, and 48 h. Incubated samples were accumulated in a walk-in freezer at −18 °C, then thawed in a walk-in chiller, 5 °C for 24 h, poured to aluminium trays (40.6L × 38.1W × 1.2H, cm; 0.4 cm i.d. perforations) to one layer depth, and dried in a convection oven (645 Freas, Precision Scientific, Winchester, VA) at 45 °C for 24 h to about 10% moisture by weight. Peanuts were roasted (Lincoln Impingement Oven Model 1452, Fort Wayne, IN) at 158 °C for 4.5 min to an *L* value of 50 ± 1 (Chroma meter, Model CR-200, Minolta, Japan), cooled using an industrial fan, skins were manually removed then blown away by the fan. Roasted peanuts were packaged (10.16 × 45.72 cm vacuum plastic bags, Koch Packaging, Kansas, MO), flushed with nitrogen gas (medical grade, South Air Gas, Griffin, GA), and vacuum sealed (Ultravac, Koch Packaging, Kansas, MO). The entire process was conducted under yellow light to avoid isomerisation or degradation of stilbene compounds (Trela & Waterhouse, 1996).

Samples were stored at −18 °C prior to analysis, about 1 year.

2.3. Extraction of trans-RES and trans-piceid

Only *trans* isomers of RES and piceid were measured using the reverse HPLC method of Potrebko and Resurreccion (2009). About 30 g sample was ground (coffee mill, Model K9M2-4, BrAun, Mexico) for 1 min, then 10g were weighed into a 250 mL centrifuge bottle and added with 30 mL of 80% ethanol and 2 mL of 60 μg/mL freshly prepared phenolphthalein (Aldrich Chemical Company, Milwaukee, WI) solution as internal standard. Contents were homogenised (PowerGen 700, Fisher Scientific, Pittsburg, PA) for 2 min on ice and centrifuged (Model J2-21 M, Beckman, Palo Alto, CA) for 5 min at 1380G at 25 °C. A 2 mL supernatant was drained by gravity, about 20 min, into a 5 mL tube through a clean-up column, to remove interfering compounds that co-eluted with RES and piceid (Sanders, McMichael, & Hendrix, 2000). Clean-up column was a 3 mL disposable syringe fitted with about 5 mm diameter pre-filter (AP25, Millipore, Bedford, MA) to prevent loss of packing, consisting of 1 g mixture of aluminium oxide (neutral activity 1, particle size of 0.063–0.200 mm, EM Science, Gibbstown, NJ) and silica gel 60 C_{18} (EM Science, Gibbstown, NJ), 1/1, w/w. Column was washed with 0.5 mL ethanol and filtrate was collected in the same tube. Contents of six tubes placed parallel in a heating block (Thermolyne, Dubuque, IO) set at #5 to maintain 60 °C, were dried for about 1 h by blowing nitrogen directly over the samples through a hollow six-pin blowdown manifold, then tubes were capped, wrapped with foil and stored at −20 °C for about 1 week until analysed. Extraction was conducted under yellow light.

2.4. HPLC analysis of trans-RES and trans-piceid

Before HPLC analysis, 0.40 mL ethanol (15%) was added to dried peanut extract, vortexed for 30 s. Six tubes at a time were immersed into water in a round plastic container (13 cm i.d. × 6 cm depth) for 2 min indirect sonication at 50% amplitude using the ultrasonic processor described in Section 2.2 Sample was poured into a 3 mL glass syringe with attached inorganic membrane filter (Anotop 10, 0.2 μm, Whatman International Ltd., Maidstone, England), filtered into a 300 μL polypropylene insert placed in a 2 mL HPLC amber vial and sealed with a screw cap fitted with a Teflon/silicon septum (National Scientific Co., Lawrenceville, GA). HPLC analysis used a Varian ProStar HPLC system consisting of ProStar410 auto sampler, solvent delivery module 210, and ProStar 335 Diode Array Detector (DAD) to set UV spectrum from 240 to 400 nm, and controlled by LC Module Add-In Star version 6 and Star WS version 5.X, 6.41 software system (Varian Inc., Palo Alto, CA). The Eclipse Plus C18 reverse column, 250 × 4.6 mm, 5 μm particle size, preceded by an Eclipse Plus C18 guard column, 7.5 × 4.6 mm, 5 μm particle size (Agilent Technologies, Deerfield, IL) was maintained at ambient temperature, 25 °C. A 1.5 mL/min flow rate was used for solvent A, 100% double deionised water vacuum filtered through a 0.2 μm nylon filter and solvent B, 100% acetonitrile (HPLC Grade, Aldrich, Milwaukee, WI). Gradient elution included: 0 min, 5% B; 7 min, 22% B; 13 min, 23% B; 26 min, 63% B; 28 min, 80% B; then finally returned to 5% B in 1 min, and held at 5% B for additional 5 min. Samples were injected at 40 μL.

Peak areas of *trans*-RES and piceid, were quantified at 307 nm and of phenolphthalein, at 280 nm (Rudolf & Resurreccion, 2005) and concentrations were calculated as follows:

$$\mu g \text{ of } i \text{ in sample} = \frac{\left(\frac{\mu g \text{ of } i \text{ in standard}}{\text{PA of } i \text{ in standard}}\right) \times \text{PA of } i \text{ in sample}}{\left(\frac{\mu g \text{ of IS in standard}}{\text{PA of IS in standard}}\right) \times \text{PA of IS in sample}} \times \mu g \text{ of IS in sample}$$

where *i* = *trans*-RES or *trans*-piceid, IS (internal standard) = phenolphthalein, and PA = peak area. Six levels of standards, 10, 5, 3, 2, 1, and 0.5 μg/mL for *trans*-RES and piceid, and 20, 10, 6, 4, 2 and

1 μg/mL for phenolphthalein were analysed at the beginning of each HPLC sample set. *Trans*-RES and piceid were reported as μg/g peanut, dry weight basis, and their sum, as total stilbenes.

2.5. Consumer acceptance test

A consumer acceptance test (Resurreccion, 1998) was conducted recruiting 50 panelists using the criteria: 18–70 years old, non-smoker, not allergic to peanuts, consumes peanuts and peanut products at least twice/month, willing to evaluate peanuts, and available during test sessions. Twenty five panelists evaluated replication 1 and the other 25, replication 2 from 8:00 am to 7:50 pm. Each panelist evaluated a total of 28 samples in two sessions conducted 1 h apart, 14 samples/session presented in three blocks with 4–5 samples/ block; had 10 min compulsory breaks in-between blocks; and expectorated all samples to prevent fatigue during evaluation. Panelists were asked to fill-out demographical questionnaire, and read and sign two copies of consent to participate forms approved by the University of Georgia Institutional Review Board. Panelists were supplied with water and crackers for rinsing in-between samples. Samples were presented using a monadic sequential order controlled by *Compusense five* (version 4, Compusense Inc., Guelph, Ontario, Canada). Panelists evaluated overall acceptance (OA) and acceptance of appearance, colour, aroma, flavour and texture using a 9-point hedonic scale, with 1, dislike extremely; 5, neither like nor dislike; and 9, like extremely.

2.6. Statistical analysis

Data were analysed using SAS, 2001 statistical software, version 8 (SAS Institute Inc., Cary, NC). General Linear Model (PROC GLM) was used to detect significant differences amongst treatments for the response variables, RES, piceid, total stilbenes, and OA. The relative significance of independent variables, ID, IT and IC for UV treatment and PD, PT and IC for US treatment, was established by ANOVA with the variable contributing the largest percentage to the total sum of squares as the most significant. Mean separation test by Fisher's least significant difference at $P \leqslant 0.05$ was used to compare means of response variables.

Regression analysis (PROC REG) was conducted to develop prediction models for each response variable based on independent variables. A second order polynomial regression model with three linear terms was used as full model as follows: $Y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_1 x_1^2 + \beta_2 x_2^2 + \beta_3 x_3^2 + \beta_{12} x_1 x_2 + \beta_{13} x_1 x_3 + \beta_{23} x_2 x_3 + \beta_{123} x_1 x_2 x_3 + \varepsilon$, where Y, response variable; β_0, intercept when x_1, x_2, and x_3 are equal to zero; β_1, β_2, and β_3 = parameter estimates of the linear terms for UV treatment, ID (x_1), IT (x_2), and IC (x_3) and for US treatment, PD (x_1), PT (x_2), and IC (x_3); and their squared and cross product terms.

RSM determined the effects of independent variables on the levels of response variables. Significant regression models were identified ($P < 0.05$) and used to generate response surfaces and contour plots using PROC GCONTOUR with two independent variables at a time, holding the third fixed at one level. Regions of interest were shaded on the contour plots to cover the area with $\geqslant$2.64 μg/g *trans*-RES (McMurtrey, Minn, Pobanz, & Schultz, 1994), $\geqslant$1.85 μg/g *trans*-piceid (Lamuela-Raventos, Romero-Perez, Waterhouse, & de la Torre-Boronat, 1995), and $\geqslant$4.33 μg/g total stilbenes (Lamuela-Raventos et al., 1995), representing predicted $\geqslant$100% of these compounds in red wines, and an OA rating $\geqslant$5.0. When response variables could not meet the set criteria for the region of interest, maximum values achievable were shaded in lieu of pre-determined values. Contour plots for all response variables were superimposed to identify the region of overlap that determined the optimum UV or US process parameters.

3. Results and discussion

3.1. RES, piceid and total stilbenes of UV treated peanuts

The mean concentrations of RES, piceid and total stilbenes of UV treated peanuts are shown in Fig. 1. UV increased ($\alpha < 0.05$) RES, range = 0.54 ± 0.05 to 3.30 ± 0.58 μg/g, and total stilbenes, 0.66 ± 0.04 to 4.00 ± 0.07 μg/g, but not piceid, 0.35 ± 0.02 to 1.05 ± 0.78 μg/g of 27 treated peanuts compared to controls with 0.02 ± 0.002, 0.05 ± 0.004 and 0.03 ± 0.002 μg/g, respectively which correspond to 27–165, 13–80, and 12–35 fold increase, respectively. UV induces increase in enzymes responsible for the biosynthesis of secondary metabolites such as flavonoids and RES, which act as screens to prevent UV-induced damage to genetic material of plant cells (Cantos, Garcia-Viguera, de Pascual-Teresa, & Tomas-Barberan, 2000) causing increased RES in UV treated peanuts. RES in controls were less than 0.29–0.48 μg/g (Rudolf & Resurreccion, 2005, 2007) but within 0.02–0.31 μg/g analysed from 14 of 15 cultivars of three market types of raw peanuts (Sanders et al., 2000). Sanders et al. (2000) reported 1.79 μg/g RES only for small white Spanish cultivar and therefore, was not included as basis for comparison. Highest ($\alpha < 0.05$) RES of 3.30 μg/g and 4.00 μg/g total stilbenes were achieved after 30 min UV treatment at 40 cm ID and incubated for 36 h. Rudolf and Resurreccion (2005) obtained similar maximum RES of 3.42 μg/g in peanuts UV treated for 10 min at 40 cm ID and incubated for 48 h. UV increased ($\alpha < 0.05$) piceid in only 4 of 27 treatments including samples exposed to UV at 40 cm ID for 10 min and IC for 24 and 48 h; and for 30 min at the same ID then incubated for 24 and 36 h for which no trend was identified, whilst others did not significantly differ from controls suggesting that UV was not effective in increasing piceid in sliced peanuts.

ANOVA (Table 1) showed that ID was the most significant ($\alpha < 0.05$) factor affecting stilbenes concentrations of UV treated peanuts. ID contributed the largest sum of squares of 29.1, 19.5 and 34.4% to the total sum of squares for RES, piceid and total stilbenes, respectively, compared to IT and IC. Mean separation test (data not shown) indicated that all stilbenes were highest at ID of 40 cm and lowest at 20 and 60 cm. Cantos, Espin, and Tomas-Barberan (2001) likewise found that 40 cm was the optimum ID achieving the highest RES compared to 20 and 60 cm in UV-treated grapes. Lower RES resulting from UV treatment at 20 cm may have been

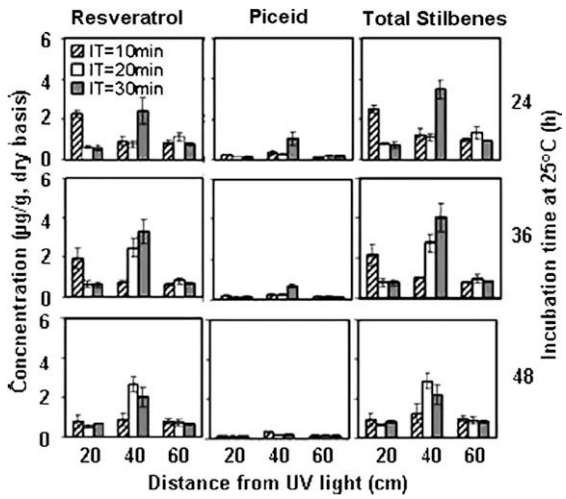

Fig. 1. Mean *trans*-resveratrol, *trans*-piceid and total stilbenes of peanuts exposed to varying doses of UV and incubated at 25 °C for varying times. IT means UV exposure time. Controls had 0.02 ± 0.002 μg/g *trans*-resveratrol, 0.03 ± 0.001 *trans*-piceid μg/g and 0.05 ± 0.002 μg/g total stilbenes.

[b] *Significant at $\alpha < 0.05$; **significant at $\alpha < 0.01$; ***significant at $\alpha < 0.001$.

"too strong" causing damage to the "biosynthetic system" of RES whilst 60 cm delayed the induction of RES biosynthesis (Cantos et al., 2001).

3.2. RES, piceid and total stilbenes of US treated peanuts

US increased ($\alpha < 0.05$) the mean concentrations of RES, 0.32 ± 0.16 to 6.39 ± 2.15 μg/g, piceid, 0.16 ± 0.05 to 6.39 ± 2.27 μg/g and total stilbenes, 0.48 ± 0.16 to 9.86 ± 0.82 μg/g, compared to controls (Fig. 2) corresponding to 16–319, 5–213, and 10–197 fold increase, respectively. US treatment at low intensities of ginseng cell cultures, stimulated growth and biosynthesis of secondary metabolites through mechanical stress and microstreaming induced by acoustic cavitations which disrupted the cell wall (Lin, Wu, Ho, & Qi, 2001). US caused rapid increase in levels of phenylammonia lyase (PAL), polyphenol oxidase and peroxidase in ginseng cell cultures with PAL enhanced most dramatically with

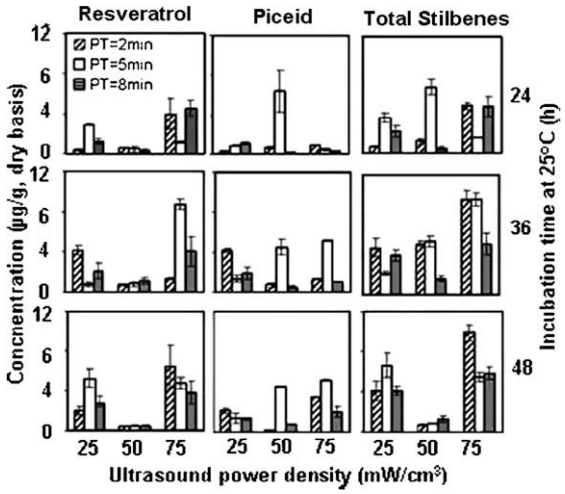

Fig. 2. Mean *trans*-resveratrol, *trans*-piceid and total stilbenes of peanuts exposed to varying doses of ultrasound and incubated at 25 °C for varying times. PT is ultrasound exposure time. Controls had 0.02 ± 0.002 μg/g *trans*-resveratrol, 0.03 ± 0.001 *trans*-piceid μg/g and 0.05 ± 0.002 μg/g total stilbenes.

5-fold higher at power level 4 after 4 days IC compared to controls (Wu & Lin, 2002). PAL is responsible for the deamination of phenylalanine, the initial step in the biosynthesis of coumaryl CoA, one of the precursors for RES synthesis (Soleas, Diamandis, & Goldberg, 1997). We believe that the release of PAL after US treatment could be responsible for increased concentrations of RES and piceid in US treated peanuts in this study and those of Rudolf and Resurreccion (2005, 2007).

ANOVA (Table 2) indicated that PD was the most significant ($\alpha < 0.05$) factor affecting RES and total stilbenes in US treated peanuts contributing the largest 35.6% and 18%, respectively, to the total sum of squares compared to PT and IC. Mean separation test (data not shown) indicated that exposing peanuts to 75 mW/cm^3 resulted in highest ($\alpha < 0.05$) increase in RES of 3.82 μg/g and total stilbenes of 5.41 μg/g, compared to 25 mW/cm^3 producing only 2.38 and 3.58 μg/g, and to 50 mW/cm^3 achieving 0.61 and 2.95 μg/g, respectively. PT ± was the most significant factor affecting piceid with the largest 6.5% contribution. Mean separation test (data not shown) indicated that the highest piceid of 2.34 μg/g was obtained at 5 min PT compared to 1.42 and 1.00 μg/g produced at 2 and 8 min, respectively.

Overall, US treatment resulted in higher ($\alpha < 0.05$) RES, piceid and total stilbenes compared to UV. US treatment had an overall mean concentrations of 2.27 ± 0.99 μg/g RES, 1.59 ± 1.09 μg/g piceid and 3.86 ± 0.92 μg/g total stilbenes, whilst UV resulted in 1.19 + 0.22, 0.24 + 0.03, and 1.43 + 0.23 μg/g, respectively. The average increase in concentrations in US compared to UV treated peanuts were 91% for RES, 562% for piceid, and 170% for total stilbenes. UV and US treated peanuts had higher RES, piceid and total stilbenes compared to blended peanut butters with 0.41 ± 0.02, 0.13 ± 0.01, and 0.54 ± 0.03 μg/g, respectively, and 100% natural peanut butters with 0.65 ± 0.02, 0.14 ± 0.01, and 0.814 ± 0.03 μg/g, respectively (Ibern-Gomez, Roig-Perez, Lamuela-Raventos, & de la Torre-Boronat, 2000). Compared to red wines with 1.85, 2.48 and 4.33 μg/mL RES, piceid, and total stilbenes, respectively (Lamuela-Raventos et al., 1995), US treated peanuts had comparable RES but lower piceid and total stilbenes whilst UV treated peanuts had lower mean values for all compounds. McMurtrey et al. (1994) reported even higher mean RES in red wines of 2.64 μg/mL, range: 0.99–5.01 μg/mL but did not report values for piceid.

Table 2

3.3. Consumer sensory overall acceptance (OA) of UV and US treated peanuts

Results of *t*-tests showed that regardless of treatment, UV treated peanuts had higher ($\alpha < 0.05$) mean OA rating of 5.7 ± 1.7, range: 5.0 ± 1.7 to 6.3 ± 1.5, compared to US treated peanuts with 5.1 ± 1.6, range: 4.2 ± 2.5 to 6.0 ± 1.8. All UV or US treated peanuts, however, had lower ($\alpha < 0.05$) OA ratings than controls with 7.4 ± 1.4. The higher OA ratings obtained in UV compared to US treated samples were unexpected since UV exposure is known to enhance off-flavour development in food due to lipid peroxidation (Duh & Yen, 1995). Phenolics in food contribute to the off-flavours such as bitterness, astringency, colour, flavour, and odour (Naczk & Shahidi, 2006). Off-flavours contributed by phenolic compounds such as RES and other stilbenes may result in lower acceptance of the food. US produced higher concentrations of up to 9.86 μg/g total stilbenes compared to 3.85 μg/g by UV and this may explain the lower OA of US treated peanuts.

Tables 1 and 2 showed that OA of UV and US treated peanuts was significantly affected by IC rather than ID and IT or PD and PT. Mean separation test (data not shown) indicated that the shortest IC of 24 h had the highest OA of 5.9 for UV and 5.2 for US treated peanuts. The longest IC of 48 h produced the least acceptable products, OA of 5.6 for UV and 4.9 for US treated samples, which did not significantly differ from those at IC of 36 h, OA ratings of 5.6 and 5.1, respectively.

3.4. Modelling, mapping of contour plots and optimum region

Table 3 shows the regression coefficients for the significant prediction models for RES, piceid, total stilbenes, and OA of UV and US treated peanuts. The superimposed contour plots of these models showing the regions of overlap are presented in Fig. 3.

3.4.1. UV treatment

Resveratrol: The region of interest of 2.64 μg/g corresponding to 100% RES in red wines was not met. Only 2.0 μg/g or 75% was produced at IC of 36 h (Fig. 3) and shaded in the contour plot (not shown). The maximum RES of 2.06 μg/g was obtained after UV treatment for 29–30 min at 40–44 cm ID and IC for 36 h. RES was highest at IC of 36 h and then decreased with further increase or decrease in ID. With increasing IT at ID of about 30–50 cm, RES increased except when IC was 24 h wherein RES decreased with increasing IT from 10–20 min and at ID of 28–40 cm, and then increased when exposed from 20–30 min with increasing ID from 38–48 cm. These results indicate that ID of 30 to about 45 cm and IT for more than 30 min followed by IC for 36 h were necessary to allow maximum production of RES in UV treated peanuts.

Piceid: The region of interest of 1.85 μg/g or 100% in red wines was not met (contour plot not shown). Only 30% or 0.55 μg/g piceid was obtained at IC of 24 h (Fig. 3). Piceid increased with decreasing IC from 48 to 24 h and as IT increased from 20–30 min, regardless of IC. As IT increased from 10–20 min, piceid increased as 40 cm was approached from 20 or 60 cm ID. As IC increased from 24–48 h, high IT was needed to obtain equal increase in piceid content. Highest piceid of 0.60 μg/g or 32% in red wines was achieved when peanuts were exposed to UV for 30 min at 35.5–46 cm ID and IC for 24 h. Results indicate that ID approaching 40 cm and IT > 30 min followed by IC for 24 h would produce highest amounts of piceid in UV treated samples.

Total stilbenes: The region of interest of 4.33 μg/g total stilbenes or 100% in red wines was not met (contour plot not shown). Only 55% or 2.4 μg/g total stilbenes was achieved at 36 h IC (Fig. 3). Total stilbenes increased from 20 or 60 cm to 40 cm ID, and increased further with increasing IT from 17–30 min, or decreasing IT from 17–10 min achieving the maximum 2.55 μg/g after 30 min UV exposure at 40–42 cm ID and IC for 36 h. Results show that ID approaching 40 cm and IT > 30 in followed by 36 h IC will achieve highest total stilbenes.

Overall acceptance (OA): The region of interest of OA rating of 5 was met (plot not shown). However, a maximum OA rating > 5.5 could be achieved (Fig. 3). A rating of 5.5 assumes that half of the panel rated the sample a 6.0 or like slightly whilst the other half rated 5.0 or neither like nor dislike. OA increased with decreasing IC from 48 to 24 h. High OA ratings were met when IC, ID and IT decreased indicating that any UV treatment will diminish acceptance. Highest rating of 6.3 or like slightly was achieved when peanuts were exposed to UV for 10–14 min at 20 cm ID and IC for 24 h.

The optimum region: This region of overlap represents the optimum UV process that will meet at least 75% RES, 20% piceid, and 55% total stilbenes in red wines and mean OA $\geqslant$ 5.5. Only peanuts incubated for 36 h met these criteria (Fig. 3). The optimum UV

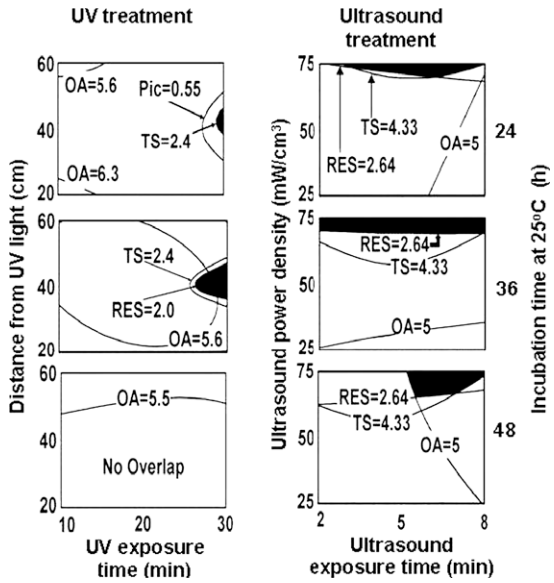

Fig. 3. Superimposed contour plots for the significant ($P < 0.05$) prediction models of resveratrol (RES, μg/g), piceid (Pic, μg/g), total stilbenes (TS, μg/g) and sensory overall acceptance (OA) of peanuts stressed by varying doses of UV and ultrasound. The regions of overlap (shaded areas) represent the optimum UV and ultrasound process at the specified incubation times.

process include all process combinations within the area of a triangle with bounded by the points, ID of 47, 41, and 33 cm for 30, 26.25, and 30 min IT, respectively and will achieve 2.00–2.06 μg/g RES, 0.40–0.47 μg/g piceid, and 2.42–.55 μg/g total stilbenes or 76–78%, 22–25%, and 56–59%, in red wines.

3.4.2. US treatment

Resveratrol: The region of interest of 2.64 μg/g or 100% of RES in red wines was met (plot not shown). RES increased as PD approached 75 and 25 mW/cm^3, with higher maximum at 75 mW/cm^3, regardless of PT from 2–8 min, with minimum RES at 44–48 mW/cm^3 PD. The areas of minimum RES concentrations decreased further as IC increased from 24–48 h. Highest RES of 4.4 μg/g was obtained when peanuts were incubated for 48 h and treated with 75 mW/cm^3 PD regardless of PT from 2–8 min. Results indicated that at the longest IC of 48 h, high RES > 3.96 μg/g or > 150% RES in red wines will be achieved by treatment with high PD of 71–75 mW/cm^3 for 2–6 min. At medium PD, e.g. 40–55 mW/cm^3, lower RES concentrations were observed.

Total stilbenes: The total stilbenes of 4.33 μg/g or 100% in red wines was met (plot not shown). At 45 mW/cm^3, amount of total stilbenes were minimum, and decreased as PT was either increased or decreased from 5 min. Highest total stilbenes, 6.5 μg/g, was reached at 75 mW/cm^3 for 2–6 min at IC of 48 and 36 h. Results indicated that both higher and lower PD of 65–75 and 25–35 mW/cm^3 will result in higher total stilbenes, reaching a maximum when using higher PD, e.g., 75 mW/cm^3.

Overall acceptance: The region of interest, OA rating of 5 was met (plot not shown). OA increased with decreasing IC from 48–24 h. At 24 h IC, OA decreased as exposure time to US increased from 2–8 min, remained at the same ratings at 36 h IC, and then increased at 48 h IC, regardless of PD. Highest OA rating of 5.4 was reached at the lowest IC of 24 h and lowest PT of 2 min at any PD.

The optimum region: This region represents the optimum US process parameters that will met at least 100% RES and total stilbenes in red wines, and OA $\geqslant$ 5. US process at all IC's met all these criteria (Fig. 3). However at 48 h IC, the highest 4.4 μg/g RES and 6.5 μg/g total stilbenes corresponding to 167% and 150% in red wines will be achieved, and determined as the optimum US process which include all US process combinations within the pentagon bounded by the points, PD of 75, 75, 72, 67 and 66 mW/cm^3 for 5.2, 8, 8, 7.1 and 5.5 min, respectively.

4. Conclusions

UV and US treatments significantly increased RES, piceid and total stilbenes in peanuts but decreased OA compared to controls. US, compared to UV, had higher stilbenes but lower OA. The optimum US process will produce 2.64–4.4 μg/g RES and 4.5–6.5 μg/g total stilbenes which are greater 2.00–2.06 and 2.64–3.8 μg/g, respectively, achieved by the optimum UV process. On a per serving, a peanut bar containing 30 g peanuts will require 3–5 bars of US- or 6 bars of UV-treated peanut bars to meet the same RES contents in a 140 mL glass serving of red wines. Further investigations on the additive or synergistic effects of combined UV and US process in increasing the amounts of stilbenes in sliced peanuts are recommended.

peroxide, sodium salicylate, pyrogallol, 2-thiobarbituric acid and other chemicals in the studies were of highest quality commercially available from local suppliers (Shanghai, China).

2.2. Sample extraction

The *P. koraiensis* seeds were collected from the Yichun Forestry Store (Heilongjiang Province, China). The voucher specimen was identified by Dr. Zhenyu Wang, College of Food Science and Engineering, Harbin Institute of Technology, China. The dried putamina of PKS (1500 g) was grinded by pulveriser and extracted with proportional ethanol (40%) by ultrasonic apparatus (KX-1740QT), at ultrasonic procedure of 80 °C, 200 W and 2 h. The extract was centrifuged at 3000 rpm for 5 min and the residue was extracted once again with new solvent under the same conditions. The supernatant was evaporated and the extract powder was obtained by freeze drying. The PKS extract powder (50 g) was stored at 4 °C until required. Before the assays, the extract was dissolved at required concentration.

2.3. Determination of total phenolic content

Total phenolic content was performed according to the Folin–Ciocalteau method (Slinkard & Singleton, 1977) with some modifications. Briefly, 0.1 ml of sample (0–5 mg/ml), 1.9 ml distilled water and 1.0 ml of Folin–Ciocalteau's reagent were seeded in a tube, and then 1.0 ml of 100 g/l Na_2CO_3 was added. The reaction mixture was incubated at 25 °C for 2 h and the absorbance of the mixture was read at 765 nm. The sample was tested in triplicate and a calibration curve with six data points for gallic acid was obtained. The results were compared to a gallic acid calibration curve and the total phenolic content of PKS extract was expressed as mg of gallic acid equivalents per gram of extract.

2.4. $OH^{\cdot}$ scavenging assay

The scavenging capacity of PKS extract on $OH^{\cdot}$ was evaluated according to the reaction of sodium salicylate and residual hydroxyl radical. $OH^{\cdot}$ scavenging assay was performed according to a literature procedure (Wang, Gao, Zhou, Cai, & Yao, 2008) with a few modifications. Hydroxyl radicals were generated by Fenton reaction in the system of $FeSO_4$ and H_2O_2. The reaction mixture was consisted of 0.5 ml $FeSO_4$ (8 mM), 0.8 ml H_2O_2 (6 mM), 0.5 ml distilled water, 1.0 ml of various concentrations PKS extract and 0.2 ml sodium salicylate (20 mM). The total mixture (3.0 ml) was incubated at 37 °C for 1 h and then the absorbance of the mixture was recorded at 562 nm. Ascorbic acid was used as the positive control. The scavenging activity was calculated using the following Eq. (1):

$$\text{Scavenging (or inhibition) rate } (\%) = [1 - (A_1 - A_2)/A_0] \times 100$$

where A_0 is the absorbance of the control (without extract), A_1 is the absorbance of the extract addition and A_2 is the absorbance without sodium salicylate. Matlab 7.0 analysis software was applied to analyse the regression of concentration and scavenging rate.

2.5. DPPH radical scavenging activity assay

The capacity of PKS extract to reduce the 2,2-diphenyl-picrylhydrazyl (DPPH) radical was assessed using the method in a literature (Blois, 2002). Two millilitres of a solution of DPPH in ethanol (8.62×10^{-2} mM) were mixed with 2 ml of various concentrations extract during 30 min at room temperature and the absorbance was recorded at 517 nm (Hsu, Coupar, & Ng, 2006). The normal purple colour of DPPH will turn into yellow when its single electron is paired with a hydrogen atom coming from a potential antioxidant. Ascorbic acid was used as the positive control. In this method, the percentage of DPPH scavenging activity was calculated according to absorbance difference, as has been depicted in Eq. (1), where A_0 is the absorbance of DPPH alone, A_1 is the absorbance of DPPH + extract and A_2 is the absorbance of the extract only.

2.6. O_2^- scavenging assay

In brief, 0.2 ml of different concentrations extract was added to 5.7 ml of 50 mM Tris–HCl buffer (pH 8.2). The mixture was incubated at 25 °C for 10 min and 0.1 ml of 6 mM pyrogallol (25 °C) was added. The absorbance of the reaction mixture was measured at 320 nm every 30 s until the reaction proceeded to 5 min (the same concentration extract was used as the blank to eliminate interference). O_2^- scavenging activity was expressed by the oxidation degree of a test group in comparison to that of the control. The percentage of inhibition effect was calculated according to Eq. (1), where A_0 is the absorbance of the Tris–HCl buffer with pyrogallol, A_1 is the absorbance of the extract addition and A_2 was the absorbance of extract blank.

2.7. Inhibition of lipid peroxidation in rat liver homogenate

The inhibition effect of PKS extract on lipid peroxidation was determined according to the thiobarbituric acid method. $FeCl_2$–H_2O_2 was used to induce the liver homogenate peroxidation (Yen & Hsieh, 1998). In this method, 0.2 ml of PKS extract (0–10 mg/ml) was mixed with 1.0 ml of 1% liver homogenate (each 100 ml homogenate solution contains 1.0 g rat liver), then 50 μl of $FeCl_2$ (0.5 mM) and H_2O_2 (0.5 mM) was added. The mixture was incubated at 37 °C for 60 min, then 1.0 ml of trichloroacetic acid (15%) and thiobarbituric acid (0.67%) was added and the mixture was heated up in boiled water for 15 min. The absorbance was recorded at 532 nm (Buege & Aust, 1978). Ascorbic acid was used as the positive control. The percentage of inhibition effect was calculated according to Eq. (1), where A_0 is the absorbance of the control (without extract), A_1 is the absorbance of the extract addition and A_2 is the absorbance without liver homogenate.

2.8. Inhibition of erythrocyte haemolysis in rat blood

The blood sample was obtained from mice eyepit and made to 0.5% erythrocyte suspension for the assay. The reaction mixture was consisted of 1.0 ml of erythrocyte suspension (0.5%), 1.0 ml extract (0.02–0.2 mg/ml) and 0.1 ml H_2O_2 (100 mM). The mixture was incubated at 37 °C for 60 min, then four times volume distilled water was added to the mixture and centrifuged at 1000 rpm for 10 min. The absorbance of the supernatant was read at 415 nm. The percentage of erythrocyte haemolysis inhibition effect was calculated according to Eq. (1), where A_0 is the absorbance of the supernatant without extract, A_1 is the absorbance of the extract addition and A_2 was the absorbance of extract solution.

2.9. Reducing ability assay

The reducing ability of PKS extract was assayed as described in a reference (Tsai, Huang, & Mau, 2006). Various concentrations extract (0–1.0 mg/ml) was added to 2.5 ml of phosphate buffer (200 mM, pH 6.6) and 2.5 ml of potassium ferrocyanate $[K_3Fe(CN)_6]$ (1%). After incubation at 50 °C for 20 min, 2.5 ml of trichloroacetic acid (10%) was added to the mixture before centrifugation at 1000 rpm for 10 min. The supernatant (5 ml) was gathered and mixed with 5 ml of distilled water and 1 ml of ferric chloride (0.1%). The absorbance was measured at 700 nm. The reducing ability was weighed by the absorbance value of the reaction solution and a higher absorbance indicated increased reducing

power (Jayaprakasha & Bhimanagouda, 2007). Ascorbic acid was used as positive control.

2.10. Ageing model

Kunming male mice, weighing about 18–22 g were obtained from the Experimental Animal Center of Heilongjiang Tumour Hospital. Mice were kept in our animal house at an ambient temperature of 25 °C and 45–55% relative humidity with a 12 h each of dark and light cycle. Animals had free access to food and water. After 1 week of acclimatisation, the mice were randomly divided into five groups (12 mice per group) and i.p. injected with 0.3 ml of D-galactose (150 mg/kg) once daily for 60 days. Simultaneously, the ageing control group (group AC) mice were p.o. administered with 0.3 ml of physiological saline each; the PKS treatment group (group PKS) mice were p.o. administered with different dose of extract (250, 500 and 1000 mg/kg). The normal control group (group NC) mice were i.p. injected and p.o. administered with 0.3 ml of physiological saline.

2.11. Radiation model

γ-Ray was used to induce radiation oxidative damage (radiation dose is 5 grey, dose-rate 0.95 grey/min; radiation time 6.15 min, radiation radius 145 cm). The mice were divided into five groups (12 mice per group). The PKS groups were p.o. administered with 250, 500 and 1000 mg/kg of extract once a day. The radiation control (group RC) and normal group (group NC) were p.o. administered with 0.3 ml of physiological saline. After 21 days, the mice were irradiated by γ-ray according to foregoing dose expect the normal group. The determination was carried out at the fifth day after γ-ray irradiation.

2.12. Measurement of superoxide dismutase (SOD) activity and malondialdehyde (MDA) level

Mice were sacrificed by dislocating; the brains and livers were removed rapidly and homogenised in physiological saline (ice-bath). Brain and liver were used for ageing model and radiation model assays, respectively. The homogenate was centrifuged at 4000 rpm (4 °C) for 15 min and the supernatant was gathered for assays. Test of total SOD activity was carried out by using commercial kits. SOD activity was expressed as units per microgram of brain or liver protein. MDA content was determined by thiobarbituric acid reaction (TBAR) method and expressed as nanomoles per milligram of brain or liver protein.

2.13. Determination of glutathione peroxidase (GSH-px) activity and glutathione (GSH) content

Mice were sacrificed by dislocating; the brains and livers were removed rapidly and homogenised in cold physiological saline (ice-bath). Brain and liver were used for ageing model and radiation model assays, respectively. GSH content and GSH-px activity were measured by commercial kits.

2.14. Protein assay

Protein concentration was measured by Bradford method (Lu, Li, Huang, & Zhang, 2007). Bovine serum albumin was used as the standard.

2.15. Statistical analysis

Data was expressed as mean ± SD. The Duncan test and a one-way analysis of variance were used for multiple comparisons by analysis of SPSS 14.0. The results were considered statistically significant if the *P*-values were 0.05 or less.

3. Results and discussion

3.1. Total phenolic content

Proportional ethanol (40%, v/v) was used for extraction and the extract yield was 3.5 g/100 g. This solvent system destroys the cell membranes, simultaneously dissolving the phenolic compounds. Phenolic content of PKS extract was measured by Folin–Ciocalteau method and the total phenolic content in the extract was 264 ± 10.52 mg/g. The Folin–Ciocalteau method is simple and can be used in characterising botanical samples, for example sorghum (Awika, Rooney, & Waniska, 2004), soybean (Takahashi et al., 2005), white and black sesame seed (Shahidi, Liyana-Pathirana, & Wall, 2006). The result showed PKS extract contained high phenolic content compared with some other plants, such as black soybean seed (Astadi, Astuti, Santoso, & Nugraheni, 2009), bayberry (Zhou et al., 2009) and Vietnam bitter tea (Thuong, Nguyen, Ngo, et al., 2009). PKS was a nice potential antioxidant plant.

3.2. $OH^{\cdot}$ scavenging activity

As the positive control, ascorbic acid showed an excellent scavenging activity on $OH^{\cdot}$, the half inhibition concentration (EC_{50}) = 0.103 ± 0.031 mg/ml. PKS extract was also observed to have strong scavenging activity, with an EC_{50} value of 0.391 ± 0.055 mg/ml (Fig. 1a).

3.3. DPPH radical scavenging activity

Fig. 1b showed the scavenging capacity of PKS extract on DPPH (ascorbic acid as the positive control). A dose–response relationship is found in DPPH scavenging activity of PKS extract and an increase in concentration is synonymous of an increase in scavenging capacity. Ascorbic acid showed high scavenging activity (EC_{50} = 0.002 ± 0.0001 mg/ml). The PKS extract also had strong DPPH scavenging effect, with an EC_{50} value of 0.023 ± 0.004 mg/ml. Among the levels used in the experiment, 0.09 mg/ml variety was the strongest one with a scavenging rate of 91.64%, ascorbic acid as standard was 96.46% at the same concentration. At 0.09 mg/ml, the scavenging ability of PKS extract on DPPH was not significantly different from ascorbic acid. The strong scavenging capacity of PKS extract on DPPH was possibly due to the phenolic compounds which could act as a hydrogen donor antioxidant.

3.4. O_2^- inhibition activity

Spontaneity oxidation of pyrogallol will proceed in slightly alkaline condition and the O_2^- was produced with absorption at 320 nm. Antioxidant can inhibit the spontaneity oxidation of pyrogallol but it has been found that the reaction is instable in 1–3 min. Repetitious tests showed the reaction was stable in 4–5 min and consequently the data at 5 min was adopted to evaluate the inhibition activity. Matlab 7.0 analysis software was applied to analyse the regression of concentration and inhibition rate. PKS extract was found to have inhibition activity and the EC_{50} was 4.37 ± 0.19 mg/ml (Fig. 2a), as the positive control, EC_{50} of ascorbic acid was 0.069 ± 0.013 mg/ml. The result showed PKS extract had a certain extent inhibition on O_2^- but was not as strong as ascorbic acid. PKS extract effectively inhibited O_2^- at concentrations of 4–8 mg/ml. The inhibition rate was above 80% at 8 mg/ml.

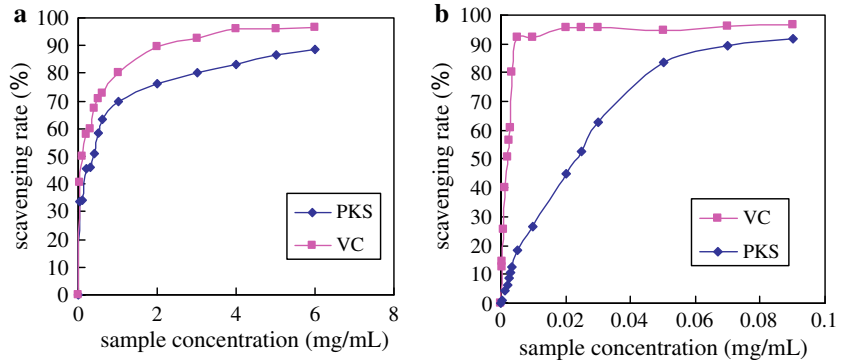

Fig. 1. (a) The OH· scavenging activity of PKS extract. (b) The DPPH radical scavenging activity of PKS extract.

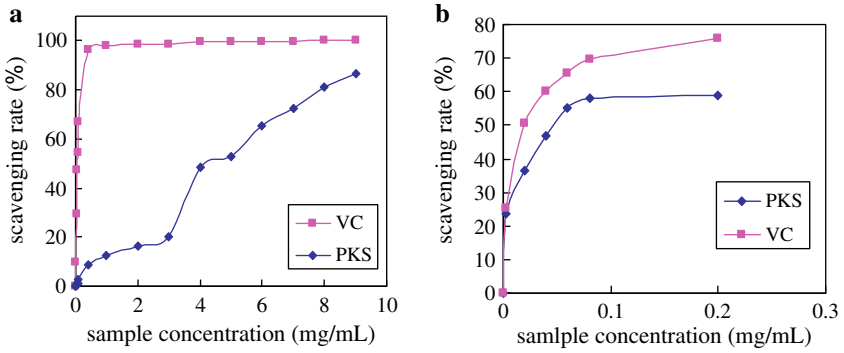

Fig. 2. (a) The O_2^- inhibition activity of PKS extract. (b) The inhibition of PKS extract for erythrocyte haemolysis in rat blood.

3.5. Inhibition of lipid peroxidation in rat liver homogenate

Lipid peroxidation was an oxidative deterioration process of polyunsaturated fatty acids which induced by radical. Lipid structure of cell velum was damaged by radical and accordingly lipid peroxidation of viscera homogenate was increased. MDA content can indicate the degree of lipid peroxidation. $FeCl_2$–H_2O_2 system was used to induce lipid peroxidation in rat liver homogenate. In the assay, PKS extract was confirmed to have strong inhibition for lipid peroxidation. 88.47% of the peroxidation was inhibited by PKS extract at concentration of 4 mg/ml (Fig. 3a). At 7 mg/ml, PKS extract showed an inhibition rate of 90.21%. Ascorbic acid, as the positive control, at concentrations of 4 and 7 mg/ml, 51.93% and 83.13% of the peroxidation was inhibited, respectively. So PKS extract has highly strong resistance on peroxidation. The phenolic compounds in PKS extract can provide phenolic hydroxyl to accept electrons and scavenge OH· which induced by $FeCl_2$–H_2O_2. The results are considered to be noteworthy when compared to the findings of other studies concerning medicinal plants (Sultana, Anwar, & Przybylski, 2007; Tepe, Sokmen, Akpulat, Yumrutas, & Sokmen, 2006).

