ABSTRACT

The scientific basis for the statement that plants and their active constituents play an important role in the prevention of chronic and degenerative diseases is continuously advancing. In fact, the origin of many therapeutic substances is due to secondary metabolism in the plant. The genus *Hibiscus* contains 220 species distributed around the world. It is an interesting source of potential bioactive molecules, as phenolic compounds, triterpene derivatives, phytosteroids, with antioxidant, cardioprotective, antihypertensive and antiproliferative activities. This work reviews the pharmacological evidence of extracts of plants from the genus *Hibiscus*, giving an overview of the most studied biological effects and the known phytochemical composition. Although more studies are necessary, *Hibiscus* spp. exhibits proven potential to become of important pharmacological interest.

Contents

1. Introduction

In recent times, focus on plant research has increased all over the world, and a large body of evidence has been collected to show the immense potential of medicinal plants used in traditional systems. Various medicinal plants have been identified and studied using modern scientific approaches. The results revealed the potential of medicinal plants in the field of pharmacology (Fiala, Reddy, & Weisburger, 1985; Tapsell et al., 2006; Triggiani et al., 2006).

Several human diseases, such as diabetes, neurodegenerative, cardiovascular diseases and specially carcinogenesis have been associated with oxidative stress. This condition occurs in a cell or in a tissue when the concentration of the reactive oxygen species (ROS) generated exceeds its antioxidant capability

(Nakabeppu et al., 2006; Valko, Izakovic, Mazur, Rhodes, & Telser, 2004, 2006). As a consequence, much attention has been directed to the research of naturally occurring protective antioxidants and their action mechanisms. In line with this, several plant extracts or their secondary metabolites have been found to show strong antioxidant activity and to protect against oxidant-induced damage (Collins, 2005; Hayatsu, Arimoto, & Negishi, 1988; Loo, 2003; Triggiani et al., 2006). Accordingly, many plant extracts have demonstrated potent cancer chemopreventive properties as observed in the last decade (Ames, 1998; Ames & Gold, 1998; Beckman & Ames, 1998; Borek, 2004; Cassady, Baird, & Chang, 1990). Most of these extracts are known to exert their effects by antioxidant mechanisms that either quench reactive oxygen species (ROS), inhibit lipid peroxidation or stimulate cellular antioxidant defenses (Valko et al., 2007; Yun et al., 1999).

Natural products extracted from plants which belong to the Malvaceae family are used in the treatment of many diseases worldwide. One important genus in this family is *Hibiscus* spp., with more than 220 species distributed in tropical and subtropical regions (Tseng & Lee, 2006). Species of the genus *Hibiscus* have been used in several applications in traditional medicine, as antidotes to poisoning with chemicals and venomous mushrooms and as a source of fibre in the pulp and paper industries. Members of the genus *Hibiscus* thrive in a variety of climates and produce a diversity of natural compounds with interesting bioactive properties (Holser, Bost, & Van Boven, 2004). Pharmacological investigations of the genus *Hibiscus* indicated the presence of some species with useful biological activities as antihypertensive, anti-inflammatory, antipyretic, hepatoprotective, anti-diarrhoeic, anti-spermatogenic, anti-tumour, antidiabetic, anticonvulsivant, antihelminthic immunomodulator, antioxidant and antimutagenic agents (Dafallah & Al-Mustafa, 1996; Sachdewa & Khemani, 2003). Amongst these species, less than 15 have had their biological effects studied. The majority of these studies mainly concentrated on *Hibiscus sabdariffa*. In this paper, we revised the phytochemical composition and the main pharmacological effects of the genus *Hibiscus*.

2. Materials and methods

2.1. Hibiscus syriacus

Hibiscus syriacus, the common garden *Hibiscus*, is called rose of Sharon in North America, a name given also to other plants. It is a flowering shrub native of Asia. The root bark of *H. syriacus* L. has been used as an antipyretic, antihelminthic, and antifungal agent in the east. From the stem and root bark of *H. syriacus*, saponarin, polyphenol compounds, betulin, canthin-6-one, carotenoids and anthocyanins have been previously isolated (Chen & Fang, 1993; Kwon, Hong, Kim, & Ahn, 2003). In this species, a lignan named hibiscuside ((+)-pinoresinol 4-*O*-[β-glucopyranosyl(1–2)-α-rhamnoside]) and a known lignan (syringaresinol) were present in the root bark of this plant, together with two feruloyltyramines and three known isoflavonoids: 6″-*O*-acetyldaidzin, 6″-*O*-acetylgenistin and 3-hydroxydaidzein. All compounds exhibited important antioxidant activity in vitro (Yoo et al., 1998). During screening for lipid peroxidation inhibitors, three naphthalene compounds: 2,7-dihydroxy-6-methyl-8-methoxy-1-naphthalenecarboxaldehyde, 2-hydroxy-6-hydroxymethyl-7,8-dimethoxy-1-naphthalene-carboxaldehyde and 1-carboxy-2,8-dihydroxy-6-methyl-7-methoxynaphthalenecarbolactone (1→8), designed as syriacusins A–C, were isolated from the chloroform extract of the root bark of this plant (Yoo et al., 1998). Recently, in investigations for biologically active substances, two pentacyclic triterpene caffeic acid esters were isolated (Fig. 1), increasing the number of molecules with potential pharmacodynamic interest in this species. These molecules inhibited lipid peroxidation in rat liver microsomes, indicating the existence of an antioxidant potential (Kwon et al., 2003; Yun et al., 1999; Yoo et al., 1998a). In the investigation of a methanolic extract of root bark, 8-hydroxy-5,6,7-trimethoxycoumarin, a derivative of coumarin, scopoletin and clemicosins A, C and D were identified (Fig. 1). The molecules with the coumarin core inhibited monoamine oxidase in vitro in a dose-dependent manner, while the coumarin derivative and clemicosin were potent antioxidative agents in vitro (Yun et al., 1999).

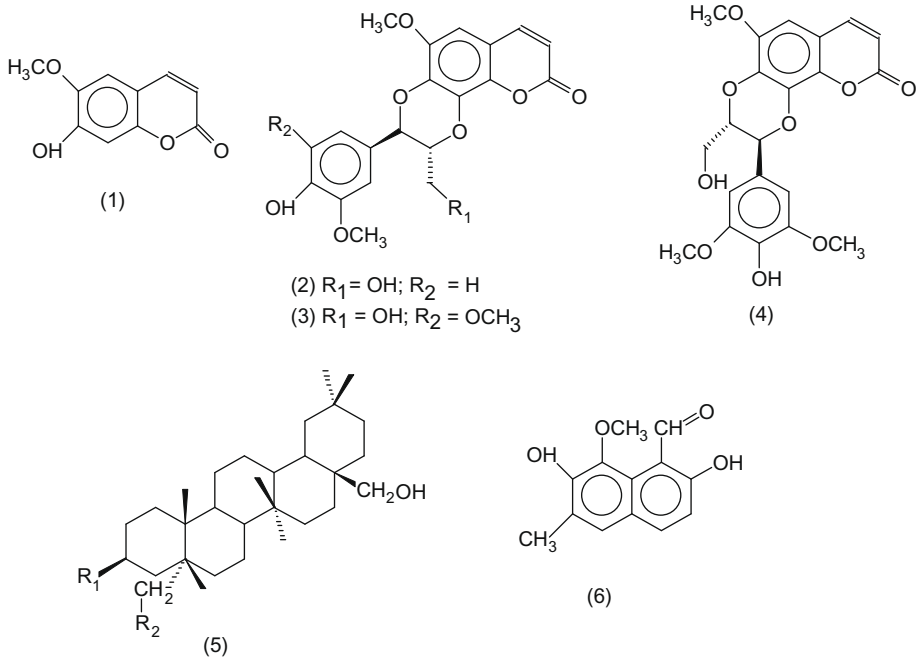

Fig. 1. Some biological compounds of *H. syriacus*: (1) scopoletin; (2) clemiscosin A; (3) clemiscosin C; (4) clemiscosin D; (5) structure of pentacyclic triterpenes; (6) syriacusin A.

More recently, the antiproliferative effect of an acetone extract of the root bark of *H. syriacus* was reported on human lung cancer cells in culture and using in vivo models, employing A549-xenograft. In this study, it was shown that this extract suppressed the expression of the proto-oncogene p53 and the apoptosis initiation factor (AIF), which can explain the cytotoxic effect of this extract, although the exact mechanisms and the molecules involved remain unclear (Cheng, Lee, Harn, Huang, & Chang, 2008).

2.2. Hibiscus cannabinus

Hibiscus cannabinus, known as kenaf, is an annual dicotyledonous herbaceous plant, well known in Asia and Africa, which has been cultivated in some Mediterranean areas. Kenaf has a long history of cultivation for its fibre by pulp and paper industries in India, Bangladesh, Thailand, parts of Africa and, to a small extent, in south eastern Europe (Moujir et al., 2007; Pappas, Tarantilis, & Polissiou, 2003).

In previous phytochemical investigations, the aliphatic composition of the bark and core were reported. In addition new lignans were identified and isolated from the core and new lignanamides were isolated, characterised and named grossamide K 1 and erythrocanabisine H 2. 2,5-Dimethyl-3-*O*-β-D-glucopyranosylnaphthol 3 was isolated and characterised as well as six other compounds from the acetone extract of the bark of kenaf (Seca et al., 2001a, 2001b). In contrast, the only previous report on the volatile leaf constituents of *H. cannabinus* concerns a biotype collected in Egypt. The authors mention the presence of 10 components, namely ethyl alcohol, isobutyl alcohol, limonene, phellandrene, R-terpenyl acetate, citral, and four unidentified components. In line with this, a group investigated the chemical composition of this essential oil: 58 components were characterised from *H. cannabinus* with (*E*)-phytol (28.2%), (*Z*)-phytol (8.02%), *n*-nonanal (5.70%), benzeneacetaldehyde (4.39%), (*E*)-2-hexenal (3.10%) and 5-methylfurfural (3.00%) as the major constituents and for which antibacterial activity was detected (Kobaisy et al., 2001). Recently, six lignans isolated from an acetone extract of the core and bark of this plant and two other compounds showed strong activity against three tumoural cell lines in several stages of cellular division (Moujir et al., 2007).

2.3. Hibiscus taiwanensis

Hibiscus taiwanensis Hu is a moderate shrub widely distributed throughout Taiwan (Wu, Wu, He, Su, & Lee, 2005). Three new phenylpropanoid esters: (7*S*,8*S*)-demethylcarolignan E, hibiscuwanin A, hibiscuwanin B and eight known phenylpropanoids: threo-carolignan E, erythro-carolignan E, cleomiscosin A, cleomiscosin C, 9,9′-*O*-feruloyl-(−)-secoisolariciresinol, dihydrodehydrodiconiferyl alcohol, boehmenan and (β)-syringaresinol have been isolated from this species (Wu et al., 2005). In the cytotoxicity evaluation of these phenyl propanoids, 9,9′-*O*-feruloyl-(β)-seco-isolariciresinol (Fig. 2) showed strong cytotoxic activity against human lung carcinoma and breast carcinoma cell lines in in vitro assays (Wu, Chuang, He, & Wu, 2004). Moreover, the crude methanolic extract has a promising cytotoxic activity against gastric and nasopharyngeal carcinoma cell lines. In addition, five new compounds, named as hibisculide A, hibisculide B, hibisculide C, hibiscutaiwanin, hibiscusin and 51 known compounds have been isolated from the stem of this species. Among them, mansonone H and uncarinic acid A inhibited HIV replication in H9 lymphocyte cells, and myriceric acid C and uncarinic acid A showed cytotoxic activity against human lung carcinoma and breast carcinoma (Wu et al., 2004).

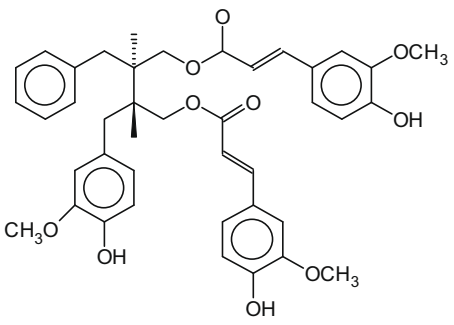

Fig. 2. The metabolite 9,9′-*O*-feruloyl-(-)secoisolariciresinol, a cytotoxic compound from *H. taiwanensis*.

2.4. Hibiscus macranthus

Hibiscus macranthus is a herbaceous plant widely distributed in tropical areas of Africa. In the western province of Cameroon, the aqueous extract from their leaf mixtures is used by tradipractioners to treat dysmenorrhoea, some cases of infertility in women and sexual weaknesses in men. Indeed, the aqueous extract from the fresh leaves was shown to increase testosteronemia in the adult male rat (Telefo, Moundipa, & Tchouanguep, 2002, 2004). Subsequently, a study evidenced the abundant presence of spermatozoa in the lumen of seminiferous tubules in rats, suggesting a useful potential of this plant in the treatment of cases of infertility due to oligospermia (Moundipa et al., 1999). Recently, Moundipa and co-workers showed that the dichloromethane and methanol extracts induced an increase in testosterone production by testes slices in vitro. However, further studies will be necessary for the isolation of androgenic bioactive components of this plant (Moundipa et al., 2005, 2006).

2.5. Hibiscus escullentus

Hibiscus escullentus L., known as lady's finger, is a very poorly studied species. The biological activity investigated in this species was the in vitro antioxidant potential. The major antioxidant molecules were identified to be quercetin derivatives and (−)-epigallocatechin (Shui & Peng, 2004).

2.6. Hibiscus vitifolius

Hibiscus vitifolius Linn is a well-adapted species in the United States of America. A new flavonol bioside from its flowers was found to exhibit significant hypoglycemic activity (Kunnumakkara et al., 2007).

2.7. Hibiscus abelmoschus

The aqueous extract of the roots of *Hibiscus abelmoschus* L. has larvicidal activity against the larvae of mosquitoes of the genera *Anopheles* and *Culex* (Dua, Pandey, Alam, & Dash, 2006). This is a useful approach to prophylaxis in countries with a high incidence of diseases transmitted by these vectors.

2.8. Hibiscus tiliaceus

Hibiscus tiliaceus L. is a common coastal plant native to Eastern and Northern Australia, Oceania and South-East Asia. The plant is also introduced as a feral species in several parts of the world including South-Western Australia and in Southern Africa. It is known by many names including hau (Hawaiian), purau (Tahitian) and "algodoeiro da praia" (Brazil) (Rosa et al., 2006). The flowers are widely used in birth control in Asian and African countries (Brondegaard, 1973). An infusion of the dried wood has been used

in folk medicine to expel the placenta and to combat postparturition disorders (Kobayashi, 1976). An aqueous extract of wood and fresh flowers has been reported to be useful to treat skin diseases (Singh, Ikahihifo, Panuve, & Slatter, 1884; Whistler, 1985). However, its chemical composition and biological and pharmacological effects are still poorly defined. Our research group has studied the biological activities of a methanolic extract of *H. tiliaceus* focusing on its antioxidant and antimutagenic effects. In preliminary work, a methanolic extract of *H. tiliaceus* flowers was studied to determine its in vivo antioxidant activity using *Saccharomyces cerevisiae* strains defective in antioxidant defense and exposed to oxidative stress induced by hydrogen peroxide and *tert*-butylhydroperoxide. The antioxidant effect verified was attributed to vitamin E and several derivatives of stigmasterol, which were identified in this extract (Rosa et al., 2006). Phytosterols present in this extract, such as stigmasterol, stigmastadienol and stigmastadienone are recognised as antioxidants and play a potential role in the chemoprevention of DNA damage in human cells induced by oxidative radicals (Wang et al., 2000).

Recently a new friedelane-type triterpene named 27-oic-3-oxo-28-friedelanoic acid and eight known triterpenoids involving five friedelane-type derivatives were isolated from the stem and bark of *H. tiliaceus* (Li et al., 2006). The knowledge of the phytochemical composition of the extracts has rapidly increased. Chen and coworkers found a new coumarin, hibiscusin and a new amide, hibiscusamide, together with 11 known compounds including vanillic acid, *p*-hydroxybenzoic acid, syringic acid, *p*-hydroxybenzaldehyde, scopoletin, *N-trans*-feruloyltyramine, *N-cis*-feruloyltyramine, a mixture of β-sitosterol and stigmasterol, a mixture of β-sitostenone and stigmasta-4,22-dien-3-one in the stem wood of this plant (Chen et al., 2006; Liu et al., 2006).

2.9. Hibiscus rosa-sinensis

Hibiscus rosa-sinensis is a glabrous shrub widely cultivated in the tropics as an ornamental plant, since it presents several forms with varying flower colours. In South Asian traditional medicine, various parts of the plant are used in the preparation of a variety of foods (Gilani, Bashir, Janbaz, & Shah, 2005). The leaves are used as a laxative, while the root is used in cough treatment. The flowers are considered to be aphrodisiac, emollient and emmenagogic and are used in bronchial catarrh, diarrhoea and fertility control (Gilani et al., 2005; Kasture, Chopde, & Deshmukh, 2000). Moreover, in India the herbal products in the market intended for hair growth include the extract of various parts of *H. rosa-sinensis* (Adhirajan, Ravi Kumar, Shanmugasundaram, & Babu, 2003).

The most ancient property studied in this species is the antifertility effect, since the benzene extract of the flowers was able to prevent pregnancy in rats (Kholkute, 1977b; Kholkute, Mudgal, & Udupa, 1977a). Other studies also show that this extract affects male fertility (Singh, Singh, & Udupa, 1882).

It is well accepted that the leaves and flowers of *H. rosa-sinensis* exhibit hair growth promoting properties in vitro and in vivo, as well as anti-greying properties, suggesting that the leaf extract could be included as a constituent in hair growth formulations (Adhirajan et al., 2003). Indeed, pharmaceutical interest in *H. rosa-sinensis* is focused on this property.

Investigations of the pharmacological properties have shown interesting effects. The ethanolic extract and acetone insoluble fractions exhibited anticonvulsant activity in pentylenetetrazol- and maximum electroshock-induced convulsion models, but failed to protect animals from strychnine-induced seizures. However, in lower doses these fractions produced signs of depression such as reduced locomotion and rearing, passivity, prostration, decreased muscle strength and diminished response to touch and noise (Kasture et al., 2000). This interesting finding suggests that the anticonvulsant action of the fractions is mediated by the chloride channel of GABA-benzodiazepine receptor complex, not by the chloride channel of glycine receptors.

The flowers of *H. rosa-sinensis*, have been reported in the ancient Indian medicinal literature to have beneficial effects in heart diseases, mainly in ischemic disease (Gauthaman et al., 2006). The mechanisms of the cardioprotective effect are controversial; in this respect, a study showed for the first time that the flower extract could enhance myocardial endogenous antioxidants by an adaptative response, without producing any cytotoxic effects. Therefore, the protection against myocardial ischemic reperfusion injury in the treated rats is attributed to enhanced endogenous antioxidant activity of this plant extract (Gauthaman et al., 2006).

In view of the traditional uses of *H. rosa-sinensis* in constipation and diarrhoea, the crude extract of aerial parts, and its subsequent fractions, were tested on isolated intestinal preparations to provide a pharmacological basis for their use in gut motility disorders. This study clearly shows the presence of two components (cholinomimetic and calcium antagonist) in the crude extract of aerial parts. The cholinomimetic activity is likely to play role as a mild laxative and provides a mechanistic basis for the possible use of the plant for constipation, while the calcium antagonistic activity provides pharmacological rationale for its use in diarrhoea (Gilani et al., 2005).

Studies have demonstrated the anti-diabetic activity of *H. rosa-sinensis* in rural populations and similar results were obtained with the leaf extract after repeated dosing in hyperglycemic rats (Sachdewa & Khemani, 1999; Sachdewa, Raina, Srivastava, & Khemani, 2001). In an elegant study using streptozotocin-induced diabetic rats, a comparable hypoglycemic effect was demonstrated after 7 and 21 days of oral administration of either the extract or glibenclamide. Besides, the extract lowered the total cholesterol and serum triglycerides and increased the HDL-cholesterol to a greater extent as compared to glibenclamide. In this manner, the hypoglycemic activity of this extract is comparable to that of glibenclamide, but is not mediated through insulin release, increasing the potential use of this species for human health purposes (Sachdewa & Khemani, 2003).

There is very important evidence of the anticancer action of this extract against the effect of benzoyl peroxide and ultraviolet radiation in mouse skin by means of antioxidant protection, decreasing the ornithine descarboxylase activity and thymidine incorporation in DNA. In this manner, *H. rosa-sinensis* extract exerts a protective effect against the tumour promotion stage of cancer development (Sharma, Khan, & Sultana, 2004b; Sharma & Sultana, 2004a).

Phytochemical studies revealed the presence of several chemicals, including flavonoids, flavonoid glycosides, hibiscetin, cyanidine, cyanidin glucosides, taraxeryl acetate, β-sitosterol, campesterol, stigmasterol, ergosterol, citric, tartaric and oxalic acids, cyclopropenoids and anthocyanin pigments (Ajay, Chai, Mustafa, Gilani, & Mustafa, 2007; Gauthaman et al., 2006; Gilani et al., 2005; Sachdewa & Khemani, 1999, 2003).

2.10. Hibiscus sabdariffa

H. sabdariffa L., an attractive plant, believed to be native to Africa, is cultivated in tropical areas as Sudan, Eastern Taiwan, and in Thailand (Chang, Huang, Hsu, Yang, & Wang, 2005; Hirunpanich et al., 2005; Lin, Chen, Kuo, & Wang, 2007). This is an annual herb that grows to 180 cm or more; stems are globular, while the lower leaves are ovate with the upper leaves being 3–5 palmately lobed. The flowers are auxiliary or in terminal racemes, the petals are white with a reddish centre at the base of the staminal column, the calyx enlarges at maturity and the fruit is fleshy and bright red. It is known as roselle (English), l'Oiselle (French), Spanish (Jamaica), karkade (Arabic), Krachiap daeng (in Thailand) and bissap

(Wolof). The calyces are used to make cold and hot beverages in many of the world's tropical and sub-tropical countries. The average consumption of these beverages in Nigeria is 150–180 mg/kg per day. Calyces are used in the West Indies to colour and flavour rum and the seeds have been used as an aphrodisiac coffee substitute. In addition, its fruits are edible too (Ali, Al Wabel, & Blunden, 2005).

The red persistent calyx of its flowers is the major component which has a sour taste and is commonly used in the preparation of cold and hot beverages and as a food colourant. Recently, it has gained an important position in the local soft drink market and commercial preparations of *H. sabdariffa* extract (HSE) are currently marketed as supplements due to their perceived potential health benefits (Ali et al., 2005). It is claimed to be a Thai traditional medicine for kidney and urinary bladder stones. It is also used as an antibacterial, antifungal, hypocholesterolemic, antispasmodic, diuretic, uricosuric, mild laxative, antihypertensive substance, against inflammation, mutagenicity and as an immune modulating compound (Ali, Salih, Mohamed, & Homeida, 1991; Chen et al., 2003; Dafallah & Al-Mustafa, 1996; Farombi & Fakoya, 2005).

The calyx and flowers of roselle have been known to contain many chemical constituents such as alkaloids, ascorbic acid, β-carotene, anisaldehyde, arachidic acid, citric acid, malic acid, tartaric acid, glycinebetaine, trigonelline, anthocyanins as cyanidin-3-rutinoside, delphinidin, delphinidin-3-glucoxyloside (also known as hibiscin, the major anthocyanin in *H. sabdariffa* flowers, Fig. 3), delphinidin-3-monoglucoside, cyanidin-3-monoglucoside, cyanidin-3-sambubioside, cyanidin-3,5-diglucoside; the flavonol glycosides hibiscetin-3-monoglucoside, gossypetin-3-glucoside, gossypetin-7-glucoside, gossypetin-8-glucoside and sabdaritrin; quercetin, protocatechuic acid, pectin, polysaccharides, mucopolysaccharides, stearic acid and wax (Hirunpanich et al., 2005). In the seed oil, the presence of campasterol, stigmasterol, ergosterol, β-sitosterol and α-spinasterol has been reported. The petals yielded 65% (dry weight) of mucilage, which on hydrolysis gave galactose, galacturonic acid and rhamnose. These molecules are bioactive in several biological models and responsible by the pharmacological effects presented by the extracts of this species. Various antioxidant constituents are found in the calyx and flower petals of roselle, such as *Hibiscus* anthocyanins, quercetin, ascorbic acid, steroid glycosides (such as β-sitosteroid glycoside) and protocatechuic acid (Tseng et al., 1997). Furthermore, HSE contained polyphenolic acids (1.7% dry weight), flavonoids (1.43% dry weight) and anthocyanins (2.5% dry weight) (Tsuda, Horio, & Osawa, 2000a; Tsuda, Shiga, Ohshima, Kawakishi, & Osawa, 1996).

Phenolic compounds are ubiquitous in vegetables, fruit and nuts, and several of them have been reported to be inhibitors of chemical carcinogenesis due to their antioxidant properties (Stich, 1991; Wattenberg, 1985). *Hibiscus* anthocyanins (HAs) (Kamei et al., 2003) are water-soluble and among the most important groups of plant pigments which significantly reduced oxidative stress induced by *tert*-butylhydroperoxide in rat hepatocytes, in vitro and in vivo. This is an important model for liver injury. They also significantly reduced the activities of the serum enzymes indicative of liver damage and ameliorated histological lesions (Chang, Huang, Huang, Ho, & Wang, 2006; Suboh, Bilto, & Aburjai, 2004; Wang et al., 2000). Similar dosages of HAs were effective in mitigating the toxicity induced by paracetamol in mice (Ali, Mousa, & El-Mougy, 2003).

Furthermore, anthocyanins not only possess antioxidant ability, but also mediate other physiological functions related to cancer suppression, which has roused increasing interest concerning the pharmaceutical function of these pigments (Kamei et al., 2003; Meiers et al., 2001; Pool-Zobel, Bub, Schroder, & Rechkemmer, 1999; Tsuda, Kato, & Osawa, 2000b). HAs have demonstrated an anti-tumour effect in HL-60 cells. The molecular mechanism underlying this effect could be described as the induction of apoptosis via activation of the p38 MAP kinase that subsequently phosphorylates the target protein c-jun and trigger the signal to further activate the apoptotic protein cascades that contain Fas-mediated signaling. As an outcome, cytochrome *c* is released from the mitochondria, leading to the cleavage of caspase-3 (Chang et al., 2005). In view of this, HAs were considered the major components of the antitumoural effect of HSE in human gastric adenocarcinoma and in promyelocytic cells in vitro, reflecting the chemopreventive potential of HSE (Lin, Chen, Kuo, & Wang, 2007).

Hibiscus protocatechuic acid (PCA) (Fig. 3) has been demonstrated to be an efficacious agent in inhibiting the carcinogenic action of various chemicals in different tissues, such as diethylnitrosamine in the liver, 4-nitroquinoline-1-oxide in the oral cavity, azoxymethane in the colon, *N*-methyl-*N*-nitrosourea in glandular stomach tissue and *N*-butyl-*N*-(4-hydroxybutyl)nitrosamine in the bladder, in murine models (Hirose et al., 1995; Tanaka, Kojima, Kawamori, & Mori, 1995; Tseng et al., 1998). PCA also shows mild cytotoxicity to PC14 and MKN45 human tumour cell lines and induces apoptosis in human leukaemia HL-60 cells by means of the reduction of retinoblastoma protein phosphorylation and Bcl-2 expression (Tseng et al., 2000). Thus, PCA possesses strong antioxidant and antitumour promotion effects and may play a role in dietary chemoprevention (Chewonarin et al., 1999; Hirose et al., 1995; Kawamori et al., 1994; Tseng et al., 1998). In addition, it has been reported that the topical application of PCA inhibited the 12-*O*-tetradecanoylphorbol-13-acetate-induced tumour promotion in the skin of mice initiated with benzo[*a*]pyrene. Moreover, it has strong potential in inhibiting LDL oxidation induced by copper or a nitric oxide donor, besides the protection against cytotoxicity and genotoxicity of *tert*-butylhydroperoxide in a primary culture of rat hepatocytes and in rat liver. This indicates that this antioxidative potential can be involved in the beneficial effects of HSE (Hirunpanich et al., 2005; Lee et al., 2002). Furthermore, PCA also inhibits lipopolysaccharide-induced rat hepatic damage (Lin et al., 2003).

Due to its chemical composition, HSE presents antioxidative potential and useful pharmacodynamic actions in diseases caused by oxidative stress, as cancer and cardiovascular pathologies. In vitro, the ethyl acetate fraction of the ethanol extract showed a strong ability to scavenge free radicals in the assay of quenching the 1,1-diphenyl-2-picrylhydrazyl radical, whereas the chloroform fraction showed the strongest inhibitory effect in the assay of xantine oxidase inhibition. Both fractions presented strong antioxidant potential in the model of *tert*-butylhydroperoxide-induced oxidative damage in the primary cultures of rat hepatocytes. In addition, HSE exerted its hepatoprotective activity against hepatic fibrosis induced by carbon tetrachloride exposure in rats with the participation, at least in part, of the antioxidant activity of protocatechuic

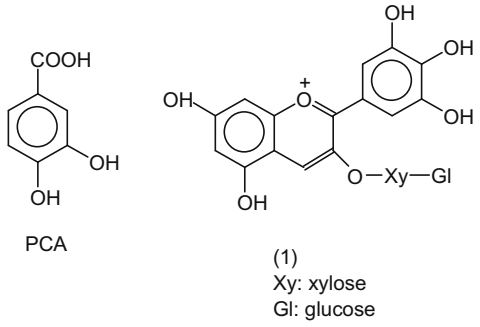

Fig. 3. Structure of delphinidin-3-glucoxyloside (1), the major anthocyanin from *H. sabdariffa* flowers, and protocatechuic acid (PCA).

acid and anthocyanins (Liu et al., 2006; Tseng, Wang, Kao, & Chu, 1996). Besides, some antioxidants such as L-ascorbic acid, vitamin E or garlic acid may play an important role in this effect (Sheweita, El-Gabar, & Bastawy, 2001). Recently, the pretreatment of rats with HSE reduced significantly the hepatotoxicity of cadmium. The extract also protected the rats against cadmium-induced liver, prostate, and testis lipoperoxidation. In this manner, the antioxidant ability of the aqueous extract can be used in cadmium poisoning (Asagba, Adaikpoh, Kadiri, & Obi, 2007). Interestingly, HSE reduced the extent of cisplatin-induced sperm abnormality and enhanced sperm motility through its antioxidant capacity, increasing the activities of testicular antioxidant enzymes, showing a possible employment of this plant in the treatment of fertility disorders (Amin & Hamza, 2006). In addition, the methanolic extracts of leaves of this species has radioprotective efficacy against gamma radiation-induced liver damage in rats, by stimulating the increase in hepatic superoxide dismutase production.

Two fractions of the ethanolic extract, the chloroform soluble fraction and ethyl acetate soluble fraction orally administered to mice simultaneously with intraperitoneal injection of ferrous chloride – ascorbic acid – ADP mixture reduced the formation of malondialdehyde content in rats and significantly inhibited the induction of micronucleated polychromatic erythrocytes by sodium arsenite showing that the antioxidant properties of this plant contribute to its antimutagenic potential (Adetutu et al., 2004; Farombi & Fakoya, 2005). The ethanolic extract of this species was also effective in decreasing the mutagenecity induced by heterocyclic amines in the *Salmonella* microsome assay and inhibits the formation of colon cancer at the initiation stage. Recently, the aqueous, ethyl acetate and chloroform extracts of the leaves of this species inhibited the mutagenicity induced by 1-nitropyrene in HeLa cells in a dose- response manner and showed an antiproliferative effect in these cells (Olvera et al., 2008).

The ancient use of *H. sabdariffa*, the best-studied species in this genus, is related to cardiovascular diseases (Ajay et al., 2007; Ali, Al Wabel, & Blunden, 2005). In this sense, several studies evaluated the anti-hypertensive effects of HSE in several biological models. The intravenous injection of HSE to anaesthetized cats and rats lowered the blood pressure in a dose-dependent manner, which was partially blocked by atropine and antihistamine H1 blockers, though the sectioning of the left and right vagi nerves did not have a significant effect on the fall in mean arterial blood pressure (Adegunloye et al., 1996; Ali et al., 1991). Recent pharmacological reports have shown that HSE significantly reduced blood pressure in humans and in experimental animals; in addition, the chronic administration of HSE decreased blood pressure and reduced cardiac hypertrophy in the 2-kidney-1-clip (2K-1C) rat model of hypertension and inhibited vascular tone in isolated vascular preparations including the rat thoracic aorta (Adegunloye et al., 1996; Ajay et al., 2007; Onyenekwe, Ajani, Ameh, & Gamaniel, 1999). However, the exact mechanisms responsible for these effects are not fully understood. In view of this, the possibility that HSE could produce a direct vasorelaxant effect was investigated: the methanolic extract of calyces induced a vasodilator effect in isolated aortas from spontaneously hypertensive rats via endothelium-dependent and -independent vasodilator pathways. The endothelium-dependent vasodilator component results from the activation of the endothelium-derived nitric oxide/cGMP-relaxant pathway, whereas the endothelium-independent component could be due to inhibition of calcium influx (Ajay et al., 2007). Thus, these findings provided rational evidence for the traditional use of the plant as an antihypertensive agent.

The first single trial involved 54 patients with moderate essential hypertension and it reported that the daily consumption of an aqueous extract resulted in a decrease of about 11% in blood pressure 12 days after the beginning of the treatment. In this study, 3

days after cessation of the treatment, the blood pressure rose again by about 6–8% (Haji-Faraji & Haji-Tarkhani, 1999). In 2004, a clinical trial involving 39 patients that were receiving HSE and 36 hypertensive patients that were treated with captopril shows that HSE was as effective and safe in the reduction of blood pressure as captopril was (Herrera-Arellano, Flores-Romero, Chavez-Soto, & Tortoriello, 2004). A recent study confirmed the anti-hypertensive effect using watery infusions, in which a natriuretic effect was also evidenced, in a randomized, controlled, and double-blind clinical trial. The results showed that the experimental treatment decreased blood pressure with therapeutic effectiveness of 65.1% as well as tolerability and safety of 100%. Under the experimental treatment, the serum chlorine level increased, the sodium level showed a tendency to decrease, while the potassium level was not modified. The possible mechanism underlying this effect could be the inhibition of angiotensin I converting enzyme, since its activity decreased in the plasma of treated patients.

Currently, the dried calyx extracts of this species are commercially prepared as health food products available in the form of granules and as tea, and are claimed to be diuretic, antihypertensive and mainly as hypolipidemic. However, the scientific data in respect of hypolipidemic efficacy of these extracts are relatively recent. In 1991, rats with hypercholesterolaemia were fed with HSE for 9 weeks and the treatment progressively lowered the different lipid fractions in plasma, heart, brain, kidney and liver. However, this treatment slightly raised the content of plasma phospholipids (El-Saadany, Sitohy, Labib, & El-Massry, 1991). In the study of Chen and co-workers, in 2003, the administration of HSE to rabbits which had been fed cholesterol for 10 weeks reduced the serum levels of triglycerides, total cholesterol and LDL, and mitigated atherosclerosis in the aorta. Moreover, it slightly decreased the susceptibility of LDL to oxidation induced by copper sulphate ex vivo and the rate of formation of conjugated dienes. Since phytoconstituents compounds such as β-sitosterol and pectin have been reported to possess a hypocholesterolemic effect in vivo, it may be speculated that the hypolipidemic effects are attributed to these compounds (Hirunpanich et al., 2006).

Many investigations highlight an additional role of polyphenolic acids, flavonoids, and anthocyanins, which may act as antioxidants or via other mechanisms, enhancing the cardioprotective actions (Hirunpanich et al., 2006; Rimm & Stampfer, 2000). This potent dose-dependent antioxidant effect in the protection of LDL oxidation induced by copper sulphate in vitro was demonstrated some years ago and stimulated the investigation of the antioxidant effect in vivo, as well as the determination of the active compounds and the correlation with the antiatherosclerotic effects (Hirunpanich et al., 2005). In some previous studies, HAs and PCA showed remarkable antioxidative activity and are able to inhibit LDL oxidation and lipid peroxidation in vitro (Wang et al., 2000). Therefore, dietary HSE may reduce the incidence of heart disease, such as atherosclerosis, through their antioxidant activity.

According to the oxidative hypothesis of atherosclerosis, LDL entrapped in the subendoethelial space of lesion-prone arterial sites is slowly oxidised through the action of resident vascular cells. In this manner, oxidation of LDL in the arterial wall is thought to be a very important step in atherogenesis. In this respect, HSE inhibits oxidation of LDL in the arterial wall, thereby exerting an antiatherosclerotic action, as observed in hystopatological and immunohistochemical analysis (Chen et al., 2003). It has been demonstrated that many antioxidants inhibit the development of atherosclerotic lesions in rabbits fed with high cholesterol diet through the prevention of LDL oxidation. In this manner, there is considerable interest in the cardioprotective potential of HSE in lowering the incidence of atherosclerosis and coronary heart disease.

Recently, new pharmacodynamic activities on this plant have been reported, as immunomodulatory effect of the ethanolic extracts of dried calyx in mouse (Falceve, Pal, Bawankule, & Khanuja, 2008) and anticandidal activity. Moreover, the extract of this plant inhibited the rat bladder and uterine contractility in a dose-dependent manner via a mechanism unrelated to local or remote autonomic receptors or calcium channels (Prasongwatana, Woottisin, Sriboonlue, & Kukorgvirivapan, 2008).

3. Concluding remarks

The main biological findings and the known phytochemical composition of the *Hibiscus* genus are summarised in Table 1. The studies conducted to date have demonstrated that the plants of the *Hibiscus* genus have the potential to provide biologically active compounds that act as antioxidants, as well as being cardioprotective, and that are able to deter the proliferation of malignant cells. Thus, the *Hibiscus* genus deserves additional evaluation as a provider of chemopreventive agents. Indeed, there is a current need for availability of new plant-derived bioactive molecules; thus *Hibiscus* sp. may be a great natural source for the development of new drugs and may provide a cost-effective mean of treating cancers and other diseases in the developing world.

Polyphenol oxidase
Anthocyanin

ABSTRACT

Anthocyanins are natural pigments responsible for red, purple, and blue colouration in plants. Human consumption of anthocyanins is increasing because of the rising awareness and interest in their potential health benefits. Pomegranate is one of the major sources of polyphenolic phytochemicals, such as anthocyanins. Dried pomegranate raisins (*anardana*) are consumed in large quantities in Asian countries, and contain substantial amounts of anthocyanins. Five anthocyanins were found to be present in pomegranate raisins. Drying adversely affected the amount of anthocyanins, with polyphenol oxidase (PPO) playing a possible role in oxidative degradation of anthocyanins. Anthocyanins are heat-stable compounds, and inactivation of PPO by processing at high temperature for short periods may prevent PPO-catalysed anthocyanin oxidation in pomegranate arils. Pomegranate PPO kinetics were partially characterised by investigating the effect of substrate (catechol) concentration; optimum pH for PPO activity was found to be 6.0.

1. Introduction

Anthocyanins are the largest and most important group of water-soluble pigments in nature. In plant tissues, they are responsible for producing red, purple, blue, and intermediate hues, depending upon the vacuolar pH and the presence of copigments (Brouillard, Figueiredo, Elhabiri, & Dangles, 1997; Clifford, 2000; Rapeanu, Loey, Smout, & Hendrickx, 2006). Anthocyanins are of considerable importance in the co-evolution of plant–animal interactions, as they contribute to the colourful appearance of flowers, fruits and vegetables, helping them to attract animals, leading to seed dispersal and pollination (Kong, Chia, Goh, Chia, & Brouillard, 2003). Anthocyanin stability is influenced by various factors such as temperature, pH, light, and oxygen. Anthocyanins also may be susceptible to degradation by oxidising enzymes.

Polyphenol oxidases (PPOs), or tyrosinases, are nuclear-coded enzymes with a dinuclear copper centre, which are able to insert oxygen in a position *ortho* to an existing hydroxyl group in an aromatic ring, followed by the oxidation of the diphenol to the corresponding quinone. These *o*-quinone intermediates are highly reactive and quickly polymerise to dark-coloured melanins (Rapeanu et al., 2006). PPO is widely distributed in animals, plants, fungi, and bacteria and plays an important role in various physiological and defence reactions (Mayer, 2006). PPO is inducible by both biotic and abiotic stresses, and is implicated in several physiological processes, including photoreduction of molecular oxygen by photosystem I (PSI), regulation of plastidic oxygen levels, aurone biosynthesis, and the phenylpropanoid pathway (Thipyapong, Stout, & Attajarusit, 2007).

The pomegranate (*Punica granatum* L.), from the Latin words *pomus* and *granatus*, meaning a seeded or granular apple, is native from Iran to the Himalayas in northern India, where it has been cultivated for thousands of years. There are over 1000 cultivars of *Punica granatum* (Levin, 1994) that are grown from Iran, eastward to China and India and westward through the Mediterranean region, on to the American Southwest, California and Mexico (Lansky & Newman, 2007). There has been a virtual explosion of interest in pomegranate as a medicinal and nutritional product because of its multifunctionality, and, as a result, the field of pomegranate research has experienced tremendous growth in the past decade. Polyphenols are the major class of pomegranate fruit phytochemicals, including flavonoids (anthocyanins), condensed tannins (proanthocyanidins) and hydrolysable tannins (ellagitannins and gallotannins) (Gil, Tomas-Barberan, Hess-Pierce, Holcroft, & Kader, 2000; Hernandez, Melgarejo, Tomas-Barberan, & Artes, 1999; Santagati, Duro, & Duro, 1984). Pomegranate juice may provide protection against cardiovascular diseases and stroke, by acting as a potent antioxidant against LDL oxidation and inhibition of atherosclerosis development (Aviram et al., 2002a, 2002b). Pomegranate

doi:10.1016/j.foodchem.2009.01.095

phytochemicals also show potential in chemoprevention of various types of cancers, by exerting antiproliferative effects on tumour cells (Kim et al., 2002; Shishodia, Adams, Bhatt, & Aggarwal, 2006).

Pomegranates are popularly consumed as fresh fruit, beverages (juice and wine) and other food products (jams and jellies). The presence of anthocyanins is responsible for the appealing bright red colour of juice and other products of pomegranate fruit. Pomegranate raisins (*anardana*) are dried arils of wild pomegranates that are manually separated from the rind and septa of the fruit and sun- or air-dried. Pomegranate raisins have a distinct sour or tart flavour, and are commercially available in many West and East Asian countries, where they are consumed in large quantities. The raisins are also used in the ayurvedic system of medicine, and are claimed to be digestive and stomachic (Pruthi & Saxena, 1984; Singh, Kingly, & Jain, 2007). Pomegranate juice, which is prepared by hydrostatic pressing of whole fruits, has been found to contain more than 26 different chemical compounds, whereas the seeds contain various fatty acids and steroidal compounds (Seeram, Zhang, Reed, Krueger, & Vaya, 2006). The aril (the seed and surrounding flesh) contains anthocyanins, which might be affected by the severity of the drying process employed for the raisin preparation.

Scarce information exists on the chemical constituents of *anardana*. This study was designed to evaluate the effect of drying on pomegranate aril anthocyanins and to investigate the role of PPO in aril anthocyanin oxidation.

2. Materials and methods

2.1. Plant material

Fresh pomegranates (*P. granatum* L. cv. Wonderful) were supplied by POM Wonderful company (Del Rey, CA). Arils were separated manually and kept in dark and cold (−80 °C) storage until analysed. Pomegranate raisins (*anardana*) were purchased from Deep Foods, Inc. (Union, NJ).

2.2. Chemicals

Cyanidin 3-glucoside (kuromanin chloride) standard for HPLC analysis, catechol, trifluoroacetic acid (TFA), acetone, acetonitrile, ethyl acetate, hexane, and methanol were purchased from Sigma–Aldrich (St. Louis, MO). Unless stated otherwise, all solvents were HPLC-grade. Diaion HP-20SS resin was purchased from Supelco (Bellefonte, PA). Triton X-100 was purchased from Bio-Rad (Richmond, CA).

2.3. Preparation of pomegranate raisins (anardana)

Commercially available *anardana* contains 2.7% moisture, whereas fresh pomegranate arils contain about 78.7% moisture. One batch of fresh pomegranate arils was dried in a cabinet dryer at 90 °C for 90 min, followed by 70 °C for 2 h, and finally 50 °C for an additional 9 h to remove the required 76% moisture. This drying regime was used following a variety of drying methods at various temperatures to achieve material that was similar to the commercial product. A second batch of fresh pomegranate arils was sun-dried in shallow trays in the summer months in the USP research greenhouse; the average temperature was 32–43 °C. The drying was continued until the arils lost the required 76% moisture.

2.4. Anthocyanin isolation and purification

Fresh and dried pomegranate arils were extracted exhaustively by maceration with acidic methanol (1:10, w/v) containing 1% 0.1 M HCl over 24 h at room temperature. The extract was filtered through a sintered glass funnel and concentrated *in vacuo* at 37 °C. The extract was partitioned sequentially with hexane and ethyl acetate, and the aqueous fraction containing the anthocyanins was lyophilised. Removal of other water-soluble constituents, such as sugars and ascorbic acid, was accomplished by chromatography over Diaion HP-20SS resin (Einbond, Reynertson, Luo, Basile, & Kennelly, 2004). The lyophilised, semi-purified anthocyanin extract was resuspended in 25 ml water, applied to the Diaion HP-20SS resin column (60 cm × 5 cm ID, 120 g) and allowed to adsorb for 20 min. The column was sequentially eluted with 500 ml water to remove sugars and then with 300 ml acidic methanol containing 0.1% 0.1 M HCl to elute all of the anthocyanins. Finally, the column was washed clean with 300 ml methanol:acetone (1:1) mixture. The methanol fraction containing anthocyanins was concentrated *in vacuo* at 37 °C and lyophilised.

2.5. Anthocyanin analysis by quantitative HPLC and LC–MS

Quantitative HPLC analysis was conducted on an Agilent 1100 HPLC system (Agilent Technologies, Santa Clara, CA) consisting of a low pressure quaternary pump, an autosampler and a photodiode array detector controlled by Agilent ChemStation [Rev. B. 01.03(204)] software. LC–MS analysis was conducted on a Shimadzu liquid chromatograph–mass spectrometer (Shimadzu, Columbia, MD), consisting of a dual-plunger parallel-flow solvent delivery module (LC-20AD), an autosampler (SIL-20AC), and a single-stage quadrupole mass analyser (LCMS-2010EV) monitored by LCMSsolution (ver.3.30) software (Shimadzu). The anthocyanin separation was done on a Zorbax SB-C8 column (4.6 mm ID × 75 mm, 3.5 μm) (Agilent). Anthocyanin samples were dissolved in HPLC-grade water containing 0.1% TFA and filtered through a 0.45 μm nylon filter (Fisher Scientific, Pittsburgh, PA) prior to the analysis. The binary mobile phase consisted of solvents **A**, 0.1% TFA in water, and **B**, acetonitrile acidified with 0.1% TFA. The gradient method was 0–10 min, 13–20% **B**; 10–18 min, 20–40% **B**; 18–21 min, 40% **B**; and post-run time of 5 min with 13% **B**. Solvent flow rate was 0.2 ml/min, and the sample injection volume was 10 μl. Detection was at 520 nm. The amounts of individual and total anthocyanins in samples extracted from fresh, oven-dried, and sun-dried pomegranate arils were quantified using a cyanidin 3-glucoside standard calibration curve ($r^2 \geqslant 0.99$).

2.6. Heat stability of anthocyanin

Cyanidin 3-glucoside was dissolved in distilled water at a concentration of 0.01 mg/ml. Two samples of 1 ml each were transferred into 5 ml glass vials. Air was replaced with nitrogen in one vial, and both vials were capped and sealed immediately. These samples were subjected to heat treatment as mentioned in the drying protocol for pomegranate raisins, i.e. heated in a cabinet dryer at 90 °C for 90 min, followed by 70 °C for 2 h, and finally at 50 °C for 9 h. The samples were cooled and analysed by HPLC to determine the amount of cyanidin 3-glucoside degraded by heat treatment. The results were compared to a freshly prepared 0.01 mg/ml standard sample.

2.7. Polyphenol oxidase enzyme extraction

Polyphenol oxidase enzyme extract was prepared following a modification of the procedure described by Coseteng and Lee (1987). Fresh and dried pomegranate arils (30 g each) were homogenised for 2 min in a prechilled blender with 50 ml ice-cold 0.1 M potassium phosphate buffer, pH 7.2, containing 1% Triton X-100. The homogenate was filtered through a sintered glass funnel and centrifuged (2 °C, 5000*g*) for 15 min in a Sorvall RC-5B+

centrifuge (Thermo Fisher Scientific, Inc. Waltham, MA). The supernatant was decanted and used as a crude enzyme preparation in the PPO activity assay.

2.8. PPO activity assay

The PPO activity was determined by measuring the initial rate of increase in absorbance at 420 nm as described by Gonzalez, de Ancos, and Cano (1999). The activity was assayed in 3 ml of reaction mixture consisting of 2.5 ml potassium phosphate buffer (pH 6.0), 0.3 ml substrate (0.5 M catechol) and 0.2 ml crude enzyme. The blank consisted of 3.0 ml potassium phosphate buffer (pH 6.0). The first control cuvette contained 2.7 ml buffer solution and 0.3 ml substrate, whereas the second control cuvette contained 2.8 ml buffer and 0.2 ml enzyme preparation. Absorbance values of these controls were subtracted from that of the sample. The enzyme activity was defined as the change in absorbance of 0.001 per min per ml enzyme.

2.9. Optimum pH for PPO activity

The effect of pH on pomegranate PPO activity was determined by catechol oxidation in 0.1 M sodium acetate buffer (pH 5.0 and 5.5) and 0.1 M potassium phosphate buffer (pH 6.0, 6.5, 7.0, 7.5, and 8.0). The sample cuvette contained 2.5 ml buffer solution (pH 5–8), 0.3 ml substrate and 0.2 ml enzyme.

2.10. Effect of boiling on PPO activity

PPO was extracted from fresh pomegranate arils and divided into two parts. The first sample was boiled for 2 min at 100 °C, and the PPO activity was determined using catechol as a substrate. The activity of boiled aril PPO was compared to that of untreated PPO from the second sample.

2.11. PPO kinetics: the Michaelis–Menten constant

Seven catechol solutions varying in concentration from 0.1 to 0.9 M were prepared, and the effect of substrate concentration on pomegranate PPO activity was investigated to partially characterise the enzyme kinetics. The sample cuvette contained 0.3 ml substrate (0.1–0.9 M catechol), 2.5 ml 0.1 M potassium phosphate buffer, pH 6.0, and 0.2 ml undiluted enzyme preparation. The Michaelis–Menten constant (K_m) and maximum velocity (V_{max}) were calculated from a double reciprocal plot of 1/velocity *vs.* 1/substrate concentration by the method of Lineweaver and Burk (1934). The reaction velocity was defined as change in optical density (ΔOD) of reaction mixture per min per ml of enzyme.

2.12. Effect of drying on anthocyanins and PPO activity

Anthocyanins were extracted from fresh, oven-dried and sun-dried pomegranate arils and quantified by HPLC using the cyanidin 3-glucoside standard calibration curve. The PPO was extracted from fresh, oven-dried and sun-dried pomegranate arils and activity determined by catechol oxidation assay.

2.13. Effect of boiling on anthocyanins and PPO activity

Two 25 g samples of fresh, frozen pomegranate arils were placed in glass bottles and immersed in an oil-bath at 100 °C. It took 14 min to bring the frozen arils (−80 °C) to 100 °C. The samples were maintained at 100 °C for 2 min (total 16 min). Anthocyanins were extracted from the first sample and quantified by HPLC using the cyanidin 3-glucoside standard calibration curve. PPO activity was determined in the second sample by the catechol oxidation assay. The results were compared to total anthocyanins and PPO activity of 25 g samples of fresh, untreated arils, extracted simultaneously.

2.14. Data analysis

Values are averages of three determinations. The results were analysed for variation (ANOVA) and statistical significance by *t*-test. Error bars shown in figures are standard deviations of the values.

3. Results and discussion

3.1. Anthocyanin analysis by quantitative HPLC and LC–MS

We determined the presence of anthocyanins delphinidin 3,5-diglucoside (*m/z* 627), cyanidin 3,5-diglucoside (*m/z* 611), delphinidin 3-glucoside (*m/z* 465), cyanidin 3-glucoside (*m/z* 449) and pelargonidin 3-glucoside (*m/z* 433) by LC–MS analysis (Fig. 1: peaks 1–5). These anthocyanins have been reported previously to be present in pomegranates (Hernandez et al., 1999; Santagati et al., 1984). The mass spectrum showed the presence of the molecular ion for the respective anthocyanin along with that of its aglycone. Depending on the variety of the pomegranates, the amount of total anthocyanins varies from 35 to 350 mg/kg fresh weight of arils (Hernandez et al., 1999). Quantitative HPLC analysis indicated that arils of the fresh pomegranates of Wonderful variety contained 250 mg/kg anthocyanins.

3.2. Heat stability of anthocyanin

The cyanidin 3-glucoside sample maintained under nitrogen showed only a small degradation that was not statistically different from the control of freshly prepared cyanidin 3-glucoside standard sample (Fig. 2). There was about 65% loss of cyanidin 3-glucoside in the sample maintained under air, signifying the role of oxygen in anthocyanin degradation. Pure anthocyanins were stable at high temperatures in the absence of oxygen, but they quickly degraded in the presence of oxygen.

3.3. Optimum pH for PPO activity

Depending upon the enzyme source and substrate, the optimum pH for browning reactions catalysed by PPO is between pH 4.0 and pH 7.0 (Severini, Baiano, De Pilli, Romaniello, & Derossi, 2003). The effect of pH on PPO activity was investigated using catechol as a substrate in the pH 5.0–8.0 range (Fig. 3). The optimum pH for pomegranate PPO activity was found to be about pH 6.0. The PPO activity decreased rapidly at pH below or above this optimum.

3.4. Effect of boiling on PPO activity

There was about a 73% decrease in activity when the PPO extract was boiled. PPO is relatively heat-labile, and temperatures above 50 °C for sufficient time result in a decrease of activity (Vámos-Vigyázó, 1981). In fact, the heat inactivation of PPO by blanching treatment is the most common method of preventing the browning reaction in fruits and vegetables (Chen, Collins, McCarty, & Johnston, 1971). However, PPO heat resistance depends on the species and cultivar of the plant from which it is extracted. The ability of the PPO assay to measure this decrease in activity indicates, to some degree, that the assay is capable of distinguishing the enzyme reaction from any chemical reactions that may be present.

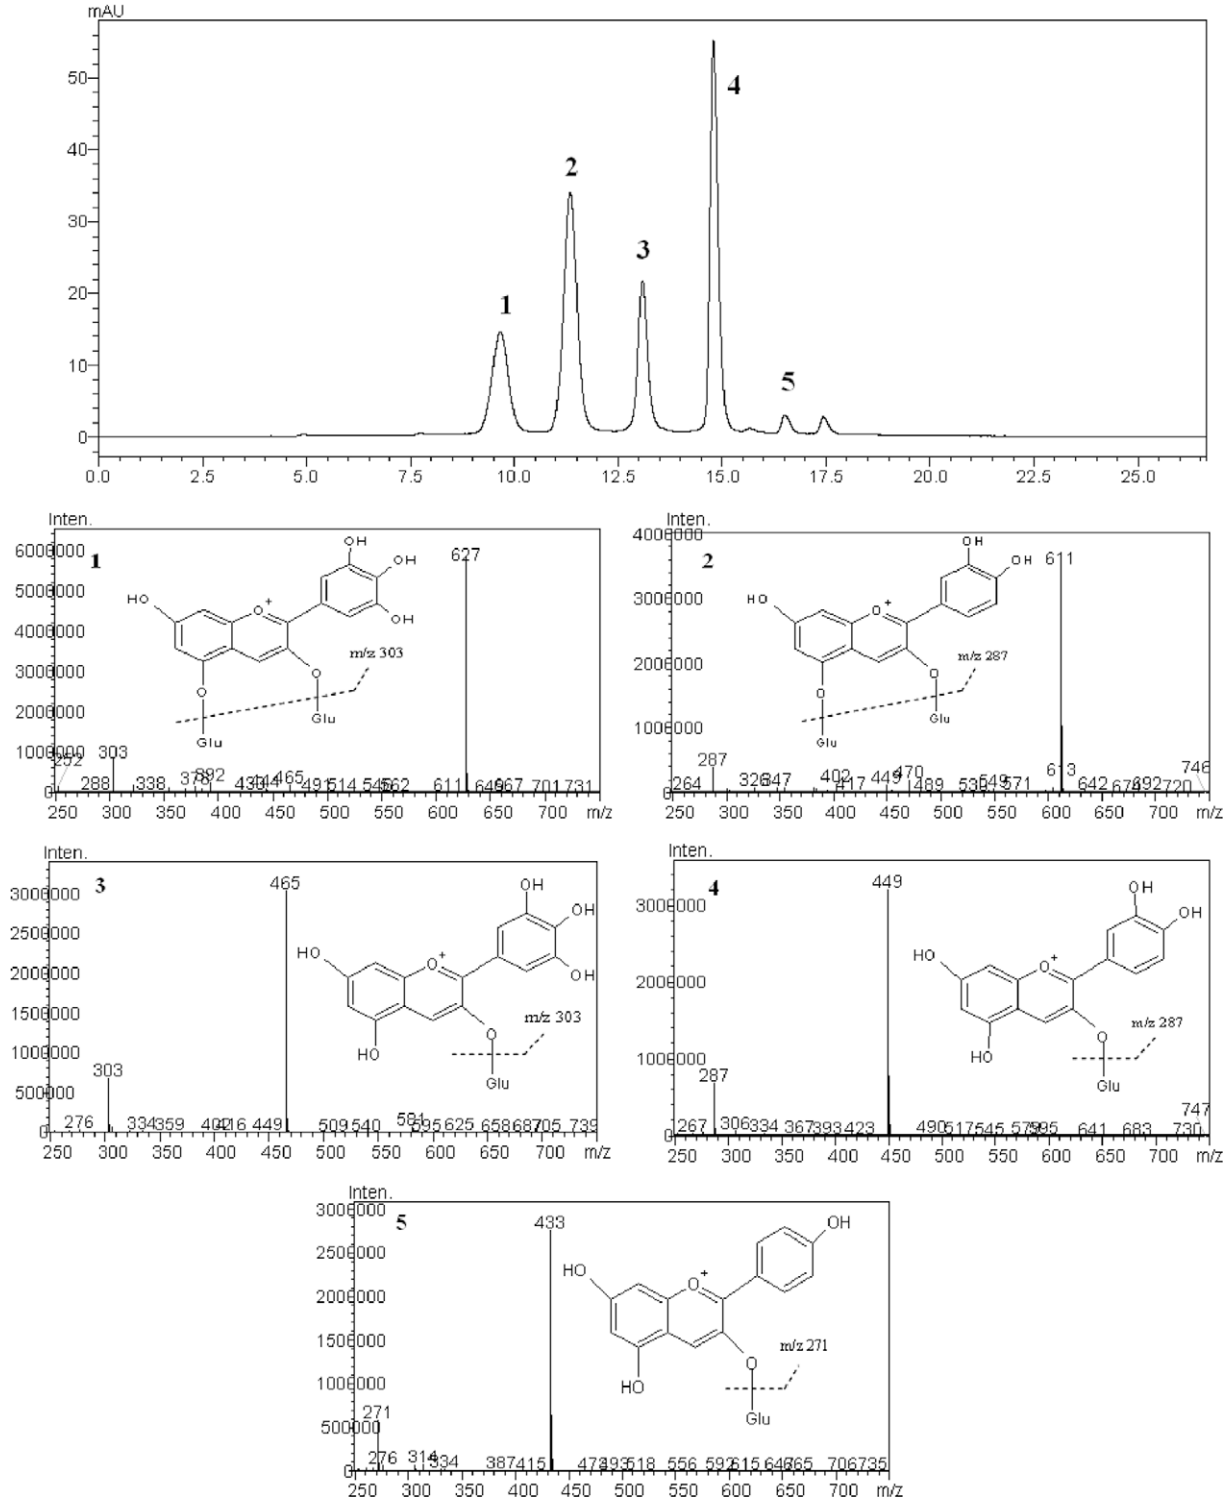

Fig. 1. Typical LC–MS chromatograms of anthocyanins from fresh, oven-dried and sun-dried pomegranate arils. Peak identities: 1 – delphinidin 3,5-diglucoside; 2 – cyanidin 3,5-diglucoside; 3 – delphinidin 3-glucoside; 4 – cyanidin 3-glucoside; 5 – pelargonidin 3-glucoside. Identity of the sixth peak is unknown.

3.5. PPO kinetics: the Michaelis–Menten constant

Pomegranate PPO kinetics were partially characterised by investigation of the effect of substrate concentration on PPO activity. The Michaelis–Menten constant (K_m) and V_{max} values were determined from a Lineweaver–Burk plot (Fig. 4). The K_m value was 635 mM, and the V_{max} value was 1.045 ΔOD/min/ml. Spinach PPO was considerably inhibited above its K_m value when dopamine was used as a substrate, whereas catechol is also shown to inhibit PPO activity at higher concentrations (Golbeck & Cammarata, 1981). Our results indicate a similar phenomenon; pomegranate PPO was inhibited above the catechol K_m value in a progressive manner proportional to the catechol concentration. Using catechol as a substrate in the PPO assay may be responsible for these non-classic enzyme kinetics. The high K_m value of 635 mM can be explained by the fact that catechol is a non-physiological substrate for pomegranate PPO.

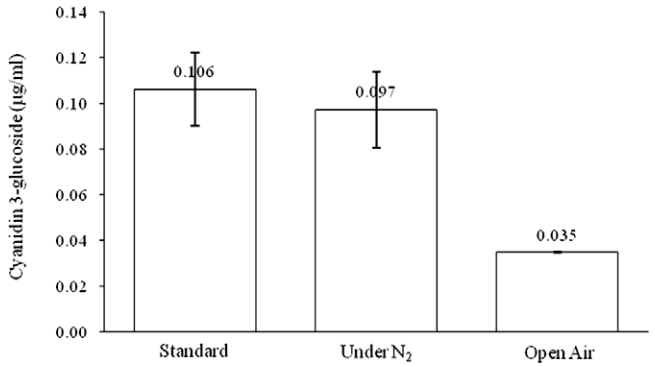

Fig. 2. Effect of temperature on anthocyanin stability. Values are averages of three determinations. Error bars are standard deviations of the values.

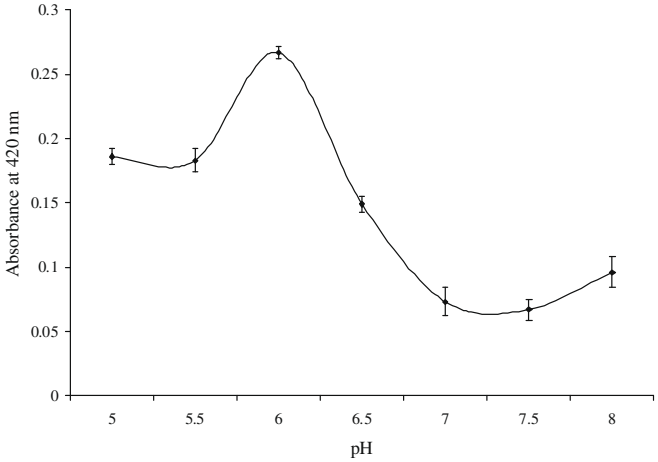

Fig. 3. Effect of pH on pomegranate PPO activity. Values are averages of three determinations. Error bars are standard deviations of the values.

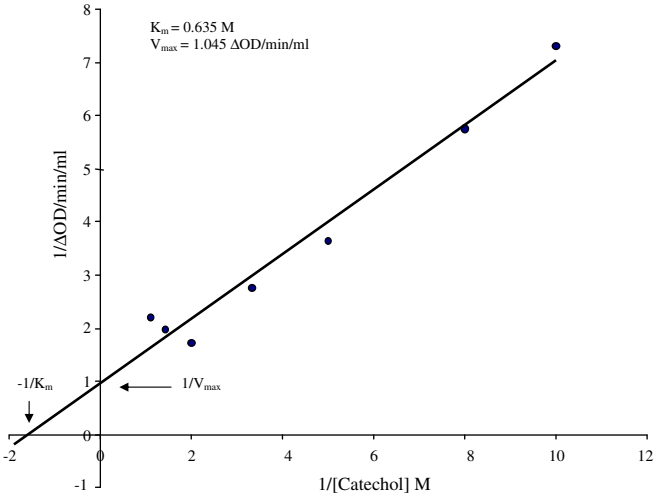

Fig. 4. Effect of substrate concentration on pomegranate PPO activity (Lineweaver–Burk plot of the reaction data). Average of three determinations.

3.6. Effect of drying on anthocyanins and PPO activity

Drying reduced the amount of anthocyanins and the PPO activity in fresh pomegranate arils (Table 1). Oven-drying resulted in 61% loss of anthocyanins and 68% loss of PPO activity. Sun-drying was more destructive to anthocyanins, resulting in about 83% loss, but only 45% loss was recorded in the PPO activity. Anthocyanins are stable at high temperatures, whereas PPO is heat-labile and is considerably inhibited above 80 °C (Severini et al., 2003). Inhibition of PPO by oven-drying at high temperature may be responsible for protecting the anthocyanins from oxidation by PPO. Sun-drying was apparently unable to inhibit PPO activity as much, resulting in enhanced anthocyanin oxidation.

Table 1
Anthocyanin amount and PPO activity in pomegranate arils. Values are averages of three determinations and the number in parentheses is the standard deviation of the corresponding value.

Characteristic	Fresh arils	Oven-dried arils	Sun-dried arils
Total anthocyanins (µg/g ± SD)	250.5 (±10.9)	97.4 (±1.8)	42.2 (±0.3)
PPO activity (units/ml ± SD)	647.7 (±9.9)	205.7 (±5.1)	356 (±23.6)

3.7. Effect of boiling on anthocyanins and PPO activity

To further investigate the role of PPO in anthocyanin degradation, the effect of boiling on anthocyanins and PPO activity in pomegranate arils was determined. PPO activity in boiled arils was reduced by 75% from that of fresh arils, whereas total anthocyanins were reduced by only 2.5% (Fig. 5). Anthocyanins were protected from oxidative degradation because of inactivation of PPO by boiling. The results of this experiment again indicate the possible involvement of PPO in anthocyanin degradation.

The role of PPO has always been speculated in anthocyanin degradation with mixed results. Although, our investigations were carried out on crude enzyme preparations, the results indicate a possible involvement of PPO in anthocyanin oxidation.

In the presence of very low levels of hydrogen peroxide, peroxidase (POD; EC 1.11.1.7) also catalyses the formation of quinones from phenolic compounds (Vaughn & Duke, 1984). To adequately understand the physiology of an enzyme, it is important that the assay used can distinguish that enzyme from all others. Unfortunately, however, the catechol oxidation assay is not sufficient to measure the true PPO activity and needs to be refined, in order to distinguish PPO activity from POD or other similar enzyme activities. Our results strongly indicate a likely involvement of PPO in anthocyanin oxidation in pomegranate arils, although further investigations are required. Instead of a non-physiological substrate, such as catechol, anthocyanin may be the most suitable substrate to evaluate the role of PPO in anthocyanin oxidative degradation.

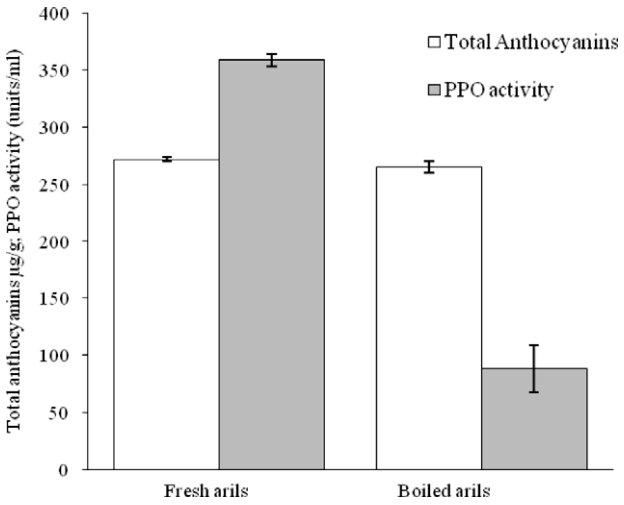

Fig. 5. Effect of boiling on total anthocyanins and PPO activity in pomegranate arils. Average of three determinations and error bars are standard deviations of the values.

ABSTRACT

The influence of different classes of naturally occurring and externally added polyphenolic cofactors on the phytochemical and colour stability of anthocyanins in açai fruit (*Euterpe oleracea*) was investigated. Model systems were based on anthocyanin isolates from açai fruit, rich in cyanidin-3-rutinoside (311 ± 27 mg/l) and cyanidin-3-glucoside (208 ± 18 mg/l), and isolated groups of naturally occurring polyphenolic cofactors in açai fruit (phenolic acids, procyanidins, and flavone-*C*-glycosides, each adjusted to ~50 mg/l). Anthocyanin degradation kinetics were assessed as a function of pH (3.0, 3.5, and 4.0) and storage temperature (5, 20 and 30 °C). During storage, anthocyanins experienced pH and temperature-dependent losses, and the half life cyanidin-3-rutinoside ($t_{1/2}$ = 2.67–210 days) was consistently longer than cyanidin-3-glucoside ($t_{1/2}$ = 1.13–144 days). The presence of flavone-*C*-glycosides induced significant hyperchromic shifts and enhanced anthocyanin stability at all pH and temperature combinations, while no significant effects were attributed to the presence of phenolic acids or procyanidins. Additional models using externally added cofactors from rooibos tea, also rich in flavone-*C*-glycosides, resulted in up to 45.5% higher anthocyanin colour and up to 40.7% increased anthocyanin stability compared to uncopigmented anthocyanin isolates and had similar copigmentation effects to a commercial rosemary-based colour enhancer. Results suggest flavone-*C*-glycosides offer potential for their use as colour enhancers and stabilizing agents in products rich in cyanidin glycosides, particularly açai fruit-containing foods, juice blends, and beverages.

1. Introduction

Anthocyanins have been categorized as the most important group of water-soluble pigments in plants, and are responsible for most blue, red, and related colours in flowers and fruits (Clifford, 2000). Anthocyanin colour is an important sensory characteristic and often a major quality parameter for a variety of fruit products. Açai (*Euterpe oleracea* Mart.), a palm fruit native to the Brazilian Amazon, has been the focus of increased international attention as a functional ingredient in fruit juices, beverage blends, dietary supplements, and dairy products (Del Pozo, Brenes, & Talcott, 2004; Schauss et al., 2006) and is a potential rich source of anthocyanins (Gallori, Bilia, Bergonzi, Barbosa, & Vincieri, 2004; Lichtenthaler et al., 2005; Pacheco-Palencia, Hawken, & Talcott, 2007a, 2007b). Two predominant anthocyanins, cyanidin-3-rutinoside and cyanidin-3-glucoside, are responsible for most of its characteristic dark purple colour, and are often a major source of colour in açai-containing juices and beverages (Lichtenthaler et al., 2005; Pacheco-Palencia et al., 2007a; Schauss et al., 2006). However, anthocyanins are highly reactive and generally experience extensive degradation during long-term storage, leading to dark, dull, brown hues (Jurd, 1972).

Anthocyanin colour changes are known to be influenced by several factors, including pH, temperature, light, and the presence of enzymes, sugars, metals, and phenolic cofactors (Markakis, 1982). Among these, the presence of non-anthocyanin polyphenolics may significantly affect anthocyanin colour, as they participate in copigmentation reactions in enhanced colour and increased stability during storage (Singleton, 1972). Intermolecular copigmentation reactions are common in nature and occur when colourless phenolic cofactors are attracted to anthocyanins via weak hydrophobic forces (Mazza & Brouillard, 1990). Anthocyanin copigmentation reactions are detected by both a hyperchromic shift, where absorbance at the λ_{max} of the absorption spectrum increases, and by a bathochromic shift, where a change toward higher wavelengths (nm) at the λ_{max} of the absorption spectrum occurs (Baranac, Petranovic, & Dimitric-Markovic, 1996; Malien-Aubert, Dangles, & Amiot, 2001).

doi:10.1016/j.foodchem.2009.02.032

Previous studies have evaluated the use of externally added polyphenolic cofactors, particularly phenolic acids, to enhance and stabilize anthocyanin colour in berry juices (Eiro & Heinonen, 2002). External addition of commercial polyphenolic cofactors from rosemary (*Rosmarinus officinalis*) has also shown to result in enhanced anthocyanin colour and increased stability in grape juices (Brenes, Del Pozo-Insfran, & Talcott, 2005; Talcott, Brenes, Pires, & Del Pozo-Insfran, 2003). Thus, the natural occurrence and predominant presence of certain groups of polyphenolic cofactors in açai fruit, including phenolic acids, flavone-*C*-glycosides, and procyanidins (Gallori et al., 2004; Pacheco-Palencia et al., 2007b; Schauss et al., 2006), may play a significant role in the structural and pigment stability of anthocyanins in açai fruit juices. The role of flavone-*C*-glycosides is of particular interest, as their presence in other anthocyanin-rich fruits has not been previously reported. Moreover, the potential use of flavone-*C*-glycoside-rich extracts as anthocyanin colour enhancers and stabilizing agents has not been evaluated. Extracts rich in flavone-*C*-glycosides may be obtained from various botanical sources, among which, rooibos (*Aspalathus linearis)* tea, a leguminous shrub native to South Africa, is among the highest, most widely available, and easily extractable sources (Krafczyk & Glomb, 2008).

This study was conducted to evaluate the influence of different groups of naturally occurring polyphenolic cofactors on the stability of anthocyanins in açai models stored under different pH (3.0, 3.5, and 4.0) and temperature (5, 20, and 30 °C) conditions and assess the influence of externally added polyphenolic cofactors from rooibos tea, rich in flavone-*C*-glycosides, and from commercial rosemary extracts on the stability of açai anthocyanin models. Relations between anthocyanin degradation and sulfite bleaching resistance, reducing capacity, and antioxidant activity were additionally determined.

2. Materials and methods

2.1. Polyphenolic isolations

Phenolic acids and procyanidins were extracted from a previously characterized, polyphenolic-enriched açai oil (Pacheco-Palencia, Mertens-Talcott, & Talcott, 2008), which contained concentrated amounts of phenolic acids and procyanidins originally present in açai fruit pulp. Açai oil was extracted from a semi-solid filter cake obtained from the Bossa Nova Beverage Group (Los Angeles, CA), commercially used for açai pulp clarification, using a hydro-alcoholic solution, as described by Pacheco-Palencia et al. (2008). Açai oil was extensively extracted with an equal volume of a 1:1 (v/v) hexane:methanol solution until complete dissolution. A known volume of 0.1 M aqueous citric acid buffer at pH 3.0 was added to the mixture, to form a bi-layer, from which the hydrophilic phase was retained. Residual methanol in the hydrophilic phase was evaporated under reduced pressure (<40 °C) and the resulting aqueous solution recovered, adjusted to pH 7.0, and loaded onto C18 Sep-Pak Vac 20 cm^3 mini-columns (Waters Corporation, Milford, MA). Phenolic acids were eluted in the unbound fraction, while procyanidins were eluted with acidified methanol (0.01% HCl). The aqueous, phenolic acid-containing fraction was then acidified to pH 3.0, loaded onto a second Sep-Pak column, and eluted with acidified methanol (0.01% HCl). Methanol from each extraction was then evaporated under vacuum (<40 °C) and each fraction was re-dissolved in a known volume of the citric acid buffer.

In a second extraction, anthocyanins and naturally occurring flavone-*C*-glycosides in açai fruit were extracted from clarified açai pulp (Bossa Nova Beverage Group, Los Angeles, CA). Clarified açai pulp was likewise loaded onto Sep-Pak mini-columns (Waters Corporation, Milford, MA), and sequentially eluted with acidified water (0.01% HCl) to remove metals, sugars, and other water soluble components followed by ethyl acetate to remove phenolic acids. Flavone-*C*-glycosides and anthocyanins were finally eluted with acidified methanol. Following solvent evaporation and re-dissolution in the citric acid buffer, the methanolic fraction was loaded onto manually packed, lipophilic Sephadex LH-20 (Sigma–Aldrich, St. Louis, MO) 40 cm^3 mini-columns, previously equilibrated with water. Columns were washed with 30% aqueous methanol (v/v) to elute anthocyanins, followed by 60% aqueous methanol (v/v) to elute flavone-*C*-glycosides, and with 100% methanol to elute procyanidins. These procyanidins were combined with the procyanidin fraction previously obtained from açai oil. All solvents were finally evaporated under reduced pressure (<40 °C) and each resulting isolate was redissolved in the citric acid buffer (pH 3.0).

2.2. Anthocyanin models

Açai fruit models were created based on the predominant anthocyanins present in the fruit (cyanidin-3-rutinoside and cyanidin-3-glucoside), adjusted to a total concentration of approximately 500 mg/l in all models. Four different anthocyanin-based models were prepared by combining açai anthocyanins with a major group of naturally occurring polyphenolics present in the fruit. Models were created by combining phenolic acids, procyanidins, flavone-*C*-glycosides, and a non-copigmented anthocyanin control. Cofactor concentrations on each model were adjusted according to the original ratio of total phenolic cofactors to anthocyanins (1:10) naturally present in 100% clarified açai pulp. Models were adjusted to three different pH levels (3.0, 3.5, and 4.0), based on the pH range of commercial açai products, and equal amounts of each were loaded into screw-cap glass test tubes in triplicate. Treatments were stored in the dark at 5, 20, and 30 °C for up to 60 days. Sodium azide (50 mg/l) was added to prevent microbial growth during storage and individual tubes were removed from storage at predetermined time intervals and held at −20 °C until analysis.

Additional models with açai anthocyanins (~500 mg/l) were evaluated that contained externally added polyphenolic cofactors from a rooibos tea extract, rich in flavone-*C*-glycosides, as compared to a commercial rosemary extract (ColourEnhance, 3.5% rosmarinic acid, Naturex, South Hackensack, NJ) and a non-copigmented control. Rooibos tea extracts were obtained from rooibos tea, prepared by brewing 50 g of loose rooibos tea (Keekanne GmbH, Dusseldorf, Germany) in 50 ml boiling water for 30 min. Both rooibos tea and commercial rosemary extracts were subsequently diluted in citric acid buffer (0.1 M, pH 3.0) and further purified using Sep-Pak columns. Sugars, organic acids, and other water soluble components were removed with water, and polyphenolic components were recovered with ethyl acetate. Following solvent removal, compounds were redissolved in a known volume of citric acid buffer (0.1 M, pH 3.0), adjusted to equal soluble phenolic contents (10,000 mg gallic acid equivalents/l) and added to anthocyanin isolates to contain final concentrations of 0.2% v/v, based on previous reports using similar rosemary extracts (Brenes et al., 2005; Talcott et al., 2003). All models were finally adjusted to pH 3.0, 3.5, or 4.0, loaded into screw-cap glass tubes in triplicate, and stored at 30 °C for up to 30 days. Sodium azide (50 mg/l) was added to all treatments to retard microbial growth and pH was measured every other day to confirm its consistency during storage. Individual tubes were removed from storage every 3 days and held at −20 °C until analysis.

2.3. Chemical analyses

Polyphenolic compounds were analyzed by reversed phase HPLC with a Waters 2695 Alliance system (Waters Corporation, Milford, MA), using previously described chromatographic condi-

tions (Pacheco-Palencia et al., 2007a). Polyphenolic identification and quantification was based on spectral properties, retention time, and comparison to authentic standards. Phenolic acid, flavonol, and anthocyanin standards were obtained from Sigma Chemical Company (St. Louis, MO), and flavone-*C*-glycoside standards were obtained from Indofine Chemical Company (Hillsborough, NJ). Mass spectrometric analyses were additionally performed on a Thermo Finnigan LCQ Deca XP Max MS^n ion trap mass spectrometer equipped with an ESI ion source (ThermoFisher, San Jose, CA). Separations were conducted using a Dionex (Dionex Corporation, Sunnyvale, CA), Acclaim 120 column (4.6 × 250 mm; 5 μm) with a C18 guard column. Mobile phases consisted of 0.5% formic acid in water (phase A) and 0.5% formic acid in methanol (phase B) run at 0.30 ml/min. A gradient elution program in which phase B changed from 5% to 30% in 10 min, from 30% to 65% in 70 min, and from 65% to 95% in 30 min was used and held isocratic for 20 min prior each injection. Electrospray ionization in the negative ion mode was conducted under the following conditions: sheath gas (N_2), 60 units/min; auxiliary gas (N_2), 5 units/min; spray voltage, 3.5 kV; capillary temperature, 250 °C; capillary voltage, 1.5 V; tube lens offset, 0 V.

Total anthocyanin contents were determined spectrophotometrically at 520 nm, according to the pH differential method described by Wrolstad, Durst, and Lee (2005) and quantified using equivalents of cyanidin-3-glucoside (mg/l) with a molar extinction coefficient of 29,600 (Jurd & Asen, 1966). Anthocyanin sulfite bleaching resistance was also determined spectrophotometrically, based on colour retention in the presence of sodium sulfite (Rodriguez-Saona, Guisti, and Wrolstad, 1999). Total soluble phenolic contents were estimated from the total metal reducing capacity of each model in the Folin-Ciocalteu assay (Singleton & Rossi, 1965) and quantified in gallic acid equivalents (GAE). Antioxidant capacity was determined by the oxygen radical absorbance capacity assay (ORAC) (Talcott & Lee, 2002), using fluorescein as the fluorescent probe, and measured on a BMG Labtech FLUOstar fluorescent microplate reader (485 nm excitation and 538 nm emission). Results were quantified and expressed as μmole Trolox equivalents per milliliter.

2.4. Statistical analyses

A 4 × 3 × 3 factorial design that included four anthocyanin-based models, three pH levels, and three storage temperatures was employed. Data from each chemical analysis was analyzed by one-way analysis of variance (ANOVA) using SPSS version 15.0 (SPSS Inc., Chicago, IL) and mean separations were conducted using Tukey–Kramer HSD ($p < 0.05$) as a post-hoc analysis. Linear regression analyses and parametric correlations were conducted using a 0.05 significance level.

3. Results and discussion

3.1. Polyphenolic composition of anthocyanin models

Anthocyanins, phenolic acids, procyanidins, and flavone-*C*-glycosides present in açai anthocyanin models were characterized based on their spectral characteristics and mass spectrometric (MS) fragmentation patterns and quantified against authentic standards when available (Table 1). All models were adjusted to equal cyanidin-3-glucoside and cyanidin-3-rutinoside concentrations (519 ± 48 mg/l, Table 1). In addition, a group of naturally occurring phenolic cofactors in açai fruit (Pacheco-Palencia et al., 2007a, 2008), was present on each model and included phenolic acids (protocatechuic, *p*-hydroxybenzoic, vanillic, syringic, and ferulic acids), procyanidins (dimers and trimers), and flavone-*C*-glycosides (isoorientin, orientin, and isovitexin), and two additional flavone *C*-glycosides, tentatively identified as apigenin 6,8-di-*C*-glycosides. Phenolic cofactor concentrations were adjusted ranging from 48.9 to 56.1 mg/l (Table 1) to yield a phenolic cofactor-to-anthocyanin ratio of 1:10 that corresponded to the natural ratio of these cofactors originally present in clarified açai pulp (Pacheco-Palencia et al., 2007a, 2008).

Identification of flavone-*C*-glycosides was based on their characteristic MS patterns, as preferential fragmentation of the glycosidic moiety typically occurs to yield typical product ions at $[M-H-60]^-$, $[M-H-90]^-$, and $[M-H-120]^-$ (Ferreres, Silva, Andrade, Seabra, & Ferreira, 2003; Gattuso, Barreca, Gargiulli, Leuzzi, & Caristi, 2007; Pereira, Yariwake, & McCullagh, 2005). Tentative identification of apigenin-6-*C*-glucosyl-8-*C*-arabinoside was based on precursor ion signals at $m/z = 563.1$ ($[M-H]^-$), and respective product ions at $m/z = 503.1$ ($[M-H-60]^-$), $m/z = 473.2$ ($[M-H-90]^-$); and $m/z = 443.1$ ($[M-H-120]^-$) as indicated in Fig. 1. Fragmentation patterns corresponded to those previously reported for apigenin-6-*C*-glucosyl-8-*C*-arabinoside (shaftoside, $m/z = 563.1$, $[M-H]^-$) in quince seeds (Ferreres et al., 2003) and in *Scutellaria baicalensis* roots (Han et al., 2007). Likewise, tentative identifica-

tion of apigenin 6,8-di-*C*-glucoside was based on ion signals at *m/z* = 593.5, $[M-H]^-$, with a similar neutral loss to yield ions at *m/z* = 533.1 ($[M-H\text{-}60]^-$); *m/z* = 503.1 ($[M-H\text{-}90]^-$); and *m/z* = 473.1 ($[M-H\text{-}120]^-$). Mass fragmentation patterns were identical to those previously reported for apigenin 6,8-di-*C*-glucoside (vicenin-2, *m/z* = 593.5, $[M-H]^-$), in both wild basil leaves (Grayer, Kite, Abou-Zaid, & Archer, 2000) and quince seeds (Ferreres et al., 2003). These are the first tentative reports on the occurrence of apigenin-6-*C*-glucosyl-8-*C*-arabinoside and apigenin 6,8-di-*C*-glucoside in açai fruit.

3.2. Influence of natural phenolic cofactors on anthocyanin stability

The influence of naturally occurring polyphenolic cofactors on the stability of anthocyanins in açai fruit was evaluated by monitoring changes in anthocyanin concentrations of model juice systems adjusted to different conditions of temperature (5, 20, or 30 °C for up to 12 weeks) and pH (3.0, 3.5, and 4.0). Initial spectrophotometric determinations for total anthocyanin contents were consistent among anthocyanin controls and models combined with phenolic acids or procyanidins (522.9 ± 27.3 mg cyanidin-3-gluco-

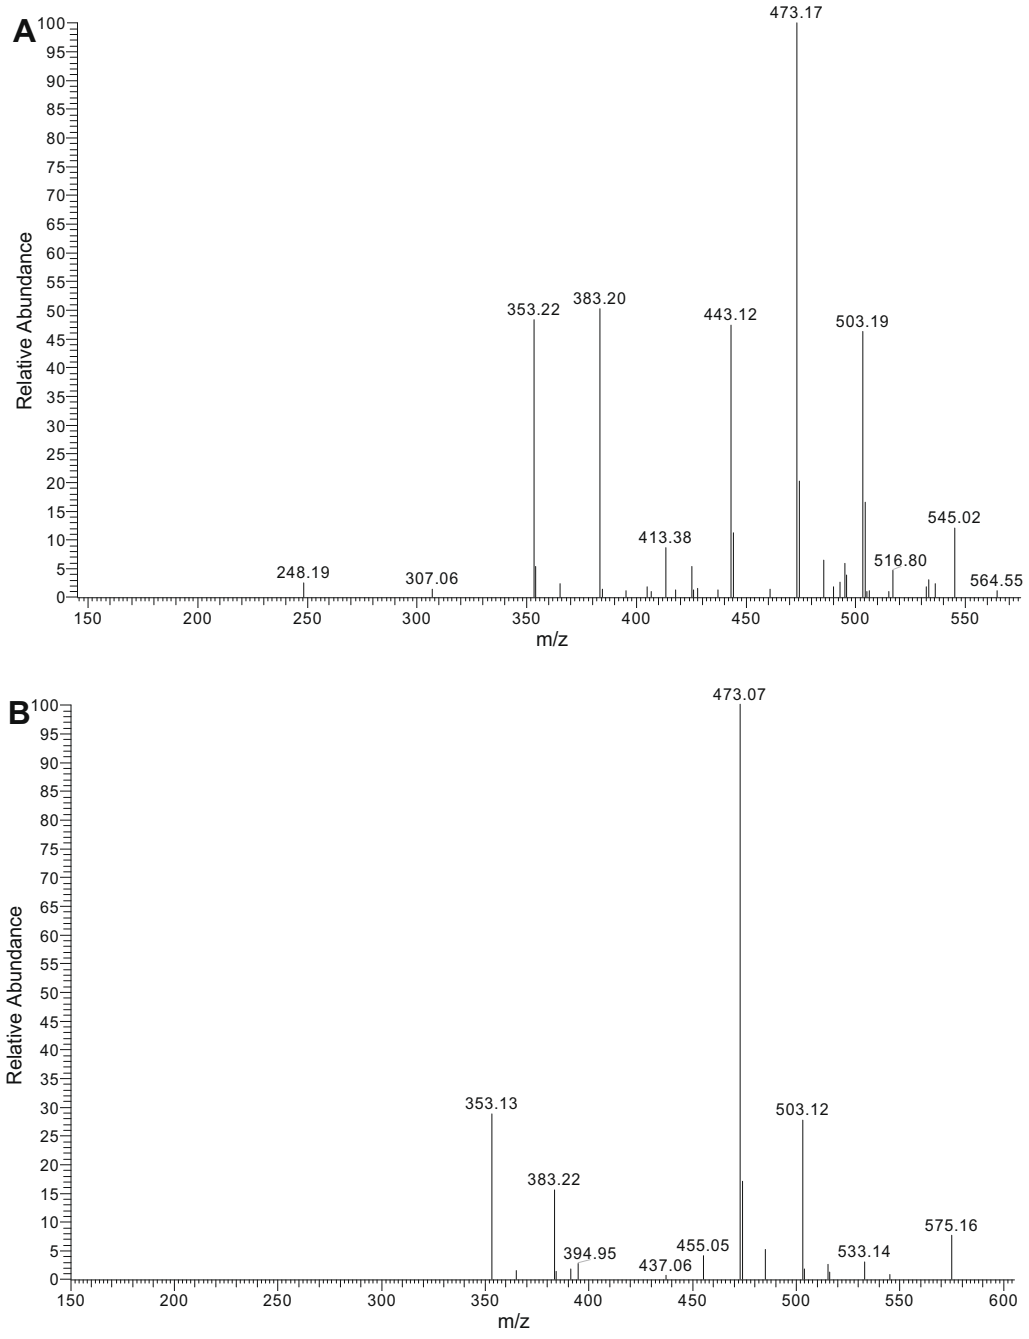

Fig. 1. ESI-MS negative product ion spectra of (A) apigenin-6-*C*-glucosyl-8-*C*-arabinoside (shaftoside, 563.1, $[M-H]^-$), and (B) apigenin 6,8-di-*C*-glucoside (vicenin-2, 593.5, $[M-H]^-$).

side equivalents/l). However, models containing flavone-*C*-glycosides were 18.0% higher in initial absorbance values (617.1 ± 30.1 mg/l), attributed to hyperchromic shifts that resulted from intermolecular copigmentation reactions with anthocyanins. These molecular associations between anthocyanins and other phenolics are commonly associated with enhanced anthocyanin colour, despite equivalent individual anthocyanin concentrations (Boulton, 2001). Copigmentation reactions are often accompanied by a bathochromic shift in the wavelength of maximum absorbance (Talcott et al., 2003); however, no change was observed in the presence of flavone-*C*-glycosides in these models.

Degradation rates for cyanidin-3-glucoside, cyanidin-3-rutinoside, and total anthocyanins followed first-order ($p < 0.01$) degradation kinetics. Rate constants (β_1, in days^{-1}), half-lives ($t_{1/2}$, time in days to achieve a 50% reduction in initial concentrations), and temperature quotients (Q_{10}, fold increase in degradation rate when temperature was increased from 20 to 30 °C) were calculated as previously described (Pacheco-Palencia et al., 2007b) and are shown in Tables 2–4. Anthocyanin models experienced significant pH- and temperature-dependent total anthocyanin losses, with half-lives ranging from 4.01 to 23.2 days for models stored at 30 °C, from 6.94 to 47.0 days when stored at 20 °C, and from 48.2 to 259 days for models kept at 5 °C (Table 2). Total anthocyanin losses were also influenced by acidity level, whereby a 45–60% increase in stability was observed when the pH was raised from 3.0 to 3.5, and by 90–100% when raised from 3.5 to 4.0, regardless of storage temperature or presence of cofactors. Similar pH and temperature-dependent degradation patterns were observed when individual cyanidin-3-glucoside and cyanidin-3-rutinoside concentrations were monitored (Tables 3 and 4) and both cyanidin-3-glucoside ($r = 0.94$) and cyanidin-3-rutinoside ($r = 0.93$) concentrations were highly correlated ($p < 0.001$) to total anthocyanin losses in all models throughout storage. However, temperature quotients (Tables 3 and 4) indicated cyanidin-3-glucoside was less stable to temperature changes ($Q_{10} = 2.9–3.2$) compared to cyanidin-3-rutinoside ($Q_{10} = 2.5–2.9$), and that individual anthocyanin concentrations were significantly less stable to temperature changes compared to total anthocyanin contents ($Q_{10} = 1.8–2.1$). Observed differences between total anthocyanin contents and changes in individual anthocyanin concentrations were likely due to the influence of other matrix components in the açai anthocyanin models (Wrolstad et al., 2005) as well as significant colour contributions from polymeric anthocyanins formed during storage.

Similar detrimental effects were observed at increasing pH values, and changes from pH 3.0 to 3.5 nearly doubled cyanidin-3-glucoside and cyanidin-3-rutinoside degradation rates (Tables 3 and 4) and increased total anthocyanin degradation rates by ~50% in all models. Detrimental effects of both high temperature and pH on anthocyanin stability and colour were attributed to shifts in the anthocyanin equilibrium toward the colourless pseudobase

and chalcone forms, expected to occur under these conditions (Clifford, 2000; Markakis, 1982). Structural differences also had a significant influence on anthocyanin stability whereas cyanidin-3-rutinoside was consistently more stable ($t_{1/2}$ = 2.67 to 210 days, Table 4) than cyanidin-3-glucoside ($t_{1/2}$ = 1.13 to 144 days, Table 3) in all models, regardless of variations in temperature, pH, or cofactor composition. These models were in agreement with our previous observations of anthocyanins stability in ascorbic acid-fortified açai juices (Pacheco-Palencia et al., 2007a). Moreover, in models that incorporated a cyanidin-3-rutinoside standard in aqueous buffer (pH 3.5) revealed a gradual conversion to cyanidin-3-glucoside over time that progressed at up to 12.5% after 20 days of storage at 30 °C, indicating hydrolysis of glycosidic bonds during storage. Applied to these fruit models, a gradual hydrolysis of glycosidic bonds would lead to increased cyanidin-3-glucoside and decreased cyanidin-3-rutinoside concentrations during storage of açai fruit anthocyanins and result in higher proportions of the more labile cyanidin-3-glucoside subsequently a more rapid rate of anthocyanin and colour degradation. Moreover, hydrolysis of the glycosidic bond has been proposed as one of the early steps in the degradation of anthocyanins, as the resulting aglycone is unstable and undergoes spontaneous ring fission and subsequent degradation (Adams, 1972, 1973; Clifford, 2000; Markakis, 1974).

The presence of phenolic cofactors had also a significant (p = 0.006) influence on the stability of açai fruit anthocyanins in all models. Overall, the presence of flavone-*C*-glycosides resulted in increased total anthocyanin stability at all temperature and pH combinations in relation to the anthocyanin control, while no significant effects were attributed to the presence of phenolic acids or procyanidins (Table 2). Protective effects were more pronounced for cyanidin-3-glucoside, where addition of flavone-*C*-glycosides resulted in higher anthocyanin stability in all models (Table 3). By contrast, cyanidin-3-rutinoside degradation rates were not significantly affected by the presence of flavone-*C*-glycosides (Table 4), likely due to its inherently higher stability in all models. Thus, the positive influence of flavone-*C*-glycosides on anthocyanin stability in açai fruit models was likely a result of their protective effect on cyanidin-3-glucoside and the colour contribution of cyanidin-3-glucoside to total anthocyanin measurements. Supporting models that used cyanidin-3-glucoside standards (205 ± 14 mg/l) adjusted to pH 3.5 and to which phenolic acid, flavone-*C*-glycoside, and procyanidin isolates from açai fruit were added confirmed the ability of flavone-*C*-glycosides to act as effective copigments and also resulted in increased ($p < 0.01$) anthocyanin stability during storage (Fig. 2). Stable anthocyanin copigment complexes with flavone-*C*-glycosides were reported to occur naturally in Iris flowers (Asen, Stewart, Norris, & Massie, 1970), yet this is the first report on the ability of flavone-*C*-glycosides to act as copigments in fruit juice anthocyanins.

Sulphite bleaching resistance of anthocyanins in açai models was also correlated ($p < 0.01$) to total anthocyanin contents (r = 0.77), and was indicative of hue changes in colour from dark red to brown. Temperature, pH, and phytochemical composition significantly ($p < 0.03$) influenced anthocyanin bleaching resistance, expressed as percent polymeric anthocyanin contents during storage. All phenolic cofactors decreased anthocyanin polymerization rates throughout storage with effects generally more pronounced in models adjusted to pH 3.0 or 3.5, regardless of storage temperature (Fig. 3).

Açai anthocyanin models were also evaluated for pH variations, soluble phenolic contents, as a measure of total reducing capacity, and for changes in antioxidant capacity throughout storage (Fig. 4). No significant pH variations were detected in any of the models following addition of phenolic cofactors or throughout storage. However, addition of phenolic copigments resulted in increased total soluble phenolic contents (23.1 ± 1.8% increase) and antioxidant capacity (30.2 ± 2.6% increase) in relation to uncopigmented anthocyanin controls that contained 974 ± 79 mg gallic acid equiv-

alents/l and an antioxidant capacity of 23.8 ± 1.15 μM Trolox equivalents/ml. All phenolic cofactors resulted in higher soluble phenolic contents and antioxidant capacity throughout storage when compared to uncopigmented anthocyanins, at all temperature and pH conditions (Fig. 4). Moreover, changes in soluble phenolic contents and antioxidant capacity were correlated ($r = 0.47$ and 0.68, respectively) to variations in total cyanidin-3-glucoside and cyanidin-3-rutinoside concentrations during storage of açai anthocyanin models.

3.3. Stability of phenolic cofactors

The overall stability of naturally occurring polyphenolic cofactors during storage of açai anthocyanin models was additionally evaluated. Phenolic acid concentrations remained unchanged ($p < 0.05$) in models stored at up to 20 °C, yet losses were <10% at 30 °C. Similarly, flavonol derivatives were stable in models stored at 5 °C but experienced temperature-dependent losses following storage at both 20 and 30 °C, of up to 12.1 ± 1.3% after 30 days, regardless of pH differences. Specifically, the predominant flavone *C*-glycosides, orientin and isoorientin, experienced temperature-dependent losses of up to 11.1% during storage at 5 to 30 °C for up to 60 days, while no changes occurred for the flavone *C*-glycosides luteolin 6,8-di-*C*-glucoside, apigenin 6,8-di-*C*-glucoside, isovitexin, and scoparin.

Table 5
Kinetic parameters of total anthocyanin degradation during storage of açai models with externally added polyphenolic cofactors.

3.4. Influence of added phenolic cofactors on anthocyanin stability

The influence of externally added flavone-*C*-glycoside cofactors on the stability of anthocyanin isolates from açai fruit was additionally evaluated and compared to a commercially available anthocyanin colour enhancer isolated from rosemary. Extracts rich in flavone-*C*-glycosides were obtained from rooibos tea (*Aspalathus linearis*), which was previously identified to contain high amounts of flavone-*C*-glycosides (Bramati et al., 2002; Krafczyk & Glomb, 2008; Marnewick et al., 2005). Chemical analyses of rooibos extracts used in these trials revealed the presence of orientin (39.9 ± 2.8%), isoorientin (48.1 ± 3.1%), vitexin (19.9 ± 1.4%), and isovitexin (19.7 ± 1.3%), along with lower concentrations of *C*-linked dehydrochalcone glycosides (12.3 ± 1.1%), likely aspalathin and nothofagin (Krafczyk & Glomb, 2008; Marnewick et al., 2005). Copigmentation of anthocyanin isolates with rooibos extracts (0.2% v/v) resulted in immediate hyperchromic shifts of up to 45.5 ± 3.8% at pH 3.0, 30.2 ± 2.3% at pH 3.5, and 14.7 ± 1.3% at pH 4.0, that related to proportionally higher increases in visual red colour at all pH levels. A less pronounced hyperchromic shift was observed with the commercial rosemary extracts (0.2% v/v), which resulted in 27.5 ± 2.2%, 21.1 ± 1.3%, and 10.7 ± 0.9% higher absorbance at pH 3.0, 3.5, and pH 4.0, respectively. Moreover, kinetic parameters of total anthocyanin degradation, expressed as the sum of cyanidin-3-glucoside and cyanidin-3-rutinoside concentrations, revealed consistently higher ($p < 0.05$) anthocyanin half-lives for anthocyanin models containing rooibos ($t_{1/2}$ = 3.32–12.9 days) or rosemary extracts ($t_{1/2}$ = 3.24–11.6 days) as compared to an anthocyanin isolate control ($t_{1/2}$ = 2.36–10.7 days) (Table 5). Changes in total anthocyanin contents were inversely correlated ($p < 0.05$) to anthocyanin bleaching resistance (r = 0.72) and directly correlated to antioxidant capacity (r = 0.65). Thus, addition of rooibos extracts, rich in flavone-*C*-glycosides, not only resulted in higher colour intensities but also increased anthocyanin stability during long-term storage (30 °C) of açai anthocyanin models, in a comparable manner to a known copigment source such as rosemary extract. Results from model systems can be related to similar effects in natural açai juices, and are thus indicative of the potential of flavone-*C*-glycoside-rich extracts for anthocyanin stabilization in açai-containing foods, juice blends and beverages.

4. Conclusion

The influence of naturally occurring and externally added polyphenolic cofactors on the chemical and colour stability of predominant anthocyanins in açai fruit (*Euterpe oleracea*), cyanidin-3-glucoside and cyanidin-3-rutinoside, was investigated. Overall, the presence of flavone-*C*-glycosides induced an increase in anthocyanin colour and enhanced total anthocyanin stability, regardless of pH (3.0, 3.5, or 4.0) or storage temperature (5, 20, or 30 °C), while no significant effects were attributed to the presence of phenolic acids or procyanidins. External addition of flavone-*C*-glycoside-rich extracts from rooibos tea also resulted in up to ~45% higher anthocyanin colour and up to ~40% higher anthocyanin stability compared to uncopigmented anthocyanin isolates, and had similar copigmentation effects to a commercial anthocyanin colour enhancer extracted from rosemary. Results suggest flavone-*C*-glycosides are a potential alternative for the food and beverage industry for their use as colour enhancers and stabilizing agents in products containing non-acylated cyanidin glycosides, particularly açai fruit juice blends and beverages.

Wine proteins
Thermo-sensitivity
Bentonite adsorption

ABSTRACT

Protein fractions in a Chardonnay wine (invertases, glucanases, chitinases and thaumatin-like proteins) were identified using 2D-electrophoresis and mass spectrometry. The sensitivity of these fractions to heat-induced denaturation and precipitation following heat-treatments at different temperatures was studied and compared to their affinity for bentonite, a clay used to adsorb proteins and stabilise wines with regards to protein hazes. The different proteins exhibited different sensitivity with regards to heat-induced precipitation, glucanases being the most sensitive and invertases the least. Thaumatines and chitinases were characterised by a wide range of behaviours attributed to structural micro-heterogeneities. Protein depletion upon the addition of increasing bentonite doses was also dependent on the considered fraction. A good correlation was shown between protein affinity for bentonite and their sensitivity to heat precipitation. Results were discussed considering the current winemaking practices used to assess white wine stability and define bentonite doses needed to achieve their stabilisation.

1. Introduction

Protein synthesis in grape berries quickly increases after veraison, along with sugar accumulation (Giribaldi, Perugini, Sauvage, & Schubert, 2007; Murphey, Spayd, & Powers, 1989; Pocock, Hayasaka, Mc Carthy, & Waters, 2000). Protein diversity in musts and wines is much lower than in grapes since only soluble proteins are extracted during the winemaking process (Ferreira, Piçarra-Pereira, Monteiro, Loureiro, & Teixeira, 2002; Murphey et al., 1989). Moreover, protein amounts in wines are always lower than in the corresponding musts. That decrease is attributed to proteolytic activity, to precipitation by polyphenols and to unfavourable conditions related to the low pHs and the increasing ethanol contents. Protein concentrations reported for white wines vary between 10 and about 500 mg l^{-1} (Santoro, 1995; Vincenzi, Polesani, & Curioni, 2005). Grape variety, maturity and winemaking process are some factors that strongly affect the final protein content. These proteins have molecular mass ranging from 9 to 66 kDa and isoelectric points ranging from 3 to 9 (Brissonnet & Maujean, 1993; Dawes, Boyes, Keene, & Heatherbell, 1994; Hsu & Heatherbell, 1987). Most of them, identified as being chitinases and thaumatin-like proteins, are found within the range 20–30 kDa and are acidic (Dawes et al., 1994; Hsu & Heatherbell, 1987; Mesquita et al., 2001; Murphey et al., 1989; Pocock et al., 2000; Pocock, Hayasaka, Peng, Williams, & Waters, 1998).

Though present in rather small amounts, proteins are of primary importance for the colloidal stability and clarity of white wines (Bayly & Berg, 1967; Hsu & Heatherbell, 1987; Waters, Wallace, & Williams, 1991). Haze or deposit formation in bottled wines, due to protein aggregation during storage, is a common defect of commercial wines making them unacceptable for consumers. Numerous works have been devoted to the identification of protein structures implied in colloidal instabilities, as well as to the elucidation of the factors that trigger or prevent haze formation (Dawes et al., 1994; Hsu & Heatherbell, 1987; Pocock, Alexander, Hayasaka, Jones, & Waters, 2007; Waters et al., 1991; Waters, Dupin, & Stockdale, 2000; Waters, Peng, Pocock, & Williams, 1995; Waters, Wallace, & Williams, 1992). Aggregation is usually attributed to slow protein unfolding during storage, induced by exposure to high temperatures. As a consequence, most studies to explore the development of these hazes have been conducted using heat-induced precipitation. Chitinases and thaumatin-like proteins, which constitute the major part of white wine proteins, are also important contributors to heat-induced protein instability (Dawes et al., 1994; Hsu & Heatherbell, 1987; Waters et al., 1992). Attempts to correlate the total wine protein contents to their sensitivity to protein haze failed (Bayly & Berg, 1967); this can be related to a different sensitivity of the various protein fractions to heat-denaturation (Hsu & Heatherbell, 1987; Waters et al., 1991, 1992), and/or to the influence of factors other than protein composition. Among others, haze formation was shown to be strongly affected by the presence of non-protein compounds such as polyphenols (Dawes et al., 1994; Waters et al., 1995), ions (Besse, Clarck, & Scollary; 2000; Pocock et al., 2007) and polysaccharides (Dupin et al., 2000; Mesquita et al., 2001).

Different tests have been proposed to assess wine stability/instability with regards to protein haze (Pocock & Waters, 2006). These tests are based upon different types of procedures, leading to protein aggregation and precipitation. Heat stability trials, based on heat-induced precipitation, are the most common. These tests

are empirical and do not necessarily reflect changes and destabilisation phenomena liable to occur in real wine storage conditions. If needed, stability is usually obtained by bentonite fining, due to protein adsorption by the clay particles. The level of bentonite addition required for stabilisation is also determined by stability tests. These levels have increased during the last 20 years, so that doses in the order of 100–200 g hl^{-1} are often employed (Dubourdieu & Canal-Llaubère, 1989). Though effective, bentonite fining generates different problems, especially when such high doses are needed. First, this treatment is not selective enough and may adversely affect wine quality by inducing significant aroma losses and sometime colour alteration (Bayonove et al., 1995; Cabaroglu, Canbas, Lepoutre, & Gunata, 2002). Bentonite fining also causes substantial volume losses (between 3% and 10%) (Hoj et al., 2001) and the disposal of spent bentonites constitute a non negligible source of waste. Finally, bentonite handling is also of concern for occupational health and safety issues. For these reasons, increasing attention is given today to the development of alternative practices for protein stabilisation, that would maintain quality, reduce costs and be more sustainable (Waters et al., 2005).

Thorough knowledge of the structures and mechanisms involved is needed to be in position to control and prevent protein hazes while avoiding excessive and detrimental treatments. In addition to the identification of the role played by the other wine compounds, additional information regarding: (i) the sensitivity of the different wine proteins to heat-induced precipitation and (ii) their adsorption by bentonites is necessary. It is clear from previous works that the wine protein fractions exhibit different behaviours with regards to heat-induced precipitation and adsorption (Dawes et al., 1994; Hsu & Heatherbell, 1987; Murphey et al., 1989). In the present study the major proteins in a Chardonnay wine were identified using 2D-electrophoresis and mass spectrometry. This identification was used to study the sensitivity of each protein fraction to heat-treatment and to correlate this sensitivity to their adsorption by bentonite. To this end, a methodology to analyse and quantify wine proteins using 1D-electrophoresis coupled with image analysis was used, which is described first.

2. Materials and methods

2.1. Materials

2.1.1. Wine sample

The Chardonnay white wine used in this study was elaborated in 2005 at the Pech Rouge Experimental Unit (INRA Gruissan, France). Following to harvest, grapes were pressed without skin maceration and the must settled down (one night, 15 °C). Alcoholic fermentation was achieved at a temperature of 15 °C using the yeast Firmivin (DSM). After fermentation, the wine was racked and the SO_2 level was adjusted to prevent oxidation and malolactic fermentation. It was then stored during two months at 15 °C and bottled after a second racking and a membrane filtration.

2.1.2. Chemicals

The bentonite used was a commercial suspension of bentonite Electra® (Martin Vialatte). Thio-urea, urea, CHAPS, Triton X-100, Dithiothreitol, bromophenol blue, Tris buffer, glycine and Sodium Docedyl Sulfate were purchased from Sigma–Aldrich. Ampholines were from GE Healthcare.

2.2. Protein quantification in white wines using 1D-electrophoresis coupled with image analysis

Problems encountered to quantify proteins in wines using 1D electrophoresis and image analysis are related to their low concentrations and to the presence of non-protein compounds, especially polyphenols, that interfere with the analysis. To overcome these problems, a methodology was developed to obtain both protein concentration and separation. This was achieved by adsorption on bentonite of the proteins contained in a 1 ml wine aliquot, followed by their desorption using Laemmli buffer. Different bentonite doses, between 20 and 500 g hl^{-1}, were assayed. After bentonite addition and 30 min under soft shaking the mixture was centrifuged for 15 min at 20,000*g* and at 4 °C. The supernatant was removed and 100 μl of Laemmli buffer were added to the pellet to allow protein desorption. The suspension was shaken for 15 min and the bentonite separated by centrifugation, as described before. Several successive desorption steps were performed (up to 5 steps) and the supernatants analysed. With the experimental wines (protein concentrations below 150 mg l^{-1}) it was verified that no protein could be detected in the treated wines at a bentonite dose of 200 g hl^{-1} and higher. Up to 200 g hl^{-1} bentonite, the first washing step using 100 μl Laemmli buffer allowed the recovery of the whole protein fraction. Conditions for further experiments were then: wine sample, 1 ml; bentonite dose, 200 g hl^{-1} and Leammli buffer volume for desorption, 100 μl. Proteins in the buffer were concentrated 10 fold by comparison to the original wine. They were separated by 1D SDS–PAGE electrophoresis, performed in 14% acrylamide resolving gel (resolving gel length, 60 mm). As their initial concentration in wine was unknown, three different volumes (10, 20 and 40 μl) were deposited in the gel. Running was first conducted at 20 mA per gel all along the stacking gel and 30 mA per gel until the run end. Gels were then stained with colloidal CBB G-250 (Biorad) (Neuhoff, Arold, Taube, & Ehrhadt, 1988) and scanned at 300 dpi with an Image scanner (GE Biosciences). A low molecular weight calibration kit (Pharmacia, Biotech), ranging from 14 400 to 97,000 Da, was included in each electrophoretic run. Image elaboration and analysis were carried out with the Totallab software (Nonlinear Dynamics Ltd.). Image analysis was used to calculate the "volume" of each staining band from sample. This volume (product of the band area by the intensity of each pixel within this area) is proportional to the protein amount in each band provided saturation of the coloration has not been reached. It can be compared to the volume of the band obtained with a calibration protein. The volume of the Bovine Serum Albumin band of the low molecular weight calibration kit was used and results expressed in μg equivalent BSA. Quantification was performed for the three different deposited volumes (between 10 and 40 μl) and results represent the linear regression of the three measures.

2.3. Separation and identification of wine proteins by 2D-electrophoresis and mass spectrometry

2.3.1. Protein extract preparation for 2DE separation

To be in position to perform a 2D-electrophoresis separation of the wine proteins it was first required to purify (partial purification) and concentrate the whole wine protein content. Proteins were then dissolved under their native form by means of a suitable tensioactive mixture.

Polyphenols in the Chardonnay wine (750 ml aliquot) were first removed by adsorption using Fractogel (50 ml, Fractogel®TSK, Toyopearl HW50F, TosoHaas, Allemagne). Adsorption was realised in batches for 30 min, under gentle stirring. Adsorbent was removed by centrifugation (14,000*g*, 15 min, 4 °C) and the supernatant recovered. Protein concentration and purification from the dephenolysed wine was then achieved by successive ultrafiltration steps. The wine was first ultrafiltered using a 150 kDa plane membrane (50 cm^2, TAMI Industry, Nyons, France) using the spirelab device developed by TAMI (Nyons, France). This first step allowed the separation between wine polysaccharides, concentrated in the

retentate, and proteins (MW <150 kDa), recovered in the permeate. A second ultrafiltration step on a 5 kDa titanium/zirconium membrane (50 cm^2, TAMI Industry, Nyons, France), along with extensive diafiltration using deionised water (Milli-Q), allowed protein concentration and the removal of salts and small molecules. Diafiltration was monitored via conductivity measurements. The 5 kDa membrane was washed twice in 2 ml of an isoelectrofocusing (IEF) rehydration solution to recover adsorbed proteins. Washing solutions were added to the ultrafiltration retentate. The composition of the rehydratation solution was: 2 M thiourea, 7 M urea, 4% CHAPS, 0.5% Triton X-100, 65 mM DTT, traces of bromophenol blue, 5% ampholines mix. Protein concentration in the final extract (after 10 fold dilution) was assessed using CBB G-250 (Bio-Rad) with BSA as standard according to the Bradford's procedure (Bradford, 1976). It was adjusted to 1 μg μl^{-1} for next experiments.

2.3.2. 2DE Separation

Isoelectrofocusing (IEF) was carried out with 300 μg protein using 18 cm long Immobiline Dry-strips (pH interval 3–10, nonlinear, GE Healthcare). Sample loading was performed passively for 8 h at 20 °C in an IPGphor system (GE Healthcare). IEF migration program was as follows: active rehydration at 50 V during 9 h, ramping until 300 V in 1 min, start focusing at 300 V for 30 min, ramping again until 8000 V in 3 h, focusing for 11 h at 8000 V, decreasing until 300 V in 3 h. For a complete focusing the total power reached 105,000 Vh. Strips were then equilibrated twice upon gentle agitation for 15 min in a 50 mM Tris–HCl (pH 8.8) buffer containing 6 M urea, 10% glycerol and 2% SDS, added first with 1% DTT, and in a second time with 2.5% iodoacetamine (Görg, Weiss, & Dunn, 2004).

Second-dimension SDS–PAGE was performed on a 12% acrylamide gel using an ISODALT apparatus (GE Healthcare). Separation was achieved at 15 °C in a buffer (pH 8.3) containing 25 mM Tris, 0.192 M glycine, and 0.1% SDS. Running conditions were 1 h at 40 V and 30 mA per gel, 1 h at 70 V and 40 mA per gel, and then 11 h at 110 V per gel. Gels were stained and scanned as described before for 1D-electrophoresis. Image elaboration and 2D analysis were completed with the ImageMaster 2D-Platinium version 5 software (GE Healthcare). Molecular weights and isoelectric points of spots were determined according to migration of 2D standards (Bio-Rad).

2.3.3. In-gel digestion and mass spectrometry

Gels spots from 2D-electrophoresis were excised and washed twice with deionised water. Destaining was realised by at least three successive washes using a 50% acetonitrile aqueous solution (ACN) and 50 mM NH_4HCO_3, as described before (Görg et al., 2004). Gel fragments were successively dehydrated by ACN, re-hydrated and dehydrated again by NH_4HCO_3/ACN washes and finally dried under vacuum on a centrifugal evaporator. Final rehydration was achieved in a digestion solution composed of 0.1 M NH_4HCO_3, 5 mM $CaCl_2$ and 0.015 mg ml^{-1} trypsin (GOLD, Promega). Samples were first left on ice for 45 min to allow trypsin activation and then during one night at 37 °C to complete the in-gel protein digestion. To collect the digested peptides, gels spots were dehydrated/re-hydrated/dehydrated twice with ACN/NH_4HCO_3 (100 mM ACN), and washed twice in 5% formic acid and ACN. Washing solutions were pooled and dried in a vacuum centrifuge. The pellets (containing digested products) were re-suspended in 10 μl of 2% formic acid and desalted using C18 Zip Tips (Millipore Inc., France) according to manufacturer's instructions. The final peptide solution ACN/TFA/water (50%/0.1%/49.9%) was concentrated to a 2 μl volume by vacuum evaporation.

MS analyses were performed using an UltraFlex matrix-assisted laser desorption ionisation time-of-flight (MALDI-TOF) mass spectrometer (Bruker Daltonics, Bremen, Germany) in reflecton mode with an accelerating voltage of 19 kV. Different peptides ions generated by trypsin autolysis were used as internal standards for calibrating the mass spectra. Spots identified by MALDI-TOF were also analysed online using nanoflow HPLC nanospray ionisation on a quadrupole time-of-flight (Q-TOF) mass spectrometer. Spectra were recorded using Analyst QS 1.1 software (Applied Biosystems).

2.3.4. Identification by database search

The NCBI non-redundant database was explored with the MASCOT software (Matrix Science, London, UK). To confirm protein identities, the SWISS-PROT and Trembl databases were also explored with Peptident™ software. For identification by peptide mass fingerprinting (MALDI-TOF), the following parameters were used for database searches (Görg et al., 2004): (1) mass tolerance of 50 ppm, (2) a minimum of four peptide mass matching the protein, and (3) up to one missed cleavage was accepted only when two consecutive lysine or arginine residues were present or when residues were followed by a proline or acidic/basic residues. Sequence coverage was at least 15% for any identification. All MS/MS spectra were searched against the *Viridiplantae* entries of either the Swiss-Prot or Trembl database or ESTs in Genbank databases by using the Mascot v 2.1 algorithm, by sequence query analysis. All significant hits were manually inspected.

2.4. Thermo-sensibility of white wine proteins

Ten millilitre aliquots of the Chardonnay wine were heated to 30, 40, 50, 60, 70 or 80 °C in a waterbath during 30 min. Samples were cooled down and left at room temperature for at least one night. Then, they were centrifuged at 20,000*g* and at 4 °C during 20 min, to separate the precipitate. Proteins in the supernatants and in the pellets were identified and quantified by 1D-electrophoresis and image analysis, as described before. Experimental protocol for the supernatants was the same than that described for wine, except that in this case, a 12% acrylamide resolving gel was used. Precipitated proteins, recovered in the pellet, were solubilised in 1 ml Laemmli buffer before electrophoresis (Hsu & Heatherbell, 1987).

2.5. Protein adsorption on bentonite

Increasing volumes of a 10 g l^{-1} bentonite suspension were added to 1 ml Chardonnay wine aliquots to obtain final bentonite concentrations between 0 and 150 g hl^{-1}. Suspensions were shaken during 30 min at ambient temperature before being centrifuged (20,000*g*, 4 °C, 15 min). Proteins in the supernatants were analysed as described for wines. Adsorbed proteins on bentonites were recovered by washing the clay particles with 0.1 ml Laemmli buffer and directly analysed using electrophoresis (14% acrylamide resolving gel) and image analysis.

3. Results and discussion

3.1. Quantification of wine proteins by 1D-electrophoresis and image analysis

In the present work, the opportunity of improving protein patterns obtained from 1D-electrophoresis of white wines was experienced. The aim was to obtain profiles allowing protein quantification by image analysis. To this end, proteins have to be concentrated and separated first. This was achieved by an adsorption/desorption step on bentonite, clay being added in excess to ensure the adsorption of all proteins. Protein profiles obtained in this way for different white wines are shown in Fig. 1; pattern quality allowed the quantification of each protein band within

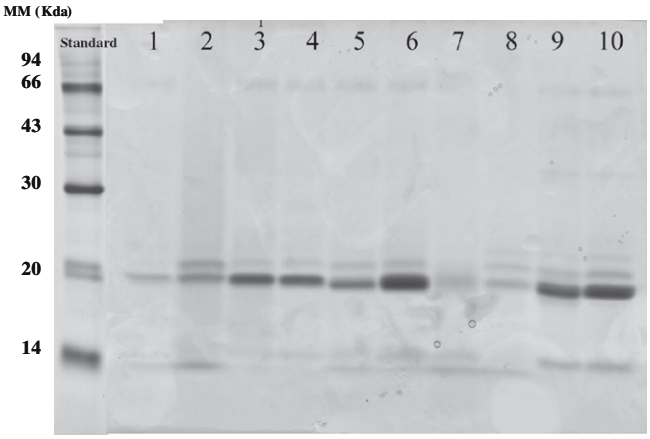

Fig. 1. Protein profiles obtained by 1D SDS–PAGE electrophoresis for white wines of different varieties and using the described extraction and concentration procedure. 1: Muscat, 2: Garganega, 3: Chasselas, 4: Moscatel, 5: Sauvignon, 6: Ugni Blanc, 7: Chardonnay I5, 8: Chardonnay I19, 9: Chardonnay I41, 10: Chardonnay I10.

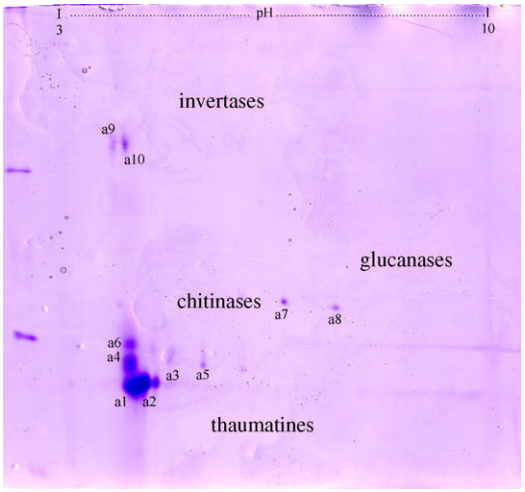

Fig. 3. Protein profile obtained by 2D-electrophoresis separation and staining using CBB-G-250. Proteins in the Chardonnay wine (I10) were identified by mass spectrometry and were: thaumatin-like proteins (spots a1, a2, a3, a5), chitinases (spots a4 and a6), glucanases (spots a7 and a8) and invertases (spots a9 and a10).

the whole pool. These patterns were typical of those reported in the literature for white wines (Dawes et al., 1994; Hsu & Heatherbell, 1987; Pocock et al., 2000), with protein fractions of molecular weight ranging from 14 to 66 kDa, the majority of them being comprised between 20 and 30 kDa.

The reproducibility of the quantification obtained via image analysis was assayed on the Chardonnay I10 wine (Fig. 2a), selected for further experiments due to its protein composition. The I10 protein pattern exhibited nine major bands so that this wine was characterised by the variety of its protein content. Results of protein quantification (Fig. 2b) represent a mean of six separate experiments, including the initial separation and concentration step. The I10 wine contained 142 mg l^{-1} protein in equivalent BSA, and the standard deviation between the six aliquots was 11%. It is important to note that when bands are quantified separately, the standard deviation may be different, depending on the concentration of each protein in the initial wine. For the I10 wine, these standard deviation fluctuated from 10% (band corresponding to the most concentrated protein fraction) to 25% (band corresponding to the less concentrated protein fraction).

3.2. Identification of white wine proteins

Proteins in the I10 wine were extracted and separated by 2D-electrophoresis for further identification by mass spectrometry. The protein profile evidenced ten major spots (Fig. 3), the number of spots detected onto 2DE gels being in agreement with the number of bands detected on 1D SDS–PAGE gels. MS analyses (Table 1) allowed identifying the different proteins in these spots: 4 thaumatin-like proteins (spots a1, a2, a3, a4), 2 chitinases (spots a5, a6), 2 glucanases (spots a7, a8) and 2 invertases (spots a9, a10). All these proteins, considered as pathogenesis-related proteins (PRPs) except for invertases, originated from grape and not from yeast. This specific grape origin of wine proteins is in accordance with previous data (Ferreira et al., 2000). However some proteins of fungal

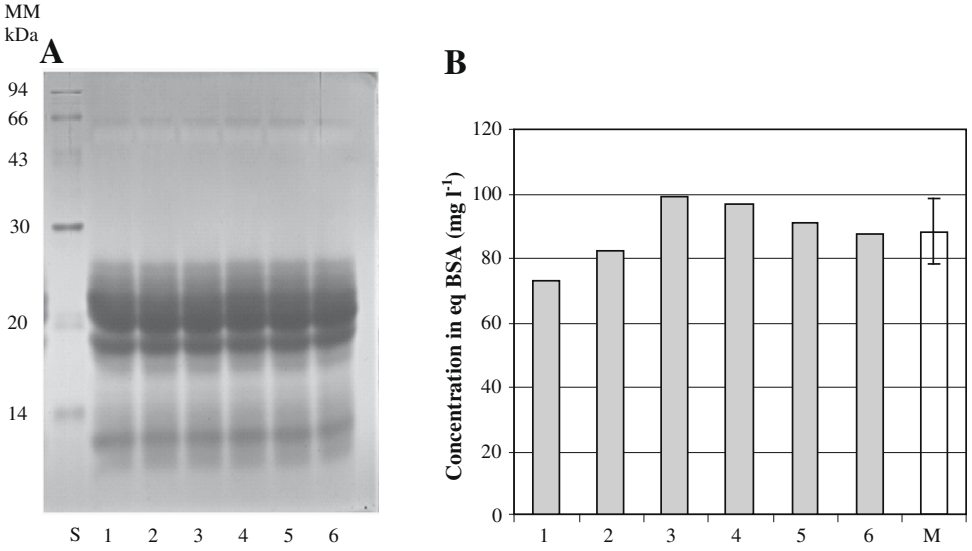

Fig. 2. (A) Protein profiles in the I10 Chardonnay wine obtained by 1D SDS–PAGE electrophoresis (14% acrylamide gel) for a deposited volume equivalent to 400 µl of wine. (B) Protein quantification on 6 aliquots, M being the average of the six quantifications. Under the experimental conditions this Chardonnay wine exhibited 9 different protein bands, corresponding to an average protein content of 142 mg l^{-1} equivalent BSA, with an 11% standard deviation.

or bacterial origin may also be present, though rarely evidenced (Monteiro et al., 2001). I10 wine proteins were mainly acidic, with isoelectric points (IEP) below 5, except for glucanases, the IEPs of which were found to be around 7. This also is in agreement with previous works (Cilindre, Castro, Clément, Jeandet, & Marchal, 2007; Dawes et al., 1994).

3.3. Heat-induced precipitation of white wine proteins

The conformational stability of proteins in a given solvent is weak and strongly affected by even small changes in the external variables (temperature, pH, salts, etc.). Changes from native to unfolded conformation, such as those induced by high temperature, are known to lead to protein aggregation (intermolecular interactions) and eventually precipitation (Chi, Krishnan, Randolph, & Carpenter, 2003; Murphy & Kendrick, 2007). However, complete unfolding is not required and also only partially unfolded structures may be prone to aggregate. In complex media such as wines, aggregation may involve proteins only, but can also result from attractive interactions between proteins and other non-protein compounds, as well-known for polyphenols. The presence of different protein structures, along with a large diversity in wine composition, makes the elucidation of mechanisms a very complex task and information is still required to rationalise both stability/instability trials and stabilization operations.

Thanks to the identification of the I10 wine protein composition it was possible to evaluate here the sensitivity of each protein family to heat-induced precipitation. Haze-forming precipitates were removed by centrifugation, and proteins in the pellets (results non shown) and non-precipitated proteins in the heat-treated wine (Fig. 4) were analysed and quantified by 1D-electrophoresis and image analysis. Results showed differences between the various protein families. The most heat-unstable were found to be glucanases (band 2); most of them were precipitated by a 30 min heat-treatment at a temperature as low as 40 °C. By contrast, temperatures higher than 60 °C were needed to significantly affect invertases (band 1). At 70 °C an important reduction of the invertase band was observed and most of them were removed when the temperature was raised to 80 °C. Chitinases (bands 3 and 4) and thaumatin-like proteins (bands 5, 6) exhibited different behaviours, depending on the considered structures. Increasing the temperature between 40 and 80 °C progressively induced an increasing precipitation of chitinases in band 4, most being eliminated after 30 min at 70 °C. Two different behaviours were observed for chitinases in band 3: most of them were highly sensitive to heat-induced precipitation (85% were precipitated at 40 °C, as glucanases) but others (15%) remained unaffected by temperatures below 80 °C. Thaumatin-like proteins were broadly more stable than chitinases, in accordance with previous results (Waters et al., 1992). The disparities observed here for chitinases and thaumatins could be related to the strong micro-heterogeneities evidenced between structurally similar wine proteins (Monteiro et al., 2001). Such micro-heterogeneities, which cannot be resolved by techniques based on separation according to the mass or the charge, were attributed to the limited proteolysis of common precursors during the wine-making process, generating a large number of structurally related but different polypeptides. Such a limited proteolysis is sufficient to induce subtle changes in the balance of intramolecular forces that affect protein conformational stability (Murphy & Kendrick, 2007). In the present conditions a large part of the proteins in the band 7 (40%) did not precipitate, even for temperatures as high as 80 °C. Proteins in band 7 were thaumatins (about 4 mg l^{-1}), along with low molecular weight (14 kDa) proteins (about 27 mg l^{-1}), not separated by the applied experimental conditions (12% acrylamide gel).

In most cases, heat-induced precipitation of wine proteins is studied using heat-tests performed at high temperature. The most widely used is that proposed by Pocock and Rankine (1973), which consists in a 6 h −80 °C treatment followed by cooling down during 12 h at 4 °C. Present results evidence that heat-induced aggregation is prone to occur for much less drastic conditions than those usually applied in these tests. They also emphasised the high heat-sensitivity of β-glucanases. This last protein class is not always found in white wines, where its presence was underlined only

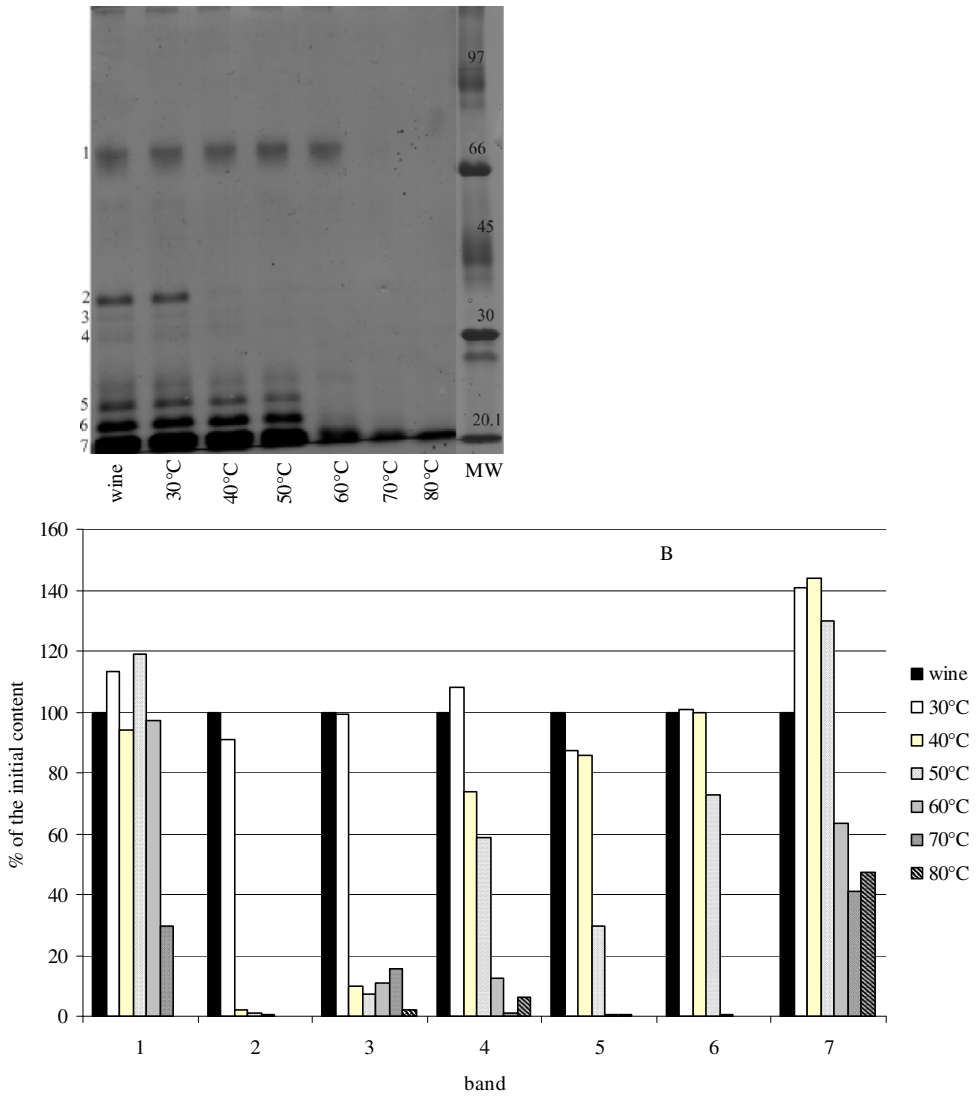

Fig. 4. Protein patterns in the I10 Chardonnay wine following to 30 min heat-treatments at different temperatures. (A) SDS–PAGE Electrophoresis (12% acrylamide resolving gel, Coomassie staining) performed on aliquots of heated-wine supernatants after cooling down and haze removal by centrifugation (molecular weight standard proteins on the right). (B) Protein contents in the supernatants as quantified by image analysis, in percentage of each protein band with regards to the initial wine. Band 1: invertases (initial content 12 mg l^{-1}); band 2: glucanases (initial content 9 mg l^{-1}); bands 3 and 4: chitinases (initial contents 8 and 11 mg l^{-1}, respectively); bands 5, 6: thaumatin-like proteins (initial contents 17 and 54 mg l^{-1}, respectively); band 7 (31 mg l^{-1}): low molecular weight unknown proteins (14 kDa, 87%) and thaumatins (13%), not separated here due to the experimental conditions (acrylamide percentage in gel of 12% and resolving gel length 60 mm).

three times (Cilindre et al., 2007; Esteruelas et al., 2009). It was recently found to be involved in naturally occurring hazes that had formed in a Sauvignon wine, along with VVTL1 thaumatin-like protein and ripening-related protein grip22 precursor (Esteruelas et al., 2009). Proteins in these spontaneous hazes were associated with phenolics and polysaccharides, present in quantitatively comparable levels. It is important to mention that β-glucanases in the I10 wine exhibited significantly higher isoelectric point (IEP) values than the other protein fractions (Fig. 3), and were then more distant from their IEP in the wine pH range. Heat-induced precipitation of proteins involves two distinct phenomena, protein unfolding and colloidal aggregation, which both are strongly influenced by protein charge (Chi et al., 2003). The influence of that charge on both intramolecular and intermolecular interactions is however complex and cannot be discussed on the only basis of protein isoelectric point; it also depends on the overall charge density and on the charged group distribution within the structure (random or anisotropic). Such structural information, along with information related to the other wine macromolecules (Vernhet, Pellerin, Prieur, Osmianski, & Moutounet, 1996), is needed to identify the exact physico-chemical mechanisms involved in protein instabilities in wines.

3.4. Protein adsorption on bentonite

Bentonite fining is the most common treatment applied to achieve white wine stabilization with regards to protein haze. One millilitre aliquots of the Chardonnay wine were treated with increasing bentonite doses, up to 150 g hl^{-1}. Adsorption was studied by the analysis of residual proteins in the fined wine along with that of the adsorbed proteins. More than 50% of the whole protein content was removed with 50 g hl^{-1} bentonite (Fig. 5). Increasing this dose up to 100 g hl^{-1} resulted in the removal of 85% of the protein content. About 15% of this protein content remained non-adsorbed even for a bentonite concentration as high as 150 g hl^{-1}, indicating that the concerned structures only have low affinity for the clay particles. Residual proteins all belonged to the thaumatin-like family. Protein patterns clearly showed selectivity in pro-

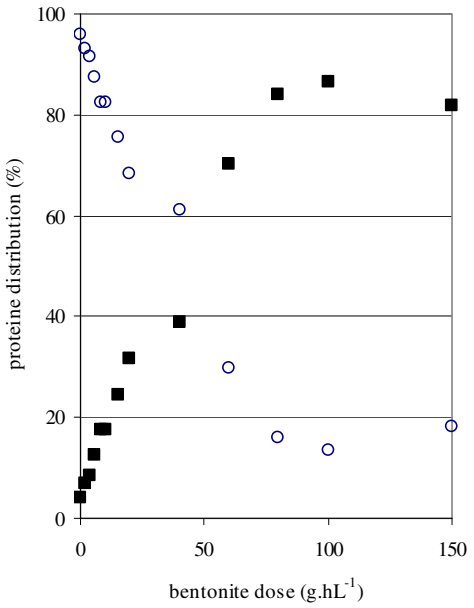

Fig. 5. Quantification of adsorbed (■) and non-adsorbed (○) proteins in the I10 wine after bentonite fining. Results are expressed in % of the whole protein content.

tein adsorption by bentonite (Fig. 6). Glucanases were adsorbed first, along with part of the thaumatin-like and low MW (14 kDa) proteins (in the order of 20%). Doses as low as 6 g hl^{-1} were enough to achieve glucanase depletion in the experimental wine. Chitinase adsorption started from 8 to 10 g hl^{-1} bentonite, progressively increased with increasing clay doses and was complete at 60 g hl^{-1}. The adsorption of thaumatin-like and 14 kDa proteins continued in parallel. A plateau value (70% adsorption) was reached for thaumatins at bentonite doses between 60 and 80 g hl^{-1}, while at 80 g hl^{-1} the depletion of 14 kDa proteins was achieved. Invertase adsorption only began at 20 g hl^{-1} and was total at 100 g hl^{-1}. Differences between wine proteins with regards to their removal by bentonite are in accordance with the earlier observations of Hsu and Heatherbell (1987). However in their work, the protein identities were still unknown.

Depletion of the protein fractions in the I10 wine as a function of bentonite concentration has to be compared to their sensitivity towards heat-induced precipitation. Glucanases, that exhibited the highest affinity for the clay, were the most heat-sensitive. Invertases, that needed the highest bentonite doses to be removed, were shown to be the most resistant to heat-induced precipitation. Chitinases, low molecular weight proteins and thaumatins exhibited intermediate behaviours, as observed with heat trials, and a specific part of the thaumatin (≈30%) remained unaffected for bentonite doses lower than 150 g hl^{-1} (it must be noted that this adsorption is achieved at a dose of 200 g hl^{-1}). Protein adsorption at interfaces often involves structural changes (partial or total unfolding) due to the formation of physico-chemical bonds between protein amino-acids and surface interaction sites (Haynes & Norde, 1995). Such structural changes have been evidenced for protein adsorption on negatively charged montmorillonites (main component of bentonites) when adsorption occur at pH values lower than the protein isoelectric point (Gougeon et al., 2003; Servageant-Noinville, Revault, Quiquampoix, & Baron, 2000). The relationship between protein adsorption on bentonite and their sensitivity to heat-induced precipitation could then be linked to their inherent conformational stability. As already discussed, the different behaviours observed in a given protein family, especially important for chitinases and thaumatins, could be related to micro-heterogeneities generated between structurally similar proteins by grape processing (Monteiro et al., 2001).

3.5. Consequences for stability tests and bentonite fining trials

Though the use of heat-stability tests to warrant white wine stability during transport and storage is a prevalent practice, the question of how they really predict situations that may occur during wine storage and transport is not yet solved. Indeed, only few works have been devoted to the study of the relationship between test procedures and long term stability of wines in real (long-time

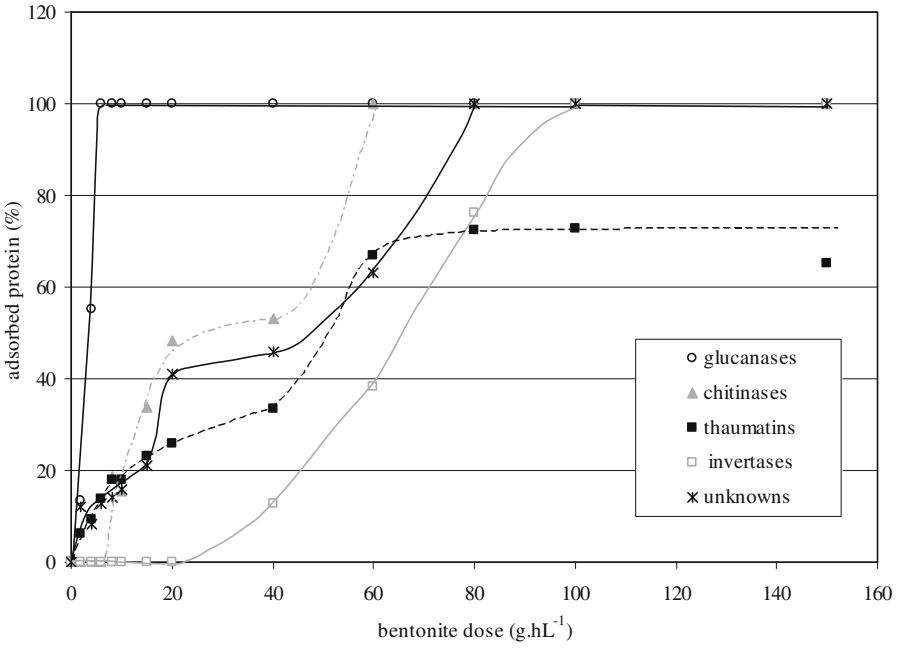

Fig. 6. Percentage of adsorbed proteins as a function of the bentonite dose, represented for each different protein family. Results showed selectivity in protein removal by the clay particles.

– low temperature) conditions (Pocock & Waters, 2006). The fact that the same tests, associated with bentonite fining trials, are used to determine the bentonite doses needed to stabilise wines raises the question of the relevance of these doses. Solving this question is a complex task due to wine variability and to incomplete knowledge concerning: (i) the precise structures and physico-chemical properties of wine proteins and, (ii) the mechanisms actually involved in their instability, including the influence of non-protein compounds. Results of the present work provide however some information to direct further studies devoted to the rationalisation of heat-test use.

With the experimental Chardonnay wine, a correlation was found between protein sensitivity to heat-induced precipitation and their removal by bentonite; the most heat-sensitive fractions were those that were also adsorbed first. These fractions are also those most likely to precipitate under excessive temperature exposure during practical storage and transport conditions. It could then be concluded that usual heat-tests, which induce the precipitation of almost all wine proteins including invertases, lead to an overestimation of the bentonite doses required for stabilization. These doses should be reasoned considering the different sensitivity of wine proteins and the conditions actually met in bottled wines. Additional information is needed to be in position to propose such less drastic heat-stability test conditions. First, heat-tests in the present study were performed at different temperatures but for a given incubation duration of 30 min. As temperature is known to affect protein unfolding rates, kinetics of heat-induced precipitation of the different protein classes have to be determined for different temperatures. Moreover, results must be validated using a large selection of wines because: (i) the wine composition is known to influence protein heat-stability and aggregation; (ii) if most wines were shown to contain the same set of structurally related proteins, the micro-heterogeneities evidenced within a same protein family (Monteiro et al., 2001) may be wine-dependent and induce conflicting results. Finally, all these results will have to be correlated with realistic storage conditions to validate the new test.

Aromatic amino acids
Singlet oxygen
Trolox
Ascorbic acid

ABSTRACT

The effects of 0, 100, 250, 500, 750 or 1000 ppm Trolox and ascorbic acid on the singlet oxygen oxidation of aromatic amino acids viz. phenylalanine, tryptophan, tyrosine in the presence of 25 ppm riboflavin were determined by measuring depleted headspace oxygen by gas chromatography and aromatic amino acid content by high performance liquid chromatography. The coefficients of variations (CVs) for headspace oxygen analysis and HPLC analysis of aromatic amino acids were 1.4% and 4.7%, respectively. Samples were stored under light (1000 lux) at 30 °C for 10 h. Both Trolox and ascorbic acid acted as antioxidants. As the concentration of Trolox and ascorbic increased from 0 to 1000 ppm, the head space oxygen depletion increased. This was due to the oxidation of Trolox and ascorbic acid along with amino acids in the presence of riboflavin. High performance liquid chromatography analysis of the samples clearly indicated that both Trolox and ascorbic acid minimised the degradation of phenylalanine, tryptophan, tyrosine significantly ($p < 0.05$), but did not prevent their oxidation completely. Trolox acted as a better antioxidant than ascorbic acid in protecting phenylalanine, tryptophan and tyrosine. Type-I mechanism was mainly responsible for riboflavin photosensitised degradation of aromatic amino acids.

1. Introduction

Riboflavin is naturally present in milk, eggs, meat products and vegetables. It is an active part of coenzymes such as flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD) that catalyse oxidation–reduction reactions (Choe, Huang, & Min, 2005). Riboflavin has complex photochemistry because of its ability to accept or lose a pair of hydrogen atoms (Crank & Pardijanto, 1995; Criado, Castillo, Yppolito, Bertolotti, & Garcia, 2003; Edwards et al., 1996; Kim, Kirschenbaum, Rosenthal, & Riesz, 1993; Li & Min, 1998; Viteri, Edwards, La Fuente, & Silva, 2003). Riboflavin under light can generate reactive oxygen species such as super oxide anions and singlet oxygen (Grzelak, Rycjlik, & Bartosz, 2001; Mahns, Melchheier, Suschek, Sies, & Klotz, 2003; Min & Boff, 2002). Formation of reactive oxygen species by riboflavin under light proceeds by both Type-I and Type-II mechanisms (Rochette, Birlouez-Aragon, Silva, & Morliere, 2003). After receiving light energy from light, riboflavin becomes excited triplet riboflavin. In the Type-I mechanism, the excited triplet riboflavin is reduced by abstraction of electrons or hydrogen ion from other food components to form riboflavin radical. In the Type-II mechanism, the excited triplet riboflavin reacts with atmosphere triplet oxygen to produce superoxide anion or singlet oxygen (Foote, 1985).

The interaction of singlet oxygen with biological molecules is of special interest both because of its effect on essential biological structures and also because in the treatment of malignancies by photodynamic therapy (Dougherty, 1992). Most of the research in the singlet oxygen oxidation of proteins has been done in the medical and pharmaceutical fields. Singlet oxygen reacts with proteins, peptides and amino acids in a variety of media (Kanofsky, 1990). The aromatic amino acids tyrosine and tryptophan as well as histidine and the sulphur containing methionine and cysteine are the major targets of attack by singlet oxygen, while aliphatic amino acids react with singlet oxygen at a significantly lower rate ($k \sim 10^4$–10^5 M^{-1} S^{-1}) (Lissi, Encinas, Lemp, & Rubio, 1993).

The indole ring of tryptophan, imidazole ring of histidine and phenol ring of tyrosine contain electron rich double bonds and can readily react with electrophilic singlet oxygen. Methionine and cysteine contain sulphur atoms with four non bonding electrons which readily react with electrophilic singlet oxygen. As amino acids become altered by singlet oxygen, the proteins and enzymes get denatured, lose functionality and can aggregate.

Song, An, and Jiang (1999) reported the use of histidine in several analytical techniques involving singlet oxygen. The reaction rate of singlet oxygen oxidation with amino acids and proteins depends on pH, temperature, the dielectric constant of the medium and the presence of singlet oxygen reactive amino acids as mentioned above. Bisby, Morgan, Hamblett, and Gorman (1999) reported that pH influences N-acetyl tyrosine ethyl ester and

doi:10.1016/j.foodchem.2009.04.022

amino acids. Singlet oxygen rate constant (k_t) by histidine is greatest when the pH $\gg$ pK_a (5×10^7) compared to 10^6 when pH $\ll$ pK_a. Fully protonated histidine had a k_t of 10^4. Tryptophan does not have any ionisable protons in the ionisable groups in the tested pH range, so did not show any pH effect. Their research showed that deprotonation of phenols in tyrosine results in an increase in k_t.

Michaeli and Feitelson (1995) compared the singlet oxygen reaction rate of large peptides to a solution of a comparative concentration of amino acids to each respective peptide. The free amino acids had a higher oxidation rate than did the native peptide. The reaction between amino acids and singlet oxygen is solvent dependent (Miskoski & Garcia, 1993). Some amino acids act as both physical and chemical quenchers. The singlet oxygen reaction rate constant of proteins is dependent on the types of amino acids, their accessibility to singlet oxygen and the dielectric constant of the medium (Michaeli & Feitelson, 1994). Jung, Kim, and Kim (1995) reported that histidine and tyrosine accelerated the riboflavin sensitised destruction of ascorbic acid and suggested that intermediate products of amino acid and singlet oxygen accelerated the oxidation of ascorbic acid.

Trolox is a water soluble analogue of α-tocopherol. Trolox is similar in structure to tocopherol with chroman ring but lacks a hydrophobic tail (Priyadarshini, Kapoor, & Naik, 2001). The phytyl tail of α-tocopherol is substituted with a carboxylic group which makes Trolox soluble in polar media. Trolox has been proved to be a better antioxidant than α-tocopherol under a wide range of conditions and test systems (Cort et al., 1975). Ascorbic acid acts as a primary and secondary antioxidant. Ascorbic acid has strong quenching ability for reactive oxygen species such as singlet oxygen and superoxide anion radical by converting their hydroperoxides into stable products (Jung, Lee, & Kim, 2000).