3.6. Inhibition of erythrocyte haemolysis in rat blood

Oxidant damage of cell film which induced by H_2O_2 can result in erythrocyte haemolysis. The result showed erythrocyte haemolysis was effectively inhibited by PKS extract at concentrations of 0.02–0.2 mg/ml. At concentration of 0.04 mg/ml, the inhibition rate was nearly 50%. At concentrations of 0.06, 0.08 and 0.2 mg/ml, the inhibition rate was 55.3%, 57.9% and 59%, respectively. Inhibition rate of ascorbic acid (the positive control) was 60% at 0.04 mg/ml. At 0.06, 0.08 and 0.2 mg/ml, the inhibition rate was 65.1%, 69.4% and 75.8%, respectively (Fig. 2b). In this assay, PKS extract was found to have inhibition activity for erythrocyte haemolysis; this

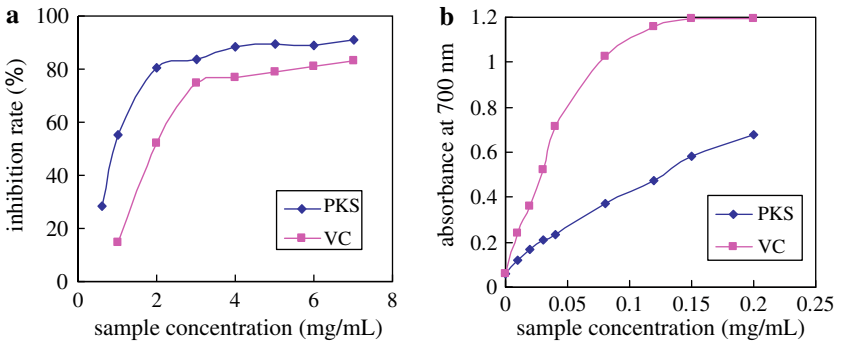

Fig. 3. (a) The lipid peroxidation inhibition activity of PKS extract. (b) The reducing ability assay of PKS extract.

Table 1
Effect of PKS extract on SOD, GSH-px activity and MDA, GSH content for ageing mice brain.

Group	SOD (U/mg protein)	GSH-px (U/mg protein)	MDA (nmol/mg protein)	GSH (mg/g protein)
NC	391 ± 32.8	688 ± 47.3	2.88 ± 0.77	3.85 ± 0.84
AC	316 ± 21.9[b]	540 ± 43.7[b]	3.64 ± 0.61[a]	3.09 ± 0.60[a]
PKS (250 mg/kg)	321 ± 36.0	550 ± 34.6	3.40 ± 0.54	3.35 ± 0.55
PKS (500 mg/kg)	345 ± 15.9[c]	559 ± 39.7	2.98 ± 0.48[c]	3.71 ± 0.58[c]
PKS (1000 mg/kg)	374 ± 36.3[d]	561 ± 30.0	2.87 ± 0.53[c]	3.86 ± 0.54[c]

$N = 12$.
[a] $P < 0.05$ vs. NC group.
[b] $P < 0.01$ vs. NC group.
[c] $P < 0.05$ vs. AC group.
[d] $P < 0.01$ vs. AC group.

effect can prevent cell films from lipid oxidation and protect erythrocyte.

3.7. Reducing ability assay

The reducing power of PKS extract was presented in Fig. 3b. As described in Fig. 3b, PKS extract was found to have strong and increased reducing ability at concentrations of 0.12–0.2 mg/ml. In this assay, the yellow colour of the test solution changes to various shades of green and blue (Barros, Baptista, & Ferreira, 2007). The presence of reducers causes the conversion of the Fe^{3+}/ferricyanide complex to the ferrous form. The reducing power of PKS extract increased with a higher concentration. All spectrophotometric measurements were repeated twice with at least three replicates. At concentrations of 0.02, 0.04 and 0.08 mg/ml, the reducing power of PKS extract was around 0.17, 0.23 and 0.38, respectively, while a solution of ascorbic acid at the same concentration, the positive control used in this test, had a reducing power value of 0.358, 0.712 and 1.713, respectively.

3.8. Antioxidative effects for ageing mice

Subacute mice ageing were induced by injection of D-galactose. The biological redox substance in mice can be disturbed by long-term injection of D-galactose, such as decreasing of GSH level, SOD and GSH-px activity. The antioxidant effect of PKS extract for ageing mice was presented in Table 1. The results indicated that PKS extract could strongly inhibit mice ageing. Mice were p.o. administered with PKS extract and the SOD activity was enhanced 9% and 18% at dose of 500 and 1000 mg/kg, respectively. The MDA content was decreased 18% and 21% at 500 and 1000 mg/kg, respectively, the GSH content was also effectively increased at dose of 500 and 1000 mg/kg. At dose of 1000 mg/kg, the PKS extract showed the greatest antioxidant effect for ageing mice. The results also indicated that PKS extract might be used as natural antioxidants and alternatives to synthetic anti-ageing reagent. The potent anti-ageing effect of PKS extract *in vivo* maybe owe to its antioxidative activity. The antioxidant principle was to reduce organism harm and prevent radical formation and histiocytic period was prolonged.

3.9. Antioxidative effects for radiation mice

Radiation can result in oxidant damage and disturb the balance of enzyme activity in mice livers. The important enzyme activity and substance content related to radiation injury were detected in this assay. The results of radiation model test were showed in Table 2. It was found that PKS extract could potently inhibit oxidant damage induced by γ-ray. PKS extract was ingested by p.o. administration and the radiation damage on mice was highly decreased. The results showed ingestion of PKS extract *in vivo* could increase SOD and GSH level of radiation mice to normal level. Ingestion of PKS extract can maintain the balance of enzyme action and release the radiation damage. At dose of 1000 mg/kg, PKS extract can remarkably enhance SOD activity. Also the MDA content was highly decreased at the same dose (decreasing of 11% and 16%, respectively). At dose of 500 and 1000 mg/kg, the GSH content in mice liver was much higher than the RC group.

PKS (homologous from *Pinus* plant) was reported to have many bioactivities, such as anti-cancer, antioxidant, anti-virus and antibacterial. Free radicals, oxidant-related enzyme and lipid peroxidation are important factors which highly impact oxidation and ageing. In this study, antioxidant properties of PKS extract (40% ethanol) were demonstrated by various assay systems. The results suggested that PKS extract had potent antioxidant activities in multiple mechanisms. Especially, the scavenging activity on $OH^{\cdot}$ was very strong and nearly as effective as ascorbic acid (Fig. 1a). It was worth mentioning that inhibition effect of PKS extract for lipid peroxidation was even higher than ascorbic acid (Fig. 3a). *In vivo* assays, the PKS extract was found to increase the levels of antioxidant enzymes (SOD, GSH) and decrease MDA content in brain and liver. It was confirmed that PKS extract could protect the tissues against oxidative damage. Enhancing of SOD activity and GSH content in mice viscera indicated the *in vivo* antioxidant activity of PKS extract and the related mechanism. The present study can be considered a forward step in this direction.

Table 2
Effect of PKS extract on SOD, GSH-px activity and MDA, GSH content for radiation mice liver.

Group	SOD (U/mg protein)	GSH-px (U/mg protein)	MDA (nmol/mg protein)	GSH (mg/g protein)
NC	501 ± 38.6	890 ± 48.2	3.98 ± 0.48	4.42 ± 0.65
RC	417 ± 22.2[b]	740 ± 43.7[b]	4.62 ± 0.48[a]	3.26 ± 0.78[b]
PKS (250 mg/kg)	423 ± 36.5	750 ± 34.6	4.40 ± 0.63	3.44 ± 0.51
PKS (500 mg/kg)	434 ± 23.4	759 ± 39.7	4.08 ± 0.42	3.83 ± 0.56[d]
PKS (1000 mg/kg)	475 ± 34.4[d]	761 ± 27.6	3.86 ± 0.52[c]	4.20 ± 0.49[d]

$N = 12$.

the biochemical and anticoagulant properties of *M. edulis* anticoagulant peptide (MEAP) isolated from blue mussel were identified. These prolonged blood coagulation times by multiple interactions with blood coagulation factors.

2. Materials and methods

2.1. Materials

Fresh live mussel (*M. edulis*) was obtained from an aquafarm in Tongyoung, S. Korea. The approximately 1 year old mussels had been cultured on a hanging line. The average width of the shell was about 7–8 cm and the average shell on weight was ~15 g. A HiPrep™ 16/10 DEAE FF anion exchange column and a Superdex™ 200 10/300 GL gel filtration column were purchased from Amersham Biosciences Co. (Uppsala, Sweden). An ACL® Coagulation analyzer (ACL® 7000), a blood coagulation assay kit (HemosIL™ APTT Lyophilized silica for APTT, HemosIL™ TT, and HemosIL™), and a Factors-Deficient Plasma were produced by the Instrumentation Laboratory Co. (Lexington, MA, USA). Human blood coagulant factors (zymogens of FII, FV, FVII, FIX, FX, FXI, FXII, and their serine proteinase type enzymes of the activated FII, FV, FVII, FIX, FX, FXI, FXII) and 6-amino-1-naphthalenesulphonamide (ANSN)-based fluorogenic substrates (SN-7; Mes-D-LGR-ANSN$(C_2H_5)_2$ and SN-59; D-VPR-ANSN$HC_4H_9 \cdot 2HCl$) were obtained from Haematologic Technologies, Inc. (Essex Junction, VT, USA). Fibrinogen, plasmin, and molecular markers for electrophoresis were purchased from Sigma Chemical Co. (St. Louis, MO, USA). The BIAcore® 2000 system for surface plasmon resonance (SPR) analysis, a sensor chip CM5, surfactant P20, HBS buffer (10 mM HEPES, 0.15 M NaCl, 3.4 mM EDTA, 0.05% surfactant P20, pH 7.4), an amine-coupling kit containing *N*-hydroxysuccinimide (NHS), *N*-ethyl-*N*′-(3-diethylaminopropyl) carbodiimide (EDS) and ethanolamine hydrochloride were obtained from Biacore AB Co. (Uppsala, Sweden). A NISSEI ACE homogenizer AM-6 with cup, cutter, vessel, and motor was a product of Nihonseiki Kaisa Ltd. (Tokyo, Japan). A Micro Acilyzer Model G3electrodialyzer was purchased from Asahi Chemical Industry Co. (Tokyo, Japan). A fast performance liquid chromatographic system, FPLC ÄKTA was produced by Amersham Bioscience Co. (Uppsala, Sweden). To perform an enzyme-linked immunosorbent assay (ELISA), an Ultramark microplate imaging system plate reader was purchased from Bio-Rad Co. (Hercules, CA, USA). The BIAcore 2000® system was produced by Biacore AB Co. (Uppsala, Sweden). The ESI-QTOF tandem mass spectrometry was produced by Micromass Co. (Manchester, UK). All other chemicals used in this study were of analytical grade.

2.2. Isolation of an exogenous anticoagulant peptide from M. edulis

All operations were done at 4 °C unless stated otherwise. Fresh *M. edulis* was washed three times with tap water to remove salts and other contaminants. After removing the shells, all of the edible parts (500 g) were minced and homogenised at 10,000 rpm for 15 min with 10 mM Tris–HCl buffer (pH 7.7), and the insoluble homogenates were removed by centrifugation at 9500*g* for 15 min with a Micro 17R centrifuge (Hanil Co., Seoul, Korea) and the supernatant was treated with 150 ml of 20% (v/v) CCl_4 and cooled to −20 °C to remove lipid. Soluble extracts in the water layer were desalted using an electrodialyzer with a 1 kDa molecular weight cut-off (MWCO) membrane (Asahi Chemical Industry Co.) until conductivity was under 0.1 mA. The dialysate was separated using a HiPrep™ 16/10 DEAE FF anion exchange column (16 × 100 mm) preliminarily equilibrated with 10 mM Tris–HCl buffer (pH 7.7) in a fast performance liquid chromatographic

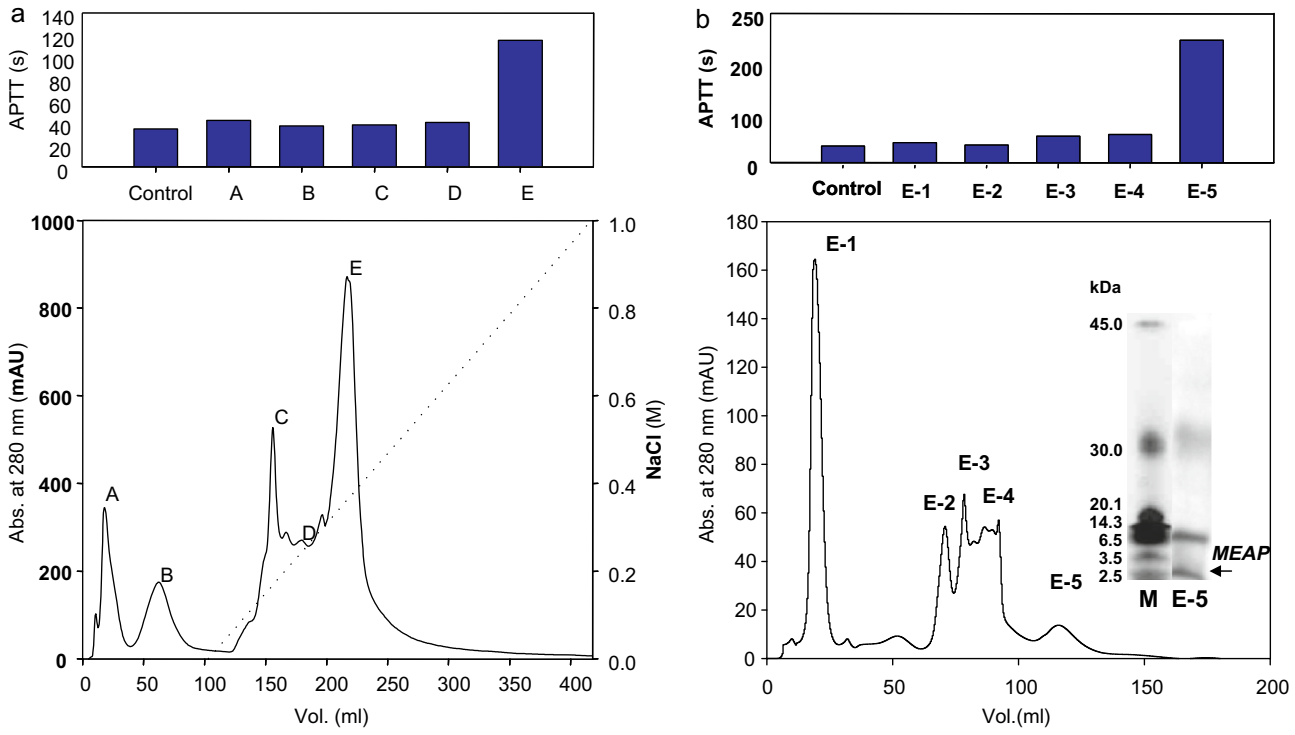

Fig. 1. Purification profiles and anticoagulant activity of MEAP. (a) Anion exchange chromatography on a HiPrep™ 16/10 DEAE FF anion exchange column (16 × 100 mm) preliminarily equilibrated with 10 mM Tris–HCl buffer (pH 7.4) in a FPLC system. A linear gradient of NaCl (0–1 M) in the same buffer was maintained at a flow rate of 1.5 ml min^{-1} and 5.0 ml fractions were collected. The upper panel shows anticoagulant activity for the APTT (s) and (b) gel filtration chromatography on a Superdex™ 200 10/300 GL gel filtration column (10 × 300 mm) preliminarily equilibrated with distilled water. Three millilitres fractions were collected at a flow rate of 0.7 ml min^{-1}. The upper panel shows the anticoagulant activity for the APTT. An inner-panel is the SDS–PAGE profile of the active fraction (E-5) under denaturing conditions.

system. A linear gradient of NaCl (0–1.0 M) in the same buffer was maintained at a flow rate of 1.5 ml min^{-1} and 5.0 ml per a fraction was collected. Absorbance was monitored at 280 nm (Fig. 1a) and anticoagulant activity was evaluated using the blood coagulation assay for the activated partial thromboplastin time (APTT) as described herein. The pooled fraction E, exhibiting the highest activity, was subsequently loaded onto a Superdex™ 200 10/300 GL gel filtration column (10 × 300 mm) with distilled water at a flow rate of 0.7 ml min^{-1} (Fig. 1b). After being separated through consecutive FPLC columns, the purity of the active fraction (E-5) was analysed by electrophoresis on a 15% SDS–PAGE using a Bio-Rad Mini-PROTEAN II electrophoresis cell (Hercules, CA, USA) according to the method of Laemmli (1970). Samples (5 μg) incubated with 2% 2-mercaptoethanol for 5 min at 100 °C were loaded on a 15.0% slab gel and stained with Coomassie Brilliant Blue R-250. Molecular markers (lane M) are ovalbumin (45 kDa), carbonic anhydrase (30 kDa), lysozyme (14.3 kDa), aprotinin (6.5 kDa), insulin β chain (3.5 kDa), and insulin α chain (2.5 kDa). For further purification, the fraction E-5 containing two peptides (Fig. 1b) was re-separated with Superdex™ 200 10/300 GL gel filtration column (10 × 300 mm) at a flow rate of 0.5 ml min^{-1}. The arrow (Fig. 1b) indicated the final active fraction (MEAP) re-separated with the Superdex™ 200 10/300 GL gel filtration column. The purified *M. edulis* anticoagulant peptide (MEAP) was analysed using ESI-QTOF tandem mass spectrometry after gel extraction. To extract the peptide from the gel, the stained peptide was excised from the slab gel and digested with trypsin (Promega Co., Madison, WI, USA). After washing with 10 mM NH_4HCO_3 and 50% CH_3CN, the gel piece was swollen in a digestion buffer containing 50 mM NH_4HCO_3, 5 mM $CaCl_2$ and 12.5 ng μl^{-1} trypsin and incubated at 37 °C for 12–16 h. The peptide was recovered by two extraction steps with 50 mM NH_4HCO_3 and 100% CH_3CN. During the chromatographic process, protein concentration was determined according to the method of Bradford (1976) using bovine serum albumin (Thermo Fisher Scientific Inc., Rockford, IL, USA) as a standard material.

2.3. Peptide sequencing and identification by mass analysis and database searching

All MS/MS experiments were performed on a QTOF tandem mass spectrometer equipped with a nano-ESI source. The molecular mass and amino acid sequence of the purified peptide were determined. The peptide solution was desalted using C18 Zip-Tip® pipette tips (Millipore, Billerica, MA). Approximately 5 μl of the sample was placed into a metal-coated glass capillary (Protana Co., Ødense, Denmark), and a 1500 eV voltage was applied to produce an electrospray; cone voltage was 30 eV. The MS/MS spectra were acquired in the data-dependent MS/MS mode, in which collision energy was increased stepwise to 25, 30, and 35 eV from 10 eV. Argon was introduced as a collision gas at a pressure of 10 psi. The instrument was calibrated externally, and no post-acquisition recalibration of the MS/MS spectra was performed. Sequencing information for the active peptide was acquired over the *m*/*z* range 50–2500 and sequenced by using the PepSeq *de novo* sequencing algorithm (Micromass Co.). For peptide identification, MS/MS spectra were searched by MASCOT (Matrix science, http://www.matrixscience.com, London, UK) using the NCBInr database. Mass tolerance was set at ±1.0 Da for the masses of peptide precursors and at ±0.8 Da for the masses of fragment ions. Proteins containing at least one significant peptide (⩾individual score) were selected from the database search results.

2.4. Blood coagulation time assay

Nine parts of blood was drawn by venipuncture into one part of 3.2% sodium citrate from three healthy human volunteers and pooled. The blood was separately centrifuged at 1600*g* for 10 min to obtain platelet poor plasma (PPP). All coagulation assays were performed with three individual replicates using the ACL® 7000 coagulation analyzer and diagnostic kit, and mean values were used. Briefly, normal citrated PPP (80 μl) was incubated with sample solution (20 μl) for 3 min at 37 °C. For the activated partial thromboplastin time (APTT) assay, 100 μl of APTT reagent was added to the mixture (PPP and sample) and incubated at 37 °C for 3 min, and clotting time (time for the change of light scatter associated with the formation of a fibrin clot) was immediately recorded after the addition of 100 μl of 20 mM $CaCl_2$. In the prothrombin time (PT) assay, PT reagent was added to the incubated mixture of PPP (80 μl) and sample (20 μl), and clotting time was recorded. For thrombin time (TT) measurements, 100 μl of anticoagulant was incubated with human thrombin (100 μl) for 3 min at 37 °C, and clotting time was determined after the addition of 200 μl PPP. For the specific factor inhibitory assays, HemosIL™ Factors-Deficient Plasma kits were used according to the manufacturer's manual, and the effects of pH, temperature, and divalent cation on MEAP activity were tested on the basis of the TT assay according to our previous method (Jung et al., 2001).

2.5. Surface plasmon resonance (SPR) analysis

To identify the binding affinity of MEAP to blood coagulation factors, surface plasmon resonance (SPR) sensorgrams were determined using a BIAcore 2000® system. A ligand peptide was directly immobilised on a CM5 sensor chip by coupling through the free amino group to a carboxylated dextran matrix, activated with a mixture of *N*-hydroxysuccinimide (NHS) and *N*-ethyl-*N*′-(3-diethylaminopropyl) carbodiimide (EDS) after pH scouting. The sensor chip surface was coated with a ligand peptide in 10 mM sodium acetate buffer at optimal pH, and unreacted groups were blocked with 1 M ethanolamine, pH 8.5. Among the four flow cells in the sensor chips, the first flow cell in each was similarly activated and blocked without immobilisation of the peptide to serve as a control surface. After immobilisation of coagulation factors on the sensor chip, an analyte (50 μg ml^{-1}) was injected onto the surface of the sensor chip in HBS buffer (Hepes-buffered saline containing 1 mM 3-[(3-cholamidopropy-l) dimethylammonio]-1-propanesulfonate, CHAPS, 0.005% surfactant P20, 5 mM $CaCl_2$, 10 nM tissue factor, pH 7.4) at 25 °C at a flow rate of 30 μl min^{-1} for 3 min followed by 2 min of dissociation. Resonance was monitored as a function of time and binding affinity and is represented as a resonance or response unit (RU) in real time. The Langmuir equation was applied for evaluation of equilibrium kinetics with a normal definition of the constants for the association rate and dissociation rate, k_a and k_d. The constants were calculated by the manufacturer's BIA Evaluation software for kinetic experiments.

2.6. Preparation of phospholipid complexes

To investigate an inhibitory activity of the exogenous anticoagulant on amidolytic functions of the major factors in the blood coagulation system, the following assays were performed according to the previous methods (Butenas, van't Veer, & Mann, 1997; Shi & Gilbert, 2003). Phospholipid (PL) vesicles were prepared by evaporating chloroform from the desired phospholipids (PS–PE–PC percentage ratio, 15:20:65), resuspending in methylene chloride, and re-evaporating twice under argon. Phospholipids were then suspended by gently swirling Tris (tris-(hydroxymethyl) aminomethane)-buffered saline (50 mM Tris, 150 mM NaCl, pH 7.4) over the dried lipid suspension until all the lipid was suspended. Vesicles were filtered through 2 stacked polycarbonate membranes (100 nm pore size, Millipore, Bedford, MA, USA) and were used as multilamellar vesicles. Some of the resuspended vesicles were then

sonicated using Branson Sonicator (Model 5510, Branson Ultrasonics, Danbury, CT, USA), and some were made by extruding these phospholipid suspensions 20× through 2 stacked polycarbonate membranes under argon in a High Pressure Extrusion Device (Sciema Technical Services, Vancouver, BC, Canada). Vesicles were used fresh; or 1.0 ml aliquots were quick-frozen in liquid nitrogen, stored at −80 °C, and thawed at 37 °C. Storage at 4 °C before incubation with microspheres or blood clotting factors did not exceed 24 h.

2.7. Intrinsic factor tenase (FXase) assay

The activation of FX by FIXa in the presence of exogenous anticoagulants was measured with an amidolytic substrate assay. FIXa (0.1 nM) was incubated with the specified concentrations of FX and varied concentrations of sample in 150 mM NaCl, 50 mM Tris (pH 7.4) containing PL vesicles, 1.5 mM $CaCl_2$, 1 nM FVIII, and 0.1 nM thrombin for 5 min at 25 °C; the final reaction volume was 40 μl. The reaction was then stopped by the addition of 0.5 M ethylenediaminetetraacetic acid (EDTA) solution to 7 mM final concentration. The amount of FXa generated was determined immediately with the use of the 6-amino-1-naphthalene-sulphonamide (ANSN) based fluorogenic substrate SN-7, Mes-D-LGR-ANSN$(C_2H_5)_2$ on an enzyme-linked immunosorbent assay (ELISA) plate reader in kinetic mode.

2.8. Prothrombinase assay

Cleavage of prothrombin (FII) to thrombin (FIIa) was measured in an amidolytic substrate assay analogous to that for FX activation. First, 1 nM FVa, 6.2 pM FXa, and the sample at specified concentrations were incubated for 5 min at 25 °C in a solution containing 150 mM NaCl, 50 mM Tris containing PL vesicles, 1.5 mM $CaCl_2$, and 0.05% w/v ovalbumin (Sigma Chemical Co., St. Louis, MO, USA), pH 7.8, prior to the addition of 1 μM prothrombin. After 5 min at 25 °C, the reaction was stopped by the addition of EDTA to a final concentration of 7 mM. Thrombin formation was assessed in a kinetic microplate reader immediately after addition of 0.1 mM fluorogenic substrate SN-59, D-VPR-ANSNH-$C_4H_9 \cdot 2HCl$.

2.9. Cytotoxicity assay

A venous endothelial cell line (ECV-304) was maintained in Roswell Park Memorial Institute (RPMI) 1640 medium containing 10% (v/v) heat inactivated foetal bovine serum (FBS) supplemented with penicillin (100 U ml^{-1}) and streptomycin (100 μg ml^{-1}) at 37 °C under 5% CO_2 (Daesung Industrial Gases Co. Ltd., Seoul, Korea) in air. The cytotoxic effect of exogenous MEAP on endothelial cells (ECV-304) was measured by using an MTT assay using heparin as the basis of comparison. The cells were seeded in a 96-well plate at a concentration of 2×10^4 cells ml^{-1} using the RPMI medium. After incubation in a humidified 37 °C, 5% CO_2 incubator (MCO-18AIC, Sanyo Co., Tokyo, Japan) for 16 h, MEAP was added to the wells at a concentration range from 0 to 500 μg ml^{-1}. The cells were then further incubated for an additional 72 h at 37 °C. MTT stock solution (50 μl of 2 mg ml^{-1} in PBS) was then added to each well for a total reaction volume of 250 μl. After incubating for 4 h in a humidified atmosphere of 5% CO_2 at 37 °C, the plate was centrifuged at 800*g* for 5 min and the supernatants were aspirated to remove untransformed MTT. The formazan crystals in each well were dissolved in 150 μl of DMSO (Merck, Darmstadt, Germany). The amount of purple formazan was determined by measuring the absorbance at 540 nm using the enzyme-linked immunosorbent assay (ELISA) plate reader. For treated cells, viability was expressed as a percentage of control cells.

2.10. Statistics

Data was analysed using Microsoft Excel 2003 (Microsoft Co., Redmond, WA, USA), and statistical analysis was performed with SPSS 8.0 (SPSS Inc., Chicago, IL, USA). All determinations were carried out in triplicate. Results are presented as mean ± SD of the mean ($n = 3$). The Student's *t*-test was used to determine the level of significance unless otherwise stated.

3. Results

3.1. Anticoagulant activity and structural conformation of M. edulis anticoagulant peptide (MEAP)

During screening for anticoagulant activity from marine bivalves, blood coagulation inhibitory activity was detected in the soluble extracts of blue mussel (*M. edulis*). In the preliminary test, the extracts prolonged blood clotting time on TT and APTT but not PT. A control clotting time on TT (11.6 ± 0.4 s) was prolonged to 42.1 ± 0.9 s by the addition of 20 μl soluble *M. edulis* extracts (3.8 mg of total soluble extract ml^{-1}). In the APTT assay, the addition of extracts with the same concentration could prolong the control (35.3 ± 0.5 s) up to 75.8 ± 0.9 s. After purification, the purified *M. edulis* anticoagulant peptide (MEAP) prolonged the normal clotting time to 321 ± 2.1 s on APTT and to 81.3 ± 0.8 s on TT, respectively, in a dose-dependant manner (Fig. 2). The results of ESI-QTOF tandem mass analysis showed that MEAP has a molecular mass of 2468 Da similar to the results with SDS–PAGE (Fig. 1b), and consistent with the amino acid sequence of MEAP which is EADIDGDGQVNYEEFVAMMTSK.

3.2. Identification and characterisation of M. edulis anticoagulant peptide (MEAP)

Specific factor inhibitory assays with normal human plasma showed that MEAP could inhibit FIX, FX, and FII containing γ-carboxyglutamic acid (gla) domains (Fig. 3). In the direct-binding assay using SPR sensorgraphy (Fig. 4), real-time resonance units (RUs) were measured for identifying molecular interactions between MEAP (ligand) and FII, FIX, FX (analytes). The binding affinity between MEAP and the factors was in the order: FIX > FX > FII; kinetic analysis determined K_D values of MEAP with FIX, FX, and FII of 11.3 ± 0.69, 21.4 ± 1.28, and 65.6 ± 1.97 nM, respectively, in the presence of Ca^{2+}. The present data suggests that MEAP has a higher

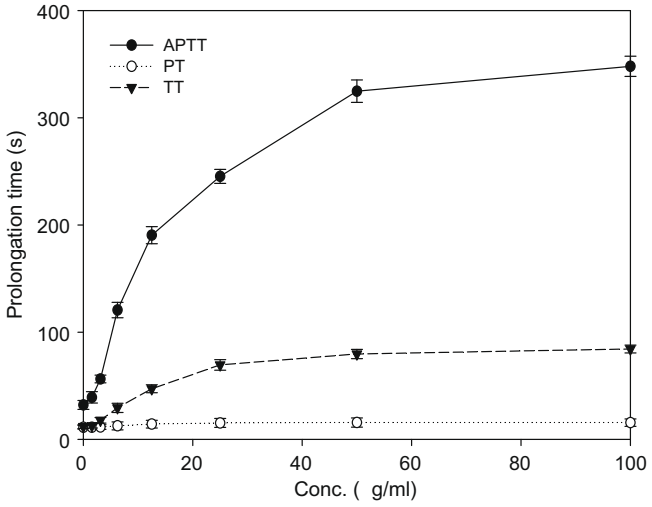

Fig. 2. Dose-dependant prolongation of MEAP. PT, TT, and APTT assays were performed with three individual replicates as described herein.

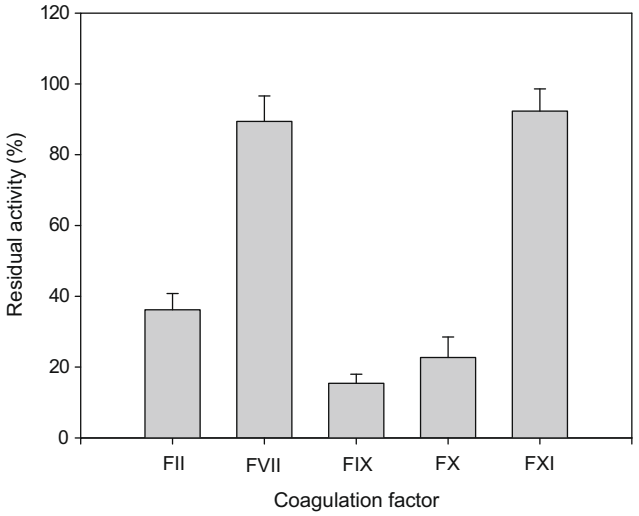

Fig. 3. Specific inhibitory assays for blood coagulation factors. The assays were performed with three individual replicates. Values are expressed as replicate means (±SD expressed as error bars).

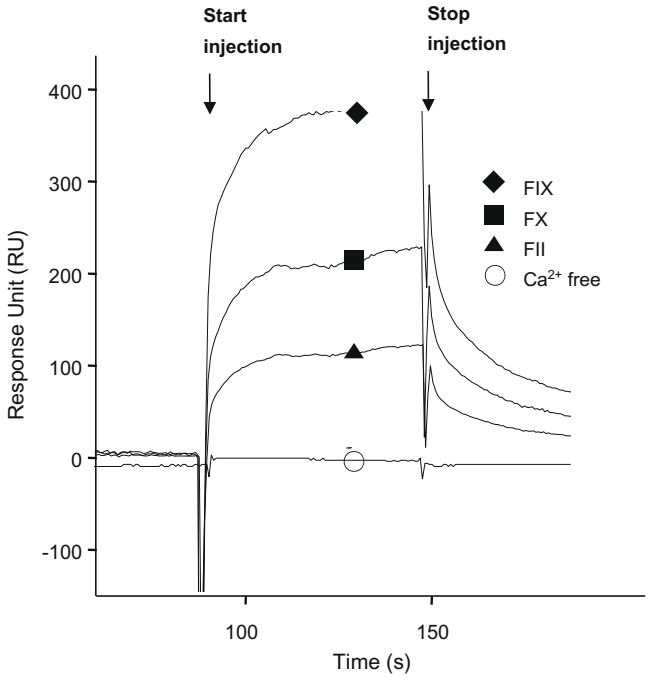

Fig. 4. The binding affinity assays with MEAP. The resonance units (RUs) of SPR real-time sensorgrams were measured to identify molecular interaction between MEAP (ligand) and FII, FIX, FX (analytes), in the presence of Ca^{2+}.

affinity for FIX and FX, which are included in the intrinsic pathway, and could potently prolong APTT as shown in Fig. 2. From the results of the amidolytic assay using fluorogenic substrates, it was shown that MEAP could inhibit the proteolytic conversion of FII by the prothrombinase complex and activation of FX by the intrinsic FXase complex. As shown in Fig. 5, the exogenous anticoagulant peptide (MEAP) inhibited in a dose-dependent manner the amidolytic activation of FX (IC_{50}; 13.6 μg protein ml^{-1}). In the prothrombinase complex, MEAP could inhibit the conversion of FII to FIIa in the prothrombinase complex (IC_{50}; 42.9 μg protein ml^{-1}). The effects of pH, temperature, and cation on MEAP activity were measured using the APTT assay (data not shown). MEAP was stable in the range of pH 6.5 and 8.0, but the activity below pH 6.0 and above pH 9.0 was destroyed. MEAP activity could be maintained at temperatures from 45 to 55 °C. After removing cations by

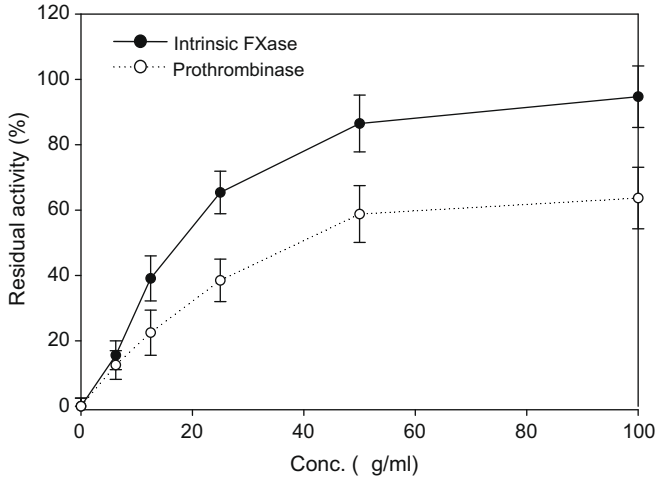

Fig. 5. Inhibitory activity of MEAP against amidolytic functions of the intrinsic FXase and the prothrombinase complex. The amount of FXa and FIIa (thrombin) generated in the blood coagulation complexes were determined immediately with the use of the fluorogenic substrates SN-7, Mes-D-LGR-ANSN(C_2H_5)$_2$, and SN-59, D-VPR-ANSNH-$C_4H_9 \cdot 2HCl$, respectively. The assay was performed with three individual replicates. Values are expressed as replicate means (±SD expressed as error bars).

EDTA-treatment and dialysis, MEAP activity could be recovered by addition of Zn^{2+}, Mg^{2+}, and Mn^{2+}, but not Cu^{2+} and Fe^{2+}. To investigate cytotoxicity of MEAP, the MTT assay was run on a venous endothelial cell line (ECV 304). MEAP-treated cell viability is slightly lower than that of heparin-treated cells; however, the result of the MTT assay showed that MEAP is not significantly cytotoxic ($P < 0.05$) to the venous endothelial cells.

4. Discussion

M. edulis anticoagulant peptide (MEAP) prolonged the normal clotting time to 321 ± 2.1 s on APTT and to 81.3 ± 0.8 s on TT in a dose-dependant manner, respectively. As reported in a previous study (Jung et al., 2001), *Scapharca broughtonii* anticoagulant protein only prolonged the activated partial thromboplastin time (APTT), corresponding to inhibition of the major coagulation factors (FVII, FIX, FX, FIX, PLs, etc.) in the intrinsic blood coagulation pathway. In that study, the addition of 100 μg ml^{-1} of *S. broughtonii* anticoagulant prolonged a 32 s control clotting time to 325 s. According to Davie et al. (1991), prolongation of thrombin time (TT) implies an inhibition of the conversion of prothrombin (FII) to thrombin (FIIa) by negative interactions with the major factors (FII, FV, FX, PLs, etc.) in the blood coagulation pathway. MEAP could specifically inhibit FII, IX and FX, all of which have a gla domain, in a calcium (Ca^{2+}) dependant manner. Among blood coagulation factors, especially, FII, FVII, FIX, and FX with a gla domain play a key role in the Ca^{2+}-mediated formation of phospholipid-factors complexes such as the intrinsic factor tenase, the extrinsic factor tenase, and the prothrombinase complex (Davie et al., 1991). The FII, FIX, and FX are considered as essential components in the intrinsic FXase and prothrombinase complex to complete human blood clotting (Mann, 1976). Specially, FII (prothrombin) with 10 gla residues converts specific glutamic acid residues to gla, which contribute to the ability of FII to bind to the negatively charged PL membranes. FIX has 12 gla residues which also facilitates the calcium dependent binding of FIX to the negatively charged PL surfaces and the epidermal growth factor (EGF) homology domains. The activated FIX contains the catalytic component of the intrinsic FXase complex (FIXa/FVIIIa/Ca^{2+}/PL) which proteolytically activates FX to FXa. Factor X also has 11 gla residues and 2 EGF homology domains. The activation of FX is catalysed by the

intrinsic FXase complex. Factor Xa serves as the enzyme component of the prothrombinase complex (FXa/FVa/Ca^{2+}/PL), which is responsible for the rapid conversion of FII to FIIa (Mann, Jenny, & Krishnaswamy, 1988). As summarised above, the gla residues enable blood coagulation factors with a gla domain to bind PL membranes (i.e., cell surfaces) in a Ca^{2+}-dependent manner for assembly of the intrinsic FXase and prothrombinase complex. It means that exogenous molecules with a high affinity for the Ca^{2+}/PL membrane may interrupt normal activation of blood coagulation factors by the PL complexes. From the NCBInr database search, it was determined that the amino acid sequence of MEAP (-EADI DGDGQVNYEE FV**A**MMTSK-) has a high identity (95%) with that of the EF-hand domain (127-EADI DGDGQVNYEE FV**T**MMTSK-148) of the calcium-binding protein, calmodulin (CaM) from scallop (Patinopecten) adductor muscle on the C-terminal end (Accession No. 0711223A) (Toda et al., 1981). These results showed that the MEAP peptide could be a fragment of the mussel calmodulin.

It is supposed that the presence of MEAP in human plasma might interrupt regular activation of FX in the intrinsic FXase complex (FIXa/VIIIa/PLs) and conversion of FII to FIIa in the prothrombinase complex (FXa/FVa/PLs) by negative interactions with gla domains in FII, FIX, and FX, due to the high affinity of MEAP for the Ca^{2+}/PL membrane. The results of the amidolytic assay showed that MEAP could potently inhibit the activation of FX and FII by prothrombinase and intrinsic FXase complex. These results suggest that the prolongation of blood clotting time in the presence of MEAP may be caused by interrupting the calcium-dependent molecular interactions between major coagulation factors with gla domains and PL membranes in the formation of the intrinsic FXase complex which activates FX and the prothrombinase complex to convert FII to FIIa (Fig. 6). In the previous study (Jung et al., 2001), the blood coagulation assay with human plasma showed that the anticoagulant protein isolated from marine arkshell (*S. broughtonii*) prolonged the activated partial thromboplastin time (APTT) and inhibited factor IX in the intrinsic pathway of the blood coagulation cascade. As reported by Koyama, Noguchi, Aniya, and Sakanashi (1998), plancinin, a potent anticoagulant peptide isolated from starfish (*Acanthaster planci*) could inhibit the prothrombinase complex by the anticoagulant action of placinin on the activation step of FII and FXa. After removing cations by EDTA-treatment and dialysis, MEAP activity could be recovered by addition of Zn^{2+}, Mg^{2+}, and Mn^{2+} in addition to Ca^{2+}. The results of the blood coagulation assay in the presence of various divalent cations showed that MEAP may easily interact with FII, FIX, and FX by stabilisation and coordination of divalent cations; moreover, Zn^{2+}, Mg^{2+}, and Mn^{2+} may play a role as a substitute for Ca^{2+} in the anticoagulant activity of MEAP in the formation of FXase and prothrombinase complex. From the result of the MTT assay, MEAP exhibits low cell cytotoxicity towards the endothelial ECV-304 cells. Most anticoagulants injected into veins encounter endothelial cells. The primary process of the haemostatic mechanism (platelet aggregation) is to be set in motion when the endothelial lining of blood vessels is denuded following vascular injury (Davie et al., 1991).

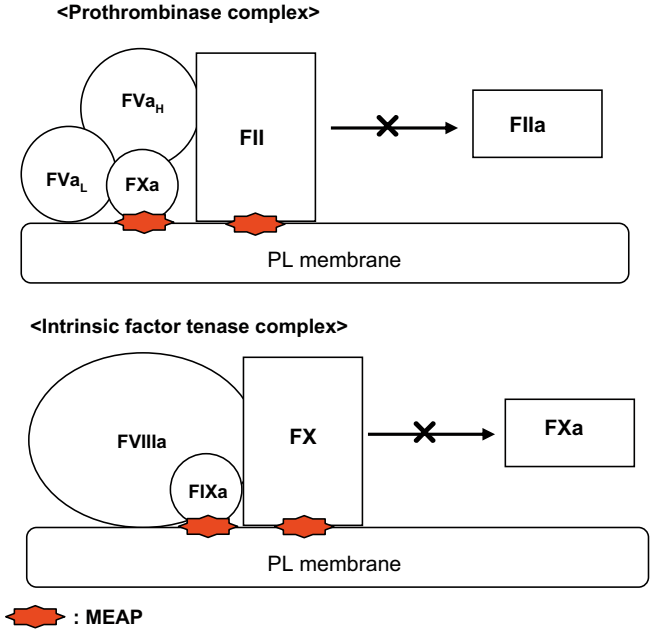

Fig. 6. The anticoagulant mechanism of MEAP in the prothrombin and intrinsic factor tenase complex. MEAP in human plasma might interrupt the conversion of FII to FIIa in the prothrombinase complex (FXa/FVa/PLs) and the regular activation of FX in the intrinsic FXase complex (FIXa/VIIIa/PLs) by negative interactions with gla domains in FII, FIX, and FX, due to the high affinity of MEAP for the Ca^{2+}/PL membrane.

5. Conclusion

This study showed that MEAP can prolong blood clotting time by inhibiting activation of FX in the intrinsic tenase complex (FIXa/VIIIa/PLs) and conversion of FII to FIIa in the prothrombinase complex (FXa/FVa/PLs).