Many studies have reported the riboflavin photosensitised oxidation of amino acids while none reported how to minimise the photosensitised oxidation of amino acids and the antioxidant properties of Trolox and ascorbic acid on the photosensitised oxidation of amino acids. The objectives of this study was to study the effects of Trolox and ascorbic acid on inhibiting the oxidation of phenylalanine, tryptophan and tyrosine in the presence of riboflavin in aqueous model system and to study the nature of reactions (i.e. Type-I or Type-II) during riboflavin photosensitised oxidation of phenylalanine, tryptophan and tyrosine.

2. Materials and methods

2.1. Materials

Trolox (>98.0%), ascorbic acid (>99.5%), riboflavin (>99.9%) phenylalanine (Phe), tryptophan (Trp), tyrosine (Tyr) and NaH_2PO_4 ($\geqslant$99.9%) were purchased from Sigma Chemical Co. (St. Louis, MO). HPLC grade acetonitrile ($\geqslant$99.9%) and methanol ($\geqslant$99.9%) were obtained from Sigma Chemical Co. (St. Louis, MO). Serum bottles, Teflon lined rubber septa and aluminium caps were purchased from Supelco Inc. (Beelfonte, PA). HPLC grade water (Sigma, St. Louis, MO) was used as solvent for sample preparation. The purity of all amino acids used in this study was $\geqslant$99.5%.

2.2. Effects of Trolox or ascorbic acid on the degradation of phenylalanine, tryptophan and tyrosine

Aqueous solutions of 0, 100, 250, 500, 750 or 1000 ppm Trolox or ascorbic acid with 25 ppm riboflavin and 1.25% of phenylalanine, tryptophan and tyrosine were prepared separately to study the effect of Trolox or ascorbic acid on the stability of Phe, Trp and Tyr. The bottles were stored in a light storage box of 1000 lux (Li, King, & Min, 2000) or in the dark at 30 °C. Phe, Trp and Tyr concentrations in the serum bottles were determined in duplicate after 2, 4, 6, 8, 10 h of storage in the light box.

Aqueous solutions of 0, 0.3, 0.6 and 0.9 mM Trolox or ascorbic acid with 100 μM riboflavin and 40 mM Phe, Trp and Tyr were prepared separately to study favourable pathway, i.e. Type-I or Type-II, in the riboflavin photosensitised oxidation of Phe, Trp and Tyr. The bottles were stored in a light storage box for 4 h as mentioned above.

2.3. Effect of Trolox or ascorbic acid on the head space oxygen depletion of samples containing phenylalanine, tryptophan and tyrosine

Aqueous solutions of 0, 100, 250, 500, 750 or 1000 ppm Trolox or ascorbic acid with 25 ppm riboflavin and 1.25% of Phe, Trp and Tyr were prepared separately to study the effect of Trolox or ascorbic acid on the head space oxygen depletion. The bottles were stored in a light storage box of 1000 lux (Li et al., 2000) or in the dark at 30 °C. The head space oxygen in the serum bottles was determined in duplicate after 2, 4, 6, 8, 10 h of storage in the light box.

2.4. Effects of riboflavin on the photosensitised oxidation of Trolox and ascorbic acid

Aqueous solutions of 500 ppm Trolox or ascorbic acid with 25 ppm riboflavin were prepared separately to study the effect of riboflavin on the photosensitised oxidation of Trolox or ascorbic acid. The bottles were stored in a light storage box of 1000 lux (Li et al., 2000) or in the dark at 30 °C. Trolox and ascorbic acid concentrations in the serum bottles were determined in duplicate after 2, 4, 6, 8, 10 h of storage in the light box.

2.5. Headspace oxygen determination

The head space oxygen of each sample was analysed every 0, 2, 4, 6, 8, 10 h for oxygen content after equilibration to 20 °C in a water bath (Precision® Model 260, Winchester, VA) for 15 min. Headspace oxygen in the sample bottles was analysed by injecting a 100 μL headspace sample into a HP 5890 gas chromatograph equipped with a stainless-steel molecular sieve column (13×, 80:100; Alltech, Deerfield, IL) and a thermal conductivity detector (GOW-MAC® Instrument Company, Bethlehem, PA) (King & Min, 1998). High-purity helium (99.99%) was used as carrier gas. The flow rate was 40 mL/min. The GC oven temperature was maintained at 40 °C. The temperature at the injector port and detector were maintained at 120 and 150 °C, respectively. Duplicated injections were performed for each sample bottle. Electronic counts were integrated on an HP 3396A integrator (King & Min, 1998; Yang, Lee, & Min, 2002).

2.6. Determination of phenylalanine, tryptophan and tyrosine content by HPLC

The concentrations of Phe, Trp and Tyr in the samples were determined by HPLC analysis (Agilent 1100, Santaclara, CA) equipped with C-18 Zorbax Eclipse AAA column (3.5 μm, 4.6 × 75 mm) (Agilent Technologies, Santaclara, CA), diode array detector (Agilent Technologies, Santaclara, CA), manual injector (Rheodyne Model 7725i, Oakharbor, WA) and Agilent HPLC software (Agilent Technologies, Santaclara, CA). Samples were filtered with a 0.2 μm membrane filter (Corning Inc., Corning, NY). The injection volume was 20 μL. The flow rate of the mobile phase was 1.0 mL/min. For the separation of amino acids the following gradient system was used; 100% A at 0 and 1 min; gradient to 43% A and 57% B at 9.8 min; 100% B at 10 and 12 min; 0% B at

12.5 and 14 min (Solvent A – NaH_2PO_4; Solvent B – acetonitrile (45):methanol (45):water (10)). Spectral data (210–350 nm) was collected during the whole run. Elution of compounds was monitored at wavelength 254 nm for phenylalanine and tyrosine and 257 nm for tryptophan. Phenylalanine, tryptophan and tyrosine concentrations were calculated using a standard curve.

2.7. Trolox and ascorbic acid analysis content by HPLC

Trolox and ascorbic acid concentration in the samples were determined by HPLC analysis (Agilent 1100, Santaclara, CA) equipped with an aqua C-18 column (5 μM, 150 mm × 4.60 mm) (Phenomenex, Torrance, CA), diode array detector (Agilent Technologies, Santaclara, CA), manual injector (Rheodyne Model 7725i, Oakharbor, WA) and Agilent HPLC software (Agilent Technologies, Santaclara, CA). Samples were filtered with 0.2 μM membrane filter (Corning Inc., Corning, NY) before injection. The injection volume was 20 μL. The flow rate of mobile phase (methanol:water = 3:7 (v/v)) was 1.0 mL/min. Spectral data (210–350 nm) was collected during the whole run. Elution of compounds was monitored at wavelength 254 nm for ascorbic acid and 294 nm for Trolox. The concentration of Trolox and ascorbic acid were calculated using a standard curve.

2.8. Light storage conditions for the oxidative study

The light storage box consisted of two rectangular chambers: a glass chamber (60 cm × 30 cm × 50 cm) for sample storage and the wooden box (70 cm × 50 cm × 60 cm) for light sources. The distance from the light sources to the glass chamber was 12 cm. Samples were placed on a wire netting which was 10 cm above the bottom of the glass chamber. The light sources, four Sylvania 15 W cool white fluorescent lamps (Danvers, MA), were placed on the bottom of the wooden box. The light intensity at the sample level was about 1000 lux.

2.9. Statistical analysis

All the experiments were done in duplicate. Analysis of variance (ANOVA) was used to determine if antioxidant levels, storage duration were significant factors in the photooxidation of amino acids. Means were compared using Tukey's studentised range using XLSTAT at $\alpha = 0.05$ (Microsoft 2007).

3. Results and discussion

3.1. Reproducibility of analysis

The coefficients of variation for headspace oxygen analysis and HPLC analysis of amino acids were 1.4% and 4.7%, respectively (data not shown). The low coefficients of variation were considered good and indicated that headspace oxygen and HPLC analyses were reproducible methods to study oxidation of amino acids in the presence of riboflavin.

3.2. Effects of Trolox and ascorbic acid on the headspace oxygen of aqueous solution containing 1.25% of phenylalanine, tryptophan and tyrosine

The effects of 0, 100, 250, 500, 750 and 1000 ppm of Trolox on the headspace oxygen of aqueous solution containing 1.25% of phenylalanine, tryptophan and tyrosine, with 25 ppm added riboflavin are shown in Figs. 1–3. As the concentration of Trolox increased from 0 to 1000 ppm, the depletion of headspace oxygen increased. After 10 h of storage under light, the headspace oxygen of samples with 0 ppm Trolox and 1.25% phenylalanine was 17.2%,

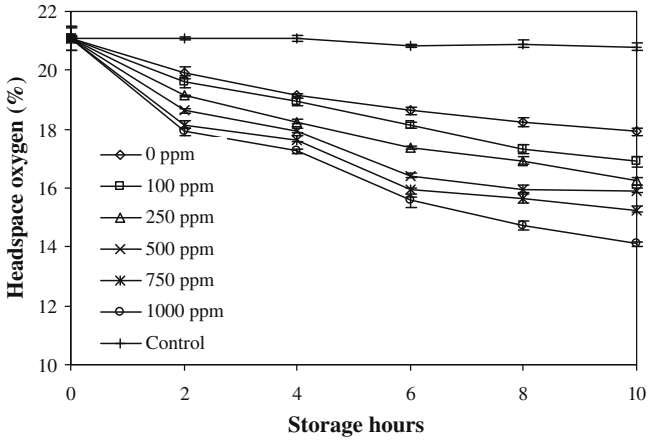

Fig. 1. Effects of Trolox on the headspace oxygen depletion of aqueous solution containing 1.25% phenylalanine and 25 ppm riboflavin under light. Data points represent means ($n = 3$) plus standard deviation.

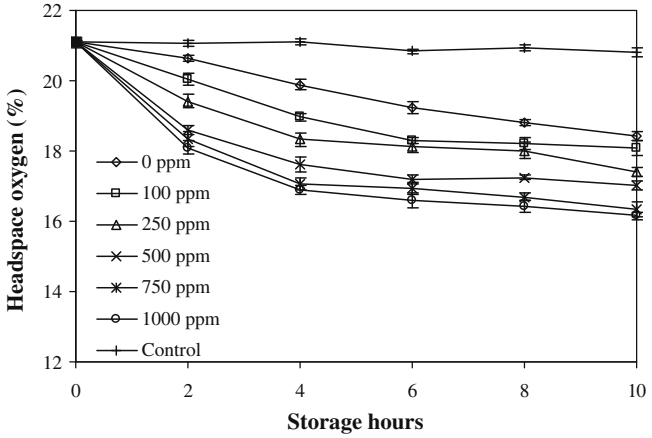

Fig. 2. Effects of Trolox on the headspace oxygen depletion of aqueous solution containing 1.25% tryptophan and 25 ppm riboflavin under light. Data points represent means ($n = 3$) plus standard deviation.

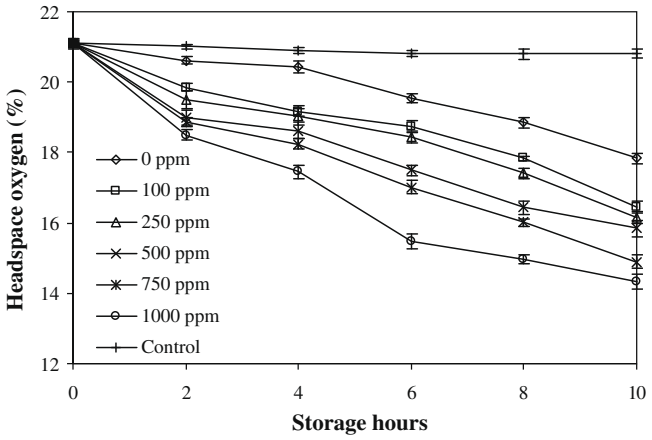

Fig. 3. Effects of Trolox on the headspace oxygen depletion of aqueous solution containing 1.25% tyrosine and 25 ppm riboflavin under light. Data points represent means ($n = 3$) plus standard deviation.

while the headspace oxygen of samples with 1000 ppm Trolox was 14.1% (Fig. 1). But under dark, after 10 h of storage the headspace oxygen remained almost the same at approximately 21% throughout the storage. Similarly, after 10 h of storage the head space

oxygen of the samples with tryptophan and tyrosine was 16.4% and 14.2%, respectively.

The effects of 0, 100, 250, 500, 750 and 1000 ppm of ascorbic acid on the headspace oxygen of aqueous containing 1.25% of phenylalanine, tryptophan, and tyrosine with 25 ppm added riboflavin are shown in Figs. 4–6. As the concentration of ascorbic acid increased from 0 to 1000 ppm, the depletion of headspace oxygen increased. After 10 h of storage under light, the headspace oxygen of samples with 0 ppm ascorbic acid and 1.25% phenylalanine was 16.8%, while the headspace oxygen of model system with 1000 ppm ascorbic acid was 12.6% (Fig. 4). But under dark, after 10 h of storage the headspace oxygen remained almost the same at approximately 21% throughout the storage. Similarly, after 10 h of storage the head space oxygen of the samples with tryptophan and tyrosine was 14.4% and 12.8%, respectively.

Riboflavin had a significant effect on the depletion of headspace oxygen in the samples stored under light but not in dark ($p < 0.05$). The disappearance of headspace oxygen in the airtight bottles was assumed to be a result of the reaction between oxygen, riboflavin and amino acids. Riboflavin in milk or soymilk increased the formation of volatiles and the depletion of headspace oxygen under light (Bradley, Kim, & Min, 2006; Huang, Choe, & Min, 2004c; King & Min, 1998). Jung, Lee, and Min (1998) removed riboflavin in milk by passing it though a Florisil column and the riboflavin-free milk did not produce volatiles during 8 h of storage under light. It suggested that the type of oxygen depleted from the headspace of sample bottles under light might not be the same as the type of oxygen depleted from the headspace of sample bottles in the dark. Ground state riboflavin having conjugated double bonds easily absorbs light and becomes excited singlet riboflavin. The excited singlet state riboflavin becomes excited triplet riboflavin through intersystem crossing mechanism. The diradical excited triplet riboflavin reacts with diradical triplet oxygen to produce singlet oxygen by triplet–triplet annihilation (Huang, Choe, & Min, 2004b; Min & Boff, 2002). Singlet oxygen is electrophilic, very reactive and a high-energy molecule. Singlet oxygen quickly reacts with food components containing double bonds such as riboflavin, polyunsaturated lipids and amino acids.

Singlet oxygen was detected in skim milk by electron spin resonance spectroscopy (Bradley et al., 2006), which showed singlet oxygen was formed in the presence of riboflavin and triplet oxygen. Singlet oxygen cannot be formed in dark, even in the presence of riboflavin. Therefore, the headspace oxygen in the airtight sample bottles stored under light probably decreased due to the formation of singlet oxygen. The type of oxygen lost from the headspace

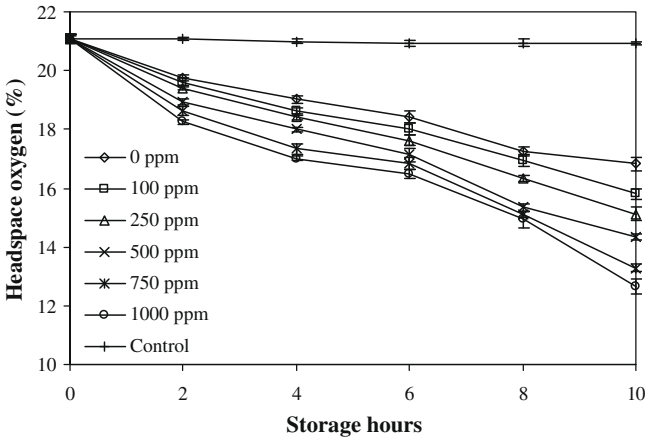

Fig. 4. Effects of ascorbic acid on the headspace oxygen depletion of aqueous solution containing 1.25% phenylalanine and 25 ppm riboflavin under light. Data points represent means ($n = 3$) plus standard deviation.

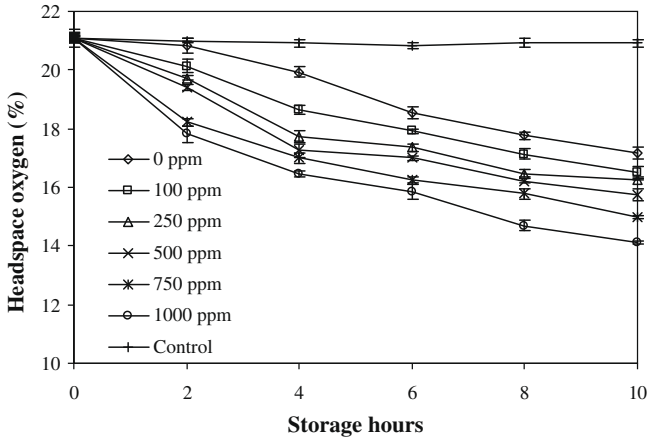

Fig. 5. Effects of ascorbic acid on the headspace oxygen depletion of aqueous solution containing 1.25% tryptophan and 25 ppm riboflavin under light. Data points represent means ($n = 3$) plus standard deviation.

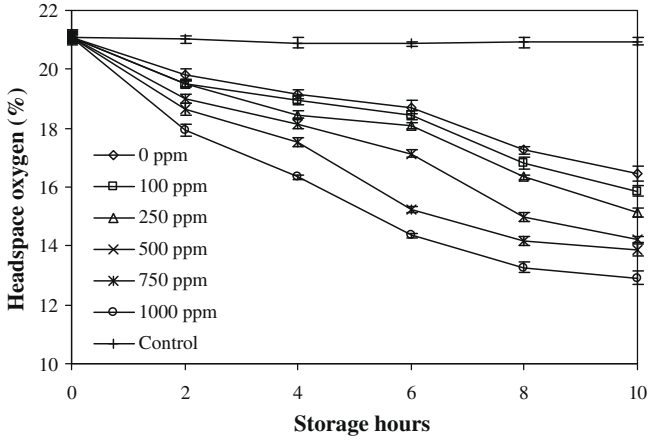

Fig. 6. Effects of ascorbic acid on the headspace oxygen depletion of aqueous solution containing 1.25% tyrosine and 25 ppm riboflavin under light. Data points represent means ($n = 3$) plus standard deviation.

of model system under light was presumably oxygen in its singlet state. The more singlet oxygen formed in model system, the more the headspace oxygen of samples decreased. The samples containing phenylalanine lost most head space oxygen (8.44%) followed by tyrosine (8.18%) and tryptophan (6.96%) at 10 h. But the samples stored in dark were relatively stable, remaining at approximately 21% of oxygen throughout storage.

3.3. Effects of Trolox and ascorbic acid on the retention (%) of phenylalanine, tryptophan and tyrosine (1.25%) under light

The effects of 0, 100, 250, 500, 750 and 1000 ppm of Trolox on the degradation of phenylalanine, tryptophan and tyrosine in the aqueous solution containing with 25 ppm added riboflavin are shown in Tables 1–3. As the concentration of Trolox increased from 0 to 1000 ppm, the degradation of amino acids decreased. After 10 h of storage under light, the samples with 0 ppm Trolox lost 23.6% phenylalanine while the samples with 1000 ppm Trolox lost 12.8% only. Trolox had a significant effect on the retention of phenylalanine, tryptophan and tyrosine at all levels of concentration.

The effects of 0, 100, 250, 500, 750 and 1000 ppm of ascorbic acid on the degradation of phenylalanine, tryptophan and tyrosine in the model system containing with 25 ppm added riboflavin are shown in Tables 4–6. As the concentration of ascorbic acid

Table 1
Effects of Trolox on the retention (%) of phenylalanine (1.25%) under light.[A]

Trolox (ppm)	Phenylalanine retention during storage (%) Storage hours					
	0	2	4	6	8	10
0	100[a]	92.4[a]	86.3[a]	81.4[a]	76.4[a]	73.6[a]

750	100[a]	98.6[c]	94.4[e]	91.4[e]	89.3[e]	87.3[e]
1000	100[a]	98.0[c]	96.3[f]	94.3[f]	92.4[f]	90.6[f]

[A] Numbers with different letters in the same column are significantly different at $\alpha = 0.05$.

Table 3
Effects of Trolox on the retention (%) of tyrosine (1.25%) under light.[A]

Trolox (ppm)	Tyrosine retention during storage (%) Storage hours					
	0	2	4	6	8	10
0	100[a]	92.1[a]	85.8[a]	82.4[a]	76.8[a]	71.4[a]
100	100[a]	94.4[b]	86.9[b]	84.8[b]	81.3[b]	78.8[b]
250	100[a]	95.6[c]	88.9[c]	86.6[c]	84.9[c]	81.1[c]
500	100[a]	96.4[d]	90.3[d]	88.9[d]	86.5[d]	84.3[d]
750	100[a]	98.0[e]	92.5[e]	90.1[e]	88.5[e]	85.4[e]
1000	100[a]	98.9[e]	94.3[f]	91.2[f]	89.4[e]	86.3[f]

[A] Numbers with different letters in the same column are significantly different at $\alpha = 0.05$.

increased from 0 to 1000 ppm, the degradation of amino acids decreased. After 10 h of storage under light, the samples with 0 ppm ascorbic acid lost 27.6% phenylalanine while the samples with 1000 ppm ascorbic acid lost 14.4% only. Ascorbic acid also had a significant effect on the retention of phenylalanine, tryptophan and tyrosine at all levels of concentration.

Trolox acted as a better antioxidant in preventing the degradation of aromatic amino acids than ascorbic acid. After 10 h of storage under light, 1000 ppm Trolox helped retain 87.2% of phenylalanine, 90.6% of tryptophan and 86.3% of tyrosine, while the samples containing ascorbic acid retained 85.6% of phenylalanine, 88.4% tryptophan and 83.2% of tyrosine. Cardoso, Olsen, and Skibsted (2007) reported that Trolox deactivates triplet-excited riboflavin in homogeneous aqueous solution (7:3 (v/v), *tert*-butanol/water).

Table 4
Effects of ascorbic acid on the retention (%) of phenylalanine (1.25%) under light.[A]

Ascorbic acid (ppm)	Phenylalanine retention during storage (%) Storage hours

1000	100[a]	98.0[e]	92.3[f]	90.2[e]	88.4[f]	83.2[f]

[A] Numbers with different letters in the same column are significantly different at $\alpha = 0.05$.

The reduction potentials of triplet riboflavin, tyrosine and tryptophan are 1.70, 0.93 and 1.01 V, respectively (Lu & Liu, 2002). Since, triplet riboflavin has a higher reduction potential than tryptophan and tyrosine, it can easily induce the photodegradation of amino acids by acting as strong oxidising species (Lu & Liu, 2002). Both Trolox and ascorbic acid quenches singlet oxygen (Huang, Choe, & Min, 2004a; Jung et al., 2000). So, the effect of Trolox and ascorbic acid can be used to estimate the relative contributions of Type-I or Type-II pathways on the degradation of phenylalanine, tryptophan and tyrosine under light. The degradation of Phe, Trp and Tyr without any singlet oxygen quencher under light is due to the sum of Type-I and Type-II pathways. The degradation observed under high concentrations of singlet oxygen of singlet oxygen quencher would be mainly contributed by the Type-I pathway (Huang et al., 2004a).

As shown in Fig. 7, the degradation rates of Phe, Trp and Tyr decreased as added Trolox increased. More than 15% of Phe, 48% of Trp and 45% of Tyr riboflavin photosensitised degradation can be prevented by 10 mM of Trolox. So, from this data, Type-I pathway was responsible for 85% degradation of Phe, 52% of Trp and 55% of Tyr. Similarly, as shown in Fig. 8, the degradation rates of Phe, Trp and Tyr decreased as added ascorbic acid increased. More than 17% of Phe, 48% of Trp and 43% of Tyr riboflavin photosensitised degradation can be prevented by 10 mM of Trolox. So, from this data, Type-I pathway was responsible for 83% degradation of Phe, 52% of Trp and 57% of Tyr. About 85% of Phe degraded through Type-I pathway in the presence of riboflavin indicating that Phe reacts with singlet oxygen at a significantly lower rate when compared to Trp and Tyr. Tryptophan and tyrosine have electron rich double

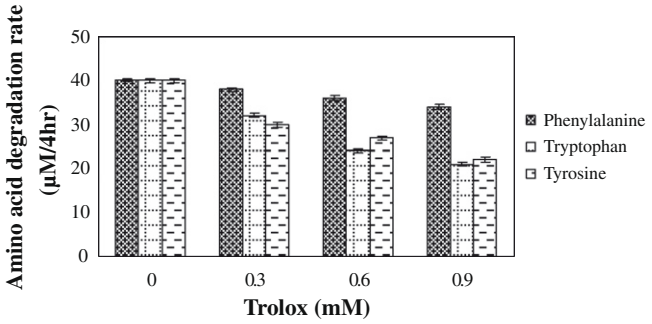

Fig. 7. Effects of 0, 0.3, 0.6 and 0.9 mM Trolox on degradation of phenylalanine, tryptophan and tyrosine. Data points represent means ($n = 3$) plus standard deviation.

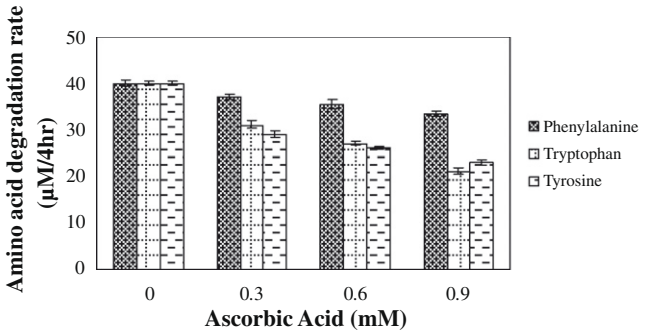

Fig. 8. Effects of 0, 0.3, 0.6 and 0.9 mM ascorbic acid on degradation of phenylalanine, tryptophan and tyrosine. Data points represent means ($n = 3$) plus standard deviation.

bonds and are excellent reactants for singlet oxygen oxidation. Photooxidation of tryptophan in the presence of riboflavin follows both Type-I and Type-II pathways (Rochette et al., 2000). Type-II pathway is favoured in riboflavin sensitised oxidation of tryptophan at high oxygen concentration under light (Rochette et al., 2000). However, in aqueous solutions the oxygen solubility is lower than other non-polar solvent systems. The lower availability of oxygen would favour the photosensitised reaction toward the Type-I pathway (Huang et al., 2004a). Cardoso, Franco, Olsen, Andersen, and Skibsted (2004) suggested that Type-I pathway may be major pathway for the light induced photooxidation of milk sensitised by riboflavin. The Type-I pathway proceeds via direct transfer of electrons from tryptophan and tyrosine side chains to triplet riboflavin yielding reduced riboflavin which subsequently generates reactive oxygen species (Cardoso et al., 2004).

The main photoproducts of tyrosine and tryptophan are bityrosine and a mixture of indole, flavin and indole flavin type aggregates, respectively (Rochette et al., 2000). Tryptophan degradation by riboflavin photosensitisation increased with oxygen concentration up to 40 μM oxygen and then decreased (Rochette et al., 2000). Ascorbic acid reduces the tryptophan photooxidation by interacting with excited triplet riboflavin (Garcia & Silva, 1997). Dalsgaard, Otzen, Nielsen, and Larsen (2007) studied riboflavin induced photooxidation of milk proteins and reported increase in carbonyl content during the oxidation of tryptophan as well as formation of dityrosine. Tyrosine and tryptophan in distilled water were oxidised in the presence of riboflavin at 7.5×10^{-6} M under light (Lu & Liu, 2002). At a low oxygen concentration of 5%, excited triplet riboflavin reacts with tyrosine (TyrOH) and produces riboflavin radicals ($RFH^{\cdot}_2$) and oxidised radicals of tyrosine ($TyrO^{\cdot}$) via electron transfer by Type-I pathway (Garcia & Silva, 1997; Viteri et al., 2003):

Table 7
Effects of light or dark on riboflavin (25 ppm) photosensitised oxidation of Trolox at 30 °C.

	Storage time (h)					
	0	2	4	6	8	10
Under light	100	95.0	88.3	83.7	80.0	75.1

Table 8
Effects of light or dark on riboflavin (25 ppm) photosensitised oxidation of ascorbic acid at 30 °C.

	Storage time (h)					
	0	2	4	6	8	10
Under light	100	86.8	78.6	73.6	68.4	64.3
In the dark	100	98.8	98.2	97.6	97.1	96.4

$$3RFH^{*} + TyrOH \rightarrow RFH^{\cdot -} + TyrOH^{\cdot +}$$
$$RFH^{\cdot -} + TyrOH^{\cdot +} \rightarrow RFH^{\cdot}_2 + TyrO^{\cdot}$$

Peptides containing tryptophan were oxidised rapidly at pH 7.5 in the presence of 21 μM riboflavin and fluorescent light mostly by singlet oxygen. The oxidation rate was higher when tryptophan was bound on the carboxyl side in dipeptide than when it was bound to the amino side (Viteri et al., 2003). In tripeptide containing tryptophan, the oxidation rate was highest when tryptophan is in the carboxyl side and lowest when tryptophan is in the middle of a tripeptide (Kanner & Fennema, 1987). Tyrosine (TyrOH) reacts with hydrogen peroxide formed by riboflavin and produces phenoxyl radicals ($TyrO^{\cdot}$) and finally bityrosine by radical–radical coupling (Pichorner, Metodiewa, & Winterbourn, 1995):

$$2TyrOH + H_2O_2 \rightarrow 2TyrO^{\cdot} + 2H_2O$$
$$TyrO^{\cdot} + TyrO^{\cdot} \rightarrow TyrO{-}OTyr \ (\text{bityrosine})$$

3.4. Effects of riboflavin (25 ppm) on the photosensitised oxidation of Trolox and ascorbic acid

Generally, the addition of singlet oxygen quenchers like Trolox and ascorbic acid should decrease the loss of head space oxygen. But the higher rate of headspace oxygen depletion indicates that oxidation reactions are occurring. This may be because of simultaneous oxidation of Trolox and ascorbic acid along with amino acids. So, to confirm our hypothesis we studied the effect of riboflavin on the oxidation of Trolox and ascorbic acid. The effects of riboflavin (25 ppm) on the degradation of Trolox and ascorbic acid are presented in Tables 7 and 8. Riboflavin had a significant effect on the degradation of both Trolox and ascorbic acid. As the storage duration increased from 0 to 10 h, the degradation of both Trolox and ascorbic acid increased under light but not in dark. At the end of 10 h 24.9% of Trolox and 35.7% of ascorbic acid was degraded. So, the higher rates of headspace oxygen losses in the samples containing Trolox and ascorbic acid were mainly due to the oxidation of Trolox and ascorbic acid. Between Trolox and ascorbic acid, the degradation rate of ascorbic acid was higher.

4. Conclusions

In conclusion, riboflavin has contributed to the photosensitised oxidation of phenylalanine, tryptophan and tyrosine. Trolox and ascorbic acid increased the depletion of headspace oxygen in the samples. The loss of headspace oxygen in the samples could be attributed to the formation of singlet oxygen and the subsequent

oxidation riboflavin, Trolox, ascorbic acid and amino acids. Trolox and ascorbic acid quenched singlet oxygen and thus reduced reactions between riboflavin and singlet oxygen. Type-I mechanism was mainly responsible for riboflavin photosensitised degradation of aromatic amino acids. Trolox and ascorbic acid can be used to effectively protect Phe, Trp and Tyr from destruction under light in the presence of riboflavin.

ABSTRACT

The impact of energy level on antioxidant properties in relation to pericarp browning and loss of disease resistance of litchi fruit was investigated. Litchi fruits were vacuum-infiltrated with distiled water (control), 1 mM adenosine triphosphate (ATP) and 0.5 mM 2,4-dinitrophenol (DNP) under 75 kPa for 3 min before being inoculated with *Peronophythora litchi* or not. ATP-treated fruits presented higher activities of antioxidant enzymes, including catalase (CAT), superoxide dismutase (SOD) and ascorbate peroxidase (APX). Higher activities of 1,1-diphenyl-2-picrylhydrazyl (DPPH) scavenging, reducing power and contents of phenolic compounds were also observed in ATP-treated fruit during storage. In contrast, DNP treatment lowered the enzymes activities, scavenging ability and the contents of phenolic compounds. Higher levels of antioxidant enzymatic system and non-enzymatic system were observed in *P. litchii*-inoculated fruits than those in non-inoculated fruits. Application of ATP and DNP exhibited a similar change patterns and effects in inoculated fruits. When related to previously reported ATP levels, the results suggested that ATP levels could regulate the antioxidant system. Sufficient available energy is crucial for inhibiting browning and preventing the loss of disease resistance in harvested litchi fruit.

1. Introduction

Adenosine triphosphate (ATP) serves as the 'energy currency of the cell' and is determinant of cell function and viability (Pradet & Raymond, 1983). Plant energy metabolism is considered as a mature field, but several important observations in plants initiated a research renaissance in ATP (both cellular and extracellular) in the last decade (Jiang, Jiang, Qu, Duan, & Jiang, 2007). This includes: (a) an ATP threshold existing for membrane lipid synthesis (Rawyler, Pavelic, Gianinazzi, Oberson, & Braendle, 1999); (b) effective preservative ways of horticultural crops closely associated with elevated ATP levels (Duan et al., 2004; Saquet, Streif, & Bangerth, 2001), energy deficiency, fruit browning and decay (Saquet, Streif, & Bangerth, 2000; Yi et al., 2008); and (c) extracellular nucleotides (eATP, eADP and hydrolyzable analogues of them) that function as regulatory agents in plant signal transduction (Roux, Song, & Jeter, 2006).

Mitochondrial oxidative phosphorylation is not only the main pathway of ATP production for eukaryotic cell, but also the major target of oxidative stress, mediated by reactive oxygen species (ROS), including superoxide anion ($O^{\cdot -}$), hydrogen peroxide (H_2O_2), hydroxyl ($HO^{\cdot}$), peroxyl ($ROO^{\cdot}$) and alkoxyl ($RO^{\cdot}$) (Bloknina, Virolainen, & Fagerstedt, 2003; Fleury, Mignotte, & Vayssiere, 2002). Such ROS, also termed active oxygen species, can disrupt cellular membranes, induce oxidative changes in DNA, and disturb cellular metabolism (Yu, 1994).

The accumulation of ROS could be prevented by two defence systems: non-enzymatic antioxidant system containing low molecular weight antioxidants (ascorbic acid, glutathione, tocopherols) and ROS-interacting enzymatic system comprising enzymes such as superoxide dismutases (SOD), peroxidase (POD), catalase (CAT), and ascorbate peroxidase (APX). Oxidative stress occurs due to the imbalance between ROS and ROS-scavenging compounds and enzymes. During senescence and stress conditions, plants cells could sense lethal dose of ROS and subsequently activate several defence enzymes and synthesise compounds as adaptional responses to scavenge ROS amount within a safe level. The processes for enzyme activation and synthesis of low molecular weight antioxidants require energy. Veltman, Lenthéric, Van der Plas, and Peppelenbos (2003) showed that energy production and ATP levels in tissues of pears play a role in regulating/inducing antioxidant enzymes, including SOD, CAT, and APX. Saquet et al. (2000) demonstrated that ATP played a vital role in the synthesis of ROS scavenging enzymes and non-enzyme scavengers in the ascorbate-gluthatione cycle. Energy depletion may result in a more dramatic oxidative stress, and consequently, damage the cell. Franck et al. (2007) suggested that membrane dysfunction, an early

doi:10.1016/j.foodchem.2009.04.074

response to senescence and stresses, is characterised by shortage of ATP and an increase in ROS production.

Browning is a common symptom during senescence or injury in fruit, resulting from breakdown of cellular compartments and consequently reaction between polyphenol oxidase (PPO) and its substrates (phenolic compounds) (Jiang, 2000). During storage, excess ROS generation accelerates the oxidisation of phenolic compounds, resulting in decreased contents of phenolics and pericarp browning (Underhill & Critchley, 1994; Zhang, Quantick, & Grigor, 2000).

The infection by pathogens increases the amount of ROS produced during fruit storage, the so-called "oxidative burst" in response to pathogen attack (Bolwell & Wojtaszek, 1997). The oxidative burst is crucial for the disease resistance in higher plants, whilst it may result in peroxidative destruction of cellular constituents if they are not timely averted. Thus, the intracellular ROS level has to be kept under tight control to prevent cell damage (Bartoli, Simontacchi, Montaldi, & Puntarulo, 1996).

Litchi (*Litchi chinensis* Sonn.) is a subtropical/tropical fruit of high commercial value in the international trade. Harvested litchi fruits are highly perishable due to water loss, pericarp browning and disease development. The objectives of present work were to measure antioxidant enzymes activities, scavenging activities and phenolic compounds contents to test whether extrogenous ATP supply will regulate the balance between the ROS and its defence system in litchi fruit during browning and pathogen infection process.

2. Materials and methods

2.1. Sample preparation

Litchi fruits were harvested when commercially matured from a local orchard (Guangzhou, China). They were washed in water containing 0.1% thiabendazole, and then infiltrated under vacuum with sterile distilled water (SDW) as control, 1.0 mM ATP and 0.5 mM DNP solution under 75 kPa for 3 min, separatively. *Peronophythora litchii* was isolated from infected litchi fruits and cultured on potato dextrose agar medium at 28 °C for 4 days. Half of the litchi fruits treated above were inoculated as previously reported by Yi et al. (2008). The fruits were kept in covered plastic boxes ($5 \times 15 \times 4$ cm) and stored at 25 °C (85–90% RH). Twenty fruits from different treatments were randomly sampled every 2 days of storage until the end of storage time (0, 2, 4, 6 days for inoculated fruits; 0, 2, 4, 6, 7 days for non-inoculated fruits). Pericarp tissue were immediately frozen in liquid nitrogen and stored at −70 °C until analysis (less than 3 months).

2.2. Determination of SOD, CAT, APX activities

Litchi pericarp tissue (2 g) was homogenised in 10 mL 0.05 M potassium phosphate buffer (pH 7.8) for SOD activity, 0.1 M potassium phosphate buffer (pH 7.0) for CAT and APX activities. The homogenate was filtered through two layers of miracloth and centrifuged at 20,000*g* for 15 min at 4 °C. The resulting supernatants were collected for the enzyme assays described below. Protein content was determined according to the Bradford (1976) method with bovine serum albumin as standard.

SOD activity was assayed by measuring its ability to inhibit the photochemical reduction of nitroblue tetrazolium (NBT) using the method of Beyer and Fridovich (1987). One unit of SOD activity was defined as the amount of enzyme required to effect 50% inhibition of the reduction of NBT per mg protein as monitored at 560 nm.

CAT activity was assayed by measuring the disappearance of H_2O_2 according to Aebi (1984). The assay mixture (3 mL) contained 2.95 mL phosphate buffer (0.05 M, pH 7.0), 15 mM H_2O_2 and 50 μL of extract. CAT activity was usually calculated by a decrease in absorbance at 240 nm and was expressed as U per mg protein.

APX activity was measured following the oxidation of ascorbic acid at 290 nm (extinction coefficient 2.8 mM^{-1} cm^{-1}) according to Nakano and Asada (1981). The reaction mixture consisted of 50 mM potassium phosphate buffer (pH 7.0), 0.5 mM sodium ascorbate, 0.1 mM H_2O_2, 0.5 mM ethylene diamine tetraacetic acid and 1 mL of extract. APX activity was calculated by the change of absorbance per minute per mg protein.

2.3. Determination of Scavenging activities of DPPH radicals and reducing power

Litchi pericarp tissue (2 g) was ground in liquid nitrogen with a mortar and pestle and homogenised in 10 mL methanol by stirring for 30 min at room temperature. The homogenate was filtered through two layers of miracloth and extracted again. Combined extract were stored at −20 °C until analysis.

DPPH radical scavenging activity was measured according to Shimada, Fujikawa, Yahara, and Nakamura (1992) with slight modification. The reaction mixture contained 0.1 mL of sample extract and 2.9 mL of 0.1 mM DPPH methanol solution. The absorbance at 517 nm was measured after 30 min of incubation at 25 °C. The inhibition of DPPH radicals by samples was calculated according to the following equation: DPPH scavenging activity (%) = (1 − absorbance of sample/absorbance of control) × 100.

Reducing power was measured at 700 nm according to Duan, Jiang, Su, Zhang, and Shi (2007). A control, devoid of any hydrolysates and a blank, containing only hydrolysate samples, was used because proteins also absorb at the same wavelength. Increased absorbance of the reaction mixture indicated increased reducing power.

2.4. Determination of total phenolic compounds

Litchi pericarp tissue (5 g) from 12 fruits was extracted three times in 100 mL methanol containing 0.1 M HCl at 25 °C for 2 h. The extract solutions were filtered and combined for total phenolic determination. Phenolic content of the extract was determined by a modification of the Prussian blue assay of Price and Buttler (1977). The extracts (50 μL) was diluted with 3 mL distiled water, and then 100 μL of 50 mM $FeCl_3$ in 0.1 M HCl plus 100 μL of 8 mM $K_3Fe(CN)_6$ added to the solution, which was incubated for 20 min. Total phenolic compounds were determined by measuring the absorbance at 720 nm on a spectrophotometer with gallic acid as standard.

2.5. Statistical analysis

Significant differences were tested by one-way analysis of variance (ANOVA) (SPSS, version 10.0). Each experiment was repeated 2–4 times.

3. Results

3.1. Effects of ATP and DNP on SOD, CAT and APX in litchi fruits

As shown in Fig. 1A and B, both the activities of SOD and CAT in control fruits slightly fluctuated in the first 4 days of storage and then continuously decreased to lower values as compared that of 0 day. Significant enhancements of both SOD and CAT activities were observed after fruits were treated with ATP ($P < 0.05$). Different with those in control fruits, the activities of SOD and CAT in ATP-treated fruits increased 23% and 45% in the first 4 days of storage, respectively. DNP-treated fruits showed much lower SOD and CAT activities than both control and ATP-treated fruits. SOD activity started to decrease after 2 days of storage and CAT activity began to decline from the beginning of the storage. Moreover, no signifi-

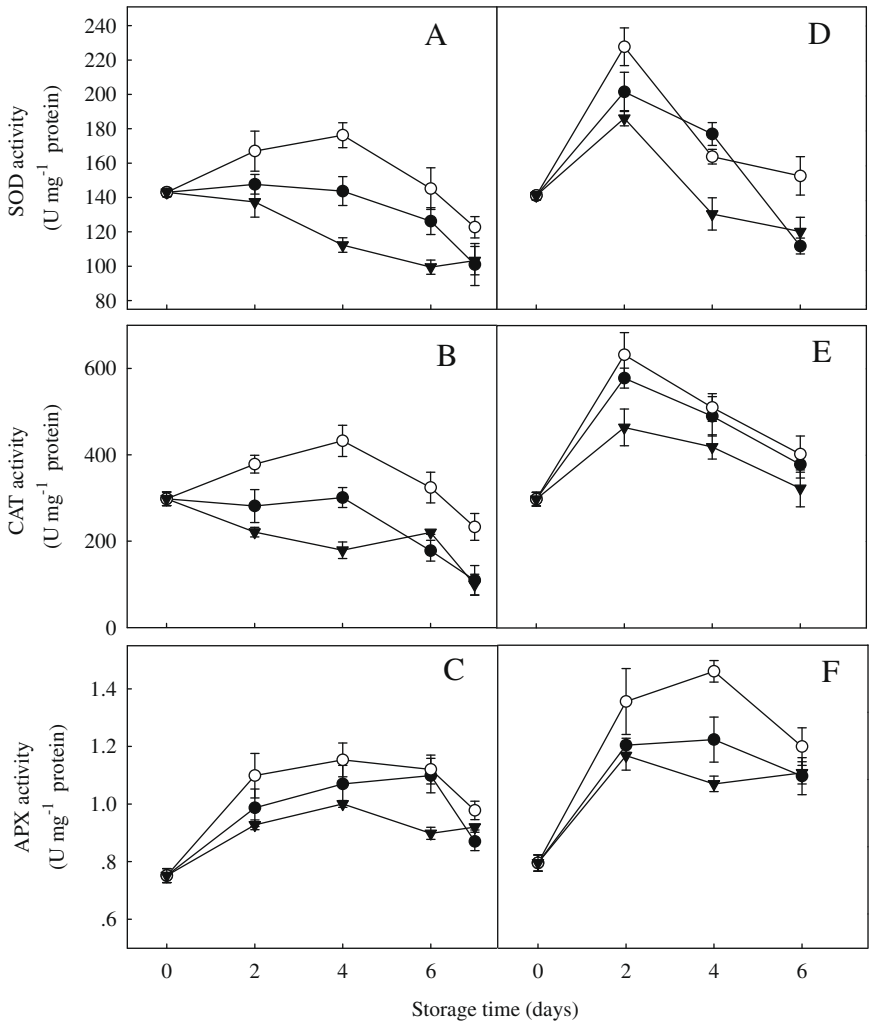

Fig. 1. Effects of ATP and DNP on SOD (A, D), CAT (B, E), APX (C, F) activities in non-inoculated (A, B, C) and *P. litchii*-inoculated (D, E, F) litchi fruits during storage. Each value is presented as mean ± standard error ($n = 3$). The vertical bars indicate standard errors where they exceeded the symbol size. (○, ATP; ●, Control; ▼, DNP).

cant difference of CAT activity between the control and DNP-treated fruits was observed in the last 3 days of storage. APX activity showed distinct change pattern with activities of other two enzymes. The activity increase from 0.75 to 1.09 U mg^{-1} protein as storage time proceeded and declined at the end of storage (Fig. 1C). ATP treatment markedly enhanced the APX activity, whilst DNP treatment lowered the activity.

The levels of SOD, CAT and APX activities in *P. litchi*-inoculated fruits were higher than those of non-inoculated fruits throughout the storage period (Fig. 1D, E, and F). Compared with non-inoculated fruits, inoculated fruits showed different trends in both SOD and CAT activities. SOD and CAT activities increased in the first 2 days of storage and then sharply decreased in the last 4 days of storage. The decrease in APX activity started from the 4 day of storage, which is 2 days earlier than that in the control and ATP-treated fruits. Likewise, higher activities of SOD, CAT and APX were found in ATP-treated fruit throughout the storage time, whilst lower activities were found in DNP-treated fruits than those in control and ATP-treated fruits.

3.2. Effect of ATP and DNP on DPPH scavenging ability and reducing power

Fig. 2 shows the effects of ATP and DNP treatment on DPPH radical scavenging ability and reducing power of litchi pericarp. In non-inoculated fruits, the scavenging activity of DPPH radicals gradually decreased as the storage time progressed. ATP treatment significantly reduced the activity of DPPH radicals (Fig. 2A). The DPPH scavenging ability decreased in DNP treated fruit. The change trends differed when the fruits were inoculated with *P. litchii*. DPPH radical scavenging ability in *P. litchii*-inoculated fruits was higher than those in inoculated fruits. It slightly increased from 100.1% to 105.2% in control fruits and significantly increased from 100.1% to 113.2% in the ATP-treated fruits in the first 2 days of storage, and then gradually declined (Fig. 2C). Also, remarkable enhancement of DPPH scavenging ability was observed in ATP-treated fruits and significantly lower scavenging ability was observed in DNP-treated fruits. The scavenging ability was in the order of ATP-treated *P. litchii*-inoculated fruit > *P. litchii*-inoculated fruit (control) > DNP-treated *P. litchii*-inoculated fruit > ATP-treated non-inoculated fruit > non-inoculated fruit (control) > DNP-treated non-inoculated fruit, throughout the storage period.

For both the non-inoculated and *P. litchii*-inoculated fruits, reducing powers of litchi pericarp extracts rapidly decreased from 1.6 to around 1.2 mg mL^{-1} (Fig. 2B and D). It was shown that the reducing power of ATP-treated fruits was higher than that in the control and DNP-treated fruits. After 2 day of storage, reducing powers in inoculated fruits were lower than those in non-inoculated fruits, suggesting stronger decline of antioxidant activity in infected tissues during storage.

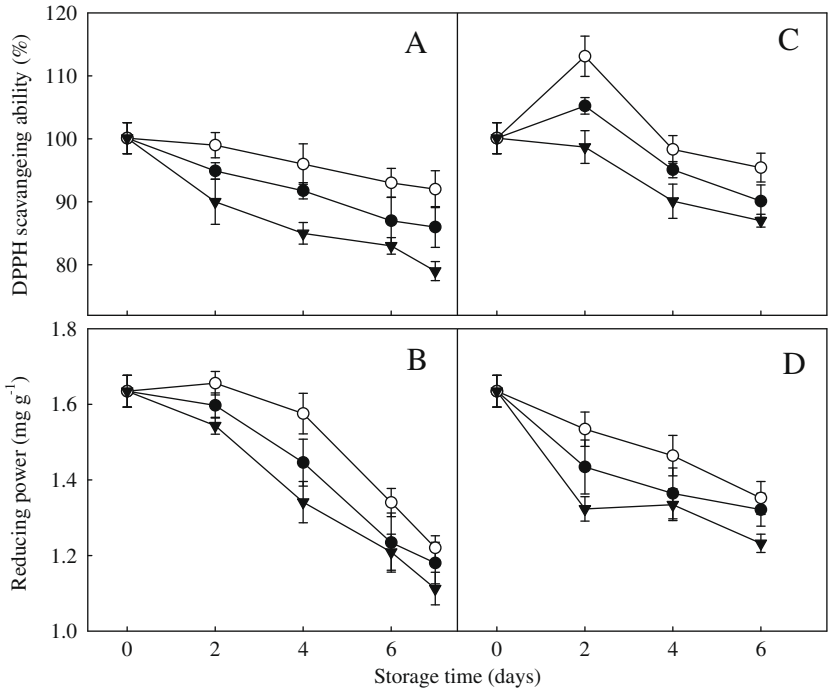

Fig. 2. Effects of ATP and DNP on DPPH scavenging activities (A, C) and reducing power (B, D) in non-inoculated (A) and *P. litchii*-inoculated (B) litchi fruits during storage. Each value is presented as mean ± standard error (n = 3). The vertical bars indicate standard errors where they exceeded the symbol size. (○, ATP; ●, Control; ▼, DNP).

3.3. Effect on the content of phenolic compounds

Contents of phenolic compounds of litchi fruit pericarp with different treatments are shown in Fig. 3. In the control fruits, the total phenolic contents decreased from 3.21 to 1.87 mg g^{-1} fresh weight (FW) in non-inoculated fruits and from 3.21 to 2.32 mg g^{-1} FW in *P. litchii*-inoculated fruits, respectively. Higher contents of total phenolic compounds in inoculated fruits were detected than non-inoculated fruits, even at the end of storage. There is a slight increase in all fruits after 2 days of inoculation. Treatment with ATP elevated the phenolic compounds contents of litchi fruit pericarp. At the second day of storage, the contents in ATP-treated fruits were 29% higher in non-inoculated fruits and 32% higher in *P. litchii*-inoculated fruits than those of DNP-treated fruits, respectively.

A correlation between the antioxidant activity in the DPPH assay and the contents of phenolic compounds were established (Fig. 4). As shown, there is a linear relationship between them with correlation coefficients of r^2 = 0.63. The increase of phenolic compounds contents will result an increase in DPPH scavenging ability.

4. Discussion

The data confirm that the ability of defence system of ROS gradually decrease during browning and pathogen infection process. According to previous results (Yi et al., 2008), ATP-treated fruits clearly exhibit less browning and disease symptom. This study shows the effects of ATP and DNP on the anti-oxidation system during browning or loss of disease resistance process.

Senescence and/or browning were caused by overproduction of ROS. The enzymes are involved in scavenging superoxide radicals, thus they could protects cells from oxidative stress (Buchanan-Wollaston et al., 2003). SOD converts two superoxide anions into a molecule of hydrogen peroxide and one of oxygen, and CAT could convert hydrogen peroxide to water and oxygen (Boonsiri, Ketsa, & van Doorn, 2007). APX prevents the accumulation of ROS by the ascorbate-gluthatione cycle (Asada, 1994). The results showed that all enzymes activities were higher in ATP-treated fruits and lower in DNP-treated fruits throughout the storage. The increased activities of SOD, CAT, and APX in ATP-treated fruits could contribute to

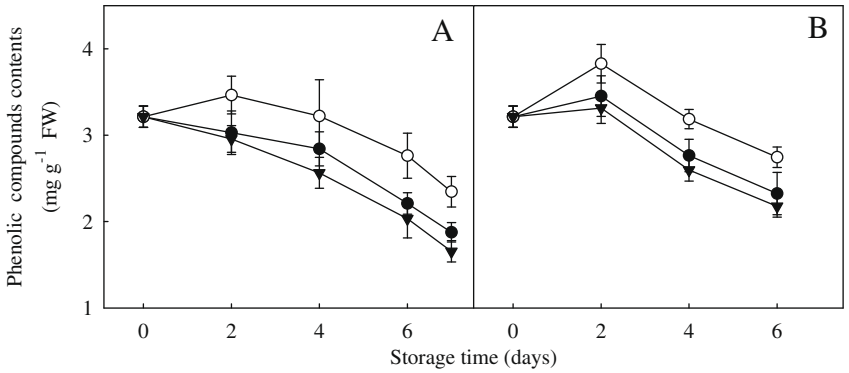

Fig. 3. Effects of ATP and DNP on contents of phenolic compounds in non-inoculated (A) and *P. litchii*-inoculated (B) litchi fruits during storage. Each value is presented as mean ± standard error (n = 3). The vertical bars indicate standard errors where they exceeded the symbol size. (○, ATP; ●, Control; ▼, DNP).

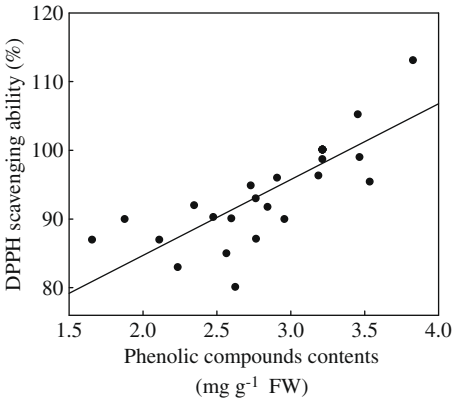

Fig. 4. Correlation between contents of phenolic compounds and DPPH scavenging ability in ATP-treated and DNP-treated litchi fruits.

avoiding or delaying the accumulation of ROS during ripening and then to prevent tissue damage.

Application of ATP to litchi fruits in the case of senescence and pathogen attack could protect the fruits against ROS generation via activating the enzymatic protecting system. Related to the ATP levels examined previously after ATP and DNP treatment, ATP treatment could elevate the ATP level and energy charge and then delay the browning process (Yi et al., 2008). By contrast, energy depletion in DNP-treated fruits fastened browning and decay process (Yi et al., 2008). Thus, the activities of SOD, CAT, and APX depended on the available energy in the cells. Therefore, energy level could regulate the balance between ROS generating and its enzymatic defence system, which could reduce the accumulation of ROS and prevent the abnormalities in cellular metabolism (Franck et al., 2007).

Free radical-scavenging is another known system for inhibiting lipid peroxidation by antioxidants. DPPH radical scavenging activity is one of the known methods used for evaluating antioxidant activity (Bloknina et al., 2003). The reducing power might also serve as a significant reflection of the antioxidant activity (Chang, Yen, Huang, & Duh, 2002). The noticeable elevated level of radical scavenging ability by ATP supply indicated that ATP might be involved in the synthesis of antioxidants, whilst decreased levels of radical scavenging ability in DNP-treated fruits corresponded to the accelerated browning process. Related to the energy levels previous examined, energy levels are positively correlated with the free radical scavenging ability. The energy level in litchi pericarp tissue could regulate the non-enzymatic ROS defence system.

Phenolic compounds are effective antioxidants in plants (Jiang, 2000), which are demonstrated by the correlation between the antioxidant activity in the DPPH assay and the contents of total phenolic compounds. The results suggested that sufficient ATP level was essential for the synthesis of phenolic compounds, and then consequently, enhance the antioxidant activity of litchi pericarp.

The results showed higher enzyme activities, higher free radical scavenging ability, and higher phenolic compounds after pathogen attack. The increased protection by enzyme activities could contribute to responses of ROS to the pathogen stress and defence pathways (Desikin, Mackerness, Hancock, & Neill, 2001). The induction of APX activity in response to stress has been reported by Garcia-Limones, Hervas, Navas-Cortes, Jimenez-Diaz, and Tena (2002). A previous study suggested two-stage behaviours with respect to pathogen invasion in litchi fruits (Yi et al., 2008). The first stage was characterised by increased ATP levels and better preserved membrane (0–4 days for non-inoculated fruits and 0–2 days for inoculated fruits), whilst the second stage was characterised by reductions in ATP contents and accumulation of lipid peroxide product (Yi et al., 2008). The present results are consistent with the two-stage behaviours as the enzyme activities remained constant or increased during the first stage and decreased during the second stage.

Moreover, phenolic compounds played vital roles in pathogen resistance (Nicholson & Hammerschmidt, 1992). Obviously, higher content and slower decrease trend of total phenolic in inoculated fruits suggested the induction of phenolic compounds synthesis under pathogen attack. A higher level of ATP may provide an advantage for phenolic compounds synthesis of rapid disease resistance in response to pathogen attack.

5. Conclusions

A fine balance between the maintenance of ATP levels and the confinement of ROS production within the amount of signal requirement is essential for inhibiting browning and loss of disease resistance. Exogenous ATP supply provides sufficient available energy to maintain or enhance the antioxidant systems and the synthesis ability of phenolic compounds, and consequently, to inhibit the accumulation of ROS and maintain the integrity of membrane. In other words, energy levels could regulate the balance between the ROS production and antioxidant system through enhancing both the enzymes activities and free radical scavenging ability.

Microenvironment

ABSTRACT

Mechanisms by which emulsifiers influence the activity of antioxidants in emulsions were investigated. To evaluate the importance of the partitioning between the different phases, the proportions of ferulic acid (FA) and isoferulic acid (iFA) at the o/w interface, in the coexisting micellar phase and in the aqueous phase were experimentally determined. An increase of the total emulsifier concentration and hence the micellar concentration led to an increased solubilisation of FA and iFA by the emulsifier pseudophases. From the point of view that the solubilisation sites of the antioxidants have different properties and thereby affect their activity, the microenvironment of each antioxidant was characterised in terms of local pH values and electrostatic potential. The degree of dissociation of both FA and iFA decreased in the order CTAB > SDS ≈ Brij. Information about the relative locations of the antioxidants was deduced from the extents to which the dissociation equilibria were affected by their environment. It was concluded that (1) the proximity to the polar headgroup of SDS, (2) a high degree of dissociation in a CTAB environment and (3) a deeper intercalation into the headgroup region of Brij were favourable for the antioxidant activity.

1. Introduction

The activity of antioxidants in emulsions is a complex issue as a result of their partitioning into different phases, each being characterised by specific properties and possible interactions with other constituents. It was proposed that the antioxidant activity in emulsions was positively correlated to the proportion of the antioxidant at the o/w interface (Frankel, Huang, Kanner, & German, 1994). In addition, it has been hypothesised that the proportion of antioxidants which is solubilised by the micellar pseudophase is not antioxidatively active. Therefore, regarding the impact of the partitioning on the antioxidant activity, a distinction between the proportion at the interface and in the micelles is necessary (Stöckmann, Schwarz, & Huynh-Ba, 2000). The ultrafiltration (UF) technique allows a distinction between the bulk aqueous phase, the micellar pseudophase and the o/w interface and maintains the initial structure of the emulsions (Oehlke, Garamus, Heins, Stöckmann, & Schwarz, 2008). However, a separation of the o/w interface and the droplet interior is not possible. To overcome this uncertainty, Gunaseelan, Romsted, Gonzalez-Romero, and Bravo-Diaz (2004) have developed a kinetic method which is based on the reaction of the antioxidant with arenidazonium salts taking place exclusively at the interface (Gunaseelan et al., 2004). They have shown that antioxidants with high and moderate hydrophilicity are predominantly located at the o/w interface rather than in the oil droplet interior. The results were in good accordance with results from UF experiments published by Stöckmann et al. (2000) and Stöckmann and Schwarz (1999).

Depending on the emulsifier concentration, a considerable amount of micelles may be present. Therefore, mass transfer in emulsions by micelles, and thereby an exchange of solutes between micelles and the o/w interface, also has to be taken into consideration (Zana, 1996).

Whether and by which mechanisms the activity of phenolic antioxidants is influenced by the pH value of the system has been investigated (Amorati, Pedulli, Cabrini, Zambonin, & Landi, 2006). It has been observed that phenolic antioxidants possess a higher antioxidant activity at neutral pH values than in acidic media, which was explained by the positive effect of the dissociated carboxylic group (Amorati et al., 2006). Schreier, Frezzatti, Araujo, Chaimovich, and Cuccovia (1984) developed a model to describe the interaction between partitioning and pK_a values of drugs in model systems. Furthermore, it has been shown that the dissociation of phenolic acids can be affected by the presence of emulsifiers in solution (Drummond, Grieser, & Healy, 1989; Polewski, Kniat, & Slawinska, 2002). These changes were ascribed to differences between mean solvent properties of the bulk and the interfacial phase. Results were also explained in terms of interactions with the emulsifier micelles and probable partitioning effects. The main objective of the present study was to relate factors which are governed by the emulsifier to the activity of antioxidants in emulsions.

The scope of this work embraced especially the acid base equilibria and the partitioning behaviour of antioxidants, utilising ferulic acid (FA) and isoferulic acid (iFA) as model compounds (Fig. 1).

2 Materials and methods

2.1. Chemicals

SDS (sodium dodecyl sulphate, ⩾99%), sodium acetate (⩾99%, anhydrous) and ferulic acid (>98%) were obtained from Carl Roth, Karlsruhe, Germany. CTAB (cetyl trimethyl ammonium bromide, ⩾99%), ABTS (2,2′-azino-bis(3-ethylbenzthiazoline-6-sulphonic acid), >99%) and potassiumperoxosulphoxide (⩾99%) were purchased from Fluka, Buchs, Switzerland. Brij 58 (polyoxy-ethylene-20-cetyl-ether) and isoferulic acid (97%) were obtained from Sigma–Aldrich, Seelze, Germany). All solvents were of analytical grade. The chemicals were used as received.

2.2. Emulsion preparation

Commercial corn oil was chromatographically purified on an aluminium oxide column and eluted with hexane according to the method of Lampi and Kamal-Eldin (1998). Hexane was evaporated under reduced pressure. The oil was stored under nitrogen at −20 °C until used.

The o/w emulsions consisted of 10 wt% purified corn oil triglycerides, 90 wt% acetic acid buffer solution (0.2 M, pH 5.0) and 10, 20 or 30 mM emulsifier, relative to the total emulsion. To prepare batches of 150 g, 15 g of oil were poured into plastic bottles, to which 60 ml of emulsifier solution were added. After shaking the solution to form pre-emulsions, sonication was applied for 30 s. During the next sonication step, the remaining 75 ml of buffer solution was added stepwise within one minute. The whole mixture was further sonicated for 120 s so that the total sonication time was 210 s (cycle 5, 40% power, Bandelin sonopuls, sonication probe VS 70, Berlin, Germany). Antioxidants were added via a concentrated ethanolic stock solution (50 μl) so that the antioxidant concentration in the emulsions was 50 μM, i.e., 500 μM relative to the oil phase. The ethanol volume was 0.2 vol% and was hence assumed to be negligible.

For the partitioning studies, emulsions were prepared with commercial corn oil, which was purchased in a local supermarket and used without any modification.

2.3. Determination of the partitioning behaviour

Ultrafiltration experiments were carried out using centrifugal devices as described earlier (Oehlke et al., 2008). Briefly, membranes with a low molecular weight cut-off (Vivaspin4 with reg. cellulose membrane, 3 kDa, Millipore, Schwalbach, Germany) were used to separate a small volume, usually not more than 10% of the initial sample volume, of the bulk aqueous phase containing emulsifier monomers and water-solubilised antioxidant molecules. To also separate a portion of the coexisting micellar phase, membranes with larger pores were utilised. Emulsions with SDS were filtered through regenerated cellulose membranes with an MWCO of 100 kDa (Centricon YM100, Millipore, Schwalbach, Germany), whereas emulsions with CTAB or Brij were filtered through inorganic membranes with a pore size of 20 nm (VectaSpin micro, Whatman, Dassel, Germany). Antioxidant concentrations in the filtrate were determined by HPLC analysis. All experiments were done in duplicate with three sampling steps each, so that the given results are means of six individual values. The experiments were carried out at room temperature.

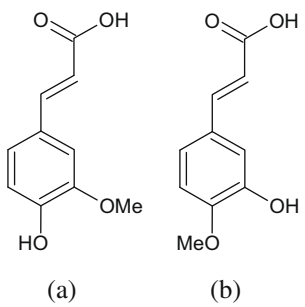

Fig. 1. Chemical structures of (a) ferulic acid (FA) and (b) isoferulic acid (iFA).

The total antioxidant concentration, $[A]_{tot}$, is the sum of the o/w interfacial concentration $[A]_{int}$, the micellar concentration $[A]_m$ and the free aqueous concentration $[A]_w$ (Eq. (1)), provided that all concentrations are given in mM (per total volume)

$$[A]_{tot} = [A]_{int} + [A]_m + [A]_w \quad (1)$$

By ultrafiltration, the different fractions are determined with

$$[A]_w = 0.903[A]_{low} \quad (2)$$

$$[A]_m = 0.903([A]_{high} - [A]_{low}) \quad (3)$$

$$[A]_{int} = [A]_{tot} - 0.903[A]_{high} \quad (4)$$

The subscripts "low" and "high" stand for the filtrate and permeate achieved with low and high MWCO membranes, respectively. The factor 0.903 accounts for the volume fraction of the oil phase, which does not directly solubilise the antioxidants (Gunaseelan et al., 2004).

2.4. Modified ABTS assay

The radical-scavenging activity was determined by a modified ABTS assay at different pH values (Ozgen, Reese, Tulio, Scheerens, & Miller, 2006). An ABTS solution was prepared (8 mM ABTS, 3 mM potassiumperoxosulphoxide in water) and left overnight in the dark. This solution was added to the different buffer solutions to yield an absorption of 1.4. From a 0.5 mM antioxidant stock solution, 50 μl were added to 2.95 ml of ABTS solution. A control sample was prepared by adding 50 μl of ethanol instead of antioxidant solution. Absorption of the samples was measured photometrically at 734 nm, before and 30 min after the addition of the antioxidant solution. The reduction of the absorption was calculated and corrected by values from the blank solutions. Between the measurements, the samples were kept at 25 °C in the dark. Measurements were done in duplicate with three independent antioxidant solutions, i.e., the given results are the means of six individual values.

2.5. Lipid oxidation experiments

The antioxidant activity was determined by a modified Schaaloven test. Samples were stored in gas-tight flasks at 40 °C in the dark and were analysed repeatedly over time. Hydroperoxide concentrations were determined by the ferric thiocyanate method modified by Stöckmann et al. (2000). The antioxidants were compared on the basis of the inhibition of hydroperoxide formation at the time when the control sample had reached a concentration of approximately 200 mmol hydroperoxides per kg of oil (Eq. (5)). This level corresponds to a peroxide value determined by iodometric titration of approximately 60 and was reached after 3–5 days, depending on the system.

$$\text{Inhibition} = 100\frac{C_{control} - C_{sample}}{C_{control}} \quad (5)$$

$C_{control}$ and C_{sample} are the hydroperoxide concentrations in the control and in the samples, respectively.

2.6. Spectrometric titration

The equilibria and species involved in the micellar solutions can be described by a thermodynamic cycle (Fig. 2) (Saikia, Bora, & Dutta, 2005; Schreier et al., 1984). It involves the dissociation of the antioxidant and the partitioning of the protonated and dissociated species between the aqueous phase and micelles.

For the determination of the pK_a values in buffer solution and buffered micellar solutions, pK_a^{obs}, solutions of 50 μM FA or iFA in acetic acid buffer solutions (0.2 M) in the pH range 3–6, with or without 30 mM of the respective emulsifiers, were prepared. Below pH 3.6 and above pH 5.6 the pH was adjusted with acetic acid to maintain a constant ionic strength in all samples. pH values were measured with a glass electrode (WTW, Weilheim, Germany). The calibration of the pH metre was carried out with a two point calibration curve. The pH value of each sample was measured until a stable value was obtained. UV absorption spectra were recorded with a spectrophotometre (Beckman Coulter, Krefeld, Germany) over the wavelength range from 200 to 400 nm. Samples were kept in a quartz cuvette with a path length of 1 cm (Hellma, Müllheim, Germany) and measurements were performed at 25 ± 0.2 °C.

For each wavelength, a curve of the absorbances vs. pH value was fitted according to a modified Boltzmann model with the software Origin 8. The pK_a^{obs} was given by the inflection point. Failed fits were discarded. The remaining 50–140 curves with the respective inflection points were used for further calculations.

2.7. Determination of acidity constants, local pH values and electric potentials

The total antioxidant concentrations and the pH value of the bulk were directly measured. The proportion of antioxidant in the bulk aqueous phase was analysed in the filtrate of UF tubes with a membrane cut-off of 3 kDa as described above. The difference of the total concentration was assigned to the micellar concentration. The resulting method to determine the acidity constants is similar to the procedure described by Schreier (1984) for drugs in a membrane model system. Abbreviations are given in Table 1.

The aqueous antioxidant concentration $[A]_w$ was determined in the ultrafiltrate of the tubes with 3 kDa membranes. The antioxidant in the aqueous phase is present in the dissociated and non-dissociated state:

$$[AH]_w + [A^-]_w = [A]_w \quad (6)$$

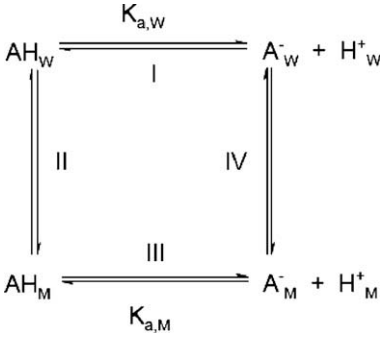

Fig. 2. Equilibria (roman numerals) and species involved in the partitioning of an antioxidant in a micellar solution (modified from Schreier et al. (1984) and Saikia et al. (2005)). *AH* and A^- represent the non-dissociated and dissociated forms of the antioxidant; for further abbreviations see Table 1.

Table 1
Abbreviations used in equations.

[]	Molar concentrations relative to the total solution
$[A]_w$	Total antioxidant in the aqueous phase: determined by UF
$[AH]_w$	Non-dissociated antioxidant in the aqueous phase[a]
$[A^-]_w$	Dissociated antioxidant in the aqueous phase[a]
$[H^+]_w$	Hydrogen ion concentration in the aqueous phase; measured with a pH electrode
$[A]_m$	Total antioxidant in micelles; determined by UF
$[AH]_m$	Non-dissociated antioxidant in micelles[b]
$[A^-]_m$	Dissociated antioxidant in micelles[b]
$[H^+]_m$	Hydrogen ion concentration in micelles
$K_{a,w}$	Acidity constant in water/the aqueous phase[b]
$K_{a,m}$	Acidity constant in micellar environment[b]
K_a^{obs}	Observed acidity constant in a micellar environment[b]
K_a^{app}	Apparent acidity constant in a micellar environment[b]

[a] Dissociation refers to the carboxylic group.
[b] For all acidity constants it is $pK_a = -\log K_a$.

The concentration of the dissociated species (Fig. 2, equilibrium II) was calculated by:

$$K_{a,w} = \frac{[A^-]_w[H^+]_w}{[AH]_w} \quad (7)$$

$K_{a,w}$ was determined in buffer solution by spectrometric titration experiments. The pH value, and hence $[H^+]_w$, was known, so that Eqs. (6) and (7) could be simultaneously solved to give $[A^-]_w$ and $[AH]_w$.

K_a^{obs} is the acidity constant which was directly observed in spectrometric titration experiments with micellar solutions. It includes dissociated and non-dissociated species in micelles and the bulk aqueous phase and can be described by:

$$K_a^{obs} = \frac{([A^-]_w + [A^-]_m)}{([AH]_w + [AH]_m)}[H^+]_w \quad (8)$$

The concentration of antioxidants solubilised by micelles $[A]_m$ was determined by UF. $[A^-]_w$ and $[AH]_w$ are known from Eq. (6) and (7). Further, the antioxidant molecules are known to be present in the micelles in both forms, dissociated and non-dissociated:

$$[AH]_m + [A^-]_m = [A]_m \quad (9)$$

Thus Eqs. (8) and (9) could be simultaneously solved, so that $[A^-]_m$, $[AH]_m$, $[A^-]_w$ and $[AH]_w$ are readily calculated.

K_a^{app} is the apparent dissociation constant in micelles and accounts for the partitioning of the solute (in contrast to K_a^{obs}). It is affected by the local pH value/electric potential and by polarity differences compared to the bulk aqueous phase.

2.8. Polarity effects in non-ionic micelles

Equilibrium III in Fig. 2 can be expressed as

$$K_{a,m} = \frac{[A^-]_m[H^+]_m}{[AH]_m} \quad (10)$$

The absence of an electric potential at the surface of non-ionic micelles makes it possible to determine the influence of a micellar environment on the acidic strength of a solute (Dupont-Leclerq, Giroux, Henry, & Rubini, 2007). Thus, if the concentrations of the acid and base forms of the compound in the micellar phase are known and the pH value is assumed to be equal to the pH value of the bulk, $K_{a,m}$ can be calculated (Eq. (10)). In the case of non-ionic micelles, $K_a^{app} = K_{a,m}$.

2.9. Potential and pH effects in ionic micelles

In ionic micelles, the electrostatic potential ψ at the micellar surface influences the local H^+ or OH^- concentration, and hence

the dissociation equilibrium of solubilised species. The influence of the electrostatic potential ψ at the micellar surface on the dissociation of acids was described by Fernandez and Fromherz (1977):

$$\Delta pK_a^{app} = pK_a^{app} - pK_{a,m} = -\frac{F}{2.3RT}\psi \quad (11)$$

with

$$pK_a^{app} = pH_w + \frac{[A^-]_m}{[AH]_m} \quad (12)$$

$pK_{a,m}$ accounts for the polarity of the local environment and therefore $pK_{a,m}^{SDS} = pK_{a,w}$ and $pK_{a,w}^{CTAB} = pK_{a,m}^{Brij}$.

The pH value at the solubilisation site (pH_{loc}) in SDS micelles was calculated according to the procedures previously described by Saikia et al. (2005) and Souza et al. (2006):

$$pH_{loc} = pK_{a,w} + \frac{[A^-]_m}{[AH]_m} \quad (13)$$

The pH_{loc} in CTAB micelles was calculated according to Pal and Jana (1996) and Dupont-Leclerq et al. (2007):

$$pH_{loc} = pK_{a,m} + \frac{[A^-]_m}{[AH]_m} \quad (14)$$

2.10. Calculation of the surface pH of ionic micelles according to the pseudophase ion exchange (PIE) model

The coverage of SDS micelles with H^+ ions is described by:

$$m_H^s = \frac{\beta[H^+]_w}{K_H^{Na}[Na]_w} \quad (15)$$

β is the micelle surface fraction covered with counter ions, K_H^{Na} is a constant which describes the exchange of protons and sodium ions between bulk and surface. $[Na]_w$ and $[H^+]_w$ are the sodium and hydrogen concentrations in the bulk.

m_H^s can be expressed as the proton concentration at the interface related to the volume of the Stern layer:

$$[H^+]_m = \frac{m_H^s[SDS]_m}{V_{Stern}} \quad (16)$$

From $[H^+]_m$, the pH value at the micellar surface can be calculated. With $K_H^{Na} = 1$, $\beta = 0.75$ and the molar volume of the Stern layer = 0.14 l, the surface pH was 3.3 in a 0.2 M sodium acetate buffer solution with pH 5.0 containing 0.03 M SDS. Values were taken from the literature (Romsted & Zanette, 1988).

A similar procedure was used for cationic micelles, but taking into account the exchange of OH^- and Br^- ions.

$$m_s^{OH} = \frac{\beta[OH]_w}{K_{OH}^{Br}[Br]_w} \quad (17)$$

$$[OH^-]_m = \frac{m_s^{OH}[CTAB]_m}{V_{Stern}} \quad (18)$$

Assuming the ion product of water to be 14 at the micellar surface, the pH can be calculated. With $K_{OH}^{Br} = 12$, $\beta = 0.8$ and the molar volume of the Stern layer = 0.14 l, the surface pH was 6.9 in a 0.2 M sodium acetate buffer solution with pH = 5.0 containing 0.03 M CTAB. Values were taken from the literature (Romsted, 1985).

3. Results

3.1. Partitioning of antioxidants

The partitioning of both antioxidants depended strongly on the type and concentration of the emulsifier (Table 2).

Table 2
Partitioning of FA and iFA in emulsions containing different emulsifiers and different emulsifier concentrations[a].

	P_w (%)	P_m (%)	P_i (%)
FA			
10 mM Brij	46.0 ± 0.4	1.0 ± 5.0	53.1 ± 5.0
20 mM Brij	34.2 ± 0.2	6.7 ± 3.3	59.1 ± 3.3
30 mM Brij	28.2 ± 0.6	13.7 ± 2.3	58.0 ± 2.5

30 mM CTAB	4.6 ± 0.1	30.5 ± 1.3	65.0 ± 1.3

[a] Errors correspond to the standard deviation according to Gauss error propagation, $n = 6$.

The proportions of FA in the aqueous phase decreased with increasing emulsifier concentration, regardless of the type of emulsifier. The highest concentrations in the aqueous phase were present in emulsions with SDS, followed by emulsions with Brij and CTAB. The micelle-bound FA concentrations increased with increasing total emulsifier concentrations. This effect was most pronounced in emulsions containing Brij 58, whereas SDS and CTAB concentrations had smaller effects. The proportion of FA at the o/w interface was not markedly affected by the total emulsifier concentration in the emulsions with CTAB and Brij, whereas an increased SDS concentration resulted in an enhanced interfacial FA concentration. The interfacial concentrations in the different emulsions decreased in the order CTAB > Brij > SDS.

The aqueous concentrations of iFA decreased in the order SDS > Brij > CTAB and were reduced with increasing emulsifier concentrations. Both micellar and interfacial concentrations decreased in the reversed order, i.e., CTAB > Brij > SDS compared to the aqueous phase in the same systems. The proportions solubilised by micelles increased with increasing Brij concentration and were less pronounced with increasing SDS concentrations. The total CTAB concentration did not influence the micellar concentration. The iFA concentrations at the o/w interface increased with increasing CTAB and SDS concentrations and decreased with increasing Brij concentration.

3.2. Apparent pK_a and local pH values

For the determination of local pH values and/or pK_a values in the respective micellar environment, the concentrations of the different species were calculated (Table 3). FA and iFA were incorporated to roughly the same extent in CTAB micelles. iFA was better solubilised by SDS micelles than FA, whereas FA was better solubilised by Brij than iFA.

The ratios of dissociated to non-dissociated acid were below 1.0 in Brij and SDS micelles, whereas they were 3.6 and 5.8 in CTAB micelles. In CTAB micelles, FA was less dissociated than was iFA. In contrast, FA was slightly more dissociated in SDS and Brij micelles. In buffer solution, the acidic strengths of both antioxidants were similar within errors. The observed pK_a values in micellar solutions

increased for both antioxidants in the order CTAB < SDS < Brij. After the correction for the partitioning, this order was maintained with regard to FA, but slightly different for iFA. Furthermore, differences between the emulsifiers increased. Also, the differences of the pK_a values of FA and iFA increased. The difference of the pK_a value in a Brij micellar environment compared to water was larger for iFA than for FA. In ionic micelles, the local pH values and electric potentials were calculated. The solubilisation site of FA was characterised by a higher pH value and a less negative electric potential than the solubilisation site of iFA. In CTAB micelles, the difference between local pH and surface pH was slightly larger for FA and FA showed a lower electric potential than did iFA.

3.3. Radical-scavenging activity

The ability to scavenge radicals was determined by a modified ABTS assay in solutions with different pH values. The loss of absorption at 734 nm related to a 1 mM antioxidant solution was determined as a measure of the number of radicals scavenged. For all pH values tested, FA was a more efficient radical-scavenger than was iFA (Fig. 3). The radical-scavenging activity of FA and iFA increased with increasing pH. An increase of the pH value from 4.0 to 6.1 resulted in a 1.2-fold increase of the activity of FA. The activity of iFA increased 1.4-fold with the most pronounced step from pH 5 to 5.6.

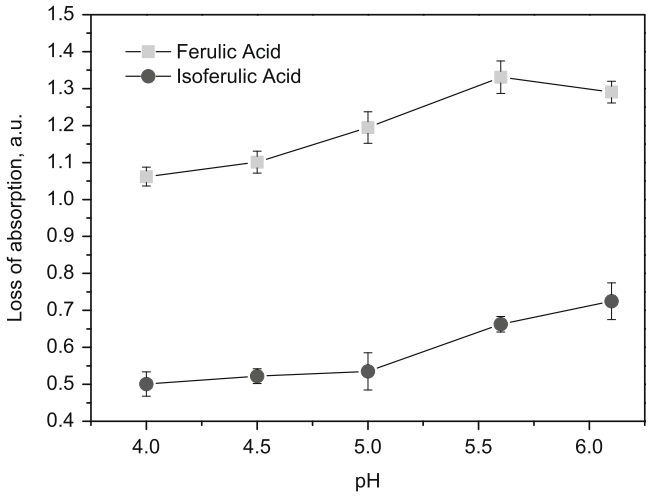

Fig. 3. ABTS radical scavenging activity of FA and iFA expressed as the reduction of absorption of the ABTS reaction solution at 734 nm after 30 min.

3.4. Inhibition of lipid oxidation

The ability of the antioxidants to inhibit the formation of hydroperoxides in emulsions during storage varied, depending on the type and concentration of the emulsifier used (Table 4). Both antioxidants showed the same trend, i.e. a decreasing activity in the order Brij > SDS > CTAB. In contrast to the ABTS assay, the inhibitory effect of iFA was stronger or comparable to that of FA. Hexanal concentrations were also measured to determine the inhibition of the formation of secondary oxidation products. The results showed the same trends (data not shown).

FA was not able to inhibit lipid oxidation in emulsions with CTAB. In emulsions with SDS, FA inhibited the formation of hydroperoxides only at the highest SDS concentration. In emulsions with Brij 58, FA had a moderate antioxidant activity, which increased with increasing Brij concentration.

In emulsions with 10 mM CTAB, hydroperoxide formation was inhibited by iFA to 16%, whereas no activity was observed when the CTAB concentration was increased. In emulsions with SDS, lipid oxidation was inhibited to 30–40% with a minimum at 20 mM SDS. In emulsions with Brij 58, iFA had moderate activity, which increased with the emulsifier concentration.

4. Discussion

4.1. Impact of the emulsifier on the partitioning

The partitioning of FA and iFA in emulsions was determined by ultrafiltration. The advantage of the technique, as applied in the present study, is the possibility to differentiate solute concentrations in the bulk aqueous phase, the micellar pseudophase and

Table 4
Inhibition of hydroperoxide formation by FA and iFA in emulsions stored at 40 °C in the dark.[a,b]

[b]The inhibition was calculated at a hydroperoxided level of 200 ± 40 mmol/kg oil in the control after three to 5 days of storage, depending on the samples.

the o/w interface without changing the physicochemical pattern of the emulsions. It was suggested earlier that the proportion of antioxidants in the micelles is antioxidatively inactive (Huang, Frankel, Aeschbach, & German, 1997; Huang, Hopia, Schwarz, Frankel, & German, 1996b). The distinction of antioxidant concentrations at the interface and in the coexisting micellar phase permits the testing of this hypothesis.

Generally, increased total emulsifier concentrations resulted in increased micellar and/or interfacial antioxidant concentrations to the expense of the proportions in the aqueous phase. Additionally, the increase of the micellar iFA concentration in emulsions with Brij was associated with decreased aqueous and interfacial concentrations.

This result reflects the partitioning of emulsifiers. When the interface is saturated with emulsifier molecules, a coexisting micellar pseudophase arises. Still, the interface had a higher solubilisation capacity than had the micellar pseudophase, which has been demonstrated by Stöckmann (1999). According to the LSER theory, hydrogen bonds in CTAB and Brij pseudophases can lead to an accumulation of antioxidants. The lower affinity of the antioxidants for the SDS pseudophases reflects the electrostatic repulsion on the one hand and the less favourable hydrogen bonding properties on the other hand (Stöckmann et al., 2000).

A direct exchange between ionic micelles and interfaces is unlikely, due to electrostatic repulsion, which would not allow a sufficient approximation of micelles and interface (Pena & Miller, 2006; Zana, 1996). In addition, the strong solubilisation of antioxidants by CTAB micelles results in an extended residence of solute molecules in the micelles (Zana, 1996). Therefore, an exchange with the aqueous phase is very slow, which results in restricted diffusion of the antioxidants to the interface. In contrast, interactions between the antioxidants and SDS molecules are very low and the exchange of antioxidants with the aqueous phase can be fast. The non-ionic Brij allows the direct exchange of solutes between the o/w interface and micelles. Therefore, it is concluded that antioxidants can freely diffuse between the phases and pseudophases, i.e., micelles could facilitate the transport of antioxidants to the o/w interface in emulsions stabilised by Brij 58 (Mukerjee & Ko, 1992; Pena & Miller, 2006).

4.2. Partitioning effects on the antioxidant activity

Regarding the activities of FA and iFA in the different emulsions, a similar trend was observed for both antioxidants, namely a decreasing activity in the systems in the order Brij > SDS > CTAB. According to the partitioning behaviour, an opposite trend would be expected, i.e., the highest activity in systems where the interfacial antioxidant concentrations are high, i.e., emulsions containing CTAB, followed by Brij and SDS.

In emulsions with the non-ionic Brij, partitioning seems to have a strong impact on the antioxidant activity. A higher proportion in micelles and interface roughly coincided with an increased activity of the antioxidants. This effect was less pronounced in emulsions containing SDS but not present in CTAB emulsions. It is suggested that Brij micelles contribute to an efficient inhibition of lipid oxidation by delivering antioxidant molecules, as discussed above. Due to the loose binding of FA and iFA by SDS, micelles may not negatively influence their activity. The presence of increasing micellar CTAB concentrations does not just inactivate the antioxidants, but promotes pro-oxidant behaviour. This is interpreted by molecular interactions or characteristic properties of the emulsifier pseudophases (Stöckmann et al., 2000).

4.3. Degree of dissociation and radical-scavenging activity

The radical-scavenging activity of FA and iFA increased with increasing pH value, the activity of iFA being slightly more sensitive to the pH value. Explanations for this may be obtained by taking mechanistic considerations into account.

The degree of dissociation changes electronic effects, which affect the mechanisms by which radicals are scavenged. Basically, many studies reveal that a dissociated carboxyl group is electron-donating and therefore activating other substituents in contrast to the non-dissociated electron-withdrawing COOH group. The positive effect on the activity may also be explained by the better stabilisation of the phenoxyl radical by the COO^- group. In addition, phenolic compounds with dissociated OH groups have been determined to be better radical-scavengers than are the parent compounds with non-dissociated phenolic OH groups. pK_a values of the phenolic OH of cinnamic acids are reported to be in the range of 8.5 (Silva et al., 2000). Amorati et al. (2006) reported that considerable dissociation of the phenolic OH started at pH 7–8. Hence, the concentration of this species is supposed to be very small under the conditions applied in this study.

The pH value can affect the activity of antioxidants in micellar solution and emulsions by two additional mechanisms. First, the partitioning and the location within micelles or the o/w interface depends on the degree of dissociation (Mei, McClements, & Decker, 1999). It was shown by Heins, McPhail, Sokolowski, Stöckmann, and Schwarz (2007) that the location in the interface has a strong impact, on the activity, which was explained by the importance of the spatial proximity of antioxidants and radicals. A high pH value may also be favourable, because metal ions, which act as pro-oxidants, can be better oxidised and thus mitigated in basic media, due to the more similar locations of metal ions and dissociated acids. In contrast, in acidic environments, phenolic acids, e.g., caffeic acids, were reported to reduce iron, thus acting as pro-oxidants themselves (Mei et al., 1999).

4.4. pH effects on antioxidant activity mediated by emulsifiers

4.4.1. pK_a values

pK_a values in buffer solution ($pK_{a,w}$) obtained by the spectroscopic method in the present study are in excellent accordance with values reported earlier (Erdemgil et al., 2007). The presence of micelles altered the dissociation equilibria of FA and iFA. The extent to which the micellar environment influences the dissociation equilibrium in micellar solutions (pK_a^{obs}) depends on the partitioning of the compound between the micellar phase and the bulk aqueous phase. Depending on the emulsifier, two effects may contribute to the influence of the micellar environment: solvation or polarity effects and the local pH (Losada Barreiro, Sánchez-Paz, Pastoriza Gallego, & Brávo-Díaz, 2008). In addition, there is a difference in the partitioning between ionised and non-ionised species, i.e., the non-dissociated forms of FA and iFA are subject to stronger hydrophobic attraction by micelles, which results in a higher incorporation (Saikia et al., 2005). On the other hand, electrostatic interactions may reduce the binding to anionic micelles and increase the binding to cationic micelles.

Drummond et al. (1989) described the impact of different emulsifiers on the pK_a value of phenolic compounds and found the same trends as reported in this work, namely an increase of the pK_a^{obs} value in the presence of SDS and Brij and a decrease in the presence of CTAB. They explained the results by the relatively low dielectric constant of the interfacial region and ascribed the effects to the difference between mean solvent properties of the interface and the bulk. The emulsifiers used in the present study have different properties and may thus provide different microenvironments as well as different solubilisation sites (Heins, Sokolowski, Stöckmann, & Schwarz, 2007). In the following sections, effects of each emulsifier will be described separately, because different mechanisms apply, depending on the charge of the emulsifier.

4.4.2. Effect of a Brij microenvironment on the acid base equilibrium and activity

The acidity constant in a homogeneous solvent mixture depends on the polarity of the mixture due to solvation effects, i.e. increasing organic solvent content increases the acidity constant (Beltrán et al., 2003). It has become common practice to evaluate the impact of a micellar environment on acid–base equilibria using non-ionic micelles, due to the altered polarity of the micellar environment compared to water (Fernandez & Fromherz, 1977; Pal & Jana, 1996; Whiddon, Bunton, & Söderman, 2003). On the other hand, it has been suggested that the acidity constant is an intrinsic property of a compound and is independent of the presence of micelles, as long as the environment is sufficiently hydrated. Hence, the acidity constants in water and in aqueous solution were set equal for further calculations in previous studies (Saikia et al., 2005; Souza et al., 2006). The dielectric constant of the headgroup region of non-ionic emulsifiers has been determined to be around 30–35 (Fernandez & Fromherz, 1977). In addition, non-ionic micelles have a higher solubilisation capacity for moderately polar compounds than has water and these compounds are located in the headgroup region of the micelles. As a conclusion, a polarity gradient is present between water and the headgroup region, which dominates over a possible pH gradient. These arguments are in line with the procedure described by Fernandez and Fromherz (1977), Pal and Jana (1996) and Whiddon et al. (2003) to evaluate the effect of the micellar environment. Thus, their method has been applied in the present study.

The pK_a^{app} values of both antioxidants were substantially higher in Brij micelles than were the $pK_{a,w}$ values obtained in buffer solution (Table 3). This is in accordance with results presented by other authors for a number of different compounds (Dupont-Leclerq et al., 2007; Pal & Jana, 1996; Whiddon et al., 2003). The difference between the pK_a values in buffer solution and in the micellar environment (ΔpK_a) was smaller for FA than for iFA. It is suggested that the larger the difference, the deeper is the probe buried in the headgroup region and thus the more non-polar is the solubilisation site. Therefore, it is concluded that FA is somewhat less deeply buried in the headgroup region of Brij micelles than is iFA.

Both FA and iFA exhibited a moderate antioxidant activity in emulsions, despite the lower radical-scavenging potential of iFA than for FA in the ABTS assay (Fig. 3, Table 4). The results show that the ratio of dissociated to non-dissociated acid ($[A^-]_m/[AH]_m$) is slightly higher for FA compared to iFA. This small difference may be superimposed by the effects of different locations. These are reflected by different pK_a^{app} values, so the proximity to radicals could be improved.

4.4.3. Effect of the SDS microenvironment on the acid–base equilibrium and activity

It has been demonstrated by NMR measurements that hydroxycinnamic acids are located in the Stern layer of SDS micelles (Heins, Sokolowski, et al., 2007). The Stern layer contains predominantly water and counter ions. The difference in the polarity between buffer solution and the outer Stern layer, where hydroxycinnamic acids are solubilised, therefore does not contribute to the pK_a^{app} value in the SDS micelle. Thus, $pK_{a,w}$ was used for calculating the pH value at the solubilisation site (pH_{loc}) according to Souza et al. (2006). In addition, it is possible to calculate the surface pH according to the PIE model. According to this model, at low pH, Na^+ of SDS is displaced from the micellar surface by H^+ (Romsted & Zanette, 1988). Increased pK_a^{app} values mean that the low pH in the Stern layer shifts the acid–base equilibria of solutes to the left (Fig. 2). For both FA and iFA, pH_{loc} was not equal to the surface pH calculated by the PIE model. The value of the pH-difference (ΔpH) could account for the distance of the molecule from the micelle surface. If a pH gradient is assumed from the micellar surface to the outer regions of the Stern layer, this would mean that iFA was closer to the surface than was FA. The electric potentials at the solubilisation sites of FA and iFA (ψ_{loc}) were in the range of values reported for SDS micelles at similar ionic strengths and led to the same conclusion (Fernandez & Fromherz, 1977).

$[A^-]_m/[AH]_m$ was higher for FA than for iFA. This result is in accordance to the local pH and electric potential, revealing a location closer to the micelle surface for iFA. The higher antioxidant activity of iFA compared to FA may thus be a result of a deeper intercalation at the o/w interface. A smaller distance to lipid radicals and a more efficient stabilisation of the antioxidant radical cation by the negatively charged headgroups may explain these results (Georges & Berthod, 1983; Murasecco-Suardi, Gassmann, Braun, & Oliveros, 1987). Thus, in an SDS microenvironment, a favourable location of an antioxidant may compensate a generally lower radical-scavenging ability.

4.4.4. Effect of the CTAB microenvironment on the acid–base equilibrium and activity

There is evidence from NMR measurements that hydroxycinnamic acids are located in the relatively hydrophobic palisade layer in CTAB micelles (Heins, Sokolowski, et al., 2007). CTAB micelles are generally drier due to a thinner Stern layer and lower water penetration than SDS or Brij micelles (Berr, 1987). The palisade layer of CTAB micelles still contains a considerable amount of water, but the polarity can be regarded to be below that of the bulk aqueous phase. Thus, a pK_a shift due to the low polarity of the micellar environment should be taken into account. The pK_a^{app} value obtained in Brij micelles, i.e., in a micellar environment without electrostatic effects, was used as $pK_{a,m}$ for the calculation of the pH_{loc} in CTAB micelles (Pal & Jana, 1996). The ionic nature of the micellar surface explains the demand for consideration of the surface pH. Any differences in the dissociation equilibrium between CTAB and Brij micelles were attributed to the electric potential of the cationic micelles and related effects. In addition, the surface pH was calculated according to the PIE model. The difference between the local pH at the solubilisation site of antioxidants and the surface pH may give information about the distance of FA and iFA from the surface plane.

According to the described procedure, FA and iFA experienced different pH values and electric potentials at their respective solubilisation sites (Table 3). The higher potential at the solubilisation site of iFA indicates that iFA is located at a smaller distance from the micellar surface plane than is FA. In addition, iFA was a stronger acid in CTAB micelles than was FA. The low or pro-oxidant activity of both antioxidants in CTAB emulsions is ascribed to the catalytic action of the cationic headgroup of CTAB which increases the homolytic decay of hydroperoxides similarly to catalytic metal ions (Pisarenko & Kasaikina, 2002). Antioxidant activity in metal ion-mediated oxidation processes, in turn, is low or even pro-oxidative (Frankel, 2005). The less pro-oxidant action of iFA compared to FA in CTAB emulsions may be related to the higher degree of dissociation, which is connected with a better stabilisation of the phenoxyl radical.

5. Conclusions

It was possible for the first time to determine the partitioning behaviour of antioxidants in emulsions by UF and to distinguish between the aqueous phase, the coexisting micellar phase and the o/w interface. It was shown that the partitioning of antioxidants in emulsions depends on the type and concentration of the emulsifier. The phenolic antioxidants used were of similar structure and polarity and are characterised by a roughly similar partitioning behaviour. From the oxidation experiments and

partitioning studies, it can be concluded that the partitioning alone cannot explain antioxidant activity in emulsions.

The comparison of the results obtained in the ABTS assay with the storage experiments reveals that the ABTS assay is not suitable for predicting the order of activity of two fairly similar antioxidants in emulsions. This is in agreement with earlier studies, which showed that the microenvironment or reaction field strongly influences the reaction of antioxidants and lipid radicals.

The microenvironment provided by the headgroup region of Brij micelles influenced the acidity of FA and iFA. The different degrees of dissociation and the location within the interface are closely related and affect the ability of the antioxidants to inhibit lipid oxidation. According to the comparison of FA and iFA, an orientation to the oil phase is favourable for increased activity. In addition, the direct exchange of micellar-bound antioxidants with the o/w interface may contribute to the high activities in emulsions with Brij 58.

The acid–base equilibria of FA and iFA in SDS micelles show that iFA was more closely located in the headgroups of SDS molecules than was FA. This decreases the dissociation rate of iFA, but could enhance the stabilisation of the iFA radical cation by the SDS headgroups, which in turn might reduce the tendency to participate in unfavourable side reactions.

In emulsions with CTAB a high degree of dissociation seems to be favourable for the antioxidant activity, as was demonstrated by the comparison of FA and iFA. However, both FA and iFA were weaker antioxidants than in the other emulsions, despite the favourable pH and degree of dissociation. It is suggested that the participation of phenolic antioxidants in side chain reactions is favoured in a CTAB environment, which may lead to the observed pro-antioxidant effects.

In conclusion, the relationships between the acid–base equilibrium of hydroxycinnamic acids, their location at the o/w interface and their ability to inhibit lipid oxidation have been investigated for the first time. Such relationships can only be detected and proven if the specific properties of emulsifiers are taken into account, so that each type of emulsifier has to be considered separately.

Sucralose degradation products
Formation of chloropropanols
Levoglucosenone
Dehydrochlorination of sucralose

ABSTRACT

Sucralose, a polychlorinated synthetic high-intensity sweetener is being increasingly used in relatively large amounts in baked products under high temperature environments. This necessitates understanding its thermal decomposition and studying the consequences of hydrogen chloride release from sucralose and its ability to chlorinate various food related ingredients such as glycerol to generate chloropropanols a potentially toxic class of compounds. Studies conducted on the thermal degradation of sucralose under dry heating conditions have indicated that the glycosidic cleavage occurs through the formation of a galactopyranosyl cation contrary to sucrose where fructofuranosyl cation dictates the major breakdown products. Consequently the major product detected was levoglucosenone and its precursor. Subsequent degradation of the two monosaccharide derivatives causes dehydrochlorination and dehydration reactions to produce furan-related products. In addition, pyrolysis of sucralose in the presence of glycerol generated significant amounts of 3-monochloropropanediol and 1,2- and 1,3-dichloropropanols based on the relative intensities of their chromatographic peaks which amounted to 15% of the total chromatographic peak area.

1. Introduction

Sucralose, a non-nutritive, high–intensity sweetener that has replaced sucrose in a broad range of food products (Goldsmith & Merkel, 2001), due to the numerous toxicological studies confirming its safety (Goldsmith, 2000; Grice & Goldsmith, 2000; John, Wood, & Hawkins, 2000a, 2000b; Roberts, Renwick, Sims, & Snodin, 2000; Sims, Roberts, Daniel, & Renwick, 2000; Wood, John, & Hawkins, 2000). Although FDA allowed its use in food products however, it has yet to grant it GRAS status. The popularity of this food additive has lead to an average daily intake (ADI) of 1.1 mg/kg body weight (bw), while the ADI of the cumulative hydrolysis products; 1,6-dichloro-1,6-dideoxyfructose (1,6-DCF) and 4-chloro-4-deoxygalactose (4-CG), is estimated at 3.2 mg/kg bw (Grice & Goldsmith, 2000). Under alkaline conditions sucralose also generates 3′,6′-anhydro-4,1′-dichlorogalactosucrose (Barndt & Jackson, 1990). Although hydrolysis of the glycosidic bond, yielding 1,6-DCF and 4-CG, may occur in aqueous systems under acidic conditions as has been reported by Goldsmith and Merkel (2001), however, these results cannot be extrapolated to high temperature, low moisture environments such as baking. As has been suggested by many (Perez Locas & Yaylayan, 2008; Queneau, Jarosz, Lewandowski, & Fitremann, 2008) the hydrolysis of sucrose, into its corresponding monosaccharides, can be viewed as a secondary reaction in which the fructofuranosyl cation, initially formed, is then hydrolyzed in the presence of water. Sucralose, being sucrose analogue, one anticipates degrading in a similar fashion. In this paper we aim to investigate thermal degradation and dehydrohalogenation reactions of sucralose in high temperature and low moisture conditions as well as examine the capacity of glycerol in capturing any hydrogen chloride released and its conversion into chloropropanol derivatives. Barndt and Jackson (1990) attempted to demonstrate using radiolabeling techniques, that sucralose minimally degrades in baked goods (180–300 °C); however, these results lack credibility due to inefficient separation technique used in analysing the degradation products. As demonstrated later by Hutchinson (1996), sucralose completely degrades with the release of chloride ions at 180 °C in aqueous solutions at all pH levels (3, 7, and 11) studied. Analysis of the volatile compounds has also indicated that dehydrochlorination steps were important for their production (Hutchinson, Ho, & Ho, 1999).

2. Materials and methods

All reagents and chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI). Glycerol was purchased from Fluka (Steinheim, Germany). Sucralose was obtained from Tate & Lyle (Montreal, Canada).

2.1. Pyrolysis-gas chromatography–mass spectrometry (Py-GC/MS) analysis

A Varian CP-3800 gas chromatograph coupled to a Saturn 2000 ion trap detector interfaced to a CDS Pyroprobe 2000 unit through a valved interface (CDS 1500) was used for Py-GC/MS analysis. In all experiments, the sucralose/glycerol model mixtures (1 mg, 1:2 M ratio) were introduced inside the quartz tube (0.3 mm thickness), which was plugged with quartz wool, and inserted into the coil probe. Prior to pyrolysis, argon gas was directed at the entrance of the pyroprobe interface to prevent the introduction of air into the pyroprobe interface. The temperature of the pyroprobe interface was set at 250 °C. Model systems were initially pyrolysed at 250 °C with a total heating time of 20 s. Samples were left in the interface for a total of 2 min, then removed. After 5 min, the sample was introduced into the interface under a steady stream of Helium. The initial temperature of the column was set at −5 °C for 5 min and then increased to 50 °C at a rate of 50 °C/min; immediately, the temperature was further increased to 280 °C at a rate of 8 °C/min and kept at 280 °C for 6 min. A constant flow of 1.5 mL/min was used during analysis. The capillary direct MS interface temperature was 250 °C; the ion source temperature was 175 °C. The ionisation voltage was 70 eV, and the electron multiplier was set at 1500 V. The mass range analysed was 20–650 amu. The column was a fused silica DB-5 MS column (50 m length, 0.2 mm i.d., and 0.33 μm film thickness; J&W Scientific). The identity and purity of the chromatographic peaks were determined by using NIST AMDIS version 2.1 software.

2.2. Pyrolysis in the presence of moisture and oxidative Py-GC/MS

Pyrolysis under air or in the presence of water was achieved through modification of the above-mentioned GC to allow gas stream switching and subsequent isolation of the pyrolysis chamber from the analytical stream. The pyrolysates generated under air or in the presence of moisture were initially collected onto the trap, which retained the organic volatiles and vented the carrier gas (air) and/or moisture. The trap was subsequently flushed with

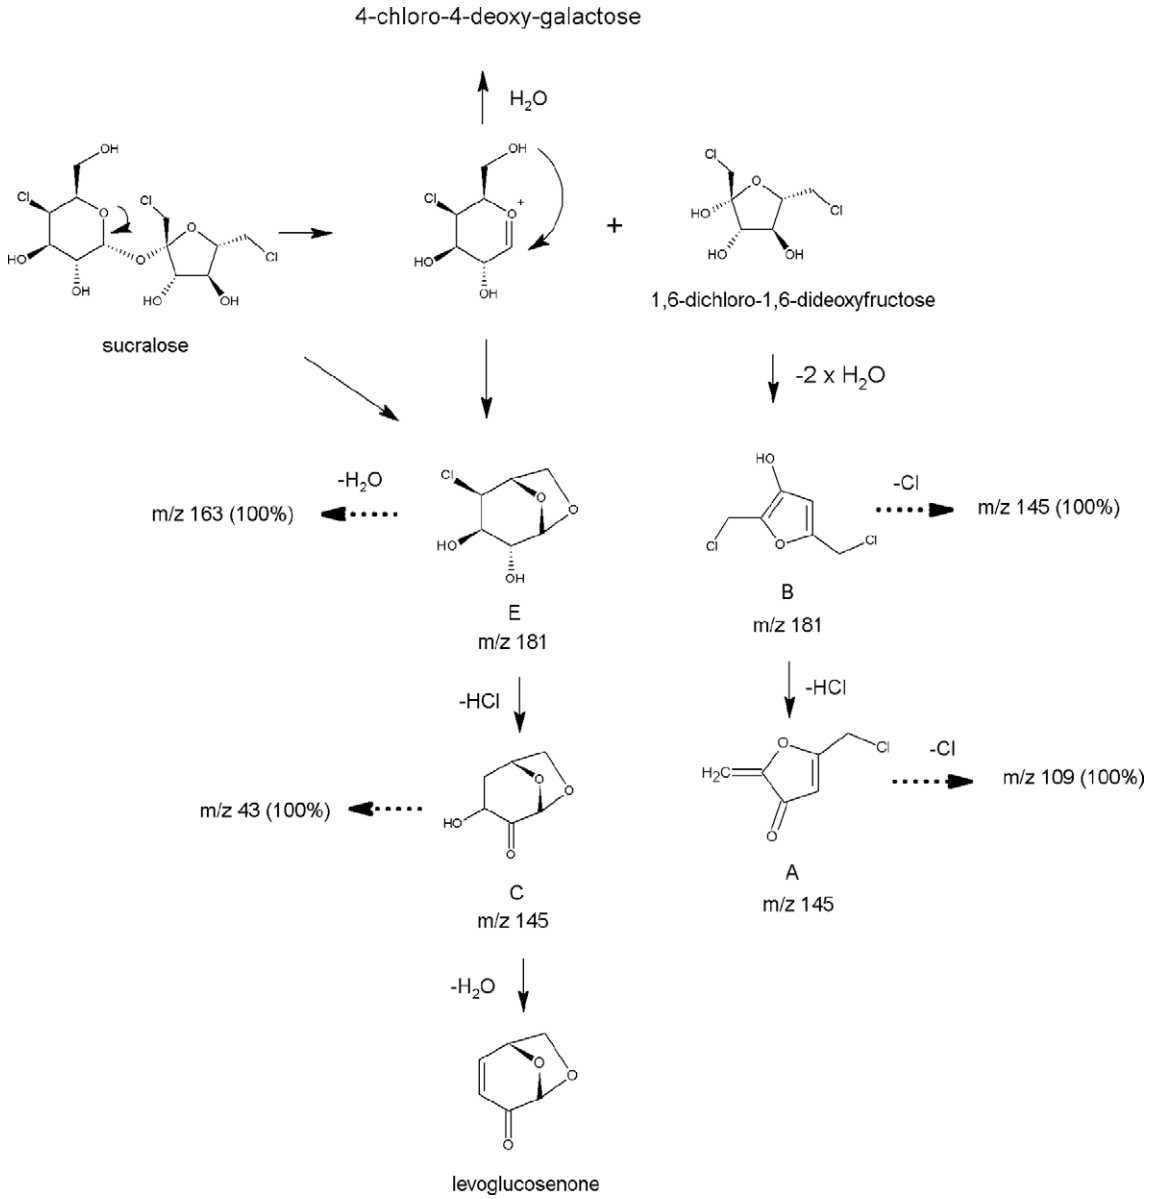

Fig. 3. Proposed mechanism of degradation of sucralose and formation of compounds A, B C, E, and levoglucosenone, showing their corresponding mass spectrometric base peaks.

helium and heated to desorb the collected volatiles. For detailed description see Yaylayan, Haffenden, Chu, and Wnorowski (2005).

2.3. Tentative characterisation of the thermal degradation products of sucralose

The mass spectra and chlorine content of the unknown peaks A to E shown in Figs. 1–3 are listed below. Chlorine content was estimated from the natural isotopic abundance of the ions in question.

- Unknown A. R_T = 19.631 min, MS 109(100), **145**(38), 144(23), 81(16), 53(13), 147(12), 146(10), 108(10), 52(9), 110(7). Number of chlorine atoms = 1, number of chlorine atoms in fragment at m/z 109 = 0.
- Unknown B. R_T = 19.810 min, MS 145(100), 39(54), 147(33), **181**(40), 40(19), 180(16), 183(25), 68(15), 43(14), 109(16). Number of chlorine atoms = 2, number of chlorine atoms in fragment m/z 145 = 1 and m/z 109 = 0.
- Unknown C. R_T = 19.986 min, MS 43(100), 29(93), 41(70), 39(66), **145**(62), 57(40), 27(39), 69(40), 70(35), 85(31). Number of chlorine atoms = 0.
- Unknown D. R_T = 22.703 min, MS 76(100), **180**(50), 39(45), 182(32), 41(35), 78(33), 48(17), 49(10), 27(10), 29(11). Number of chlorine atoms = 2, number of chlorine atoms in fragment at m/z 105 = 1 and m/z 76 = 1.
- Unknown E. R_T = 24.491 min, MS 163(100), **181**(47), 165(34), 39(21), 81(17), 162(24), 183(13), 103(14), 180(13), 97(13). Number of chlorine atoms = 1, number of chlorine atoms in fragment at m/z 163 = 1.

2.4. Statistical analysis

Statistical analysis was performed using SAS 9.1 TS level 1MS, (SAS Institute Inc., Cary, N.C., USA, 2002–2003). Two statistical tests were performed; analysis of variance (ANOVA) and least significant difference (LSD). A value of 0.05 for "alpha" was used throughout the statistical analysis. Shapiro–Wilk test was also used to establish the data collected came from a normally distributed population, while ANOVA was used to establish that the means for each compound significantly varied, depending on the reaction conditions listed in Tables 2 and 3. To distinguish the effect of each reaction on the production of each compound LSD was performed.

2.5. Identification of chloropropanols

All chloropropanols were identified by their retention times and through mass spectral library comparisons except 1,2-dichloropropanol which was confirmed only through NIST library match (see Table 1).

Table 2
Normalized relative formation efficiency[a] of levoglucosenone and chloropropanols in sucralose glycerol mixture heated at 250 °C for 20 s based on area/mole of sucralose ($\times 10^{10}$).

	Levoglucosenone	1,2-DCP	3-MCPD	1,3-DCP
He	1.1	3.4	105.2	19.4
Air	4.6	5.1	99.2	18.3
1 μL H_2O	2.4	1.3	55.2	16.5
2 μL H_2O	1.5	1.0	70.7	17.6

3-MCPD = 3-chloropropanediol; 1,3-DCP = 1,3-dichloropropanol; 1,2-DCP = 1,2-dichloropropanol.
[a] Based on three replicates with relative standard deviation of % 6.3.

Table 3
Relative and per cent chloropropanol distribution[a] in sucralose glycerol mixture heated at 250 °C for 20 s.

	1,2-DCP	3-MCPD	1,3-DCP
He	1 (2.6%)	31 (81.6%)	6 (15.7%)
Air	1 (4.1%)	19 (79.2%)	4 (16.6%)
1 μL H_2O	1 (1.7%)	43 (75.4%)	13 (22.8%)
2 μL H_2O	1 (1.1%)	71 (78.8%)	18 (20%)

3-MCPD = 3-chloropropanediol; 1,3-DCP = 1,3-dichloropropanol; 1,2-DCP = 1,2-dichloropropanol.
[a] Based on values reported in Table 2.

3. Results and discussion

3.1. Thermal degradation of sucralose

To gain insight into the thermal degradation pathways of sucralose, the degradation profile of sucrose generated by Pyrolysis-GC/MS was studied and compared due to their structural similarities and due to lack of available isotopically labelled sucralose. In a previous study, Perez Locas and Yaylayan (2008) using specifically ^{13}C-labelled sucrose at C-1 of the fructose moiety have identified the main event in the thermal degradation of sucrose under dry heating conditions to be the glycosidic bond cleavage initiated by the lone pair electrons of the ring oxygen of the fructofuranosyl moiety generating a free glucose and a fructofuranosyl cation (see Fig. 1). As a consequence of the formation of this reactive fructofuranosyl cation the efficiency of the conversion of sucrose into 5-(hydroxymethyl)-2-furaldehyde (HMF) was increased by 28-fold relative to glucose and that HMF generated from sucrose constituted one of the major peaks of the degradation product with 90% originating from the fructose moiety as indicated by the label incorporation into the HMF (Perez Locas & Yaylayan, 2008). The subsequent conversion of the glucose moiety into levoglucosan and levoglucosenone constituted only minor pathways of its degradation profile. Contrary to sucrose, the thermal degradation of sucralose under dry heat-

ing conditions generated levoglucosenone as one of the major peaks in the chromatogram (see Fig. 2) and this amounted to a 160-fold increase in intensity compared to sucrose under identical conditions. This dramatic increase in the intensity of the levoglucosenone may indicate a shift in the sucralose degradation pathway compared to sucrose. Due to the presence of two electron withdrawing chlorine atoms in the fructose moiety of sucralose, the electron flow during glycosidic bond cleavage may be directed towards fructose moiety away from galactose ring resulting in the formation of either a reactive galactopyranosyl cation or the direct formation of structure E; both can be considered as efficient precursors of levoglucosenone (Fig. 1). The galactopyranosyl cation can be easily converted into E through nucleophilic attack of the C-6 hydroxyl group or in the presence of water can be converted into 4-chloro-4-deoxygalactose (4-CG). The structure E which can be considered as equivalent to levoglucosan (see Fig. 1) through dehydration and dehydrochlorination reactions can be converted into levoglucosenone one of the major degradation products of sucralose. Further evidence was provided for the possible formation of the galactopyranosyl cation when sucralose was heated in refluxing methanol in the presence of *p*-toluenesulfonic acid and then analysed for the changes observed in the intensities of compound E and levoglucosenone. The results have indicated a significant reduction in the intensities of both compounds. As has been demonstrated in the case of sucrose (Perez Locas & Yaylayan, 2008), methanol is able to trap such cations as methyl glycosides and prevent their further degradation.

If the glycosidic cleavage of sucralose indeed proceeds as proposed in Fig. 1, then logical intermediates resulting from the degradation of E and 1,6-dichloro-1,6-dideoxyfructose should be formed and could tentatively be identified using the calculated molecular weights as shown in Fig. 3. The inspection of the pyrogram of sucralose has revealed that the major peak (24.49 min) in the pyrogram corresponded to the proposed structure E (see Fig. 2) having a molecular ion at *m*/*z* 181 and possessing only one chlorine atom based on natural isotope distribution pattern and generating a base peak at *m*/*z* 163 through a neutral loss of a water molecule. The base peak at *m*/*z* 163 retains the chlorine atom, consistent with the proposed structure. If intermediate E undergoes dehydrochlorination it should produce the structure C (see Figs. 2 and 3). A peak (19.98 min) in the chromatogram (Fig. 2) with a molecular ion at *m*/*z* 145 was identified and the natural isotope distribution pattern indicated that this compound does not contain a chlorine atom, consistent with proposed structure. On the other hand, 1,6-dichloro-1,6-dideoxyfructose can lose two molecules of water to generate structure B which in turn can undergo dehydrochlorination to generate structure A (see Figs. 2 and 3). Two peaks one eluting at 19.81 min (peak B) and other at 19.63 min (peak A) were identified in the pyrogram of sucralose (Fig. 2) that are consistent with the specifications of the two structures. Structure B contains two chlorine atoms and it generates a base peak at *m*/*z* 145 through loss of chlorine atom. The base peak at *m*/*z* 145 contains only one chlorine atom. Finally structure A with a molecular ion at *m*/*z* 145 containing a single chlorine atom was identified. The base peak generated through the loss of chlorine atom at *m*/*z* 109 that contains no other chlorine atoms supporting the proposed structure. Although all the intermediates A to E mentioned above are proposed logical structures, however, levoglucosenone was positively characterised using a mass spectral library and by the retention time of the suspected levoglucosenone peak with the known levoglucosenone peak resulting from pyrolysis of D-glucose and sucrose (Halpern, Riffer, & Broido, 1973; Riffer, 2000; Sharfizadeh, Furneaux, Stevenson, & Cochran, 1978) supporting the identity of the peak.

3.2. Sucralose as a chlorinating agent: formation of chloropropanols

As demonstrated above, degradation of sucralose through dehydrochlorination reactions is a viable pathway that can theoretically generate three moles of hydrochloric acid per mole of sucralose through such transformation as E–C and B–A. In addition, sucralose being utilised in baked goods at concentrations between 300–600 ppm (Chapello, 1998; Goldsmith & Merkel, 2001) can release hydrogen chloride in these products during baking that can react with glycerol generating various chloropropanols known for their toxicity. To evaluate the potential of sucralose to chlorinate glycerol, glycerol–sucralose mixtures were investigated using Py-GC/MS in the presence and absence of air and water to determine their effect on the efficiency of formation of chloropropanols. Analysis of the data (see Table 1) have indicated that indeed degradation of sucralose in the presence of glycerol generated the following three chloropropanols (amounting to 15% of the total area count of all the peaks); 3-monochloropropanediol (3-MCPD), 1,2-dichloropropanol (1,2-DCP) and 1,3-dichloropropanol (1,3-DCP) with relative amounts indicated in Table 2, however, 2-monochloropropanediol (2-MCPD) was not detected. Literature data (Collier, Cromie, & Davies, 1991) indicates that the initially formed 3-MCPD and 2-MCPD are further chlorinated to form 1,2- and 1,3-DCP with 3-MCPD and 1,3-DCP being always the major products consistent with our observation. Under pyrolytic conditions 2-MCPD formed may quickly be converted into 1,2-DCP and due to its lower yield may not be detected. When 3-MCPD was pyrolysed in the presence of sucralose the further chlorination resulted in the formation of 1,2- and 1,3-DCP in a ratio of 1:22 compared to 1:6 observed in sucralose glycerol model system (Table 3). This excess can be attributed to the formation of 1,2-DCP from the undetected 2-MCPD in sucralose glycerol model system. To evaluate the role of moisture and oxidative conditions on the production and the relative distribution of chloropropanols, statistical analysis was used to determine whether their generation was significantly affected by the experimental conditions. The results of such analysis have indicated that although oxidative pyrolysis or pyrolysis in the presence of moisture did not alter much relative distribution of chlorophenols in the reaction mixture, however, it did enhance slightly generation of 1,3-DCP on the expense of 3-MCPD.

4. Conclusion

Degradation of sucralose in the presence of glycerol may generate different chloropropanols in addition to levoglucosenone a well documented degradation product of sucrose and glucose. Caution should be exercised in the use of sucralose as a sweetening agent during baking of food products containing glycerol and or lipids due to the potential formation of toxic chloropropanols.

Cytotoxicity

ABSTRACT

Fruits of wampee [*Clausena lansium* (Lour.) Skeels] contain a significant amount of coumarins with many health benefits. The activity-guided separation of an ethyl acetate-soluble fraction on a polyamide column followed by silica gel column and high performance liquid chromatography (HPLC) preparation afforded a pure compound, which was identified to be 8-hydroxypsoralen based on the ^{1}H, ^{13}C NMR (nuclear magnetic resonance), and ESI-MS (electrospray ionisation mass spectrometric) analysis. This isolate exhibited good scavenging activities against DPPH radical and superoxide anion as well as significant reducing power. It also showed potent proliferation inhibitory activity against human hepatocellular liver carcinoma cell line (HepG2), human lung adenocarcinoma epithelial cell line (A549) and human cervical carcinoma cell line (HELA). This is the first report on the antioxidant and cytotoxic properties of *C. lansium* fruit extract. The food and pharmaceutical industry could be benefited by the usage of this extract containing this constituent.

1. Introduction

Antioxidants possess the ability to protect the cellular organelles from damage caused by free radicals induced oxidative stress. Free radicals include hydroxyl radical, superoxide anion radical and hydrogen peroxide. Highly reactive free radicals which are formed by exogenous chemicals, stress or in the food system are capable of oxidising biomolecules, resulting in cancer, coronary heart disease and hypertension (Thomson, 1995). Generally, most of the free radicals generated from metabolism are scavenged by endogenous defence system such as catalase, superoxide dismutase and peroxidase–glutathione system (Hu, Louie, Cross, Motchink, & Halliwell, 1992). However, in many cases such as in unhealthy physical condition, ageing, or under stress environments, the exogenous antioxidants are either exhausted or insufficient to scavenge these radicals generated which resulted in diseases associated with oxidative stress and damage. Thus, the search for natural products represents an area of great interest in which the plant kingdom has been documented the most important source to provide many antioxidant and cancer chemopreventive agents with novel structures and unique mechanism of action (Kalt, 2001). Therefore, the phytochemicals from fruits and vegetables hold promising potential in the development of health foods, nutritional supplements and herbal medicines for the application as antioxidants and cancer chemopreventive agents.

Wampee [*Clausena lansium* (Lour.) Skeels] belongs to *Rutaceae* family which is distributed widely in India, southern China, Thailand and Vietnam. The fruit is about 2 cm in diameter, ripens from May to July and can be eaten with the peel at a full ripe stage. It contains 1–3 seeds and the pulp is highly acidic. The pulp can be added to fruit cups or made into pie, jam or jelly. Previous chemical studies on *C. lansium* included the characterisation of coumarin (Khan, Naqvi, & Ishratullah, 1983) from the bark, triterpene alcohol from aerial parts (Lakshmi, Raj, & Kapil, 1989), amide derivatives from the seeds (Lin, 1989), cyclic amides form the leaves (He, Yong, & Liang, 1988) and volatile compounds from leaf, fruit and seed (Chokeprasert, Charles, Sue, & Huang, 2007). The bioactivities from wampee are mainly focused on its leaf, stem and seed which include hepatoprotective activity (Liu, Li, Chen, & Wei, 1996), hypoglycemic (Ma, Wu, & Huang, 2008), antifungal and antiviral activities (Ng, Lam, & Fong, 2003), antiplatelet (Fan, Han, Kang, & Park, 2001), anti-inflammatory, antidiabetic and antioxidant activities (Adebajo et al., 2008). However, there is no study on the use of wampee peels even though it is applied as folk medicine in India and China for the treatment of stomachic and bronchitis as a vermifuge. Therefore, in the present study, the possibility of wampee

peel used as natural antioxidant and anticancer agents was investigated for the first time, and the responsible compound for its activity was isolated and identified as well. This study can help the food industry use it as a natural compound for antioxidant and anticancer activities.

2. Materials and methods

2.1. Sample

Fresh fruits of wampee [*C. lansium* (Lour.) Skeels] at the mature stage were collected from an orchard in Guangzhou, China. Fruits with uniformity in shape and colour were chosen and washed carefully in potable water. The peels were manually separated, and then dried for 24 h using a hot air oven at 60 °C, and finally powdered using a blender. The moisture content of the dried peel was determined to be 85%.

2.2. Chemicals and reagents

1,1-Diphenyl-2-picrylhydrazyl (DPPH), nitro blue tetrazolium (NBT), methionine, riboflavin and 3-(4,5-dimethylthiazole-2yl)-2,5-diphenyl tetrazolium bromide (MTT) were purchased from Sigma Chemical Co. (St. Louis, Missouri, USA). Trypsin, RPMI-1640 medium (pH 7.4) was obtained from Gibco, Invitrogen, New York, USA while foetal bovine serum was supplied by Ebioway (Guangzhou, China). Butylated hydroxytoluene (BHT) was purchased from Sinopharm Chemical Reagent Co. (Shanghai, China). All other chemicals and solvents used in this study were of analytical grade and obtained from Tianjin Reagent Company (Tianjin, China).

2.3. Extraction and total phenolic content

The dried powder (50 g) of wampee peel was extracted for 24 h in a rotary shaker with 1000 ml of 50% ethanol in a conical flask at 30 °C. The extract was then filtered and concentrated using a rotary evaporator (RE-52A, Shanghai Woshi Co., Shanghai, China) and then partitioned sequentially with 100 ml of hexane, ethyl acetate and 1-butanol. The different fractions of hexane, ethyl acetate, butanol and water were separately collected. Total phenolic content of each fraction was determined by the method of Singleton and Rossi (1965) and then expressed as gallic acid equivalents.

2.4. Purification

Since the ethyl acetate-soluble fraction contained the highest phenolic content, it was selected for further purification. The ethyl acetate-soluble fraction (10 g) was subjected to a 450 × 25 mm column of polyamide (200 g, 20–40 mesh, Taizhou Luqiao Biochemical Corp. Taizhou, China), and eluted with a linear gradient of ethyl acetate/ethanol from 100:0 to 0:100 (v/v). About 40 fractions (50 ml per fraction) were collected and concentrated. After the analysis by TLC, these fractions were grouped into 21 major fractions (Fractions 1–21). Then, each fraction was reacted with 0.5% ferric chloride solution to detect the presence of polyphenol (Sun, Shi, Jiang, Xue, and Wei (2007). Among them, the major fraction (Fraction 5) containing the highest polyphenol content determined by the above method of Singleton and Rossi (1965) was concentrated under vacuum to obtain a brownish syrup (2 g). This syrup was re-chromatographed over a 400 × 25 mm silica gel (200 g, 60–100 mesh, Qiandao Marine Chemical Factory, Qingdao, China) column and eluted with the solvents of increasing polarity (hexane, hexane–ethyl acetate, ethyl acetate and ethyl acetate–methanol) to obtain 28 fractions which were pooled into 12 subfractions (Fractions 5.1–5.12) based on the TLC monitor. Each subfraction was allowed to react with 0.5% ferric chloride solution to identify the presence of polyphenol. Among them, the subfraction 5.5 (90 mg) containing the highest polyphenol content was finally purified by HPLC (LC-20 AT, Shimadzu Corporation, Tokyo, Japan) equipped with a Rheodyne injection valve and a 100-μl sample loop with a preparative column (Shim-Pack, PRC–ODS, 20 × 25 cm, Shimadzu, Kyoto, Japan) using a gradient system consisting of solvents A (2% acetic acid, v/v) and B (acetonitrile–methanol, 10:15, v/v) as mobile phase at a flow rate of 1.5 ml/min, and a diode array detector (Rheodyne, Waltham, Massachusetts, USA) with UV detection at 270 nm.

2.5. ^{1}H and ^{13}C NMR analyses

^{1}H NMR (400 MHz) and ^{13}C NMR (100 MHz) spectra of the purified compound were recorded on a Bruker DRX-400 NMR spectrometer (Bruker Co., Rheinstetten, Germany), using deuterated dimethylsulphoxide as the solvent residual peak as the reference standard. Chemical shifts (δ) were given in parts per million (ppm) relative to TMS.

2.6. ESI-MS analysis

Electrospray ionisation mass spectroscopic (ESI-MS) analysis was performed on an Applied Biosystems (API2000 LC/MS/MS System, ABI, Foster City, California, USA). Mass spectra were achieved by electrospray ionisation in both positive and negative modes. The capillary 4500 V (negative) and 5500 V (positive) were used in this study. The electrospray probe-flow was adjusted to 20 ml/min. Continuous mass spectra were obtained by scanning from 100 to 800 m/z.

2.7. Antioxidant activity determination

2.7.1. DPPH radical scavenging activity

The DPPH radical scavenging activities of the test samples were evaluated by the method of Blois (1958) with minor modifications. Initially, 0.1 ml of the samples at a concentration of 25, 50, 75 and 100 μg/ml was mixed with 1 ml of 0.2 mM DPPH (dissolved in methanol). The reaction mixture was incubated for 20 min at 28 °C under dark. The control contained all reagents without the sample while methanol was used as blank. The DPPH radical scavenging activity was determined by measuring the absorbance at 517 nm using a spectrophotometer. The scavenging DPPH radical activity (%) of the tested sample was calculated as (1 − absorbance of sample/absorbance of control) × 100. The DPPH radical scavenging activity of BHT was also assayed for comparison.

2.7.2. Superoxide anion radical scavenging activity

Superoxide anion radical scavenging activity was determined as described by Beauchamp and Fridovich (1971) with some modifications. All solutions were prepared in 0.2 M phosphate buffer (pH 7.4). The test samples at different concentrations (12.5, 25, 37.5 and 50 μg/ml) were mixed with 3 ml of reaction buffer solution (pH 7.4) containing 1.3 μM riboflavin, 0.02 M methionine and 5.1 μM nitro blue tetrazolium. The reaction solution was illuminated by exposing them to two 30 W fluorescent lamps for 20 min and the absorbance was measured at 560 nm. Butylated hydroxytoluene (BHT) was used as a comparison. The reaction mixture without any tested sample was used as control. The superoxide anion radical scavenging activity (%) was calculated as (1 − absorbance of sample/absorbance of control) × 100.

2.7.3. Determination of reducing power

The reducing power assay was determined according to the method of Oyaizu (1986) with little modification. The tested samples (0.1 ml) were mixed with phosphate buffer (2.5 ml, 0.2 M, pH

6.6) and potassium ferricyanide (2.5 ml, 1%). After the mixture was incubated at 50 °C for 20 min. Trichloroacetic acid (2.5 ml, 10%) was added to each sample and centrifuged at 650*g* for 10 min. A 5-ml aliquot of the upper layer was mixed with distilled water (5 ml) and ferric chloride (1 ml, 0.1%) was added and then the absorbance was measured at 700 nm against a blank which consists of all the reagents without the tested sample. The higher absorbance indicated higher reducing power. The reducing power of BHT was also determined for comparison.

2.8. Evaluation of cytotoxic activity

2.8.1. Cell line and culture

HepG2 (human hepatocellular liver carcinoma), A-549 (human lung adenocarcinoma epithelial cell line) and HELA (human cervical carcinoma) cell cultures were obtained from Biomedicine Research and Development Centre of Jinan University (Guangzhou, China). The cell lines were cultured in growth medium (RPMI-1640 medium, pH 7.4), supplemented with 10% foetal bovine serum (FBS) and antibiotics (penicillin, 100 U/ml) and streptomycin sulphate (100 μg/ml). The cell lines were grown in 50 cm^2 tissue culture flasks (Corning, New York, USA) and used for cytotoxicity assay.

2.8.2. Cytotoxicity assay

The cytotoxicity assay of the samples was determined according to the method of Zhao et al. (2007) by MTT (3-(4,5-dimethylthiazole-2yl)-2,5-diphenyl tetrazolium bromide) assay. In brief, human cancer cells were plated at 2×10^4 cells per well in 96-well microtitre plates (Costar 3599, Corning, New York, USA) with 100 μl RPMI-1640 growth medium and incubated for 24 h at 37 °C, with 5% CO_2 in a humidified atmosphere (Incu-Safe, Sanyo, Japan), during which period a partial monolayer was formed. Later, the medium was removed and fresh growth medium containing different concentrations (100, 50, 25, 12.5, 6.5 and 3.125 μg/ml) of the tested compound was added. After 2 days of incubation at 37 °C, with 5% CO_2, the growth medium was removed and MTT reagent (0.1 mg/ml) was added. After incubating at 37 °C for 4 h, the MTT reagent was removed and dimethylsulphoxide (100 μl) was added to each well and then shaken for another 15 min. The absorbance was then determined by an ELISA reader (Bio-Rad, Hercules, California, USA) at a wavelength of 492 nm. Control wells received only the media without the tested compound. The conventional anticancer drug, cisplatin, was used as a positive control in this study. The inhibition of cellular growth by the tested sample was calculated as the percent inhibitory activity and expressed as the IC_{50} value (concentration of the tested sample to inhibit 50% growth of the cells).

2.9. Statistical analysis

Data were expressed as means ± standard deviations (SD) of three replicate determinations and then analysed by SPSS V.13 (SPSS Inc., Chicago, Illinois, USA). One way analysis of variance (ANOVA) and the Duncan's New Multiple-range test were used to determine the differences among these means. p-Values < 0.05 were regarded to be significant.

3. Results and discussion

3.1. Total phenolic content

The ethyl acetate fraction exhibited the highest phenolic content (330 ± 9.9 μg/g dry weight, expressed as gallic acid equivalents), followed by water (54 ± 6 μg/g), butanol (30.3 ± 5.4 μg/g) and hexane fraction (7.9 ± 0.4 μg/g). Generally, hexane is used to extract nonpolar compounds and ethyl acetate is applied to extract medium polar compounds and glycosides while butanol and water are used for extracting polar compounds like aglycones, glucosides and sugars (Markham, 1982). Previously, the higher phenolic content was obtained in the ethyl acetate fraction of litchi fruit pericarp compared to butanol or water fraction (Prasad, Yang, Ruenroengklin, Zhao, & Jiang, 2009). Thus, the ethyl acetate fraction in this study was selected for further purification.

3.2. Purification of the ethyl acetate fraction

The ethyl acetate fraction obtained from wampee peel was first purified by polyamide column chromatography and then 40 fractions were collected and pooled into 21 major fractions as monitored by TLC (Fractions 1–21). Among them, Fraction 5 exhibited a highest polyphenol content. The fraction was then purified further by silica gel column chromatography. Twenty eight fractions were obtained and then grouped into 12 subfractions (Fractions 5.1–5.12) based on TLC analysis. Among them, the major subfraction (5.5, 90 mg) which exhibited a highest polyphenol content was further purified using the HPLC preparative column to get a pure compound (20 mg).

3.3. Structure elucidation of the purified compound

The purified compound isolated from wampee peels was identified as 8-hydroxypsoralen (xanthotoxol) (Fig. 1), on the bases of ESI-MS, ^1H and ^{13}C NMR analyses. The compound was obtained as white needle-like crystals with mp 247 °C. The ESI-MS in the positive and negative mode exhibited signals of quasi-molecular ions at m/z 203 $[M+H]^+$, 225 $[M+Na]^+$, and 201 $[M-H]^-$, respectively, which corresponded to a molecular formula of $C_{11}H_6O_4$ in combination of its 11 carbon signals in the ^{13}C NMR spectrum (DMSO-d_6, 100 MHz) at δ 160.54 (C-2), 114.26 (C-3), 146.01 (C-4), 116.70 (C-4a), 110.51 (C-5), 125.68 (C-6), 145.91 (C-7), 130.62 (C-8), 140.24 (C-8a), 147.87 (C-2′), and 107.50 (C-3′). The proton NMR spectrum (DMSO-d_6, 400 MHz) showed characteristic signals of a furanocoumarin at δ 6.40 (1H, d, J = 9.6 Hz, H-3), 8.11 (1H, d, J = 9.6 Hz, H-4), 7.45 (1H, s, H-5), 8.07 (1H, d, J = 2.0 Hz, H-2′), 7.04 (1H, d, J = 2.0 Hz, H-3′) and 3.36 (1H, br s, OH-8). The above NMR and ESI-MS data were in agreement with the reported values of 8-hydroxypsoralen in the literature (Harkar, Razdan, & Waight, 1984; Wei, Zhang, & Ito, 2004). Previously, 8-hydroxypsoralen was reported in the fruit of *Cnidium monnieri* (Ng, Liu, & Wang, 2000; Wei et al., 2004), roots of *Angelica officinalis* (Harkar et al., 1984) and the whole plant of *Saussurea involucrate* (Yang, Xie, Liu, & Wu, 2006).

3.4. Antioxidant activity

3.4.1. DPPH radical scavenging activity

The ethyl acetate-soluble fraction showed stronger DPPH free radical scavenging activity than 8-hydroxypsoralen and BHT at all the concentrations tested (Fig. 2). At 50 μg/ml, the highest percentage of DPPH radical scavenging activity of 95% was observed in

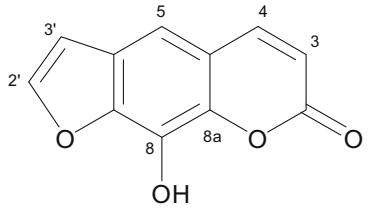

Fig. 1. The chemical structure of 8-hydroxylpsoralen.

the ethyl acetate-soluble fraction, significantly higher ($p < 0.05$) than that of BHT (73%) and 8-hydroxypsoralen (63.3%). From 0 to 50 μg/ml, the DPPH radical scavenging activity of 8-hydroxypsoralen increased but increased slowly when the concentration exceeded 50 μg/ml probably because the reaction of the scavenging radical activity gradually tended to stabilise at 50–100 μg/ml. A similar observation was noticed by Sun et al. (2007) in longan pericarp. Psoralen with free hydroxyl groups have a potent antioxidant activity while substitution of hydroxyl with methoxy or glucose can led to a dramatic drop in antioxidant activity (Ng et al., 2000). It is noteworthy that 8-hydroxypsoralen examined in the present investigation also possesses a hydroxyl group attached to an aromatic ring. It was found that the DPPH radical scavenging activity was reduced by the hydrogen donating ability (Prasad, Divakar, Shivamurthy, & Aradhya, 2005). The results revealed that the DPPH radical scavenging activity of ethyl acetate-soluble fraction and 8-hydroxypsoralen might be attributed to the electron donating ability.

3.4.2. Superoxide anion scavenging activity

In this study, the superoxide anion scavenging activities of ethyl acetate-soluble fraction, 8-hydroxypsoralen, and BHT were analysed, and were concentration dependent (Fig. 3). The ethyl acetate-soluble fraction exhibited an excellent superoxide anion scavenging activity, higher than 8-hydroxypsoralen and BHT in a dose-dependent manner. At 50 μg/ml, the superoxide anion scavenging activity of the ethyl acetate-soluble fraction, 8-hydroxypsoralen and BHT were 88 ± 2.2, 30 ± 1.4 and 25 ± 0.5%, respectively. Therefore, the superoxide anion scavenging activity was in increasing order, the ethyl acetate-soluble fraction > 8-hydroxypsoralen > BHT. It was reported that the superoxide anion scavenging activity could be due to the action of a free hydroxyl group (Siddhuraju, Mohan, & Becker, 2002). 8-Hydroxypsoralen has a free hydroxyl group at the 8th position and this might be responsible for its superoxide anion scavenging activity.

3.4.3. Reducing power

Reducing power is widely used to evaluate the antioxidant activity of polyphenols. The reducing power is generally associated with the presence of reductones, which exerts antioxidant action by breaking the free radical chain by donating a hydrogen atom (Duan, Wu, & Jiang, 2007). As shown in Fig. 4, the ethyl acetate-soluble fraction exhibited higher reducing power than BHT, suggesting that the fraction of wampee peels possessed a stronger electron donating capacity. Furthermore, a linear relationship existed between the concentration and reducing power of the ethyl

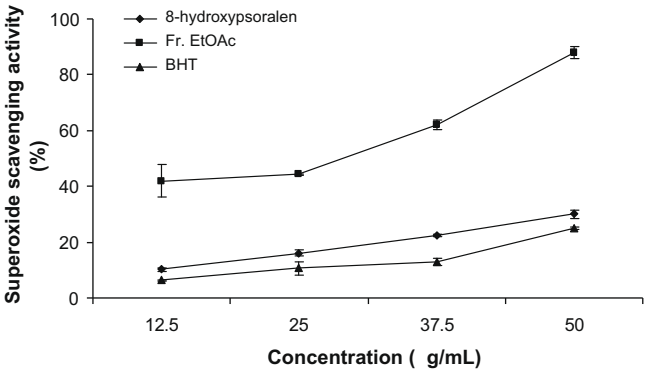

Fig. 3. Superoxide radical scavenging activity of the ethyl acetate fraction (Fr. EtOAc), 8-hydroxypsoralen and BHT.

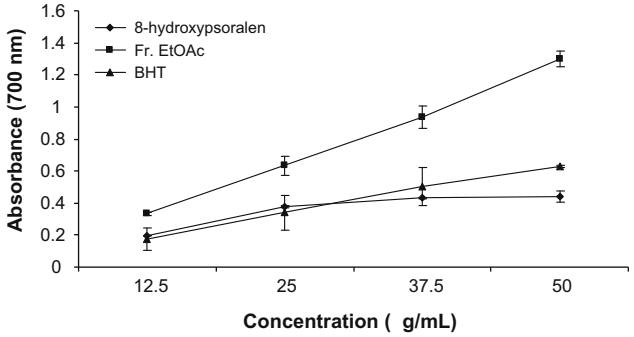

Fig. 4. Reducing power of the ethyl acetate fraction (Fr. EtOAc), 8-hydroxypsoralen and BHT. Higher absorbance values indicate higher reducing activity.

acetate-soluble fraction, 8-hydroxypsoralen and BHT, with their correlation coefficients of 0.9979 ($y = 0.0256x$), 0.9966 ($y = 0.527x + 3.2$) and 0.9968 ($y = 0.0122x + 0.0325$), respectively. Li, Wang, Li, Li, and Wang (2009) have reported the existence of linear relationships between antioxidant capacity (assessed as copper reducing power) and total phenol content in Chinese wine.

The antioxidant activity of 8-hydroxylpsoralen was previously reported by Ng et al. (2000) and the scavenging activity was due to the presence of hydroxyl group of 8-hydroxypsoralen. Usually, coumarins with free hydroxyl groups have a potent antioxidant activity while the substitution of the hydroxyl group with methoxy or sugar can lead to the decrease in the antioxidant activity. The

Table 1
Anticancer activities of the ethyl acetate-soluble fraction (Fr. EtOAc) and 8-hydroxypsoralen isolated from wampee peels.

Sample	IC_{50} value (μg/ml)		
	Hep-G2	HELA	A-549
Fr. EtOAc	13.1 ± 0.9^{b}	ND	30.7 ± 2.4^{b}
8-Hydroxypsoralen	0.34 ± 0.02^{a}	0.013	28.2 ± 3.2^{a}
Cisplatin*	87.9 ± 2.3^{c}	349.9 ± 6.2	101.3 ± 1.2^{c}

IC_{50} value represents the concentration of the tested sample to kill 50% of the cancer cells. ND, Not determined; *, positive control; HepG-2, human hepatocellular liver carcinoma; HELA, human cervical carcinoma; and A-549, human lung adenocarcinoma epithelial cell line. For each treatment, the means within the column followed by different superscript letters were significantly different at $p < 0.05$.

antioxidant activity of the ethyl acetate-soluble fraction was more potent than 8-hydroxypsoralen, which might be due to the synergistic activity of other phenolics. Similar findings were reported by Prasad et al. (2005).

3.5. Anticancer activity

Anticancer activity of 8-hydroxypsorelen were reported by Gawron and Kruk (1987, 1992) and Madari and Jacobs (2004). In this study, the anticancer activities of the ethyl acetate-soluble fraction, 8-hydroxypsoralen and cisplatin were investigated using an 3-(4,5-dimethylthiazole-2yl)-2,5-diphenyl tetrazolium bromide assay on three human cancer cell lines, HELA, HepG2 and A-549. A mitochondrial enzyme in living cells, succinate-dehydrogenase, cleaves the tetrazolium ring and converts the MTT to an insoluble purple formazan and the amount of formazan produced is directly proportional to the number of viable cells (Lee, Hwang, & Lim, 2004). Table 1 shows that 8-hydroxypsoralen significantly inhibited ($p < 0.05$) the growth of cancer cells, HELA, A549 and HePG2 cell lines, compared to the ethyl acetate-soluble fraction and cisplatin. Our results are in agreement with the report of Gawron and Kruk (1987, 1992) and Madari and Jacobs (2004). The mechanism of action of anticancer activity of 8-hydroxypsoralen could be by disturbing the cellular division during mitosis at the telophase stage. It was also reported that 8-hydroxypsoralen decreased the amount of cellular protein and mitotic index, and the colony formation during cell proliferation (Gawron & Kruk, 1992).

4. Conclusions

In the present study, a compound was isolated and purified from wampee peels and then identified as 8-hydroxypsoralen, while its antioxidant and anticancer activities were evaluated. The study indicated that the 8-hydroxypsoralen exhibited high antioxidant and anticancer activities. Further work about the anticancer activity using *in vivo* models is worth investigation.

Fluorescence

ABSTRACT

The aim of the present work was to analyse the influence of the variables reaction temperature, casein–sucrose ratio and pH, on the kinetic parameters of gelation reactions, the gelation time and the functionality of casein micelles in concentrated milk systems containing sucrose.

Global constant rate reaction order of gelation and were calculated, the first varying between four different orders of magnitude and the second between 1 and 7.

Mathematical models allowing the prediction of gelation time with a good fit ($r^2 > 0.94$) were obtained.

Activation energy (E_a) for gelation decreased as pH decreased. In presence of sucrose, E_a values showed a higher temperature dependence. Gel functionality showed to be pH independent. Although the kinetic aspects of the reactions were affected by pH, the thermodynamic ones remained almost unchanged. Aggregation and gelation were very fast at pH 6. When comparing gelation kinetics with those corresponding to fluorescence and colour development, gelation showed to be produced much earlier than the latter two phenomena.

1. Introduction

At temperatures above 100 °C, the thermal process of concentrated dairy systems containing sucrose induces thermal gelation of milk proteins (Pauletti, Castelao, & Seguro, 1996), which defines the texture of products such as milk jam (dulce de leche) and condensed milk, either during manufacture or sterilization (Moro & Hough, 1985).

Several authors have studied certain characteristics corresponding to this type of systems, such as density (Moro & Hough, 1985), rheological properties (Navarro, Ferrero, & Zaritzky, 1999) and colorimetric aspects (Rozycki, 1999, 2003). However, little research has been carried out on the influence of sucrose on gelation, fluorescence and colour development phenomena and on the comparison of the kinetics of these processes.

Comparatively, much more work has been performed on heat induced gelation of whey proteins, or on by acid and enzymatic induced gelation in milk, than on thermal gelation of milk proteins (Considine, Patel, Anema, Singh, & Creamer, 2007; Lucey, 2002). Moreover, various authors have studied heat-induced gelation of milk and dairy concentrates (Fox, 1981, 1982; McSweeney, Mulvihill, & O'Callaghan, 2004) but there has not been an in-depth investigation on sucrose effect yet. The knowledge of kinetic parameters corresponding to heat-induced gelation processes, such as the specific global constant of gelation reaction rate (k), its global pseudo-order of reaction (n) and its activation energy (E_a) are necessary to design continuous production equipments both for heat-gelified dairy products (milk jam – dulce de leche –, sterilized condensed milk) and those products in which this phenomenon is not desired (ice cream base, dairy desserts).

The most influential variables in the gelation processes of these systems are temperature (T), pH and protein concentration, which is determined by casein–sucrose ratio, here represented by R (the relative amounts whole milk powder (WMP)/sucrose (Rozycki, 1999).

Micellar hydration, related to zeta potential, is of great importance in gelation, its mechanism involving a kinetic scheme of controlled reaction where big particles react much faster than small ones. This leads to an "explosive" increase of aggregate size (Clark, 1992) where protein molecules, on hydration, increase their hydrodynamic volume and consequently the aggregation rate and gelation.

The main feature characterising the cascade mechanism applied to polymers is that each molecule or molecule aggregate has a number of reactive groups (f) which are able to join other molecules to form branched systems. As the process advances, cross-links between non-reacting branched groups take place, the relative average molecular mass tending faster and faster to infinity and reaching the gel point (Fox, 1982). The gel point was suggested to correspond to gelation time. For monodisperse systems, functionality f takes integer values: $f = 1$ for dimerization, $f = 2$ for linear polymerisation and $f = 3$ for branched polymerisation.

Under certain conditions, colour presents an induction period where colourless though fluorescent precursors occur, followed

doi:10.1016/j.foodchem.2009.04.096

by intermediate steps with brown, and also fluorescent compounds. In the final steps of heating, when the system achieves an intense brown colour (as in dulce de leche), colour formation rate begins to decrease, which is not the case for fluorescence. Hence, the fluorescent compounds would be considered the promoters of brown compounds (Petriella, Resnik, Lozano, & Chirife, 1985) in the initial steps, colour and fluorescence following parallel paths (Matiacevich & Buera, 2006).

As regards colour and fluorescence, numerous sugar–aminoacid model systems have been investigated, mainly under accelerated storing conditions (55 °C), but few have been carried out in "real" food systems, at low water activity a_w = 0.83–0.87 and temperatures above 100 °C, as in this study.

In the present work, the influence of the initial system pH, reaction temperature and casein concentration (R) on the heat-induced gelation process and its governing kinetic parameters was studied, comparing the kinetic aspects corresponding to colour development and fluorescence.

2. Material and methods

2.1. Sample preparation

Table 1 shows each sample formulation. Whole milk powder composition was: 25.05% protein (21.30% casein), 26.45% fat, 40.02% lactose, 6.05% minerals and 2.43% water. Total solids percentage (70%) was kept constant. Casein concentration of each sample, calculated from the whole milk powder (WMP) content was: 3.41%, 4.90%, 5.96%, 6.92% and 7.67%.

R value was defined as the ratio WMP/sucrose. The samples were obtained by mixing whole milk powder, sucrose and distilled water at 45 °C during 4 min, using a magnetic stirrer. The pH was adjusted with calcium hydroxide p.a. and/or lactic acid 1:10, as necessary.

2.2. Experimental design

To evaluate the influence of temperature, pH and R on gelation time, a factorial experimental design (Montgomery, 1991) involving two variables (T and R) in five levels and three pH values (6, 7 and 8) was selected. Table 2 shows coded and uncoded variable values.

After adjusting the pH to the desired value, about 2 g of each sample were put in Pyrex glass flame-sealed tubes (150 mm length, 8 mm inner diameter and 1 mm wall thickness). Three samples (replicates) of each formulation were taken and their individual gelation times were determined (gel point) at the five design temperatures. The same procedure was applied for pH 6, 7 and 8 and every experience was carried out in duplicate. Gelation time was obtained from the average of the times corresponding to replicates of at least two determinations (α = 0.05).