In this paper we report on quantifying EC in commercial brands of pot still cachaças from Paraíba State, Northeastern Brazil; and discuss the results in light of the brands' characteristics and distillation profile.

2. Materials and methods

2.1. Sampling of cachaças and selecting distilleries

Duplicate samplings of 25 brands of cachaças, produced in all 19 approved pot still distilleries in Paraíba, the third major Brazilian State in pot still production of cachaça (Cachaça Official Guide, 2005), were conducted from retail outlets in Paraíba's capital, between September and October 2007. In order to obtain a valid representation of each brand's EC level, samples of different batch codes were purchased. General characteristics of the brands, including the distillation method, were obtained from local inspecting authorities and from label information. Detailed information on distillation was collected in visits to 11 distilleries, which were selected on the basis of their interest in participating in the project. According to label information, the samples contained no added sugar.

2.2. Chemicals

Ethyl carbamate (99.0%), for calibration, and propyl carbamate (98.0%), internal standard, were purchased from Chem Service (West Chester, USA) and Aldrich (Milwaukee, USA), respectively. The analytical solutions were dissolved in LC grade ethanol (Merck, Darmstadt, Germany) at 40% (v/v).

2.3. Analysis of ethyl carbamate

Preparation of calibration curves and EC analysis were based on Andrade-Sobrinho et al. (2002) and Reche et al. (2007), respectively. An Agilent 6873 autosampler was used to introduce, in splitless mode, 2 μl aliquots of each cachaça brand ($n = 2$) onto a capillary column (FFAP, 50 m × 0.2 mm i.d. × 0.3 μm film thickness; HP) installed in an Agilent 6890 gas chromatograph (GC) coupled to an Agilent 5973 mass selective detector (MS). The MS was operated in the electron impact mode with an ionisation energy of 70 eV and helium at 1.5 ml/min was used as carrier gas. The GC oven was initially kept at 90 °C (2 min), followed by an increase to 150 °C (0 min) at 10 °C/min, then up to 230 °C at 40 °C/min. The injector temperature was 250 °C, and the GC/MS interface was maintained at 230 °C. Quantification was performed in terms of single ion monitoring mode for m/z 62 mass fragment and was based on an internal standard procedure. The limits of detection and quantitation were 10 and 40 μg/l of EC, respectively.

2.4. Analysis of alcoholic strength

The alcoholic strenghts (% volume at 20 °C) of the spirits were determined using a Densimat hydrostatic balance coupled to an Alcomat converter (Gibertini Elettronica, Milano, Italy).

3. Results and discussion

3.1. EC levels in commercial brands of pot still cachaças

Table 1 shows the EC concentrations, in increasing order, of 25 brands of pot still cachaças produced in Paraíba State, Brazil. EC was detected in all samples. The brands' EC concentration range and average value were 55–700 μg/l and 221 μg/l, respectively. Ethyl carbamate levels in 70% of the brands exceeded the international limit for spirits (150 μg/l).

The average EC levels found in pot still cachaças from Paraíba State are considerably lower than the mean values reported previously for 34 samples of pot still cachaças from different parts of Brazil (630 μg/l, Andrade-Sobrinho et al., 2002) and for several

commercial cachaças produced in Minas Gerais State (1205 μg/l, Baffa Júnior et al., 2007; 893 μg/l, Labanca et al., 2008). Although not stated, the samples investigated by Baffa Júnior et al. (2007) and Labanca et al. (2008) are likely to be pot still types, because Minas Gerais State, in Southeastern Brazil, is the national leader in pot still production of cachaça (Cachaça Official Guide, 2005). However, the average level reported here are higher than the values reported in 13 commercial samples of pot still cachaças produced in Rio de Janeiro State (123 μg/l, Bruno, Vaitsman, Kunigami, & Brasil, 2007).

No clear connections between the brands' characteristics (cachaça's colour, distillation [single or double], and bottle colouration) and EC were observed, as shown by these characteristics' random distribution along the EC concentration range (Table 1).

The relationship between the bottle's colour and the EC level was researched because EC can form in spirits not only during distillation, but also during storage, especially by the light-induced formation mechanism from hydrogen cyanide (Mildau, Preuß, Frank, & Heering, 1987). However, this mechanism appears to be negligible in cachaça, because our finding regarding bottle colour is in line with Andrade-Sobrinho et al. (2002), who also found no connections between EC levels and bottle colour in 103 samples of various types of cachaças.

Ethyl carbamate has a low volatility (bp 182–184 °C); and therefore, double distillation has been proposed as a measure to reduce the amount of EC in pot still cachaças, which are typically single-distiled. In fact, an early study by Nagato, Silva, Yonamine, and Penteado (2000) on 13 samples of commercial cachaças reported an average EC level of approximately 317 μg/l; but the authors observed that samples with the lowest concentrations (~38–48 μg/l) were double-distiled. Our study, in which three brands were double-distiled (Table 1), found no such low levels, suggesting that double distillation alone is an insufficient mitigating measure. Other factors might also play important roles in reducing the EC level, such as using low distillation rates and adequately separating the first ("heads") and last ("tails") distiling fractions.

No apparent association was seen between the cachaça's colour (which reflects cask maturation) and their EC levels, as shown by the random distribution of white and yellowish cachaças along the EC concentration range (Table 1). When we look at the white and yellowish single-distiled cachaças produced by distilleries A (brands 01 and 13), B (brands 02 and 20), and D (brands 04 and 17), however, we see that the EC concentration in yellowish cachaças is four times higher (on average) than in the corresponding white cachaças. This effect was less evident for distillery N (brands 15 and 22), which showed a 1.7-fold increase for the yellowish cachaça. Interestingly, no such effect was observed for white and yellowish double-distiled cachaças produced by distilleries F (brands 06 and 07) or Q (brands 21 and 24).

According to information collected from the distilleries in Paraíba State, freshly single-distiled cachaças, with "heads" and "tails" already separated to some extent, are typically matured in large (~20,000–30,000 l) freijó wood (*Cordia goeldiana*) containers or small (~250 l) reconditioned oak casks, if white or yellowish/matured cachaças are desired, respectively. The study observed that the cachaças' maturation time was typically 6–12 months.

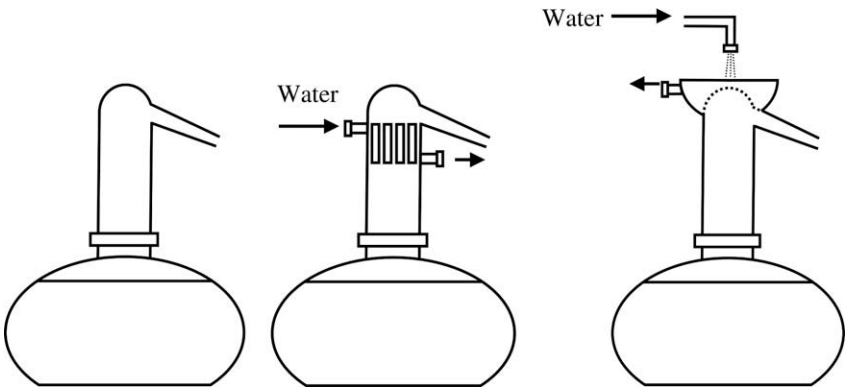

Fig. 2. Schematic cachaça alembics (ascending parts) showing different cooling systems: hot head (left), tubular dephlegmator (centre), and head cooler (right).

According to Aylott et al. (1990), the final amount of EC present in mature grain spirits includes the initial EC measured immediately after distillation, plus that formed from active precursors such as hydrogen cyanide, cyanate, and copper cyanide complexes. Taking into account the pot still cachaças' maturation periods, and the fact that most EC forms ~24–48 h after distillation (Aylott et al., 1990; Riffkin, Wilson, Howie, & Müller, 1989), it appears that factors other than maturation time are playing important roles to cause the high EC levels in yellowish single-distiled cachaças (Table 1). The relatively similar EC levels in white and yellowish double-distiled cachaças (Table 1) can be explained by the depletion of EC precursors between the first and second distillations (prior to maturation), combined with inadequate second distillation procedures (e.g., high distillation rates and poor separation of "heads" and "tails").

3.2. Distillation profile of distilleries and EC levels

Table 2 shows the EC levels, in increasing order, of 11 brands of pot still cachaças and the distillation profiles obtained during visits to corresponding distilleries. To maintain homogeneity in the comparisons, the distillation profiles are associated with only one type of product, white, single-distiled cachaças.

No clear connections were observed between EC levels and distillation scale, heating system, or kettle shape (Fig. 1), as shown by these characteristics' random distribution along the EC concentration range (Table 2).

With regard to the cooling system, however, a clear concentration of hot head systems (Fig. 2) in the most heavily contaminated range (200–700 μg/l) was observed. Contrarily, a clear prevalence of dephlegmator and head cooler systems, particularly the former, in the less contaminated range (55–100 μg/l) was observed (Table 2). These observations are in line with those of Bruno et al. (2007), who also found a close connection between low levels of EC in cachaças and distillation in alembics using high reflux rates.

With respect to brand 25, reasons were sought in distillery S for its exceedingly high EC level (Table 2). Contrary to the other distilleries visited, distillery S did not separate the "heads" at all. Interestingly, brand 25 has the highest ethanol concentration (Table 1); thus strengthening the information collected at distillery S. This observation is in line with results of Andrade-Sobrinho et al. (2009), who found higher EC levels in "heads" than in other distiling fractions of pot still cachaças. Although Andrade-Sobrinho et al. (2009) explained their finding solely on the basis of EC's solubility (higher in ethanol than in water), the fact that "heads" contain the abundance of cyanides (Christoph, Schmitt, & Hildenbrand, 1987; Guerain & Leblond, 1992), which may react with ethanol forming EC, is a more plausible explanation than solubility. The exceedingly high EC levels observed in brand 25 might thus be explained by the combined effects of full incorporation of "heads" into the final product with the use of a "hot head" alembic.

4. Conclusions

This work has shown that most brands of pot still cachaças produced in Paraíba State, Brazil, do not comply with the maximum permissible EC level for spirits (150 μg/l) tolerated in several countries, including Brazil. No clear connection between the characteristics of cachaça brands (colour, distillation [single or double], and bottle colour) and their corresponding EC levels was observed. However, focusing on the white and yellowish single-distiled cachaças from the same distilleries provided some evidence suggesting that the yellowish cachaças tend to be more contaminated than the white. An on-site investigation of 11 pot still distilleries shows that the brands with low (55–100 μg/l) and high (200–700 μg/l) contamination levels in white single-distiled cachaças are associated with pot stills equipped with cooled and non-cooled columns, respectively. A study larger than the present one is currently in progress to strengthen these observations.

are unrecognizable, being of great utility in the questions previously described.

In this field, the DNA analyses are the best option, since provide more information than protein due to the degeneracy of the genetic code and the presence of many non-coding regions (Lockley & Bardsley, 2000). By other way, mitochondrial DNA has several advantages over nuclear DNA, including its high mutation rate, multi-copy nature and maternal inheritance (Mackie et al., 1999). Particularly, the mitochondrial *cytochrome b* gene has been widely used by many authors to carry out the genetic identification of very different taxa (Infante et al., 2006; Perez & Garcia-Vazquez, 2004; Santaclara, Cabado, & Vieites, 2006; Santaclara, Espiñeira, & Vieites, 2007). The main advantage of this gene is that accepts mutations quickly enough, so that closely related organisms can show nucleotide differences, but not so rapidly that the variation within a species is significant (Bartlett & Davidson, 1992). In this manner, even closely related species as tuna and bonito or frigate tuna can be identified (Bartlett & Davidson, 1991; Infante, Catanese, Ponce, & Manchado, 2004; Pardo & Perez-Villareal, 2004; Ram, Ram, & Baidoun, 1996; Terol, Mascarell, Fernandez-Pedrosa, & Perez-Alonso, 2002; Unseld, Beyermann, Brandt, & Hiesel, 1995). The methodological approaches used to date are varied, amongst them are the *PCR–RFLP* (Polymerase Chain Reaction–Restriction Fragment Length Polymorphism) (Aranishi, 2005; Quinteiro et al., 1998), the phylogenetic analysis (Terol et al., 2002), Taqman RT–PCR technology (Lopez & Pardo, 2005) and the Multiplex primer-extension PCR assay (Lin & Hwang, 2008). Many of these works only take into account one or few genera of the family Scombridae and do not study all species included in each genus, so that, incorrect identifications can take place.

In the present work, a method of authentication of scombroid products based on DNA amplification by PCR and phylogenetic analysis of DNA sequences was designed. This methodology allows discriminating successfully scombroid species of important commercial value using the mitochondrial *cytochrome b* as molecular marker.

2. Materials and methods

2.1. Sample collection, storage and DNA extraction

Samples of different scombroid species were collected from several locations around the world (Table 1). The individuals were

[d] Accession numbers to sequences deposited in the *GenBank* database.

identified attending to morphological characteristics (Collette & Nauen, 1983; Collette, Reeb, & Block, 2001).

DNA was extracted from 30 mg of muscle in fresh and frozen samples, according to the method described by Roger and Bendich with slight modifications (Rogers & Bendich, 1985). In processed products, DNA was extracted from 150 mg in processed products, using the *NucleoSpin Tissue kit* (*Macherey-Nagel*). The purity and concentration of the extracted DNA was measured using a UV–vis spectrophotometer (*Biophotometer*, *Eppendorf*). Scombroid samples and DNA extractions were appropriately labelled and stored at −80 °C for subsequent studies.

2.2. PCR amplification and DNA sequencing

A fragment of the *cytochrome b* gene was amplified by PCR using the forward primer L14735 (Burgener, 1997) and the reverse BRmod (primer BR described by Terol (Terol et al., 2002) slightly modified). This primer set amplified the herein called *Fragment B*569.

In all cases, PCR reactions were carried out in a total volume of 50 μL with the following composition: 100–300 ng of DNA template were added to PCR mix consisting of 0.8 mM of dNTP mix (*Bioline*), 5 μL of 10X buffer, 2 mM of $MgCl_2$, 0.75 unit of BioTaq™ DNA pol (*Bioline*), 0.8 μM of each primer (*Sigma Genosys*) and molecular biology grade water (*Eppendorf*) to adjust to the final volume.

PCR were carried out in a *MyCycler*™ thermocycler (*BIO-RAD*). Conditions for the primer set L14735/BRmod were as follows: a preheating step at 95 °C for 3 min, 35 cycles of amplification (95 °C for 30 s, 60 °C for 30 s, 72 °C for 30 s) and a final extension step of 72 °C for 3 min.

PCR amplicons were visualised on 2% agarose gels (*Sigma*) in 1X TBE buffer (*Sigma*) with 0.3 μg/mL of ethidium bromide (*Sigma*). DNA fragments were visualised using the *Molecular Imager Gel Doc XR System* transilluminator and the software *Quantity One® v* 4.5.2 (*BIO-RAD*). The *pGEM* (*Promega*) and 50 *Base Pair Ladder* (*GE Healthcare*) DNA markers were used to estimate the size of the amplicons.

The PCR products were purified using the *Nucleospin Extract II kit* (*Macherey-Nagel*) according to the manufacturer's instructions. The concentration and purity were estimated by means of a UV–vis spectrophotometer *Biophotometer* (*Eppendorf*). Subsequently were sequenced on an *ABI Prism* 310 *Genetic Analyzer* (*Applied Biosystems*) using the primers of the PCR amplification and the *BigDye Terminator Cycle Sequencing Ready Reaction Kit v* 1.1 (*Applied Biosystems*) following the supplier's recommendations.

The electropherograms obtained were analysed using the *DNA Sequencing Analysis Software v* 3.4 (*Applied Biosystems*) and corrected at hand with *Chromas v* 1.45 (Mc Carthy, 1996). The nucleotide sequences obtained were aligned with *BioEdit v* 7.0 software (Hall, 1999) and used for estimating intraspecific and interspecific distances with *DnaSP v* 4.0 (Rozas, Sanchez-DelBarrio, Messeguer, & Rozas, 2003).

2.3. Primers design for species identification in canned products

From the sequences of the *fragment B569* obtained two new internal primers were designed: BD1-R, BD2-D. These primers were used together BD described by Terol et al. (2002) and BRmod. The PCR products obtained from BD/BD1-R and BD2-D/BRmod primer sets were herein called *Fragment* 1 and *Fragment* 2, respectively. These fragments are overlapped, generating the *Fragment* B239 (Table 2 and Fig. 1).

Table 2
Primers used in this work.

Name	Sequence 5′–3′	Described
L14735	AAA AAC CAC CGT TGT TAT TCA ACT A	Burgener (1997)
BRmod	AAT CGG GTG AGG GTG GCR TTG T	In this work
BD	GGC CGA GGC CTT TAC TAC GGC	Terol et al. (2002)
BD2-D	ACG TMC TTC CCT GAG GRC A	In this work
BD1-R	RGT AAT GAC GGT AGC TCC T	In this work

The PCR amplifications of the *Fragment* 1, *Fragment* 2 and *B*239 were carried out with the following conditions: a preheating step of 94 °C for 5 min was followed by 35 cycles of amplification (94 °C for 20 s 52 °C for 20 s and 72 °C for 20 s) and a final extension step of 7 min at 72 °C.

Next, PCR products obtained were visualised, cleaned, and sequenced as reported previously.

2.4. Development of FINS methodology using the cytochrome b gene

The sequences herein obtained and those ones downloaded from *GenBank* database were used to carry out the phylogenetic analyses. The following DNA sequences belonging to scombroid species were downloaded from the *NCBI* database: NC005313, AB105165 (*A. rochei*), NC005318, AB105447 (*A. thazard*), AB098092 (*E. affinis*), AB099716 (*E. alleteratus*), NC005316 (*K. pelamis*), DQ497857–DQ497859 (*R. kanagurta*), AB098098, EF141178, DQ497888, DQ497890 (*S. orientalis*), EF439573, EF427593, EF392613 (*S. sarda*), AB032519 (*S. australasicus*), AB032517 (*S. japonicus*), NC006398 (*S. scombrus*), AB032518, AB098098, EF141178, NC008109 (*S. cavalla*), DQ497885–DQ497887 (*S. niphonius*), AF231666 (*S. tritor*), AB098103 (*T. albacares*), AB098106 (*T. maccoyii*), AB098110 (*T. obesus*), AB185022 (*T. orientalis*), X81563 (*T. thynnus*), AB098115, AF239964 (*T. tonggol*), EF512291 (*D. maruadsi*).

The phylogenetic analyses were carried out with *Mega 3.0* (Kumar, Tamura, & Nei, 2004) using the Tamura–Nei model (Tamura & Nei, 1993) to calculate the genetic distances between sequences. The inference of the phylogenetic tree was carried out with the Neighbor-Joining method (Saitou & Nei, 1987). The three species of the genus *Decapterus* were used as outgroup. The reliability of the groups was evaluated by means of bootstrap test with 2000 replications.

2.5. Methodological validation

Individuals of the different species were authenticated on the basis of their morphological traits. These reference individuals were used to manufacture different products (salted, smoked and canned) in the pilot plant of CECOPESCA (*Spanish National Centre of Fish Processing Technology*). The most extreme treatment applied

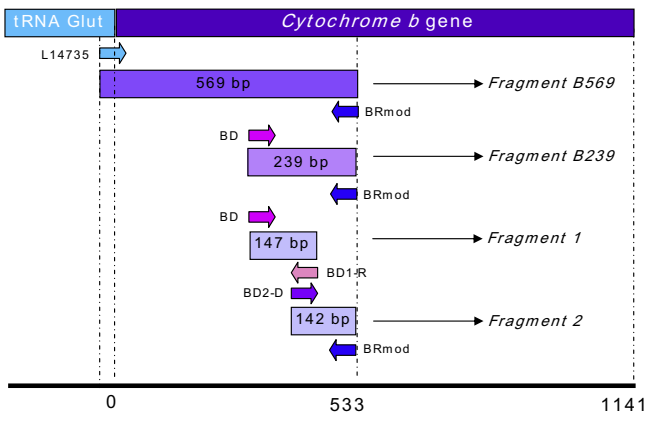

Fig. 1. Location and size of the DNA fragments of *cytochrome b* amplified in this work and position of primer sets used.

to the samples was the sterilization in a horizontal retort steel–air, at 115 °C for 50 min, with 1.2 bars of overpressure (cans of 125 mL).

Next the samples were analysed with the methods developed in the present work. Results of the species assignment on the basis of morphology and genetic probes were compared. The coincidence percentage between the species identified on the basis of morphological traits and the genetic methodology developed was calculated to establish the specificity of the method.

2.6. Application to commercial samples

Once the methods were validated, these ones were applied to 20 cans labelled as tuna, bonito, mackerel and frigate tuna. These products were purchased in supermarkets and shops from European countries, amongst them Spain, Germany, Finland, Portugal and Poland, with the aim of evaluating their correct labelling.

3. Results and discussion

3.1. PCR amplification and DNA sequencing

A high source of genetic markers which can be used for species identification has been created associated to the development of molecular techniques (Taggart, Hynes, Prodohl, & Ferguson, 1992; Young, Wheeler, Coryell, Keim, & Thorgaard, 1998). Specifically, in the present study the mitochondrial *cytochrome b* gene was used as target to develop a DNA-based method for the identification of Scombridae species.

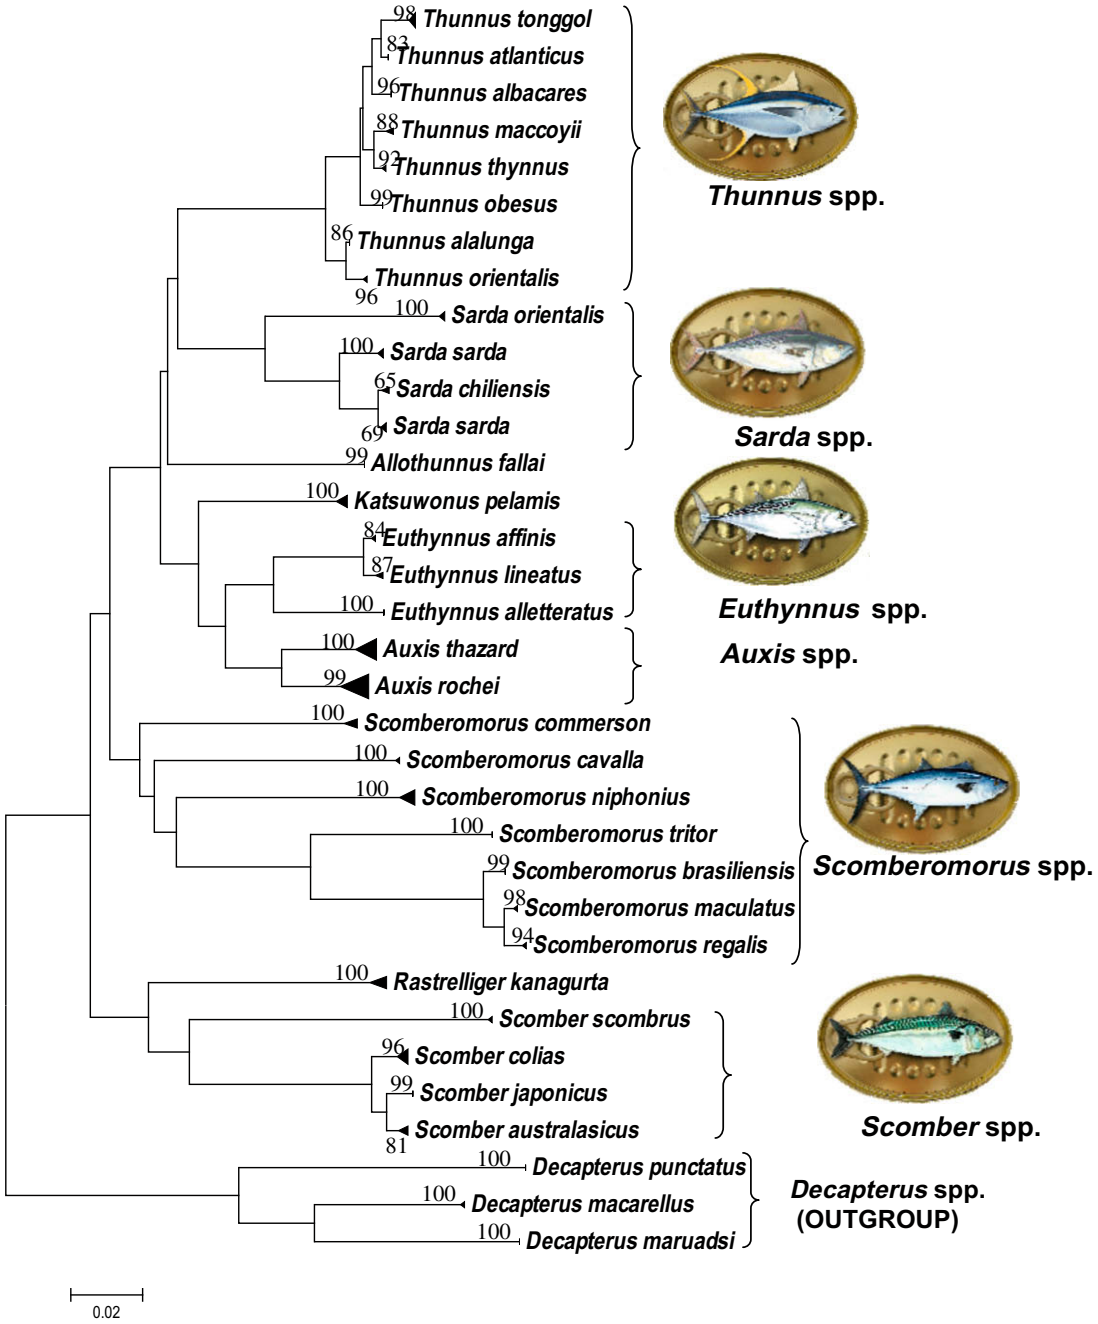

Fig. 2. Neighbor-Joining tree of genetic relationships amongst studied species, carried out from the alignment of 522 bp sequences.

The sequences of *Fragment B*569 were obtained from different species of *Thunnus*, *Scomber*, *Auxis*, *Sarda*, *Scomberomorus*, *Euthynnus*, *Allothunnus*, *Katsuwonus*, *Rastrelliger* and *Decapterus* genera (Accession numbers in Table 1). In all the species analysed the length of this PCR product was 569 bp, except for *Rastrelliger kanagurta* that was 570 bp. This PCR product is located from position 37 of the glutamic acid tRNA to position 533 of the *cytochrome b* (Fig. 1). The additional base in *R. kanagurta* is situated on tRNA of the glutamic acid, so that, there is not reading frame shift of the *cytochrome b* protein.

3.2. Development of the genetic method: PCR product amplification

In order to allow the authentication of scombroid species in canned and other seafood products, several methodological strategies were developed. In fresh or frozen fish, it is possible to amplify the *Fragment B*569. Subsequently, in order to carry out the genetic identification easily. In the case of fishes undergoing different treatments, it is not possible to amplify the mentioned PCR product because the thermal treatment generates DNA fragmentation. For this reason, in products only subjected to moderate temperature in the processing (such as smoked or salted fish), the *Fragment B*239 was amplified (Fig. 1).

In the case of cans, fragments of little size were amplified because the thermal treatment and pressure applied generated high levels of DNA fragmentation. Quinteiro et al. (1998) established a maximum fragment size of 176 bp to ensure the amplification in canned products. Pardo & Perez-Villareal, 2004 under certain conditions, amplified fragments higher than 200 bp from canned products. However, we consider that it is important to have at one's disposal a method that can be used routinely, allowing the amplification of DNA easily and that provides a reliable species identification. Because of this, PCR amplifications of *Fragment* 1 and *Fragment* 2 were carried out. The length of these amplicons was 147 and 142 bp, respectively. These fragments are overlapped and generate the *Fragment B*239 (Fig. 1).

3.3. Phylogenetic analysis: FINS methodology

The *FINS* technique was evaluated because it has been extensively used in the past for the genetic identification of fish and shellfish as for instance cephalopods (Santaclara et al., 2007), bivalves (Espiñeira, González-Lavín, Vieites, & Santaclara, 2009; Santaclara et al., 2006), flatfishes (Espiñeira, González-Lavín, Vieites, & Santaclara, 2008a), anglerfishes (Espiñeira, González-Lavín, Vieites, & Santaclara, 2008b) or anchovies (Santaclara, Cabado, & Vieites, 2006). The main advantage of this technique is that uses the information of all nucleotide positions of the amplified DNA, compared to *RFLP* or other techniques which only assess a low number of nucleotides. However, the *FINS* technique allows the genetic identification of species by means of phylogenetic analyses using a DNA sequence database. Like this, reference sequences belonging to morphologically identified individuals and the sequence of an unknown individual are compared. From this analysis, a distance matrix is constructed and this allows the assignment of the unknown species to a group according to the genetic distance. The genetic distances between the obtained *cytochrome b* gene sequences reveal that the intraspecific distance mean was 0.03 ± 0.00 and interspecific ones were one order of magnitude higher than the intraspecific ones (the mean value for these ones was 0.141 ± 0.012). The mean interspecific distance between species of the same genus was 0.099 ± 0.009.

From the distance matrix, the phylogenetic tree was constructed allowing the genetic identification of species because samples belonging to the same species were grouped into the same clade. The bootstrap method can be used to obtain the support of the different groups obtained in the phylogenetic tree. It has been calculated that bootstrap values higher or equal to 70% usually correspond to a probability higher or equal to 95% that the corresponding cluster is real (Hillis & Bull, 1993), giving a quantitative measurement of the certainty of the assignment of a sample to a particular species. The phylogenetic tree constructed from 522 bp sequences (*Fragment B*569 without primers) shows that all the sequences belonging to individuals of the same species are grouped in the same cluster (Fig. 2). All clusters are strongly supported, with bootstrap values higher than 80% (except for *Sarda chiliensis*), allowing the reliable assignation of each individual to a particular species. Also, bootstrap values higher than 80% were obtained in the phylogenetic reconstruction carried out with the 196 bp fragment (*Fragment B*239 without primers) (Fig. 3), showing that *Fragments B*569 and *B*239 allows the reliable assignment of an unknown sample to its species.

Therefore, the proposed strategies of amplification allow the amplification of a DNA fragment sufficiently long to discriminate successfully all the scombroid species of commercial importance, even in canned products and others formats in which the DNA is highly degraded.

3.4. Inclusion of Decapterus species in the methodology

The species of *Decapterus* genus were included in this work because canned products elaborated with the species *Decapterus*

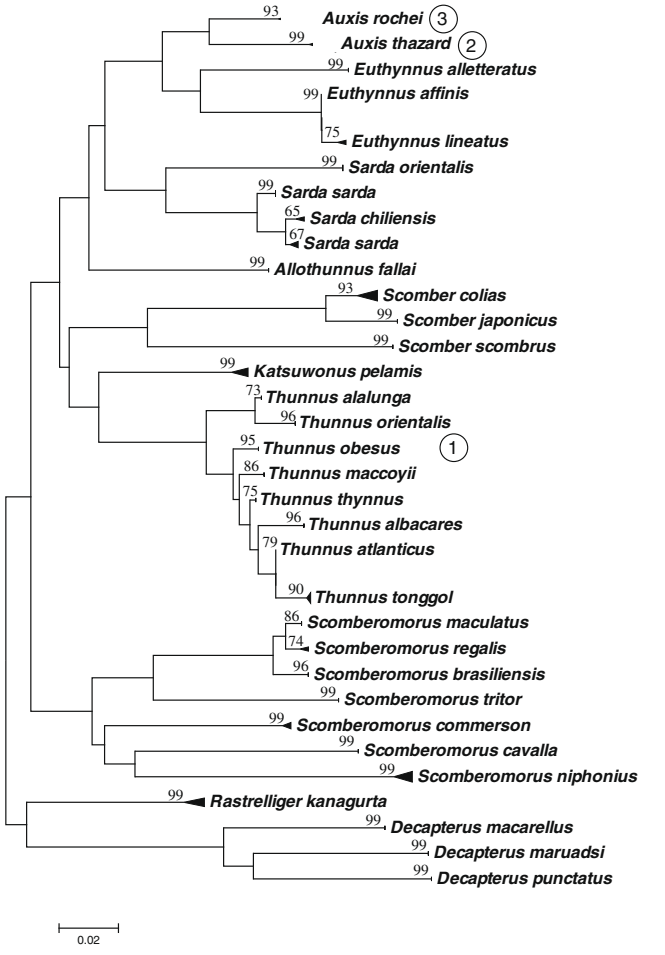

Fig. 3. Neighbor-Joining tree of genetic relationships amongst studied species, carried out from the alignment of 196 bp sequences. Circled numbers belong to the commercial samples analysed where a mislabelling was detected.

macarellus are labelled using the commercial denomination "Mackerel scad". This fact can produce confusion with several scombroid species, which include "Mackerel" in their denomination. Moreover, the organoleptic properties of some canned *Decapterus* species are very similar to the *Scomber* ones. The phylogenetic analysis shows that all the *Decapterus* species form a taxon clearly differentiated from the family Scombridae. Therefore, the three *Decapterus* species included in this study can be identified with total reliability with the proposed methodology.

3.5. Considerations derived from the phylogenetic analysis

The phylogenetic analysis clarified and confirmed some questions about several taxonomic groups. First of all, the results observed in the phylogenetic reconstruction performed in this work are in accordance with the recognition by fish taxonomy of the species *Scomber colias*, distributed in the Atlantic Ocean as a separate species from *S. japonicus* that inhabits the Pacific Ocean (Fig. 2). These species are included in two separated clades strongly supported. Infante, Blanco, Zuasti, Crespo, and Manchado (2007) carried out a phylogenetic differentiation between *S. colias* and *S. japonicus* based on nuclear 5S rDNA sequences. The results of this work are in agreement with the ones obtained in the present study based on mitochondrial sequences.

Also, it is worth mentioning that there are two groups for the species *Sarda sarda*. There are several genetic studies of *S. sarda* that suggest the existence of two subpopulations in the Mediterranean Sea (Pujolar, Roldán, & Pla, 2001; Viñas, Alvarado Bremer, & Pla, 2004). This is in accordance with the results obtained in the phylogenetic reconstruction made in the present work.

Regarding the clade of *Thunnus* genus, although the internal structure was weak, the bootstrap values for each species were higher than 83%, allowing the assignment of an unknown sample to a species belonging to this genus. Moreover, a high number of individuals belonging to all the geographical distribution range for each species were considered to carry out the phylogenetic reconstruction.

3.6. Methodological validation

The results of the genetic analyses of the samples manufactured in the pilot plant of CECOPESCA were in accordance with the expected based on the morphology characterisation. Therefore, the developed method showed a specificity of 100%. Also it was checked whether the canning process or any other kind of processing, such as smoking salting, or canning do not affect to the correct operation of the developed methods.

3.7. Application to commercial samples

The aim of this study was to assess the fulfilment of labelling requirements for the commercial canned samples. The *FINS* method herein developed was applied to all commercial canned samples analysed. Three analysed samples contained a different species from those indicated in the label, meaning 15% of the samples were incorrectly labelled.

Except for one sample of tuna, and two samples of bullet and frigate tuna, the labelling and the species identified by the proposed technique were in agreement. The exceptions were canned products labelled as *T. albacares*, *A. rochei* and *A. thazard* that were respectively identified as *T. obesus*, *A. thazard* and *A. rochei*.

In conclusion, the technique described in this paper is a useful tool to authenticate scombroid species in all kind of products, from fresh fish to canned products. It can be useful to verify the correct labelling of fishing products elaborated with these species. Also, this methodology could be useful to check the import and export of these species and therefore their traceability or origin and to control the catch of protected species, for example the "bluefin tuna" *Thunnus thynnus*, which is nowadays overexploited.

Moreover, the analysis can be carried out in less than two work days, and it allows a high throughput screening of all kind of samples. Also, different methodological strategies are proposed, allowing analysis of fresh, frozen or processed products with total reliability.

Amongst the advantages of this method it is worth mentioning its rapidness and reliability to authenticate processed commercial products. Also, it includes 33 species and all of which are used as substitutes of others of higher value in processed food, meaning this is the most complete method developed up to now. Moreover, it can be applied to any product, independently of the degree and type of processing to which it has been subjected (fresh, frozen, salted, smoked, and canned, amongst other products).

et al., 2009; Spanjer, Rensen, & Scholten, 2008; Sulyok, Berthiller, Krska, & Schuhmacher, 2006), are more frequently applied. Most of these chromatographic methods are based on the determination of a single mycotoxin or multiple mycotoxins belonging to the same group (Berthiller et al., 2005; Cervino et al., 2008; D'Arco et al., 2008; Faberi et al., 2005; Silva et al., 2009), whereas the number of methods for the simultaneous determination of more than one group of mycotoxin is still limited (Cavalieri et al., 2005; Lattanzio et al., 2007; Sulyok et al., 2006). In general, these methods require considerable analysis time (higher than 20 min) (Cavalieri et al., 2005; Lattanzio et al. 2007; Spanjer et al., 2008; Tanaka et al., 2006), and in some cases, two injections are required (Sulyok et al., 2006), as well as the application of a clean-up step (Cavalieri et al., 2005; Lattanzio et al., 2007; Tanaka et al., 2006). On the other hand, mycotoxins are compounds with different physicochemical properties, and multimycotoxin determination requires the development of appropriate optimisation methods for the simultaneous extractions of these compounds.

Ultra-high performance liquid chromatography (UHPLC) is a relatively new technique that shows improved sensitivity, resolution and speed compared to LC (Pastor-Montoro, Romero-González, Garrido-Frenich, Hernández-Torres, & Martínez-Vidal, 2007). These advantages result from the use of columns filled with sub-2 μm particle size and instruments with high pressure fluidic modules. There are few published studies in which mycotoxins have been analysed in food using UHPLC (Mol et al., 2008; Ren et al., 2007). For instance, the second method requires a clean-up step, and two consecutive chromatographic runs of 7.5 min each.

The aim of this study was to develop and validate a simple and rapid UHPLC–MS/MS multimycotoxin method for the simultaneous determination of aflatoxins B1, B2, G1, G2, M1, fumonisins B1 and B2, ochratoxin A, deoxynivalenol, HT-2 and T-2 toxin and zearalenone in maize, walnuts, biscuits and breakfast cereals at trace levels. The method is based on a single extraction step using acetonitrile/water mixture (80/20 v/v), without the need of any clean-up procedure. The chromatographic analysis time was reduced to 8.5 min, which meets the requirement for a high throughput determination; in addition the method shows better detection limits than previously published methods for the target compounds (Cavalieri et al., 2005; Lattanzio et al., 2007; Sulyok et al., 2006; Tanaka et al., 2006).

2. Materials and methods

2.1. Reagents and chemicals

Ochratoxin A, deoxynivalenol, T-2 toxin and stock solution of aflatoxin M1 (in acetonitrile) were obtained from Biopure (Tulln, Austria). Aflatoxins B1, B2, G1, G2, zearalenone and stock standard solution of fumonisin B1 and HT-2 toxin (in acetonitrile) were purchased from Sigma–Aldrich (St. Louis, MO, USA). Stock solution of fumonisin B2 (in acetonitrile) was supplied by Fluka (Steinheim, Germany). First, stock standard solutions (200 mg/L) were prepared by exact weighing of those mycotoxins obtained in powder and dissolved in 50 mL of HPLC-grade acetonitrile (Sigma). Then, a multicompound working solution (2 mg/L except for aflatoxin M1 which was 0.2 mg/L) was prepared by combining suitable aliquots of each individual standard stock solution and diluting them with appropriate amounts of acetonitrile. These solutions were kept at 4 °C and renewed weekly.

Acetic acid (purity > 97%), formic acid (purity > 98%), ammonium formate and ammonium acetate were obtained from Panreac (Barcelona, Spain). HPLC-grade methanol was supplied by Sigma. Ultrapure water was obtained from a Milli-Q Gradient water system (Millipore, Bedford, MA, USA).

2.2. Equipment

Chromatographic analyses were performed in an ACQUITY UPLC™ system (Waters, Milford, MA, USA), using an Acquity UPLC BEH C_{18} column (100 mm × 2.1 mm), with 1.7 μm particle size, from Waters. MS/MS detection was performed using an Acquity TQD tandem quadrupole mass spectrometer (Waters, Manchester, UK). The instrument was operated using an electrospray (ESI) source in positive mode. Data acquisition was performed using MassLynx 4.0 software with QuanLynx software (Waters). Centrifugations were performed in a high-volume centrifuge from Centronic (Barcelona, Spain). A Vortex mixer Heidolph, model Reax 2000 and an analytical AB204-S balance (Mettler Toledo, Greinfesee, Switzerland) were also used. A Braun MX 32 kitchen blender (Barcelona, Spain) was used to process samples. A Reax-2 rotary agitator from Heidolph (Schwabach, Germany) was used for sample extraction.

2.3. UHPLC–MS/MS analysis

Chromatographic analyses were carried out using a gradient elution with eluent A being methanol and eluent B consisting of an aqueous solution of ammonium formate (5 mM). The analysis started with 25% of eluent A, which was increased linearly up to 75% in 3 min, and then, to 100% in 2 min. This composition was held for further 1.5 min before being returned to 25% of eluent A in 1 min, followed by a re-equilibration time of 1 min, to give a total run time of 8.5 min. The flow rate was set at 0. 35 mL/min and column temperature was maintained at 30 °C. Aliquots of 5 μL of sample extract were injected into the chromatographic system.

For MS/MS detection, the ionisation source parameters were: capillary voltage 3.5 kV, extractor voltage 3 V, source temperature 120 °C, desolvation temperature 350 °C, cone gas flow 50 L/h and desolvation gas flow 650 L/h (both gases were nitrogen). Collision-induced dissociation was performed using argon as collision gas at a pressure of 4×10^{-3} mbar in the collision cell. The multiple reaction monitoring (MRM) transitions and the applied cone voltages and collision energies are summarised in Table 1.

2.4. Sample preparation

Mycotoxins were extracted from samples using a solid–liquid extraction procedure. Briefly the procedure was as follows: 5 g of ground samples (maize, walnut, biscuit and breakfast cereal) were weighed in a polypropylene centrifuge tube (40 mL) and 10 mL of an acetonitrile/water solution (80/20, v/v) was added and the mixture was vortexed for 2 min. However for biscuit samples, 20 mL of the mixture acetonitrile/water were needed. After that, the tube was put into a rack in the rotary agitator for 10 min at 60 rpm. After centrifugation at 4500*g* for 5 min, 2 mL of the supernatant layer were taken and filtered through a Millex-GN nylon filter (0.20 μm, Millipore, Carrightwohill, Ireland), before the sample was injected into the UHPLC–MS/MS system.

2.5. Samples

The following food items were collected: three samples of maize and walnuts were obtained from farms located in the Southeast of Spain. Five breakfast cereals and five different brands of biscuits were purchased from local supermarkets (Almeria, Spain) and were analysed before the expiration date. The maize, walnut and the content of each package were grounded before mycotoxin extraction. All samples were analysed following the procedure described above and those samples showing the absence of the target compounds were used as blank samples in the preparation of standards and recovery studies.

Table 1
Retention time windows (RTWs) and UHPLC–MS/MS parameters.

Compound	RTW (min)	Channel	Dwell time (ms)	Cone voltage (V)	Quantitation transition[a]	Confirmation transition[a]
Deoxynivalenol	1.41–1.59	1	0.200	25	297.4 > 249.4 (10)	297.4 > 231.3 (15)
Aflatoxin G2	2.61–2.75	2	0.015	60	331.4 > 313.5 (25)	331.4 > 245.3 (30)
Aflatoxin M1	2.72–2.94	2	0.015	50	329.4 > 273.4 (20)	329.4 > 259.3 (25)
Aflatoxin G1	2.77–2.91	2	0.015	45	329.2 > 243.1 (25)	329.2 > 311.4 (25)

Zearalenone	4.14–4.32	4	0.015	30	319.5 > 301.6 (10)	319.5 > 283.6 (12)

[a] Collision energies (eV) are given in brackets.

3. Results and discussion

The aim of this work was to develop a simple and fast method for high throughput determination of mycotoxins in cereals and related foods by UHPLC–MS/MS.

3.1. Optimisation of the UHPLC–MS/MS determination

First, the experiments to select the optimum MS conditions and the appropriate ions were performed by column injection of individual standards at 500 μg/L. ESI positive and negative mode were evaluated, observing that whereas all toxins were detectable in the positive mode, not all of them were efficiently ionised in the negative mode, and ESI in positive mode was selected for all the mycotoxins. Full-scan mass spectra and product ion scan were acquired in order to obtain at least one precursor and two product ions for each compound for both identification and quantification purposes, selecting the most abundant product ion for quantification and the second one for confirmation. Table 1 shows the MS/MS transitions as well as the cone voltages and collision energies optimised for each compound. In all the cases, $[M+H]^+$was selected as parent compound, except for T-2 and HT-2 toxins, which formed the ammonium adduct $[M+NH_4]^+$. For ochratoxin A, the most intensive product ion was at *m/z* 358 which correspond with the loss of water and carbon monoxide whereas the other ion selected corresponded with the loss of phenylalanine at *m/z* 239 (Sforza, Dall'Asta, & Marchelli, 2006). On the other hand, non-specific transitions such as loss of water were avoided although for some compounds such as aflatoxin G2 and G1 was selected due to its higher sensitivity.

Finally, it must be indicated that although some published papers use ESI in negative mode to determine some mycotoxins such as deoxynivalenol and zearalenone (Sorensen & Elbaek, 2005) good sensitivity was obtained when ESI in positive mode was applied.

Secondly, the influence of the several variables involved in the chromatographic process was evaluated in order to reduce analysis time, increase sensitivity and provide good peak shape. Due to the chemical diversity of the analysed toxins, a suitable composition of the mobile phase must be selected. The organic solvent used in the mobile phase was evaluated, observing that methanol provided better sensitivities than acetonitrile for all analytes, especially for trichothecenes such as deoxynivalenol, T-2 and HT-2 toxins.

Ammonium acetate or formate can be added to avoid the formation of stable sodium adducts, mainly for trichothecenes and aflatoxins. On the other hand, fumonisins have four carboxylic groups in the molecular structure and acidic chromatographic conditions can be used in order to obtain good peak shape (Sulyok et al., 2006). Formic acid (0.1%), ammonium acetate (5 mM) and ammonium formate (5 mM) were added to the mobile phase and better results were obtained for aflatoxins, deoxynivalenol, T-2 and HT-2 toxin when ammonium formate was used, whereas for fumonisin B1 and B2, slightly better results were obtained when formic acid was used. Furthermore, better responses were always obtained when formate was selected instead of acetate. Based on these data, 5 mM of formate ammonium was used in the mobile phase, bearing in mind that is still acidic for the suitable separation of fumonisins.

Several initial percentages of the mobile phase were studied, ranging from 5% to 40% of methanol, observing that good peak shape and high sensitivity were achieved with the increase of methanol content in the initial composition, and analysis time can decreased. However, it can be noted that when the gradient started at 40% of methanol, bad peak shapes were obtained for fumonisin B1. Considering the combined factors between separation efficiency and sensitivity, 25% of methanol was selected as the initial composition of the mobile phase.

Other parameters such as flow rate, injection volume, and column temperature were optimised selecting as optimum conditions: 0.35 mL/min as flow rate, 30 °C as column temperature and 5 μL as injection volume.

With the optimised conditions, the analysis time was lower than 9 min, including cleaning and re-equilibration steps, which allows high sample throughput, and retention time ranges from 1.5 (deoxynivalenol) to 4.3 (zearalenone). The analytes were distributed in four overlapping functions, using a maximum of five mycotoxins (10 transitions) per function. Different dwell times were evaluated (0.005–0.200 s) to find the best detection parameters, observing that better results were obtained when 0.015 s was selected except for function 1 and 3 (Table 1), where 0.200 and 0.025 s were used as the dwell time, respectively, due to the different compounds analysed simultaneously in the selected overlapping functions. Using the selected dwell time, a sufficient number of data points per peak can be acquired in order to have enough sensitivity and allow reproducible integration for quantitative results.

Furthermore, the use of UHPLC–MS/MS combines the separation capability of UHPLC and the selective detection power of MS/MS, which facilitates the identification of unresolved peaks even if coeluted interfering peaks are present. For instance, aflatoxin G1 and M1 coeluted and they have the same parent ion (*m/z* 329). Bearing in mind that retention time and precursor ion were very similar for both analytes, the product ions were selected taking into account that they must be different in order to avoid this interference. In this sense, both aflatoxins produce an intensive product ion at *m/z* 229, and this can be rejected because both compounds can interfere each other during their determination, so specific transitions for each aflatoxin were selected to monitor both compounds (see Table 1).

3.2. Optimisation of the extraction procedure

In multiresidue mycotoxin methods, the critical step is the extraction and clean-up procedure. To reduce sample handling and increase throughput, a simple solid–liquid extraction was used before chromatographic determination. For the optimisation, maize was used as representative matrix.

First, the optimum extraction solvent was evaluated, checking different solvents such as methanol, acetonitrile, a mixture of acetonitrile/methanol (50/50, v/v), water and several ratios of methanol and acetonitrile aqueous solution, obtaining better results when acetonitrile was used. Only, T-2 and HT-2 toxins shown slightly better responses when methanol was used. Most of the published paper used a mixture of acetonitrile/water (Zöllner & Mayer-Helm, 2006), and different ratios of acetonitrile/water was checked. For all the mycotoxins, the highest peak areas were obtained when a acetonitrile/water composition of 80/20 (v/v) was used as extracting solvent, except for fumonisin B1 and B2 that slightly better signals were achieved when the ratio was 60/40 (acetonitrile/water), as it was indicated by Sulyok et al. (2006). Furthermore, it can be indicated that when the percentage of water increased, the signal decreased considerably.

Finally, the extraction time was evaluated, testing times from 0 to 60 min. It can be highlighted that mycotoxins can be extracted just with vortex and no further agitation steps are needed except for T-2 and HT-2 toxins. For these compounds, peak area increased with extraction time up to 10 min, and then kept constant, so 10 min was selected as extraction time.

The proposed extraction method was evaluated in other type of matrices such as walnuts, breakfast cereals and maize based food such as some biscuits. It can be highlighted that mycotoxins can be extracted using the proposed method in these matrices, but fumonisin B1 and B2 were not extracted from walnuts and biscuits, as it was observed by other authors in other matrices, (Spanjer et al., 2008; Sulyok et al., 2006), indicating that the method should be modified to extract these critical compounds. Furthermore, for the extraction of mycotoxins from biscuits, 20 mL of extractant agent must be used instead of 10 mL, in order to obtain a suitable volume to be injected into the chromatographic system and reproducible results, because when 10 mL were used a doughy mixture was obtained, and irreproducible results were achieved.

Fig. 1 shows a typical chromatogram of a blank maize sample spiked with 50 μg/kg of the target mycotoxins (5 μg/kg for aflatoxin M1). It can be observed that the optimised extraction pro-

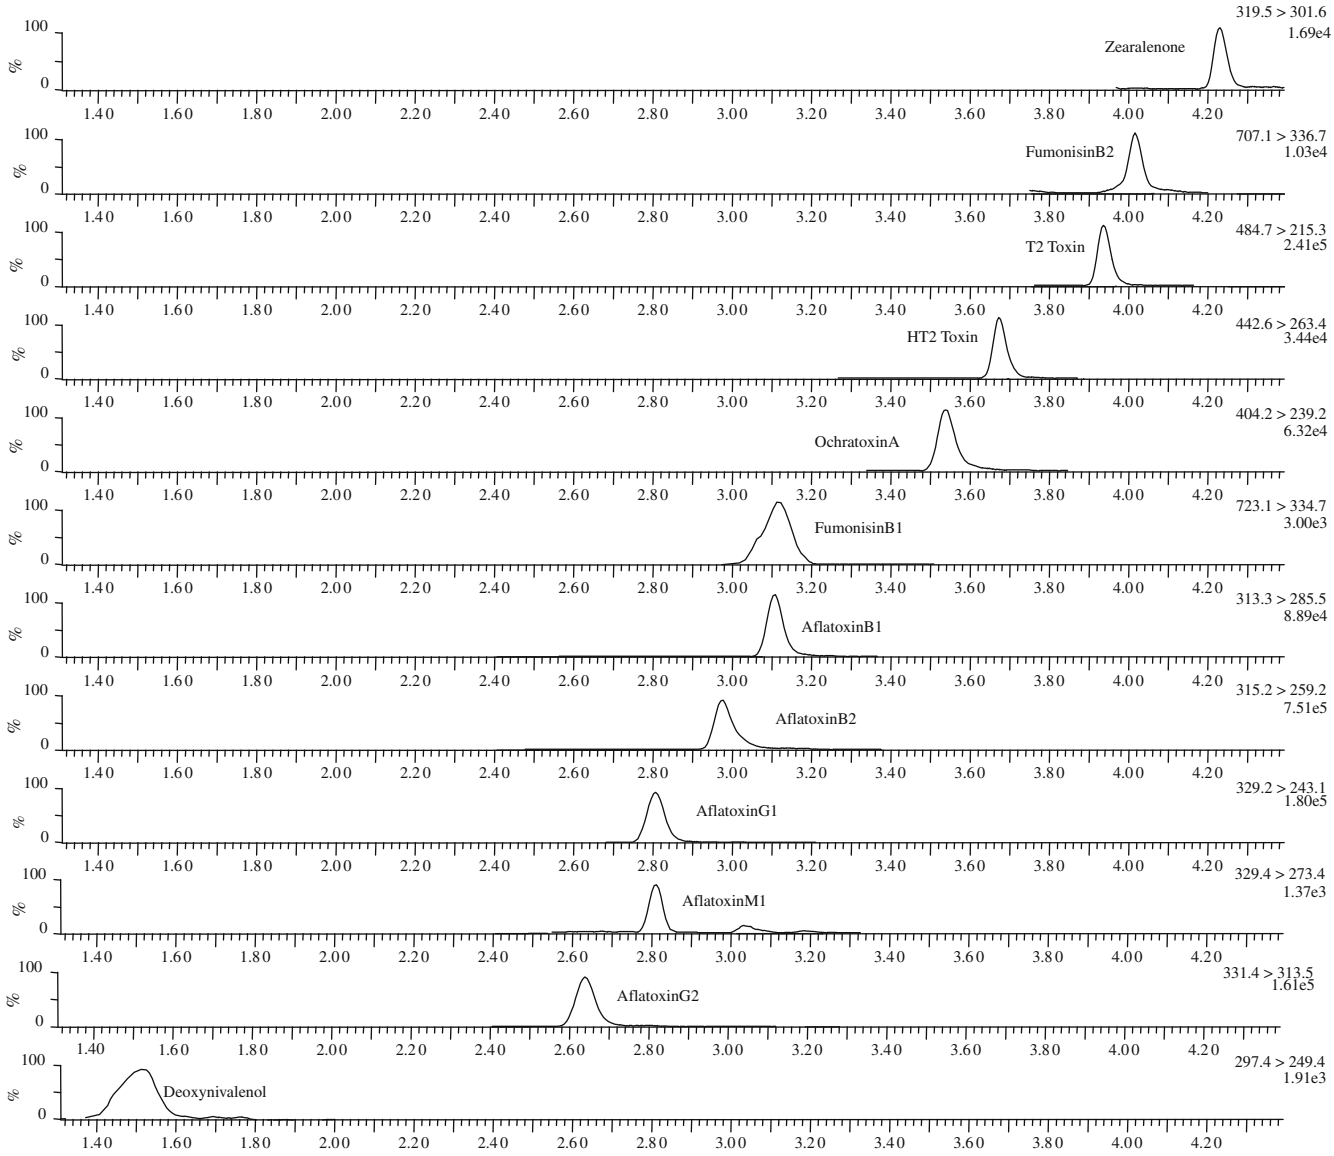

Fig. 1. UHPLC–MS/MS chromatograms obtained from a blank maize sample spiked at 25 μg/kg (2.5 μg/kg for aflatoxin M1).

cedure coupled to MS/MS provides a clean chromatogram without interferences, so further clean-up procedures were avoided in order to increase sample throughput, when the proposed extraction method is combined with UHPLC separation. Furthermore, it can be observed that complete resolution was not obtained but MS/MS detection allows the selective analysis of all the compounds.

3.3. Validation of the proposed method

Method validation was performed in terms of selectivity, linearity, accuracy, repeatability, interday precision, limits of detection (LODs) and quantification (LOQs).

One of the main problems of LC–MS/MS is that that the presence of matrix components can affect the ionisation of the target compounds, reducing or enhancing the response compared with standards in solvents, and the influence of the matrix effect on the response must be studied. In this work, several matrices were selected for evaluation of matrix effect, including maize, walnuts, breakfast cereals and biscuits. Several concentrations (from 5 to 100 μg/kg, except for aflatoxin M1 which was 10× lower) were analysed in pure solvent and in blank samples, and the slopes of the calibration curves were compared by an analysis of covariance (García-Campaña, Cuadros-Rodríguez, Aybar-Muñoz, & Alés-Barrero, 1997). Table 2 shows the obtained results. It can be noted that except for ochratoxin A and HT-2 toxin, the slopes are statistically different (*p*-value was lower than 5% for all the mycotoxins), indicating that a matrix effect was detected and this effect must be corrected in order to obtain reliable results. It can be observed an extensive matrix effect mainly due to the solvent:sample ratio, which were lower than other ratios published by Sulyok et al. (2006) and Spanjer et al. (2008), which used a ratio of 8:1, and minor matrix effects were obtained.

Because the diversity of the matrices and compounds evaluated, a representative matrix can not be used for this type of matrices, because depending on the matrix and the mycotoxin the matrix effect is different. For instance, for aflatoxin G2, the same matrix matched calibration can be used if maize and walnuts are analysed, whereas different calibrations must be prepared if zearalenone is determined in these matrices. For routine analysis, if several matrices must be evaluated, one matrix-matched calibration should be prepared for each matrix in order to obtain accurate results. Bearing in mind the short extraction time and chromatographic analysis, the preparation and injection of several matrix-matched calibrations does not increase the analysis time per batch considerably.

Although representative matrices can be selected in order to correct matrix effect, it could be detected some differences in the matrix effect within a given matrix (Sulyok, Krska, & Schuhmacher, 2007) and other approaches can be applied such as the use of isotopically labelled internal standard. However standard addition methodology can be used when mycotoxin concentrations were close to the limits indicated in international regulations in order to assure the reliability of the obtained results.

The linearity of the method was tested by spiking blank extract samples at five concentration levels between 1 and 100 μg/kg (except for aflatoxin M1 which was 10× lower). Peak area was selected as peak response and good linearity was found for all the mycotoxins within the tested interval, with determination coefficients higher than 0.98.

The recovery of the extraction step of each mycotoxin at two fortification levels (5 and 50 μg/kg, and 0.5 and 10 μg/kg for aflatoxin M1) was studied, showing the obtained results in Table 3. It can be noted that recovery of the extraction step ranged from 70.0% to 108.4% that fulfils the requirements established by European Union (Commission Regulation 401/2006, 2006). Furthermore, recoveries do not depend on the matrix evaluated and no significant differences were observed.

Repeatability (intraday precision) was evaluated at the two concentration levels of the recovery studies, performing six replicates for each level (Table 3), whereas interday precision was studied analysing one spiked sample at 10 μg/kg (1 μg/kg for aflatoxin M1) during six consecutive days (Table 4). For all the cases, repeatability was lower than 20%, except for fumonisin B1 and B2, which show some values slightly higher than 20%. In relation to interday precision, RSDs values lower than 20% were obtained for all the mxycotoxins and matrices evaluated, except for aflatoxin M1 and zearalenone in biscuit and fumonisin B2 in breakfast cereal, with RSDs values of 21.9, 21.8 and 24.5, respectively.

LODs and LOQs were calculated analysing blank spiked samples, and they were determined as the lowest concentration of the analytes that produce chromatographic peak at S/N of 3 and 10, respectively (Table 4). For instance, the lowest LODs and LOQs were obtained for aflatoxins (0.01 and 0.03 μg/kg for aflatoxin M1 in maize), whereas the highest values were achieved for deoxynivalenol and zearalenone, which LOQs values ranging from 3.70–5.90 and 5.10–6.30 μg/kg, respectively. In all the cases, LOQs were always lower than the maximum residue limits established by European Union (Commission Regulation 2006/1881/EC, 2006), indicating the suitability of the proposed method for the determination of trace concentration of these compounds, as well as they are lower than other obtained by related methods (Spanjer et al., 2008), which can be mainly attributed to the reduction of chromatographic dispersion when UHPLC is used, that provokes an increase in the analytical sensitivity.

Identification of the mycotoxins was carried out by searching in the appropriate retention time windows (RTWs), defined as the retention time ± three standard deviations of the retention time

Table 2
Evaluation of matrix effect, using maize, walnut, biscuits and breakfast cereal matrix-matched calibration and solvent-based standards.

of 10 blank maize samples spiked at 25 μg/kg for each mycotoxin, except for aflatoxin M1 which was 2.5 μg/kg (Table 1), and confirmation was carried out by comparison of the signal intensity ratios of the two transitions (quantification and confirmation), with those obtained using fortified blank samples. Furthermore, the selectivity of the proposed method was evaluated by the analysis of blank samples. The absence of any chromatographic signal at the same retention time as the target compounds indicated the absence of chemical or matrix interferences.

In order to show the feasibility of the proposed method, matrix effects and LODs obtained with the proposed method were compared with those published in bibliography (Table 5). It can be ob-

served that despite of higher matrix effects were obtained when the proposed method is used, LODs were considerably lower than previous results, indicating that the sensitivity of the presented method has been improved at the cost of increased matrix effect, due to the solvent:sample ratio used. The observed matrix effects can be compensated by the use of matrix-matched calibration, standard addition methodology or by the use of isotopically labelled internal standards.

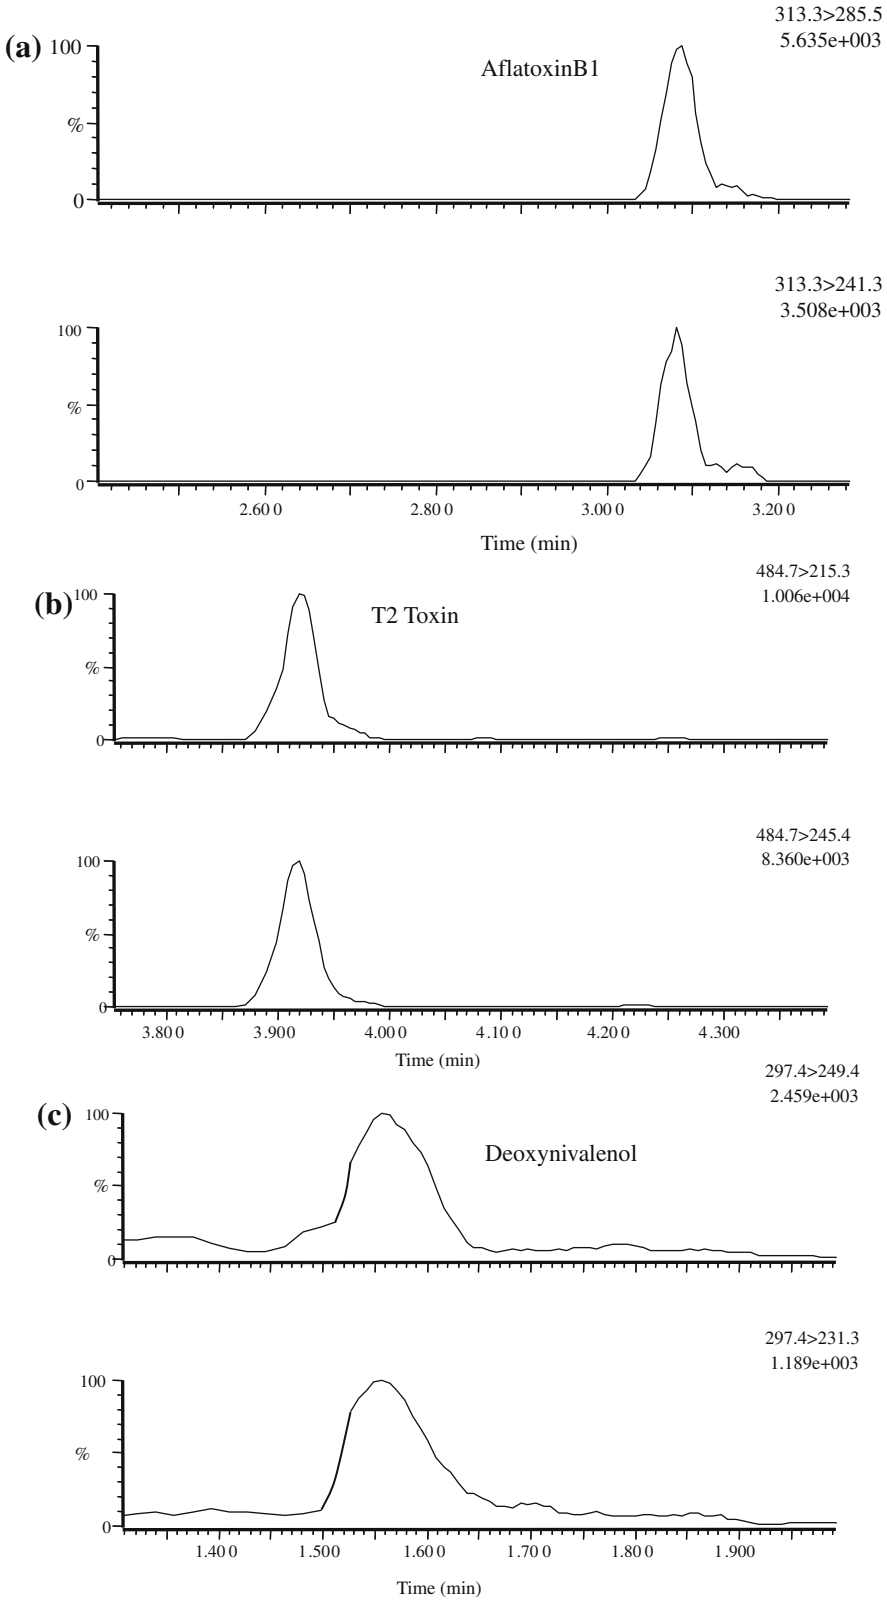

Fig. 2. UHPLC–MS/MS chromatograms for: (a) maize containing aflatoxin B1 at 2.7 μg/kg; (b) the same sample containing T2 at 5.1 μg/kg, and (c) breakfast cereal containing deoxynivalenol at 42.1 μg/kg. Quantification and confirmation transitions were shown for the three compounds.

3.4. Sample analysis

The developed method was applied to several samples (maize, walnuts, biscuits and breakfast cereals). An internal quality control was carried out for every batch of samples to check if the system is under control, and it implies a matrix-matched calibration, a reagent blank, a matrix blank and a spiked blank sample at 10 μg/kg in order to check the reliability of the proposed method.

Three sets of maize samples were collected from two farms located in two different areas. Two sets were collected from the same farm located in Granada, but in two different years (2007 and 2008), whereas the third set was collected from another farm. Mycotoxins were only detected in the maize collected in 2007, which was stored at room temperature in the farm. Aflatoxin G2 was detected at 3.4 μg/kg, aflatoxin G1 at 3.3 μg/kg, aflatoxin B2 at 2.2 μg/kg and aflatoxin B1 at 2.7 μg/kg. Furthermore, T2 toxin was found at 5.1 μg/kg, and traces of HT-2 toxin were detected. Although these levels were below the maximum level established by European Union (Commission Regulation 2006/1881/EC, 2006), they can indicate that more attention should be paid to storage conditions, in order to minimise the content of these analytes.

Three different sets of walnuts were collected from two different farms from the South of Spain, and only traces of deoxynivalenol were detected in one set.

Finally, five types of biscuits and breakfast cereals were collected from stores located in Almeria, and only deoxynivalenol was detected in one breakfast cereal sample at 42.1 μg/kg, which was far below the maximum residue limit established by the European Union (200 μg/kg).

Fig. 2 shows representative chromatograms of aflatoxin B1 and T2 Toxin in maize and deoxynivalenol in breakfast cereal. It can be observed that despite of the relatively high complexity of the analysed matrices, good selectivity and sensitivity were obtained.

4. Conclusions

A rapid and quantitative method has been developed for the simultaneous determination of mycotoxins in several types of matrices, with minimal sample preparation and clean-up. The use of a triple quadrupole mass spectrometer allows the unambiguous identification of 12 mycotoxins, allowing the determination of these compounds in the low μg/kg, fulfilling the requirements established by the European Union. Although significant matrix effect was observed, it was successfully compensated using matrix matched calibration. This quantitative method has many advantages including simple pre-treatment, avoid time-consuming and error-prone clean-up steps, rapid determination by the use of UHPLC, and high sensitivity due to the low LODs and LOQs obtained, which could be applied to the determination and quantification of multicomponent mycotoxins in routine analysis or in monitoring food programs, in which a large number of samples must be analysed.

Fig. 1. The structures of A-type and B-type dimers present in grape seeds and peanut skins, respectively. EC = epicatechin, C = catechin and *ent* = enantiomer.

degree of polymerisation (DP) > 2 are believed to be unabsorbable, data on the absorption of dimers are not consistent (Baba, Osakabe, Natsume, & Terao 2002; Donovan et al., 2002; Holt et al., 2002; Sano et al., 2003). Furthermore, A-type PAs have not been included in these bioavailability studies. In order to fully explore the biofunctional potential of PAs, research should focus on the relation between their structure, bioavailability and bioactivity. Isolated and well-characterised PA dimers are, therefore, of great importance.

Efficient isolation of different types of PA dimers requires sources containing high amounts and a large diversity of dimers. Commonly used sources for the isolation of B-type PCs are apple and cocoa, which primarily consist of epicatechin units (Guyot, Marnet, Laraba, Sanoner, & Drilleau, 1998; Rigaud, Escribanobailon, Prieur, Souquet, & Cheynier, 1993) that are mainly 4-8 linked (Foo & Lu, 1999; Rigaud et al., 1993). Grape seeds are also rich in B-type PCs (Gu et al., 2004) with relatively more catechin units (Saucier, Mirabel, Daviaud, Longieras, & Glories, 2001) compared to apple and cocoa. Additionally, 4-6 linkages and galloylated derivatives are present (Ricardo da Silva, Rigaud, Cheyner, Cheminat, & Moutounet, 1991; Rigaud et al., 1993; Santos-Buelga, Francia-Aricha, & Escribano-Bailon, 1995). Therefore, grape seed is a promising source to isolate a large diversity of B-type dimers. A-type PCs can be found in peanuts, plums, cranberries and cinnamon (Gu et al., 2004). Peanut skins contains up to 17% (w/w) PCs (Karchesy & Hemingway, 1986) and both C4–C8 and C4–C6 linked A- (with an additional C2–*O*–C7 linkage) and B-types have been identified (Karchesy & Hemingway, 1986; Lou et al., 1999).

The methods reported to obtain pure A- and B-type dimers are laborious as they include multiple chromatographic steps. The first

step in isolation usually consists of a separation based on DP. Previously, size exclusion materials like Sephadex LH-20 (McMurrough, Madigan, & Smyth 1996; Foo & Lu, 1999) and Toyopearl (Ricardo da Silva et al., 1991; Yanagida, Shoji, & Shibusawa, 2003) were used for this purpose. A combination of five different columns, including four size exclusion columns, was required to isolate several A-type dimers from peanut skins (Lou et al., 1999). The high diversity of B-type PC dimers in grape seeds makes it a good but also challenging source for the current chromatographic methods to isolate the dimers. Recently, a high-speed counter-current chromatographic (HSCCC) technique was used to isolate PC dimers from grape seeds (Kohler, Wray, & Winterhalter, 2008). However, an elution of many hours was needed and additional reversed-phase (RP) HPLC was a prerequisite to obtain pure dimer fractions. Nowadays, more specific silica-based stationary phases are used (Gu et al., 2002; Kelm, Johnson, Robbins, Hammerstone, & Schmitz, 2006; Natsume et al., 2000; Rigaud et al., 1993; Yanagida et al., 2000) and separations of PAs from several sources up to DP 10 have been described (Gu et al., 2002). Additionally, fractions up to DP 8 have been purified from apple (Shoji, Masumoto, Moriichi, Kanda, & Ohtake, 2006). Nevertheless, when pure dimer fractions are to be isolated, often size exclusion chromatography, instead of normal phase (NP) HPLC, in combination with RP-HPLC has been used. Advantages to use NP-HPLC followed by RP-HPLC are: (1) only one HPLC system is required instead of the multiple systems needed for HSCCC, (2) peak shape on NP and thereby purity of the different DP fractions is better than that on size exclusion or HSCCC, (3) a baseline separation of dimers on NP-HPLC facilitates isolation of a fraction containing only all dimers while size exclusion or HSCCC often results in inefficient isolation of dimers to prevent contamination with monomers or trimers due to overlap of peaks.

The combination of NP- and RP-HPLC to obtain pure dimers has rarely been used and little is known about the behaviour of A-type PCs on such columns. In this study an efficient method for the isolation of both A- and B-type dimers is described by combining NP- and RP-HPLC chromatography, yielding sufficient amounts of material for bioavailability studies.

2. Materials and methods

2.1. Materials

Sources to isolate PCs were peanut skins, kindly provided by Imko-The Nut Company BV (Doetinchem, The Netherlands) and a commercially available procyanidin extract from grape seeds (Vitaflavan, DRT, Levita Chemical International NV, Antwerpen, Belgium). PC dimer standards B1, B2, B3 and B4 were obtained at Apin Chemicals (Abingdon, UK). Organic solvents used for HPLC analysis were all HPLC-grade. Milli-Q water from a Millipore system was used.

2.2. Extraction of peanut skins

Peanut skins (~75 g) were defatted with hexane using soxhlet extraction. The residue was air dried. The defatted skins (~60 g) were extracted three times with 1 L of 20% (v/v) aqueous methanol. After each extraction the suspension was filtered over a 595 ½ filter (Schleicher & Schuell, Dassel, Germany), after which the pellet was subjected to the next extraction. The three 20% (v/v) methanol fractions were combined, concentrated by evaporation under vacuum and lyophilised. During the extractions and evaporation, light was excluded as much as possible by the use of marquees and tinfoil. Solvent partitioning was used for further purification. The lyophilised extract was put into a separation funnel to which 500 mL H_2O and 500 mL ethyl acetate was added. This was placed in an ultrasonic bath for 10–15 min at room temperature. After vigorous mixing, the H_2O phase and ethyl acetate phase were collected separately. The H_2O phase was put back into the funnel and the solvent partitioning procedure was repeated twice resulting in three ethyl acetate phases and one H_2O phase. The ethyl acetate phases were combined and subsequently extracted with H_2O (1:1, v/v) twice. The ethyl acetate phase was vacuum evaporated, dissolved in H_2O and lyophilised, resulting in the final extract referred to as: peanut skin extract.

2.3. Removal of gallic acid from grape seed procyanidins

Gallic acid substituents were enzymatically removed from grape seed PCs as described elsewhere (Appeldoorn, Vincken, Aura, Hollman, & Gruppen, 2009) to improve resolution on NP-HPLC. In short, grape seed PCs were dissolved in a sodium acetate buffer (0.1 M, pH 5.0), and incubated with tannase (EC 3.1.1.20, Gamma Chemie, Darmstadt, Germany). PCs were separated from free gallic acid by solid phase extraction. PCs were eluted with methanol, vacuum evaporated, dissolved in H_2O and lyophilised.

2.4. Preparative isolation of A- and B-type dimers

2.4.1. Normal phase HPLC

Fractionation by DP was performed on an Inertsil PREP-SIL 30 mm ID × 250 mm column with a 10 μm particle size (GL sciences Inc., Tokyo, Japan). A Waters system equipped with a 2767 sample manager, a 2525 binary gradient module, a 2996 photodiode array detector (PDA) and an UV fraction manager was used. The binary mobile phase consisted of (A) hexane and (B) acetone. The elution was as follows: 0–30 min, 40–60% B; 30–50 min, isocratic at 60% B; 50–70 min, 60–75% B, followed by a washing step at 98% B for 3 min, and reconditioning of the column. The flow rate was 27.22 mL/min and PDA spectra from 210–300 nm were recorded. In a run, 10 mL (~70 mg/mL in acetone/hexane/ethanol (7:3:2)) peanut skin extract or the tannase-treated grape seed extract was applied. The fraction containing dimers was collected from 22.3 to 28.2 min for the peanut skin extract and from 28.2 to 38.1 min for the grape seed extract. The fractions were evaporated under vacuum and lyophilised.

2.4.2. Reversed phase HPLC

An XterraRP 50 mm ID × 100 mm column with a 5 μm particle size (Waters) was used with a flow rate of 82.7 mL/min. The fractions containing dimers (~70 mg), which were obtained with preparative NP-HPLC, were dissolved in methanol using ultrasonic treatment if needed and filtered over a Spartan® 0.45 μm filter (Schleicher & Schuell, Dassel, Germany) before injection. The binary mobile phase consisted of (A) H_2O + 0.1% (v/v) acetic acid and (B) acetonitril + 0.1% (v/v) acetic acid. The elution for the separation and isolation of the individual peanut skin dimers was as follows: the first 3 min isocratic on 0% B; 3–23 min, B: linearly 0–22%; 23–28 min, B: linearly 22–89% followed by reconditioning of the column. The elution for the grape seed dimers was as follows: the first 10 min isocratic on 10% B; 10–23 min, B: linearly 10–50%; 23–27 min, B: linearly 50–95% followed by reconditioning of the column. PDA spectra were recorded from 210 to 300 nm. The fractions that were collected after injecting peanut skin dimers were; I_P (15.7–16.6 min), II_P (17.6–18.7 min), III_P (18.7–19.6 min), IV_P (19.6–20.5 min), V_P (21.2–22.0 min) and VI_P (22.0–22.8 min). The fractions that were collected after injecting grape seed dimers were; I_G (10.0–12.2 min), II_G (13.0–13.7 min), III_G (13.9–14.2 min), IV_G (14.8–15.5 min), V_G (15.7–15.9 min), VI_G (16.1–16.3 min), VII_G (16.5–17.0 min) and $VIII_G$ (17.4–17.8 min). Subsequently, the fractions were evaporated under vacuum and either lyophilised or

solubilised in methanol prior to further analysis. Fraction IV_G consisted of two PC dimers, which were further purified on an Atlantis dC18 (19 mm ID × 100 mm, 5 μm particle size; Waters). The fraction (~16 mg) was dissolved in 10 mL 50% (v/v) aqueous methanol, filtered over a Spartan® 0.45 μm and injected. The flow rate was 17.1 mL/min. The binary mobile phase consisted of (A) H_2O + 0.1% (v/v) acetic acid and (B) methanol + 0.1% (v/v) acetic acid combined in the following elution pattern: 0–16.7 min, B: linearly 5–45%; 16.7–20 min, B: linearly 45–60%; 20–23.3 min, isocratic at 60% B, followed by reconditioning of the column. Fractions were collected from 9.5 to 10.5 min (IV_{G1}) and from 10.8 to 12.0 min (IV_{G2}).

2.5. Analytical HPLC

2.5.1. Normal phase HPLC

A Thermo Spectra system was used containing a P 4000 pump, an AS 300 autosampler and an UV 3000 detector (Thermo Separation products, Fremont, CA, USA). Analysis was performed on a Luna Silica (2) 4.6 mm ID × 250 mm column with a 5 μm particle size (Phenomenex, Torrance, CA) operated at room temperature. Samples were dissolved in methanol. The mobile phase consisted of (A) dichloromethane, (B) methanol and (C) acetic acid/H_2O (50% v/v). The flow rate was 1 mL/min and detection was performed at 280 nm. The elution was as follows; C was kept constant at 4% throughout the elution; 0–20 min, B: linearly 14–23.5%; 20–50 min, B: linearly 23.5–35% followed by a washing step at 96% B for 10 min and reconditioning of the column.

2.5.2. Reversed phase HPLC

The same Thermo Spectra system was used and analysis was performed on a XterraRP dC18, 4.6 mm ID × 150 mm column with a 3.5 μm particle size (Waters). Samples were dissolved in methanol. The mobile phase was composed of (A) H_2O + 0.1% (v/v) acetic acid and (B) acetonitril + 0.1% (v/v) acetic acid. The flow rate was 0.7 mL/min and detection was performed at 280 nm. The elution for peanut skin dimers was as follows; the first 5 min isocratic on 10% B; 5–35 min, B: linearly 10–30%; 35–40 min, B: linearly 30–90% and reconditioning of the column. The elution for grape seed dimers was as follows; the first 15 min isocratic on 10% B; 15–35 min, B: linearly 10–50%; 35–40 min, B: linearly 50–95% followed by reconditioning of the column. Samples were compared to retention times of B-type dimer standards B1, B2, B3 and B4.

2.6. Characterisation of B-type dimers by phloroglucinolysis

Fractions I_P and VI_P, obtained after preparative HPLC, were analysed on RP-HPLC before and after acid-catalysed degradation as described by Fournand and coworkers (Fournand et al., 2006). Briefly, intact dimers were analysed on RP-HPLC-UV. After acid-catalysed degradation of the dimers in the presence of excess phloroglucinol, released terminal units and extension unit-phloroglucinol adducts were analysed by RP-HPLC-UV. Dimers were identified based on the retention time of the intact dimers and the retention time of (epi)catechin and their phloroglucinol adducts, released after acid-catalysed degradation.

2.7. Spectroscopic-analysis

2.7.1. ESI-MS detection

An LCQ Classic equipped with an ESI source was used and controlled by the software Xcalibur (Thermo Finnigan, San Jose, CA). The detector was coupled to an HPLC system by means of a splitter (Acurate, LC Packings, Amsterdam, The Netherlands), which reduced the flow rate 20 times. Measurements were performed in the negative mode with an ion spray voltage of 4.5 kV, a capillary voltage of −5.0 V and a capillary temperature of 270 °C. The scan range was set from *m/z* 100–2000. The MS/MS function was performed in the data dependant mode. The collision energy value was 27%.

2.7.2. Maldi-TOF-MS

Samples were analysed on an Ultraflex instrument equipped with a nitrogen laser of 337 nm and controlled by the software Flexanalysis (Bruker Daltonics B.V., Wormer, The Netherlands). A laser intensity of 29% was applied and data were collected within a mass range of 400–2000 Da. The apparatus was operated in both the positive and the negative mode with a delayed extraction time of 100 ns and an acceleration voltage of 20 kV. Samples were mixed with the matrix 2,5-dihydroxybenzoic acid (Bruker Daltonics) (10 mg/mL H_2O) (1:1) and 2 μL was put on a stainless steel metal plate, crystallised under a blow drier and analysed.

2.7.3. NMR spectroscopy

NMR experiments were performed on a Varian UNITY INOVA 500 MHz spectrometer (Varian NMR instruments, Palo Alto, CA, USA) equipped with a 3 mm indirect detection probe operating at 500 MHz for ^1H and 125.7 MHz for ^{13}C. One-dimensional (1D) ^1H, two dimensional (2D) ^1H TOCSY and ROESY, and 2D (^1H–13C) HSQC and HMBC spectra of samples dissolved in methanol-d_4 (fractions I_P, II_P and IV_P) or dimethyl sulphoxide-d_6 (fractions III_P, V_P and VI_P) were recorded at 298 K. Chemical shifts (δ) are given in ppm and coupling constant (J) values are given in Hertz. Spectra signals were referenced to the solvent signals, either DMSO (^1H signal at 2.5 ppm and ^{13}C signal at 39.5 ppm) or methanol (^1H signal at 3.3 ppm and ^{13}C signal at 49.0 ppm). Spectra were processed and analysed with V NMR software (Varian, CA, USA).

3. Results and discussion

3.1. Preparative isolation of A- and B-type dimers

3.1.1. Use of NP-HPLC for the isolation of a dimeric fraction

To be able to isolate the grape seed dimers, gallic acid substituents were enzymatically (tannase) removed, which improved the resolution especially between the dimers and trimers, as described previously (Rigaud et al., 1993). The dimers from the tannase-treated grape seed extract, as well as from the peanut skin extract, were isolated with preparative NP-HPLC (Fig. 2), which separates by DP. The total recovery of all material after NP-HPLC was 85% (w/w) (n = 1) for the peanut skin extract and 78% (w/w) ± 4.8 (n = 4) for the grape seed extract. This is comparable to recoveries obtained for apple extracts obtained with the same method (Shoji et al., 2006). The dimers represented 16.8% (w/w) (n = 1) of the peanut skin extract and 21.2% (w/w) ± 2.1 (n = 5) of the grape seed extract, similar to previously reported amounts in grape seeds (Nunez, Gomez-Cordoves, Bartolome, Hong, & Mitchell, 2006). Both dimer fractions were free of monomers and trimers as their masses, *m/z* 289 $[M-H]^-$ and *m/z* 865, 863 (1 A-interflavanic linkage (IFL)), and 861 $[M-H]^-$ (2 A-IFL), respectively, were not detected by NP-HPLC–UV–MS. The A- and B-type dimers could be distinguished by their parent ions (*m/z* 575 $[M-H]^-$ and *m/z* 577 $[M-H]^-$, respectively) and accompanying MS/MS spectra. PCs have three characteristic fragmentation routes, which have been described as: quinone methide (QM), retro-Diels–Alder (RDA) and heterocyclic ring fission (HRF) cleavage (Gu et al., 2003). A lower retention of the peanut skin dimers compared to grape seeds dimers on the silica stationary phase (Fig. 2) could hint at the presence of A-type dimers, which are less polar than the B-type dimers due to the additional bond. This was confirmed by the MS/MS spectra, which showed parent ions of *m/z* 575 for the peanut skin dimers with *m/z*

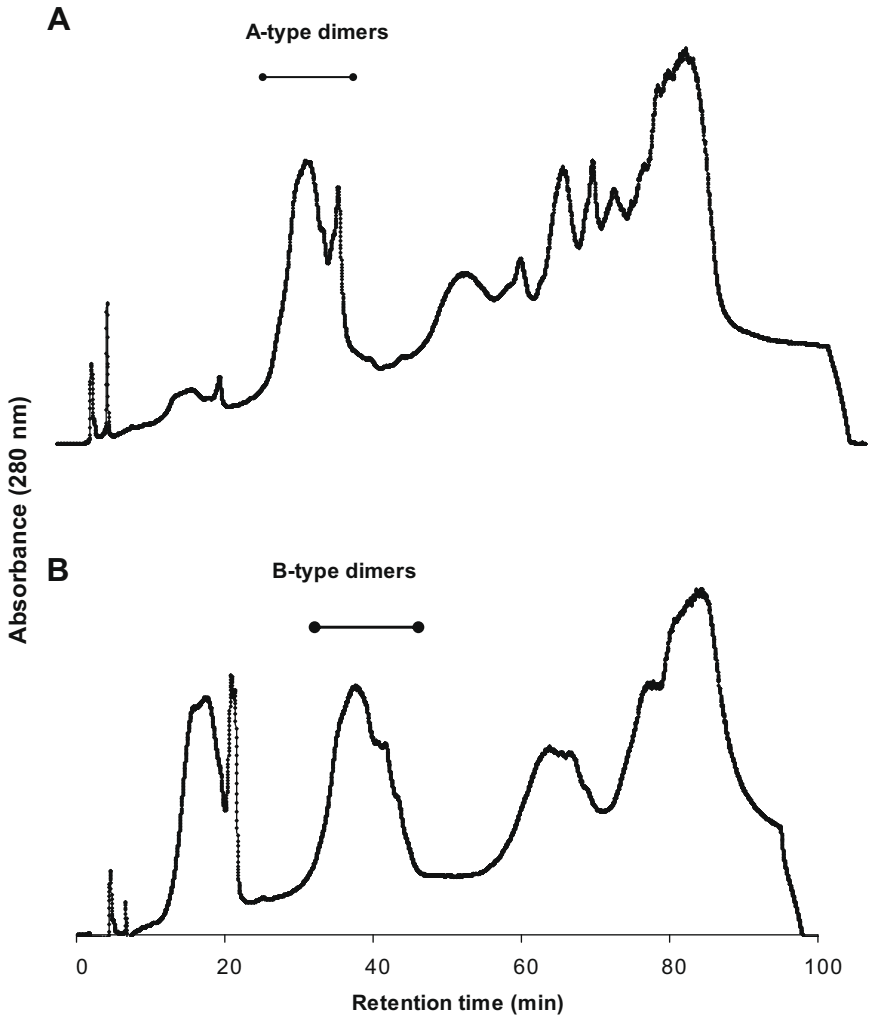

Fig. 2. Isolation of A-type dimers from peanut skins (panel A) and B-type dimers from grape seeds (Panel B) by preparative NP-HPLC. The fractions containing the A- or B-type dimers were collected, evaporated under vacuum and lyophilised.