2.3. Determination of gelation time (t_g)

Each sample tube was put in an oscillating system of 5 cycle/minute, inside a thermostatic bath of silicon oil (Haake DC3, Karlsruhe, Germany) at controlled temperature (+0.1 °C). To determine t_g, the Subjective Test of Heat stability (Fox, 1982), proposed by Hyslop and Fox (1981), was used. Each tube was subjected to a complete oscillation every 12 s, the originally liquid mix flowing from one tube end to the other at 10 times per minute and twice per cycle. Gelation time, which is the time ranging from sample introduction into the bath and the occurrence of fluidity loss due to gelation, was visually determined.

Table 1
Composition of the formulations employed.

Content (g)	Samples				
	A	B	C	D	E
Sucrose (%)	54	49	44	39	34
WMP[a] (%)	16	21	26	31	36
Water (%)	30	30	30	30	30
R [b]	0.296	0.429	0.591	0.795	1.059

[a] WMP = whole milk powder.
[b] R = ratio WMP/sucrose [% w/w].

2.4. Colorimetric evaluation

Colorimetric measurements of each sample were made using non-standard white and black cylindrical plastic cells (28 mm diameter, 4 mm high). The reflectance values for 450, 560, and 685 nm were determined to obtain the Kubelka–Munk index (K/S) using the SBRT software (Shelf Backing Reflectance Transformation software) appropriate for small samples (Rozycki, 1999). Measurements were made using a Minolta CM 508d spectrophotometer with illuminant C, 2 degrees standard observer angle and specular component excluded.

2.5. Fluorescence and optical density measurements

Three gram of each sample were exactly weighed, mixed with about 15 ml of 80% ethanol (Park & Kim, 1983) and shacked at 150 agitation cycles per minute, during 30 min. The samples were filtered twice through filter paper in order to obtain a clear solution. Optical density (OD) at 420 nm was measured in an aliquot of this solution with a Génesis 5 UV–Visible spectrophotometer (Spectronic Instruments, Inc., Rochester, NY, USA). Another aliquot (1 ml) was diluted 10-fold with bi-distilled water and fluorescence was determined in a Biorad Versafluor fluorimeter TM, excitation maximum at 380 nm and emission maximum at 465 nm, employing a standard solution of quinine sulphate quinina, of 1 μg/ml de SO_4H_2 0.1 N (Park & Kim, 1983), which fluorescence value was 1435 UF (fluorescence units), as an average of triplicate measurements. The fluorescence of each sample was referred to as a percent of this reference.

2.6. Chemical determinations

Casein concentration was determined in a reconstituted sample of whole milk powder (13% total solids) and water, using a FIL-IDF standard method (International Dairy Federation, 1964). To determine pH, an E516 pHmeter (Metrom Herisau, Switzerland) was used.

2.7. Water activity determination

Water activity (a_w) was measured at 25 °C, in coded samples ($X_2 = X_3 = 0$), and for $R = -1$, 0 and +1 (Table 2). The equipment used was AQUA Lab – CX-2T (Washington, USA).

2.8. Functionality determination

Average functionality of casein monomers (f) was determined from the kinetic equations below, in accordance with Pauletti et al. (1996):

$$\ln t_g = [\ln(B/k)] - [(n-1)\ln C_o] \quad (1)$$

$$\ln k = \ln A - E_a/RT \quad (2)$$

$$\ln k/B = \ln A/B - E_a/RT \quad (3)$$

where t_g = gelation time [min]; C_o = casein concentration [% w/w]; k = specific global reaction rate coefficient [g casein^{-1} min^{-1}];

Table 2
Values of coded and uncoded variables.

WMP (%)	Sucrose (%)	X_1[a]	X_1 (coded)	X_2[b]	X_2 (coded)	X_3[c]	X_3 (coded)
16	54	0.296	−1	378	−1	6	−1
21	49	0.429	−0.5	388	−0.429		
26	44	0.591	0	395.5	0	7	0
31	39	0.795	+0.5	403	+0.429		
36	34	1.059	+1	413	+1	8	+1

[a] $X_1 = R$ = ratio WMP/sucrose.
[b] $X_2 = T$ = temperature (K).
[c] X_3 = pH.

n = global pseudo-order of reaction (adimensional); E_a = activation energy [kJ/mol].

B parameter is defined according to the following equation:

$$B = \frac{\left[\frac{f-1}{f-2}\right]^{n-1} - 1}{(n-1)\cdot f^{n-1}} \quad (4)$$

If B/k and n are known for every temperature, functionality can be obtained from an iterative process, since f value satisfies Eqs. (2)–(4).

2.9. Statistical analysis

Results were subjected to a multiple regression and variance analysis (Statgraphics Plus 3.0, 1994), t Student tests being used to determine the coefficient significance and standard error ($p > 0.95$). To determine multiple correlations between t_g and the design variables, Table Curve 3D (1993) program was used.

3. Results and discussion

For any R and pH studied, gelation times decreased as heating temperature increased, as shown in Fig. 1a–c for the samples with the different R (0.291, 0.678, and 1.059), and at initial pH values 6, 7 and 8. Temperature increase encourages several chemical changes in casein micelles, which result in their irreversible aggregation. These changes are probably related to whey protein denaturation, casein complex formation, Ca^{++} saturation in the soluble phase, and the resulting pH decrease (Fox, 1982).

Casein accounts for approximately 80% of bovine milk proteins and casein micelles constitute the basic blocks conforming the milk gel. The position of κ-casein on the micelle surface has a fundamental meaning in the gelation process (Horne, 1998). When milk is treated at temperatures above 70 °C, the different whey proteins inter-react in a very complex way, and soluble complexes are formed in the first stages, which act as intermediates in the association of β-lactoglobulin the casein micelles (Corredig & Dalgleish, 1999; Anema, Lowe, & Li, 2004) and with α-lactalbumin, which then precipitate on the surface of the casein micelles. Heat treatment markedly affects the interactions among whey denatured proteins, and among them and with the casein micelles. As shown in Fig. 1, gelation times were very high at 105 °C (278 K), and, in the case of samples with the lowest protein and the highest sucrose proportions (lowest R values) studied, gelation was still not complete after 3 h of heating.

As R increased, the gelation times decreased, regardless of the pH or temperature. This is due to the fact that at higher R values, the casein percentage in the medium is higher, which in turn increases, by cross-linking, the proportion of reactive sites involved in the gelation process (Donato, Guyomarch, Amiot, & Dagleish, 2007). Also, an increase of sucrose proportion (R decrease) resulted in an increase of the gelation time, which could be partly explained by the capacity of sugars to delay heat-induced protein denaturation (Carpenter, Chang, Garzón Rodríguez, & Randolph, 2002; Passot, Fonseca, Alarcon-Lorca, Rolland, & Marin, 2005), which, as discussed before, is fundamental for the gel development. Thus, as the relative amount of sugar decreases (R increases) it is expected that proteins are more subjected to denaturation and consequently to develop the different stages leading to gel formation.

As previously discussed, denaturation of whey proteins, and, particularly of β-lactoglobulin is the necessary initial step which allows the formation of a tri-dimensional network in milk (Donato et al., 2007). However, the modifications occurring on the surface of the casein micelles are also of fundamental importance (Anema & Li, 2003). These modifications are manifested by changes in the micelle volume, which are sensitive to even slight pH modifications (Anema & Li, 2003).

When comparing samples with the same composition and treatment temperatures, gelation times were very low (usually below 1 min) for samples with initial pH 6 (Fig. 1), and the highest gelation times were obtained for samples with an initial pH 7, since this pH is very close to that of maximum casein thermal stability (Walstra & Jenness, 1987a, chap. 17). Gelation times of samples with initial pH 8 were higher than those obtained for pH 6, though lower than those for pH 7.

Anema and Li (2003) showed that at pH 6.5, about 70% of denatured whey proteins are associated to the casein micelle, and the degree of association decreases as increasing pH. Thus, it could be expected that at pH 8 the gelation times would be the highest. However, the low gelation times observed at pH 8 (compared to those at pH 7) could be a consequence of the fact that alkaline conditions promote the kinetics of browning reactions, which contribute to a marked and faster pH decrease (Buera, Chirife, Resnik, & Wetzler, 1987) than those obtained with samples of initial pH 7, and, consequently, to a shorter gelation time. Sugar hydrocarbon chain fragmentation and heat-induced acid generation from lactose were reported to occur during heating, contributing to the acid formation and pH decrease (Fox, 1982; Rozycki, 1999). The faster pH decrease at pH 8 than that occurring at pH 7, would lead to gelation in a shorter time. There seems to be a kind of competition between the rate of pH decrease, caused by Maillard reaction, and the narrowness of conditions for the point of highest micelle stability.

pH has also opposite effects on sucrose hydrolysis (which is favoured at acid pHs (Flink, 1983)) and on Maillard reaction (which is favoured at neutral pHs) and a compromise between both types of reactions was reported (Buera et al., 1987). The values of (B/k) from the ordinate to the origin, and of $(n-1)$ from the slope, were obtained for all casein concentrations, with good correlation coefficients ($r^2 > 0.94$) for the different heating temperatures and pH values under study. Table 3 shows the kinetic parameter values (n, k and B).

As discussed before, at pH values 7 and 8, the kinetic parameters for gelation, B and n, were very similar, probably by a partial compensation of the above-mentioned effects.

The high values of n (Table 3) show the complexity of the reactions involved and the diversity of the changes produced (Walstra

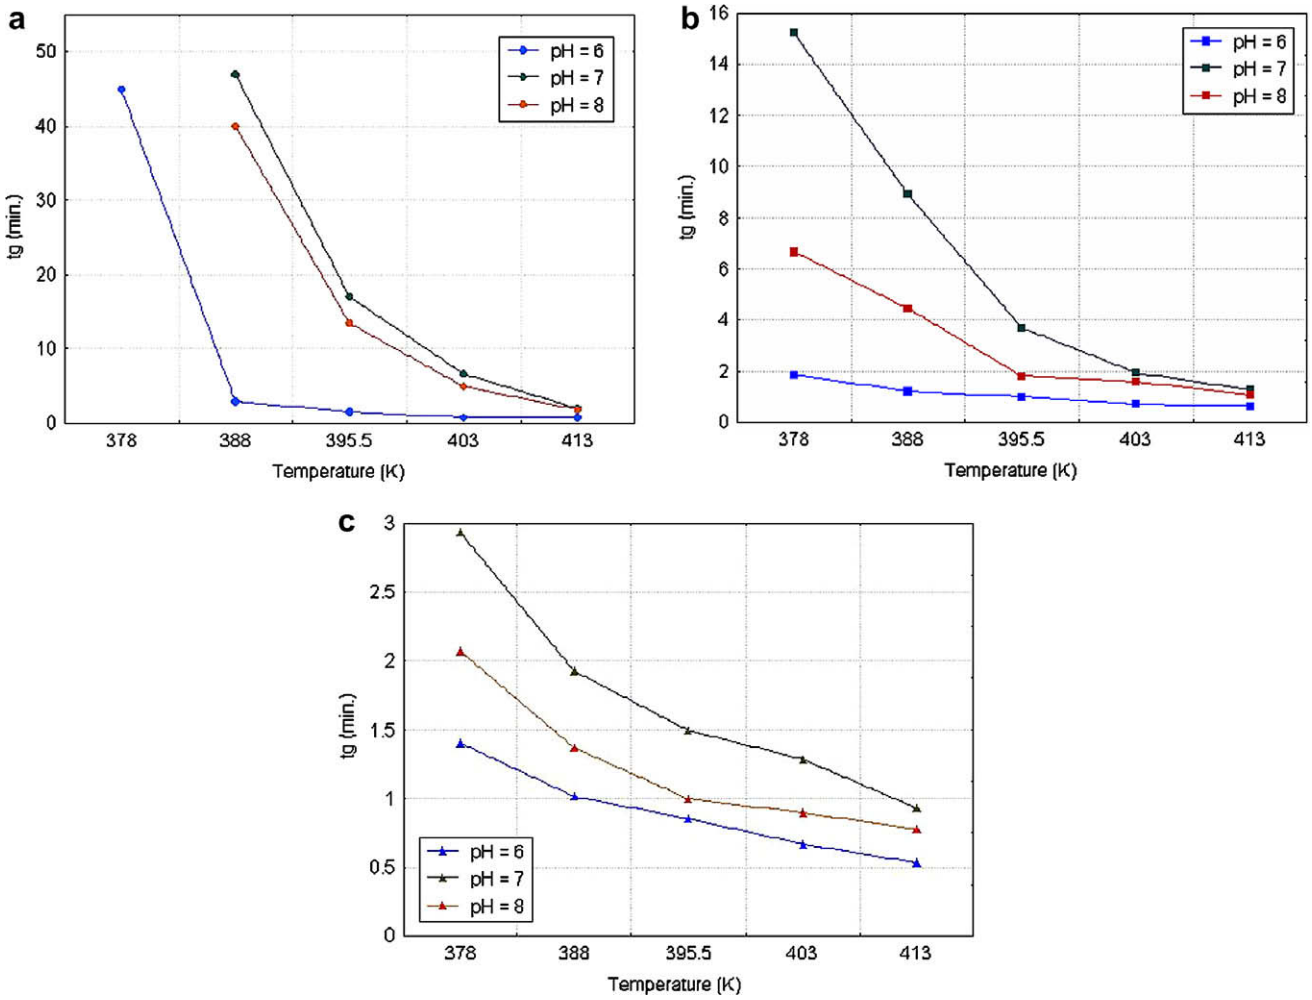

Fig. 1. Gelation time vs. temperature for samples with whole milk/sucrose ratios (R): $R = 0.291$ (a); $R = 0.678$ (b) and $R = 1.059$ (c), at different pH values.

& Jenness, 1987a, 1987b, chaps. 17, 10.2). Since thermal treatment at high temperatures can promote changes in the reaction mechanisms of the simultaneous reactions that take place, this could significantly influence n values (Villota & Hawkes, 1992, chap. 2).

The average casein micelle functionality (f), related to reactive sites in the casein micelles was calculated for all the samples by the method proposed by Pauletti et al. (1996). The f values obtained were the following: 2.37 (pH 6), 2.43 (pH 7) and 2.45 (pH 8), reflecting no significant changes on the average functionality of casein monomers when varying the mixture initial pH between 6 and 8. However, as shown in Table 3, k values at pH 6 were much higher than at pH 7 and 8. This could indicate that the pH 6 has a marked influence on the kinetic aspects of gelation reactions (k), but it does not significantly affect the thermodynamic aspects of gelation.

Consequently, the number of reactive (directly related to functionality f) sites per protein molecule is higher than 2 ($f > 2$) and it remains almost unchanged when varying pH between 6 and 8. It can be thus proposed that cross-linked branched polymers develop due to the thermal treatment, generating a three dimensional protein network involving the whole system, similar to other systems with whey and egg proteins (Rector, Matsudomi, & Kinsella, 1991).

The evolution of water activity (a_W) with reaction time was analysed in three samples, varying R between 0.296 and 1.059, keeping T (122.5°) and pH (7) constant and the results are shown in Table 4. At initial time (time = 0), as expected, a_W was lower as lower was the R value (higher the sucrose proportion). However, regardless of R, water activity decreased with increasing reaction time, which implies that as heating progresses, polymer–solvent interactions prevail over polymer–polymer one (Katsuta, Rector, & Kinsella, 1990). The solvation of the micelles, increases the hydrodynamic protein volume by increasing their "effective" radius which, according to the statistical gelation theory, would turn them more gelation reactive. Thus, the presence of sucrose limit

the water availability for micelle surface hydration, necessary for gelation to occur (Boye, Alli, Ramaswamy, & Raghavan, 1997). This would partly account for the fact that the higher the R (and the lower the S) values, the lower t_g and the more the amount of gelation reactive sites due to the increase in protein concentration.

By representing $\ln(k/B)$ for every pH as a function of $1/T$, straight lines were obtained (Fig. 2), and the obtained activation energy values resulting from their slopes are shown in Table 5.

The E_a values of the studied concentrated milk samples (Table 4) are more than twice higher than those corresponding to milk (100–120 kJ/mol), according to Pauletti et al. (1996). This effect can also be due to the sucrose–protein interaction, which increases micelle stability.

E_a values were significantly lower for the samples at pH 6 than for those at pH 7 and 8, which were similar. The little dependence on temperature for the samples at pH 6 may be associated to the fact that, at working temperature, there is a closer proximity in these samples to the optimum gelation pH for the concentrated milk. This could indicate that at pH 6 a different gelation mechanism could operate from that in the samples at PH 7 and 8.

7.0	371.3	0.996	4.274	3,69,285	0.995	1804
8.0	398.2	0.997	3.605	4,16,753	0.972	4883

[a] E_a = activation energy.
[b] r^2 = correlation coefficient.
[c] s.e = standard error.
[d] B^* = energy associated to network formation (kJ/mol).

Kim and Kinsella (1989) have defined the network formation energy, B^*, starting from a linear, Arrhenius-type, model

$$\ln k = \ln A - B^*(1/T) \quad (5)$$

where A = frequency factor; B^* = network formation energy.B^* is associated to the amount of consumed energy that is required for the network formation during gelation: as higher is B^* value, gelation is slower, thus favoring a wider micelle–micelle interaction and a denser network structure (Kim & Kinsella, 1989).

Using k values calculated above (Eqs. ((1)–(3)), and relating them with $(1/T)$ (Eq. (5)) by means of the linearisation method, B^* values are obtained from the slope of the straight lines, and are also shown in Table 5.

The analysis of these values shows that as the E_a values, the energy needed to form the network (B^*) increases with pH, being at pH 6 half the value of that at pH 8, and that energy is very similar for pHs 7 and 8.

By applying a multiple regression analysis (Statgraphics, 3.0) to the gel times and design variables (T, R and pH), the mathematical model represented by Eq. (6), which allows t_g value prediction, was obtained.

$$t_g = 4.681 - 11.255 \cdot X1 - 12.248 \cdot X2 + 3.510 \cdot X3 + 7.882 \cdot X12 + 9.755 \cdot X22 + 6.828 \cdot X32 + 17.481 \cdot X1 \cdot X2 - 4.870X1 \cdot X3 - 4.830 \cdot X2 \cdot X3 \quad (6)$$

($r^2 = 0.812$; standard error of estimation = 9.8515).

Linear regression coefficients show t_g to vary inversely with R and reaction temperature, gel time decreasing when casein proportion and temperature increase. Also, t_g is directly affected by initial pH, t_g decreasing when pH decreases.

When comparing linear and quadratic regression coefficients, it was observed that temperature was the most influential individual variable, though the influence of temperature–R interaction was also important.

In order to obtain simpler gel time prediction equations, and also a better fit, the regression analysis of experimental data (Table Curve 3D) as a function of two variables was carried out, at pH 6, 7 and 8, respectively. The following mathematical models were obtained ($r^2 > 0.94$):

$$\ln t_g = -3.661 + 1.356 \cdot e - X1 + 1.388 \cdot e - X2 \quad \text{pH6} \quad (7)$$

$$\ln t_g = 3.700 - 4.579 \cdot X1 - 1.936 \cdot e - X1 - 1.526 \cdot X2 \quad \text{pH7} \quad (8)$$

$$\ln t_g = 3.107 - 4.389 \cdot X1 - 1.705 \cdot e - X1 - 1.553 \cdot X2 \quad \text{pH8} \quad (9)$$

Heating affects the rate of two processes which mutually influence each other: gelation and non-enzymatic browning processes. The pH decrease promoted by non-enzymatic browning reactions affects system gelation. Gelation, in turn, causes variations in transport properties and sucrose hydrolysis kinetics, which influences directly and indirectly the kinetics of browning reactions.

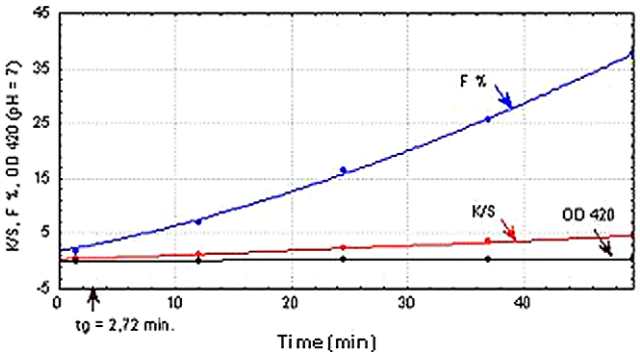

Fig. 3. Fluorescence, Kubelka–Munk index and optical density for the samples of $R = 0.591$, at pH 7, as a function of time. The arrow indicates the gelation time.

However, gelation and browning reactions have different kinetics, as activation energy and reaction pseudo-order values show (Rozycki, 1999).

In order to compare the kinetics of the gelation process in parallel to the non-enzymatic browning development, the browning indicators fluorescence (F), optical density at 420 nm (OD_{420}) and the Kubelka–Munk colour function K/S were measured and represented as a function of time. Fluorescence (F) presented higher sensitivity than the other colour functions or absorbance readings employed to follow browning development, as shown in Fig. 3, for the samples of $R = 0.591$, at pH 7. The corresponding gelation times (t_g), indicated as arrows noticeably show that the system gelation (at $T > 105$ °C) occurs much earlier than colour development can be appreciated, whereas fluorescence is clearly detected from the beginning of the reaction. It is concluded that both gelation and browning processes could be separated, as well as their individual design and control, which can be employed for the continuous production of concentrated and sucrose dairy products, whose organoleptic and texture characteristics would vary according to their future application.

4. Conclusions

The present work has shown temperature to be the most influential individual variable on the thermal-induced gelation of milk in the presence of sucrose. At temperatures close to the boiling point, at atmospheric pressure, both gelation and browning processes are slow and even below a certain proportion of milk solids there is no convenient system gelation. Also, the presence of sucrose increases gelation rate and its dependence on temperature.

At pHs 7 and 8, the system shows a similar behaviour, though sensibly different from that at pH 6, which shows the possibility of a change in the mechanism of the reactions involved in the gelation process.

The pH variation studied has no apparent influence on the thermodynamic aspects of gelation reactions and the average functionality of casein micelles, though it does influence the process kinetics, aggregation and gelation being fast at pH 6.

The mathematical models obtained were adequate to predict the system behaviour as far as its stability is concerned, combining technological variables commonly used in the industry.

pH was shown to noticeably affect the firmness and structural density of dairy gels obtained, these characteristics increasing at higher pHs (pH 8) since they produce a less fast (controlled) rate which allows a minimum heating time needed for establishing a higher number of bonds and the subsequent gel "reaffirmation".

System gelation occurs much earlier than the development of a noticeable brown colour.

These aspects are very useful for the development of continuous methods to obtain concentrated and sucrose products of different organoleptic and texture characteristics, for the optimisation of the designed processes, and the formulation of new products.

Essential oil
Antimicrobial activity
Coriandrum sativum

ABSTRACT

The aim of this study was to evaluate the chemical and antifungal activity of the essential oil from *Coriandrum sativum* L. (Apiaceae) against different *Candida* species. The essential oil (EO) was obtained by hydrodistillation and submitted to dry-column chromatography, resulting in six fractions, which were then submitted to TLC and GC–MS analysis. The main compounds identified were alcohols: 1-decanol (24.20%); 2E-decenol (18.00%); 2Z-dodecenol (17.60%); and aldehydes (89%). Antibacterial activity of the EO and its fractions was tested against five species of *Candida albicans*. The EO showed antimicrobial activity against all the species of *Candida* tested, except for *Candida tropicalis* CBS 94. Fractions 4 and 6 had a greater antibiotic spectrum, probably due to the presence of such alcohols as 3-hexenol, 1-decanol, 2E-decenol and 2Z-dodecenol. In conclusion, the EO and its fractions could be used as potential antimicrobial agents to treat or prevent *Candida* yeast infections.

1. Introduction

There has been a high incidence of nosocomial infections caused by opportunistic microorganisms, especially species of *Candida;* the therapeutic approach to such infections is a great challenge due to the resistance developed by pathogens towards a number of widely-used drugs (Chopra, 2007). *Candida* spp may cause several infections involving oral mucosal lesions (candidiasis or candidosis) and potential systemic dissemination, which might be due to antibiotics use, as they kill the competing bacterial flora, leading to an overgrowth of yeasts (Koneman, Allen, Janda, Schreckenberger, & Winn, 2001; Xu, Samaranayake, & Samaranayake, 1999).

A growing demand for natural antimicrobial agents has been observed in the past few years. Several studies have investigated the antimicrobial activity against *Candida albicans* of the essential oil and other substances extracted from medicinal plants; however, no phototherapeutic products with antimicrobial activity have been developed for human or animal use so far (Duarte, Figueira, Sartoratto, Rehder, & Delarmelina, 2005; Rosato, Vitalli, Gallo, Balenzano, & Mallamaci, 2008; Runyoro, Matee, Ngassapa, Joseph, & Mbwambo, 2006).

Coriandrum sativum L. (Umbelliferae/Apiaceae), popularly known as coriander, is commonly found in Brazilian cuisine and medicinally believed to have several therapeutic properties: hypoglycaemic (Otoom, Al-Safi, Kerem, & Alkofani, 2006; Waheed, Miana, Ahmad, & Khan, 2006), anti-inflammatory and hypolipidaemic (Chithra & Leelamma, 1997; Chithra & Leelamma, 2000; Lal, Tkumar, & Pillai, 2004), analgesic and sedative (Chaudhry & Tariq, 2006; Emamghoreishi & Heidari-Hamedani, 2006), anxiolytic (Emamghoreishi, Khasaki, & Aazam, 2005), antimutagenic (Cortes-Eslava, Gomez-Arroyo, Villalobos-Pietrini, & Espinosa-Aguirre, 2004), antihypertensive (Medhim, Hadharzy, Bakos, & Verzar-Petri,1986), diuretic (Benjumea, Abdala, Hernandez-Luiz, Pérez-Paz, & Martin-Herrera, 2005; Maghrani, Zwggwagh, Haloui, & Eddouks, 2005), antioxidant (Melo, Bion, Filho, & Guerra, 2003; Ramadan, Kroh, & Morsel, 2003), antimicrobial (Kubo, Fujita, Kubo, Hihei, & Ogura, 2004; Lo Cantore, Iacobelli, Marco, Capasso, & Senatore, 2004), and carminative, antispasmodic and relaxant (Vejdani et al., 2006).

Antimicrobial activity has been reported for the essential oil (EO) extracted from *C. sativum* seeds against different species of *Candida*, Gram-positive/negative bacteria, and fungi (Elgayyar, Draughon, Golden, & Mount, 2001; Hammer, Carson, & Riley, 1998; Lo Cantore et al., 2004).

Matasyoh, Maiyo, and Ngure (2008) reported antibacterial activity for the EO obtained from *C. sativum* leaves against Gram-positive (*Staphylococcus aureus, Bacillus* spp.) and Gram-negative bacteria (*Escherichia coli*, *Salmonella typhi*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Pseudomona aeruginosa*), as well as fungi (*C. albicans*). Duarte, Figueira, Delarmelina, and Sartoratto (2007) showed antimicrobial activity of *C. sativum* leaves against *Pityrosporum ovale*, while Wong and Kitts (2006) demonstrated antimicrobial activity for the ethanolic and aqueous extracts of *C. sativum* against *Bacillus subtilis* and *E. coli*.

doi:10.1016/j.foodchem.2009.04.089

Therefore, the aim of the present study was to evaluate the antimicrobial activity of the EO extracted from *C. sativum* leaves and its fractions against different species of *Candida* (*C. albicans* CBS 562, *Candida tropicalis* CDS 94, *C. parapsilosis* CBS 604, *C. dubliniensis* CBS 7987, and *C. krusei* CBS 573), as well as to identify the chemical constituents responsible for such activity.

2. Materials and methods

2.1. Plant material

Leaves of *C. sativum* L. were obtained at CEASA (grocery wholesalers and retailers) in Campinas, January 2007.

2.2. Microorganisms

Microorganisms were obtained from the Department of Oral Diagnosis, Division of Microbiology and Immunology, at Piracicaba Dental School, University of Campinas (UNICAMP). Antibacterial assays involved such *Candida* species, as *C. albicans* CBS 562, *C. tropicalis* CDS 94, *C. parapsilosis* CBS 604, *C. dubliniensis* CBS 7987, and *C. krusei* CBS 573.

2.3. Distillation of essential oil and fractionation

The essential oil was obtained by the hydrodistillation of fresh leaves (7.5 kg) using a Clevenger-type apparatus for 4 h. The resulting oil/water mixture obtained was extracted using dichloromethane. The organic layer was then separated, dried over Na_2SO_4, filtered and the solvent removed by means of vacuum evaporation at room temperature, resulting in *C. sativum* essential oil (yield: 0.03% w/w).

The EO of the *C. sativum* (0.5 g) was further fractionated by dried column chromatography (cellulose 2 × 30 cm) using Si gel 60 (Merck; Darmstadt, Germany) and dichloromethane as the eluent. The columns were cut into six parts and extracted using dichloromethane, yielding the following fractions: **1** (84.3 mg), **2** (49.5 mg), **3** (21.6 mg), **4** (82.4 mg), **5** (164.8 mg), and **6** (50.9 mg). The fractions were analysed by thin layer chromatography and gas chromatography–mass spectrometry (GC–MS) and then submitted to antimicrobial assays.

2.4. Analysis

The EO and its fractions were analysed through thin layer chromatography (TLC) using silica gel 60 F_{254} layers (Merck) eluted with dichloromethane and visualised under UV 254 nm, following anisaldehyde solution application and drying at 105 °C for 5 min. The samples of the EO and its fractions were diluted in ethyl acetate (10 mg/ml). GC–MS analyses were carried out using gas chromatography (Agilent 6890), with mass selective detector (Agilent 5975; Agilent; Santa Clara, CA), using an HP-5 MS capillary column (25 m × 0.25 mm i.d. × 1.0 μm d.f.). Injection temperature was 220 °C, detector temperature was 250 °C, column temperature was increased from 60 °C to 240 °C at 3 °C per min. Carrier gas was He at 1.0 ml/min and split injection was used.

The programmed temperature retention index of each compound was determined in relation to *n*-alkanes. The MS was operated in the EI mode at 70 eV in the *m*/*z* range from 42 to 350. Compounds were identified by comparing the mass spectra with those in a mass spectral library database (NIST 05), co-injection of hydrocarbon standards to calculate the retention indices (RI's), and analysis of data described by Adams (2007). The relative proportions of the essential oil constituents were expressed as percentages obtained by peak area normalisation; all relative response factors were taken as one.

2.5. Anti-Candida assay – minimal inhibitory concentration (MIC) test

The yeast was grown overnight at 36 °C in Sabouraud dextrose agar (Merck) plates. Inocula for antimicrobial assays were prepared by diluting the scraped cell mass in 0.85% NaCl solution, adjusted to 0.5 McFarland scale and confirmed by spectrophotometric readings at 580 nm.

Cell suspensions were finally diluted to 10^4 CFU ml^{-1} (colony forming units) for use in the assays. Minimum inhibitory concentration (*MIC*) tests were carried out in RPMI-1640 medium according to NCCLS. (2002) using a tissue culture test plate (96 wells). The EO was diluted in 0.1% Tween 80 solution in sterile water and the stock solution transferred into the first well, and serial dilutions were performed, to obtain concentrations ranging between 0.003 and 2 mg/ml.

Nystatin (Merck) was used as the reference antimycotic control (5–60 μg/ml), the yeast inoculum was added to all wells and the plates were incubated at 36 °C for 24 h.

Table 1
Chemical composition of *Coriandrum sativum* leaves essential oil and fractions.

Compounds	Relative amount (%)						
	Oil	Fraction 1	Fraction 2	Fraction 3	Fraction 4	Fraction 5	Fraction 6
Alcohols							
3-Hexenol	10.30	–	–	–	0.70	10.50	16.30

Table 2
Antimicrobial activity of essential oil and its fractions from *Coriandrum sativum* against different species of *Candida*.

	MIC (μg/ml)								
Candida spp.	Oil	Fraction 1	Fraction 2	Fraction 3**	Fraction 4	Fraction 5	Fraction 6	Nistatin	Fluconazole
C. albicans CBS 562	500	*	1000	–	31	63	31	2	63
C. krusei CBS 573	250	*	125	–	63	250	63	0,5	15
C. parapsilosis CBS 604	125	31	1000	–	7	10	7	8	7
C. dubliniensis CBS 7987	250	*	500	–	7	31	15	1	7
C. tropicalis CBS 94	*	*	*	–	63	125	63	16	125

* MIC > 1000 μg/ml.
** The essential oil fraction three was not subjected to the tests of antimicrobial activity due the insufficient mass.

Minimal inhibitory concentration was determined as the lowest concentration of the EO to inhibit visible growth of yeast (RPMI medium is known to change colour, pink to yellow, as microbial growth occurs).

3. Results and discussion

The EO from the C. *sativum* obtained through hydrodistillation was submitted to GC–MS analysis. The main constituents identified were alcohols (78.13%) and aldehydes (11.96%), with linear chains ranging from 6 to 14 carbon atoms (Table 1). The major alcohols were 1-decanol (24.17%), 2E-decenol (18.05%), 2Z-dodecenol (17.55%) and 3-hexenol (10.34%), while the major aldehydes were decanal (4.76%), dodecanal (3.02%) and 2-dodecenal (2.88%).

These results were observed to be different from those concerning the EO of *C. sativum* leaves collected in Kenya (Matasyoh et al., 2008) and Tunisia (Msaada, Hosni, Ben Taarit, Chahed, & Marzouk, 2007), where the main compounds identified were the aldehydes (E)-2-decenal and (*E*)-2-dodecenal.

In the present study, the EO (*C. sativum*) showed antimicrobial activity, varying from 125 μg/ml (*C. parapsilosis* CBS 604) to 500 μg/ml (*C. albicans* CBS 562), against most of the Candida species tested, except for *C. tropicalis* CBS 94. These results showed a greater antimicrobial potential of the EO, when compared to those obtained by Matasyoh et al. (2008), reporting an *MIC* value of 163 mg/ml for *C. albicans*.

Fractionation of the EO through dry-column chromatography resulted in 6 fractions with different polarities and their main constituents were identified by GC–MS (Table 1).

Aldehydes were the main compounds observed in fractions **1**, **2** and **3** (56–71%) while alcohols were found in fractions **4**, **5** and **6** (85–97%). Results showed potential bacterial inhibition for fractions **4**, **5** and **6,** with *MIC* values varying from 7 to 250 μg/ml. The other fractions showed higher *MIC* values and lower antimicrobial activity, which might be explained by the greater concentration of aldehydes found.

Fractions **4**–**6** and the antibiotics tested showed similar antimicrobial activity against *C. albicans* CBS 562, *C. parapsilosis* CBS 604, *C. dubliniensis* CBS 7987, and *C. tropicalis* with *MIC* values ranging from 7 to 63 μg/ml. These values showed potential antimicrobial activity when compared to those obtained for the EO (125–500 μg/ml), which might be explained by the higher concentration of alcohols found (Table 2).

4. Conclusion

A high concentration of alcohols and aldehydes was observed for the EO of C. *sativum* fresh leaves, showing antimicrobial activity against different species of *Candida*, except for *C. tropicalis* CBS 94.

Chemical fractions of the EO possessed greater antimicrobial activity (*MIC*: 7–63 μg/ml), similar to that of standard antibiotics. The high concentration of alcohols found in these fractions might be responsible for such activity.

Extra virgin olive oil adulteration
Fourier-transform infrared spectroscopy
Linear discriminant analysis
Multiple linear regression

ABSTRACT

Fourier-transform infrared spectroscopy (FTIR), followed by multivariate treatment of the spectral data, was used to classify vegetable oils according to their botanical origin, and also to establish the composition of binary mixtures of extra virgin olive oil (EVOO) with other low cost edible oils. Oil samples corresponding to five different botanical origins (EVOO, sunflower, corn, soybean and hazelnut) were used. The wavelength scale of the FTIR spectra of the oils was divided in 26 regions. The normalized absorbance peak areas within these regions were used as predictors. Classification of the oil samples according to their botanical origin was achieved by linear discriminant analysis (LDA). An excellent resolution among all categories was achieved using an LDA model constructed with eight predictors. In addition, multiple linear regression models were used to predict the composition of binary mixtures of EVOO with sunflower, corn, soybean and hazelnut oils. For all the binary mixtures, models capable of detecting a low cost oil content in EVOO as low as 5% were obtained.

1. Introduction

Oil genuineness is a very important aspect of quality edible oils. Extra virgin olive oil (EVOO) has unique nutritional and sensory characteristics, being also a basic component of the Mediterranean diet. The importance of EVOO is mainly attributed to its high content of oleic acid and its richness in phenolic compounds, which act as natural antioxidants (Bendini et al., 2007). On the other hand, EVOO is expensive owing to the hard and time-consuming tasks involved in the cultivation of olive trees, the harvesting of the fruits, and the extraction of the oil. For these reasons, adulterations of EVOO with olive oils of lower quality, or with oils of a different botanical origin are occasionally detected (Catharino et al., 2005; Chiavaro, Vittadini, Rodriguez-Estrada, Cerretani, & Bendini, 2008; Marcos-Lorenzo, Pérez-Pavón, Fernández-Laespada, García-Pinto, & Moreno-Cordero, 2002; Mariani, Bellan, Lestini, & Aparicio, 2006; Poulli, Mousdis, & Georgiou, 2006; Tay, Singh, Krishnan, & Gore, 2002; Vlachos et al., 2006). For this reason, European Mediterranean countries, which are major suppliers of olive oil in the world market, have adopted common regulations to protect growers and consumers from fraud (European Union Commission, 1991).

To establish the authenticity of edible oils, a number of chromatographic (Brodnjak-Voncina, Kodba, & Novic, 2005; Marcos-Lorenzo et al., 2002; Mariani et al., 2006), thermal (Chiavaro et al., 2008) and spectroscopic methods, including fluorescence (Poulli et al., 2006; Sikorska, Górecki, Khmelinskii, Sikorski, & Kozioł, 2005), NIR (Christy, Kasemsumran, Du, & Ozaki, 2004; Downey, McIntyre, & Davies, 2002; Kasemsumran & Kang, 2005; Sato, 1994; Wesley, Pacheco, & McGill, 1996; Yang, Irudayaraj, & Paradkar, 2005), FTIR (Baeten et al., 2005; Dupuy, Duponchel, Huvenne, Sombret, & Legrand, 1995; Lai, Kemsley, & Wilson, 1999; Ozen & Mauer, 2002; Tay et al., 2002; Vlachos et al., 2006; Yang et al., 2005), FT-Raman (Baeten & Meurens, 1996; López-Díez, Bianchi, & Goodacre, 2003; Yang et al., 2005), NMR (Dais & Spyros, 2007; García-González, Mannina, D'Imperio, Segre, & Aparicio, 2004; Vigli, Philippidis, Spyros, & Dais, 2003) and MS (Catharino et al., 2005; Lay, Liyanage, Durham, & Brooks, 2006; Lerma-García, Ramis-Ramos, Herrero-Martínez, & Simó-Alfonso, 2007, 2008; Lerma-García, Simó-Alfonso, Ramis-Ramos, & Herrero-Martínez, 2007; Marcos-Lorenzo et al., 2002), followed by multivariate statistical analysis of the data, have been described. For this purpose, the contents of fatty acids (Brodnjak-Voncina et al., 2005), tocopherols (Lerma-García, Simó-Alfonso, et al., 2007; Sikorska et al., 2005), volatile compounds (Marcos-Lorenzo et al., 2002), amino acids (Lerma-García, Ramis-Ramos, et al., 2007) and sterols (Lerma-García et al., 2008; Mariani et al., 2006), have been used.

FTIR is a rapid and non-destructive powerful analytical tool for the study of edible oils and fats, requiring minimum sample preparation. FTIR is also an excellent tool for quantitative analysis, since the intensities of the spectral bands are proportional to concentration. For this reason, FTIR has been used to distinguish oils from different botanical origins using non-supervised classificatory techniques (Dupuy et al., 1995; Lai et al., 1999; Rusak, Brown, & Martin, 2003). FTIR has been also used to distinguish EVOOs from different geographical origins (Bendini, Cerretani, et al., 2007; Galtier et al., 2007; Tapp, Defernez, & Kemsley, 2003) and different genetic varieties (Gurdeniz, Tokatli, & Ozen, 2007). FTIR

applications addressed to detect olive oil adulteration with low cost edible oils (Baeten et al., 2005; Ozen and Mauer, 2002; Tay et al., 2002; Vlachos et al., 2006), to evaluate olive oil freshness (Sinelli, Cosio, Gigliotti, & Casiraghi, 2007), to study changes produced by frying (Valdes & Garcia, 2006) and to assess oil oxidation (Guillén & Cabo, 2002; Muik, Lendl, Molina-Diaz, Valcarcel, & Ayora-Canada, 2007; Vlachos et al., 2006) have been also described.

In this work, FTIR followed by linear discriminant analysis (LDA) of the spectral data was used to classify vegetable oils according to their botanical origin. Also, data treatment by multiple linear regression (MLR) was used to detect and quantify EVOO adulteration with other low cost edible oils, including sunflower, corn, soybean and hazelnut oils.

2. Experimental

2.1. Oil samples and mixtures

The vegetable oils employed in this study (Table 1) were either purchased at the local market or kindly donated by the manufacturers. The botanical origin and quality grade of all the samples were guaranteed by the suppliers. As indicated in Table 1, four samples of each botanical origin were used for training purposes in classification studies, being the other two samples of each category used to evaluate the prediction capability of the classification models. To estimate the adulteration of EVOO with low cost oils by using regression models, binary mixtures containing EVOO and increasing percentages of low cost oil (sunflower, corn, soybean or hazelnut) were prepared. To improve robustness of MLR models, the objects of the calibration matrix were prepared using EVOOs and low cost oils from different geographical origins. For instance, for the sunflower-EVOO pair, oils from different geographical origins were selected to prepare a total of seven mixtures containing 0%, 5%, 10%, 30%, 50%, 75% and 100% sunflower oil. Sets of mixtures containing the same percentages of low cost oil were also prepared for the corn-, soybean- and hazelnut-EVOO pairs. The resulting 28 mixtures were used as calibration set to construct regression models. Additional mixtures of the sunflower-, corn-, soybean- and hazelnut-EVOO pairs, also using oils from different geographical origins, and containing 5%, 50% and 80% low cost oil were prepared. These 12 additional binary mixtures were used to validate the prediction performance of the regression models.

2.2. FTIR spectra

FTIR spectra were obtained using a Nicolet Nexus FTIR spectrophotometer (Thermo Electron Corporation, Waltham, MA, USA) with a resolution of 4 cm^{-1} at 32 scans. A small quantity of the oil samples (≈2 μL) was directly deposited between two well-polished KBr disks, creating a thin film. Duplicated spectra were recorded for all the oil samples and binary mixtures, except the 12 mixtures used as validation set in regression studies which were recorded three times each. Spectra were scanned in the absorbance mode from 4000 to 500 cm^{-1} and the data were handled with the EZ OMNIC 7.3 software (Thermo Electron Corporation).

2.3. Data treatment and construction of matrices

FTIR spectra were divided in the 26 wavelength regions described in Table 2. Each selected spectral region corresponds to a peak or a shoulder, representing structural or functional group information, either about the lipids or minor components of the oil samples (see Table 2). For each region, the peak/shoulder area was measured. In order to reduce the variability associated to the total amount of oil sample used, and to minimize other sources of variance also affecting the intensity of all the peaks, such as the thickness of the sample and radiation source intensity, normalized rather than absolute areas were used. Two normalization procedures were tried. In procedure A, for each spectrum, the area of each region was divided by the sum of the areas of the 26 regions. In procedure B, the area of each region was divided by each one of the areas of the other 25 regions; in this way, and since any pair of areas should be considered only once, $(26 \times 25)/2 = 325$ normalized variables were obtained.

For classification studies, two matrices containing 20 objects each, which corresponded to the averages of the duplicated spectra of the training samples of Table 1, were constructed. These matrices had either 26 or 325 predictors, according to normalization procedures A and B, respectively. A response column, containing the categories corresponding to the five botanical origins of the oils (corn and corn germ were considered as a single category), was added to the training matrices. In order to reduce the internal dispersion of the categories, which was important to reduce the number of variables selected during model construction, the means of the two spectra of each sample, instead of the individual spectra, were used. For evaluation purposes, two more matrices containing 10 objects each, which corresponded to the averages of the duplicated spectra of each evaluation sample of Table 1, were constructed. These matrices also had either 26 or 325 predictors, according to normalization procedures A and B, respectively.

Concerning to the regression studies, and for the sunflower-EVOO pair, two calibration matrices containing seven objects each, which corresponded to the averages of the duplicated spectra of the calibration mixtures, were constructed. According to normalization procedures A and B, the number of predictors was either 26 or 325, respectively. A response column, containing the low cost oil percentages of the mixtures, was added to these matrices. For validation of the prediction performance, two more matrices containing three objects each, which corresponded to the averages of triplicate spectra of validation mixtures, were constructed. The number of predictors was either 26 or 325 predictors, as indicated. Analogously, matrices for the corn-, soybean- and hazelnut-EVOO pairs were also constructed. Statistical treatment of the data was performed using SPSS (v. 12.0.1, Statistical Package for the Social Sciences, Chicago, IL, USA).

3. Results and discussion

3.1. Classification of vegetable oils according to their botanical origin using LDA

FTIR spectra of the 30 oil samples of Table 1 were collected. Fig. 1 shows the spectra of five oils, one for each botanical origin, tailored at two absorbance units. As it can be observed, the differences between them were small. Interpretation of the absorption bands provides information about the molecular skeleton and functional groups (see Table 2); however, to obtain information about the botanical origin of the oils, band interpretation is not required. Information related to the origin was obtained by measuring the peak areas at the selected wavelength ranges. These data were conveniently handled by multivariate statistical techniques.

LDA, a supervised classificatory technique, is widely recognized as an excellent tool to obtain vectors showing the maximal resolution between sets of objects belonging to previously defined categories. In LDA, vectors minimizing the Wilks' lambda, λ_w, are obtained (Vandeginste et al., 1998). This parameter is calculated as the sum of squares of the distances between points belonging to the same category divided by the total sum of squares. Values of λ_w approaching zero are obtained with well resolved categories, whereas overlapped categories made λ_w to approach one. Up to $N-1$ discriminant vectors are constructed by LDA, being N the lowest value for either the number of predictors or the number of categories.

Using the normalized variables, LDA models capable of classifying the oil samples according to their botanical origin were constructed. To select the variables to be included in the model, the SPSS stepwise algorithm was used. According to this algorithm, a predictor is selected when the reduction of λ_w produced after its inclusion in the model exceeds F_{in}, the entrance threshold of a test of comparison of variances or F-test. However, the entrance of a new predictor modifies the significance of those predictors which are already present in the model. For this reason, after the inclusion of a new predictor, a rejection threshold, F_{out}, is used to decide if one of the other predictors should be removed from the model. The process terminates when there are no predictors entering or being eliminated from the model. The default probability values of F_{in} and F_{out}, 0.05 and 0.10, respectively, were adopted.

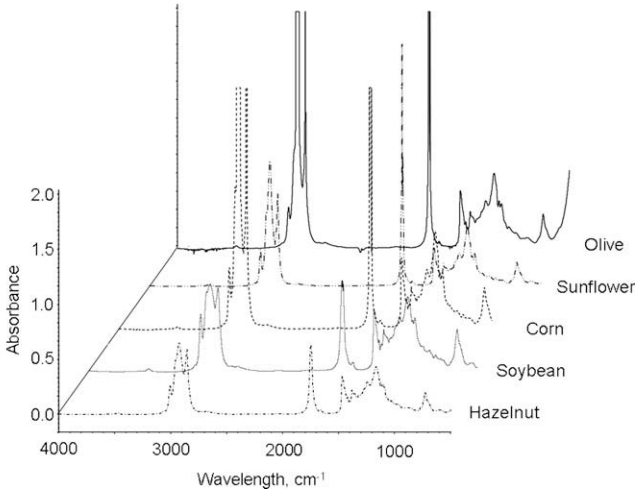

Fig. 1. FTIR spectra of representative samples of EVOO, sunflower, corn, soybean and hazelnut oils. Data were tailored at 2 absorbance units to better show the differences among small peaks.

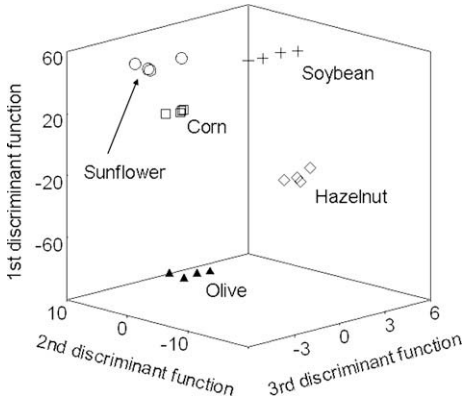

Fig. 2. Score plot on an oblique plane of the 3-D space defined by the three first discriminant functions of the LDA model constructed to classify vegetable oils according to their botanical origin.

Table 3
Predictors selected and corresponding standardized coefficients of the LDA model constructed to predict the botanical origin of vegetable oils.

Predictor[a]	f_1	f_2	f_3	f_4
8/9	19.00	8.20	5.14	3.63
10/12	0.75	9.37	4.03	0.92
11/13	−28.35	5.40	−3.19	−2.13
14/17	16.01	−3.49	−1.50	0.65
15/17	−6.81	5.74	−1.01	1.68
19/25	−13.73	4.33	1.25	0.91
21/26	12.51	−3.76	−0.64	−0.95
22/24	7.84	−5.13	2.26	−1.36

[a] Pairs of wavelength regions identified according to Table 2.

To classify oils according to the five botanical origins, two LDA models, one for each normalization procedure, were constructed. Normalization procedure B, which gave a model with a lower λ_w value and a smaller number of predictors than normalization procedure A, was selected for further studies. As shown in Fig. 2 for normalization procedure B, an excellent resolution between all category pairs was achieved ($\lambda_w = 0.362$). Taking into account that a large number of categories were simultaneously distinguished, this λ_w value was quite low. The predictors selected by the SPSS stepwise algorithm, and the corresponding standardized coefficients of the model, showing the predictors with large discriminant capabilities, are given in Table 3. According to Table 2, the main wavelength regions selected by the algorithm to construct the LDA model corresponded to =C–H (bending), O–H (bending in plane), –C–H (CH_3, bending sym), –C–O (stretching), –CH_2– (bending), –HC=CH– (trans, bending out of plane), O–H (bending out of plane) and C=C (bending out of plane). When leave-one-out validation was applied, all the objects of the training set were correctly classified. Concerning to the prediction capability of this model, and using a 95% probability, all the objects of the evaluation set were correctly assigned; thus, the prediction capability of the model was 100%. On the other hand, the variables obtained by measuring the peak areas along the 26 spectral regions of Table 2 were forced to be included in the model. An improvement of the LDA model was achieved but at the cost of introducing a large number of predictors with low significances. For this reason, variable selection by the stepwise algorithm was maintained.

Finally, an LDA model with all the available objects, including those used above for either training or evaluation, was constructed. The predictors selected by the SPSS stepwise algorithm were basically the same that those selected above, but the λ_w value was smaller (0.202), indicating a satisfactory stability of the model.

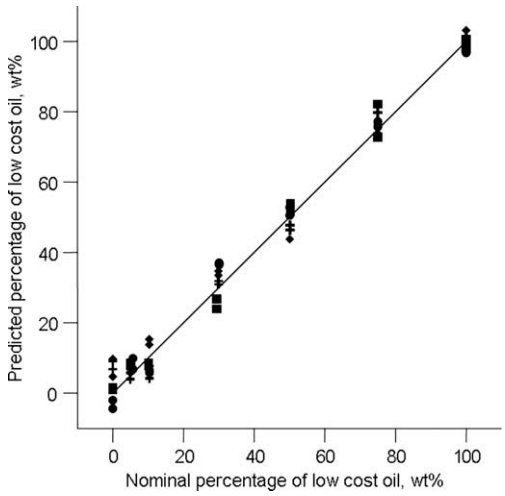

Fig. 3. Predicted (MLR) versus nominal oil percentages for binary mixtures of EVOO with sunflower (●), corn (■), soybean (+) and hazelnut (♦) oils. The straight-line is $y = x$.

3.2. Determination of EVOO adulteration by MLR

In order to quantify EVOO adulteration, the binary mixtures of EVOO with sunflower, corn, soybean and hazelnut oils (Section 2.1), were measured. To select the predictors used in the construction of MLR models, the SPSS stepwise algorithm, with the default probability values of F_{in} and F_{out}, 0.05 and 0.10, respectively, was adopted. MLR models, one for each binary combination of oils, and in each case according to normalization procedures A and B, were constructed. Normalization procedure B, which gave models with higher linear regression coefficients than normalization procedure A, was selected. A plot showing the predicted versus the nominal oil percentages for all the binary mixtures is shown in Fig. 3. The predictors selected and their corresponding non-standardized model coefficients are given in Table 4. It is interesting to observe that, except in the case of the corn-EVOO mixtures, a single predictor was selected to predict the composition of the other three binary mixtures. According to Table 2, the main wavelength transitions selected to construct the MLR model for the sunflower-EVOO pair were =CH_2 (wagging), O–H (bending out of plane) and C=C (bending out of plane). Analogously, for the hazelnut-EVOO pair, the selected transitions were =C–H (trans and cis, stretching), –C–O (stretching) and –CH_2– (bending). Those selected for the soybean-EVOO pair were –$(CH_2)_n$– (rocking) and –HC=CH– (cis, bending out of plane), and those selected for the corn-EVOO pair were –C–O (stretching) and =C–H (trans and cis,

Table 4
Predictors selected and their corresponding non-standardized model coefficients (coef.), linear regression coefficients (R^2), average prediction errors (av. pred. error) and limits of detection (LODs) obtained for the MLR models constructed to predict olive oil adulteration.

Binary mixture	Predictor	Coef.	R^2	Av. pred. error,%	LOD,%
Hazelnut-EVOO	1/15 Constant	−1080 348	0.912	2.0	4.8
Sunflower-EVOO	23/26 Constant	325 −270	0.989	1.7	4.0
Corn-EVOO	1/17 1/16 Constant	−353 221 309	0.994	1.5	1.3
Soybean-EVOO	13/25 Constant	324 −228	0.980	1.9	1.7

stretching). For all binary combinations of oils, a transition implying a double bond was selected, which suggest that unsaturated fatty acids were important in the quantification of the mixtures. The regression coefficients, average prediction errors (calculated as the sum of the absolute differences between expected and predicted oil percentages divided by the number of predictions) and the limits of detection (LODs, calculated as three times the standard deviation at 5% low cost oil level) are also given in Table 4. For all the MLR models and using leave-one-out validation, the average prediction errors were lower than 2%. The four sets of validation mixtures, one for each binary combination of oils ($4 \times 3 = 12$ mixtures), gave average prediction errors below 5%. LODs were in all cases below 5%, being lower than those previously reported in literature for binary mixtures of the same oils, namely 4% versus 6% (Vlachos et al., 2006) for sunflower-EVOO, 1.3% versus 9% (Vlachos et al., 2006) for corn-EVOO, 1.7% versus 6% (Vlachos et al., 2006) for soybean-EVOO and 4.8% versus 25% (Ozen and Mauer, 2002) and versus 8% (Baeten et al., 2005) for hazelnut-EVOO mixtures.

4. Conclusions

The possibility of classifying vegetable oils according to their botanical origin by using FTIR data has been demonstrated. Using eight wavelength regions, all the oil samples belonging to five different botanical origins were correctly classified with an excellent resolution among the categories. In addition, four MLR models constructed with one predictor for sunflower-, soybean- and hazelnut-EVOO mixtures, and with two predictors for corn-EVOO mixtures, were capable of detecting a low cost oil content in EVOO as low as 5%. Thus, the capability of the proposed method to identify the botanical origin of the oils, and to quantify low cost oils in EVOO has been demonstrated.

DNA strand breakage
D-Galactose model

ABSTRACT

The antioxidant activities of malt extract from barley were evaluated by various methods *in vitro* and *in vivo*. Scavenging effects on the hydroxyl and superoxide radicals, and protection against reactive oxygen species induced lipid, protein and DNA damage were evaluated. The D-galactose induced mouse aging model was used to evaluate ability of malt extract to behave as an antioxidant *in vivo*. The extract exhibited high antioxidant activities both *in vitro* and *in vivo*, evidenced by its ability to scavenge hydroxyl- and superoxide-radicals, high reducing power, and protection against biological macromolecular oxidative damage. Furthermore, malt extract prevented the decrease of antioxidant enzyme activities, decreased liver and brain malondialodehyde levels and carbonyl content, and improved total antioxidant capability in D-galactose-treated mice. In conclusion, these results demonstrate potential antioxidant activities and antiaging effect of malt, providing scientific support for the empirical use of malt as an antioxidant for diseases caused by reactive oxygen species.

1. Introduction

It is commonly recognised that reactive oxygen species (ROS) are involved in a variety of physiological and pathological processes, including cellular signal transduction, cell proliferation, differentiation and apoptosis, as well as ischemia – reperfusion, inflammation, and many neurodegenerative disorders (Ames, Shigenaga, & Hagen, 1993; Bland, 1995). In healthy individuals, ROS production is continuously balanced by natural antioxidative defence systems. Oxidative stress is a process where the physiological balance between pro-oxidants and antioxidants is disrupted in favour of the former, ensuing in potential damage for the organism (Halliwell & Gutteridge, 1990). ROS production can induce DNA damage, protein carbonylation, and lipid peroxidation, leading to a variety of chromic health problems, such as cancer, aging, Parkinson's disease, Alzheimer's disease and amyotrophic lateral sclerosis (Collin, 1999; Floyd, 1999).

Dietary antioxidant intake may be an important strategy for inhibiting or delaying the oxidation of susceptible cellular substrates, and is thus relevant to disease prevention in many paradigms. Phenolic compounds such as flavonoids, phenolic acids, diterpenes and tannins have received attention for their high antioxidative activity (Rice-Evans, Miller, & Paganga, 1996). Converging evidence from both experimental and epidemiological studies have demonstrated that cereals, vegetables, and fruits contain a myriad of phenolic compounds.

Barley is a widely consumed cereal among the most ancient cereal crops, but mainly (80–90%) barley production is for animal feeds and malt (Liu & Yao, 2007). There are growing interests in barley products because of their high content of phenolic compounds such as phenolic acids (benzoic and cinnamic acid derivatives), proanthocyanidins, tannins, flavonols, chalcones, flavones, flavanones, and amino phenolic compounds (Goupy, Hugues, Boivin, & Amiot, 1999).

Malt, used for the manufacturing of beer, contains various compounds from barley (endogenous phenolic compounds) or from the malting process (Maillard reaction products) that can play a significant role in malting and brewing through their antioxidative properties (Maillard, Soum, Boivin, & Berset, 1996). Malting had significant influences on individual and total phenolic contents as well as antioxidant activities. The contents of some phenolic compounds and the antioxidant activities increased remarkably during the later stages of germination and subsequent kilning (Lu et al., 2007).

Barley and malt are now gaining renewed interests as ingredients for the production of functional foods due to their concentration of antioxidant compounds. Most previous studies reported the antioxidative properties of barley. Attention was paid above all to the identification of the individual components of the phenolic

doi:10.1016/j.foodchem.2009.04.094

fraction and to their antioxidant effects (Bonoli, Verardo, Marconi, & Caboni, 2004; Zhao et al., 2006).

The objective of the present study was to evaluate the antioxidant activity of malt extract from barley *in vitro* and *in vivo*. While the antioxidant activity of barley or malt has been studied *in vitro*, there is no literature documenting an antioxidant role for barley or malt *in vivo*. In the present study we set out to determine the antioxidant properties of malt *in vitro*, by measuring scavenging effects on the hydroxyl radical and superoxide radical, reducing power, inhibition of lipid peroxidation, protein carbonlytaion and DNA damage. We then evaluated the potential antioxidant potential of malt *in vivo*, in the D-galactose induced mouse aging model.

2. Materials and methods

2.1. Chemicals and reagents

D-Galactose was purchased from Amresco. Commercial kits used for determination of T-AOC, MDA, SOD, GSH-Px and MAO were purchased from Jiancheng Institute of Biotechnology (Nanjing, China). 2,2′-azo (2-amidinopropane) dihydrochloride (AAPH), (Butylated hydroxytoluene) BHT, (bovine serum albumin) BSA, (sodium dodecyl sulphate) SDS, agarose, plasmid pBR322 DNA, ascorbic acid and 6-hydroxy-2,5,7,8-tetramethylchromancarboxylic acid (Trolox) were purchased from Sigma–Aldrich (St. Louis, MO, USA). Acrylamide, *N*,*N*′-methylene – bis–acrylamide and guanidine HCl were purchased from Fluka (Buchs, Switzerland). Dimethyl sulphoxide (DMSO) was purchased from the Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China).

2.2. Preparation of malt samples

Malt was obtained from Lanzhou Huanghe Enterprise Co., Ltd. (Gansu, China). Two hundred grams of the defatted malt was separately extracted with 80% acetone (v/v) at room temperature for 24 h, following separation of the supernatant and the sediment by vacuum filtration. The residue was re-extracted with 80% acetone for another 24 h and supernatants obtained were pooled with those from the first extraction. The extraction solutions were concentrated by vacuum-evaporator at 50 °C. The resulting concentrated solutions were lyophilised for 72 h at −49 °C and 25×10^{-3} mbar. The dried extract was dissolved in DMSO to a concentration of 50 mg/ml and stored at 4 °C until analysis.

2.3. Animal treatment

Male Kunming mice weighing 20–24 g were purchased from the Experimental Animal Center of Lanzhou University. The mice were housed in the temperature and humidity controlled room with a 12 h light–dark cycle and free access to standard pellet diet and drinking water. After an adaptation period of 6 days, the mice were randomly divided into five groups and received intraperitoneal (i.p.) injections with 300 mg/kg D-galactose (0.9% saline solution) once a day for 60 days. The aging control group (group AC) mice were introgastric gavage (i.g.) administered with 0.2 ml of saline each; the malt extract treatment group (group MET) mice were i.g. administrated malt extract (100, 200 and 400 mg/kg, dispersed in 0.9% saline). The normal control group (group NC) mice were i.p. injected with 0.2 ml of saline for 60 days and i.g. administration 0.2 ml saline only (Song, Bao, Li, & Li, 1999).

2.4. Determination of total phenolic content

The Folin–Ciocalteu reagent assay was used to determine the total phenolic content in malt extract (Liu & Yao, 2007). About 1 ml of barley extract (0.25 mg/ml) was mixed with 2 ml of Folin–Ciocalteu reagent and 2 ml of 15% Na_2CO_3 were then added. After 1 h of reaction at room temperature, the absorbance was read at 760 nm. Total phenolics were expressed as milligrams of gallic acid equivalents (GAE) per gram of dry weight.

2.5. Hydroxyl radical scavenging assay

Hydroxyl radical ($OH^{\cdot}$) scavenging capacity was measured according to the method of Liu, Liu, Song, and Fang (2002). The reaction mixture contained 2.06×10^{-3} mM methyl violet, 0.2 mM Fe^{2+}, 0.35 M H_2O_2, and 0.1 M Tris–HCl (pH 4.7) and various concentrations of malt samples in a final volume of 5 ml. After incubation for 5 min at 20 °C, the absorbance of the methyl violet complex was measured at 582 nm. Trolox was used as control. The scavenging rate was obtained according to the formula: $OH^{\cdot}$ scavenging rate $(\%) = [1 - (A_0 - A_2)/(A_0 - A_1)] \times 100$. where A_0 was the absorbance of the negative control (without Fe^{2+} and H_2O_2), A_1 was the absorbance of the positive control (without extract), A_2 was the absorbance in the presence of the extract.

2.6. Superoxide radical scavenging assay

Superoxide radical ($O_2^{-\cdot}$) scavenging capacity of malt extract was examined by a pyrogallol autoxidation system with minor modifications (Xiang & Ning, 2008). The reaction mixture contained 70 μl 10 mM pyrogallol, 4.5 ml 50 mM Tris–HCl (pH 8.2) and 0.5 ml various concentrations of malt samples. The absorbance at 325 nm was recorded immediately at 30 s and then recorded once every minute. Trolox was used as control. The scavenging rate was obtained according to the formula: $O_2^{-\cdot}$ scavenging rate $(\%) = [1 - (A_1 - A_2)/A_0] \times 100$, where A_0 was the absorbance of the control (without extract), A_1 was the absorbance in the presence of the extract, A_2 was the absorbance of without pyrogallol.

2.7. Reducing power

The reducing power was determined by the method of Oyaizu (1986). About 1 ml of malt extract of varying concentrations was mixed with sodium phosphate buffer and potassium ferricyanide $[K_3Fe(CN)_6]$. The mixture was incubated at 50 °C for 20 min. followed by addition of trichloroacetic acid and then centrifugation at 3000 rpm for 10 min. The upper layer was mixed with deionized water and $FeCl_3$, then, the absorbance was measured at 700 nm. Increased absorbance of the reaction mixture indicated increased reducing power. Trolox was used for comparison.

2.8. Determination of lipid peroxidation

Peroxidation of liver microsomes was induced by Fe^{2+}/Vc. Liver microsomes were prepared and the lipid peroxidation assay was conducted according to Cai, Fang, Ma, Li, and Liu (2003). Briefly, 0.2–0.44 mg/ml microsomes were incubated with 1 mM Vc and 0.1 mM Fe^{2+} with various concentrations of malt samples. After incubation at 37 °C for 1 h, the formation of malondialdehyde (MDA) in the incubation mixture was measured at 532 nm. Trolox was used as control. The inhibitory rate was obtained according to the formula: inhibitory rate $(\%) = [1 - (A_1 - A_2)/A_0] \times 100$, where A_0 was the absorbance of the control (without extract), A_1 was the absorbance in the presence of the extract, A_2 was the absorbance of without liver microsomes.

2.9. Determination of protein oxidation

Protein oxidation was assayed as described previously (Kwon, Choi, Won, Kang, & Kang, 2000) with minor modifications. Oxida-

tion of BSA in PBS was initiated by AAPH and inhibited by various concentrations of test compounds. After incubation for 24 h at 37 °C, 0.02% BHT was added to the reaction mixture to prevent the formation of further peroxyl radical. The samples were then assayed with normal SDS–PAGE.

2.10. Determination of oxidative DNA strand breakage

Conversion of the supercoiled form of plasmid DNA to the open circular and further linear forms has been used as an index of DNA damage (Jung & Surh, 2001). To assay inhibition of DNA damage induced by peroxyl radical by the malt extract, 100 ng of pBR322 DNA was incubated with various concentrations of compounds and 10 mM AAPH in PBS for 1 h at 37 °C. Then the samples were electrophoresed in a horizontal slab gel apparatus in TAE buffer for 1 h. The agarose gel was stained with ethidium bromide and then photographed under a transilluminator.

2.11. Measurement of T-AOC in mouse blood

At the end of treatment, mice were decapitated and blood was collected. The total antioxidant capability (T-AOC) was examined by commercial kits (Nanjing Jiancheng Bioengineering Institute, Nanjing City, PR China). The spectrometric method was applied to evaluate T-AOC. In the reaction mixture ferric ion was reduced by antioxidant reducing agents and blue complex Fe^{2+}–TPTZ (2,4,6-tri(2-pyridyl)-*s*-triazine) is produced. The optical density was measured at 520 nm. One unit (U) of T-AOC was defined as the amount that increased the absorbance by 0.01 at 37 °C. Data were expressed as U/ml blood.

2.12. Measurement of SOD, GSH-Px and MAO activity in mouse brain and liver

After mice were sacrificed, their brain and liver were removed rapidly and homogenised in cold saline. The homogenate was centrifuged at 3000*g* at 4 °C for 20 min, and the supernatant was collected for analysis. The determination of the activity of superoxide dismutase (SOD), glutathione peroxide (GSH-Px) and (monoamine oxidase) MAO were performed using commercial kits (Nanjing Jiancheng Bioengineering Institute, Nanjing City, PR China).

The assay for total SOD was based on its ability to inhibit the oxidation of oxymine by the xanthine–xanthine oxidase system. One unit (U) of SOD activity was defined as the amount that reduced the absorbance at 550 nm by 50%, and data were expressed as U/mg protein. The activity of GSH-Px was determined by quantifying the catalysed reaction rate of GSH per minute on the base of its catalysis. The final result was expressed as a decrease of 1.0 μM GSH per 5 min at 37 °C after the nonenzymatic reaction is subtracted, and data were expressed as U/mg protein. Ultraviolet chromatometry was used for MAO activity determination. One unit (U) of MAO activity was defined as the amount that increased the absorbance by 0.01 at 37 °C, and the MAO activity was expressed as U/h/mg protein.

2.13. Measurement of MDA levels and carbonyl content in mouse brain and liver

The determination of the levels of MDA was performed using commercial kits (Nanjing Jiancheng Bioengineering Institute, Nanjing City, PR China). The level of lipid peroxidation was indicated by the content of MDA in tissue. Thiobarbituric acid reaction (TBAR) method was used to determine the MDA. MDA content was expressed as nmol per milligram of protein. Protein carbonyl contents was detected by the reaction with 2,4-dinitrophenylhydrazine (DNPH) method as reported by Levine et al. (1990). The results were expressed as μmol carbonyl groups per mg protein.

2.14. Protein assay

Protein concentration was measured by the Lowry method (Lowry, Rosebrough, Farr, & Randall, 1951). Bovine serum albumin was used as the standard.

2.15. Statistical analysis

The experimental results are expressed as means ± standard deviation (SD) of three measurements at least. Statistical Package for Social Science (SPSS 13) was used to analyse the variance (ANOVA). *P*-values < 0.05 were regarded as significant.

3. Results and discussion

3.1. Extract yields, total phenolic content

Previous studies reported that relatively higher phenolic compounds and antioxidant activities were observed from acetone extract in barley compared with the other solvents including water, ethanol and methanol (Liu & Yao, 2007; Zhao et al., 2006). We therefore used acetone as our extraction solvent and obtained a 7.425% yield of extracted materials from malt and 4.325% from barely, and the total phenolic content in malt was 3.19 mg GAE/g of d*w* and 3.11 mg GAE/g of d*w* in barley, indicating that both extract yields and total phenolic content are higher in malt than in barley. Those could partially be explained by the enzymatic release of bound phenolic compounds during malting or under the effect of temperature during kilning.

3.2. Antioxidative activities of malt extract

3.2.1. Hydroxyl radical scavenging assay

The hydroxyl radical is one of representative reactive oxygen species generated in the body. Fig. 1A depicts the scavenging capacity of malt extract. When the concentration is from 31.25 to 500 μg/ml, the percentage scavenging of malt extract ranged from 5.1% to 63.1%, and Trolox ranged from 23.3% to 72.9%, demonstrating enhanced hydroxyl radical scavenging ability relative to controls. That may be phenolic compounds in malt extract such as ferulic acid product in Maillard reaction contain phenolic hydroxyl group, with the ability to accept electrons, which can combine with free radical competitively to decrease hydroxyl radical (Thomas, Michaelh, & Jennifer, 2005).

3.2.2. Superoxide radical scavenging activity

The superoxide radical is the most common free radical generated *in vivo*. Pyrogallic acid can auto-oxidise in alkaline conditions to produce superoxide radical directly, and the constant rate of this auto-oxidation reaction is dependent on the pyrogallic acid concentration. In this study, as shown in Fig. 1B, malt extract and Trolox showed moderate superoxide radical scavenging activities. Even at 2000 μg/ml, malt extract and Trolox have only 47.1% and 42.1% scavenging effect, and malt extract is more efficient than Trolox.

3.2.3. Reducing power

The reducing power is associated with antioxidant activity and may serve as a significant reflection of the antioxidant activity (Meir, Kanner, Akiri, & Philosoph-Hadas, 1995). In this assay system, the presence of antioxidants causes the reduction of the Fe^{3+}/ferricyanide complex to the ferrous form (Fe^{2+}) monitored at 700 nm. As evidenced in Fig. 2, the malt extract presented a con-

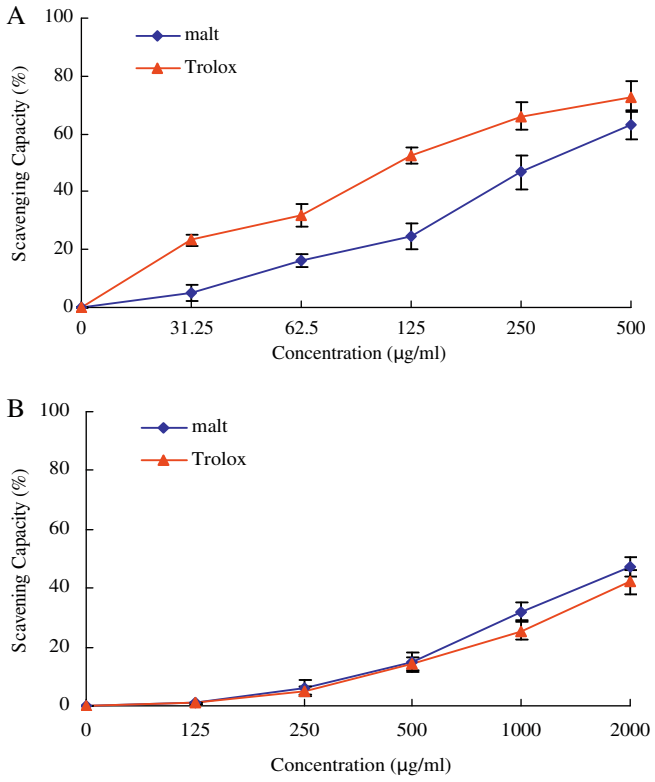

Fig. 1. (A) The hydroxyl radical scavenging capacity of malt extract and Trolox. (B) The superoxide radical scavenging capacity of malt extract and Trolox. Values are means ± SD of three parallel determinations.

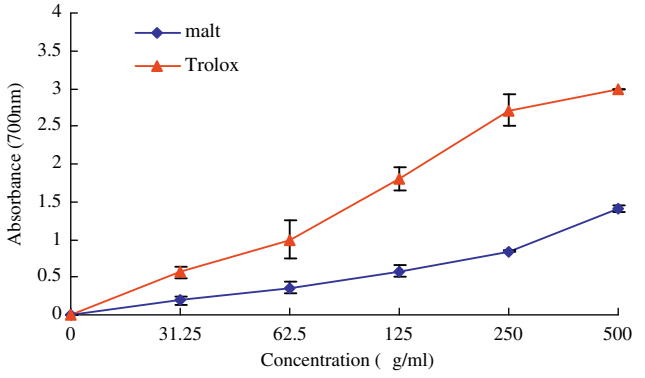

Fig. 2. Reducing power of malt extract and Trolox. Values are means ± SD of three parallel determinations.

centration-dependent activity increase. The malt extract absorbance varied from 0.19 (31.25 μg/ml) to 1.4 (500 μg/ml), while Trolox absorbance varied from 0.56 (31.25 μg/ml) to 3 (500 μg/ml). The reducing power of Trolox is stronger than malt extract in this system. Indeed, some phenolic compounds such as flavanoids and phenolic acids exhibited antioxidant activity through their reductive capacity in a Fe^{3+}–Fe^{2+} system (Zhao et al., 2006). The data presented here indicate that the marked reducing power of malt extracts seem to be attributed to their antioxidant activity.

3.2.4. Inhibition of lipid peroxidation

In biological systems, lipid peroxidation generates many aldehydes products, among which MDA is considered to be the most important derivative. Lipid peroxidation is a cause of cell membrane disruption and cell damage (Barrera, Pizzimenti, & Dianzani, 2008). This process is initiated by hydroxyl- and superoxide-radicals leading to the formation of peroxy radicals ($LOO^{\cdot}$) that ultimately propagates the chain reaction in lipids. Thus, antioxidants capable of scavenging peroxy radicals could prevent lipid peroxidation. In the present study, we measured the potential of malt extract to inhibit lipid peroxidation in rat liver microsomes, induced by the Fe^{2+}/ascorbate system. Trolox possesses increased inhibitory activity (IC_{50} = 22.74 μg/ml) relative to malt extract (IC_{50} = 231.49 μg/ml) (Fig. 3).

3.2.5. Inhibition of protein oxidation

A currently popular hypothesis postulates that a progressive accumulation of macromolecular oxidative damage is the fundamental underlying cause of senescence-associated deleterious alterations. Oxidation of cellular proteins has been described under many pathological conditions. The vulnerability of various amino acid residues of proteins to oxidation varies with reactive oxygen species. AAPH is a water–soluble initiator, which decomposes at physiological temperature producing alkyl radicals followed by fast reaction with oxygen to give alkyl peroxyl radicals (Cai et al., 2003) to initiate protein oxidation or DNA oxidative fragmentation.

The protection against protein oxidative damage was determined by the oxidation of BSA initiated by AAPH. After incubation for 24 h at 37 °C, the samples were assayed with normal SDS–PAGE. The results (Fig. 4) demonstrated that malt extract exhibited significant protective effect against oxidation of BSA (Fig. 4A lane 6), an effect that was augmented by increasing concentrations of extract. For example, at 2000 μg/ml (Fig. 4A lane 9), it completely inhibited the degradation of BSA. While Trolox at 1000 μg/ml (Fig. 4B lane 10), displayed a completely protective effect.

3.2.6. Inhibition of DNA damage

DNA damage alters replication and transcription, causes cell death or leads to mutations and neoplastic transformation in many organisms. Oxidative modifications of DNA have been suggested to contribute to aging and various diseases including cancer and chronic inflammation (Yang, Weissman, Bohr, & Mattson, 2008). To assay the potential of these compounds to prevent DNA damage, oxidative DNA strand breakage induced by peroxyl radical was measured with pBR322 DNA.

As showed in Fig. 5, the plasmid DNA was mainly of the supercoiled (bottom band) and open circular (top band) form in the absence of AAPH (Fig. 5 lane 1). With the addition of 10 mM AAPH the DNA supercoiled form decreased gradually and converted into the open circular and linear form (between the supercoiled and open circular, in Fig. 5 lane 2). Addition of malt extract or Trolox significantly inhibited the increasing of open circular and linear form of

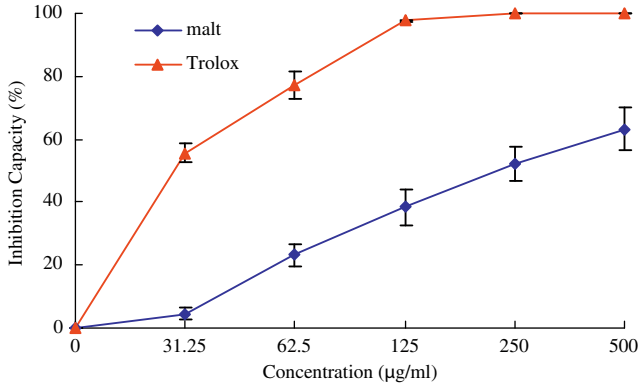

Fig. 3. Inhibition of lipid peroxidation by malt extract and Trolox in rat liver microsomes. Each value represents mean ± SD ($n \geqslant 3$).

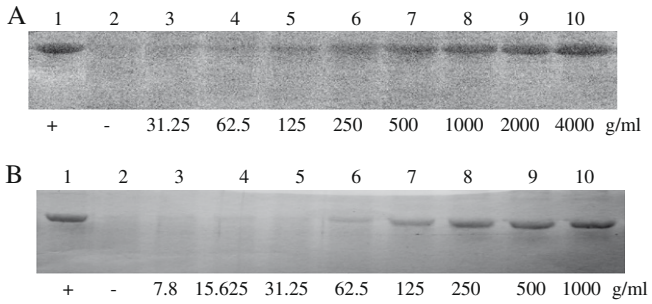

Fig. 4. The inhibitions of malt extract and Trolox to 20 mM AAPH induced BSA oxidative fragmentation. (A) BSA fragmentation was inhibited by malt extract in the presence of 20 mM AAPH. Lane 1, BSA; lane 2, BSA + 20 mM AAPH; lane 3–10, BSA + 20 mM AAPH + 31.25–4000 μg/ml malt extract. (B) BSA fragmentation was inhibited by Trolox in the presence of 20 mM AAPH. Lane 1, BSA; lane 2, BSA + 20 mM AAPH; lane 3–10, BSA + 20 mM AAPH + 7.8–1000 μg/ml Trolox.

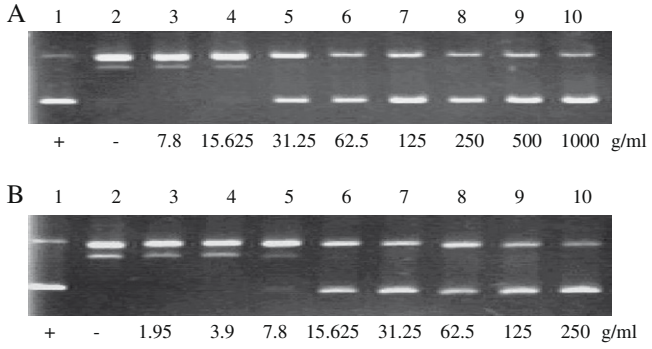

Fig. 5. The protections of malt extract and Trolox to 10 mM AAPH induced pBR322DNA strand breakage. (A) DNA damage was inhibited by malt extract in the presence of 10 mM AAPH. Lane 1, pBR322DNA; lane 2, pBR322DNA + 10 mM AAPH; lane 3–10, pBR322DNA + 10 mM AAPH + 7.8–1000 μg/ml malt extract. (B) DNA damage was inhibited by Trolox in the presence of 10 mM AAPH. Lane 1, pBR322DNA; lane 2, pBR322DNA + 10 mM AAPH; lane 3–10, pBR322DNA + 10 mM AAPH + 1.95–250 μg/ml Trolox.

pBR322 DNA, an effect dependent upon the concentration of compounds. Malt extract completely inhibited the DNA fragmentation at the concentration of 31.25 μg/ml (Fig. 5A lane 5), while Trolox (Fig. 5B lane 6) prevented DNA damage completely at 15.625 μg/ml.

3.3. Antioxidant effects of malt extract in D-galactose induced aging mice

The injection of D-galactose into mice induces a senescent phenotype (Song et al., 1999). The aging model shows neurological impairment, decreased activity of antioxidant enzymes, and compromised immune responses.

Long-term administration of D-galactose induced redox-related changes in these mice, including decrease in T-AOC, SOD, GSH-Px activities, as well as increase of the MAO activity, MDA level and carbonyl content. The activities of antioxidant enzymes SOD, GSH-Px in brain and liver were given in Table 1. A significant decrease in the activities of enzymates was observed in D-galactose treated mouse when compared with control ($P < 0.01$). In comparison to NC group mice, the SOD activity declined by 35.1% and 34.4% in brain and liver, the GSH-Px activity declined by 31.7% and 41.6% in brain and liver, respectively. Administration of malt extract to D-galactose treated mouse with 200 and 400 mg/kg increased the activities of these enzymatic antioxidants both in brain and liver ($P < 0.05$). Free-radical scavenging enzymes such as SOD and GSH-Px are the first line of defense against oxidative injury. SOD reduces superoxide radicals to form hydrogen peroxide, which in turn is decomposed to water and oxygen by GSH-Px and CAT, thereby preventing the formation of hydroxyl radicals (Yao et al., 2005). Therefore, malt extract may reduce oxidative stress and aging phenotypes by increasing SOD and GSH-Px activities, although these mechanisms remain to be elucidated.

Aging characteristics include an alteration of brain MAO metabolism. Studies involving MAO activity measurements in human and rodents brain or liver have shown a generalised age-related increase in MAO activity (Nicotra, Pierucci, Parvez, & Senatori, 2004). As shown in Table 1, MAO activity of brain and liver in D-galactose treated mice was significantly higher than NC group mice ($P < 0.01$). Malt extract, at doses of 200 and 400 mg/kg, inhibited brain and liver MAO activity significantly ($P < 0.01$).

Lipid peroxidation can reduce membrane fluidity, inactivate membrane-bound proteins, and decompose into cytotoxic aldehydes such as malondialdehyde or hydroxynonenal (Richter, 1987). The oxidative damage to proteins is reflected by increase in levels of protein carbonyls. Reaction of free radicals with the side chains of lysine, arginine, proline, threonine and glutamic acid residues of proteins leads to the formation of carbonyl derivatives (Stadtman & Berlett, 1997). Furthermore, aldehydes, such as 4-hydroxy-2-nonenal or malondialdehyde produced during lipid perox-

[d] $P < 0.01$ compared with NC group.

idation can be incorporated into proteins by reaction with either the ε-amino moiety of lysine or the sulfhydryl group of cysteine residues to form carbonyl derivatives (Uchida & Stadtman, 1993). Therefore, levels of MDA are a marker of lipid peroxidation and protein carbonyl content provide a reasonable marker for free radical induced protein oxidation.

In this study, the increase in the levels of MDA and protein carbonyl content in the D-galactose-treated mice was observed in Table 1. And both increased significantly compared with controls ($P < 0.01$). In the current study, malt extract treatment abrogated these effects in brain and liver ($P < 0.05$). Hence, lipid oxidation and protein oxidation is closely associated to aging caused by D-galactose, and malt extract effectively prevented the oxidation damage.

Age-induced oxidative injury was found to reduce the T-AOC, which reflects the non-enzymatic antioxidant defense system, as well as antioxidant enzyme levels (SOD, GSH-Px) in test organs of aged mice. Effect of the malt extract on T-AOC of the blood in aged mice was shown in Table 1. Significant differences in T-AOC were detected between normal control and aged control groups ($P < 0.01$). When treated with 200 and 400 mg/kg malt extract, the T-AOC increased significantly. This means the total antioxidant capability of the antioxidant systems in organism had been enhanced.

4. Conclusion

The results in the present work indicate the presence of phenolic compounds and antioxidant potential in malt extracts. We demonstrated that malt extract is able to scavenge the hydroxyl- and superoxide-radical, has high reducing power, conferred protection against biological macromolecular damage, significantly prevented the decrease of antioxidant enzyme activity in aging brain and liver, decreased brain and liver malondialodehyde level and carbonyl content, and improved total antioxidant capability in organism. The extract exhibited high antioxidant activities both *in vitro* and *in vivo*, and the phenolic compounds in extract were responsible for their effective antioxidant properties, this antioxidant property could be explained by a free-radical scavenging ability (such as scavenging hydroxyl-radical, superoxide-radical and carbon centred free radicals). It is proposed that hydroxyl was the most important factor in determining the antioxidant activities of the phenolic compounds.

The enhanced activity of SOD and GSH-Px and increased total antioxidant capacity in the aging animals can be very effective in scavenging the various types of oxygen free radicals and their products. So the inhibitory effect of malt extract on lipid peroxidation and protein oxidation might be, at least in part, attributed to its influence on the antioxidant enzymes and nonenzymatic system. In our previous study, malt extract showed significant scavenging activity on the superoxide anion and hydroxyl free radical. The direct oxygen free-radical scavenging activity of malt extract might also contribute to its *in vivo* antioxidant activity. In light of our observations that malt contains many phenolic compounds and significant antioxidant activities *in vitro* and *in vivo*, malt should be considered as a new source of natural antioxidant for pharmaceutical or dietary needs.

ABSTRACT

Time dependent aroma release was studied in skim milk, heated skim milk as well as in acid-induced gels derived from them using static headspace – gas chromatography analysis. A variable order kinetic model was fitted to experimental data and was used to determine headspace equilibrium concentration and initial rates of release. When compared to water, retention in milk based matrices was increased for hydrophobic aroma compounds, while it was decreased for more hydrophilic volatiles. Acid gelation reduced the initial rate of aroma release by a factor varying from 2.0 to 3.8, depending on the compound. Positive deviation from the first order kinetics was observed and suggests that a concentration gradient is established in the matrix during measurement. The interaction between milk based matrices and aroma compounds is discussed in relation to their chemical structure and the physico-chemical characteristics of the matrices.

1. Introduction

The growing demand for foods with improved nutritional qualities has prompted the food processing industry to cut down on ingredients such as fat, sugar and additives, thereby necessitating some important changes in sensory qualities that influence consumer acceptance of food products. Controlling food texture and aroma release represents a significant challenge for the industry. Both of these quality attributes are affected by changes in food composition, especially a reduction in fat. Furthermore, texture is thought to influence flavour perception.

From a physico-chemical standpoint, the release of aroma compounds depends not only on the properties of the compounds and their affinity for the product's components, but also on the structural complexity of the matrix. Interactions between macromolecules modify the nature and the number of binding sites available for aroma compounds. In general, these factors govern the equilibrium partitioning of aroma compounds between the different phases. The rate at which this equilibrium is achieved is driven by interfacial mass transport and diffusion phenomena (Taylor, 2002). Dairy proteins and lactose are the main components that affect aroma release from skim milk. In aqueous systems, increased volatility has been observed in the presence of lactose (van Willige, Linssen, & Voragen, 2000), suggesting that competition occurs between aroma compounds and lactose for interaction with water. In highly hydrated systems, however, proteins may bind aroma compounds via hydrophobic interactions (Fischer & Widder, 1997; Guichard & Langourieux, 2000; Landy, Druaux, & Voilley, 1995; O'Neill & Kinsella, 1987), although chemical bonds could be involved especially in the case of aldehydes (Fischer & Widder, 1997; Plug & Haring, 1993), which may react with amino groups of proteins to form imine bonds. Factors in food systems that influence protein conformation may have a considerable effect on the interaction between proteins and aroma compounds. The principal factors include ionic strength, concentration of other food components, temperature, pH and time (Fischer & Widder, 1997).

In yogurt production, milk is subjected to heat treatment, which is one of the most important processing parameters affecting the final product. The effects of milk heating on the

rheological properties and microstructure of fat-free dairy gels have been studied fully (Harwalkar & Kalab, 1980; Lucey, Cheng, Munro, & Singh, 1999). Milk heating prior to acidification is known to increase yogurt firmness. Heating milk above 70 °C induces denaturation and aggregation of whey proteins and their association with casein micelles. The denatured whey proteins in the serum and those associated with casein micelles participate in the acid-induced gel structure. The highly branched structure of acid gels made from heated milks has been clearly shown using electron microscopy (EM) (Harwalkar & Kalab, 1980) or confocal scanning laser microscopy (CSLM) (Lucey et al., 1999). The increase in the number and strength of bonds linking protein particles helps to increase the firmness of acid gels made from heated milk.

The microstructure of the matrix itself may affect aroma release. Seuvre, Espinosa Diaz, Cayot, and Voilley (2004) compared the percentage of 2-nonanone release in set gels of β-lactoglobulin versus the same type of gel following destructuring; the release was slightly higher for the destructured gel. The gelled structure of polysaccharidic matrices has also been shown to cause increased retention of aroma compounds (Juteau, Doublier, & Guichard, 2004; Rega, Guichard, & Voilley, 2002) and slower transfer across the vapour/matrix interface (Juteau, Doublier, et al., 2004).

Milk heating is known to affect the microstructure and rheology of acid-induced dairy gels. However, little information is available about the associated impact on the release of aroma compounds. The objective of this project was to measure the influence of heat treatment (before aromatisation) and acid-induced gelation on the release of selected aroma compounds from flavoured skim milk matrices. Acid-induced gels were prepared from heated or unheated skim milk to study the relationship between gel firmness and aroma release from a complex dairy system. The thermodynamic and kinetic components of aroma release were both studied.

2. Material and methods

2.1. Materials

Spray dried low heat skim milk powder (32.9% protein) was obtained from Ingredia (Arras, France). Glucono-δ-lactone (GDL), ethyl acetate (EA), ethyl hexanoate (EH) and pentan-2-one (PO), hexanal (H) were obtained from Sigma–Aldrich (Steinheim, Germany). Ethyl butyrate (EB) was supplied by Aldrich (Milwaukee, USA). The purity of all the aroma products was higher than 97%.

2.2. Preparation of milk based matrices

Skim milk, heated skim milk, and gels from skim milk and heated skim milk were prepared from low heat skim milk powder rehydrated at ambient temperature in deionised water at 13.1% solids. From a previous study (Fairise, Cayot, & Lorient, 1999), reconstituted skim milk powder showed no sign of glycation or soluble protein denaturation and was considered similar to raw skim milk. Heat treatment was carried out at 90 °C for 5 min on 15 ml milk aliquots (Pyrex reaction tubes) according to the method of Cayot, Fairise, Colas, Lorient, and Brulé (2003). All of the aroma compounds (ethyl acetate, ethyl butyrate, ethyl hexanoate, pentan-2-one and hexanal) were added directly to skim milk and heated skim milk (500-g samples), each at 50 ppm concentration. The physico-chemical characteristics of the aroma compounds are presented in Table 1. Sodium azide (VWR, Prolabo, VWR International, Fontenay/Bois, France) was added at 0.02% to prevent microbial growth. Acid gels were produced by adding glucono-δ-lactone (GDL) to skim milk and heated skim milk. The GDL concentration was fixed to 1.7%, allowing the pH to drop to 4.5 after the incubation period. After the GDL was mixed with milk, liquid samples were quickly transferred to 21-ml vials for the gas chromatography measurements. Each vial was filled with 10 ml of the product and hermetically sealed with a Teflon-coated seal. In addition, beakers (80 ml) were filled with 65 g of the product for texture measurements and covered with two layers of parafilm. Samples were incubated at 30 °C for 10 h (Sanyo Incubator MIR 153, Sanyo Electric Co., Ltd., Japan) and then stored at 7 °C for 48 h before analysis.

2.3. Gel texture

The firmness of the gels was measured using a texture analyser (model 1122, Instron Ltd., Buckinghamshire, England) equipped with a stainless steel cylindrical sensor of 2.51×10^{-2} m^2 surface with constant compression speed (8.33×10^{-4} m s^{-1}). Penetration tests were performed at 20 ± 2 °C. Gel sample surface and thickness were 1.45×10^{-1} m^2 and 4.6×10^{-2} m, respectively. From the force-deformation data, the true stress–strain curve was derived, and Young's modulus of elasticity was obtained from the initial slope.

2.4. Static headspace analysis

Vials containing milk or acid gel samples were equilibrated at 20 °C in a water bath for at least 30 min before analysis. This temperature corresponds to the average temperature reached by a thick yogurt in the mouth during the first seconds of consumption (Paci Kora, 2003). Before the experiment started ($t = 0$), the vial headspace (11 ml) was flushed with nitrogen (150 ml min^{-1} for 25 s). The loss of each aroma compound during this operation was less than 1%. Samples were then sealed again and maintained at 20 °C for up to 300 min. At selected intervals, the headspace was analysed by gas chromatography, with a new sample being used for each analysis. Samplings and injections were carried out with a CombiPAL autosampler (CTC Analytics, Switzerland). The gas chromatograph (GC; CP3800; Varian Analytical Instruments, Walnut Creek, USA) was equipped with a 3-m stainless steel column (2.2 mm i.d.) packed with Chromosorb W-AW 80–100 mesh with a stationary phase of Carbowax 20 M-10%. The operating conditions were as follows: helium carrier flow rate 30 ml min^{-1}; hydrogen flow rate 30 ml min^{-1}; air flow rate 300 ml min^{-1}; injector (splitless) temperature 190 °C; flame ionisation detector (FID) temperature 200 °C. The oven temperature was maintained at 80 °C for 6 min and then increased to 140 °C at a rate of 5 °C min^{-1}, and finally to 180 °C at a rate of 10 °C min^{-1}. The chromatograms were recorded and analysed using the Star Chromatography Workstation software (v5.31, Varian Associates Inc.).

Six concentrations of the aroma compounds in pure water were analysed in quadruplicate for calibration, allowing quantification of the compounds in the gas phase. To verify that no aroma compounds were formed during the incubation, blank samples (non-aromatised) treated the same way as the experimental units were analysed after a 210-min equilibration.

2.5. Statistical analysis

The experiment was repeated four times according to a 2^2 factorial design, milk heat treatment and acid-gelation being the two variables under study. The analysis of variance (ANOVA) was used to determine whether the factors and their interactions had a significant effect on the measured parameters (SAS Institute Inc., Cary, NC).

Table 1
Physico-chemical characteristics of aroma compounds.

	Aroma compound				
	Ethyl acetate	Ethyl butyrate	Ethyl hexanoate	Hexanal	Pentan-2-one
Chemical class	Ester	Ester	Ester	Aldehyde	Ketone

3. Results and discussion

3.1. Time dependent release curves

Fig. 1a shows the time-dependent release curves for the different aroma compounds in flavoured raw skim milk. Aroma concentration in the gas phase increased until the thermodynamic equilibrium was reached. Final concentration in the gas phase increased in the following order: pentan-2-one (PO) < hexanal (H) < ethyl acetate (EA) ⩽ ethyl hexanoate (EH) < ethyl butyrate (EB). Partition between the aqueous and gas phases is driven by the physico-chemical characteristics of the flavour compounds and specific interactions with milk constituents (Nongonierma, Springett, Le Quéré, Cayot, & Voilley, 2006). The initial part of the release curves is presented in Fig. 1b. The concentration in the gas phase increased rapidly and half equilibrium concentration was reached between 0.8 and 3.0 min depending on aroma compound.

In order to describe the effect of heat treatment and acid-induced gelation on aroma release, and especially on its kinetic component, it is common practice to fit experimental data to an appropriate mathematical model. The variable order kinetic model (Eq. (1)) was compared to the Weibull function (Eq. (2)) as previously used by Juteau, Cayot, Chabanet, Doublier, and Guichard (2004).

$$C_t = C_\infty - (C_\infty^{1-n} + knt - kt)^{1/1-n} \quad (1)$$

$$C_t = a \times [1 - \exp(-b(t-d)^c)] \quad (2)$$

where C_t is the concentration in the headspace at time t; C_∞, the concentration in the headspace at equilibrium; n, the reaction order and k, the kinetic constant.

The two models showed good fit for t values larger than ~3 min. However, deviation from experimental data was observed with the Weibull function in the initial part of the curve. Fig. 2 shows the first 2 min of ethyl hexanoate release curve fitted with both models. The first derivative of the models, representing the rate of release, is also presented. The Weibull function is not defined for $t \lesssim d$ (when constant c is not a whole number), and cannot be used to estimate the initial rate of aroma release. The variable order kinetic model fitted the experimental data over the entire curve with a homogeneous distribution of residues and r^2 ranging from 0.988 to 0.999. The extrapolation of the first derivative (Eq. (3)) to $t = 0$ allows appropriate estimation of the initial rate of release.

$$dC/dt = k(C_\infty - C_t)^n \quad (3)$$

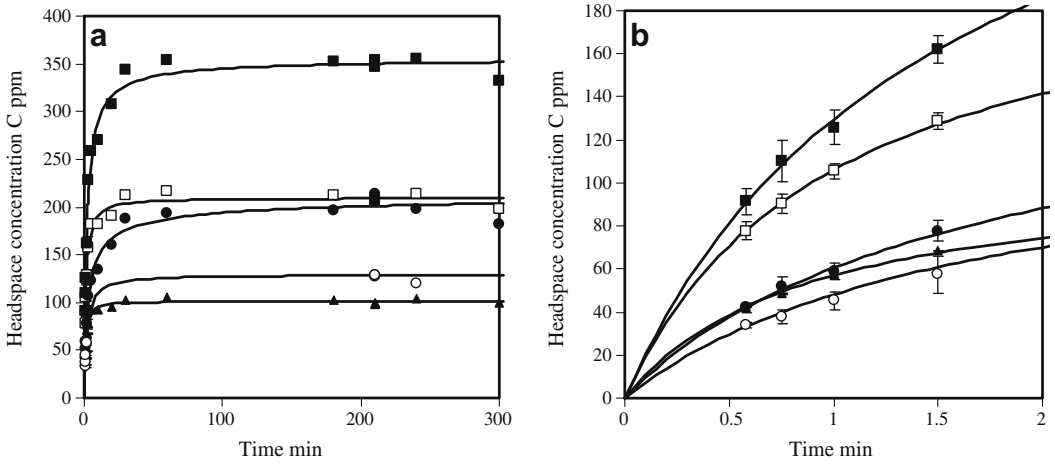

Fig. 1. Time-dependent aroma release from flavoured raw skim milk. (a) Entire experiment; (b) first 2 min. Aroma compounds were: ▲, pentan-2-one; ○, hexanal; ●, ethyl hexanoate; □, ethyl acetate and ■, ethyl butyrate. Experimental data were fitted to Eq. (1).

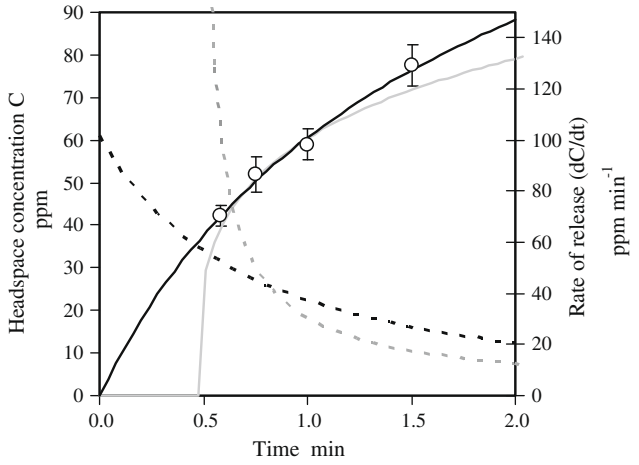

Fig. 2. Experimental data (○) from ethyl hexanoate release from raw skim milk (0–2 min) fitted to the variable order kinetic model (solid black line) and the Weibull function (solid grey line). First derivative (release rate) of these models is presented as dashed lines.

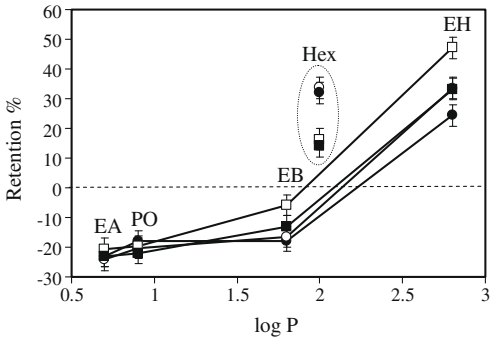

Fig. 3. Retention of aroma compounds (EA: ethyl acetate; PO: pentan-2-one; EB: ethyl butyrate; Hex: hexanal and EH: ethyl hexanoate) in: ○, raw skim milk; ●, heated skim milk; □, gel from raw milk and ■, gel from heated milk.

The variable kinetic order model was then used throughout the paper to characterise aroma release profiles.

3.2. Thermodynamic equilibrium

The equilibrium concentrations (C_∞) of aroma compounds in the headspace from milk based matrices and water are presented in Table 2. When dispersed in water, the homologous series of esters exhibited an increase in C_∞ with increasing carbon chain length and increasing hydrophobicity index (log *P*) (Table 1), which is in agreement with previous studies (Landy et al., 1995; Philippe, 2003). Among the compounds with the same number of carbons, the ester compound (ethyl butyrate) showed a higher C_∞ than the aldehyde (hexanal). The saturated vapour pressure of ethyl butyrate is higher than that of hexanal (Table 1), which could explain the difference (Covarrubias Cervantes, Mokbel, Champion, Jose, & Voilley, 2004).

Modification of flavour compound volatility in different matrices is attributed to physicochemical interaction with the matrices components (Landy et al., 1995). Percentages of retention, relative to water, were calculated according to Nongonierma et al. (2006) (Eq. (4)) and results are plotted as a function of hydrophobicity (log *P*) of each aroma compound (Fig. 3).

$$R\% = \left[1 - C_\infty^{\text{matrix}} / C_\infty^{\text{water}}\right] \times 100 \quad (4)$$

The four matrices under study showed negative retention (or rejection) for low hydrophobicity aroma compounds (log $P < 2$). Similar results were observed in non-fat stirred yogurts (Nongonierma et al., 2006) and suggest that competition for interaction with water occurred between aroma compounds and other milk solids. Lactose, which is highly hygroscopic, is present at a high concentration in milk based matrices (6.4%). Lactose has been shown to increase aroma compounds volatility in simple media (van Willige et al., 2000). In addition, it has been suggested that the high concentration of ions in milk could cause a salting-out effect, contributing to reduce aroma retention (Nongonierma et al., 2006). Ethyl hexanoate (log $P = 2.8$), was strongly retained in milk based matrices. Hydrophobic interactions with caseins (Fischer & Widder, 1997; Landy et al., 1995) and whey proteins, especially β-lactoglobulin (Guichard & Langourieux, 2000), could explain lower volatility of ethyl hexanoate in milk based matrices.

Heat treatment and acid gelation did not influence the retention for hydrophilic ethyl acetate and pentan-2-one (log $P < 1$). However, for more hydrophobic ethyl butyrate (log $P = 1.8$) and ethyl hexanoate (log $P = 2.8$), acid gelation increased retention. Heat treatment was shown to reduce retention only for ethyl hexanoate. Heat treatment induces unfolding and rearrangement of protein structures. Whey proteins are known to aggregate and associate with casein micelles in heated milk. These changes in protein structure affect its binding capacity for hydrophobic compounds. The affinity of thermally treated β-lactoglobulin for aroma compounds has been shown to be lower than that of native β-lactoglobulin (O'Neill & Kinsella, 1987). Well-defined hydrophobic cavities, known to be the binding sites for the majority of hydrophobic aroma compounds appear to be disrupted by heat treatments. Lowering of pH also causes changes in protein

Table 2
Headspace equilibrium concentration and initial rate of aroma release in milk based matrices.

	Raw milk	Heated milk	Raw milk gel	Heated milk gel	Water
Headspace equilibrium concentration C_∞ (ppm)					
Ethyl acetate	209	207	203	207	168
Ethyl butyrate	357	361	324	346	306
Ethyl hexanoate	217	247	172	218	326
Pentan-2-one	100	98	99	101	83
Hexanal	130	133	164	168	196
Initial rate of aroma release V_0 (ppm min^{-1})					
Ethyl acetate	196	215	57	60	416
Ethyl butyrate	211	226	57	57	335
Ethyl hexanoate	101	106	27	29	147
Pentan-2-one	111	120	37	49	237
Hexanal	77	84	40	41	163

Standard error for C_∞ and V_0 were, respectively, 10 ppm and 12 ppm min^{-1}.

conformation. With slow acidification of milk, colloidal calcium phosphate in the casein micelles gradually solubilises, casein micelles become unstable and aggregation occurs through hydrophobic interactions as pH approaches 4.6 (Cayot & Lorient, 1998). Acidification also induces dissociation of hydrophobic β-casein from the micelle. Retention of the more hydrophobic aroma compounds may be explained by increased accessibility of casein hydrophobic domains as a result of milk acidification.

The retention of hexanal by milk based matrices was higher than expected from its hydrophobicity index (Fig. 3). Furthermore, unlike ethyl hexanoate, retention of hexanal was not affected by milk heat treatment, but strongly decreased after acid gelation. Schiff's base formation resulting from the reaction of carbonyl with amino groups of proteins is likely to occur and explain high retention of hexanal in milk based matrices (Plug & Haring, 1993). The rate of Schiff's base formation is known to decrease with decreasing pH (Jirousova & Davidek, 1975) which explains the lower hexanal retention in acid gels (pH 4.5) than in non-acidified milks (pH 6.7). Mills and Solms (1984) reported similar finding for heptanal interaction with whey protein for pH ranging from 4.66 to 6.89.

3.3. Kinetics of flavour release

During the short time period of eating process, flavour behaviour will depend on the initial rate of release. The first derivative of the variable order kinetic model (Eq. (3)) was extrapolated to $t = 0$ to determine initial rate of flavour release (Table 2). Acid gelation was the most important factor controlling the initial rate of flavour release ($P < 0.0001$). Depending on aroma compound, acid gelation reduced the initial rate of release by a factor ranging from 2.0 (hexanal) to 3.8 (ethyl butyrate). Acid gelation eliminated convective transport of aroma compounds within the matrix which reduced the initial rate of release. Milk heat treatment had no significant effect on the initial rate of release ($P = 0.1626$).

The rate of aroma release is driven by interfacial mass transport and diffusion phenomena, but also depends on the volatility of aroma compounds. To better isolate the influence of the physical characteristics of milk based matrices on the rate of aroma release, kinetic data were normalised according to the equilibrium concentration. For that purpose the time required to reach 50% of the equilibrium concentration in the gas phase ($T_{1/2C_\infty}$) was calculated for each aroma compound. In agreement with the diffusion controlled transport to the interface (Seuvre, Philippe, Rochard, & Voilley, 2007), the $T_{1/2C_\infty}$ increased with increasing molar volume of aroma compound (Fig. 4a). Heat treatment had no significant effect on $T_{1/2C_\infty}$ ($P = 0.1373$) and half equilibrium concentration in the gas phases of skim milk and heated skim milk was reached within 0.8–3.3 min depending on aroma compound. Acid gelation significantly retarded aroma release from both raw and heated skim milks ($P < 0.0001$), and the $T_{1/2C_\infty}$ increased by an average factor of 3.2. However, no significant difference was observed between gels made from raw and heated skim milk ($P = 0.2418$). The firmness (Young's modulus) of acid gel made from heated milk (7116 ± 427 Pa) was higher than the firmness of gel made from raw milk (917 ± 62 Pa), suggesting that the structure of the matrix has little influence on the aroma release kinetics. Similar results were reported in the literature regarding the transport of aroma compounds in structured matrices (Juteau-Vigier et al., 2007). According to Juteau-Vigier et al. (2007), the presence of a macromolecular network would likely have little effect on diffusivity of small molecules. These authors have shown that the structural level of carrageenan matrices had negligible influence on diffusion properties of ethyl hexanoate and suggest that mobility through the open spaces is not disturbed. As predicted by the Stokes–Einstein equation, viscosity of the continuous phase would be the main factor driving the diffusion of aroma compounds. However, our results suggest that for matrices with low viscosity continuous phase, the formation of a gel eliminates convective transport and reduces aroma compounds mobility.

Fitting the kinetic model parameters (Eq. (1)) to the experimental data allows the determination of the kinetic order (n) for aroma release from the various matrices. In convective transfer conditions, with homogeneous aroma concentration in the matrix, a kinetic order of one is expected (Juteau, Cayot, et al., 2004). In the present study, aroma release experiments were performed in an unstirred closed system and kinetic orders larger than one were observed for milk based matrices (Fig. 4b). This deviation is attributed to the establishment of a concentration gradient between the surface layer and the bulk of the matrix (Juteau, Cayot, et al., 2004). The aroma concentration in the very first layers, located near the interface, is rapidly depleted and a gradient is established according to the mobility of aroma compounds in milk based matrices. The kinetic order increased with the molar volume of the aroma compound (Fig. 4b). According to the Wilke and Chang equation (1955), the diffusion coefficient is inversely related to the molar volume. Aroma compounds with high molar volume would be more prone to the establishment of a concentration gradient in milk based matrices. Milk heat treatment had no significant effect on the kinetic order, but an increase was observed in acid gels (Fig. 4b). As previously suggested, acid gelation eliminates convective transport in low viscosity media (milks), which further reduces macroscopic diffusion of aroma compounds. This, could be

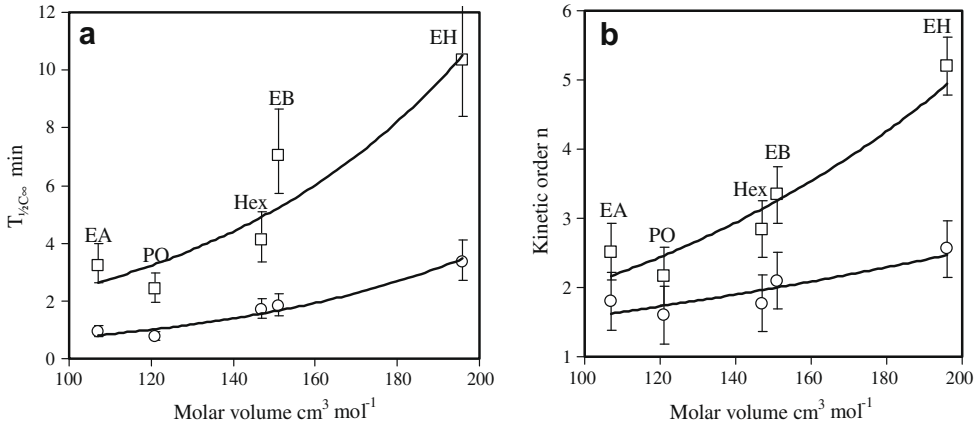

Fig. 4. Time required to reach 50% equilibrium concentration ($T_{1/2C_\infty}$) (a) and kinetic order of aroma release (b) in the headspace of ○, liquid skim milks and □, skim milk gels. EA: ethyl acetate; PO: pentan-2-one; EB: ethyl butyrate; Hex: hexanal and EH: ethyl hexanoate.

responsible for the establishment of a steeper concentration gradient in gels than in milks.

4. Conclusion

Milk heat treatment decreased retention of highly hydrophobic aroma compounds Ethyl hexanoate in milk based matrices, while acid-induced gelation retarded the release of all tested compounds. Gel formation reduced the rate of flavour release, but increasing gel firmness had no further effect. In an unstirred closed system, the formation of a concentration gradient between the surface layer and the bulk of the matrix controls the kinetics of aroma release in milk based matrices and this gradient depends on the characteristics of both, the aroma compound (molar volume) and the matrix. More targeted research is required to better understand the effect of matrix microstructure on the aroma release profile.

ACE inhibitory peptide
Tuna frame protein
Enzymatic hydrolysate
Antihypertensive effect

ABSTRACT

Tuna frame protein was hydrolysed using Alcalase, Neutrase, pepsin, papain, α-chymotrypsin and trypsin. Peptic hydrolysate exhibited the highest ACE I inhibitory activity among them and was fractionated into three ranges of molecular weight (below 1, 1–5 and 5–10 kDa) using an ultrafiltration membrane bioreactor system. The 1–5 kDa fraction showed the highest ACE inhibitory activity and was used for subsequent purification steps. During consecutive purification, a potent ACE inhibitory peptide from tuna frame protein (PTFP), which was composed of 21 amino acids, Gly-Asp-Leu-Gly-Lys-Thr-Thr-Thr-Val-Ser-Asn-Trp-Ser-Pro-Pro-Lys-Try-Lys-Asp-Thr-Pro (MW: 2,482 Da, IC_{50}: 11.28 μm), was isolated. Lineweaver–Burk plots suggest that PTFP plays as a non-competitive inhibitor against ACE. Furthermore, antihypertensive effect in spontaneously hypertensive rats (SHR) also revealed that oral administration of PTFP can decrease systolic blood pressure significantly ($P < 0.01$). These results suggest that the PTFP would be a beneficial ingredient for nutraceuticals and pharmaceuticals against hypertension and its related diseases.

1. Introduction

Hypertension is one of the major risk factors for the development of cardiovascular diseases, stroke and the end stage of renal disease (Zhang et al., 2006). The renin–angiotensin system plays a key role in maintaining blood pressure homeostasis, as well as fluid and salt balance in mammals (Turner & Hooper, 2002; Weinberg, Weinberg, & Zappe, 2000). Angiotensin I converting enzyme (peptidyl carboxy peptidase, EC 3.4.15.1, ACE) belongs to the class of zinc proteases that needs zinc and chloride for activation. This enzyme plays an important physiological role in regulating blood pressure by virtue of the renin–angiotensin system (Fujita, Yokoyama, & Yoshikawa, 2000). ACE converts an inactive form of decapeptides, angiotensin I, to a potent vasopressor octapeptide, angiotensin II, and inactivates catalytic function of bradykinin. Therefore, inhibition of ACE is considered to be an important therapeutic approach for controlling hypertension. Since the discovery of ACE inhibitors in snake venom (Ferreira, Bartelt, & Greene, 1970), many studies have attempted to synthesise ACE inhibitors such as captopril, enalapril, alacepril and lisinopril which are currently used in the treatment of essential hypertension and heart failure in humans (Ondetti, 1977). However, these synthetic ACE inhibitors are believed to have certain side effects such as cough, taste disturbances and skin rashes (Atkinson & Robertson, 1979). Therefore, search for non-toxic ACE inhibitors as alternatives to synthetic drugs is of great interest among researchers and many natural ACE inhibitors have been isolated from functional food and natural bio-resources (Goretta, Ottaviani, & Fraga, 2006).

The peptides derived from food proteins are considered to be milder and safer compared with synthetic drugs. Furthermore, these peptides usually have multifunctional properties and are easily absorbed (Yike et al., 2006). Bioactive peptides usually contain 3–20 amino acid residues and their activity is based on their amino acid composition and sequence (Pihlanto, 2000). Bioactive peptides, which are inactive within the sequence of the parent protein, could be released by enzymatic hydrolysis and exhibit various regulatory effects such as antioxidant (Je, Qian, Byun, & Kim, 2007), immune defense (Tsuruki et al., 2003), opioid (Pihlanto, 2000) and antihypertensive activities (Yike et al., 2006). Many reports have demonstrated the antihypertensive effect of ACE inhibitory peptides or foods containing these bioactive peptides in hypertensive patients (FitzGerald & Meisel, 2000). Several studies on spontaneously hypertensive rats (SHR) suggested a significant

doi:10.1016/j.foodchem.2009.04.086

suppression of hypertension with a diet rich in ACE inhibitory peptides (Hong et al., 2008). Many ACE inhibitory peptides have been identified from the enzymatic hydrolysates of various natural sources such as cheese whey (Amhar, Saito, Aimar, & Itoh, 1996), casein (Yamamoto, Akino, & Takano, 1994), bovine skin gelatin (Kim, Byun, Park, & Shahidi, 2001), Alaska pollack skin gelatin (Byun & Kim, 2001), bigeye tuna dark muscle (Qian, Je, & Kim, 2007), oyster (Je, Park, Jung, & Kim, 2005) and yellowfin sole (Jung et al., 2006).

Tuna frame proteins are usually discarded as processing waste or used for animal feed because of its poor functional properties. However, frame proteins can be converted into value-added products by enzymatic hydrolysis, which may be widely applied to improve functional and nutritional properties of proteins. Previously, for the efficient recovery of fish frame proteins, we investigated the antioxidant properties of hoki and Alaska pollack frame protein hydrolysates using various enzymes. We also investigated the ACE inhibitory activity of yellowfin sole frame protein hydrolysate. In the present study, the objective was to isolate ACE inhibitory peptides from tuna frame protein hydrolysate (TFPH) and to characterise the isolated peptide with respect to ACE inhibitory activity. Furthermore, we have also investigated the inhibition pattern of the isolated peptide on ACE, toxicity on MRC-5 and its antihypertensive action by oral administration in SHR.

2. Materials and methods

2.1. Materials

Fresh tuna frame proteins were kindly donated by Dongwon fisheries Co. (Busan, Korea) and stored at −20 °C until use. Digestive proteases (pepsin, α-chymotrypsin, trypsin and papain), ACE (EC 3.4.15.1) from rabbit lung and hippuryl-histidyl-leucine (HHL) as a substrate peptide of ACE were products of Sigma Chemical Co. (St. Louis, MO). Other proteases (Alcalase and Neutrase) were purchased from Novozymes (Bagsvaerd, Denmark). Ultrafiltration membrane (UF) reactor system (Minitane) and membranes were purchased from Millipore Co. (Bedford, MA). MRC-5 (ATCC CCL-171) was obtained from American Type Culture Collection (Manassas, Va). Cell culture media and other materials required for culturing were obtained from Gibco (Grand Island, NY). All other reagents used in this study were reagent grade chemicals.

2.2. Preparation of tuna frame protein hydrolysate (TFPH)

To extract ACE inhibitory peptide from Tuna frame protein, enzymatic hydrolysis was performed using various commercial enzymes (Alcalase, α-chymotrypsin, papain, pepsin, Neutrase and trypsin) with each optimal condition. A 100 g substrate (on the basis of protein weight) and 1 g enzyme were mixed in a 10 L reactor with temperature and pH control devices. The mixture was incubated for 8 h at each optimal temperature with stirring and then heated in a boiling water bath for 10 min to inactivate the enzyme. Degree of hydrolysis was determined by measuring the nitrogen content soluble in 10% (v/v) trichloroacetic acid as discussed by Kim et al. (2001). The resultant TFPH were fractionated through UF membranes with a range of molecular weight cutoffs (M_{WCO}) of 1, 5 and 10 kDa, respectively. Fractionates were designed as follows: TFPH I with MW distribution of below 1 kDa, TFPH II with MW distribution of 1–5 kDa and TFPH III with MW distribution of 5–10 kDa. All recovered TFPH fractions were lyophilised and stored under −80 °C until used.

2.3. Measurement of ACE inhibitory activity

ACE inhibitory activity assay was performed using the method of Cushman and Cheung (1971) with slight modifications. The reaction mixture contained 5 mM HHL as a substrate, 0.3 M NaCl and 5 ml ACE in 50 mM sodium borate buffer (pH 8.3). A sample (50 μl) was added to the above reaction mixture (50 μl) and mixed with 8.3 mM HHL (150 μl) containing 0.5 M NaCl. After incubation at 37 °C for 30 min, the further reaction was stopped by the addition of 0.1 M HCl (250 μl). The resulting hippuric acid was extracted by the addition of 1.5 ml ethyl acetate. After centrifugation (800g, 15 min), 1 ml of the upper layer was transferred into a glass tube and evaporated at room temperature for 2 h in vacuum. The hippuric acid was redissolved in 3.0 ml of distilled water, and absorbance was measured at 228 nm using UV-spectrophotometer (Model U-3210, Hitachi Co., Tokyo, Japan). The IC_{50} value was defined as the concentration of inhibitor required to inhibit 50% of the ACE activity.

2.4. Purification of ACE inhibitory peptide

2.4.1. Ion exchange chromatography

The lyophilised TFPH (20 mg/ml) was loaded into a Hiprep 16/10 DEAE FF anion exchange column equilibrated with 20 mM sodium acetate buffer (pH 4.0, $CH_3COONa{\cdot}3H_2O$), and eluted with a linear gradient of NaCl (0–2 M) in the same buffer at a flow rate of 62 ml/h using fast protein liquid chromatography (FPLC, ÄKTA, Amersham Bioscience Co., Uppsala, Sweden). Each fraction was monitored at 280 nm, collected at a volume of 4 ml and concentrated using a rotary evaporator after removing salt. The lyophilised fraction having the highest ACE inhibitory activity was subjected to the next purification step.

2.4.2. High performance liquid chromatography (HPLC)

The fraction exhibiting the highest ACE inhibitory activity was further purified using reverse-phase HPLC on a Primesphere 10 C_{18} (20 × 250 mm, Phenomenex Co., Ltd., Torrance, CA, USA) column with a linear gradient of acetonitrile (0–50% for 20 min) containing 0.1% trifluoroacetic acid (TFA) at a flow rate of 2 ml/min. The absorbance of eluent was monitored at 215 nm. Active peak representing ACE inhibitory activity was pooled and lyophilised immediately. The active fraction from analytical column was further applied onto a Synchropak RPP-100 analytical column (4.6 × 250 mm, Eprogen, Inc., Chicago, IL, USA) with 15% acetonitrile containing 0.1% TFA at flow rate of 1.2 ml/min for 20 min. The finally purified peptide was analysed amino acid sequence.

2.5. Determination of amino acid sequence of the purified peptide

Molecular mass and amino acid sequence of purified peptide from tuna frame protein (PTFP) was determined by Q-TOF mass spectrometer (Micromass, Altrincham, UK) coupled with electrospray ionisation (ESI) source. The purified peptide dissolved in methanol/water (1:1, v/v) was infused into the ESI source and molecular mass was determined by doubly charged $(M + 2H)^{2+}$ state in the mass spectrum. Following molecular mass determination, peptide was automatically selected for fragmentation and sequence information was obtained by tandem MS analysis.

2.6. Determination of the inhibition pattern on ACE

To clarify the inhibitory mechanism of PTFP on ACE, Different concentrations of PTFP were added to each reaction mixture according to Bush, Herny, and Slusarchyk (1984) with slight modifications. The enzyme activities were measured with different concentrations of the substrate (HHL) following the above procedure.

The kinetics of ACE in the presence of the inhibitor was determined by the Lineweaver–Burk plots.

2.7. Cell culture and cytotoxic assessment using MTT assay

MRC-5, Human lung fibroblast cell line was cultured and maintained in Dulbecco's modification of eagle's medium (DMEM, GIBCO, New York, USA) containing 100 μg/ml penicillin–streptomycin, 10% fetal bovine serum (FBS) and maintained at 37 °C under a humidified atmosphere with 5% CO_2. Cytotoxicity levels of the purified peptide on MRC-5 were measured using MTT (3-(4,5-dimethyl-2-yl)-2,5-diphenyltetrazolium bromide) method as described by Hansen, Nielsen, and Berg (1989) with slight modifications. MRC-5 cells were cultured in 96-well plates at a density of 5×10^3 cells/well. After 24 h, cells were washed with fresh medium and were treated with different concentrations of PTFP. After 24 h of incubation, Cells were washed two times with PBS and 100 μl of MTT solution (1 mg/ml) was added to each well. After 4 h of incubation, 100 μl of dimethyl sulfoxide (DMSO) were added to solubilise the formazan salt. The optical density was measured at 540 nm by using UV microplate reader (Tecan Austria GmbH, Groedig, Austria). Relative cell viability was calculated compared to the non-treated blank group. The data were expressed as means of at least three independent experiments.

2.8. Animals and measurement of systolic blood pressure

Spontaneously hypertensive rats (SHR, 10-week-old, male, specific pathogen-free, 180–240 g body weight) with tail systolic blood pressure (SBP) over 180 mm Hg were obtained from Korea Research Institute of Bioscience and Biotechnology (Daejeon, Korea). SHRs were housed individually in steel cages in a room kept at 24 °C with a 12 h light–dark cycle, and fed a standard laboratory diet. Tap water was freely available. PTFP was dissolved in saline at a dose of 10 mg/kg body weight and injected orally using a metal gastric zoned in SHR. The lowering efficacy of PTFP on systolic blood pressure (SBP) was compared with that of captopril. Control rats were administrated with the same volume of saline solution. Following oral administration, SBP was measured by tail-cuff method with a Softron BP system (Softron BP-98A, Tokyo, Japan) after warming up SHR in a chamber maintained at 37 °C for 10 min.

2.9. Statistical analysis

All results were expressed as means ± S.E.M. (n = 3). The significance of the differences of SBPs between control group and administration group was analyzed using Student's t-test.

3. Results

3.1. Preparation of tuna frame protein hydrolysates (TFPH) and their ACE inhibitory activity properties

To produce ACE inhibitory peptides, tuna frame protein was separately hydrolysed using various commercial digestive enzymes. In this experiment, six proteolytic enzymes such as Alcalase, a-chymotrypsin, papain, pepsin, Neutrase and trypsin were selected to evaluate their effectiveness on degradation of tuna frame protein for ACE inhibitory activity. Degrees of hydrolysis

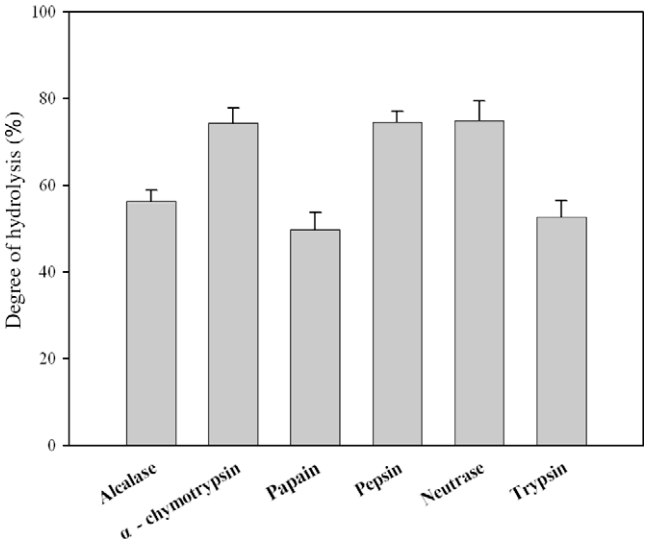

Fig. 1. Degrees of hydrolysis of tuna frame protein using various enzymes. Hundred gram substrate and 1 g enzyme were mixed in a 10 L reactor and the mixture was incubated for 8 h at optimal condition of each enzymes. Degrees of hydrolysis were determined by measuring the nitrogen contents soluble in 10% (v/v) trichloroacetic acid.

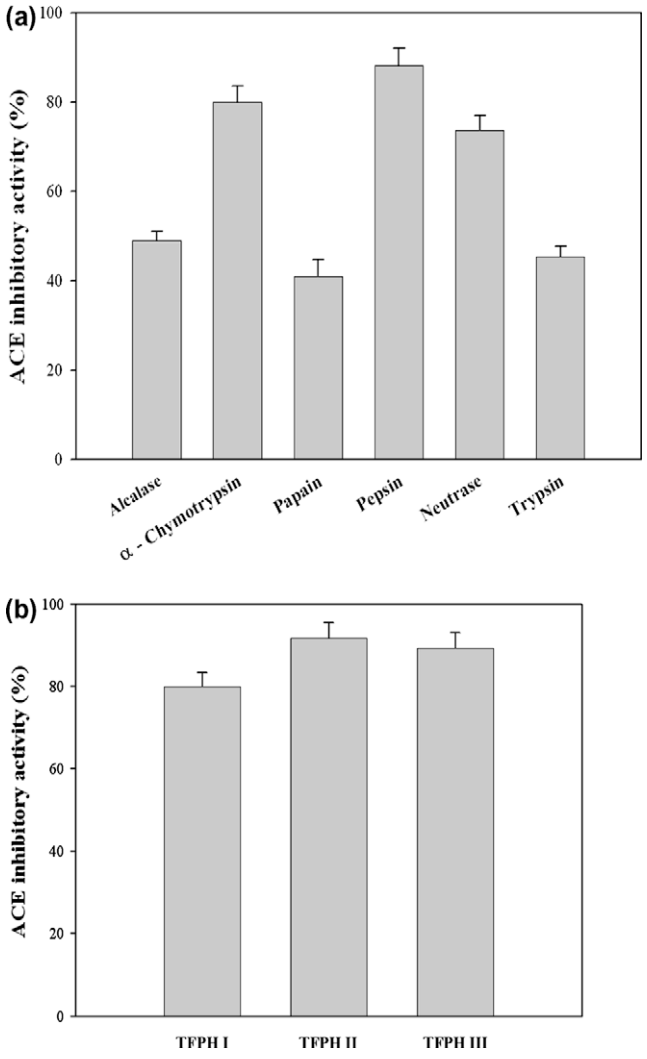

Fig. 2. (a) ACE inhibitory activities of enzymatic hydrolysates from tuna frame protein. Experiments were carried out in the presence or absence (control) of enzymatic hydrolysates as described in the text using HHL as the enzyme substrate for 30 min at 37 °C. (b) Comparison of ACE inhibitory activities of peptic hydrolysates of tuna frame protein with different molecular weight range. TFPH I (MW < 1 kDa), TFPH II (MW = 1–5 kDa) and TFPH III (MW = 5–10 kDa).

(DH) after proteolytic digestion were observed to be 74.3%, 74.5% and 74.8% for α-chymotrypsin, pepsin and Neutrase, respectively. However, the other proteolytic enzymes showed DH lower than 60% (Fig. 1). In ACE inhibitory activity assay (Fig. 2a), pepsin-proteolytic hydrolysate, which showed the highest ACE inhibitory activity (88.2%) among the tested hydrolysates at the concentration of 2 mg/ml, was selected for further study. Peptic hydrolysate was further separated into three MW groups, TFPH I (MW < 1 kDa), TFPH II (MW = 1–5 kDa) and TFPH III (MW = 5–10 kDa), using UF membrane (Mwco = 10, 5 and 1 kDa). The three MW groups were lyophilised and investigated by ACE inhibitory assay. As show in Fig. 2b, most of MW groups showed significant ACE inhibitory activity (over 80%) at the concentration of 1 mg/ml. Among the all MW groups, TFPH II exhibited highest ACE inhibitory activity (91.6%). However, TFPH III also exhibited similar activity (89.4%) compared to TFPH II. Bioactive peptides usually contain 3–20 amino acid residues and low MW peptides are more potent as bioactive peptides than high MW peptides (Pihlanto, 2000). Therefore, we selected TFPH II for the purification of the ACE inhibitory peptide.

3.2. Isolation of ACE inhibitory peptide

TFPH II was fractionated on a Hiprep 16/10 DEAE FF anion exchange column using FPLC. As shown in Fig. 3a, there were three major absorbance peaks at 280 nm and three fractions (F-1, F-2 and F-3) associated with the peaks were pooled and lyophilised for ACE inhibitory activity. F-3 which was eluted with 0.2–0.3 M NaCl exhibited a strong activity (76.4%) at the concentration of 0.2 mg/ml. The lyophilised active fraction, F-3 was further separated by reverse-phase HPLC on a Primesphere 10 C_{18} (20 mm × 250 mm) column with a linear gradient of acetonitrile (0–50% for 20 min) containing 0.1% TFA. The elution profiles of peptides are shown in Fig. 3b. Peptide peaks were separated into three fractions (F-3-1-1, F-3-2 and F-3-3) and each fraction was pooled and lyophilised for ACE inhibitory activity assay. F-3-3 showed the most potent ACE inhibitory activity (86.5%) at a concentration of 0.1 mg/ml. To obtain purified peptide, F-3-3 was further purified by reverse-phase HPLC on SynChropak RPP-100 analytical column (4.6 mm × 250 mm) with 15% acetonitrile containing 0.1% TFA (Fig. 3c). After two times of chromatography, finally we obtained the purified peptide from tuna frame protein (PTFP) and IC_{50} value of PTFP was 11.28 μM. In the N-terminal animo acid sequence analysis (Fig. 3d), it revealed that PTFP was composed of 21 amino acids, Gly-Asp-Leu-Gly-Lys-Thr-Thr-Thr-Val-Ser-Asn-Trp-Ser-Pro-Pro-Lys-Try-Lys-Asp-Thr-Pro (MW: 2,482 Da).

3.3. Determination of ACE inhibition pattern of PTFP

The ACE inhibition pattern of PTFP was investigated by Lineweaver–Burk plot and was found to be non-competitive (Fig. 4). This result means that the PTFP can combine with ACE molecule to pro-

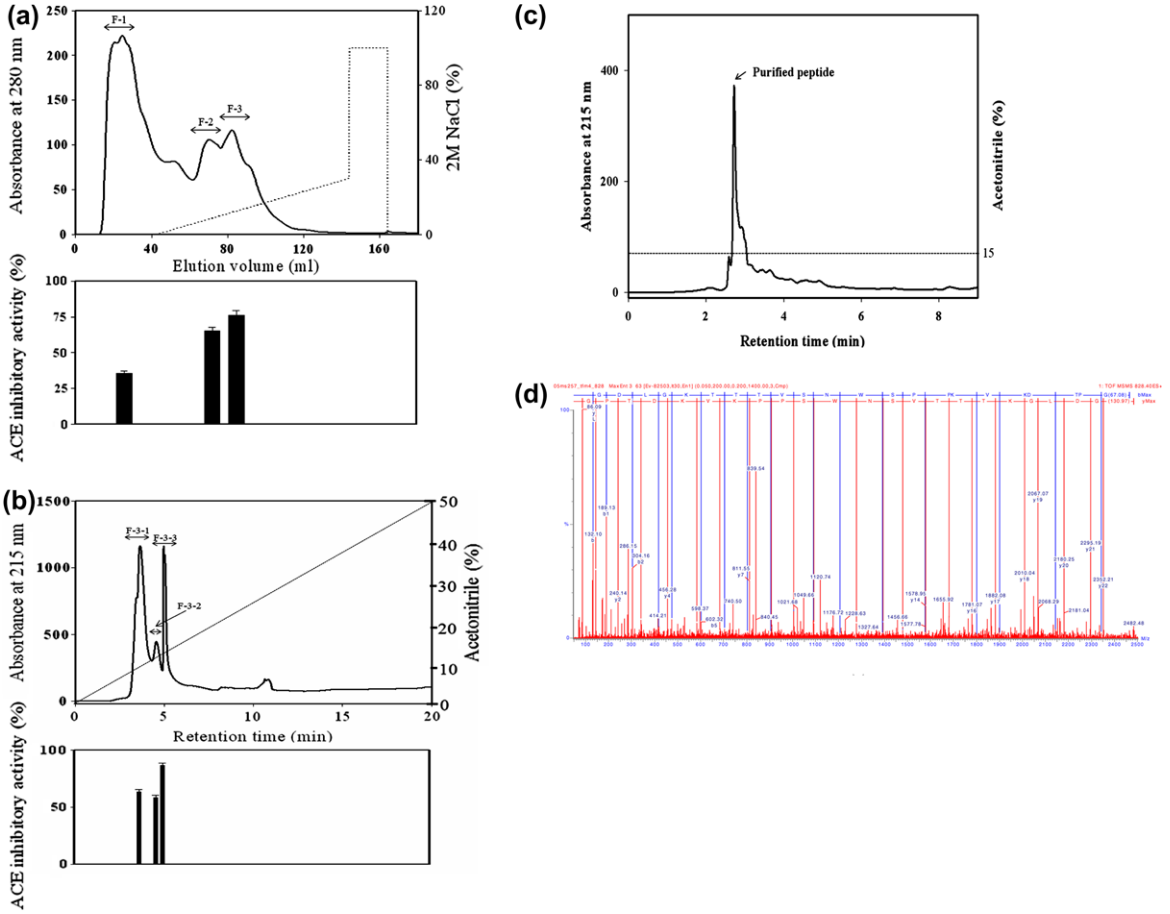

Fig. 3. (a) A FPLC chromatogram of TFPH II loaded on a Hiprep 16/10 DEAE FF ion-exchange column (upper panel) and the ACE inhibitory activity (lower panel). Active fractions were eluted with a NaCl linear gradient (0–2 M) at a flow rate of 62 ml/h. The sample concentration of each fraction was 0.2 mg/ml for measurement of ACE inhibitory activity. (b) A reverse-phase HPLC chromatogram of the active fraction (F-3) from FPLC loaded on Primesphere 10 C_{18} column (upper panel) and the ACE inhibitory activity (lower panel). Active fractions were eluted with an acetonitrile linear gradient (0–50% for 20 min) containing 0.1% TFA at a flow rate of 2 ml/min. The sample concentration of each fraction was 0.1 mg/ml for measurement of ACE inhibitory activity. (c) A reverse-phase HPLC chromatogram of the active fraction (F-3-3) on Synchoropak RPP-100 column using isocratic elution with 15% acetonitrile containing 0.1% TFA at a flow rate of 1.2 ml/min. (d) Identification of the molecular mass and amino acid sequence of the purified peptide (PTFP) using Q-TOF mass spectrometer.

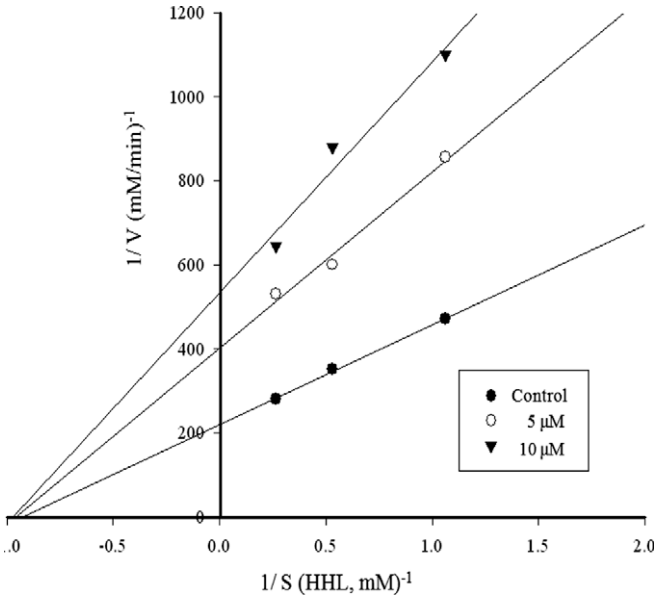

Fig. 4. Lineweaver–Burk plot for determination of inhibitory mode of PTFP on ACE. ACE inhibitory activity was determined in the presence or absence of PTFP (●; Control, ○; 5 μM, ▼; 10 μM) as described in the text using HHL as the enzyme substrate.

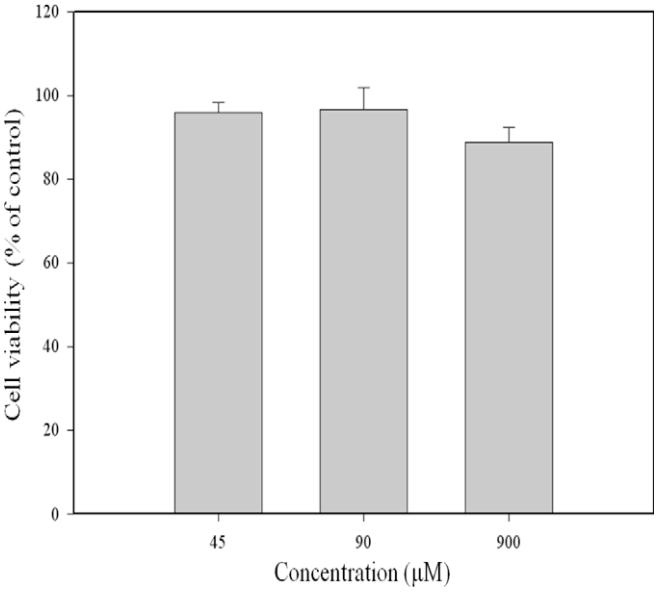

Fig. 5. Effect of PTFP on viability of MRC-5 cell lines using MTT assay. The cells were treated with various concentrations (45, 90 and 900 μM) of PTFP for 24 h. Values represent means ± S.E (n = 3).

duce a dead-end complex, regardless of whether a substrate molecule is bound or not.

3.4. Antihypertensive effect of PTFP on SHRs

For cytotoxic assessment of PTFP before oral administration in SHRs, cell viability of MRC-5 was tested using MTT assay after treatment of PTFP with various concentrations. PTFP showed no cytotoxicity up to 900 μM on MRC-5 (Fig. 5). Antihypertensive activity of PFTP was evaluated by measuring the change of systolic blood pressure (SBP) at 1, 2, 3, 6, and 9 h after oral administration of 10 mg/kg of body weight. Captopril was used as a positive control, and the control group was injected with the same volume of saline. As shown in Fig. 6, the SBP in quiescent state of SHR was 182 ± 2.0 mm Hg. After oral administration of PTFP and captopril, SBP was clearly decreased and the activities were maintained for 9 h. The maximal decrements in SBP of PTFP and captopril treatment groups were 21 and 26 mm Hg at 6 h, respectively.

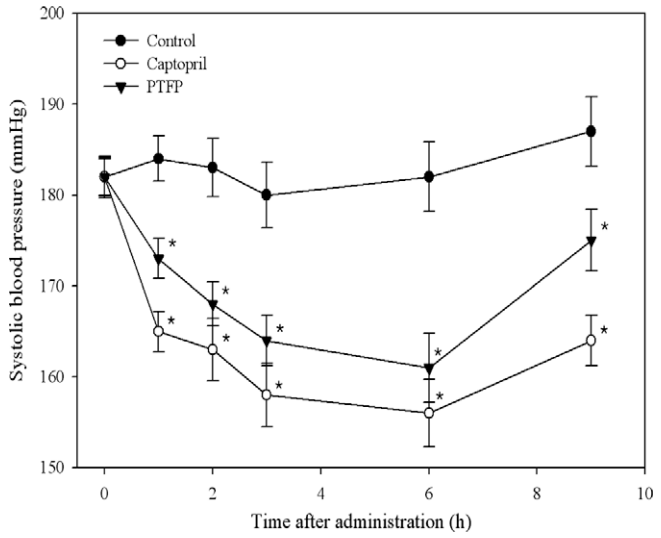

Fig. 6. Change of SBP after oral administration of PTFP in SHR. Captopril was used as a positive control. Single oral administration was performed with a dose of 10 mg/kg body weight, and SBP was measured 0, 1, 2, 3, 6 and 9 h after oral administration of PTFP. The significance of the difference from control at $^{*}P < 0.01$.

4. Discussion

To obtain the novel active ACE inhibitory peptide, six proteases were used under optimal conditions to hydrolyse tuna frame protein. Peptic hydrolysate showed the highest ACE inhibition and was fractionated in three portions (TFPH I = below 1 kDa, TFPH II = 1–5 kDa and TFPH III = 5–10 kDa) using UF membrane system. TFPH II showed highest ACE inhibitory activity and was selected for further isolation using FPLC and HPLC.

After three-step isolation, the novel ACE inhibitory PTFP which was composed of 21 amino acid was obtained. Several peptides derived from the enzymatic hydrolysates of various natural sources such as cheese whey (Amhar et al., 1996), casein (Yamamoto et al., 1994), bovine skin gelatin (Kim et al., 2001), Alaska pollack skin gelatin (Byun & Kim, 2001), sauce of fermented blue mussel (Je, Park, Byun, Jung, & Kim, 2005), bigeye tuna dark muscle (Qian et al., 2007) and porcine haemoglobin (Yike et al., 2006) are known to have ACE inhibitory activities and to exhibit antihypertensive activities in experimental animals. The identified ACE inhibitory peptides are Ile-Val-Tyr (IC_{50} = 0.48 μM) from wheat germ hydrolysate; Leu-Gln-Pro (IC_{50} = 9.6 μM) from zein; Glu-Val-Met-Ala-Gly-Asn-Leu-Try-Pro-Gly (IC_{50} = 2.98 μM) from sauce of fermented blue mussel; Leu-Gly-Phe-Pro-Thr-Thr-Lys-Thr-Tyr-Phe-Pro-His-Phe (IC_{50} = 4.92 μM) and Val-Val-Tyr-Pro-Trp (IC_{50} = 6.02 μM) from porcine hemoglobin; Trp-Pro-Glu-Ala-Ala-Glu-Leu-Met-Met-Glu-Val-Asp-Pro from bigeye tuna dark muscle (IC_{50} = 21.6 μM). In this study, the isolated ACE inhibitory PTFP was composed of Gly-Asp-Leu-Gly-Lys-Thr-Thr-Thr-Val-Ser-Asn-Trp-Ser-Pro-Pro-Lys-Try-Lys-Asp-Thr-Pro (MW: 2482 Da) and exhibited a higher or similar activity (IC_{50} = 11.28 μM) compared to other reports. The kinetic study revealed that ACE inhibitory PTFP acts as a non-competitive inhibitor, which means that it cannot bind at active site but at the other exclusive of the active site of ACE. Generally, ACE inhibitors contain one or more molecular functionalities such as a zinc

binding ligands (usually either a phosphate or carboxylate oxygen, or thiol sulphur), a hydrogen-bond donor and carboxyl-terminal group (Andrews, Carson, Caselli, Spark, & Woods, 1985). In case of ACE inhibitory peptides, the most potent and specific peptide inhibitors have similar structures and ACE activity is strongly influenced by the C-terminal tripeptide sequence of those. The tripeptides with Trp, Tyr, Phe, Pro and a hydrophobic amino acid at the C-terminal were effective for ACE inhibitory activity because of the interaction between three subsites at the active site of ACE (Pihlanto, 2000). In this study, a novel ACE inhibitory peptide from tuna frame protein hydrolysate (TFPH) contained hydrophobic amino acids and Pro at the C-terminal tripeptide sequence, which may contribute to ACE inhibitory activity.

A single oral administration (10 mg/kg) of PTFP showed a strong suppressive effect on SBP of SHRs and this antihypertensive activity was similar with captopril. Some antihypertensive drugs are known to cause side effects such as abnormal elevation of the blood pressure after administration. However, we could not observe any side effect after administration. Fujita and Yoshikawa (1999) classified the ACE inhibitory peptides into three groups based on the fates observed after preincubation with ACE. IC_{50} values of the inhibitor-type peptides (di- or tripeptides) are not affected by preincubation with ACE. Prodrug-type peptides were converted to their true inhibitors with smaller IC_{50} values by ACE, and substrate-type peptides exhibit an elevation of IC_{50} values after preincubation with ACE. According to this report, PTFP would be a prodrug-type inhibitor. It is well known that small peptides, such as di- or tripeptides are easily absorbed in their intact forms in the intestine. Even though PTFP has relatively high MW compared to other reports, the results clearly showed that PTFP exert a substantial effect on reduction of SBP in SHR. If this peptide was not effectively absorbed without digestion, it was difficult to observe this kind of antihypertensive effect on SHR. These results suggest that PTFP would be digested by gastric juice or protease in the small intestine, and then digested small peptide would be absorbed in the intestine. Matsui et al. (2004) reported an accumulation of ACE inhibitory dipeptide (Val-Tyr) in tissue of orally treated SHR. Val-Tyr accumulated in the kidney, lungs and abdominal aorta and caused decrease of ACE activity and angiotensin II levels. Matsui et al. (2003) demonstrated that Val-Tyr acts on the human rennin–angiotensin system through the retardation of angiotensin II formation-related enzyme activity. Therefore, further studies are needed to identify the mechanism of PTFP for the potent antihypertensive effect in SHR.

In conclusion, we isolated and characterised an ACE I inhibitory peptide (PTFP) to investigate beneficial effect against hypertension of tuna frame peptide hydrolysed using various digestive enzymes. PTFP exhibited potent inhibitory activity with 11.28 μM of IC_{50} value and was evaluated as a non-competitive inhibitor against ACE. Antihypertensive effect in SHR also revealed that oral administration of PTFP can decrease systolic blood pressure significantly. In addition, MTT assay showed no cytotoxicity on MRC-5. The result of this study suggests that the ACE inhibitory peptide from tuna frame protein hydrolysate could be potential candidates to develop nutraceuticals and pharmaceuticals against hypertension and its related disease. In addition, it is expected that this study will contribute to developing interest in basic research and potential application of bioactive peptides.

Transversal relaxation time
Browning
Fluorescence
Browning inhibition

ABSTRACT

The modification of Maillard reaction kinetics induced by $MgCl_2$ was evaluated in both liquid and dehydrated model systems with special emphasis on the interactions of the salt with water and/or the sugars. In liquid trehalose systems, browning is accelerated by the presence of $MgCl_2$ due to the increased sugar hydrolysis and to the reduction of water mobility caused by the salt (shown by the decrease in ^1H NMR relaxation times T_2), counteracting the inhibitory effect of water on the reaction. In water restricted trehalose systems, $MgCl_2$ inhibited the Maillard reaction. The salt–sugar interactions, manifested by the delayed sugar crystallization, decreased the reaction rate by affecting the reactivity of reducing sugars. Molecular and supramolecular effects in the presence of $MgCl_2$ have been observed in the present work, and must be taken into account considering high technological interest in finding strategies to either inhibit or enhance the Maillard reaction depending on the application.