289 + 285 (QM), *m/z* 423 + 407 (RDA) and *m/z* 449 (HRF) as fragment ions. The grape seed dimers had parent ions of *m/z* 577, and *m/z* 289 + 287 (QM), *m/z* 425 + 407 (RDA) and *m/z* 451 (HRF) as fragment ions. The observation that the fragmentation of A-type dimers, just like the B-type, yields a fragment ion of 407 rather than 405 has been reported earlier (Zhu, Hammerstone, Lazarus, Schmitz, & Keen, 2003).

3.1.2. Use of RP-HPLC for purification of individual dimers

The fractions containing the dimers were further separated on an XterraRP dC18 column. The total recovery of all material after RP-HPLC was 65.1% (w/w) ($n = 1$) for the peanut skin dimers and 68.7% (w/w) ± 5.3 ($n = 3$) for the grape seed dimers. The peanut skin dimers contained 6 peaks in total indicated by I_P till VI_P (Fig. 3, panel A). Separation of the grape seed dimers resulted in 8 peaks, I_G till $VIII_G$ (Fig. 3, panel B). Peak IV_G consisted of 2 components based on reinjection on an Atlantis dC18 column. Preparative separation on this column resulted in two pure fractions: IV_{G1} and IV_{G2} (Fig. 4). The total recovery was 66.4% (w/w) ($n = 1$).

3.2. Structure elucidation of isolated dimers

3.2.1. A-type dimers

Four peaks (II_P to V_P) were characterised as A-type dimers based on their parent ions (*m/z* 575 $[M-H]^-$) and MS/MS fragments. Because no commercial standards were available for A-type dimers, NMR spectroscopy was performed for structural identification (Tables 1 and 2 in Supplementary material).

3.2.2. Determination of interflavanic linkage (IFL)

The NMR spectra of the fractions II_P, III_P, IV_P and V_P were very similar and typical for A-type dimers as described previously (Lou et al., 1999). In short, an isolated AB system in the heterocyclic proton region (δ 4.0–4.5 ppm, J = 2.8–3.5 Hz) was attributed to protons at carbon 3 and 4 of the C-ring (C3-C and C4-C). Two meta-coupled doublets and a singlet in the aromatic region (δ ± 6 ppm) were assigned to the protons of the A-ring and the residual proton of the D-ring, respectively. Two AMX systems in the aromatic downfield region (δ 6.5–7.5) were detected as B- and E-ring protons. The other signals were unambiguously attributed to the F-ring protons. Therefore, the A-IFL involved both the C4 and C2 of the upper unit. The junctions at the lower unit were determined through the analysis of both ^{1}H–13C long-range HMBC and ^{1}H through space ROESY correlations.

The bond positions of fractions II_P, III_P and IV_P were determined in a similar way as illustrated in Fig. 5, panel A. First, C8a-D was attributed through its correlation with the proton at C2-F, whereas C5-D was identified through its correlations with both protons at C4-F. The residual proton of the D-ring showed correlations with two deshielded carbons (δ > 150 ppm). One could easily be

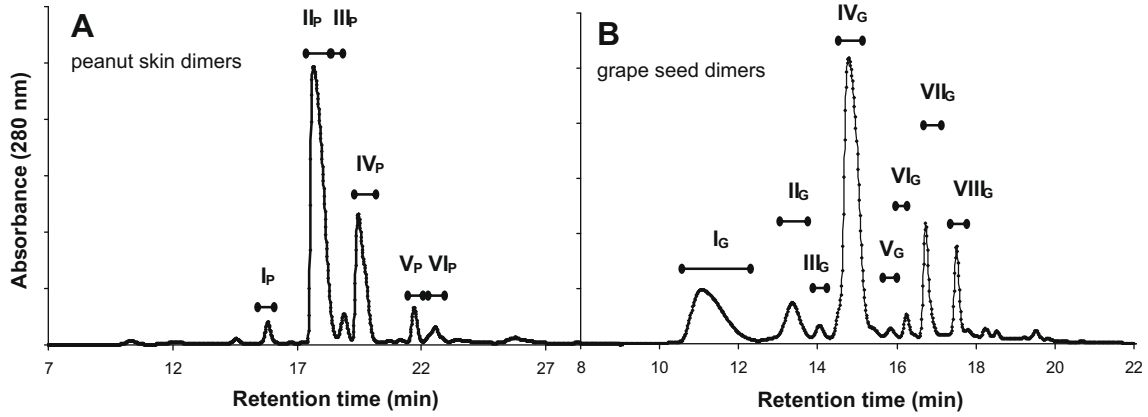

Fig. 3. Isolation of dimers from peanut skins (A) and grape seeds (B) on a preparative XterraRP C18 column. Fractions were collected as indicated by I through VIII. The origin is indicated by P (peanut skins) and G (grape seeds).

determined to be the C5-D, while the other one was deduced to be C7-D, since its chemical shift was different from that of C8a-D. Therefore, the residual proton was determined to be at C6-D. Consequently, the IFL implied attachment to C8 of the D-ring. Also the long range correlation between the proton at C4-C and C8a-D and ROESY spectra, which showed correlations between the proton at C4-C and E-ring protons, were in agreement with a C4–C8 linkage. The ether bond was deduced to be C2–*O*–C7, as it is the only possibility in case of a C4–C8 linkage. Therefore, the components of fractions II_P, III_P and IV_P were identified to be (C2–*O*–C7, C4–C8) double linked dimers.

In the case of fraction V_P, no conclusive evidences of the IFL positions could be found based on long-range HMBC correlations. The residual D-ring proton could not be determined, because C8a-D and C5-D overlapped. However, ROESY correlations between the proton at C4-C and protons of E-ring were clearly lacking, which indicated a C4–C6 linkage (Lou et al., 1999) (Fig. 5, Panel B). In this case, the ether linkage can be either C2–*O*–C7 or C2–*O*–C5. Since a weak, but clear, correlation occurred between the proton at C8-D and the proton at C2-F, as well as one between the proton at C8-D and protons at C2 and C6 of the B-ring, the linkage can be deduced to be C2–*O*–C7. The C2–*O*–C7 linkage was also in accordance with the ^{13}C chemical shift of C7-D, which was upfield (δ 150) compared to free hydroxylated C7-A (δ 156.3). Based on all the data the component of fraction V_P was identified as a (C2–*O*–C7, C4–C6) double linked dimer.

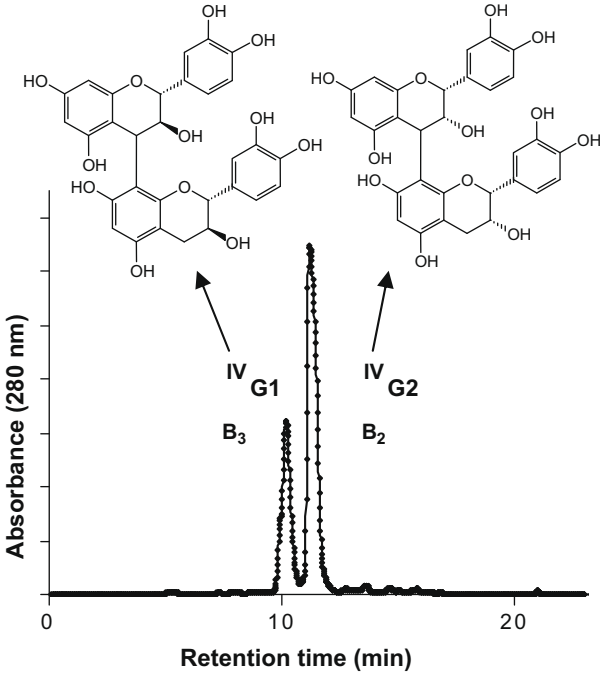

Fig. 4. Isolation of dimers B2 (IV_{G2}) and B3 (IV_{G1}) on a preparative Atlantis dC18 column from fraction IV_G, previously isolated on XterraRP (Fig. 3, Panel B).

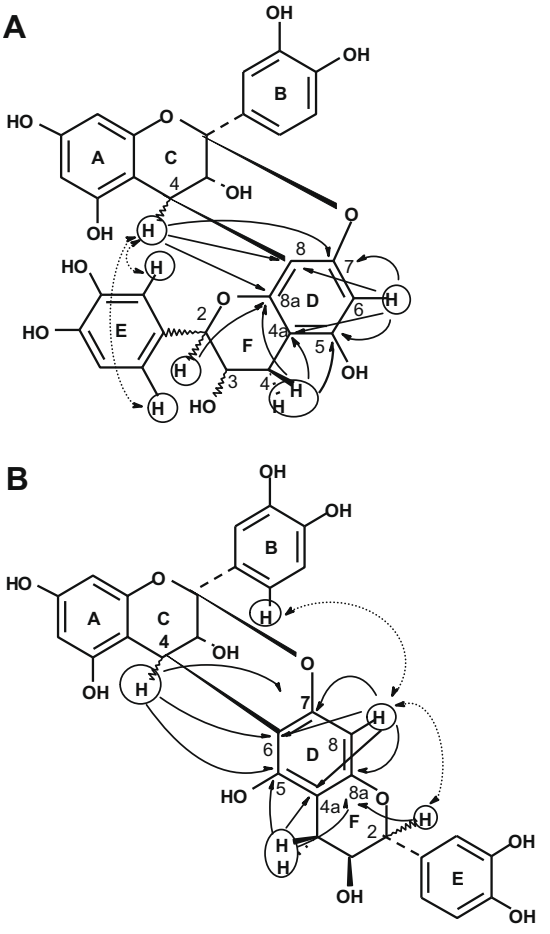

Fig. 5. Main HMBC (→) and ROESY (→) correlations allowing linkage positions to be established, in either (C2–*O*–C7, C4–C8) (A) or (C2–*O*–C7, C4–C6) (B) dimers.

NMR spectra of fraction VI_P were not conclusive because of its low purity. The major compound, which, based on NMR signals, represented about 35% of fraction VI_P, exhibited some typical NMR signals (an AB C-ring system) of an A-type dimer. However, structural identification was difficult due to numerous overlaps and poor signal intensities. Phloroglucinolysis of fraction VI_P did not result in depolymerisation, which supported the hypothesis of the presence of an A-type dimer in this fraction.

3.2.3. Monomeric composition

In the case of fractions II_P, III_P, and V_P, the large values observed for the J_{23} F-ring coupling constants ($J \sim 7$ Hz) were characteristic for catechin. In contrast, for fraction IV_P this value was relatively low (~1 Hz), which is characteristic for an epicatechin unit. The upper units of fractions II_P–V_P were supposed to be epicatechin, as Lou and coworkers (Lou et al. 1999) found that A-type dimers from peanut skins always contained epicatechin as upper units.

Therefore, the two major peaks, II_P and IV_P, were identified as epicatechin-(2-*O*-7, 4-8)-catechin (**1**), also referred to as A1, and epicatechin-(2-*O*-7, 4-8)-epicatechin (**2**), referred to as A2. Fraction III_P showed similar NMR spectra compared to fraction II_P (A1). Dimer A1 has been identified in peanut skins before and seems to be abundantly present (Karchesy & Hemingway, 1986; Lou et al., 1999). Therefore, the major fraction II_P was annotated to be A1, while the less abundant fraction III_P, containing a similar NMR spectra, was tentatively identified as the enantiomer of A1 (**3**). The presence of enantiomers in peanut skins was also found by Lou and coworkers (Lou et al., 1999), who identified the enantiomer of dimer A2. However, the enantiomer of A1 has not been identified in peanut skins before. Fraction V_P was characterised as epicatechin-(2-*O*-7, 4-6)-catechin (**5**).

3.2.4. B-type dimers

The fractions obtained from grape seeds all represent B-type dimers (*m/z* 577 $[M-H]^-$) based on RP-HPLC-UV-MS and their fragment products with MS/MS. Comparison with standards resulted in the identification of I_G as B1 (**9**), II_G as B4 (**12**) and IV_G, which consisted of both B2 (**10**) and B3 (**11**). The remaining peaks could not be identified further. Peak IV_G was further separated on an Atlantis dC18 column, resulting in pure fractions of B2 (**10**) (IV_{G2}) and B3 (**11**) (IV_{G1}) (Fig. 4).

One peak isolated from peanut skins (I_P, Fig. 3, panel A) was identified as a B-type dimer, which was B7 (epicatechin-(4-6)-catechin) (**13**) based on its retention time before phloroglucinolysis and its products after phloroglucinolysis. This was confirmed with NMR (Tables 1 and 2 in Supplementary material). Both 1D and 2D homonuclear ^{1}H and 2D heteronuclear ^{1}H–13C experiments were performed. The main difference compared to the spectra of an A-type dimer is the presence of a proton at C2-C. The structure of this dimer was determined as follows: C8a-D (δ 154.7) was first identified through its long range correlation with the proton at C2-F. The bond location was determined from the long range correlations of the proton at C4-C. This proton had no correlation with C8a-D at δ 154.7 but exhibited correlations with several deshielded carbons at δ 155.6, 159.2, 159.2 and 157.8, which were attributed to C5-D, C7-D, C8a-A and C5-A. A long range correlation of the proton at C4-C with C5-D and the lack of a correlation with C8a-D indicated that C4-C is linked to C6-D (De Bruyne et al., 1996). The J_{23} F-ring coupling constant values allowed to discriminate between epicatechin ($J \sim 1$ Hz) or catechin ($J \sim 7$ Hz) (2,3 *cis* or *trans*) configuration of the lower unit (Davis, Cai, Davies, & Lewis, 1996) and was determined to be catechin since the J_{23} coupling constant value was 7.7 Hz.

4. Conclusion

The main A-type dimers, A1 (**1**) and A2 (**2**), were efficiently isolated. In comparison to a previously published method (Lou et al., 1999), the required chromatographic methods were reduced from five to two, while simultaneously the yields of A1 and A2 increased 20–400 times. To compare both methods, the yields of A1 and A2 were expressed as weight percentage of the total amount of peanut skins that was used. Lou and coworkers (Lou et al., 1999) used skins of 279 kg peanuts. The amount of skins they used was calculated to be ~11 kg, assuming that the skins represents 4% (w/w) of the total peanut (Pominski, Daquin, Molaison, McCourtney, & Vix, 1952). Differences in extraction procedure and the origin of peanut skins might also have contributed to the pronounced yield differences found. Next to A1 and A2, four other peanut skin dimers were isolated including the tentatively identified enantiomer of A1 (**3**), not previously detected in peanut skins, epicatechin-(2-*O*-7, 4-6)-catechin (**5**), B7 (**13**) and one unidentified dimer.

Although grape seeds have been used before as a source to isolate PC dimers, data on the efficiency of those isolations are not well documented. Dimers isolated with NP-HPLC resulted in about 21% (w/w) of the PC extract, which is in accordance with compositional LC–MS analysis of PC dimers in grape seed extracts performed by others (Nunez et al., 2006; Santos-Buelga et al., 1995). The yield for B1–4 from the grape seed extract using NP/RP-HPLC was about 10 times higher compared to a recently published HSCCC method (Kohler et al., 2008). Recoveries for the additional

RP-HPLC that was performed after HSCCC were not given, but would likely lower their total yield. Furthermore, pre-purification steps like precipitation or SPE to remove polymers and improve resolution, prior to HSCCC, were not needed.

The combination of NP/RP-HPLC is suitable to efficiently isolate a large variety of both A- and B-type dimers with a limited number of chromatographic steps. Table 1 summarises the purity, yield and structure of each peak that was isolated. Sufficient amounts of material were obtained to study the bioavailability of both A- and B-type dimers, which is subject of further research in our laboratory.

The overall sampling scheme for each pork cut was

$$3\,\text{States} \times 3\,\text{SEC} \times 2\,\text{replicate suburbs} \times 2\,\text{retailer types} \times 2\,\text{conditions (raw, cooked)} = 72\,\text{samples (purchases)}$$

where State = Australian State; retailer type = butcher/supermarket; SEC = socioeconomic status of suburb (high, medium, low).

The 13 cuts which were advised to be the more popular consumer cuts and therefore selected were: loin chop, loin steak, fillet, rump steak, round steak, topside steak, silverside steak, diced pork, pork strips, pork mince, loin roast, round (mini) roast, scotch (neck) roast. One cut, the loin chop, was studied in more detail across all three States, in order to provide additional data on variability.

Sample collection and handling generally followed Food and Agriculture Organization/International Network of Food Data Systems (FAO/INFOODS) international guidelines (Greenfield & Southgate, 2003). Pork loin chop samples were collected in December 2005, and the other cuts progressively from February to May 2006. For the 13 cuts the number of actual purchases was 911 instead of the planned 936 because of a small number of cuts that were unavailable on the day of collection. Sample collection was organised by APL representatives in each of the three States and shoppers were commissioned to purchase duplicate samples (e.g. two pork roasts or ~2 kg of smaller cuts) anonymously from each nominated retail outlet. Shoppers were instructed not to specify whether trimmed or untrimmed cuts were desired. The meat samples were packed and freighted chilled to the Food Science Australia (FSA) laboratory in Queensland by air from Melbourne, Victoria and Perth, Western Australia and by road from Brisbane. Meat temperatures were checked on arrival at FSA and all samples were stored at 1–2 °C until required for processing, either immediately or later on the same day. Where incorrect cuts had been supplied attempts were made to obtain replacements, or were later designated as missing values along with those that were not available.

The duplicate samples purchased for each cut were randomly allocated to either raw or cooked treatment. Samples were held at 1–2 °C before and during handling, and kept covered in closed polyethylene bags to minimise evaporation of moisture.

2.2. Cooking methods

All cuts for analysis were analysed in the raw state and in the cooked state. Cooking methods were as specified by APL home economists to reflect household practice then adapted for the available equipment. Details of cooking methods are given in Müller et al. (2009).

2.3. Preparation of analytical homogenates

Preparation of the analytical homogenates was carried out following FAO/INFOODS international guidelines for food composition studies (Greenfield & Southgate, 2003, Fig. 5.1, Table 5.4). For each cut, except loin chop, duplicates of four national analytical homogenates (namely, raw lean, cooked lean, raw fat and cooked fat) were formed as homogenised composites from the State duplicate purchases. For loin chop, 24 analytical homogenates were formed so that for each of the three States, duplicate homogenates were formed for each of the following: raw lean, cooked lean, raw fat, cooked fat. The State duplicates were obtained by combining the two retailer types from one randomly selected set of a high, a medium and a low SEC area as one composite, and the remaining high, medium and low SEC areas as a second composite. The dissected meat was weighed and aliquot samples were allocated for aggregation according to the experimental design for the particular cut. The aggregate meat sample was coarsely cut, hand mixed and minced through a meat mincer (IRCEM Srl Tritacarne Type I-E 22, 240 V, Italy) using a single blade and a 4 mm mincing plate. The samples were then recombined and minced again to attain adequate homogeneity. Contact with metal was minimised wherever possible. The mincer was dismantled and washed after each sample was minced to eliminate cross contamination between samples. Temperatures were maintained at 1–2 °C throughout preparation of analytical homogenates.

Initially, a number of individual samples were assessed by measuring homogeneity by the reproducibility of their moisture contents to establish the degree of mixing required. Samples within a 2% moisture range were assessed as sufficiently homogenised, e.g., 75% ± 2%. The samples were then packed in plastic jars and stored chilled or frozen until required for further evaluation. The four (4) composite samples that were obtained for each of the cuts were raw lean, cooked lean, raw fat and cooked fat. For some cuts, only raw lean and cooked lean data were required due to the absence of separable fat on cuts such as fillet.

2.4. Transport of analytical homogenates

Depending on the nutritional analyses that were required, samples were coded and sent chilled (for folate analysis) to the University of NSW, and either chilled (for water, thiamin and riboflavin analyses) or frozen (for the rest of the analyses) to National Measurement Institute (NMI) in Melbourne. All samples were freighted in insulated containers by overnight courier. All chilled samples were dispatched on the same day as dissection and aggregation, and all frozen samples on the day following. A small amount (100 g) of each sample was vacuum-packed and retained by FSA in a −80 °C freezer as back-up samples for re-analysis if required.

2.5. Variability study of pork loin chop

All 24 composites of loin chop (2 duplicate composites for each of 4 portions, raw lean, raw fat, cooked lean, cooked fat from each of three States) were analysed. The cut collection and gross composition work was carried out in December 2005. The nutrient analytical work was completed in February 2007.

2.6. Representative study, all cuts

The remaining 12 cuts were analysed as 34 national composites (for 5 cuts: national duplicates × 4 portions, lean/fat x raw/cooked, total = 20; for 7 cuts: national duplicates × 2 portions, lean only (e.g. fillet) or lean + fat mixed (e.g. mince), raw/cooked, total = 14). The cut collection and gross composition work was done from February to May 2006. The nutrient analytical work was completed in April 2007.

2.7. Methods of nutrient analysis

Methods of analysis were agreed in terms of availability and appropriateness for pork, and in terms of the expected ranges of nutrient levels in this commodity.

Methods for proximate components were: moisture, air-drying at 102 °C, AOAC (1995) method nos., 934.06, 950.46B; protein, nitrogen by Kjeldahl method, AOAC (1995) method nos. 981.1, 928.08, protein conversion factor 6.25; fat, Soxhlet extraction, gravimetric determination, AOAC (1995) method nos. 920.39, 960.39; ash, incineration and gravimetry, AOAC (1995) method nos. 923.03, 920.153. Energy calculation was: (g protein × 17 kJ) + (g fat × 37 kJ) (Greenfield & Southgate, 2003).

Methods for vitamins were: retinol, HPLC (Brubacher, Müller-Mulot, & Southgate, 1985); α- and β-carotene, HPLC (Brubacher et al., 1985); α-tocopherol, HPLC (De Leenheer, Lambert, & de

Ruyter, 1985); thiamin and riboflavin, HPLC (Wehling & Wetzel, 1984); niacin, capillary zone electrophoresis and HPLC (Ward & Trenerry, 1997); vitamin B_6, HPLC (Bergaentzlé, Arella, Bourguignon, & Hasselmann, 1995); pantothenic acid, gas–liquid chromatography (Davidek, Velisek, Cerna, & Davidek, 1985); vitamin B_{12}, microbiological assay using *Euglena gracilis* (Anderson & Sourial, 1983); total folate, microbiological assay with *Lactobacillus casei (subsp. Rhamnosus ATCC 7469).* The method followed was the tri-enzyme treatment according to Tamura, Mizuno, Johnson, and Jacob (1997) with a modification using a cryoprotected frozen culture and preparation of the extract as suggested by Shrestha, Arcot, and Paterson (2000). Extraction was carried out on the chilled samples with an additional lipase treatment (Vishnumohan & Arcot, 2006). Separately, comparisons of the tri-enzyme treatment and the tri-enzyme plus lipase treatment were carried out on fresh convenience samples of pork purchased from local retail outlets.

Methods for minerals were: ICP/MS (Inductively Coupled Plasma Mass Spectrometry) (AOAC (1995), method nos. 984.27, 993.14) for sodium, potassium, iron, calcium, magnesium, zinc, manganese, selenium, iodine; ion selective electrode (Dabeka & McKenzie, 1981; Dabeka, McKenzie, & Conacher, 1979) for fluoride.

2.8. Apparent retention of nutrients

Apparent nutrient retention (%) was calculated as: nutrient content per g of cooked food (dry basis)/nutrient content per g of raw food (dry basis) × 100 (Murphy, Criner, & Gray, 1975).

2.9. Quality control

All analyses were performed in duplicate apart from folate (in triplicate) and vitamin E (single analyses).

Quality control procedures for all nutrient analyses included the use of National Institute of Standards and Technology (NIST) Standard Reference Material 1546 Meat Homogenate, in-house reference materials, precision of replicates, recoveries of standards, use of blanks and other routine quality control checks. For folate analyses NIST Certified Reference Material Pig Liver CRM 487 was used and additional quality control included triplicate analyses and performing recovery studies on samples. Quality control procedures are shown in Table 1.

2.10. Data scrutiny

All authors scrutinised the analytical data on receipt. Further scrutiny, including integrity checks, of the complete data sets was performed by three of the authors (JB, HG and JC). All scrutineers compiled their own independent lists of queries. After agreement between the scrutineers reached by teleconference, a consolidated list of queries and, in some cases, requests for reanalyses was sent to NMI, Melbourne. Further scrutiny was done, including of repeated analytical results, until all scrutineers were satisfied with the reliability of the analytical data.

2.11. Statistical analyses

For each loin chop variable a three-way analysis of variance was performed; 3 States × 2 types (lean/fat) × 2 cooking categories (cooked/raw). A split plot-type analysis was performed as each of the six States × replicates was regarded as a main plot and was split for the four types × cooking categories. Variation between duplicate (or triplicate) readings was obtained as a final split within the analysis, which enabled the reliability of the analytical methods to be assessed. For moisture, fat, protein, ash, total N, thiamin, niacin, vitamin B_6, vitamin B_{12}, Se, Zn, Na, K and Mg, measurements on lean and fat samples were analysed separately by two-way analyses of variance, as the values for lean and fat were distinctly different with the type with lower values having lower variability, making it inappropriate to use the single analysis. In all cases the key assumptions of analysis of variance, namely homogeneity of variation across the range of values and normally distributed error terms, were checked and found to hold, so no variables required transformation before analysis. The package GenStat for Windows (2007) was used for these analyses.

As composites for all the other cuts were formed over all replicate samples, no estimates of variability could be obtained and results are expressed as means over duplicate (or triplicate) determinations.

3. Results and discussion

3.1. Performance of analytical methods

Results of quality assurance procedures as shown in Table 1, were rated as satisfactory overall.

The analytical variability for individual methods is demonstrated in Table 2 which shows that confidence can be placed in the reliability of most of the analytical methods; high variance ratios and low *P*-values indicate that intra-sample variance is much lower than inter-sample variance. *Fat:* It had been decided to use the Soxhlet method as this is a standard method for fat in meat. It is comparable with the Mojonnier acid hydrolysis method for meat (Mills, van den Voort, & Usborne, 1983) therefore comparing results with those obtained in the 1980s (Hutchison et al., 1987, acid hydrolysis) and the 1990s (Barnes et al., 1996, Soxhlet) is valid. *Retinol*: Table 2 shows poor results for analytical variability for retinol analysis (CVs 27–29%). *Vitamin E:* Initial analyses on loin chop produced data that were below the level of reporting for this nutrient, and it was therefore decided not to do further analyses on the other cuts. Subsequently the analyses were repeated on stored samples (where available) by NMI using newly acquired improved instrumentation. Single (not duplicate analyses) were performed and indicative results were provided. While method performance cannot be assessed from these vitamin E analytical data, the results have been included in Tables 3 and 5. *Folate:* Total folate is notoriously difficult to measure in foods (Hyun & Tamura, 2005). The analytical method used in this study for total folate performed well in terms of precision with a low coefficient of variation at 0.3%. Recoveries from the pig liver reference material were moderately high at about 68% and also of folic acid (measured as total folate) from pork lean tissue at 66%. Results reported are those from the internationally accepted tri-enzyme technique (Tamura et al., 1997) with an additional lipase treatment (Vishnumohan & Arcot, 2006). *Vitamin B_{12}:* As this is a method developed for analysis of serum not foods (Anderson & Sourial, 1983), poor precision for these food samples was not unexpected. *Pantothenic acid*: The variance ratio was disappointingly and unaccountably low.

3.2. Variability study of pork loin chop

The analysis of two composites per State for loin chop enabled testing for differences between States, between cooked and raw, between lean and fat, and the interactions between these factors. For all nutrients, the majority of significant differences were between cooked and raw, and between lean and fat. There were some significant differences between the States and a few significant interactions, however these were not readily interpretable and the differences were generally much less than those for cooked vs. raw and lean vs. fat. Accordingly, means and standard deviations were calculated for nutrients in raw lean, raw fat, cooked lean and cooked fat, for this cut, across the six composite samples (3 Australian States × 2 replicates) (Table 3). It must be borne in mind

Table 1
Quality assurance results for nutrient analyses of pork.

Nutrient	Units	Limit of reporting	Difference between test sample duplicates (%)	Recovery of pure standard (%)	Reference/control materials	Certificate value/control value for reference/control materials	Analysed values for reference/control materials
Moisture	g/100 g	0.2 g/100 g	<1	NA	Flour check sample, batch 0706 RACI	12.0 g	11.1–12.8

[a] Variance ratio = variation between samples after removing effects of state, cooking and fat vs. lean, divided by variability between analytical duplicates. Higher values indicate more reliable analytical techniques.
[b] Triplicate analyses were performed for folate.

that these data reflect in part variability in method performance (particularly for fat tissue, which is difficult to handle in the laboratory) as well as any variability across States and replicate composites. Inspection of the standard deviations shows that those for fat were much greater than for lean, reflecting the difficulty of obtaining good homogenates for fat tissue (this is supported by calculations for the proximate analyses alone which showed that the CVs for lean samples ranged from 0.7 to 16.1, while those for fat samples ranged from 4.2 to 28.1). The standard deviations in Table 3 must be interpreted with caution as they reflect analysis of six composite samples, not analysis of individual pork chop samples, so do not represent true variation in nutrient composition of loin chop between States. This compromise was an understood condition of the sampling plan adopted (Müller et al., 2009).

3.2.1. Differences in nutrient composition within States for pork loin chop

Due to the fact that samples within each State were bulked to two composite samples to reduce the number of analyses for cost reasons, it is not possible to carry out statistical analyses which would indicate whether there were significant variation within States. Inspection of the data, however, indicated sufficient variability in some cases to demonstrate that it was wise to collect and analyse State duplicates, and that this feature should be part of future projects of this nature.

Table 3
Nutrient composition of loin chop (means ± SD for 6 national composites)/100 g.

Analyte	Raw lean Mean ± SD	Cooked lean Mean ± SD	Raw fat Mean ± SD	Cooked fat Mean ± SD
Moisture (g)	74.1 ± 0.7	63.3 ± 0.5	23.8 ± 4.9	21.3 ± 2.4

[a] Contains values below level of reporting.
[b] No data, limited sample.
[c] No SD calculated because $n = 2$.
[d] Calculated from means for tetra-enzyme treatment using individual replicates.
[e] Approximate only; includes samples (5 of 24) with levels below detection level (<0.02 mg/100 g) where 0.01 was used.

3.3. Summary of nutrient composition of pork loin chop

Inspection of Table 3 allows some comment to be made regarding the occurrence of nutrients in the lean and the fat portions of pork loin chop and their behaviour on cooking.

3.3.1. Proximate composition

Overall recoveries (sum of proximate components) ranged from 99.8 to 101.4 g/100 g, which can be regarded as satisfactory. Moisture was lost on cooking and other proximate components increased as a result of this loss, causing their concentration. Calculation of apparent retention of fat during cooking showed that there was a slight tendency for fat to move into the lean tissue during cooking. True retention of fat (Murphy et al., 1975) cannot be calculated as each individual cut was not weighed before and after cooking.

3.3.2. Fat-soluble vitamins

Carotenes: Neither α- nor β-carotene were detectable in fat or lean of loin chop. Therefore, analyses for these nutrients were not carried out in the other pork cuts studied. *Retinol*: This vitamin

Table 4
Proximate composition and energy content of 12 other pork cuts, raw and cooked (means for 2 national composites)/100 g.

Cut	Cooking method	Moisture (g)	Fat (g)	Protein (g)	Ash (g)	Total N (g)	Energy (kJ)
Loin steak or medallion	Dry-fried						
Lean, raw		75.5	1.6	24.1	1.2	3.86	469

Fat, cooked		26.1	67.0	8.8	0.4	1.40	2629
Round (mini) roast	Roast						
Lean, raw		75.5	1.1	23.7	1.3	3.78	444
Lean, cooked		64.5	2.5	34.7	1.4	5.55	682
Fat, raw		45.3	44.6	11.3	0.7	1.81	1842
Fat, cooked		41.4	45.5	16.3	0.9	2.60	1961
Scotch roast	Roast						
Lean, raw		72.6	7.6	20.6	1.0	3.29	631
Lean, cooked		58.9	12.0	30.6	1.2	4.88	964
Fat, raw		38.1	52.5	10.7	0.5	1.70	2124
Fat, cooked		39.8	50.5	12.2	0.6	1.94	2076

was only measured above the limit of detection in the fat portions of loin chop. Due to the indications of presence in the lean portions of loin chop it was decided that both lean and fat portions of the other cuts should be analysed for retinol. *Vitamin E*: Levels were higher in fat tissue than lean tissue, as expected.

3.3.3. Water-soluble vitamins

All water-soluble vitamins were at higher levels in lean tissue than fat tissue; an exception was vitamin B_{12} which was, unexpectedly, higher in fat tissue than in lean tissue. Water-soluble vitamins were well-retained in the loin chop by the cooking method employed. The exceptions were vitamin B_6 and folate, and to a lesser extent, riboflavin. *Folate*: the total folate data derived from the tri-enzyme method plus lipase treatment are very unusual. Animal tissues (apart from liver) are not usually considered to be significant sources of folate. There was a very high level of variation between samples and the four means presented in Table 3 were not significantly different; further the results are high in terms of existing recorded knowledge about total folate levels in pork. Noting the high reliability of the technique for measuring folate (Tables 1 and 2) it is possible that folate was distributed non-uniformly in the composite samples. These values in Table 3 for loin chop, adjusted for comparisons made with the tri-enzyme method alone on different samples as described in Section 2, would become in μg/100 g: raw lean, 35.5 ± 11.8; cooked lean, 44.3 ± 1.5; raw fat, 20.0 ± 8.0; cooked fat, 7.9 ± 3.4.

3.3.4. Minerals

Minerals tended to be at higher levels in lean tissue than fat tissue, except in the case of calcium. Minerals were reasonably well retained by cooking except for potassium. *Iron*: Iron levels were low when compared with earlier studies, and with pork loin values from other countries. Special attention was paid in data scrutiny and re-analyses for iron, together with inspection of the analytical quality control reports for this nutrient. Even though the method for iron used in this study, ICP/MS, was different from that used

in the earlier studies in the 1980s and 1990s (atomic absorption spectrophotometry (AAS)) no reason was found to reject the iron data reported in this study. Feeds are fortified to the level of 100 g iron/tonne (Gannon, pers. commun.) *Iodine:* Iodine levels were low and not detectable in some samples. Geographical location might have had some influence on iodine levels. Feeds are fortified to the level of 1 g per tonne (Gannon, pers. commun.) *Fluoride:* In some samples of loin chop, fluoride was not detectable. Levels would, to some extent, indicate water fluoridation practices in the different parts of the country. It should be noted, however, that due to industry distribution practices, pork may be retailed in a different State from where it was produced.

3.4. Summary of representative nutrient study of 12 other pork cuts

3.4.1. Proximate composition

Results for proximate and energy composition are shown in Table 4. Total recoveries as% ranged from 100.2 to 104.0, reflecting a tendency towards over-extraction. Data examination revealed no consistent trend to over-extract particular proximate components, however, the higher recoveries were for fat tissue homogenates, which tend to be difficult to handle in the laboratory. Fat content of the lean section of all cuts was low (range 1.0–2.2 g/100 g) except for Scotch (neck) roast at 7.6 g/100 g, probably reflecting the difficulty in totally separating fat from lean tissue in this shoulder cut

which is comprised of several muscles with some intermuscular fat (Australian Pork Limited (APL), 2002). Mince, strips and diced, all being mixed lean and fat tissue, had slightly overall higher fat levels, ranging from 2.3 to 9.4 g/100 g. The method used for fat analysis in this study was Soxhlet extraction, as used in the study in the 1990s, but different from the acid hydrolysis method used in the 1980s. Since both methods are standard methods for meat, any variation in fat content is unlikely to be due to method changes. Since the separable fat section of pork has been reduced and the lean tissue increased, the energy content of pork cuts has been reduced because fat provides more kJ per gram than protein. Fat content of cooked lean ranged from 1.7 g/100 g for dry-fried round steak to 12.0 g/100 g for scotch roast. Lean-only cuts (fillet, round steak, topside steak, and silverside steak) appeared to lose little fat during cooking (from apparent nutrient retention data, not shown, calculated according to Murphy et al., 1975) while cuts with separable fat according to similar calculations tended to retain lipid in the lean tissue from the fat tissue during the cooking process.

3.4.2. Vitamin composition

Results for vitamin composition of 12 other pork cuts are given in Table 5. All water-soluble vitamins were at higher levels in the lean tissue than the fat tissue, as expected, but the reverse was true for vitamin B_{12} as was found for loin chop. The USDA food tables SR21 also give values for vitamin B_{12} of a similar distribution and order, i.e. 0.92 μg/100 g for vitamin B_{12} in pork fresh, separable fat, raw (NDB No: 10006); 0.67 μg/100 g for vitamin B_{12} in pork, fresh, composite of trimmed retail cuts (leg, loin, shoulder), separable lean only, raw (NDB No: 10002); and, 0.53 μg vitamin B_{12} in pork, fresh, loin, centre rib (chops or roasts), boneless, separable lean only, raw (NDB No: 10199) (USDA., 2009).

Thiamin levels appear to be high and well-retained on cooking. Riboflavin levels were low or undetectable in some cuts, notably those from some thinly sliced cuts. Retinol and vitamin E levels were higher in the fat tissue than the lean tissue of cuts, as anticipated. Vitamin E levels must be interpreted with caution as values are from single unreplicated analytical samples.

As for loin chop, total folate levels were highly variable. Results reported in Table 5 are those from the lipase treatment in addition to the tri-enzyme extraction with an adjacent column showing, in parentheses, the results adjusted according to comparative studies with the tri-enzyme method alone. According to Gannon (1991), folate levels could be expected to fluctuate widely in pig tissue depending on conditions. Folic acid is added to pig grower/finisher feeds at the level of 0.25 g per tonne of feed (Gannon, pers. commun.) The findings of folate in pork may reflect this fortification. However, this is a question that can only be resolved by controlled feeding studies and the application of a validated and reliable method for measuring folate in pork tissue. The reported results should be accepted as a guide to the presence of moderately high levels of total folate in pork lean tissue, but it would be inadvisable to promote lean pork as a good source of folate without further confirmatory research. Folate was not detectable in current Australian red meats (Williams, Droulez, Levy, & Stobaus, 2007) but those analytical samples were frozen not chilled so a true comparison cannot be made. The most recent release of the US nutrient database, SR21 (USDA, 2009) lists folate levels for fresh pork, derived from 2007 tri-enzyme method analyses, in the range 0–12 μg/100 g, while UK pork has been reported to contain folate at levels of 1–11 ug/100 g with data from 1995 (Food Standards Agency, 2008).

3.4.3. Mineral composition

Results for mineral composition of the 12 cuts are given in Table 6. The low iron levels of pork loin chop (Table 3) were confirmed by the data from the other cuts. Cuts from the loin area were the lowest in iron. The iron level of loin chop has fallen by about 50% since the 1980s and 1990s. It is suspected that this is due to current feeding regimes geared to producing a faster-growing, leaner carcase without any adjustment to the iron levels in vitamin and mineral premixes. Research is needed to identify feeding practices that could rectify these lower levels of iron in present-day Australian pork. They are lower than levels reported for UK pork (Food Standards Agency, 2008) and US pork (USDA, 2009). Other minerals appear to be unchanged since the 1980s. These results provide comprehensive new information for additional minerals, notably selenium, manganese, copper and fluoride, not previously analysed in Australian pork. These 12 cuts were not analysed for iodine, as levels in loin chops were very low so no further analyses were warranted.

3.5. Summary of comparisons with previous studies and current data from other countries

Previous Australian studies: Table 7 summarises the changes over time for the lean only, raw, of all cuts analysed in each study, and for loin chop only. As composition varies from muscle to muscle, the most appropriate comparison is for loin chop. The decline in iron over 20 years can be noted, with a possible trend to an increase in niacin. These trends are unlikely to be due to the method change for minerals from AAS to ICP/MS. For niacin, the method in this study was CZE/HPLC, not the colorimetric method utilising cyanogen bromide used in the 1980s and 1990s, and the observed increase may therefore be due to a more efficient analytical method.

Current data from other countries: Comparisons with data for fresh pork cuts from other countries are not explored in detail since such comparisons are hampered by the different cut names and butchering criteria, and by the lack of source information for the data given in national food composition tables. Experimental pig production studies are available but tend to focus more on lipid composition outcomes than the nutrients of interest in this study.

4. Conclusions

Present-day pork separable lean tissue continues to be low in fat, probably due to the stated objectives of the improved breeding, feeding and rearing practices implemented by the industry in Australia, and remains a good source of protein, and of thiamin and other vitamins. It would appear that previous studies underestimated the levels of water-soluble vitamins in edible pork since only the lean tissues were analysed. Research is needed to improve the estimates of folate levels in pork. Mineral levels have been maintained apart from those of iron, which appear to have declined. It is concluded that pork can no longer be promoted as a source of iron and that research is needed to optimise iron and other nutrient levels which may be affected by feeds in Australian pig production.

Acknowledgements

The authors thank Janet Stark, Sharon Kennedy, Keith Pitts and Steve Humphries of FSA for technical assistance, dissection and processing of meat samples and Mendi Sulentic for data entry and data verification. We are grateful to Zuraidah Nasution for technical assistance with folate analyses, AgriQuality North Melbourne for assistance with the pantothenic acid analyses, and PathWest, Perth, for assistance with the vitamin B_{12} analyses. This study was funded by Australian Pork Limited.

acetate were obtained from Sigma–Aldrich (St. Louis, MO, USA). Toluene-α-thiol was from Fluka (St. Louis, MO, USA). Polyphenol standards were supplied as follows: gallic acid, protocatechuic acid, (+)-catechin, (−)-epicatechin, phloridzin, and hydroxycinnamic acids (*p*-coumaric acid, caffeic acid and chlorogenic acid), by Sigma (St. Louis, MO, USA); procyanidin B2 and quercetin glycosides (hyperin, avicularin and quercitrin) by Extrasynthèse (Genay, France), and reynoutrin was from Apin Chemicals (Abingdon, UK). Phloretin-2′-xyloglucoside, trimer C1 and tetramer were kindly furnished by Dr. Lea (Reading, UK). Water was purified with a Milli-Q system from Millipore (Bedford, MA, USA). Solvents were purchased from Panreac (Barcelona, Spain) and were of analytical or HPLC grade.

2.2. Samples

Five apple pomaces (1 kg each one) were obtained from local cider-making industries and six single-cultivar pomaces (0.5–0.6 kg each one) from experimental pressings, which characteristics are summarised in Table 1. To obtain the experimental pomaces, between 1.5 and 2.0 kg of healthy and ripe apples were milled (SPEC RC2000) and quickly pressed by means of a small hydraulic press (Hafico). The resulting pomaces were immediately packed in plastic bags and frozen at −20 °C. The whole process (milling, pressing and packing) took about 15 min. Mean moisture content of apple pomaces were between 70% and 76%. The samples were dried (oven-dried at 60 °C for 48 h) finely milled (sieve 0.5 mm) with a Cyclotek 1093 (Foss-Tekator) and kept protected from light and humidity until analysis.

2.3. Polyphenol extraction

Between 2 and 2.5 g of apple pomace powder were extracted with acetone:water (70:30) (3 × 15 mL) for 5 min in an ultrasonic bath at 20 °C. The extracts were pooled, centrifuged (10 min at 10 °C and 17,000*g*) and evaporated to dryness at 30 °C with a rotary evaporator. The residue was reconstituted in 10 ml of methanol, filtered through 0.22 μm PVDF membrane (Teknokroma, Barcelona, Spain) and analysed.

2.4. Analytical procedures

HPLC analysis was performed according to a previously validated method (Suárez, Palacios, Fraga, & Rodríguez, 2005), by means of a Waters system, equipped with a 717 automatic injector, a column oven (30 °C), two pumps (model 510), a diode array detector (model 2996), and Empower v.2.0 software data module. The interval for absorbance measurements was between 190 and 450 nm. Separation of polyphenols was carried out on a reversed-phase Nucleosil 120 C_{18} (250 × 4.6 mm I.D, 3 μm) column from Teknokroma (Barcelona, Spain). The elution solvents were aqueous 2% acetic acid (solvent A) and 100% methanol (solvent B). The samples were eluted according to the following gradient: a linear step from 0% to 45% of solvent B in 55 min, an isocratic step for 15 min and a final linear increase of solvent B to 55% in 10 min. Flow rate was 0.8 ml/min and the injection volume was 10 μl.

Quantification was done by the external standard method, using as standards (−)-epicatechin for flavanols, phloridzin for dihydrochalcones (λ = 280.0 nm), quercitrin for flavonol glycosides (λ = 350.0 nm), and *p*-coumaric acid (λ = 313.0 nm) and chlorogenic acid (λ_{max} = 326.3; sh. at 297.7 nm) for hydroxycinnamic acid derivatives.

Total phenol analyses were done by spectrophotometry by the Folin–Ciocalteu method, according to that described by the European Union Official Methods of Analysis (1998), by means of a Perkin–Elmer Lambda 35 equipped with an autosampler and a 1 cm optical quartz flow cell. The reaction is developed in 100 ml volumetric flasks, where the different reactants are added in this order: 1 ml of sample, 50 ml of water, 5 ml of Folin–Ciocalteu reagent, 20 ml of 20% sodium carbonate and water, to reach the final volume. The absorbance was measured at 750 nm, after 30 min at room temperature. The results are expressed as g gallic acid/kg of dry matter (DM).

2.5. Antioxidant capacity

2.5.1. DPPH assay

The antiradical activity was determined by spectrophotometry in 1 cm disposable plastic cells. 40 μL of sample or standard (diluted 1/10 with methanol, reaching a concentration range of 100–300 mg gallic acid/L) were added to 1.460 mL of DPPH$^{\bullet}$ solution (40 mg/L) in methanol, and left to stand in the dark (Brand-Williams, Cuvelier, & Berset, 1995). The absorbance at 515 nm was measured at the beginning ($A_{t=0}$) and after 240 min ($A_{t=240\ min}$), when the reaction reached the steady state. The inhibition percentage was calculated as follows:

$$\%IP = \frac{(A_{control} - A_{t=240\,min})}{A_{control}} \times 100$$

The antioxidant capacity was referred to as ascorbic acid (AA) equivalents (g AA/kg DM).

2.5.2. FRAP assay

The working FRAP reagent was prepared freshly every day by mixing 2.5 mL of TPTZ (10 mM in 40 mM hydrochloric acid), 2.5 mL of ferric chloride (20 mM) and 25 mL of sodium acetate buffer (300 mM, pH 3.6). The FRAP assay was carried out at 37 °C, in 1-cm disposable plastic cells. 900 μL of the FRAP reagent were mixed with 90 μL of water and 30 μL of apple pomace extract (diluted 1:25 with methanol). After 120 min, the absorbance at 595 nm was measured (Pulido, Bravo, & Saura-Calixto, 2000).

The antioxidant capacity of the apple pomaces were expressed as AA equivalents.

2.6. Thiolysis of the crude apple pomace and extracts

In order to confirm the structure of the unknown flavanols, the thiolysis reaction was applied both to the acetone extract and directly to the dried apple pomace, according to the procedure described elsewhere (Guyot, Marnet, Sanoner, & Drilleau, 2001). Briefly, between 50 and 100 mg of apple pomace or 500 μL of the pomace acetone:water extract were treated with acidic methanol (400 μL, HCl 3.3% v/v) and toluene-α-thiol (800 μL 5% in methanol), incubated at 40 °C for 30 min, cooled, filtered through a PVDF

membrane and injected. The mean polymerisation degree (DPn) was calculated by the molar ratio between all the flavan-3-ols (benzylthioether adducts + terminal units) to the sum of terminal units ((+)-catechin and (−)-epicatechin)).

2.7. Statistical analyses

ANOVA, non-linear regression and Principal Component Analysis, taking a 95% confidence interval were performed by means of the SPSS v.11.0 statistical package for Windows. Multivariate partial least squares regression (PLSR) analyses were done with the PARVUS v.1.0 statistical package (Forina, Leardi, Armanino, & Lanteri, 1988).

3. Results and discussion

3.1. Phenolic profiles of cider apple pomaces

In Fig. 1 are shown two characteristic profiles of apple pomaces. As seen in Fig. 1A, major compounds correspond to dihydrochalcones (phloridzin and phloretin-2′-xyloglucoside, and others, probably 3-hydroxyphloretin), acids (protocatechuic, chlorogenic, caffeic and others), flavanols ((−)-epicatechin, procyanidin B2, trimer, tetramer, and others), and flavonols (hyperin, isoquercitrin, rutin, reynoutrin, avicularin, and quercitrin). At the beginning of both chromatograms (Fig. 1A and B), a series of four unknown compounds were observed. These components were not assigned

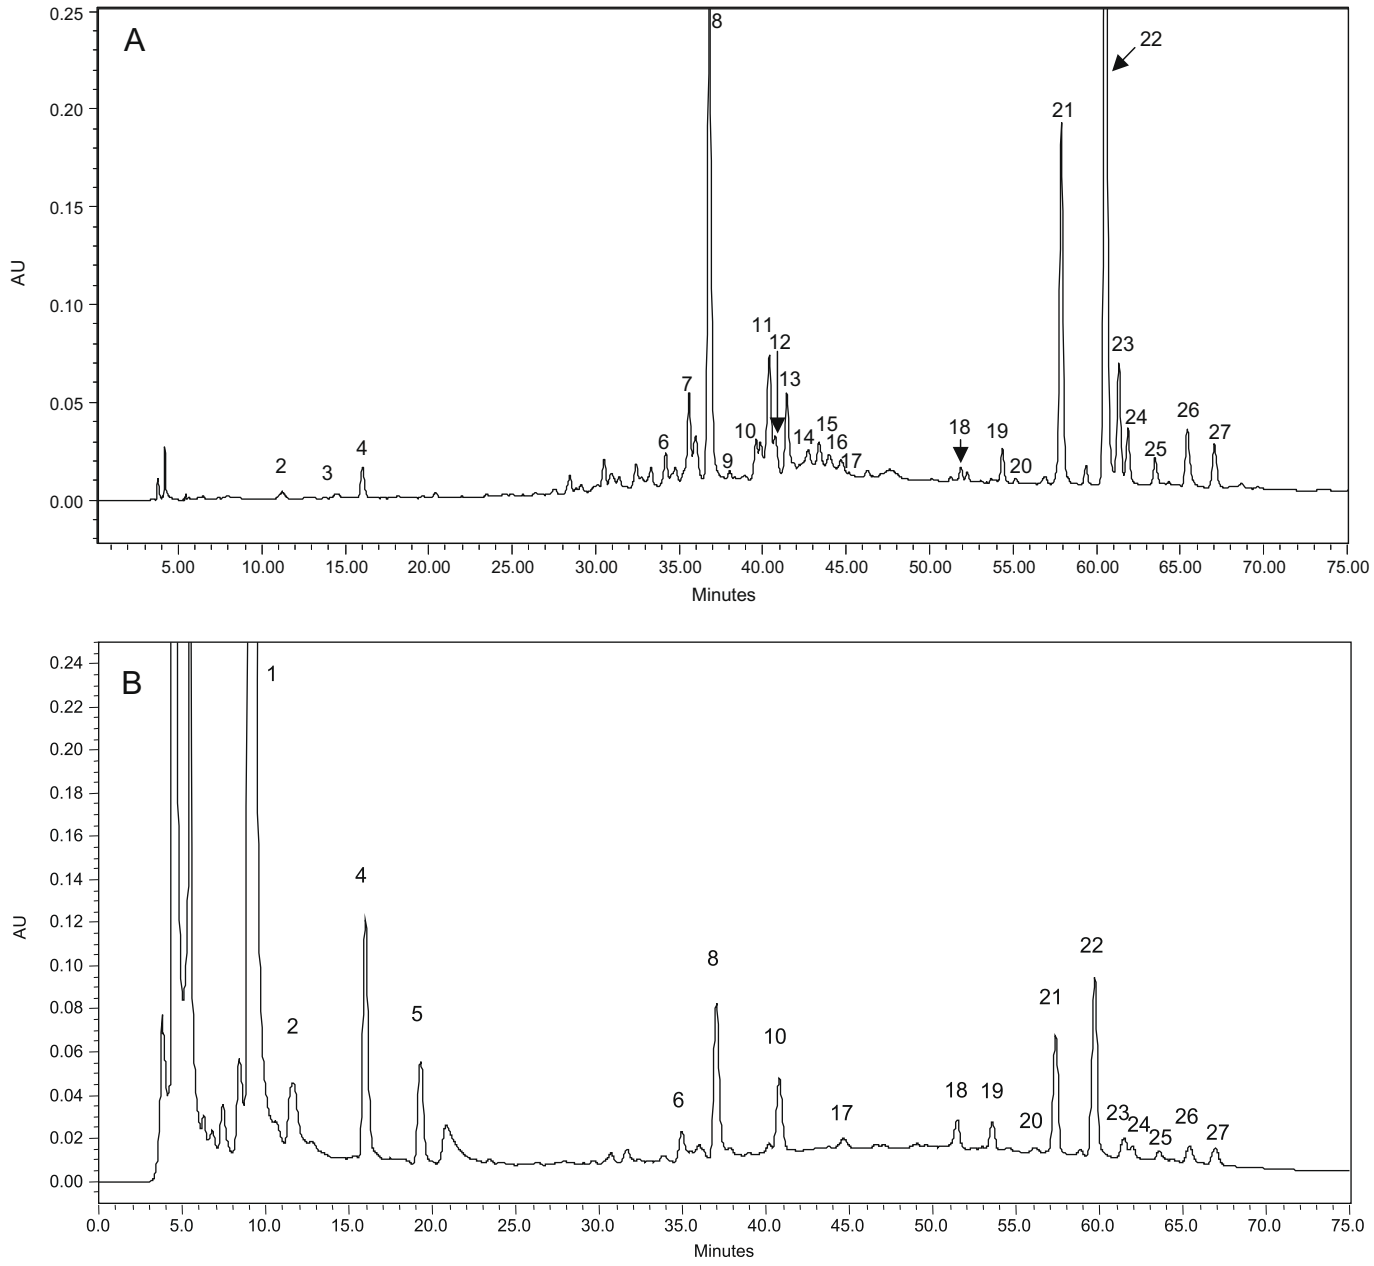

Fig. 1. Typical chromatogram at 280 nm of apple pomace (A: single-cultivar; B: industrial). Analytical conditions, see Section 2. Peaks: 1, Unk-1 (λ_{max} 268 nm); 2, Unk-2 (λ_{max} 270 nm); 3, Unk-3 (protocatechuic acid-type; λ_{max} 256 nm); 4, Unk-4 (λ_{max} 284 nm); 5, protocatechuic acid; 6, cinnamic acid-1 (λ_{max} 315 nm; sh. 283 nm); 7, procyanidin B2; 8, chlorogenic acid; 9, caffeic acid; 10, cinnamic acid-2 (λ_{max} 312 nm); 11, trimer + tetramer; 12, (−)-epicatechin; 13, cinnamic acid-3 (λ_{max} 312); 14–16, unknown flavanols; 17, cinnamic acid-4 (λ_{max} 312 nm); 18–20, unknown dihydrochalcones; 21, phloretin-2′-xyloglucoside; 22, phloridzin; 23, hyperin; 24, rutin + isoquercitrin; 25, reynoutrin; 26, avicularin; 27, quercitrin.

to any group because their UV-spectra did not correspond to any of the phenolic families analysed. The absorption maxima ranged between 256 and 284 nm, and their amounts were expressed in area $\times 10^{-6}$/kg DM.

The compounds tentatively identified as flavanols by spectra and by co-elution with the corresponding standards (procyanidin B2, trimer and tetramer, (−)-epicatechin) were confirmed as flavanols. Thus, one single-cultivar apple pomace, both the direct powder and the extract, were submitted to thiolysis, according to the method reported elsewhere (Guyot et al., 2001). As expected, the reaction with the thiol reactant gave rise to the disappearance of the peaks assigned to procyanidin B2, trimer + tetramer and other flavanols, by cleavage of the interflavanyl linkages, leading to the formation of the benzylthioether adducts at the end of the chromatogram, and the release of the terminal monomeric units ((+)-catechin and (−)-epicatechin), thus confirming these components as flavanols. No differences were observed between the treatments with toluene thiol of the dried apple pomace powder and the corresponding extract. The resulting mean polymerisation degree was close to 4 in both samples. The (−)-epicatechin monomer content was 4.5-fold higher than that of (+)-catechin.

3.1.1. Single-cultivar samples

Six single-cultivar pomaces from different technological groups were chosen among the cider apple varieties included in the Protected Designation of Origin "Cider from Asturias".

Significant differences were observed among varieties for all of the parameters analysed ($p < 0.05$). Folin index varied in this order: C > DR = M > DT = P > LM. The flavanol contents ranged between 1.7 and 2.5 g/kg. As shown in Table 2, Meana was the cultivar with the lowest amount of trimer + tetramer, and the highest in other flavanols, followed by De la Riega and Carrió. Phloridzin was always the main dihydrochalcone present in the apple pomaces, with contents ranging between 0.6 and 1.5 g/kg. Phloretin-2′-xyloglucoside was the second one, with contents in the range of 0.08 and 1.0 g/kg. Considering phenolic acids, their contents were between 0.5 and 1.6 g/kg, being chlorogenic acid the major one in all the cases. Chlorogenic acid contents varied in the order DR > C > DT > P = LM > M. Maximum content of caffeic acid was 25 mg/kg, and corresponded to DT cultivar. Protocatechuic acid was always a minor component, excepting in LM cultivar, with 144.7 mg/kg. Six quercetin glucosides were identified in the apple pomaces: hyperin, isoquercitrin, rutin, reynoutrin, avicularin and quercitrin, as described by others (Lu & Yeap Foo, 1997; Schieber, Hill, Conrad, Beifuss, & Carie, 2002; Sánchez Rabaneda et al, 2004). These components were present in high levels in apple pomaces, ranging between 0.4 and 1.4 g/kg, hyperin being the major one.

Comparing with previous results on single-cultivar apple pomaces (Ćetković et al., 2008), the samples reported here exhibited higher levels of polyphenols. Phenolic profiles are closely related to cultivar (Alonso-Salces et al., 2004; Mangas, Rodríguez, Suárez, Picinelli, & Dapena, 1999; Marks, Mullen, & Crozier, 2007), the cultural conditions of the apple trees (Chinnici et al., 2004; Lea & Beech, 1978; Veberic et al., 2005) and season (Lata, Przeradzka, & Bińkowska, 2005).

On a dry weight basis, it is possible to compare the phenolic contents of the cider apple varieties analysed in this paper with others. Thus, these Asturian cultivars present higher mean contents of (−)-epicatechin (232.4 mg/kg), chlorogenic acid (824.6 mg/kg) and phloridzin (913.1 mg/kg) than those from the Basque region, (respectively, 162.1, 409.0 and 21.0 mg/kg, as calculated from Alonso-Salces et al. (2004)). The concentrations of (−)-epicatechin in the Spanish cider varieties were remarkably lower

[1] Expressed in Area $\times 10^{-6}$/kg DM.

than those found in the English cider cultivars (632.2 mg/kg, calculated from Marks et al. (2007)).

Regarding the not identified compounds, that referred to as Unk-4 was the major one, followed by Unk-3 and Unk-1 (Table 4). The order observed for compound Unk-4 was M ≈ P > DR > DT > C > LM. Likewise, cultivars M and P exhibited the highest amounts of compounds Unk-3 and Unk-1, whereas the compound referred to as Unk-2 was present in DT cultivar only (data not shown).

3.1.2. Industrial samples

In Table 3 are presented the results for the industrial apple pomaces. As seen, the sample referred to as M4 had the highest Folin index, followed by M2. There were significant differences among the samples for all the parameters analysed. Unlike the single-cultivar samples, in the industrial pomaces protocatechuic acid was present in all the cases; among the flavanols, (−)-epicatechin was absent in all the samples, except that referred to as G. Chlorogenic acid was predominant among the phenolic acids, and phloridzin was the main dihydrochalcone, as observed for single-cultivar samples. It is worth to note the unknown compound 1, which proportion in the sample referred to as M4 is remarkable (Table 3). This component was found to be the major one among the non identified phenols, followed by Unk-4 and Unk-2.

Comparing with the single-cultivar pomaces, significant differences were found for many of the phenolic compounds analysed. No differences were observed in the cases of Folin index, caffeic and other acids, trimer + tetramer, other dihydrochalcones, most of the flavonols and the compound referred to as Unk-4 (Table 4).

Among the phenolic acids, chlorogenic acid content was significantly higher in the group of the single cultivars, whereas the industrial pomaces had higher concentrations of protocatechuic acid. Another difference between the two groups of pomaces were the contents in (−)-epicatechin procyanidin B2 and other flavanols, significantly lower in the industrial ones, or absent. Although not significantly different, the maximum concentration of trimer + tetramer observed in the industrial residues was nearly twice that of the single-cultivar pomaces (Table 4). Finally, the contents of dihydrochalcones were also lower in the industrial samples than in the experimental single cultivar ones.

The areas of the unknown compounds referred to as 1, 2 and 4 were significantly higher in the industrial pomaces than in the single cultivar samples, whereas the last ones had higher contents of compound referred to as 3 (Table 4). Even though chlorogenic acid, and in a lesser extent, flavanols and phloridzin are good substrates for enzymatic oxidation catalysed by polyphenol oxidases (Bernillon, Guyot, & Renard, 2004), and that the apple pomaces were exposed to different degrees of oxidation, we did not observed any trace of those compounds associated with phloridzin oxidation (λ_{max} = 430 nm), reported elsewhere (Le Guernevé, Sanoner, Drilleau, & Guyot, 2004). Instead, the unknown compounds analysed in the apple pomaces, which identification is still in progress, could be related to the colourless compounds resulting from the enzymatic oxidation of phloridzin by apple polyphenoloxidase at low pH values (Le Guernevé et al., 2004).

A data matrix was constructed with all the samples analysed and nine variables (protocatechuic acid, chlorogenic acid, (−)-epicatechin, procyanidin B2, other flavanols, phloretin-2′-xyloglucoside, phloridzin, hyperin and rutin + isoquercitrin), and a PCA was performed. Three significant components explaining the 84.17% of the variance were obtained. In Fig. 2 is shown the projection of samples and variables onto the plane formed by the first two principal components. From this figure, a data structurisation can be visualised, since the single-cultivar pomaces (referred to as 1) were placed on the right side of the first axe and the industrial ones (referred to as 2) were on the left side. Procyanidin B2, other flavanols and phloridzin had the highest score on the positive side of this axe, whereas hyperin and rutin + isoquercitrin had the highest score on the second axe.

3.2. Phenolic profiles and antioxidant activity of apple pomace

DPPH and FRAP assays are two of the most employed for antioxidant quantitation, due to their operating simplicity. The first one is usually performed by monitoring at 515 nm the changes of a mixture of the reactant and the antioxidant, until the absorbance is stable. The percentage of the DPPH remaining is proportional to the antioxidant concentration. The second one is typically run at 595 nm, taking 4 min as reaction time (Benzie & Strain, 1996).

One extract of apple pomace, properly diluted with methanol to reach a final range of total polyphenols between 30 and 300 mg gallic acid/L, was used to optimise the analytical methods for antioxidant activity.

For DPPH assay, as reaction time is a critical point of control of antioxidant activity assessment, the percentage of inhibition was monitored against time until not significant changes were observed. The steady stage of the inhibition reaction was obtained at 220 min, thus, a final time of 4 h was selected for further analyses. Subsequently, the antioxidant activity of three apple pomaces were determined five times within 1 day for repeatability, while reproducibility was examined in triplicate for three different days.

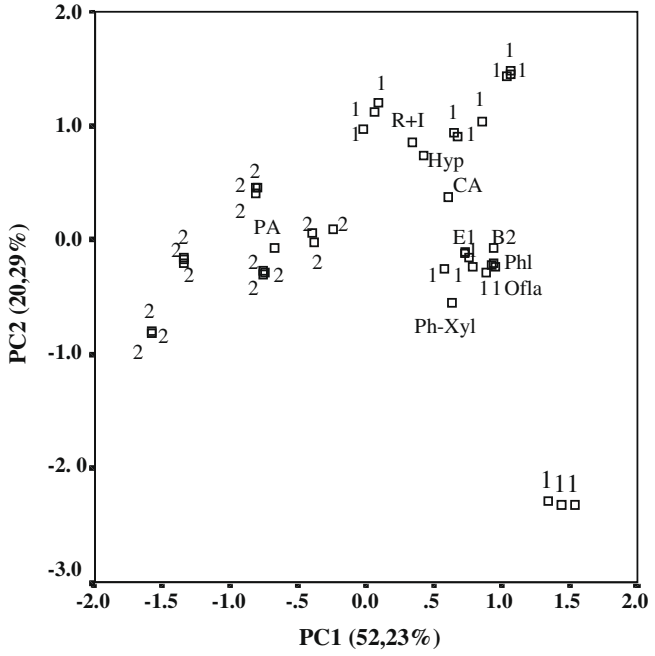

Fig. 2. Projection of samples and variables on the factorial plane formed by the first two principal components. Sample references: 1, single cultivars; 2, industrial apple pomaces. Abbreviations: CA, chlorogenic acid; B2, procyanidin B2; E, (−)-epicatechin; R + I, rutin + isoquercitrin; Ofla, other flavanols; Hyp, hyperin; PA, protocatechuic acid; Phl, phloridzin; Ph-Xyl, phloretin-2′-xyloglucoside.

The relative standard deviations in terms of ascorbic acid equivalents were, respectively, 2.6% and 5.4%.

Regarding the FRAP assay, most of the previous reports on the application of this assay for antioxidant measurements used a reaction time of 4 min, however, different time-dependent kinetic behaviours are observed when reaction times longer than 4 min are taken (Pulido et al., 2000). In the case of the apple pomace, the steady stage was not reached but the absorbance at 595 nm continuously increased. A final time of 120 min was chosen. Within and intra-day precision were calculated as described before. Mean values obtained for relative standard deviation were, respectively, 1.8% and 5.7%.

The antioxidant activities of cider apple pomaces ranged between 4.1 and 14.5 (FRAP assay), or 4.4–16.0 (DPPH assay) g ascorbic acid/kg DM (Table 4). Considering that this material is constituted by a 25% of dry matter, the presented values are equivalent to 1.0–4.0 g AA/kg of fresh weight (FW), Thus, comparing with previous studies, the apple pomace exhibited similar antioxidant activity than that of fresh apples (1.36 g AA/kg FW, reported by Kim et al. (2002), for Gala apples) or extracts of peels and pulps (1.25 g AA/kg FW for pulps, 3.3 g AA/kg FW for peels, as reported by Chinnici et al. (2004)), which confirms the suitability of apple pomace as a valuable material.

Among the single-cultivar pomaces, the antioxidant capacity determined by the DPPH assay showed this order: C > DR > LM > P = M = DT, whereas the results from the FRAP assay did not show significant differences among varieties (Table 2). Regarding the industrial samples, that referred to as M3 exhibited the lower antioxidant value. M2, exposed to air for 10 h, presented

the maximum value, followed by M4, aerated for 36 h (Table 3). The samples referred to as G (1.5 h pressing) and M1 (48 h pressing) had intermediate values for antioxidant capacity. Thus, no apparent relationship could be inferred from the present data between the pressing time, and therefore, the exposure of the pomaces to oxygen, and their antioxidant capacity.

Removing from the sample set those referred to as M, among the single-cultivars, and M4, among the industrial ones, highly significant correlations were observed between the antioxidant activity and several of the parameters analysed. Phloridzin (0.89; $p < 0.01$) and total phenols (0.85; $p < 0.01$) exhibited the highest values, followed by those of other flavanols (0.84; $p < 0.01$), chlorogenic acid (0.78; $p < 0.01$), procyanidin B2 (0.73; $p < 0.01$) and phloretin 2′-xyloglucoside (0.69; $p < 0.01$). Lower but still significant values for correlation were found for (−)-epicatechin, and for hyperin and rutin + isoquercitrin when using the DPPH assay. In general, the correlation values were higher when the antioxidant capacity was measured by the DPPH method, except for chlorogenic acid.

A multivariate partial least squares regression analysis was performed taking the antioxidant activity of the apple pomaces as dependent variables (A) and their phenolic profiles (X_n) as predictor ones. The linear models were constructed as:

$$A = b_0 + b_1X_1 + b_2X_2 + \cdots + b_nX_n$$

A final data matrix containing fourteen phenolic compounds (protocatechuic acid, chlorogenic acid, procyanidin B2, other flavanols, phloretin 2′-xyloglucoside, phloridzin, other chalcones, and flavonols) and all the samples analysed gave two models with three latent variables and good prediction ability. Values obtained for explained and cross-validated variances for prediction of the antioxidant activity as measured by the DPPH were 91.4% and 80.3%, respectively, and 84.4% and 72.2% in the FRAP assay. The variables with the higher modelling power were phloridzin > procyanidin B2 > rutin + isoquercitrin > protocatechuic acid > hyperin. All these compounds have been previously reported for their antioxidant activity (Chinnici et al., 2004; Nakamura, Watanabe, Miyake, Kohno, & Osawa, 2003; Natella, Nardini, Di Felice, & Scaccini, 1999; Tsao et al., 2005). It is interesting to note that phloridzin was the most relevant variable (even though its antioxidant activity is much lower than that of flavanols and flavonols), whereas chlorogenic acid, another major compound in cider apple pomace, with recognised antioxidant capacity (Moreira, Monteiro, Ribeiro-Alves, Donangelo, & Trugo, 2005) was not included in these models. In this sense, as quite long reaction times have been used in these assays, the influence on the antioxidant activity of less active compounds, as phloridzin, or more complex structures, as highly polymerised procyanidins may become important.

4. Conclusions

Apple pomace is a valuable source of polyphenols relevant for their antioxidant activity, as flavanols and flavonols. The antioxidant activity of apple pomace should be mainly related to apple cultivars, and it resulted to be equivalent to that previously reported for fresh apples. The apple pomaces coming from the cider-making industry exhibited lower, but still appreciable antioxidant activity than the single-cultivar samples considered in this study, which can be attributed to differences in their phenolic profiles. Both DPPH and FRAP assays, with optimised reaction times, allowed to perform reliable routine determinations of antioxidant capacity of apple pomace, and provided equivalent results. The antioxidant activity of apple pomace can be predicted by the contents of phloridzin, procyanidin B2, rutin + isoquercitrin, protocatechuic acid and hyperin.

practice that chromatographic results from this method were less than satisfactory and ultimately traced the root cause of the deficiency to the lot-to-lot variability found among guard columns. Desiring to exploit the advantages that LC–MS affords in reduced sample preparation and sample analysis time while avoiding the potential pitfalls simultaneously, we have succeeded in generating an alternative chromatographic method based on a standard micro-bore HPLC column. Described within this report is the development of this new chromatographic method and its application as a screening method to rapidly determine the content and character of limonoid glucosides found in a variety of citrus derived samples.

2. Materials and methods

2.1. Materials

Solvents, HPLC grade acetonitrile and methanol, and formic acid (88%, ACS reagent grade) were purchased from Fisher Scientific Ltd. (Waltham, MA). Water was deionized to $\geqslant$18.1 MΩ/cm resistance using a Barnstead NANOpure Deionisation System (Dubuque, IA) and filtered through a 0.45 μm type HA membrane filter (Millipore, Billerica, MA) before use. Pure crystalline limonin glucoside was available in our laboratory from previous studies. Other limonoid glucosides used to establish chromatographic retention times were available as mixtures or obtained from extracts. Samples for this study were taken from our in-house limonin glucoside isolation efforts, with additional samples obtained from the USDA's A.H. Whitmore Foundation Farm located in Groveland, FL and from fruit purchased from local grocery stores.

2.2. Sample preparation

Juice samples or samples containing limonoid glucosides were clarified by centrifugation (14,000*g*, 5 min, 8 °C) and the resulting supernatant collected and filtered (0.45 μm, 25 mm GD/X filter, Whatman Inc., Clifton, NJ). Syringe filtration is not required for colorimetric determination, but is done as a precaution to prevent fouling of the HPLC column.

2.3. Estimation of total limonoid glucoside content

Before LC–MS analysis, the limonoid glucoside content of each sample was estimated by the colorimetric method of Breksa and Ibarra (2007) with the following modification: In place of the solid phase extraction step, samples (200 μL) were simply diluted with water (500 μL) and acetonitrile (300 μL) and analysed directly without further treatment. Samples having concentrations in excess of the calibration range were further diluted using 30% acetonitrile (aq) and reassessed.

2.4. HPLC apparatus for method development

A Waters HPLC system equipped with a Model 2695 Separations Module coupled to a Waters model 996 diode array detector (190–250 nm) (Milford, MA) and Sedex 55 ELS detector (50 °C, 2.5 bar N_2, S.E.D.E.R.E., Alfortville, France) was used for initial method development experiments. Instrument control and data acquisition were accomplished using Masslynx (Version 4.0) with a SAT/IN module used to capture the signal from the ELS detector. Initial experiments determined the effects of mobile phase acidity (formic acid 1–50 mM) on the chromatographic properties of limonin glucoside. Subsequent experiments used a sample containing all six limonoid glucosides to examine the effects of solvent polarity (acetonitrile 10–30%) and flow rate (0.2–0.5 mL/min) and were conducted using a Waters 2695 system controlled by Xcalibur (Version 1.4) and coupled to a TSP UV 2000 detector (l = 210 nm) and Thermo Finnigan LCQ Advantage Mass Spectrometer (San Jose, CA). Tuning of the mass spectrometer was accomplished in negative ion mode through optimisation on the limonin glucoside signal at *m/z* 649.3 generated by introduction of a limonin glucoside solution (5 ppm) into the mass spectrometer in the LC mobile phase at the flow rate used for analysis. Following tuning, the mass spectrometer was operated in the negative ion mode using a capillary temperature of 380 °C, spray voltage of 4.50 kV, and capillary voltage of 9.0 V. The mass spectrometer was set to acquire data over a mass range from 475–750 *m/z*. All method development experiments were conducted at 30 °C under isocratic conditions using a 50 × 2.0 mm Phenomenex Phenosphere-Next-5μ Phenyl column (Torrance, CA) equipped with a guard column of the same stationary phase. Injection volumes varied from 3 to 20 μL.

2.5. Screening method for evaluating limonoid glucoside content and character of samples

The screening method consists of two steps. First, the total limonoid glucoside content of each sample was estimated using the modified colorimetric method described above. Based on these results, samples were diluted with water to concentrations between 75 and 125 mg L^{-1} limonin glucoside equivalents. Next, the samples were analysed by LC–MS using the system and MS set-

tings described above and conducted as follows: Samples (10 μL) were injected into a 50 × 2.0 mm Phenosphere-Next-5μ Phenyl column equipped with a guard column of the same stationary phase maintained at 30 °C and flowing isocratically at a rate of 1.0 mL per min. The solvent composition was 15:85 acetonitrile: 4 mM formic acid, and the total run time was 4.0 min. The flow from the TSP UV 2000 detector was directed through an LC Packing's Acurate flow splitter (Sunnyvale, CA), so that only 1/5 of the flow was introduced into the mass spectrometer. Using the Xcalibur software package, mass traces for individual limonoid glucosides were extracted from the total ion chromatograms. Subsequent data analysis including identification of the limonoid glucosides present and integration of individual peak areas was accomplished using Xcalibur. For quantification of the limonoid glucosides, an approach commonly applied in metabolic profiling of arabidopsis plants was used (Nikiforova et al., 2005). On a per sample basis, raw peak areas of individual limonoid glucosides were normalised to the sum of the areas of the detected limonoid glucosides for each chromatogram and reported as a relative percent. Spike recovery experiments were conducted on some samples. In those experiments, samples were first diluted within the linear range of the LC–MS method, and then spikes of limonin glucoside were added at two concentrations (10 and 25 mg L^{-1}). To calculate the percent recovery, the observed concentration was divided by the expected concentration and resulting product multiplied by 100%. Spike recovery experiments were conducted in triplicate.

2.6. Evaluation of run-to-run and day-to-day variability

A set of eleven randomly chosen samples, including juice, extracts, and liquid samples of partially purified limonoid glucosides, were evaluated in triplicate on three consecutive days to evaluate inter-run and inter-day variability of the method.

3. Results and discussion

Initial experiments on the application of the phenyl stationary phase to the analysis of citrus limonoid glucosides were evaluated using an HPLC system coupled to an evaporative light scattering (ELS) detector. The choice of ELS detection during the method development stage was based upon recommendations found in the literature (Charlesworth, 1978; Webster & Diaz, 2002) and made by instrument manufacturers suggesting that ELS would be a less expensive alternative to a mass spectrometer during the development of LC–MS methods. A second reason for choosing ELS was to determine if ELS detection afforded any improvement over UV detection of limonoid glucosides since the ELS is mass dependent and not dependent on the presence of an appropriate chromophore. Limonin glucoside (LG) was evaluated first because it is the predominant limonoid glucoside found in most *Citrus* and was available in our laboratory from previous studies. Before starting these experiments, the ELS operating parameters of temperature and nebulizer pressure were optimised. Operating temperature (30–55 °C) and nebulizer pressure (1.9–2.5 bar N_2) were varied as 20 μL injections of LG (5 mg L^{-1}) were introduced into an aqueous solvent stream flowing into the detector at a rate of 500 μL per min. The best response (data not shown) was observed using an operating temperature of 50 °C in conjunction with a nitrogen pressure of 2.5 bar. Comparison of the ELS response to that of a UV (λ = 210 nm) detector over a range of LG concentrations (1–50 mg L^{-1}) revealed that ELS detection afforded at least a twofold increase in signal when the instrument's gain was set to its maximum level; however, in contrast to the linear response of the UV detector ($y = 8.896x + 37.373$, $R^2 = 0.987$), response of the ELS detector was parabolic and was fit using a polynomial equation ($y = 1.9032x^2 + 21.318x + 57.437$, $R^2 = 0.999$). From these experiments the instrument limit of quantitation for LG by ELS was estimated to be approximately 5 ng.

Limonoid glucosides contain one or two carboxylic acid groups and we anticipated that the pH of the mobile phase would affect retention time. Fig. 2 shows the effects of mobile phase acidity (formic acid 1–50 mM) on the retention of LG on the phenyl stationary phase. Retention time increased from 1.09 min to 2.14 min with increasing acidity of the mobile phase. Formic acid concentrations above 50 mM had no further effect on retention time, but did result in an increase in baseline noise from the ELS detector. Based upon the observed results, a formic acid concentration of 4 mM was selected for subsequent experiments examining the effects of solvent polarity and flow rate (0.2–0.5 mL min^{-1}).

For the next phase of the method development, the LC–MS system was used to analyse a sample containing all six limonoid glucosides. We wished to evaluate both methanol and acetonitrile as organic components of the mobile phase. A side-to-side comparison of chromatograms revealed that methanol runs were plagued with significant peak tailing (data not shown). We thus focused our evaluation exclusively on acetonitrile, varying its concentration stepwise from 10% to 30%. At the lowest acetonitrile concentration, the analytes were eluted as broad peaks barely discernable over the baseline and required a run time in excess of 10 min to complete their elution. Whereas when 30% acetonitrile was used, the analytes were not retained, but were immediately co-eluted. Ultimately, a mobile phase composition of 85:15, 4 mM formic acid:acetonitrile was chosen as the optimal compromise between analysis time and resolution. Changes in flow rate under the conditions examined affected neither peak shape nor resolution of the analytes.

Fig. 3 illustrates by mass spectrometry data the resolution and order of elution, such that quantitation of each of the six glucosides in a mixture may be accomplished without worry of isotope contribution. Of the limonoid glucosides present in the standard solution, DNAG was the first of the analytes to be eluted. Examining the structures of the six glucosides (Fig. 1), it is not surprising that DNAG was the first to be eluted considering that DNAG is the most polar of the six compounds. DNAG was followed by LG, DNG, NAG, NG, and finally OG. In contrast, the reported order of elution for the same glucosides from a C-18 stationary phase was LG followed by DNAG, DNG, NG, NAG, and finally OG (Herman et al., 1990; Ohta et al., 1993; Schoch et al., 2001). Thus, shifting from C-18 to a phenyl stationary phase, the elution order of two sets of compounds, LG and DNAG, and NG and NAG, are reversed.

The differences observed in elution order between the two stationary phases are the result of the modes in which each phase can interact with the analytes in solution. The long carbon chains of the C-18 phase are like long fingers that can interact with analytes with a significant degree of freedom in a number conformations, whereas the phenyl phase in contrast is much shorter, ending with a planar phenyl ring, which is likely constrained to interact directly with the furan ring of limonoid glucosides and perhaps the double bond in the A-ring of obacunone. The apparent contrast in the ability of individual phases to interact with analytes suggests that limonoid glucosides with open A-rings (NAG and DNAG) can have conformations in solution that allow additional interactions with a C-18 phase. These subtle differences in selectivity between the two phases may be useful in the isolation of limonoid glucosides.

Having established chromatographic conditions suitable to resolve limonoid glucosides we further optimised the method by reducing analysis time to maximize sample throughput. To reduce analysis time, we doubled the flow rate from 0.5 to 1.0 mL min^{-1} and found chromatographic resolution of the analytes unaffected by increased flow. Concurrent with the increase in flow rate, col-

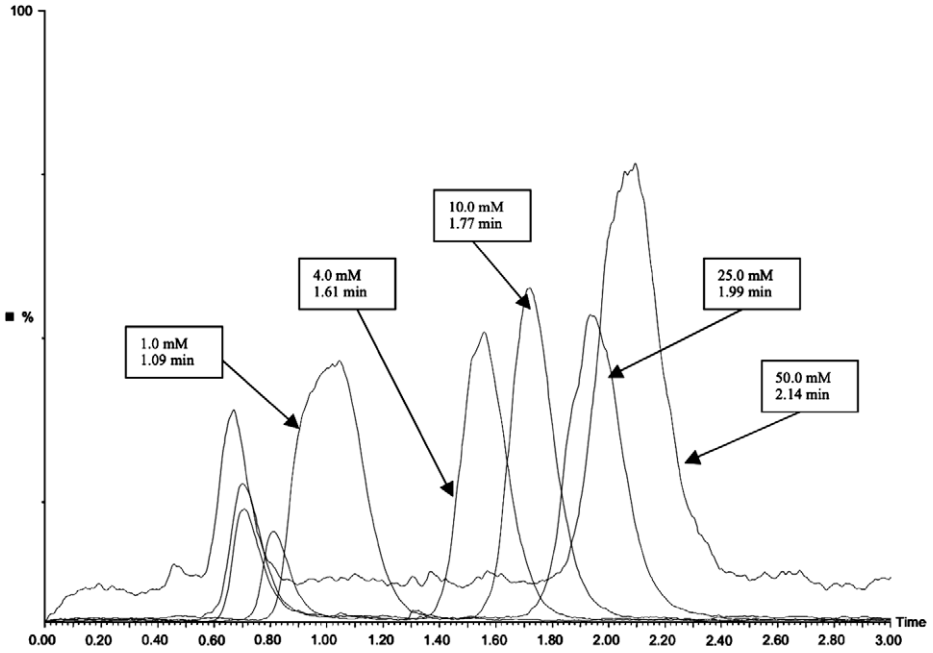

Fig. 2. Retention time of limonin glucoside on the phenyl stationary phase increases with increasing formic acid concentrations in the mobile phase. Experiments were conducted using a 25 mg L^{-1} solution of limonin glucoside and chromatograms monitored with an evaporating light scattering detector. Additional details are found in Section 2.

umn backpressure doubled and reached a value around 2200 psi. Although the LCQ Advantage mass spectrometer could handle a flow rate of 0.5 mL min^{-1}, it was overwhelmed by a flow of 1.0 mL min^{-1} so that it was necessary to introduce a flow splitter (1:5) prior to the mass spectrometer to accommodate the increased flow rate.

Utilizing the LC–MS conditions described above, response was confirmed to be linear over three orders of magnitude (1–150 mg L^{-1}; $R^2 > 0.98$) and the limit of quantitation was estimated to be near 2 ng. Both results are consistent with a previous report on the detection of limonoid glucosides by LC–MS (Schoch et al., 2001). Considering that limonoid glucoside concentrations in orange juice and citrus molasses typically range from 250 to 396 mg L^{-1} (Fong, Hasegawa, Herman, & Ou, 1990; Herman et al., 1990) and 470–7960 mg L^{-1} (Schoch et al., 2001), respectively, we were concerned that analyte concentrations in neat samples would be out of the linear range of the detector unless diluted. Therefore, before LC–MS analysis, the total limonoid glucoside content of each sample was estimated by the modified colorimetric method described in Section 2. After the concentration was determined, the sample was diluted with water to a total limonoid glucoside concentration between 50 and 100 mg L^{-1}. Since a single limonoid glucoside usually accounts for more than 50% of the total glucoside content of a given sample, this concentration range was targeted to ensure that the concentrations of the predominate glucosides would be within the linear range of the MS detector. A 5:1 dilution was sufficient for most juice samples, whereas for more concentrated samples (e.g., molasses or concentrated extracts) 50 to 1000-fold dilutions were required.

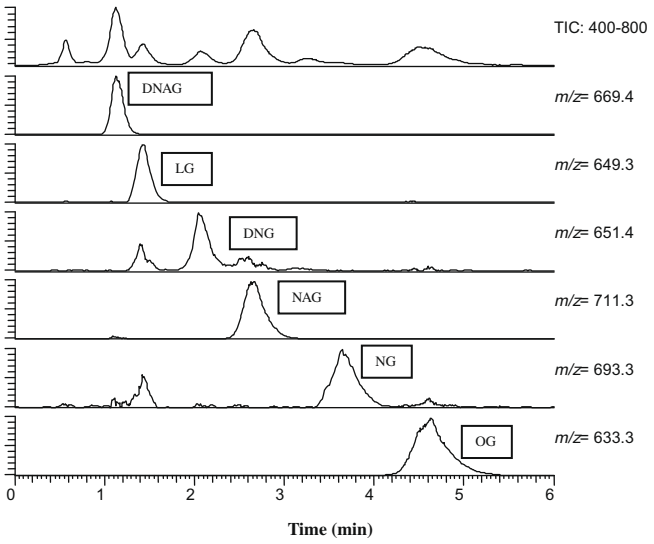

Fig. 3. Total ion and selective ion chromatograms resulting from the LC–MS analysis of a standard solution containing the six limonin glucosides using a Phenosphere-Next-5μ Phenyl column, 50 × 2.0 mm. Injection volume = 3.0 μl, column temperature of 30°, isocratic mobile phase of ACN:4.0 mM formic acid in water (15:85), flow rate = 0.5 mL min^{-1}.

Washington Navel, Hamlin and Valencia sweet oranges purchased from a local grocery store were hand squeezed, diluted 5:1 with water and analysed for their limonoid glucoside content. Results for the analysis of each of these samples along with the results previously reported for orange juices are listed in Table 1. Amongst the juices tested, Washington Navel and Valencia juices were the most similar and exhibited LG compositions close to those previously reported for orange juices. We have observed that NG is slowly converted to DNAG under the acidic conditions found in juice it is probable that its conversion into DNAG prior to the analysis may have been the cause for the reduced NG composition reported for the orange juices. The compositional differences between these samples and those for the Hamlin, Pera Rio and Natal samples suggest that in addition to harvest time (Fong et al., 1992), the limonoid glucoside contents found in *Citrus* fruits are also greatly influenced by variety.

Because we wished to apply this method on an ongoing basis and results were to be reported as relative percentages, we evaluated the inter-run and inter-day variability associated with the

Table 1
Limonoid glucoside contents found in common commercial varieties and previously reported values as relative percentage.