1. Introduction

The rate of the Maillard reaction and the nature of its products are governed by the immediate chemical environment of the reactants, defined by the chemical composition of the system (water content, pH, presence and type of buffer salts, temperature and exposure to light) (Baisier & Labuza, 1992; Bell, 1997; Cerruti, Resnik, Seldes, & Ferro Fontán, 1985; Petriella, Chirife, Resnik, & Lozano, 1988). The development of fluorescent products from the Maillard reaction (excitation 340–370 nm/emission 420–475 nm) was described during the storage of different types of food products and model systems. The application of fluorescence measurement is considered a potential tool for addressing key problems of food deterioration as it is an early marker or index of the biomolecular damage (Matiacevich, Santagapita, & Buera, 2005). The behaviour of model systems in the presence of divalent cations (Mg^{2+} or Ca^{2+}) was previously studied. Salts may affect important properties of sugar systems, including fluorescence and browning development from the Maillard reaction, the kinetics of sugar crystallization and sugar hydrolysis (Matiacevich & Buera, 2006; Santagapita & Buera, 2006; Santagapita & Buera, 2008; Schebor, Burin, Buera, & Chirife, 1999). Gökmen & Şenyuva (2007) showed that acrylamide formation is prevented by divalent cations during the Maillard reaction in fructose-asparagine model systems; however, ionic associations between the charged groups of asparagine and Ca^{2+} were not observed. Sugar–cation (Morel-Desrosier, Lhermet, & Morel, 1991) and brown pigment-cation complexes (O'Brien & Morrissey, 1997) have been shown to form in solution. The development of strategies for inhibiting the Maillard reaction employing additives other than sulphites (Lester, 1995) has a high technological interest. Alternatively, in other applications it may be beneficial to enhance the Maillard reaction. However, there has been little work carried out on the role of food-compatible salts in the kinetics of the Maillard reaction. The effect of cations can be analysed through their impact on the modification of solid–water interactions, and water availability, which govern and modulate the kinetics of the Maillard reaction (Acevedo, Schebor, & Buera, 2006).

Nuclear magnetic resonance (NMR) is a very useful technique for investigating the behaviour of water mobility in foods (Schmidt, 2007). The differences in relaxation times of protons from different environments have been exploited in NMR studies to measure the relative amounts of water with different degrees of interaction with solids and consequently, with different mobility (Acevedo et al., 2006; Farroni, Matiacevich, Guerrero, Alzamora, & Buera, 2008). The spin–spin or transversal relaxation time constants of protons (T_2) are related to the molecular mobility of protons in the system. The relaxation processes are affected by the chemical exchange taking place in sites of different mobility. Protons of water molecules which interact tightly with solids, and therefore have reduced mobility (although they are still exchangeable), show small T_2 values, whereas protons which are readily

mobile have relatively long T_2 values (Kuo, Gunasekaran, Johnson, & Chen, 2001).

The purpose of the present work was to analyse the modification of Maillard reaction kinetics induced by the presence of $MgCl_2$ in both liquid and dehydrated model systems, with special emphasis on the interactions of the salt with water and/or the sugars.

2. Materials and methods

2.1. Preparation of model systems

2.1.1. Liquid systems

Liquid systems were prepared from 5% to 70% w/v of D(+)glucose (Merck, Darmstadt, Germany) or α-α-trehalose (Hayashibara Co, Ltd., Okayama, Japan) and 0.5% L-glycine (Merck) with and without $MgCl_2$ (Mallinckrodt Chemical Works, St. Louis, USA), in a 5:1 sugar:salt molar ratio; controls without $MgCl_2$ and glycine were also prepared. Aliquots (2.5 ml) of each model system were placed in 5 ml vials. The systems were prepared in 0.1 M phosphate buffer, pH 5 (Merck, Darmstadt, Germany). All reactants were analytical grade. The vials were hermetically sealed and stored at 70 ± 1 °C in a forced air convection oven.

2.1.2. Solid systems

Solid systems consisted of freeze-dried solutions containing 20% w/v trehalose and 1% w/v L-glycine. The systems were prepared in 0.1 M phosphate buffer at pH 5. The salt $MgCl_2$ was added in a 5:1 sugar:salt molar ratio; controls without $MgCl_2$ and without glycine were also prepared. Aliquots (2.5 ml) of each model were placed in 5 ml vials, frozen at −26 °C for 24 h and immersed in liquid nitrogen immediately before freeze-drying. Freeze-drying was performed in a Heto Holten A/S, cooling trap model CT 110 freeze-dryer (Heto Lab Equipment, Denmark) operating at a condenser plate temperature of −111 °C and a chamber pressure of 4×10^{-4} mbar. After freeze-drying, the systems were transferred to vacuum desiccators and exposed to different relative vapour pressure conditions (RVP): 22%, 43%, 52%, 84% and 97% (Greenspan, 1977) at 25 ± 1 °C for 2 weeks. After humidification, the vials were hermetically sealed and stored at 70 ± 1 °C in a forced air convection oven.

2.2. Determination of browning and fluorescence development

The progress of the Maillard reaction was followed by a browning index defined as absorbance units at 445 nm (UV–vis 1203 spectrophotometer, Shimadzu, Kyoto, Japan) multiplied by the dilution factor, and by fluorescence intensity with excitation at 340 nm/emission 492 nm (model USB 2000 spectrofluorometer, Ocean Optics Inc., FL, USA). The samples employed for the determination of fluorescence were diluted in order to avoid inner filter effect, with absorbance values lower than 0.1 at excitation wavelength (340 nm). Since trehalose is a non-reducing sugar, its participation in Maillard reaction can only occur after hydrolysis.

Browning and fluorescence development as a function of reaction time followed a quadratic dependence, which indicates a half order reaction, which results from the combination of two steps of zero and first order (Matiacevich & Buera, 2006).

The confidence intervals for browning and fluorescence values were 3% and 5% for 95% certainty, respectively.

2.3. Disaccharide hydrolysis

Sugar hydrolysis was analysed by measuring the amount of glucose released during the incubation time by means of an enzymatic method (Wiener Lab. S.A.I.C., Rosario, Argentina) described previously (Bergmeyer & Grassi, 1983).

2.4. Fluorescence quantum yield

Sugar systems solutions (70% w/v) were diluted in order to obtain absorbance below 0.05 to avoid inner filter effects (Lakowicz, 1999). Four dilutions (in duplicate) were prepared for each time of incubation. Fluorescence quantum yields (Φ_F) were determined using quinine sulphate in 0.1 N sulphuric acid as a reference fluorophore of known quantum yield ($\Phi_F = 0.546$) (Lakowicz, 1999), using the classical Eq. (2.1):

$$\Phi_F^S = \Phi_F^R \cdot \frac{I_\lambda^S}{I_\lambda^R} \cdot \frac{A_\lambda^R}{A_\lambda^S} \cdot \frac{n_S^2}{n_R^2} \tag{2.1}$$

where Φ_λ^S and Φ_λ^R are the fluorescence quantum yield of the sample (S) and the reference (R), respectively; I_λ^S and I_λ^R are the integrated areas of their fluorescence spectra; A_λ^S and A_λ^R are their absorbances at the excitation wavelength λ, and n_S and n_R are the refractive index of each solution. In Eq. (2.1), it is assumed that the sample and reference are excited at the same wavelength.

2.5. Nuclear magnetic resonance (NMR) measurements

Transversal or spin–spin relaxation times (T_2) were measured by time resolved proton nuclear magnetic resonance (^{1}H NMR) in a Bruker Minispec mq20 (Bruker Biospin Gmbh, Rheinstetten, Germany) with a 0.47 T magnetic field operating at a resonance frequency of 20 MHz. Proton populations of different mobility were measured using two spin-echo sequences: (a) Hahn (Hahn, 1950), for protons from solids or from water strongly interacting with the solid matrix, and (b) Carr–Purcell–Meiboom–Gill (CPMG) (Carr & Purcell, 1954; Meiboom & Gill, 1958), for more mobile protons. All samples were previously equilibrated at 25.00 ± 0.01 °C in a thermal bath (Haake, model Phoenix II C35P, Thermo Electron Corporation Gmbh, Karlsruhe, Germany).

2.5.1. Measurements using a Hahn sequence

Hahn spin-echo consists of a (90°–τ–180°) sequence. This method allows for analysis of the less mobile protons interacting with the solid matrix; the more mobile protons could not be analysed using this sequence due to diffusion problems during measurement at long times, caused by inhomogeneities in the magnetic field. Trehalose dehydrated systems humidified between 22% and 97% RVP were analysed using this sequence. The following settings were used: scans = 4, recycle delay = 1.5 s, gain = 75 dB, number of points = 20, time for decay curve display = 1 s and interpulse (τ) range of 0.001–0.5 ms. The interpulse range was selected in order to record the complete relaxation of the signal. No phase cycling was used. A polyvinylpyrrolidone (PVP of 58 000 Da) system equilibrated at 43% RVP was used for the automatic update of the equipment which tunes the pulse duration, detection angles, gain and magnetic field homogeneity.

2.5.2. Measurements using a CPMG sequence

Liquid systems were analysed using a CPMG sequence, which consists of $90^\circ_x - \tau - \left[180^\circ_y - \tau - \text{echo} - \tau\right]_n$ sequence, with the following setting: $\tau = 0.5$, scans = 4, number points = 256, dummy shots = 15, gain = 68 dB; phase cycling was used. The automatic update of the equipment was performed employing a 40% w/v trehalose system without thermal treatment.

For both sequence measurements, an exponential function (as stated below in Eq. (2.2)) was found to fit the experimental data adequately, from which transverse relaxation time constant (T_2) was obtained.

$$A = A^{(-t/T_2)} \quad (2.2)$$

where A is the signal amplitude that is proportional to the amount of protons in the sample relaxing after the pulse sequence. This mono-exponential model was used for the liquid samples and for most of the dehydrated systems, obtaining the contributions of protons in the most representative fraction. A bi-exponential model fitted some dehydrated systems with high water content (corresponding to samples at 97% and 84% RVP containing $MgCl_2$), but it is important to note that, for these samples, the signal amplitude of the detected second proton fraction represented a very small contribution to the total proton population, and the mono-exponential approach was selected as the best model for comparative purposes.

2.6. Determination of water content

The total water content of the trehalose solid rehumidified systems was determined gravimetrically by difference in weight before and after drying in a vacuum oven for 48 h at 96 ± 2 °C. These drying conditions were selected in previous studies with samples of similar composition (Mazzobre, Longinotti, Corti, & Buera, 2001) and they were adequate to determine water content in the studied systems with a confidence interval of 6% for a 95% certainty. Duplicate analyses were performed and the average of the results is reported on a dry basis (db).

2.7. Thermal transitions measurements

Melting events were determined by dynamic differential scanning calorimetry (DSC), in the temperature range from 20 to 120 °C, by means of a Mettler Toledo model 822 equipment (Mettler Toledo AG, Greifensee, Switzerland) at a heating rate of 10 °C/min. Melting temperature values were taken as peak temperatures. All measurements were made in duplicate with 10–25 mg sample mass using hermetically sealed aluminium pans of 40 μl inner volume (Mettler Toledo AG). An empty pan was used as a reference and average values are reported. The instrument was calibrated using standard compounds (indium and zinc) of defined melting point and heat of melting (ΔH_m). All thermograms were analysed using STAR^e Software v. 6.1 (Mettler Toledo AG). The samples were initially amorphous as determined by the absence of endothermal peaks in the DSC scans. The amount of trehalose dihydrate formed (degree of crystallization, ϕ) during the storage time was calculated from the ratio of the area of the endothermic melting peak of the sample and the calorimetric enthalpy of the melting of pure trehalose dihydrate measured under the same conditions in a dynamic DSC run, as Eq. (2.3).

$$\phi = \frac{\Delta H_m}{\Delta H_{mT}} * 100 \quad (2.3)$$

where ΔH_m is the heat of melting of trehalose in the sample and ΔH_{mT} is the heat of melting of pure trehalose (139 J/g) measured under the same conditions (Santagapita & Buera, 2006). The relative error for ϕ (calculated with a 95% confidence interval) was about 10% of the ϕ value.

3. Results and discussion

3.1. Maillard reaction development: fluorescence and absorbance data

3.1.1. Liquid systems

Browning and fluorescence development of the liquid systems increased with increasing storage time at 70 °C, for the whole composition range studied (5–70% w/v), as shown in Fig. 1 (a–d). The 70% w/v sugar systems, for example, showed corresponding visual colour changes: uncoloured → yellow → golden → cinnamon → reddish brown. The type and sugar concentration and the presence of $MgCl_2$ were critical for the rate of pigment and fluorescent compounds formation. In the model systems without amino acid (control samples), no increase in the absorbance or the fluorescence was detected, indicating that there was no contribution to colour or fluorescence due to caramelization in the experimental time frame. The decreasing order for browning development was found according to sugar reactivity/stability: glucose > trehalose (Burton, Mc Weeny, Pandhi, & Biltcliffe, 1962; O'Brien & Morrissey, 1997) in all analysed sugar concentrations, as shown in Fig. 1a and c for the 70% w/v samples. In liquid glucose systems, inhibitory effects of $MgCl_2$ on browning and development of fluorescent products, observed for the 70% w/v samples in Fig. 1a and b (respectively), were also noticed in the whole composition range studied (5–70% w/v), extending our previous results for 5% and 40% w/v samples (Matiacevich & Buera, 2006; Santagapita & Buera, 2006). However, as shown in Fig. 1c and d for the 70% w/v systems, an accelerating effect of $MgCl_2$ was observed for both browning and development of fluorescence in liquid systems containing trehalose, in the whole composition range studied. Fig. 2 shows the kinetic constants for browning development in trehalose systems, calculated through a quadratic model, plotted as a function of different water contents. Although trehalose is very stable to hydrolysis (Santagapita & Buera, 2006; Schebor et al., 1999), it was hydrolysed during heat treatment at 70 °C and the hydrolysis rate was accelerated by the presence of $MgCl_2$ (Santagapita & Buera, 2006), as confirmed by glucose analysis (data not shown). For example, for the range between 5% and 40% w/v trehalose system, the rate of trehalose hydrolysis was lower than 1% in systems without salt and increased to 2.3–2.5% in the presence of $MgCl_2$. Pigment development through the Maillard increased accordingly, as observed in Fig. 1c and d.

3.1.2. Solid systems

In the freeze-dried trehalose samples humidified at relative vapour pressures (RVPs) in the range 22–97%, the development of fluorescence was parallel to the development of browning, and the hydrolysis rate increased in the presence of salt as was seen in the analysed liquid systems (also in agreement with Santagapita & Buera, 2006). In the samples containing $MgCl_2$ at 10% (db) water content, only 1.1% trehalose was hydrolysed after 24 h at 70 °C. Under the same conditions, disaccharide hydrolysis was 0.13% for trehalose samples without salt. However, contrary to the results observed in trehalose liquid samples, in solid trehalose samples the presence of $MgCl_2$ delayed browning development, as shown in Fig. 2. It is clearly shown that $MgCl_2$ inhibited the Maillard reaction at low water contents in solid trehalose systems (Fig. 2, left side of the dotted line), but in liquid systems, the presence of the salt increased the reaction rate (Fig. 2, right side of the dotted line, and Fig. 1c). Thus, the effect of $MgCl_2$ on browning development in trehalose samples was dependent on the state of the systems.

3.2. Fluorescence characteristics and quantum yield study

In order to analyse the effects associated with sugar type and their interactions with $MgCl_2$ on the Maillard reaction kinetics in liquid systems shown in Fig. 1, fluorescence characteristics of the samples were studied. In agreement with previous studies (Matiacevich et al., 2005), the maximum wavelength for emission was 450 nm in all systems, and the fluorescence development at zero time of incubation was negligible. Fig. 3 shows the fluorescence emission spectra of trehalose or glucose systems with and without $MgCl_2$, after 0 and 120 h of storage at 70 °C. As seen in this figure, the spectral characteristics were independent of the studied

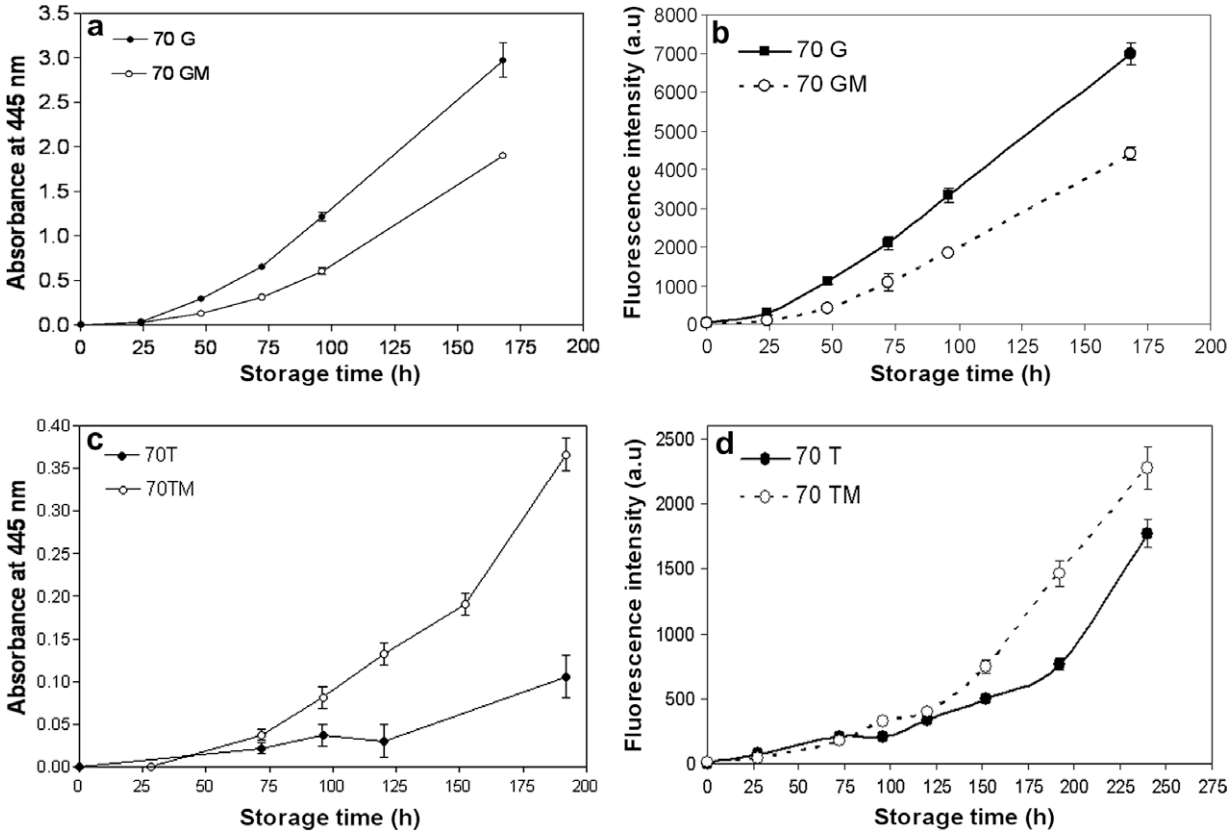

Fig. 1. Browning and fluorescence development for 70% w/v glucose (a, b), or trehalose (c, d) systems with $MgCl_2$ (open symbols) and without $MgCl_2$ (closed symbols) as a function of storage time at 70 °C. Excitation/emission 340/450 nm. T, trehalose; G, glucose; M, $MgCl_2$. Bars on symbols represent the 95% confidence interval.

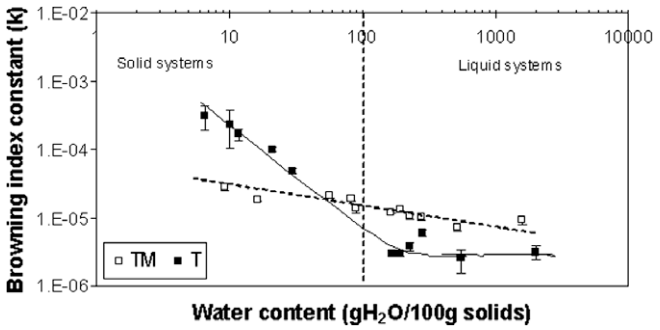

Fig. 2. Kinetic constants for the Maillard reaction (obtained by a quadratic model) as a function of water content for trehalose systems. Solid lines correspond to sugar systems without salt and dashed lines to $MgCl_2$ -containing systems. T, trehalose; M, $MgCl_2$. Bars on symbols represent the 95% confidence interval.

system, indicating that neither the type of sugar nor the presence of salt affected the type of fluorophore obtained in each system.

The fluorescence quantum yield, which is defined as the ratio between the number of photons involved in the emission and the total number of excited photons, may provide information on molecular structural properties of the fluorophores and their interactions. The fluorescence quantum yield was calculated for the samples as a function of heating time at 70 °C, in order to further analyse the effect of $MgCl_2$ on the Maillard reaction (shown in Figs. 1 and 2). As shown in Fig. 4, the fluorescence quantum yield was constant as a function of heating time in glucose systems after a slight initial increase. It is important to note that the presence of $MgCl_2$ did not affect the quantum yield. Thus, the increase of fluorescence observed in Fig. 1b is due to the increasing concentration of fluorophores with increased incubation time, and not to an increase of the fluorophores quantum yield. The same conclusion could be obtained for trehalose systems (Fig. 1d), considering that trehalose must be hydrolysed to two glucose units in order to participate of the Maillard reaction.

Therefore, in agreement with previous studies, the presence of $MgCl_2$ affected the kinetics of the reaction without affecting the chromatic and fluorescent spectral characteristics of samples (Matiacevich & Buera, 2006; Santagapita, Matiacevich, & Buera, in press) or the fluorescence quantum yield properties of the fluorophores.

3.3. Proton mobility studies by NMR

In order to evaluate the possible contribution of water–salt interactions in the results observed in Figs. 1 and 2, proton mobility in each liquid system was studied by ^1H NMR transversal relaxation times (T_2). In liquid systems, T_2 values were calculated after the spin-echo CPMG sequence by a mono-exponential decay model and the results are shown in Fig. 5. With increasing sugar concentration, T_2 values diminished for all sugar systems, indicating a reduced mobility of water protons. As also observed in Fig. 5, T_2 values were not affected by $MgCl_2$ in systems containing glucose (i.e., water–glucose interaction was unmodified by salt), whilst in trehalose systems they were between 6% and 14% lower in the presence of salt, reflecting a reduced mobility. The T_2 values obtained indicated that the $MgCl_2$ interaction affects water mobility in the trehalose samples, but not in glucose systems. Since an inhibitory effect of water has been observed on the Maillard reaction (Acevedo et al., 2006; Labuza, 1994), the accelerating effect of $MgCl_2$ on the reaction rate observed in the disaccharide samples in Figs. 1 and 2 can be associated with water–salt interactions. According to Miller and de Pablo (2000), the local environment

of the ions contained in a trehalose system has more water molecules compared to those uniformly distributed in water, which can explain the lower T_2 values obtained in the disaccharide-salt containing systems.

In the case of glucose liquid systems (Fig. 1a and b) the retarding effect of $MgCl_2$ can be attributed to sugar–salt interactions. The formation of sugar-cation complexes, which may affect the sugar availability for the reaction, has been previously reported and depends on the tautomeric forms and spatial position of the hydroxyl groups of the sugar (Angyal, 1973). It is to be noted that in trehalose systems, the reactant participating in the Maillard reaction is glucose, as in the pure glucose systems. However, in the trehalose

Table 1

27	88	54
32	80	35

* $\phi = \frac{\Delta H_m}{\Delta H_{mT}} * 100$; where ΔH_m is the melting enthalpy of trehalose at a given time and ΔH_{mT} is the melting enthalpy of pure trehalose (Santagapita & Buera, 2006). The relative error for ϕ (calculated for a 95% confidence interval) was about 10% of the ϕ value.

systems the reaction is accelerated by $MgCl_2$, whilst it is delayed in the glucose systems in the presence of salt. Thus, it is not an effect of the type of reactants involved in the reaction, but of the kind of water-matrix interactions: whilst in the glucose systems the water–glucose interactions were not affected by the presence of $MgCl_2$ (as shown by ^1H NMR relaxation times), in the trehalose systems a decreased relaxation time indicated lower water mobility in the presence of salt. A probable interaction between Mg^{2+} and phosphate buffer, which may cause the inhibition of Maillard reaction, has been reported (Akagawa, Miura, & Suyama, 2002) and must also be taken into account.

In other set of experiments, in the trehalose solid systems (with and without $MgCl_2$), the spin–spin ^1H NMR relaxation times were obtained by the spin-echo Hahn sequence (indicated as T_{2H}) in samples at different RVP. The T_{2H} values in samples of similar water content (between 10% and 20% db) were 25 ± 2 μs either in the presence of $MgCl_2$ or without the salt, showing no differences between them. The T_{2H} values obtained correspond to matrix and water protons displaying strong interactions with the matrix, and no changes in their mobility could be detected by the presence of $MgCl_2$. Therefore, the water–salt interactions manifested by the relaxation times from ^1H NMR in the trehalose solid systems could not explain the inhibitory effect of salts on the browning kinetics. Of the dehydrated systems, only the trehalose–$MgCl_2$ systems at RVP 84% and 97% and the trehalose systems at 97% showed a second set of T_{2H} with values higher than 1 ms, which correspond to water molecules of weak interactions with the solid matrix. It is to be noted that the effect of $MgCl_2$ in these solid systems (in which mobile water molecules were detected) was not as important on the browning kinetic constants of these systems as at lower water contents (Fig. 4).

Another effect of the salt interactions in restricted water environments could be manifested by the modification of the sugar

crystallization kinetics by $MgCl_2$. Table 1 shows that the degree of trehalose crystallization (ϕ) in solid trehalose systems containing $MgCl_2$ was lower than in samples without salt. The delay of sugar crystallization by the presence of salts in supercooled systems has been previously reported (Longinotti, Mazzobre, Buera, & Corti, 2002; Santagapita & Buera, 2008) and may be explained by dynamic water–salt–sugar interactions, which take place at a molecular level and are related to the charge/mass ratio of the cation present. An interaction/complexation between the magnesium cation and the Maillard reaction products has also been reported (O'Brien and Morrissey, 1997) and is not discarded as another factor influencing molecular mobility.

In conclusion, the Maillard reaction kinetics can be affected by the presence of salts to a different degree, depending on the type of sugar present (either acting as reactant or as part of the solid matrix) and the state of the system. Molecular and supramolecular effects of the presence of $MgCl_2$ have been observed in this work.

Due to the inhibitory effect of water on the Maillard reaction, modifications in water–solids interactions promoted by salts could be responsible for changes in the reaction rates. In liquid trehalose systems (or when mobile water protons were detected), the browning reaction is accelerated by the presence of $MgCl_2$ due to the increased sugar hydrolysis and the reduction of water mobility caused by the salt, counteracting the inhibitory effect of water on the Maillard reaction. On the other hand, in water restricted (freeze-dried) trehalose systems, $MgCl_2$ inhibited the Maillard reaction. In this case, the salt–sugar interactions, manifested by the delayed sugar crystallization, decreased the reaction rate by affecting the reactivity of reducing sugars.

Cultivar, growing location

ABSTRACT

The effects of cultivar, growing location and year on physicochemical and cooking characteristics of field pea (*Pisum sativum*) were investigated and the relationship between these characteristics was determined. Six diverse field pea cultivars were grown in five different growing locations for two subsequent years (2006 and 2007). Cultivar, location and year had a significant effect on the seed weight, seed size, water hydration capacity, cooking time and firmness of cooked peas. Significant cultivar and location differences in protein, starch, crude fibre, fat, ash and phytic acid contents of peas were observed. Most of the traits were significantly affected by the interactions: cultivar-by-location, cultivar-by-year and location-by-year. Both seed weight and seed size were negatively correlated with crude protein and crude fibre contents. Cooking time was negatively correlated with crude fibre, ash and phytic acid contents, but positively correlated with firmness and starch content. A significant positive correlation was observed between ash content and phytic acid level in peas.

1. Introduction

Pulses, including pea (*Pisum sativum*), play an important role in the diet of most of the people in the world because of their nutritive value. Pulses are consumed after cooking, both in the form of whole seed and decorticated splits in various types of food. Cooking time is one of the most important quality–determining processes for field peas for human consumption (Moscoso, Bourne, & Hood, 1984). One of the constraints in the utilisation of pulses is their long cooking time. Reduction in the nutritive value of the proteins, due to excessive cooking of pulses, has been reported (Walker & Kochhar, 1982). Apart from cooking time, cooked texture is also an important cooking quality characteristic for pulses. Cooking is required to render pulses edible and to ensure acceptable sensory quality (Bourne, 1982). Cooking causes some physicochemical changes in pulses, including gelatinization of starch, denaturation of proteins, solubilisation of some of the polysaccharides, and softening and breakdown of the middle lamella, a cementing material found in the cotyledon (Stanley & Aguilera, 1985; Vindiola, Seib, & Hoseney, 1986). Cooking also inactivates or reduces the levels of anti-nutrients such as trypsin inhibitors and flatulence-causing oligosaccharides, resulting in improved nutritional quality (Ayyagari, Rao, & Roy, 1989; Jood, Mehta, Singh, & Bhat, 1985; Wang, Hatcher, & Gawalko, 2008; Wang, Lewis, Brennan, & Westby, 1997).

Factors affecting cooking quality of pulses include cultivar, seed characteristics, composition of seeds, growing location and environment (Bishnoi & Khetarpaul, 1993; Gubbels & Ali-Khan, 1991; Gubbels, Chubey, Ali-Khan, & Stauvers, 1985; Stanley & Aguilera, 1985). Physical properties, such as size and weight, as well as seed coat and cotyledon characteristics, influence pulse cooking quality (Sefa-Dedeh & Stanley, 1979a). Pulses are generally soaked before cooking, to ensure uniform expansion of the seed coat and cotyledon for uniform cooking and to ensure their tenderness (Hoff & Nelson, 1965). The ability of seeds to hydrate has been linked to cooking quality. Bishnoi and Khetarpaul (1993) found that higher hydration capacity of peas was associated with shorter cooking time. The texture of cooked cowpeas (*Vigna unguiculata*) showed a negative correlation with the amount of water absorbed (Sefa-Dedeh, Stanley, & Voisey, 1978). Sefa-Dedeh and Stanley (1979b) reported that seed thickness and hilum size of cowpeas influenced water absorption during the initial stage of soaking whilst protein content became an important factor affecting water absorption in the later stages of soaking. Cooking brings about a number of changes in chemical composition of peas (Wang et al., 2008). However, little information is available on how cultivar and growing location affect the cooking quality attributes of field pea.

Variation in chemical composition in pulses might be due either to intrinsic factors (mainly genetic) or to extrinsic factors, such as storage, type of soil, agronomic practices (such as plant density, weeds, or soil fertility), climatic factors (such as rainfall, light

intensity, length of growing season, length of day or temperature (Eppendorfer & Bille, 1974; Holl & Vose, 1980; McLean, Sosulski, & Youngs, 1974; Nikolopoulou, Grigorakis, Stasini, Alexis, & Iliadis, 2006, 2007; Singh, Campbell, & Salunkhe, 1972) and technological treatments (Babiker, Elsheikh, Osman, & El Tinay, 1995; McLean et al., 1974). Data on the chemical composition and nutritive values of field pea have been reported (Davies, 1984; Petterson, Sipsas, & Mackintosh, 1997; Wang & Daun, 2004). However, information on the relationships amongst physical, cooking and chemical characteristics of peas is not readily available. This study aimed to investigate how cultivar, growing location and year affect the physicochemical and cooking characteristics of field peas, and to determine the relationships between these characteristics.

2. Materials and methods

2.1. Materials

Six registered field pea cultivars (CDC Striker, Cooper, Cutlass, Eclipse, SW Marquee and SW Sergeant) were grown over two seasons (2006 and 2007) at five locations (Indian Head, Melfort, Rosthern, Saskatoon and Swift Current) in Saskatchewan, Canada, in a randomized complete block design as part of the provincial regional variety trials. The cultivars chosen are commonly grown in western Canada (Saskatchewan Crop Insurance Corporation, personal communication). CDC Striker (Warkentin, Vandenberg, Banniza, & Slinkard, 2004) was developed by the Crop Development Centre (CDC), University of Saskatchewan; Cutlass (Blade, Warkentin, & Vandenberg, 2004) was jointly developed by the CDC and Alberta Agriculture; Cooper and Eclipse were developed by Cebeco Zaden, The Netherlands, and SW Marquee and SW Sergeant were developed by Svalof-Weibull, Sweden. Cutlass, Eclipse and SW Marquee have yellow cotyledons, whilst CDC Striker, Cooper and SW Sergeant have green cotyledons.

Growing season weather conditions at the five sites of the 2006 and 2007 Saskatchewan regional field pea variety trials are shown in Table 1. The Swift Current site was relatively warm and dry; the Indian Head site was relatively dry, whilst the Rosthern site was the wettest.

Broken and damaged seeds and foreign material were handpicked from the samples before testing commenced. Seed samples were ground into flour using an Udy grinder with a 0.5 mm sieve and stored at 4 °C in sealed plastic bags prior to further analysis.

2.2. Physical tests

Seed weight was determined according to the AACC method 56-35 (AACC, 2000) by counting one hundred seeds using a custom-made counting board and weighing. Results were expressed as means of duplicate determinations. Water hydration capacity was determined by soaking the 100-seed weight samples in deionized water at a ratio of 1:4 (sample weight:water weight) at room temperature for 16 h in accordance with the method AACC 56-35 (AACC, 2000). After the water was drained, the soaked seeds were blotted dry with a paper towel and weighed. Hydration capacity was expressed as the amount of water absorbed per kg of seeds (g H_2O/kg seeds) after soaking for 16 h. The mean diameter of pea seeds was determined using the image analysis technique of Shahin and Symons (2001).

2.3. Cooking quality

Cooking time of each pea sample was determined using an automated Mattson Cooker (Wang & Daun, 2005), which consists of 25 plungers, a cooking rack with 25 reservoir-like perforated saddles, a sensor assembly, which mounts on top of the cooking rack, an interface box, an input/output card and a computer. Each plunger was calibrated to a weight of 90 g by adjusting the lead buckshot inside each plunger. A pea sample (50 g) was soaked in distiled water at a ratio of 1:4 (seed:water, w/w) for 24 h at room temperature. Twenty-five soaked seeds were randomly selected and then positioned into each of the 25 saddles of the cooking rack so that the tip of each plunger rested on top of the soaked seed. The rack was then placed into a 2 l metal beaker containing 1.2 l of boiling water, which was placed on a hotplate. When a seed became sufficiently tender, the plunger penetrated the seed and dropped through the hole in the saddle. The time when each plunger dropped was recorded through a windows-based programme. The optimum cooking time was assigned when 80% of the seeds were cooked. The cooking time in minutes was determined as an average of triplicate determinations.

The firmness of cooked peas was measured with a TA-HDi texture analyzer (Texture Technologies Corp., Scarsdale, NY). A pea sample (50 g) was soaked in 300 ml of distiled water at room temperature for 24 h. After draining the water, the soaked sample was cooked in 1.0 l distiled water in a 2 l metal beaker placed on a hotplate for its predetermined cooking time, as described above. The cooked peas were drained for 15 s with a strainer and then the strainer was placed in a plastic container containing 700 ml of distiled water (20 ± 2 °C) for 30 s. The cooked seeds were drained and then transferred to another plastic container holding 700 ml of distiled water (20 ± 2 °C) for an additional 90 s to cool the cooked seeds to room temperature. The cooked seeds were then drained and transferred to a thermos flask, 250 ml capacity (Thermos L.L.C. Corp. Headquarters, Rolling Meadows, Illinois, USA), to keep the seeds at room temperature. Approximately 9.0 ± 0.5 g of cooked peas were loaded onto a TA-91 Kramer Shear Cell holder (Texture Technologies Corp., Scarsdale, NY). The TA-91 Kramer Shear Cell was attached to a load cell of 250 kg capacity. System parameters were: (a) arm speed prior to sample contact, 2.0 mm/s, (b) arm speed during compression of the sample, 1.5 mm/s, and (c) arm speed during

Table 1
Summary of growing season (May–August) mean temperature and total precipitation at five sites of the 2006 and 2007 Saskatchewan regional field pea variety trials[A].

Location	Soil zone	Year	Mean temperature (°C)	Total precipitation (mm)
Swift Current	Brown	2006	17.2	184
		2007	16.9	122
Saskatoon	Dark Brown	2006	16.5	210
		2007	16.6	274
Melfort	Black	2006	15.8	221
		2007	14.7	259
Rosthern	Black	2006	15.8	320
		2007	15.0	346
Indian Head	Black	2006	15.6	135
		2007	15.0	206

[A] Data source: based on the Environment Canada reporting site nearest to the field pea regional variety trial site.

retraction, 2.0 mm/s. The maximum shear force measured was recorded. The firmness of the cooked peas was defined as the maximum force required to shear the cooked peas and expressed as the maximum shear force per gram of cooked sample (N/g cooked sample). Values reported were averages of six determinations.

2.4. Chemical analysis

Nitrogen (N) was determined by the Dumas combustion method using a Leco FP-528 combustion nitrogen analyzer (Leco Corp. St. Joseph, MI, USA) calibrated with EDTA (AOAC, 2000). Crude protein content was calculated using N × 6.25. Moisture and ash contents were determined gravimetrically in accordance with AACC methods 44-17 and 08-16, respectively, (AACC, 2000). Starch content was determined colorimetrically as described by the method AACC 76-13 (AACC, 2000). Fat content was determined gravimetrically by hot extraction of the ground sample with petroleum ether for 2 h on a Soxtec extraction unit (Foss-Tecator, Höganäs, Sweden) (AOCS, 1998). Crude fibre (CF) was determined as described by the method of Ankom Technology (Ankom Technology, 1998) using the ANKOM^{2000} Fibre Analyzer (Ankom Technology, Macedon, NY).

Phytic acid was extracted and separated by ion-exchange chromatography, according to the method of AOAC (2000), before being quantified colorimetrically using an Ultrospec 3000 spectrophotometer (Biochrom Ltd., Cambridge, England) at 500 nm (Latta & Eskin, 1980). One gram of ground pea sample was extracted with 20 ml of 0.65 M HCl for 2 h at room temperature on a rotary shaker. The extract was centrifuged (3500 × *g*) at room temperature for 20 min and the supernatant was decanted. A 3 ml aliquot of the supernatant was diluted to 25 ml with deionized water. Diluted sample extract (10 ml) was passed through a column (7 × 150 mm) (Bio-Rad Laboratories, Inc., Hercules, CA) packed with 100–200 mesh AG1-X4 chloride anion-exchange resin (Bio-Rad Laboratories, Inc., Hercules, CA). Inorganic phosphorus was eluted with 15 ml 0.1 M NaCl, followed by elution of phytate with 0.7 M NaCl. The phytate content was measured colorimetrically at 500 nm, using the Wade reagent (0.03% $FeCl_3 \cdot 6H_2O$ and 0.3% sulfosalicylic acid in deionized water).

2.5. Statistical analysis

All statistical analyses were conducted using the SAS (v.9.1.3, SAS Institute, Cary, NC). The analysis of variance (ANOVA) for the main effects (cultivar, growing location and year) and interactions were determined using the GLM procedure. The Duncan multiple range test was used to separate means and significance was accepted at $p < 0.05$. The different parameters were correlated with each other by Pearson two-tailed significance correlation.

3. Results and discussion

3.1. Physical and cooking characteristics

A significant ($p < 0.001$) effect of cultivar, growing location and year on the physical characteristics of field peas was found (Table 2). Interaction of cultivar-by-location, cultivar-by-year and location-by-year also significantly affected 100-seed weight, seed size and water hydration capacity. Seed weights ranged from 16.6 to 31.7 g per 100 seeds whilst mean seed sizes varied from 6.1 to 7.5 mm (Table 3). Cultivar Cooper had the highest seed weight (26.8 g per 100 seeds) and the largest seed size (7.1 mm). The lowest seed weight and the smallest mean seed size were observed for cultivars SW Marquee and SW Sergeant. Pea samples from Indian Head, Melfort and Rosthern had significantly ($p < 0.05$) higher seed weight and larger seed size than had those from Saskatoon and Swift Current (Table 4). Results from the present study confirmed results of Singh, Erskine, Robertson, Nakkoul, and Williams (1988) who reported that seed size was a cultivar characteristic and was influenced by the environmental conditions. Water hydration capacity ranged from 936.0 to 1316.6 (g H_2O/kg seeds) (Table 3). Cultivar SW Marquee had the highest water hydration capacity whereas CDC Striker exhibited the lowest. Significantly ($p < 0.05$) higher water hydration capacity values were observed in peas from Swift Current than in those from other growing locations (Table 4). Peas grown in the 2006 season had significantly ($p < 0.05$) higher mean seed weights and larger mean seed sizes but had significantly ($p < 0.05$) lower mean water hydration capacities than in the 2007 season (Table 4).

Cultivar, growing location and year significantly affected cooking time and firmness of cooked pea samples (Table 2). Cultivar-by-location showed a significant effect on cooking time ($p < 0.001$) and firmness ($p < 0.01$) (Table 2). Cultivar-by-year had a significant effect on firmness ($p < 0.05$), but had no effect on cooking time. Location-by-year showed a significant effect on cooking time ($p < 0.001$), but no effect on firmness was observed. Cooking time and firmness varied from 6.2 to 33.5 min and 14.5 to 31.3 N/g seed, respectively, (Table 3). The cultivar Eclipse had the longest cooking time, whereas CDC Striker and SW Marquee exhibited the shortest (Table 3). Shorter cooking time is important from the point of view of convenience and nutritional value. Prolonged cooking of pulses has been reported to increase the percentage of leached solids, to destroy heat-labile vitamins and to decrease the protein quality of cooked product (Walker & Kochhar, 1982). Cultivars Eclipse and SW Sergeant had significantly ($p < 0.05$) higher firmness value than had the other cultivars (Table 3). Pea samples from Melfort and Swift Current had significantly ($p < 0.05$) longer cooking time and firmer texture than had those from Indian, Rosthern and Saskatoon (Table 3). Pea samples from 2006 exhibited significantly ($p < 0.05$) longer cooking time and firmer texture than did those from 2007 (Table 4).

3.2. Chemical composition

Analysis of variance showed a strong cultivar, growing location and year effect on crude protein, starch, crude fibre, fat, ash, and phytic acid contents (Table 2). Crude protein content (N × 6.25) varied from 213 to 284 g/kg dry matter with a mean of 248 g/kg dry matter (Table 3), in accordance with values previously reported (Black, Singh, & Meares, 1998; Owusuh-Ansah & McCurdy, 1991; Wang & Daun, 2004). The wide variations in protein content were due to a combination of genetic and environmental factors (growing location and year), confirming the findings reported previously (Nikolopoulou et al., 2007; Reichert & MacKenzie, 1982; Vidal-Valverde et al., 2003). Cultivar CDC Striker had the highest mean protein content whereas Cutlass had the lowest (Table 3). The highest protein level of the pea cultivars was observed at the location in Swift Current (Table 4). Starch content ranged from 433 to 496 g/kg dry matter, which was within the range reported by Borowska, Zadernowski, and Konopka (1996) and Wang and Daun (2004). Cooper and Cutlass had the highest starch contents, whilst CDC Striker had the lowest (Table 3). Pea samples from Melfort had the highest starch content, whereas pea samples from Indian Head and Swift Current had the lowest (Table 4). Peas grown in 2006 had significantly ($p < 0.05$) higher starch contents than those grown in 2007. Crude fibre content varied from 43.4 to 62.2 g/kg dry matter with a mean of 52.4 g/kg dry matter (Table 2). CDC Striker and SW Sergeant had the highest crude fibre contents, whereas Cooper had the lowest (Table 3). Pea samples from Rosthern and Saskatoon had significantly ($p < 0.05$) higher crude fibre content than had those from the other locations

(Table 4). Crude fat content was in the range of 6.7–11.7 g/kg dry matter and ash content varied from 23.0 to 31.3 g/kg dry matter. SW Sergeant had the highest fat content (Table 3). Copper, Cutlass and SW Marquee had significantly ($p < 0.05$) higher ash content than had the other cultivars. Pea samples from Melfort had the highest mean fat content whilst samples from Indian Head had

the highest ash content (Table 4). Both fat and ash values in this study were in agreement with data reported (Nikolopoulou et al., 2007; Petterson et al., 1997; Wang & Daun, 2004). Phytic acid level ranged from 4.2 to 11.9 g/kg dry matter with a mean value of 8.1 g/kg dry matter (Table 3), which was comparable with that reported for peas, lentils and beans (Bhatty & Slinkard, 1989; Lolas & Markakis, 1975; Wang & Daun, 2004). Cooper showed the highest mean phytic acid level. Pea samples from Indian Head had the highest phytic acid content, whereas samples from Swift Current had the lowest. Higher phytic acid content could be attributed to higher soil phosphorus (P) content, since the major portion of total P in plant tissues is stored in the form of phytate (Ravindran, Ravindran, & Sivalogan, 1994). Higher phytic acid levels, due to higher P content in the soil of the cultivation area, have been observed for chickpeas (Nikolopoulou et al., 2006). Peas grown in 2006 had significantly ($p < 0.05$) higher crude fibre and fat contents but had significant ($p < 0.05$) lower ash and phytic acid contents than those grown in 2007 (Table 4).

3.3. Relationships between various characteristics

Seed weight had a significant positive correlation with seed size ($r = 0.95$, $p < 0.001$), which is expected (Table 5). Both seed weight and seed size were negatively correlated with protein ($p < 0.05$) and crude fibre contents ($p < 0.05$), indicating that smaller size seeds had higher protein and higher fibre contents than had larger size seeds. Seed size showed a significant negative correlation with fat content ($p < 0.05$). No correlations between seed weight/size and water hydration capacity were observed in this study. By contrast, Williams, Nakoul, and Singh (1983) and Singh, Williams, and Nakoul (1990) reported a positive correlation between seed size and water hydration capacity. Generally, the water absorption patterns of peas were characterised by rapid water uptake at initial soaking times (data not shown), after which the rate of water absorption slowed and reached a saturation level. In the present study, water hydration capacity was determined at 16 h of soaking when peas reached saturation level. Sefa-Dedeh and Stanley (1979b) reported that characteristics of seed coat and cotyledon structures for pulses were important factors affecting water absorption rate at initial stages of soaking. With increasing soaking time and consequent hydration of the seed coat, this structure no longer exerted an important influence on water absorption and other factors, such as intrinsic properties of the cotyledon components, the cotyledon structure and growing conditions, became important. It was observed that water hydration capacity was negatively correlated with crude fibre ($p < 0.001$) and fat contents ($p < 0.001$) (Table 5).

Cooking time was positively correlated with firmness of cooked peas ($p < 0.001$). A similar result for dry beans was reported by Deshpande and Cheryan (1986). Cooking time had no correlations with seed weight, seed size or water hydration capacity (Table 5). However, Black et al. (1998) reported that seed weight had a positive correlation with cooking time of peas. Cooking time was negatively correlated with crude fibre ($p < 0.05$) and ash ($p < 0.001$) but positively correlated with starch content ($p < 0.01$) (Table 5). Our results suggest that the composition of the cultivar and growing conditions play important roles in influencing cooking time. A significant negative correlation between cooking time and phytic acid content ($r = -0.61$, $p < 0.001$) was observed. This was in agreement with the results reported by other researchers (Stanley & Aguilera, 1985; Vindiola et al., 1986). It has been postulated that phytic acid chelates divalent cations (Ca^{2+}, Mg^{2+}) and prevents their binding to pectin in the cell wall for the formation of the insoluble calcium and magnesium pectates, thereby facilitating cell wall dissolution during the cooking process. In peas, grown under field conditions, the critical level of phytic acid sufficient to bind the divalent cations is not known. Nevertheless, reductions in phytic acid content of pea may increase its cooking time. Phytic acid has been implicated in reducing the availability of essential minerals, and possibly the utilisation of protein due to formation of phytate–mineral and phytate–protein complexes (Reddy, Sathe, & Pierson, 1988). However, phytic acid seems to have a beneficial role in reducing cooking time of pulses.

Firmness of cooked seeds was negatively correlated with seed weight ($p < 0.05$), seed size ($p < 0.05$) and water hydration capacity ($p < 0.05$), confirming the results reported by Wang, Daun, and Malcolmson (2003). However, Black et al. (1998) reported that firmness had a positive correlation with seed weight. Wang et al. (2003) reported that firmness is a function of both seed coat and cotyledon properties. They found that small size peas, having a greater surface to volume ratio than large size peas, had a greater proportion of seed coat to cotyledon, resulting in higher firmness value. Firmness also had a significant negative correlation with fat ($p < 0.05$), ash ($p < 0.001$) and phytic acid ($p < 0.001$) contents. It has been reported that softening of pulses during cooking was accompanied by structural changes in the seed, primarily breakdown of the middle lamella, leading to the easy separation of cells (Sefa-Dedeh et al., 1978; Vindiola et al., 1986). Other changes reported include the gelatinization of starch and the consequent deformation of the spherical granules. Differences in the gelatinization pattern of the starch and the susceptibility of the cell constituents (notably the protein matrix) to softening, may also contribute to the overall texture of the cooked seed.

– Blank spaces indicate no significance.
[A] n = number of samples (6 cultivars × 5 sites × 2 years × 2 duplicates = 120).
[B] WHC = water hydration capacity (g H_2O/kg seed).

Protein content was negatively correlated with the starch content ($p < 0.001$) (Table 5), which is expected, since these two constituents form the bulk of the composition of pea seeds in reverse proportions. Similar significant correlations have been reported by others (Black et al., 1998; Wang & Daun, 2004). Protein content was also negatively correlated with fat ($p < 0.001$) and ash contents ($p < 0.01$) but positively correlated with phytic acid ($p < 0.001$). Crude fibre had a significant ($p < 0.001$) positive correlation with fat content. Ash content was positively correlated with phytic content ($r = 0.88$, $p < 0.001$), confirming the findings reported by Wang and Daun (2004).

4. Conclusions

Significant effects of cultivar, growing location and year were detected on the physical, chemical and cooking characteristics of diverse pea cultivars over two seasons at five locations in Saskatchewan, Canada. Significant cultivar-by-location interactions were noted for all quality parameters except crude fibre, ash and phytic acid contents. There were significant interactive effects of cultivar-by-year on all quality parameters except cooking time. Significant location-by-year interactions were also observed for all quality parameters, except firmness, of cooked peas. These findings indicated that selection of a field pea cultivar with required quality characteristics must take into consideration, not only the genetic factors, but also the environmental parameters, namely climate conditions and growing locations during the growing season.

Protein content was negatively correlated with starch, fat and ash contents but positively correlated with phytic acid. A significant positive correlation between ash and phytic acid contents was noted. Seed weight and seed size were negatively correlated with protein and crude fibre contents. There was a negative correlation between water hydration capacity and crude fibre contents. Cooking time was positively correlated with starch content, but negatively correlated with crude fibre, ash and phytic acid contents. Firmness of cooked seeds was positively correlated with cooking time, but negatively correlated with fat, ash, phytic acid content, seed weight, seed size and water hydration capacity. Our results suggest that the physical characteristics and chemical composition of peas played important roles in influencing cooking characteristics (cooking time and texture). Phytic acid content in peas had a beneficial role in reducing cooking time of peas. Knowledge of how cultivar and environment influence quality traits of field peas, and the variation in physicochemical and cooking characteristics of different cultivars will be useful for breeders in efforts to improve the quality of peas.

Cynomoriaceae
Tannin
Catechin
SOD
α-glucosidase

ABSTRACT

Flavan-3-ol oligomers from the stems of *Cynomorium songaricum* were found to show potent SOD-like activity with one of the dimers being most potent. The flavan-3-ols also showed inhibitory activity on α-glucosidase, implying the beneficial effects of this herb on diabetes patients. The total (extractable and non-extractable) tannin content of this herb was found to be as high as 18.3%. The contents of catechin, flavan-3-ol oligomers and extractable tannins using 70% acetone, methanol or water were analysed. It was found that 70% acetone was the most efficient extract solvent amongst these three solvents, especially for higher flavan-3-ol oligomers.

1. Introduction

The stems of *Cynomorium songaricum* Rupr (Cynomoriaceae) is a well known tonic in Traditional Chinese Medicine (State Administration of Traditional Chinese Medicine of People's Republic of China, 1999). This herb is also frequently added to teas and wines and consumed by the local people as vegetable or food. Previous studies have reported the occurrence of phenolic compounds, triterpenes and other compounds in this plant (Chu, Tian, Lin, & Ye, 2006; Jiang, Tanaka, Sakamoto, Jiang, & Kouno, 2001; Ma, Nakamura, Miyashiro, Hattori, & Shimotohno, 1999; Zhang, Xu, & Li, 1997; Zhang & Zhang, 1991). Phenolic compounds are known to have antioxidative activity and to have scavenging effects on reactive oxygen species (ROS) (Hatano et al., 1989; Shahidi, 1997a; Yokozawa, Dong, Liu, & Shimizu, 1997), whilst oxidative stress (free radicals) is believed to be a cause of ageing (Larsen, 1993). In addition to ageing process, it was suggested that increased ROS levels is an important trigger for insulin resistance in numerous settings and that antioxidant therapy might be a useful strategy in type 2 diabetes and other insulin-resistant states, such as cancer, obesity, and metabolic syndrome (Houstis, Rosen, & Lander, 2006). Glycosidases are hydrolytic enzymes that play a vital role in digestion of carbohydrates and biosynthesis of glycoproteins. Due to the ability to reduce blood glucose level, α-glucosidase inhibition, is one of the currently selected and preferred targets for development of anti-type II diabetes agents. Some inhibitors of this enzyme have been developed as clinical drugs, such as acarbose.

The present research was carried out to investigate the antioxidative (SOD-like) and α-glucosidase inhibitory activity of *C. songaricum* and to elucidate the active components of this herbal medicine. In addition, catechin and two flavan 3-ol dimers were quantified by HPLC–MS, the extractable and non-extractable tannin contents were determined, and the flavan 3-ol components in extracts using three different solvents were compared.

2. Materials and methods

2.1. Plant material

C. songaricum Rupr (Cynomoriaceae) stems were collected in Wulateqianqi, Innermongolia, China, in 1995 and kept in dark at 20–28 °C. Herbarium voucher specimens were deposited at Division of Metabolic Engineering, Institute of Natural Medicine, University of Toyama, Japan.

2.2. Extraction and purification of flavan 3-ols from the stems of *C. songaricum*

The ground powder (passed through a 20-mesh sieve, particle size < 0.853 mm, 200 g) of the stems of *C. songaricum* was extracted

twice, each with 2000 ml of 100% methanol by sonication at room temperature for 30 min. The combined solution was concentrated under vacuum to dryness to obtain 29 g of a methanol extract. The extract was chromatographed on a DIAION-HP20 (Mitsubishi Chemical Corporation, Tokyo, Japan) column (9 × 55 cm) eluted with water followed by methanol. The respective eluates were concentrated under vacuum to obtain 11 g of fraction I from the water eluate and 16 g of fraction II from the methanol eluate. Repeated column chromatograph of fraction II on Sephadex LH-20 (GE Healthcare Bio-Sciences AB, Uppsala, Sweden) and MCI gel CHP20P (Mitsubishi Chemical Corporation, Tokyo, Japan) furnished the flavan-3-ol monomer and oligomers. The flavan-3-ol monomer (**1**) and dimers (**2a** and **2b**) were isolated as pure compounds. The trimers (**3**), tetramers (**4**) and pentamers (**5**) were obtained as mixtures of isomers. The structures of these compounds were determined by comparing their NMR and MS spectral data with reported as described in the literature (Ma et al., 1999).

2.3. Quantification of total tannins in different extracts

The extraction was carried out in sealed centrifuge tubes under sonication for 30 min with an herb to solvent at ratio of 1:20 (w/v). Three solvents [acetone–H_2O (7:3, v/v) or MeOH or H_2O] were used for extraction to yield different extracts. For detection of total tannin contents, 10 mg of the herb powder were suspended in 0.2 ml of MeOH to determine the tannin content directly. Standard catechin was dissolved in MeOH at concentrations of 10, 5, 1 and 0.1 mg/ml.

The tannin contents were determined by *n*-BuOH–HCl–Fe^{III} method (Porter, Hrstich, & Chan, 1986). The reaction was carried out in 1.5 ml centrifuge tubes. To each tube was added 0.2 ml of an extract, 1.2 ml of a solution of *n*-BuOH-conc. HCl (95:5, v/v) and 40 μl of a ferric ammonium sulphate reagent. The reagent was a 2% (w/v) solution of ferric ammonium sulphate dodecahydrate ($NH_4Fe(SO_4)_2{\cdot}12H_2O$) in 2 M HCl. The tubes were capped and clamped with the top clips before the solutions were thoroughly mixed and heated at 95 °C for 40 min. The absorbance of released cyanidin at 560 nm was measured with a TECAN GENios plate reader (Wako, Osaka, Japan). The catechin equivalent was calculated by comparing the absorbance of samples with a concentration–absorbance curve of catechin.

2.4. HPLC–ESI/MS quantification of catechin and the two flavan 3-ol dimers

HPLC–PAD–MS was carried out on an Agilent 1100 system (Agilent Technologies, Waldbronn, Germany) equipped with degasser, binary pump, photodiode array detector and electrospray ionisation spectrometry (ESI, Esquire 3000^{plus}, Bruker Daltonik GmbH, Bremen, Germany). Data were acquired, integrated and analysed using a ChemStation with the software provided by the manufacturer. HPLC separation was performed on COSMOSIL 5C18-MS-II Waters columns (4.6 × 150 mm, Nacalai Tesque, Inc. Kyoto, Japan). The mobile phase containing solvents A and B, where A was water/formic acid (99.9:0.1, v/v) and B was acetonitrile/formic acid (99.9:0.1, v/v). The linear gradient profile was from 4% to 14% B in 10 min, 14–40% B in 6 min, 40–100% B in 1 min and kept at 100% B for 5 min. The flow rate was 1 ml/min for HPLC and 0.2 ml/min for MS detection with a splitter between PAD and MS detectors. ESI–MS was operated in negative mode with scanning range of *m/z* 200–1500 and trap drive of 47.6. High-purity nitrogen (99.99%) was used as dry gas at a flow rate of 9 l/min and temperature of 350 °C. Pure compounds **1**, **2a** and **2b**, in methanol at five concentrations (0.00167, 0.0333, 0.0667, 0.133 and 0.167 mg/ml) were used for the standard curves. Standard curves were plotted by using the areas of compound MS peaks in extract ion chromatograms as Y axis and the concentrations of compounds as X axis. Injection volumes were 10 μl for all compounds and extracts (see Fig. 1).

2.5. Assay for SOD-Like and α-glucosidase inhibitory activity

Superoxide dismutase (SOD)-like activity of the extract, fractions and compounds was evaluated on 96-well plates using a SOD Assay Kit-WST following the procedure provided by the supplier (Dojindo Chemical, Kumamoto, Japan). Briefly, 20 μl of sample solution and 200 μl of WST working solution were mixed in the well. The reaction was initiated by the addition of 20 μl of xanthine oxidase solution and the plates were incubated at 37 °C for 20 min. The absorbance at 450 nm was measured with an InterMed ImmunoReader (Nippon InterMed K.K. Tokyo, Japan) and the SOD-like activity (inhibition rate%) was calculated using the following equation. SOD-like activity (inhibition rate %) = $\{[(A_{\text{blank 1}} - A_{\text{blank 3}}) - (A_{\text{sample}} - A_{\text{blank 2}})]/(A_{\text{blank 1}} - A_{\text{blank 3}})\} \times 100$, where blank 1 contained water in place of sample solution; blank 2 contained buffer in place of enzyme; blank 3 contained water and buffer in place of sample solution and enzyme.

The α-glucosidase inhibitory activity was determined using 4-nitrophenyl α-D-glucopyranoside (purchased from TCI, Tokyo, Japan) in 100 mM potassium phosphate buffer (pH 7.0) as substrate and α-glucosidase from *B. stearothermophilus* as the enzyme. The assay was carried out on 96-well plates and the activities were calculated by the reported method (Ma, Hattori, Daneshtalab, & Wang, 2008).

Table 1
Contents of tannins in the stems of *C. songaricum*.

Sample	Catechin eq (mg)/g Herb	Tannin% of Herb	% of Total Tannin	RSD%
Total tannin	183.3	18.3		16.2
70% Acetone ext	65.0		35.4	3.1
Methanol ext	15.5		8.5	3.2
Water ext	9.6		5.2	8.3

The results are expressed as catechin equivalents.

3. Results and discussion

The *n*-BuOH–HCl–Fe^{III} method revealed that there were 18.3% of total flavan 3-ols (in catechin equivalent), in the stems of *C. songaricum*. Of these, 35.4%, 8.5% and 5.2% could be extracted with 70% acetone, 100% MeOH and 100% H_2O, respectively (Table 1). The contents of catechin and the small flavan-3-ol oligomers were investigated by HPLC–ESI/MS. The results indicated that in 1 g of the herb, there were 65 mg catechin equivalents of flavan 3-ols extractable by 70% acetone (Table 1), amongst which were 0.74 mg of catechin, 0.26 mg of the dimer **2a** and 0.62 mg of the dimer **2b** (Table 2). As there were no standard pure compounds available for the larger oligomers, their absolute contents were not determined, instead, the relative extraction efficiencies of the three solvents for the flavan-3-ols up to tetramers could be obtained by comparing the HPLC peak areas of the oligomers in different extracts. As shown in Fig. 2, extract ion chromatograms of these compounds displayed distinct peaks up to tetramers, and thus the relative contents of these compounds in methanol and water extracts compared to those in 70% acetone extract were summarised in Table 3. The 70% acetone is the best extract solvent for all these compounds. As the molecular weight increased, the extract efficiencies of methanol and water decreased, except for **2a** which was a little more exhaustively extracted with methanol or water than catechin was. For the tetramers, methanol and water could only extract 44.8% and 42.5% of that extracted by 70% acetone, respectively.

The antioxidative activities of the extract, fractions, isolated flavan-3-ol monomer and oligomers were evaluated as SOD-like activity using a SOD Assay Kit-WST. WST-1 produces a water-soluble formazan upon reduction with superoxide anion. The reduction rate is linearly related to the xanthine oxidase (XO) activity, and is inhibited by SOD or other antioxidative compounds. Therefore, the inhibition activity of the compounds can be determined by colorimetric measurement of the formazan dye. The activity was expressed as IC_{50} representing the concentration that inhibited the formation of WST-1 formazan by 50%. As shown in Table 4, the methanol extract of *C. songaricum* showed potent SOD-like activity (as methanol is a good solvent to extract not only tannins but also other constituents of plants, we used methanol for the activity guided fractionation). The methanol extract was fractionated to two fractions by DIAION-HP20 column chromatography. More potent activity was observed on Fraction II, from which flavan-3-ol monomer (**1**) and oligomers (**2a**, **2b** and **3**–**5**) were isolated. Flavan-3-ol monomer and oligomers noted showed significant SOD-like activity, with the IC_{50} of the oligomers being equal or lower than 0.01 μg/ml. Of the isolated compounds, the

Dimer (**2b**)	0.010	430
Trimers (**3**)	0.009	90
Tetramers (**4**)	0.010	70
Pentamers (**5**)	0.007	30

IC_{50}: concentration that inhibited the formation of WST-1 formazan by 50% using a SOD Assay Kit-WST.
IC_{50g}: concentration that inhibited α-glucosidase activity by 50%.

most potent antioxidative activity belonged to one of the dimers, compound **2a**, with an IC_{50} of 0.006 μg/ml.

The α-glucosidase inhibitory activity was determined with 4-nitrophenyl α-D-glucopyranoside as substrate and the α-glucosidase from *B. stearothermophilus* as enzyme. The absorbance of released 4-nitrophenol at 405 nm was measured and the results were represented as IC_{50g}, the concentration at which 50% of α-glucosidase activity was inhibited. As shown in Table 4, the methanol extract of *C. songaricum* and the tannin-rich fraction (fraction II) showed moderate α-glucosidase inhibitory activity. Of the isolated flavan-3-ol monomer and oligomers, the α-glucosidase inhibitory activity increased as the molecular weight increased with a significant difference (32 times) in the potency between the strongest ones (pentamers) (Ma et al., 1999) and the weakest one (monomer). The strongest compounds (pentamers) showed an IC_{50} of 30 μg/ml.

Flavan-3-ol oligomers and polymers are known as condensed tannins and had been considered as antinutrients to herbivores and life stocks. However, in recent years, it has been proposed that some antinutrients, such as tannins may possess beneficial health effects and the mechanism by which the antinutritional and beneficial effects of food antinutrients operate are the same (Shahidi, 1997b). Tannins particularly those with smaller molecular weights (around 1000 or smaller) may show significant therapeutic and pharmaceutical potential for diseases in modern society that are associated with fundamental changes in nutrition and lifestyle (Ren & Chen, 2007). The present results that *C. songaricum* possessed potent SOD-like activity and moderate α-glucosidase inhibitory activity may suggest the use of this herbal medicine for the lifestyle-related diseases such as type II diabetes. The results also showed that *C. songaricum* is a rich source of condensed tannins and amongst the three solvents, 70% acetone is significantly better than MeOH and H_2O in extraction of these compounds, especially of relatively larger tannin oligomers. The result is consistent with the report in literature that 70–80% acetone is the best extract solvent for tannins (Naczk, Pegg, Zadernowski, & Shahidi, 2005).

Phenolic rich fractions
Monechma ciliatum
Prunus mahaleb

ABSTRACT

The antioxidant activities of phenolic rich fractions (PRFs) from crude methanolic extract (CME), and its fractions using ethyl acetate (EAF), hexane (HF) and water (WF) of black mahlab (*Monechma ciliatum*) and white mahlab (*Prunus mahaleb*) seedcakes were investigated. The total phenolic compounds were found to be higher in white mahlab than black mahlab seedcakes. The antioxidant activity determined by the DPPH method revealed that black mahlab PRFs had the highest antioxidant activity, compared to white mahlab fractions. The presence of antioxidants in the two mahlab PRFs reduced the oxidation of β-carotene by hydroperoxides from these extracts/fractions. The effect of the two mahlab PRFs on the oxidative stability of corn oil at 70 °C was tested in the dark and compared with butylated hydroxyanisole (BHA). The CME performed better antioxidant activity in inhibiting the formation of both primary and secondary oxidation products. The qualitative and quantitative characterisation of phenolic compounds was carried out by HPLC/DAD.

1. Introduction

There is increasing evidence that consumption of a variety of phenolic compounds present in natural foods may lower the risk of serious health disorders because of the antioxidant activity of these compounds (Hertog, Feskens, Hollman, Katan, & Kromhout, 1993; Surh, 2002; Surh et al., 1999). When added to foods, antioxidants minimise rancidity, retard the formation of toxic oxidation products, maintain nutritional quality, and increase shelf life (Jadhav, Nimbalkar, Kulkarni, & Madhavi, 1996). The antioxidant activity of extracts of several plants, including their leaves, bark, roots (Mariod, Matthaus, & Hussein, 2008), fruits, seeds (Liyana-Pathirana & Shahidi, 2006; Malencic, Maksimovic, Popovic, & Miladinovic, 2008) and seedcake (Mariod, Matthaüs, Eichner, & Hussein, 2006; Matthaüs 2002) has been extensively studied. Tocopherol, tertiary-butylhydroquinone (TBHQ), butylated hydroxytoluene (BHT) and butylated hydroxyanisole (BHA) are the most commonly used primary antioxidant in oils. However, many researchers reported the adverse effects of synthetic antioxidants such as toxicity and carcinogenicity (Williams, Iatropoulos, & Whysner, 1999). Due to safety and limitation of synthetic antioxidant usage, natural antioxidants obtained from edible materials, edible by-products and residual sources have become alternately interesting (Moure et al., 2000).

Edible fats and oils, such as vegetable oils or lard, are usually used as substrates for evaluating the antioxidant activity from natural sources (Duh & Yen, 1997). Hydroperoxides are the primary products of lipid oxidation, and their content (i.e. peroxide value, PV) is often used as an indicator for the initial stages of oxidation. In the same time hydroperoxides decompose rapidly during storage. For these reasons, PV may not necessarily be indicative of the actual extent of lipid oxidation (Sherwin, 1978). The anisidine value is a more meaningful test for the assessment of the oils quality during heating than the peroxide value, because it measures aldehydes, which are formed as secondary products of oxidation reactions. These compounds are less easily destroyed under these conditions (Pantzaris, 1999).

Monechma ciliatum, family Acanthaceae is an annual glabrous herb, 30–65 cm high, known in Sudan as black mahlab, where the seeds are used as flavouring material in different food products e.g. Kisra (traditional fermented sorghum flour sheets) and bread. The seeds also used as an effective laxative, and contain a fixed oil which emits a sweet and pleasant odor. It's further used in traditional Sudanese fragrances, lotion and other cosmetics used for wedding preparation and childbirth (Sharief, 2002). *M. ciliatum* was used in remedy of general body pain, liver, cold, diarrhea and sterility in women and its leaves methanolic extract showed oxytocic property in vivo and in vitro (Ayoub & Babiker, 1981;

Uguru, Okwuasaba, Ekwenchi, & Uguru, 1995). White mahlab (*Prunus mahaleb)* known as: English cherry, Rock cherry, St. Lucie cherry (in English) family Rosaceae is a deciduous tree, 1–2 m high. The kernels form an important source of protein (30.98%) and oil (40.40%). Its oil is valuable in the preparation of lacquers and varnishes; it contains little cyanogenic glycosides and coumarin derivatives (Aydin, Ogut, & Konak, 2002). In Sudan the kernels are used as a flavouring material in bread, as cosmetic in wedding preparation, and in remedy of diarrhoea in children.

High performance liquid chromatography (HPLC) with diode array detection (DAD) is an indispensable tool for the provisional identification of the main phenolic structures present in foods (Chirinos et al., 2009).

To the best of our knowledge this is the first report on polyphenol contents and antioxidant activity of the seedcakes of black and white mahlab. Hence, the aim of this study was to study and determine the total phenolic content (TPC) and antioxidant activities (AOA) of black and white mahlab seedcakes and their effect on the oxidation of corn oil. The different phenolic rich fractions (PRF) were applied to corn oil at levels of 0.25% and 0.5% to examine their antioxidative activity; the development of the peroxide conjugated diene, TBARS and anisidine values during oxidation of corn oil were evaluated at 70 °C for 72 h.

2. Materials and methods

2.1. Sample material, standards and reagents

All solvents used were of HPLC grade. Methanol, ethyl acetate, hexane, chloroform, butylated hydroxyanisole (BHA), β-carotene, linoleic acid and Folin–Ciocalteau reagent as well as polyoxyethylene sorbitan monopalmitate (Tween 40) were obtained from Merck (Merck, Darmstadt, Germany). Ferulic acid, chlorogenic acid *p*-coumaric acid, 3,4-dihydroxybenzoic acid, (−)-epicatechin and (+)-catechin, and syringic acid were obtained from Sigma–Aldrich (Hamburg, Germany), gallic acid and vanillin were obtained from Fluka Chemie AG (Buchs, Switzerland). The pure flavonoid compound quercetin was obtained from Extrasynthese (Genay Cedex, France).

Black and white mahlab seeds were obtained from a local store at Khartoum North, Sudan. The seeds were cleaned under running tap water for 10 min, rinsed twice with distilled water and air-dried in oven at 40 °C for overnight. The seeds were grinded to powder using an electric grinder (National, Model MX-915, Kadoma, Osaka, Japan) for 10 min and then passed through a 35 mm (42 mesh) sieve. The cakes were obtained after oils were extracted from the ground seeds by extraction with *n*-hexane (b.p. 50–60 °C) using Soxhlet apparatus for 6 h following the AOCS (1993) method Aa 4-38 and the obtained seedcakes were used to extract phenolic compounds.

2.2. Corn oil

The refined edible corn oil which was produced by Lam Soon edible oil Co. Ltd., Shah Alam, Selangor, Malaysia was obtained from local store Serdang Malaysia; the oil was free of any synthetic antioxidant.

2.3. Extraction of phenolic compounds

Twenty grams of the dried ground seedcakes from black and white mahlab were extracted with 80% methanol by sonication (Hwasin Technology, Seoul, Korea) to obtained crude methanolic extract (CME) with solid to solvent ratio of 1:10 (w/v) at room temperature for 1 h, the obtained CME was fractionated using the following solvent namely; hexane, ethyl acetate and water. Each extraction process involved homogenisation of CME and its fractions and solvent at 13000 rpm for 15 min followed by sonication (Hwasin Technology, Seoul, Korea) at constant temperature of 30 °C for 1 h. The CME and its fractions (hexane fraction, HF; ethyl acetate fraction, EAF; water fraction, WF) were filtered through filter paper Whatman no. 1. Then solvents were removed by using rotary evaporator (Buchi, Flawil, Switzerland). The yield of each extract and its fractions was measured before kept in −80 °C for further analysis.

2.4. Determination of total phenolic compounds (TPC) in black and white mahlab seedcakes

The total phenolic (TPC) contents of each extracts/fractions were determined using the Folin–Ciocalteu reagent (Zhou & Yu, 2006). The reaction mixture contained 1 ml of CME and each individual fraction, 0.5 ml of the Folin–Ciocalteu reagent, 3 ml of 20% sodium carbonate and 10 ml of distilled water. After 2 h of reaction at ambient temperature, the absorbance at 765 nm was measured using spectrophotometer (Shimazu Co. Ltd., Kyoto, Japan) and used to calculate the phenolic contents, using gallic acid as a standard. The total phenolic contents were then expressed as gallic acid equivalents (GAE), in mg/g dry sample.

2.5. Antioxidant activities (AOA) measurement

The antioxidant activities (AOA) of CME and its fractions of black and white mahlab seedcakes were addressed using the following methods.

2.5.1. 1,1-Diphenyl-2-picrylhydrazyl (DPPH) radical scavenging activity test

The hydrogen atom or electron-donation ability of the corresponding extracts/fractions was measured from the bleaching of a purple-coloured methanol solution of DPPH. The antioxidant activity of the extracts/fractions, on the basis of the scavenging activity of the stable 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical, was determined by the method described by Gordon, Paiva-Martins, and Almeida (2001). A methanolic solution (100 μl) of the extracts/fractions was placed in a cuvette and 0.5 ml of a methanolic solution of DPPH (50 mg DPPH/100 ml MeOH) was added. After 30 min absorbance at 515 nm was determined using a spectrophotometer (Shimadzu Co. Ltd., Kyoto, Japan), and IC_{50}, was reported which is the concentration of antioxidant required for 50% scavenging of DPPH radicals in the specified time period. All determinations were performed in triplicate.

2.5.2. The β-carotene–linoleic acid assay

The antioxidant activity (AOA) of the different extracts/fractions was evaluated using the β-carotene–linoleic acid assay following the method of Amarowicz, Wanasundara, Wanasundara, and Shahidi (1993). In brief, a solution of β-carotene was prepared by dissolving 2 mg of β-carotene in 10 ml of chloroform. Two millilitres of this solution were pipetted into a 100 ml round-bottom flask. After chloroform was removed under vacuum, using a rotary evaporator at 40 °C, 40 mg of purified linoleic acid, 400 mg of Tween 40 as an emulsifier, and 100 ml of aerated distilled water were added to the flask with vigorous shaking. Aliquots (4.8 ml) of this emulsion were transferred into a series of tubes containing 200 μl of the extract (200 ppm in methanol). The total volume of the systems was adjusted to 5 ml with methanol. As soon as the emulsion was added to each tube, the zero time absorbance was measured at 470 nm with a Shimadzu spectrophotometer (Shimadzu Co. Ltd., Kyoto, Japan). Subsequent absorbance readings were recorded over a 2 h period at 20 min intervals by keeping the samples in a water

bath at 50 °C. Blank samples, devoid of β-carotene, were prepared for background subtraction.

2.5.3. Stability of corn oil as affected by the addition of different extracts/fractions from black and white mahlab seedcakes

Commercial edible corn oil was obtained from local market. It contained no added antioxidants originally. The dried extracts/fractions or BHA were mixed with a minimum amount of absolute methanol in an ultrasonic water bath (Hwasin Technology, Seoul, Korea) then applied directly to the oil samples at levels of 0.25% and 0.5% before the accelerated tests, and samples with no added antioxidants were kept as a control (Moure et al., 2000). The oxidative stability of storage oil (at 70 °C for 72 h) was evaluated by measuring the absorbance at 270 and 234 nm, and by determining the peroxide value (PV), conjugated diene (CD), thiobarbituric acid reactive substances (TBARS) and *p*-anisidine values (as indicators for the primary and secondary oxidation of the corn oil) following the method of AOCS (1993). The PVs, CD, TBARS and AVs were determined every 0, 6, 12, 24, 36, 48 and 72 h. All treatments were carried out three times. For the UV absorbance, 10 ml of each sample was mixed with 10 ml of isooctane, and the absorbance was followed at 234 and 270 nm using cells of 1 cm (Roussis, Tzimas, & Soulti, 2008). Pure isooctane was used as a reference. The conjugated diene values were calculated according to the equation below.

$$\text{CD value} = A/(C \times l)$$ (Shahidi, Desilva, & Amarowicz, 2003)

where CD = conjugated diene; A = absorbance at 234 nm; C = concentration (g/100 ml); and 1 = path length (cm).

TBARS test. Each sample (200 mg) was weighed into a 25-ml volumetric flask. It was then made up to the mark with 1-butanol (ACS grade) and mixed thoroughly. A 5-ml portion of this solution was transferred into a dry test tube, and a 5-ml quantity of fresh TBA reagent (200 mg TBA in 100 ml 1-butanol) was added to it. The tube was placed in a 95 °C water bath for 120 min. The tube was cooled, and the absorbance of the solution was read at 532 nm. The TBARS value was calculated as follows:

$$\text{TBARS value} = (A \times 0.415)/m$$ (Shahidi et al., 2003)

where A = absorbance at 532 nm and m = mass of the sample.

2.6. HPLC–DAD system for analysis of phenolic compounds

HPLC analysis was performed using Agilent G1310A pumps (Agilent, Stevens Creek Blvd. Santa Clara, CA, USA), with diode array detector and chromatographic separations were performed on a LUNA C-18 column (5 μm, 250 × 4.6 mm) (Phenomenex, Torrance, California, USA). The composition of solvents and used gradient elution conditions were described previously by Chirinos et al. (2009) with some modifications. The mobile phase was composed of solvent (A) water–acetic acid (94:6, v/v, pH 2.27) and solvent (B) acetonitrile. The solvent gradient was as follows: 0–15% B in 40 min, 15–45% B in 40 min, and 45–100% B in 10 min. A flow rate of 0.5 ml/min was used and 20 μl of sample were injected. Samples and mobile phases were filtered through a 0.22 μm Millipore filter, type GV (Millipore, Bedford, MA, USA) prior to HPLC injection. Each fraction was analysed in duplicate. Phenolic compounds were identified and quantified by comparing their retention time and UV–Vis spectral data to known previously injected standards (Chirinos et al., 2009).

2.7. Statistical analyses

Statistical analyses were conducted using SPSS (Statistical Program for Social Sciences, SPSS Corporation, Chicago, IL) version 12.0 for Windows. Analysis of variance (ANOVA) in a completely randomised design, Duncan's multiple range test and Pearson's correlation coefficients were performed to compare the data. All determinations were done at least in triplicate and all were averaged. The confidence limits used in this study were based on 95% ($P < 0.05$).

3. Results and discussion

3.1. Amount of extractable compounds vs extractable phenolic compounds

The results of using different solvents for the extraction/fractionation of phenolic compounds are given in Table 1. From this table it is clear that the different solvents had different abilities to extract substances from these seedcakes. In general, the amount of total extractable compounds decreased with decreasing polarity of the solvent in the order water, methanol, ethyl acetate and hexane. The extraction of phenolic compounds from mahlab seedcakes with water was found most effective. With this solvent, the highest amount of TEC was found to be 810.1 and 698.2 mg/g followed by CME 201.6, 185.8 mg/g, EA 107.6, 159.9 and hexane 85.9, 140.8 mg/g in black and white mahlab seedcake, respectively. The extraction with hexane showed the lowest TEC (85.9 and 140.8 mg/g, respectively) in comparison with that of the other solvents. The TEC were significantly different between the two mahlab seedcakes as well as between extracts/fractions ($P < 0.05$). These findings are in good agreement with that of Matthaüs (2002) who found that extraction with water gave the highest amounts of phenolic compounds from fat-free residues of different oilseeds.

Table 1
Total extractable compounds (TEC), total phenolic compounds (TPC), IC_{50} of different extracts/fractions obtained from seedcakes of black and white mahlab seeds.

Extraction	TEC (mg/g)	TPC (mg GAE/g extract/fraction)	TPC/TEC (%)	IC_{50} (μg/ml)
Black mahleb				
CME	201.6 ± 0.5	17.1 ± 0.04	8.5	0.460 ± 0.1
HF	85.9 ± 0.4	6.7 ± 0.02	7.8	0.648 ± 0.2
EAF	107.6 ± 0.2	26.3 ± 0.1	24.4	0.413 ± 0.1
WF	810.1 ± 0.6	9.9 ± 0.02	1.2	0.525 ± 0.3
Ascorbic acid				0.017 ± 0.01
White mahleb				
CME	185.8 ± 0.4	71.9 ± 0.31	38.7	2.942 ± 0.4
HF	140.8 ± 0.2	53.1 ± 0.41	37.7	5.563 ± 0.1
EAF	159.9 ± 0.3	72.9 ± 0.35	45.5	5.201 ± 0.2
WF	698.2 ± 0.6	65.7 ± 0.21	9.4	5.091 ± 0.2
Ascorbic acid				0.017 ± 0.01

3.2. Total phenolic compounds (TPC)

The content of the total phenolic compounds of CME and its different fractions (HF, EAF and WF) from black and white mahlab seedcakes determined using Folin–Ciocalteau method is shown in Table 1. Results in this table show that EAF in both black and white mahlab contained the highest amount of total phenolic compounds followed by CME, WF, and HF, respectively. Ethyl acetate is often used as an extraction solvent with a significant selectivity in the extraction of low-molecular-weight phenolic compounds and high-molecular-weight polyphenols (Scholz & Rimpler, 1989). The percentages of total phenolics that found in the TEC were significantly ($P < 0.05$) higher in all white mahlab fractions in comparison with that of black mahlab. The percentage of total phenolic compounds to the total extractable compounds ranged from 9.4% to 45.5% in white mahlab and from 1.2% to 24.4% in black mahlab (Table 1). From these results it can be understood that in white mahlab more than 50% of the extractable materials were compounds other than phenolic compounds. While in black mahlab more than 75% of the extractable materials were compounds other

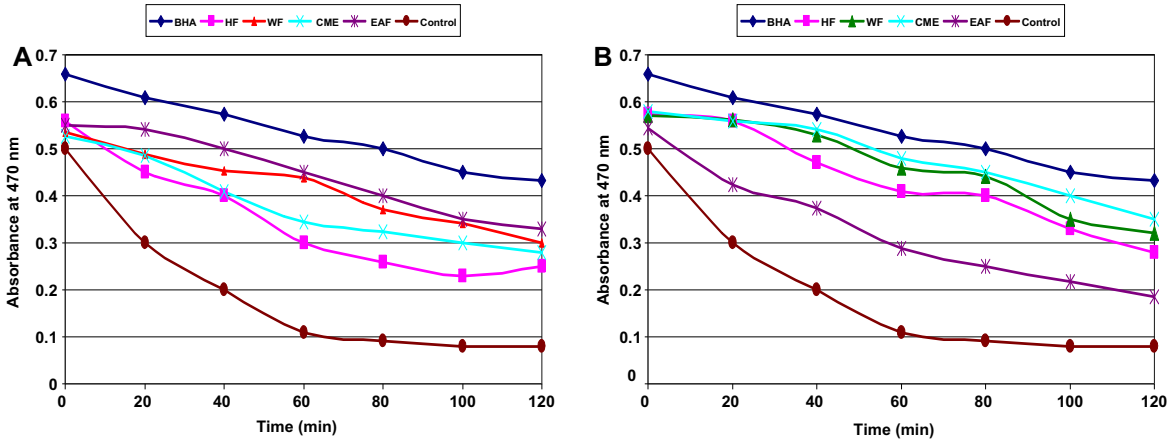

Fig. 1. Effect of black (A) and white (B) mahlab extract/fractions on oxidation of β-carotene/linoleic acid at 50 °C. BHA: butylated hydroxyanisole, HF: hexane fraction, WF: water fraction, CME: crude methanolic extract, EAF: ethyl acetate fraction.

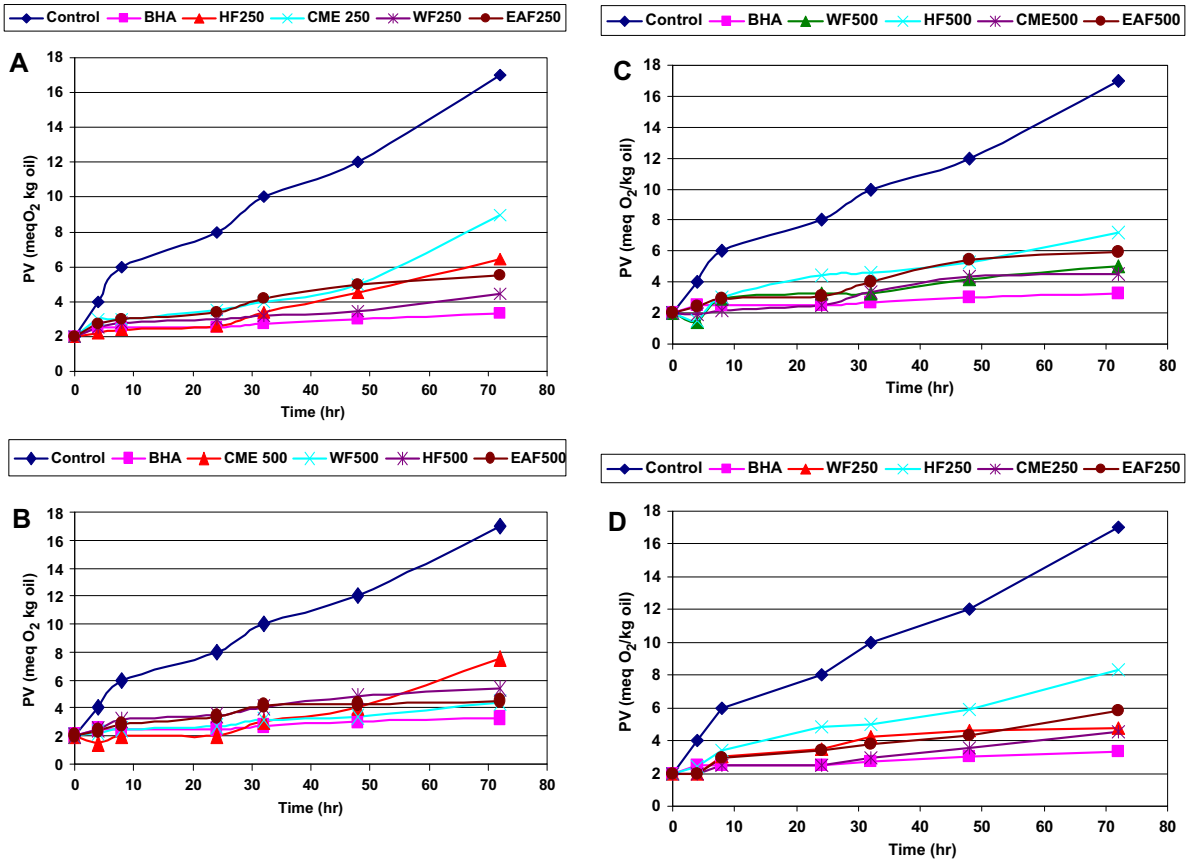

Fig. 2. Oxidation of corn oil treated with black mahlab (A, B) and white mahlab (C, D) CME and its fractions 250 and 500 mg /100 g oil during storage at 70 °C. BHA: butylated hydroxyanisole, HF: hexane fraction, WF: water fraction, CME: crude methanolic extract, EAF: ethyl acetate fraction.

than phenolic compounds. It becomes clear that the total phenolic compound was not related to the total extractable compounds. There was no significant correlation between the amount of total extractable compounds and the total phenolic compounds ($P < 0.05$). The extraction solvents influenced the amount of total phenolic compounds.

3.3. 1,1-Diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activity test

The DPPH scavenging activities of different extracts/fractions of black and white mahlab seedcakes are shown in Table 1. The DPPH radical scavenging capacity assay was used to examine the antioxidant activity of black and white mahlab seedcakes extracts/fractions. The extracts/fractions were assayed over a range of dilutions to establish the concentration of each extract/fraction required to scavenge 50% of the DPPH radical present in the assay medium, referred to as the IC_{50} defined as the concentration of the antioxidant needed to scavenge 50% of DPPH present in the test solution. Lower IC_{50} value reflects better DPPH radical scavenging activity (Molyneux, 2004). Under the assay conditions employed here, the IC_{50} of ascorbic acid as standard was 0.017 μg/ml, between the extract/fractions of black mahlab seedcake EAF possessed greater DPPH radical scavenging activity with the lowest IC_{50} value of 0.413 μg/ml. DPPH scavenging activity of black mahlab seedcake extract/fractions increased in the order of ascorbic acid > EAF > CME > WF > HF. Among the extract/fractions of white mahlab seedcake, CME showed the greatest DPPH-scavenging activity with IC_{50} values of 2.94 μg/ml, followed by WF, EAF and HF, respectively, with IC_{50} of 5.091, 5.201 and 5.563 μg/ml, respectively (Table 1). In general, the black mahlab CME and its fractions showed higher DPPH radical scavenging activity ($P < 0.05$) than that of white mahlab, from Table 1 it can be said that, no significant correlation found between total phenolic content (TPC) and DPPH assay of black and white mahlab seedcake extract/fractions. Malencic et al. (2008) found that antioxidant activity of soya bean seed extracts increased proportionally to the polyphenol content with a linear relationship between DPPH values and total polyphenol. At the same time, they found that, there was no positive correlation between DPPH values and flavonoid content.

3.4. β-Carotene bleaching (BCB) assay

In the BCB assay, the oxidation of linoleic acid generates peroxyl free radicals due to the abstraction of hydrogen atom from diallylic methylene groups of linoleic acid (Kumaran & Karunakaran, 2006). The free radical then will oxidise the highly unsaturated β-carotene. The presence of antioxidants in the extract will minimise the oxidation of β-carotene by hydroperoxides. Hydroperoxides formed in this system will be decomposed by the antioxidants from the extracts. Thus, the degradation rate of β-carotene depends on the antioxidant activity of the extracts. Most studies showed there was no correlation between TPC and BCB (Amarowicz et al., 1993; Mariod et al., 2006; Matthaüs, 2002).

Effect of black mahlab extracts/fractions (CME, HF, WF and EAF) on oxidation of β-carotene/linoleic acid at 50 °C is shown in Fig. 1A. It was clear that the presence of antioxidants in the mahlab seedcakes extracts/fractions reduced the oxidation of β-carotene by hydroperoxides from these extracts/fractions. There were significant differences ($P < 0.05$) between the different extracts/fractions, control and BHA effect as shown in Fig. 1A. EAF, WF fractions were better in their effect on reducing the oxidation of β-carotene than

Table 2
Comparative inhibition of edible corn oil oxidation at 234 nm, 270 nm, *p*-anisidine and TBARS value by black mahlab seedcake phenolic rich fractions at 250 mg/100 g oil.

HF: hexane fraction, WF: water fraction, CME: crude methanolic extract, EAF: ethyl acetate fraction.
* Means in every row without a common superscript differ significantly at $P < 0.05$. BHA, butylated hydroxyanisol.

CME and HF fractions, and that their degradation rate of β-carotene clearly depends on their antioxidant activity. There was a correlation between the degradation rate and the bleaching of β-carotene; where the extract with the lowest β-carotene degradation rate exhibited the highest antioxidant activity. All extracts had a lower antioxidant activity than BHA (Fig. 1A).

Effect of white mahlab extracts/fractions (CME, HF, WF and EAF) on oxidation of β-carotene/linoleic acid at 50 °C is shown in Fig. 1B. The antioxidant activity of these extract/fractions was confirmed by this assay. β-Carotene molecules were protected by the extract/fraction to be bleached by linoleic acid. There is a significant difference ($P > 0.05$) between anti-bleaching effects of extract/fractions and positive control, BHA. From Fig. 1B the antioxidant activity of white mahlab extract/fractions reduces the oxidation of β-carotene in the order of CME, WF, HF and EAF, as CME exhibited the highest antioxidant activity.

3.5. Stability of corn oil as affected by the addition of different extracts/fractions from black and white mahlab seedcakes

Since the PRFs were effective as an antioxidant mixture in an emulsion (β-carotene–linoleate) and in DPPH, the next step was to test the activity of both the extracts/fractions in corn oil under accelerated conditions. Similar accelerated storage tests have been used by other authors to evaluate the efficacy of antioxidants (Shahidi et al., 2003; Mariod et al., 2006, 2008). Increasing primary and secondary lipid peroxidation products of corn oil during storage was measured by peroxide value and conjugated dienes (primary) and *p*-anisidine and TBARS values (secondary), during storage for the antioxidative effect of phenolic rich fractions from black and white mahlab seedcake. The effect of black and white mahlab extracts/fractions and BHA on oil oxidation measured by peroxide value is shown in Fig. 2A–D. From these figures the PV of corn oil (control) with and without black and white mahlab extracts/fractions (CME, HF, WF and EAF) added as 250, 500 mg/100 g oil or BHA (200 ppm), showed a gradual increase. As demonstrated in these figures a maximum PV of 17.5 meq O_2/kg was reached after 72 h of storage in the control without addition of extract or BHA. Significant differences ($P < 0.05$) were found between the control and CME, HF, WF and EAF or BHA, which decreased and slowed down the rate of peroxide formation, resulting in lower PVs after 72 h of storage at 70 °C. The PVs of corn oil containing WF, and EAF fractions from black mahlab were found to be less (more effective) than HF, and CME fractions (Fig. 2A and B) and all the fractions from black and white mahlab seedcakes were found to be less effective than the synthetic antioxidant. Using black and white mahlab seedcakes as natural antioxidants to prevent oxidation of corn oil in the rate of 250 mg/kg oil seem to be better and more effective and of course economically than using 500 mg (peroxide value data of black and white mahlab seedcakes extracts/fractions added as 500 mg/100 g was not shown).

Phenolic rich fractions from black and white mahlab seedcakes were tested as inhibitor of edible corn oil oxidation at 70 °C (Tables 2 and 3). The *A* 234 nm (conjugated dienes), *A* 270 nm, TBARS and *p*-anisidine values were monitored. All PRFs at 250 mg/100 g oil appeared to be strong inhibitors of corn oil oxidation. The most active fraction in both black and white mahlab was CME which exhibited an antioxidant activity seem to be similar to BHA at 200 mg/kg, the other three fractions (HF, EAF and WF) exhibited antioxidant activity lower than that of BHA. The antioxidant activity of black and white mahlab seedcakes PRFs was significantly different ($P < 0.05$). From the above studied results it was clear that

Table 3
Comparative inhibition of edible corn oil oxidation at 234 nm, 270 nm, *p*-anisidine value, and TBARS value by white mahlab seedcake phenolic rich fractions at 250 mg/100 g oil.

HF: hexane fraction, WF: water fraction, CME: crude methanolic extract, EAF: ethyl acetate fraction.

PRFs obtained from black and white mahlab seedcakes extracted by different solvents seem to be a good source of natural antioxidants that can be used to inhibit edible corn oil oxidation and these results were in agreement with different authors (Shahidi et al., 2003; Mariod et al., 2006, 2008; Roussis et al., 2008) who studied different extracts from different sources to be used as inhibitor of edible oil oxidation. Anisidine values of corn oil without black and white mahlab seedcakes extracts/fractions was rapidly increased ($P > 0.05$) to 6.94 after 72 h of storage and it was also significantly different to the other groups (BHA, HF, EAF, CME and WF) after the same period of storage, while corn oil containing 0.25% (w/w) of black and white mahlab seedcake extracts/fractions differed significantly from corn oil with 0.02% BHA after the 72 h storage at 70 °C (Tables 2 and 3). Addition of black and white mahlab extracts/fractions and BHA to corn oil had a significant ($P < 0.05$) effect on reducing TBARS formation as compared with the control sample in the following order: BHA > CME > HF > EAF > WF. CME was the strongest antioxidant among the PRFs tested.

3.6. Identification of phenolic compounds using HPLC–DAD

To know what is/are the responsible active ingredient(s) in black and white mahlab extracts/fractions, HPLC–DAD was used. Of the four solvent extracts, methanolic extracts exhibited high yield, and antioxidant activity (high in TPC and better AOA). Therefore, methanolic extract was used for further investigations towards identification by HPLC–DAD. The HPLC–DAD analysis of black and white mahlab seedcakes extracts revealed the presence of phenolic compounds. By this means, the crude methanolic extracts CME in the two samples were analysed. Fig. 3A and B shows a representative chromatogram of the CME of white and black mahlab seedcake PRFs, respectively, monitored at 280 nm. (+)-catechin, chlorogenic, hydroxybenzoic, *p*-cumeric and syringic acids were detected. These compounds have been identified according to their retention time and the spectral characteristics of their peaks compared to those of standards in Fig. 3C, as well as by spiking the sample with standards. Hydroxybenzoic acid was detected to be the major phenolic component in the two samples (white and black mahlab seedcake), contributing about 91.3% and 82.1% to the total amount, respectively, and showing the levels of 14.530 and 11.091 mg/100 g dry weight (DW) in CME of white and black mahlab, respectively. (+)-catechin, *p*-cumeric and syringic acid were also predominant in CME of white mahlab seedcake and showing the levels of 1.018, 0.234 and 0.125 mg/100 g DW, respectively. While in CME of black mahlab seedcake chlorogenic, (+)-catechin, and *p*-cumeric acid were the predominant phenolics showing the levels of 1.038, 0.885, and 0.404 mg/100 g DW, respectively. Results demonstrated that differences in CME of white and black

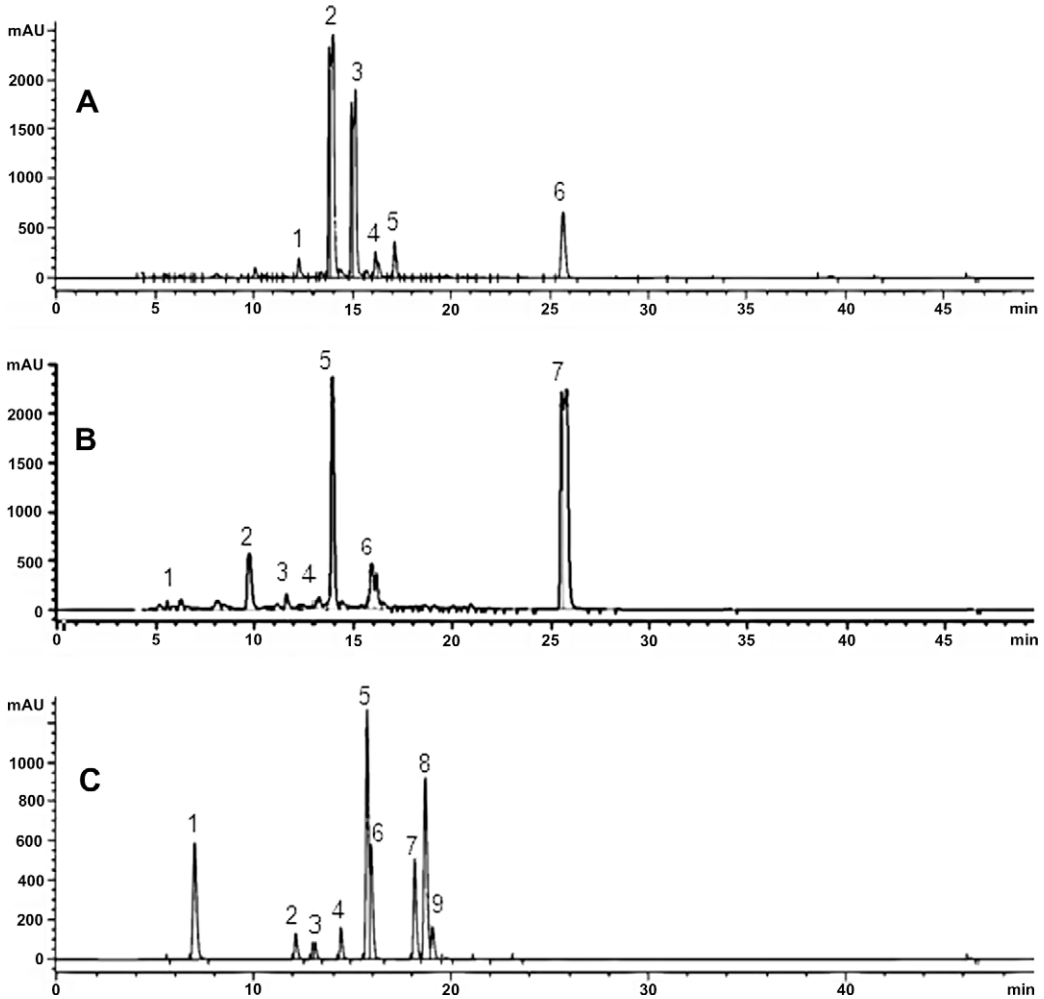

Fig. 3. (A) HPLC–DAD chromatogram of phenoilc compounds in white mahlab CME. Detection was at 280 nm. Peak: (1) (+)-catechin, (2) hydroxybenzoic acid (3) syringic acid, (4) *p*-cumeric (5) unknown, (6) unknown. (B) HPLC–DAD chromatogram of phenoilc compounds in black mahlab CME. Detection was at 280 nm. Peak: (1) gallic caid, (2) unknown, (3) (+)-catechin, (4) chlorogenic acid, (5) hydroxybenzoic acid, (6) *p*-cumeric, (7) unknown. (C) HPLC–DAD representative chromatogram of standards of phenolic acids recorded at 280 nm. Peak: (1) gallic caid, (2) (+)-catechin, (3) chlorogenic acid, (4) hydroxybenzoic acid, (5) syringic acid, (6) *p*-cumeric (7) vanillin, (8) ferulic (9) quercetin.

mahlab seedcake phenolic composition were significantly quantitative and qualitative, where white mahlab showed higher amounts in hydroxybenzoic and catechin than black mahlab. While, black mahlab seedcake contains chlorogenic acid which was not found in white mahlab seedcake. The levels of total phenolic compounds in CME of white and black mahlab determined by HPLC were 0.159 and 0.135 mg/g DW, respectively, and thus lesser than (71.9 and 17.1 mg/g) the ones obtained by the Folin–Ciocalteu method. This result is predictable due to the weak selectivity of the Folin–Ciocalteu reagent, as it reacts positively with different antioxidant compounds (phenolic and non-phenolic substances). The WF, EAF and HF fractions of black and white mahlab seedcake also presented some phenolic compounds with less area (data not shown). Previous studies reported that phenolic compounds such as hydroxybenzoic, syringic and *p*-cumeric containing significant antioxidant activities (Zhang, Liao, Moore, Wua, & Wang, 2009). The above mentioned HPLC–DAD results indicate that such phenolic rich fractions from black and white mahlab seedcake may inhibit the oxidation of corn oil. Isolation and characterisation of such PRFs may be useful in developing natural antioxidants.

4. Conclusions

This investigation shows that the peroxide, CD, TBARS and *p*-anisidine values were reliable methods that can be used to determine the lipid peroxidation in corn oil, containing various concentrations of black and white mahlab phenolic rich fractions (PRFs). Therefore, these PRFs can provide potential sources of natural antioxidants for inhibition of lipid oxidation. Six different individual phenolic compounds were identified in the studied samples by HPLC–DAD. All of the obtained results show that the black and white mahlab seedcakes extracts/fractions can be used as an easily accessible source of natural antioxidants and as a possible food supplement mainly in edible oils. Further studies in isolation of phenolic compounds using HPLC, GC/MS in mahlab seedcakes, and effects of these phenolics on antioxidant status in animal models are needed to evaluate their potential benefits.

Acknowledgements

The first author is grateful to IBS/UPM for the senior research fellowship granted during the period of this work. We thank Siti Muskinah, Laboratory of Molecular Biomedicine IBS/UPM for analysis in HPLC–DAD equipment and excellent technical expertise needed for this work. This study was funded by Intensifying Research Priority Areas (IRPA) grants provided by Government of Malaysia and Universiti Putra Malaysia.

ABSTRACT

Relation between isoflavones production and antioxidant activity in *Psoralea corylifolia* cell cultures was studied. High performance liquid chromatography analysis revealed that root-derived callus cultures produced maximum amount of daidzein whereas genistein by leaf-derived callus. Cell cultures grown under continuous illumination (40-μmol m^{-2} s^{-1}) produced several-fold more isoflavones daidzein (2.28% dry wt) and genistein (0.21% dry wt) than that of field grown plants. The antioxidant activity of extracts was determined using 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging assay, phosphomolybdenum assay and correlated with the content of total phenolics in the extracts. Calli grown under continuous illumination exhibited strong antioxidant activities compared to dark grown callus cultures and explants materials.

1. Introduction

Psoralea corylifolia L. (Fabaceae) is a rich source of isoflavones daidzein (4′,7-dihydroxyisoflavone) and genistein (4′,5,7 trihydroxyisoflavone). In view of the action of natural dietary estrogens, they are recognised as potentially health-protective food compounds (neutraceuticals), which provide health benefits, including the prevention of sex hormone related ailments, cancer and cardiovascular diseases (Shinde, Malpathak, & Fulzele, 2009). Isoflavones also exert antioxidant properties thereby provide protective effect against oxidative damage (Akitha Devi et al., 2009; Slavin, Cheng, Luther, Kenworthy, & Yu, 2009).

Consumption of antioxidant constituents reported to have protection against oxidative damage induced degenerative and pathological processes including ageing and cancer (Tadhani, Patel, & Subhash, 2007). Antioxidant properties have been studied in several plant species for the development of natural antioxidant formulations in the areas of food, medicine and cosmetics (Miliauskas, Venskutonis, & Van Beek, 2004). However, chemical constituents of medicinal plants depending on several factors such as cultivation area, climatic conditions and genetic modification (Miliauskas et al., 2004; Santos-Gomes, Seabra, Andrade, & Fernandes-Ferreira, 2002).

Plant cell culture offers uniform secondary product synthesis by eliminating effect of unforeseen climatic conditions and diseases as observed in field grown plants. Plant tissue cultures have been used to derive isoflavones from various medicinal plants (Bouque, Bourgaud, Nguyen, & Guckert, 1998; Luczkiewicz & Glod, 2003; Matkowski, 2004). Light irradiation is one of the important factors that can act as a switch for controlling the expression of secondary metabolism to enhance the yield of useful bioactive compounds in plant cell cultures (Guo, Liu, Yan, & Liu, 2007; Park, Kim, Yang, Chung, & Choi, 2003).

No information is available about the influence of plant growth regulators and light regime on growth and isoflavones production in callus cultures of *P. corylifolia.* Further antioxidant potential of callus cultures was also not studied. This article deals with isoflavone production in callus cultures of *P. corylifolia* under influence of plant growth regulators and light intensity. Antioxidant potential of *in vitro* and *in vivo* cultures of *P. corylifolia* was also reported for the first time.

2. Material and methods

2.1. Plant material and tissue culture

Plants and seeds of *P. corylifolia* were collected from botanical garden, University of Pune, India. Plants were separated into different parts and analysed for daidzein and genistein content. *In vitro* seedlings were raised as described elsewhere (Shinde et al., 2009). Three-week-old *in vitro* germinated seedlings were used as a

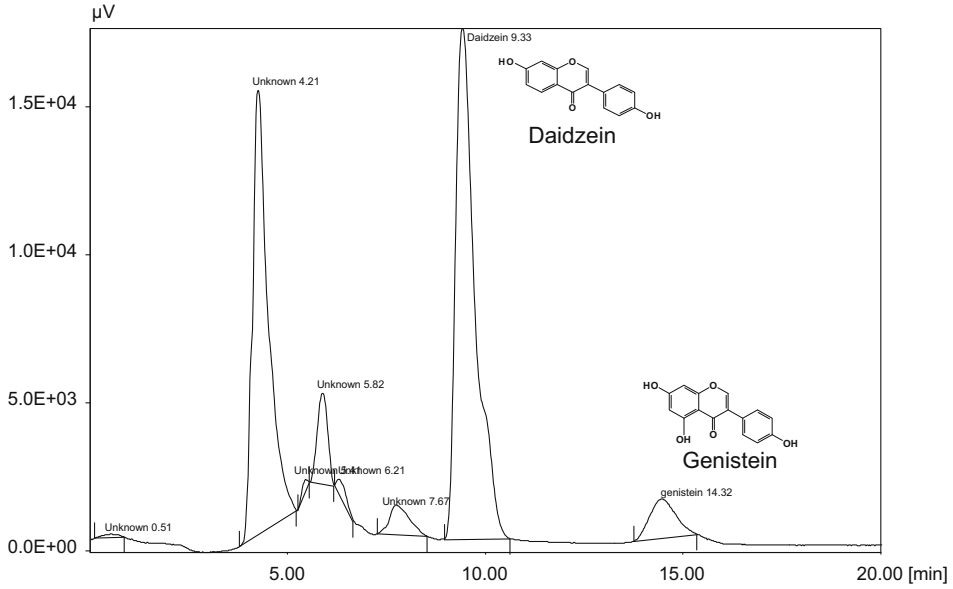

Fig. 1. HPLC analysis showing presence of daidzein and genistein in *P. corylifolia* extracts.

source of explants for initiation of callus cultures. Leaves and roots were incised into small pieces (9–10 mm) and cultured aseptically on MS medium (Murashige & Skoog, 1962) supplemented with different combinations and concentrations of 2,4-dichlorophenoxyacetic acid (2,4-D; 2.26–9.05 µM), α-naphthalene-acetic acid (NAA; 5.37–10.74 µM), Indole-3-acetic acid (IAA; 5.71–11.42 µM) and 6-bezylaminopurine (BAP; 4.40 µM) and denoted as (M1–M7) in Fig. 2. The cultures were maintained on similar media compositions and sub-cultured after every four weeks. After a period of 10-subculture, established callus cultures were taken up for growth study and quantification of isoflavones daidzein and genistein.

For light experiment, cultures were maintained under different light intensities ranges from 13 to 40 µmol m^{-2} s^{-1}. For studying the effect of photoperiod conditions, callus cultures were incubated under continuous light illumination, photoperiod (16 h light and 8 h dark) and in dark conditions.

2.2. Growth parameters

Callus cultures were gently pressed on filter papers (Whatman No. 1) to remove excess water for fresh weight (FW) determination. Cultures were dried in an oven at 55 °C for 16 h to get dry weight (DW). All experiments were replicated three times. Growth was determined as Growth index (GI) using formula:

$$\frac{\text{Final wt of Biomass} - \text{Initial wt of biomass}}{\text{Initial wt of biomass}}$$

2.3. Extraction of isoflavones and High Performance Liquid Chromatography analysis

Isoflavones were extracted from dried and powered plant material using method described elsewhere (Shinde et al., 2009). An isocratic analytical HPLC was performed on Jasco Liquid Chromatograph (Model 980, Japan) equipped with 25 µl loop and a variable wavelength detector (Model No. UV-975, Japan). Separations were performed on Inertsil C_{18} (250 mm × 4.6 I.D, Sigma, USA) column using acetonitrile:water (40:60 v/v) as a mobile phase. The flow rate was 0.6 ml/min and the elution was monitored at 250 nm (Shinde et al., 2009).

2.4. Preparation of extract for antioxidant activity

Callus cultures derived from roots and leaves grown under different conditions were used for antioxidant activities. Explant material was collected from greenhouse grown plants. Biomass was dried at 55 °C for 16 h and dried materials (1 g) mixed with 40 ml of methanol followed by sonication at 33 KH_z for 40 min. Thereafter, extracts were filtered by filter paper (Whatman No. 1) and filtrate evaporated under reduced pressure by BÜCHI Rotavapor (RI 111, Switzerland) at 45 °C. The residues were dissolved in an appropriate volume of methanol to obtained 100 mg/ml concentration and stored at −20 °C until used.

DPPH (2,2-diphenyl-1-pycrilhydrazil hydrate) and phosphomolybdenum reduction assay was carried out as described elsewhere (Ho, Tsai, Chen, Huang, & Lin, 2001; Prieto, Pineda, & Aguilar, 1999). The free radical (DPPH) scavenging activity was expressed as % inhibition whereas phosphomolybdenum reduction capacity of extract as equivalents of ascorbic acid (µmol/g of extract) at 50 µg/ml concentrations. Total phenolics content was estimated

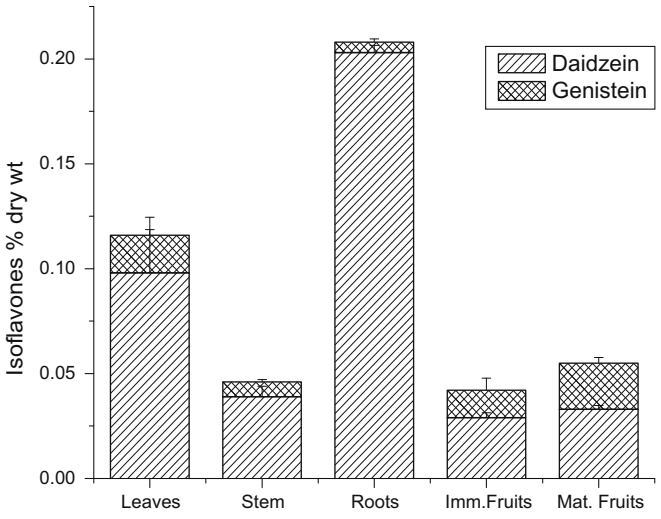

Fig. 2. Distribution of isoflavones daidzein and genistein in different organs of *P. corylifolia* plant. Results are the mean of five replicates ± SD.

as gallic acid equivalents (GAE) and expressed as mg gallic acid/g extract (Singleton, Orthofer, & Lamuela-Raventos, 1999).

2.5. Statistical analysis

The influence of various treatments on growth and isoflavones content was analysed by one-way analysis of variance (ANOVA). Values are mean of five replicates from two experiments. The data was analysed statistically by analysis of variance (ANOVA) and difference between means of the samples was analysed by the least significant difference (LSD) at a probability level of 0.05.

3. Results and discussion

3.1. Daidzein and genistein content in P. corylifolia plant material

Isoflavones content was determined in different parts of field grown plants (Fig. 1). The chromatographic analysis revealed that highest levels of daidzein was accumulated in roots (0.20% dry wt) whereas genistein (0.03% dry wt) by immature fruits (Fig. 2).

3.2. Callus growth and isoflavone production

Callus cultures were developed on MS medium supplemented with different combinations and concentrations of plant growth regulators (M1–M7). High growth index (8.4, 7.0 and 6.6) was achieved from root-derived callus on M6, M2 and M4 medium respectively. Leaf-derived callus exhibited slower growth (Growth index 6.1, 5.8, and 5.3) on similar media compositions (Fig. 3A and B). HPLC profiles revealed that highest daidzein (1.74% dry wt) was produced in callus derived from roots on M6 medium (Fig. 3A) whereas genistein (0.165% dry wt) by leaf-derived callus on similar medium (Fig. 3B). Medium containing 2,4-D was found to be optimum for isoflavone accumulation in callus cultures of *Pueraria lobata* and *Psoralea* sp. (Bouque et al., 1998; Matkowski, 2004). Similarly, present results indicated that the content of isoflavones

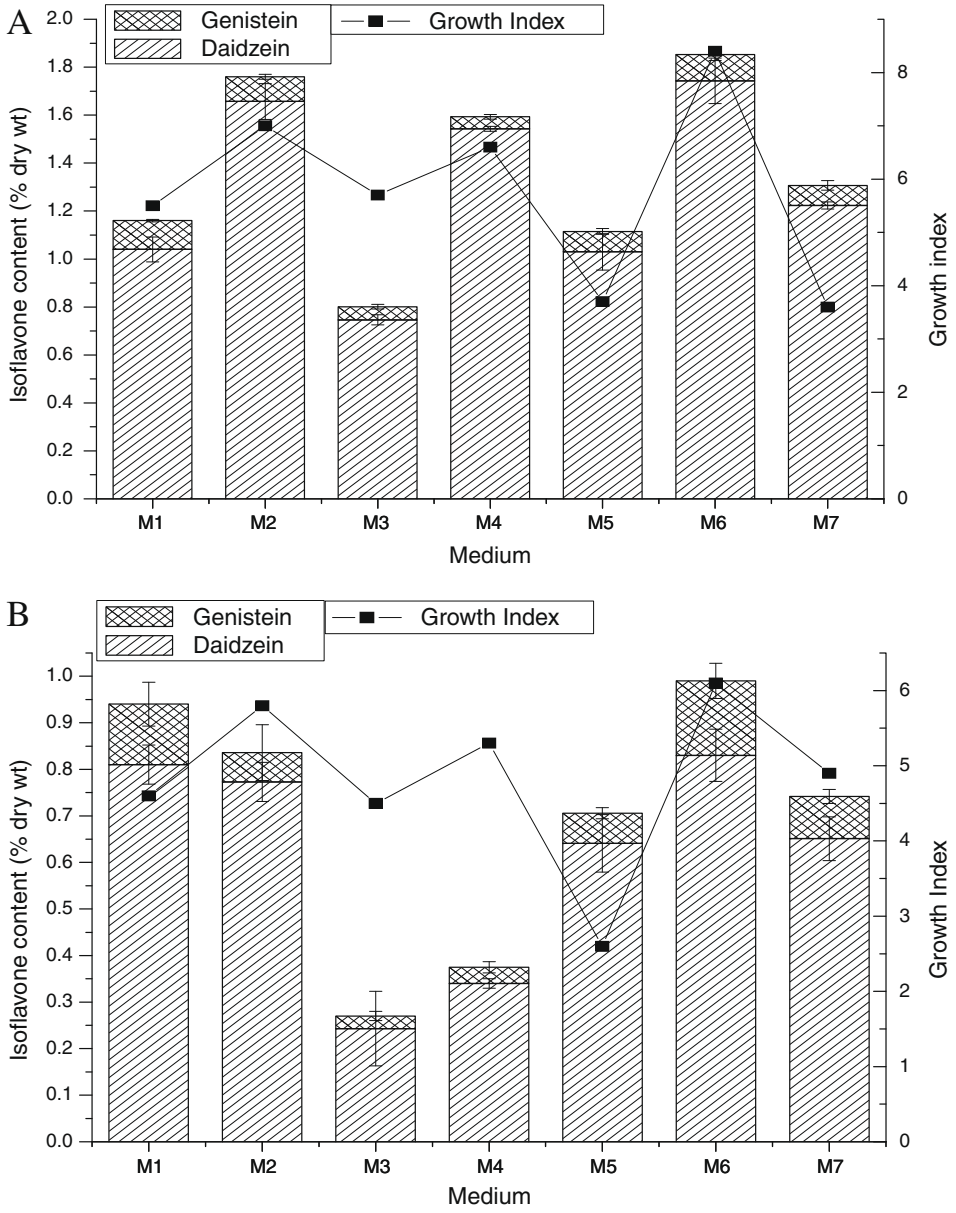

Fig. 3. Chromatographic analysis of daidzein and genistein in callus cultures obtained from roots (A) and leaf (B) explants on MS medium supplemented with different combinations and concentrations of plant growth regulators. Results are the mean of five replicates ± SD [M1: 2,4-D (4.52 μM) + BAP (4.40 μM); M2: 2,4-D (9.05 μM) + BAP (4.40 μM); M3: NAA (5.37 μM) + BAP (4.40 μM); M4: NAA (10.74 μM) + BAP (4.40 μM); M5: IAA (2.26 μM) + BAP (4.40 μM); M6: IAA (5.71 μM) + BAP (4.40 μM); M7: IAA (9.05 μM) + BAP (4.40 μM)].

Table 1
Effect of different light intensities and photoperiod conditions on growth and isoflavones production in callus cultures of *P. corylifolia* on 30th day.

Light intensity and photoperiod conditions	Dry wt (g)	Daidzein (% dry wt)	Genistein (% dry wt)
13.7 μmol $m^{-2}s^{-1}$, 16 h light + 8 h dark	0.20 ± 0.01^{b}	1.257 ± 0.13^{b}	0.09 ± 0.001^{ba}
27 μmol $m^{-2}s^{-1}$, 16 h light + 8 h dark	0.22 ± 0.03^{ab}	1.597 ± 0.12^{b}	0.11 ± 0.001^{b}
40 μmol $m^{-2}s^{-1}$, 16 h light + 8 h dark	0.25 ± 0.01^{a}	1.890 ± 0.20^{a}	0.15 ± 0.003^{ab}
40 μmol $m^{-2}s^{-1}$, continuous illumination	0.23 ± 0.01^{ab}	2.283 ± 0.11^{a}	0.21 ± 0.005^{a}
Dark condition	0.196 ± 0.01^{b}	0.623 ± 0.20^{c}	0.06 ± 0.002^{b}

Results are the mean of three replicates ± SD (Means with common letters (a–b) within column are not significantly different at $P \leqslant 0.05$ according to LSD test).

Table 2
Content of total phenolics and antioxidant activity of *in vitro* and *in vivo* cultures of *P. corylifolia*.

Plant material	DPPH assay EC_{50} value (μg/ml)	Phosphomolybdenum assay (50 μg/ml)	Total phenolic content (mg GAE/g dry wt)
Leaf	117.16 ± 2.48^{c}	84.5 ± 7.77^{b}	41 ± 1.41^{a}
Roots	273.27 ± 2.30^{a}	75.5 ± 5.16^{d}	28 ± 2.82^{e}
Leaf-derived callus	112.93 ± 2.80^{d}	53 ± 4.24^{e}	28.7 ± 1.76^{e}
Root-derived callus	104.89 ± 3.76^{e}	104 ± 8.48^{b}	39 ± 1.41^{c}
Dark grown callus	271.15 ± 5.99^{b}	78 ± 1.31^{c}	35.5 ± 0.70^{d}
Light grown callus	99.53 ± 2.95^{f}	169 ± 4.24^{a}	45 ± 0.10^{b}

Each value is expressed as the mean ± S.D. of three replicate determinations. (Means with common letters (a–f) within column are not significantly different at $P \leqslant 0.05$ according to LSD test).

in root and leaf-derived callus cultures was higher on 2,4-D and IAA containing medium. Matkowski (2004) reported that root-derived callus produced high concentrations of daidzin than leaf-derived callus of *P. lobata*. Similar to this, in case of *P. corylifolia*, root-derived callus cultures synthesized high amount of daidzein.

3.3. Effect of light intensity on growth and daidzein and genistein production

Root-derived callus cultures grown on M6 medium showed rapid growth and high accumulation of daidzein and genistein compared to other medium (M1–M7). Therefore, similar cultures were selected and consequently used for further experiments. The light intensities and different photoperiod conditions did not show significant effects on callus growth. Maximum light intensity (40 μmol m^{-2} s^{-1}) and continuous light illumination stimulated production of daidzein (2.28% dry wt) and genistein (0.21% dry wt) on day 30. It was observed that increased light intensity and illumination period enhanced isoflavones production level. On the contrary, absence of light inhibited the daidzein and genistein production (Table 1). Our findings strengthen the fact reported earlier that, presence of light enhanced isoflavone production in callus cultures of *Genista tinctoria* (Luczkiewicz & Glod, 2003). Similarly, edible legume seedlings showed enhanced levels of isoflavonoids production when grown in light compared to dark (Lal, Warber, Kirakosyan, Kaufman, & Duke, 2003). Light irradiation is one of the important factor that acts as a switch for controlling the expression of specific genes involved in growth and secondary metabolism of plants (Liu et al., 2006). Our findings are in agreement with the various results obtained for production of flavonoids by cell cultures exposed to light (Guo et al., 2007).

3.4. Antioxidant activities and total phenolics content

The most effective DPPH radical scavenging and phosphomolybdenum reducing property was shown by root-derived callus cultures grown under continuous illumination (at 40 μmol m^{-2} s^{-1} intensity) compared to dark grown cultures and explant material (Table 2). Similarly highest total phenol content was found in callus cultures grown under continuous illumination of light (45 mg GAE/g dry wt) compared to other callus cultures and explants used (Table 2). Correlation analysis indicated that content of phenolics is partially correlated with DPPH radical scavenging ($r = 0.4664$) and phosphomolybdenum reducing ($r = 0.7030$) activity. It is generally stated that only flavonoids of certain structure and with hydroxyl position in the molecule determine antioxidant properties. However antioxidant potential of the extracts does not solely depend on phenolics. Terpenes are another major group of chemicals showed antioxidant potential against lipid peroxidation and DPPH radical scavenging activity (Karagozler, Erdag, Emek, & Uygun, 2008) which could be an additional contributory factor for antioxidant activity of extracts.

In vitro cultures of *P. corylifolia* exhibited highest antioxidant activity compared to field grown plant parts. It was generally assumed that dedifferentiated cultures proved to be less active as antioxidants (Grzegorczyk, Matkowski, & Wysokinska, 2007). However, present results indicated that callus extracts showed significant antioxidant potential compared to *in vivo* materials, which could be explored further for source of natural antioxidants. Similar improved antioxidant activity was observed in *in vitro* cultures of *Salvia officinalis and Rosmarinus officinalis* compared to its field grown plant materials (Grzegorczyk et al., 2007; Yesil-Celiktas, Nartop, Gurel, Bedir, & Vardar-Sukan, 2007).

4. Conclusion

Levels of daidzein (2.28% dry wt) accumulated in callus cultures on day 30 was ~11-fold more than that of 60-day-old plants. These results exhibited that appropriate light intensities effectively enhanced accumulation of daidzein and genistein in callus cultures. In addition *in vitro* cultures of *P. corylifolia* exhibited highest antioxidant activity compared to field grown plant parts. Isoflavones production and antioxidant activities of *P. corylifolia* will help to select callus culture type as a source of natural antioxidants and nutraceuticals to enhance health benefits.

Salmonella microsome assay

ABSTRACT

The recent increase in phytosterol-enriched functional food provokes questions concerning the safety of their oxidation products. However, most of the existing toxicity studies have been performed with mixtures instead of single compounds, a consequence of the lack of pure phytosterol oxidation product (POP)-standards.

The objectives of this study were to take in use a method for the isolation of β-sitosterol oxidation products and to assess their mutagenic and pro-oxidative potential. Oxides were prepared by thermo-oxidation, purified by column chromatography and separated by a NP–HPLC–UV system. 7-ketositosterol, 7β-OH-sitosterol, 7α-OH-sitosterol, a mixture of 6β-OH-3-ketositosterol/6α-OH-3-ketositosterol (ratio 4:3) and a mixture of polar oxides were fractionated. Yields in the range of several milligrams per fraction were achieved within one HPLC-run. Identification and quantification was done by GC–MS and GC–FID, respectively. In the Ames test the collected fractions failed to show a mutagenic activity towards Salmonella typhimurium strains TA98, TA100 and TA102.

1. Introduction

Recently phytosterols (plant sterols) have become a focus of interest due to their serum cholesterol lowering effect and consequently their protection against cardiovascular diseases (Piironen, Lindsay, Miettinen, Toivo, & Lampi, 2000). According to the literature an uptake of 1.5–3 g phytosterols per day is recommended in order to achieve a reduction of 10–15% in serum LDL cholesterol (Katan et al., 2003). As the daily intake from natural sources is estimated to range from 150 to 440 mg a day, a wide variety of products fortified with phytosterols has been introduced to the market in order to reach the advised uptake levels. However, besides their positive aspects concerns in terms of health are emerging.

It is well known that during food preparation and storage cholesterol oxidation products (COPs) are formed from cholesterol through autoxidation, photoxidation and enzymatic oxidation (Boesinger, Luf, & Brandl, 1993). Mutagenic, carcinogenic, angiotoxic, cytotoxic and atherogenic properties of the thereby generated COPs are generally accepted and have already been extensively documented (for review see Osada, 2002).

Similar to cholesterol, phytosterols consist of a tetracyclic cyclopenta[α]phenanthrene ring, they mainly differ in their side chain (Piironen et al., 2000). Because of their structural similarities, phytosterols are expected to undergo analogous chemical reactions as cholesterol, including oxidation. But information on phytosterol oxidation products (POPs) is still rather limited.

Existing knowledge on POPs is mainly concentrated on their quantification in food. In first studies concerning their absorption in vivo a significant uptake of POPs was proven (Grandgirard et al., 2004).

Regarding their possible harmful effects only a few studies were conducted and most of them dealt with a potential cytotoxicity. Investigations with different cultured mammalian cells showed comparable damage to that caused by COPs, but higher concentrations of POPs were needed (Adcox, Boyd, Oehrl, Allen, & Fenner, 2001; Maguire, Konoplyannikov, Ford, Maguire, & O'Brien, 2003; Ryan, Chopra, McCarthy, Maguire, & O'Brien, 2005). So far only Lea, Hepburn, Wolfreys, and Baldrick (2004) investigated the mutagenic potential of POPs in the Ames test and reported no evidence of genotoxicity. However, in this investigation only a non-specified mixture with 30% of POPs was analysed. Due to the lack of commercial POP-standards in most cases a blend instead of single oxidation products has been used for toxicity studies. But evidence exists that compared to mixtures individual POPs behave in a different way (Maguire, Konoplyannikov, Ford, Maguire, & O'Brien, 2003). Therefore the biological and safety aspects of POPs remain rather unclear.

Hence, the aim of the present study was to scale up a method for the isolation of single phytosterol oxidation products. ß-sitosterol served as the model compound as it is the most abundant plant sterol in nature. Gram scale amounts of toxicologically relevant oxidation products with sufficient purity were collected in order to undergo toxicity tests.

The second objective of this study was to investigate the collected oxides regarding their possible mutagenic and pro-oxidative properties in the Ames test. Since it is assumed that the toxicity of oxidation products varies depending on their chemical structure (Osada, 2002) a hierarchy of toxicity of the isolated compounds would be essential. In addition a mixture of all oxidation products was prepared and analysed in the same way, to further investigate whether or not single isolated products react differently from mixtures.

2. Materials and methods

2.1. Chemicals

24β-Ethylcholest-5-en-3β-ol (purity: β-sitosterol ~76%, sitostanol ~13%, campesterol ~9,5%, campestanol ~1,5%) was purchased from Fluka Chemie (Buchs, Switzerland). 5-Cholesten-3β-ol (cholesterol), Cholest-5-en-3β-ol-7-one (7-ketocholesterol) and Cholestan-5α,6α-epoxy-3β-ol (5α,6α-epoxycholesterol) were provided by Sigma Chemical Co. (St. Louis. MO, USA). Cholest-5-en-3β,7α-diol (7α-hydroxycholesterol), Cholest-5-en-3β,7β-diol (7β-hydroxycholesterol) and 5-Cholesten-3β,19-ol (19-hydroxycholesterol), the latter was used as an internal standard (ISTD) in GC-analysis, were obtained from Steraloids (Wilton, NH, USA). All the other cholesterol oxides were used as reference solutions in TLC and HPLC analysis, as standards of phytosterol oxides are not available.

Silica gel 60 (0.2–0.5 mm) for column chromatography and thin layer chromatography (TLC) plates (silica gel 60, 20 × 20 cm) were purchased from E. Merck (Darmstadt, Germany). Spots were visualized by staining with 10% sulphuric acid (H_2SO_4) (E. Merck) in methanol (Rathburn Chemicals Ltd., Walkerburn, Scotland). Bis(trimethylsilyl) trifluoroacetamide (BSTFA) and trimethylchlorosilane (TMCS) were obtained from E. Merck and Fluka Chemie, respectively, and were used as a 99:1 (v/v) mixture for silylation of the oxidation products. Analytical grade pyridine (>99%) from Sigma was also used. Ethyl acetate (E. Merck), diethyl ether (J.T. Baker, Deventer, The Netherlands), *n*-heptane and acetone (Rathburn Chemicals Ltd.), 99.5% ethanol (Primalco, Rajamäki, Finland) and water (purified by Milli-Q Plus, Millipore, Molsheim, France) all of analytical grade, were used.

All chemicals used for the Ames test were obtained from Sigma (Vienna, Austria), unless otherwise stated. The Salmonella typhimurium strains TA98, TA100 and TA102 were obtained from Discovery Partners International (San Diego, USA) and from Trinova Biochem GmbH (Giessen, Germany). The S9 liver homogenate (from Sprague–Dawley rats induced with Aroclor 1254 prepared as a KCL homogenate) was obtained from MP Biomedicals (Illkirch, France). Agar No. 1 and Nutrient Broth were obtained from Oxoid/Bertoni (Vienna, Austria), Dulbecco's PBS was from PAA (Pasching, Austria). All mutagens and other reagents were of analytical reagent grade or higher and stored at – 80 °C if necessary.

2.2. Production and isolation of phytosterol oxidation products

2.2.1. Preparation of oxides by thermo-oxidation

POPs were formed by thermo-oxidation. Commercial available β-sitosterol was heated in open glass vials (300 mg, 25 mm, I.D.) in a ventilated oven for 24 h at 130 °C. Optimal heating conditions were evaluated in pre-tests. Different temperatures and time periods (130 °C/24 h, 120 °C/48 h and 130 °C/48 h) were tested and resulting oxidation mixtures were analysed using GC–FID and GC–MS. After the heating period the samples were cooled down in a desiccator, dissolved in 15 mL of *n*-heptane/diethyl-ether (90:10, v/v), solubilised using a sonicator and finally stored in a freezer (−20 °C).

2.2.2. Purification and enrichment of phytosterol oxidation products by column chromatography (CC)

The purification method used was based on former investigations by Lampi, Juntunen, Toivo, and Piironen (2002) and Apprich and Ulberth (2004). Briefly, 72 g silica gel (loaded with 10% distilled water) was dry packed into a glass column and pre-wetted with 150 mL *n*-heptane. The whole sample (300 mg heated β-sitosterol/15 mL *n*-heptane/diethyl-ether (90:10, v/v)) was applied to the column and first nonoxidized sterols and apolar components were eluted with 150 mL *n*-heptane/diethyl-ether (90:10, v/v) followed by 450 mL *n*-heptane/diethyl-ether (50:50, v/v). Thereafter POPs were extracted with 150 mL acetone. The acetone fraction was evaporated to dryness. To get rid of the water ethanol was added during the evaporation step. The residue was dissolved in 550 μL *n*-heptane/2-propanol (93:7, v/v).

To confirm the performance of the CC TLC was conducted. 100 μL of the purified sample were applied to silica gel G 60 TLC plates (0.5 mm layer thickness). The identification of the single oxidation products was done using a standard solution, which contained 5α,6α-epoxy-, 7-hydroxy- and 7-ketocholesterol. As eluent *n*-heptane/ethyl-acetate (50:50, v/v) was used. Components were visualized by spraying with 10% sulphuric acid in methanol followed by heating for a few minutes at 100 °C.

2.2.3. Separation of single oxidation products by a NP–HPLC–UV system

For the collection of single oxidation products a preparative normal-phase HPLC-method was used. The method was based on papers published by Kemmo, Soupas, Lampi, and Piironen (2005) and Säynäjoki, Sundberg, Soupas, Lampi, and Piironen (2003) with some modifications. A preparative HPLC-instrument (Waters Delta Prep 3000, Milford, USA) equipped with a silica Supelcosil column (250 mm × 21.1 mm, 12 μm; Supelco, Bellefonte, PA, USA) and a UV detector at 206 nm (Waters 484 Milford, USA) was applied. Several mobile phase systems (90:10, 92:8, 93:7, 94:6, 95:5 and 97:3 *n*-heptane/2-propanol) and flow rates (5, 7, 9.9, 15 and 17 mL/min) were examined. Determination of purity levels and identification of the collected fractions was done by GC–MS. The best separation was achieved at room temperature under isocratic conditions using a mobile phase of *n*-heptane/2-propanol (93:7, v/v) with a flow rate of 17 mL/min. The injection volume was 1.8 mL. The performance of the separation was checked daily using a cholesterol oxides standard solution (7-ketocholesterol, 7β-hydroxycholesterol and 7α-hydroxycholesterol) by monitoring the retention times. For the generation of the mixture no HPLC separation was performed, therefore it includes all polar β-sitosterol oxidation products.

2.2.4. Identification and quantification

For identification and quantification of the collected fractions GC–mass spectrometry (GC–MS) and GC–flame ionization detection (GC–FID) were used, respectively. Both methods have been developed earlier by co-workers (Lampi et al., 2002; Soupas, Juntunen, Säynäjoki, Lampi, & Piironen, 2004) and are routinely used for analysing POPs.

Prior to the GC analysis the samples were converted to TMS-ether derivatives. Therefore 100 μL aliquots of each fraction and 1 mL of internal standard solution (19-OH-cholesterol, 18.55 μg/mL) were evaporated to dryness under nitrogen, dissolved in 100 μL of pyridine and subjected to silylation by 100 μL BSTFA/TMCS

(100 μL, 99:1, v/v) over night at room temperature. The reagent mixture was then evaporated and the residue was dissolved in 200 μL *n*-heptane before GC analysis.

2.2.5. GC–MS analysis

For identification of the collected oxidation products and verification of the purity of the fractions GC–MS was used as described in Soupas et al. (2004). The GC–MS equipment consisted of a Hewlett–Packard 6890 Series gas chromatograph (Wilmington, PA, USA) including a Rtx-5MS w/Integra fused-silica capillary column (60 m × 0.25 mm i.d., crossbond 5% diphenyl – 95% dimethyl polysiloxane, 0.1 μm film with 10 m Integra-Guard column; Restek, Bellefonte, PA, USA) and was coupled to an Agilent 5973 mass spectrometer (Palo Alto, CA, USA). Helium was used as carrier gas at 240 kPa. Initial oven temperature was 70 °C, after 1 min the temperature was raised to 280 °C at 40 °C/min and was then held at 280 °C for 35 min. Interface temperature and ion source were 280 °C and 230 °C, respectively. Spectra were scanned within the mass range of *m*/*z* 100–600 using the electron impact mode (70 eV).

2.2.6. GC–FID analysis

The quantification was done by GC–FID measurements using a Hewlett–Packard 6890 Series II gas chromatograph equipped with an HP-7673 autosampler (Hewlett–Packard, Karlsruhe, Germany), an automated on-column injection system, a flame ionization detector (FID), ChemStation 3.1 software and a RTX-5w/Integra fused-silica capillary column (60 m × 0.32 mm i.d., 5% diphenyl – 95% dimethyl polysiloxane, 0.1 μm film with 10 m Integra-Guard column; Restek, Bellefonte, PA, USA). Helium (99.996% AGA, Espoo, Finland) was used as the carrier gas at a constant flow (110 kPa at 200 °C). The initial temperature was 70 °C, which increased after 1 min to 245 °C by 60 °C/min. After 1 min at 245 °C it raised by 3 °C/min to 275 °C and remained at this temperature for 41 min. The detector temperature was 300 °C. The concentrations of the POPs were quantified by the added internal standard (19-OH-cholesterol).

2.3. Salmonella microsome assay

2.3.1. Preparation of reaction mixtures

Three individual oxidation products, 7-ketositosterol, 7β-OH-sitosterol, 7α-OH-sitosterol, a mixture of 6β-OH-3-ketositosterol/6α-OH-3-ketositosterol (ratio 4:3) and a mixture of the polar oxidation products of β-sitosterol were investigated. Considering the results of pre-tests, four concentrations (0.04, 0.2, 1.0 and 5.0 mg per plate (≈%)) of each compound were analysed. The concentration range used was a broad spectrum from very low physiological to nonphysiologically high concentrations, all below the solubility range, which is recommended for this test procedure.

Due to precipitation in the highest concentration of 7α-OH-sitosterol, only 3 doses of this compound could be used (0.04–1%). There were similar but minor solubility problems with the mixture of 6β-OH-3-ketositosterol/6-α-OH-3-ketositosterol, therefore as highest concentration 2.5 mg/plate was tested. On the other hand the mixture of all oxidation products showed very good solubility, so a 10 mg/plate dilution could also be included in the experiments (Table 1).

In order to obtain appropriate dilutions, each sample was predissolved in a mixture of acetone/tween80 (3:1, v/v). Afterwards two parts of sterile, distilled water was added to keep the concentration of acetone as low as possible and to avoid potential toxic effects on the bacterial strains. This procedure was tested to be safe for the strains in pre-experiments.

Table 1
Overview of the used concentrations of the sterol oxides in the study.

	10%	5%	2.5%	1%	0.2%	0.04%
7-ketositosterol		x		x	x	x
7β-OH-sitosterol		x		x	x	x
7α-OH-sitosterol				x	x	x
6α-OH-3-keto-/6β-OH-3-ketositosterol			x	x	x	x
Mixture	x	x		x	x	x

2.3.2. Metabolic activation

In order to simulate in vivo conditions the oxidation products were treated with a rat liver enzyme mixture (S9, which mainly consists of phase I enzymes) for metabolic activation. The S9 mix was prepared according to the recipes of Maron and Ames (1984) consisting of 19.75 mL distilled water, 25 mL of PBS buffer, 0.5 mL of $MgCl_2$ (0.85 M), 0.5 mL of KCl (1.65 M) and 2 mL of NaDP (90.8 mM), 250 μL of glucose-6-phosphate (1.08 M), and 2 mL of S9. The reagent was stored on ice throughout the whole experiment and discarded after 50 min.

2.3.3. Experimental design

The Ames Salmonella/microsome mutagenicity assay (Salmonella test, Ames test) was performed according to Maron and Ames (1984). The preincubation assay with an incubation period of 25 min (37 °C) was chosen, as reported earlier (Wagner, Reichhold, Koschutnig, Cheriot, & Billaud, 2007). Briefly, 500 μL of PBS or S9 mix, 200 μL of reaction mixture and 100 μL of overnight bacterial culture were added to test tubes. The tubes were shortly vortexed and then placed in an incubator on a rotary shaker and incubated for 25 min at 37 °C. After this period 2 mL of molten top agar were added to each tube. The mixture was vortexed and poured on glucose minimal agar plates. As soon as the agar had solidified the plates were inverted and stored in an incubator for 48 h at 37 °C. Thereafter his^+-revertants were counted manually.

In the present study three generally recommended tester strains (TA98, TA100 and TA102) were applied. TA98 gives information on frame-shift mutations, TA100 on base-pair substitutions and TA102 detects cross-linking agents, additionally it is specifically used to inform on oxidative stress. To further investigate the anti-/pro-oxidative effects the pro-oxidant tertiary-butyl hydroperoxide (*t*-BOOH, 0.7 mM) was used for a challenge test. The concentration of the oxidant was chosen in order to obtain suitable numbers of revertants on the plates. This test was performed with and without metabolic activation.

Each experiment included a positive control (2,4,7-Trinitro-9-fluorenone, Sodiumazide or 2-Aminofluorene), which confirmed the reversion capacity of the bacterial strains as well as a negative control, the sample solvent. All concentrations and the positive control were tested in triplicate. For the negative control even six plates were prepared. Each test was done at least twice ($n = 6$ in total).

2.3.4. Statistical analysis and evaluation of the mutagenic experiments

All data are expressed as mean ± SD (standard deviation). Obtained data ($n = 6$ for each concentration used) were analysed by one-way analysis of variance (ANOVA) and the Student's *t*-test since they were all normally distributed, using SPSS 15.0 for Windows. Statistical differences were considered significant at a value of $p < 0.05$.

In addition to the statistical, a nonstatistical evaluation was carried out. According to Mortelmans and Zeiger (2000) a compound is considered as "mutagenic" if the total number of his^+-revertants per plate was at least twice as high as the negative control (200%). Moreover a dose related increase of the number of his^+-revertants has to be shown.

3. Results and discussion

As already mentioned POPs are not commercially available, so they have to be laboratory-prepared. Applied methods are based on chemical synthesis (Bortolomeazzi, De Zan, Pizzale, & Conte, 1999; Zhang et al., 2005), thermo-oxidation in solid state (Lampi et al., 2002) or aqueous dispersion (Dutta & Appelqvist, 1997). Existing techniques are mostly very complex and time-consuming with the requirement of special equipment. Besides they are usually designed for the production of only small amounts of oxidation products. Therefore the initial target of this study was the development of a fast, simple and effective method for the isolation of common β-sitosterol oxides.

3.1. Performance of the method

3.1.1. Preparation of the test compounds by thermo-oxidation

In the present study thermo-oxidation in solid state was used for formation of oxides. Different temperatures and heating periods were tested and generated amounts of oxysterols were estimated by GC–FID (Fig. 1). Heat treatment for 24 h at 130 °C showed to be the best option, yielding to an oxidation rate of nearly 20%. The total amount of oxidation products decreased throughout longer heat exposure, even at a lower temperature (120 °C compared to 130 °C). This observation can be explained by conversion reactions to other secondary oxidation products as well as further reactions such as polymerisation, leading to non polar compounds, dimers and polymers. The latter occurs further particularly at higher heating conditions. The oxidation products observed in the heating experiments were analogous to those cited in the literature, mainly 7-ketositosterol followed by 7β-OH-sitosterol, 7α-OH-sitosterol, 5,6β-epoxy-sitosterol, 5,6α-epoxy-sitosterol, 6β-OH-3-ketositosterol, 6α-OH-3-ketositosterol, 6β-OH-sitosterol and 6-ketositosterol. Our findings supported those of Kemmo et al. (2005), who assessed that at different heating temperatures the same kind of oxidation products were formed, but the amount of the single products varied. Already Caboni, Costa, Rodriguez-Estrada, and Lercker (1997) noticed that the ratios of the formed products were influenced by the oxidation conditions.

The high amount of 7-ketositosterol and the generation of 7β-OH-sitosterol rather than 7α-OH-sitosterol was in accordance with previous studies (Chien, Wang, & Chen, 1998; Kemmo et al., 2005).

3.2. Purification and enrichment of the test compounds

When β-sitosterol is heated a mixture of oxidation products, non oxidized material and several unknown by-products is formed. Because of the complexity of the gained blend usually a combination of different separation techniques is applied to isolate single oxidation products. In this work CC was used for the first separation step. In contrast to the often employed solid-phase extraction (SPE) cartridges self prepared glass columns offer a higher loading capacity. Since our interest was focused on POPs with a higher polarity than non oxidized β-sitosterol a stepwise elution order to remove apolar components up to free sitosterol was applied.

Solvent mixtures of *n*-heptane/diethyl-ether in combination with silica gel and a final elution of the desired components with acetone were already successfully applied by others (Apprich & Ulberth, 2004; Lampi et al., 2002; Piironen, Toivo, & Lampi, 2002). TLC was used to confirm the separation process. No products with a lower polarity than β-sitosterol were detected. In addition a relevant reduction of non oxidized β-sitosterol could be noted. In other publications preparative TLC was also used to fractionate oxidation products. But this is only appropriate when small amounts of samples for analytical purpose are separated. In addition to its low loading capacity it also allows long exposure of the sample to air, which facilitates the possibility of artefact formation.

3.3. Separation, isolation and fractionating of the oxidation products by NP–HPLC–UV

The final separation of the oxidation products was achieved by a NP–HPLC–UV system. Due to its mild characteristics preparative HPLC is particularly suitable for the isolation of oxides. Both normal- and reverse phase chromatography has already been successfully used for the analyses of cholesterol (Caboni et al., 1997; Chien et al., 1998; Csallany, Kindom, Addis, & Lee, 1989; Mazalli, Sawaya, Eberlin, & Bragagnolo, 2006) and plant sterol (Kemmo, Ollilainen, Lampi, & Piironen, 2007; Kemmo et al., 2005) oxidation products. In general normal phase chromatography is considered to be the more effective option.

Table 2
Retention times and yield of single oxidation products (mg) within one HPLC-run (average values were obtained in over hundred HPLC-runs).

Compound	Retention time (min)	mg/injection
6β-OH-3-ketositosterol		5.7
6α-OH-3-ketositosterol	7.82	4.34
7-ketositosterol	11.09	16.9
7β-OH-sitosterol	13.36	11.03
7α-OH-sitosterol	14.82	6.12

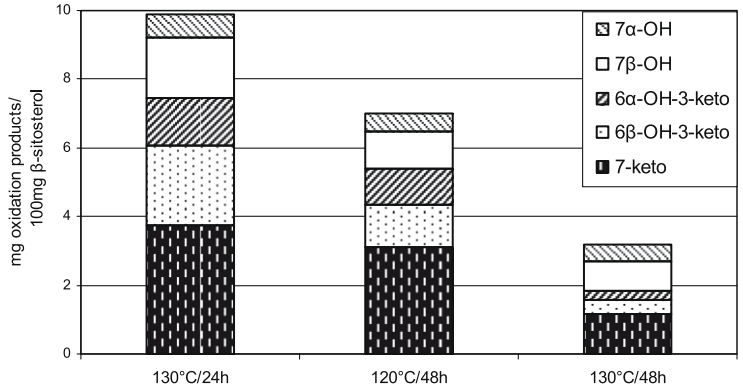

Fig. 1. Proportion of collected β-sitosterol secondary oxidation products (mg) after different oxidation conditions (130 °C/24 h, 120 °C/48 h and 130 °C/48 h) measured by a GC-FID system. Results are average values of at least two different heat treatments.

Different mobile phase systems with changing percentages of IPA were tested based on former investigations by Kemmo et al. (2007, 2005) and Säynäjoki et al. (2003). Best separation was achieved with a mobile phase of *n*-heptane/IPA (93:7, v/v). The same solvent system was already used earlier for the separation of COPs (Csallany et al., 1989). The elution order in this system was as follows: 6β-OH-3-ketositosterol/6α-OH-3-ketositosterol, 7-ketositosterol, 6β-OH-sitosterol, 7β-OH-sitosterol and 7α-OH-sitosterol. A rapid separation in one single HPLC-run was achieved within 20 min. The application of a big preparative silica column (25 cm × 21.2 mm, 12 μm) allowed an injection volume of 1.8 mL of the obtained oxidation mixture, containing the oxidation products derived from about 1000 mg unoxidized β-sitosterol (collected oxides of several purification steps by CC were combined). This led to yields in the range of several milligrams for the single fractions. Within one HPLC run, for example, 15–20 mg of 7-ketositosterol could be collected. For detailed information see Table 2.