Limonoid glucoside ([M−H]$^-$ m/z)	LG (649)	NG (693)	DNG (651)	NAG (711)	DNAG (669)	OG (633)
Variety						
Washington Navel	53.6	26.2	0.8	10.6	8.1	0.7
Valencia	57.1	23.1	1.8	5.2	11.6	1.2
Hamlin	33.2	31.4	0.9	9.7	21.3	3.5

method in order to determine if there were any limitations with this strategy. For this evaluation, a set of eleven randomly chosen samples, including juice, extracts and liquid samples of partially purified limonoid glucosides were evaluated in triplicate on three consecutive days. Each sample was diluted to within the linear range of the MS detector before analysis. Results from the intra-run evaluation are shown in Fig. 4. Variability was more heavily influenced by concentration rather than by limonoid identity. The more concentrated the analytes the smaller the variability. For limonoid glucosides that accounted for 10% or more of the normalised total, the observed %CV was typically less than 5%. As the percent composition decreased further, the %CV continued to increase. Results from the second two days of testing were similar (data not shown). Evaluating the results obtained across the three days, we found that the %CV increased by a factor of two or less for each of the samples tested and this result provided us with the confidence to move forward with our strategy to utilise relative concentrations as an alternative to reporting absolute concentrations and the need to run calibration curves on a daily basis. However, considering the variability observed, we adopted specific uncertainty levels (%CV = 5%, 10% and 20%) and recommend that these guidelines be used when evaluating results. For relative concentrations that were equal to or greater than 50%, a %CV of 5% was utilised (i.e., assigned uncertainty = relative concentration (%) × 0.05). A %CV of 10% was used for relative concentrations between 5 and 50% and for relative concentrations below 5% a %CV of 20% was applied.

As part of an ongoing project to characterise chemical phenotypes of genetic resources found within the USDA's A.H. Whitmore Foundation Farm, juice obtained from fruits from trees located within the collection were analysed. The UV (λ = 220 nm), total ion and selective ion monitoring (SIM) chromatograms obtained for two representative samples are shown in Fig. 5A–F. Detection of analytes by mass spectrometry can be hindered by matrix components, in particular by salts or other species in significant concentrations (e.g., sugars, organic acids) that are often not bound by reverse phase stationary phases. Thus with abbreviated chromatographic methods, such as this one and typical of many LC–MS methods, there is a need to resolve the majority of sample matrix components sufficiently from the analytes of interest. Comparison of the UV and SIM traces reveals that the limonoid glucosides are well-resolved from the unbound matrix components eluting in the void volume of the column. Spike recoveries observed after the addition of limonin glucoside (10 and 25 mg L^{-1}) to juice and other samples were observed to range from 95% to 103% and provide further support that, for at least limonin glucoside, the analytes are resolved from interfering matrix components.

The relative percentage concentration for each limonoid glucoside in these two representative samples was calculated as described above and in Section 2. Limonoid glucosides detected at greater than 1% for the first sample included (Fig. 5C) LG (14.2 ± 1.4%), NAG (74.0 ± 3.7%), and NG (10.2 ± 1.0%), whereas for the second sample (Fig. 5F) DNAG (19.6 ± 2.0%), LG (4.9 ± 1.0%), DNG (54.5 ± 2.7%), NAG (17.1 ± 1.7%), and NG (3.4 ± 0.7%) were detected. Although, the fruit samples came from two different trees that are members of a F1 population generated from a cross between *C. Grandis* and *Poncirus trifoliata* (Nakon × Flying Dragon) × *C. Sinensis* (Succari), the relative concentrations of the limonoid glucosides found in the samples is distinctly different. We are currently continuing our analysis of this population in

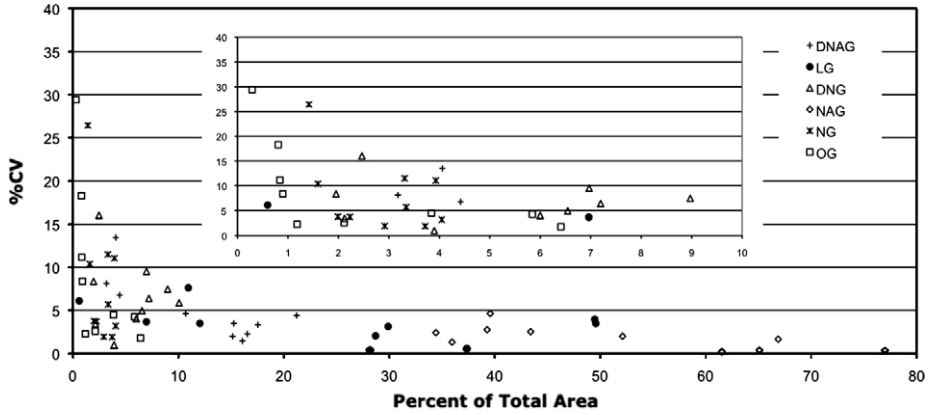

Fig. 4. Evaluation of intra-run variability: %CV and its relationship to percent total composition. Inset is a magnification of the same graph from 0% to 10%.

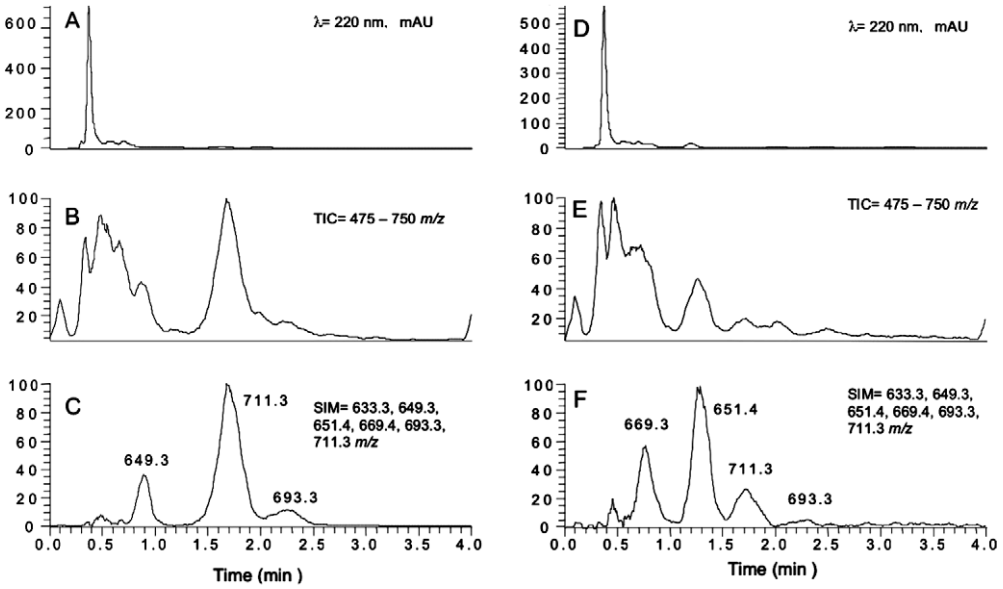

Fig. 5. UV (λ = 220 nm), total ion and selective ion monitoring (SIM) chromatograms obtained for two representative juice samples. Juice samples were obtained from two different trees that are members of a F1 population generated from a cross between *C. grandis* and *Poncirus trifoliata* (Nakon × Flying Dragon) × *C. sinensis* (Succari).

the hope that results from the analysis of their limonoid glucosides content and character will yield segregating populations that may be further examined by genomic tools in order to establish the genetic basis of the observed phenotypes.

Our goal was to develop a rapid and robust LC–MS method to characterise limonoid glucosides found in citrus juices, extracts, and fractions obtained from our isolation efforts. The majority of methods described thus far for the HPLC and LC–MS analysis of limonoid glucosides have relied upon C-18 stationary phases. In this report, we describe our evaluation of a phenyl stationary phase as an alternative to C-18 and show that, in addition to resolving the analytes of interest, the phenyl stationary phase, when compared to C-18 phases, also exhibits differences in selectivity that might further aid in isolating limonoid glucosides. Additionally, we demonstrate that the chromatography is rapid and robust, and, when paired with mass spectral detection, provides a method that is applicable to the analysis of samples having complex matrices. Furthermore, we believe that this method and its use, in conjunction with the colorimetric estimation of total limonoid glucoside concentration, will be of value to those with experience in the analysis of citrus limonoid glucosides and equally valuable to other researchers who do not have the means or resources to obtain analytical standards, but wish to evaluate citrus samples for their limonoid glucoside content and character.

Zukas, A. A., Breksa, A. P., III, & Manners, G. D. (2004). Isolation and characterization of limonoate and nomilinoate A-ring lactones. *Phytochemistry, 65*(19), 2705–2709.

the prevention of cardiovascular diseases and hormone dependent cancers (Harris, Besselink, & Seeram, 2006; McCutcheon, Udani, & Brown, 2008; Seeram, Zhang, Reed, Krueger, & Vaya, 2006; Syed, Malik, Hadi, Schmitt, & Afaq, 2006). Although pomegranate and its juice are highly esteemed for their putative weak phytoestrogenic properties, the presence of substances responsible for such activities has not been confirmed and literature is mainly focused upon the efficacy of the flavonoidic fraction (Kim, Mehta, Yu, Neeman, & Livney, et al., 2002); moreover, the previously suggested presence of sexual hormones estrone or estradiol in *P. granatum* has been recently challenged (Choi, Kim, Choi, Jung & Kim et al., 2006; Heftaman & Bennett, 1966; Moneam, El Sharasky, & Badreldin 1988; van Elswijk, Schobel, Lansky, Irth, & van der Greef, 2004).

In this paper we report for the first time a complete description of lignan distribution in *P. granatum* juice, fruit parts (seeds, pulp, endocarp) and wood knots from different cultivars.

In this paper we report for the first time a complete description of lignan distribution in *P. granatum* juice, fruit parts (seeds, pulp, endocarp) and wood knots from different cultivars.

2. Materials and methods

2.1. Standards and reagents

Betulinol was purchased from Sigma–Aldrich; (+)-Pinoresinol was obtained from ArboNova (Turku, Finland); BSTFA (N,O-Bis trimethylsilyl-trifluoroacetamide) with 1% trimethylchlorosilane was purchased from Fluka. All solvents (analytical grade) have been obtained from Carlo Erba Reagenti (Milano, Italy).

2.2. Plant material

Pomegranate plant material was collected in September 2008. *P. granatum* L. var. Wonderful concentrated juice, its by-products (pulp, seeds, endocarp) and a concentrated juice from Tunisian pomegranates obtained from an experimental industrial process were kindly provided by Dr. Massimiliano Rinaldi, Dipartimento di Ingegneria Industriale, Università di Parma, Italy. Seeds and endocarp of the Tunisian variety were obtained by manual removing of the pericarp from the rest of the fruit, isolating the endocarp and subsequently carefully splitting the tegumental pulp surrounding the seeds. Wood knots were obtained from young branches of Italian pomegranate trees, following the manual procedure previously described for *Picea abies* (Piispanen, Willfor, & Saranpaa, 2008). Three different commercial pure pomegranate juices of different brands were purchased in local groceries and herbal shops in June 2008 and anonymised by means of numbering. Flax and sesame seeds utilised to confirm lignan identification were purchased in local herbal shops. Flax, sesame and pomegranate seeds, endocarp and wood knots were ground in a blade grinder and both the powders obtained and the juices were stored in the dark at −20 °C, until analysis.

2.3. Hydrolysis and extraction

Lignan glycosides were extracted as previously reported (Smeds, Eklund, Sjoholm, Willfor, & Nishibe et al., 2007); briefly, the plant materials (5 g, dry weight) or the juices (15 ml) were first delipidised under reflux with 100 ml *n*-hexane (1 h), then extracted with 100 ml acetone (1 h) and finally with 100 ml acetone–water (70:30, v/v, 1 h). The acetone and acetone–water fractions were then pooled and evaporated under vacuum to remove acetone. The aqueous residue (30 ml) was hydrolysed according to a protocol available in literature (Sicilia, Niemeyer, Honig, & Metzler, 2003), by adding 4 ml of HCl 6 N and heating for 1 h at 95 °C, in order to recover the lignan aglycones. After the addition of 0.1 ml betulinol (520 ppm, in acetone) as internal standard, the hydrolysed mixture was extracted three times with 10 ml of an ethyl acetate/*n*-hexane mixture (1:1, v/v). The organic phases were pooled, taken to dryness and then sylanized with 100 μl of BSTFA reagent (1 h, 60 °C) for the GC–MS analysis. The recovery of the ethyl acetate/n-hexane extraction was determined on pinoresinol, by directly injecting in GC–MS silylated pinoresinol and betulinol standards and the same standards subjected to the complete extraction procedure. The recovery resulted 90 ± 3%.

2.4. GC–MS

Gas chromatography–mass spectrometry (GC–MS) analysis was performed with an Agilent Technologies 6890 N gas chromatograph coupled to an 5973 N mass selective detector (Agilent Technologies, Santa Clara, CA, USA), under the following instrumental conditions: SLB-5MS capillary column (30 m, 0.25 mm i.d., 0.25 μm film thickness; Supelco, Bellefonte, PA) with oven temperature programmed from 60 °C for 1 min, increased to 250 °C at 30 °C/min, kept at 250 °C for 10 min, increased to 280 °C at 1 °C/min, then kept at 280 °C for 13 min. Initial head pressure was 8.13 psi; injector temperature: 280 °C; injection mode: splitless 0.2 min; volume injected 1 μl; detector temperature: 280 °C; carrier gas: helium 5.0. MS conditions: ion source temperature: 230 °C; electron ionisation: 70 eV; acquisition mode: scan (*m/z* 50–750). The quantification of the lignans identified was performed utilising betulinol as internal standard, as previously reported (Willför, Ahotupa, Hemming, Reunanen, &, Eklund, 2003), integrating the total chromatografic area. The GC retention times of lignans were as follow: isolariciresinol 24.16 min; anhydrosecoisolariciresinol 24.74 min; secoisolariciresinol 25.44 min; pinoresinol 39.17 min; medioresinol 45.09 min; syringaresinol 51.62 min. Retention time of betulinol was 48.38 min. The GC–MS response factor, calculated in respect to pinoresinol, was 1.03 ± 0.02. The quantitative results are the mean value of three different extractions and three injections performed for each sample. It is important to highlight that the quantitative data reported represent an estimate, as the response factor was calculated only for pinoresinol and applied to all the other lignans.

2.5. Lignan identification

Because no mass spectra of silylated lignans were available in common commercial databases, lignans were identified by comparison with authentic reference compounds or utilising mass spectra previously reported in literature, and confirmed by analysing known sources of the specific lignans (Meagher, Beecher, Flanagan, & Li, 1999; Penalvo, Haajanen, Botting, & Adlercreutz, 2005; Sicilia et al., 2003; Smeds et al., 2007). The mass spectra of the silylated lignans identified in pomegranate samples are reported in Fig. 1. Pinoresinol was identified by comparing the retention time and the mass spectra with those of authentic standards. The fragment ion at *m/z* 209 is attributable to the stable tropylium ion structure substituted with $-OCH_3$ and –OTMS groups (Meagher et al., 1999; Sicilia et al., 2003). This ion is strong and is often the base peak in lignans. Medioresinol and syringaresinol can be considered substituted pinoresinols and molecular peaks at *m/z* 532 for medioresinol and 562 for syringaresinol, are in agreement with the addition, respectively, of one and two methoxy group to the pinoresinol structure (Penalvo et al., 2005). Moreover, the addition of a second methoxy group to the aromatic rings causes a shift of the ion *m/z* 209–239. This ion is present in medioresinol spectrum and becomes the base peak in syringaresinol. A further confirmation of the presence of medioresinol and syringaresinol in

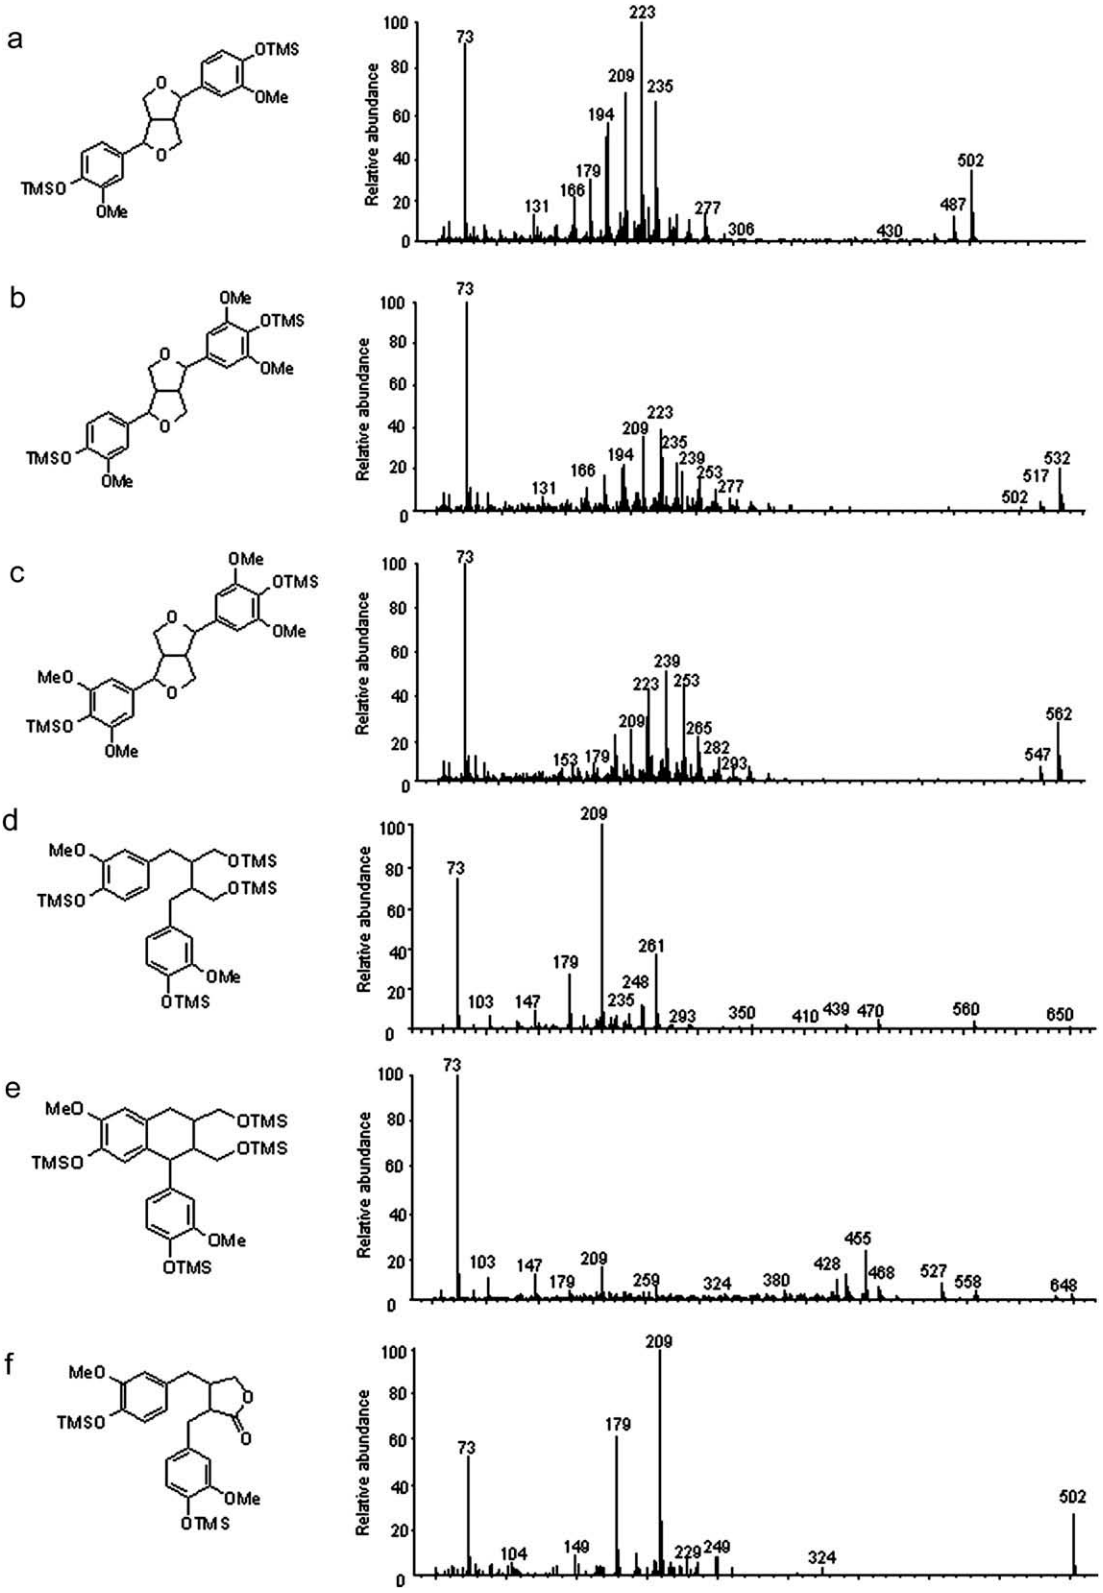

Fig. 1. Mass spectra of TMS derivatives of lignans characterised in pomegranate extracts: (a) pinoresinol, (b) medioresinol, (c) syringaresinol, (d) secoisolariciresinol, (e) isolariciresinol and (f) matairesinol.

pomegranate extract was obtained analysing in the same conditions the sesame seeds (*Sesamum indica* L.), a known source of these lignans (Smeds et al., 2007). Secoisolariciresinol spectrum is in agreement with those reported in literature for *Linum usitatissumum* (Sicilia et al., 2003). In most GC–MS chromatograms it was observed also a signal identified as anhydrosecoisolariciresinol, an artefact of the acid hydrolysis, resulting from the dehydration of secoisolariciresinol (Meagher et al., 1999). Matairesinol and

isolariciresinol spectra are in agreement with literature data (Sicilia et al., 2003).

3. Results and discussion

Lignans are produced by dimerization and subsequent rearrangement of two identical phenylpropane units, most frequently coniferyl alcohol. They are mainly stored in plant cell vacuoles in form of glycosides, to increment their solubility in aqueous media and reduce the risk of autotoxicity. Their distribution in the Plant Kingdom is scattered and do not seem to follow an unequivocal pattern allowing to predict their presence or absence in a peculiar specie or food (Umezawa, 2003). The distribution of lignans with different structures (Fig. 1), namely furofuran (a, b and c), dibenzylbutane (d and e) and dibenzylbutyrolactol (f) in *P. granatum* is described in Table 1. With respect to their selective presence in different plant parts and organs, lignans were almost absent in the inner teguments of the balausta, in which only a small amount of pinoresinol was detected, while their presence was relevant in both seeds and arils. The remarkable presence of these substances in wood knots is in accordance with previous reports evidencing an elective allocation of lignans in young woody tissues rather than in stemwood and branches; a distribution likely consequent to their strong relationship with lignin biosynthesis (Piispanen et al., 2008). The relevant presence in seeds may be also in line with previous observations, evidencing that seeds are an elective site of lignan accumulation also in soft-red berries and in most seeds of drupaceous fruits, likely as a consequence of the lignification of the seed testa. Such distribution seems to be in accordance with the fact that the drugs most abundant in lignans are seeds, i.e. sesame, buckwheat and linseed or seed-like fruits as caryopsis and brans of rye and wheat. Such an elective distribution may be a consequence of specific roles played by lignans in the plant's defensive system, as antifungals, antioxidants and in particular as feed deterrent for insects, roles that may be of particular value in oil-rich seeds that have to spend the whole winter almost defenceless before sprouting and thus may be palatable for insects (Schroeder, del Campo, Grant, Weiber, & Smedley et al.,2006). All the lignans detected in *P. granatum* share the same biosynthetic pathway, stemming from coniferyl alcohol and then modified following the sequent order: pinoresinol→lariciresinol→secoisolariciresinol and isolariciresinol→matairesinol (Umezawa, 2003). Their simultaneous presence in a single species is thus not surprising.

Concentrated juices and commercial beverages made of pure pomegranate juice have been also evaluated, evidencing an inferior presence of secoisolaricresinol, pinoresinol and syringaresinol (Table 2). Both amounts of total lignan aglycones and the qualitative profile were however rather different between the tested samples. Natural variability of plant sources (in terms of both phylogenetic and ontogenetic variability) and different industrial protocols due to dissimilar squeezing techniques and dilution rate may account for these fluctuations. A remarkable difference was noticed between concentrated and commercial fruit juices. It must be noticed, however, that most pomegranate juices available on the market are produced by dilution of concentrates, a step that is obviously detrimental in terms of lignan content. Nevertheless, a serving of filtered, freshly squeezed pomegranates (250 ml) may provide up to 0.5 mg of phytoestrogen convertible lignans.

Table 2
Amount of lignans (μg/g) in different pomegranate fruit juices, obtained by extraction under reflux in acetone–water.

	CdJ[a] – Tunisia	CdJ – Wonderful	CJ[b] brand #1	CJ brand #2	CJ brand #3

[c] Obtained as a sum of secoisolariciresinol and anhydrous secoisolariciresinol.
[d] The results reported are the mean of three independent extractions and three chromatographic analyses for each extraction.

Regarding the possible contribution of pomegranate-derived foods to dietary intake of lignans it must be noticed that in absence of a clear RDI/RDA for lignans, general nutritional suggestions rely on the epidemiologic correlations between intake and the onset of diseases. Recent surveys in representative European populations evidenced a mean total lignan daily intake of approximately 1 mg (Milder et al., 2005; Touillaud, Thiébaut, Fournier, Niravong, & Boutron-Ruault et al., 2007), which would be almost doubled by the assumption of less than 50 g of fresh pomegranate arils with seeds or home made pomegranate squeeze or approximately 200 ml of pomegranate concentrated juice. In terms of nutraceutical value, it must be noticed that higher dietary intakes of lignans were associated with a reduction in the risk of postmenopausal breast cancers, in particular when the daily intake of lignans is above 1.5 mg (McCann et al., 2006; Touillaud et al., 2007).

A particularly high value was recorded for seeds of Wonderful variety, in which the most abundant lignan was syringaresinol. This compound however cannot be considered a true phytoestrogen. Its conversion rate into enterolactone and enterodiol by human gut flora is in fact extremely low and thus syringaresinol may not be a relevant contributor of the purported phytoestrogenic effect of *P. granatum* fruits (Heinonen et al., 2001). Nevertheless, syringaresinol is however known for its involvement in the inhibition of nitric oxide in the inflammatory cascade and for its activity against *Helycobacter pilori* (Miyazawa et al., 2006).

Table 1
Distribution of ligans (μg/g) in different plant part of *Punica granatum*, obtained by extraction under reflux in acetone–water.

[a] The results reported are the mean of three independent extractions and three chromatographic analyses for each extraction.
[b] Obtained as a sum of secoisolariciresinol and anhydrous secoisolariciresinol.

4. Conclusions

Besides the renowned abundance of flavonoids, anthocyanins, catechins and specific hydrolysable ellagic derivatives named punicalagins, pomegranates proved to be rich also in lignans. As a consequence of their significant presence, lignans may act in synergy with other healthy polyphenolics of the plant's phytocomplex and represent a potential contributor to the purported oestrogenic functional properties of pomegranate juice. Their abundance may constitute a relevant marker in quality definition of *P. granatum* fruit and its nutraceutical byproducts. At the same time, the considerable presence of lignans in waste material from *P. granatum* fruit industrial processing may suggest the development of new lignan-rich food additives or herbal supplements and represent an intriguing and economic renewable source of these healthy compounds.

The main objectives of this study were, therefore, to screen the antioxidants in *H. cordata* and to further identify and quantify those compounds using LC–MS coupled with DPPH assay.

2. Materials and methods

2.1. Materials and reagents

The following herbal teas were examined: (1) *Orthosiphon grandiflorus* Bolding (Lamiaceae), (2) *Houttuynia cordata* Thunb. (Saurraceae), (3) *Morus alba* L. (Moraceae), and (4) *Vernonia cinerea* L. (Asteraceae). The samples were obtained from Bangkratum hospital, Phitsanulok, Thailand.

The standard compounds, catechin, kaempferol were purchased from Wako (Pure Chemical Industries Ltd., Japan). Chlorogenic acid, quercetin dihydrate, ascorbic acid (vitamin C), quinic acid, butylated hydroxyanisole (BHA) and 1,1 diphenyl-2-picrylhydrazyl (DPPH) were obtained from Sigma–Aldrich Chemie (Steinheim, Germany). Trolox (6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid) was purchased from Fluka Chemie AG (Buchs, Switzerland). Procyanidin B2 was purchased from Indofine (Somerville, NJ, USA). Methanol (LC/MS reagent) was purchased from JT Baker (Mallinckrodt Baker Inc., Phillipsburg, NJ, USA). Formic acid (analytical grade) was purchased from Merck (Darmstadt, Germany). Water was purified using Elga USF system (Bucks, England).

2.2. Sample preparation

For the off-line antioxidant activity determination, each sample (dry leaves) 250 mg was extracted with 2 × 10 ml 70% (v/v) methanol by sonication for 15 min then filtered through Whatman No. 1 filter paper (Kent, England). The filtrate was adjusted to a volume of 25 ml. The extracts were directly tested for antioxidant activity using DPPH assay.

For the analysis using on-line LC–ESI–MS coupled with DPPH assay. *H. cordata* dry leaves (2 g, 1 sachet) were infused in boiling water (100 ml) for 10 min, filtered through Whatman No. 1. The filtrate volume was readjusted to 100 ml and further filtered through a 0.2 μm Nylon syringe filter (Chrom Tech, Inc., MN, USA) prior to injection to the LC–ESI–MS coupled with DPPH assay system.

2.3. Off-line antioxidant activity determination

The potential antioxidant activity of a plant extract was assessed on the basis of the scavenging activity of the stable 1,1-diphenyl-2-picrylhydrazyl (DPPH) free radical. Different concentrations (10–10,000 μg/ml in 70% (v/v) methanol) of test samples were prepared. The reaction mixtures consisting of 75 μl of test samples and 150 μl of 0.2 mM DPPH in methanol were mixed in 96 well plates and incubated for 30 min. The absorbance (OD) was measured at 515 nm. The antioxidat activity was obtained from the following equation: antioxidant activity (%) = [(OD control-OD sample)/(OD control)] × 100. Percent antioxidant activity was plotted against log concentration (μg/ml).The antioxidant activity of plant extracts was expressed as EC_{50}, which was defined as the concentration in μg/ml. The measurement was performed in triplicate. Trolox, ascorbic acid and BHA were used as positive controls.

2.4. LC–ESI–MS coupled with DPPH assay

The HPLC was coupled on-line to MS (line A) and a continuous flow DPPH assay (line B) as described in the previous study (Nuengchamnong & Ingkaninan, 2009). The set up system was shown in Fig. 1. Line A; Agilent 1100 series HPLC system (Agilent Technologies, Palo Alto, CA) is coupled to a PE SCIEX API 4000 triple quadrupole tandem mass spectrometer (Applied Biosystem, Foster city, CA) equipped with electrospray ionization interface. The chromatographic separation was achieved by a phenomenex Gemini column (5 μm, 250 × 4.6 mm i.d.) (Phenomenex, Torrance, CA) protected with an ODS C18 guard column, operated at 25 °C. The mobile phase consisted of solvent A (1 ml formic acid in 1 l of deionized water) and solvent B (methanol). The elution program started from 90:10 solvent A: solvent B for 4 min, then changed to 80:20 solvent A: solvent B in 6 min, and linearly increased to 10:90 solvent A: solvent B in 30 min and the ratio of solvent A: solvent B was constant at 10:90 for 5 min then changed to 90:10 solvent A: solvent B in 5 min and was kept constant at 90:10 solvent A: solvent B for 5 min for reconditioning of the column. Mass spectra were recorded within 55 min. The injection volume was 5 μl. The flow rate was set at 600 μl/min. The Analyst 1.3.2 software was used for data acquisition and processing. The full scan mass spectra from *m/z* 100–1000 amu were acquired both in positive and negative ion modes. The optimum conditions of the interface were as follows: ESI-positive; ion spray voltage of 4500 V, curtain gas of 69 Kpa (10 psi), ion source gas 1 of 450 Kpa (65 psi), ion source gas 2 of 380 Kpa (55 psi). The interface temperature was set at 400 °C. The entrance and declustering potential were 10 and 80 V, respectively. ESI-negative; the condition was similar to ESI positive except the voltage was set in negative mode. Line B represents the continuous flow system for antioxidant activity detection. It consisted of an HPLC pump, LC20AD prominence (Shimadzu, Kyoto, Japan), home-made knitted reaction coil PEEK tubing with an inner diameter of 180 μm and a total reaction coil volume of 100 μL. The flow of 0.1 mM DPPH was set to 200 μl/min and the reduction was detected as a negative peak at 515 nm using the UV–VIS detector (SPD 20AV, Shimadzu, Kyoto, Japan). The residence time in the coil is 0.45 min. The LC solution software was used for data acquisition and processing. The polarity of the signal output was reversed in order to obtain positive signals. The system was operated at 25 °C. Line A coupled to line B with a 24 cm length of 0.17 mm i.d. PEEK tubing by a *Y*-connector. The eluent flow was split in a ratio of 8:2 between the MS ion source and DPPH line. For the characterization of antioxidant peaks, the fragment ions from their corresponding parent ions in negative mode were induced with collision gas (CAD) of 41 Kpa (6 psi), collision energy (CE) between −5 and −50 V and collision cell exit potential (CXP) of −6 V, DP in the range of −20 to −110 V. In positive mode, the ions were induced with CAD of 48 Kpa (7 psi). CE, CXP and DP were set in the range of 5–25, 3–13 and 20–100 V, respectively. Quinic acid and kaempferol at a final concentration of 100 μg/ml were added to the sample to synchronise an antioxidant peak in line B with the MS peak in line A.

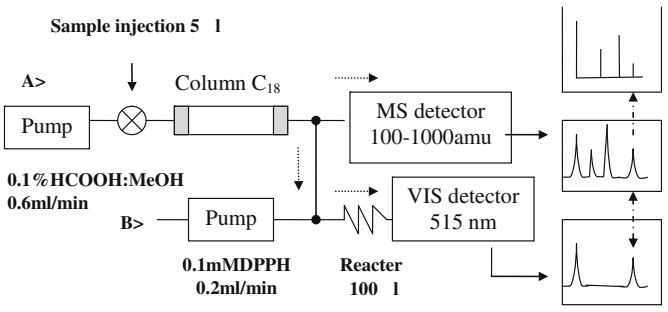

Fig. 1. Scheme of the HPLC on-line coupled to ESI-MS and DPPH assay. The arrows indicate flow directions.

2.5. Peak identification

Peak identification was performed by comparison of the retention time, mass spectra and fragmentation patterns with reference compounds and published data.

2.6. Quantitative analysis

For quantitative analysis of the antioxidants in *H. cordata* herbal tea, the same column was used and the gradient system was changed to shorten analysis time. The system was employed from solvent A:B (90:10) to (10:90) in 10 min, followed by isocratic elution with solvent A:B (10:90) for 5 min and linear gradient elution from solvent A:B (10:90) to (90:10) for 2 min and equilibration with solvent A:B (90:10) in 3 min before injecting a new sample. The flow rate was set at 600 μl/min. The injection volume was 5 μl. The MS parameters were operated in negative multiple reactions monitoring (MRM) scan mode. Optimal operating parameter of ESI–MS with maximum signal intensity of molecular ions and fragment ions were obtained by direct infusion of the standard solution at concentration 10 μg/ml in methanol, using a Harvard syringe pump (Syringe Pump 11 plus, Harvard apparatus Inc., Holliston, USA) at a flow rate of 5 μl/ml. The optimum conditions of the interface were as follows: ion spray voltage of −4500 V, curtain gas of 138 Kpa (20 psi), ion source gas 1 of 380 Kpa (55 psi), ion source gas 2 of 310 Kpa (45 psi). The interface temperature was set at 400 °C. The entrance potential was −10 V. The dwell time per transition was set at 100 ms. The individual optimized parameters for detection of each compound are as follows. For chlorogenic acid, the transition at *m/z* 353.2 → 190.8 amu with DP, CE and CXP of −120, −22 and −30 V were set. Catechin was detected at two transitions. At *m/z* 288.9 → 245.0, DP, CE and CXP were set at −150, −22 and −12 V, respectively. At *m/z* 288.9 → 125.1 amu, DP, CE and CXP were set at −150, −30 and −20 V. For quercetin, the two transitions were set at *m/z* 300.9 → 151.0 amu and *m/z* 300.9 → 178.9 amu. The DP and CE for both transitions were set at −150 and −30 V. The CXP was set at −22 for *m/z* 300.9 → 151.0 and at −26 V for *m/z* 300.9 → 178.9 detection. Chlorogenic acid, catechin and quercetin in various concentrations were used for preparation of calibration curves. The curves were generated by linear regression based on the peak area. Analyses were performed in triplicate. Other standards were not available; hence neo-chlorogenic acid and crypto-chlorogenic acid were quantified as chlorogenic acid equivalents and also procyanidin B and quercetin hexoside were quantified as catechin and quercetin equivalents, respectively. The limit of detection (LOD) was determined as the analyte signal having a peak area equal to three times of that of noise (S/N = 3) using Analyst software.

3. Results and discussions

3.1. Off-line antioxidant activity determination

The antioxidant activities of four herbal teas were measured using DPPH assay on 96 welled microplate. This assay is based on a measurement of the scavenging ability of antioxidants towards a stable radical, DPPH. DPPH, which shows absorption at 515 nm, is reduced to the corresponding hydrazine when it reacts with hydrogen donors and this can be detected as a decrease of absorption (Brand-Williams, Cuvelier, & Bersec, 1995). The antioxidant activities of the methanolic extracts of *O. grandiflorus*, *H. cordata*, *M. alba* and *V. cinerea* were expressed as EC_{50} values of 217.2 ± 12.6, 341.5 ± 17.2, 874.9 ± 83.4 and 886.9 ± 53.1 μg/ml, respectively. The positive controls BHA, ascorbic acid and Trolox gave EC_{50} values of 4.5 ± 2.1, 6.7 ± 0.2 and 7.9 ± 1.3. The results showed that the methanolic extracts of *O. grandiflorus* and *H. cordata* had the highest activity among all the teas tested.

3.2. LC–ESI–MS coupled with DPPH assay for the rapid identification of antioxidants

An aqueous extract of *H. cordata* was subjected to the on-line LC–ESI–MS coupled with DPPH assay. The DPPH based antioxidant activity profile (Fig. 2a) exhibited that at least ten compounds showed antioxidant activity peak. The deprotonated molecular ion peaks of standard quinic acid and kaempferol were found at 5.7 and 39.3 min, respectively. The delay time between the read out from the MS detector and the corresponding peak from the antioxidant activity was then calculated as 0.6 min. Negative ionization gave a better result than positive ionization (Fig. 2b). The negative ions of the major active compounds are listed in Table 1 and the identification of these compounds is proposed. The aqueous extract was used in this study as it will provide the same form of antioxidants as that present in the tea.

Peak 1 (t_R = 5.8 min) was a standard quinic acid that mixed in the sample to a concentration of 100 μg/ml as a delay time marker for the two detectors. Peak 2 has a mass spectra and fragmentation pattern nearly identical to standard quinic acid but difference in retention time (t_R 9.3 min). So, peak 2 was tentatively identified as quinic acid derivative.

Peaks 3–5 (t_R = 12.3, 14.7 and 17.9 min) with *m/z* 371.2 and fragmentation at *m/z* 197.3 [caffeic acid-H+18]$^-$, *m/z* 191.0 [quinic acid-H]$^-$, *m/z* 179.0 [caffeic acid −H]$^-$ and *m/z* 173.3 [quinic acid-H–H_2O]$^-$.These *m/z* are characteristic of caffeic acid. Therefore, these three compounds were identified as caffeic acid derivatives.

Peak 6 (t_R = 20.3 min) exhibited [M−H]$^-$ base ion at *m/z* 577.3. It gave secondary fragment at *m/z* 289.0 [M−288.3]$^-$ due to the cleavage of the inter-flavanoid C–C linkages with losses of 288 amu and *m/z* of 425 [M−152]$^-$ evolved from retro Diels–Alder fragmentation of the heterocyclic ring. The *m/z* of 407 [M−152–18]$^-$ resulted from water elimination of *m/z* 425. When comparing with standard procyanidin B2 (t_R 23.13 min), the fragmentation pattern of this compound is nearly identical but the retention time was different. This compound might be one of procyanidin B group, but stereochemistry of this compound cannot be indicated by this MS technique.

Peak 8 (t_R = 23.04 min) with *m/z* 289.0 [M−H]$^-$ and fragmentation at *m/z* 245.0 and 125.1(cleavage of the C ring) was identified as catechin by the comparison of the authentic standard.

Peak 9 (t_R = 24.8 min) with *m/z* 353.6 and fragmentation at *m/z* 191.0 [quinic acid-H]$^-$, *m/z* 179.0 [caffeic acid –H]$^-$ and *m/z* 173.3 [quinic acid-H–H_2O]$^-$. By comparing its mass spectra and t_R with standard compound, this compound was assigned to be chlorogenic acid (5-*O*-caffeoyl quinic acid). Compounds 7 and 10 were most likely naturally occurring isomers of chlorogenic acid. According to their elution order, neo-chlorogenic acid (3-*O*-caffeoyl quinic acid) was eluted prior to crypto-chlorogenic acid (4-*O*-caffeoyl quinic acid) (Carini, Facino, Aldini, Calloni, & Colombo, 1998). Therefore, peaks 7 and 10 were assigned as neo-chlorogenic acid and crypto-chlorogenic acid, respectively (Fig. 3a).

Peak 11 (t_R = 32.5 min) with a molecular ion at *m/z* 463.3 and fragment ions at *m/z* 300.0 and *m/z* 301.0 [M−162]$^-$ (loss of a hexose unit) was tentatively identified as quercetin hexoside. Standard quercetin was eluted at 37.2 min (Fig. 3c).

Peak 12 (t_R = 39.3 min) with *m/z* 285 was kaempferol standard at concentration 100 μg/ml was used as delay time marker for the two detectors.

The general structures of the antioxidant compounds identified in *H. cordata* are shown in Fig. 4.