Table 3
Purity of the obtained oxidation products as measured by GC–FID.

Fraction	Purity (%)	Campesterol counterpart (%)	Others (%)
6β-OH-3-ketositosterol/6α-OH-3-ketositosterol	88	12	
7-ketositosterol	82	10	8
7β-OH-sitosterol	90	10	
7α-OH-sitosterol	70	10	20

However, as already ascertained earlier no full resolution of the entire polarity range of the oxidation products is possible under isocratic conditions (Guardiola, Bou, Boatella, & Codony, 2004). 6β-OH-3-ketositosterol and 6α-OH-3-ketositosterol co-eluted, so they were collected in one fraction. When analysing the collected fractions with GC–FID high proportions of 7-ketositosterol were

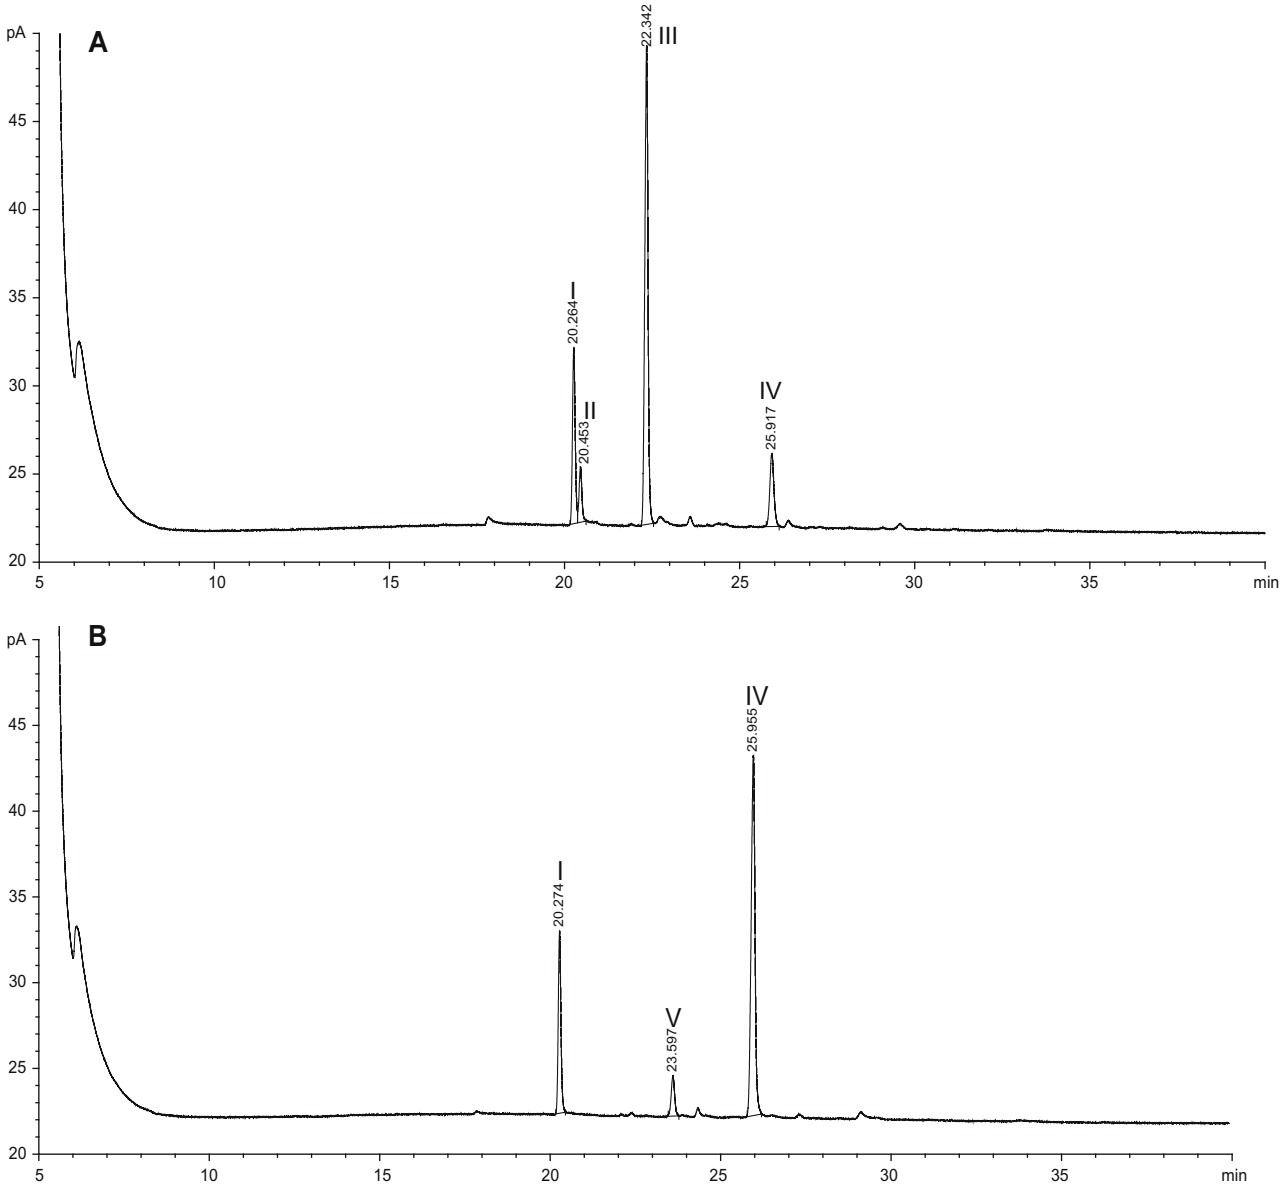

Fig. 2. GC–FID chromatograms of isolated β-sitosterol oxide fractions ((A) 7α-hydroxysitosterol; (B) 7β-hydroxysitosterol; (C) 7-ketositosterol; (D) 6α-OH-3-ketositosterol/6β-OH-3-ketositosterol) as TMS-ether derivatives on a RTX-5w/Integra fused silica capillary column (60 m × 0.25 mm i.d., 0.1 μm film). Analytical conditions are described in Section 2. Peaks are identified as: (I) 19-hydroxycholesterol (ISTD); (II) 7α-hydroxycampesterol; (III) 7α-hydroxysitosterol; (IV) 7β-hydroxysitosterol; (V) 7β-hydroxycampesterol; (VI) + (VII) unidentified compounds; (VIII) 7-ketocampesterol; (IX) 7-ketositosterol; (X) 6β-OH-3-ketocampesterol; (XI) 6β-OH-3-ketositosterol; (XII) 6α-OH-3-ketocampesterol; (XIII) 6α-OH-3-ketositosterol.

found in the 6β-OH-sitosterol-sample. Therefore 6β-OH-sitosterol was excluded from subsequent toxicology tests.

Moreover as already observed in earlier investigations (Dutta & Appelqvist, 1997) it was not possible to separate campesterol oxides from their sitosterol counterparts. Since the applied commercial β-sitosterol included some amount of campesterol (~10%) also a low amount of campesterol oxides (~10%) was present in the oxidation mixture. Average values of the purity of the collected compounds are listed in Table 3 and GC–FID chromatograms of each isolated oxide fraction are given in Fig. 2. However, bearing in mind the velocity of our method we put up with these minor impurities.

Among all detection systems available UV detection is still the most frequently applied for sterol analyses. Separation of the oxidation products was monitored using a wavelength of 206 nm. It is the common wavelength employed for oxysterols (Csallany et al., 1989). Since products without double bonds like epoxy-compounds and triols have poor UV absorption they were not included in collected oxides.

3.4. Bacterial tests

Although indications for adverse health effects exist, knowledge on biological properties of POPs is rather small. Further almost all of the so far conducted toxicology studies were done with cell lines, among others because of the small sample amounts needed for these assays. As data concerning the mutagenic potential of isolated POPs is lacking, the collected oxidation products were tested in Salmonella typhimurium strains TA98, TA100 and TA102 in the Ames test. To our knowledge it is the first time that single oxides of β-sitosterol are tested on their behaviour towards Salmonella typhimurium strains.

3.5. Mutagenicity testing

According to literature the here applied preincubation assay is the most sensitive form of the Ames test. It allows a closer contact of the test compounds and the indicator strain since the bacteria

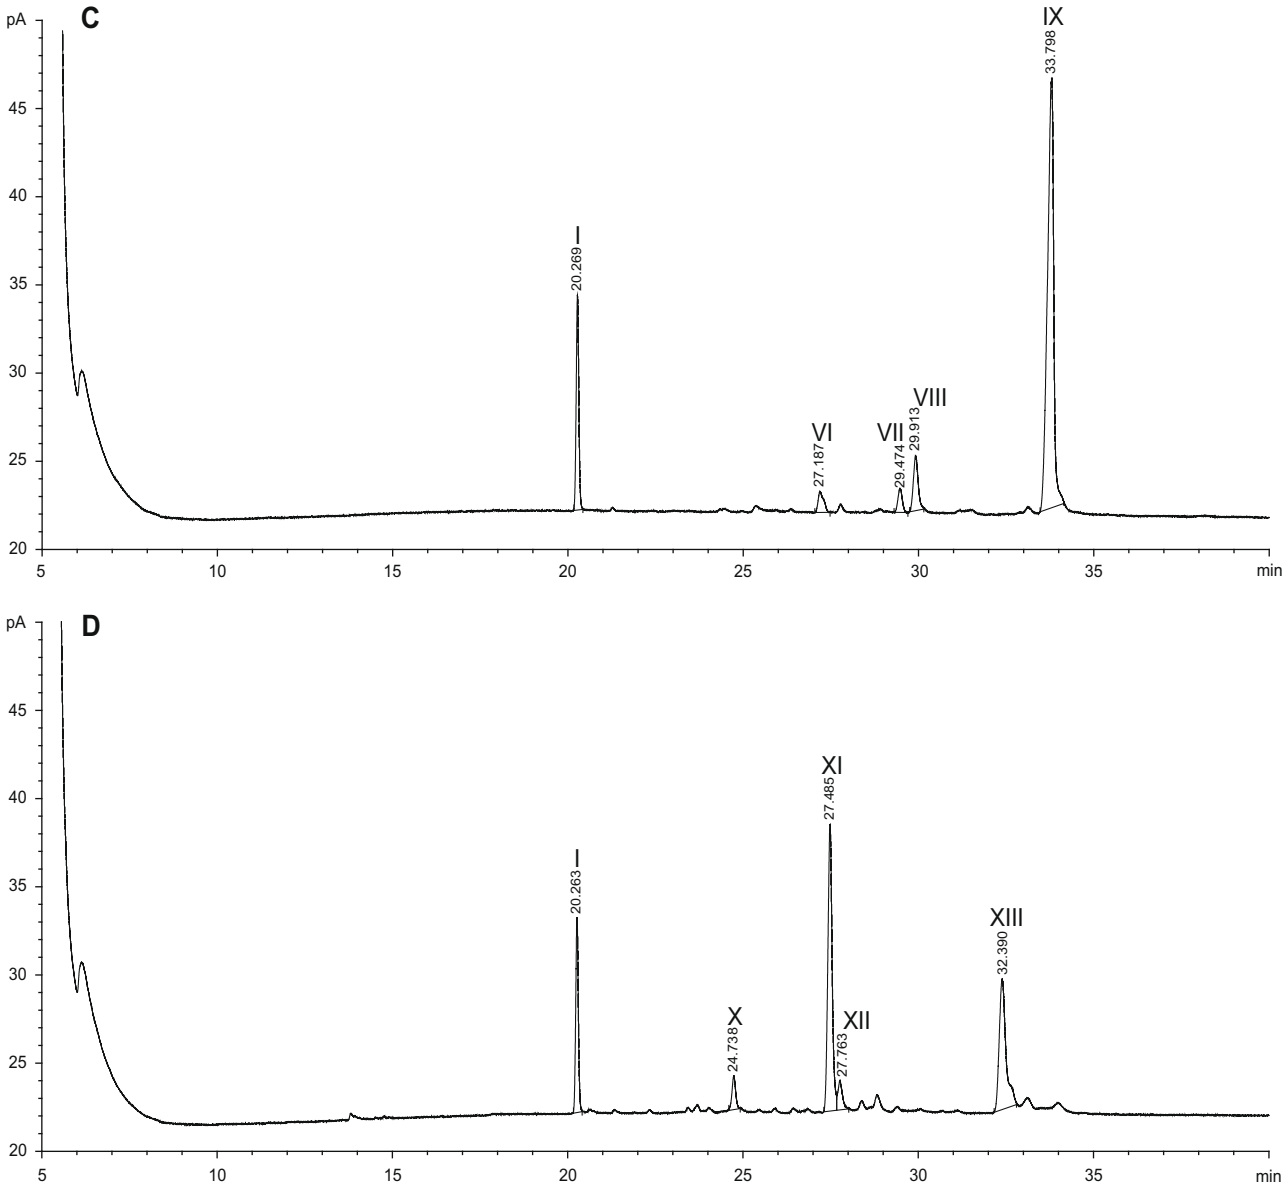

Fig. 2 (*continued*)

are able to react in a small volume, which is an advantage for detecting short-living mutagens (Mortelmans & Zeiger, 2000).

Throughout the whole test period the spontaneous mutation frequency of the strains was in accordance with the control levels published (Mortelmans & Zeiger, 2000) and each POP sample was significantly different to the positive control ($p < 0.05$).

In strain TA98 no mutagenic activity could be seen; neither with nor without metabolic activation. Also in TA100 the number of his$^+$-revertants remained in the range of the negative control and therefore were mutagenic not active (data not shown).

These results were in accordance with those published recently by Lea et al. (2004) who tested a mixture of oxidized and unoxidized products of β-sitosterol by using different Salmonella strains (TA98, TA100, TA102, TA1535 and TA1537). However, the amount of oxidation products in their tested samples was only 30%.

It is already well known that oxide mixtures react differently from individual oxidation products (Maguire, Konoplyannikov, Ford, Maguire, & O'Brien, 2003). Also additive, synergistic as well as inhibitory effects of single oxidation products in mixtures have been noted (O'Sullivan, O'Callaghan, & O'Brien, 2005). Therefore, in contrast to our study, the results of Lea et al. (2004) allow no sufficient information about the safety aspects of single oxidation products.

In the aforementioned publication also toxicity and precipitation problems during their work with TA102 were reported. Consequently in these experiments sample amounts had to be reduced. Throughout all of our research work no problems in this regard were observed.

Although in the present study none of the oxidation products were able to increase the number of revertants beyond the doubled negative control, yet for some oxides a certain response was observed in strain TA102 (Table 4). In the preincubation test without metabolic activation the highest concentrated fraction of 7-ketositosterol (5%) increased the number of his$^+$-revertants significantly, but not beyond twice of the negative control, which was set as threshold for mutagenic activity. Moreover a concentration-dependent tendency was seen for the lower concentrations but not for the 5%-fraction, mainly due to its higher standard deviation. With the addition of S9 the increase of 7-ketositosterol (5%) was even more pronounced ($p < 0.05$). On the other hand the highest concentrated fraction of 7β-OH-sitosterol (5%) reduced the number of his$^+$-revertants significantly compared to its lower concentrated fractions ($p < 0.05$).

The strain TA102 was chosen as besides its capability of detecting cross-linking agents it additionally informs on oxidative stress (Grey & Adlercreutz, 2003; Mortelmans & Zeiger, 2000). Based on that, the increase in revertants induced by 7-ketositosterol (5%) could be an indication of a pro-oxidant tendency. On the other hand the decline in revertant numbers of 7β-OH-sitosterol (5%) could be interpreted as a marginal sign of antioxidative effects. However, it could also be the result of increased cytotoxicity (Mortelmans & Zeiger, 2000).

To date no papers other than the one by Lea et al. (2004) had been published dealing with possible mutagenic actions of POPs. Hence, more information is available on mutagenic effects of COPs. Due to their structural similarity an analogous mode of action is expected. As early as in 1979 mixtures of COPs have been shown to possess mutagenic effects towards Salmonella typhimurium strains TA98, TA1535 and TA1537 (Smith, Smart, & Ansari, 1979). Several studies followed and in spite of contradictory results it seems that particularly epoxy and triol compounds of cholesterol possess mutagenic activity. Epoxy and triol compounds of β-sitosterol had never been tested before in regard of their mutagenicity and they were also not included in the present study. Oxysterols might in general possess rather cytotoxic properties whereas for epoxide epimeres and triols a mutagenic action could also be possible. For the mutagenic reactivity of COPs the authors also suggested ROS to be involved in the mutagenic action (Cheng, Kang, Shih, Lo, & Wang, 2005; Smith et al., 1979), as antioxidant enzymes diminished the mutagenic response.

Table 4
Overview of all obtained data in the preincubation assay with the strain TA102.

Compound	Concentration (mg/plate)	TA102 revertants/plate −S9	TA102 revertants/plate + S9	TA102 + tBOOH revertants/plate −S9	TA102 + tBOOH revertants/plate + S9

Numbers of his$^+$-revertants are mean ± SD.
[a] $p < 0.05$ to negative control.
[b] $p < 0.05$ to positive control.

3.6. Antioxidant testing

To strengthen the information on oxidative stress challenge tests with the pro-oxidant *t*-BOOH were included in our experiments. *t*-BOOH is commonly used in in vitro assays, as it is known as an initiator of lipid peroxidation, where it leads to the formation of alkoxyl and alkyl radicals (Grey & Adlercreutz, 2003).

A prevention of the thereby caused mutagenicity would indicate possible antioxidant properties of the tested compounds. Per definition a reduction of the revertant colony number below 50% of the negative control level is necessary for an anti-mutagenic effect (Mortelmans & Zeiger, 2000). This was never seen in any of our conducted tests (Table 4). However, with the addition of *t*-BOOH 7β-OH-sitosterol (5%) caused a significant decrease in his^+-revertants ($p < 0.05$); even though not lower than the threshold level. With the addition of S9 the number of his^+-revertants was still lower compared with the less concentrated fractions, but here this tendency was not significant ($p = 0.196$).

4. Conclusion

The applied method was proven to be a powerful tool for the collection of oxidation products, as yields in the range of several milligrams per fractions were achieved within only one HPLC-run. Thus the collection of oxysterols for a later application in toxicity tests was possible.

The results of the Ames test demonstrated that the analysed common oxidation products of β-sitosterol were not mutagenic towards Salmonella typhimurium strains TA98, TA100 and TA102. Even though literature on the mutagenic response of COPs is conflicting, for some oxidation products a mutagenic action could be proved. In spite of their similar structure there could still be a difference in the mutagenic behaviour of cholesterol- and plant sterol oxidation products.

Analytical Methods

Application of artificial neural networks to the prediction of the antioxidant activity of essential oils in two experimental *in vitro* models

ABSTRACT

Introduction: The antioxidant properties of essential oils (EOs) have been on the centre of intensive research for their potential use as preservatives or nutraceuticals by the food industry. The enormous amount of information already generated on this subject provides a rich field for data-miners as it is conceivable, with suitable computational techniques, to predict the antioxidant capacity of any essential oil just by knowing its particular chemical composition. To accomplish this task we here report on the design, training and validation of an Artificial Neural Network (ANN) able to predict the antioxidant activity of EOs of known chemical composition.

Methods: A multilayer ANN with 30 input neurons, 42 in hidden layers (20 → 15 → 7) and one neuron in the output layer was developed and run using Fast Artificial Neural Network software. The chemical composition of 32 EOs and their antioxidant activity in the DPPH and linoleic acid models were extracted from the scientific literature and used as input values. From the initial set of around 80 compounds present in these EOs, only 30 compounds with relevant antioxidant capacity were selected to avoid excessive complexity of the neural network and minimise the associated structural problems.

Results and discussion: The ANN could predict the antioxidant capacities of essential oils of known chemical composition in both the DPPH and linoleic acid assays with an average error of only 3.16% and 1.46%, respectively. We also discuss on the contribution of different compounds to these chemical activities.

Conclusions: These results confirm that artificial neural networks are reliable, fast and cheap tools for predicting antioxidant activity of essential oils from some of its components and can be used to model biochemical properties of complex natural products including the prediction of parameters associated with nutraceutical properties of food ingredients.

1. Introduction

The antioxidant properties of essential oils (EOs) have been on the centre of intensive research for their potential use as preservatives, supplements, cosmeceuticals or nutraceuticals by the food and cosmetics industry. Literally 100s of works reporting both on the composition and antioxidant properties of EOs have been written during the last decade. However, this kind of work is under an increasing criticism as the inherent intra-specific variability of the essential oils composition – depending on the location, altitude, meteorology, type of soil and many other factors – make this kind of work virtually irreproducible.

To further complicate matters, the evaluation of the antioxidant capacity of different fractions or pure constituents of EOs often affords controversial results. For example, when Radonic and coworkers (Radonic & Milos, 2003) isolated the hydrocarbon fraction of *S. montana* EO, containing γ-terpinene, α-terpinene, *p*-cymene and terpinolene – which previously were identified as potential antioxidants – it showed the poorest effectiveness. On the other hand, thymol and carvacrol, the most active components of *Thymus pectinatus* EO were individually found to possess weaker antioxidant activity than the crude oil itself (Vardar-Ünlü et al., 2003). These data indicate that some of the constituents of the essential oils may act synergistically, and this interplay might be even more complex as antagonisms with other components cannot be discarded *a priori*.

Despite this controversy, the enormous amount of information produced on the antioxidant activity of EOs provides a rich field for data-miners, and it is conceivable to apply suitable computational techniques to predict the activity of any essential oil by just knowing its particular chemical composition. The challenge is the complexity of the countless chemical interactions between dozens of EOs components and the free radicals used as probes. It is virtually impossible to address all of them in the laboratory but it may be solved by the use of computational models such as artificial neural networks (ANNs). In fact, ANNs are algorithms which has the capacity of approximating an output value based on input data

doi:10.1016/j.foodchem.2009.04.070

without any previous knowledge of the model and regardless the complexity of its mechanisms, in this case the relationship between the antioxidant capacity of a given essential oil (input data) and its chemical composition (parameters affecting the assay).

An ANN is composed by a set of virtual/artificial neurons organised in interconnected layers. Each neuron has a specific weight in the processing of the information. The optimal weights are calculated with available pairs of input and output data constituting the training set. Using this pairs, the ANN is able to minimise output error modifying weights as required. While two of these layers are connected to the 'outside world' (input layer, where data is presented and output layer, where a prediction value is obtained), the rest of them (hidden layers) are defined by neurons connected to each other, avoiding connections between neurons of the same layer.

To our knowledge only one previous report (Buciński, Zieliński, & Kozłowska, 2004) show the possibility of applying ANNs to predict antioxidant capacity of food products. The authors chose to use the amount of total phenolics present in cruciferous sprouts as input data. Thus, no attempt has been made yet to use an ANN for the prediction of the antioxidant capacity of EOs, a popular subject in natural products chemistry. Moreover, all previous antecedents in the food field do not take into account more than 4–5 input variables whilst EOs would imply to use dozens of them. To accomplish this task we here report on the design, training and validation of an ANN in order to predict the antioxidant activity of EOs of known chemical composition in two widely used *in vitro* models of antiradical and antioxidant activity, namely DPPH and linoleic acid, respectively.

2. Materials and methods

2.1. Design of the ANN

An ANN was developed and run on a personal computer using Fast Artificial Neural Network software ver. 1.2.0-1 (Nissen, 2007). This package was downloaded from its original repository in http://leenissen.dk/fann/ and installed following the guidelines provided by the developers under Ubuntu 7.04 and Microsoft Windows XP Professional SP2.

FANN is a free, open source neural network library, which implements multilayer artificial neural networks in C language with support for both fully connected and sparsely connected networks. Cross-platform execution in both fixed and floating point is supported. We chose this software because it is versatile, well

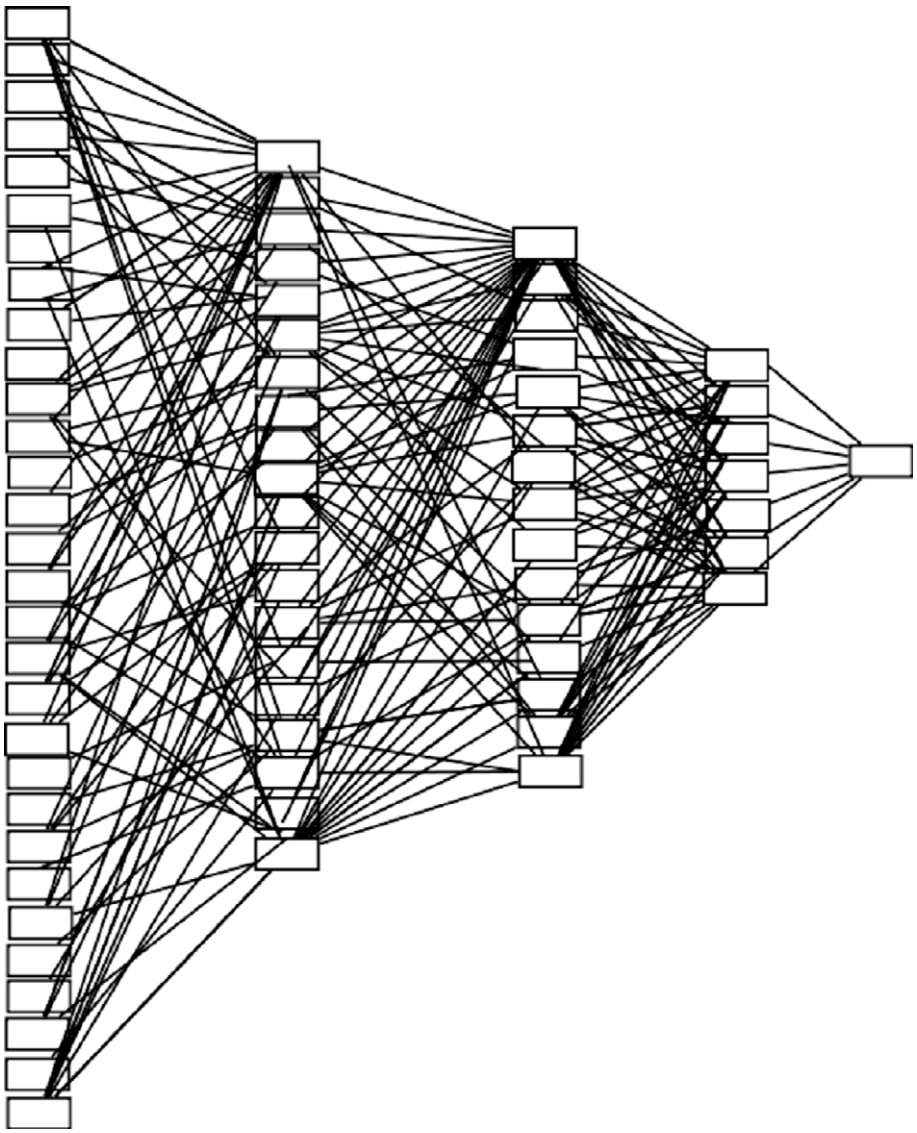

Fig. 1. Structure of the ANN (to reduce the complexity of the figure, not all the relationships between the neurons are displayed).

documented, and fast as well as including a framework for easy handling of training data sets (Nissen, 2007).

We design a multilayer ANN with 30 input neurones, 42 in hidden layers (20 → 15 → 7) and one neuron in the output layer. A general overview is shown in Fig. 1. Additionally, activation functions, both for hidden and output neurons, were set to FANN_SIGMOID_SYMETRIC. Training was based on a supervised method with back-propagation strategy and the parameters giving maximum accuracy were a learning rate equalled to 0.7, minimum error to 0.0001 and maximum epochs to 500,000.

The training-validating tests were run in automated manner by using an *ad hoc* program in C language developed by one of the authors (AC) running under Linux (Ubuntu 7.04). The most accurate networks were selected as potential candidates and further validated.

2.2. Data retrieval

All data selected were extracted from previous studies with similar results reported for the positive control butylhydroxytoluene (BHT) in order to reduce noise data as much as possible (Bozin, Mimica-Dukic, Samojlik, & Jovin, 2007; Burits & Bucar, 2000; Candan et al., 2003; Çetinus, Göze, Saraç, & Vural, 2007; Dermirci, Koşar, Dermirci, Dinç, & Başer, 2007; Eminagaoglu et al., 2007; Fraternale, Giamperi, Bucchini, & Ricci, 2007; Gülüce et al., 2007; 2003; Jirovetz et al., 2006; Kartal et al., 2007; Mimica-Dukic, Bozin, Sokovic, & Simin, 2004; Özer et al., 2007; Ricci et al., 2005; Sacchetti et al., 2004; Sharififar, Moshafi, Mansouri, Khodashenas, & Khoshnoodi, 2007; Sökmen et al., 2004a; Sökmen et al., 2004b; Tepe et al., 2006; Tepe, Daferera, Sihoglu-Tepe, Polissiou, & Sökmen, 2007; Tepe, Daferera, Sökmen, Polissiou, & Sökmen, 2004; Tepe et al., 2004; Tepe, Sihoglu-Tepe, Daferera, Polissiou, & Sökmen, 2007; Tepe et al., 2005; Tepe, Sökmen, Sökmen, Daferera, & Polissiou, 2005).

The chemical composition of the selected EOs consisted of up to 79 different compounds. To avoid excessive complexity of the neural network and minimise the associated structural problems, only 30 compounds with the higher antioxidant capacity according Ruberto and Baratta (2000) were selected as input values (Fig. 2). The resulting array of input sets is shown in Table 1 (Supplementary information), and the corresponding output values – i.e.

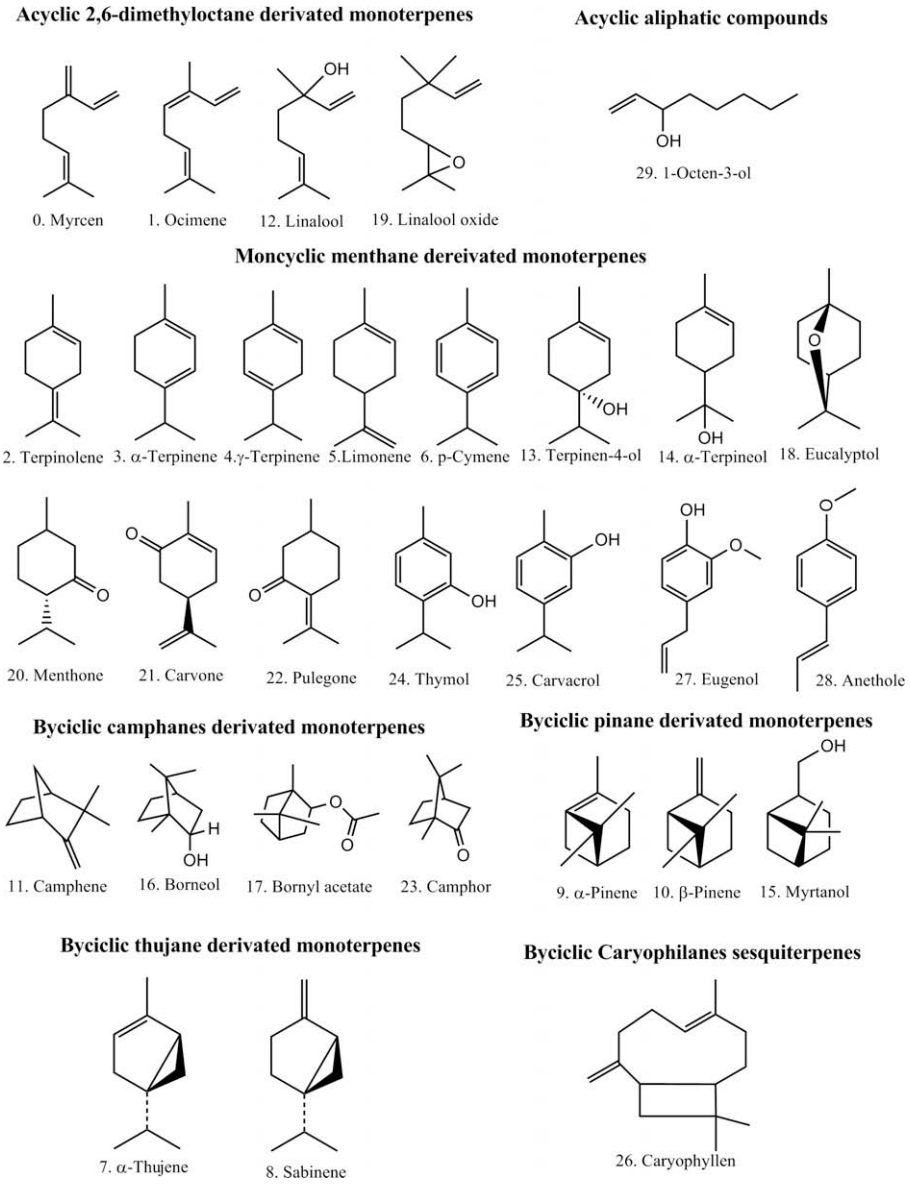

Fig. 2. Chemical structures of the 30 selected inputs.

antioxidant activity – are shown in Table 2 (Supplementary information).

2.3. Modelling the radical scavenging behaviour of essential oils in the DPPH assay

Chemical composition data – expressed in percentage of each compound – were retrieved from previous studies on the antioxidant activity of essential oils. Only studies reporting similar IC_{50} values for the reference compound BHT were selected to assure data uniformity among different articles/authors. The data were transformed into a suitable interval (0–1) for input neurons by dividing percentages by 100. The IC_{50} output values were reduced to an interval from 0 to 1 by applying Log in base 100,000. Then, all paired values were randomly divided in two sets: a learning set of 26 elements and a validating set of 4 elements.

2.4. Modelling the antioxidant behaviour of essential oils in the linoleic acid assay

In a second approach, the object of prediction was capacity of inhibition of the volatile organic compounds and the conjugated diene hydroperoxides arising from linoleic acid oxidation in a β-carotene–linoleic acid mixture.

Identical considerations for input data were taken in this estimation, using BHT positive controls to assure data uniformity and transforming values to 0–1 interval. In this case output values were transformed in a suitable set for output neurons dividing the reported percentages of inhibition (*%I*) by 100.

In this case, a training set of 27 elements and a validating set of 4 elements were used to predict percentage of inhibition of the linoleic acid oxidation.

2.5. Validation of the ANN

Statistical analyses were carried out to verify the accuracy of predictions in both cases. Output values of testing and validating sets were used in a linear regression test with ANOVA to determinate if they are statistically related with experimental values from the studies. All statistical analyses were performed using SPSS v. 15 (SPSS Inc. Chicago, USA).

3. Results and discussion

We could predict the antioxidant capacities of essential oils of known chemical composition in both the DPPH and linoleic acid assays using an artificial neuronal network (ANN) with an average error of only 3.16% and 1.46%, respectively.

A final set of the 30 compounds with the highest antioxidant activity according Ruberto and Baratta (2000) was used as inputs (Fig. 2). Fig. 3A shows the result of the ANN training with the reported values for the DPPH assay. As shown in Fig. 3B, all predicted values (Log in base 100,000 of IC_{50}) in the DPPH assay for the validating set could be correlated with the experimental values within an interval of confidence 95% with a relative error of 3.16% on average. Regression tests for the results in the linoleic acid assay are presented in Fig. 3C and D. They indicate that the prediction ability gained during the learning process was fully operational when using the validating set. The designed ANN proved to be able to produce values correlating well with experimental data (medium relative error of 1.46%). Furthermore, all statistical tests showed a significant relationship between experimental and predicted values ($p < 0.05$) in the validating set, the training set scoring even higher signification ($p < 0.0001$).

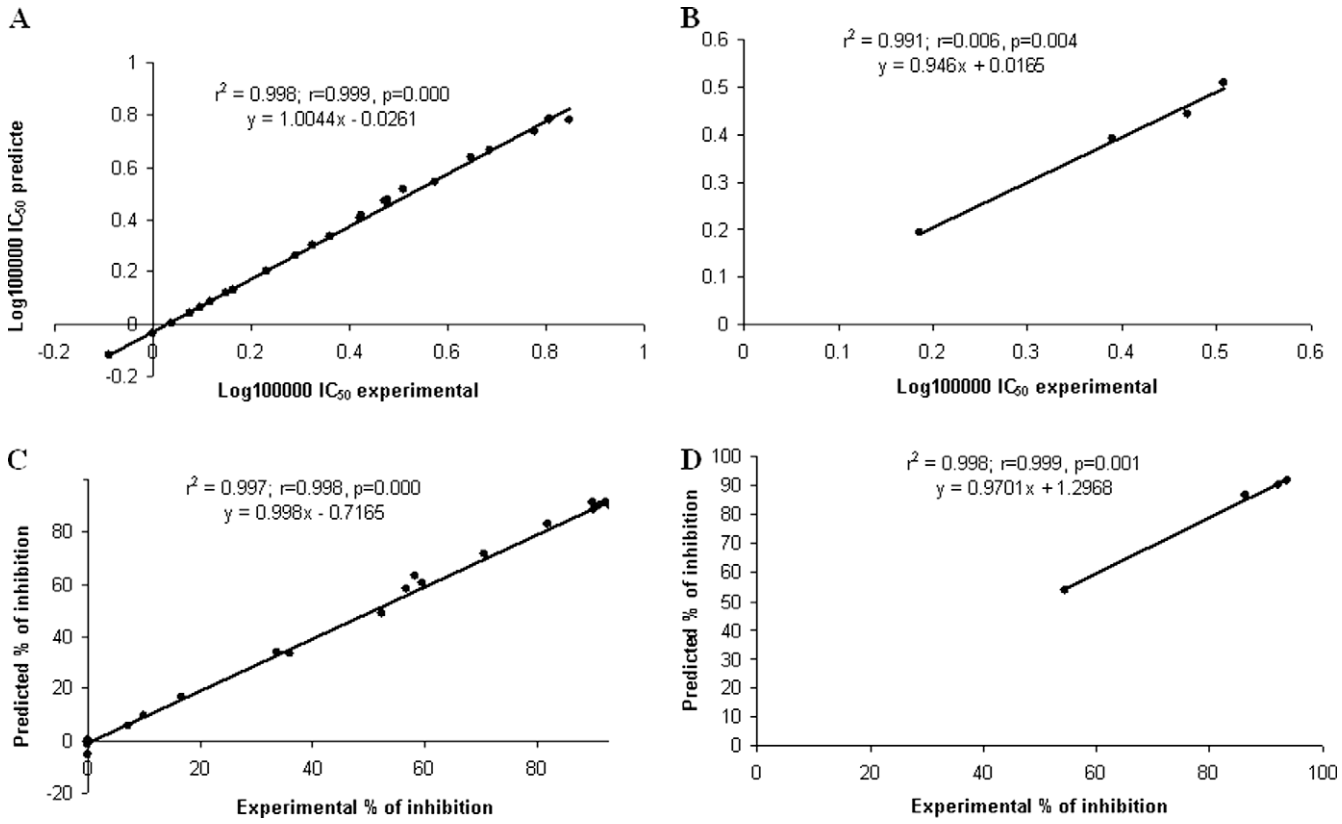

Fig. 3. Accuracy of the predictions. (A) Training set for the DPPH assay; (B) validating set for the DPPH assay; (C) training set for the linoleic acid assay; (D) validating set for the linoleic acid assay.

We could therefore successfully model the biochemical activity of essential oils in two standard, widely used and accepted *in vitro* chemical models whilst overcoming some of the limitations in the application of ANNs. Some of the reported problems in the application of ANNs are caused by their inherent structure and the most important are 'overtraining', 'peaking effect', and 'network paralysis'. Overtraining the ANN may lead to the noise of data used for training being fixed in the network weights. The peaking effect is experienced when an excessive number of hidden neurons minimise error in training but increase error in testing. Finally network paralysis appears when an excessive adjustment of neurons weight raise high negative or positive values leading to a near zero output with sigmoid activation functions (Kröse & van der Smagt, 1996). These limitations have to be taken into account and minimised with an adequate network topology and parameters. In our case noise reduction was achieved by selecting carefully the data sets by using only papers with similar values of BHT. By reducing the inputs to the most relevant compounds – i.e. keeping those with higher antioxidant activity as described in Section 2 – we could reduce the number of hidden neurons and all the problems associated with topology complexity. However, the number of inputs used in this work remains far higher than any of the previous attempts reported by the literature (Buciński et al., 2004; Torrecilla, Mena, Yáñez-Sedeño, & García, 2007) The reduced numbers of validating elements in both experiments are in line with previous studies confirming the possibility of using short sets for similar applications (Buciński et al., 2004).

Insights on the particular contribution of every single compound in the essential oil and their possible synergies/antagonism were not possible. Unfortunately our feed forward ANN did not allow us to determinate the final contribution of each input element – chemical compound – to the antioxidant activity of the EO due to the elevate number of hidden neurons. Therefore, relationships between all antioxidant compounds could not be established. According the literature phenolic compounds, eugenol, carvacrol and thymol, are known to be major players in the reduction of the DPPH radical (Brand-Williams, Cuvelier, & Berset, 1995). The linoleic acid oxidation assay occurs in a less polar environment than this of DPPH where phenols seem to be less soluble and therefore their antioxidant potential might be diminished. Interestingly, in our ANN model of the linoleic acid assay, the neurones weights for the first layer suggest significant initial contributions of non phenolic substances. In particular, *p*-ocimene seems to be an input as important as carvacrol or thymol, followed in less extend by eugenol and anethole, though this may not necessarily be important for the final output.

Antioxidant capacity is nowadays accepted as a criterion of food quality and to monitor the impact of food processing in the nutraceutical value of food products. As a consequence, developing ANNs able to predict antioxidant values of EOs could become an important tool for the food industry as they could predict their antioxidant capacity without implementing any experimental procedure within their premises.

Neural networks are fast-spreading in chemistry (Zupan & Gasteiger, 1991) but only a few applications to natural product's chemistry/food chemistry have been reported so far. Our results confirm that artificial neural networks are reliable, fast and cheap tools and open the way for predicting the antioxidant activity of essential oils. Therefore, can be used to model nutraceutical properties or predict the quality of food ingredients.

ABSTRACT

A reversed phase high performance liquid chromatography (RP-HPLC) separation coupled with an electrospray ionisation mass spectrometry detection (ESI-MS) and the 2,2-diphenyl-1-picrylhydrazyl (DPPH) assay was used for the screening of multiple antioxidant compounds in *Antidesma thwaitesianum* Muell. fruit wine. The active compounds were identified by comparison with authentic standards and published mass spectra. With the help of the multidimensional information of LC–ESI-MS/MS and DPPH assay, the compounds with different chemical structures could be determined in one run successfully. The antioxidant compounds were separated and identified as gallic acid, cyanidin-3-sophoroside, monogalloyl glucoside, delphinidin-3-sambubioside, catechin, caffeic acid, and pelargonidin-3-malonyl glucoside. This result shows that an on-line HPLC–MS–DPPH assay can be a powerful technique for the rapid characterisation of antioxidant compounds in plant extracts.

1. Introduction

Over the last decade, the healthy effects of red wine have been studied in depth. Epidemiological studies have shown that moderate intake of red wine reduced the incidence of coronary heart disease (Criqui & Ringel, 1994; Serafini, Laranjinha, Almeida, & Mainai, 2000; Stanley & Mazier, 1999; Sun, Simonyi, & Sun, 2002). Fruit wines have also been claimed for health promoting effects which may be related to their antioxidant activity. The tropical climate and naturally fertile geography of Thailand is the home of some of the world's most exotic and delicious tropical fruits. Some of the fruits used for making particular wines are unique to this region. *Antidesma thwaitesianum* Muell. (Euphorbiaceae) is a wild plant found in the north-eastern area of Thailand. The fruits are round or ovoid, up to 1/3 in. (8 mm) in diameter, borne in grapelike, pendent clusters (often paired) which are extremely showy because the berries ripen unevenly. The pale yellowish-green, white, bright-red, and nearly black stages are all present at the same time. The trees flower in May–July and the fruits mature in August–October (Morton, 1987). The ripen fruits are consumed fresh or can be processed into juice or a type of wine. These fruits are believed to be a good source of natural antioxidants but it is still not clear which compounds are responsible for their antioxidant property. *A. thwaitesianum* red wine is another product that becomes more popular among Thai consumers as healthy nourishment.

HPLC methods coupled on-line with an antioxidants detection unit using post column reaction of the eluates with free radicals have been reported to be successfully applied to identify and quantify antioxidants in biological samples (Niederländer, van Beek, Bartasiute, & Koleva, 2008; Nuengchamnong & Ingkaninan, 2009). In several plant extracts, antioxidants are usually found as complex mixtures and the composition changes according to the plant examined. In such cases, hyphenated techniques are needed for the analysis of the extracts. In this study, we used a readily available on-line HPLC technique coupled to MS and an antioxidant activity detector using the DPPH method as a tool to directly screen and characterise the antioxidants in this fruit wine. The antioxidant compounds can be monitored spectrophotometrically by the decrease of the absorbance at 515 nm of the reduced form of the free radical, 2,2-diphenyl-1-picrylhydrazyl (DPPH). Combination of LC–MS techniques with on-line post-column detection of antioxidant compounds has an advantage of the simultaneous use of chromatography as a separation method, an ESI-MS/MS as an identification method, and a DPPH assay as an activity evaluation method.

In this paper, we report the evaluation of the antioxidant activity in Thai fruit wines using off-line DPPH assay and the use of an on-line HPLC–MS–DPPH assay for the analysis of phenolic antioxidant compounds in fruit wine, *A. thwaitesianum*. An LC–MS/MS in MRM mode was used to quantify the active compounds.

2. Materials and methods

2.1. Materials and reagents

Pure standards of gallic acid, caffeic acid, catechin, quercetin, were purchased from Sigma (St. Louis, MO, USA). DPPH was

* Corresponding author. Tel.: +66 55 261000x3618; fax: +66 55 261057.

doi:10.1016/j.foodchem.2009.04.069

obtained from Sigma–Aldrich Chemie (Steinheim, Germany). Methanol (LC/MS reagent) was purchased from JT Baker (Mallinckrodt Baker, Inc. Phillipsburg, NJ, USA). Formic acid (analytical grade) was purchased for Merck (Darmstadt, Germany). Water was purified using Elga USF system (Bucks, England).

2.2. Wine samples

Thirty wine samples from 26 kinds of fruits were products from the "One Tambon One Product" (OTOP) project that supported by the Thai government. The name of the fruit wines and source of the product were listed in Table 1.

2.3. Sample preparation

The wine samples were tested for off-line antioxidant activity without any sample preparation. For the analyses using the on-line HPLC–MS–DPPH assay, *A. thwaitesianum* fruit wine from Mae Hong Sorn were filtered through a 0.2 μm Nylon syringe filter (Chrom Tech, Inc. MN, USA) and the filtrates were then injected into the on-line system.

2.4. Off-line DPPH assay for evaluation of antioxidant activity

The DPPH assay was slightly modified from the method of Brand-Williams, Cuvelier and Berset (1995). In the assay, 0.1 ml fruit wine was mixed with 2.9 ml of 0.1 mM DPPH in methanol and incubated in the dark at room temperature for 30 min. The absorbance (A) of the sample was measured on a Perkin Elmer Lambda II (Perkin Elmer, USA) spectrophotometer at 515 nm using methanol as a blank. All tests were performed in triplicate. The total antioxidant activity (TAA) was expressed in terms of percentage activity as calculated with the following equation: % TAA = $100 \times [(Ac - As/Ac)]$, where Ac is the absorbance of the control and As is the absorbance of the tested sample after 30 min.

2.5. On-line HPLC–MS–DPPH assay

An HPLC was on-line coupled to an MS (line A) and a continuous flow of DPPH assay (line B) as shown in Fig. 1. The details of the instrumental set up are as follows.

Line A represents the HPLC system. Agilent 1100 series HPLC system (Agilent Technologies, Palo Alto, CA, USA) is equipped with a binary pump, a degasser, an autosampler, a thermostated column compartment and a control module. The HPLC system was coupled to a PE SCIEX API 4000 triple quadrupole tandem mass spectrometer (Applied Biosystem, Foster City, CA) equipped with an electrospray ionisation interface. The Analyst 1.3.2 software was used for data acquisition and processing. The full scan mass spectra from m/z 100–1000 amu were acquired both in positive and negative ion modes. The optimum conditions of the interface were as follows: ESI-positive mode; ion spray voltage of 4500 V, curtain gas of 10 psi, ion source gas 1 of 65 psi, ion source gas 2 of 55 psi. The interface temperature was set at 400 °C. The entrance and declustering potential were 10 and 80 V, respectively. ESI-negative mode; ion spray voltage of −4500 V, curtain gas of 10 psi, ion source gas 1 of 65 psi, ion source gas 2 of 55 psi. The interface temperature was set at 400 °C. The entrance and declustering potential were −10 and −80 V, respectively.

The chromatographic separation was on a phenomenex Gemini column (5 μm, 250 × 4.6 mm i.d.) (Phenomenex, Torrace, CA) protected with an ODS C18 guard column, operated at 25 °C. The mobile phase consisted of 0.1% (v/v) formic acid in deionized water (solvent A) and methanol (solvent B), starting from 90% solvent A (4 min), from 90% to 80% solvent A (6 min), from 80% to 10% solvent A (30 min), constant at 10% solvent A (5 min), from 10% to 90% solvent A (5 min), and then constant at 90% solvent A for

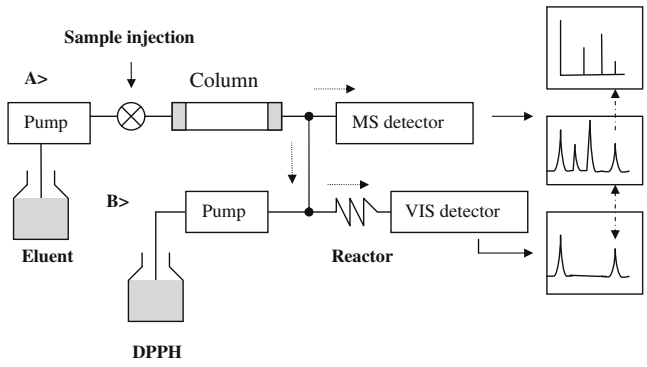

Fig. 1. Scheme of the on-line HPLC–MS–DPPH assay. The arrows indicate flow directions.

5 min for reconditioning of the column. A mass spectra was recorded within 55 min. The injection volume was 5 μl. The flow rate was set at 600 μl /min.

A polyetheretherketone (PEEK) tubing with the length of 10 cm and an i.d. of 0.25 mm was used as the post-column tubing. A 24 cm length of 0.17 mm (i.d.) PEEK tubing was coupled line A to line B by a Y-connector. A 30 cm 0.13 mm (i.d.) PEEK was connected to MS. The eluent flow was split in ratio of 8:2 between the MS ion source and DPPH line. Quercetin at concentration of 200 μg/ml was spiked into the wine sample and used as a standard to synchronise antioxidant activity in the DPPH trace with the mass trace.

Line B represents the continuous flow system for antioxidant activity detection. It consisted of an HPLC pump, LC20AD prominence (Shimadzu, Kyoto, Japan), home-made knitted reaction coil PEEK tubing with an inner diameter 180 μm and a total reaction coil volume of 100 μL. The flow of 0.1 mM DPPH was set to 0.2 ml/min and induced bleaching was detected as a negative peak at 515 nm using the UV–VIS detector (SPD 20AV, Shimadzu, Kyoto, Japan), and the LC solution software was used for data acquisition and processing. The polarity of the signal output was reversed in order to obtain positive signals. The system was operated at 25 °C.

To characterise the antioxidant peaks, the fragment ions from their corresponding parent ions in negative mode were induced with collision gas (CAD) of 6 psi, collision energy (CE) between −5 and −50 V and a collision cell exit potential (CXP) of −6 V, DP in the range of −20 to −110 V. In the positive mode, the ions were induced with CAD of 7 psi. CE, CXP, and DP were set in the range of 5–25, 3–13, and 20–100 V, respectively.

2.6. Peak identification

Peak identification was performed by comparison of the retention time and mass spectrum with reference compounds. Tentative identification of peaks of which standard compounds unavailable was obtained by comparing their elution order and their molecular ion with the data from the literature.

2.7. Quantitative analysis

For quantitative analysis of antioxidants, the same HPLC condition was used. The MS parameters were operated in negative multiple reactions monitoring (MRM) scan. The individual optimised parameters for each compound are provided in Table 2. Standard compounds, gallic acid, cathechin, and caffeic acid at the concentrations of 0.1–10 μg/ml were used for preparation of calibration curves. The curves were generated by linear regression based on peak area. Contents of antioxidant compounds in *A. thwaitesianum* fruit wine were determined in triplicate experiments.

3. Results and discussion

The antioxidant activities of 30 fruit wine samples were evaluated by DPPH assay. The method is based on the reduction of the stable radical, DPPH, to the formation a non radical form in the presence of hydrogen donating antioxidant. The fruit wines showed an antioxidant activity by reducing DPPH to the yellow coloured diphenylpicrylhydrazine derivatives. The results of the screening are shown in Table 1. Most of these fruit wines showed high antioxidant activity. *A. thwaitesianum* wine was selected for further study due to the fact that the chemical constituents of this plant had not been reported before. Investigation of its antioxidant components is, therefore, of interest.

3.1. Identification of phenolic antioxidants in A. thwaitesianum wine

An HPLC was linked to a triple quadrupole mass spectrometer and a DPPH assay for the rapid identification of antioxidant components of the fruit wine of *A. thwaitesianum* (Fig. 2). The DPPH assay monitors the activity of the antioxidant compounds that separated from the gradient reversed-phase HPLC system. The mass spectrometry was used to elucidate the structures based on their mass spectra and fragmentation patterns. Moreover tandem mass spectrometry (MS/MS), particularly product ion analysis and precursor ion analysis, was extensively used for the specific identification and characterisation of the antioxidants.

The separation of phenolic compounds in *A. thwaitesianum* wine was achieved using a reversed phase C_{18} column with gradient methanol under acidic condition as a mobile phase. The eluate was split to the activity monitor and to the mass spectrometer with an electrospray interface generated in full scan MS mode. The sample was analysed twice in positive ionisation and negative ionisation modes. The DPPH based antioxidant activity profile (Fig. 2a) showed that at least nine compounds had antioxidant activity. The deprotonated molecular ion $[M-H]^-$ peaks of a standard reference, quercetin, was found at 37.70 min. The delay time between the read out from the MS detector and the corresponding peak from the antioxidant activity assay (38.17 min) was calculated as ca. 0.47 min. The retention time (t_R) values of the DPPH-positive compound and MS data obtained with individual compounds are summarised in Table 3. Peaks 1, 3, 5, and 6 were analysed using negative ionisation mode, while better MS spectra of peaks 2, 4, 7, 8, and 9 were obtained with the positive ionisation mode (Fig. 2b and c).

In the negative ionisation mode, peak 1 with a $[M-H]^-$ at *m/z* 169.4 and a fragment ion at *m/z* 125.2 (170-H–CO_2) and peak 6 with a $[M-H]^-$ at *m/z* 179.1 and a fragment ion at *m/z* 135.2 were assigned as gallic acid and caffeic acid respectively by comparison of their retention times and their mass data with standard compounds.

Peak 3 showing a $[M-H]^-$ at *m/z* 331.3 was assigned as monogalloyl glucoside by comparison with published data (Nawwar, Marzouk, Nigge, & Linscheid, 1997; Zywicki, Reemtsma, & Jekel, 2002).

Peak 5 with an $[M-H]^-$ at *m/z* 289.2 and a fragment ion at *m/z* 245.2 was identified as catechin by comparison with published data (Rio et al., 2004) and a reference standard.

In positive ionisation, peak 2 showing a $[M+H]^+$ at *m/z* 611.5 and a fragment ion at *m/z* 287.6 (cyanidin; M-324, loss of the sophorosyl unit) was identified as cyanidin-3-sophoroside by comparison with published data (Mullen et al., 2002). In the same fashion, peak 4 with an $[M+H]^+$ at *m/z* 597.5 and a fragment ion at *m/z* 303.6 (M−293.9) and peak 7 showing an $[M+H]^+$ at *m/z* 519.7 and a fragment ion at *m/z* 271.7 (M−248) were identified as delphinidin-3-sambubioside (Giusti, Rodriguez-Saona, Griffin & Wrolstad, 1999), and pelargonidin-3-malonyl glucoside, respectively. The general structures and substitution patterns of compounds identified are shown in Fig. 3.

Table 2
Mass parameters in negative MRM scan mode for quantitative analysis.

Compound	Parent ion (*m/z*)	Product ion (*m/z*)	Declustering potential (V)	Collision energy (V)	Collision cell exit potential (V)
Gallic acid	169.0	125.1	−70	−20	−18
Catechin	288.9	245	−150	−22	−12
Caffeic acid	178.7	134.9	−70	−23	−20

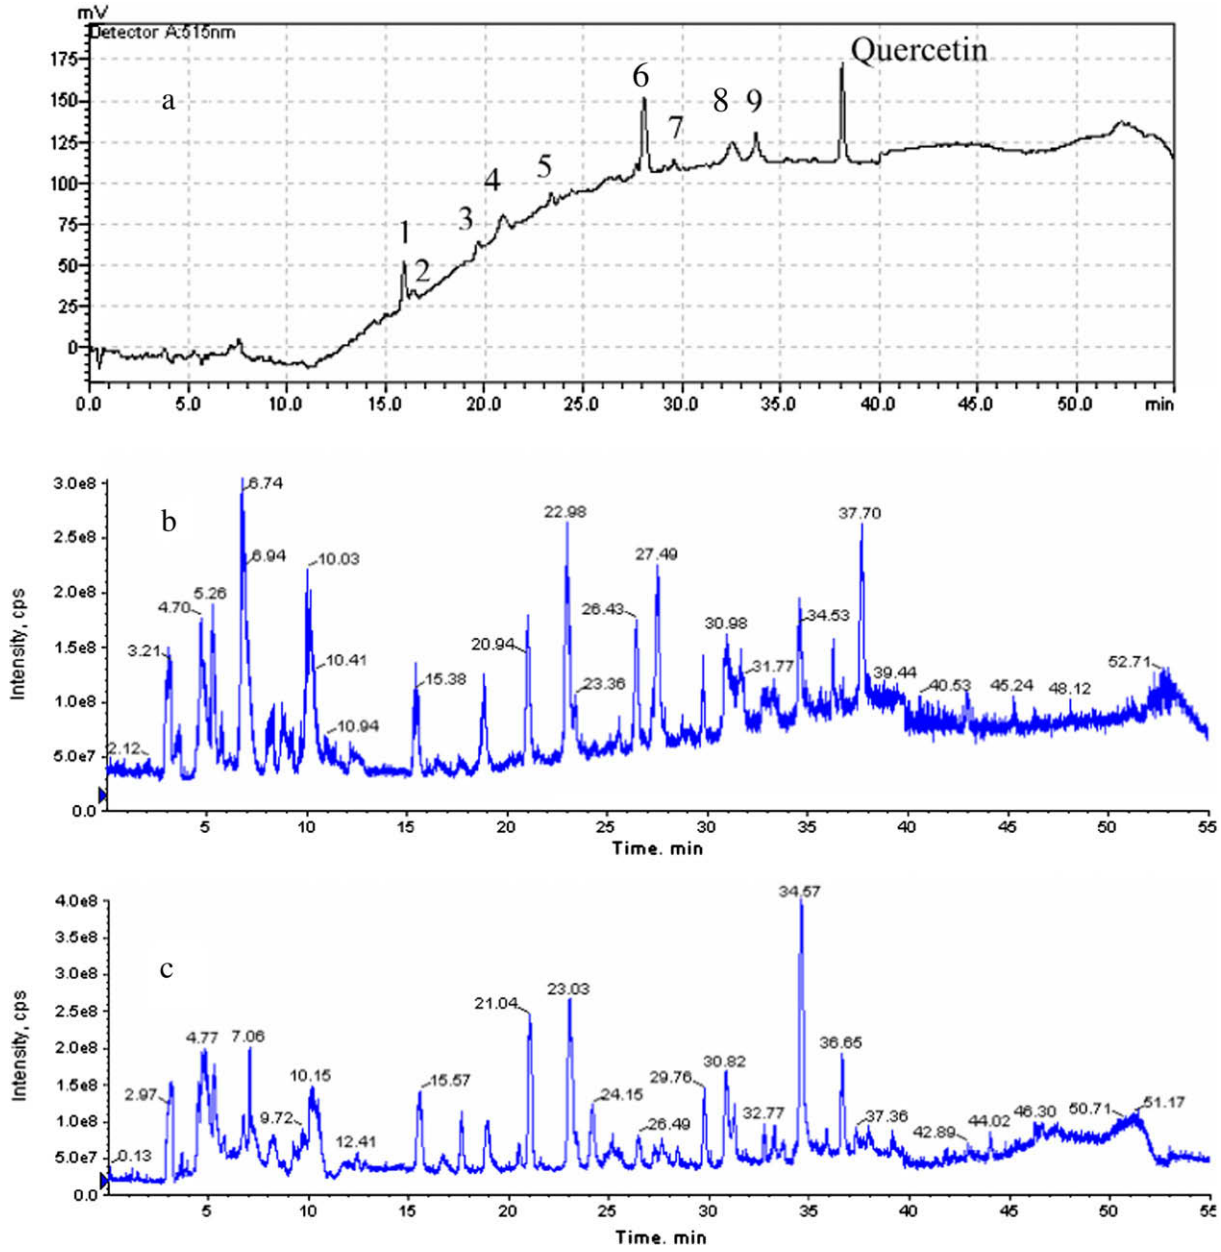

Fig. 2. The results from the analysis of *A. thwaitesianum* wine from Mae Hong Sorn using on-line HPLC–MS–DPPH assay. (a) The chromatogram from the antioxidant assay detection at 515 nm. (b) The total ion current (TIC) output from the ESI-MS in negative mode. (c) The total ion current (TIC) output from the ESI-MS in positive mode.

Peak 8 with fragment ions at *m/z* 401.3 and 385.5 and peak 9 with fragment ions at *m/z* 489.8 and 473.9 remained unidentified. Their structures still need to be elucidated by comparison of MS data with reference standards or using other spectroscopic techniques such as NMR.

Generally, an antioxidant activity depends on the number and positions of hydroxyl groups and other substituents and the glycosylation of the flavonoid molecules. Substitution pattern in the B ring and A ring as well as the 2,3-double bond and the 4-oxo group in the C ring also affect the antioxidant activity of flavonoids. Glycosylation of flavonoids reduces their activity (Rice-Evans, Miller, & Paganga, 1996). The aglycone of delphinidin, cyanidin, gallic acid, catechin pelargonidin, and caffeic acid showed high activity with the ABTS assay with TEAC value (mM) of 4.44, 4.40, 3.01, 2.40,

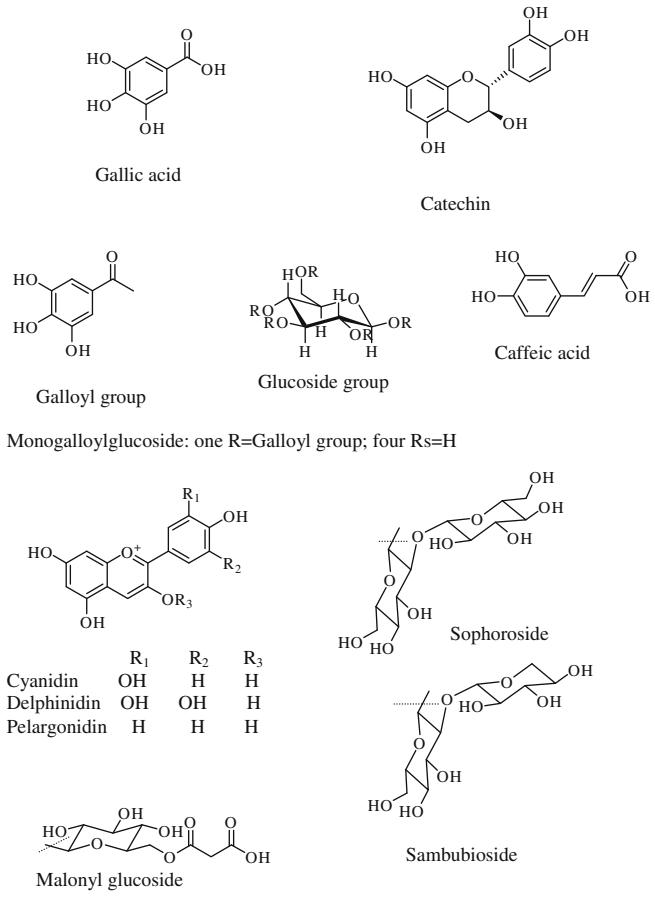

Fig. 3. Structure of phenolic compounds found in *A. thwaitesianum* wine: monogalloylglucoside; one R = galloyl group, four Rs = H; cyanidin: R_1 = OH,R_2,R_3 = H; delphinidin: R_1,R_2 = OH,R_3 = H; pelargonidin: R_1,R_2,R_3 = H; cyanidin-3-sophoroside: R_3 = sophoroside; Delphinidin-3-sambubioside: R_3 = sambubioside; Pelargonidin-3-malonyl glucoside: R_3 = malonyl glucoside.

1.30, 1.24, respectively (Cai, Sun, Xing, Luo, & Corke, 2006; Rice-Evans et al., 1996). In our previous study, it is proved that intensity of antioxidant peaks depend on both types and amounts of the antioxidant compounds present in the sample (Nuengchamnong et al., 2005).

Antioxidant compounds in *A. thwaitesianum* wine can be quantitatively analysed using LC–MS/MS in MRM mode if the standard compounds are available. In our studies, gallic acid, cathechin and caffeic acid at various concentrations were used for preparation of calibration curves. The satisfactory linearity was obtained. Regression equations ($1/x_2$ weighting) of gallic acid, cathechin, and caffeic acid were $Y = 8.49e + 005x + 5.49e + 003$, $Y = 1.47e + 004x - 6.62e + 004$, and $Y = 1.53e + 006x + 1.01e + 004$, with the *r* values of 0.9976, 0.9858, and 0.9995, respectively. The limits of detection (LOD) with signal to noise ratio of three were also determined. The LOD of gallic acid and caffeic acid were 0.05 ng while that of cathechin was 5.0 ng. The triplicate analyses of *A. thwaitesianum* fruit wine showed that caffeic acid was present in the highest amount (21.40 ± 0.26 μg/ml) comparing with gallic acid (16.9 ± 0.26 μg/ml) and catechin (4.91 ± 0.04 μg/ml). Unfortunately, not all antioxidant compounds in this wine were quantitatively determined due to lack of standard compounds.

4. Conclusions

The fruit wine of *A. thwaitesianum* was screened for antioxidant activity using an on-line HPLC–MS–DPPH assay. The active antioxidants were simultaneously monitored and identified. This is a clear example of how a hyphenated chromatographic technique can accelerate the procedure for identification of biologically active compounds in plants. The hyphenated technique used here successfully provided information of the antioxidant activity and the possible chemical structures of various phenolic antioxidant compounds in fruit wine of *A. thwaitesianum*.

Acknowledgements

We thank the staff from the Regional Medical Sciences Centers; Chiang Mai, Chiang Rai, Songkhla, Konkaen, Nakornratchasima and Chonburi for providing the samples and assisting in some of the preliminary analyses. Professor Dr. Hans Junginger is thanked for critically reviewing this manuscript. The Center of Excellence for Innovation in Chemistry (PERCH-CIC), Thailand is acknowledged for the support of the last author.

Analytical Methods

High-power gradient diffusion NMR spectroscopy for the rapid assessment of extra-virgin olive oil adulteration

Olive oil
Adulteration
Diffusion NMR spectroscopy
Discriminant analysis

ABSTRACT

A high gradient diffusion NMR spectroscopy was applied to measure diffusion coefficients (*D*) of a number of extra-virgin olive, seed, and nut oils in order to ascertain the suitability of this rapid and direct method for discrimination of adulterated olive oils. Minimum adulteration levels that could be detected by changes in *D* were 10% for sunflower (SuO) and soybean oil (SoO), and 30% for hazelnut (HO) and peanut oil (PO). Qualitative and quantitative prediction of adulteration was achieved by discriminant analysis (DA). The highest prediction accuracy (98–100%) was observed only when two DA models were concomitantly used for sample classification. The first DA model provided recognition of high adulterated EVOO with more than 20% of SuO or SoO, and 30% with PO, whilst the second model could differentiate EVOO adulterated with 10% of SuO or SoO, and more than 30% of HO. The validation test performed with an independent set of randomly adulterated EVOO samples gave 100% classification success. The high accuracy levels together with minimal requirements of sample preparation, and short analyses time, prove the high-power gradient diffusion NMR spectroscopy as an ideal method for rapid screening of adulteration in valuable olive oils.

1. Introduction

High quality food products demanding higher market prices often become subjects of unscrupulous food mislabelling, or increased volume of good quality batches through adulteration with sub-standard procedure. With the increasing awareness of food safety and quality, consumers continuously demand reassurance of food origin and content (Schieber, 2008). Thus, there is a great effort, both from consumers and industrial site, to develop rapid, inexpensive, reliable and non-destructive screening techniques for the determination of food authenticity at any point of the distribution chain (Downey, Kelly, & Rodriguez, 2006; Schieber, 2008).

Recently, major concern was paid to frauds in olive oil industry. Production of olive oil represents about ~3% of the world oils and fat markets, with ~78% of global production taking place in Mediterranean countries (Aparicio & McIntyre, 1998; Rezzi et al., 2005), where oil industry is important in sustaining viability of agricultural economy (Vlachos et al., 2006). Virgin olive oils (VOO), and in particular, extra-virgin olive oils (EVOO), that are produced using solely cold pressing techniques, belong to the most sought after olive oil product on the account of their organoleptic (aroma and taste), antioxidant, and nutritional properties (Aparicio & McIntyre, 1998; Boscou, 1996; Harwood & Yaqoob, 2002). The cultivation of olive trees, harvesting of olive fruits, and extraction of olive oil are hard and time consuming tasks that add to its relatively high commercial price (Fragaki, Spyros, Siragakis, Salivaras, & Dais, 2005). Therefore, attempts to adulterate the high cost VOO with less expensive vegetable oils or low quality olive oils (López-Díez, Bianchi, & Goodacre, 2003) are by no means rare. Such fraud practise is not only unfair to consumers in terms of cost, but also comprises a threat for the economic development and prosperity of Mediterranean agricultural countryside communities, and, in addition, it may cause severe health and safety problems (López-Díez et al., 2003; Vlachos et al., 2006), such as the occurrence of food poisoning in Spain in 1981 (Wesley, Barnes, & McGill, 1995; World Health Organization, 1992).

Authentication and detection of VOO adulteration is based on the comparison of chemical compositions of suspected samples with identified characteristics of olive oils promulgated by the European Union (European Union, 1995, 1996). Despite the fact that composition of VOO differs with various factors such as geographical origin or weather conditions during growths and harvesting (Downey et al., 2006), good results were obtained applying classical analytical methods, such as gas chromatography (GC), high-performance liquid chromatography (HPLC), and pyrolysis mass spectrometry (Aparicio & Aparicio-Ruiz, 2000 and references therein). However, these methods are generally sample destructive and rather unsuitable for oil screening on a large scale,

due to many necessary time-consuming steps required to achieve a complete quantification. Recent research, performed mainly in the last decade, is focused on the determination of adulterants using rapid spectroscopic techniques. Amongst these, Raman (López-Díez et al., 2003), ultraviolet (Aparicio & Aparicio-Ruiz, 2000), mid-infrared (Guillén & Cabo, 1997), near-infrared (Christy, Kasemsuran, Du, & Ozaki, 2004), fluorescence (Poulli, Mousdis, & Georgiou, 2007; Sayago, García-González, Morales, & Aparicio, 2007) and common solution-state NMR spectroscopy (Fauhl, Reniero, & Guillou, 2000; Mannina, Sobolev, & Segre, 2003; Sacchi et al., 1996; Vigli, Philippidis, Spyros, & Dais, 2003) were, with some limits, successfully proved as suitable tools for the detection of various adulterants.

This work discusses the potential of a high-power pulsed-field gradient NMR probe (Diff30) in enabling a direct observation of diffusion coefficient of viscous samples, and detecting adulterated EVOO oils. The suitability of this nondestructive, and rapid spectroscopic technique was evaluated on binary mixtures of olive oil adulterated with soybean, sunflower, peanut and hazelnut oil, all belonging to the most commonly found adulterants in VOO (Guimet, Ferré, & Boqué, 2005; Poulli et al., 2007). Discrimination of authentic and adulterated EVOO was assessed by chemometric approach, in particular, by discriminant analysis (DA).

2. Materials and methods

2.1. Materials

Twenty five extra-virgin olive oil (EVOO) samples of Leccino (L1–L6), Frantoio (F1–F6), Pendolino (P1–P7) and Coratina (C1–C6), obtained from the territory around Salerno, Italy, were kindly provided by the local producer "De Falco". Sunflower (SuO), soybean (SoO), hazelnut (HO), and peanut oil (PO) were purchased from local distributors. The authentic EVOO samples and the same ones but adulterated with 5%, 10%, 20%, 30% and 50% of SuO, SoO, PO and HO, reaching a total volume of 1 ml, were transferred into 5 mm NMR tubes, placed in the NMR probe, and left to equilibrate at 24.5 °C for 15 min prior to diffusion measurements.

2.2. Diffusion NMR measurements

Pulsed field gradient diffusion NMR measurement was carried out on a Bruker Wide-Bore Avance 300 MHz spectrometer, equipped with a 5 mm inverse Bruker high-power diffusion Diff30 probe yielding a maximum Z gradient strength of 350 G/cm. To avoid probe heating and control sample temperature, the probe was continuously cooled by flowing water at a constant temperature of 24.5 °C. Diffusion spectra (accumulation of four scans) were obtained using a spin-echo pulse sequence with a gradient pulse of 5 ms, diffusion time of 120 ms and gradient amplitude ranging from 11 to 140 G/cm in 128 increments. The total experimental time was 20 min per sample. Diffusion coefficients were calculated from the monoexponential decay dependence of attenuation of signal intensity on the gradient amplitude using Bruker Topspin 1.3 software. All measurements were performed in triplicate. A standard calibration sample (D_2O, $D = 1.872 \times 10^{-9}$ at 25 °C) was run prior to every set of experiments to ensure consistency between datasets.

2.3. Statistical analysis

All data were expressed as the means of at least three replications. Analysis of variance (ANOVA) was performed applying Duncan's multiple comparisons test to determine statistically significant differences at $P \leqslant 0.05$ confidence level. For discrimi-

Table 1
Mean values and standard deviations of diffusion coefficients ($D \times 10^{-12}$ m^2 s^{-1}) for different NMR peaks in spectra of extra-virgin olive (EVOO), hazelnut (HO), peanut (PO), sunflower (SuO), and soybean oil (SoO). Different letters indicate statistical differences (Duncan test) at $P \leqslant 0.05$ confidence level. Peak assignment is given in Table S1 in Supplementary data.

F4	10% SuO	EVOO	?	SuO, SoO 10%	Yes

nant analysis (DA), all analysed samples were employed as training set in order to establish classification rules. The predictive ability of DA model was validated by a supplementary data set consisting of 15 randomly adulterated EVOO samples (Table 2). The statistical data processing was performed by XLSTAT 7.5.2 (Addinsoft SARL, Paris, France).

3. Results and discussion

3.1. ^{1}H NMR analysis

The main constituents of olive oil are variously substituted esters of glycerol and saturated (palmitic, stearic) or unsaturated (oleic, linoleic, linolenic) fatty acids (Sacchi, Addeo, & Paolillo, 1997). Due to the chemical similarity of these triglyceride esters, clusters of co-resonating signals are typically observed in ^{1}H NMR spectrum. This is reflected in Fig. 1 that shows ^{1}H NMR spectra of extra-virgin olive oil (EVOO) acquired with (a) Diff30 and (b) BBI (indirect) probe at 300 and 400 MHz, respectively. Although some resolution is lost when acquiring a spectrum with the Diff30 probe, the number of resonating clusters and their relative intensities are comparable to those observed by common ^{1}H NMR acquisition. The signal assignment of olive oil samples is well recognised and for the main signals is given in Table S1 in Supplementary data (Sacchi et al., 1996). Commonly reported resonance frequency of linolenyl chain, occurring at around 0.95 ppm, observable only upon enlargement of high resolution ^{1}H NMR spectra, was not detected with the Diff30 probe.

Inspection of ^{1}H NMR spectra, acquired with the Diff30 probe (Fig. 2) revealed that the composition of PO and HO did not significantly differ from that of EVOO. Conversely, significantly increased signal intensities can be noticed for peaks 1 and 4 in the spectrum of SoO and SuO. Peak 1 is attributed to the olefinic protons of all unsaturated fatty acids, whilst increased amount of peak 4 usually reflects larger amount of linoleic but at the same time smaller content of oleic acid (Vigli et al., 2003). The concentration of olefinic protons detected below peak 1 is one of the important input parameters for the estimation of the degree of oil unsaturation, known as iodine value (Sacchi et al., 1996). In fact, VOO having lower iodine value than SuO and SoO, are characterised by high amounts of monounsaturated fatty acid, such as oleic acid, and low content of polyunsaturated fatty acids, that include linoleic and linolenic acid (Vigli et al., 2003). The increased intensities of peak 1, and particularly of peak 4, were also noticeable for mixtures of EVOO containing more than 20% of SuO and SoO adulterants (data not shown).

3.2. Diffusion analysis

The mean values and standard deviations of diffusion coefficients (D) of all vegetable oils are summarised in Table 1. Diffusion values of signals 2, 4 and 6 are not reported since these peaks became undetectable under the optimised conditions for the applied NMR spin-echo sequence. This is noticeable in Fig. S1 in Supplementary data that reports 1D diffusion profiles of vegetable oils. With exception of peak 7, that was weighted by a maximum of

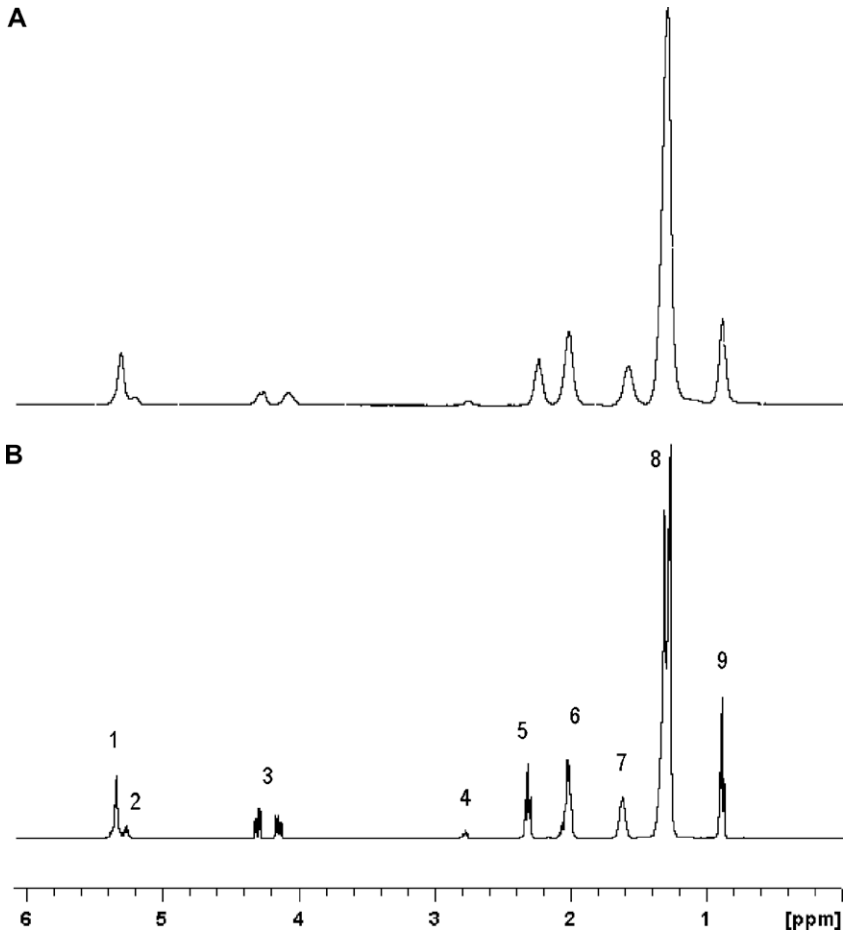

Fig. 1. ^{1}H NMR spectrum of olive oil obtained with: (A) diff30 probe (AV 300), and (B) BBI probe (AV 400, $CDCl_3$ solvent). Assignment of peaks is given in Table S1 in Supplementary data.

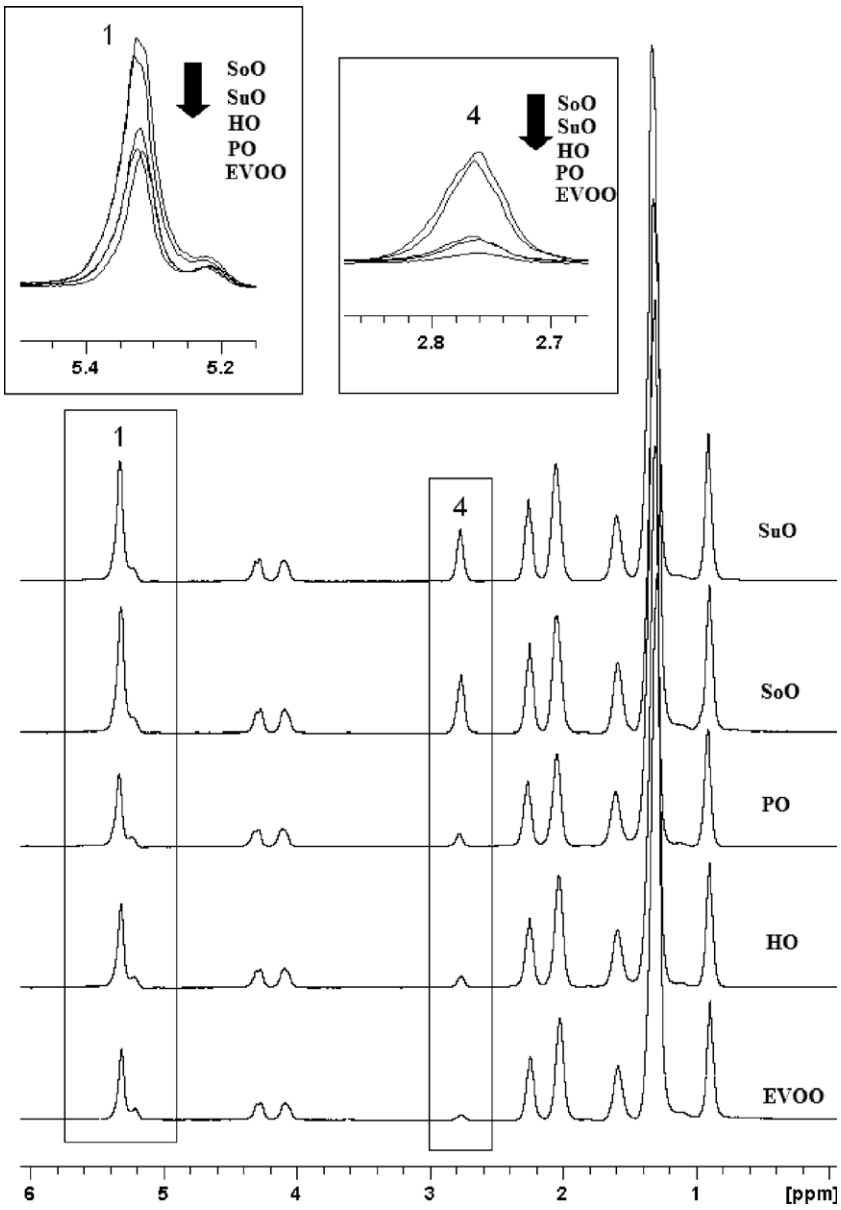

Fig. 2. ^{1}H NMR spectra of vegetable oils obtained with diff30 probe (AV 300). Assignment of peaks is given in Table S1 in Supplementary data. EVOO, HO, PO, SuO, and SoO refer to extra-virgin olive, hazelnut, peanut, sunflower, and soybean oil, respectively.

15% error (Table 1), standard deviations (SD) of less than 1% were observed for the triplicate diffusion measurements of SuO, SoO, PO and HO (Table 1), thereby indicating an excellent method reproducibility. Interestingly, low variability of diffusion coefficients for peaks 1, 3, 5, 8 and 9 was also noted for the 25 different EVOO samples (Table 1). The larger deviation observed for peak 7 was caused by the low signal/noise ratio of this resonance in the 1D diffusion spectra (Fig. S1 in Supplementary data).

The mean values for *D* (Table 1) further give information about dissimilarities in physical properties, namely viscosity, of seed and nut oils as compared to EVOO. The most similar diffusion behaviour to EVOO was noted for HO, whereby, except for signal 7, only a slight increase in *D* was observed for the remaining signals. The *D* value of signal 7 was also the only one greatly reduced in the case of PO, for which a small decrease in diffusion was otherwise noted. For these reasons, *D* calculated for signal 7 was later used as an input for statistical analysis, though it was weighted by a larger statistical error than similar coefficients observed for remaining signals. Unlike nut oils, a substantial difference in diffusion behaviour was noted for SuO and SoO. In comparison to EVOO, the SuO and SoO oils showed significantly larger diffusion for signals 3, 5, 8, and 9, and a smaller but still greatly varied diffusion coefficient for signal 7. In addition, signal 1 became undetectable in diffusion spectra of SuO and SoO under the experimental set-up conditions optimised for EVOO oils (Fig. S1 in Supplementary data).

3.3. Discriminant analysis

Dissimilarities of *D* reported in Table 1 suggested that high-power gradient diffusion NMR spectroscopy might be able to detect the presence of SuO, SoO, PO and HO in EVOO. To assess this possibility, diffusion spectra were collected for a set of 25 binary mixtures, each containing EVOO diluted with 5%, 10%, 20%, 30% and 50% of adulterant seed and nut oils. The obtained diffusion data were used as inputs for discriminant analysis (DA), a statistical technique applied for supervised pattern recognition. The main

DA task is to find the best linear discriminant functions of a set of variables, which reproduce, as far as it is possible, *a priori* grouping of the considered cases. The set of linear functions that are used to build a model for samples of known classes are then in turn used as predictors in order to determine group membership of anonymous samples (Brereton, 2003).

Preliminary DA analyses (DA plot not shown) performed on diffusion data of EVOO adulterated with HO indicated a strong overlay of authentic olive samples with samples adulterated up to 20%. Similar finding was observed for PO adulteration. In both cases, only the more largely adulterated samples were well separated from EVOO samples. The SuO- and SoO-diluted olive oil samples showed close grouping with EVOO for adulteration of 5%, acceptable separation for 10% adulteration, and well distinctive separation for adulteration larger than 20%. However, there was a strong overlay amongst groups adulterated with SuO and SoO. These findings indicate that the high-power gradient diffusion NMR technique was not sensitive enough to recognise adulterations lower than 20% in case of HO and PO, and 5% in case of SuO and SoO. Nor it was able to distinguish whether the adulteration was caused by SuO or SoO. To overcome this limitation in the development of a universal DA model, oil samples were divided into seven pre-defined groups. One group comprised all authentic EVOO; SuO and SoO adulterated EVOO samples were grouped together into four classes according to the adulteration percentage: 10%, 20%, 30% and 50%; and the last two predefined classes were formed by EVOO samples containing 30–50% of HO, and 30–50% of PO.

The best results were observed only when two DA models were used concomitantly. These models are shown in Figs. 3 and 4. The first DA model (Fig. 3) involved EVOO samples with an adulteration of 30–50% of PO, and 20%, 30% and 50% of SuO and SoO. The prediction ability of this training set was 98%. There was no prediction error in the classification of EVOO. A 2% error was observed due to the slight overlay between 20% and 30% adulterated samples with SuO and SoO. The second DA model (Fig. 4) is complementary to the first one and indicates the presence of SuO and SoO when as low as 10%, whereas that of HO was detected only when present from 30% to 50%. The prediction ability of the second DA model reached 100%. Therefore, due to the very good predictability of both model training sets, it is expected that the combined use of

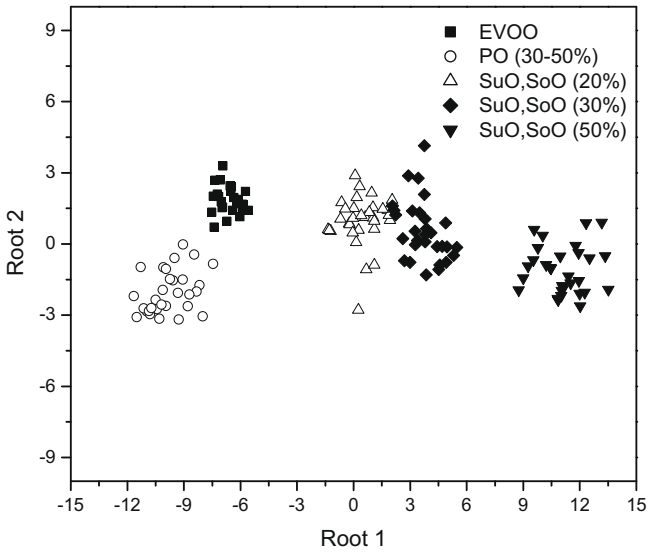

Fig. 3. Classification model I as calculated by discriminant analysis from diffusion data. EVOO, PO, SuO, and SoO refer to extra-virgin olive, peanut, sunflower, and soybean oil, respectively.

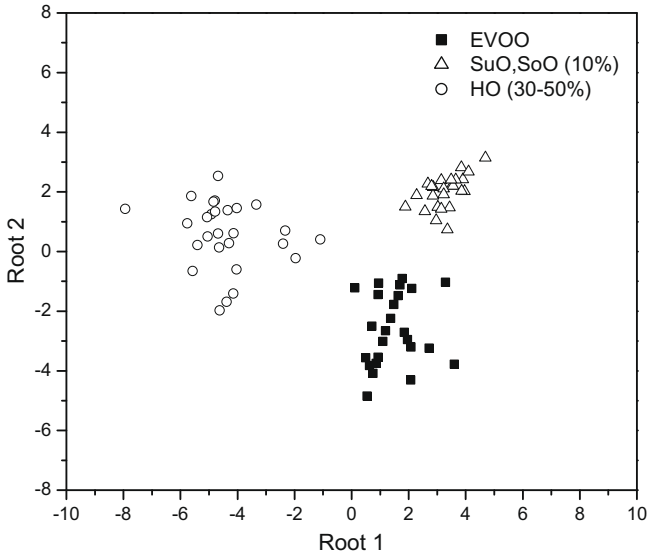

Fig. 4. Classification model II as calculated by discriminant analysis from diffusion data. EVOO, HO, SuO and SoO refer to extra-virgin olive, hazelnut, sunflower, and soybean oil, respectively.

the two DA models should ensure certain recognition of EVOO adulterated by more than 10% with SuO or SoO, and 30% with PO and HO. Concomitantly, olive oil samples classified by both models as EVOO are to be considered as unadulterated, or possessing smaller amounts of adulterants which are under the detection limits of the high-power gradient diffusion NMR technique, as indicated above.

In order to validate such approach, a set of randomly adulterated EVOO samples was prepared. The list of chosen EVOO and the amounts of added adulterants is shown in Table 2. The observed diffusion data were used as input variables in terms of supplementary observations, and the two DA models were applied to compute the probabilities by which such anonymous samples could be recognised in a specific group. The first DA model was initially employed to evaluate samples with high percentage adulteration (Fig. 3). As it is indicated in Table 2, samples F2, C2, P3, P1, C3, C5 and F3 were recognised as adulterated EVOO samples, whilst the remaining samples were temporarily labelled as belonging to unadulterated EVOO group. However, as discussed earlier, an authentic EVOO can be such only when both models classify it as unadulterated. Therefore, the second DA model (Fig. 4) was applied on the remaining dataset, and this time only four samples out of eight were further confirmed as unadulterated (Table 2). It can be noticed that these four samples (P4, L6, C3 and F1) were the only authentic EVOO amongst the independent test samples (Table 2). Moreover, a group membership was correctly recognised for all the 11 remaining adulterated test samples. Therefore, the validation gave 100% success.

Furthermore, it must be noted that the validation success can be expected to be somewhat reduced by interchanging class assignment of EVOO samples adulterated with 20% and 30% of both SuO and SoO. This may be due to the overlay between these two groups in the training set used to build the DA model (Fig. 3). Nevertheless, such reduction of validation does not have any effect on the recognition of an adulterated EVOO.

4. Conclusions

Using a limited number of authentic and adulterated oils, this work demonstrates that a combination of a high-power gradient

diffusion NMR technique with multivariate classification method can successfully discriminate between authentic and high adulterated EVOO with hazelnut (as low as 30%), peanut (as low as 30%), soybean (as low as 10%) and sunflower oil (as low as 10%). The main advantage of this approach is the rapid recognition (5–20 min of analysis) of such adulteration without employing any pre-extraction. The greatest classification success was observed by a combined use of two DA models, one of them involving high (more than 20%) adulteration with SuO, SoO and PO, whilst the other one was based on the diffusion data measured at low adulteration levels (10%) for SoO and SuO and high amount for HO (30–50%). The correct recognition of adulterated EVOO samples was as high as 98%, whilst, concomitantly, the detection accuracy of nonadulterated EVOO was 100%. Such high accuracy levels together with minimal requirements of sample preparation, call for the high-power gradient diffusion NMR spectroscopy as the ideal method for rapid screening of adulteration in olive oils. Only EVOO samples that pass such screening as authentic oils might undergo more costly and time consuming analyses in order to confirm their real authenticity. In addition, future diffusion NMR studies should indicate whether it is possible to apply this technique to detect adulteration of EVOO by an admixture of two and more vegetable oils.

High performance liquid chromatography (HPLC)

ABSTRACT

A simple and rapid HPLC method using UV detector for determination of tryptophan (Trp) contents in pure fermented soy sauces, acid-HVP, and commercial soy sauces was developed. The method requires only simple sample pretreatment. The limit of detection (LOD) is estimated at 1 mg/L (signal-to-noise ratio of 3), and the recovery yields ranged from 92% to 108%. The analysis showed that Trp in all of the analysed acid-HVP samples was not detected and there was obvious detection of Trp (ranged from 136.4 to 261.8 mg/L) in all of the analysed fermented soy sauce samples. The observations suggest that Trp is a practical index of pure fermented soy sauce. The absence of Trp contents or lower level of Trp contents than that in pure fermented soy sauces suggests the soy sauces are not pure fermented soy sauces or presence of soy sauce adulteration. Simultaneous determination of levulinic acid (LV) in samples may be a good help in making assessment of soy sauce adulteration with acid-HVP.

1. Introduction

Soy sauce is a popular seasoning in many Asian countries. Two types of soy sauces are used for cooking and the preparation of diverse foods in China. One type is fermented soy sauce, which is manufactured by brewing of a mixture of cooked soybeans and wheat (National Standard of China, 2000). The second type is blended soy sauce, which is manufactured more economically by combining fermented soy sauce and acid-hydrolysed vegetable protein (acid-HVP) at an appropriate ratio (Food Industry Standard of China, 2000). Up to now, an ideal method for identification of soy sauce that is adulterated is still lacking. In fact, many commercial soy sauces labelled as "Pure fermented soy sauce" are blended soy sauce or produced solely with acid-HVP (Jiang, Ni, & Zhu, 2006; Peng, Yang, & Chen, 2007).

It was reported that levulinic acid (LV) was a proper index for determination of the acid-HVP content in blended soy sauce (Sano et al., 2007; Wang, Lin, Lee, & Choong, 1999). The analysis showed that there was no LV in naturally brewed soy sauce and there was apparent detection of LV in acid-HVP and blended soy sauces with acid-HVP (Sano et al., 2007). But it should be pointed out that levels of LV in some acid-HVP samples were very low. During our analysis, we also found that three commercial acid-HVP samples contained LV at levels (0.09–0.16 mg/mL) significantly lower than 1 mg/mL, which is the maxim allowed level of LV regulated by Soy sauce standard of Taiwan for fermented soy sauce (Taiwan CNS, 1993). Meanwhile, it was reported that LV can be detected in most of caramel colours, which was a common additive in soy sauce (Li & Geng, 2005). We also detected the presence of LV in caramel colour samples, although the detected level of LV (0.02–0.08 mg/mL) was not high. In view of the observations above, it is possible that sometimes LV can not be detected in soy sauce added with acid-HVP, but can be detected in the pure fermented soy sauce added with caramel colour.

Tryptophan (L-2-amino-3-(indol-3-yl)propionic acid, Trp) is a vital constituent of proteins and is indispensable in human nutrition for establishing and maintaining a positive nitrogen balance. As an essential amino acid, it is considered exceptional in its diversity of biological functions. In particular, it is the precursor of the neurotransmitter serotonin. Manufactures of nutritional products are often required to demonstrate an adequate Trp content in their products (Alwarthan, 1995; Delgado-Andrade, Rufián-Henares, Jiménez-Pérez, & Morales, 2006). As traditional seasonings, amino acids are the important constituents of soy sauces. For fermented soy sauces, the amino acids mainly come from the enzyme-catalysed protein hydrolysis under microbial fermentation. For the acid-HVP, the amino acids mainly come from the acid-induced protein hydrolysis. It is well known that, in the classical HCl hydrolysates, a considerable amount of Trp

is destroyed (Molnár-Perl, 1997; Molnár-Perl, Pintér-Szakás, & Khalifa, 1993). So the contents of Trp might be a good index of soy sauce adulteration.

In the present work, we first developed a simple and rapid method for determination of Trp in soy sauce. Then we detected the content of Trp in acid-HVP, pure fermented soy sauces, commercial soy sauces and exploring the potential of Trp contents as an index of soy sauce adulteration.

2. Materials and methods

2.1. Soy sauce samples

Acid-HVP (11 samples, amino acid nitrogen contents $\geqslant$1.0 g/100 mL, formol nitrogen determination) were purchased from five manufactures in China. Pure fermented soy sauces (12 samples, amino acid nitrogen contents $\geqslant$0.4 g/100 mL, formol nitrogen determination) were obtained from six soy sauce companies in China. The authenticity of the 12 pure fermented soy sauces was guaranteed by sampling on the production spot. Commercial soy sauces (21 samples, amino acid nitrogen contents $\geqslant$0.4 g/100 mL, formol nitrogen determination) were purchased from local supermarkets in Chongqing.

2.2. Reagents

HPLC grade methanol was purchased from SK Chemicals (Korea). Trp standard was purchased from Beijing Dingguo Biological Technology Co., Ltd (China). Analytical grade ethanol was obtained from Chengdu Kelong Chemicals Factory (Sichuan province, China). All aqueous solutions were prepared with ultra-pure water purified with the Molecular® ΣH_2O system (Shanghai Molecular Biological Scientific & Technological Co., Ltd., China).

Standard stock solutions of Trp (1000 mg/L) were prepared in 10% ethanol and stored at 4 °C. Working solutions for Trp was prepared from the stock solution with 10% ethanol, and then five concentration levels (1.0, 2.0, 5.0, 10.0, and 20.0 μg/mL) were analysed. The stock solution was prepared every 2 weeks, and the working solutions were prepared the same day that they were used. For quantification, peak areas were correlated with the concentrations according to the calibration curve.

2.3. Instrumentation and chromatographic conditions

The HPLC system was a LC-20AB equipped with an autosampler SIL-20A, a system controller CBM-20A, a pump LC-20AB, a column oven CTO-20A, a UV–vis detector SPD-20AV (Shimadzu, Japan).

The chromatographic analysis was performed using an analytical scale (25 × 0.46 cm i.d.) venusil MP-C18 column with a particle size 5 μm (Agela Technologies, USA). The HPLC column temperature was set to 30 °C during all running procedures, and the injection volume was 10 μL. Absorbance was monitored at 280 nm. Two mobile phases were used to generate a gradient with 1 mL/min flow-rate. Mobile phase A is ultra-pure water, and mobile phase B was methanol. An isocratic elution gradient of 12% B was used.

2.4. Sample pretreatment

One volume of sample was placed in a centrifuge tube with cap. Three volumes of ethanol was then added. The mixture was mixed thoroughly and centrifuged at 4000 rpm for 5 min. The supernatant was diluted 4-fold with water. The diluted supernatant was then filtered through 0.45 μm membrane into HPLC vials for analysis and 10 μL of the final solution was injected into HPLC.

3. Results and discussion

Numerous methods for determination of Trp in complex samples have been proposed. Literature cited many efforts to apply a general method for Trp analysis in various samples (Molnár-Perl, 1997, 1999; Nielsen & Hurrell, 1985). Trp is degraded during classical aminogram analysis of proteins by acid hydrolysis. Several approaches have been proposed for direct Trp determination or after derivatisation, such as second-derivative spectroscopy, *p*-dimethylaminobenzaldehyde, *p*-phenylenediamine, *O*-phthaldehyde, and ninhydrin. Acidic (HCl, HCl with additives), alkaline (NaOH, LiOH) and enzymatic (pronase, pepsin, enzyme cocktail) hydrolysis of the protein has been carried out, followed by chromatographic (ion exchange or reversed-phase), colorimetric or fluorimetric determination of Trp (Aitken & Learmonth, 1996; Fabian, Pinter-Szakas, & Molnár-Perl, 1990; Fletouris, Botsoglou, Papageorgiou, & Mantis, 1993; Hugli & Moore, 1972; Ng, Pascaud, & Pascaud, 1987; Slump, Flissebaalje, & Haaksman, 1991; Yust, Pedroche, Girón-Calle, Vioque, & Millán et al., 2004). Direct spectrophotometric analysis is rapid and does not require hydrolysis of the protein. However, direct determination is subject to error due to interferences and can only be considered as an approximate procedure. Colorimetric methods can be tedious and suffer from problems such as colour stability and interferences (Yust et al., 2004). At present, HPLC is often used for the determination of Trp.

Up to now, the reports about HPLC method without derivatisation using UV detector for direct determination of free Trp in soy sauce samples were not seen. The reports about the application of the free Trp content in soy sauce adulteration were also not seen.

3.1. Sample pretreatment

A simple pretreatment method was developed in this work. The sample pretreatment steps only include precipitating sample with ethanol, dilution of supernatant fluid with water, and then directly analysed by HPLC-UV without further concentration and derivatisation. The simplified sample pretreatment procedures could shorten the analytical time and improve the repeatability of the method. It was found that ethanol could effectively precipitate solids of the samples, decolourise the sample and make the sample become more clarified. Because samples were pretreated directly without hydrolysis procedures, only free Trp in samples was determined.

3.2. HPLC separation and identification

To determine optimal chromatographic conditions for the determination of Trp, we performed preliminary tests with standard solution. When HPLC analysis for Trp standard solution was performed on different columns using different mobile phase, a good symmetrically shaped peak were easily obtained. But when the analysis for the soy sauce samples were performed, the interference peaks could be separated better from the target analyte by using hydrophilic HPLC columns (e.g. venusil MP-C18 columns) (Fig. 1).

The Trp was identified by comparison of retention times against those obtained from Trp standard solutions. The retention time of Trp in different samples was very stable, with the variability less than 0.2%.

3.3. Linearity, detection sensitivity, precision, and recovery yields

We found that there was a linear relationship between the concentrations and the peak area up to 104 mg/L (10 μL injected, $r^2 \geqslant 0.995$). The limit of detection (LOD) calculated from the

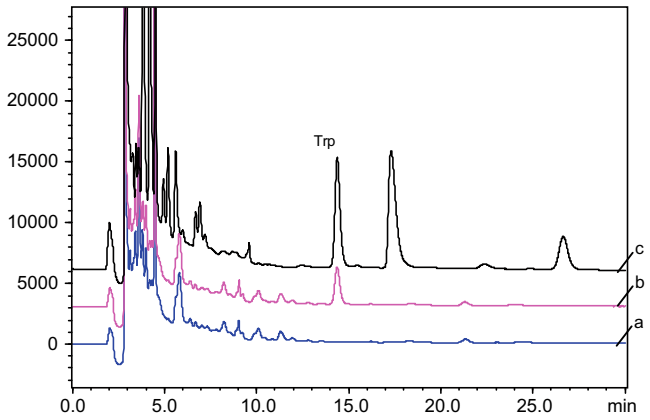

Fig. 1. HPLC–UV chromatograph at 280 nm of samples. (a) acid-HVP; (b) acid-HVP added with Trp (50 mg/L); (c) pure fermented soy sauce (170 mg/L). HPLC column: Venusil MP-C18 column.

measurement of standard solution is estimated at 1 mg/L (signal-to-noise ratio of 3), and the limit of quantitation (LOQ) at 3.3 mg/L (signal-to-noise ratio of 10).

The precision study was validated by replicate analysis of three different samples (including acid-HVP, pure fermented soy sauce, and commercial soy sauce added with large amount of caramel colour) under repeatability and intermediate reproducibility conditions. The samples were first analysed six times in parallel so as to get information about within-day variation. Good repeatability was obtained for three above-mentioned samples. The Trp content in the three samples ranged between 0 (not detected) and 170 mg/L, with repeatability relative standard deviations ranged between 2.1% and 4.7%. Additional precision data was obtained by duplicate analysis of the same products on three different days, which gave a low intermediate reproducibility relative standard deviations ranged between 3.2% and 4.9%.

The recovery of the method was determined in four tests employing the method of standard addition ranging from 50 to 150 mg/L. Three different samples (including acid-HVP, pure fermented soy sauce, and commercial soy sauce added with large amount of caramel colour) were selected. The recovery yields of Trp in acid-HVP, in which Trp was not detected, were estimated by adding 50 and 150 mg/L Trp. For the pure fermented soy sauce and commercial soy sauce, 150 mg/L Trp were added. Excellent percentage recovery yields (92–108%) were obtained according to the established method.

3.4. Determination of Trp in samples

3.4.1. Trp contents in acid-HVP

Totally 11 acid-HVP samples were analysed for determination of Trp contents. Results were listed in Table 1. It was found that Trp was not detected in all the acid-HVP samples. The results suggested that Trp in acid-HVP was destroyed nearly completely.

3.4.2. Trp contents in pure fermented soy sauce

Totally 12 pure fermented soy sauce samples were analysed for determination of Trp contents. Results were listed in Table 2. It was found that Trp was detected in all the pure fermented soy sauce samples. The contents of Trp in the samples were ranged from 136.4 to 261.8 mg/L. In view of that Trp was not detected in acid-HVP, it is possible to use Trp content as an index of soy sauce adulteration with acid-HVP. The absence or low level of Trp contents suggest the soy sauces are not pure fermented soy sauces or adulterated with Acid-HVP.

3.4.3. Trp contents in commercial soy sauce

Totally 21 commercial soy sauce samples were analysed for the Trp contents. Of 21 samples, 3 samples were labelled as "blended soy sauce", 18 samples were labelled as "fermented soy sauces. The results were listed in Table 3. It was found that Trp was not detected in three blended soy sauces and five fermented soy sauces, which suggested that these soy sauces contained no fermented components and are faked fermented soy sauces and blended soy

[b] FSS = fermented soy sauce.
[c] BSS = blended soy sauce.

sauces. According to (Food Industry Standard of China (2000), the blended soy sauce should contain an appropriate ratio of fermented components. It was also found that Trp contents (14.23–46.28 mg/L) in some samples (samples 9–11, 19 and 20) were significantly lower than that in pure fermented soy sauces, which strongly suggested that these samples contained some fermented components and were not "100% pure" fermented soy sauces. In view of the fact that acid-HVP adulteration was common in soy sauce adulteration, absence or low level of Trp in soy sauce could suggest the possibility of acid-HVP adulteration in soy sauce.

But for some samples whose Trp contents are not very low (62.06–83.99 mg/L) (e.g. samples 12, 13 and 21), it is relatively difficult to make a judgement about the presence of acid-HVP adulteration. In these instances, it is necessary to detect another useful indicator that could suggest the addition of acid-HVP. Although levulinic acid (LV) was not an ideal index for determination of acid-HVP as mentioned above, it is still useful as an indicator of acid-HVP at present. Simultaneous determination of LV in samples may be a good help in making assessment of sample authenticity. During this study, LV contents of the above tested commercial soy sauces were also determined. It was found that LV was detected in most of the samples not detected with Trp. Both Trp and LV were not detected only in one sample (sample 4). Of the samples detected with low levels of Trp (14.23–83.99 mg/L) (samples 9–13 and 19–21), 7 samples were detected with LV. Of the samples detected with relatively high levels of Trp (157.46–248.15 mg/L) (samples 14–18), none was detected with LV. But it should be pointed out that the presence of LV in samples sometimes cannot definitely indicate soy sauce adulteration with acid-HVP, especially when the detected LV contents were very low. Now we are screening other specific indicator that could identify acid-HVP adulteration or other adulteration.

Because Trp contents may be correlated with the contents of amino acid nitrogen or total nitrogen, the ratio of Trp and amino acid nitrogen (or total nitrogen contents) may be more meaningful for the authenticity measurement of soy sauce samples. For the soy sauces with a higher amino acid nitrogen contents, it should contain higher levels of Trp. For the soy sauces with a lower amino acid nitrogen contents, it should contain lower levels of Trp. Now we are exploring the experimental relationship between Trp and amino acid nitrogen content (or total nitrogen contents) in different soy sauce samples and the effects of different fermenting process and material components on the experimental relationship (ratio). If a relatively fixed ratio is existed, it is possible to add this ratio as a specification requirement for the fermented soy sauce products.

4. Conclusions

The HPLC method presented in this study is simple and reliable for determination of Trp contents in pure fermented soy sauces, acid-HVP, and commercial soy sauces. The method requires only a simple sample preparation. The analysis showed that Trp was not detected in all of the analysed acid-HVP samples and there was obvious detection of Trp (ranged from 136.4 to 261.8 mg/L) in all of the analysed fermented soy sauce samples. These results indicate that Trp is a practical index of pure fermented soy sauces. The absence or low level of Trp in soy sauces suggests that the soy sauces are not pure fermented soy sauces or may be adulterated with acid-HVP. In some instances, simultaneous determination of LV in samples may be a good help in making assessment of soy sauce adulteration with acid-HVP.

Analytical Methods

The potential of coupling information using three analytical techniques for identifying the geographical origin of Liguria extra virgin olive oil

Head-space mass spectrometer

ABSTRACT

The combined use of data obtained from different analytical instruments is a complex problem.

In this paper the potential of coupling three analytical techniques for building a class model for extra virgin (e.v.) olive oil from Liguria, was investigated.

A sampling design for the Ligurian e.v. olive oil was developed by the selection of a representative subset from all possible e.v. olive oil samples of the Liguria region.

Thus, in order to choose this subset with uniform distribution on the production area and representative of the production density, two algorithms for sampling have been used: Kennard–Stone and Potential Function.

The samples were analysed by head-space mass spectrometry (electronic nose), UV–visible and NIR spectroscopy.

In particular, the exceptional possibility provided by Chemometrics to effectively extract and combine (fusion) the information from these multivariate and non-specific data and to build a class model for Liguria e.v. olive oil was studied.

1. Introduction

The development of new and increasingly sophisticated techniques for the authentication of food products continues with increasing consumer awareness of food safety and authenticity issues (Reid, O'Donnell, & Downey, 2006). Food authentication is also of concern to genuine food processors who do not wish to be subjected to unfair competition from unscrupulous processors who would gain an economic advantage from the misrepresentation of the food they are selling.

The rights of consumers and genuine food processors in terms of food adulteration and fraudulent or deceptive practices in food processing are set out in a European Union Regulation regarding food safety and traceability.

The European Council Regulation (EC) No. 2081/92 establishes that foodstuffs which are produced, processed and prepared in a given geographical area using recognised know-how, are indicated with the Protected Designation of Origin (PDO).

Among the numerous analytical methods applied to food authentication in the last decade, spectroscopy (UV, NIR, MIR, visible, Raman) and electronic nose have been frequently used.

IR spectroscopy is a rapid and non-destructive technique for the authentication of food samples. NIR spectroscopy utilises the spectral range from 14 000 to 4000 cm^{-1} and provides much more complex structural information relating to the vibrational behaviour of combinations of bonds. This technique is suited for use in an industrial setting due to its ease of use and the relatively low financial cost of obtaining and running the equipment. A lot of foods have recently been effectively tested for adulteration using NIR spectroscopy; with regards to olive oil, several studies are published (Christy, Du, & Ozaki, 2004; Galtier et al., 2007).

As far as the electronic nose is concerned, there has been some success using this technology for the differentiation of olive oils on the basis of geographical origin (Cerrato Oliveros, Boggia, Casale, Armanino, & Forina, 2005; Cosio, Ballabio, Benedetti, & Gigliotti, 2006). Electronic nose technology is based on the detection of the volatile compounds present in the headspace of a food sample and its advantages include the relatively small amount of sample preparation that is involved and the speed of analysis.

Regarding the UV–visible spectroscopy, the information of visible spectra has been evaluated for its ability to trace the geographical origin of e.v. olive oils coming from several Mediterranean regions (Forina, Boggia, & Casale, 2007) but in general the visible region has been rarely used in the characterisation of food origin.

All these analytical techniques provide multivariate and non-specific signals and for this reason Chemometrics is necessary to filter out the most relevant information from the data.

Chemometric methods for classification of olive oils have become of increasing importance (Aranda, Gómez-Alonso, Rivera

del Álamo, Salvador, & Fregapane, 2004; Brescia, Alviti, Liuzzi, & Sacco, 2003; Casas, Bueno, Garcia, & Cano, 2003; Cichelli & Pertesana, 2004) and different Chemometric tools are applied in various laboratories.

Marini et al. (2004) authenticated e.v. olive oil varieties using linear discriminant analysis (LDA) and back propagation artificial neural networks (BP-ANN). Christy, Kasemsumran, Du, and Ozaki (2004) detected and quantified adulteration in olive oil by near-infrared spectroscopy and using Chemometric techniques: principal component analysis (PCA), partial least squares regression (PLS) and methods for data pretreatments such as multiplicative signal correction. Downey, McIntyre, and Davies (2003) studied the visible and NIR spectra of e.v. olive oils and correctly classified 94% of the samples according to the geographical origin, using PLS, LDA and *k*-nearest neighbour method (KNN).

In the literature, there are several examples that demonstrate the possibility of using "non conventional technologies", as spectroscopy and electronic nose, for the characterisation of e.v. olive oil, while papers about the coupling of information provided by different instruments are not frequent (Karoui et al., 2005; Mazerolles, Devaux, Dufour, Qannari, & Courcoux, 2002). On the contrary, the use of predictors from different instrumental sources, or with different treatments, should be one of the developmental directions in food chemistry in consequence of the fact that laboratories working on food problems have, in general, several instruments, many providing non specific information.

The objective of this study was to build a class model that would confirm the authenticity of e.v. olive oil from Liguria, an Italian region, using Chemometrics to extract and especially to combine the information from multivariate and non-specific data obtained by head-space mass spectrometry, UV–visible and NIR spectroscopy.

In order to reach this goal, two Chemometric strategies to manage all the information provided by three analytical techniques were developed.

Moreover, in order to select a representative subset of olive oil samples taken from the population of all possible samples in the Liguria region, a sampling strategy was developed. In classification and class-modelling problems, a sampling design should always be applied for the selection of samples to be used as a training set for building a class model, but, in reality, few sampling examples are present in the literature.

2. Materials and methods

2.1. Samples

One-hundred and eighty-nine extra virgin olive oils were analysed: 126 of these were authentic oils from Liguria and 63 were commercial samples.

The authentic samples were obtained from the 2005–2006 olive crop by collecting them directly and personally from farmers and oil mills in the Liguria region.

These samples comprehended both "fresh" and "bottled" oils, but they were defined "authentic" because their origin was guaranteed. Among these 126 samples, 65 representative samples were selected by means of a sampling strategy described below and used as training set to build a class model for Liguria olive oil.

The 63 commercial samples were bought in grocers and in supermarkets and comprehended 26 samples labelled as Ligurian e.v. olive oil (six of them labeled as PDO) and 37 samples of a different geographical origin (i.e. from Spain and other Italian regions).

The samples were stored in hermetically sealed topaz glass flask in a cold dark place until analysis in order to avoid losses or oxidations.

2.2. Sampling design

Sampling design in the context of this study refers to the selection of a statistical sample from the population of all (possible) samples.

A statistical sample should be representative of the population it is taken from, containing all variability of the relevant attributes describing its population.

The composition of olive oil is influenced by many factors, such as olive variety or cultivar, soil composition and climate, the procedure for collection of olives, pesticide treatments and phytosanitary conditions, month of collection, technology of production, manuring, transport and storage conditions before and after milling. Some of these factors are related to the specific production area while others cause a variation between oils of the same location as, for instance, month of collection, year of production, ripening or harvesting. In order to capture this variation, this study would need to be repeated over time.

In order to select Liguria e.v. olive oil samples with uniform distribution in the production area and representative of the production density, two algorithms for sampling have been sequentially used: Kennard–Stone design and Potential Function design.

2.2.1. Kennard and Stone algorithm

Kennard and Stone (1969) developed an algorithm for the selection of objects in multivariate space, such that the objects span the cloud of all objects as much as possible. This approach has been successfully applied in the field of Chemometrics, e.g. for the selection of a calibration set out of a population of samples. Here, this approach was applied to select a subset of samples with uniform distribution in the production area.

In this work, the Kennard and Stone algorithm was applied on the data matrix of 126 rows and 2 columns, containing the 126 Ligurian authentic samples described by the GPS coordinates of the oil mills in which they were collected.

The Kennard and Stone algorithm selects a predefined number of points (here the samples) in the space under the criterion that the sampled points are the best possible representation of the population of all points.

2.2.2. Potential Functions design

Many sampling designs are based on the statistical distribution of factor values, where a normal distribution is assumed to be the case. In many situations, however, a normal distribution is not appropriate, even after transformation of the data.

Complex distributions can be estimated by defining a Potential Function (Forina, Armanino, Leardi, & Drava, 1991). Potential Functions were introduced in Chemometrics several years ago for modelling groups (classes) of objects in multivariate space.

A sampling design based on the density functions was developed by Pizarro Millan, Forina, Casolino, and Leardi (1998) and in this study it was used to select samples representative of the production density of Liguria.

The probability density is determined as the sum of the individual contributions of each object. The individual contribution can have different shapes, however, one of the more common is the Gaussian-like shape (normal potential).

I is the number of training set objects. The selection of a subset of M objects from I ($I > M$) objects is performed as follows:

The object with the highest cumulative potential is selected.

Then, the potential in each point is recalculated after subtraction of the individual contribution of the selected object k multiplied by a selection factor r; r usually is $r = I/M$, i.e. the total number of objects I divided by the number of objects M to be selected.

In the new step, the object with the highest new potential is then selected as the second of the subset, and so on, till the predetermined number M of objects has been selected.

The density function computed with the selected objects must be very similar to the initial density function obtained from all the objects: this is a measure of the goodness of the representativity of the subset.

2.3. Apparatus and procedure

E.v. olive oil samples were measured with electronic nose, NIR and UV–visible spectrophotometers.

NIR measurements were performed with a FT near-infrared spectrometer based on a Polarization Interferometer (Buchi NIR-Flex N-500) in the 4000–10 000 cm^{-1} range at 4 cm^{-1} resolution. The samples were analysed in the transmittance mode using quartz cells with 5 mm path length. A total of 16 scans were averaged for every spectrum. Between samples, the cell components were washed with detergent in warm water, rinsed with acetone and then dried.

In order to eliminate the influence of the temperature in the variation between spectra, samples were measured in thermostatic conditions at 35 ± 0.5 °C.

Two replicates of each sample were taken and the average spectrum was calculated and used in subsequent analysis.

In order to remove the oil turbidity that could compromise the NIR spectra, in particular of the authentic samples, all the e.v. olive oils were centrifuged at 3000 rpm for 30 min before being analysed.

The electronic nose used in this study is not a traditional electronic nose based on sensors but it is a headspace mass spectrometer; it was assembled in our laboratory and is formed by an automatic sample introduction system, directly coupled to a mass detector without performing any chromatographic separation. A detailed description of this instrument and procedure of analysis can be found elsewhere (Cerrato Oliveros et al., 2005).

Absorption spectra in the ultraviolet and visible regions were obtained in the range 190–1100 nm using an Agilent 8453 spectrophotometer. The radiation source is a combination of a deuterium-discharge lamp for the ultraviolet wavelength range and a tungsten lamp for the visible wavelength range. The cells are rectangular cells in quartz glass with path length of 10 mm.

Isooctane (spectrophotometer grade) was used as a blank and it was purchased by Sigma–Aldrich (St. Louis, MO, USA). E.v. olive oils were directly analysed with no sample pre-treatment step other than filtration trough paper. Oil spectra were collected at room temperature, filling the quartz cell with samples (0.9 ml approximately).

2.4. Data analysis

The training set comprised two classes:

1. Authentic e.v. olive oils from Liguria, corresponding to the 65 samples selected using the sampling strategy.
2. Commercial e.v. olive oils from other regions corresponding to the 37 commercial samples of different geographical origin.

The 26 commercial samples labelled as Ligurian were joined to the 61 authentic Ligurian samples not selected by means of the sampling strategy and used only to test the class models.

Data analysis was performed using the Chemometric package V-PARVUS 2007 (Forina, Lanteri, Armanino, Casolino, & Casale, 2007).

As far as the NIR spectra is concerned, one segment of the signal without absorption was removed and only the range from 4380 to 10 000 cm^{-1} was considered. So, the data matrix had 189 rows (samples) and 1406 columns (variables, wavelengths).

Several mathematical transformations—standard normal variate (SNV) (Barnes, Dhanoa, & Lister, 1989), de-trending (DT) and derivatives—were tested to NIR transmittance spectra to eliminate the effect of particle size, scatter, and multi-collinearity and the use of first derivative only was effective in reducing the major factor inhibiting the interpretation of near-infrared spectra.

Therefore, the method of Savitzky and Golay (1964) with third-order smoothing polynomials through eleven points was used to compute the first derivatives of the NIR spectra that were used for all the subsequent analysis.

As far as the headspace mass spectrometry is concerned, the "spectral fingerprint" of each sample was obtained. The procedure is described in detail elsewhere (Cerrato Oliveros et al., 2005). The obtained data matrix for data analysis contained as many rows as samples (189) and as many columns as m/z recorded during the data acquisition time (151 m/z values, from 50 to 250). This data matrix was submitted to a row profile pre-treatment, a scaling that results in unit sum of the scaled elements:

$$y_{iv} = x_{iv} \Big/ \sum_{v=1}^{V} x_{iv}$$

As far as the UV–visible spectra is concerned, the parts of the signal saturated or without absorption were removed and only the range from 400 to 715 nm was considered. So, the data matrix had 189 rows (samples) and 316 columns (variables, wavelengths). Also in this case, first derivative spectra were calculated with a Savitzky–Golay filter using a third-order polynomial and an eleven point window.

The data from the three instruments were pre-treated separately and then, two strategies were considered:

1. The principal component analysis (PCA) was performed separately for each data set (HS-MS, UV–vis, NIR) and the first principal components of each data set were considered and joined. Then Unequal-Quadratic Discriminant Analysis (UNEQ-QDA) and Soft Independent Modelling of Class Analogy (SIMCA), as class-modelling techniques, were performed on these principal components.
2. The three data sets were joined and a procedure of variable selection was applied.

Then UNEQ-QDA and SIMCA were performed on the selected variables.

The two class-modelling techniques, SIMCA (Forina & Lanteri, 1984; Wold & Sjostrom, 1977) and UNEQ-QDA (Derde & Massart, 1986; Hotelling, 1947) were used to build a class model for Liguria e.v. olive oils.

SIMCA builds a class model based on the principal components of the category that are generally computed after individual category autoscaling.

K components are used to build the model. These K components define the inner space, the space of the structure.

The other dimensions are the outer space, the space of noise. The model of SIMCA is a hyper volume in the space of the first components, delimited by the range of the scores.

The Coomans plots (Coomans, 1982) were used to display the SIMCA results.

In these plots the coordinates of each object are the SIMCA distances from the models of two classes (in our case, distance from

class 1 on *X*-axis and distance from class 2 on *Y*-axis) or, better, their ratio to the critical distance corresponding to the boundary of the class space. The critical distances (95%) are drawn in the plot so that it is divided in four parts. The objects in the left bottom square are accepted by the models of the two classes because they have small distances from both models whereas the objects refused by both models are in the right upper square. The objects accepted by only one model fall in the other two parts (rectangles) of the Coomans plot.

UNEQ is the name currently used in Chemometrics for the class modelling technique developed by H. Hotelling and based on the Hotelling T^2 statistics. UNEQ is the class modelling version of quadratic discriminant analysis (QDA), where each category is described by the estimates of the means of the variables and the category variance-covariance matrix.

In this paper, classification and prediction abilities were computed as the average of the classification abilities for every class. The prediction ability was computed by the G-fold cross-validation method: the objects are divided into G cancellation groups. The objects are assigned to a cancellation group by their index *n* (row in the data matrix): the first object is assigned to the cancellation group 1, the second to group 2, the gth to the group G. Then the (g + 1)th is assigned again to group 1, and so on.

The model is computed G times. Each time, the objects in the corresponding cancellation group form the evaluation set. The objects in the other groups are the training set, used to compute the model parameters. At the end of the procedure, each object has been $(G - 1)$ times in the training set and once in the evaluation set. The final model is computed with all objects in the training set.

We used five cancellation groups for validation.

The *sensitivity* of a model (for a category) is the percentage of the objects of a class accepted by the class model. The specificity is the percentage of the objects of the categories different from the modelled one rejected by the class model.

The selection of discriminant variables was performed by means of a feature selection technique based on the stepwise decorrelation of the variables, SELECT (Forina, Lanteri, Casale, & Cerrato Oliveros, 2007; Kowalski & Bender, 1976), implemented in the V-PARVUS software.

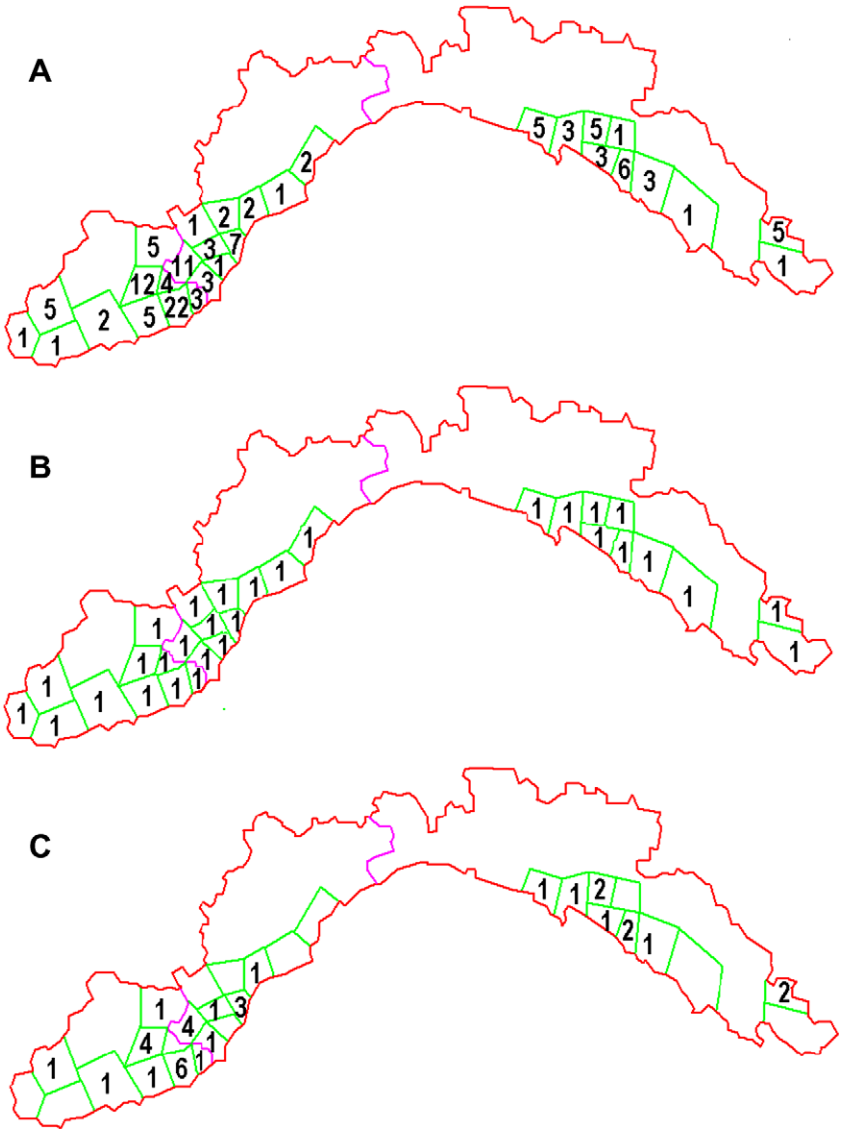

Fig. 1. (A) Repartition of oil-mills in the Liguria region; (B) distribution of the samples selected in the first step (Kennard Stone); (C) distribution of the samples selected in the second step (Potential Function). The three geographical denominations of the PDO "Riviera Ligure" are shown.

This technique generates a set of decorrelated variables ordered according to their Fisher weights. SELECT searches, at each step, for the variable with the largest classification weight. This variable is selected and decorrelated from the other variables; then the algorithm is repeated until a fixed number of variables is selected or the Fisher weight is lower than a specific cut-off value.

3. Results and discussion

3.1. Sampling design

The e.v. olive oil of Liguria is a PDO with name "Riviera Ligure", divided in three additional geographical denominations, namely "Riviera dei Fiori", "Riviera del Ponente Savonese" and "Riviera di Levante".

The sample distribution is analogous to the density of oliveyards, because an oil-mill receives olives from a relatively small neighbourhood. Fig. 1A, on the top, shows the repartition of oil-mills in the three geographical denominations of Liguria, that is the population of all (possible) samples.

For each of the three areas, the number of available samples was, respectively:

"Riviera dei Fiori"	60
"Riviera del Ponente Savonese"	33
"Riviera di Levante"	33

for a total of 126 samples.

The selection of a subset of samples was performed in two steps, using the sampling techniques described in Section 2.2.

1. Fist step – Kennard Stone algorithm was used to have a subset of 10 samples with uniform distribution on the production area of each geographical denomination; these 30 selected samples are shown in Fig. 1B.
2. Second step – The Potential Function design was used to select, among the samples not selected in the first step, a subset representative of the production density (and consequently of variability factors different from the geographical position). These selected samples are shown in Fig. 1C.

The number of samples selected in the second step was 15 for "Riviera dei Fiori", 10 for both "Riviera del Ponente Savonese" and for "Riviera di Levante". This difference can be justified by the fact that the "Riviera dei Fiori" has a larger production of olive oil.

The number of selected samples was:

"Riviera dei Fiori"	25
"Riviera del Ponente Savonese"	20
"Riviera di Levante"	20

for a total of 65 samples.

These 65 selected samples constituted the class 1 of the training set. The remainder 61 authentic samples were assigned to the test set.

Strategy 1: The PCA was performed separately for each of the three data set (HS-MS, UV–vis, NIR).

The first two principal components of each data set were considered and joined.

At first attempt, the PCA was applied as display method on these six principal components, after autoscaling.

Table 1
SIMCA and UNEQ-QDA results for Strategy 1 and Strategy 2, respectively.

SIMCA	(%)	UNEQ	(%)
Classification ability	96.1	Classification ability	99.0
Prediction ability (5CV)	92.2	Prediction ability (5CV)	97.1
Mean sensitivity	91.2	Mean sensitivity	90.7
Mean specificity	96.1	Mean specificity	100.0

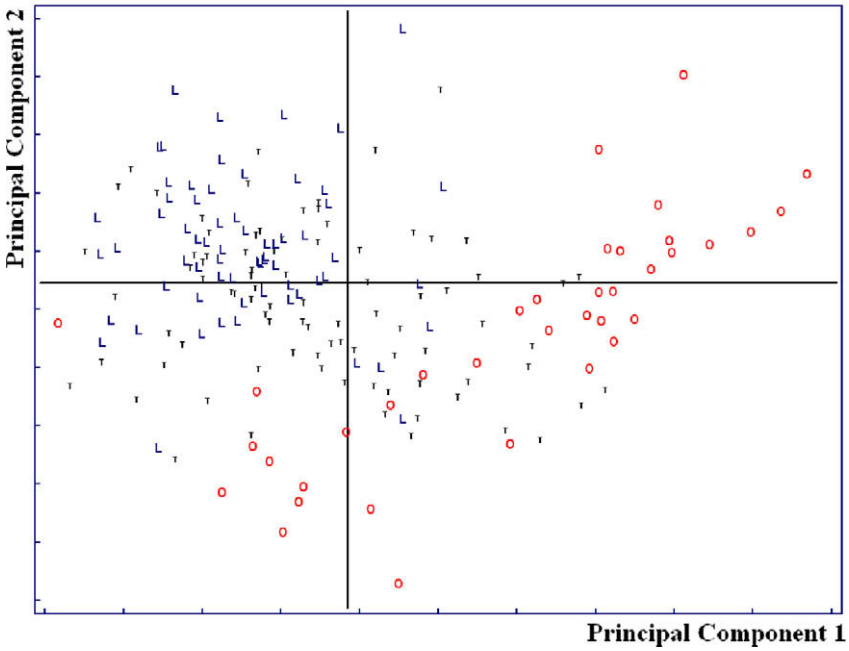

Fig. 2. Score plot on the first two principal components of the data fused according to Strategy 1. Samples are represented by a class symbol: L (Liguria), O (other regions), T (test set).

The first two PCs explained the 62.3% of total variance. In Fig. 2, score plot on the 1st–2nd components, a good discrimination between the two classes (authentic Ligurian oils and oils from other regions) is shown.

Then, in order to build class models in the multidimensional space, some class-modelling methods were applied using only the six principal components (the scores on the first two PCs for each of the three data sets).

Thus, UNEQ-QDA and SIMCA were performed as class-modelling tools; the results, shown in Table 1, were similar and both satisfactory. UNEQ-QDA allowed building Liguria class model with good predictive ability, high sensitivity and 100.0% specificity.

Fig. 3 shows the Coomans plot for the SIMCA models: the test set objects are not displayed, to make clearer the visualisation of the training set samples.

The samples having small distance from the model of class 1 fall in the vertical rectangle on the left, representing the model of authentic Ligurian e.v. olive oils. Four Ligurian samples are out of this model: the sensibility is not 100.0%. The horizontal rectangle on the right is the model of class 2 (oils from other regions). Four samples of class 2 are out of this model, its sensibility is 90.0% and the mean value between the sensitivities of the two classes 91.2%.

All samples of class 2 are rejected by the model of class 1: the specificity of this model is 100.0%. On the contrary, the model of class 2 accepts some Ligurian samples (those in the left bottom square), so that its specificity is lower. The value 96.1% reported in Table 1, is the mean value between the specificities of class 1 and 2.

Strategy 2: The three data sets were joined and SELECT, as feature selection technique, was applied to choose a subset of variables. In order to obtain a reliable model, there is a suggested number of samples to number of variables ratio, so 12 variables were retained.

Fig. 4 shows the score plot on the first two principal components of these 12 selected variables, after autoscaling. The use of autoscaling before computing principal components was necessary because the variables were of a different nature.

The first two PCs explained the 42.1% of total variance.

UNEQ-QDA and SIMCA were performed using these 12 variables; the results are shown in Table 1. Fig. 5 shows the Coomans plot for the SIMCA models: in this case, only three Ligurian samples are refused by the model of authentic Ligurian e.v. olive oils. Moreover, this model refuses all samples of class 2 and no Ligurian samples fall in the model of class 2: the mean specificity is 100.0% (no samples in the left bottom square).

The SIMCA and UNEQ-QDA results were improved by using the selected variables: as average values 100.0% of samples were correctly classified, 100.0% of total internal prediction (5 cross-validation groups) were achieved and both methods allowed building Liguria class models with good sensitivity and specificity.

Finally, the results (classification and prediction errors, sensitivity and specificity of the models) obtained by data fusion, were compared with the results obtained using the three data sets separately and this comparison showed that the results always improved through combining information from different sources. Using only the UV–visible variables, the prediction abilities were not so good (85.3% with SIMCA and 90.1% with UNEQ-QDA) and the specificities were lower (69.6% for SIMCA model and 55.5% for UNEQ-QDA model); also the results obtained using only the NIR spectra were worse: the prediction abilities were 91.2% for SIMCA and 84.3% for UNEQ-QDA but especially the specificities were not satisfactory (63.7% SIMCA and 46.0% UNEQ-QDA). Also using only the head-space mass spectrometry data, it was not possible to achieve the results

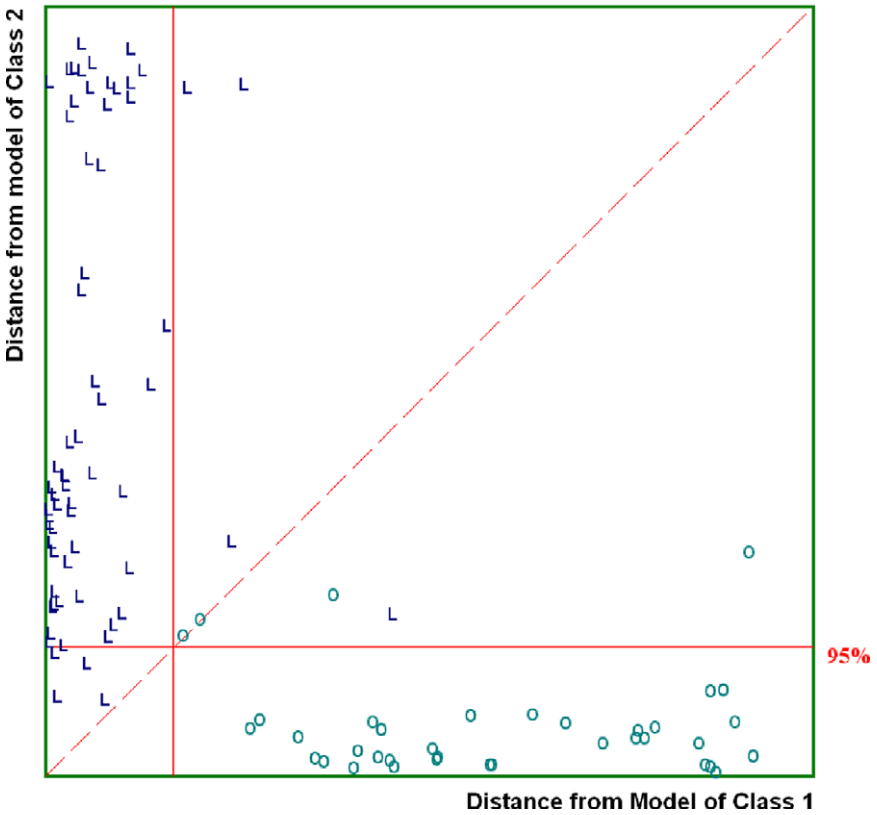

Fig. 3. Coomans plot for the SIMCA models computed according to Strategy 1. Samples are represented by a class symbol: L (Liguria), O (other regions).

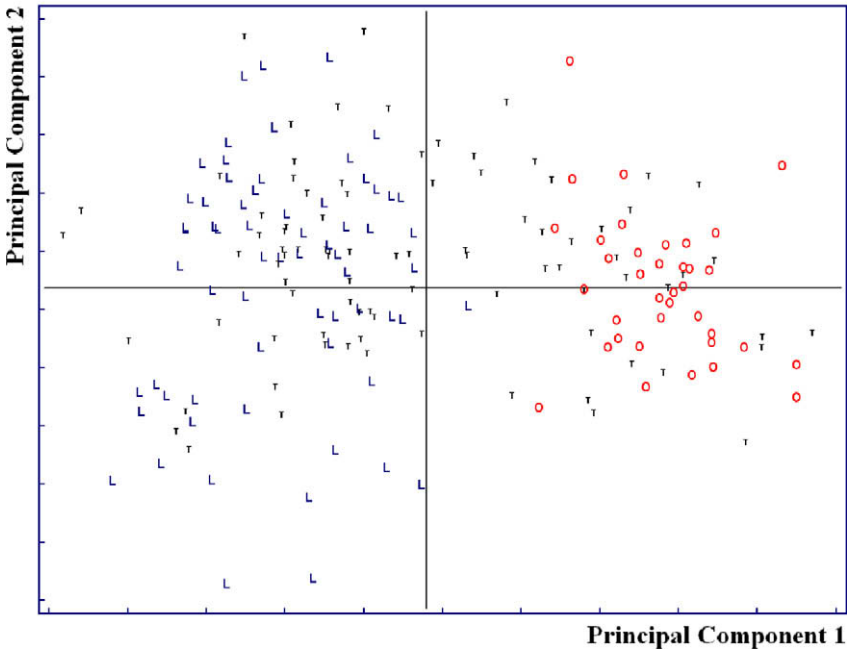

Fig. 4. Score plot on the first two principal components of the data fused according to Strategy 2. Samples are represented by a class symbol: L (Liguria), O (other regions), T (test set).

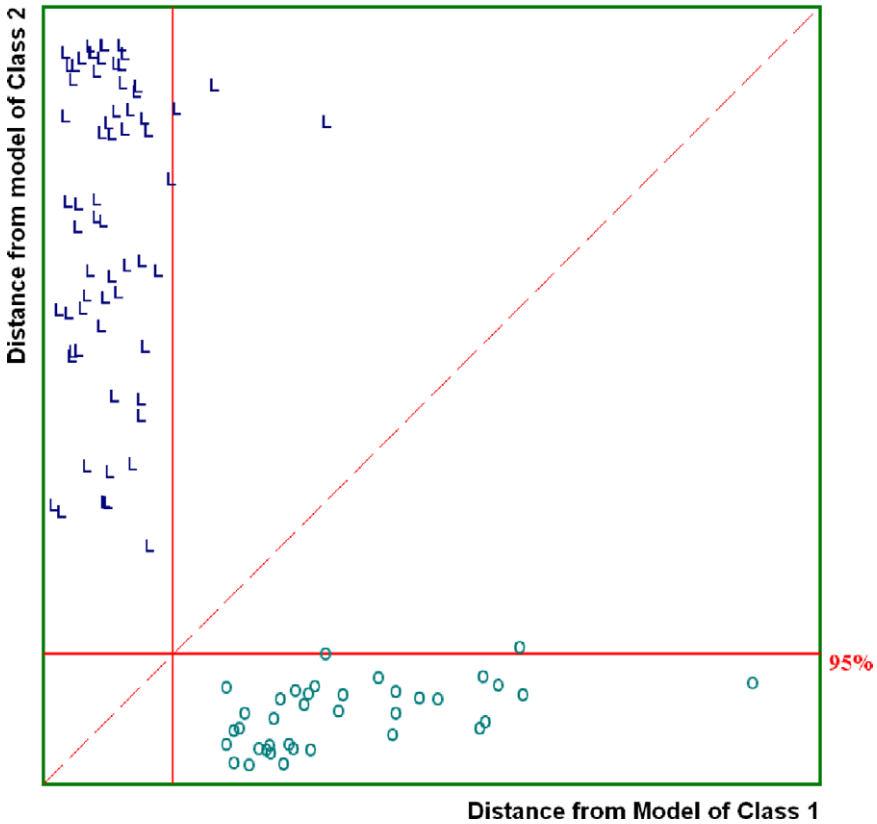

Fig. 5. Coomans plot for the SIMCA models previous feature selection by SELECT (Strategy 2). Samples are represented by a class symbol: L (Liguria), O (other regions).

obtained coupling the three analytical techniques: in this case the sensitivities of the models were worse (89.0% for SIMCA and 93.0% for UNEQ-QDA).

In addition, also as far as the test set is concerned, the results improved with the data fusion. In fact, with both strategies, the 61 authentic samples of the test set collected from oil mills in the Liguria region, were accepted by the class model of category

1: both SIMCA and UNEQ-QDA models had 100.0% of sensitivity considering the authentic samples. Otherwise, using the three data sets separately, some authentic samples were refused by the Liguria class model.

Among the 26 commercial samples of the test set labelled as Ligurian e.v. olive oils, some samples were accepted in the authentic Liguria e.v. olive oil model but other ones were refused by this model. It is interesting to note that the six PDO samples were always accepted from the model of authentic Liguria e.v. olive oils. In fact these commercial samples are of known and guaranteed origin. On the contrary, the remaining 20 samples were labelled as Ligurian samples, but their origin was dubious: these samples were produced in Liguria but not necessarily using Liguria olive cultivars.

4. Conclusion

In this paper, in order to build a class model for confirming the authenticity of Liguria e.v. olive oil, the fusion of data obtained by different instruments was tested.

In particular, non-specific data obtained by head-space mass spectrometry, UV–visible and NIR spectroscopy were considered and two Chemometric strategies to manage all the information provided by these three analytical techniques were developed.

In order to build a class model for a typical food as e.v. olive oil, that is a complex analytical matrix, it is necessary to extract an overall sample, constituted by a number of individual samples, representative of the food. For this reason a sampling strategy was developed and applied.

All the obtained results (classification and prediction errors, sensitivity and specificity of the models) were compared with the results obtained using the three data sets separately.

The results confirmed the potential of the fusion of data obtained by different analytical techniques (HS-MS, UV–Vis and NIR) using appropriate Chemometric methods for testing food authenticity.

ABSTRACT

The goal of this study was to examine the possibility of verifying the geographical origin of honeys based on the profiles of volatile compounds. A head-space solid phase microextraction (SPME) combined with comprehensive two-dimensional gas chromatography–time-of-flight mass spectrometry (GC × GC–TOF-MS) was used to analyze the volatiles in honeys with various geographical and floral origins. Once the analytical data were collected, supervised pattern recognition techniques were applied to construct classification/discrimination rules to predict the origin of samples on the basis of their profiles of volatile compounds. Specifically, linear discriminant analysis (LDA), soft independent modeling of class analogies (SIMCA), discriminant partial least squares (DPLS) and support vector machines (SVM) with the recently proposed Pearson VII universal kernel (PUK) were used in our study to discriminate between Corsican and non-Corsican honeys. Although DPLS and LDA provided models with high sensitivities and specificities, the best performance was achieved by the SVM using PUK. The results of this study demonstrated that GC × GC–TOFMS combined with methods like LDA, DPLS and SVM can be successfully applied to detect mislabeling of Corsican honeys.

1. Introduction

Nowadays, the identification of the origin of food is one of the most important issues in food chemistry and in food quality control. Recently the European Commission has decided to introduce regulations for labeling food commodities. The origin of food, together with its main ingredients, should be available to the consumer. These regulations aim to guarantee product quality, safety, authenticity and to protect the rights of consumers. In light of the new regulations, there is an urgent demand to deliver cost-effective procedures for detecting fraudulent products and checking compliance with the quality specifications. This is essentially the goal of the EU-funded project "TRACE" (Tracing food commodities in Europe, www.trace.eu.org). This paper describes a part of the research done within the TRACE project on the commodity of honey.

Honey is a natural product, the consumption of which has increased in recent years. The traditional approach to recognizing the botanical origin of honey relies on a microscopic examination of its pollen (melissopalynology) (Anklam, 1998; Soria, González, de Lorenzo, Martínez-Castro, & Sanz, 2004). Melissopalynology can also be used to identify the geographical origin of honey if the pollen is specific enough in the area of interest. However, this method is expensive, time-consuming and strongly dependent on the qualifications and judgment of the analyst. Therefore, there is a tendency to replace pollen analysis by finding analytical and/or physicochemical markers for honey discrimination. Minerals and trace elements (Fernández-Torres et al., 2005; Hernández, Fraga, Jiménez, Jiménez, & Arias, 2005; Latorre et al., 1999), volatile compounds (Guyot, Scheirman, & Collin, 1999; Radovic et al., 2001; Soria et al., 2004), the protein pattern, flavonoids, physicochemical parameters like electrical conductivity, pH, total acidity and water activity (Acquarone, Buera, & Elizalde, 2007; Corbella & Cozzolino, 2006; Devillers, Morlot, Pham-Delegue, & Dore, 2004; Marini, Magrì, Balestieri, Fabretti, & Marini, 2004) are some of the parameters that have been extensively examined for the recognition of the floral and geographical origin of honeys.

Although the volatile composition has mainly been used for the characterization of the floral source of honey, the aim of this work was to evaluate whether the volatile profile also allowed for the identification of the geographical origin of honey. Specifically, its

doi:10.1016/j.foodchem.2009.04.079

use for discriminating between Corsican honeys and honeys from other geographical regions was studied. The reason for choosing Corsican honeys was to demonstrate the usefulness of the volatile profiles for tracing the origin of a PDO (protected designation of origin) commodity. The PDO label guarantees that the product consumers purchase is prepared, processed and produced in a specific region and consequently possesses unique properties. However, an emerging authenticity problem is the labeling of a non-PDO product as PDO. In other words, the aim of our study is to develop a reliable methodology to detect such a fraud in Corsican honey, i.e. a strategy for the successful differentiation of Corsican honeys from honeys originating from other regions (PDO or non-PDO) in Europe.

To meet the goal of the study, a large number of honey samples were collected in a two-year campaign (2006 and 2007) and their volatile constituents were analyzed using head-space solid phase microextraction (SPME) sampling followed by the separation/identification step employing comprehensive two-dimensional gas chromatography–time-of-flight mass spectrometry (GC × GC–TOFMS). This approach offers a quick (19 min GC run vs. 30–90 min using one-dimensional GC) and comprehensive analysis of honey volatiles, while minimizing the risk of their erroneous identification, which cannot be avoided in one-dimensional GC separation (Čajka, Hajšlová, Cochran, Holadová, & Klimánková, 2007).