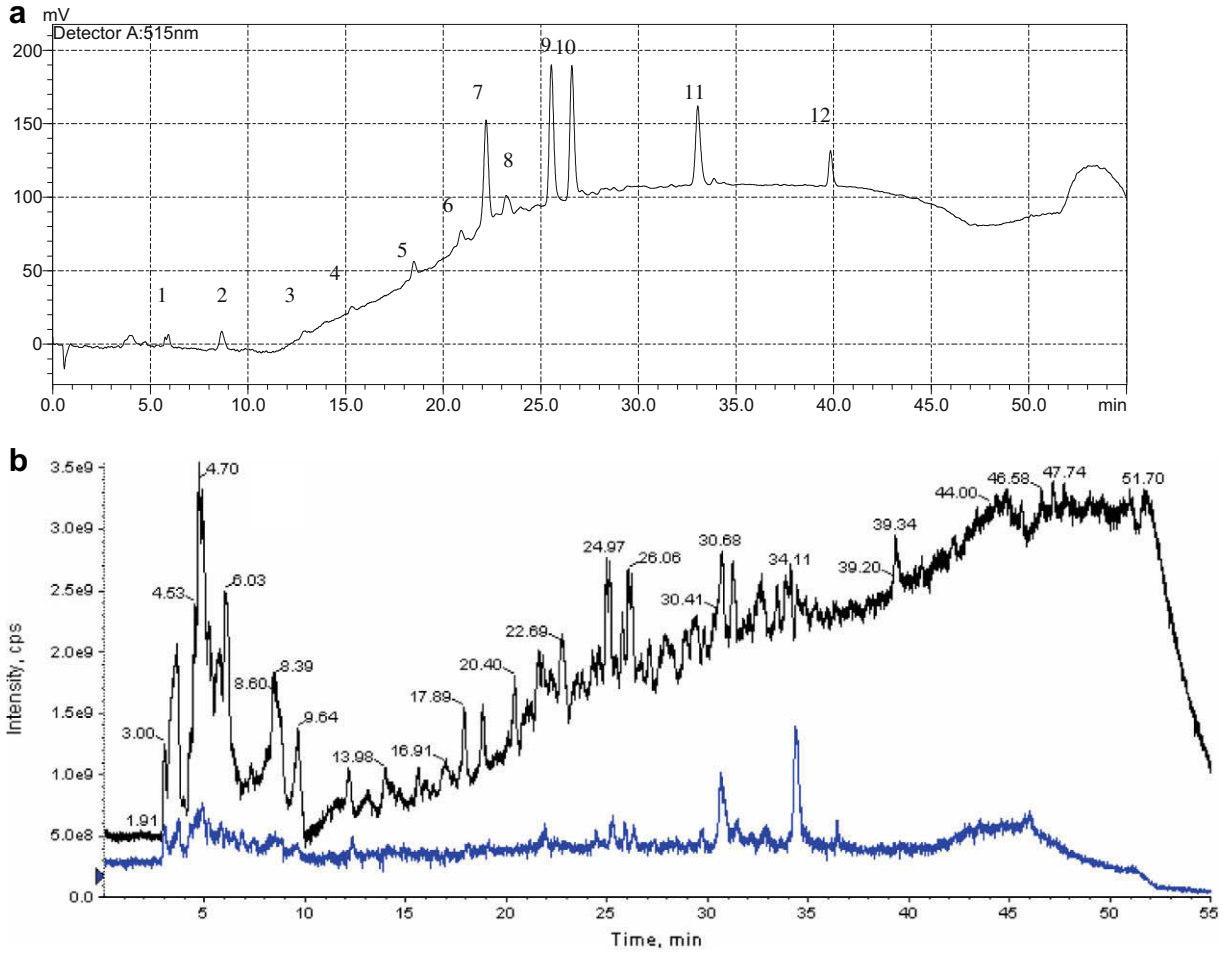

Fig. 2. Analysts of *H. cordata* aqueous extract using LC–ESI–MS coupled with DPPH assay. (a) The chromatogram from the antioxidant activity assay detection at 515 nm. (b) The total ion current (TIC) output from the ESI–MS in negative mode (upper line) and positive mode (lower line). Conditions are described in the text. For peak assignments, see Table 1. Peak 1 and 12 are quinic acid and kaempferol added to the extract for delay time measurement.

Table 1
Identification of antioxidant compounds in water extracts of *H. cordata* by using their LC–ESI–MS–DPPH assay; data in negative ionization.

Peak no.	t_R (min)	ESI–MS (m/z)		Identification
		MS	MS/MS	
1	5.8	190.9	127.3	Quinic acid*
2	9.3	190.9	127.3, 111.1	Quinic acid derivative
3	12.3	371.2	197.3, 191.0, 179.0, 173.3	Caffeic acid derivative
4	14.7	371.2	197.3, 191.0, 179.0, 173.3	Caffeic acid derivative
5	17.9	371.2	197.3, 191.0, 179.0, 173.3	Caffeic acid derivative
6	20.3	577.3	425.0, 407.2, 289.0	Procyanidin B**
7	22.2	353.6	191.0, 179.0, 173.3	Neo-chlorogenic acid
8	22.7	289.2	245.0, 125.1	Catechin**
9	24.8	353.6	191.0, 179.0, 173.3	Chlorogenic acid**
10	26.5	353.6	191.0, 179.0, 173.3	Crypto-chlorogenic acid
11	32.5	463.3	301.3, 300.0	Quercetin hexoside
12	39.8	285.0	–	Kaempferol*

3.3. Quantitative analysis of antioxidants using LC–MS/MS

Antioxidant compounds in *H. cordata* can be quantitatively analyzed using LC–MS/MS in MRM mode. In order to shorten the run time, the elution profile was changed and the analysis was finished in 20 min. In our studies, chlorogenic acid, catechin and quercetin at various concentrations were used for the preparation of calibration curves. The regression equation of chlorogenic acid at concentrations of 5–100 μg/ml was $y = 4.37e + 005x - 2.3e + 006$; with r value of 0.9985. The regression equation of catechin at concentrations of 1–100 μg/ml was $y = 2.36e + 004x + 7.86e + 003$; with r value of 0.9991. The regression equation of quercetin at concentrations of 1–100 μg/ml was $y = 9.26e + 004x + 6.6e + 004$; with r value of 0.9977. The limits of detection (LOD) with signal

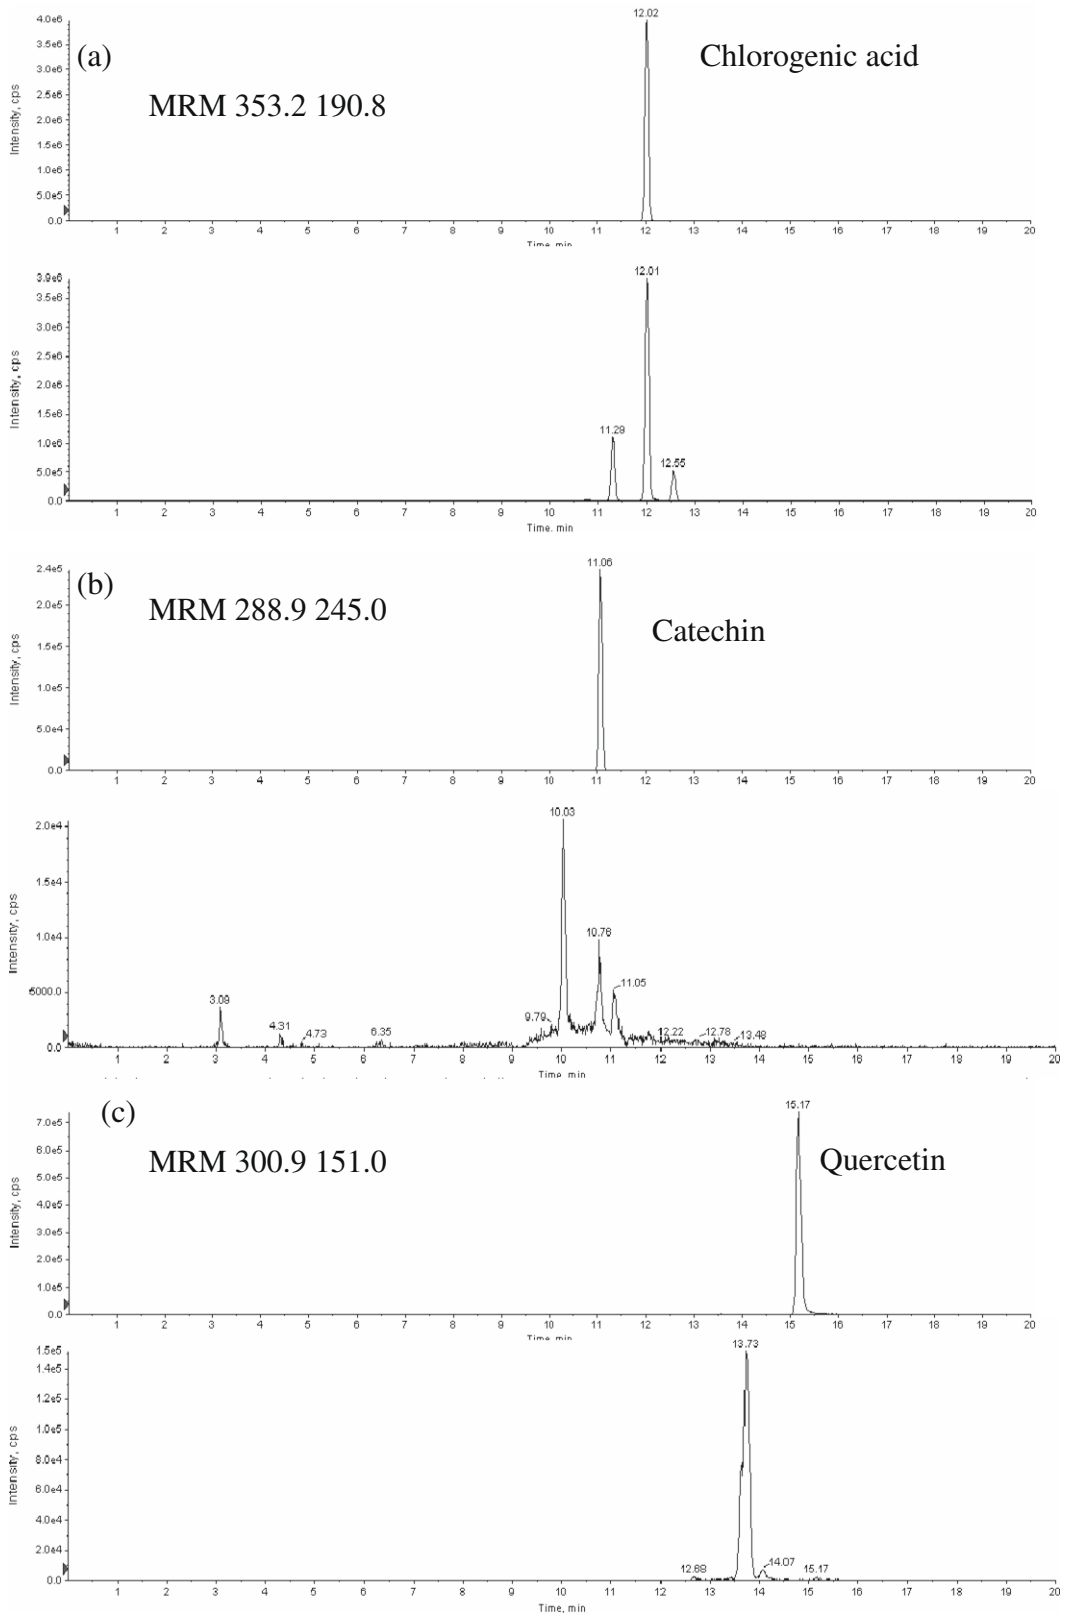

Fig. 3. Chromatograms of (a) chlorogenic acid (upper pane) and *H. cordata* extract (lower pane) obtained from the extract mass in MRM mode at transition of *m/z* 353.2 → 190.8, (b) catechin (upper pane) and *H. cordata* extract (lower pane) obtained from the extract mass in MRM mode at transition of *m/z* 288.9 → 245.0, (c) quercetin (upper pane) and *H. cordata* extract (lower pane) obtained from the extract mass in MRM mode at transition of *m/z* 300.9 → 151.0.

to noise ratio of three were determined. LOD of chlorogenic acid, catechin and quercetin was 2.5, 2.5 and 5.0 ng per injection, respectively. Neo-chlorogenic acid and crypto-chlorogenic acid were quantified by using a linear regression line of chlorogenic acid. Procyanidin B and quercetin hexoside were also quantified as catechin and quercetin. The extracts mass in MRM quantification

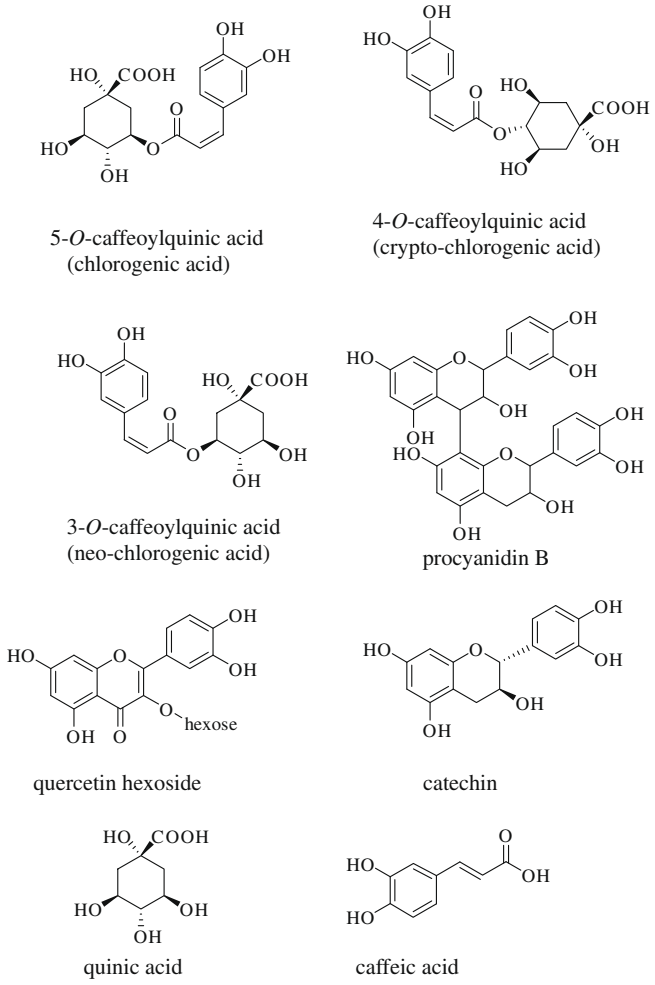

Fig. 4. Structure of phenolic compounds identified in the *H. cordata* tea.

of the standard compounds and compound equivalent in the *H. cordata* tea aqueous extracts were shown in Fig. 3. The amounts of antioxidant compounds found in *H. cordata* tea were shown in Table 2. Quinic acid derivative and caffeic acid derivatives were not quantified due to contain in a small amount.

The major antioxidative components in this plant were found to be chlorogenic acid and its derivatives. Several reports showed that chlorogenic acid exhibited antivirus, anticancer, anti-inflammation activities, and anxiolytic-like effects (Bouayed, Rammal, Dicko, Younos, & Soulimani, 2007; Jiang, Satoh, Watanabe, Kusama, & Sakagami, 2001; Jin et al. 2005; Nakamura et al. 1997). Some of these compounds such as chlorogenic acid and quercetin glycoside have already been reported in *H. cordata* (Meng et al., 2005). However, this is the first time that the presence of catechin, and procyanidin B in the aqueous *H. cordata* tea extract are reported. The results suggest that these compounds could be partly responsible for antioxidant activity of *H. cordata* tea.

Table 2
Content of phenolic antioxidant found in *H. cordata* aqueous extract analysis by LC–MS/MS in MRM mode.

Compound	Content (μg/g)
Chlorogenic acid	2808.7 ± 7.5
Neo-chlorogenic acid	921.7 ± 2.9
Crypto-chlorogenic acid	603.5 ± 2.9
Catechin	28.0 ± 0.8
Procyanidin B*	52.4 ± 5.2
Procyanidin B*	189.5 ± 0.6
Quercetin hexoside	730.0 ± 5.0

* The stereochemistry of procyanidin B could not be identified.

4. Conclusions

The preparative isolation of the active compounds of herbal extracts in adequate quantities for off-line spectral and biological analysis is a laborious and time consuming. In this study, the use of on-line rapid screening of the antioxidants in herbal tea and their subsequent identification are reported. Antioxidants in the aqueous extract of *H. cordata* mainly consisting of chlorogenic acids and its derivatives, catechin and procyanidin B were characterized using on-line LC–MS coupled with DPPH assay for the first time.

Mn content can increase in foods packed in glazed ceramic containers (Cabrera et al., 1996).

In general, estimates of the total element content in food are insufficient and its bioavailability also needs to be considered. Mineral bioavailability has gained increasing interest in the field of nutrition. *In vivo* studies are both expensive and laborious, and the possibility of measuring certain parameters during the experiments is often limited (Cabañero, Madrid, & Cámara, 2007; Perales, Barberá, Lagarda, & Farré, 2007). *In vitro* methods of simulated digestion are an alternative for calculating the percentage that is transformed into absorbable forms in the digestive tract (bioaccessibility) (Perales et al., 2007). These procedures are rapid, usually inexpensive, and they allow individual experimental variables to be easily controlled. The results are usually expressed as dialyzable fraction under given experimental conditions such as pH, enzyme addition and temperature (Cabañero et al., 2007; Cabrera et al., 1996; Velasco-Ryenold, Navarro-Alarcón, López-García de la Serrana, Perez-Valero, & López-Martinez, 2008).

On the other hand, Cr and Mn analysis in food are difficult because of low presence and problems in sample collection, storage, processing and final determination without outside contamination. Electrothermal atomic absorption spectrometry (ETAAS) is the most widely used technique and gives reliable results (Cabrera et al., 2003a; López et al., 2002; Taylor et al., 1997).

In this study, Cr and Mn content in convenience and fast food and its dialyzable fraction after simulated *in vitro* the digestion process was determined by ETAAS. The present findings are of potential use in food composition tables and to estimate the total dietary intake of these elements in accordance with the actual dietary habits. Modern societies appear to consume large amounts of convenience and fast food. For example, its consumption in Spain has been increased in recent years and has been established approximately as 32 kg person^{-1} year (Ministry of Agriculture, Fisheries, & Food, 2006).

2. Materials and methods

2.1. Sample collection

A total of 170 samples of 43 different convenience and fast food including beef-, chicken-, fish-, and pork-based products, as well as samples containing egg as major constituent and several types of sauces, were analyzed. Several brand names of each product, representing the most widely accepted and consumed in Spain, was selected for testing. The selection was specially made to reflect the popular types consumed by the different income groups. All samples are commercially available and made in Spain. Appropriate quality assurance procedures and precautions were carried out to ensure reliability of the results. Samples were carefully handled to avoid contamination.

2.2. ETASS instrumentation and conditions

A Perkin–Elmer 1100B double beam atomic absorption spectrometer equipped with deuterium-arc-background correction (Perkin–Elmer, Norwalk, CT, USA) and a Perkin–Elmer HGA-700 graphite furnace atomizer were used. Pyrolytically coated graphite tubes (Ref. B013–5653) and Pyrolytic graphite platforms (Ref. B012–1092) were obtained from Perkin–Elmer. Wall tube atomization system was used for Cr determination and platform atomization system for Mn. Argon of 99.999% purity (Sociedad Española de Oxígeno, Barcelona, Spain) at 300 mL/min was used as internal gas during all stages except atomization when the flow was stopped. A 10-μL volume of analytical solution and 10 μL of $Mg(NO_3)_2$ was used as chemical modifier were injected into the furnace. Measurements were performed at 357.9 nm for Cr and 279.5 nm for Mn using a hollow cathode lamp (Perkin–Elmer) with a slit width of 0.7 and 0.2 nm, respectively. Background-corrected integrated absorbance was used as analytical signal. A Selecta digestion block (Selecta SA, Barcelona, Spain) and Pyrex tubes were used for sample mineralization. A Moulinex microwave oven (Moulinex, Bagnolet, France) was used to dry samples. A Moulinex blender (Moulinex, Bagnolet, France) was used to sample homogenization. A shaking and thermostatic water bath Selecta (Selecta SA, Barcelona, Spain) was used to *in vitro* assays. Bidistilled deionized water from a Milli-Q system (Millipore, Milford, MA) was used.

2.3. Material

In order to decrease the risk of contamination, the use of glassware was reduced to minimum and plastic (polypropylene) vessels and pipette tips were used. All the materials were nitric acid-washed and rinsed several times with bidistilled deionized water.

2.4. Chemicals

Standard solutions of Cr and Mn (1.00 ± 0.002 g) (Tritisol, Merck, Darmstadt, Germany) were used and diluted as necessary to obtain working standards. High quality concentrated nitric acid (65%), perchloric acid (70%) and vanadium pentaoxide (Merck) were used for sample mineralization. Magnesium nitrate (Merck) was used as chemical modifier for Cr and Mn determination. Ammonium molybdate (Merck) was used to precondition the furnace tubes. All reagents used were of analytical grade. Pepsin (Sigma P7000 *porcine pancreas*, Sigma–Aldrich Chemie Gmbh, Steinheim, Germany), pancreatin (Sigma P1500 *porcine pancreas*, Sigma–Aldrich Chemie Gmbh, Steinheim, Germany) and bile salts (Sigma B8756) were used to simulate gastric and intestinal digestion. A pepsin solution was prepared dissolving 16 g of pepsin in 100 mL of 0.1 mol/L HCl; pancreatin-bile extract mixture was prepared by dissolving 4 g of pancreatin and 25 g of bile extract in 1L of 0.1 mol/L $NaHCO_3$. Sodium hydroxide (0.5 M) and hydrochloric acid (6 M) were used to adjust pH. Dialysis tubing Spectra with a molecular mass cut-off of 10–12 kDa ('Visking size 3–20/32́ Medicell International, London, GB) was used. The dialysis tubing was freed of trace metal impurities by boiling in a 2% (w/v) $NaHCO_3$, 0.1% (w/v) sodium dodecyl sulphate and 0.01 M ethylenediaminetetraacetic acid disodium salt (EDTA) for 30 min, followed by thoroughly washing with bidistilled deionized water and preserved in 20% ethanol solution.

Table 1
Analytical characteristics for Cr and Mn determination in convenience and fast foods.

Analytical parameter	Chromium	Manganese
Detection limit, pg	4.0	2.0
Sensitivity, pg	10.0	2.5
Accuracy,%	98.80 ± 1.20	98.6 ± 0.50
Precision, RSD%[a]	4.5–4.7	4.5–4.8
Slope ratio blank/addition	0.999–1.010	0.998–0.999
Against certified reference material (*Mixed human diet* IAEA-H9)		
Measured value[b], mg/kg	0.148 ± 0.015	11.75 ± 0.50
Certified value[b], mg/kg	0.150 ± 0.054	11.80 ± 0.20
Δ_m[c]	0.02	0.05
U_Δ[d]	0.112	1.077

[a] RSD, relative standard deviation for 10 replicate determinations in each of five randomly chosen samples.
[b] Mean ± S.D. at 95% CI interval about the mean (n = 10), refereed to dry weight.
[c] Absolute difference between mean measured value and certified value.
[d] Expanded uncertainty of difference between result and certified value. $\Delta_m \leqslant U_\Delta$, no significant difference between measurement result and certified value at 95% confidence level.

2.5. Sample preparation and analysis

Preliminary assays established the appropriate amount of sample for analysis to ensure homogeneity between samples and that they were representative. Food samples were subjected to a simulated eating procedure. Different food items were sliced and inedible parts thrown away. The remaining parts were homogenized in a blender and the total amount of food weighed. Three aliquots of approximately 100 g were dried in a microwave oven under controlled temperature conditions (García et al., 2001a). Each dried aliquot sample was again homogenized in the blender and three portions of 0.250 g of sample was treated with 5 mL of 65% HNO_3 and a few micrograms of V_2O_5 (as a catalyst) in Pyrex tubes placed in an acid digestion block, first it was heated at 60 °C for 30 min and then, at 120 °C for 60 min. The solutions were cooled to room temperature, treated with 1 mL 65% $HClO_4$, and heated at 120 °C for 90 min. The solutions were cooled to room temperature, transferred to a calibrated flask and diluted to a final volume of 25 mL with bidistilled deionized water. Cr and Mn were determined in this solution by ETAAS. Temperature selected for the ashing stage was 1650 °C and 1400 °C for Cr and Mn, respectively. For the atomization stage the selected temperature was 2500 °C and 2200 °C for Cr and Mn, respectively. All analyses were done in triplicate.

CAUTION: Perchloric acid should not be allowed to evaporate to dryness and should only be used in an appropriate fume hood.

2.6. In vitro method for estimating Cr and Mn dialyzable fraction

On order to simulate the gastrointestinal digestion, a portion of 10 g of homogenized sample was added to 80 mL of bidistilled deionized water and pH was adjusted to 2.0 with 6 M HCl. 3 mL of freshly prepared pepsin solution were added to the sample and the mixture was made up to 100 g with bidistilled deionized water. Then, the mixture was incubated in a shaking and thermo-

static water bath at 37 °C for 2 h. After the simulated gastric digestion, duplicate 20 g samples of pepsin digest were transferred to 250 mL Erlenmeyer flask. The dialysis tubing containing 25 mL of bidistilled deionized water and an amount of $NaHCO_3$ equivalent to the titrable acidity measured previously were placed in the Erlenmeyer flask and incubated in the shaking bath at 37 °C for 30 min. Then, 5 mL of the pancreatin–bile extract mixture were added to each Erlenmeyer flask and incubated for 2 h. The dialysis tubing was removed and the dialyzate was weighed. In this dialyzate, Cr and Mn content were determined by ETAAS in the same conditions above described. Titrable acidity was defined as the number of equivalents 0.5 M NaOH required to titrate the amount of combined pepsin digests pancreatin-bile extract mixture to pH 7.5. This was determined on a 20 g aliquot of the pepsin digest to which 5.0 mL of pancreatin-bile extract mixture has been added with 0.5 M NaOH at 20 °C. All digestions were done in triplicate and blanks were prepared and analyzed in the same procedure.

2.7. Statistical analysis

Each value of all the statistical variables studied corresponds to the average of three independent measurements of a sample food. The amount of Cr (μg/g), Mn (μg/g), Cr per portion (μg), Mn per portion (μg), Cr dialyzable fraction (%), Mn dialyzable fraction (%) and food group were the statistical variables taken into account. The numerical variables were studied as marginals, as a vector of dimension six and conditionally to the qualitative one. The analysis implemented has been mainly descriptive analysis, correlation, regression, analysis by subsets and non parametric analysis. Statistical analysis was performed by Statgraphics Plus package (1999).

3. Results and discussion

3.1. Method validation

A rapid and accurate analytical method is reported for the determination of Cr and Mn by ETAAS in convenience and fast food, useful for food routine analysis. In addition, the sample mineralization procedure provides a set of advantages including rapid and complete mineralization without analyte losses or additional contaminations. For method validation, detection limit (corresponding to three times the standard deviation of 10 replicates of the blank), sensitivity (expressed as characteristic mass for 0.0044 absorbance units), precision and accuracy (recovery assays of five randomly chosen samples) were tested for each element (Horwitz, Albert, Deutsch, & Thompson, 1990). Standard addition method was applied to five randomly chosen samples. A comparison of the slopes of aqueous and standard addition calibration graphs was performed. To check the similarity of slopes, the Student's *t*-test was applied and the results showed that the values were similar with an absence of matrix effects (slope ratios approaching 1). Thus, calibration was performed using aqueous standard. The reliability of the method was further corroborated by using a certified reference material of the International Atomic Energy Analytical Quality Services of Vienna (IAEA-H-9 *Mixed human diet*). Comparison of the measurement result with the certified value indicates that there is no significant difference between the measurement result and the certified value at a confidence level of about 95% (Linsinger, 2005). Results are summarized in Table 1.

3.2. Cr levels in convenience and fast foods

Cr levels in the analyzed samples ranged from 0.01 to 1.10 μg/g referred to fresh weight of the edible portion. The foodstuffs were classified according to their major constituent (beef, chicken, fish, pork and egg); also some sauces were included. Data are summarized in Table 2. With regard to the size of the portions (see Table 2), in most cases the weight of the packed product was taken even although in some cases it cannot be assumed that the whole portion would be eaten by one person all at once. In certain cases, however, the portion was estimated on the basis of several observations and literature (López et al., 2002).

Cr presence has been detected in all the samples and the content in a specific class of food did not appear to vary markedly among the brands. The most elevated Cr concentrations were found in beef and pork-based-food, but there is a high variability inside of each one of these food groups (Fig. 1). A higher content appears in products that contain spices and aromatic herbs, whole cereals, dry fruits, cheese and mushrooms. Some mushroom species seemed to be a major source of Cr, Mn and other elements (López et al., 2002). Wilplinger, Schonsleben, and Pfannhauser (1995) and Ashton, Barclay, Louie, Wu, and Di (2003) indicated that the best sources of Cr in diet are yeast products, chocolate derived products, prawns, processed meats, soy-based meat substitutes and breakfast cereals. In the same way, Mateos, Aguilar, and Martínez-Para (2003) found high Cr values that ranged from 0.09 to 0.55 μg/g in breakfast cereals. According to the bibliography, meat products showed a wide range of Cr content, generally lower than fresh meat, which was dependent on product composition and added materials, e.g. the high fat content in sausages (Ashton et al., 2003; Bratakos et al. 2002).

In previous studies, we analyzed several foods and beverages widely consumed in Spain, in order to estimate its possible contribution to the total Cr dietary intake (García, Cabrera, Lorenzo, & López, 2000; García, Cabrera, Sánchez, Lorenzo, & López, 1999). A high Cr presence in dairy products, meat, stimulant drinks and infusion (especially tea and coffee), whole cereals, brown sugar, spices and aromatic herbs was observed (Cabrera et al. 2003a, 2003b; Lendínez, Lorenzo, Cabrera, & López 2001). The presence of Cr in convenience and fast foods is similar to Cr content of potatoes (0.028–0.071 μg/g fresh weight of edible portion), and legumes and nuts (0.05–0.06 and 0.25–1.05 μg/g dry weight, respectively). On other hand, a moderate increase of Cr presence

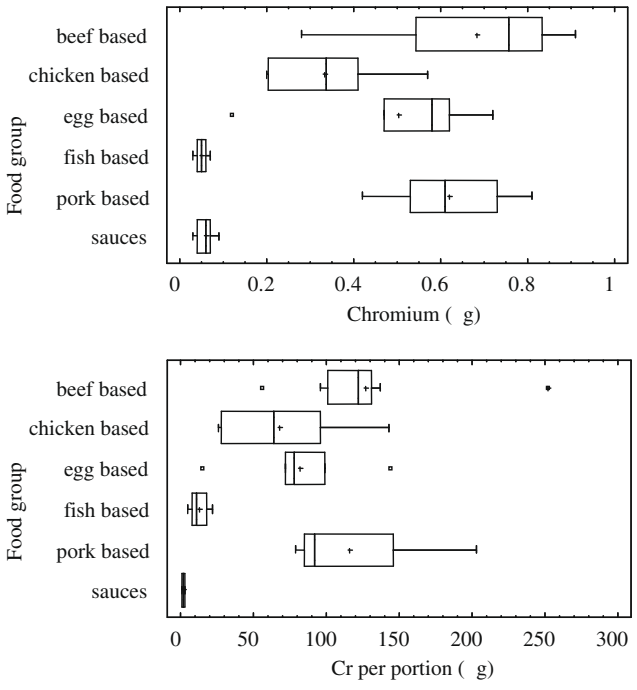

Fig. 1. Box and Whisker plot for Cr and Cr per portion by food group analyzed.

in the samples of beef in ale, chicken with aromatic herbs, chicken with mushrooms and sole with white sauce that are packed in aluminium-containers was observed. These type of containers are sometimes used as packaging material in convenience and fast foods, and often used for direct heat food cooking (e.g. during grilling or baking). In the same way, Lendínez, López, Cabrera, and Lorenzo (1998) reported significant higher Cr levels in canned beer than in bottled beers.

With regard to the Cr levels found in the present study, the mean Cr supplied per normal portion (125–300 g) of the convenience and fast foods could oscillated between 6 and 252 μg (Table 2). For sauces, a portion (25–50 g) could contribute a Cr dietary intake of 0.75–3.50 μg. The most elevated levels of Cr per portion were found in beef and pork-based food (see Fig. 1). It is important to distinguish between Cr amount and Cr amount per portion, these are different variables and they behave differently in each food group. Even so, data show that there is a strong positive relationship between Cr and Cr per portion. In fact, a regression analysis was made and it was found out that a square root-Y model describes very well the relationship between both variables. The equation model is Cr/portion = $(2.2615 + 13.2481\ Cr)^2$ given a correlation coefficient of 0.9386. A Kruskal–Wallis test has been applied to both variables, Cr and Cr per portion. Even without the sauce group, the most different one, there is no statistical evidence of similarity between the medians of the food groups (p-value = 0.000028 and 0.00019, respectively) what could be intuitively expected observing Fig. 1. García et al. (2001a) measured Cr dietary intake in southern Spain by sampling duplicate diets for seven consecutive days in different population groups that ranged between 9.39 and 205.16 μg/day with a mean of 100 μg/day. These results are similar to levels found in other countries (Ashton et al., 2003; Bocio, Nadal, & Domingo, 2005; Santos, Lauria, & Da Silveira, 2004) but higher to the range recommended by the USA Institute of Medicine (2002). These data indicate that convenience and fast food could contribute a large amount of this essential element.

Table 3
Manganese levels in convenience and fast foods.

Sample	*n*	Mn content (μg/g)[a]		Portion size (g)	Mean Mn supplied per portion (mg)
		Mean	Range		
Beef-based foods

[a] Referred to fresh weight of edible portion.

3.3. Mn levels in convenience and fast foods

Mn levels in the analyzed samples ranged from 0.15 to 2.90 μg/g referred to fresh weight of the edible portion. Data are summarized in Table 3. Mn presence was detected in all the samples but notable differences from sample to sample even in each food group were observed. The most elevated Mn concentrations were found in chicken-based foods (mean of 2.07 μg/g), pork-based foods (mean of 1.75 μg/g) and sauces (mean of 1.90 μg/g) (Fig. 2). Among each group, elevated levels were detected in dairy products that contain cocoa or chocolate, nuts, egg-yolk, whole cereals, and green leaf vegetables. Stobbaerts, Robberecht, and Deelstra (1995) determined the Mn content of several duplicate meals consumed by different population groups in Belgium; these authors reported that the intake level of vegetarians is similar to that of omnivorous adults, 2.9 ± 2.0 and 2.5 ± 0.3 mg/day, respectively. These authors indicated that a lower energy intake may in part be associated with a lower Mn intake. Bocio et al. (2005) estimated the mean dietary intake of Mn in the general population of Tarragona (Spain) as 2.42 mg/day, Santos et al. (2004) in Rio de Janeiro (Brazil) as 2.5 mg/day, and Velasco-Ryenold et al. (2008) in south eastern Spain as 3.05 ± 0.61 mg/day.

According to our results, a normal portion of convenience and fast foods (125–300 g) supplied between 22.5 and 650 μg of Mn (crème caramel and chicken with mushroom, respectively) whereas the mean supplied by a sauce portion (25–50 g) could ranged between 35 and 100 μg. There is not a good linear correlation between Mn and Mn per portion ($r = 0.4298$) and a deeper regression study did not find any good model to fit the data. It is important to note that the highest levels of Mn per portion were found in chicken based food and the lowest in sauces (Fig. 2) in contradiction to Mn levels (Fig. 2). The Kruskal–Wallis tests for Mn and Mn per portion indicate that there is no statistical evidence of similarity between the medians of the food groups (p-value = 0.00019 and 0.00011, respectively) what could be intuitively expected observing Fig. 2. These data indicates that certain convenience and fast food could contribute a notable amount of Mn, whereas the dietary intake repercussion of others is scarce. In accordance with Cabrera et al. (1996), it is found a low moderate increase of Mn presence in pudding, custard and crème caramel packed in glazed ceramic containers but the number of samples with this type of container was scarce. The most usual containers are the aluminium ones. It is interesting to compare the Mn content between convenience and fast food and a dish of the raw components; generally, foods produced from Mn-rich ingredients were themselves high in Mn. However, food processing and additional ingredients of the instant meal contribute to a higher final Mn concentration or conversely they may further dilute the initial low Mn content. Taking into account the differences between the metal content and its content per portion, let us remark that the Cr per portion mean was 64.93 μg, its 95% confidence interval (46.17 μg, 83.70 μg), the Mn per portion mean was 240.56 μg and its 95% confidence interval (191.02 μg, 290.09 μg). It is also interesting to note that there was no correlation between Cr and Mn or Cr per portion and Mn per portion.

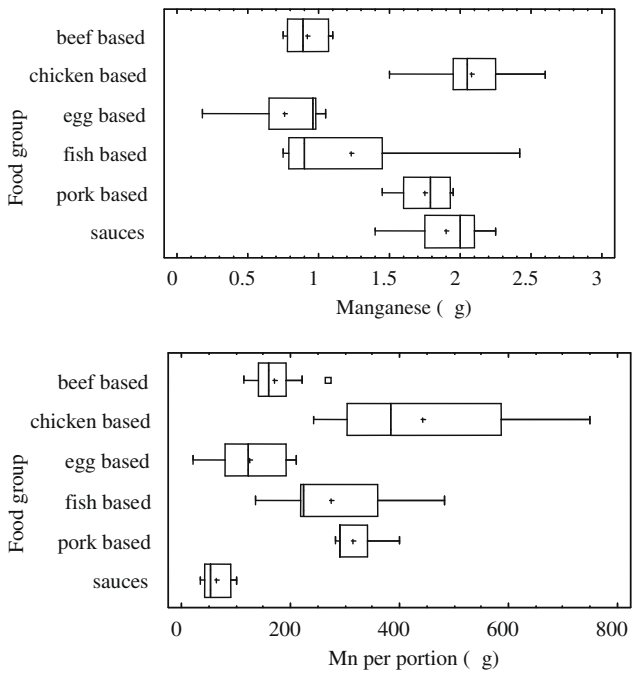

Fig. 2. Box and Whisker plot for Mn and Mn per portion by food group analyzed.

3.4. In vitro Cr and Mn dialyzable fraction

Table 4 shows the results of Cr and Mn dialyzable fraction after simulated *in vitro* the digestion process. *In vitro* analyses were done with 10 randomly chosen samples. Cr and Mn dialyzable fraction ranged from 0.38% to 1.05% and from 7.75% to 15.60%, respectively. These percentages express the element fraction that would be available for absorption by intestinal cells (bioaccessible Cr and Mn). The statistical analysis found that the data variability decreases considerably from a variation coefficient of 90% for Cr to 35.46% for Cr dialyzable fraction and from 35.92% for Mn to 23.83% for Mn dialyzable fraction. It may point out that the absorption level is limited. Cr dialyzable fraction of is quite positively correlated with Cr levels ($r = 0.7706$). However, there is no correlation between Mn dialyzable fraction and Mn levels ($r = 0.2444$). Then, data suggests that the relation between dialyzable-total Cr content in food is stronger than in Mn case. In addition, the latter is more irregular. As what happened with Cr and Mn, there is no good correlation between absorbable Cr and absorbable Mn. Cr bioaccessibility may depend on interactions with other dietary components, including other minerals, and both competitive and cooperative interdependence have been reported. Van Cauwenberg, Hendrix, Robberecht, and Deelstra (1996) suggested that Cr intake may increase parallel to energy intake. García, Cabrera, Lorenzo, López, and Sánchez (2001b) estimated Cr bioaccessibility from the diet by an *in vitro* method as 0.4–1.6% for a total dietary intake from 16 to 117 μg/day. These authors observed the influence of the total Cr content in the diet on the Cr dialyzable fraction. Cr absorption was higher for low levels of daily dietary intake (<40 μg) than for levels of 40–80 μg; for high levels (>80 μg) there was an increase in the dialyzable fraction. Cabrera et al. (1996) determined the mean absorbable fraction of Cr and Mn in dairy products using an *in vitro* method as 2.0 ± 1.0% and 5.0 ± 2.0%, respectively. Velasco-Ryenold et al. (2008) reported that Mn absorption (1–16%) is affected by dietary factors, such as element concentration, chemical form, source and oxidation state, lumen intestinal content, endogenous physiological factors, interaction with other nutrients and meal composition. Phytate, ascorbic acid, proteins and other dietary constituents interacts with Mn in absorption process. These authors indicated that foods with higher protein, carbohydrate and therefore energy contents, e.g. cereals, legumes, vegetables and fruits, would be primary sources of bioaccessible Mn in the diet and established the mean bioaccessible fraction of Mn from duplicate meals as 22.0 ± 8.93%. These findings suggest the need for further studies aimed at identifying the factors that can modify the bioavailability of Cr and Mn in the diet. The resulting data will also be useful to estimate the nutritional requirements of these elements.

Table 4
Cr and Mn dialyzable fraction in convenience and fast foods, estimated by an *in vitro* method.

Sample	Cr total content(μg/g)[a]	Cr dialyzablefraction (%)[b]	Mn total content(μg/g)[a]	Mn dialyzablefraction (%)[b]
Hamburger (beef)	0.89 ± 0.05	1.05 ± 0.06	1.09 ± 0.06	8.50 ± 0.10
Lasagne meat	0.47 ± 0.04	0.60 ± 0.02	0.75 ± 0.02	10.75 ± 0.15
Chicken and vegetable soup	0.20 ± 0.03	0.54 ± 0.03	2.05 ± 0.07	12.10 ± 0.10
Salmon cottage pie	0.05 ± 0.005	0.67 ± 0.02	0.78 ± 0.02	9.50 ± 0.15
Hake with green sauce	0.07 ± 0.01	0.54 ± 0.02	1.00 ± 0.03	8.90 ± 0.12
Pork with mushroom sauce	0.81 ± 0.02	1.02 ± 0.07	1.90 ± 0.06	7.80 ± 0.10
Ham-cheese-tomato-pizza	0.42 ± 0.02	0.38 ± 0.02	1.66 ± 0.07	15.60 ± 0.20
Pudding (chocolate)	0.65 ± 0.03	0.90 ± 0.04	0.99 ± 0.04	10.35 ± 0.10
Tomato sauce	0.06 ± 0.007	0.65 ± 0.02	1.80 ± 0.08	8.90 ± 0.08
Roquefort sauce	0.47 ± 0.03	0.40 ± 0.02	1.50 ± 0.07	7.75 ± 0.05

[a] Mean ± standard deviation of three replicate of each sample.
[b] Mean ± standard deviation of three assays in each sample.

4. Conclusion

This study contributes new data on Cr and Mn content in foods that are potentially useful as supplementary and/or previously unavailable information to current food composition tables and also to estimate reliably the total dietary intake of these elements in accordance with the actual dietary habits. Periodical determinations and additional studies on Cr and Mn bioaccessibility are advisable because the growing popularity and the large amount of these products that are consumed as part of the habitual diet, especially elder people who live alone, young people and children. It also derives information about the bioaccessibility of these essential elements.

FOOD CHEMISTRY

Aims and Scope

Food Chemistry publishes original research papers dealing with the chemistry and biochemistry of foods and raw materials covering the entire food chain from *'farm to fork.'* Topics include:

- Chemistry relating to major and minor components of food, their nutritional, physiological, sensory, flavour and microbiological aspects;
- Bioactive constituents of foods, including antioxidants, phytochemicals, and botanicals. Data must accompany sufficient discussion to demonstrate their relevance to food and/or food chemistry;
- Chemical and biochemical composition and structure changes in molecules induced by processing, distribution and domestic conditions;
- Effects of processing on the composition, quality and safety of foods, other bio-based materials, by-products, and processing wastes;
- Chemistry of food additives, contaminants, and other agro-chemicals, together with their metabolism, toxicology and food fate.

Analytical Section

Analytical papers related to the microbiological, sensory, nutritional, physiological, authenticity and origin aspects of food. Papers should be primarily concerned with new or novel methods (especially instrumental or rapid) provided adequate validation is described including sufficient data from real samples to demonstrate robustness. Papers dealing with significant improvements to existing methods, or data from application of existing methods to new foods, or commodities produced in unreported geographical areas, will also be considered.

- Methods for the determination of both major and minor components of food especially nutrients and non-nutrient bioactive compounds (with putative health benefits) will be considered.
- Results of method inter-comparison studies and development of food reference materials for use in the assay of food components;
- Methods concerned with the chemical forms in food, nutrient bioavailability and nutritional status;
- General authentication and origin [e.g. Country of Origin Labelling (COOL), Protected Designation of Origin (PDO), Protected Geographical Indication (PGI), Certificate of Specific Character (CSC)] determination of foods (both geographical and production including commodity substitution, and verification of *organic, biological* and *ecological* labelling) providing sufficient data from authentic samples should be included to ensure that interpretations are meaningful.

FOOD CHEMISTRY

Aims and Scope

Food Chemistry publishes original research papers dealing with the chemistry and biochemistry of foods and raw materials covering the entire food chain from *'farm to fork.'* Topics include:

- Chemistry relating to major and minor components of food, their nutritional, physiological, sensory, flavour and microbiological aspects;
- Bioactive constituents of foods, including antioxidants, phytochemicals, and botanicals. Data must accompany sufficient discussion to demonstrate their relevance to food and/or food chemistry;
- Chemical and biochemical composition and structure changes in molecules induced by processing, distribution and domestic conditions;
- Effects of processing on the composition, quality and safety of foods, other bio-based materials, by-products, and processing wastes;
- Chemistry of food additives, contaminants, and other agro-chemicals, together with their metabolism, toxicology and food fate.