A verification of the origin of food and/or checking the authenticity can be facilitated using chemometric approaches. The goal of supervised pattern recognition techniques is to create classification/discrimination rules using a set of training samples of a known origin and then using the created rules to predict the belongingness of new samples of an unknown origin to the available classes. Since the choice of a classification/discrimination method is strongly data dependent, performances of several pattern recognition methods (Berrueta, Alonso-Salces, & Héberger, 2007; González, 2007), which cover different aspects of data investigation, were evaluated for the two-class problem studied. These were linear discriminant analysis (LDA) (Fisher, 1936; Lebart, Morineau, & Warwick, 1984), discriminant partial least squares (DPLS) (Næs, Isaksson, Fearn, & Davies, 2002), soft independent modeling of class analogy (SIMCA) (Wold, 1976) and support vector machines (SVMs) (Vapnik, 1995) equipped with the recently proposed Pearson VII universal kernel (PUK) (Üstün, Melssen, & Buydens, 2006). The results of this study will help to confirm or reject the hypothesis that the volatile profiles of Corsican honeys can be used for tracing products that do not comply with the label information.

The following section describes the theoretical basis of LDA, DPLS, SIMCA and SVM. Next the experimental conditions and data are presented in Section 3. In Section 4, the results obtained from all the methods applied to the data collected in a two-year sampling campaign are discussed. Finally, the conclusions of the study are given in Section 5.

2. Theory

2.1. Linear discriminant analysis (LDA)

In LDA, it is assumed that the data of each class follow the normal distribution; the classes are linearly separable and the class variance–covariance matrices are equal. The objective of LDA is to find linear combinations of explanatory variables called discriminant functions that maximize the between-classes variance and at the same time minimize the within-classes variance. This is the well-known Fisher criterion (Fisher, 1936). The number of discriminant functions found is equal to the number of classes minus one, if the number of variables is larger than the number of classes. A disadvantage of LDA is that it is appropriate only for data in which the total number of objects is considerably larger than the number of variables. When this condition is not fulfilled, compression of data by means of PCA, regularized LDA, stepwise LDA or feature reduction methods (Wu et al., 1996) should be considered.

2.2. Discriminant partial least squares (DPLS)

The partial least squares model expresses a linear relationship between a response variable $\mathbf{y}$ ($n \times 1$) and a set of p explanatory variables $\mathbf{X}$ ($n \times p$). It can be seen as an extension of multiple linear regression that can deal with multicollinearity in the data by constructing new latent factors, $\mathbf{T}$ ($n \times f$), which maximize the covariance between $\mathbf{X}$ and $\mathbf{y}$. In discriminant PLS, the elements of $\mathbf{y}$ are usually coded as 0 and 1 (a binary variable) or as -1 and 1 (a bipolar variable) that provide information about the belongingness of n objects to two defined classes.

The optimal number of factors, f, is usually selected through the use of a cross-validation procedure and the model selected has a complexity for which the smallest root mean square error of cross-validation (RMSCV) is observed. The prediction power of a model is scored by a root mean square error (RMSEP) calculated for an external set of samples (test set) that is not used during the development of the model. Similar to LDA, an optimal DPLS model can be constructed when the training set is balanced i.e. it contains two classes with an equal number of samples and a comparable variance (Brereton, 2006).

2.3. Soft independent modeling of class analogy (SIMCA)

The main idea in SIMCA (Wold, 1976) is to build a confidence limit for each class with the help of principal component analysis (PCA) and then to project the unclassified samples into each principal components space and to assign them to the class in which they fit best.

Selection of the optimal number of PCs (f) is a key point in SIMCA and is usually determined using a leave-one object out cross-validation (Vandeginste et al., 1998). In our study, the classification of samples to a given category was done by means of the distance–distance plot (Daszykowski, Kaczmarek, Stanimirova, Vander Heyden, & Walczak, 2007). The Mahalanobis distance in the score space and the orthogonal distance from the PCA model constructed were calculated for each object. The default cut-off value for each of the absolute-centered distances (Mahalanobis or orthogonal) obtained using the cross-validated score values was determined at three times its standard deviation. By setting the cut-off value in this way, it was assumed that 99.90% of the centered distances for samples could be found within the interval of three times the standard deviation. One can make a distinction among regular samples and three categories of outlying observations. In general, each sample is fitted to each of the PCA models constructed and is assigned to the model for which its z-scores for the Mahalanobis and orthogonal distances are smaller than three.

2.4. Support vector machines (SVMs)

Support vector machine (SVM) is a binary classification tool that performs classification by constructing an optimal separating hyperplane (OSH) (Vapnik, 1995). The optimal separating hyperplane is defined as the one that maximizes the distance between the objects of the two classes (margin). Consider a data set $\{(x_1, y_1), \ldots, (x_n, y_n)\}$ with input data $\mathbf{x}_i \in \mathrm{R}^{\mathrm{d}}$ (d-dimensional input space) and output data y with binary class labeling $\mathbf{y} \in \{-1, +1\}$. SVM tries to separate the given set of binary-labeled data (two-class problem) with a hyperplane that is maximally distant from them. The objects lying on the margin are called support vectors

that control the discrimination power of the hyperplane. Moreover, SVM has a regularization constant *C* that controls the trade-off between errors of the SVM on the training data and the margin maximization. Using a non-linear kernel function, SVM can deal with complex, e.g. non-linear relationships in data. The kernel function transforms the original data into a high dimensional feature space, where non-linear relationships can be present in a linear form.

Some commonly used kernel functions in the literature are the inner-product based linear and polynomial kernels and the Euclidean distance-based Gaussian (Radial Basis Function (RBF)) kernel (Schölkopf & Smola, 2002). The particular choice of a kernel function greatly depends on the nature of the data, i.e. which kind of underlying relationship needs to be estimated to relate the input data to the desired output. The nature of the data is usually unknown, so the kernel function will be determined experimentally by applying and validating various kernel functions and selecting the one with the highest generalization performance. In this paper we used the recently proposed Pearson VII universal kernel (PUK) (Üstün et al., 2006). The PUK function has the flexibility to change easily from a Gaussian into a Lorentzian shape and into intermediate shapes as well. This flexibility results in a higher mapping power for PUK in comparison to the commonly used linear, polynomial and RBF kernel functions.

The PUK kernel contains two parameters, namely σ and ω. The parameters σ and ω control the width (also named Pearson width) and the actual shape (tailing behavior) of the Pearson VII function. In order to use SVM, both the kernel parameters and the SVM regularization constant, *C*, need to be defined by the user.

In this paper, those parameters were defined by means of a grid search optimisation. To decrease the number of parameter possibilities (time saving) an internal scaling factor β was introduced, according to (Melssen, Üstün, & Buydens, 2006).

3. Experimental

3.1. Honey samples

In total, 374 honey samples were collected within the framework of the EU TRACE project (www.trace.eu.org). The samples were obtained directly from the producers, which guarantees their authenticity. In 2006 (first harvest), 111 Corsican, 18 non-Corsican-French, 15 Italian, 18 Austrian, 2 Irish, and 18 German honey samples were collected. During 2007 (second harvest), 108 Corsican, 28 non-Corsican-French, 15 Italian, 23 Austrian, and 18 German samples were collected. Before distribution, each honey sample was incubated at 40 °C overnight in an air oven, then manually stirred, and adjusted with distilled water to a content of solids of 70° Brix. Prior to analysis, the honey sample (2 g) was placed into a 10 mL vial for SPME; after adding 2 mL of distilled water, the vial was sealed with a magnetic cap with PTFE/silicon septum and vortexed until complete homogenisation was achieved.

As regards the Corsican samples, products collected in spring and autumn, both with specified origin (maquis, bushes, sweet chesnut, strawberry-tree and Clémentinier – Citrus Reticulata) and non-specified were included in the experimental set.

3.2. Chemicals and materials

The SPME fibre 50/30 μm divinylbenzene/carboxen/polydimethylsiloxane, (DVB/CAR/PDMS) used for the sampling of honey volatiles was supplied by Supelco (Bellefonte, PA, USA). Prior to use, the fibre was conditioned following the manufacturer's recommendations.

The system used for GC × GC experiments comprised a DB-5 ms, 5% phenyl polysilphenylenesiloxane (J&W Scientific, Folsom, CA, USA) primary column; 30 m × 0.25 mm id, 0.25 μm film thickness, coupled via a column connector (Agilent, Palo Alto, CA, USA) to a SUPELCOWAX 10, polyethylene glycol (Supelco, Bellefonte, PA, USA) second column of dimension 1.25 m × 0.1 mm id, 0.1 μm film thickness.

The mixture of *n*-alkanes (C_8–C_{20}) dissolved in *n*-hexane employed for retention index determinations was supplied by Supelco (Bellefonte, PA, USA). The calculation was done for components eluting between *n*-octane and *n*-eicosane.

3.3. Instrumentation

A Pegasus 4D system consisting of an Agilent 6890 N gas chromatograph equipped with a split/splitless injector (Agilent Technologies, Palo Alto, CA, USA), an MPS2 autosampler for automated SPME (Gerstel, Mülheim an der Ruhr, Germany), and a Pegasus III high-speed time-of-flight mass spectrometer (Leco Corp., St. Joseph, MI, USA) was used. Inside the GC oven a cryogenic modulator (N_2 jets–hot air jets technology) and a secondary oven (Leco Corp., St. Joseph, MI, USA) were mounted. Resistively heated air was used as a medium for hot jets, while cold jets were supplied by gaseous nitrogen cooled by liquid nitrogen.

3.4. Operating conditions

The operating conditions of the optimised HS-SPME–GC × GC–TOFMS method were as follows (Čajka et al., 2007):

- HS-SPME: incubation time: 5 min; incubation temperature: 40 °C; agitator speed: 500 rpm; extraction time: 20 min; desorption temperature: 250 °C; desorption time: 45 s (splitless). After 6 min exposure in the injector the fibre is automatically withdrawn and incubation and extraction of the next sample ensues.
- GC × GC: primary oven temperature program: 45 °C (0.75 min), 10 °C/min to 200 °C, 30 °C/min to 245 °C (1.25 min); secondary oven temperature: +20 °C above the primary oven temperature;

Table 1

modulator offset: +35 °C above the primary oven temperature; modulation period: 3 s (hot pulse 0.6 s); carrier gas: helium (purity 99.9999%); column flow: 1.3 mL/min.
- TOFMS: electron ionisation mode (70 eV); ion source temperature: 220 °C; mass range: *m/z* 25–300; acquisition rate: 300 spectra/s; detector voltage: −1750 V (first harvest), −1500 V (second harvest).

ChromaTOF (LECO Corp.) software (v. 2.31) was used for instrument control, data acquisition, and data processing. Identification of compounds was based on a NIST 2005 mass spectra library search and was further confirmed by comparing the linear retention indexes available in the same library.

In total, 26 aroma compounds (markers) were selected on the basis of a careful examination of the GC × GC chromatograms of honey samples by identifying the peaks that significantly varied in their intensities or those that described the quality of the honeys. The list of the markers selected is given in Table 1.

For the markers selected, the repeatability of SPME–GC × GC–TOFMS measurements (expressed as relative standard deviation, RSD) ranged between 2.1% and 12% ($n = 10$). Also, the quality of mass spectra was checked during the data processing of real samples and only those target volatiles with a mass-spectral match (i.e. similarity) higher than 700 were considered for chemometric analysis.

3.5. Data preprocessing prior to chemometric analysis

Before the construction of any classification/discriminant model, the raw data (374 × 26) presented in the form of absolute peak intensities were preprocessed using the row-closure operation (Vandeginste et al., 1998). This procedure involves the division of each row element by the corresponding row-sum. Row-closure enables an easier comparison of the sample profiles.

4. Results and discussion

LDA, DPLS, SIMCA and SVM were used to construct models for the discrimination of Corsican from non-Corsican honeys for each year of sampling and for the data of both years. This was done in order to investigate whether the year of sampling might have an influence on the discrimination. To estimate properly the predictive abilities of the built models, the data were divided into training and external test sets, respectively. Since LDA and DPLS are sensitive to the number of samples in the training set, special attention was paid when selecting this number. Table 2 shows the number of samples included in the training and test sets for each set of data.

One can see that the training set is balanced, i.e. it contains an equal number of Corsican and non-Corsican samples. This number was chosen as 75% of the total non-Corsican samples of each year and of both years because, in general, a smaller number of non-Corsican samples are available in comparison with the Corsican samples. The subsets were selected randomly and the selection was applied to each class separately. A leave-one object out cross-validation procedure was adopted to optimise all the models constructed and two figures of merit such as sensitivity and specificity were used to characterize the quality of the models' predictions. For a two-class problem, sensitivity is defined as the percentage of samples from the first class that are correctly predicted by the model, while specificity is the percentage of samples that are correctly classified as belonging to the other class. The ideal model would have sensitivity and specificity of 100%. Together with the sensitivity and specificity, one can define the so-called efficiency, also known in the literature as the non-error rate, which is the total percentage of correctly classified test samples.

4.1. Classification/discrimination of the Corsican honeys using data from 2006

The efficiency, sensitivity and specificity obtained from all models are listed in Tables 3 and 4.

The LDA model has an efficiency of 89.5% (see Table 3), which is related to eight incorrectly classified samples in the test set. An analysis of these misclassified samples showed that 6 out of 58 Corsican samples were recognized as non-Corsican and two non-Corsican samples fell within the domain of the Corsican samples. This resulted in a high sensitivity of 89.7% and a specificity of 88.9% of the LDA model (see Table 4). A slightly worse efficiency of 85.5% was obtained from the DPLS model with complexity four. RMSCV was equal to 0.59 and RMSEP was 0.63. Similar to the LDA model, six Corsican samples were incorrectly classified as non-Corsican resulting in the same sensitivity of 89.7%. However, compared to the LDA model, the DPLS model showed a decrease of 16.7% in specificity because of five non-Corsican honeys that were identified as Corsican. In contrast to the quality of the predictions obtained from LDA and DPLS, the eight-component SIMCA model showed a relatively poorer efficiency of 77.5%. Even though the sensitivity of the SIMCA model is the highest observed (93.1%), the specificity is quite low (64.8%). A good performance was achieved using the SVM method combined with the Pearson VII universal kernel (PUK) function. The optimal values for σ, w and C are presented in Table 5.

A total of ten samples were misclassified, when the SVM model was tested, which resulted in an efficiency of 86.8%. Again six Corsican samples were incorrectly rejected and the sensitivity is the same as the one found for the LDA and DPLS models. Because of the four incorrectly identified non-Corsican honeys, the SMV model has a specificity of 77.8%.

Comparing the prediction abilities of the models built for data of year 2006, all the models, except SIMCA, showed the same sensitivity, but they present different specificities. This means that the probability of recognizing a Corsican honey as a non-Corsican is the same with all methods, while the probability of identifying a non-Corsican honey as a Corsican increases in the order LDA, SVM, DPLS and SIMCA (see Table 4).

4.2. Classification/discrimination of the Corsican honeys using data from 2007

Again four different models were built for a randomly chosen training set. The number of samples considered in the training

Table 2
Number of Corsican and non-Corsican samples in the training and test sets for 2006, 2007 and for the two-year sampling.

	Training set		Test set	
	Corsica	Non-Corsica	Corsica	Non-Corsica
2006	53	53	58	18
2007	63	63	45	21
Two-year sampling	116	116	103	39

Table 3
Efficiency (in percentage) of the models.

	LDA	DPLS	SIMCA	SVM
Corsica vs. non-Corsica				
2006	89.5	85.5	77.5	86.8
2007	89.4	83.3	60.0	95.5
Two-year sampling	85.2	86.6	64.3	91.5

Table 4
Sensitivity (in percent) and specificity (in percent) of the models.

	LDA		DPLS		SIMCA		SVM	
	Sensitivity	Specificity	Sensitivity	Specificity	Sensitivity	Specificity	Sensitivity	Specificity
Corsica vs. non-Corsica								
2006	89.7	88.9	89.7	72.2	93.1	64.8	89.7	77.8
2007	91.1	85.7	86.7	76.2	97.8	42.9	97.8	90.5
Two-year sampling	86.4	82.1	87.4	84.6	93.2	45.2	93.2	87.2

and test sets are presented in Table 2, while the efficiency, sensitivity and specificity of the models are shown in Tables 3 and 4. For honey data from 2007, all models, except SIMCA, presented comparable or improved efficiencies with respect to the corresponding models built for the data of the first year of sampling (see Table 3). The LDA model has an efficiency of 89.4%, when tested. After analyzing the misclassified test samples, it was found that four Corsican honeys were incorrectly recognized as non-Corsican and three non-Corsican honeys were found to have similar volatile compositions as the Corsican honeys. This analysis showed a fairly high sensitivity of 91.1% and a specificity of 85.7% for the LDA model.

The seven-component DPLS model with RMSCV equals 0.64 and a RMSEP of 0.72 lacks a correct assignment for six Corsican samples and therefore, a reduced sensitivity of 86.7% was observed in comparison with LDA. A decrease in specificity by 9.5% was also the result of the incorrect recognition of five non-Corsican honeys as Corsican. In contrast to both models built, the five-component SIMCA model had an efficiency of only 60.0% when tested. Although the model had a sensitivity of 97.8%, which is higher than the one found by LDA and DPLS, the majority of the non-Corsican honeys were assigned as Corsican and therefore, the specificity of the SIMCA model is considerably low (42.9%).

From the values presented in Table 3, it became clear that the SVM model has the best efficiency of 95.5% among the models built. Only three samples (one Corsican and two non-Corsican) were misclassified, when the SVM model was tested. Consequently, the SVM model offered the same fairly high sensitivity of 97.8% as the five-component SIMCA model and the best specificity (90.5%) among the all models constructed.

The difference in the classification results between the data of year 2006 and year 2007 might be explained by the possible differences in the volatile profiles of honeys from year to year.

4.3. Classification/discrimination of the Corsican honeys using the two-year data

One possibility is to construct a model for samples of one year and then to use this model to predict the belongingness of samples collected in the next year of sampling. However, due to the large variation in the sample profiles between the years possibly caused by different meteorological conditions, such a model would either be no longer valid or with poor predictive ability and therefore, a model updating would be required. A more reliable approach is to model the data of a two-year sampling together, i.e. for each class the training set contains representative samples of both years. Again, the training set was selected randomly and LDA, DPLS, SIMCA and SVM models were constructed.

Table 5
Optimal settings of σ, w and C of SVM models built using the PUK function.

	σ	w	C
Corsica vs. non-Corsica			
2006	2	10	10
2007	1	1	10^2
Two-year sampling	5	16	10^3

The efficiency of LDA (85.2%) is lower than that observed for the first and second year of sampling (see Table 3). There were 21 honey samples, which were incorrectly classified, when the model was tested. From the analysis of these samples, it followed that 14 Corsican and 7 non-Corsican honeys were predicted incorrectly, which led to a reduced sensitivity of 86.4% and a specificity of 82.1% in comparison with the predictions obtained from the LDA models constructed for the data from separate years of sampling (see Table 4).

DPLS showed an improved predictive ability compared to the LDA model. With DPLS, 13 out of 103 Corsican samples were identified as non-Corsican resulting in a sensitivity of 87.4%. Because 6 out of 39 non-Corsican honeys were recognized as Corsican, the specificity of the model was 84.6%. It should be noted that DPLS had a complexity of five factors, while RMSCV and RMSEP were both equal to 0.64.

Although, with the six-component SIMCA model 93.2% of the Corsican samples were predicted well, 54.8% of the non-Corsican samples were incorrectly recognized (see Table 4). Again, the worse predictive ability was observed for the SIMCA model.

The classification model constructed by SVM presented the best efficiency of 91.5% among all the methods. A total of 12 test samples (7 Corsican and 5 non-Corsican) were wrongly predicted and consequently the SVM model yielded a sensitivity of 93.2% and a specificity of 87.2%.

5. Conclusions

The main conclusion of this study is that the volatile profiles of Corsican honeys are specific enough and allow for their discrimination from honeys of different geographical origins. In general, all models, except SIMCA, showed good efficiencies, high sensitivities and specificities for data of separate sampling years and for data of both years. Moreover, all the models presented higher sensitivities than specificities. This demonstrates that the probability of recognizing Corsican honeys as non-Corsican on the basis of their volatile profiles is small. LDA, DPLS and especially SVM using the PUK function can be successfully used to detect the mislabeling of honeys.

Moreover, this study also demonstrated the flexibility of SVM using the PUK function in building models with better predictive abilities than those obtained from LDA and DPLS for the problem studied. The reason might be that the peak intensities of the 26 volatile compounds are not completely linearly related to the geographical origin of the honey samples.

It should be noted here that there is another important issue, namely which particular volatile compounds are the most descriptive in the classification/discrimination of the honey samples according to their origin. However, this matter will be the subject of a future study.

Adulteration

ABSTRACT

Since durum wheat is ~20% more expensive than common wheat and considered of superior quality for the manufacture of pasta products, efficient methods for the detection of accidental or intentional admixtures of common wheat to durum wheat products are required. This paper describes a novel approach for the detection and quantification of whole grain common wheat adulteration in whole grain durum flour and dried pasta. We found that differences in the C17:0 to C21:0 alkylresorcinol homologue ratios between the two cereal species may serve as a suitable tool for whole grain durum product authentification. To detect and estimate adulteration, the C17:0/C21:0 ratios of flour and pasta admixtures with added whole grain flour of common wheat were analysed. A linear relationship between C17:0/C21:0 ratios and level of admixture in pasta samples showed that adulteration can be estimated within the range of 5–100% of admixture. Furthermore, di- and triunsaturated as well as oxygenated alk(en)ylresorcinols are reported to occur in *Triticum durum* Desf. for the first time.

1. Introduction

Traditionally, pasta is manufactured solely from durum wheat (*Triticum durum* Desf.), which results in a product considered to be of superior quality to pasta made from cheaper common wheat (*T. aestivum* L.) or a blend of the two species. Nevertheless, price differentials between both wheat species could provide some manufactures with the incentive to benefit economically by the undeclared addition of common wheat. The manufacture of pastas from mixtures of durum and common wheat without adequate labelling is usually considered as adulteration. National laws in Italy, France and Greece prohibit the inclusion of common wheat to pasta for sale in their countries, but not for subsequent export (Food Surveillance Paper No. 47, 1994). Durum wheat pasta for export outside the European Union may contain a maximum of 3% common wheat from unavoidable adventitious contamination during agricultural processing (EG Commission Regulation, Official Journal of the European Community, 1994; International Standard, ISO 11051: 1994 (E)).

Since pasta products purporting to be prepared solely from durum wheat are increasingly introduced in the market place, methods are consequently required that can be applied to these products to check the validity of such claims, if food legislation is to be enforced. The detection of the presence of *T. aestivum* in *T. durum* semolina and pasta can be addressed by a number of analytical methods, most of which rely upon detection of certain proteins expressed by the D-genome present in hexaploid wheat but absent from *T. durum* (Food Surveillance Paper No. 47, 1994). Electrophoretic methods are used, whereby D-genome encoded proteins like gliadins (Bonetti et al., 2004; Burgoon, Ikeda, & Tanner, 1985) or specific polyphenoloxidases (Feillet & Kobrehel, 1974) are separated and detected by gel electrophoresis. McCarthy, Scanlon, Lumley, and Griffin (1990) reported the use of RP-HPLC for the detection of common wheat flour in durum wheat flour/semolina, based on the separation and detection of specific gliadins, and the method has been extended for application to pasta products (Barnwell, McCarthy, Lumley, & Griffin, 1994). Specific D-genome encoded proteins have also been detected by free zone capillary electrophoresis (FZCE); however the method was only applied for blends of durum wheat and common wheat flour and has not been validated for quantitative analysis so far (Bonetti et al., 2004). Other techniques involve the separation and quantification of sterol palmitates by TLC (Gilles & Youngs, 1964) and HPLC (Sarwar & McDonald, 1993) or the detection of a specific DNA sequence amplified in the D-genome of common wheat by PCR (Bryan,

doi:10.1016/j.foodchem.2009.04.080

Dixon, Gale, & Wiseman, 1998; Pasqualone, Montemurro, Griffin-Gofron, Sonnate, & Blanco, 2007).

However, environmental growing conditions and genetic variation between wheat cultivars may affect the expression of proteins used as markers of contamination (Food Surveillance Paper No. 47, 1994) or adversely influence sterol palmitates content used for verification of semolina and pasta authenticity (Sarwar & McDonald, 1993). The principal limitation of most of the methods involving protein extraction is the effect of denaturation, resulting from the widespread introduction of high-temperature drying processes (>70 °C), to accelerate drying of the product during pasta manufacture (Aktan & Khan, 1992).

In contrast, alkylresorcinols (Fig. 1) used as marker compounds in this study, have been shown to be thermostable during pasta manufacturing (Landberg, Kamal-Eldin, Andresson, & Åman, 2006) and even baking processes (Ross et al., 2003), thus meeting a fundamental criterion for authenticity control of dried pasta products. Alkylresorcinols (1,3-dihydroxy-5-alkylbenzene derivatives) are phenolic lipids present in a number of plants and bacteria. Of plants commonly used for food, apart from mango (Knödler, Kaiser, Carle, & Schieber, 2008), alkylresorcinols are present in high amounts in common wheat, durum wheat and rye kernels (~0.03–0.15% of dry kernel weight; Landberg et al., 2006; Ross et al., 2003). The odd-numbered alkyl side-chain of alkylresorcinols isolated from cereal grains varies from 13 to 27 carbon atoms (Knödler et al., 2008; Kozubek & Tyman, 1999). Recently, the ratio of the homologues C17:0 to C21:0 was found to be ~0.01 in whole grain durum wheat and products prepared thereof (Landberg et al., 2006), thus differing from that of common wheat which displays a C17:0/C21:0 ratio of ~0.1 (Andersson, Kamal-Eldin, Fras, Boros, & Åman, 2008; Chen, Ross, Åman, & Kamal-Eldin, 2004). Thus, the ratio of C17:0 to C21:0 can be used to distinguish between these cereals. Interestingly, 99% of alkylresorcinols are found in the hyaline layer, inner pericarp and testa of cereal grains (Landberg, Kamal-Eldin, Salmenkallio-Marttila, Rouau, & Åman, 2008), limiting the marker compounds for authentification of whole grain durum flour and pasta. However, with the whole grain trend in many countries, the consumption of pasta from whole grain durum wheat is rapidly increasing and, thus, demanding the development of methods valid for whole grain durum products. The following investigation reports the detection and estimation of whole grain common wheat flour adulteration in whole grain durum wheat flour and pasta, based on the analysis of the C17/C21 alkylresorcinols ratios.

2. Experimental

2.1. Cereals and pasta products

Ten samples of winter and spring durum wheat kernels (cv. Floradur, Prowidur, Durobonus, Topdur, Helidur, Ambrodur, Extradur and Rosadur) and ten samples of winter and spring soft wheat kernels (cv. Saturnus, Toronit, Capo, AC Vista and Cltr 17272) harvested in the years 2006 and 2007, respectively, were obtained from the Institute of Crop Cultivation and Plant Breeding at the University of Natural Resources and Applied Life Sciences in Vienna. Soft wheat kernels of the cultivars Tommi 220, Manhattan and Wasmo were cultivated at Ihinger Hof, Germany, an experimental station of Hohenheim University, in 2004.

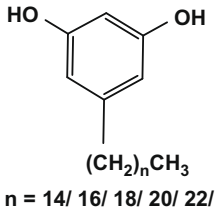

Fig. 1. Structures of 5-*n*-alkylresorcinols present in *Triticum durum* Desf. and *T. aestivum* L.

For the preparation of defined blends of whole grain flour and pasta, the durum wheat cultivar Rosadur and the common wheat cultivar Tommi 220 were used. Approximately 3 kg of durum and common wheat, respectively, were milled using an Ultra Centrifugal Mill ZM 200 (Retsch GmbH & Co. KG, Haan, Germany). Whole grain durum flours were blended with 0%, 20%, 40%, 60%, 80% and 100% common wheat flours).

Blended whole grain pasta samples with soft admixtures of 5%, 10%, 20%, 40%, 60%, 80% and 100%, respectively, were prepared with a Marcato pasta machine, (Marcato S.p.A., Padova, Italy). The pasta samples were dried at 90 °C to moisture content below 13%. Dry matter (DM) was determined using an infrared moisture-analyser (Sartorius AG, Göttingen, Germany).

2.2. Solvents and reagents

All reagents and solvents used were purchased from VWR (Darmstadt, Germany) and were of analytical or HPLC grade. Synthetic alkylresorcinols (5-pentadecylresorcinol, C15:0; 5-heptadecylresorcinol, C17:0; 5-nonadecylresorcinol, C19:0; 5-heneicosylresorcinol, C21:0; 5-tricosylresorcinol, C23:0; 5-pentacosylresorcinol, C25:0) were obtained from ReseaChem (Burgdorf, Switzerland).

2.3. Sample preparation

Cereal and pasta samples were ground using a water-cooled Yellow Line A10 laboratory mill (Ika-Werke, Staufen, Germany) and stored in vacuum-sealed polyethylene pouches at −20 °C until used for extraction. Ground samples (3 g) were extracted by continuous stirring with 50 ml ethyl acetate for 2 h under nitrogen atmosphere. Exhaustive extraction was ensured by extraction of the residue with 50 ml ethyl acetate for 1 h. After filtration through a paper filter, the extracts were evaporated to dryness *in vacuo* at 30 °C and the residue dissolved in 0.5 ml methanol. The solution was membrane filtered (0.45 μm, Whatman, Clifton, NJ) and used for HPLC–DAD and LC–MS/MS analysis.

2.4. HPLC and LC–MS/MS

Alkylresorcinol (AR) analyses were performed using an Agilent HPLC series 1100 (Agilent, Waldbronn, Germany) equipped with ChemStation software, a model G1322A degasser, a model G1312A binary pump, a model G1313A autosampler, a model G1316A column oven, and a model G1315A diode array detection system. The column used was a 150 × 3.0 mm i.d., 3 μm particle size, analytical scale Phenomenex C18 Aqua (Torrance, CA), with a C18 ODS guard column (4.0 × 2.0 mm, i.d.), operated at 25 °C. The mobile phase consisted of 100% methanol (eluent **A**) and 100% water (eluent **B**), and the following gradient programme was used: 11% **B**–0% **B** (38 min), 0% **B** isocratic (5.5 min), 0% **B**–11% **B** (3.5 min). Total run time was 50 min. The injection volume was 10 μl for cereal samples and 50 μl for blends of flour and pasta. All AR were monitored at 275 nm at a flow rate of 0.6 ml/min. Additionally, UV/Vis spectra were recorded in the range of 200–600 nm at a spectral acquisition rate of 1.25 scans/s (peak width 0.2 min).

LC–MS/MS analyses were performed with the HPLC system described above coupled to a model Esquire 3000+ ion trap mass spectrometer fitted with an APCI source (Bruker, Bremen, Germany). Data acquisition and processing were performed using

Esquire Control software. Positive ion mass spectra of the column eluate were recorded in the range of *m/z* 50–500 at a scan speed of 13,000 mass units/s (peak width 0.6 mass units, FWHM). Mass spectrometric conditions have been reported in detail in a recently published study (Knödler et al., 2008).

Individual compounds were identified by their retention times and UV and mass spectra (Knödler et al., 2008) and quantified using a calibration curve of the corresponding standard compound (Knödler, Reisenhauer, Schieber, & Carle, 2009).

3. Results and discussion

3.1. Differences in alkylresorcinols content and homologue composition of durum and soft wheat

In this novel approach to authenticity control of whole grain durum wheat flour and pasta prepared thereof, we have evaluated the detection and estimation of adulteration of whole grain durum wheat flour and pasta by flour of whole grain soft wheat using differences in the alkylresorcinol homologue composition between the two cereal species. While species-specific resorcinolic compounds could not be observed, we found that differences in the C17:0 to C21:0 homologue ratio between the hexaploid common wheat and durum wheat may serve as a suitable tool for the authentification of durum wheat products.

The HPLC pattern of alk(en)ylresorcinols with chain lengths varying from 15 to 25 carbons of durum and soft wheat extracts is illustrated in Fig. 2. Since their characterisation has recently reported in detail (Knödler et al., 2008), UV and mass spectrometric data are not given in the present communication. The use of tandem mass spectrometry in addition to diode array detection enabled the identification of up to 22 saturated, mono-, di- and triunsaturated and oxygenated alk(en)ylresorcinols, the latter three have so far not yet been reported in *T. durum* Desf.

While a number of qualitative and quantitative data on alkylresorcinols in common wheat are available (Andersson et al., 2008; Kozubek & Tyman, 1999; Kulawinek, Jaromin, Kozubek, & Zarnowski, 2008; Ross et al., 2003), only very few studies have reported on durum wheat (Andersson et al., 2008; Landberg et al., 2006; Sagi, Sagi, & Acs, 1983; Sagi-Lomnicizi & Sagi, 1982; Zarnowski, Suzuki, & Pietr, 2004). Total alkylresorcinol contents and homologue composition of saturated homologues of 10 durum wheat and 15 soft wheat samples are summarised in Table 1. Generally, soft wheat cultivars possessed higher total alkylresorcinol contents, ranging from 591 to 1077 mg/kg DM, compared to durum wheat cultivars, with contents of 430 to 797 mg/kg DM. Considerable differences in total alkylresorcinol contents were observed within some cultivars harvested within two consecutive vegetative years (e.g., cv. Prowidur and Saturnus harvested in 2006 and 2007), highlighting the advantage of using ratios of certain homologues, thus providing a tool for species authentification, irrespective of alkylresorcinol content, and hence, not being affected by varietal differences and environmental growing conditions. Total alkylresorcinol contents of soft and durum wheat varieties were exceptionally high, compared to those reported by other authors (Andersson et al., 2008; Landberg et al., 2006; Ross et al., 2003; Zarnowski et al., 2004), which may be explained by cultivar differences and by different methods of analysis. In accordance with previous findings (Landberg et al., 2006), the alkylresorcinol homologue composition in durum wheat was found to be completely different to that of common wheat, by having a higher proportion of the longer chained homologues, but was highly consistent within a given species (Table 1). The C17:0/C21:0 ratio, used as a marker to distinguish between durum and soft wheat in this study, was determined as ~0.01 for the durum wheats, which is different from that of common wheat cultivars displaying a C17:0/C21:0 ratio of ~0.1 (Table 1, Fig. 2, peaks highlighted in grey), which is consistent with previous investigations on durum (Andersson et al., 2008;

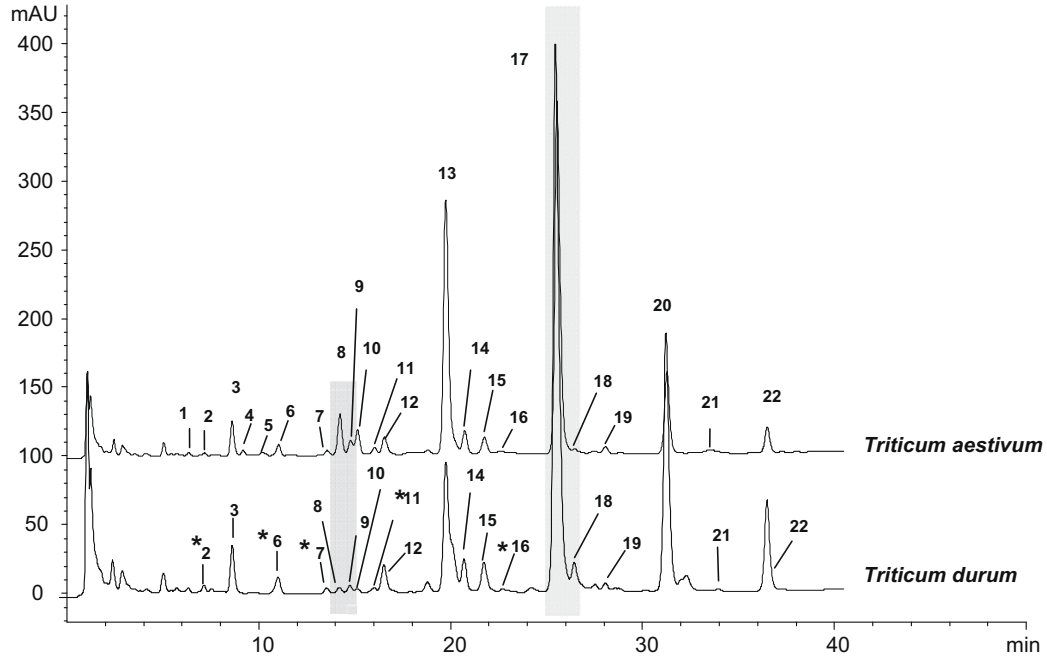

Fig. 2. HPLC separation (275 nm) of alk(en)ylresorcinols in common wheat (cv. Tommi 220) and durum wheat (cv. Rosadur) extracts. Peak assignments: **1**, heptadecadienylresorcinol (C17:2); **2**, nonadecatrienylresorcinol (C19:3); **3**, pentadecylresorcinol (C15:0); **4**, heptadecenylresorcinol (C17:1); **5**, hydroxynonadecenylresorcinol (C19:1-OH); **6**, nonadecadienylresorcinol (C19:2); **7**, heneicosatrienylresorcinol (C21:3); **8**, heptadecylresorcinol (C19:0); **9**, nonadecenylresorcinol (C19:1); **10**, nonadecenylresorcinol (C19:1); **11**, hydroxyheneicosenylresorcinol (C21:1-OH); **12**, heneicosadienylresorcinol (C21:2); **13**, nonadecylresorcinol (C19:0); **14**, heneicosenylresorcinol (C21:1); **15**, heneicosenylresorcinol (C21:1); **16**, hydroxytricosenylresorcinol (C23:1-OH); **17**, heneicosylresorcinol (C21:0); **18**, tricosenylresorcinol (C23:1); **19**, tricosenylresorcinol (C23:1); **20**, tricosylresorcinol (C23:0); **21**, pentacosenylresorcinol (C25:1); **22**, pentacosylresorcinol (C25:0). Novel compounds for durum wheat are marked with an asterisk (*).

Landberg et al., 2006) and soft wheat (Andersson et al., 2008; Chen et al., 2004), respectively. These authors analysed a number of cultivars grown in different countries and environmental growing conditions. Whereas the total content of alkylresorcinols varied between cultivars grown under different conditions, the profile and thus, the C17:0/C21:0 ratios, were found to be highly characteristic for durum and common wheat.

Striking differences with respect to species differentiation were also observed for the C19:0 and the C23:0 homologues, showing levels of 10–15% and 19–25%, respectively, in durum wheat and from 26% to 36% and 9% to 17%, respectively, in common wheat, which may serve as an additional tool for species authentification. However, compared to these homologue ratios, the C17:0/C21:0 ratios were found to be the most constant ones and, thus, most suitable for species differentiation.

3.2. Detection and quantification of whole grain soft wheat admixture to flour of whole grain durum wheat

Defined blends of whole grain durum wheat (cv. Rosadur) and whole grain soft wheat (cv. Tommi 220) flour, containing 0%, 20%, 40%, 60%, 80% and 100% durum and soft wheat, respectively, were analysed for their C17:0/C21:0 homologue ratios. Fig. 3 shows the plot of the calculated ratios, in relation to common wheat adulteration in the flour mixtures. It was found that the C17:0/C21:0 ratios increased linearly (R^2 = 0.986) with the level of common wheat admixture. The linear equation even permits quantitative estimation of common wheat proportions in the blended flours. Since this study mainly focused on the detection and quantification of common wheat adulteration in pasta samples, control samples containing <20% common wheat were not prepared for the flour mixtures. However, it was demonstrated that common wheat adulteration in whole grain durum flour can be detected easily by analysing the C17:0/C21:0 homologue ratios. For example, a C17:0/C21:0 ratio of >0.01 analysed for a suspect sample may generally indicate adulteration, if the durum wheat cultivars are known. For unknown durum wheat cultivars the significance may be of diminished value, considering varietal differences in the C17:0/C21:0 ratio within durum wheat (from 0.01 to 0.02) and soft wheat (from 0.08 to 0.1) cultivars. However, even when taking into account varietal differences within the species, a quantitative estimate of adulteration in a suspect sample is still feasible. Therefore, the proposed method for authentification may provide a powerful tool for inspection of incoming components at whole grain pasta manufacturers.

3.3. Detection and quantification of whole grain soft wheat admixture to whole grain durum wheat pasta

Alkylresorcinols are believed to form inclusion complexes with starch during thermal treatment, thus hindering quantitative recovery by conventional ethyl acetate extraction, while time-consuming extraction with hot water/1-propanol (1/3) was reported to allow their quantitative recovery (Ross et al., 2003). However,

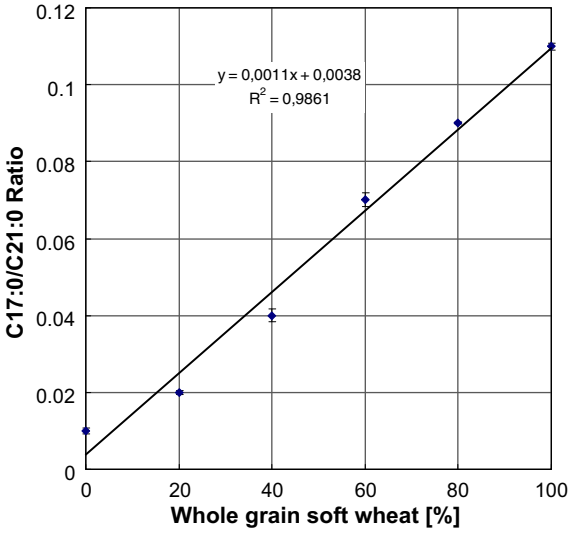

Fig. 3. Ratios of the homologues C17:0 to C21:0 determined in mixtures of whole grain durum wheat (cv. Rosadur) flour with 0%, 20%, 40%, 60%, 80% and 100% whole grain soft wheat (cv. Tommi 220) flour, respectively. In the graph, the linear equation and the coefficient of determination (R^2) of the standard curve is reported. Data points are means from two independent experiments, and bars represent SD where larger than symbol size.

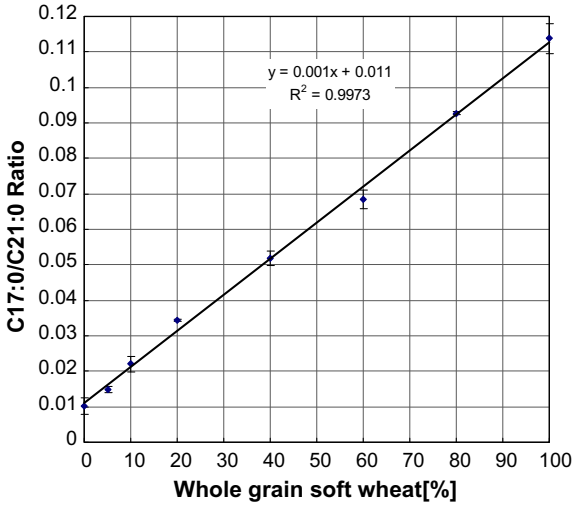

Fig. 4. Ratios of the homologues C17:0 to C21:0 determined in whole grain durum wheat (cv. Rosadur) pasta adulterated with 0%, 5%, 10%, 20%, 40%, 60%, 80% and 100% soft wheat (cv. Tommi 220), respectively. In the graph, the linear equation and the coefficient of determination (R^2) of the standard curve is reported. Data points are means from two independent experiments, and bars represent SD where larger than symbol size.

we observed that analysed homologue composition and hence C17:0/C21:0 ratio remained unchanged when comparing both extraction procedures (data not shown). Therefore, albeit not permitting quantitative recovery, pasta samples were extracted with ethyl acetate.

The effect of whole grain common wheat (cv. Tommi 220) adulteration of dried whole grain durum wheat (cv. Rosadur) pasta is illustrated in Fig. 4. The C17:0/C21:0 homologue ratios analysed for the control adulterated pasta samples containing 0%, 5%, 10%, 20%, 40%, 60%, 80% and 100% of soft wheat, respectively, increased with the level of admixture. A linear relationship between the C17:0/C21:0 ratios and adulteration level (R^2 = 0.997) provided a standard curve. As evident from Fig. 4, with the proposed method, adulteration may be estimated in the range of 5–100% by using linear regression analysis and thus approaching even small but economically most likely adulteration levels. Furthermore it could be shown that even high drying temperatures used in this study did not affect the applicability of alkylresorcinols as authentification markers, which was found to be the major disadvantage for methods involving proteinogenic markers (Surveillance Paper No. 47, 1994).

However, information on cultivar is often not obtained and commercial whole grain wheat flours often constitute blends of several cultivars and thus, the varietal differences in the ratios of the homologues C17:0/C21:0 within a species (Table 1) have to be considered when calculating adulteration levels using standard curves valid for a given cultivar.

With this study a novel approach to authenticity control of whole grain pasta, purporting to be made solely from durum wheat, was performed. It is expected that the present method can be further extended to the authentification of non-whole grain durum wheat products. Therefore, a method for the quantification of even very low alkylresorcinol contents in refined cereal products by MS/MS is currently being developed in our laboratory.

Acknowledgments

The authors express their gratitude to Mrs. Elke Rummel and Mr. Klaus Mix for their valuable technical assistance. Prof. Dr. Heinrich Grausgruber, University of Natural Resources and Applied Life Sciences, Vienna, Austria is gratefully acknowledged for providing the cereal samples.

ABSTRACT

The volatile profile of the Spanish soft cheese of the Protected Designation of Origin (PDO) Torta del Casar, made from raw ewes' milk, was studied in four different stages of ripening (1, 30, 60 and 90 days) by the method of SPME–GC–MS. A total of 46 compounds were detected: 13 acids, 9 esters, 4 ketones, 7 alcohols, 3 aldehydes, 7 aromatic compounds and 3 compounds which could not be classified into those groups. Carboxylic acids were the most abundant group isolated; their levels significantly increased during ripening and comprised 61.5% of the total aroma extract at the end of ripening. At day 90, acids of microbial origin were the most abundant, followed by acids derived from amino acids while acids from lipolysis of triglycerides were the least abundant. Esters were the next most important group and their amount also increased significantly during maturation, as did ketones, while alcohols content slightly decreased at the end of the ripening. At day 90, the compounds at highest levels were acetic acid, 3-methylbutanoic acid, butanoic acid propyl ester and 2-butan-one; so these compounds, due to their high levels and their low threshold value could play an important role in the final aromatic profile of this cheese.

1. Introduction

Cheese flavour is one of the most important criteria determining consumer choice and acceptance. It is generally accepted that the volatile profile reflects the image of the odour and aroma of cheeses. So, the unique flavour of a cheese variety is the result of a complex balance among volatile and non-volatile chemical compounds, originating during the ripening process from milk fat, protein and carbohydrates (Fox & Wallace, 1997); as a consequence, each product has a characteristic and unique composition of volatile components (Plutowska & Wardencki, 2007). It is well-known that most cheese aroma volatile compounds are formed during ripening. The principal pathways for the formation of flavour compounds in cheese are metabolism of lactose and lactate, lipolysis and proteolysis. In the first pathway, depending on variety, microflora and ripening conditions, lactate may be metabolised by a number of pathways to various compounds which contribute to cheese flavour. The second pathway generates fat-derived compounds formed by lipolysis and lipid oxidation reactions, such as free fatty acids, esters, lactones and ketones, with low aroma thresholds (Kinsella, 1975; Siek, Albin, Sather, & Lindsay, 1971). Finally, proteolysis of caseins provides a range of small- and intermediate-sized peptides and free amino acids, which probably only contribute to the background flavour of most cheese varieties. However, free amino acids are important precursors for a range of poorly-understood catabolic reactions, which produce volatile compounds essential for flavour (McSweeney & Sousa, 2000).

Volatile compounds are generally analysed by gas chromatography (GC) coupled to mass spectrometry (MS), with a prior step involving the extraction and pre-concentration of the volatile fraction. The technique of solid phase microextraction (SPME) requires only a small amount of sample and permits the isolation of volatile analytes from matrices both in the solid and liquid states in a short time, in a simple way. For this reason, nowadays SPME is commonly used for the extraction of flavour compounds in cheese (Coda et al., 2006; Guillén, Ibargoitia, Sopelana, Palencia, & Fresno, 2004; Lecanu, Ducruet, Jouquand, Gratadoux, & Feigenbaum, 2002; Lee, Diono, Kim, & Min, 2003).

The volatile profile of some Spanish cheeses made from raw ewes' milk that belong to Protected Designation of Origins (PDO) have been previously studied, such as Manchego (Fernández-García, Carbonell, & Nuñez, 2002a, 2002b; Villaseñor, Valero, Sanz, & Martínez-Castro, 2000), La Serena (Carbonell, Núñez, & Fernández-García, 2002a, 2002b), Roncal (Izco & Torre, 2000), Zamorano (Fernández-García, Gaya, Medina, & Núñez, 2004b) and Idiazábal (Barron et al., 2007).

The soft cheese with the Protected Designation of Origin (PDO) Torta del Casar is produced in Extremadura region, in the southwest of Spain. It is a well-known cheese with an increasing production every year, since it is much appreciated by consumers for its

doi:10.1016/j.foodchem.2009.04.081

high quality and unique flavour. This cheese has a light and thin semi-hard rind and a very soft texture. Raw milk, from Merino or Entrefina breed ewes reared outdoors, is used (DOE, 2001). In addition, no starter cultures are added, and vegetable rennet, previously obtained from maceration of thistle flowers (*Cynara cardunculus*) in water, is used to coagulate the milk. The most known cheeses made of raw ewes milk and vegetable coagulant are La Serena cheese (Spain) and Serra da Estrela cheese (Portugal). The use of Merino ewes' raw milk and plant coagulant provides characteristic slightly bitter taste and a spreadable texture.

Microbial characterisation of Torta del Casar cheese has been previously published (Cáceres, Castillo, & Pizarro, 1997; Poullet, Huertas, Sánchez, Cáceres, & Larriba, 1991; Poullet, Huertas, Sánchez, Cáceres, & Larriba, 1993). However, its volatile profile and changes during ripening have not been previously studied despite their importance. Therefore, the main objective of this paper are the characterisation of the volatile profile of the cheese Torta del Casar during the ripening process by SPME–GC–MS, in order to determine the compounds that provide its characteristic aroma.

2. Materials and methods

2.1. Cheese manufacture

Torta del Casar cheese was produced from Merino ewes' raw milk. No starter cultures were added and a plant coagulant obtained from the the flowers of the thistle *C. cardunculus* L. were used to coagulate the milk. The milk was heated to 28–32 °C, and coagulation took place after 50–80 min. The curd was cut to increase the surface area, which increases the movement of whey out of the curd. Then the curd was transferred into suitable moulds, where it was pressed for 3–4 h at pressures of 1–2.5 kg/cm^2. The cheeses were then salted with sodium chloride. Afterwards, they were ripened for 60–90 days at 4–12 °C and relative humidity of 75–90%. Legislation does not allow the consumption of these cheeses before 60 days of ripening since they are made with raw milk. According to the regulation of the PDO, the physicochemical properties must be a minimum of 50% of fat content in dry matter, a minimum of 50% of dry matter, a pH of 5.2–5.9 and a maximum of 3% NaCl (DOE, 2001).

Four cheeses from 3 different producers from the PDO were analysed at four different stages of ripening: 1, 30, 60 and 90 days. A total of 48 cheese were analysed, 12 at each stage of ripening. For each producer, four cheeses of the same batch were collected at each time of ripening. During the first 60 days of ripening, cheeses were matured in each dairy. The proximate composition of the cheeses after 60 days of ripening was 43.3% moisture, 32.5% fat and 16.9% protein and the pH was ~5.4, with a salt content of 1.29%. After 60 days of ripening, when cheeses can be sold, they were shrink-wrapped with a thin plastic film and put inside a thin wooden box (a decorative packaging) to simulate purchase conditions. For the last month, packed cheeses were stored at 5 °C. From each cheese, samples were taken from the inner part of the cheese and were stored at −20 °C until they were analysed (<2–3 weeks).

2.2. SPME–GC/MS

For the extraction of volatile compounds the method of Lee et al. (2003) was followed. Ten grams of cheese were placed in a 50-ml vial and then 10 ml NaH_2PO_4 (25%, w/v) were added. The sample was stirred for 30 min at 50 °C to accelerate equilibrium of headspace volatile compounds between the cheese matrix and the headspace. Then, volatile compounds extraction was carried out by injecting a 50/30 μm divinylbenzene/Carboxen/polydimethylsiloxane SPME fibre (Supelco, Bellefonte, PA) into the vial and exposing it to the headspace for 30 min at 50 °C. After extraction samples were directly desorbed into the injection port of the GC which was at 250 °C. The analyses of volatile compounds were performed on a Varian CP-3800 GC gas chromatograph coupled to a Varian Saturn 2200 MS (Varian Inc., Palo Alto, CA). Volatile compounds were separated using a capillary column (HP Innowax; 60 m × 0.25 mm ID × 0.50 μm film thickness; Agilent, Santa Clara, CA). The carrier gas was helium with a flow of 1 ml/min. The temperature programme was isothermal at 40 °C for 10 min, then raised at 5 °C/min to 240 °C and held for 11 min. The GC–MS transfer line temperature was at 280 °C. The MS operated in electron impact mode with electron impact energy of 70 eV; and collected data at a rate of 0.7 scans/s over a range of *m/z* 40–650. *n*-Alkanes (Sigma R-8769) were analysed under the same conditions to calculate retention indices (RI) for the volatile compounds. The compounds were identified by comparison with commercial reference compounds provided by Sigma–Aldrich (St. Louis, MO) by comparison of RI with those described in the literature and by comparison of their mass spectra with those contained in the NIST and Varian libraries.

2.3. Statistical analysis

The differences in the volatile profiles during ripening were analysed using the analysis of variance (ANOVA) procedure of SPSS, Version 14.0 (SPSS Inc., Chicago, IL). HSD Tukey's test was applied to compare the mean values of the volatile compounds of different days of ripening. Mean values with standard deviations are reported. The relationships between parameters were assessed by principal component analysis (PCA) using the Unscrambler 6.11 software (Camo Software AS, Oslo, Norway).

3. Results and discussion

3.1. General

Volatile compounds (area units, AU, $\times 10^5$) isolated from Spanish soft cheese Torta del Casar by SPME–GC–MS during 90 days of ripening are shown in Table 1. A total of 46 compounds were detected: 13 acids, 9 esters, 4 ketones, 7 alcohols, 3 aldehydes, 7 aromatic compounds and 3 compounds which could not be classified in these groups. Significant differences were found in the volatile compounds during ripening, as most of the volatile compounds detected tended to increase and new compounds were formed during maturation, while few tended to decrease. Compared to Day 1, an important increase of total area units (AU) was found in the first 60 days of ripening, while in the last 30 days, the amount of volatile compounds slightly increased (Day 1: 230×10^5 AU, Day 30: 808×10^5 AU, Day 60: 1426×10^5 AU, Day 90: 1530×10^5 AU). These results agree with the time when cheeses can be sold, after 60 days of maturation, so at purchase time they have developed most of the volatile compounds which form their characteristic profile.

Fig. 1 shows the evolution of volatile compounds grouped by their chemical nature. Total carboxylic acid content tended to increase during ripening, especially in the first 60 days. Lipolysis seems to be an important pathway of formation of linear carboxylic acids with more than 4 carbon atoms. However, the shorter carboxylic acids can also be derived from ketones, esters and aldehydes by oxidation (Molimard & Spinnler, 1996), as the metabolic products of lactose metabolism, deamination of amino acids and possibly lipid oxidation. Esters gradually increased during ripening, as very low levels of ester volatiles were detected at Day 1 and their levels were significantly increased after 90 days of ripening. Ketone volatiles followed a similar trend as described for

[w] RI: retention index.
[x] Method of identification: RF, mass spectrum and retention time identical with a reference compound; RI, mass spectrum and retention index from literature in agreement; TI, tentative identification by mass spectrum.
[y] P: Probability.
[z] Percentage (%): percentage of volatile compounds of each chemical group in each day of ripening of cheese.

esters. However, the levels of alcohols tended to increase in the first month of storage but tended to decrease after Day 30. This decrease could be probably due to the increase of esters, formed from the esterification of acids and alcohols. Finally, the level of aromatic compounds tended to increase at the beginning of the ripening but then remained constant.

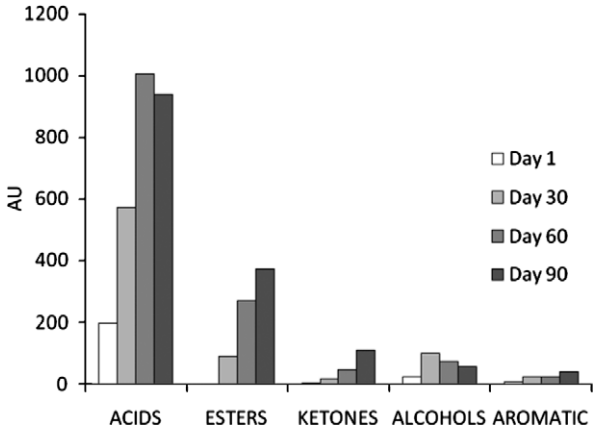

Fig. 1. Changes of the main chemical groups of volatile compounds (AU × 10^5) isolated in the soft cheese Torta del Casar during ripening.

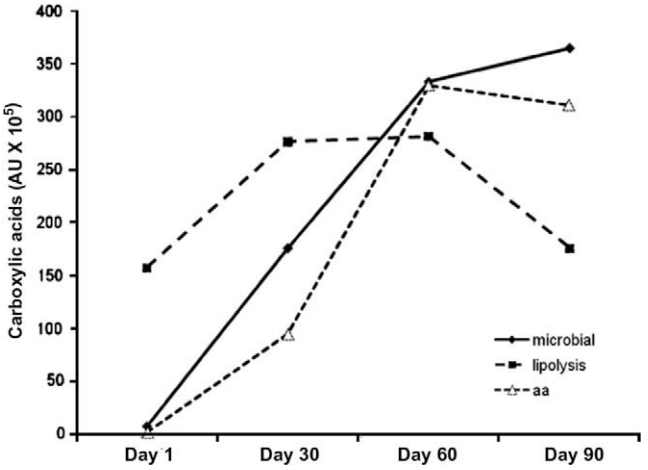

Fig. 2. Carboxylic acids with a microbial origin (acetic and propionic acids). Carboxylic acids with origin in lipolysis (butanoic, pentanoic, hexanoic, heptanoic, octanoic, decanoic and dodecanoic acids). Carboxylic acids with origin in amino acids (aa) (2-methylpropanoic and 3-methylbutanoic acids).

3.2. Carboxylic acids

Fig. 2 shows the evolution of carboxylic acids according to their most probable origin. During ripening of cheeses, carboxylic acids can originate from three main biochemical pathways: lipolysis, proteolysis and lactose fermentation (reviewed by Curioni & Bosset, 2002). Enzymes with lipolytic activity (esterases, lipases) may cause the release of linear-chain acids (butanoic, pentanoic, hexanoic, heptanoic, octanoic, decanoic and dodecanoic acids), whereas proteolytic enzymes are responsible for the formation of branched-chain acids (2-methylpropanoic and 3-methylbutanoic acids) by the deamination of amino acids, such as valine and leucine (Curioni & Bosset, 2002; Kuzdzal-Savoie, 1980). In this case, as these cheeses are made from raw milk, lipolysis could originate by the action of indigenous lipases from the milk, since no starter was added for the manufacture of the cheeses. Finally, acetic and propionic acids could have a microbial origin as a result of lactose fermentation, since the changes in those acids have been previously associated with the growth of lactic acid and propionic bacteria (Ziino, Condurso, Romeo, Giuffrida, & Verzera, 2005), respectively. The origin of (*E*)-3-hexenoic and (*E,E*)-2,4-hexadienoic acids is not clear in the literature, so they are not included in Fig. 2.

At Day 1, most acids detected came from lipolysis, while no acids had their origin in amino acid or microbial degradation. The amount of acids derived from lipolysis tended to increase in the first month of ripening, was constant until Day 60 and then decreased. However, carboxylic acids from amino acids increased during the first 60 days of ripening and then slightly decreased until Day 90. Acids with a microbial origin increased significantly during ripening, so at Day 90, they were the most abundant, followed by those acids derived from amino acids, while acids from lipolysis of triglycerides were the least abundant at the end of ripening. The high amount of acids derived from amino acids could be related to the high proteolysis of these cheeses during ripening, as a result of the addition of vegetable coagulant (Carbonell et al., 2002a; Fernández-Salguero & Sanjuan, 1999).

Carboxylic acids were the most abundant volatile compounds isolated in the headspace of Torta del Casar cheese on all days of ripening (Table 1) with a percentage of 61.5–81.8% of total compounds. They are not only aroma compounds by themselves but also they are precursors of other compounds, such as methyl ketones, alcohols, lactones, aldehydes and esters (Collins, McSweeney, & Wilkinson, 2003). Due to their low aroma thresholds, short and medium-chain carboxylic acids are considered to be important contributors to the flavour profile in a wide variety of cheeses (Kraggerud, Skeie, Høy, Røkke, & Abrahamsen, 2008; Moio & Addeo, 1998; Pinho, Ferreira, & Ferreira, 2003; Tavaria, Silva Ferreira, & Malcata, 2004; Woo & Lindsay, 1982; Zerfiridis, Vafopoulou-Mastrogiannaki, & Lipoulou-Tzanetaki, 1984).

At the beginning of maturation, the most abundant acids were hexanoic, (*E*)-3-hexenoic, octanoic and decanoic acids. However, at Day 90, high amounts of acetic acid and 3-methylbutanoic acid were isolated. Acetic acid content significantly increased after 90 days of ripening and it was the major compound isolated in the headspace of Torta del Casar soft cheese. The content of acetic acid, propanoic acid, 2-methylpropanoic acid, 3-methylbutanoic acid, octanoic acid and 2,4-hexanedienoic acid all significantly ($P < 0.05$) increased at the end of the ripening. However, the content of butanoic, pentanoic, decanoic and dodecanoic acids tended to decrease after 30 or 60 days of ripening, probably due to their transformation into other compounds, such as esters. High amounts of acetic and propanoic acids are related with vinegar odour, which could be associated with the slightly acid taste of these cheeses. Acetic acid originates from different reactions by the action of lactic acid bacteria (Ur-Rehman et al., 2000). The other major acid detected 3-methylbutanoic acid, has its origin in the breakdown of the aminoacid leucine (Kuzdzal-Savoie, 1980) and it provides a rancid, cheese and sweaty odour (Yvon & Rijnen, 2001). This compound could also originate from the oxidation of its Strecker aldehyde 3-methylbutanal. Of the other acids formed at high concentrations, propanoic acid has its origin in the metabolism of lactate by *Propionibacterium sp* (Steffen, Flueckiger, Bosset, & Ruegg, 1987) while 2-methylpropanoic acid is produced by the metabolism of the amino acid valine (Molimard & Spinnler, 1996; Urbach, 1997). Both propanoic and 2-methylpropanoic acids contribute with sour odour notes to cheese aroma (Avsar et al., 2004).

(*E*)-3-Hexenoic acid followed an opposite trend to hexanoic acid, since hexanoic acid tended to decrease after 30 days of ripening while the level of (*E*)-3-hexenoic acid tended to increase; we consider that probably there is a relationship between both compounds.

The volatile profile of La Serena cheese (Carbonell et al., 2002a, 2002b), with similar characteristics to Torta del Casar (made from raw ewes' milk, with vegetable coagulant), contained more alcohol compounds and less acids. These important differences could be explained by the different headspace extraction methods utilised, since they used purge-and-trap and we have used SPME. Mallia,

Fernández-García, and Bosset (2005) compared both methods and found that SPME fibres were more effective for extracting medium- and high-boiling compounds, especially volatile acids, while purge-and-trap was better for extracting highly volatile compounds and alcohols. However, these differences could also be evidence of the different volatile profiles of these cheeses.

3.3. Esters

Esters were the second most abundant compounds isolated in the headspace of Torta del Casar. The microorganisms involved in ester formation are mainly yeasts (Molimard & Spinnler, 1996); however, and also some lactic acid bacteria and *Micrococcaceae*, as well as chemical reactions, can also be responsible (Gripon, Monnet, Lamberet, & Desmazeaud, 1991). The action of the last two seems to be more probable in the Torta del Casar cheese (Cáceres et al., 1997; Poullet et al., 1991; Poullet et al., 1993).

Due to the microbial origin of esters, their levels were low at the beginning and then increased at the end of the ripening, especially butanoic acid propyl ester (propyl butyrate/butanoate).

Among the esters, 6 ethyl esters, 1 propyl ester and 1 3-methylbutyl ester were detected. Ethyl esters, due to their high amount, probably contribute to the overall flavour of Torta del Casar cheese as they have low detection thresholds. Some of the most important odorant compounds detected in other cheese varieties were ethyl esters such as butanoic acid ethyl ester (Cheddar, Emmental, creamy Gorganzola, Grana Padano, Pecorino, Ragusano), hexanoic acid ethyl ester (Cheddar, Emmental, natural Gorganzola, Grana Padano, Pecorino, Ragusano) and octanoic acid ethyl ester (Flor de Guia) (Curioni & Bosset, 2002). According to de Frutos, Sanz, and Martinez-Castro (1991), fruity notes provided by ethyl esters may minimise the sharpness of rancidity derived from excessive concentrations of carboxylic acids.

The increase of some esters, such as butanoic acid ethyl ester and butanoic acid propyl ester, could be associated with the decrease of butanoic acid at the end of ripening, although differences were not significant. Additionally, the reduction of some alcohols at the end of ripening, e.g., 3-methylbutan-1-ol, could also be related to the increase of esters, such as acetic acid 3-methylbutyl-1-ol ester. As far as we are concerned, these esters have not been previously isolated in other ewes' milk cheeses, so they could provide unique and characteristic aromatic notes to the Torta del Casar cheese. However, the increases during ripening of hexanoic acid ethyl ester and butanoic acid ethyl ester have been previously described in other ewes' milk cheeses (Barron et al., 2007; Carbonell et al., 2002a; Di Cagno et al., 2003; Mariaca, Fernández-García, Mohedano, & Nuñez, 2001).

3.4. Ketones

Ketones are abundant constituents of most dairy products, although in this case they were only 7.3% of the total compounds isolated at Day 90. They have typical odours and low perception thresholds. 2-Butan-one and 2-heptan-one were the most abundant ketones detected during ripening. They were not detected at trace levels at Day 1, but they greatly increased after 90 days of ripening, so they could play an important role in the final aroma of the Torta del Casar cheese. Similar results have been found in other cheeses made from raw ewes' milk such as Zamorano, Manchego and La Serena cheeses (Carbonell et al., 2002a, 2002b; Fernández-García et al., 2002a, 2002b). The opposite trend was found for 2-propan-one, which decreased during ripening, while, 3-hydroxy-2-butan-one (acetoin) increased at the beginning of ripening but then decreased slightly.

3.5. Alcohols

Alcohols were abundant at the beginning of the ripening, with a percentage of 10–12% of total volatiles detected at Day 30, while their level decreased to 3.7% at the end of ripening. These results contrast with those previously reported in other Spanish cheeses from ewes' raw milk, since alcohols were quantitatively the main chemical group found in the volatile fraction of Zamorano, Manchego, La Serena and Castellano cheeses (Carbonell et al., 2002a; Fernández-García, Gaya, Medina, & Núñez, 2004a; Fernández-García et al., 2004b). The levels of 1-dodecan-ol and 2,4-hexa-dien-1-ol did not change during ripening; however, the levels of 2-butanol and 2-methyl-5-hex-en-3-ol increased at the end of ripening, while the levels of 1-methoxy 2-propan-ol and 2,5-dimethyl-1-hexan-ol were the highest at Day 30 and then tended to decrease. These different patterns during ripening could be associated with the different metabolic pathways involved in the formation of alcohols in cheese, namely lactose metabolism, methyl ketone reduction, amino acid metabolism and degradation of linoleic and linolenic acids (Molimard & Spinnler, 1996).

3.6. Aromatic compounds

Most aromatic compounds tended to increase during ripening, except for benzeneacetaldehyde, which was not detected in Torta del Casar cheese samples after 90 days of ripening. So, the levels of ethyldimethylbenzene, benzaldehyde and phenol were significantly highest at Day 90, while the level of 2-phenylethanol was highest after 30 days of ripening and remained constant until Day 90. The amounts of styrene and benzyl alcohol did not change during ripening.

Some of the aromatic compounds detected originate from the Strecker reaction, e.g., benzaldehyde, which adds aromatic notes of bitter almond to cheese (Molimard & Spinnler, 1996), may be produced from the α-oxidation of phenyl acetaldehyde, as they followed an opposite trend; phenylacetaldehyde is derived from phenylalanine, *via* a Strecker reaction (Sieber, Buetikofer, & Bosset, 1995). On the other hand, Strecker degradation of phenylalanine is also responsible for 2-phenylethanol production and this reaction has been attributed to yeast metabolism (Correa Lelles Nogueira, Luachevsky, & Rankin, 2005).

3.7. Aldehydes

Aldehydes are not major compounds in cheese, as they are rapidly converted to alcohols or their corresponding acids (Lemieux & Simard, 1992), so their levels during ripening were 0.1–0.5% of total volatile compounds isolated. The low level of aldehydes indicated an optimal maturation because a high concentration of aldehydes may cause off-flavours (Moio & Addeo, 1998).

Three aldehydes were isolated which showed different patterns: 3-methylbutanal was detected at the beginning of maturation but not at Day 60 and 90, 2,4-hexa-dienal did not change during ripening, and dodecanal, which was only detected after 60 days of ripening reached its highest level at Day 90. The first is a Strecker aldehyde, while the other two could by formed by lipid oxidation of their respective alcohols. So the origin of dodecanal could be due to the oxidation of 1-dodecan-ol, as they followed an opposite pattern, and the same could happen with 2,4-hexa-dienal and 2,4-hexa-dien-1-ol.

3.8. Others

A branched alkane, 3-methylpentane, was isolated at the beginning of ripening, at Day 1, but its amount decreased during maturation and it was not detected at Day 90. The contribution of

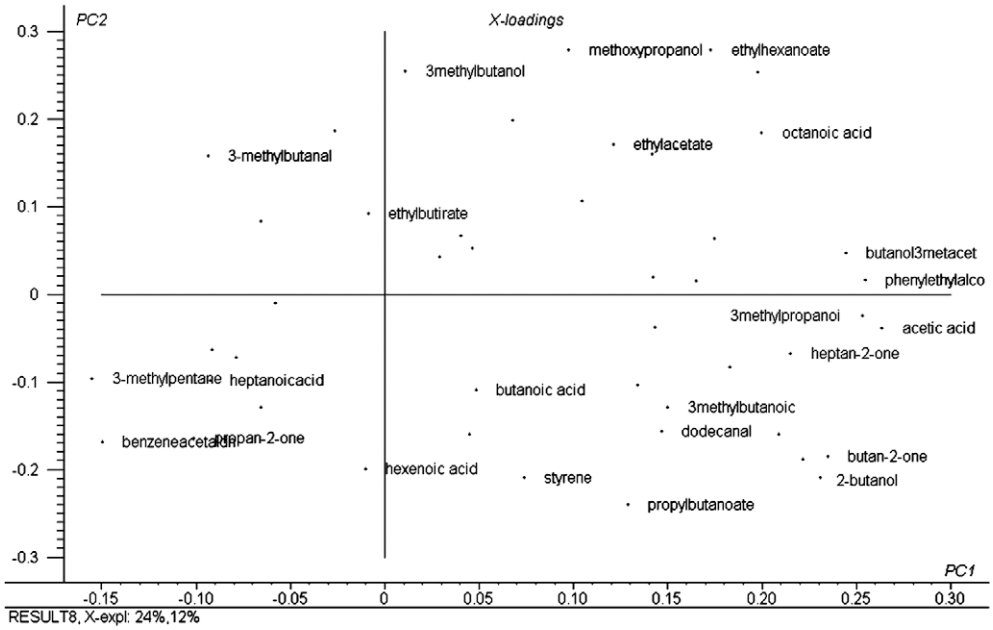

Fig. 3. Loading plots after principal components analysis of the variables in the plane defined by the two first principal components (PC #1 and PC #2).

aliphatic hydrocarbons to the global aroma of Torta del Casar cheese could be low as these compounds have high threshold values.

Only one sulphur compound, originating from methionine (Yvon & Rijnen, 2001) was found. 3-Methylthio-1-propan-ol or methionol probably has limited importance in the final aroma of Torta del Casar as it was not detected at the end of ripening.

Only one lactone was detected, δ-decalactone, which was not isolated at Day 1 but its level increased during ripening and the highest amount was found at Day 90. δ-Decalactone is one of the lactones most commonly detected in cheeses. Lactones have fruity and sweet, creamy, fermented notes (Dufosse, Latrasse, & Spinnler, 1994), so they could contribute pleasant odour notes to the aroma of Torta del Casar. δ-Lactones may be formed from δ-hydroxyacids following their release from triacylglycerides by lipolysis, so concentration of lactones usually correlate with lipolysis extent (Collins et al., 2003), which agrees with our results.

3.9. Multivariate analysis

A principal component analysis (PCA) was carried out to determine which were the most important volatile compounds on each day of maturation. PCA is a mathematical procedure for resolving sets of data into orthogonal components, whose linear combinations (principal components) approximate the original data to any desired degree of accuracy. In most cases, two principal components are sufficient to explain a great proportion of the variation in the original variables, thus resulting in a considerable

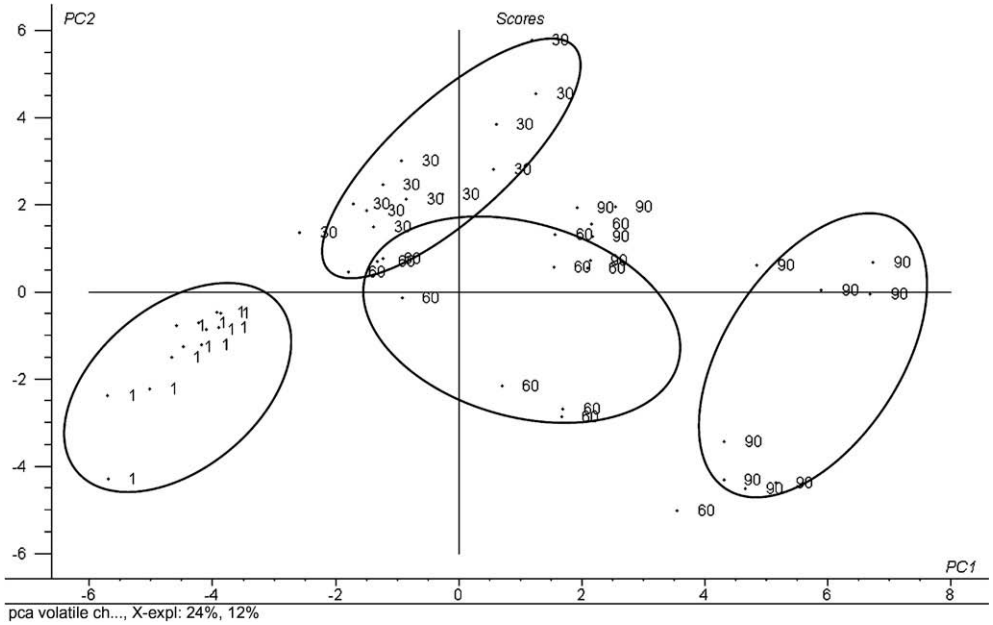

Fig. 4. Scores plot after principal component analysis of the individuals in the plane defined by the two first principal components (PC #1 and PC #2).

compression of the data. In this case, 24% and 12% of the variability was explained by principal components (PC) #1 and #2, respectively.

Fig. 3 shows the score plot of the different variables (coefficients of the eigenvectors) for the two first principal components (PC #1 and PC #2). Although all volatiles were included in the analysis, only volatile compounds which explained variation of the data have been identified in the figure. On the positive axis of PC #1, far from the origin and explaining an important part of the variation are located volatile compounds isolated to a higher extent in cheeses with 90 days of ripening, such as carboxylic acids (acetic acid, 3-methylbutanoic acid, 2-methylpropanoic acid), esters (acetic acid 3-methylbutyl-1-ol ester), ketones (2-heptan-one, 2-butan-one) and others (2-butan-ol, dodecanal). On the negative axis of PC #1 are compounds related to the flavour of cheese at the beginning of the ripening (3-methylpentane, heptanoic acid, benzeneacetaldehyde, 2-propan-one). Regarding PC #2, some volatile compounds were located in the positive axis of the plane (3-methyl-1-butanol, 1-methoxy-2-propanol, hexanoic acid ethyl ester) while others were located in the lower part of the plane in the negative axis (hexenoic acid, butanoic acid propyl ester).

The distribution of the scores on the first two PCs (Fig. 4) shows 4 separate groups of points, corresponding to the different days of ripening. Cheeses at Day 90 are located in the positive area of PC #1 while in the negative area are those with 1 day of ripening. In the middle of the plane are located cheeses with 30 and 60 days of ripening, so PC #1 cannot explain differences between these groups, however, PC #2 could explain differences between cheeses with 30 and 60 days of ripening as cheeses with one month of maturation are in the upper part of the plane and those with 2 months are in the low part of the plane. Volatile compounds located at the extremes of PC #2 are associated with the volatile profile of cheeses at 30 days and at 60 days of ripening.

4. Conclusions

The greater importance of carboxylic acids with origin in microbial activity (acetic and propionic acids) and amino acid degradation (2-methylpropanoic and 3-methylbutanoic acids) than those from lipolysis (butanoic, pentanoic, hexanoic, heptanoic, octanoic, decanoic and dodecanoic acids) is a unique characteristic, which could be associated with the typical aroma of Torta del Casar soft cheese, and which could differentiate its aroma from other cheeses on the market.

Toasted durum wheat flour

ABSTRACT

Durum wheat kernels were subjected to a toasting process and the proteins characterised by size exclusion-high performance liquid chromatography (SE-HPLC) and sodium dodecyl sulphate–polyacrylamide gel electrophoresis. With this physical process, albumins and globulins, as well as glutenins and gliadins, polymerised as seen by a shift of the SE-HPLC profile to lower elution times. The polymerisation seemed to happen mainly through disulphide bonds, even though the participation of ω-gliadins to the aggregation suggested the involvement of other kinds of interactions. It led to the revelation of a new peak originated by thermal aggregation of small polymeric proteins. The changes in the chromatographic profile were accompanied by increasing amounts of total unextractable polymeric proteins. The replacement of semolina with toasted durum wheat flour (5%, 10%, 15%, 20% and 30%) for the production of pasta in the shape of spaghetti significantly ($p < 0.001$) affected the molecular size distribution of the polymeric proteins, even though the replacement of semolina with 5% and 10% of toasted durum wheat flour (TDWF) did not significantly ($p > 0.05$) change the unextractable polymeric proteins (UPP) when compared with spaghetti made with 100% durum semolina. On the other hand, the replacements of semolina with 15–30% TDWF showed significant ($p < 0.001$) increase in UPP when compared with 100% durum semolina spaghetti.

1. Introduction

Wheat is currently the most important crop in the world, with total annual yields of almost 600 million tonnes. Much of the success of wheat stems from its processing properties and in particular its ability to form cohesive doughs which can be baked into bread or formed into pasta and noodles. These properties derive largely from the gluten proteins, which form a continuous viscoelastic network within the dough. Gluten contains hundreds of proteins components, which are present either as monomers or, linked by interchain disulphide bonds, as oligo- and polymers (Wrigley & Bietz, 1998). They are unique in terms of their amino acids composition, which are characterized by high contents of glutamine and proline and by low contents of amino acids with charged side groups. Traditionally gluten proteins have been divided into gliadins and glutenins, according to their polymerisation properties: gliadins are monomeric proteins that form only intra-molecular disulphide bonds, if present, whereas glutenins are polymeric proteins whose subunits are held together by inter-molecular disulphide bonds, although intra-chain bonds are also present. Among these storage proteins, glutenins (polymeric proteins) have been shown to be extremely important in determining rheological properties. Moreover, a certain amount of these polymers remains unextractable in various extracting systems (e.g. acetic acid solution or SDS–phosphate buffer) and the proportion of this fraction, known as unextractable polymeric proteins (UPP), is reported to be related to the technological response (Gupta, Khan, & MacRitchie, 1993; Jia, Fabre, & Aussenac, 1996).

Gluten proteins are susceptible to heat treatment and their behaviours subjected to relatively high temperatures have been studied by a numbers of workers. It was shown that molecular size of the glutenin aggregates increases and, hence, their extractability decreases (Booth et al., 1980; Schofield, Bottomley, Timms, & Booth, 1983; Weegels, de Groot, Verhoek, & Hamer, 1994b). At 100 °C, gliadins undergo similar changes. The extractability of gliadins from bread by 60% ethanol is much lower than that from flour, and α-and γ-giadins are more affected than ω-giadins (Wieser, 1998). The effects have been ascribed to sulphidryl

doi:10.1016/j.foodchem.2009.04.100

(SH)-disulphide interchange reactions induced by heat, that affect all gluten proteins except the cysteine-free ω-giadins (Booth et al., 1980; Schofield et al., 1983). Morel, Redl, and Guilbert (2002) suggested that below 60 °C no changes in free sulphydryl groups occur. Heating to at least 90 °C leads to disulphide bond linked aggregates and conformational changes affecting mostly gliadins and low molecular weight albumins and globulins (Guerrieri, Alberti, Lavelli, & Cerletti, 1996). Although, Kokini, Cocero, Madeka, and de Graaf (1994) proposed that cross-links among gliadin molecules are formed above 70 °C in the absence of glutenins, others believed that gliadins cross-link only with glutenins (Redl, Morel, Bonicel, Vergnes, & Guilbert, 1999; Singh & MacRitchie, 2004). As a matter of fact, the incorporation of gliadin monomers in the glutenin network leads to a three-dimensional structure (Morel et al., 2002).

Apart from its fundamental interest, the effects of heating on gluten proteins are relevant to practical processes, such as drying of rain-damaged wheat, drying of gluten from starch/gluten manufacturing plants and, in relation to effects on gluten proteins during baking, pasta making and extrusion and the potential for producing modified glutens with unique technological properties. A traditional pasta used by poor Apulian people, which lived in Southern Italy, was home made brown pasta by durum semolina obtained from toasted kernel. The toasted kernel was the product of burning remained straw in the fields; in this way residual kernels were subjected to high temperature treatment. The poor people looked for toasted kernel in the straw ash and picked up it manually. Today pasta from toasted kernel, "Grano arso" called in Italy, is an actual commercial activity in Puglia.

To increase our insight into the behaviour of gluten proteins during heat treatment, the size exclusion-high performance liquid chromatography (SE-HPLC) was used to examine polymerisation of the different protein fractions of durum wheat kernels subjected to a toasting process and to evaluate their changes in molecular size distribution. In addition, the effect of the partial replacement of semolina with toasted durum wheat flour (5%, 10%, 15%, 20% and 30%) was studied to improve and optimize the process of traditional pasta production from "Grano arso". To reach this objective, SE-HPLC profiles and the UPP of the composite pasta were evaluated thus to gain a better understanding of size distribution and possible interactions at the molecular level.

2. Experimental

2.1. Raw materials

Semolina and toasted durum wheat flour (TDWF) derived from the same commercial blend of Italian durum wheats (Simeto, Ciccio, Arcangelo) were supplied by Molino Daddario Antonia (Cerignola, Foggia, Italy). The toasted meal was obtained by the milling of heat treated caryopses previously harvested and threshed. In particular, cleaned durum wheat grains were arranged on steel bearing placed into direct contact with a wood-fire for 120 s until kernels browned; then, grains were cleaned again and dampened; and after eight hours the grains were subjected to grinding using a roller mill. The particle size of the TDWF used was in the range of 200–355 μm.

2.2. Pasta production

Pasta was produced in a 2-kg pilot plant (NAMAD, Rome, Italy) consisting of a mixer, an extruder and a dryer. The flour was mixed with tap water (for 10 min) to obtain a dough water content of 44–45%. The extrusion conditions were as follows: temperature = 50 °C (the extrusion temperature varied between 45 °C and 55 °C); kneading time = 15 min, pressure = 60–125 atm as a function of the specific formulation and vacuum degree = 700 mm Hg. A Teflon die-plate of 1.70 mm diameter was used. Pasta in the shape of spaghetti was dried at 50 °C for 16 h. The diameter of the obtained spaghetti was about 1.70 ± 0.03 mm. Six kinds of spaghetti were produced: a control, made of 100% durum wheat semolina and pasta in which 5%, 10%, 15%, 20% and 30% of semolina was replaced with TDWF (named respectively as 5% TDWF-, 10% TDWF-, 15% TDWF-, 20% TDWF-, and 30% TDWF-wheat spaghetti).

2.3. Proteins extraction for SE-HPLC

Proteins from semolina, toasted durum wheat flour and milled spaghetti samples were extracted following the method of Gupta et al. (1993). Samples (10 mg) were suspended in 1 mL 0.5% sodium-dodecyl-sulphate (SDS)–phosphate buffer (pH 6.9) and mixed initially in a vortex-mixer and later kept at room temperature for 30 min. The suspensions were then centrifuged for 10 min at 17,000 g to obtain supernatant ("extractable" or "SDS-soluble" proteins).

The resulting residues were extracted with 0.9 ml 0.5% SDS–phosphate buffer (pH 6.9) by sonication for 15 s using a Microson Ultrasonic (Falc Instrument, Bergamo, Italy) cell distributor, ensuring that the samples were completely dispersed within the first 5 s and then heating to 35 °C for 30 min. The supernatants from centrifugation for 10 min at 17,000*g* were termed "unextractable" proteins. All extracts were filtered through a 0.45 μm PVDF filter prior to SE-HPLC analysis.

2.4. SE-HPLC analysis

Polymeric proteins from the semolina, toasted durum wheat flour and milled spaghetti samples were fractionated through size exclusion-high performance liquid chromatography (SE-HPLC) using a Phenomenex Biosep TM SEC 4000 column (Phenomenex) (Kuktaite, Johansson, & Juodeikiene, 2000; Kuktaite, Larsson, & Johansson, 2003). Proteins from semolina and milled spaghetti were extracted with a two step extraction procedure (Gupta et al., 1993). The first step in this method extracts the SDS-extractable proteins (soluble in diluted SDS), whilst the second extract contains the SDS-unextractable proteins (proteins soluble only after sonication). The extracted proteins were separated on SE-HPLC according to Tosi et al. (2005) by loading 20 μl of sample into an eluant of 50% (v/v) acetonitrile and water containing 0.05% (v/v) trifluoracetic acid (TFA) at a flow rate of 0.7 mL/min for 30 min. Proteins were detected at a wavelength of 214 nm. Three replicates of each samples were used for the investigation of protein composition. The percentage of unextractable polymeric protein (UPP) was calculated as described by Gupta et al. (1993). Briefly, the percentage of total UPP was calculated as [peak 1 + 2 area (unextractable)/peak 1 + 2 area (total)] × 100. Peak 1 + 2 (total) refers to the total of peak 1 + 2 (extractable) and peak 1 + 2 (unextractable) (Johansson, Prieto-Linde, & Jonsson, 2001; Kuktaite et al., 2000, 2003).

The SE-HPLC column was calibrated using protein standards with a range of molecular weights (KDa) as follows: ribonuclease A (13.7), chymotripsinogen (25.0), ovalbumin (43.0), bovine serum albumin (67.0), aldolase (158), catalase (232), ferritin (440) and thyroglobulin (669).

The molecular weights were calculated from the line of best fit through the calibration points, given by: log molecular weight = 8.1448–0.1995 × elution time (min).

2.5. SDS–PAGE (sodium dodecyl sulphate–polyacrilamide gel electrophoresis) analyses

One hundred gram were sequentially extracted by the Osborne procedure (Osborne, 1907) with modifications. Albumin and globulins

were extracted with 0.1 N NaCl for 30 min, vortexing for 1 min, every 10 min at 24 °C (room temperature). The mixture was centrifuged at 11,294*g* for 10 min at 24 °C using a Model IEC CL 31R Multispeed Centrifuge (Thermo Electron Corporation, 81 Wyman St. Waltham, MA 02454–9046 Stati Uniti). Four volumes of cold pure acetone were added to the supernatant (albumin/globulin extract) and stored at −20 °C overnight to precipitate the albumin/globulin. The solution was centrifugated at 4 °C for 10 min at 11,294*g* and the pellet was dissolved with buffer containing Tris–HCl 0.0625 M, SDS 2%, Glycerol 10% and Dithiotreitol (DTT) 1.5%.

The centrifuged albumin/globulin (pellet) was washed with deionized water for 30 min vortexing for 1 min, every 10 min at 24 °C. The mixture was centrifuged at 24 °C for 10 min at 11,294*g*. The washing was repeated four times with deionized water to reduce the effect of the salt in the centrifugate for the extraction of gliadins in the following steps. The gliadin fractions were extracted with 70% aqueous ethanol for 30 min, vortexing for 1 min, every 10 min at 24 °C. The mixture was centrifuged at 24 °C for 10 min at 11,294*g*. Four volumes of cold pure acetone were added to the supernatant (gliadins extract) and stored at −20 °C overnight to precipitate the gliadins. The solution was centrifuged at 4 °C for 10 min at 11,294*g* and the pellet was dissolved with buffer containing Tris–HCl 0.0625 M, SDS 2%, Glycerol 10% and 1.5% DTT. Glutenins were extracted by incubating the gliadins centrifuged (pellet) with 50% (v/v) 1-Propanol and 0.08 M Tris–HCl (pH 8.0) for 30 min, vortexed for 1 min every 10 min. The mixture was centrifuged at 24 °C for 10 min at 11,294*g*. Four volumes of cold pure acetone were added to the supernatant and stored at −20 °C overnight. The solution was centrifuged at 4 °C for 10 min at 11,294*g* and the pellet was dissolved with buffer containing Tris–HCl 0.0625 M, SDS 2%, Glycerol 10% and 1.5%. DTT. Each protein fraction (7.5 μl) was subjected to SDS–PAGE according to Laemmli (1970), at 25 mA for 3 h at 24 °C. The acrylamide content of a separation-slab-gel (13.5 × 11 cm) was 12.5%. The gels were stained with 0.25% w/v Coomassie Brilliant Blue (CBB) overnight.

2.6. Statistical analysis

The results were compared by one-way variance analysis (ANOVA). A Duncan's multiple range test, with the option of homogeneous groups ($p < 0.05$), was used to determine significant differences between samples. STATISTICA 7.1 for Windows (StatSoft, Inc, Tulsa, OK, USA) was used for this purpose.

3. Results and discussion

3.1. Effect of seed toasting on flour protein fractions

Proteins profile from semolina chromatogram is depicted in Fig. 1a. It shows a polymeric-protein peak of high molecular weight glutenin proteins at the extreme left of the profile and indicated as large polymeric protein (LPP), followed by a small peak of low molecular weight glutenin proteins, indicated as small polymeric proteins (SPP), and finally by a notable peak of large monomeric proteins (LMP) called gliadins and small peaks of albumins and globulins, indicated as small monomeric proteins (SMP) (Carceller & Aussenac, 2001; Larroque, Gianibelli, Batey, & MacRitchie, 1996, 1997; Tosi et al., 2005).

The SE-HPLC elution profile for TDWF (Fig. 1b) shows, respect to the semolina profile, a peak fusion, indicating a protein denaturation. Nevertheless, four main peaks are distinguishable: LPP, LMP, SMP and a new intermediate protein (IP) peak, with a molecular weight comprised between LMP and SMP. The TDWF profile shows a greatest proportion IP and a higher proportions of LPP than that of semolina. The chromatogram of TDWF did not show

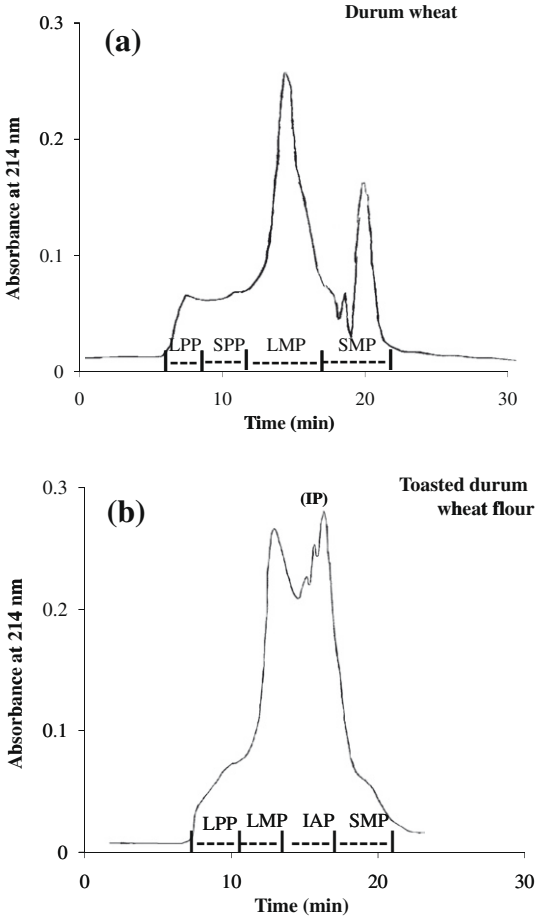

Fig. 1. SE-HPLC elution profile of durum wheat semolina (a) and TDWF (b). LPP: large polymeric proteins; LMP: large monomeric proteins; IAP: intermediate aggregates proteins; SMP: small polymeric proteins; IP: intermediate proteins.

the peak corresponding to the SPP in the semolina, that probably have been included in the LPP by polymerisation. This is consistent with results obtained by Singh and MacRitchie (2004) and Lamacchia et al. (2007), that observed the same changes in the polymerisation of gluten proteins when gluten was subjected to heating. The occurrence of the IP and the increase of the LPP are explainable with the concomitant decrease of the SMP and LMP peaks and the disappearance of the SPP. Considering that LPP, SMP and LMP are mainly represented by glutenin, albumin/globulin and gliadin proteins, respectively, (Carceller & Aussenac, 2001; Larroque et al., 1996), the high temperature applied may cause both the formation of intermolecular hydrogen bonding (Eckert, Amend, & Belitz, 1993) and disulphide cross-linking by the oxidation of glutenin free SH groups (Gobin, Ng, Buchanan, & Kobrehel, 1997; Weegels, Verhoek, de Groot, & Hamer, 1994a; Weegels et al., 1994b) among these proteins, leading to their aggregation into larger or new polymers (as evidenced from the SE-HPLC profile).

However the occurrence of the IP indicates that albumins and globulins have coagulated and reacted with gliadins forming protein aggregates. These data are not consistent with results obtained by Schofield et al. (1983), Lavelli, Guerrieri, and Cerletti (1996), Singh and MacRitchie (2004) and Lamacchia et al. (2007) that showed the incorporation, at high temperatures, of the albumins and globulins into high-molecular-weight polymers eluting in LPP peak.

A possible explanation for this phenomenon could be that the incorporation of albumins and globulins into the high-molecular-weight

polymers, during high temperature treatment, occur after gluten is already formed. In the case where the wheat proteins are subjected to high temperature treatment while present in the endosperm, polymerisation between the LPP and SMP protein classes cannot occur. This is probably due to the deposition of the two classes of proteins in different protein bodies. Indeed, it is well known that in the wheat endosperm two major transport routes run from the ER to the vacuole, one that by-passes the Golgi apparatus and another one that passes through it. Proteins travelling along either route converge as two types of protein bodies: the Endoplasmic Reticulum (ER)-derived protein bodies and the vacuolar protein bodies. Rubin, Levanony, and Galili (1992) reported that the glutenins (LPP and SPP) are retained predominantly within the ER, while the gliadins (LMP) are present in both ER-derived and vacuolar protein bodies. Furthermore, Krishnan, Franceschi, and Okita (1986) and Lending, Chesnut, Shaw, and Larkins (1989) found that cereal globulins (SMP) are deposited in vacuolar protein bodies via the Golgi apparatus.

The glutenin, gliadin and albumin/globulin fractions of semolina and TDWF were separated on SDS–PAGE under reducing (Fig. 2a) and non reducing conditions (Fig. 2b). As can be inferred by the gels, the toasting process caused both a decrease in the number of bands at higher molecular weight in the glutenins, gliadins and albumins/globulins lanes and a decrease in intensity of the bands at lower molecular weight, suggesting polymerisation of these proteins. The polymerisation seems to occur mainly through disulphide bonds, as evidenced by the non-reducing SDS–PAGE gel, although it is possible to notice some bands corresponding to ⟨omega⟩-gliadins disappear in the TDWF gliadins lane. Since ⟨omega⟩-gliadins do not contain cysteine residues, it can be suggested that the cross-linking is not occurring only through disulphide bonds.

3.2. Effect of substitution of semolina with increasing amount of toasted durum wheat flour on the pasta SE-HPLC profiles

Fig. 3 shows the SE-HPLC profiles for total proteins in spaghetti made of semolina and increasing amount (5%, 10%, 15%, 20% and 30%) of TDWF. The wheat spaghetti elution profile (Fig. 3a), used as a control, is essentially similar to that of semolina, showing a polymeric-protein peak of glutenins at the extreme left of the profile (LPP > 1,00,000 Da), followed by a large peak of monomeric gliadin proteins (LMP < 1,00,000 Da) and finally small peaks of albumins and globulins (SMP) (Larroque et al., 1996, 1997; Carceller & Aussenac, 2001). The SPP peak that contains low-molecular-weight glutenins (Larroque et al., 1996, 1997) is not present in the pasta elution profile, but present in the durum semolina profile. Lamacchia et al. (2007) demonstrated that SPP is included in the LPP, through polymerisation, during pasta drying cycles at ~60 °C. The temperatures used for pasta/spaghetti drying may promote the formation of both intermolecular hydrogen bonding between gluten protein subunits (Eckert et al., 1993) and protein disulphide cross-linking due to the oxidation of free SH groups of glutenin (Gobin et al., 1997; Weegels et al., 1994a,1994b), leading to aggregation of the pasta proteins into larger polymers. The elution profiles of 100% durum semolina spaghetti (Fig. 3a) and spaghetti with 5%, 10%, 15%, 20% and 30% semolina replaced with TDWF (Fig. 3b–f) were essentially similar. They all showed three main peaks (i.e., low-, medium- and high-molecular-weight), although their proportions varied on the basis of the percentage of TDWF added. In particular, it is possible to notice that the LPP peak of TDWF-wheat spaghetti increased significantly ($p < 0.001$) with respect to 100% durum semolina spaghetti. As the amount of TDWF increased to 15% there was an increase in the IP peak, while the LMP and SMP peaks decreased. On the contrary, in spaghetti made with 20% and 30% TDWF, the IP and SMP peaks decreased, while the

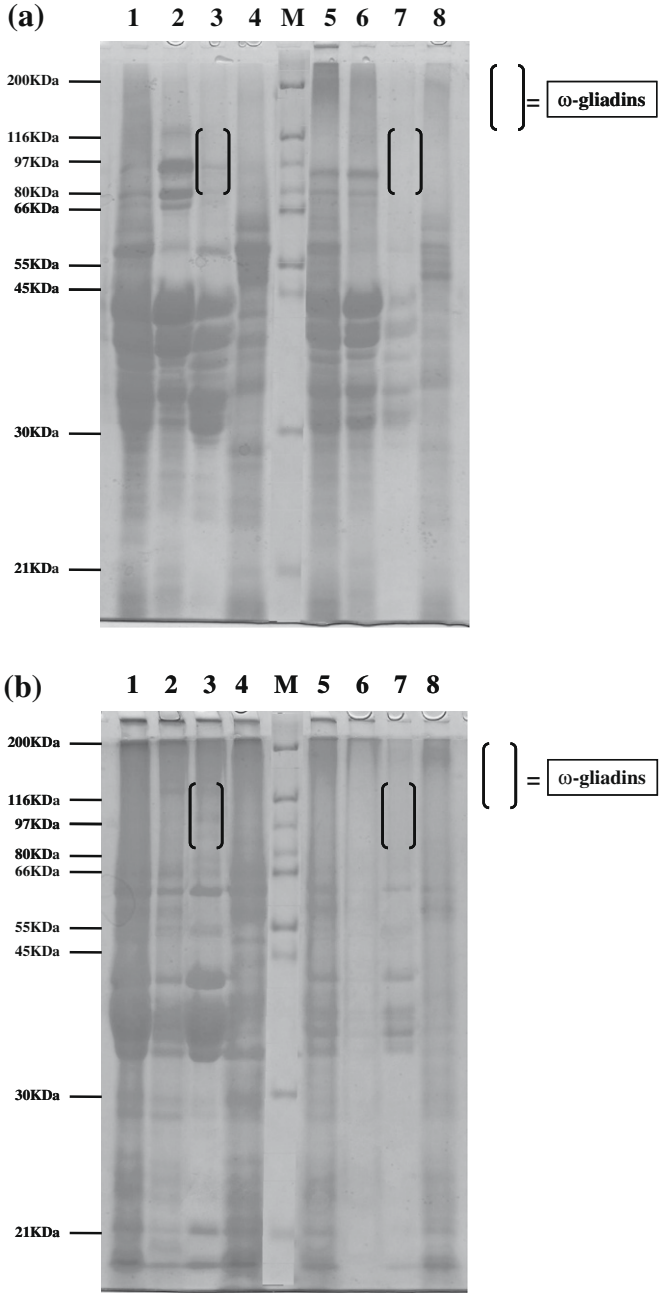

Fig. 2. SDS–PAGE separation of durum wheat semolina and TDWF protein fractions under reducing (a) and non reducing (b) conditions. Lane 1: durum wheat semolina total proteins; lane 2: durum wheat semolina glutenins; lane 3: durum wheat semolina gliadins; lane 4: durum wheat semolina albumins/globulins: M: marker; lane 5: TDWF total proteins; lane 6: TDWF glutenins; lane 7: TDWF gliadins; lane 8: TDWF albumins/globulins.

LMP peak increased. Therefore, it may be suggested that based on the amount of TDWF added for the preparation of spaghetti, two different aggregation arrangements occurred.

3.3. Changes in molecular weight distribution (MWD) and protein extractability

The changes in amount of protein measured by the chromatogram area, for the different protein fractions of TDWF and spaghetti samples, are shown in Table 1 and Table 2, respectively. The LPP peak increased significantly in TDWF when compared with semolina (Table 1), and a decrease of SPP, LMP and SMP peaks and

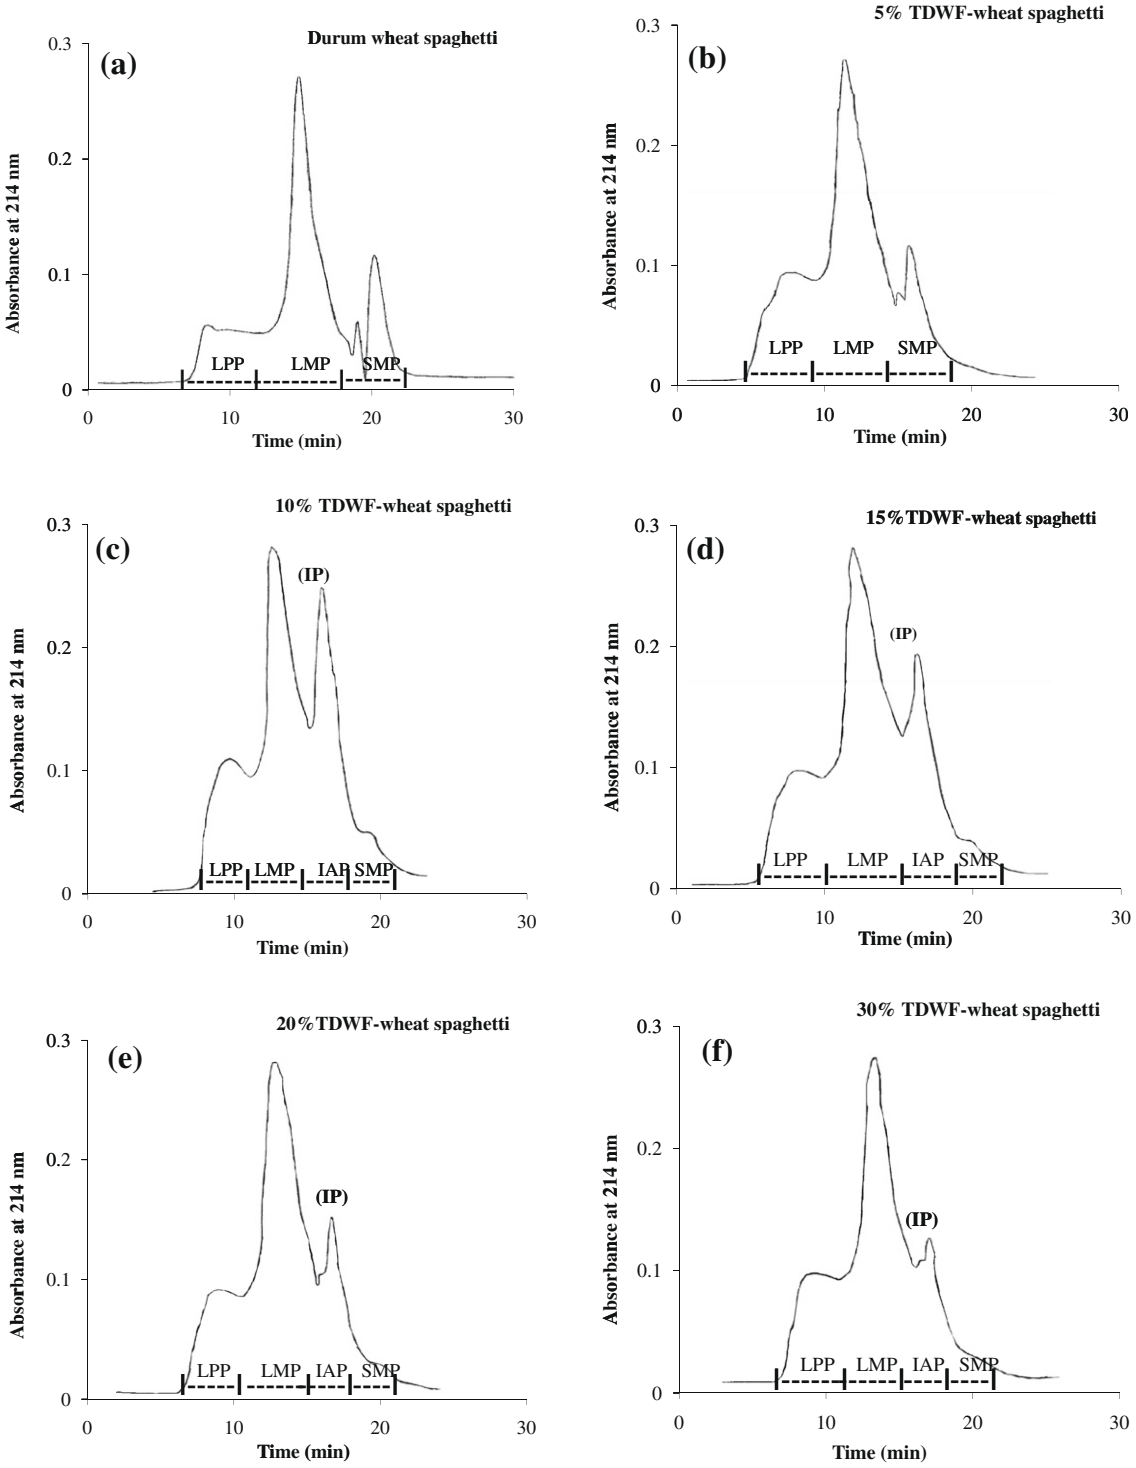

Fig. 3. SE-HPLC elution profile of spaghetti made of semolina (a) and semolina and increasing amount of TDWF: 5% TDWF-wheat spaghetti (b), 10% TDWF-wheat spaghetti (c), 15% TDWF-wheat spaghetti (d), 20% TDWF-wheat spaghetti (e) and 30% TDWF-wheat spaghetti (f).

the formation of an IP peak is detected (Table 1). It is evident that the toasting process caused a major upward shift in protein molecular weight distribution. Thus, the polymeric proteins with low-molecular weight (i.e., gliadins and albumins/globulins) were denatured and polymerised into high-molecular weight proteins eluting in the LPP and IP peaks. However, a decrease in the area of peaks SPP, LMP and SMP does not appear to be sufficient on its own to account for the increased area of the LPP peak and for the formation of the IP peak. In fact, Table 1 shows a significant decrease of total peak areas, indicating the possibility that part of the monomeric proteins and possibly SPP were denatured and made unextractable. These results are consistent with reports by Lagrain, Brijs, Veraverbeke, and Delcour (2005) and Lamacchia et al. (2007) who observed a similar phenomenon in both wheat proteins subjected to high temperature treatment and in wheat pasta proteins subjected to high temperature during the drying cycles. On the contrary, Table 2 shows a significant increase in the total peak area of the composite pasta (i.e., TDWF-wheat spaghetti) compared to

Table 1
Values of the SE-HPLC peaks area for the semolina and the TDWF.

that of the traditional pasta (i.e., 100% durum semolina spaghetti). Even though only LPP and IP showed increased peak areas, the increase of these peaks was accompanied by a decrease in the SMP and LMP peak areas. In particular, in pasta containing 5% TDWF, the LMP and SMP were probably completely denatured at high temperature and incorporated into the high-molecular weight polymers eluting as LPP peak. In the spaghetti containing 10%, 15%, 20% and 30% TDWF, LMP and SMP were denatured and prob-

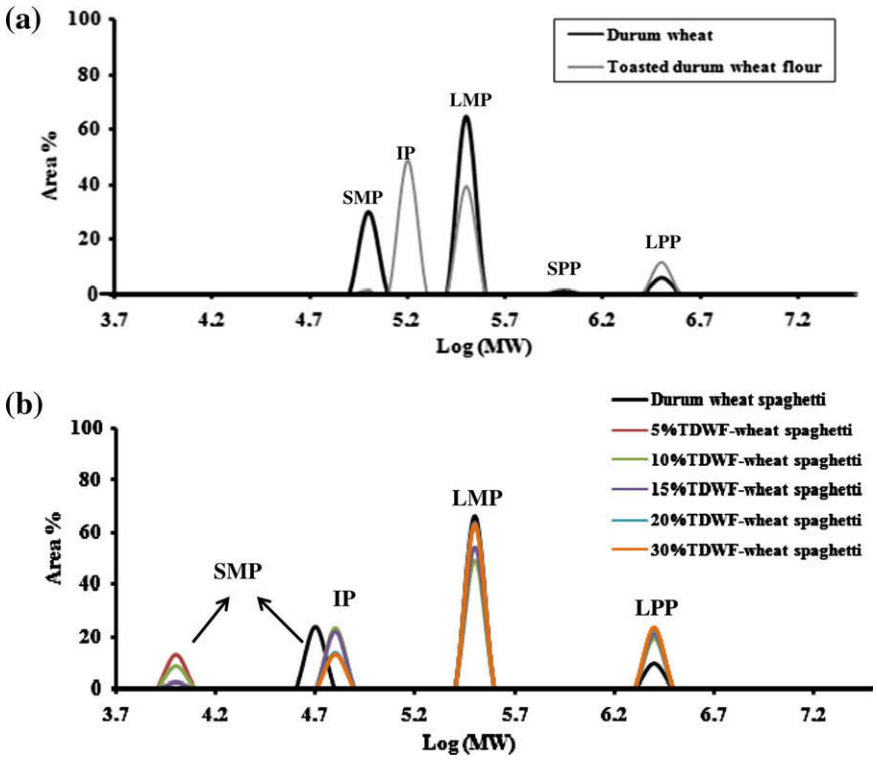

Fig. 4. Changes in molecular weight distribution induced by toasting process on durum semolina proteins (a): LPP: large polymeric proteins; SPP: small polymeric proteins; LMP: large monomeric proteins; IP: intermediate proteins; SMP: small monomeric proteins. ably incorporated into both LPP and IP peaks; and there seems to exist a sort of equilibrium between the LPP and IP polymers in the TDWF-wheat spaghetti. In fact, when the IP peak increased (i.e., in 10% TDWF-wheat spaghetti), a decrease in LMP, SMP and LPP peaks was detected, when compared with 5% TDWF-wheat spaghetti. On the other hand, when IP decreased (i.e., in 15%, 20% and 30% TDWF-wheat spaghetti), a decrease in SMP and an increase in LPP and LMP peak areas was detected, when compared with the 5% TDWF-wheat spaghetti. The increase in the LMP peak may suggest that the aggregates from IP and SMP assume a similar molecular weight to LMP, and that further aggregation among these produced other LPP. This indicated that SMP initially forms an intermediate aggregate, which we refer to as intermediate aggregated proteins (IAP) and corresponds to the IP peak. Therefore an aggregation sequence could occur according to the following schematic diagram.

- TDWF: LMP + SMP → IAP;
- 5% TDWF-wheat spaghetti: $\mathrm{LMP} + \mathrm{SMP} \xrightarrow{(\text{drying cycle } 60\ ^\circ\mathrm{C})} \mathrm{LPP}$;
- 10% TDWF-wheat spaghetti: (<LPP;>IP) $\mathrm{LMP} + \mathrm{SMP} + \mathrm{LPP} \xrightarrow{(\text{drying cycle } 60\ ^\circ\mathrm{C})} \mathrm{IAP}$;
- 15, 20, 30% TDWF-wheat spaghetti: (>LPP;<IP) $\mathrm{IAP} + \mathrm{SMP} \xrightarrow{(\text{drying cycle } 60\ ^\circ\mathrm{C})} \mathrm{LMP} + \mathrm{LPP}$;

An MWD curve (Fig. 4b) illustrates how this parameter changes with the replacement of durum wheat semolina with increasing amount of TDWF. On the contrary, Fig. 4a shows the changes in molecular weight distribution (MWD) induced by the toasting process on durum wheat proteins. These results also support our hypothesis of sequential aggregation, as shown in the schematic diagram above.

3.4. Effect of seed toasting on percentage of total UPP of durum wheat flour and composite pasta

The percentage of unextractable polymeric proteins in the total polymeric proteins in wheat flour and spaghetti samples were calculated from the chromatograms obtained by protein fractionation using SE-HPLC. The unextractable polymeric proteins of TDWF proteins (100% UPP) was significantly ($p < 0.001$) higher than that of semolina (20.33% UPP) (Fig. 5a). The higher proportion of UPP in TDWF may be explained by considering the fact that during the toasting process modification in sulphydryl (SH) and disulphide bonds occur and oxidation state generates dityrosyl bonds. This results in aggregation of monomeric and polymeric proteins to larger, insoluble protein aggregates. These results are consistent with the SE-HPLC profiles and the MWD curves, and are in agreement with reports by Ewart (1979), Graveland et al. (1985) and Gobin et al. (1997). Fig. 5b shows the percentage of total UPP in spaghetti samples; and surprisingly shows that the unextractable polymeric proteins in the 5% TDWF- and 10% TDWF-wheat spaghetti were not significantly ($p > 0.05$) different from spaghetti made with 100% durum semolina. On the contrary, the unextractable polymeric proteins in 15% TDWF-, 20% TDWF- and 30% TDWF-wheat spaghetti were significantly ($p < 0.001$) higher than 100%

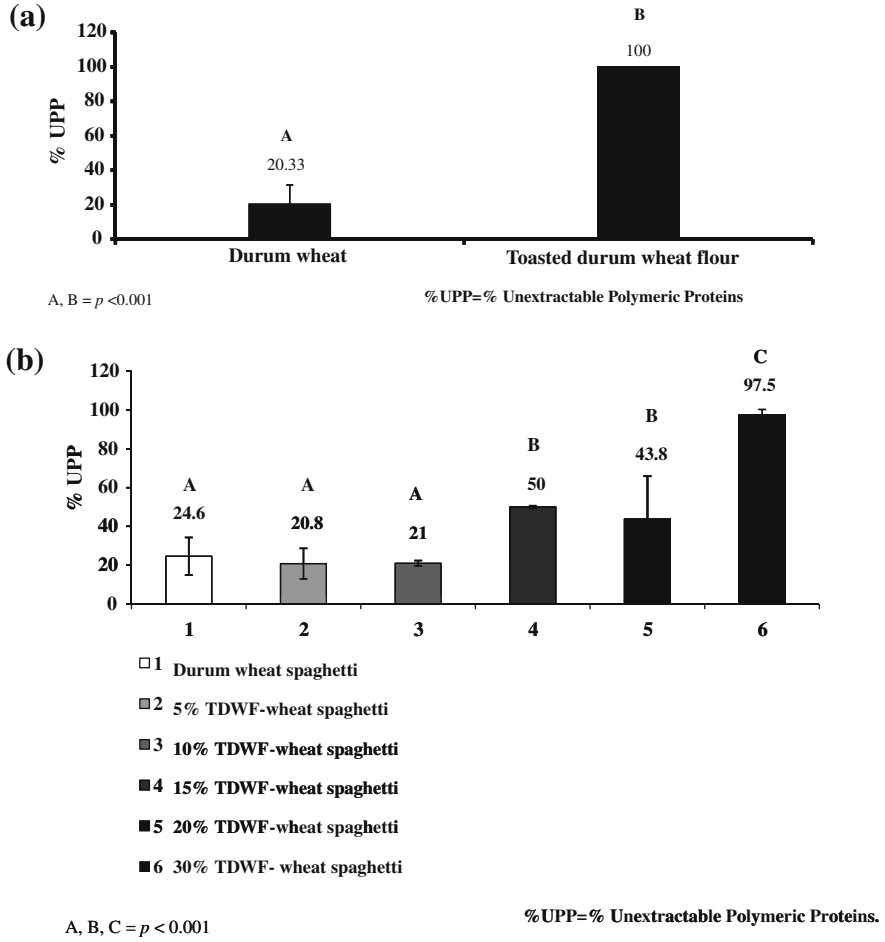

Fig. 5. Percentage of total UPP (unextractable polymeric proteins) of durum wheat semolina and TDWF (a) and in the investigated spaghetti samples (b).

durum semolina spaghetti. There was no significant difference ($p > 0.05$) between the 5% TDWF- and 10% TDWF-wheat spaghetti. Similarly there was no significant difference ($p > 0.05$) between the 15% TDWF- and 20% TDWF-wheat spaghetti. The fact that the UPP level is influenced by the different conformational structures derived from aggregate and polymer formation, may suggest that the large protein aggregates (formed by heat denaturation during the toasting of durum wheat kernels) further interacted with gluten proteins during the preparation of pasta. So, all aggregates derived from denatured proteins, since their hydrophobicity increased, interacted among them and this phenomenon is supported by covalent bonds induced by high temperature. Consequently, the formation of very large, insoluble and stable protein aggregates occurred.

4. Conclusions

The high temperature applied to durum wheat kernels induced significant changes in proteins. size exclusion-high performance liquid chromatography profile indicates that proteins were denatured and polymerised and that albumins and globulins tended to coagulate and interact with gliadins, to form protein aggregates of intermediate molecular weight revealed as a new Intermediate Protein (IP) peak, which corresponds to an Intermediate Aggregate Protein designated as IAP. The participation of the < omega > gliadins to the changes suggests that interactions other than disulphide bonds were involved. The physical modification process, to which the durum wheat kernels were subjected, altered also the size distribution of proteins that increased in size and insolubility. The replacement of durum wheat semolina with increasing percentage of Toasted durum wheat flour affects significantly the molecular weight distribution of derived pasta and induced variations in sodium-dodecyl sulphate-unextractable components, which become the major part of the proteins (97%) in the 30% of toasted durum wheat flour-wheat pasta.

Since an high content of sodium-dodecyl sulphate-unextractable polymeric proteins is known to be correlated with the good quality of the final wheat product, the best mixture to make pasta from ''Grano arso", on the basis of our results, was that containing higher percentage of toasted durum wheat flour.

Carotenoids
Phenols
Antioxidant activity
Antiproliferative activity

ABSTRACT

Fifty-nine secondary metabolites have been isolated from *Cydonia vulgaris* peels and characterised on the basis of their spectroscopic features. Among them, five metabolites, 3β-(18-hydroxylinoleoyl)-28-hydroxyurs-12-ene (**12**), 3β-linoleoylurs-12-en-28-oic acid (**15**), 3β-oleoyl-24-hydroxy-24-ethylcholesta-5,28(29)-diene (**24**), tiglic acid 1-*O*-β-D-glucopyranoside (**35**), and 6,9-dihydroxymegastigmasta-5,7-dien-3-one 9-*O*-β-D-gentiobioside (**46**), have been isolated and elucidated for the first time. All of the compounds were tested for their radical-scavenging and antioxidant activities by measuring their capacity to scavenge the 2,2′-diphenyl-1-picrylhydrazyl (DPPH) radical, and anion superoxide radical and to induce the reduction of Mo(VI) to Mo(V). The antiproliferative activity of all the most abundant compounds by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) bioassay on murine B16-F1 melanoma cells has been also assessed.

1. Introduction

Plant-based foods provide, not only essential nutrients needed for life, but also other bioactive compounds for health promotion and disease prevention. In fact, fruit and vegetables contain significant amounts of phytochemicals that may afford desirable health benefits beyond basic nutrition and reduce the risk of chronic diseases (Liu, 2003). Numerous researches suggest that a wide variety of phytochemicals, such as phenolics and carotenoids, is able to prevent or slow down oxidative stress-induced damage leading to cancer. Kinghorn et al. (2004) reviewed the potential cancer chemopreventive effects of over 150 compounds in terms of the quinone reductase induction ability of flavonoids and withanolides and the cyclooxygenase-1 and -2 inhibitory activities of flavanones, flavones and stilbenoids. Epidemiological studies have shown that consumption of vegetables, mainly onion and garlic, reduces the risk of the intestinal stomach cancer (Gonzalez & Riboli, 2006).

In the investigation of health-protective compounds from edible plants, characteristic of the Campania Region (Italy), we identified several phytochemicals from local apple cultivars (Cefarelli et al., 2006; D'Abrosca, Fiorentino, Oriano, Monaco, & Pacifico, 2006; D'Abrosca, Pacifico, Cefarelli, Mastellone, & Fiorentino, 2007). Continuing this research we, recently, reported the isolation and antioxidant evaluation of carotenoid and phenol derivatives from *Cydonia vulgaris* fruits, also known as Quince (Fiorentino et al., 2006, 2007, 2008). *C. vulgaris* Pers. (sin. *C. oblonga* Mill.) is a small shrub belonging to the same family as apples and pears (Rosaceae). This species is the sole member of the genus. It is a small tree with bright golden yellow pome fruits, when mature. The fruit of *C. vulgaris*, known as Quince, resembles an apple, but differs in having many seeds in each carpel. Pomes of Quince, known in Italy as 'cotogna' apple, have hard flesh of high flavour, but very acid, and these are largely used for marmalade, liqueur, jelly and preserves. It has been reported that the leaves and fruits of Quince have some positive effects in the medical treatment of various conditions, including cardiovascular diseases, haemorroids, bronchial asthma, and cough (Yildirim, Oktay, & Bilaloğlu, 2001).

The present research reports the complete characterisation of the organic extracts of *C. vulgaris* peels. Among them, five metabolites, namely 3β-(18-hydroxylinoleoyl)-28-hydroxyurs-12-ene (**12**), 3β-linoleoylurs-12-en-28-oic acid (**15**), 3β-oleoyl-24-hydroxy-24-ethylcholesta-5,28(29)-diene (**24**), tiglic acid 1-*O*-β-D-glucopyranoside (**35**), and 6,9-dihydroxymegastigmasta-5,7-dien-3-one 9-*O*-β-D-gentiobioside (**46**), have been isolated and elucidated for the first time. All of the compounds were tested for their radical-scavenging and antioxidant activities by measuring their capacity to scavenge the 2,2′-diphenyl-1-picrylhydrazyl (DPPH)

radical, and anion superoxide radical and to induce the reduction of Mo(VI) to Mo(V). The antiproliferative activities of terpenoid and isoprenoid constituents, as well as the most abundant polyphenol components, by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide bioassay on murine B16-F1 melanoma cells have also been assessed.

2. Materials and methods

2.1. Fruit collection and extraction

C. vulgaris Pers. (syn. *Cydonia oblonga* Mill.) fruits were collected in Durazzano, near Caserta (Italy), in October, 2005, when the fruit had just been harvested. The fruits were sliced and the peels (3.1 kg) were infused in ethanol (5.0 l) for seven days in a refrigerated chamber at 4 °C in the dark. After removal of the ethanol, the peels were re-extracted first with Et_2O for seven days and then with petroleum ether (PE) for a further seven days. After distillation of the solvents in a vacuum, we obtained the EtOH crude extract (261.6 g), Et_2O crude extract (15.0 g) and a PE crude extract (13.0 g).

2.2. General experimental procedures

NMR spectra were recorded at 300 MHz for ^1H and 75 MHz for ^{13}C on a Varian Mercury 300 Fourier transform NMR or 500 MHz for ^1H and 125 MHz for ^{13}C on a Varian Inova Fourier transform NMR spectrometer in $CDCl_3$, DMSO d_6 or CD_3OD, at 25 °C. Proton-detected heteronuclear correlations were measured using HSQC (optimised for $^1J_{HC}$ = 140 Hz) and HMBC (optimised for $^nJ_{HC}$ = 8 Hz). UV spectra were recorded on a UV-1700 Shimadzu spectrophotometer in MeOH solution. Optical rotations were measured on a Perkin–Elmer (Perkin–Elmer Co., Norwalk, CT) 141 in MeOH solution. Electron ionisation mass spectra (EIMS) were obtained with a HP 6890 instrument equipped with a MS 5973 N detector. Electrospray mass spectra were recorded using a Waters ZQ mass spectrometer (Waters Co., Milford Massachusetts, USA) equipped with an electrospray ionisation (ESI) probe operating in positive or negative ion mode. The scan range was *m*/*z* 80–2000. The HPLC apparatus consisted of a pump (Shimadzu LC-10AD), a refractive index detector (Shimadzu RID-10A) and a Shimadzu Chromatopac C-R6A recorder. Preparative HPLC was performed using NH_2 (Luna 10 μm, 250 × 10 mm i.d., Phenomenex, Torrance, CA, USA) and SiO_2 (Kromasil 10 μm, 250 × 10 mm i.d., Phenomenex, Torrance, CA, USA) columns. Analytical HPLC was performed using RP-8 (Luna 5 μm, 250 × 4.6 mm i.d., Phenomenex, Torrance, CA, USA) or Polar-RP-80A (Synergi 4 μm, 250 × 4.6 mm i.d., Phenomenex, Torrance, CA, USA) columns. Analytical TLC was performed on Merck Kieselgel 60 F254 or RP-18 F254 plates with 0.2 mm layer thickness. Spots were visualised by UV light or by spraying with H_2SO_4/AcOH/H_2O (1:20:4). The plates were then heated for 5 min at 110 °C. Preparative TLC was performed on Merck Kieselgel 60 F254 plates, with 0.5 or 1.0 mm film thickness. Flash column chromatography (fcc) was performed on Merck Kieselgel 60 (230–400 mesh) at medium pressure. Column chromatography (CC) was performed on Merck Kieselgel 60 (70–240 mesh), Amberlite XAD-4 (Fluka, Buchs, Switzerland), Sephadex LH-20 (Pharmacia, Piscataway, U.S.A.), or on NH_2 silica (LiChroprep NH_2, 40–63 μm, Merck, Darmstadt, Germany).

2.3. Organic crude extracts fractionation and chemical characterisation

The EtOH extract (261.6 g) was dissolved in water and shaken with EtOAc to obtain an organic (8 g) and an aqueous fractions. The aqueous fraction (190.0 g) was chromatographed on Amberlite XAD-4, eluting with water first and then with MeOH. The methanolic fraction was chromatographed on Sephadex LH-20, eluting with water/methanol solutions to obtain fractions A–D. Fraction A, eluted with H_2O, was chromatographed on RP-8 CC, eluting with MeOH/MeCN/H_2O solutions to obtain six fractions. The first, purified by RP-8 HPLC, eluting with MeOH/MeCN/H_2O (1:1:8), furnished pure **25** (10.0 mg). The second fraction was purified by preparative TLC, eluting with the organic lower phase of $CHCl_3$/MeOH/H_2O (13:7:3) biphasic solution to give pure compound **37** (19.6 mg). The third fraction was purified by RP-8 HPLC using MeOH/MeCN/0.1% TFA (1:2:8) solution as mobile phase, to obtain metabolite **43** (3.0 mg); the fourth fraction was resolved by TLC, eluting with the organic lower phase of $CHCl_3$/MeOH/H_2O (13:7:2) biphasic solution to obtain pure **35** (3.0 mg), **36** (1.0 mg), **41** (3.5 mg) and **46** (2.0 mg). The fifth fraction was chromatographed by NH_2 HPLC, using (as mobile phase) a MeCN/H_2O solution (9:1), to obtain compounds **42** (2.3 mg), **44** (7.3 mg), and **45** (6.0 mg). Finally, the sixth fraction contained pure metabolite **40** (9.4 mg).

Fraction B, eluted with MeOH/H_2O (1:4), was chromatographed by RP-8 CC, eluting with MeOH/MeCN/H_2O solutions. The fraction eluted with MeOH/MeCN/H_2O (1:1:8) gave two fractions, identified respectively as the carotenoid glycoside **38** (15.3 mg) and its isomer **39** (8.0 mg). The fraction eluted with MeOH/MeCN/H_2O (5:1:1) afforded pure **47** (12.0 mg). The fraction eluted with MeOH/MeCN/H_2O (7:1:1) furnished pure **27** (12.0 mg) and a mixture which was resolved by TLC chromatography, eluting with the organic phase of $CHCl_3$/MeOH/EtOH/H_2O (10:7:5:5) to obtain the glucoside **26** (7.0 mg), and 4-hydroxybenzylamine **34** (5.0 mg). Fraction C, eluted with MeOH/H_2O (1:1), was purified by RP-8 HPLC-UV, using (as mobile phase) a MeOH/H_2O solution (1:149), to obtain metabolite **28** (11.0 mg). Fraction D, eluted with pure MeOH, was chromatographed by RP-8 HPLC-UV, eluting with MeOH/MeCN/H_2O (1:2:14), to obtain pure rutin **33** (23.1 mg).

The EtOAc organic fraction (7.4 g) of the ethanol extract was pooled with the Et_2O crude extract (15.0 g) and chromatographed by SiO_2 fcc to obtain two fractions E–F. Fraction E, eluted with CH_2Cl_2 and re-chromatographed by SiO_2 fcc, eluting with $CHCl_3$/MeOH (19:1), furnished three fractions: the first one was purified by SiO_2 CC, eluting with hexane/methylethylketone [MEK] (4:1), to give the pure ursane triterpenes **14** (312.1 mg), and **18** (66.1 mg); the second mixture was resolved by SiO_2 HPLC [hexane/MEK (41:9)] to obtain pure compounds **16** (43.2 mg), and **17** (4.5 mg), while the third fraction was purified by preparative TLC, eluting with hexane/MEK (3:2) to obtain the oleanane triterpene **9** (31.5 mg). Fraction F, eluted with CH_2Cl_2/MeOH (1:1), was re-chromatographed by SiO_2 fcc, eluting with the organic lower phase of $CHCl_3$/MeOH/H_2O (13:7:5) to give a fraction which, purified by RP-8 HPLC-UV [MeOH/H_2O (1:149)], yielding to chlorogenic acids **28** (62.0 mg), **29** (6.0 mg), **30** (35.2 mg), and **31** (10.1 mg).

The PE crude extract (13.0 g) was chromatographed on SiO_2 by aspiration under vacuum to obtain three fractions G–I.

Fraction G, eluted with pure CH_2Cl_2, was chromatographed on NH_2 silica, yielding three fractions. The first one, eluted with EtOAc/PE (1:19), furnished pure **4** (2.8 mg), **5** (31.0 mg) and **12** (30.7 mg) and a mixture which was chromatographed by RP-8 HPLC [MeOH/MeCN (4:1)], to give pure metabolite **24** (3.6 mg). The fraction eluted with EtOAc/PE (1:9), was purified by NH_2 CC, to give pure compound **15** (53.0 mg). The third fraction, eluted with EtOAc/PE (1:4), furnished a mixture which was chromatographed on SiO_2 by preparative TLC, eluting with PE/$CHCl_3$/EtOAc (6:3:1) to give two spots. The first contained the acyl benzoic acids **6a–c** (3.0 mg), which were separated by RP-18 HPLC, eluting with MeOH/MeCN (4:1), while the second consisted in the acyl benzaldehydes **7a–c** (4.0 mg).

Fraction H, eluted with CH_2Cl_2/acetone [Me_2CO] (1:1), chromatographed by SiO_2 fcc, eluting with hexane/$CHCl_3$/Me_2CO (13:6:1), furnished four fractions. The first one was purified by RP-18 HPLC, eluting with MeOH/MeCN (4:1) to give pure **1c** (2.5 mg), **1d** (2.1 mg), **1e** (2.2 mg), **1f** (1.8 mg), **2b** (2.9 mg) and **2c** (3.1 mg); the second fraction, purified under the same conditions, gave **1a** (2.6 mg), **1b** (2.3 mg), **2a** (3.2 mg), **3a** (1.0 mg) and **3b** (1.1 mg). The third fraction was purified by RP-8 CC to give pure **13** (30.1 mg), and mixtures A and B: mixture A was chromatographed by RP-8 CC [MeOH/MeCN (4:1)], to give pure metabolite **21** (61.7 mg); mixture B was purified by SiO_2 fcc [hexane/EtOAc (19:3)] to yield compound **20** (92.0 mg). The fourth fraction, chromatographed by RP-8 CC, furnished two fractions; the first was purified by RP-8 CC [MeOH/MeCN/H_2O (6:3:1)] to obtain pure **8** (119.8 mg), **11** (9.0 mg) and **32** (191.0 mg), while the second fraction was chromatographed by RP-8 HPLC, eluting with MeOH/MeCN/H_2O (7:2:1), to furnish metabolite **19** (4.9 mg).

Fraction I, eluted with CH_2Cl_2/MeOH (1:1), and chromatographed by SiO_2 fcc, furnished two fractions. The first, eluted with CH_2Cl_2/MeOH (19:1), was purified by preparative TLC [hexane/$CHCl_3$/MeOH (4:5:1)] to obtain compound **10** (7.8 mg), while the second fraction, eluted with CH_2Cl_2/MeOH (9:1), was chromatographed by preparative TLC [hexane/$CHCl_3$/MeOH (5:13:2)] to furnish metabolites **22** (21.0 mg) and **23** (26.0 mg).

2.4. Chemical characterisation

2.4.1. 3β-18-Hydroxylinoleoyl-uvaol (**12**)

$[\alpha]_D$ +23.9 (c = 0.82, $CHCl_3$); EIMS m/z 720 $[M]^+$; Anal. Calcd for $C_{48}H_{80}O_4$: C, 79.94; H, 11.18. Found: C, 80.01; H, 11.25. ^{1}H NMR (300 MHz, $CDCl_3$): see Table 1. ^{13}C NMR (75 MHz, $CDCl_3$): see Table 2.

2.4.2. 3β-Linoleoyl-ursolic acid (**15**)

$[\alpha]_D$ +30.6 (c = 0.15, $CHCl_3$); EIMS m/z 718 $[M]^+$; Anal. Calcd for $C_{48}H_{78}O_4$: C, 80.17; H, 10.93. Found: C, 80.22; H, 11.05; ^{1}H NMR (300 MHz, $CDCl_3$): see Table 1. ^{13}C NMR (75 MHz, $CDCl_3$): see Table 2.

Table 1
Selected ^{1}H NMR data of the new compounds **12**, **15** and **24** in $CDCl_3$ d = doublet, dd = doublet of doublet, m = multiplet, ov = overlapped, s = singlet, ob = obscured,; the J values are reported in the brackets.

Position	12	15	24

2.4.3. 3β-Oleoyl-24-hydroxy-24-ethylcholesta-5,28(29)-diene (**24**)

$[\alpha]_D$ −25.9 (c = 0.19, $CHCl_3$); EIMS m/z 692 $[M]^+$; Anal. Calcd for $C_{47}H_{80}O_3$: C, 81.44; H, 11.63. Found: C, 81.52; H, 11.57. ^{1}H NMR (300 MHz, $CDCl_3$): see Table 1. ^{13}C NMR (75 MHz, $CDCl_3$): see Table 2.

2.4.4. Tiglic acid 1-O-β-D-glucopyranoside (**35**)

$[\alpha]_D$ +15.9 (c = 0.62, MeOH); ESIMS m/z 285 $[M+Na]^+$, 123 $[M-C_6H_5O_{10}+Na]^+$; Anal. Calcd for $C_{11}H_{18}O_7$: C, 50.38; H, 6.92. Found: C, 50.51; H, 6.77. ^{1}H NMR (300 MHz, CD_3OD): δ 7.00 (1H, dq, J = 6.9 and 1.5 Hz, H-3), 5.52 (1H, d, J = 7.2 Hz, H-1′), 3.83 (1H, dd, J = 12.0 and 1.8 Hz, H-6′a), 3.66 (1H, dd, J = 12.0 and 4.5 Hz, H-6′b), 3.50–3.33 (4H, ov, H-2′–H-5′), 1.84 (3H, d, J = 1.5 Hz, H-5), 1.82 (3H, d, J = 6.9 Hz, H-4). ^{13}C NMR (75 MHz, CD_3OD): δ 168.0 (C-1), 140.4 (C-3), 129.1 (C-2), 95.9 (C-1′), 78.8 (C-3′), 78.1 (C-5′), 74.0 (C-2′), 71.1 (C-4′), 62.3 (C-6′), 14.5 (C-4), 12.0 (C-5).

2.4.5. 6,9-Dihydroxymegastigmasta-5,7-dien-3-one 9-O-β-D-gentiobioside (**46**)

UV (EtOH) λ_{max} (log ε) 286.0 (2.66), $[\alpha]_D$ +10.5 (c = 0.15, MeOH); ESIMS: m/z 571 $[M+Na]^+$, 409 $[M-C_6H_5O_{10}+Na]^+$, 247 $[M-C_6H_5O_{10}-C_6H_5O_{10}+Na]^+$; Anal. Calcd for $C_{25}H_{40}O_{13}$: C, 54.74; H, 7.35. Found: C, 54.61; H, 7.47. ^{1}H NMR (300 MHz, CD_3OD): δ 5.84 (3H, ov, H-4, H-7, H-8), 4.24 (1H, d, J = 7.8. Hz, H-1′), 4.20 (1H, d, J = 7.6 Hz, H-1″), 4.13 dd (1H, dd, J = 11.9 and 2.1 Hz, H-6′), 3.81 (1H, dd, J = 11.9 and 5.3 Hz, H-6′), 2.52 (1H, d, J = 16.8 Hz, H-2), 2.17 (1H, d, J = 16.8 Hz, H-2), 1.92 (3H, d, J = 1.5 Hz, H-13), 1.30 and 1.29 (6H, s, H-11 and H-12), 1.03 (3H, d, J = 6.3 Hz, H-10). ^{13}C NMR (75 MHz, CD_3OD): δ 199.2 (C-3), 166.2 (C-5), 136.0 (C-8), 130.0 (C-4), 125.0 (C-7), 104.8 (C-1″), 102.2 (C-1′), 79.1 (C-9), 79.0 (C-6), 78.0 (C-3′, C-3″), 77.9 (C-5′, C-5″), 75.1 (C-2′, C-2″), 71.6 (C-4″), 71.4 (C-4′), 69.7 (C-6′), 62.7 (C-6″), 49.5 (C-2), 42.1 (C-1), 23.7 (C-12), 22.6 (C-13), 21.0 (C-10), 19.2 (C-11).

2.5. GC–MS analyses of fatty acid moieties

Pure ester (0.1 mg) was dissolved in 0.2 ml of 2 N KOH in methanol in a 1 ml vial. After stirring the solution for 30 min, heptane (0.8 ml) was added. The solution was mixed by a Vortex mixer and centrifuged, using a Beckman GS-15R centrifuge, for 10 min at 4000 rpm. Organic upper phase (1 μl) was analysed by GC–MS, fitted with 30 m × 0.25 mm i.d., 0.2 μm Zebron ZB5MS, fused silica capillary column (Phenomenex, Torrance, CA, USA). The column oven temperature was held at 80 °C for 1 min, then increased to 260 °C at 10 °C-min. Injector and detector temperatures were 250 and 150 °C, respectively; the carrier gas was He and the flow rate was 1.0 ml/min. The fatty acid methyl esters were identified on the basis of their EIMS spectra and by comparing their retention times with those of the standard fatty acid methyl esters (Supelco 37 Component FAME Mix).

2.6. DPPH radical-scavenging capacity

The DPPH radical-scavenging capacity of metabolites was measured according to the method of Brand-Williams, Cuvelier, and Berset (1995). DPPH· (2 mg) was dissolved in 54 ml of MeOH. The investigated metabolites were prepared by dissolving 0.4 μmol of each compound in 1 ml of MeOH. Then, 38 μl of each solution containing a compound were added to 1.46 ml of DPPH· solution at room temperature. The absorbance at 517 nm was measured in a cuvette at 30 min vs blank (38 μl MeOH in 1.46 ml of DPPH· solution), using a UV-1700 Shimadzu spectrophotometer. The analysis was carried out in triplicate and the results were expressed in terms of the percentage of radical-scavenging capacity (RCS).

Table 2
^{13}C NMR data of the new compounds **12**, **15** and **24** in $CDCl_3$.

2.7. Superoxide radical-scavenging activity

The assay of superoxide radical-scavenging capacity was based on the capacity of each isolated metabolite (0.4 mM) to inhibit the photochemical reduction of nitroblue tetrazolium (NBT) (Fluka, Buchs, Switzerland) in the riboflavin–light–NBT system (Dasgupta & De, 2004). Each 3 ml reaction mixture contained 50 mM sodium phosphate buffer (pH 7.8), 13 mM methionine (Fluka, Buchs, Switzerland), 2 μM riboflavin (Riedel-de Haën, Seelze, Germany), 100 μM EDTA (Carlo Erba Reagents, Rodano, Milano, Italy), 75 μM NBT and 100 μl of sample solution. The production was followed by monitoring the increase in absorbance at 560 nm after 10 min illumination from a fluorescent lamp. The analysis was carried out in triplicate and the results were expressed in terms of the percentage of radical-scavenging capacity (RCS).

2.8. Evaluation of total antioxidant capacity

Spectrophotometric evaluation of antioxidant capacity through the formation of a phosphomolybdenum complex was carried out according to Prieto, Pineda, and Aguilar (1999). Sample solutions (100 μl) containing reducing metabolites (0.4 μmol in 1 ml of dimethylsulphoxide) were combined in an Eppendorf tube with 1 ml of reagent solution (0.6 M sulphuric acid, 28 mM sodium phosphate and 4 mM ammonium molybdate). The tubes were capped and incubated in a thermal block at 95 °C for 90 min. After the samples were cooled to room temperature, the absorbance of aqueous solution of each was measured at 820 nm against a blank. The analysis was carried out in triplicate and the antioxidant activity was expressed as caffeic acid equivalents (CAE).

2.9. Cell line and culture conditions

Murine melanoma B16-F1 cells were purchased from the American Type Culture Collection (ATCC; Manassas, VA, USA). Freshly trypsinised cells were seeded and grown in RPMI-1640 medium supplemented with 10% (v/v) faetal bovine serum (FBS), 1% L-glutamine (v/v), 100 units/ml of penicillin and 100 μg/ml of streptomycin. The cells were grown at 37 °C in a humidified 5% CO_2 atmosphere.

2.10. MTT assay

To evaluate the effect of isolated metabolites on B16-F1 cells, the MTT colorimetric assay was performed as described by Mosmann (1983). The test is based upon the selective ability of living cells to reduce the yellow salt MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide] to a purple-blue colour in soluble formazan precipitate. MTT was dissolved in phosphate buffer saline (PBS) at 5 mg/ml. Experiments were performed in 100 μl of media in sterile 96-well plates. After a 24 h incubation of B16-F1 cells at an initial density of 1×103 cells/well, medium was removed and replaced by 10% FCS medium containing test compounds (0–500 μM). After 24 h of incubation, stock MTT (Sigma–Aldrich) solution was added and plates were incubated at 37 °C in 5% CO_2 for 4 h. Blue crystals of MTT reduced by cells were dissolved with DMSO and cellular metabolism was determined by measuring the absorbance of samples at 570 nm in a microelisa reader.

3. Results and discussion

3.1. Chemical characterisation of phytochemicals

Structures of phytochemicals isolated from *C. vulgaris* extracts are shown in Figs. 1–4. The separation scheme of the secondary metabolites from the organic extracts of *C. vulgaris* is shown in Fig. 5. All of the structures were elucidated on the basis of 1D and 2D NMR experiments and by EI or ESI mass spectrometry. Compounds **1a–f** (Fig. 1) were identified as acyl derivatives of the *trans* isomer of the *p*-coumarylic alcohol. Compounds **2a–c** were identified as acyl derivatives of the *cis* isomer of the *p*-coumarylic alcohol. The structures of the fatty acid esters of *cis*-and *trans*-*p*-coumaryl alcohol were elucidated by GC–MS and ^{1}H and ^{13}C NMR spectroscopy after purification of the individual compounds by HPLC (Fiorentino et al., 2008). Compounds **3a**, **3b** and **4** were fatty acid esters characterised by the presence of a coniferyl alcohol moiety. In particular, metabolites **3a** and **b** were identified as acyl derivatives of the *E* isomer of the coniferyl alcohol, and compound **4** as the acyl derivative of its *Z* isomer. Compound **5**, identified for the first time in *C. vulgaris*, was characterised as *E*-

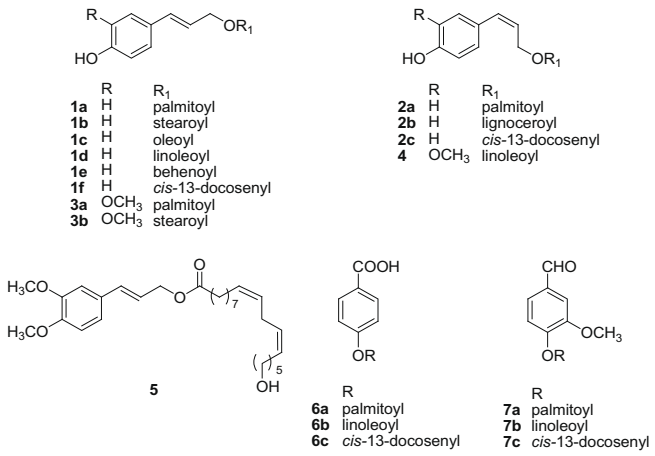

Fig. 1. Chemical structures of metabolites **1**–**7** from *C. vulgaris* peels.

3,4-dimethoxycinnamyl ω-hydroxylinoleate. Compounds **6a**–**c** were identified as 4-hydroxybenzoic acids, esterified through the 4-hydroxyl group to palmitic, linoleic and *cis*-13-docosenoic acids, respectively. Compounds **7a**–**c** were identified as 3-methoxy-4-hydroxy aldehydes, esterified by the hydroxyl group with the same fatty acid moiety as the previous compounds.

Compounds **8**–**10** (Fig. 2) were characterised as oleanane triterpenes: compound **8** was identified as oleananic acid (Kamiya, Yoshioka, Saiki, Ikuta, & Satake, 1997), while compounds **9** and **10** were identified as hederagenic acid (Bhandari & Rastogi, 1984) and its 2α-hydroxy derivative (Kojima & Ogura, 1988). The triterpenes **11**–**19** (Fig. 2) were characterised by the ursane skeleton. Compound **11** was identified as uvaol (Hota & Bapuji, 1994), and the new compound, **12**, as its acyl derivative. Its molecular formula was $C_{48}H_{80}O_4$, as suggested by the elemental analysis and the EIMS spectrum. The methyl signals in the ^{1}H and ^{13}C NMR spectra (Tables 1 and 2) were in good accordance with those of compound **11**, but some differences were evident. Besides, the H-12 proton at δ 5.12, in the ^{1}H NMR spectrum, further overlapped four olefinic protons, as a multiplet at δ 5.34, was present. In the same experiment, a methine at δ 4.49, and two methylenes as a triplet at δ 3.63 and as two doublets at δ 3.52 and 3.17 were also evident. In the upfield of the spectrum, seven methyls were detectable as five singlets at δ 1.09, 0.98, 0.96, 0.86 and two doublets at δ 0.90 and 0.83, besides signals due to doubly allylic protons at δ 2.76, a methylene at δ 2.29, methylene signals of the acyl chain in the range between 2.1 and 1.1 ppm, and a methylene triplet at δ 3.63. The downshifted H-3 proton at δ 4.49 indicated the linkage with an acyl group. The ^{13}C NMR and DEPT spectra were in good agreement with the presence of 48 carbons identified as 7 methyls, 23 methylenes, 11 methines and 7 tetrasubstituted carbons. These data led us to hypothesise the presence of the uvaol esterified with an unsaturated fatty acid. However, the absence of a methyl carbon, besides those of the triterpene, and the presence of the methylene at δ 63.3, suggested the presence of an ω-hydroxy fatty acid. The correlations in the HMBC experiment between the carbon at δ 173.9 (C-1′) with the protons at δ 4.49 (H-3), 2.29 (H-2′), and 1.62 (H-3′) confirmed this hypothesis. The acyl moiety was elucidated by GC–MS analysis of the methyl ester derivative of the fatty acid, obtained by reaction with KOH in MeOH, which showed a molecular peak at *m*/*z* 310. These data and the pattern of fragmentation, indicated the presence of the methyl ester of the ω-hydroxylinoleic acid, which was definitively confirmed by the 2D NMR data. Compounds **13** and **14** were identified as ursanaldehyde (Hota & Bapuji, 1994) and ursolic acid (Seo, Tomita, & Tori, 1975), respectively. The new compound **15** was identified as the 3-linoleoyl derivative of **14**. Its 1D NMR spectra (Tables 1 and 2) showed signals of the ursolic acid and signals attributable to a polyunsaturated fatty acid moiety. The downfield shift of the H-3 proton at δ 4.49 suggested the acylation point at the 3β-hydroxyl group of the triterpene. The acyl chain was confirmed by GC–MS analysis of the methyl derivatives obtained after methanolysis. Compounds **16**–**18** were characterised as 2α-hydroxy ursolic acid (Yamagishi et al., 1988), pomolic acid (Dong-Liang & Xiao-Ping, 1992) and

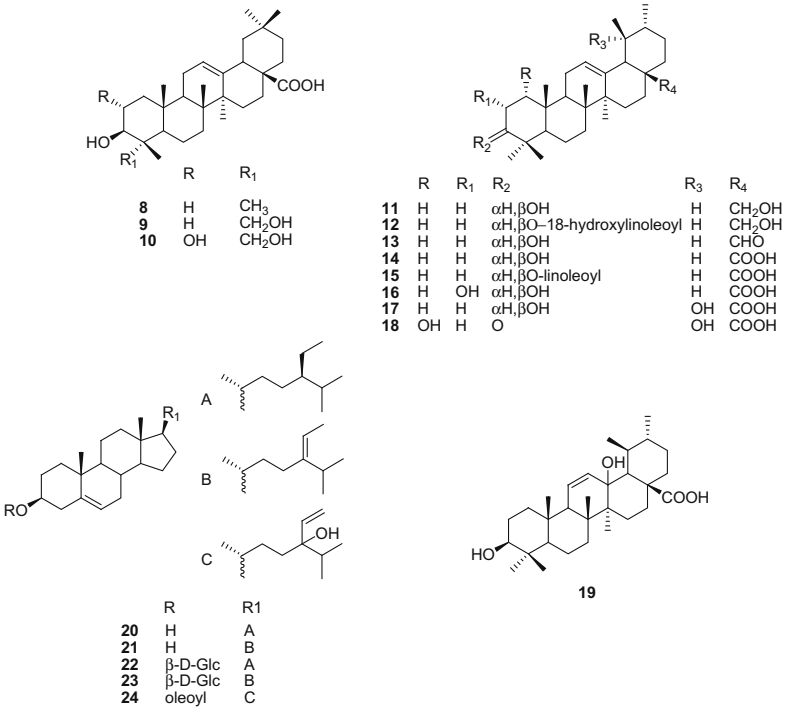

Fig. 2. Chemical structures of metabolites **8**–**24** from *C. vulgaris* peels.

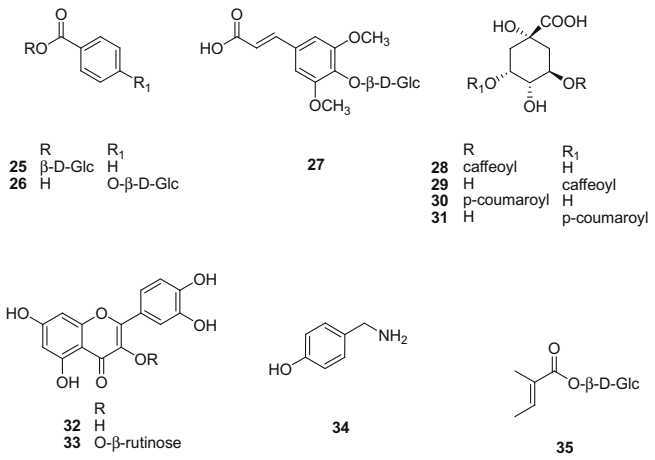

Fig. 3. Chemical structures of metabolites **25**–**35** from *C. vulgaris* peels.

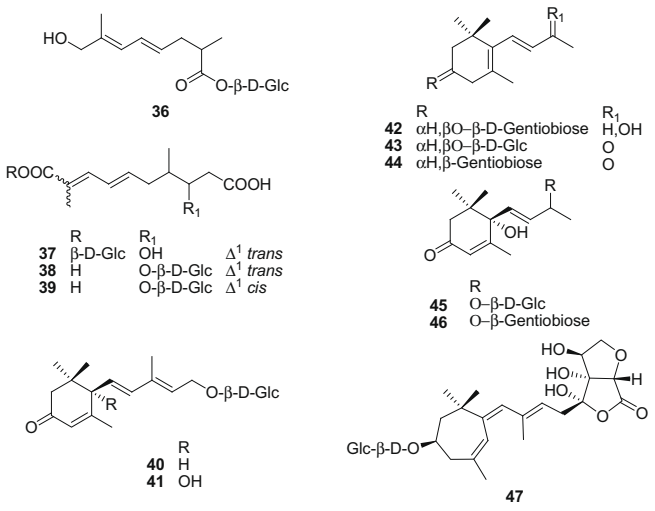

Fig. 4. Chemical structures of metabolites **36**–**47** from *C. vulgaris* peels.

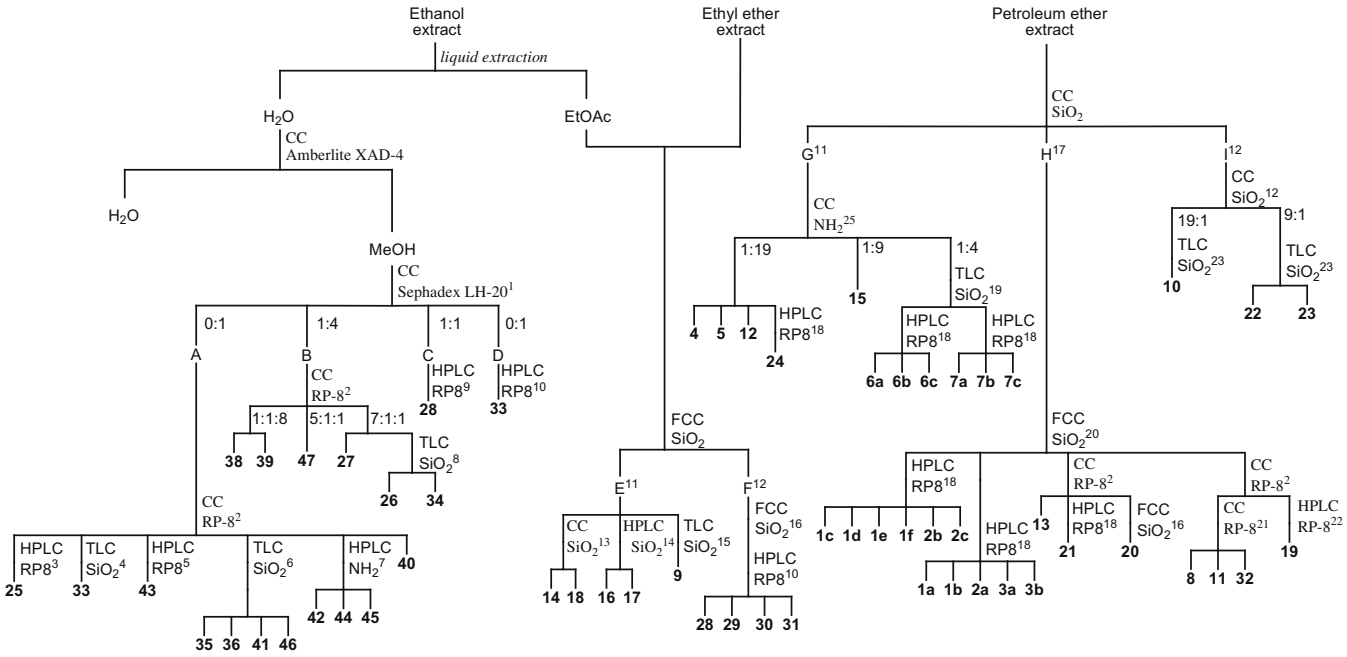
annurcoic acid, respectively (D'Abrosca et al., 2006). Until now, this latter compound has been reported solely as a constituent of Annurca apple fruits. Finally, compound **19** was identified as 3β-13β-dihydroxyurs-11-en-28-oic acid (Huang, Sun, & Zhao, 1996).

All the steroids of *C. vulgaris* had a stigmastane skeleton (Fig. 2). Compounds **20** and **21** were identified as β-sitosterol (Wright et al., 1978) and fucosterol (Atta-ur-Rahman et al., 1999), while the glycosides **22** and **23** were characterised as 3-*O*-β-D-glucopyranoside derivatives (De Rosa, De Giulio, & Tommonaro, 1997; Tsai, Hsieh, Duh, & Chen, 1999). Compound **24** was characterised for the first time. It showed the molecular formula $C_{47}H_{80}O_3$ according to the elemental analysis and the EIMS spectrum showing the molecular peak at *m*/*z* 692. In the upfield region of the ^{1}H NMR spectrum (Table 1) methyl signals of a steroid were evident as two singlets at δ 0.68 and 1.01, and three methyl signals at δ 0.95, 0.87 and 0.85. In the downfield part of the spectrum, there were a multiplet at δ 4.59, and six olefin protons, three of which were present as an ABM spin system as three double doublets at δ 5.74, 5.27 and 5.15, suggesting the presence of a vinyl group, while the remaining protons were overlapped at δ 5.36. In the ^{13}C NMR (Table 2), there were a carboxyl carbon at δ 173.6, six olefinic carbons, confirming the presence of three double bonds, and two carbinol carbons at δ 73.9 and 89.3, besides other carbons ranging from 56.9 to 14.4 ppm. The DEPT experiment allowed us to identify all the carbons as 6 methyls, 25 methylenes, 11 methines and 5 quaternary carbons. The 2D NMR data allowed the complete assignment of all the protons and carbons in the molecule. In particular the tetrasubstituted carbinol at δ 89.3 correlated, in the HMBC experiment, with the vinyl protons, and with both the H-26 and H-27 methyls. These data suggested the presence of a hydroxyl group at the C-24 carbon and the double bond among the C-28 and C-29 carbons. ^{1}H and ^{13}C NMR values, relative to the steroidal skeleton, were in good accordance with the presence of a double bond at the C-5 carbon and an acyl group at the 3-hydroxyl, that was identified as oleic acid after reaction with KOH in MeOH and GC–MS analysis. The 2D NMR experiments confirmed our hypothesis.

Phenols **25**–**26** (Fig. 3) were identified as glucosides of benzoic acid, already identified from *Pinus contorta* needles (Higuchi & Donnelly, 1977) and from *Picea glauca* (Kraus & Spiteller, 1997); compound **27** was identified as synapyl acid 4-*O*-β-D-glucopyranoside (Beejmohun, Grand, Mesnard, Fliniaux, & Kovensky, 2004). Compounds **28**–**31** were characterised as chlorogenic acids, already reported as components of Hemerocallis (Clifford, Wu, & Kuhnert, 2006), while the flavones **32** and **33** were identified as quercetin and rutin, respectively (D'Abrosca et al., 2001). Compound **34** was identified as 4-hydroxybenzylamine (Lu, Rodriguez, Gu, & Silverman, 2003). Compound **35** was identified as the glucosyl derivative of tiglic acid. It showed a molecular formula $C_{11}H_{18}O_7$, as suggested by the ^{13}C NMR and ESIMS experiments. The ^{1}H NMR spectrum showed an olefinic quartet at δ 7.00, and two methyls as a singlet at δ 1.84 and a doublet at δ 1.82, a doublet of a sugar unity at δ 5.52, and a diastereotopic methylene as two double doublets at δ 3.83 and 3.66, besides four other protons geminal to oxygen in the range 3.50–3.33 ppm. The ^{13}C NMR spectrum revealed the presence of glucose, showing six carbinols at δ 95.9 (C-1′), 78.8, 78.1, 74.0, 71.1 and 62.3. The coupling constant of the anomeric proton was in good agreement with a β configuration for the C-1′ carbon. Furthermore, in the ^{13}C NMR spectrum, there were an ester carboxyl carbon at δ 168.0, two olefin signals as a methine at δ 140.4 and a tetrasubstituted carbon at δ 129.1 and two methyls at δ 14.5 and 12.0. The ^{13}C chemical shift values indicated the presence of a tiglic acid moiety in the molecule. Finally, the correlation between the carboxyl carbon and the anomeric proton confirmed the linkage of the glucose to the C-1 carbon of the aglycone trough an ester bond. Compounds **36**–**46** (Fig. 4) have been identified as carotenoid derivatives. Compound **36** was identified as (4*E*,6*E*)-8-hydroxy-2,7-dimethylocta-4,6-dienoic acid 1-*O*-β-D-glucopyranoside. This compound is reported as a precursor of isomeric marmelo lactones from Quince fruit (Winterhalter, Lutz, & Schreier, 1991). Carotenoids **37**–**40** (Fiorentino et al., 2006), **41** (Luts & Winterhalter, 1993), **42** (Winterhalter, Harmsen, & Trani, 1991) and **44** (Guldner & Winterhalter, 1991) were already reported as constituents of *C. vulgaris*, while compound **45** has been reported as a leaf constituent of *Alangium premnifolium* (Otsuka, Yao, Kamada, & Takeda, 1995). The new C_{13} norterpene glycoside, 46, had a molecular formula $C_{25}H_{40}O_{13}$ in accordance with ESIMS and ^{13}C NMR spectra. In the ^{1}H NMR, there were three overlapped protons at δ 5.84, two doublets at δ 4.20 and 4.24, two diastereotopic methylene protons at δ 2.52 and 2.17, three singlet methyls at δ 1.92, 1.29 and 1.30, and a doublet methyl at δ 1.03, besides other protons ranging from 4.18 to 3.10 ppm. In the ^{13}C NMR spectrum, 25 signals were evident, identified by a DEPT experiment, as four methyls, three methylenes, fourteen methines, and four tetrasubstituted carbons. The values of the carbinolic carbon were in good accordance with the presence of a gentiobiose moiety in the molecule. The remaining two carbinols were attributed to the C-6 and C-9 carbons on the basis of heterocorrelations shown in the HMBC experiment. In fact, the methyl at δ 1.92 correlated with the olefin carbons at δ 130.0 and 166.2, and with the tertiary carbinol at δ 79.0. The methyl doublet correlated with the carbons



[1]MeOH-H_2O; [2]MeOH/MeCN/H_2O; [3]MeOH/MeCN/H_2O (1:1:8); [4]$CHCl_3$/MeOH/H_2O (13:7:3); [5]MeOH/MeCN/0.1% TFA (1:2:8); [6]$CHCl_3$/MeOH/H_2O (13:7:2); [7]MeCN/H_2O (9:1); [8]$CHCl_3$/MeOH/EtOH/H_2O (10:7:5:5); [9]MeOH/H_2O (1:149); [10]MeOH/MeCN/H_2O (1:2:14); [11]CH_2Cl_2; [12]CH_2Cl_2/MeOH (1:1); [13]hexane/MEK (4:1); [14]hexane/MEK (41:9); [15]hexane/MEK (41:9); [16]$CHCl_3$/MeOH/H_2O (13:7:3); [17]CH_2Cl_2/Me_2CO (1:1); [18]MeOH/MeCN (4:1); [19]PE/CH_2Cl_2/etOAc (6:3:1); [20]hexane/$CHCl_3$/Me_2CO (13:6:1); [21]MeOH/MeCN/H_2O (6:3:1); [22]MeOH/MeCN/H_2O (7:2:1); [23]hexane/$CHCl_3$/Me_2CO (4:5:1); [24]hexane/$CHCl_3$/Me_2CO (5:13:2); [25]EtOAc/PE;

Fig. 5. Isolation scheme of the secondary metabolites from *C. vulgaris* extracts.

at δ 136.0 and 79.1. This latter showed a cross peak with the anomeric proton of the gentiobiose at δ 4.24. Furthermore, the carbonil carbon at δ 199.2, attributed to the C-3 carbon, correlated with the methylenes at δ 2.52 and 2.17 and with the proton at δ 5.84. These data allowed us to assign the structure of 6,9-dihydroxy-megastigmast-4,7-dien-3-one 9-*O*-β-D-gentiobioside. Finally, compound **47** was identified as cydonioside A (Fiorentino et al., 2007).

3.2. Antioxidant and radical-scavenging capacities

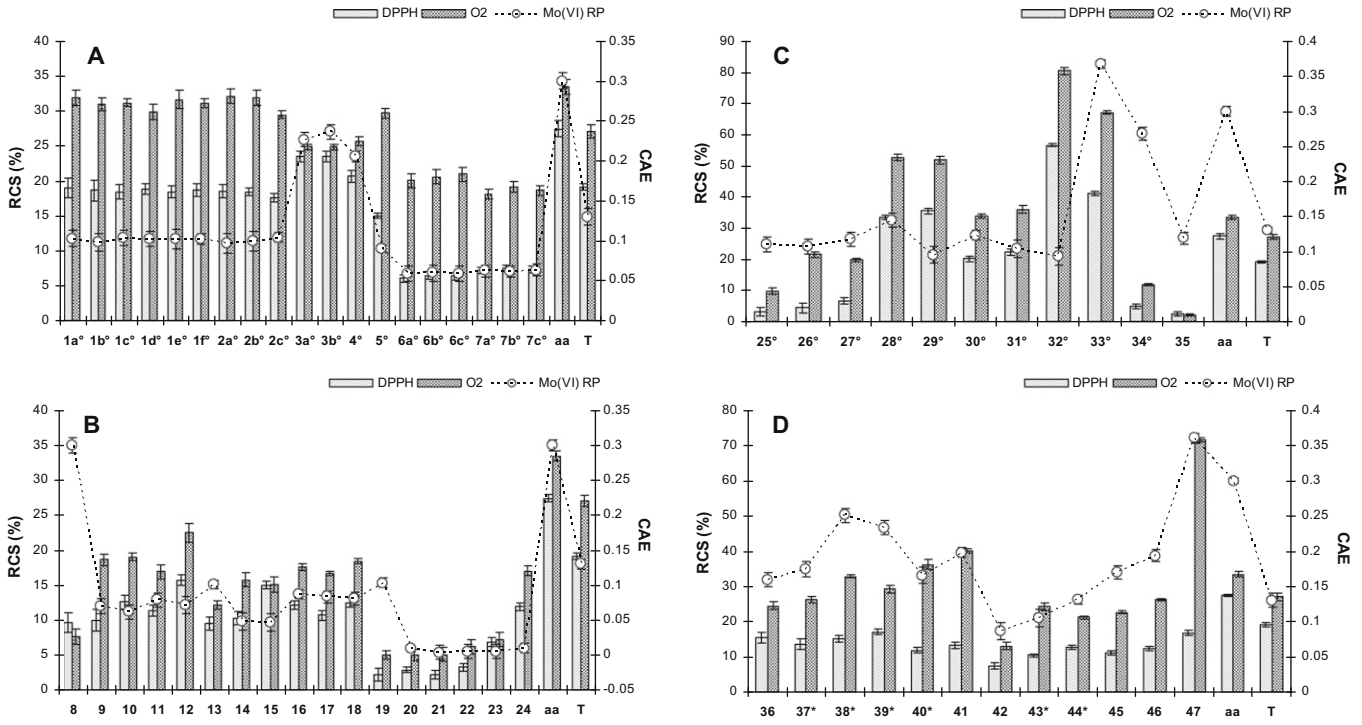
All the isolated metabolites were tested for their antioxidant capacity, using three different methods. Two of these methods estimate the radical-scavenging activities of the investigated substances against the DPPH radical and the anion superoxide radical; the remaining test evaluates the capacity to induce the Mo(VI) reduction. The standards used in all the methods were α-tocopherol and ascorbic acid, known natural antioxidants, and the results are shown in Fig. 6.

When radical-scavenging capacities were tested, the strongest antioxidant capacity was observed for the flavonol quercetin (**32**) and its 3-*O*-rutinoside (**33**). In particular, quercetin reduced the DPPH radical by 56.7% and the anion superoxide radical by 80.4%. The quinic acid derivatives, chlorogenic acid (**28**) and neochlorogenic acid (**29**) determined an average DPPH radical reduction of 35.0% and were able to scavenge O_2^- by 52.8% and 51.8%, respectively. Among triterpenes, compounds **12** and **15** were the most active substances. In particular, uvaol ω-hydroxylinoleate (**12**) was able to reduce the DPPH radical absorbance by 15.7% and the anion superoxide radical by 22.5%. The uvaol acyl derivative showed a higher activity than did uvaol (**11**). Carotenoid derivative metabolites appeared to be strong radical-scavenger substances, exhibiting activities comparable to that of the positive standards. All the other compounds showed weak inhibiting capacities. Spectrophotometric quantisation of the antioxidant capacity of tested metabolites, through the formation of a phosphomolybdenum complex, showed that, in the complex, the substances were feebly able to induce the reduction of Mo(VI) to Mo(V). Quercetin and rutin exhibit a massive reducing capacity, greater than that exercised by α-tocopherol and ascorbic acid. Good antioxidant activity was observed for the phenylpropanoid esters **3a**, **3b** and **4**: they are able to induce the reduction of Mo(VI) to Mo(V), much more so than α-tocopherol.

3.3. Antiproliferative activity

The most abundant compounds present in the Quince peels, were subjected to the MTT bioassay on murine B16-F1 melanoma cells. Besides the isoprenoid and carotenoid metabolites, the main polyphenols isolated from *C. vulgaris* (Fiorentino et al., 2008) have also been tested. Besides the flavonoids quercetin (**32**) and rutin (**33**), four caffeoyl and *p*-coumaroyl derivatives of quinic acid (**28**–**31**), as well as the ester dimethoxycoumaryl alcohol (**5**) and the sinapic acid glucoside (**27**), were subjected to the bioassay. The results of the bioassays are listed in Table 3.

A significant antiproliferative activity was recorded for the triterpenoids. In particular, the most active metabolite was ursolic acid, **14**, with an IC_{50} of 10.2 μM. Compounds **8**, **9**, **11**, **13**, **18**, **19** and **21** showed very good activities toward B16-F1 cells in the range 32.7–80.5 μM. The presence of the acyl chain in the triterpenoid derivatives, **12** and **15**, determined a lower activity than those of the related **11** and **14**, respectively. Furthermore, the highest IC_{50}, recorded for the ursane triterpene, **16**, suggested that the introduction of a 2α-hydroxyl function was able to reduce the ursane skeleton antiproliferative ability. Interestingly, annurcoic acid showed an IC_{50} value of 77.6 μM. This compound has been reported in the cv Annurca apple alone, and the presence in the *C. vulgaris* peels led us to suppose its occurrence also in other apple cultivars (Rosaceae).



°Data according to Fiorentino *et al*., 2006; *Data according to Fiorentino *et al*., 2008.

Fig. 6. Radical-scavenging and antioxidant capacities of phenolic esters **1**–**7** (A), triterpenes **8**–**19** and steroids **20**–**24** (B), polyphenols **25**–**34** (C) and carotenoid derivatives **36**–**47** (D) isolated from *C. vulgaris*. (A) Values are presented as percentage differences from control ±SD. AA = ascorbic acid; T = α-tocopherol. CAE = caffeic acid equivalent.

Among polyphenolic compounds, quercetin (**32**) and rutin (**33**) were found to exhibit strong effects on B16-F1 cells with IC_{50} values of 85.1 and 92.5 μM, respectively.

Antiproliferative activity of the triterpenoids has been extensively reported in the literature. He and Liu (2007) demonstrated the high antiproliferative capacity of 13 triterpenoids isolated from apple peels against human HepG2 liver cancer cells, MCF-7 breast cancer cells, and Caco-2 colon cancer cells. They suggested that these phytochemicals, characterised by ursane or oleane skeletons, may be partially responsible for the anticancer activities of whole apples. Zuco et al. (2002) showed that betulinic acid exerted a selective cytotoxicity on nine neoplastic cell lines, including melanomas, small- and non-small cell lung carcinomas, ovarian and cervical carcinomas in a very narrow range of doses (1.5–4.5 μg/ml).

It has been suggested that phytosterols possess antitumour properties in both animals and humans. Rats (Raicht, Cohen, Fazzini, Sarwal, & Takahashi, 1980) administered methylnitrosourea, a direct acting carcinogen, produced a significantly higher incidence of tumours after 28 weeks compared to rats administered the same compound and fed a diet containing 0.2% β-sitosterol.

Carotenoids have been implicated as important dietary phytonutrients having cancer preventive activity (Van Poppel, 1993). Little is known about carotenoid derivatives' antiproliferative capacity. The metabolite **38**, a C-12 carotenoid saccharide derivative, with a diene α,ω-diacid skeleton, already isolated from the plant Oryctanthus, has been identified as an inhibitor of the vascular endothelial growth factor (VEGF) receptor (Hedge et al., 2005).

There is increasing interest in plant-derived dietary polyphenols, because several representatives of these compounds proved to be proliferation inhibitors and apoptosis inducers in tumour cells. Quercetin, has been shown to exhibit anti-carcinogenic properties by inducing cell cycle arrest and apoptosis, and inhibiting proliferation in diverse cancer cell lines as single compounds (Choi et al., 2001; Richter, Ebermann, & Marian, 1999; Yoshida, Yamamoto, & Nikaido, 1992).

Table 3
Growth inhibition (IC_{50}) of phytochemicals against murine B16-F1 melanoma cells.

Compounds	IC_{50} (μM)	Compounds	IC_{50} (μM)	Compounds	IC_{50} (μM)

C-6 glioma cells
Antioxidant properties

ABSTRACT

An anthocyanin-rich extract, generated from açai (AEA), was investigated for its antioxidant properties and antiproliferative activity against C-6 rat brain glioma cells and MDA-468 human breast cancer cells. AEA has an ORAC value of 2589 μmoles trolox equivalents (TE)/g dried powder and a DPPH radical-scavenging activity of 1208 μmoles TE/g, suggesting that AEA is an exceptional source of natural antioxidants. In addition, AEA remarkably suppresses proliferation of C-6 rat brain glioma cells, but has no effect on the growth of MDA-468 human breast cancer cells. Further experiments demonstrated that the AEA treatment dose-dependently inhibited the growth of C-6 rat glioma cells with an IC_{50} of 121 μg/ml. The DNA ladder fragmentation results indicated that AEA induced apoptosis of C-6 rat brain glioma cells. To compare açai with other anthocyanin-rich extracts, a number of berry extracts, including blueberry, strawberry, raspberry, blackberry and wolfberry, were assessed for potential antiproliferative activity against C-6 rat brain glioma cells. However, none of them showed suppressing effect. The results suggest that the active antiproliferative constituents in AEA are unlikely to be anthocyanins normally found in common berries.

1. Introduction

A growing body of epidemiological and clinical evidence suggests a beneficial role of foods rich in antioxidants in reducing incidences and mortality of certain cancers (Bandera, Kushi, Moore, Gifkins, & McCullough, 2007; Parsons et al., 2008). Fruits, especially berries, have been shown to contain high levels of antioxidant compounds, such as polyphenols, phenolic acids, flavonoids, and carotenoids (Wang & Lin, 2000). These antioxidants are thought to prevent chronic complications in part through their interactions with reactive oxygen species (ROS) and ability to scavenge free radicals (Seifried, Anderson, Fisher, & Milner, 2007). Mammalian cells are constantly exposed to ROS as a result of normal metabolic processes occurring during aerobic respiration (Wei & Lee, 2002). For instance, superoxide is a type of ROS that is generated within the mitochondria and can result in the induction of additional ROS, such as hydrogen peroxide and hydroxyl radicals (Grivennikova & Vinogradov, 2006). As a result, increased levels of these ROS create an environment referred to as oxidative stress, which has the potential to lead to DNA damage and subsequently promote the mutations that initiate tumour progression (Wiseman & Halliwell, 1996). Human tumour cell lines *in vitro* have been shown to produce ROS at a greater rate than non-transformed cell lines (Szatrowski & Nathan, 1991). ROS may cause damage to DNA, such as strand breaks, alterations in guanine and thymine bases, and sister chromatid exchanges (Wiseman & Halliwell, 1996).

Açai (*Euterpe oleracea* Mart.) is a native palm plant in northern South America which has recently emerged as a promising source of natural antioxidants. A recent study showed that the açai extract possessed noticeable activity against superoxide and the highest activity of any food reported to date, against the peroxyl radical when measured by the oxygen radical absorbance capacity assay ($ORAC_{FL}$) (Schauss et al., 2006a). The antioxidant activities of açai against the peroxynitrite and hydroxyl radicals were also noticeable (Schauss et al., 2006a). Similarly, other studies have reported significant antioxidant activities of açai berries and seeds by employing a variety of measurements (Hassimotto, Genovese, & Lajolo, 2005; Rodrigues et al., 2006). The potential beneficial effects attributed to açai-derived extracts are believed to be related to abundance of phenolic compounds found in this fruit. However, investigations of the medicinal role of the polyphenol-rich açai, in mediating cancer cells, are very limited, despite the recent increased interest in its antioxidant properties. The polyphenolic extract of açai has been shown, *in vitro,* to suppress proliferation of HL-60 leukaemia cells through caspase-3 activation in a dose- and time-dependent manner (Del Pozo-Insfran, Percival, & Talcott, 2006). Another study reported that a non-anthocyanin polyphenolic fraction from the açai pulp extract inhibited proliferation of HT-29 human colon adenocarcinoma cells (Pacheco-Palencia, Talcott,

doi:10.1016/j.foodchem.2009.04.099

Safe, & Mertens-Talcott, 2008). Açai fruit was reported to be rich in anthocyanins (Schauss et al., 2006b) and a number of anthocyanin-rich fruit extracts have exhibited the strong antiproliferative activities on different cancer cells (Balasundram, Bubb, Sundram, & Samman, 2003; Faria et al., 2005; Hosseinian et al., 2007b; Solomon et al., 2006; Vattem, Ghaedian, & Shetty, 2005). In this study, we have prepared an anthocyanin-rich extract from açai (AEA) and investigated its effect on proliferation of C-6 rat brain glioma cells and MDA-468 human breast cancer cells. The antioxidant properties of AEA were also assessed, as studies have shown that the anticancer effects of berry bioactives are partially mediated through their abilities to reduce and repair damage resulting from oxidative stress and inflammation (Seeram, 2008).

2. Materials and methods

2.1. Sample preparation

Lyophilised açai powder was obtained from the Van Drunen Farms (Momence, IL). The oil in the açai powder was removed with hexane by Soxhlet extraction at 45 °C for 3 h. The remaining residue was dried in a fume hood. Afterwards, 10 g of oil-free açai powder were extracted with 100 ml of 50% acetone at ambient temperature under stirring for 18 h. Extract was then filtered through a Whatman No. 4 filter paper. The residue was further extracted with 50 ml of 50% acetone. Following filtration, both filtrates were combined. The acetone in the extract was removed by a rotary evaporator (Thermo Scientific, Rockford, IL) at 45 °C. The remaining mixture was lyophilised. The anthocyanin-rich extract was obtained after purifying the lyophilised açai extract by solid phase extraction. Specifically, 100 mg of the açai crude extract were reconstituted in 10 ml of 15% methanol and then loaded onto a preconditioned Oasis HLB cartridge (Waters, Milford, MA). Water-soluble constituents, such as sugars, organic acids and minerals, were removed with distilled water. The anthocyanin fraction was eluted with 60% methanol in acidic water. The eluted material was collected and methanol was removed by a nitrogen evaporator (Organomation Associates, Berlin, MA). The collected residue was lyophilised (AEA) and stored at −20 °C for further investigation.

2.2. Total phenolic content (TPC)

TPC of AEA was determined using the Folin–Ciocalteu reagent with gallic acid as the phenolic standard (Zhou, Su, & Yu, 2004). In brief, appropriate dilutions of AEA were mixed with Folin–Ciocalteu reagent and 20% sodium carbonate (Na_2CO_3) at ambient temperature. After incubation for 2 h, the absorbance of blue colour developed in each assay mixture was recorded at 760 nm by a Genesys 10-UV scanning spectrophotometer (Thermo Electron Corporation, Madison, WI). The TPC of AEA was expressed in mg gallic acid equivalents (GAE) per gramme of dried AEA powder.

2.3. Total anthocyanin content

Total anthocyanin content of AEA was quantified using a pH differential method (Moyer, Hummer, Finn, Frei, & Wrolstad, 2002). In brief, 100 ml each of 0.025 M potassium chloride (pH 1.0) and 0.4 M sodium acetate (pH 4.5) buffer solutions were prepared. Each sample and standard (cyanidin 3-glucose) was diluted first with 0.025 M potassium chloride buffer (pH 1.0) and the absorbance was measured at 520 nm and 700 nm with a UV spectrophotometer (Genesys 10-UV scanning, Madison, WI) against a reagent blank (distilled water). A second aliquot of each sample was diluted to the same value with 0.4 M sodium acetate buffer (pH 4.5) and measured at 520 and 700 nm. The absorbance (A) was calculated using the following equation:

$$A = (A_{520\text{nm,pH 1.0}} - A_{700\text{nm,pH 1.0}}) - (A_{520\text{nm,pH 4.5}} - A_{700\text{nm,pH 4.5}}).$$

The total anthocyanin content was calculated and expressed as mg of cyanidin 3-glucoside equivalents (CGE) per gramme of AEA (mg/g).

2.4. Total flavonoid content

Total flavonoid content of AEA was analysed according to a reported colorimetric method (Veluri et al., 2006). In brief, 1 ml of AEA or standard (rutin) was mixed with 0.3 ml of 5% sodium nitrite, 0.3 ml of 10% aluminium chloride, and 2 ml of 1 M sodium hydroxide. All samples were run in duplicate and compared against a blank at an absorbance of 510 nm. Results were expressed as microgrammes rutin equivalents (RE) per gramme of AEA powder (mg/g).

2.5. Oxygen radical absorbance activity ($ORAC_{FL}$)

The $ORACFL_{FL}$ assay was conducted to measure the peroxyl radical-scavenging activity of AEA with trolox as the antioxidant standard (Zhou et al., 2007). A fluorescein stock solution (100 μM) in phosphate buffer (75 mM, pH 7.4) was prepared and kept at 4 °C in the dark. Fresh working fluorescein solution (100 nM) was prepared daily by diluting the stock solution in phosphate buffer. The fluorescein solution (200 μl) was added to each 40 μl of sample or trolox standard prepared in phosphate buffer (20, 40, 80, 100, and 200 μM) in a black 96-well plate and incubated for 20 min at 37 °C. The reaction was initiated by adding the peroxyl radical generator. Thirty-five microlitre of 0.36 M 2,2′-azobis-2-amidinopropane (AAPH), prepared in 75 mM phosphate buffer (pH 7.4), were added and the fluorescence was measured (λ_{ex} = 485 nm and λ_{em} = 535 nm) every minute using a Victor^3 multilabel plate reader (Perkin–Elmer, Turku, Finland) maintained at 37 °C until the reading had declined to less than 5% of the initial reading. Standards and samples were run in triplicate. Results for ORAC were determined by regression, relating trolox concentrations and the net area under the kinetic fluorescein decay curve. The $ORAC_{FL}$ value of each grape extract was expressed as micromoles of trolox equivalents per gramme of sample (μmoles/g).

2.6. DPPH·-scavenging activity

A high-throughput assay, based on the reduction of the free radical DPPH·, was carried out using a Victor^3 multilabel plate reader (Cheng, Moore, & Yu, 2006). The reaction mixture contained 100 μl of antioxidant açai extract and 100 μl of 0.208 mM DPPH$^•$ solution. The absorption at 515 nm was determined immediately after the reaction was initiated by gentle shaking. Each plate was read once every minute for 1.5 h. The relative DPPH$^•$-scavenging capacities (RDSC) were expressed as micromoles of trolox equivalents (TE) per gramme of sample (μmoles/g).

2.7. Cell culture

C-6 rat brain carcinoma cells and MDA-468 human breast cancer cells (American Type Culture Collection, Manassas, VA) were maintained at 37 °C in 5% CO_2 in a humidified incubator (Thermo Scientific, Rockford, IL) in Dulbecco's modified Eagle's medium (DMEM) containing 10% heat-inactivated foetal bovine serum and antibiotics (100 units/ml penicillin G, 100 μg/ml streptomycin) (Gibco BRL, Grand Island, NY). Cells (2.5×10^4 cells/ml) were plated in 48-well plates in complete media (FBS-containing media), and allowed to attach for 24 h.

2.8. Cell viability

C-6 brain carcinoma cells and MDA-468 breast cancer cells were treated for 24, 48, and 72 h in experimental media (without FBS in media) with sterile AEA dosed at 50, 100, and 200 μg/ml. The cell viability was assessed by the MTT assay according to the procedure previously described with slight modification (Chen, Jeng, Lin, Wu, & Chen, 2006). Cells were plated at a density of 2.5×10^4 cells/ml. After 24 h of incubation, the cells were washed with HBSS and then treated with AEA in the experimental medium or water alone, in a 48-well plate. Each treatment was repeated in 4 wells. The cells were further incubated for either 24, 48, or 72 h periods at 5% CO_2 37 °C in a humidified chamber. The treated media were removed at the end of each incubation period, washed with HBSS, and then cells were incubated for 4 h with 500 μl of MTT reagent solution (0.5 mg/ml in DMEM) added to each well; thus the tested AEA were present only during incubation treatments (24, 48, and 72 h). The MTT solution was aspirated and the formazan crystals were dissolved in dimethyl sulfoxide (DMSO) (500 μl) for 30 min on a plate rocker protected from UV light. Absorbance was recorded at 570 nm wavelength by a multilabel plate reader (Victor^3, Perkin–Elmer, Waltham, MA). Absorbance data acquired for cellular viability were expressed as percentages of the control (surviving control cells) in the experiment. After each treatment period, prior to MTT assays, cells were photographed with a Nikon microscope (Melville, NY) in order to observe gross cellular morphology of the cells after AEA treatments under 100× magnification.

2.9. DNA ladder fragmentation assay

Apoptosis or programmed cell death is a biological response of cells after exposure to DNA damage. DNA fragmentation in C-6 brain glioma cells was measured using a published method with the following modifications (Ray, Kamendulis, Gurule, Yorkin, & Corcoran, 1993). Briefly, C-6 glioma cells, treated with AEA (50–200 μg/ml) for 48 h, were washed with 1 × phosphate-buffered saline and harvested with plastic scrapers after trypsinization. Cells (15×10^4 cells per 100 mm culture dish) were lysed in 50 mM Tris–HCl, pH 7.5, 20 mM EDTA, and 1% Nonidet P-40 for approximately 10 s. This lysate was then centrifuged at 3000 rpm for 5 min at 4 °C to separate the fragmented DNA (supernatant) from the intact chromatin (pellet). A 10% SDS solution (10 μl) was added to the supernatant before it was treated with RNase A (final concentration of 5 μg/μl) and incubated for 2 h at 56 °C, followed by another incubation for 2 h at 37 °C with proteinase K (final concentration of 2.5 μg/μl). After extraction of the supernatant, fragmented DNA was precipitated with 100% cold ethanol and 0.5 M ammonium acetate for 1 h in −80 °C. Samples where then centrifuged at 12,000 rpm for 20 min, the supernatant was discarded and the white pellet was washed with 80% ice-cold ethanol and subsequently allowed to air-dry for 10 min at room temperature. The DNA sample was dissolved in 1× Tris–EDTA buffer, pH 8.0. DNA concentration was determined (Abs 260 nm) and 2% agarose gel electrophoreses of the same concentration of DNA was conducted (6 μg DNA per well). Electrophoresis was conducted in the TBE buffer for 120 min at 80 V. Gels were observed and photographed under UV light.

Table 1
Phenolic composition and antioxidant properties of AEA.

	AEA (lyophilized)
Total phenolic content	312 ± 5.6 mg GAE/g
Total flavonoids	124 ± 3.3 mg RE/g
Total anthocyanins	100 ± 2.4 mg CGE/g
ORAC	2589 ± 63.1 μmoles TE/g
DPPH scavenging activity	1208 ± 130 μmoles TE/g

GAE: gallic acid equivalents; RE: rutin equivalents; CGE: cyanidin 3-glycoside equivalents; TE: trolox equivalents.

2.10. HPLC–MS/MS detection of anthocyanins in AEA

Since anthocyanin compounds are the major components in AEA, its profile was analysed with HPLC–MS (high performance liquid chromatography–mass spectrometry). The chromatographic separation was performed with a Luna C18 column (150 × 2.1 mm, 4 μm dp; Phenomenex, Torrance, CA). AEA (20 μl) was injected onto the column with a Thermo Survey autosampler (San Jose, CA) maintained at 10 °C. Mobile phase A consisted of 1% aqueous formic acid, and mobile phase B consisted of 1% (*v*/*v*) formic acid in acetonitrile. The mobile phase was delivered to the HPLC column at a flow rate of 0.2 ml/min. The gradient elution programme was as follows: 0 min, 97/3 A/B; 40 min, 70/30 A/B; 45 min, 0/100 A/B; 50 min, 97/3 A/B). The HPLC column effluent was pumped directly without any split into a Finnigan LCQDUO mass spectrometer (Thermo Scientific, Waltham, MA) with electrospray ionisation. The MS/MS parameters were as follows: positive mode; nebulizer, 45 psi; dry gas, 11.0 psi, dry temperature, 340 °C; MS/MS, scan from *m*/*z* 350 to 1500; ion trap, scan from *m*/*z* 100 to 1500; maximum accrual time, 100.00 ms.

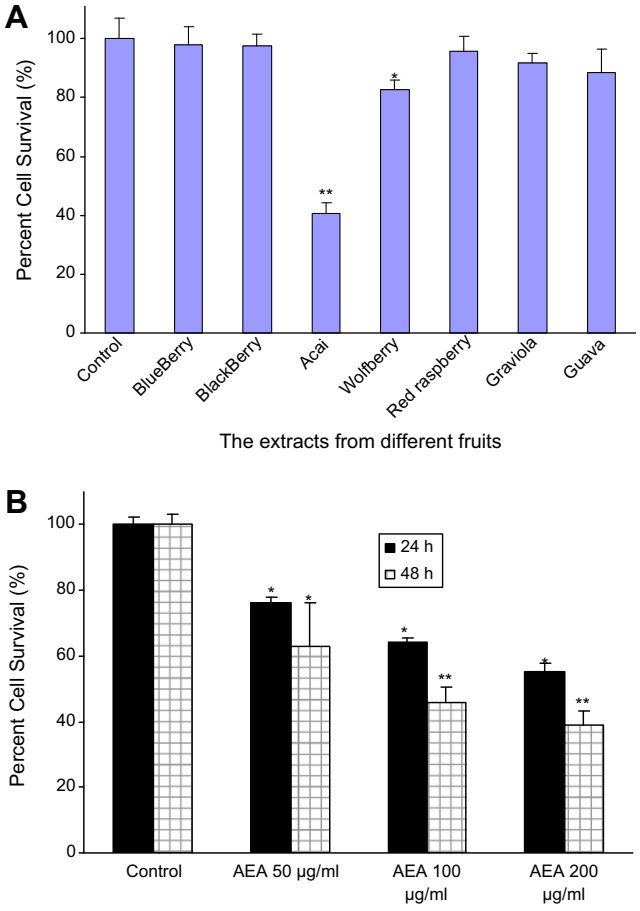

Fig. 1. Inhibitory effect of AEA on proliferation of C6 rat brain glioma cells. (A) AEA and other anthocyanin-rich fruit extracts on the cell growth. (B) Time and dose-dependent responses of AEA on the cell growth. C6 cells (2.5×104 cells/ml) followed 24 or 48 h exposure to AEA. The experiments were run in quadruplicate. * indicates significant difference compared to untreated control, ($P < 0.05$), ** indicates significant difference between 24 and 48 h of AEA treatments at the same dose.

2.11. Statistical analysis

Data were reported as means ± SD for triplicate determinations. Difference between two groups was analysed by two-tailed Student's *t* test and, between three or more groups, was analysed by one-way ANOVA multiple comparisons (SPSS 13.0, SPSS, Inc. Chicago, IL). Difference was considered statistically significant when the *P* value was <0.05.

3. Results and discussion

3.1. Total phenolic, flavonoid and anthocyanin contents

The total phenolic content of AEA was 312 mg gallic acid equivalents (GAE) per gramme (Table 1). This is considerably higher than in a previous report of 13.9 mg GAE per gramme of açai (Schauss et al., 2006a). The açai juice was reported to have TPC up to 2.1 mg GAE per ml of juice, predominantly consisting of anthocyanins and proanthocyanidins (Schauss et al., 2006b; Seeram et al., 2008). The result suggested that our AEA preparation method was able to efficiently extract and enrich phenolic compounds from açai powder. The flavonoid and anthocyanin contents in AEA were 124 mg rutin equivalents (RE) and 100 mg cyanidin 3-glycoside equivalents (CGE) per gramme, respectively, indicating that anthocyanins were the major flavonoids in AEA. Anthocyanins also were the major components in AEA and their concentration was well above those in certain other anthocyanin-rich fractions, such as grape skin (8.9 mg/g) (Munoz-Espada, Wood, Bordelon, & Watkins, 2004), Idared apple peels (0.3 mg/g) (Wolfe, Wu, & Liu, 2003), and a variety of berries (e.g. gooseberry, 0.8 and bilberry, 3.1 mg/g dry weight) (Kahkonen, Hopia, & Heinonen, 2001).

3.2. Oxygen radical absorbance capacity ($ORAC_{FL}$)

The hydrophilic $ORAC_{FL}$ value of AEA was 1800 μmol TE/g, which was more than twice higher than the 997 μmol TE/g of freeze-dried açai, as reported by Schauss et al. (2006a). AEA has considerably higher ORAC than have common phenolic-rich fruits or extracts, such as blueberry, strawberry, raspberry, chokecherry, and seabuckthorn, with ORAC values between 5.1 and 19.2 μmol TE/g fresh weight (Hosseinian et al., 2007a; Wang, Chen, Sciarappa, Wang, & Camp, 2008). This suggests that AEA is an exceptional source of natural antioxidants and consumption of AEA may provide potential antioxidant protection, thereby promoting human health.

3.3. $DPPH^{\bullet}$-scavenging activity

Traditional DPPH-scavenging assay measures the remaining radicals after reacting with antioxidants for a certain duration (30–90 min), which does not include an antioxidant standard. Thus, it is difficult to compare the data acquired from different laboratories because the experimental conditions, including temperature, reaction time, and sample/radical concentrations, can significantly affect the results. In this study, we used trolox as the antioxidant standard. The $DPPH^{\bullet}$-scavenging capacity of AEA was 839 μmol of TE/g. AEA, at 50 μg/ml, quenched 39.6% of DPPH radicals (1 mM) after 45 min of reaction. This result, along with the ORAC data, provided evidence that AEA is capable of interacting with different radicals, suggesting that AEA may have biomedical applications in reducing body oxidative stress, a deteriorating situation arising from elevation of various reactive oxygen species (ROS).

3.4. Cell viability

AEA treatments significantly suppressed proliferation of C-6 rat brain glioma cells (Fig. 1A and B). However, the growth of MDA-468 breast cancer cells was not affected by AEA treatments. For C-6 brain glioma cells, all three dosage treatments by AEA resulted in cell mortality. Specifically, 50, 100, and 200 μg/ml AEA treatments resulted in 62%, 45%, and 38% cell viability, respectively. The results revealed a distinct dose response and an IC_{50} value of 121 μg/ml after AEA treatments for 48 h. It appears that AEA inhibited the growth of C-6 glioma cells in a time-dependent manner as less pro-

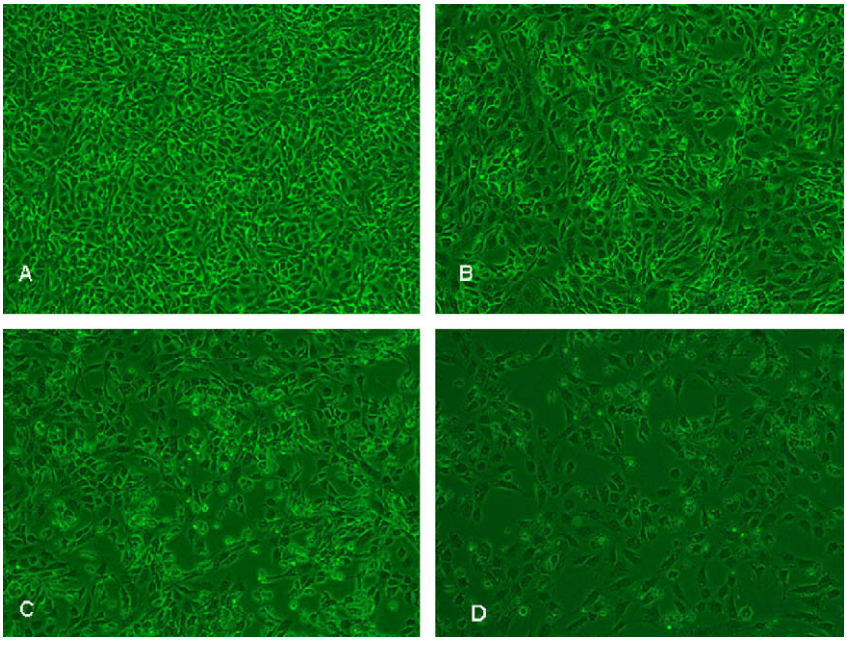

Fig. 2. Cell morphology of C-6 rat brain glioma cells after 48 h treatments by different doses of AEA. (A) The glioma cells grown in culture dishes were treated in experimental media only (control); (B) 50 μg/ml AEA treatment; (C) 100 μg/ml AEA treatment; (D) 200 μg /ml AEA treatment. Cell morphology was examined by microscopy under 100× magnification.

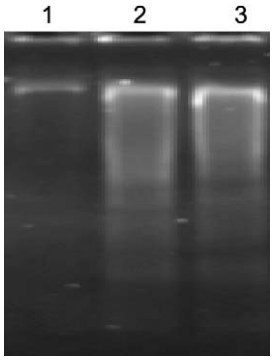

Fig. 3. DNA fragments of rat glioma C-6 cells treated with 100 and 200 μg/ml of açai for 48 h. Lane 1 represents control DNA from glioma cells in experimental media only, Lane 2 represents DNA fragments of glioma cells exposed to AEA at 200 μg/ml, Lane 3 represents DNA fragments after 100 μg/ml AEA treatments.

Table 2
Mass spectrometric data for identified phenolic compounds in AEA.

	Retention time (min)	Parent ion (*m*/*z*)	MS/MS fragments (*m*/*z*)
Cyanidin-3-glucoside	10.8	449	287
Cyanidin-3-rutinoside	11.34	595	449, 287
Peonidin-3-(6″-malonylglucoside)	13.20	549	463, 301
Delphinidin 3-(6″-acetoyl)glucoside	17.08	507	303
Peonidin-3-rutinoside	19.34	609	463, 301

nounced growth inhibitory effects were observed at 24 h treatments. The açai extract was recently reported to dose-dependently inhibit proliferation of HT-29 colon carcinoma cells (Pacheco-Palencia et al., 2008). The same research group also found that non-hydrolysed, anthocyanin-containing fractions of the açai extract strongly suppressed proliferation of HL-60 cells by inducing cell apoptosis (Del Pozo-Insfran et al., 2006). Anthocyanin-rich extracts, in particular berry extracts, have been widely investigated for their potential antiproliferative properties against a variety of cancer cells, and some have shown promising results. For instance, the strawberry and raspberry extracts strongly inhibited proliferation of CaCo-2 human colon cancer cells (McDougall, Ross, Ikeji, & Stewart, 2008); The bilberry extract was effective against HL-60 human leukaemia cells (Katsube, Iwashita, Tsushida, Yamaki, & Kobori, 2003); The blueberry and cranberry suppressed proliferation of MCF7 human breast cancer cells and HT-29 colon carcinoma cells (Seeram et al., 2006). In the cell experiments, we also evaluated other anthocyanin-rich extracts, including blueberry, strawberry, raspberry, blackberry, and wolfberry, against C-6 brain glioma cells as a comparison. However, none of the tested berry extracts inhibited proliferation of C-6 brain glioma cells (Fig. 1A). These observations indicate that the antiproliferative constituents, in AEA, on C-6 rat brain glioma cells, are unlikely to be the anthocyanins normally found in berries. Additional research is required to investigate the underlying mechanisms, and to characterise the chemical structures contributing to the antiproliferative capacity.

3.5. Cell morphology

To examine the effect of AEA on C-6 brain glioma cell proliferation, changes in cell morphology were also assessed at 48 h after AEA treatments with three different doses. Under experimental media-treated control conditions, C-6 cells appeared healthy and to be growing to 100% confluency (Fig. 2A). After exposure to 50 μg/ml of AEA for 48 h, C-6 cells numbers were noticeably reduced and appeared to be less dense (Fig. 2B). Further, at 100 μg/ml AEA concentration, cells exhibited the characteristic features of cell shrinkage, rounding, and partial detachment and demonstrated the lobulated appearance of apoptotic cells (Fig. 2C). When exposed to 200 μg/ml of AEA for 48 h, glioma cells had even more

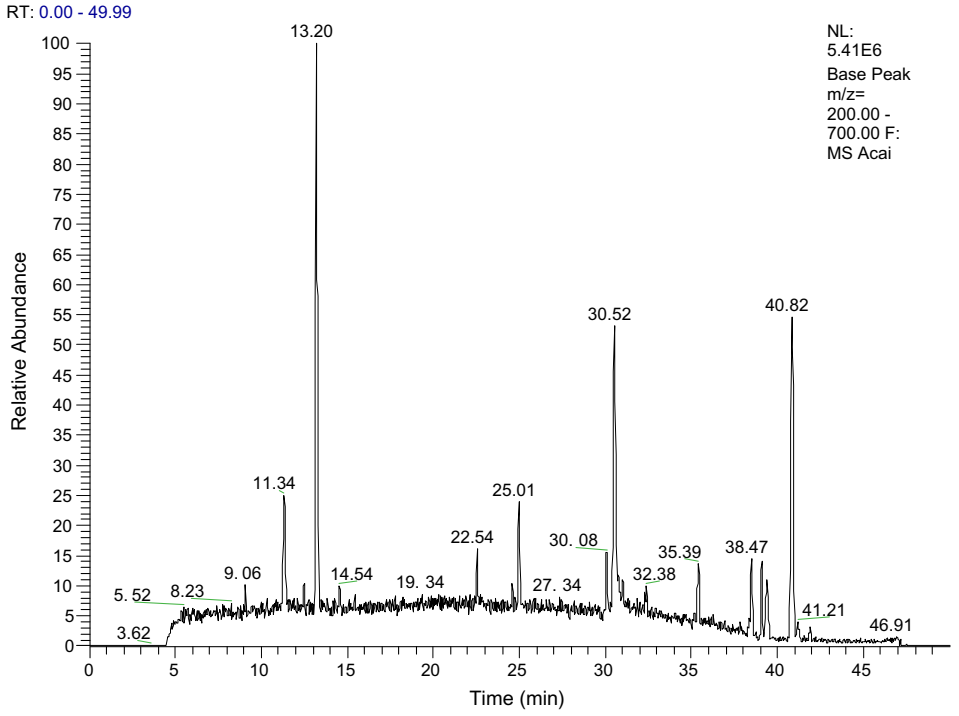

Fig. 4. HPLC–MS detection of anthocyanin compounds in AEA. The chromatograph was conditioned with the *m*/*z* range of 200–700. The peaks at the retention time of 10.80, 11.34, 13.20, 17.08, and 19.37 min represent cyanidin-3-glucoside, cyanidin-3-rutinoside, peonidin-3-(6″-malonylglucoside), delphinidin 3-(6″-acetoyl)glucoside, and peonidin-3-rutinoside, respectively.

profound features, characteristic of cell death (Fig. 2D). Similarly to the observations in the MTT experiments, the cell morphology results suggest that AEA reduced proliferation of C-6 brain glioma cells in a dose-dependent manner.

3.6. DNA ladder fragmentation

Fragmentation of DNA, observed from agarose gel results, is an indication of programmed cell death or apoptosis. No DNA fragmentation was detected in the control DNA from C-6 brain glioma cells in experimental media only (Fig. 3). However, fragmentation of DNA (laddering or banding observed in the image) was observed in C-6 glioma cells after 48 h treatments with either 100 or 200 μg/ml of AEA. The results suggest that the antiproliferative effect of AEA against C-6 glioma cells is caused by inducing cell apoptosis. The açai extract was previously reported to induce apoptosis in HL-60 human leukaemia cells by activating caspase-3 (Del Pozo-Insfran et al., 2006). In the future, it is necessary to examine whether the inhibition of AEA on C-6 glioma cells proliferation is through caspase-3 activation or other apoptotic pathways, to better understand antiproliferative mechanisms of AEA.

3.7. HPLC–MS/MS detection of anthocyanins in AEA

The chromatographic analysis identified three major anthocyanins in AEA with peonidin-3-(6″-malonylglucoside) being most abundant, followed by cyanidin-3-rutinoside, delphinidin 3-(6″-acetoyl)glucoside, and cyanidin-3-glucoside. In addition, one of the minor anthocyanins was identified as peonidin-3-rutinoside. The determination of anthocyanins was based on selective MS detection of the molecular ions and subsequent MS fragmentation experiments. Previous reports on the anthocyanin composition of açai fruit have been limited. A previous study determined cyanidin-3-glucoside and cyanidin-3-rutinoside as the major anthocyanins in açai (Lichtenthäler et al., 2005), while others found that cyanidin-3-arabinoside and cyanidin-3-arabinosylarabinoside were the most abundant (Bobbio, Bobbio, Oliveira, & Fadelli, 2002). However, both cyanidin-3-arabinoside and cyanidin-3-arabinosylarabinoside were not detectable in AEA under our experimental conditions. Moreover, AEA contained markedly more peonidin-3-(6″- malonylglucoside) than other anthocyanins. Table 2 presents the MS data for the identified compounds (see Fig. 4).

In summary, we have demonstrated that the anthocyanin-rich extract from açai possesses strong antioxidant activities and antiproliferative activity against C-6 brain glioma cells. The effect of AEA on C-6 glioma cells is unique as other selected anthocyanin-rich berry extracts do not have similar inhibitory activity. In addition, AEA has no effect on growth of MDA-468 human breast cancer cells, suggesting that it may specifically target C-6 glioma cells. The DNA ladder results indicated that AEA induces apoptosis in C-6 glioma cells. Further research is needed to identify active constituents in AEA and elucidate its inhibitory mechanisms on C-6 rat brain glioma cells.

Xylo-oligosaccharides
Prebiotic activity

ABSTRACT

Water extractable polysaccharides (WEPs) were isolated from Bengal gram husk and wheat bran. These WEP were subjected to driselase enzyme hydrolysis to obtain oligosaccharide mixtures, which were purified successively on Biogel P-2 and high performance liquid chromatographies. The molecular weight and structural features of the purified oligosaccharides were deduced using ESI-MS and ^{1}H NMR, respectively. The prebiotic properties of these purified oligosaccharides were studied by using *Bifidobacterium adolescentis* NDRI 236. Increase in dry cell mass (0.7–0.9 mg/ml) and decrease in pH (<5.8) due to production of short chain fatty acid (SCFA) indicated oligosaccharide fermentation. Acetate was the chief SCFA produced and its amount varied from 97.2% to 100%. The activities of xylanase (257–470 mU/ml), xylopyranosidase (53–60 mU/ml) and arabinofuranosidase (60–70 mU/ml) in the culture broth indicated the breakdown of xylo-oligosaccharides and their subsequent utilisation by the bacterium for its growth.

1. Introduction

Dietary fibres and their degradation products reaching the colon undergo different degrees of fermentation, out of which highly fermentable types include water-soluble hemicelluloses, pectins and gums and also include non-digestible oligosaccharides (NDOs) which resist digestion by endogenous enzymes within the human intestinal tract (Van Laere, Hartemink, Bosveld, Schols, & Voragen, 2000). Soluble dietary fibres, such as β-D-glucans and soluble arabinoxylans, are readily fermented by colonic microorganisms; where as insoluble dietary fibres are only degraded partially, resulting in an increase in the faecal bulk. Beneficial colonic bacteria such as lactic acid bacteria and bifidobacteria produce carbohydrate degrading enzymes which ferment the oligosaccharides and produce short chain fatty acids such as acetate, propionate and butyrate which provide metabolic energy for the host and help in the acidification of the bowel (Swennen, Courtin, & Delcour, 2006). Acidification can affect the balance of the bacterial species, bacterial metabolic activity and product formation as well as the epithelial proliferation. *Bifidobacterium* strains are largely described as capable of efficiently fermenting xylose-based oligo and polysaccharides (Crittenden et al., 2002).

Functional foods, which can enhance the health of the consumer, are having a large market in today's food industry. Of the currently known functional foods, non-digestible oligosaccharides hold an important position with respect to their prebiotic activity. A prebiotic is defined as "a non-digestible food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, and thus improves the host health" (Gibson & Roberfroid, 1995). Many studies have now confirmed that the prebiotics incorporated in the diet is a valid approach to the dietary manipulation of the colonic microflora (Gibson & Roberfroid, 1995). Health promoting bacteria also produce vitamins, SCFA and other nutrients for their host, providing up to 15% of the total caloric intake (Gibson, 1999). Prebiotic effect of fructo-oligosaccharides (FOS) and galacto-oligosaccharides (GOS) were reported (Delzenne & Kok, 2001). Studies on GOS and FOS have also shown that they are effective in increasing the mineral absorption (Chonan, Takahashi, & Watanuki, 2001). However, xylo-oligosaccharides as active prebiotic components have not yet been effectively exploited. Only few reports mention the fermentability of crude cereal non-starch polysaccharides/oligosaccharides (Cotta, 1993; Jaskari et al., 1998; Karppinen, Liukkonen, Aura, Forssell, & Poutanen, 2000).

Monitoring fermentation in vivo is very difficult. The fermentation of polysaccharides/oligosaccharides can be measured from faeces, but SCFA are readily absorbed in the colon and the amount found in faeces does not describe the true situation. Knowledge of the extent of fermentation of polysaccharides/oligosaccharides and of the SCFA production *in vitro* by beneficial bacteria are therefore of great importance. Bifidobacteria and lactic acid bacteria are

doi:10.1016/j.foodchem.2009.04.108

shown to poorly utilise arabinoxylans, but readily utilised arabinoxylans hydrolysates (Jaskari et al., 1998). It was shown that arabinofuranosidase and xylopyranosidase cannot degrade long chain xylan and they act best on arabinoxylo-oligosaccharides (unpublished results). Acid hydrolysis of polysaccharides is nonspecific and restricts its wider application. Utilisation of enzymes might improve the technical and economic feasibility of biotechnological processes for arabinoxylan hydrolysis. Endoxylanase hydrolyses the arabinoxylans randomly producing xylo-oligosaccharides (Kormelink, Gruppen, Vietor, & Voragen, 1993) of varying degree of polymerisation (D.P. 2–10). Apart from their prebiotic effect, xylo-oligosaccharides are believed to alleviate disease symptoms such as diabetes, arteriosclerosis and colon cancer (Swennen et al., 2006).

Cereal brans and pulse husks (agricultural wastes) are available in plenty in India. They are used as feedstuffs for various non-ruminant farm animals. Arabinoxylans are rich in cereal bran and pulse husks. Development of an economically viable technology can therefore be explored in order to obtain high value added products such as bioactive oligosaccharides from agricultural wastes. Hence a study has been carried out by isolating xylo-oligosaccharides from the water extractable polysaccharides of agricultural wastes such as Bengal gram husk and wheat bran and the results pertaining to their purification, structural characterisation and determination of the prebiotic properties are reported here.

2. Materials and methods

2.1. Materials

Wheat bran (*Triticum aestivum*) was obtained from local market. Bengal gram (*Cicer arietinum*) was dehusked in the GST Department of C.F.T.R.I., Mysore, India. HPLC (μ-Bondapak-NH_2 carbohydrate) and GLC (OV-225 and PEG 20M) columns were obtained from Shimadzu Corporation, Kyoto, Japan. Sugars, enzymes (Driselase), substrates and other fine chemicals were purchased from Sigma Chemical Company, MO, USA. Microorganisms were obtained from National Dairy Research Institute (NDRI), Karnal, India. Microbiological culture media and media ingredients were obtained from HiMedia, Mumbai, India. All other chemicals and solvents were of analytical grade.

2.2. Isolation of water extractable polysaccharides (WEP)

Water extractable polysaccharides were isolated from wheat bran and Bengal gram husk as described earlier (Rao & Muralikrishna, 2004). In brief, bran/husk was powdered and extracted with water (200 ml × 4 at 25 °C), centrifuged (at 3000×*g* for 20 min) and the supernatant thus obtained was precipitated with three volumes of ethanol, which was separated out by centrifugation followed by dialysis (cut off range ≈8 Kda) and lyophilisation. These water-soluble fractions were further dissolved in water (10%) and insoluble portion was separated out by centrifugation (at 3000×*g* for 20 min). Soluble portion was heated at 95 °C for 10 min to denature associated enzymes and proteins. It was further centrifuged (at 7500×*g* for 10 min) and the supernatant thus obtained was dialysed and lyophilised to obtain water extractable polysaccharides.

2.3. Liberation of oligosaccharides from WEP

WEP of wheat bran and Bengal gram husk (500 mg each) were dissolved in acetate buffer (pH 4.8, 0.1 M, 10 ml) and incubated with driselase (0.28 U/mg protein) in a constant shaking water bath at 50 °C for 2 h. Subsequently the reaction was stopped by adding 3 volumes of ethanol and the precipitated material was removed by centrifugation (at 3000×*g* for 15 min). The resultant supernatant consisting of oligosaccharides was concentrated and used for further analysis.

2.4. Purification of oligosaccharides on Biogel P-2

The individual oligosaccharide mixtures obtained from WEP of wheat and Bengal gram by driselase action (10–15 mg) were separated on Biogel P-2 column (0.9 × 105 cm). Triple distilled, degassed water was used as the eluent at a flow rate of 6 ml/h and fractions (1 ml each) were collected (Guillon et al., 2004). The carbohydrate containing fractions were pooled and concentrated for further characterisation.

2.5. HPLC of oligosaccharides

Oligosaccharides obtained after purification on Biogel P-2 column chromatography were further purified by Shimadzu HPLC system using μ-Bondapak-NH_2 carbohydrate column (4.1 × 300 mm) using refractive index detector. The Biogel P-2 purified oligosaccharides (2 mg) were dissolved in water (0.2 ml) passed through a Millipore filter (0.2 micron), and an aliquot of 20 μl was injected to the column and eluted by using acetonitrile and water (70:30) at a flow rate of 1 ml/min (McGinnis & Fang, 1980).

2.6. Determination of neutral sugar composition of poly/oligosaccharides by GLC

The polysaccharides (10 mg) isolated from wheat bran and Bengal gram husk were suspended in water and were completely hydrolysed by prior solubilisation with 72% sulphuric acid at ice-cold temperature followed by diluting to 8% acid and heating at 100 °C for 10–12 h (Rao & Muralikrishna, 2004). The oligosaccharides (10 mg) were hydrolysed with sulphuric acid (2 N) for 8 h. The above mixtures were neutralised with barium carbonate (solid), filtered, deionized with Amberlite IR-120(H^+) resin and concentrated. Sodium borohydride (20 mg) was added to reduce the monosaccharides obtained from the polysaccharide/oligosaccharide hydrolysates and the tubes were kept at room temperature for 4–6 h. The excess borohydride was decomposed by adding acetic acid (2 N) drop wise till the effervescence of hydrogen stopped. The boric acid formed was removed by co-distillation with methanol (2 ml × 5). To the dry glycitols were added acetic anhydride and pyridine (1.0 ml each) and the mixture was kept at 100 °C for 2 h. After acetylation excess reagents were removed by co-distilling with water and toluene (2 ml × 3 each). The alditol acetates were extracted with chloroform, filtered through glass wool and dried by flushing nitrogen (Sawardekar, Slonekar, & Jeanes, 1965). The derivatives were taken in known amount of chloroform and analysed by GLC for qualitative and quantitative analysis.

2.7. Proton NMR spectra of oligosaccharides

Oligosaccharides samples (2–5 mg) were dissolved in D_2O (0.5 ml). The proton spectra collected with 7500 Hz spectral width with wet water suppression scheme. The proton spectra referenced with external TMS as standard (Hoffmann, Kamerling, & Vliegenthart, 1992). The experiments were done at 25 °C with 128 scans. The recycle delay kept at 3 s, with proton 90R above of 10.5 μs used.

2.8. ESI-MS of purified oligosaccharides

Mass spectra of the purified oligosaccharides were recorded by Alliance, Waters 2695 mass spectrometer instrument using

positive mode electrospray ionisation with the following operational conditions, i.e. capillary voltage 3.5 kV, core voltage 100 V, source temperature 80 °C, disolvation temperature 150 °C, core gas (Argon) 35 l/h and disolvation gas (nitrogen) 500 l/h (Fernandez, Obel, Scheller, & Roespstorff, 2004).

2.9. Uronic acid determination

To the test solutions (0.5 ml, kept in ice-cold temperature bath) was added conc. sulphuric acid (3 ml) and the solutions were mixed properly. The above mixture was kept in a boiling water bath for 20 min cooled and then carbazole solution (0.1 ml, 0.1% – prepared by dissolving recrystallized carbazole in alcohol) was added. The tubes were kept in dark for 2 h and the absorbance was read at 530 nm (Knutson & Jeanes, 1968). Uronic acid content was determined by referring to the standard graph prepared by using D-glucuronic acid (10–50 μg/0.5 ml). Averages of triplicate values were reported.

2.10. Protein determination

Protein concentration was determined according to the dye binding method of Bradford (1976) with bovine serum albumin (BSA) as standard. Averages of triplicate values were reported.

2.11. Microorganism and culture conditions

B. adolescentis NDRI 236 culture was used for the prebiotic activity determination studies. The culture was maintained at 6 °C in lactobacillus MRS broth medium supplemented with cysteine HCl (0.05%) and sub cultured at regular intervals of 30 days.

2.12. Inoculum

The culture was grown (24 h) in lactobacillus MRS broth medium supplemented with cysteine HCl (0.05%) and subjected to centrifugation (at 8000×*g* for 10 min at 4 °C) and the resultant cells were suspended in 0.85% normal saline. Serial dilutions were prepared to get the requisite cell population (10^{-6}). Lactobacillus MRS agar and broth medium and all the glassware, centrifuge tubes were sterilized (autoclaved at 121 °C for 15 min) and used for the microbiological experiments.

2.13. In vitro fermentation experiments

Membrane filter (0.22 mμ, Millipore) sterilized individual purified wheat bran oligosaccharides (WBO) and Bengal gram oligosaccharides (BGO) in 10× concentration were incorporated at 0.25% (w/v) level into 2 ml MRS broth medium (formulated without beef extract, yeast extract, sodium acetate and dextrose and replaced protease peptone to tryptone) and inoculated with 100 μl aliquots of culture suspension giving a cell number of 5×10^3 CFU/ml and incubated at 37 °C for up to 48 h. A change in the broth colour from colourless to deep yellow was considered as positive test. Growth of bacteria and utilisation of oligosaccharides by bacteria were monitored by measuring pH and absorbance of culture broth. Turbidity was monitored spectrophotometrically with an UV–Visible spectrophotometer at 600 nm. After 48 h of incubation, cultures were centrifuged (at 3000×*g* for 20 min) and cells were oven dried (for constant weight, at 80 °C) to determine the dry cell mass. Resultant supernatant was analysed for SCFA. Besides, viable cell population was enumerated by pour plating using lactobacillus MRS agar and incubating at 37 °C for 48 h. All the experimental values are averages of three independent experiments.

2.14. Enzyme assays

Culture broth (24 h old) was assayed for the presence of various enzyme activities. For determining the xylanase activity, larch wood xylan (1 ml, 0.5% in sodium acetate buffer, 0.1 M, pH 4.8) was incubated with sample (0.1 ml of culture broth) for 30 min at 50 °C. Reaction was stopped by adding 1 ml of DNS (dinitrosalicylic acid) reagent and the reducing sugar was quantified (Miller, 1959). One unit of activity was defined as the amount of enzyme required to liberate 1 μmol of xylose/min under assay conditions. β-D-xylopyranosidase (Beldman, Osuga, & Whitaker, 1996), α-L-arabinofuranosidase (Beldman et al., 1996), α-D-galactopyranosidase and β-D-galactopyranosidase activities were determined by monitoring the release of p-nitro phenol from respective substrates i.e. p-nitro phenol glycosides (0.5 ml of 2 mM substrate in sodium phosphate buffer, 0.1 M, pH 5.7) by incubating them with sample (0.1 ml of culture broth) for 1 h at 37 °C. For determining acetyl esterase activity, substrate (1 ml of saturated solution of p-nitro phenyl acetate in sodium potassium phosphate buffer, 0.2 M, pH 6.5) was incubated with sample (0.1 ml of culture broth) for 30 min at 25 °C. Reactions in the above enzyme assays were stopped by adding saturated solution of sodium tetra borate (0.5 ml). Absorbance was read at 400 nm. One unit of activity was defined as the amount of enzyme required to liberate 1 μmol of p-nitro phenol/min under assay conditions. Averages of triplicate values were reported.

2.15. SCFA analysis

The culture supernatant was acidified with sulphuric acid (50%) and extracted with diethyl ether (Karppinen et al., 2000) and analysed for SCFA by GLC on PEG-20 M by maintaining, column injector and detector temperatures at 120, 220 and 230 °C, respectively (Silvi, Rumney, Cresci, & Rowland, 1999), using nitrogen as the carrier gas (40 ml/min). Acetate, propionate and butyrate (10 μmol each/ml in diethyl ether) were used as standards. Quantity of individual SCFA in the sample was estimated by using peak area standard curve.

3. Results and discussion

3.1. Chemical composition of WEP extracted from Bengal gram husk and wheat bran

Water extractable polysaccharides (WEP) were isolated from Bengal gram husk and wheat bran (Rao & Muralikrishna, 2004) in yields of 2.78% and 4.8%, respectively. The protein content and uronic acid content of the polysaccharides were 2.5% and 24.6% (Bengal gram husk) and 6.4% and 11.3% (wheat bran). The neutral sugar composition of Bengal gram WEP showed rhamnose, arabinose, xylose, galactose and glucose in a ratio (mol%) of 12.5:17.8:16.7:30.9:22.6 whereas WEP of wheat bran consisted of rhamnose, arabinose, xylose, mannose, galactose and glucose in the ratio (mol%) of 1.3:21.2:38.5:1.6:26.4:11.3. The presence of high amount of uronic acid in these polysaccharides seems to be a characteristic of water-soluble arabinoxylans (Rao & Muralikrishna, 2004). However, presence of glucose and galactose in these polysaccharides may be due to the co-extraction of β-D-glucans and arabinogalacto-proteins present in the cell wall along with the enriched arabinoxylans (Loosveld et al., 1998).

3.2. Liberation of oligosaccharides from polysaccharides

The WEP from Bengal gram husk and wheat bran were subjected to commercial driselase (EC 3.2.1.8) hydrolysis in order to obtain oligosaccharides in the yields of 5.8% and 14.4% in Bengal

gram husk and wheat bran, respectively. Driselase from *Basidiomycetes* sp. is an endoxylanase, which cleaves arabinoxylans randomly (unbranched regions of both internal and external chains), resulting in the liberation of oligosaccharides with varying degree of polymerisation.

3.3. Purification of oligosaccharides

The oligosaccharides thus obtained from enzymatic hydrolysis of WEP of Bengal gram husk and wheat bran were separated by gel permeation chromatography (Biogel P-2 stationary media). Five major oligosaccharide fractions were obtained (elution volumes of oligosaccharides are given in parenthesis) in case of Bengal gram husk WEP and were designated as BGO-I (77 ml), BGO-II (83 ml), BGO-III (86 ml), BGO-IV (90 ml) and BGO-V (96 ml). Four fractions obtained in case of wheat bran WEP and were designated as WBO-I (72 ml), WBO-II (78 ml), WBO-III (86 ml) and WBO-IV (104 ml). BGO-V and WBO-IV exclusively consisted of monosaccharides, hence not taken for further studies.

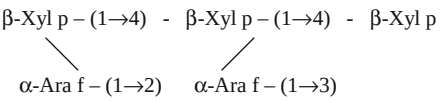
Biogel P-2 purified oligosaccharides from Bengal gram husk (BGO-I and BGO-IV) and wheat bran (WBO-I and WBO-III), were further resolved into 1–3 sub fractions on HPLC (figures not shown). The major purified fractions were collected in each case and used for the structural characterisation and determination of their prebiotic activity.

3.4. ^{1}H NMR analysis of purified oligosaccharides

^{1}H NMR was used for elucidating the structures of the purified oligosaccharides. ^{1}H NMR analysis of purified oligosaccharides BGO-I, BGO-IV, WBO-I and WBO-III indicated chemical shifts in the region of δ 3.00 to δ 5.00 ppm characteristics of α-linked arabinofuranoside as well as β-linked xylopyranoside residues (Gruppen et al., 1992) (Table 1).

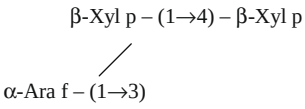
3.4.1. BGO-I fraction

The ^{1}H NMR spectrum of BGO-I (Fig. 1a) showed a peak at around δ 5.194 ppm representing the anomeric proton of xylopyranose at the reducing end, whereas δ 3.403 ppm represented that second β-xylopyranose (from reducing end) is linked to α-arabinofuranose residue at O-3 position (Gruppen et al., 1992). The signals at around δ 4.150 and δ 3.952 ppm represented the α-arabinofuranose linked to the O-2 position of third β-xylopyranose residue, which form the non-reducing end of the oligosaccharide. The signals at around δ 4.187 and δ 3.797 ppm represent that α-arabinofuranose linked to the O-3 position of second β-xylopyranose residue from reducing end. The ^{1}H NMR data is presented in Table 1 and the probable structure of BGO-I is as follows:



3.4.2. BGO-IV fraction

The ^{1}H NMR spectrum of BGO-IV fraction (Fig. 1b), gave a peak around δ 3.547 ppm representing the presence of β-xylopyranose residue at reducing end position. Signals at δ 3.292 and δ 3.765 ppm represents second β-xylopyranose residue from the reducing end, which is branched at O-3 position and forms the non-reducing end of the oligosaccharide (Gruppen et al., 1992). A signal at δ 3.914 and δ 3.800 ppm indicated that α-arabinofuranose might be linked to the O-3 position of the second β-xylopyranose residue. The ^{1}H NMR data is presented in Table 1 and the probable structure of BGO-IV is as follows:



3.4.3. WBO-I fraction

The ^{1}H NMR spectrum of WBO-I (Fig. 2a) gave a peak at around δ 5.193 ppm representing the anomeric proton of xylopyranose at the reducing end. Signals at δ 3.546 and δ 3.730 ppm also indicated

Table 1
Chemical shifts[a] (δ) of proton resonances of purified oligosaccharides (^{1}H NMR data).

Oligosaccharide	Residue[b]	Chemical shifts (ppm)				
		H-1	H-2	H-3	H-4	H-5
BGO-I	Xyl *p*-1	5.194	3.547	3.730	–	3.820
	β-Xyl *p*-2^{II}	4.490	3.403	3.745	3.690	3.340
	β-Xyl *p*-3^{I}	4.475	3.400	3.579	3.663	3.340
	α-Ara *f*-A^{3X2}	5.427	4.159	3.902	4.187	3.797
	α-Ara *f*-A^{2X3}	5.221	4.150	3.952	3.829	3.817
BGO-IV	Xyl *p*-1	5.194	3.547	3.730	–	3.820
	β-Xyl *p*-2^{II}	4.421	3.292	3.765	3.795	4.004
	α-Ara *f*-A^{3X2}	5.443	4.162	3.914	4.308	3.800
WBO-I	Xyl *p*-1	5.193	3.546	3.730	–	3.820
	β-Xyl *p*-2	4.467	3.298	3.554	3.792	3.416
	β-Xyl *p*-3^{III}	4.639	3.572	3.670	3.724	3.431
	β-Xyl *p*-2	4.432	3.237	3.409	3.591	3.269
	α-Ara *f*-A^{2X3}	5.225	4.148	3.932	4.301	3.828
	α-Ara *f*-A^{3X3}	5.271	4.164	3.932	4.301	3.720
	β-Xyl *p*-4	4.432	3.237	3.409	3.591	3.269
WBO-III	Xyl *p*-1	5.194	3.547	3.73	3.820	–
	β-Xyl *p*-2^{III}	4.596	3.539	3.689	3.724	3.344
	α-Ara *f*-A^{2X2}	5.246	4.151	3.956	4.132	3.720
	α-Ara *f*-A^{3X2}	5.246	4.175	3.973	4.198	3.706

β-Xyl *p*-3^{I} means β-Xyl *p*-3 branched at O-2; β-Xyl *p*-3^{II} means β-Xyl *p*-3 branched at O-3; β-Xyl *p*-3^{III} means β-Xyl *p*-3 branched at both O-2, 3 and α-Ara *f*-A^{2X3} means α-arabinofuranose linked to O-2 of Xyl *p*-3, etc.

[a] Measured at 7500 Hz on solutions in D_2O at 25 °C.

[b] The Xyl *p*-1 means xylopyranose residue at reducing end position, etc.

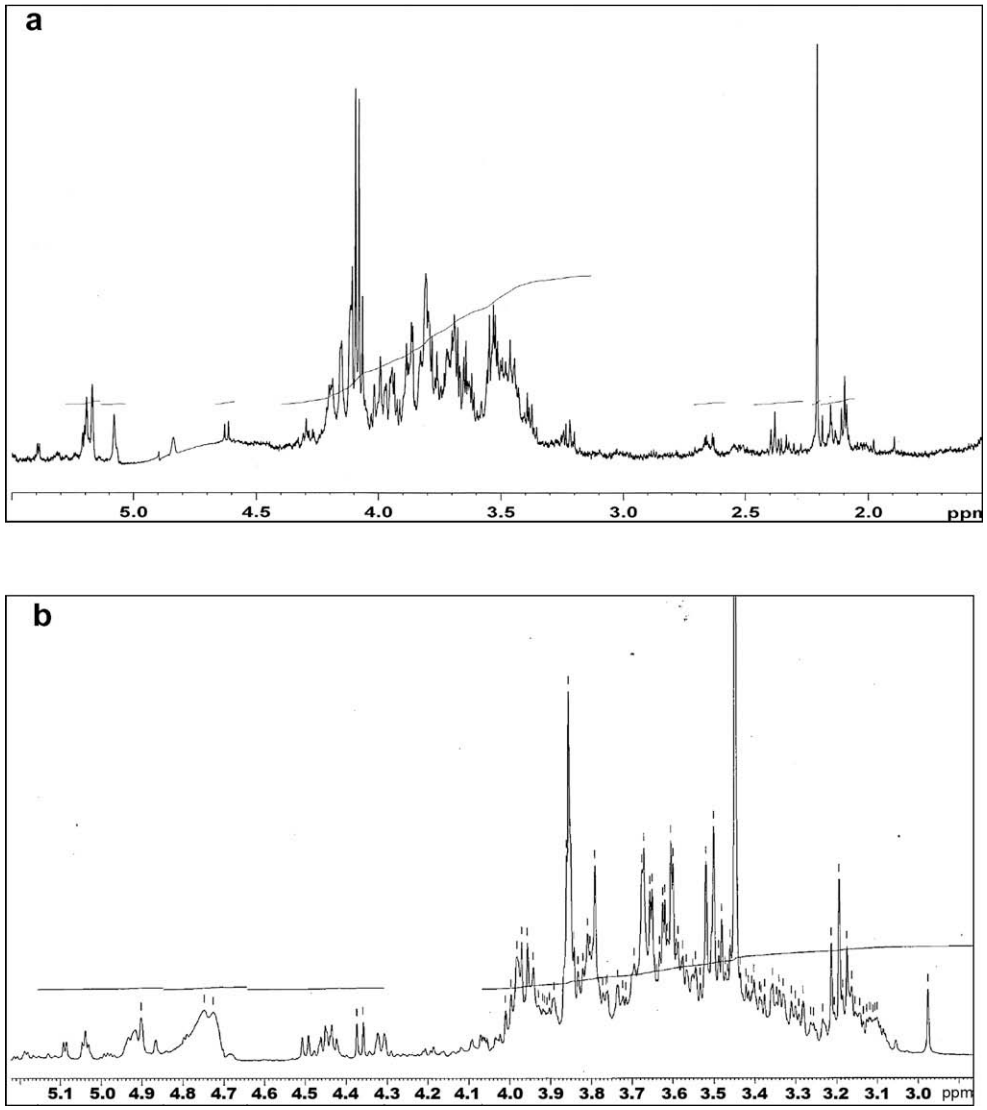


Fig. 1. ^{1}H NMR spectra of purified oligosaccharides: (a) BGO-I and (b) BGO-IV.

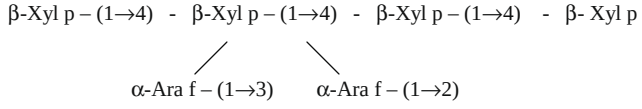
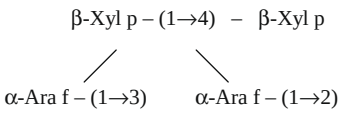
xylopyranose at the reducing end. Signals at δ 4.639 and δ 3.670 ppm represent the disubstituted β-xylopyranose residue which is present at position-3 from reducing end of the oligosaccharide. δ 5.271 ppm indicated that α-arabinose is linked to O-3 of xylopyranose-3 residue from the reducing end (Gruppen et al., 1992). δ 5.225 and δ 3.932 ppm represent α-arabinofuranose linked to O-2 position of 3rd β-xylopyranose residue from the reducing end. ^{1}H NMR signals at δ 4.432 and δ 3.237 ppm represent the fourth unbranched β-xylopyranose residue, which forms the non-reducing end (Harry Gruppen et al., 1992). The ^{1}H NMR data is recorded in Table 1 and the probable structure of WBO-I fraction is as follows:



3.4.4. WBO-III fraction

The ^{1}H NMR spectrum of WBO-III fraction (Fig. 2b), gave a signal around δ 5.194 and δ 3.547 ppm which represents the presence of xylopyranose residue at reducing end. Signals at δ 4.596 and δ 3.689 ppm represent disubstituted xylopyranose-2 residue. Signals around δ 5.246 and δ 4.175 ppm represented that α-arabinofuranose is linked to O-3 position of xylopyranose-2 residue which forms the non-reducing end of the oligosaccharide (Harry Gruppen et al., 1992). The peaks around δ 5.238 and δ 4.151 ppm indicated that the α-arabinofuranose residue, which is linked to O-2 position of xylopyranose-2 residue. The ^{1}H NMR data is recorded in Table 1. Probable structure of WBO-III is given below:



3.5. ESI-MS analysis of purified oligosaccharides

ESI-MS analysis of purified oligosaccharides of BGO-I, BGO-IV, WBO-I and WBO-III gave the molecular ion signals at *m*/*z* 701.3, 437.2, 833.3 and 569.2, respectively (Fig. 3A–D). The xylo-oligosaccharide ions present in the mass spectra were identified as sodium

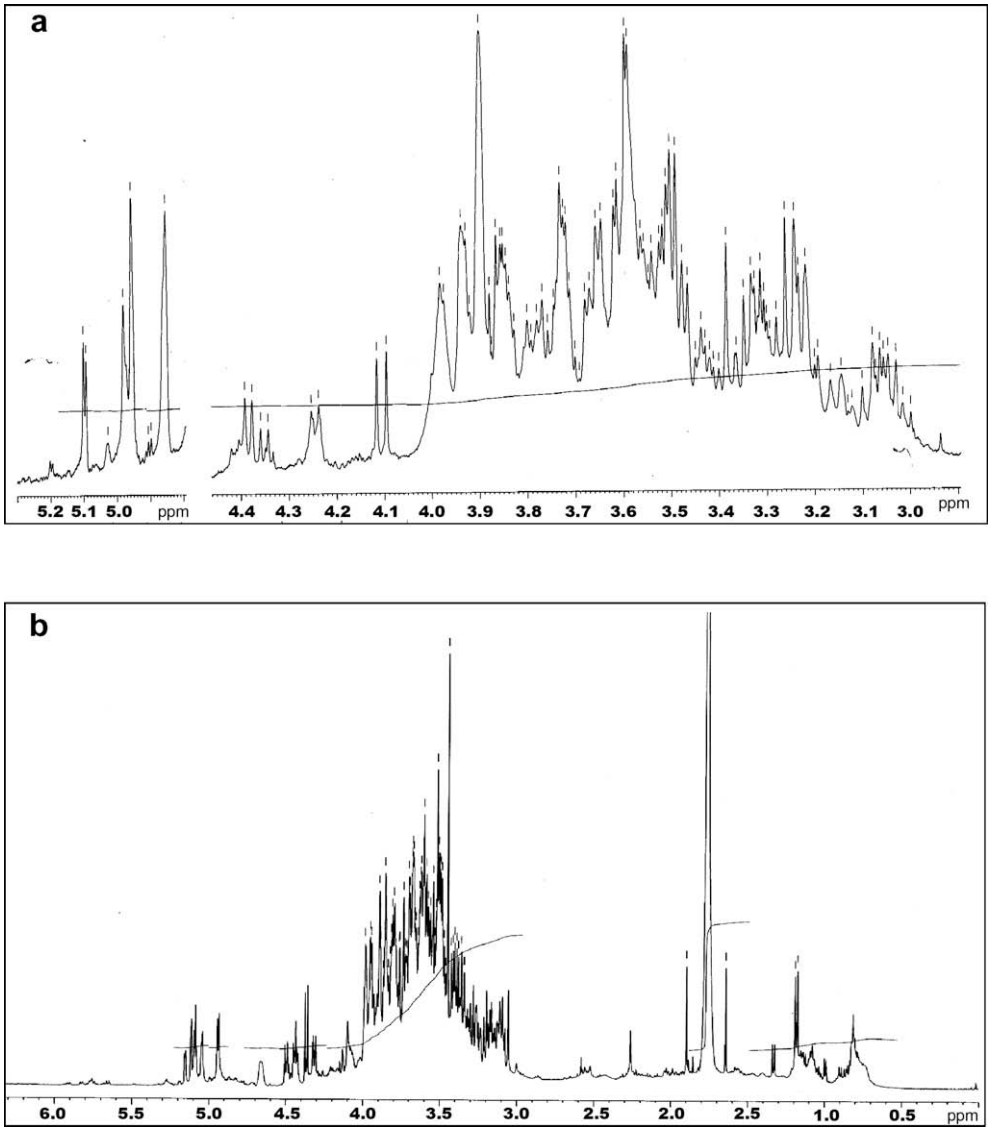


Fig. 2. ^{1}H NMR spectra of purified oligosaccharides: (a) WBO-I and (b) WBO-III.

adducts, $[M+Na]^{+}$ as described by Reis, Coimbra, Domingues, Ferrer-Correia, and Domingues (2002). ESI-MS analysis indicated BGO-I, BGO-IV, WBO-I and WBO-III as pentasaccharide (DP-5), trisaccharide (DP-3), hexasaccharide (DP-6) and tetrasaccharide (DP-4), respectively, varying in their arabinose and xylose ratio as determined by GLC analysis of the purified oligosaccharides (results not shown). These signals can be identified and assigned according to the nomenclature introduced by Domon and Castello (1998). From these spectra it was not possible to obtain information regarding the presence and branching pattern of arabinofuranosyl residues and their possible distribution along the xylopyranose backbone hence the oligosaccharides were taken for ^{1}H NMR analysis to elucidate the same.

3.6. In vitro fermentation of oligosaccharides

The strain of *Bifidobacterium* readily utilised both the WBO and BGO as indicated by increased biomass compared to control. There was a change in broth colour from colourless to deep yellow in all the culture tubes indicating oligosaccharides fermentation by the bacterium. There was an increase in the dry cell mass (0.7–0.9 mg/ml) compared to control value (0.04 mg/ml) (Table 2). Similar increase in the viable cell count was also observed (results not shown). *B. adolescentis* NDRI 236 growth is maximum in WBO-I (O.D. 0.518) followed by WBO-III, BGO-IV and BGO-I. A similar profile of decrease in pH, increase in dry cell mass and production of SCFA were observed (Table 2). There was a decrease in pH of the culture broth compared to control due to the production of SCFA by bifidobacteria. Decrease in pH can be used as an indication of the prebiotic effect of the oligosaccharides incorporated in the culture broth (Berggren, Bjorck, Nyman, & Eggum, 1993). The bacterium produced SCFA in different proportions in all the culture tubes inoculated with oligosaccharides as carbon source. The amount of total SCFA produced varied for individual oligosaccharides. Acetate was the chief SCFA produced and its amount varied from 97.2% to 100% (Table 2) similar results were reported for human faecal bacteria (Karppinen et al., 2000). Acetate, propionate and butyrate are the major SCFA produced during fermentation of carbohydrates in the large bowel. Acetate is mainly metabolized in human muscle, kidney, heart and brain, whereas propionate acts as a possible gluconeogenic precursor suppressing the cholesterol synthesis (Gibson, 1999). Butyrate is known to have pro-differentiation, anti-proliferation and anti-angiogenic effects on colonocytes (Mai & Morris, 2004).

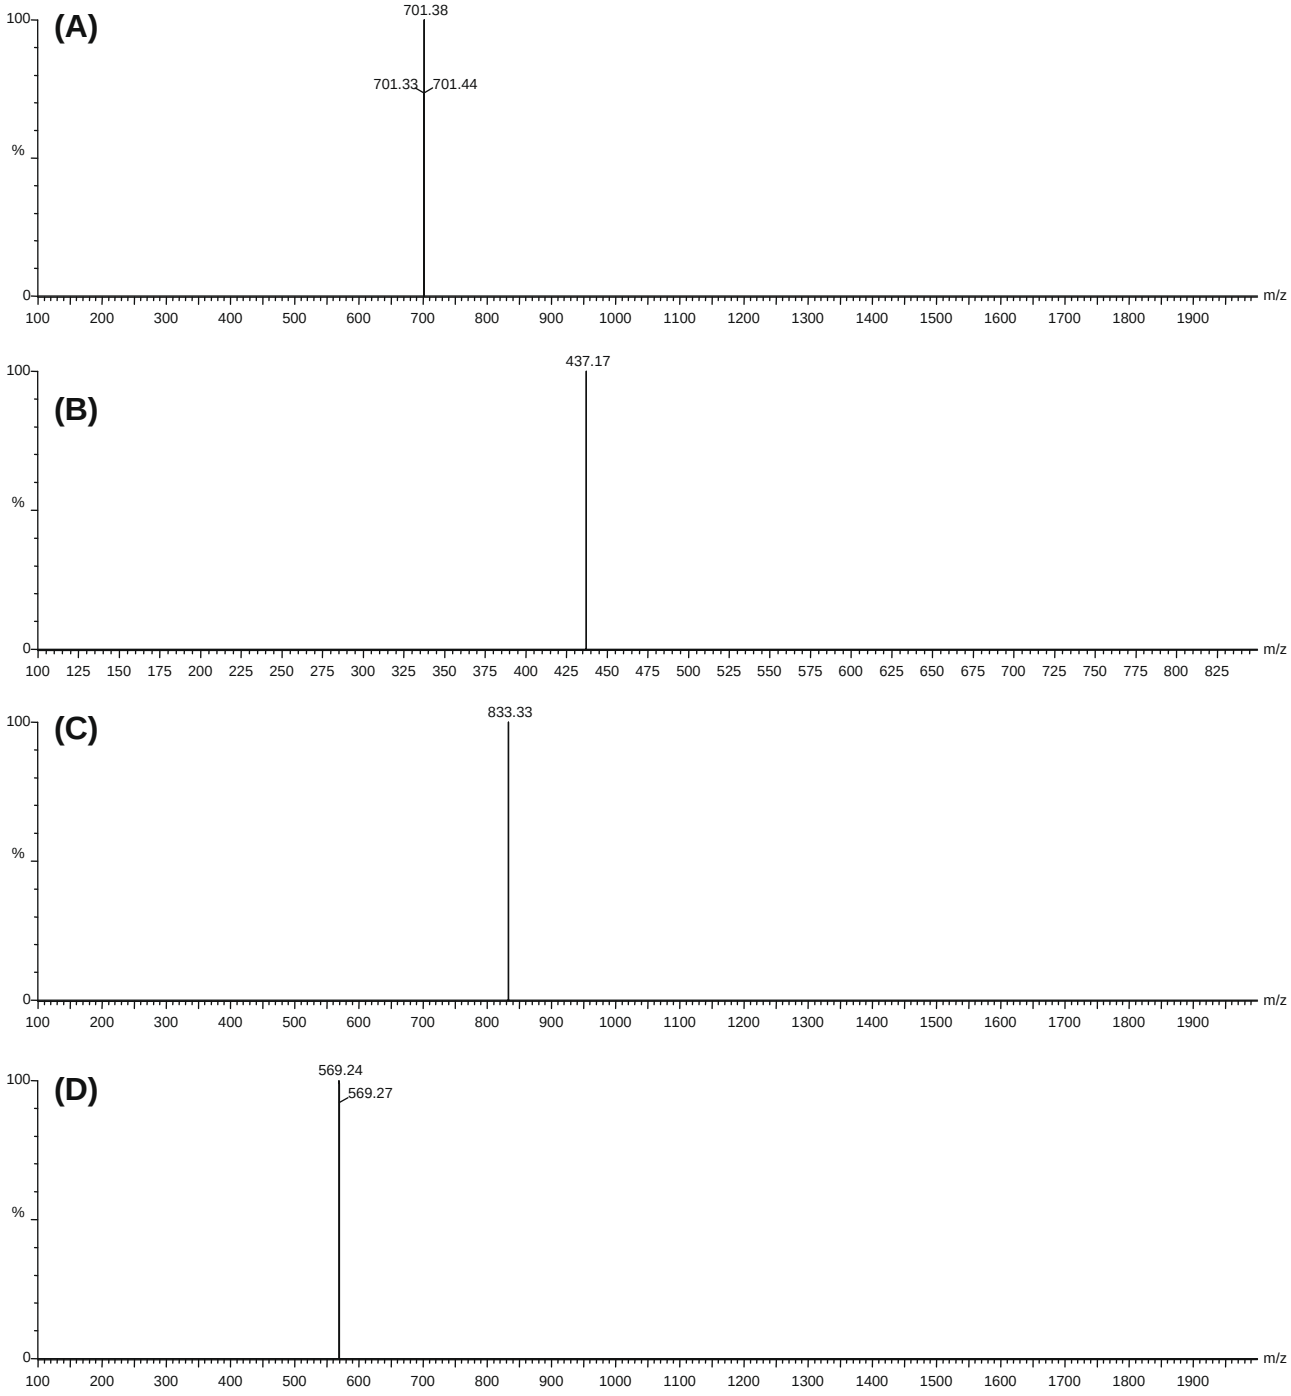

Fig. 3. ESI-MS of purified oligosaccharides: (A) BGO-I; (B) BGO-IV; (C) WBO-I and (D) WBO-III.

Table 2
Growth characteristics of *Bifidobacterium adolescentis* NDRI 236 on 0.25% (w/v) purified oligosaccharides.

Microorganism	Carbon source[a] (0.25%)	Absorbance at 600 nm	pH	Dry cell mass (mg/ml)	SCFA identified		
					Acetate	Propionate	Butyrate
Bifidobacterium adolescentis NDRI 236	Control[b]	0.031	6.65	0.04	–	–	–
	BGO-I	0.405	5.78	0.7	100	–	–
	BGO-IV	0.442	5.19	0.8	98.3	1.7	–
	WBO-I	0.518	5.03	0.9	97.2	1.8	1.0
	WBO-III	0.465	5.62	0.8	98.0	1.3	0.9

Reported values were corrected for the blank tube and baseline values.
[a] Carbon source is purified oligosaccharides incorporated to MRS broth.
[b] Control is culture broth without oligosaccharides and inoculated with microorganism.

Table 3
Enzyme activities (mU/min/ml) in *Bifidobacterium adolescentis* NDRI 236 culture filtrate grown on purified oligosaccharides as carbon source.

Microorganism	Carbon source (0.25%)	Xylanase	Xylosidase	Arabinosidase	α-Galactosidase	β-Galactosidase	Acetyl esterase
Bifidobacterium adolescentis NDRI 236	BGO-I	257.3	53.0	60.8	24.2	6.3	9.2
	BGO-II	268.6	57.5	62.9	27.5	9.6	9.9
	WBO-I	470.0	60.8	70.4	32.4	16.7	13.9
	WBO-III	445.3	59.0	64.8	28.8	13.4	12.2

Reported values were corrected with control values and blank tube values.

3.7. Determination of enzyme activities in the culture broth

The 24 h old cultures showed the presence of various enzyme activities such as xylanase, β-D-xylopyranosidase, α-L-arabinofuranosidase, α-D-galactopyranosidase, β-D-galactopyranosidase and acetyl esterase activities. All the cultures showed maximum xylanase activity. The activities of xylanase, xylopyranosidase and arabinofuranosidase were more compared to the α-D-galactopyranosidase, β-D-galactopyranosidase and acetyl esterase activities (Table 3). The relatively higher activities of xylanase, xylopyranosidase and arabinofuranosidase indicated the breakdown of arabinose and xylose, constituent sugars of xylo-oligosaccharides and subsequent utilisation of them by the bacteria for their growth. Bifidobacteria and lactic acid bacteria are shown to poorly utilise arabinoxylans, but readily utilise arabinoxylan hydrolysates (Jaskari et al., 1998). Arabinofuranosidase has been characterised and a large number of genes/proteins appeared to be specialised for catabolism of a variety of plant oligosaccharides were reported in bifidobacteria (Schley & Field, 2002; Shin, Park, Sung, & Kim, 2003). Xylanase activity is maximum in WBO-I (470 mU) followed by WBO-III (445 mU), BGO-IV (268.6 mU) and BGO-I (257.3 mU) (Table 3). The activity of enzyme xylopyranosidase is maximum in WBO-I (60.8 mU) followed by WBO-III (59.0 mU), BGO-IV (57.5 mU) and BGO-I (53.0 mU) (Table 3). The hydrolytic enzymes produced by the microorganisms help in the digestion of non-digestible oligosaccharides (NDOs) which escape digestion in the upper gastrointestinal tract and produce SCFA resulting in the reduction of pH of the culture broth. Decrease in pH in bowel creates acidic environment, which in turn reduces the number of pathogenic microorganisms (Morisse, Maurice, Boilletot, & Cotte, 1993).

4. Conclusions

In conclusion, the above study indicated that both Bengal gram husk and wheat bran are rich sources of arabinoxylans from which bioactive xylo-oligosaccharides can be obtained by driselase treatment. The purified xylo-oligosaccharides obtained from Bengal gram are penta and trisaccharides whereas from wheat bran they were found to be hexa and tetrasaccharides, respectively with varying ratios of arabinose and xylose. *B. adolescentis* NDRI 236 readily utilised purified oligosaccharides. Purified xylo-oligosaccharides from wheat bran are having much more potential than Bengal gram oligosaccharides as indicated by their prebiotic activity experiments.

Fatty acid

ABSTRACT

The pomfret, *Pampus punctatissimus*, is an important fisheries resource in China, but little is known about its amino acid and fatty acid compositions. Pomfret muscle contained 18.6% crude protein and 4.95% crude fat. Pomfret protein has a well-balanced amino acid composition, with high amounts of glutamic acid (114 mg/g), lysine (82.8 mg/g), leucine (76.7 mg/g), and aspartic acid (76.0 mg/g). Twenty two fatty acids were found in pomfret oil and saturated fatty acids were the most abundant (48.3%). Palmitic acid (16:0) was the dominant fatty acid, followed by oleic acid (18:1), DHA (22:6n-3), myristic acid (14:0) and stearic acid (18:0), with percentages of 30.5, 26.3, 12.2, 7.37 and 6.86, respectively. The ratio of n-3/n-6 polyunsaturated fatty acids (PUFAs) was 8.04; thus, pomfret muscle is rich in n-3 PUFA.

1. Introduction

Muscle tissue of fish is an important source of protein for humans. The amino acid composition is one of the most important nutritional qualities of protein and the amino acid score (AAS; FAO/WHO, 1990) is used to evaluate protein quality world-wide (Iqbal, Khalil, Atgeeq, & Khan, 2006).

The nutritional quality of fish, is to a great extent, associated with its content of essential fatty acids (EFAs). Lipids of marine fish species are generally characterised by low levels of linoleic acid (18:2n6) and linolenic acid (18:3n3) and high levels of long-chain n3 polyunsaturated fatty acids (LC n-3 PUFA; Steffens, 1997). LC n-3 PUFA cannot be synthesised by humans and must be obtained from the diet (Alasalvar, Taylor, Zubcov, Shahidi, & Alexis, 2002). The n-3 fatty acids are essential for neural development in human infants *in utero* and during the first few years after birth (Montaño, Gavino, & Gavino, 2001). Also, n-3 PUFA have beneficial health effects in conditions of hypertension, inflammation, arrhythmias, psoriasis, aggression, depression, coronary heart disease, inflammatory and auto-immune disorders, and cancer (Candela, Astiasarán, & Bello, 1997; Pike, 1999).

The pomfret, *Pampus punctatissimus* (Temminck & Schlegel, 1845), is distributed in saline water along China's coast from the Yellow Sea to the South China Sea, and in Korean and Japanese coastal waters (Liu, Li, & Li, 2002). In 2006, Chinese fisheries of *Pampus spp.* captured almost 4,00,000 metric tons, and the pomfret was one of the main species in these fisheries.

Several papers have reported the compositions of pomfret fish; however, they are all about the silver pomfret *Pampus argenteus* (Chakraborty, Ghosh, & Bhattacharyya, 2005; Osman, Suriah, & Law, 2001). Determining the amino acid and fatty acid profiles of pomfret muscle will improve the nutritional information available to consumers. The objectives of this study were to analyse the amino acid and fatty acid composition of *P. punctatissimus* muscle and to determine its nutritional quality.

2. Materials and methods

2.1. Sample preparation

Fifteen adult pomfrets were caught from the wild in the waters of Zhoushan (30°39°N, 122°11 E), Zhejiang, China. Body length was 17.80–21.50 cm; wet body weight was 229.37–373.52 g. Sample fish were divided into three groups (five fish, each group). Boneless muscles, used for analysis, were collected from the back of the fish, and then mashed. Mashed muscle sample of each group (five fish) was mixed and stored in a plastic bag, and then kept in refrigerator at −20 °C.

2.2. Proximate composition analyses

Moisture content was determined by drying sample in an oven at 105 °C until a constant weight was obtained (AOAC, 1990).

doi:10.1016/j.foodchem.2009.04.110

Crude protein content was determined by the Kjeldahl method (AOAC, 1990), and a conversion factor of 6.25 was used to convert total nitrogen to crude protein. Fat was determined by using the Soxhlet extraction method (AOAC, 1990). Ash was determined by incineration in a muffle furnace at 550 °C for 24 h (AOAC, 1990).

2.3. Amino acid analyses

Amino acid content of samples was measured according to the GB/T14965-1994 in China: the sample was hydrolysed for 22 h at 110 °C with 6 M HCl in sealed glass tubes filled with nitrogen. The hydrolysed samples were taken, and the amino acid concentration was diluted to 50 nM with 0.2 N sodium citrate buffer, pH 2.2. The pH-adjusted samples were analysed by a Biochrom 20 Automatic Amino Acid Analyzer (GE, USA). The content of tryptophan was determined by the colorimetric method of Basha and Roberts (1977) after alkaline hydrolysis of each sample. All determinations were performed in triplicate.

2.4. Amino acid score

Essential amino acid score was calculated with respect to the FAO/WHO reference amino acid pattern of the pre-school child (age, 2–5 year; FAO/WHO/UNU, 1985).

$$\text{Amino acid score} = \text{Sample amino acid}/\text{Reference amino acid} \times 100$$

2.5. Fatty acid analyses

Fatty acids were extracted and fatty acid methyl esters (FAMEs) were prepared according to the ISO5509 method (ISO, 2000): first, Soxhlet extraction, and then, saponification, followed by esterification, and finally, extraction of FAMEs in hexane. FAMEs were subsequently analysed by capillary gas chromatography (column: 30 m × 0.25 mm I.D., 0.5 μm film thickness; Supelco. Flame ionisation detected temperature at 210 °C; carrier gas N_2 at 1.0 ml/min; injector temperature at 210 °C; oven temperature programmed from 180 to 250 °C) using an Agilent 6890 capillary gas chromatograph. Quantitative data were calculated using the peak area ratio (% total fatty acids).

3. Results and discussion

3.1. Proximate composition

The proximate composition of the pomfret is shown in Table 1. Crude protein, crude fat and crude ash contents of the pomfret muscle were 18.59%, 4.95% and 1.36%, respectively.

The crude fat content was higher than the amount found in silver pomfret, *P. argenteus* (Chakraborty et al., 2005; Osman et al., 2001). Based on the moisture and fat contents, the pomfret is a medium-fat fish, with a fat content of 5–10% by weight (Bennion, 1997). According to Feeley, Criner, and Watt (1972), low-fat fish have higher water contents, and as a result, their flesh is white in colour. Fatty fish store the fat in muscle tissue, and their flesh is yellow, grey, pink or another colour (Gurr, 1992). Fat content is influenced by species, season, geographical regions, age and maturity (Piggot & Tucker, 1990).

Table 1
Proximate composition of pomfret muscle.

	Moisture (%)[a]	Crude protein (%)[a]	Crude fat (%)[a]	Crude ash (%)[a]
Mean	75.35	18.6	4.95	1.36
SD	0.32	0.38	0.12	0.02

[a] Percentage of total wet weight.

3.2. Amino acid composition

The amino acid composition of pomfret muscle is shown in Table 2. Pomfret protein contained a high amount of glutamic acid (114 mg/g of crude protein), followed by lysine, leucine aspartic acid, arginine, valine, alanine in decreasing amounts.

Over the past 20 years, increasing evidence suggests the importance of glutamine in the function of many organ systems (Christina, Palmer, & Griffiths, 1999). Glutamine is the most abundant free amino acid in the body, comprising nearly 60% of the free intracellular amino acids in skeletal muscle. The efflux of glutamine from muscle in critical illness serves as an important carrier of ammonia (nitrogen) to the splanchnic area and the immune system (Deutz, Reijven, Athanasas, & Soeters, 1992). As a donor of nitrogen in the synthesis of purines and pyrimidines, glutamine is essential for the proliferation of cells.

Pomfret protein is also rich in lysine, which is the limiting amino acid in cereal-based diets of children in developing countries (Iqtidar & Khalil, 1995; Kim & Lall, 2000). Taurine, a sulfonated β-amino acid derived from methionine and cysteine metabolism, is not utilised in protein synthesis, but is found either as a free amino acid or in simple peptides (Jacobsen & Smith, 1968). Taurine plays a pivotal role in numerous physiological functions of human infants (Redmond, Stapleton, Neary, & Bouchier-Hayes, 1998; Stapleton, O'Flaherty, Redmond, & Bouchier-Hayes, 1998).

Table 2
Amino acid composition of pomfret muscle.

Amino acid	Content (% DW) Mean ± SD	Content (mg/g crude protein)
Taurine	0.11 ± 0.06	1.46
Serine	2.81 ± 0.06	37.2
Tyrosine	2.64 ± 0.29	35.0
Proline	1.92 ± 0.17	25.5
Aspartic acid	5.73 ± 0.07	76.0
Glutamic acid	8.61 ± 0.05	114

	∑PUFAn-6	2.13 ± 0.15	∑PUFAn-6/∑PUFAn-3	0.12

[a] Percentage of total fatty acids.

Amino acid scores are summarised in Table 3. When compared to the reference amino acid pattern of pre-school children (2–5 years old), all of the amino acid scores were >100, except for sulphur-containing amino acids (cysteine and methionine). According to the amino acid score, the amount of S-containing amino acids (cysteine and methionine) was the lowest amongst amino acids in pomfret. However, in this study, cysteine was totally lost when the muscle tissue was hydrolysed without performing acid oxidation; thus, the correct S-containing amino acid score would likely exceed 100. The protein in pomfret muscle was well-balanced in essential amino acid composition and is of high quality.

3.3. Fatty acid composition

Fatty acid composition is shown in Table 4. The fatty acid profile of the pomfret was dominated by saturated fatty acids (SFAs), which comprised about half (48.3%) of the total fatty acids. The SFA contents are similar to those published for silver pomfret (Chakraborty et al., 2005). Among the SFAs, palmitic acid (16:0) was the dominant saturated amino acid, accounting for 30.3% of the total fatty acids. Myristic acid (14:0) and stearic acid (18:0) were also abundant. Monounsaturated fatty acids (MUFAs) and polyunsaturated fatty acids (PUFAs) accounted for 32.5% of the total fatty acids and 19.3% of the total fatty acids, respectively. The main monounsaturated fatty acid was oleic acid (18:1), accounting for 26.3% of the total fatty acids, followed by palmitoleic acid (5.22%). The dominant PUFA was DHA (22:6n-3), accounting for 12.2% of the total fatty acids, followed by EPA (20:5n-3), AA (20:4n-6), LA (18:2n-6) and ALA (18:3n-3). However, except for EPA (4.47%), all of these three fatty acids were present in minor amounts (0.47–1.12%).

DHA and EPA prevent human coronary artery disease (Leaf & Webber, 1988). Bowman and Rand (1980) reported that AA is a precursor for prostaglandin and thromboxan, which influences clotting of blood and the healing process. Apart from this function, AA also plays a role in growth. Therefore, fish have been suggested as a key component for a healthy diet of humans (Abd Rahman, The, Osman, & Daud, 1995).

The n-3 and n-6 PUFAs of the pomfret accounted for 17.1% and 2.13% of the total fatty acids, respectively, and the ratio of n-3/n-6 was 8.04, which was greater than the values reported by Osman et al. (2001) for silver pomfret. As normal diets have lower amounts of n-3 fatty acids than n-6 fatty acids, a dietary intake of fish with a high ratio of n-3/n-6 would be beneficial. The n-3/n-6 ratio is a good index for comparing relative nutritional value of fish oils of different species, and a higher ratio of n-3/n-6 PUFAs has often been cited as an index of high nutritional value. The ratio of n-6/n-3 PUFAs found in this study was lower than the value (4.0 at maximum) recommended by the UK Department of Health (HMSO, 1994). Values higher than the maximum are harmful to health and may promote cardiovascular disease (Moreira, Visentainer, de Souza, & Matsushita, 2001).

Compared with the silver pomfret and other marine fish (Osman et al., 2001), the pomfret had higher amounts of SFAs and MUFAs, but lower amounts of PUFAs. Differences in fatty acids of fishes are based on their diet (Sargent, Bell, Bell, Henderson, & Tocher, 1995), and are also affected by size, age, reproductive conditions, and environmental conditions, especially water temperature, which can influence lipid content and fatty acid composition (Saito, Yamashiro, Alasalvar, & Konno, 1999).

In summary, pomfret muscle is a high quality protein source with a well-balanced composition of essential amino acids. With a n-3/n-6 PUFAs value of 8.04, it is also rich in n-3 PUFA.

ABSTRACT

Four new compounds, a noreudesmanolide (**1**), a guaianolide (**4**), and acetylenes (**7**–**8**), together with 16 other known compounds, were isolated from *Ajania przewalskii*. The novel sesquiterpenolide (**1**) possesses a rare carbon skeleton. Acetylation of **1** gave **1a**. New compounds were elucidated as 1β-hydroxyl-2-noreudesm-4(15)-en-5α,6β,7α,11αH-12,6-olide (**1**), 1β-acetoxyoxyl-2-noreudesm-4(15)-en-5α,6β,7α,11αH-12,6-olide (**1a**), 8α-angeloyloxyl-3α,4α-dihydroxyguaia-1,9,11(13)-trien-6,12-olide (**4**), (E)-3β,4α-dihydroxyl-2-(2′,4′-hexadiynylidene)-1,6-dioxaspiro[4,5]decane (**7**) and 2-hydroxyl-2-[(E)-1α,2β,3-trihydroxyl-3-nonaene-5,7-diyne]-4H-pyran (**8**), by chemical and spectroscopic methods, including HRESIMS, 1D and 2D NMR. Cytotoxicity of nine compounds was assessed by their effects on selected cancer cell lines, K562, K562/ADM, BGC-823, and Hep-G2 cells. Phenolic acid **12** exhibited strong activity against K562 and K562/ADM cells and sesquiterpenolide **3** strong activity against K562/ADM cells. Radical-scavenging activities of 12 compounds, the mixed solvent extract (petrol ether–ether–methanol = 1:1:1), and the *n*-butanol extract were determined by ABTS and DPPH radical-scavenging assays. Phenols and coumarins (**11**–**16**), MSE, and *n*-BE displayed significant antioxidation (IC_{50} < 20 μg/ml).

1. Introduction

The genus *Ajania*, belonging to the family *Asteraceae*, includes around 28 species that are distributed over central and south Asia, China, and Japan. Most of them are widespread in the northwest of China. Some species of the genus have long been used as Chinese traditional folk medicines for treatments of intestinal ulcers, bronchitis, lung diseases, and rheumatism (Editorial Committee for Flora of the Chinese Academy of Science, 1983). So far, four species, *A. achilloides*, *A. fastigiata*, *A. fruticulosa*, and *A. przewalskii*, have been chemically investigated. Guaianolides, eudesmanolides, glaucolides, and phenolic constituents were isolated from *A. achilloides* (Belenovskaya & Markova, 1979; Zdero, Bohlmann, & Huneck, 1990). Guaianolides and flavonoids were isolated from *A. fastigiata* (Chumbalov, Glyzin, & Zhubaeva, 1974; Yusupov, Kasimov, & Abdullaev, 1982). Guaianolides, eudesmanolides, germacranolides, and flavonoids were isolated from *A. fruticulosa*. The guaianolides from this plant possess antifungal activity and have been used to inhibit the growth of *Candida albican*. Additionally, the flavonols have xanthine oxidase inhibitory activities (Adekenov et al., 1998; Li et al., 1999; Meng, Hu, Chen, & Tan, 2001). Lignans, flavonoids and phenolic compounds were isolated from *A. pzewalskii* Poljakov in our previous phytochemical investigation (Zhang, He, & Zhu, 2006).

In conjunction with our continuing interests in the chemical constituents of *A. przewalskii*, we further isolated four new compounds (**1**, **4**, **7**–**8**) and 16 known constituents: three eudesmane lactones (**1**–**3**), a highly oxygenated guaiane lactone (**4**), a bisabolene sesquiterpene (**5**), a monoterpene (**6**), five acetylenes (**7**–**10**), three phenylpropanoids (**11**–**13**), a phenolic glycoside (**14**), and six coumarins (**15**–**20**) by extraction with a mixed solvent (petrol ether–ether–methanol = 1:1:1) and by extraction with ethanol from *A. przewalskii* (Fig. 1). The structures of four new compounds were identified by chemical and spectroscopic methods, especially HRESIMS, ^1H–^1H COSY, HMQC, HMBC and 1D NOE experiments. The carbon skeleton of noreudesmanolide **1**, which was named Ajaniaolide A, was found to be rare and novel. Acetylation of **1** gave **1a**, further confirming the structure of **1**.

The cytotoxicity of compounds, **3**, **5**, **6**, **9**, **11**–**13**, **16**, and **18**, was evaluated by assessing their effects on the human erythroleukemia adriamycin-resistant subline (K562/ADM), compounds **9**, **11**–**13**, **16**, and **18** on the human erythroleukemia (K562), **3**, **5**, and **6** on the human stomach carcinoma (BGC-823), and **9**, **16**, and **18** on human hepatoma (Hep-G2) cell lines. Among them, sesquiterpene **3** exhibits strong activities against K562/ADM cell lines (IC_{50} 11.1 for 48 h and 13.1 μg/ml for 72 h) and phenolic acid **12** exhibits strong activities against K562 and K562/ADM cell lines (IC_{50} of 5.57 for 48 h and 0.78 μg/ml for 72 h on K562; 7.25 for 48 h and 3.29 μg/ml for 72 h on K562/ADM). Compounds **3**, **6**, **9**, and **11**–**19**, the mixed solvent extract (petrol ether–ether–methanol = 1:1:1, MSE), and the *n*-butanol extract (*n*-BE) were tested

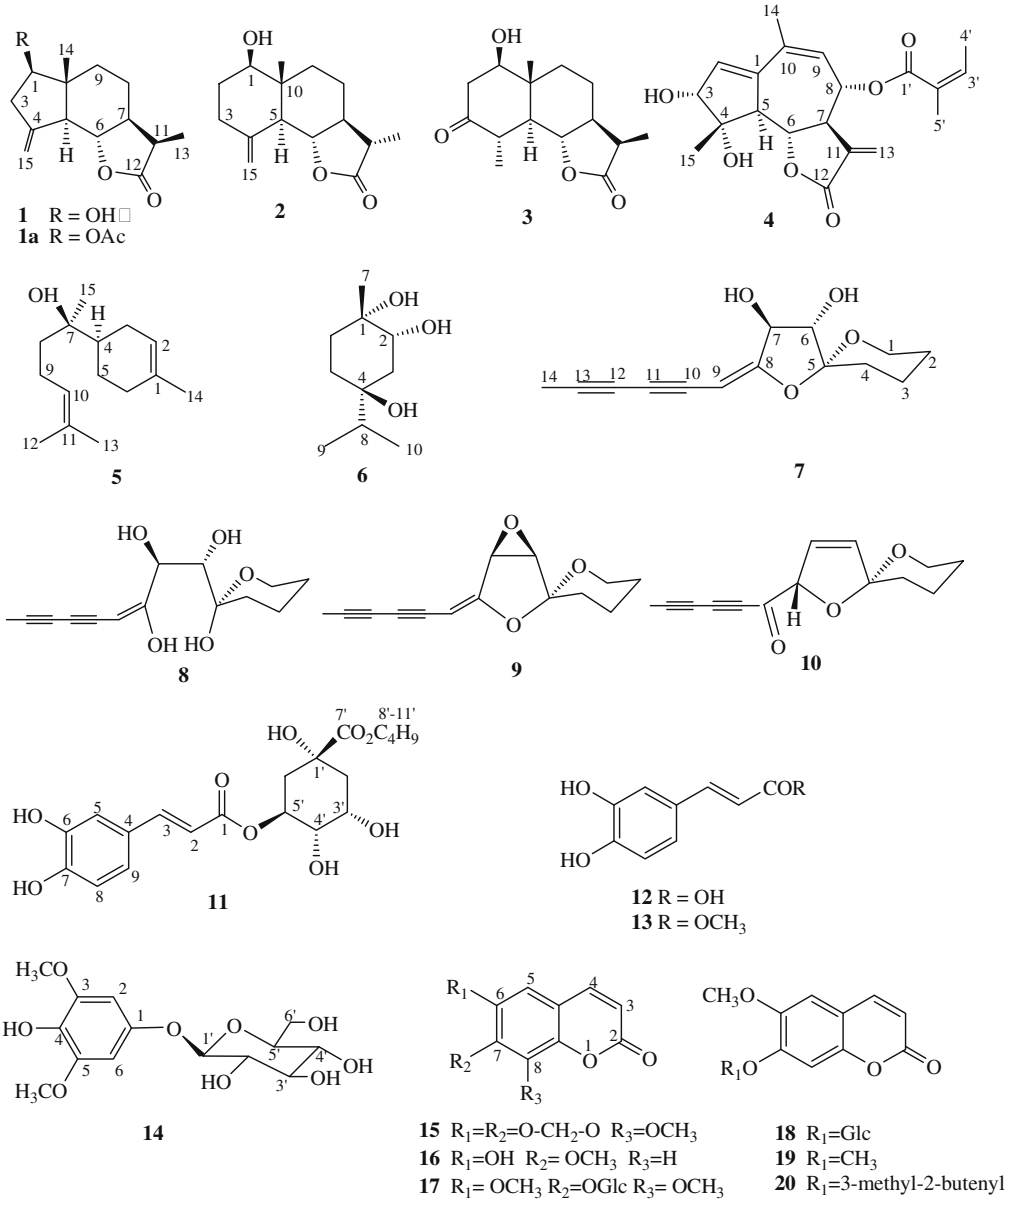

Fig. 1. The structures of compounds isolated from *A. przewalskii*.

by ABTS radical-scavenging assays, as well as six compounds, **3**, **11**, **13**–**15**, **17**, and **19** by DPPH radical-scavenging assays. The results indicated that phenols and coumarins (**11**–**16**), MSE, and *n*-BE display significant antioxidant activity (IC_{50}<20 μg/ml), especially, and phenolic compounds **12**, **13**, and coumarin **16** are strong antioxidants (IC_{50} of 2.83, 3.38 and 2.83 μg/ml by ABTS). Phenolic acid **12** shows, not only strong cytotoxic activity against K562 and K562/ADM cell lines, but also strong antioxidant activity.

2. Materials and methods

2.1. General methods

Melting points were measured on an uncorrected Koffler hot plate. Optical rotations were measured at 20 °C, in chloroform on a Perkin-Elmer Model 341 polarimeter. UV spectra were obtained on a Shimadzu UV-260 spectrophotometer. IR spectra were recorded on a Nicolet 170SX FT-IR instrument or Avatar 360 FT-IR over the range of 400–4000 cm^{-1}. EIMS data were obtained as measured on an HP5988 or a VG-ZAB-HS by a direct inlet at 70 ev and HRESIMS data were obtained on a Bruker Daltanics APEX II FT-ICR spectrometer. NMR spectra were recorded on a Varian MercuryPlus-300/400BB NMR spectrometer using TMS as an internal standard in chloroform-d_1, dimethyl sulfoxide-d_6 (DMSO-d_6), acetone-d_6 or deuterium oxide (D_2O). Column chromatography was carried out on Si gel (200–300 mesh and Type 60) and TLC on Si gel (GF_{254}, 10–40 μm), both supplied by Qingdao Marine Chemical Co.

2.2. Plant material

The whole plant of *A. przewalskii* was collected in Qinghai province, China in 2001, and identified by Professor Yao-Jia Zhang, the college of Life Science from Lanzhou University. A voucher specimen (Ap20010801) is preserved at the State Key Laboratory of Applied Organic Chemistry, Lanzhou University.

2.3. Extraction and isolation

The dried and powdered whole plants of *A. przewalskii* (6 kg) were extracted at room temperature by the mixed solvent of petrol ether (PE)–ether–methanol (1:1:1, v:v:v), three times, each using 20 l of the solvent for 4 days. The extracts were firstly concentrated under reduced pressure and then filtered. They afforded 220 g of the crude residue. The whole plants were again extracted by ethanol three times at room temperature (each 18 l, 3 days) to give 215 g of the residue. About 160 g of the mixed solvent crude residue were subjected to silica gel column chromatography (CC) using PE-acetone (1:0–0:1) to give 11 fractions, which were further isolated and purified. The ethanol extract was suspended in water (1.5 l) and then successively extracted with chloroform, ethyl acetate, and *n*-butanol. After concentration of the ethyl acetate-soluble fraction and *n*-butanol-soluble fraction, the ethyl acetate-soluble fraction (40 g) and the *n*-butanol-soluble fraction (42 g) were each subjected to silica gel CC. Isolation details are depicted in Fig. 2. In particular, the percentage values are the ratio of each compound's weight over the total weight of the air dried whole plant (6 kg).

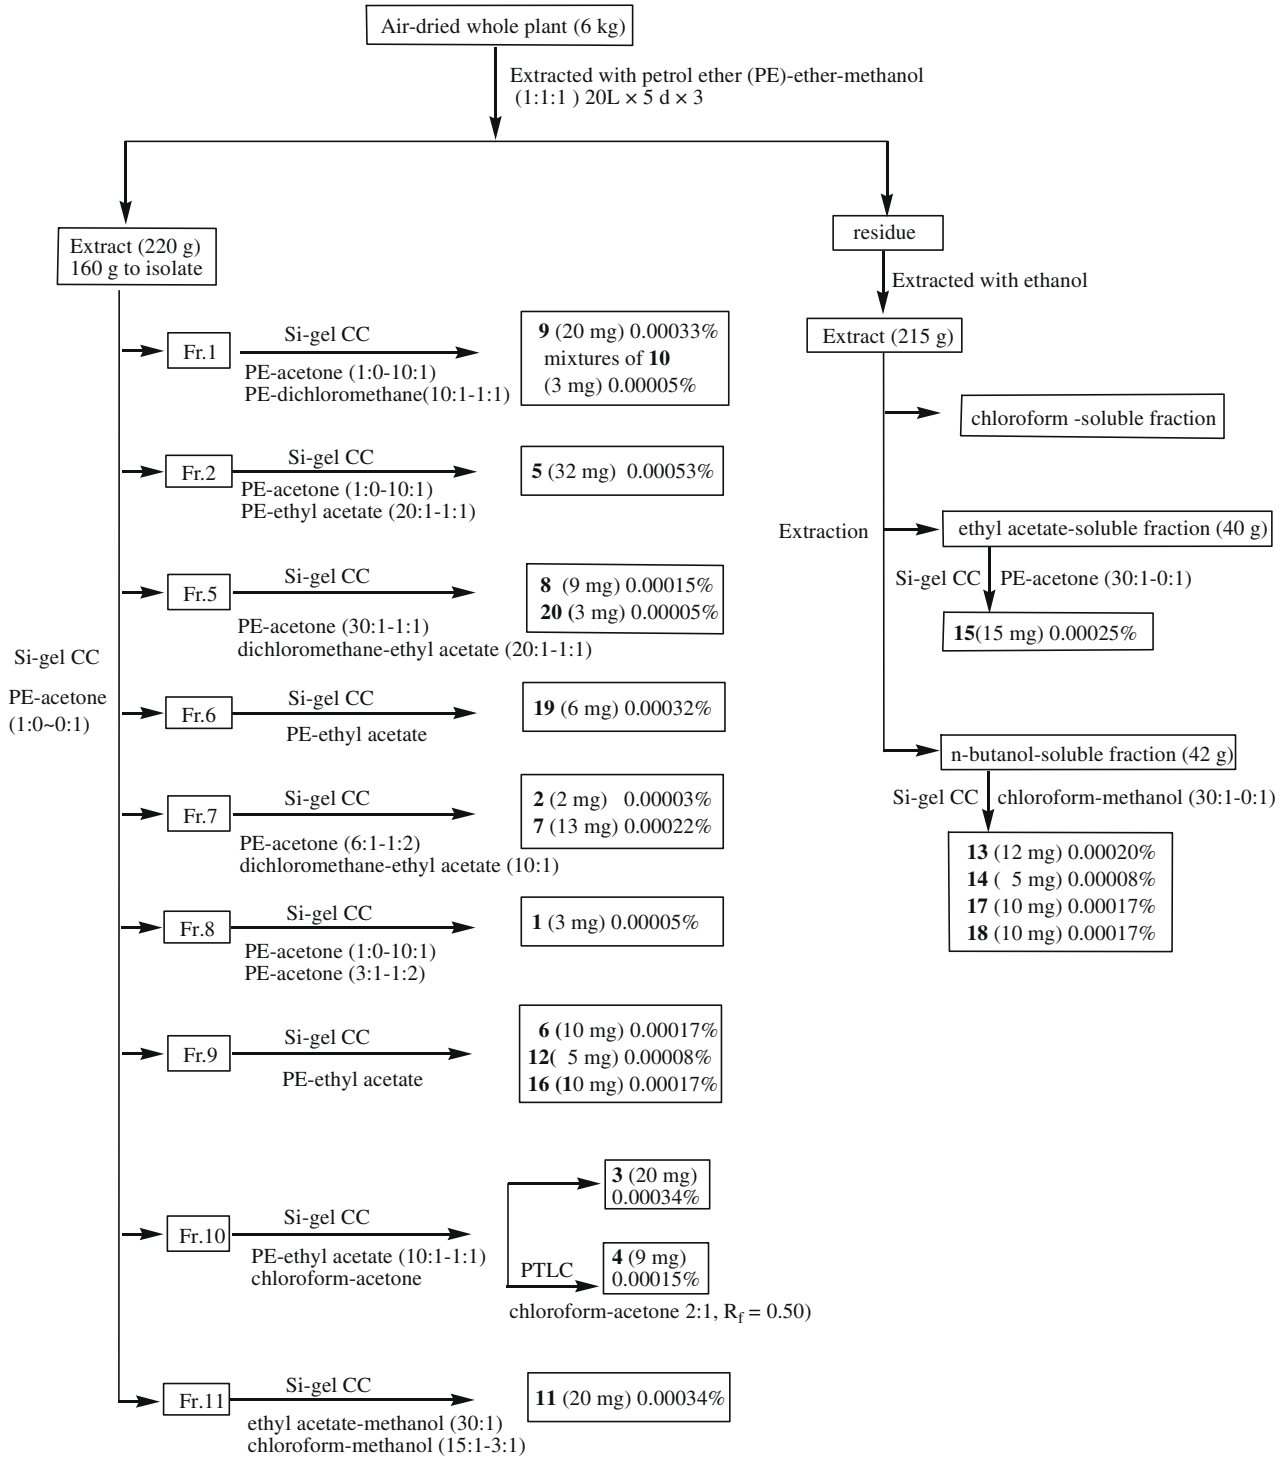

Fig. 2. Isolation scheme for *A. przewalskii*; the percentage values are the ratios of each compound's weight over the total weight of the whole plant (6 kg).

2.4. Acetylation of compound **1**

Four milligrammes of **1** were acetylated with a mixture (1:1) of Ac_2O in pyridine. The solution was allowed to stand overnight at room temperature. After the usual work-up, pure compound **1a** was obtained.

2.5. Cytotoxic assay

The cytotoxicity of the tested compounds was determined using the [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] (MTT) colorimetric assay, as previously reported (Hussain, Nouri, & Oliver, 1993). A stock solution of a compound under study was prepared by dissolving it in dimethyl sulfoxide. It was diluted to a working solution before usage and the final dimethyl sulfoxide concentration was 0.1% v/v. Logarithmically growing K562 cells, containing 2×10^8 cells/l, K562/ADM cells, containing 2×10^8 cells/l, BGC-823 cells, containing 1×10^8 cells/l, and Hep-G2 cells, containing 1×10^8 cells/l, were seeded in 96-well flat-microtitre plates (NUNC, Nunclon, Nagle, Denmark). After 24 h of incubation, the cells were treated with the tested samples at various concentrations (0, 10, 50, 100 and 200 μg/ml). Samples were grown in a humidified atmosphere at 37 °C in 5% CO_2 for 48 to 72 h. Parallel controls were performed in deionized water with the same dimethyl sulfoxide concentration. Three replicate wells were used for each point measurement. 10 μl of a MTT solution (5 mg/ml in PBS) were added to each well and then incubated for 4 h before the termination of culture. Then 100 μl of extraction buffer (10% SDS with 0.01 M HCl) were added to each well. After an overnight incubation at 37 °C, the absorbance was measured at a wavelength of 570 nm, using a microplate reader (Power Wave X200, Bio-TEK, USA) for calculating the inhibition rate (IR) of the cell proliferation. The IC_{50} value was defined as the concentration of sample which reduced absorbance by 50% relative to the vehicle-treated control. The cytotoxicity (IR) of a compound was calculated as

$$IR(\%) = [(A_{570} \text{ of untreated cells} - A_{570} \text{ of treated cells})/A_{570} \text{ of untreated cells}] \times 100\%.$$

By their structural features, the tested compounds **11–13** are strong antioxidants and can reduce MTT, whose cytotoxicity was not determined by MTT methods. Therefore the treated cells viability were observed by trypan blue dye exclusion, then counted by microscopy.

2.6. Antioxidant capacity assay

2.6.1. Chemicals

ABTS (2,2′-azino-bis(3-ethylbenzo-thiazoline-6-sulphonic acid) diammonium salt, 98%), BHA (butylated hydroxy anisole, 90%), DPPH· (2,2′-diphenyl-1-picrylhydrazyl, 90%), and trolox (6- hydroxy-2,5,7,8-tetramethylchroman-2-carboxylicacid, 97%) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). All other chemicals and solvents were of analytical grade.

2.6.2. ABTS free radical-scavenging assay

The antioxidant capacity of the tested samples, to scavenge ABTS radical cation ($ABTS^{\cdot+}$), was measured by using a method previously reported (Re et al., 1999; Van den Berg, Haenen, Van den Berg, & Bast, 1999). $ABTS^{\cdot+}$ was generated by the reaction of a 7 mM aqueous solution of ABTS with a 2.45 mM aqueous solution of $K_2S_2O_8$ (final concentration), kept in the dark at room temperature for 16 h before use. The $ABTS^{\cdot+}$ solution was diluted with ethanol and phosphate buffered saline (PBS), pH 7.4, to an absorbance of 0.70 (±/0.02) at 734 nm and equilibrated at 30 °C. About 50 μl of an ethanolic solution of each sample were mixed with an ethanolic solution of $ABTS^{\cdot+}$ (2 ml). The vitamin E analogue, trolox, was used as a positive control. The optical density of the mixture was determined in comparison with $ABTS^{\cdot+}$ solution and pure ethanol. All testing samples were replicated at least three times. The scavenging ability of antioxidant was calculated, based on the following equation:

$$\text{Inhibition } (\%) = [A_0 - (A_t - B)]/A_0 \times 100\% \quad (t = 6 \text{ min})$$

where A_0 is the absorbance of the $ABTS^{\cdot+}$ solution without adding sample and A_t is the absorbance of sample after acting with $ABTS^{\cdot+}$ solution for 6 min, and B is the absorbance of the sample solution. IC_{50} values, which represented the concentration of samples that caused 50% neutralisation of $ABTS^{\cdot+}$ radicals, were calculated from the plot of inhibition percentage against concentration of the samples.

2.6.3. DPPH free radical-scavenging assay

The ability of the tested samples to scavenge DPPH stable radicals was measured by using the method previously reported (Von Gadow, Joubert, & Hansmann, 1997). Various concentrations of the samples were made, from 2.5 to 50.0 μg ml^{-1}. About 50 μl of an ethanol solution of each sample were mixed with 2 ml of 60 μM DPPH solution and made up with ethanol solution, to a final volume of 4 ml. The absorbances of the resulting solutions and the blank were recorded after 1 h at room temperature. The optical density of the mixture was determined in comparison with DPPH radical solution and pure ethanol. Ethanol was used to zero the spectrophotometer. Two reference antioxidants (BHA and trolox) were used as positive controls and standards for the evaluation of the antioxidant power of the tested samples. For each sample, three replicates were recorded. The disappearance of DPPH· was read spectrophotometrically at 515 nm using a spectrophotometer (Unico WFZ UV-2000, Tokyo, Japan). The inhibition percentage of the DPPH radical by the samples was calculated using the following equation:

$$\text{Inhibition } (\%) = [(A_0 - A_t)/A_0] \times 100\%$$

where A_0 is the absorbance of the DPPH radical solution without adding sample and A_t is the absorbance of sample after reacting with DPPH radical solution for 20 min. IC_{50} values, which represented the concentrations of samples that caused 50% neutralisation of DPPH radicals, were calculated from the plot of inhibition percentage against concentration of the samples.

2.7. Characteristic data of compounds

1β-Hydroxyl-2-noreudesm-4(15)-en-5α,6β,7α,11αH-12,6-olide (**1**). Colourless oil; $[\alpha]_D^{20} + 63$ (*c* 0.31, chloroform); HRESIMS *m/z*: 259.1306 (calcd. for $C_{14}H_{20}O_3 + Na^+$, 259.1305); IR (film) λ_{max}: 3390, 2929, 2859, 1773, 1652, 1121, 1065, 1038 and 1006 cm^{-1}; EIMS *m/z* (rel int): 236 (7) $[M]^+$, 218(9) $[M-18]^+$, 165 (44), 121 (18), 109 (31), 91 (47) and 55 (100); ^1H NMR see Table 1 and ^{13}C NMR (DEPT) see Table 2.

1β-Acetoxyoxyl-2-noreudesm-4(15)-en-5α,6β,7α,11αH-12,6-olide (**1a**). Colourless gum, $[\alpha]_D^{20} + 13$ (*c* 0.27, chloroform); UV (chloroform, log ε): λ_{max} 242 (0.37) nm; ^1H NMR see Table 1.

8α-Angeloyloxyl-3α,4α-dihydroxyguaia-1,9,11(13)-trien-6,12-olide (**4**). Colourless oil, $[\alpha]_D^{20} + 66$ (*c* 0.9, $CHCl_3$); HRESIMS: 378.1907 (calcd. for $C_{20}H_{24}O_6 + NH_4^+$, 378.1911); UV (chloroform, log ε): λ_{max} 244 (1.18) nm; IR (film) λ_{max}: 3422, 2926, 1770, 1712, 1647, 1455, 1379, 1361, 1228, 1146, 1038 and 961 cm^{-1}; EIMS *m/z* (rel int): 260 (4) $[M-AngOH]^+$, 99 (2), 100 (3), 83 (84), 55 (74) and 43 (100); ^1H NMR and ^{13}C NMR (DEPT) see Table 3.

1*S*,2*R*,4*S*-trihydroxyl-*p*-methane (**6**). NMR (acetone-d_6, 300 MHz): 3.5 (1H, brs, H-2), 3.0 (3H, brs, OH), 1.94 (dq, 14.2, 6.0, H-8), 1.85 (dd, 12.9, 3.6, H-3a), 1.58 (dd, 11.7, 5.7, H-3b),

3. Results and discussion

3.1. Phytochemical investigation

Compound **1** was obtained as a colourless oil. The molecular formula was established as $C_{14}H_{20}O_3$ by HR ESI MS, which showed a quasimolecular ion peak $[M+Na]^+$ at *m/z* 259.1306 (calcd. 259.1305). The EIMS peaks at *m/z* 236 $[M]^+$ and 218 $[M-H_2O]^+$ suggested the presence of a hydroxyl group. IR spectrum showed the absorption bands for hydroxyl (3390 cm^{-1}), γ-lactone (1773 cm^{-1}), and terminal olefinic (1652, 917 and 891 cm^{-1}) groups. The ^{13}C NMR spectrum of **1** showed 14 carbon signals which are assigned to two methyls, four methylenes, five methines, and three quaternary carbons (Table 2). ^{1}H and ^{13}C NMR spectra showed the characteristic signals of Me-14 of an eudesmanolide at δ_H 0.84 (s) and δ_C 11.7, an α-methyl-γ-lactone moiety at δ_H 1.20 (d, *J* = 7.6 Hz, H-13), 4.25 (t, *J* = 10.6 Hz, H-6) and δ_C 79.7 (C-6), 49.2 (C-7), 180.2 (C-12) and 9.6 (C-13), one terminal double bond: at δ_H 5.17 (d, *J* = 2.8 Hz, H-15a) and 4.90 (d, *J* = 2.0 Hz, H-15b); δ_C 145.5 (C-4) and 107.6 (C-15), and a skeletal quaternary carbon signal at δ_C 46.8 (C-10). ^{1}H NMR data for **1** are similar to those of **2**, **3** and 1β-hydroxyeudesm-4(15)-en-5α,6β,7α,11αH-12,6-olide (Marco, 1989), except for the signals of H-2 and C-2 which are not present in **1**. All these data indicated that **1** is a 2-nor eudesmanolide. In Fig. 1, Tables 1 and 2, the atomic numbers of **1** are noted according to the normal eudesmanolide numbering convention, for the sake of comparing NMR data of **1** with those of eudesmanolides **2** and **3**.

^{1}H–^{1}H COSY correlations of H-1 to H-3, H-5 to H-6, H-8 to H-7 and H-9; H-11 to H-13 suggested that **1** possesses the structure shown in Fig. 1. The carbon skeleton was confirmed to be a noreudesmane sesquiterpene by HMBC correlations of C-1 at δ_C 79.0 to H-3b at δ_H 2.16, H-9b at δ_H 1.29, and H-14, C-3 to H-1, H-15a, and H-15b, C-4 to H-3a at δ_H 2.82 and H-3b, C-5 to H-14, H-15a, and H-15b, C-6 to H-7 and H-11, C-7 to H-8b at δ_H 1.61, C-8 to H-9b, C-9 to H-14 and H-1, C-11 to H-13, C-12 to H-11 and H-13, H-13 to C-7, C-11, and C-12, H-14 to C-1, C-5, C-9, and C-10. In order to confirm the position of the hydroxyl group, compound **1** was acetylated to **1a**. The ^{1}H NMR spectrum of **1a** showed the presence of an acetyl methyl signal. In addition, the downfield shift of signal of H-1 at δ_H 3.95 in **1** to δ_H 4.87 in **1a** indicated acetylation at C-1. This provided an evidence for the hydroxyl being located at C-1.

The stereochemistry of **1** was determined by the coupling constants and the NOE difference spectrum. The large coupling constants for H-6 (t, J = 10.6 Hz) suggested that H-6 should be in a β orientation, and H-5 and H-7 being α-oriented, which indicated the junction of *trans* A/B and *trans* B/C rings. The configuration of CH_3-13 was assigned as β by comparison between the chemical shift of C-13 of **2**, **3** and the reported value in the literature (Marco, 1989), about δ_C 9.5 for β-orientation and δ_C 12.5 for *a*-orientation. In the NOE difference spectrum experiments, irradiation of H-5 led to an enhancement of H-1 (+5.14%) and H-3a (+5.34%); irradiation of H-6 led to an enhancement of H-14 (+3.08%) and irradiation of H-13 led to an enhancement of H-6 (+4.46%). All of these observations suggested that H-1 has α-orientation, whereas both H-13 and H-14 have β-orientation. Therefore, the structure of **1** was assigned to a novel noreudesmanolide, 1β-hydroxyl-2-noreudesm-4(15)-en-5α,6β,7α,11αH-12,6-olide. A trivial name, Ajaniaolide A, was adopted for it.

Compound **4** was obtained as colourless oil. The molecular formula was established as $C_{20}H_{24}O_6$ by HRESIMS which gave the

[c] Deuterium oxide.

quasimolecular ion peak $[M+NH_4]^+$ at *m/z* 378.1907 (calcd. 378.1911). The EIMS peak at *m/z* 260 $[M-AngOH]^+$ suggested the presence of an angeloyloxy group. The presence of hydroxyl, γ-lactone, carbonyl, and a double band was characterised by IR bands at 3422, 1770, 1712, and 1647 cm^{-1}, respectively. ^{13}C NMR (DEPT) spectra (Table 3) showed 15 skeletal carbons which included one γ-lactone at δ_C 169.1, two methyls at δ_C 24.8 and 29.6, one exo-methylene at δ_C 123.9, seven methines containing three oxymethines at δ_C 78.6, 77.0, and 71.5, five quaternary carbons containing one oxyquaternary carbon at δ_C 79.2, and three vinylic quaternary carbons. ^{1}H and ^{13}C NMR were assigned to vinylic signals, δ_H 6.19 (1H, br s) and 5.50 (br s) and δ_C 142.1 s, 132.4 d, 128.3 d and 130.6 s, exhibiting the presence of a conjugated double bond system. This assignment was further confirmed by a UV (MeOH) absorption at λ_{max} (log ε) 244 nm. The characteristic NMR signals of an angeloyloxyl group are shown in Table 3. All these observations suggested that compound **4** was a highly oxygenated guaiane lactone (Meng et al., 2001). This assignment was confirmed by 2D NMR spectroscopic analyses (^{1}H–^{1}H COSY and HMBC). As a consequence, it allowed us to unambiguously assign all ^{1}H and ^{13}C NMR spectroscopic data in Table 3.

The conjugated double bond system was established to be located among C-1, C-2, C-9, and C-10, as deduced by correlation between H-2 and H-3 in the ^{1}H–^{1}H COSY, and the correlations between C-1 and H-5, H-9, H-14, and the correlations between H-14 and C-1, C-9, C-10 in HMBC experiments. The angeloyloxyl group was located at C-8 at δ_C 71.5, as deduced by HMBC correlations between the carbonyl carbon C-1′ at δ_C 166.7 and H-8 at δ_H 5.69. Two hydroxyl groups were located at C-3 and C-4, respectively, as deduced by HMBC correlations between the Me-15 at δ_H 1.38 and C-3 at δ_C 78.6, C-4 at δ_C 79.2, respectively.

The relative stereochemistry of **4** was determined by the coupling constants and NOE difference spectra. The large coupling constants, $J_{5,6} = J_{7,6} = J_{7,8} = 9.9$ Hz, suggested that H-6, H-7, and H-8 were all located at *trans* position. In the NOE difference spectrum, irradiation of H-6 led to an enhancement of H-15 (+3.70%), and irradiation of H-3 led to an enhancement of H-15 (+3.08%). These observations suggest that H-3, H-6, H-8, and H-15 were β-oriented, while H-5 and H-7 were α-oriented. Therefore, compound **4** was assigned as 8α-angeloyloxyl-3α,4α-dihydroxyguaia-1,9,11(13)-trien-6,12-olide, as shown in Fig. 1.

Compound **7** was isolated as colourless needles. Its molecular formula was established as $C_{14}H_{16}O_4$ from HRESIMS which gave the quasimolecular ion peak $[M+H]^+$ at *m/z* 249.1120 (calcd. 249.1123) and $[M+Na]^+$ at *m/z* 271.0944 (calcd. 271.0941). The IR spectrum showed absorbances for hydroxyl (3367 cm^{-1}) and conjugated acetylene-olefine (2139, 1651 cm^{-1}). The existence of the latter was also confirmed by the UV (MeOH) spectrum (λ_{max} 279 nm). ^{13}C NMR (DEPT) spectra showed peaks assigned to an acetylene skeleton: four acetylenic quaternary carbons at δ_C 79.8 (C-10), 70.0 (C-11), 83.7 (C-12), and 64.7 (C-13), an olefine conjugated with acetylene, signals at δ_C 83.7 (CH, C-9) and 171.1 (C, C-8). Two characteristic signals of the terminal methyl and the olefine proton were determined at δ_H 1.96 (H-14) and 5.17 (H-9), respectively. ^{1}H NMR data of **7** were similar

to those of a glycol reported by Matsuo, Uchio, Nakayama, and Hayashi (1974), whose structure is an acetylenic compound of dioxaspiro[4,5]decans. However, the relative stereochemistry of them is different because their optical rotation values are exactly opposite, i.e. $[\alpha]_D^{20} - 50$ (*c* 1.17, $CHCl_3$) for **7** and +112 (*c* 0.37%, $CHCl_3$) for the glycol. The structure of **7** and its ^1H and ^{13}C NMR assignment were confirmed by ^1H–^1H COSY and HMBC experiments.

A spirocyclic system was established by ^1H–^1H COSY correlations between H-2 and H-1, H-3, H-4, between H-3 and H-2, between H-6 and H-7, and between H-9 and H-14, H-7. A quaternary carbon, C-5 at δ_C 110.5, was also observed. The conjugated acetylene-olefine skeleton, connecting to a five-membered epoxide, was established by HMBC correlations between H-7 at δ_H 4.59 and C-5, C-6, between C-7 at δ_C 76.3 and H-6, H-9, between C-8 at δ_C 71.5 and H-6, H-9, and between the terminal methyl H-14 at δ_H 1.96 and C-10, C-11, C-12, C-13, C-8. These observations suggested two hydroxyl groups located at C-7 and C-8.

The relative stereochemistry of **7** was elucidated by coupling constants and NOE experiments. The chemical shift of a broad singlet H-9 at δ 5.17 indicated that the 8,9-double bond was in an *E* conformation (Matsuo et al., 1974). NOE experiments indicated that irradiation of H-7 did not lead to an enhancement of H-6, suggesting that an *anti* relationship between H-7 and H-6, exists, and irradiation of H-6 led to an enhancement of H-4 (6.51%), suggesting that H-7 was located at the α-orientation and both H-6 and H-4 at the β-orientation. Therefore, compound **7** was elucidated as 3β,4α-dihydroxy-2(*E*)-(2′,4′-hexadiynylidene)-1,6-dioxaspiro [4,5]decane.

Compound **8** was isolated as colourless needles. The molecular formula of **8** is found to be $C_{14}H_{18}O_5$ from the EIMS, which exhibits a molecular ion peak at *m/z* 266, and this is further confirmed by ^{13}C NMR (DEPT) spectra. The molecular weight of **8** was 18 amu more than that of **7** and its ^1H and ^{13}C NMR spectra are very similar to those of **7**. The ^{13}C NMR spectrum showed 14 carbons, assigned to one methyl, four methylenes, three methines, and six quaternary carbons. A ^1H–^1H COSY experiment showed couplings from H-9 to H-14, H-7, from H-7 to H-6, from H-3 to H-2 and H-4, from H-2 to H-1e, H-1a, H-3, and H-4. In comparison with **7**, chemical shifts of C-5, C-6 and C-9 moved downfield, whereas those of C-7 and C-8 moved upfield. These observations suggest that the five-membered ring was broken and two hydroxyl groups were located at C-5 and C-8 in **8**. Consequently, compound **8** was elucidated to be 2-hydroxyl-2-[(E)-1α,β,3-trihydroxyl-3-nonaene-5,7-diyne]-4H-pyran. Compound **8** was not stable. Even stored at 5 °C, it was completely decomposed within one week.

The known compounds were identified by comparing their physical and spectroscopic data with values reported in the literature. They are 1β-hydroxyeudesm-4(15)-en-5α,6β,7α, 11βH-12,6-olide (**2**) (Marco, 1989), 1β-hydroxyeudesm-3-oxo-4β, 5α,6β,7α,11αH-12,6-olide (**3**) (Ahmed et al., 2003; Marco, 1989), α-bisabol (**5**) (Jequier, Nicollier, Tabacchi, & Garnero, 1980), 1*S*,2*R*,4*S*-trihydroxyl-*p*-methane (**6**) (Gomes & Antunes, 2001), (*E*)-3β,4β-epoxy- 2-(2′,4′-hexadiynylidene)-1,6-dioxaspiro[4,5] decane (**9**) (Birnecker, Wallnöfer, Hofer, & Greger, 1988), 2β-(2′,4′-hexadiynoyl)-1,6-dioxaspiro[4,5]deca-3-ene (**10**) (Tan, Jia, Zhao, & Feng, 1992), chlorogenic acid butyl ester (**11**) (Rumbero-Sanchez & Vazquez, 1991), caffeic acid (**12**) and caffeic acid methyl ester (**13**) (Bolzani, Trevisan, & Young, 1991), 4-hydroxyl-3,5-dimethoxyl-6-*O*-β-D-glucosebenzene (14) (Cui et al., 1990), sabandinin (**15**) (Sarker, Gray, Waterman, & Armstrong, 1994), isoscopoletin (**16**) and scoparone (**19**) (Tsukamoto, Hisada, Nishibe, Roux, & Rourke, 1984), 6,8-dimethoxyl-7-*O*-β-D-glucosecoumarin (**17**) (Tsukamoto, Hisada, & Nishibe, 1985; De Rosa, Mitova, Handjieva, & Calis, 2002), scopolin (**18**) (Kuroyanagi et al., 1986), and 7-(3-methyl-2-butenyloxy)-6-methoxycoumarin (**20**) (Debenedetti, Nadinic, Coussio, De Kimpe, & Boeykens, 1998).

3.2. Anticancer activity

The cytotoxic activities of compounds **3**, **5**, **6**, **9**, **11–13**, **16**, and **18** were evaluated by assessing their effects on K562/ADM cell lines, **9**, **11–13**, **16**, and **18** on K562 cell lines, **3**, **5–6** on BGC-823 cell lines and **9**, **16**, and **18** on Hep-G2 cell lines using MTT colorimetric assay, as previously reported (Hussain et al., 1993). The results of the inhibition of compounds on the viabilities of cancer cells after 48 or 72 h of incubation are presented in Table 8, which does not include the compounds without inhibition toward selected cancer cell lines. IC_{50} values of all tested compounds are given in Table 9. Among them, sesquiterpene **3** and phenolic acid **12** exhibit strong activities against the K562/ADM lines: IC_{50} of 11.1 for 48 h and 13.1 μg/ml for 72 h for **3**, and 7.25 for 48 h and 3.29 μg/ml for 72 h for **12**. Compounds **5**, **11**, **13**, and **16** display weak activities (IC_{50} > 70 μg/ml), but **6**, **9**, and **18** display no activity toward K562/ADM cell lines. Compound **12** also exhibits strong activity against the K562 cell lines (IC_{50} of 5.57 for 48 h and 0.78 μg/ml for 72 h), while **11** and **13** display a moderate activity (IC_{50} of 82.3 μg/ml for 48 h and 45.4 μg/ml for 72 h for **11** and 65.0 μg/ml for 48 h and 22.5 μg/ml for 72 h for **11**), and **16** displays very weak activity (IC_{50} > 100 μg/ml), but **9** and **18** display no activity toward K562 cell lines. Compounds **3**, **5**, and **6** display very weak activity toward BGC-823 cell lines (IC_{50} > 100 μg/ml). Compound **16** displays very weak activity (IC_{50} > 100 μg/ml), but **9** and **18** show no activity toward Hep-G2 cell lines.

The data indicate that **3** is more sensitive to K562/ADM cancer cells than BGC-823 gastric cancer cells as measured by growth inhibition and apoptosis assays at the same drug concentration. This suggested that **3** might possess different anticancer activities toward solid tumours and hemocytein tumours. Experiment showed that **3** obviously inhibited the proliferation of K562/ADM cancer cells and induced apoptosis of tumour cells. Therefore, the interference mechanism of **3** on K562/ADM cancer cells was assumed to inhibit a variety of cellular functions which direct cells into apoptosis. From Fig. 3, compounds **3** and **12** possessed inhibitory effects upon K562/ADM cells growth at lower concentrations, suggesting that the observed growth inhibition was caused by a cytostatic effect, as also by **11–13** upon K562 cells (Fig. 4). However compounds **5**, **11**, **12**, **13**, and **16** possessed inhibitory effects upon K562/ADM cells growth at higher concentrations, suggesting that the observed growth inhibition was caused by a cytotoxic effect rather than a cytostatic effect (Fig. 3), as also for **16** upon K562 cells (Fig. 4). This showed a close agreement with previous work on potential mechanisms (Kampa et al., 2004).

Previous studies of natural sesquiterpenes and synthetic analogues show that the main determining factor responsible for the cytotoxicity and antitumor activity of compounds under study is the existence of an α,β-unsaturated system (Barla, Topçu, Öksüz, Tümen, & Kingston, 2007), which is likely to serve as an alkylating centre and can be a part of an ester, ketone, or lactone moiety. The activity of **3** may be relevant to the 6,12-lactonization in the molecule. The activity of **3** against K562/ADM cells might be due to the absence of an α-methylene bearing a γ-lactone moiety. We found that only **3** possessed an α-methyl-γ-lactone moiety among all tested compounds. Results for their bioassays indicate that bioactive molecules must possess an α-methyl-γ-lactone sesquiterpene skeletal type of structure. By means of its structural feature, caffeic acid, **12,** exhibits strong antioxidant and cytotoxic activity against K562 and K562/ADM cell lines, not only containing two hydroxyl groups and but also carboxyl groups (Gomes et al., 2003).

Table 8
Inhibition (ratios) of selected compounds in tested concentrations (0, 10, 50, 100, and 200 μg/ml), against K562, K562/ADM, BGC-823, and Hep-G2 cell lines (incubation time 48 and 72 h).

Compound No.	Time (h)	Concentration (μg/ml)

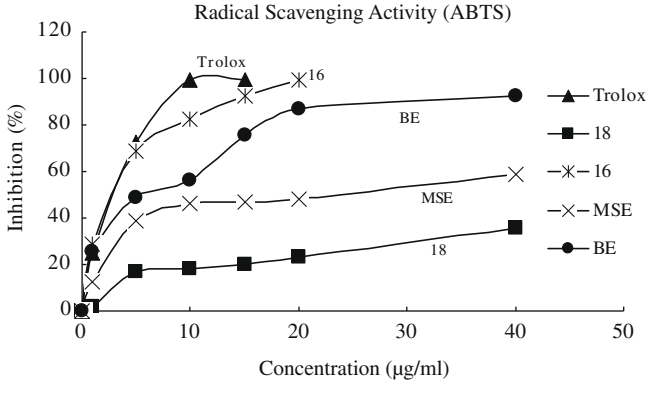

Fig. 5. ABTS· assay of compounds **16**, **18**, MSE, and BE in comparison to trolox.

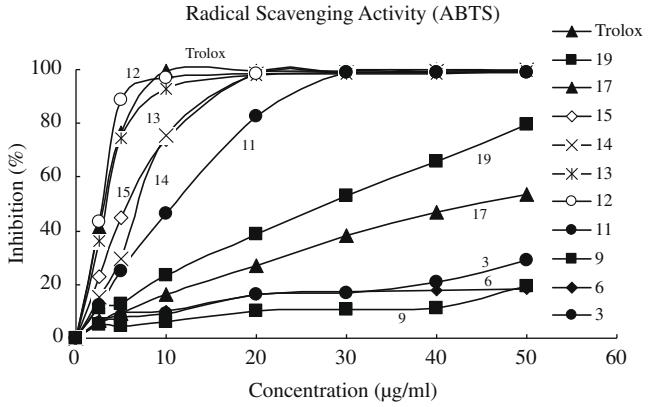

Fig. 6. ABTS· assay of compounds **3**, **6**, **9**, **11**–**15**, **17**, and **19** in comparison to trolox.

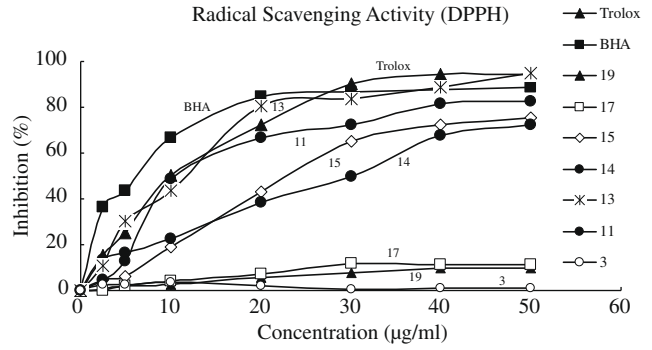

Fig. 7. DPPH· assay of compounds **3**, **11**, **13**–**15**, **17**, and **19** in comparison to BHA and trolox.

3.3. ABTS and DPPH free radical-scavenging activity

Free radical-scavenging activities of 12 compounds (**3**, **6**, **9**, **11**–**19**) as well as the mixed solvent extracts (MSE) and *n*-butanol extracts (*n*-BE) were evaluated in comparison with trolox, using ABTS·+ radical cation. Trolox was used as an antioxidant standard for ABTS·+. Free radical-scavenging activities of four compounds (**11** and **13**–**15**) were evaluated in comparison with trolox and BHA, using DPPH. Trolox and BHA were used as antioxidant standards for DPPH·. Free radical-scavenging capacities of the selected compounds, trolox and BHA measured by the ABTS· and the DPPH· assay are presented in Figs. 5–7 and their IC_{50} values are given in Table 10. Phenolic compounds and coumarins, **11**–**16**, MSE, and *n*-BE displayed significant scavenging capacities towards ABTS·+ and DPPH· (IC_{50} < 20 μg/ml). Coumarins **17**–**19** tested under the same conditions exhibited lower antioxidant activity, while non-phenolic compounds **3**, **6**, and **9** exhibited no antioxidant activity. Based on their IC_{50} values, the order of antioxidant activity of the compounds is as follows: **16** = **12** > trolox > **13** > **15** > **14** > **11** > **19** > **17** > **18** for ABTS· assay; BHT > trolox > **11** > **13** > **15** > **14** for DPPH· assay. In our study, an increase in the number of the OH ring substituents, and existence of the terminal carboxylate groups leads to higher antioxidant and cytotoxic activities. Therefore phenolic compounds **12**, **13**, and **16** are strong antioxidants.

4. Conclusions

It is known that sesquiterpenes are characteristic constituents of the family Compositae (*Asteraceae*). Our results show that there are three different types of sesquiterpeneolides: eudesmane lactones, guaiane lactone, and bisabolene. Except for the typical eudesmane framework, a few other eudesmane types exist in nature. They are secoeudesmanes, lindelanes, cycloeudesmanes, isomeric eudesmanes, noreudesmanes, and dimers. Most of them contain two six-ring skeletons (Wu, Shi, & Jia, 2006). However, the rearranged eudesmanes, such as cyperane, iphionane, and oppositane skeleton, were few, and are not found in eudesmane sesquiterpene lactones. To our best knowledge, Ajaniaolide A (**1**) is a novel noreudesmane sesquiterpene lactone with a rare rearranged carbon skeleton.

According to the phytochemical studies on *A. przewalskii*, we isolated sesquiterpenolides, monoterpene, acetylenes, flavonoids, lignans, coumarins, phenylpropanoids, and aromatic compounds. The results showed that various natural products with diverse structures exist in *A. przewalskii*. Its compound types show a close relationship with the genus *Ajania* in which similar guaianolides, eudesmanolides, flavonoids, and aromatic compounds are present. Except for the above compounds, bisabolene-, acetylene-, monoterpene- and lignan-type compounds have been isolated from the genus *Ajania* for the first time.

We found that there are abundant phenolic compounds in *A. przewalskii*, including coumarins, flavonoids, lignans, phenylpropanoids, and aromatic compounds. Therefore, the potent antioxidant activity of *A. przewalskii* might be attributed to the presence of these important polyphenolics, flavonoids, and coumarin compounds, which are attractive additives for the food and drug industry and are of great interest for use in complementary medicine supplements.

ABSTRACT

This study investigated the effect of hot water extract of wasabi (*Wasabia japonica* Matsum.) leaves (WLE), without its specific pungent constituents, such as allyl isothiocyanate, on the differentiation of 3T3-L1 preadipocytes. WLE suppressed the increase in glycerol-3-phosphate dehydrogenase (GPDH) activity and triglyceride (TG) accumulation, markers of adipogenesis, in a dose-dependent manner. Quantitative real time RT-PCR results showed that WLE significantly reduced the mRNA expression levels of peroxisome proliferator-activated receptor (PPAR) γ and CCAAT/enhancer-binding protein (C/EBP) α, both key adipogenic transcription factors, as subsequently were the mRNA expression levels of their target genes, such as adipocyte fatty acid binding protein 2 (aP2). Western blot analysis results showed that the protein expression levels of both PPARγ and C/EBPα were also inhibited by WLE. Thus, WLE suppressed the differentiation of 3T3-L1 preadipocytes, and the suppressive effect was mediated, in part, through the altered regulation of PPARγ, C/EBPα, and other specific genes, such as aP2. These results suggest that WLE may prevent obesity and insulin resistance by inhibiting the differentiation of preadipocytes.

1. Introduction

In humans, obesity has become a serious medical problem in developed countries as it is intimately implicated in metabolic syndrome and type 2 diabetes, which ultimately lead to atherosclerosis (Kopelman, 2000; Zimmet, Magliano, Matsuzawa, Alberti, & Shaw, 2005). Therefore, the prevention of obesity should naturally decrease the risk for developing these diseases. Obesity results from an imbalance between energy intake and expenditure, and is mainly characterized at the cell biological levels by an increase in the size of adipocytes differentiated from preadipocytes, through the conversion of extra energy to lipids and pooling in adipose tissues. In trials of obesity prevention, researchers have investigated whether some food components exhibit an ability to suppress intracellular lipid accumulation. For example, tea catechin has been reported to be effective in the inhibition of adipogenesis in 3T3-L1 cells (Furuyashiki et al., 2004), and *in vivo* studies have shown that oral administration of green tea decreases the weight of adipose tissue in rats and mice (Han, Takaku, Li, Kimura, & Okuda, 1999; Sayama, Lin, Zheng, & Oguni, 2000; Sayama, Ozeki, Taguchi, & Oguni, 1996). Also, the same suppressive effects have been demonstrated with mioga extract (*Zingiber mioga* Rosc.) (Iwashita, Yamaki & Tsushida, 2001), red yeast rice extract (Jeon et al., 2004), flavonoids (Harmon & Harp, 2001; Iwashita, Yamaki & Tsushida, 2001), and mushroom extracts (Ohtsuru, Horio, & Masui, 2000) on 3T3-L1 or C3H10T1/2 B_2C_1 adipocyte differentiation.

Wasabi (*Wasabia japonica* Matsum.) is a native Japanese plant and was used as a medicinal herb in ancient times. In most parts, wasabi is used as a spice or as pickles as it contains strong pungent constituents, including isothiocyanates such as allyl isothiocyanate. In previous studies, isothiocyanates have been reported to have various physiological properties, including antimicrobial activity (Isshiki, Tokuoka, Mori, & Chiba, 1992), antioxidative activity (Fukuchi et al., 2004), anti-platelet aggregative activity (Kumagai et al., 1994), and anti-carcinogenic activity (Fuke, Haga, Ono, Nomura, & Ryoyama, 1997). However, there have been few studies of the functional properties of other components, particularly in summer leaves, which are too late of stage, and have little pungency (Mochida & Ogawa, 2008).

To develop an effective use for summer leaves, which are discarded as an agricultural waste, we investigated the possible

existence of any anti-obesity function of wasabi leaves, *i.e.* the effect of their hot water extract (WLE), without its specific pungent constituents, such as allyl isothiocyanate, on the differentiation of 3T3-L1 preadipocytes, measuring glycerol-3-phosphate dehydrogenase (GPDH) activity and triglyceride (TG) content in 3T3-L1 cells as markers of adipogenesis. To determine whether WLE affected the alteration in the differentiation programme, we also investigated the expression of PPARγ and C/EBPα, both of which act as central regulators of adipocyte differentiation, and their target genes, such as aP2.

2. Materials and methods

2.1. Reagents

Dulbecco's Modified Eagle's Medium (DMEM) was purchased from Invitrogen (Carlsbad, CA). Fetal bovine serum (FBS) was obtained from AGC Techno Grass Co. Ltd. (Chiba, Japan). Dexamethazone (DEX), gentamicin sulfate and insulin were purchased from Sigma–Aldrich Co. (St. Louis, MO). 3-Isobuthyl-1-methylxanthine (IBMX), (−)-epigallocatechin (EGC) and allyl isothiocyanate (AIT) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). ISOGEN, for total RNA isolation from cells, was purchased from Nippon Gene (Tokyo, Japan). ReverTra Ace -α-, for cDNA synthesis, was purchased from TOYOBO Co., Ltd. (Osaka, Japan). The PCR reagents and the oligonucleotide primers of mouse (Table 1) were obtained from Takara Bio Inc. (Shiga, Japan). Rabbit polyclonal antibodies against PPARγ and C/EBPα were purchased from Upstate (Lake Placid, NY) and Santa Cruz Biotechnology (Santa Cruz, CA), respectively. As secondary antibodies, horseradish peroxidase-conjugated goat anti-rabbit IgG, and chemiluminescent substrate (SuperSignal West Femto Maximum Sensitivity Substrate), to detect immunoreactive band, were obtained from Thermo Fisher Scientific Inc. (Rockford, IL). A polyvinylidene fluoride (PVDF) membrane (Immun-Blot PVDF Membrane) was purchased from Bio-Rad Laboratories (Hercules, CA). All other chemicals used were of analytical grade.

2.2. Preparations of wasabi extract

Wasabi (*W. japonica* Matsum.) leaves were harvested in Shimane Prefecture, Japan, in July, 2004, and pooled at −50 °C until used for experiments. After lyophilisation in a vacuum at room temperature for 3 days and milling with a vibrating sample mill TI-100 (Heiko Seisakusho Ltd., Tokyo, Japan), the samples were ready for experiment. One gramme of lyophilized sample of wasabi leaves in 10 ml of distilled water was boiled for 10 min in a hot water bath, and then centrifuged at 12,000*g* for 10 min at 4 °C; the supernatants were then filtered through a 0.45 μm membrane filter (Adovantec Toyo Kaisha Ltd., Tokyo, Japan). The solid contents of the extract were calculated by evaporating the sample in a vacuum and subsequently measuring the dry weight. Wasabi rhizomes and stalks were also used in this study. To examine the differences of suppressive effects of WLE, from samples of different harvesting periods, on adipocyte differentiation, wasabi leaves harvested from July, 2004, to June, 2005, were also used. The extract from these leaves, as well as from the rhizomes and stalks, was prepared as described above.

2.3. Cell culture and treatment

Murine 3T3-L1 cells (JCRB 9014) were obtained from the Health Science Research Resources Bank (Osaka, Japan). The cells were grown in maintenance medium (MM, DMEM supplemented with 10% FBS and 50 μg/ml of gentamicin) at 37 °C in 5% CO_2. The medium was changed every two or three days. For adipocyte differentiation, the cells were cultured in 6-well plates to full confluence for 2 days and were then treated with differentiation medium containing 0.25 μM DEX, 0.5 mM IBMX, and 1.5 μg/ml of insulin (DMI). After 2 days of induction (day 2), the medium was changed to MM containing 1.5 μg/ml of insulin, and WLE, at final concentrations of 333, 667 or 1333 μg/ml, was added every 2 days. In the case of examining the differences of suppressive effects on adipocyte differentiation of WLE from samples of the various harvesting periods, 15 μl of WLEs were added to 1.5 ml of MM containing 1.5 μg/ml of insulin. After 6 days of incubation from the initiation of differentiation, the cells were harvested. For quantitative real time RT-PCR and Western blot analysis, the cells were treated with WLE, or EGC as positive control, at the same time as DMI induction of differentiation (day 0), and then incubated in the same manner as described above. All samples were prepared in triple cell culture wells.

2.4. Measurement of GPDH activity and quantification of TG accumulation

The cells were washed twice with ice-cold 0.9% saline solution, collected in 1 ml of cold sonication buffer (25 mM Tris buffer

Table 1

[b] F: forward, R: reverse.

containing 1 mM EDTA, pH 7.5) using a cell scraper, and then sonicated. Twenty microlitres of suspension were used to measure TG concentrations, using a commercial kit (Triglyceride E-test Wako, Wako Pure Chemical Industries, Ltd., Osaka, Japan) according to manufacturer's instructions. The remaining portion of the suspension was centrifuged at 8000*g* for 10 min at 4 °C, and the supernatant was assayed for GPDH activity. This was done by measuring the decrease in the absorbance of NADH at 340 nm at 37 °C. Protein concentrations were determined using Protein Quantification Kit-Rapid (Dojindo Molecular technologies, Inc., Rockville, MD). The GPDH activity and the TG concentration per mg of protein in the cells were calculated and expressed as ratios (%) of the control value.

2.5. Analysis of allyl isothiocyanate (AIT) content in hot water extract of wasabi

The AIT contents of the test samples were measured by high-performance liquid chromatography (L-7100, Hitachi, Ltd., Tokyo, Japan), using the following analytical conditions: column, TSKGEL ODS-80TS (φ4.6 × 250 mm); mobile phase, acetonitrile–water = 50/50; flow rate, 1.0 ml/min; detection, UV 240 nm. On the HPLC analysis, limit of detection (LOD) and limit of quantification (LOQ) of AIT were 0.01 mM and 0.02 mM, respectively.

2.6. Quantitative real time RT-PCR

Total RNA was isolated from the cells using ISOGEN, according to the manufacturer's instructions. One microgramme of total RNA was used for the single strand cDNA synthesis with a cDNA synthesis kit, ReverTra Ace -α-. Gene expression levels were analyzed by quantitative real time RT-PCR, using the ABI PRISM 7000 Sequence Detection System (Applied Biosystems, Foster City, CA). The cDNA was denatured at 95 °C for 10 s, followed by 40 cycles of PCR (95 °C, 5 s; 60 °C, 31 s). Results were obtained from at least three independent experiments. The mRNA levels of all genes were normalized, using GAPDH as an internal control.

2.7. Western blot analysis

The cells were washed twice with ice-cold PBS, scraped with RIPA buffer, and allowed to stand on ice for 1 h to permit lysis. After centrifugation at 18,000*g* for 20 min at 4 °C, protein content in the supernatant was determined, using a DC-protein assay kit (Bio-Rad Laboratories, Hercules, CA), and aliquots (20 μg) of protein were separated by SDS-polyacrylamide gel electrophoresis and transferred onto a PVDF membrane. The membrane was blocked with 0.3% (w/v) non-fat dried milk in TBST (25 mM Tris–HCl, pH 7.4, 150 mM NaCl, and 0.1% (v/v) Tween 20) for 1 h, and then incubated for 1 h with primary antibody in TBST containing 0.3% (w/v) non-fat dried milk. The blots were treated with horseradish peroxidase-conjugated secondary antibody in TBST containing 0.3% (w/v) non-fat dried milk for 1 h, and then reacted with a chemiluminescent substrate. An immune complex was detected using a multiimager (Bio-Rad SU-115, Bio-Rad Laboratories, Hercules, CA).

2.8. Statistical analysis

Statistical analysis of the data was done with SPSS statistical analysis software (Version 17.0J, SPSS Inc., Tokyo, Japan). One-way ANOVA was used to assess the differences between the individual groups, and *post hoc* analyses were performed by the Bonferroni test for two independent variables. Differences were considered significant at $p < 0.025$. The significance of differences between two groups (samples and control) were analyzed by the Student's *t*-test, and were determined at $p < 0.05$.

3. Results

3.1. Suppressive effects of wasabi extract on GPDH activity and TG accumulation

The extracts from all parts of the wasabi plant suppressed the increase in GPDH activity and TG accumulation in a dose-dependent manner (Fig. 1). Particularly, the cells treated with 667 μg/ml of extract from leaves and stalks showed suppression of increase in GPDH activity up to 36% and 25%, respectively, in comparison with control cells. However, in the case of treatment with 1333 μg/ml of extract from them, the cells were damaged (#), so GPDH activity and TG accumulation could not be evaluated clearly. From the results obtained above, the adipocyte differentiation-inhibitory activities of the extracts of leaves and stalks were higher than those of rhizomes. Table 2 shows AIT content of the extracts. The extracts of all wasabi parts tested had little or no AIT, so we surmised that the results obtained here were not because of isothiocyanates, such as AIT. The differences in suppressive effects on adipocyte differentiation of WLE, from samples of the various harvesting periods were also examined (Fig. 2). The effects of WLE from samples harvested in winter were greater, on the whole, but the summer samples (July/2004) also showed significant effects. Hence we focused on WLE in this study, which also had inhibitory activity on adipogenesis.

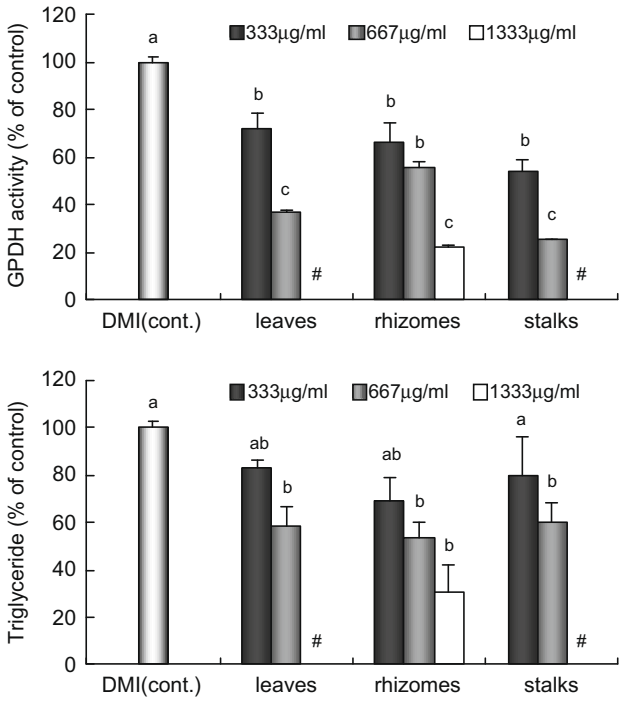

Fig. 1. Hot water extracts of wasabi leaves, rhizomes and stalks suppress glycerol-3-phosphate dehydrogenase (GPDH) activity and triglyceride accumulation in 3T3-L1 cells in a dose-dependent manner. Samples are used at indicated concentrations. Cells were treated with samples at 2 days after DMI induction of differentiation (day 2). All values are represented as a percentage of the results from control which is taken as 100%, and are expressed as means ± SE of triplicate experiments. Different letters between samples and control, or among samples in each part, indicate significant differences by the Student's *t*-test ($p < 0.05$) and the Bonferroni test ($p < 0.025$), respectively. #: GPDH activity and TG accumulation of the cells treated with 1333 μg/ml of extract from both leaves and stalks were not evaluated clearly because these treatments damaged the cells. DMI: a mixture of dexamethazone, 3-isobuthyl-1-methylxanthine and insulin.

Table 2
AIT content in hot water extract of the wasabi parts.

Parts	AIT contents (mM)
Leaves	ND[a]
Rhizomes	0.03
Stalks	0.04

The sample extracts were obtained as follows: 1 g of lyophilized samples in 10 ml of distilled water was boiled and centrifuged, and then the supernatants were filtered. AIT contents in the extracts were analyzed by HPLC. LOD: 0.01 mM, LOQ: 0.02 mM.
[a] Not detected.

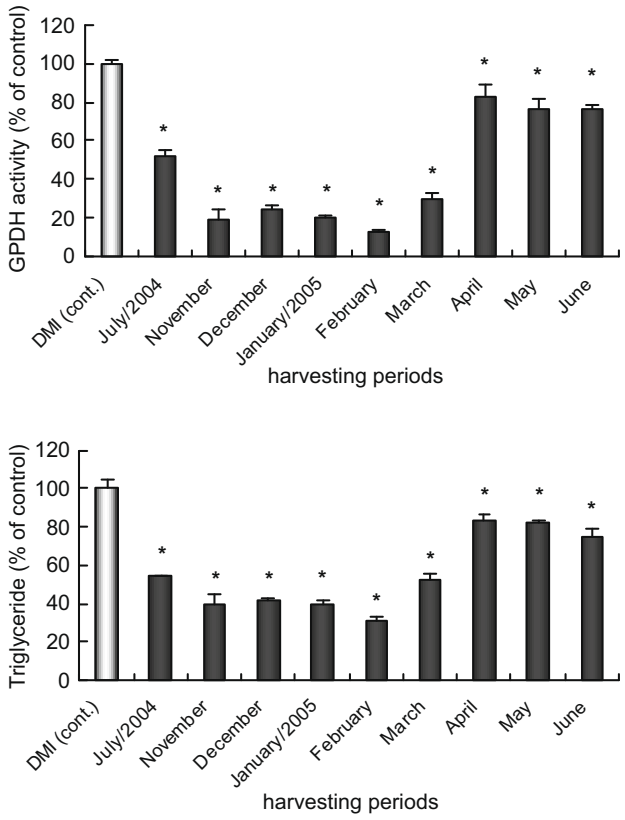

Fig. 2. Suppressive effects of WLE from samples harvested in different periods on GPDH activity and triglyceride accumulation in 3T3-L1 cells. Wasabi leaf samples were harvested at indicated periods and used. The sample extracts were obtained as follows: 1 g of lyophilized samples in 10 ml of distilled water was boiled and centrifuged, and then the supernatants were filtered. The cells were treated with 15 μl of sample extracts at 2 days after DMI induction of differentiation (day 2). All values are represented as a percentage of the results from control, which is taken as 100%, and are expressed as means ± SE of triplicate experiments. Asterisk indicates significant differences compared to the control ($*p < 0.05$). DMI: a mixture of dexamethazone, 3-isobuthyl-1-methylxanthine and insulin.

3.2. Suppressive effect of WLE on mRNA expression of adipogenic transcriptional factors

Adipocyte differentiation involves a series of programmed changes in gene expression. To determine whether the suppressed increase in GPDH activity and reduced TG accretion resulted from a WLE-mediated alteration in the differentiation programme, the expression of a number of adipogenic genes was investigated by quantitative real time RT-PCR. In the cells treated with WLE, as in those treated with EGC, we noted a significant decrease in the mRNA expression levels of PPARγ and C/EBPα, both key transcriptional factors, and followed by reduced mRNA expression levels of their target genes, such as aP2, in a dose-dependent manner (Fig. 3). For example, the mRNA expression level of PPARγ in cells treated with 333 or 667 μg/ml of WLE decreased to 76% and 40%, respectively, of that of the control cells.

3.3. Suppressive effect of WLE on protein expression of PPARγ and C/EBPα

During DMI induction of 3T3-L1 adipocyte differentiation, PPARγ and C/EBPs are activated by DMI (Rangwala & Lazar, 2000; Rosen & Spiegelman, 2000). To investigate the inhibitory mechanism of WLE, protein expression levels of PPARγ and C/EBPα were examined. We found that the WLE-associated attenuation of PPARγ and C/EBPα gene expressions was accompanied by a decrease in the corresponding proteins. For example, at 667 μg/ml of WLE, protein expression levels of PPARγ and C/EBPα decreased to 43% and 30%, respectively, of the control levels (Fig. 4).

4. Discussion

In the present study, we demonstrated that hot water extracts of several parts of the wasabi plant, suppressed the adipocyte differentiation in 3T3-L1 cells, while preventing increases in GPDH activity and TG accumulation, markers of adipogenesis, in a dose-dependent manner (Fig. 1). Iwashita et al. (2001) reported that only mioga (*Z. mioga* Rosc.) extract, among 15 edible-plant PBS-soluble extracts examined, proved effective in inhibiting 3T3-L1 adipocyte differentiation without cell damage, and that cells treated with 200 or 500 μg/ml of extract suppressed increases in GPDH activity to about 60% and 20%, respectively, of that of the control cells. Our results, where cells treated with 667 μg/ml of WLE suppressed increase in activity to about 40% compared to control cells, showed nearly the same as or slightly less than mioga extract.

At the molecular level, cells treated with WLE reduced mRNA and protein expression levels of PPARγ and C/EBPα, both of which act as key adipogenic transcription factors (Figs. 3 and 4). During subsequent terminal differentiations of preadipocytes into mature adipocytes with mitotic clonal expansion in adipose tissues, the adipocyte differentiation programme is regulated by transcriptional activators, such as C/EBPα, PPARγ2, fatty acid-activated receptor (FAAR), and transcriptional receptors, such as preadipocyte repressor element binding protein (PRE) and C/EBP undifferentiated protein (CUP) (MacDougald & Lane, 1995). For example, under induced preadipocyte differentiation into adipocyte in the presence of IBMX in 3T3-L1 cell cultures, C/EBPβ, belonging to a basic leucine zipper family of transcriptional factors, is induced temporarily at the early stage of differentiation (Ko et al., 2005), which, in turn, C/EBPβ induces downstream transcriptional factors, PPARγ and C/EBPα (Wu, Bucher, & Farmer, 1996), followed by the expression of genes, including ap2, GLUT4, LPL, SCD1 and CD36, which mediate fatty acid or glucose uptake into adipocyte, triglyceride hydrolysis and lipogenesis (Abumrad, El-Maghrabi, Amri, Lopez, & Grimaldi, 1993; Brun, Kim, Hu, Altiok, & Spiegelman, 1996; Long & Pekala, 1996; Miller & Ntambi, 1996; Tontonoz, Hu, Graves, Budavari, & Spiegelman, 1994). Thereafter, adipocytes incorporate glucose and free fatty acids to synthesize and accumulate lipids as energy, resulting in an increase in cell size. Huang et al. (2006) reported that berberine (BBR), a compound purified from *Cortidis rhizoma*, inhibited differentiation of 3T3-L1 adipocytes through PPAR pathways; not only were the mRNA and protein expression levels of PPARγ and C/EBPα directly affected, but levels of C/EBPβ were inhibited by BBR, resulting in the down-regulation of the target genes, such as CD36. In our study, in which the treatment with WLE suppressed adipocyte differentiation in 3T3-L1 cells, we supposed that PPARγ and C/EBPα gene expressions might be down-regulated directly, as with BBR, by reason that their expressions were also inhibited after treatment with WLE at 2 days after DMI induction of 3T3-L1 cells (day 2, data not shown). However, it re-

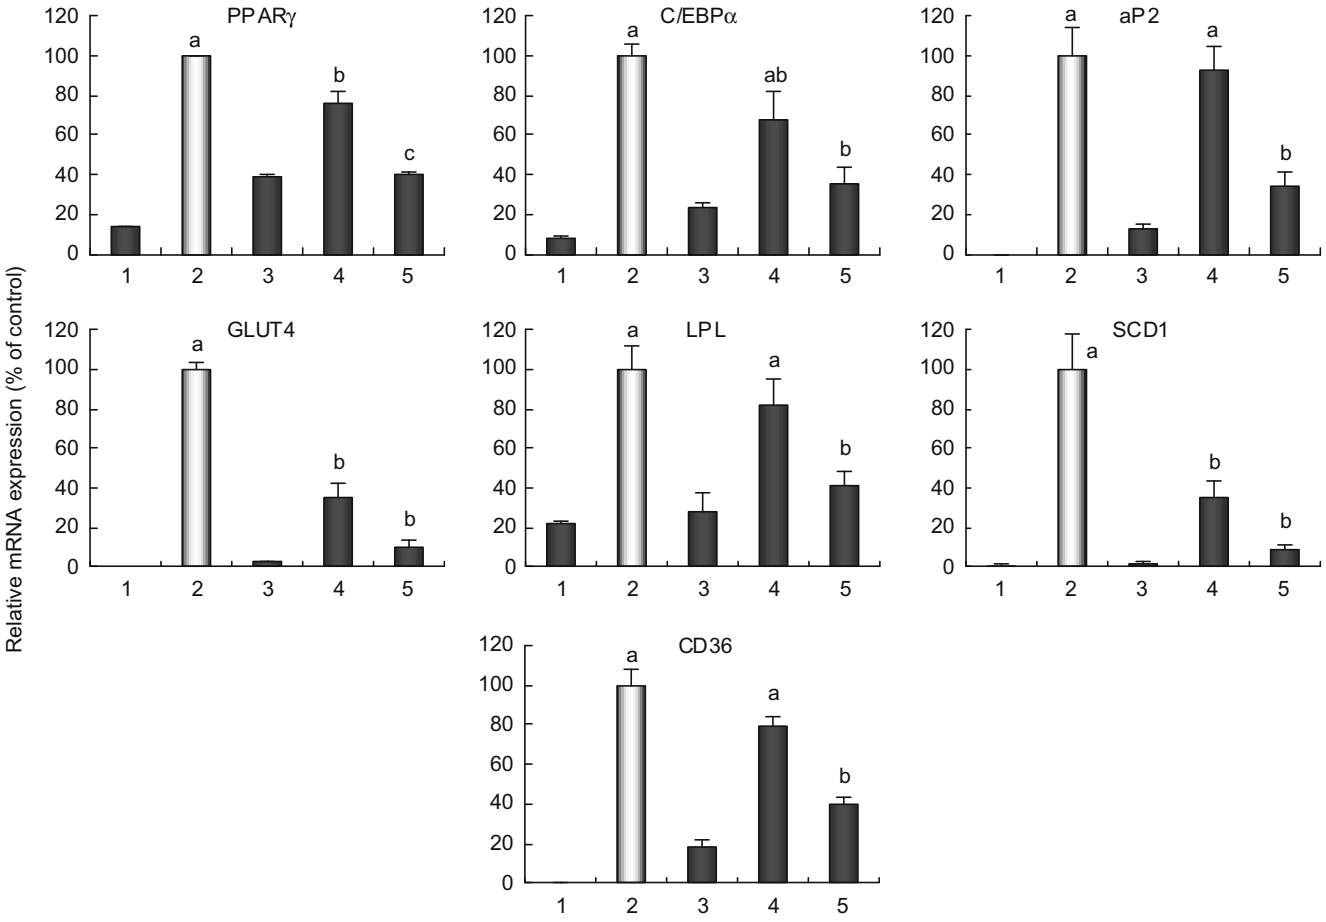

Fig. 3. WLE suppresses mRNA expressions of PPARγ, C/EBPα and their target genes in 3T3-L1 cells. The cells were treated with WLE at the same time as DMI induction of differentiation (day 0). Quantitative real time RT-PCR results are shown for (1) undifferentiated cells, (2) control cells differentiated by DMI, and cells treated with (3) 30 μM of EGC, (4) 333 μg/ml of WLE, and (5) 667 μg/ml of WLE, respectively. The mRNAs of GAPDH in the same samples were used as an internal control. All values are represented as a percentage of the results from control which is taken as 100%, and are expressed as means ± SE of triplicate experiments. Different letters among WLE samples and control indicate significant differences ($p < 0.025$). DMI: a mixture of dexamethazone, 3-isobuthyl-1-methylxanthine and insulin. EGC: (−)-epigallocatechin (positive control).

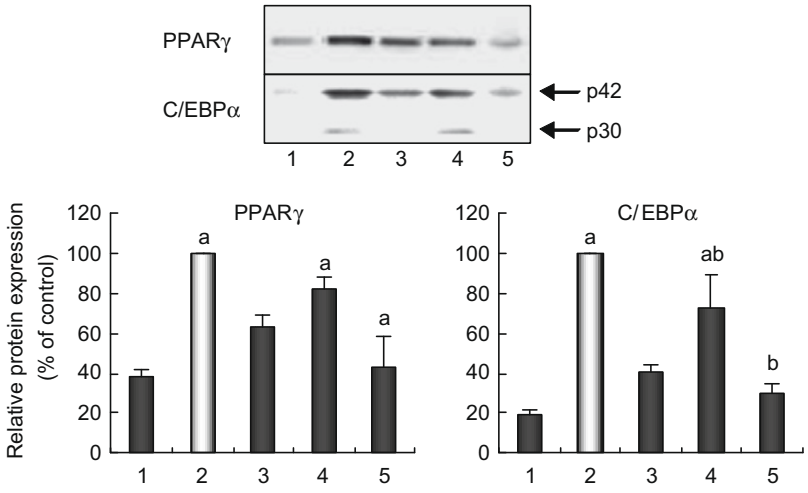

Fig. 4. WLE suppresses protein expressions of PPARγ and C/EBPα in 3T3-L1 cells. The cells were treated with WLE at the same time as DMI induction of differentiation (day 0). A set of representative Western blots for PPARγ and C/EBPα is shown in the upper panel. The quantitative changes of the target proteins are determined by densitometry, as shown in the lower panel. Lanes 1–5 are samples from (1) undifferentiated cells, (2) control cells differentiated by DMI, and cells treated with (3) 30 μM of EGC, (4) 333 μg/ml of WLE and (5) 667 μg/ml of WLE, respectively. All values are represented as percentages of the results from the control, which is taken as 100%, and are expressed as means ± SE of triplicate experiments. Different letters among WLE samples and control indicate significant differences ($p < 0.025$). DMI: a mixture of dexamethazone, 3-isobuthyl-1-methylxanthine and insulin. EGC: (−)-epigallocatechin (positive control).

mains unclear whether WLE affects upstream transcriptional factors, such as C/EBPβ.

In conclusion, we have demonstrated, in the present study, that WLE suppressed the differentiation of 3T3-L1 preadipocytes by

inhibiting increases in GPDH activity and TG accumulation, and that the suppressing effects were mediated, in part, through the altered regulation of adipogenic transcriptional factors, PPARγ and C/EBPα, and other specific genes, such as aP2. These results, combined with the findings that aP2 is central to the pathway that links obesity to insulin resistance (Hotamisligil et al., 1996), suggest that WLE may prevent obesity and insulin resistance by inhibiting the differentiation of preadipocytes.

Low-nitrite
Chinese sausage

ABSTRACT

Anka rice (AR), previously inoculated with *Monascus purpureus*, was added during manufacturing of low-nitrite Chinese sausages. Chemical compositions and water activities of sausages were not affected. "*L*", "*a*", and "*b*" values of sausages with less nitrite (25 ppm) and 0.5% AR added were not significantly different from those with more nitrite (100 ppm) added. Colours of the sausages without AR were light red whereas those with AR added were darker red. Addition of AR did not inhibit lipid oxidation. Higher VBN (volatile basic nitrogen) values of the samples with AR added were observed. With addition of AR, the nitrite degrading rate was retarded. Microbial counts of the sausages with AR added were significantly higher than those of the controls (100 ppm nitrite). The low-nitrite Chinese sausage with addition up to 1.5% AR was acceptable when stored at 4 °C for 28 days.

1. Introduction

Monascus spp. which is a food fungus, has been widely applied for making wines and other fermented food products, especially in Taiwan, China, and many Asian areas for many years (Tseng, 1999). Many metabolic derivatives, such as ethanol, monascus pigments (red in colour), γ-aminobutyric, monacolins K, can be produced by *Monascus* spp. (Ma et al., 2000). In addition, it has also been reported in many ancient Chinese scripts to have some beneficial effects, such as improvement of food digestion and blood circulation (Ma et al., 2000). In Taiwan, as a natural food additive source, *Monascus* spp. has been granted edible natural colourant status and allowed in foods (DOH, 2008). Anka rice, also known as *Monascus*-fermented rice, monascal rice, and red koji, is a fermented food made by cultivating *Monascus* spp. on cooked rice, and has been widely used as a colouring and flavouring agent to make many Chinese roasted products (Tseng, Chen, & Lin, 2000).

Nitrite salts, mainly sodium nitrite and potassium nitrite, have been used in the preparation of cured meats for years and for many purposes. First, nitrite can be used as a potent anti-bacterial agent to provide protection against food microorganisms (Gill & Holley, 2003), as well as a potent antioxidant. In addition, nitrite is reduced to nitric oxide, which then interacts with myoglobin to produce nitric oxide myoglobin, which contributes to the characteristic pink cured meat colour (Honikel, 2008). Nitrite can also be applied to preserve desirable meaty flavour (Hedrick, Aberle, Forrest, Judge, & Merkel, 1994). Even though nitrite is known to participate in numerous reactions in cured meats, with many desirable functions, as mentioned previously, concern regarding the levels of nitrite used in meat curing has arisen because of the possibility of nitrosamine, which is a known carcinogen, being formed in cured meat (Osterlie & Lerfall, 2005). Therefore, many studies have been conducted to attempt to reduce the nitrite contents in cured meat products. Walsh et al. (1998) indicated that a combination of dietary vitamin E supplementation at a level of 500 mg α-tocopheryl kg feed^{-1} with nitrite at the level of 50 mg nitrite kg meat^{-1} could be used to produce cured pork products similar to those obtained from meat containing high nitrite levels (100 mg nitrite kg meat^{-1}). Osterlie and Lerfall (2005) recommended mixing minced meat with a lycopene-containing product that could be used to reduce nitrite levels. Jiménez-Colmenero, Carballo, and Cofrades (2001) pointed out that combining several compounds, which together have a cumulative effect on colour, flavour, antioxidant, and antimicrobial activity, could be considered when attempting to reduce the addition of nitrite in meat products. Functionality, such as colour enhancement and antioxidative properties, makes anka rice a potent candidate to be applied in low-nitrite products. Fink-Gremmels, Dresel, and Leistner (1992) indicated that *Monascus* extracts might be used as an alternative to nitrite in some meat products. Therefore, the purposes of this study were to compare the effects of anka rice on the qualities of low-nitrite Chinese sausages during refrigerated storage and to identify the volatile compounds from the anka rice and the sausages with anka rice added.

2. Materials and methods

2.1. Anka rice preparation

Monascus purpureus (CCRC No. 31499) was obtained from the Culture Collection and Research Center, Food Industry Research

and Development Institute, Hsinchu, Taiwan. The methods described by Tseng (1999) were utilised. *M. purpureus* was inoculated into a yeast glucose broth medium which contained 10% glucose and 0.8% yeast extract; the pH was adjusted to 5.5 and it was incubated at 35 °C with 120 rpm shaking (Yih Der LM-570R, shaker incubator, Taiwan) for 7 days. Then, the inocula were homogenised with a sterile blender (Waring Commercial, New Hartfor, Connecticut, USA) at high speed for 2 min. The microbial suspension was prepared accordingly. After being rinsed and soaked in water for 12 h, indica rice was shaken to remove excess water, autoclaved for 30 min, and then removed for cooling. The microbial suspension prepared previously [5% (w/w), with the yeast glucose broth as 100%], yeast glucose broth and pre-autoclaved rice (same weight as the yeast glucose broth) were mixed thoroughly, and then cultivated at 30 °C for 20 days. After drying in an oven (Model RHD, S-Tai Co., Kaohsiung, Taiwan) at 45 °C for 24 h, and cooling at room temperature, the mixture was ground with a grinder (Type 780A, Krups, Ireland), and then stored at −20 °C.

2.2. Sausage preparation

Frozen pork hams, frozen pork backfat, and salted natural pork casing were purchased from a local market in Nantou, Taiwan. Lean tissue and pork backfat were ground through a 10 mm plate. Ground pork was mixed thoroughly with non-meat ingredients, including 10% sugar, 2% rice wine, 1.6% salt, 0.5% monosodium glutamate, 0.2% polyphosphate, 0.08% onion powder, 0.05% white pepper powder, 0.05% five-spice powder, 0.02% clove powder, 0.02% sodium erythorbate, and sodium nitrite (25 ppm for treatments A, R1, R2, and R3 samples, and 100 ppm for treatment C samples), and then cured under refrigeration at 7 °C for 3 days. In addition, 0.5%, 1%, and 1.5% anka rice which were previously inoculated with *M. purpureus* were also added to the formula for the sample treatments R1, R2, and R3, respectively. Then, ground pork backfat (25%) was mixed with the meat mixture, and stuffed (Stuffer, Dick D-73779, Germany) into natural casings, which were previously soaked in water. Raw sausages were dried in a preheated oven (Model RHD, S-Tai Co., Kaohsiung, Taiwan) at 50 °C for 3 h. Following drying, sausages were cooled, vacuum-packaged (HAS02G, Europack, Holland) and stored at 4 °C.

2.3. Proximate composition, water activity and pH

Samples were first ground with a grinder (Type 780A, Krups, Ireland). Proximate compositions of samples, including moisture, crude fat, crude protein, and ash contents, were measured according to AOAC (1990) methods. Crude fat was measured using a fat extractor (Sotec System HT 1043 Extraction Unit, Tecator Co., Sweden) with ethyl ether as a solvent and extracted for 16 h. Crude protein was measured by the Kjeldahl method, using a digester (Model 2006, Foss tecator, Sweden) and a distillation unit (Model 2100, Foss tecator, Sweden). Approximately 2 g of ground samples were put into a holding cup, and measured with a water activity analyser (Aqualab-CX2, Decagon Devices Inc., USA). Eleven gramme samples were blended with 99 ml distilled water in a polyethylene bag for 1 min using a stomacher (Stomacher 400, Seward Ltd., England) at high speed, and then the pH of the mixture was measured using a pH meter (Micro-computer pH meter, Model 6210, Taiwan).

2.4. Instrumental colour measurement

Ground samples were placed in a measuring container, and then the "*L*" (lightness), "*a*" (redness), and "*b*" (yellowness) values of samples were measured with a colour meter (Spectrophotometer, Model TC1, Tokyo Co., Ltd. Japan). A standard plate with "*Y*" = 86.53, "*X*" = 82.45, and "*Z*" = 91.28 was used as a reference.

2.5. Thiobarbituric acid (TBARS) values and volatile basic nitrogen (VBN)

TBARS values of the samples were determined according the methods described by Faustman, Specht, Malkus, and Kinsman (1992). TBARS value was expressed as mg malonaldehyde/kg meat. Volatile basic nitrogen was determined according to CNS (1982) by the Conway micropipette diffusion method.

2.6. Nitrite residue

Nitrite residue was measured according to the methods of Lin (1984), briefly as follows: five grammes of ground sausage samples in a 250 ml flask were homogenised with 100 ml of 80 °C reverse osmosis water, using a homogenizer (Type PT 10/35, Brinkmann Instruments Inc., Westbury, NY, USA) for 60 s at 10,000 rpm. The homogenate was washed with reverse osmosis water to 150 ml totally, sealed with an aluminium foil cap, and heated for 30 min in an 80 °C shaking water bath (50 rpm). After adding 2 ml of saturated $HgCl_2$, cooling with ice water to room temperature, and filtering (Toyo No. 1) immediately, 10 ml of filtrate were transferred into a tube; 2 ml of Griess solution (a combination of sulfanilic acid solution and α-naphthlamine solution in a 1:1 ratio; 0.5 g sulfanilic acid was added to 150 ml of 15% acetic acid solution and 0.1 g α-naphthlamine was dissolved in 20 ml of boiled reverse osmosis water and 150 ml of 15% acetic acid solution) were placed in the tube, covered with aluminium foil, and kept for 30 min. OD values were measured, using a Spectrophotometer (U3210, Hitachi, Japan) at 540 nm wave-length. A nitrite standard curve was made by adding 0.2 g of $NaNO_2$ dissolved in 1000 ml DW and 10 ml of solution were withdrawn and diluted to 1000 ml. The concentration values were then determined according to the equation: $Y = 5.3527 \times X - 0.089$, with Y representing the concentration (ppm), and X representing OD values at 540 nm wave-length.

2.7. Microbial evaluation

Microbial qualities of samples were evaluated according to Bacteriological Analytical Manual for Foods (FDA, 1996), briefly follows: at specified sample times, sausages were aseptically removed from the bags. Eleven gramme samples were placed in a sterile bag containing 99 ml of sterile distilled water and homogenised with a stomacher (Stomacher blender, Model 400, Seward) for 1 min. Serial dilutions were then made. Plate count agar (PCA, Merck) and potato dextrose agar (PDA, Merck) were used for enumeration of total plate count, and mould count, respectively, using the pour plate method to enumerate bacteria. Total microflora and mould were incubated at 37 °C for 48 h and 37 °C for 96 h, respectively. For anaerobic plate counts, dilutions were poured into anaerobic agar (AA, Merck), placed in an anaerobic jar (BBL GasPak System, USA) and incubated at 37 °C for 48 h. Microbial counts in this study were expressed as $\log_{10}$ colony forming units (CFU) per gramme of sample.

2.8. Sensory evaluation

At days 0, 28 and 56, during storage, sausages were first cooked on a grill, until the internal temperature of the sausages reached and was held at 75 °C for 8 min, cooled to room temperature (approximately 25 °C), sliced (approximately 0.3 cm thickness), and then served to a sensory panel which consisted of 10 meat science-majored faculty and students. Sensory attributes, including colour, flavour, odour, and overall acceptance, was conducted using

a 1 to 7-point hedonic scale test, with 1, 4, and 7 representing extremely dislike, neither like nor dislike, and extremely like, respectively, for the attributes.

2.9. Statistical analyses

Data were analysed using the general linear model (GLM) of Statistical Analysis System's Procedures (SAS Institute Inc., Cary, NC) with a 5% level of significance. Means were separated using the Duncan's new multiple range test.

3. Results and discussion

3.1. Proximate composition, water activity and pH

The results showed that chemical compositions of low-nitrite Chinese sausages were not affected by the addition of different levels of anka rice (data not shown). The contents of moisture, crude protein, crude fat, and ash were 44.96–47.30%, 17.9–20.0%, 20.25–23.30%, and 2.78–3.07%, respectively, without significant ($P > 0.05$) differences between the samples. Also, the water activities of all treatments ranged from 0.92 to 0.93, and were not significantly different over storage time or between treatments ($P > 0.05$).

In this study, the sausage pH values significantly decreased from approximate pH 6.3 at day 0 to pH 4.7 at day 56. This pH reduction was probably due to the fact that lactic acid bacteria were the predominant microorganisms in vacuum-packaged meat products, which produced lactic acid, which then reduced pH values of products (Kuo & Chu, 2003). Banwart (1979) indicated that cured meat became sour, with lower pH values, because of the fermentation of carbohydrates by lactic acid bacteria. Similarly, Kuo and Chu (2003) reported that the pH values of Chinese sausages decreased during storage at 4 °C, when lactic acid bacterial counts increased over storage time. Typically, Chinese sausages had higher carbohydrate contents than had most sausages, for example, 10% sugar in this study, which probably could be utilised by lactic acid bacteria to produce more lactic acid, which could result in lower pH values during storage. In this study, the low-nitrite Chinese sausages with anka rice added, especially for the higher level of anka rice-added samples (R3), tended to have a slower pH decline during refrigerated storage. At days 0, 7 and 14, no significant differences of the pH values between the samples were observed. However, at day 28, the pH values of A (lower nitrite level added, i.e. 25 ppm sodium nitrite added) and C (higher level of nitrite added, i.e. 100 ppm sodium nitrite added) samples dropped rapidly to 4.68 and 4.92, respectively, while the pH values of the samples with anka rice added (R1, R2, and R3 treatments with lower level of nitrite added, i.e. 25 ppm sodium nitrite added) were 5.21, 5.17, and 5.38, respectively. In this study, a higher level of anka rice addition (R3, with 1.5% anka rice added) could retard the pH decrease rate for the low-nitrite Chinese sausage at day 28. After refrigeration for 56 days, all the pH values dropped to approximately 4.52–4.86, without significant differences between treatments.

3.2. Instrumental colour measurement

The data indicated that sausages with anka rice added (R1, R2, and R3) tended to have higher "*a*" values, indicating more red colour (Table 1). Especially, R2 (1% anka rice) and R3 (1.5% anka rice) samples had significantly higher "*a*" values than had those of A and C treatments (no anka rice added). In addition to monascin, ankaflavin and rubropunctatin, a red pigment, monascorubramine, was detected in *M. purpureus* extracts (Chen & Johns, 1993). These pigments, produced by *M. purpureus*, might contribute to the increase of redness of the samples observed in this study. In addition, there were no significant differences of the "*L*", "*a*" and "*b*" values between the C samples (with higher nitrite level, i.e. 100 ppm sodium nitrite added) and R1 samples (with lower level of nitrite, i.e. 25 ppm sodium nitrite and 0.5% anka rice added). Samples that had more anka rice added tended to have lower "*L*" values, indicating a darker colour. Especially, after storage for more than 7 days, R3 samples had significantly lower "*L*" values than had C and A samples. In this study, sausages without anka rice showed a lighter red colour whereas sausages with anka rice added had a darker red colour which could also be observed subjectively, through a sensory colour evaluation.

3.3. TBARS and VBN

TBARS values, which are indicators of lipid oxidation, are shown in Fig. 1a. The TBARS values of the sausage samples increased with

Table 1
Changes of colour values of Chinese sausages with addition of anka rice during storage at 4 °C.

Treatment[A]	Storage time (day)

refrigerated storage time during the first 7 days, indicating that lipid oxidation had occurred during this stage. This increase of TBARS values of Chinese sausages during storage has also been reported by other researchers (Kuo & Chu, 2003). In this study, TBARS values increased up to a maximum point at day 7, and then decreased gradually. Gokalp, Ockerman, Plimpoton, Parrett, and Cahill (1978) explained that, during storage, malonaldehyde, which is an intermediate by-product of lipid oxidation, is further oxidised to other organic acids and alcohols that can not react with TBA agent. This might be the reason why the TBARS values first increased and then decreased during storage. Also, a reduction in TBARS values of cooked meat during storage was probably due to interactions between malonaldehyde and proteins (Igene & Pearson, 1979). In this study, the TBARS values of the samples with anka rice added (R1, R2, and R3) were higher than those of the C and A samples. Higher TBARS values were observed when anka rice levels increased. This increase of TBARS values was probably due to the fact that *M. purpureus*, which was previously inoculated to the anka rice, might produce some lipases, and this then speeded up fat hydrolysis, and finally increased the TBARS values of samples (Tseng, 1999). The results of this study showed that the addition of anka rice did not inhibit the lipid oxidation of Chinese sausages, which agreed with other studies. When evaluating the TBARS values of samples, Cheng and Ockerman (1998) reported that addition of anka rice had little retarding effect on lipid oxidation in roast beef.

Increased amounts of volatile basic nitrogen (VBN), a result of decomposition of protein during storage by microorganisms, can be an index of loss of meat product freshness (Jay, 1992). Fig. 1b illustrates that VBN values of the sausage samples increased with storage time, as expected. This result agreed with other studies (Lin, Chen, & Yen, 1995). Also, samples with anka rice added (R1, R2, and R3) had significantly higher VBN values than had A and C samples. In addition, samples that had more anka rice added had significantly ($P < 0.05$) higher VBN values. This increase of VBN values was probably because anka rice itself had higher VBN values, which was also reported by Gui (1984). In this study, higher VBN values might suggest greater bacterial populations for the samples with more anka rice added, which were previously inoculated with *M. purpureus*, and this result was is in agreement with the microbial counts shown.

3.4. Nitrite residue

Table 2 illustrates the nitrite residue of sausages during storage. For the C samples, with high nitrite level (100 ppm), the nitrite contents dropped rapidly from 36.2 ppm at day 0 to 21.0 ppm at day 14, and 11.7 ppm at day 56. With addition of anka rice, the degrading rate of nitrite was reduced. Collins-Thomposon and Lopez (1981) reported that nitrite salts were converted to NO, NO_2, or N_2O by lactic acid bacteria isolated from vacuum-packed bologna, and depleted the nitrite contents in the samples. Similar nitrite depletion was also accomplished by lactic acid bacteria isolated from kimchi and other foods (Oh, Oh, & Kim, 2004). Faster nitrite depletion at lower pH values was also reported by Theiler, Sato, Aspelund, and Miller (1981). Therefore, a comparatively lower pH of the A samples (no anka rice added) in this study might be the reason why a lower residual nitrite content was observed after storage for more than 28 days.

3.5. Microbial qualities

In this study, the total plate counts of all samples remained stable during refrigerated storage (Fig. 2a). The total plate counts of Chinese sausage with different levels of anka rice added (R1, R2, and R3) were between 7.19 and 7.91 log CFU/g, which were significantly ($P < 0.05$) higher than those of the C and A groups (3.34–4.84 log CFU/g). The higher bacterial counts of the R1, R2, and R3 samples were probably due to the addition of *M. purpureus* to samples. Adding anka rice to the formula caused the samples (R1, R2, and R3) to have significantly higher mould counts (6.98–8.05 log CFU/g) during storage than those of the samples without anka rice added (3.14–4.19 log CFU/g). Samples with anka rice added (R1, R2, and R3) had anaerobic counts of 7.22–7.99 log CFU/g, which were significantly higher than those of the A and C samples during refrigerated storage. In addition, the C samples (without anka rice added, but with 100 ppm sodium nitrite added) had lower anaerobic counts than had the A samples (without anka rice, but with 25 ppm sodium nitrite added) during the first two weeks of storage. A higher nitrite level, which might inhibit some microbial growth, led to a lower count.

Table 3

Overall acceptance			
C	$5.6 \pm 1.3^{a,x}$	$3.4 \pm 0.8^{b,y}$	$3.1 \pm 1.0^{a,y}$
A	$5.0 \pm 1.1^{a,x}$	3.3 ± 1.2^{bx}	$3.1 \pm 1.4^{a,y}$
R1	$4.5 \pm 1.0^{a,x}$	$5.0 \pm 0.9^{ab,x}$	$2.3 \pm 1.1^{a,y}$
R2	$4.5 \pm 0.7^{a,x}$	$5.4 \pm 0.5^{a,x}$	$3.3 \pm 1.3^{a,y}$
R3	$5.8 \pm 0.8^{a,x}$	$4.2 \pm 0.9^{ab,xy}$	$3.6 \pm 1.2^{a,y}$

[a–d]Means within the same column for the same test with different superscripts are significantly different ($P < 0.05$).
[x–y]Means within the same row for the same test with different superscripts are significantly different ($P < 0.05$).
[A] A 7-point hedonic scale test was used in this study. 1 = extremely dislike, 4 = neither like nor dislike, 7 = extremely like.
[B] C: 100 ppm sodium nitrite; A: 25 ppm sodium nitrite; R1: 25 ppm sodium nitrite + 0.5% anka rice which was inoculated with *M. purpureus*; R2: 25 ppm sodium nitrite + 1.0% anka rice which was inoculated with *M. purpureus*; R3: 25 ppm sodium nitrite + 1.5% anka rice which was inoculated with *M. purpureus*.

3.6. Sensory evaluation

Table 3 illustrates the sensory evaluation results. A 7-point hedonic scale test was used in this study, where scores 1, 4, and 7 representing extremely dislike, neither like nor dislike, and extremely like, respectively. The sausages with anka rice added tended to have significantly higher colour scores than did the A and C samples. Also, all the colour scores of the anka rice-added sausages were higher than 4 over the entire storage time, whereas lower nitrite sausages (A) had the lowest colour scores. This result illustrates that addition of anka rice could improve colour acceptance of low-nitrite Chinese sausages. In this study, samples' aroma and flavour scores tended to decrease as storage time increased.

The aroma and flavour scores of the control samples with higher nitrite level (C) significantly decreased after 56 days of refrigerated storage. Overall, Chinese sausage with 0.5%, 1% and 1.5% anka rice (R1, R2, and R3) could be accepted when stored at 4 °C for 28 days, whereas the overall acceptance scores of the C and A samples were less than 4.

4. Conclusion

Addition of anka rice up to 1.5% (w/w), which was previously inoculated with *M. purpureus*, did not affect the chemical compositions and water activities of the Chinese sausages. Samples with anka rice added had darker red colours, higher TBARS values, higher microbial counts and less nitrite degradation. Based mainly on the results of overall acceptance, it could be concluded that anka rice, inoculated with *M. purpureus*, could be used in the production of low-nitrite Chinese sausages when stored at 4 °C for 28 days.

Raffinose oligosaccharides
Debaryomyces hansenii
α-Galactosidase
Digestibility

ABSTRACT

The objectives of this work were to establish a safe and economically viable process for the removal of raffinose oligosaccharides (RO) from soy flour and compare the effects of RO elimination from diets with regard to nutritional parameters by testing in Wistar rats. *Debaryomyces hansenii* UFV-1 was cultivated in suspension of defatted soy flour (1:10 w/v). An increase in α-galactosidase activity was observed in the medium, with a consequent decrease in the RO concentration. A total reduction of RO was achieved at 36 h of incubation. The diet containing soy flour free of RO presented higher digestibility, 91.28%, in relation to the diet containing soy flour with RO, 87.14%. However, the removal of the oligosaccharides from the diet did not promote a significant improvement in the values of weight gain, and other nutritional parameters tested on rats, during the experimental period of 14 days.

1. Introduction

Soybeans and their derivatives possess excellent nutritional value, principally high protein levels. However, the consumption of this legume is limited due to the presence of raffinose oligosaccharides (RO), in particular raffinose and stachyose, which can cause abdominal discomfort in humans and monogastric animals, such as cramps, flatulency and diarrhoea. This occurs because the mucous in the small intestine does not possess the α-galactosidase (E.C. 3.2.1.22 α-galactoside galactohydrolase) enzyme necessary for the hydrolysis of the α-1,6 linkages present in RO, allowing these sugars to pass intact to the large intestine where they are fermented by anaerobic microorganisms creating excessive gas (Karr-Lilienthal, Kadzere, Grieshop, & Fahey, 2005). These compounds are also likely to be responsible for increasing viscosity of digesta, which interferes with digestion of nutrients by decreasing their interaction with digestive enzymes in the intestine (Smits & Annison, 1996).

As a result, there is a large demand for RO-free soybean products. Various processes for the reduction or elimination of RO have been proposed, such as the addition of α-galactosidases to the diet (Igbasan, Guenter, & Slominski, 1997; Smiricky et al., 2002) or the fermentation of soy products by microorganisms capable of producing this enzyme (Donkor, Henriksson, Vasiljevic, & Shah, 2007; Leblanc et al., 2004). The α-galactosidase is found in plants, microorganisms and animals (Kim et al., 2002). However, many α-galactosidase producing microorganisms do not present GRAS (generally recognised as safe) status for their use in foods. On the other hand, the use of isolated enzymes increases processing costs since the production and purification of enzymes are critical steps in order to make the enzymatic removal of RO economically viable. Isolated α-galactosidases from the *Debaryomyces hansenii* yeast have proven to be adequate for biotechnological applications, especially for RO hydrolysis in soy products (Viana et al., 2006, 2007). This is the most frequently used yeast in traditional cheese and sausages, contributing to the special flavours of these products (Saldanha-Da-Gama, Malfeito-Ferreira, & Loureiro, 1997) and there should be no restriction, regarding safety, for its use in food processing.

Despite various studies showing positive effects for the enzymatic removal of RO from soy based foods (Leblanc et al., 2004; Veldman, Veen, Barug, & Van Paridon, 1993), some authors have reported no improvements in protein digestibility when diets were supplemented with α-galactosidase (Irish, Barbour, Classen, Tyler, & Bedford, 1995; Smiricky et al., 2002).

The objectives of this work were to establish a safe and economically viable enzymatic process for the removal of RO from soy flour and compare the effects of RO elimination from diets with regard to nutritional parameters by testing in Wistar rats.

2. Materials and methods

2.1. Microorganisms and culture maintenance

The yeast strain used in this study was isolated from a dairy environment in Minas Gerais, Brazil, and maintained in the culture

doi:10.1016/j.foodchem.2009.04.124

collection of the Microorganism Physiology Laboratory, BIOAGRO, Federal University of Viçosa (UFV), Brazil. The yeast was identified by the Institute of Yeasts Identification, Centraalbureau voor Schimmelcultures, Utrecht, The Netherlands, as *D. hansenii* (Zopf) Lodder & Kreger-van Rij var *fabryi* Nakase & Suzuki. In this study, it is designated as *D. hansenii* UFV-1.

A stock culture of *D. hansenii* UFV-1 was maintained at −80 °C in glycerol and YPD medium (1% yeast extract, 2% peptone and 2% glucose). *D. hansenii* UFV-1 was streaked on a YPD agar surface (1.5% agar) and maintained in an incubation chamber at 30 °C for 36 h. The plates were maintained at 4 °C and this stock was restreaked monthly.

2.2. Treatment of soy flour with viable Debaryomyces hansenii cells

The yeast was activated in YPD liquid medium, incubated for 12–15 h, at 200 rpm and 30 °C and the culture was centrifuged (4000*g* for 5 min at 4 °C). Commercial fat-free soy flour was mixed with deionised water (1:10 w/v). The cells obtained after centrifugation were inoculated in the soy flour suspension and incubated at 200 rpm and 30 °C for 72 h. Samples of 2 ml were taken at 12 h intervals for the determination of α-galactosidase activity and percentage of RO hydrolysed. The reaction mixtures were dried, and the soluble sugars from 20 to 30 mg of lyophilised samples were extracted with 80% aqueous ethanol (v/v) according to Guimarães, de Rezende, Moreira, Barros, and Felix (2001). The solvent was evaporated at 50 °C, and the sugars were resuspended in 1 ml of 80% ethanol and analysed by high-performance liquid chromatography (HPLC). Hydrolysis efficiency was evaluated by the reduction of RO levels present in the soy flour suspension, as a function of incubation time with the yeast.

2.3. HPLC analysis of soluble sugars

Sugars were analysed by HPLC on a Shimadzu series 10A chromatograph equipped with an analytical column [aminopropyl ($-NH_2$)], eluted with an acetonitrile–water isocratic mixture (80:20 v/v) at 35 °C and a flow rate of 1 ml/min, according to Guimarães et al. (2001). The individual sugars were automatically identified and quantified by comparison with the retention times and standard sugar concentrations. Gentiobiose was used as an internal standard since it does not interfere with other sugars and is not found in soybean seeds.

2.4. Production of soybean flour free of raffinose oligosaccharides

Viable *D. hansenii* cells (equivalent to 0.533 mg/ml of dry cell mass) were mixed with an autoclaved suspension of defatted soy flour 1:10 (w/v) and the mixture was incubated at 200 rpm and 30 °C for 36 h. After this period, the suspension was lyophilised in order to obtain soy flour free of oligosaccharides. This flour was used as a protein source of the diet (D1). The soy flour containing oligosaccharides was prepared as described earlier, with the exception of the yeast cells being added to the soy flour suspension.

2.5. Enzyme assay

The enzyme was assayed using a reaction system (1 ml final volume) containing 650 μl of 0.1 M sodium acetate buffer, pH 5.0, 100 μl of enzyme preparation and 250 μl of 2 mM ρ-nitrophenyl α-D-galactopyranoside (ρNPGal) or, other synthetic substrates. The reaction was conducted for 15 min at 40 °C and stopped by the addition of 1 ml of 0.5 M sodium carbonate. The amount of ρ-nitrophenol (ρNP) released was determined at 410 nm. One unit of enzyme activity (U) was defined as the amount of protein required to produce 1 μmol of ρ-nitrophenol per minute.

2.6. Determination of the biochemical composition of the soy flours

Determination of the protein, lipid, ash and carbohydrate concentrations in the soy flours were performed according to the Association of Official Analytical Chemists (1997) method.

2.7. Biological assay

2.7.1. Diet preparation

The soy flours containing RO and no RO were used as protein sources in the experimental diets (Table 1). The diet composition was based on that of AIN-93G, according to Reeves, Nielsen, and Fahey (1993), with protein levels adjusted to 9–10%. The protein concentration of each diet was determined by the semimicro Kjeldahl method, using a conversion factor of 6.25 to obtain protein values.

2.7.2. Animals and experimental conditions

The male Wistar breed rats used were newly weaned, with an average age of 23 days and weight varying from 50 to 60 g. They were provided by the Biotery Center from the Center of Biological Sciences and Health (CCB) of the Federal University of Viçosa (UFV).

The rats were divided into four groups with each group containing six rats so that the difference in average weight between each group did not exceed 5 g. They were placed in individual cages where they received water and their *ad libitum* experimental diets for 14 days. The rats were maintained under controlled conditions of temperature (22 ± 3 °C) and luminosity (12 h photoperiod), with the weekly monitoring of feeding. Experimental procedures were approved by the Veterinary Commission Department of Ethics/UFV (protocol no. 57/2007).

2.7.3. Nutritional evaluation

In order to evaluate the effect of RO removal from the diets, the following were determined: animal weight gain, true digestibility, protein efficiency ratio (PER), and net protein ratio (NPR).

Animal weight gain: to compare weight gain, the animals were weighed before beginning the experiment and randomly distributed in the cages so that the difference between the average rat weight of each group did not exceed 5 g. At the end of each week the animals and diets were both weighed, discounting any remaining.

Table 1
Composition of experimental diets.[a]

Ingredient (%)	Diet			
	Aproteic	Casein	D1[a]	D2[b]
Casein	–	11.96	–	–
Soy flour	–	–	14.11	16.61
Dextrinized cornstarch	13.20	13.20	13.20	13.20
Sucrose	10.0	10.0	10.0	10.0
Soy oil	7.00	7.00	7.00	7.00
Fibre	5.00	5.00	2.80	2.80
Mineral mix (AIN-93G-MX)	3.50	3.50	3.50	3.50
Vitamin mix (AIN-93-VX)	1.00	1.00	1.00	1.00
Choline bitartrate	0.25	0.25	0.25	0.25
L-Cystine	0.30	0.30	0.30	0.30
Cornstarch	59.75	47.79	47.84	45.34

Font: Reeves et al. (1993).
[a] D1 – diet containing RO-free soy flour.
[b] D2 – diet containing soy flour with RO.

True digestibility: the diets were marked with 0.02% indigo carmin and the faeces were collected after 10 and 14 experimental days, packed in individual recipients and maintained under refrigeration. The faeces were dried at 105 °C for 24 h, cooled in a desiccator, weighed and ground. The nitrogen content in the faeces was determined using the semimicro Kjeldahl method, with tests being performed in triplicate. True digestibility was calculated by measuring the quantity of ingested nitrogen in the diet, quantity excreted in the faeces and the metabolic loss of nitrogen in the faeces, which corresponds to the faecal nitrogen from the aproteinic diet group. This was possible since one group of six rats was administered an aproteinic diet.

Protein efficiency ratio (PER): the PER was determined using the Osborne, Mendel and Ferry method, according to the Association of Official Analytical Chemists (AOAC) (1975).

Net protein ratio (NPR): the NPR was determined on the 14th experimental day, taking the weight gain of the test group plus the weigh loss from the group with the aproteinic diet, in relation to the protein consumption of the test group, according to the Bender and Doell (1957) method.

2.8. Extraction and concentration determination of short-chain fatty acids

The extraction and concentration determination of short-chain fatty acids (acetic, propionic and butyric) contained in the caecal was performed according to the techniques reported by Smiricky-Tjardes, Grieshop, Flickinger, Bauer, and Fahey (2003) with some modifications. Samples to be analysed for SCFA were mixed with 0.5 ml of 3.12 M metaphosphoric acid, precipitated at room temperature for 30 min, and then centrifuged at 16,100*g* for 30 min. The supernatant was decanted and again centrifuged at 16,000*g* for 20 min and frozen at −20 °C. After freezing, the supernatant was thawed and centrifuged at 13,000*g* for 10 min. Concentrations of SCFA were determined *via* gas–liquid chromatography. Concentrations of acetate, propionate, and butyrate were determined in the supernatant using a Shimadzu series 17A gas chromatograph and a 30 m × 0.25 mm Nukol column (Supelco Inc., Bellefonte, PA). Helium was the carrier gas with a flow rate of 1.90647 ml/min. The column temperature was maintained at 100 °C for 4 min and increased to 185 °C at a rate of 8.5 °C/min and maintained at this temperature for 15 min. The temperature of the detector (FID) and injector were 250 °C and 220 °C, respectively.

2.9. Statistical analysis

A statistical analysis (ANOVA) was used to determine the value of "*F*". For "*F*" significance, the Duncan test was used with a 5% significance level for comparison of the means. The dispersion of the means was expressed in the result tables with standard deviations from the average. Calculations were performed using SAEG version 9.1 (Federal University of Viçosa).

3. Results and discussion

During the cultivation of *D. hansenii* yeast in the soy flour suspension, an increase in α-galactosidase activity and a consequent decrease in the RO concentration present in soy flour was observed (Fig. 1). Various studies suggest the use of microorganisms, principally from the *Lactobacillus* and *Bifidobacterium* genus, for the removal of RO from soymilk and other products derived from soybeans (Scalabrini, Rossi, Spettoi, & Matteuzzi, 1998; Yoon & Hwang, 2008). However, there are no studies on the direct use of *D. hansenii* in soy products for the removal of RO. *D. hansenii* is

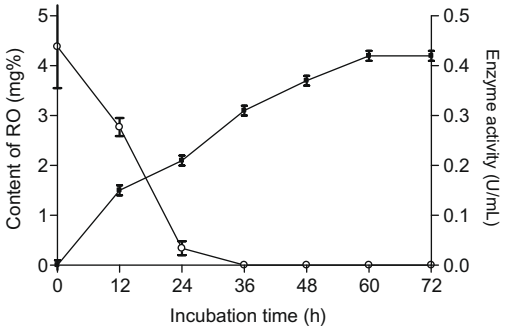

Fig. 1. α-Galactosidase activity (■) and raffinose oligosaccharides content (raffinose and stachyose) (○) in the suspension of defatted soy flour after inoculation of *Debaryomyces hansenii*.

the yeast most frequently found in several food products such as traditional cheese and sausages, and there should be no restriction regarding safety for its use in food processing.

Extracellular activity of α-galactosidase increased and stabilised after 60–72 h of *D. hansenii* cultivation in the soy flour suspension, and RO concentration reduced drastically during the first 24 h of cultivation (Fig. 1). Interestingly, the increase in the extracellular α-galactosidase activity, even after total reduction of RO, was observed (Fig. 1). Induction of α-galactosidase activity could be due to the higher concentration of galactose in the medium, which was released as a product of the RO hydrolysis. Galactose was considered to be the more efficient carbon source compared to raffinose and stachyose for the induction of α-galactosidase activity in microorganisms (Nobre, Lucas, & Leão, 1999; Yoshida, Tan, Shimokawa, Turakainen, & Kusakabe, 1997). Hydrolysis of RO may be achieved either by α-galactosidase, invertase or both. While α-galactosidase hydrolyses the α-1,6 linkage of raffinose producing galactose and sucrose, invertase hydrolyses α-1,2 linkage producing melibiose and fructose. During cultivation of *D. hansenii* in the soy flour suspension, no invertase activity was detected in the culture supernatant, indicating that RO hydrolysis was catalysed by α-galactosidase only. No hydrolysis was detected in the control samples, in which the soy flour suspension was not inoculated with any yeast.

The average raffinose and stachyose content in the defatted soy flour was 1.15% and 3.23%, respectively (Table 2). Oligosaccharides found in the majority of soybeans and its derivatives are stachyose followed by raffinose, making up approximately 4–6% of soybean flour's dry weight (Grieshop, Kadzere, Clapper, Frazier, & Fahey, 2003; Karr-Lilienthal et al., 2005). After 12 h of *D. hansenii* cultivation in the soy flour suspension, 96.2% of stachyose concentration was reduced and, the raffinose concentration increased by 132% in the culture medium (Table 2). This difference may be due to the accumulation of raffinose in the medium which is formed during hydrolysis of stachyose by cleaving of the α-1,6 bond and removal of the galactose residue. Kinetic studies of α-galactosidase

Table 2
Hydrolysis of oligosaccharides present in soybean flour by treatment with *Debaryomyces hansenii* UFV-1.

Incubation time (h)	Concentration (%) ± SD	
	Raffinose	Stachyose
0	1.15 ± 0.08	3.23 ± 0.75
12	2.67 ± 0.12	0.10 ± 0.06
24	0.34 ± 0.14	0
36	0	0
48	0	0
60	0	0
72	0	0

from *D. hansenii* confirm these results since the K_m value of the enzyme for the stachyose substrate was lower than the K_m value for raffinose, suggesting greater enzyme affinity for stachyose (Viana et al., 2006). Because stachyose is the most abundant nondigestible oligosaccharide found in soy flour, the high hydrolysis capacity of this sugar exhibited by α-galactosidase from *D. hansenii* makes its use extremely interesting as a biocatalyst for elimination of RO in soy products. Total reduction of RO was observed after 36 h of *D. hansenii* cultivation in the soy flour suspension. *Bifidobacterium breve*, *B. infantis* and *B. longum* incubated in soy milk for 48 h promoted the total reduction of raffinose and reduction of 68%, 73% and 35%, respectively in stachyose content (Scalabrini et al., 1998), while at the same time, *B. lactis* B94 promoted raffinose and stachyose content reductions of 77.4% and 63.5%, respectively (Donkor et al., 2007). The ability of *D. hansenii* to grow on the soy flour suspension, to produce α-galactosidases and to use the ROs, indicates the possibility of the direct utilisation of this yeast for RO reduction in soybean derivatives, what is advantageous in terms of facility and costs of the process.

The biochemical composition of soy flours free of RO (SF1) and containing RO (SF2) are presented in Table 3. Cultivation of yeast on soy flour promoted the increase in the protein content and decrease in the content of total carbohydrates in relation to the untreated soy flour. These data suggest that the treatment of soy flour with *D. hansenii* cells may be advantageous from a nutritional point of view since they eliminate RO, which are considered antinutritional factors, as well as increase the protein content of the flour.

For the evaluation of the nutritional effect of RO elimination from the soy flour, diets were prepared with soy flours SF1 and SF2, as well as the control diets (Table 1) and this was used to feed Wistar rats for a period of 14 days. The diet containing soy flour free of RO (D1) presented a digestibility of 91.28%, statistically significant ($p \leqslant 0.05$) and superior in relation to the diet containing soy flour with RO (D2), which presented a digestibility of 87.14% (Table 4). According to Graham, Kerley, Firman, and Allee (2002), the decrease in RO content may potentially reduce the viscosity of ingested food, increasing its retention time and promoting greater periods for enzyme digestion of substrates, consequently increasing the absorption of nutrients in the intestinal mucous. The presence of RO in swine diets containing concentrated soy proteins showed a significant reduction in the digestibility of proteins (Smiricky et al., 2002). Sakaguchi, Sakoda, and Toramaru (1998) confirmed a reduction in the true digestibility of proteins when RO was added to casein diets for rats. Veldman et al. (1993) also reported that the addition of soy molasses containing 18% RO to swine diets promoted a reduction of 25% in protein digestibility, but the addition of α-galactosidase improved the digestibility of these sugars and proteins. Therefore, RO reduction in diets can improve digestibility, both by reducing the viscosity of ingested food as well as promoting hydrolysis of these sugars into digestible monosaccharides. On the contrary, Gabert, Sauer, Mosenthin, Schimitz, and Abrens (1995) reported that swine diets produced from soy flour containing RO had no effect on the ileal digestibility of proteins and the majority of amino acids. Similarly, Irish et al. (1995) observed no effect on the ileal digestibility of proteins when α-galactosidase was added to chicken rations.

The values of weight gain, PER and NPR, did not differ statistically, with a 5% significance level, for the rats fed with the diet containing soy flour free of RO (D1) and containing RO (D2), during the experimental period (Table 4). Similarly, Graham et al. (2002) observed improvements in the digestibility of diets containing soy flour when supplemented with α-galactosidase, however, no variation in the weight gain of the broiler chickens was observed. Zdunczyk, Juskiewicz, Frejnagel, and Gulewicz (1998) reported that the presence of RO in rat diets decreased digestibility in relation to the same diet without these sugars, but the PER values for the two did not statistically differ.

The RO are considered indigestible carbohydrates due to their resistance to digestion in the small intestine, caused by the absence of the α-galactosidase in intestinal mucous in humans and monogastric animals (Sakaguchi et al., 1998). These sugars are kept intact until reaching the large intestine where they are fermented by anaerobic bacteria. The principal products of this fermentation are short-chain fatty acids (SCFA), which are absorbed and used as sources of energy by the epithelial cells in the large intestine (Roediger, 1980).

In this study, the production of SCFA does not statistically differ for animals fed with the diet containing soy flour free of RO (D1) and with RO (D2) during the experimental period (Table 5). Similarly, no difference in the production of SCFA was detected in the intestines of rats given a diet of bean flour with high and low RO contents during a period of 14 days (Henninsson, Margareta, Nyman, & Björck, 2001). Contrary to these results, Sakaguchi et al. (1998) found greater levels of propionic and butyric acid in rats when RO was added to a casein diet. Levrat, Behr, Rémésy, and

D1	91.28[b] ± 2.07	2.63[b] ± 0.14	3.56[b] ± 0.16	29.17[b] ± 4.26
D2	87.14[c] ± 2.98	2.71[b] ± 0.22	3.53[b] ± 0.22	33.83[b] ± 5.49

[a] Mean ± standard deviation of triplicate determinations. Values with common superscript letter in each row are not significantly ($p > 0.05$) different by Duncan test.
[b] D1 – diet containing RO-free soy flour.
[c] D2 – diet containing soy flour with RO.

Demigné (1991) observed that in rats given a soy based diet, the maximum production of SCFA occurred 16 days after beginning the experiment. However, the fermentation of RO and SCFA production was slower when RO was in the leguminous form, compared to when purified RO was added to the diet and production of gas and SCFA was greater when originating from the fermentation of raffinose compared to stachyose (Smiricky-Tjardes et al., 2003). In the present work, the low raffinose content in the diets and the short duration of the experiments probably explain why no significant differences were detected in SCFA production in the caecum of rats fed with a diet containing RO in relation to the diet free of RO.

4. Conclusions

The results presented in this study demonstrated that the removal of RO from soy flour using viable *D. hansenii* cells makes up a safe, simple and economical process. Rats administered a diet free of RO presented better protein digestibility compared to the rats given the diet containing RO, confirming preliminary results which indicated that RO may interfere in the absorption of nutrients in the diet, acting as an antinutritional factor. This suggests that the removal of RO can improve the nutritional values and the acceptance of products derived from soybeans for use in both human and animal nourishment.

ABSTRACT

The aim of this work was to investigate the products of the reactions between isoeugenol and eugenol with the stable 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical and their role in the radical scavenging mechanism. The reaction of isoeugenol and eugenol with the DPPH radical produced, as evidenced by GC–MS and HPLC–MS, a complex mixture of dimeric species in which dehydrodiisoeugenol and its adducts with methanol (reaction solvent) and dehydrodieugenol were the main reaction products, respectively. The antioxidant activity of dehydrodiisoeugenol, determined by the DPPH method, resulted lower than that of isoeugenol considering both the parameters Effective Concentration (EC_{50}) and Antiradical Efficiency (AE). In particular, due to its very slow kinetic behaviour ($T_{EC_{50}} = 201$ min), the possible contribution of dehydrodiisoeugenol to the DPPH radical scavenging activity of isoeugenol ($T_{EC_{50}} = 3.1$ min) was practically negligible. On the contrary, dehydrodieugenol had an antioxidant activity higher than that of eugenol and its lower $T_{EC_{50}}$ (85 min with respect to 126 min) made it possible to contribute to the DPPH radical scavenging activity of eugenol.

1. Introduction

Several analytical methods are routinely used to evaluate the antioxidant capacity of a large variety of compounds both in pure form and in complex mixture like herbs, spices, fruits and seeds extracts. Among them, the oxygen radical absorbance capacity (ORAC) assay, the 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical assay, the trolox equivalent antioxidant capacity (TEAC) assay and the ferric reducing antioxidant power (FRAP) assay are probably the most widely used. The ORAC method is based on the scavenging of peroxyl radicals generated by an azo compound, and fluorescein is used as target molecule. The decrease in fluorescence in the absence and in the presence of an antioxidant is monitored. The assay is carried out in phosphate buffer at pH 7.4, and the results are expressed as trolox equivalents (Cao, Alessio, & Cutler, 1993; Ou, Hampsch-Woodill, & Prior, 2001). The DPPH method is based on the scavenging of the stable DPPH radical by the antioxidant. The decrease in absorbance of the radical is monitored at 515 nm, in methyl alcohol, until the reaction reaches a steady state. The results are expressed by the parameters Effective Concentration (EC_{50}) that represent the [antioxidant]/[DPPH] concentration ratio, which decreases the initial DPPH concentration by 50%, the stoichiometry value (n) defined as the DPPH moles scavenged by one mole of antioxidant and the Antiradical Efficiency defined as $AE = 1/(EC_{50} \times T_{EC_{50}})$, where $T_{EC_{50}}$ represents the time needed to reach the steady state for EC_{50} (Brand-Williams, Cuvelier, & Berset, 1995; Sanchez-Moreno, Larrauri, & Saura-Calixto, 1998). With a similar approach, the Trolox Equivalent Antioxidant Capacity (TEAC) method is based on the ability of a compound to scavenge the 2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid) radical ($ABTS^{\bullet-}$) with respect to trolox C. The decrease in absorbance of the blue-green radical is monitored at 652 nm for 6–10 min. The assay is carried out in ethanol or in phosphate-buffered saline (PBS) at pH 7.4 and the results are expressed as trolox equivalents (Re et al., 1999). On the contrary, the FRAP method does not use free radical scavenging but is based on the reducing ability of the antioxidant versus the ferric-tripyridyltriazine complex. The increase in absorbance due to the formation of the coloured reduced ferrous complex is monitored and the results are expressed as trolox equivalents (Benzie & Strain, 1996). This brief description is enough to show the different approach and the different conditions of reaction time, reaction medium, temperature and treatment of the results used by these methods and the consequent difficulty to

compare the results obtained for the same compounds. Foti and Ruberto (2001) observed a dependence of the antioxidant activity of some flavonoids and phenolic antioxidants on the hydrogen bond acceptor activity of the solvents. The effect of solvent and food components on the antioxidant activity obtained by applying the ORAC, DPPH, TEAC and FRAP methods to the mixture of catechin and gallic acid has been recently outlined by Perez-Jimenez and Saura-Calixto (2006). Also the oxidation processes involved are different: hydrogen atom transfer (HAT) in the case of the ORAC assay and single electron transfer (SET) in the other methods (Foti, Daquino, & Geraci, 2004; Huang, Ou, & Prior, 2005). These problems are even more enhanced by the possible occurrence of side reactions involving chemical species other than the antioxidant under testing. Studying the reaction mechanism of the DPPH radical with BHT, eugenol and isoeugenol, Brand-Williams et al. (1995) and Bondet, Brand-Williams, and Berset (1997) evidenced an inverse relationship between stoichiometry and reaction rates suggesting the intervention of a more complex reaction mechanism, eventually involving dimeric species, for the compounds with a slow kinetic behaviour such as eugenol. Recently, Ordoudi, Tsimidou, Vafiadis, and Bakalbassis (2006), studying the DPPH radical scavenging activity of guaiacol acid derivatives, reported the difficult to interpret the stoichiometry values of some compounds. Eklund et al. (2005) reported the formation of dimers in the reaction of lignans with DPPH radical. The EC_{50} of compounds with long reaction time can therefore reflect a radical scavenging capacity comprehensive not only of the contribution of the original antioxidant but also of other chemical species. Similar considerations were more recently outlined by Arts, Dallinga, Voss, Haenen, and Bast (2003) and Arts, Haenen, Voss, and Bast (2004) about the TEAC assay. In the reaction between $ABTS^{\cdot-}$ and the flavonoid chrysin, these authors reported the formation of a product with an antioxidant capacity higher than that of the parent compound. Hotta, Sakamoto, Nagano, Osakai, and Tsujino (2001) and Hotta, Nagano, Ueda, Tsujino, Koyama and Osakai (2002), studying the antioxidant capacity of natural compounds by column flow electrolysis, observed an increase of exchanged electrons by decreasing the flow and they attributed this effect to the oxidation of compounds formed by chemical reactions following the first oxidation process.

The aim of this work was to investigate the products formed by reaction of isoeugenol (**1**) and eugenol (**2**) with the DPPH radical under the same conditions used in the DPPH assay. The structural identification of these compounds, as well as the determination of their radical scavenging activity, may provide an insight into the antioxidant mechanism involved.

2. Materials and methods

2.1. Materials and reagents

All solvents were of analytical grade or LC–MS grade. 2,2-Diphenyl-1-picrylhydrazyl (DPPH) radical, eugenol (**1**), isoeugenol (**2**; mixture of *E* and *Z* isomers), N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA) and horseradish peroxidase (HRP, type II) were purchased from Sigma–Aldrich (Milan, Italy). Silica gel 60, 70–230 mesh ASTM and the thin-layer chromatography (TLC) silica gel plates, 0.25 mm thickness were provided by Merck (Darmstadt, Germany).

2.2. Melting point determination

Melting point determination was performed by differential scanning calorimetry (DSC) (Mettler TA 4000 system equipped with TC15 TA Controller, DSC 30 measuring cell and Star software version 8.10, Mettler, Greinfensee, Switzerland). Heat flow calibration was performed with indium, temperature calibration was done with *n*-hexane, distilled water and indium. Samples were placed into 40-μL aluminium pans that were hermetically sealed and scanned under 10 mL min^{-1} dry nitrogen flow to at least 10 °C above the endset of melting at a rate of 1 °C min^{-1}. The reported values were the average of two onset T_m.

2.3. ^1H and ^{13}C NMR spectra

^1H and ^{13}C NMR spectra were recorded on a Bruker AC-F 200 spectrometer at 200 and 50 MHz, respectively, using $CDCl_3$ as solvent at room temperature. NMR chemical shifts are reported as δ values from TMS.

2.4. Gas chromatography–mass spectrometry (GC–MS)

A Shimadzu gas chromatograph coupled to a quadrupole mass spectrometer QP-2010 (Shimadzu Corporation, Kyoto, Japan) was used. The column was a 30 m × 0.25 mm i.d., 0.25 μm film thickness, fused silica Equity 5 (Supelco, Sigma–Aldrich, Milan, Italy). The initial oven temperature was 60 °C for 2 min, then programmed to 280 °C at 15 °C min^{-1}. The injection was in splitless mode (2 min) with helium as carrier gas at a flow rate of 1 mL min^{-1}. The injector, transfer line and ion source temperatures were, respectively 280, 280 and 200 °C. The mass spectrometer operated in electron impact ionisation mode at 70 eV.

2.5. High performance liquid chromatography–mass spectrometry (HPLC–MS)

A Finnigan LXQ linear trap (Thermo Electron Corporation) was used for ESI-MS^n analysis in the positive and negative ion modes. The general conditions were capillary temperature 275 °C, sheath and auxiliary gas flows 25 and 5 (arbitrary units), respectively, source and capillary voltage in the positive polarity 4.0 kV and 2.0 V and 4.7 kV and −50.0 V in the negative polarity, respectively. Collision-induced dissociation (CID) multiple MS spectra (MS^n experiments) were acquired using helium as the collision damping gas in the ion trap at a pressure of 1 mTorr. Direct infusion of the standard solutions of pure dehydrodiisoeugenol (**3**) and dehydrodieugenol (**4**) and intact reaction mixtures diluted with MeOH or MeCN were performed with the aid of a syringe pump, using a flow rate of 5 μL min^{-1}. The LC-ESI-MS analyses were obtained with the same instrument coupled with a Finnigan Surveyor LC Pump Plus equipped with a Waters Spherisorb 5 μm ODS2 analytical column (4.6 × 250 mm) at 30 °C. Elution was carried out at a flow rate of 0.8 mL min^{-1} using an Accurate post-column flow splitter with a split ratio of 1:4 and MeCN/H_2O (65/35, v/v) as mobile phase.

2.6. DPPH radical scavenging method

The radical scavenging activity of the compounds was determined following the method used by Bortolomeazzi, Sebastianutto, Toniolo, and Pizzariello (2007). DPPH was dissolved in methanol at a final concentration of about 6×10^{-5} M. The exact concentration of DPPH was calculated from a calibration curve, ε = 11870 M^{-1} cm^{-1} at 515 nm. Different aliquots of a methanolic solution of the phenolic compounds were added to 2450 μL of DPPH solution and the volume was adjusted to a final value of 2500 μL with methanol. Five different concentrations were used for each assay. The decrease in the DPPH radical was followed at 515 nm until the reaction reached a steady state by using a Varian Cary 1E spectrophotometer equipped with a thermally controlled multicell block set at 25 °C. The concentrations of DPPH at the steady state, corrected for the natural disappearance of the DPPH radical, were plotted as a function of the molar concentration ratio

[AH]/[DPPH] to determine the Effective Concentration (EC_{50}). The time needed to reach the steady state for EC_{50} ($T_{EC_{50}}$) and the Antiradical Efficiency $AE = 1/(EC_{50} \times T_{EC_{50}})$ were also calculated.

2.7. Reaction of isoeugenol-DPPH radical

The conditions used to analyse the reaction products between isoeugenol (**1**) and DPPH were similar to those used in the DPPH assay. To 2450 μL of a methanolic DPPH solution were added 40 μL of methanol and 10 μL of an isoeugenol (**1**) methanolic solution. The final concentration was about 6×10^{-5} M and 4.4×10^{-5} M for DPPH and isoeugenol (**1**), respectively. After 5 min, the reaction mixture was reduced to dryness by a rotavapour at 40 °C, dissolved with 200 μL of acetonitrile and analysed by GC–MS. To the acetonitrile solution was then added 100 μL of BSTFA and was let to react for 1 h at room temperature before GC–MS analysis. The reaction was carried out also by using acetonitrile as solvent both for DPPH and isoeugenol (**1**) and analysed after 5 and 30 min.

2.8. Reaction of eugenol-DPPH radical

Similar conditions were used also for the analysis of the reaction products between DPPH radical and eugenol (**2**), final concentration was about 6×10^{-5} M and 4.7×10^{-5} M, respectively. The reaction was stopped after 10 min using methanol and after 30 min in the case of acetonitrile as solvents.

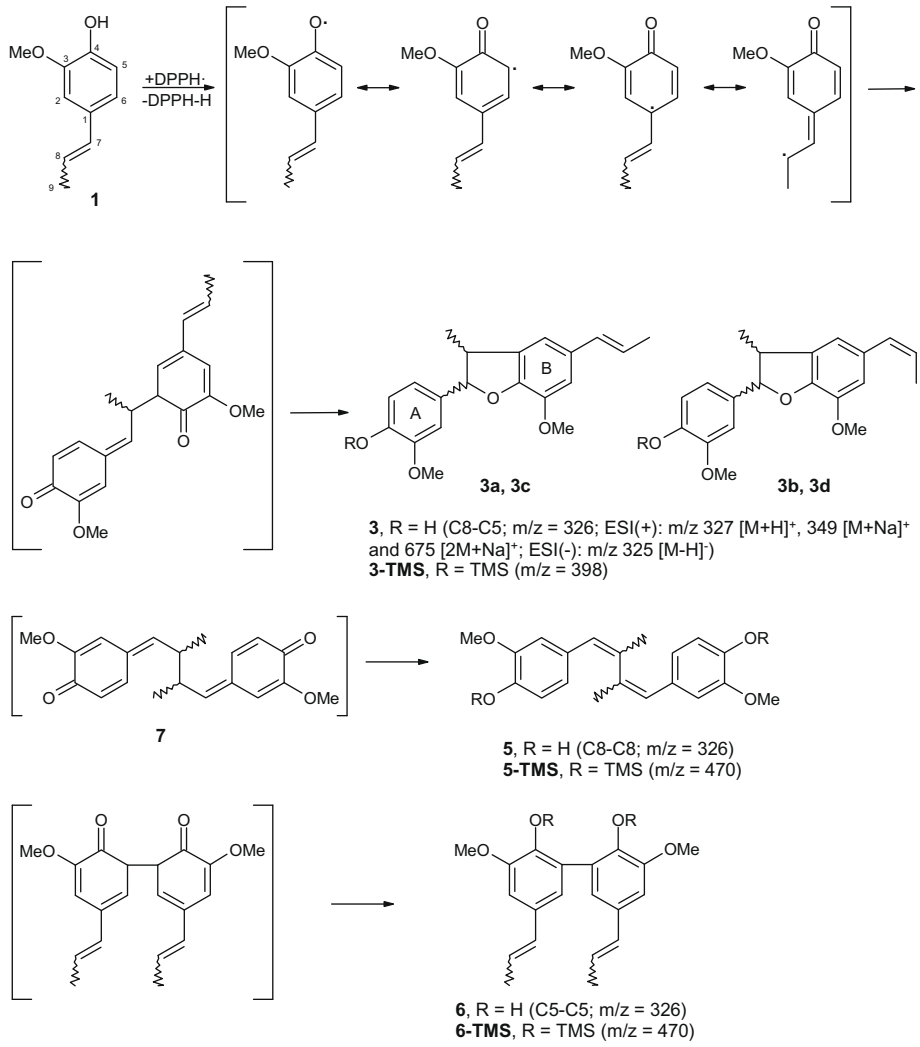
2.9. Synthesis of dehydrodiisoeugenol (*3*)

Dehydrodiisoeugenol (**3**) was prepared by oxidative coupling of isoeugenol (**1**) using the peroxidase-H_2O_2 system, following the method reported by Nascimento, Lopes, Davin and Lewis (2000) with minor modifications. To a solution of isoeugenol (**1**) (1.01 g, 6.2 mmol) in 30 mL of MeOH were added 275 mL of citrate–phosphate buffer (20 mM, pH 3) and horseradish peroxidase (8.5 mg, 1500 U) in 10 mL of buffer. 0.31 mL of H_2O_2 (3.05 mmol) was then added dropwise over 10 min and under magnetic stirring. The reaction mixture was stirred for an additional 10 min and then transferred in a separatory funnel and extracted with 100 mL of ethylacetate. The organic phase was washed with water, dried over anhydrous Na_2SO_4 and reduced to dryness. The crude product was loaded into a silica chromatography column (20 cm length × 2 cm i.d.) and eluted with *n*-hexane/ethylacetate mixture from an initial 8.5/1.5 (v/v) ratio. The chromatographic separation was monitored by TLC. The fractions containing the product (Rf 0.41, *n*-hexane/ethylacetate, 8/2, v/v) were combined, reduced to dryness (268 mg, 27%) and crystallised from MeOH/H_2O. m.p. 132.5 °C [lit. 128–130 °C (Shiba, Xiao, Miyakoshi, & Chen, 2000); 129–132 °C (Juhász, Kürti, & Antus, 2000)]; calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79; found C, 73.56; H, 6.71. EIMS *m*/*z* (rel. int.): *m*/*z* 326 (M^+, 100), 311 (M^+-CH_3, 16), (1 × TMS) *m*/*z* 398 (M^+, 100), 383 (M^+-CH_3, 14), 368 ($M^+-2 \times CH_3$, 10). ESI (+)-MS (infusion, MeOH), *m*/*z*: 327 $[M + H]^+$ (MS^3 transitions 327 > 203 > 171), 349 $[M + Na]^+$, 675 $[2\,M + Na]^+$. ESI (−)-MS (infusion, MeOH), *m*/*z*: 325 $[M-H]^-$ (MS^5 transitions 325 > 310 > 295 > 277 > 249). ^1H NMR ($CDCl_3$/TMS): δ 1.37 (d, 3H, *J* = 6.8 Hz, ACH$_3$-9), 1.86 (dd, 3H, *J* = 6.4, 1.5 Hz, BCH$_3$-9), 3.37–3.52 (m, 1H, ACH-8), 3.86 (s, 3H, AMeO-3), 3.88 (s, 3H, BMeO-3), 5.09 (d, 1H, *J* = 9.5 Hz, ACH-7), 5.67 (br s, 1H, OH), 6.10 (dq, 1H, *J* = 15.6, 6.5 Hz, BCH-8), 6.36 (dd, 1H, *J* = 15.6, 1.5 Hz, BCH-7), 6.76 (br s, 1H, BCH-6), 6.78 (br s, 1H, BCH-2), 6.87–6.93 (m, 2H, ACH-5, ACH-6), 6.97 (br s, 1H, ACH-2). ^{13}C NMR ($CDCl_3$): δ 17.5 (AC-9), 18.3 (BC-9), 45.5 (AC-8), 55.8 (AMeO-3), 55.9 (BMeO-3), 93.7 (AC-7), 108.8 (AC-2), 109.1 (BC-2), 113.2 (BC-6), 114.0 (AC-5), 119.9 (AC-6), 123.4 (BC-8), 130.8 (BC-7), 132.0 (BC-1), 132.1 (AC-1), 133.2 (BC-5), 144.1 (BC-3), 145.7 (AC-4), 146.5 (BC-4), 146.6 (AC-3) (Scheme 1).

The GC–MS analysis of the crystallised product evidenced the presence of four compounds with practically the same mass spectra and M^+ at *m*/*z* 326. The relative retention times (RRTs) to the most abundant compound were 0.96, 0.97, 1, 1.01 and the corresponding percent chromatographic areas, calculated on the basis of the *m*/*z* 326 ion signal, were 2.1, 0.1, 95.7 and 2.1%, respectively. The HPLC–MS analysis of the same product evidenced the presence of three compounds with *m*/*z* 327 $[M + H]^+$ and the same fragmentation patterns till MS^3. Sarkanen and Wallis (1973) reported the formation of (*E*)-1-[(2*RS*,3*SR*)-2,3-dihydro-2-(4-hydroxy-3-methoxy phenyl)-7-methoxy-3-methyl-1-benzofuran-5-yl]-1-propene [(*E*)-(±)-*trans*-dehydrodiisoeugenol] (**3a**) and (*Z*)-1-[(2*RS*,3*SR*)-2,3-dihydro-2-(4-hydroxy-3-methoxyphenyl)-7-methoxy-3-methyl-1-ben zofuran-5-yl]-1-propene [(*Z*)-(±)-*trans*-dehydrodiisoeugenol] (**3b**) by peroxidase catalysed oxidation of (*E*)- and (*Z*)-isoeugenol, respectively. Due to the presence in isoeugenol (**1**) standard of both the (*E*)- and (*Z*)-isomers in the proportion of about 93% and 7%, respectively, the formation of both the dehydrodimers **3a** and **3b** would be expected. On this basis the structure of (*E*)-(±)-*trans*-dehydrodiisoeugenol (**3a**) has been assigned to the most abundant compound and the structure of (*Z*)-(±)-*trans*-dehydrodiisoeugenol (**3b**) to one of the other three compounds. Regarding the other two, the following structures (*E*)-1-[(2*RS*,3*RS*)-2,3-dihydro-2-(4-hydroxy-3-methoxyphenyl)-7-methoxy-3-methyl-1-ben zofuran-5-yl]-1-propene [(*E*)-(±)-*cis*-dehydrodiisoeugenol] (**3c**) and (*Z*)-1-[(2*RS*,3*RS*)-2,3-dihydro-2-(4-hydroxy-3-methoxyphenyl)-7-methoxy-3-methyl-1-benzofuran-5-yl]-1-propene [(*Z*)-(±)-*cis*-dehydrodiisoeugenol] (**3d**) have been hypothesised (Scheme 1). The ^1H and ^{13}C NMR spectra were in agreement with the structure of (*E*)-(±)-*trans*-dehydrodiisoeugenol (**3a**) (Barbosa-Filho, Leitão da-Cunha, & Sobral da Silva, 1998; Juhász et al., 2000; Shiba et al., 2000) which purity was about 95.7%. The structure-numbering system used in the ^1H and ^{13}C NMR data does not follow the actual compound names but is based on the numbering of the monomer so as to maintain consistency.

2.10. Synthesis of dehydrodieugenol (*4*)

Dehydrodieugenol (**4**) was prepared by oxidative coupling of eugenol (**2**) using potassium ferricyanide as oxidising agent following the method reported by De Farias Dias (1988). To a solution of eugenol (**2**) (1.0 g, 6.1 mmol) in an acetone/H_2O mixture (2:1, v/v, 30 mL) 18 mL of aqueous NH_4OH (28%) was added and the mixture was stirred for 10 min. To the mixture a saturated aqueous solution of $K_3Fe(CN)_6$ (2.0 g, 6.1 mmol) was then added dropwise over a period of about 5 h and then 18 mL of aqueous NH_4OH (28%) was added. The mixture was stirred for an additional 16 h at room temperature and then neutralised with HCl 10%. There was the formation of a solid precipitate which was filtered, washed with water and dried (720 mg, 72%). The crude product was crystallised from ethanol after decolourisation with activated charcoal. m.p. 105.8 °C, [lit. 105–106 °C, (De Farias Dias, 1988)]; calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79; found C, 73.10; H, 6.84. EIMS *m*/*z* (rel. int.): *m*/*z* 326 (M^+, 100), 297 (M^+-HCO, 34), 285 ($M^+-CH_2CHCH_2$, 6), 284 [$M^+-(CH_2CHCH_2 + H)$, 7], 267 [$M^+-(CH_2CHCH_2 + H_2O)$, 6], 253 [$M^+-(CH_2CHCH_2 + H + CH_3O)$, 22], 244 ($M^+-2 \times CH_2CHCH_2$, 11), 221 [$M^+-(CH_2CHCH_2 + H + CH_3O + CH_3OH)$, 9]; (2 × TMS) *m*/*z* 470 (M^+, 100), 455 (M^+-CH_3, 46), 440 ($M^+-2 \times CH_3$, 36). ESI (+)-MS (infusion, MeOH), *m*/*z*: 327 $[M + H]^+$, 349 $[M + Na]^+$ (MS^3 transitions 349 > 308 > 277), 675 $[2\,M + Na]^+$. ESI (−)-MS (infusion, MeOH), *m*/*z*: 325 $[M-H]^-$ (MS^5 transitions 325 > 310 > 295 > 254 > 226). ^1H NMR ($CDCl_3$/TMS): δ 3.36 (d, 4H, *J* = 6.7 Hz, CH_2-7, CH_2-7′), 3.89 (s, 6H, 2 × OMe), 5.01–5.18 (m, 4H, CH_2-9, CH_2-9′), 5.87–6.09 (m, 2H, CH-8, CH-8′), 6.05 (br s, 2H, OH), 6.72 (d, 2H, *J* = 1.9, CH-2, CH-2'), 6.75 (d, 2H, J = 1.9, CH-6, CH-6′). ^{13}C NMR ($CDCl_3$): δ 39.9 (C-7, C-7′), 56.0



Scheme 1.

(2 × OMe), 110.6 (C-2, C-2′), 115.6 (C-9, C-9′), 123.0 (C-6, C-6′), 124.4 (C-5, C-5′), 131.8 (C-1, C-1′), 137.6 (C-8, C-8′), 140.8 (C-4, C-4′), 147.2 (C-3, C-3′). The ^{1}H and ^{13}C NMR spectra were in agreement with the data reported in literature (De Farias Dias, 1988).

3. Results and discussion

3.1. Reaction products of isoeugenol (*1*)

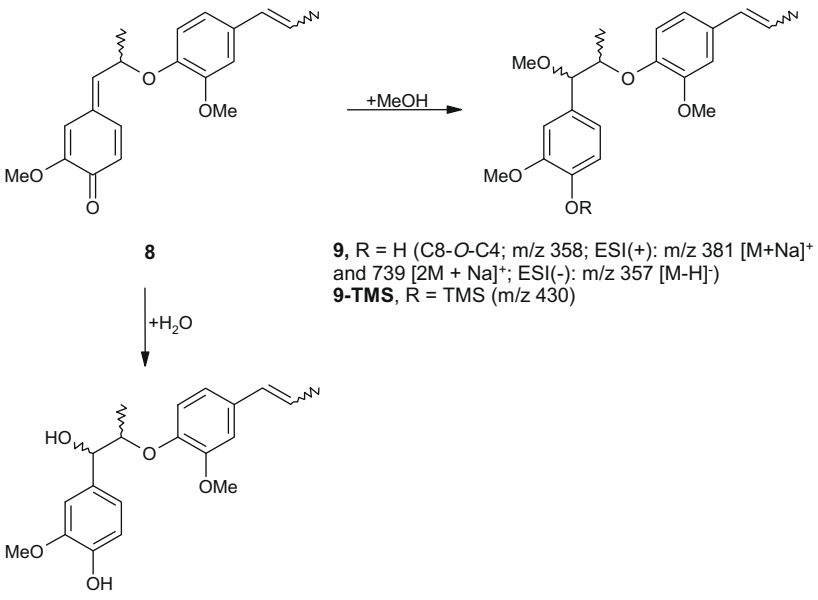
3.1.1. GC–MS analysis

The GC–MS chromatogram of the reaction mixture of isoeugenol (**1**) and DPPH radical in methanol evidenced the presence of two groups of compounds characterised by the M_r 326 and 358, respectively. The first group was composed of six compounds with M^+ at m/z 326 (Scheme 1), four of which had the same retention times of those present in the GC–MS chromatogram of the synthesised dehydrodiisoeugenol (**3**). In particular, the compound present in the highest amount (83.0%) had the same RT and mass spectrum of (*E*)-(±)-*trans*-dehydrodiisoeugenol (**3a**). The other two compounds with m/z 326 accounted for only 2.0% of the total chromatographic area.

The other group was composed of three compounds characterised by the same mass spectrum with M^+ at m/z 358. Compounds with M_r 358, which corresponded to an increase of 32 u with respect to the M_r 326, can be considered as the methanol adducts **9** arising from the addition of methanol to the C8–*O*–C4 quinone methide intermediate **8** (Scheme 2).

The formation of two diastereomeric forms of **9** was previously reported by Miller (1972) among the dimeric compounds obtained by 2,4,6-tri-*tert*-butylphenoxyl radical oxidation of (*E*)- or (*Z*)-isoeugenol in benzene/methanol solution. Also Chioccara et al. (1993) reported the formation of a mixture of *erythro* and *threo* diastereomers **9** by addition of methanol to a quinone methide intermediate formed by C8-*O*-C4 coupling of two phenoxyl radicals during the reaction of (*E*)-isoeugenol with hydrogen peroxide and HRP in aqueous buffer and methanol from 10% to 90%. The same authors observed an increase in the yields of these compounds with increasing methanol content. The addition of methanol to a quinone methide structure formed by reaction of lignans and DPPH radical was recently reported by Eklund et al. (2005). To confirm these structures, the reaction mixture was acetylated (Ac_2O, pyridine) and analysed by GC–MS. The analysis evidenced the presence of four compounds with m/z 400 (M^+) and fragment ions at m/z 237, 236, 209, 195, 194, 167 and 164. The M_r and the fragmentation patterns were in agreement with those reported by Chioccara et al. (1993) for the acetate derivatives of the methanol adducts of the C8–*O*–C4-coupled dimers **9**.

The GC–MS chromatogram of the TMS derivatives of the reaction products of isoeugenol (**1**) and DPPH radical in methanol is shown in Fig. 1A. Some compounds were detectable only after



Scheme 2.

TMS derivatisation probably due to a better chromatographic behaviour of the TMS derivatives and, in particular, of the compounds present in very low amount. The GC–MS analysis evidenced the presence of four compounds with M^+ at m/z 398 corresponding to 326 + TMS, four compounds with M^+ at m/z 430 corresponding to m/z 358 + TMS, three compounds with M^+ at m/z 470 corresponding to 326 + 2 × TMS and three compounds with M^+ at m/z 502 corresponding to 358 + 2 × TMS. The mixture of products resulting from the reaction between DPPH radical and **1** was very complex, also due to the presence of (*E*)- and (*Z*)-isoeugenol, and can be rationalised by considering basically two groups of compounds characterised by M_r 326 and 358, respectively. The compounds with M_r 326 (Scheme 1) are dimeric form of **1** which, after silylation, produced two separate classes of isomers. The first class had originally one phenolic hydroxy group and the M_r of 398 corresponds to a mono-TMS derivative. Among the dimers with one phenolic hydroxy group, the most abundant was that corresponding to (*E*)-(±)-*trans*-dehydrodiisoeugenol (**3a**) arising from a C8–C5 coupling process (Scheme 1).

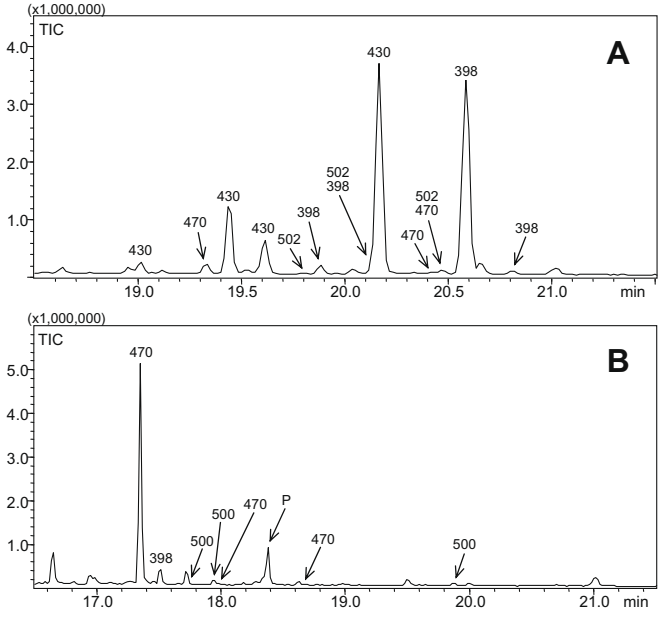


Fig. 1. GC–MS chromatograms of the dimer regions of the silylated reaction mixtures of isoeugenol (**1**) and eugenol (**2**) with DPPH radical in methanol. The number above the peaks represents the m/z ratio of the molecular ion of the corresponding compound. (**A**) isoeugenol – DPPH radical (for m/z 398 and 470 refer to Scheme 1, for m/z 430 refer to Scheme 2, for m/z 502 refer to Scheme 3); (**B**) eugenol – DPPH radical (for m/z 470 and 398 refer to Schemes 4 and 5, for m/z 500 refer to Scheme 6); P = phthalate contaminant.

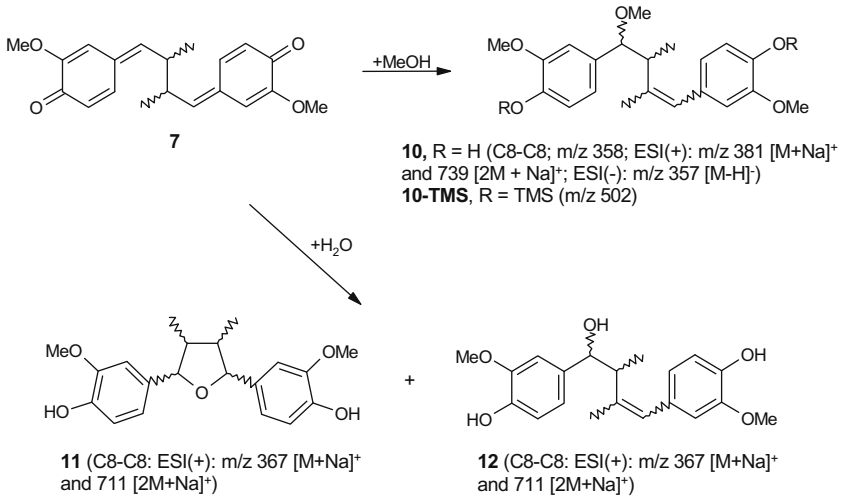
The second class had two phenolic hydroxy groups and the M_r of 470 corresponded to a bis-TMS derivative. The dimers with two phenolic hydroxy groups **5** and **6** were present at a very low amount compared to **3a** and all the other compounds and can be originated from the C8–C8 and C5–C5 coupling processes, respectively, as hypothesised in Scheme 1. Sarkanen and Wallis (1973) reported the formation of compounds arising from the addition of water to a bisquinone methide system, such as **7** shown in Scheme 1, formed by a C8–C8 coupling process in the case of the enzyme-catalysed oxidation of both (*E*)- and (*Z*)-isoeugenol. Although the same authors did not report the formation of the C8–C8-coupled dimer **5** (Scheme 1), its formation in very low amount by aromatisation of bisquinone methide **7**, before the addition of water, cannot be excluded. Regarding the C5–C5-coupled dehydrodimer **6** (Scheme 1), Sarkanen and Wallis (1973) did not report its formation among the oxidation products of both (*E*)- and (*Z*)-isoeugenol. On the other hand, Ralph, Quideau, Grabber and Hatfield (1994) and Hatfield, Ralph and Grabber (1999) reported both the presence of C8–C8 and low amounts of the C5–C5 dehydrodimers of ferulic acid in plant cell wall extracts.

Like the compounds with M_r 326, also the compounds with M_r 358 produced, after silylation, two classes of isomers. The first class, which comprehended the methanol adducts of the C8–*O*–C4-coupled dimers **9**, had originally one phenolic hydroxy group and the M_r of 430 (326 + 32 + 72) corresponded to the mono-TMS derivatives **9-TMS** (Scheme 2).

The second class, present in very low amount, had two phenolic hydroxy groups and the M_r of 502 (326 + 32 + 2 × 72) corresponded to a bis-TMS derivative. The addition of methanol can take place only to the quinone methide intermediate **7** formed by the C8–C8 coupling process yielding **10** (Scheme 3). This consideration



Scheme 3.

suggested that the dimers with two hydroxy groups were probably of the C8–C8 type (Scheme 1). The necessity of the presence of methanol to produce the adducts was demonstrated by carrying out the reaction in acetonitrile. In this case neither compounds with M_r 358, due to methanol addition, nor compounds with M_r 430 and 502 after silylation were observed.

Besides the dimers, other peaks corresponding to unreacted isoeugenol (**1**) and DPPH radical thermodegradation products were present in the GC–MS chromatogram, in particular diphenylamine and 2,4,6-trinitroaniline, which were the most abundant compounds in the reaction mixture as identified on the basis of the mass spectrum and comparison with the NIST library.

3.1.2. HPLC–MS analysis

Due to the possible risk of artifacts formation in the hot injection port of the gas chromatograph, the reaction mixture between isoeugenol (**1**) and DPPH radical was analysed also by HPLC–MS. The HPLC–MS analysis evidenced the presence of three compounds with ESI (+)-MS at m/z 327 $[M + H]^+$, 349 $[M + Na]^+$ and 675 $[2\,M + Na]^+$ and ESI (−)-MS at m/z 325 $[M - H]^-$ with the same retention times and fragmentation patterns of the synthesised dehydrodiisoeugenol (**3**). Moreover, three compounds with ESI (+)-MS at m/z 381 $[326 + 32 + Na]^+$ and 739 $[2 \times (356 + 32) + Na]^+$ and ESI (−)-MS at m/z 357 $[326 + 32 - H]^-$ which corresponded to the methanol adducts **9** and/or **10** were present (Schemes 2 and 3). These results confirmed the previous findings obtained by GC–MS apart from the number of isomers detected which can depend by the different resolving powers of the two chromatographic techniques. HPLC–MS analysis showed six other compounds with m/z at 367 $[326 + 18 + Na]^+$ and 711 $[2 \times (326 + 18) + Na]^+$ which probably corresponded to the addition of water to the quinone methides **7** and **8** with the formation of **11** and **12** (Scheme 3) and **13** (Scheme 2), respectively.

The formation of **11** (Sarkanen and Wallis, 1973) and **13** (Sarkanen and Wallis, 1973; Shiba et al., 2000) was previously reported in the case of the enzyme-catalysed oxidation of **1** moreover, like the addition of methanol leading to **10**, the addition of water to **7** could afford **12** (Scheme 3). The formation of water adducts could be due to the dilution of the methanolic reaction mixture with water to a final concentration of about 35% like the mobile phase prior to HPLC–MS analysis.

The HPLC–MS analysis of the reaction mixture carried out in acetonitrile and diluted with water, before analysis, evidenced the formation of the dimers of **1** and the water adducts, but not the formation of the methanol adducts, confirming the results obtained by GC–MS. The reactions carried out in acetonitrile were visibly slower than those carried out in methanol.

Neither termination products by coupling of **1** and DPPH radicals nor compounds arising by the abstraction of two hydrogen atoms from **1** were detected under our experimental conditions.

From the data obtained it can be concluded that the main products formed by reaction of isoeugenol (**1**) and DPPH radical in methanol were the (*E*)-(±)-*trans*-dehydrodiisoeugenol (**3a**) and the methanol adducts **9**.

*3.2. Reaction products of eugenol (**2**)*

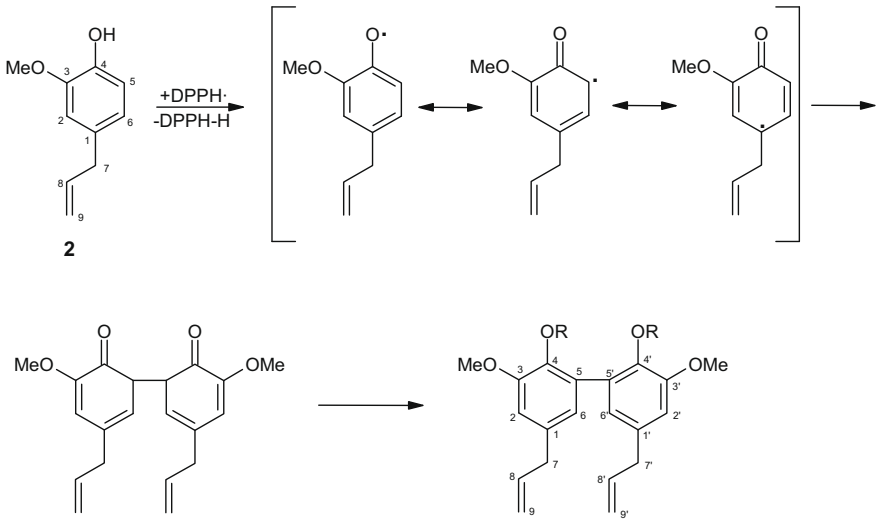
3.2.1. GC–MS analysis

The GC–MS chromatogram of the TMS derivatives of the reaction products of eugenol (**2**) and DPPH radical in methanol is reported in Fig. 1B. The GC–MS analysis evidenced the presence of three peaks with M_r 470, one peak with M_r 398 and three peaks with M_r 500. The compounds with M_r 470 ($326 + 2 \times$ TMS) corresponded to the bis-TMS derivatives of eugenol dimers and the most abundant had the same retention time and mass spectrum of the TMS derivative of the dehydrodieugenol (**4**) synthesised, derived from a C5–C5 coupling process (Scheme 4). The other two compounds, which accounted for only 0.2% of the chromatographic area, could arise from the addition of eugenol-5-radical **14** at the 7 and 9 position of the quinone methide intermediate **15** affording **16** and **17**, respectively, as hypothesised in Scheme 5.

The compound with M_r 398 (326 + TMS) could be interpreted as mono-TMS derivative of eugenol dimer with only one hydroxy phenolic group, a C5–*O*–C4 coupling process could be the mechanism leading to compound **18** (Scheme 5). The formation of a compound formed by a C5–*O*–C4 coupling process was reported by Sy and Brown (1998) in the case of the oxidative coupling of 4-allylphenol.

The compounds with M_r 500 ($326 - 2 + 32 + 2 \times$ TMS), present in very low amount, could have structures **19** and **20**, corresponding to the bis-TMS derivatives of the addition products of methanol to the quinone methide **21**, as hypothesised in Scheme 6. As in the case of isoeugenol (**1**), the necessity of the presence of methanol to produce these adducts was demonstrated by carrying out the reaction in acetonitrile, in this case no compounds with M_r 500 were observed.

Unreacted eugenol (**2**) and DPPH radical thermodegradation products were also present in the GC–MS analysis of the reaction mixture.



Scheme 4.

3.2.2. HPLC–MS analysis

The HPLC–MS analysis of the reaction mixture of eugenol (**2**) and DPPH radical evidenced the presence of a compound with ESI (+)-MS at *m/z* 327 $[M + H]^+$, 349 $[M + Na]^+$ and 675 $[2\,M + Na]^+$ and ESI (−)-MS at *m/z* 325 $[M - H]^-$ corresponding, as retention time and mass spectrum, to the synthesised dehydrodieugenol (**4**). Moreover, two compounds with *m/z* 379 $[326 - 2 + 32 + Na]^+$ and 355 $[326 - 2 + 32 - H]^-$ which could correspond to **19** and **20** (Scheme 6) were present. These results confirmed the previous findings obtained by GC–MS.

As in the case of isoeugenol (**1**), the reactions carried out in acetonitrile were visibly slower than those carried out in methanol, and neither termination products by coupling of **2** and DPPH radicals nor compounds arising by the abstraction of two hydrogen atoms from **2** were detected under our experimental conditions.

*3.3. DPPH radical scavenging activity of dehydrodiisoeugenol (**3**) and dehydrodieugenol (**4**)*

The DPPH radical scavenging activity of **3** and **4** was determined in order to evaluate their possible contribution to the activity of the corresponding parent compounds, isoeugenol (**1**) and eugenol (**2**), respectively. Only these two dimeric species have been considered from the point of view of the antioxidant activity being the most abundant among the products originated from the reactions of **1** and **2** with the DPPH radical. The results expressed as EC_{50}, stoichiometry (*n*), $T_{EC_{50}}$ and AE are reported in Table 1 together with the radical scavenging activity of **1** and **2** previously determined by Bortolomeazzi et al. (2007) under similar conditions of analysis.

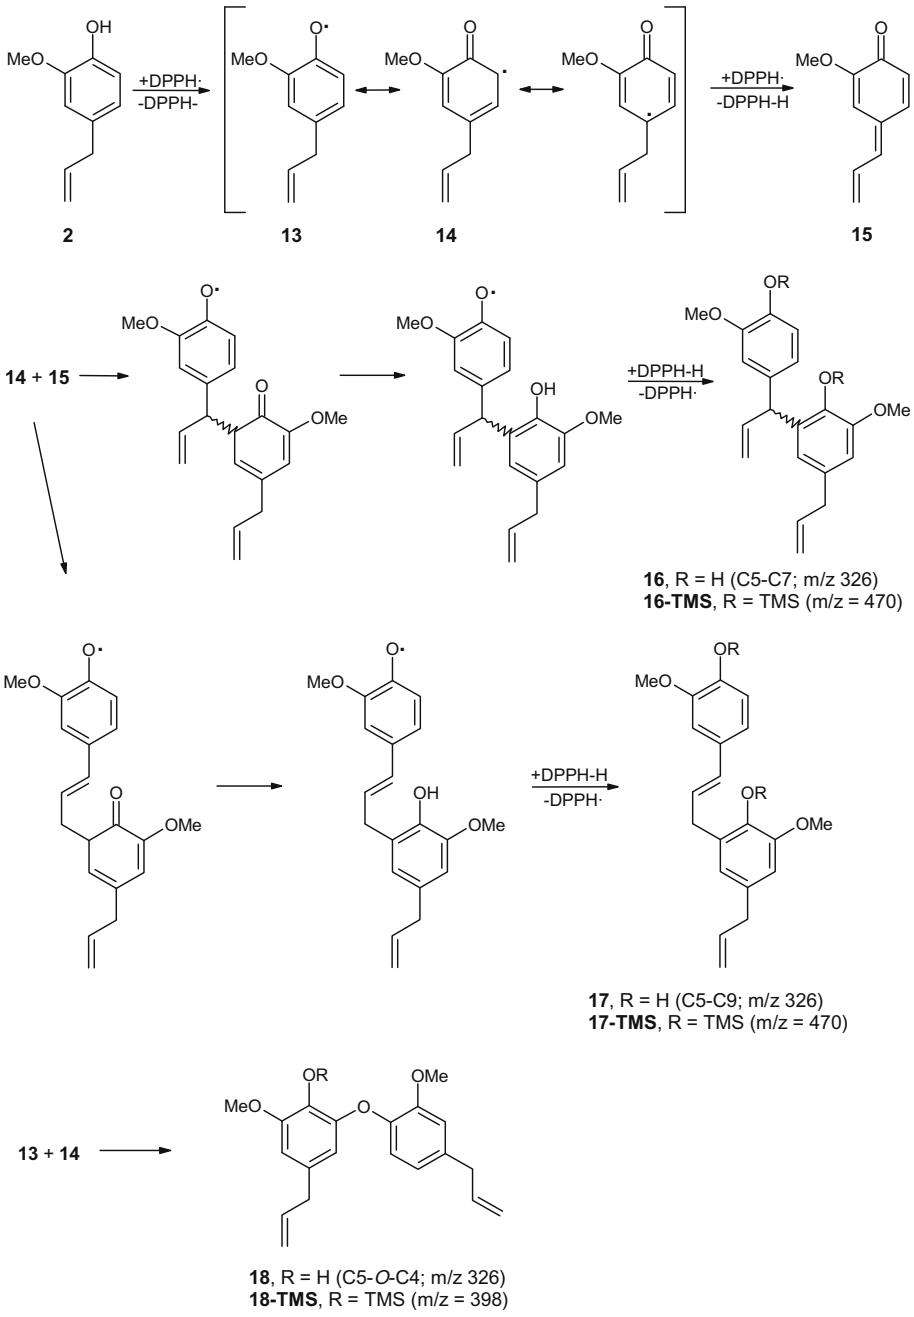
The EC_{50} of dehydrodiisoeugenol (**3**) was slightly higher than that of isoeugenol (**1**) and one mole of both compounds roughly scavenged one mole of DPPH, with a stoichiometry value of 0.7 and 0.9, respectively, corresponding to the number of phenolic OH present in the molecular structure. On the contrary, their kinetic behaviour was completely different with **3** acting much more slowly ($T_{EC_{50}} = 201$ min) than **1** ($T_{EC_{50}} = 3.1$ min). The very rapid kinetic of **1** has been explained by the presence, at the para position relative to phenol, of a propenyl group with the double bond conjugated to the benzene ring. This allows a better stabilisation of the phenoxyl radical by extending the delocalisation and lowers the Bond Dissociation Enthalpy (BDE) of the phenolic O–H bond (Barclay, Xi, & Norris, 1997; Wrigth, 2002; Wrigth, Johnson, & Di Labio, 2001). This structure was lost in the formation of **3** and the eventually stabilising electron-donating (+I) effect of the aliphatic part of new heterocyclic moiety was moreover impaired by the −I effect of the oxygen linked to the ᴀC7 in **3** (Scheme 1).

The radical scavenging activity of the methanol adducts **9** was not determined, due to the lack of the pure compounds; however, on the basis of their structure it was sensible to hypothesise an antioxidant activity similar to that of **3**.

Sanchez-Moreno et al. (1998) outlined the presence of compounds with comparable EC_{50} but with very different kinetic behaviour. These authors introduced the parameter AE that takes into account both the radical scavenging activity (EC_{50}) and the kinetic behaviour ($T_{EC_{50}}$). On the basis of the AE values, isoeugenol (**1**) resulted about 90 times more active than its corresponding dimer dehydrodiisoeugenol (**3**) (Table 1).

Dehydrodieugenol (**4**) had an EC_{50} value lower than that of eugenol (**2**) and one mole can scavenge about 2.7 mol of DPPH, whereas **2** scavenged 2 mol of DPPH radical. Also the $T_{EC_{50}}$ value was lower and, on the basis of the AE parameter, the antioxidant activity of **4** resulted about twice that of **2** (Table 1). The higher activity of **4** with respect to **2** can be explained by the presence of two phenolic OH groups and an ortho benzene ring which allowed an extensive conjugation stabilising the phenoxyl radical of **4**.

The $T_{EC_{50}}$ values of the compounds analysed deserve some more comments. The $T_{EC_{50}}$ of isoeugenol (**1**) was very low in comparison to those of dehydrodiisoeugenol (**3**) and eugenol (**2**) attributing this effect to the lower BDE of the phenolic OH bond in **1** as a consequence of the extended conjugation. A similar consideration has been applied also to **4** although, in this case, the substituent is attached to the ortho position, relative to the two phenolic OH. Wrigth et al. (2001) reported that a vinyl group in the ortho position relative to phenol showed a stabilising electronic effect only slightly lower than in the para position. On this basis, the kinetic behaviour of dehydrodieugenol (**4**) could be expected to be more rapid with a $T_{EC_{50}}$ more similar to that of isoeugenol (**1**). The slow reaction between **4** and DPPH radical can, however, be explained

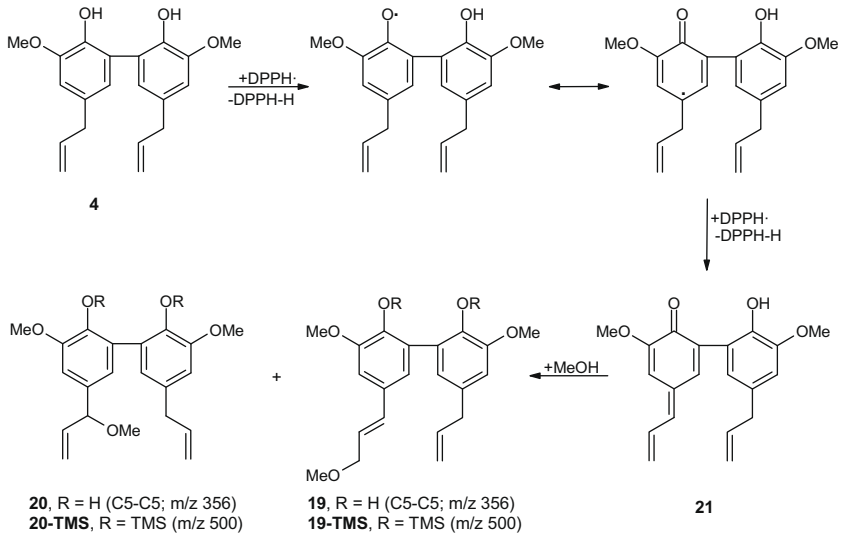


Scheme 5.

by the intervention of steric hindrance which can interfere with the planar conformation of **4** necessary to achieve optimal stabilisation of the phenoxyl radical by resonance as hypothesised by Barclay et al. (1997) in the case of 2,2′-dihydroxy-3,3′-dimethoxy-5,5′-dimethoxymethylbiphenyl.

Brand-Williams et al. (1995) and Bondet et al. (1997) reported that in the case of compounds reacting very quickly, the number of DPPH molecules reduced equals the number of hydroxyl groups present in the antioxidant molecule ($n = 1$). On the contrary, in the case of slow reacting compounds the stoichiometric value is, in general, larger than one ($n > 1$). This aspect was evidenced by the behaviour of isoeugenol (**1**) and eugenol (**2**) which had a kinetic fast (0.5 min) and slow (120 min) and $n = 1.1$ and 1.9, respectively. These authors explained the finding of stoichiometric values larger than one by hypothesising three reaction pathways after the initial formation of the antioxidant radical, such as donation of a second hydrogen atom to DPPH radical, dimerisation by coupling of two antioxidant radicals and coupling of antioxidant and DPPH radicals. In particular, for **2**, these authors suggested a dimerisation mechanism, while in the case of **1** none of these reactions would take place.

The results obtained in our work evidenced that, contrary to the hypothesis of Brand-Williams et al. (1995) and Bondet et al. (1997), the phenoxyl radical of isoeugenol (**1**) underwent extensive dimerisation and, moreover, the solvent methanol was involved in the reaction mechanism. The 0.9 stoichiometric value of **1** (Table 1) can, however, be explained by the very low kinetic behaviour of dehydrodiisoeugenol (**3**) with respect to **1**. When the DPPH method was applied to **1**, the time of the analysis was too short for the formed **3**, and eventually the methanol adducts **9**, to reveal their contribution to the total radical scavenging activity of **1**.



Scheme 6.

Table 1
Effective Concentration (EC_{50}), stoichiometry (n), $T_{EC_{50}}$ and antiradical efficiency (AE) obtained with the DPPH assay. (The values are the mean of three determinations ± standard deviation).

Compound	EC_{50}[a]	n[b]	$T_{EC_{50}}$[c]	AE × 10^3[d]
Isoeugenol (**1**)	0.54[e] ± 0.04	0.93 ± 0.07	3.12 ± 0.06	592 ± 45[e]
Dehydrodiisoeugenol (**3**)	0.74 ± 0.02	0.67 ± 0.02	201 ± 3	6.7 ± 0.3
Eugenol (**2**)	0.26[e] ± 0.01	1.94 ± 0.07	126 ± 8	31 ± 2[e]
Dehydrodieugenol (**4**)	0.184 ± 0.002	2.72 ± 0.03	85 ± 1	64 ± 1

[b] Mol DPPH/mol AH.
[c] Min.
[d] Mol DPPH/(mol AH × t); AH, phenolic antioxidant.
[e] Bortolomeazzi et al. (2007).

In the case of eugenol (**2**), the formation of dehydrodieugenol (**4**), as the main reaction product, confirmed the hypothesis of Brand-Williams et al. (1995) and Bondet et al. (1997) regarding the dimerisation of **2**. The 1.9 stoichiometry value of **2** (Table 1) can then be explained by the formation of the dimer and its reaction with DPPH radical. In fact, considering the $T_{EC_{50}}$ of **2** and **4**, the time window of the reaction between DPPH radical and **2** can overlap with that of the reaction between DPPH radical and **4** which can then contribute to the radical scavenging activity of eugenol (**2**).

The formation of a complex mixture of dimeric compounds originated by different coupling processes and finding that also the solvent, methanol, and eventually water can be involved, evidenced that the reaction mechanism can be more complex than previously hypothesised. The possible contribution of the reaction products to the radical scavenging activity of a compound limits the use of the DPPH method to evaluate structure–activity relationship and the possibility to correlate the results with the antioxidant activity obtained by other methods.

ABSTRACT

The effects of raspberry, strawberry and bilberry juices and green and black tea on early atherosclerosis in hamsters were investigated. They received an atherogenic diet and at the same time either a juice or a tea at a daily dose corresponding to the consumption of 275 ml by a 70 kg human. After 12 weeks berry juices and teas inhibited aortic lipid deposition by 79–96% and triggered reduced activity of hepatic antioxidant enzymes, not accompanied by lowered plasma cholesterol. These findings suggest that moderate consumption of berry juices and teas can help prevent the development of early atherosclerosis. There were substantial differences between the five beverages in terms of composition and concentration of individual phenolic compounds that were present. This indicates that anti-atherosclerotic effects can be induced by a diversity of phenolic compounds rather than a few specific components. The possible mechanisms by which this is brought about are discussed.

1. Introduction

The postulated involvement of lipid peroxidation in atherogenesis invoked intensive research on antioxidants. Consumption of fruits and vegetables has been linked with lower prevalence of coronary heart disease (Bazzano, 2006; Dauchet, Amouyel, Hercberg, & Dallongeville, 2006; Feldman, 2001; Liu et al., 2000). Drinking tea has also been linked with reduced mortality arising from cardiovascular disease (Kuriyama et al., 2006), although some epidemiological data are inconclusive (Yang & Landau, 2000). Fruits, vegetables and teas contain a wide range of antioxidant compounds, including phenolic compounds and vitamins. Phenolic compounds, such as anthocyanins, flavan-3-ols, flavonols, hydroxycinnamates and tannins, are widespread in fruits and vegetables, with especially high quantities being found in berries and teas. Berries are rich in anthocyanins and can also contain substantial quantities of ellagitannins, while flavan-3-ols and their related derivatives predominate in teas (Crozier, Jaganath, Marks, Saltmarsh, & Clifford, 2006).

Golden Syrian hamsters represent an useful test system because when fed a fat-rich diet they develop dyslipidemia and atherosclerotic plaques, similar in many respects to human atheroma (Auger et al., 2002).

A relatively straight-forward way to evaluate influences on atherosclerosis progression in animal models is to measure the extent of fatty streak development, the continuous accumulation of lipids (due mainly to large accumulations of macrophages) in the subendothelial space. Using this approach, we have evaluated the effects of raspberry, strawberry and bilberry juices and green and black tea, sources of potentially anti-atherogenic phenolic compounds, by feeding the beverages to golden Syrian hamsters on a high fat diet for a 12-week period.

2. Materials and methods

2.1. Chemicals

5-*O*-Caffeoylquinic acid, procyanidin B2, (−)-epicatechin (+)-catechin, (−)-gallocatechin, (−)-epicatechin, (−)-epicatechin gallate, (−)-epigallocatechin, (−)-epigallocatechin gallate, gallic acid, caffeine, theobromine, theaflavins and ellagic acid were purchased from Sigma–Aldrich (Poole, UK). Quercetin, myricetin, quercetin-3-*O*-rutinoside, quercetin-3-*O*-glucoside, quercetin-3-*O*-arabinoside, quercetin-3-*O*-galactoside, kaemperol-3-*O*-rutinoside, kaemperol-3-*O*-glucoside, caffeic acid and *p*-coumaric acid were obtained from AASC Ltd. (Southampton, UK). Cyanidin-3-*O*-glucoside was purchased from Extrasynthese (Genay, France). Methanol and acetonitrile were obtained from Rathburn Chemicals (Walkerburn, Peebleshire, UK). Formic acid was obtained from Fisher Scientific (Loughborough, UK).

2.2. Berries juices and teas

Bouvrage raspberry (*Rubus idaeus* L.;1 ml = 0.6 g berries), bilberry (*Vaccinium myrtillus*; 1 ml = 0.32 g berries) and strawberry juices (*Fragaria ananassa*; 1 ml = 0.22 g berries) drinks were obtained from Ella Drinks Ltd. (Alloa, Clackmannanshire, UK). The green and black teas (The Tetley Group, Greenford, Middlesex, UK) were prepared by adding 300 ml of boiling water to 3 g of leaves. After brewing for 3 min with continuous stirring, tea solids were removed by filtration through a sieve and the resulting tea was allow to cool before preparation of aliquots which were stored at −20 °C prior to use.

2.3. HPLC–PDA–MS^2 analysis of berry juices and teas

Berry juices and teas were analysed on a Surveyor HPLC system comprising of a HPLC pump, photodiode array detector (PDA) scanning from 250 to 700 nm, and an autosampler set at 4 °C (Thermo Finnigan, San Jose, USA) with the separation carried out using a 250 × 4.6 mm i.d. 4 μm Synergi RP-Max column (Phenomenex, Macclesfield, UK) eluted at a flow rate of 1 ml/min. A mobile phase consisting of a 5–40% gradient over 60 min of acetonitrile in 0.1% formic acid was used for the analysis of all samples. After passing through the flow cell of the diode array detector the column eluate was split and 0.3 ml was directed to a LCQ Deca XP ion trap mass spectrometer fitted with an electrospray interface (Thermo Finnigan, San Jose, USA). Analysis was carried out using full scan mode from 100 to 2000 amu, with data dependent tandem MS (MS^2) scanning, in both negative and positive ion mode.

A combination of co-chromatography with authentic standards, where available, absorbance spectra and mass spectra, using MS^2, were used to confirm the identity of compounds previously reported in the literature (Stewart, Mullen, & Crozier, 2005). Quantitative estimates are based on calibrations generated by the PDA detector using the compound under study when a standard was available – see Chemicals. When this was not possible, a closely related derivative was used instead. For instance, all anthocyanins, were quantified by reference to cyanidin-3-*O*-glucoside, while chlorogenic acids, such as 3-*O*-*p*-coumarylquinic acid were quantified by reference to the appropriate aglycone. In all instances the standard curve of reference compounds ranged from 2 to 500 ng.

The thearubigin content of the black tea was estimated as described by Stewart et al. (2005).

2.4. Animals, diets and experimental design

Sixty weanling male Syrian golden hamsters (Elevage Janvier, Le Genest-St-Isle, France) weighing ca.100 g were maintained in plastic cages in a temperature controlled environment (23 ± 1 °C) subjected to a 12-h light/dark cycle and allowed free access to both food and water. Hamsters were handled according to the guidelines of the Committee on Animal Care at the University of Montpellier and NIH guidelines (National Research Council, 1985).

They were randomly assigned to six groups of 10 not statistically different for weight. For 12 weeks all the hamsters were fed a semi-purified atherogenic diet (Scientific Animal Food and Engineering, Augy, France) consisting of casein (200 g/kg), L-methionine (3 g/kg), corn starch (393 g/kg), sucrose (154 g/kg), cellulose (50 g/kg), lard (150 g/kg), and cholesterol (5 g/kg) (Auger et al., 2002). The diet also contained vitamin (10 g/kg) and mineral mixes (35 g/kg). It was formulated according to AIN-93 guidelines (Reeves, Nielsen, & Fahey, 1993) and was devoid of selenium, vitamin C and vitamin E. During the 12-week period, the hamsters received either water (control), raspberry juice, strawberry juice, bilberry juice, green tea or black tea daily by gavage. The volume of solutions fed was adjusted daily to the weight of hamsters. The calculation is based on a consumption of 275 ml/day for a 70 kg human as based on the US Food and Drug Administration Center for Drug Evaluation and Research dose calculator (http://www.fda.gov/cder/cancer/animalframe.htm).

2.5. Analytical procedures

At the end of the 12-week experimental period the hamsters were fasted overnight and blood was drawn by cardiac puncture under anesthesia. Plasma was prepared by centrifugation at 2000*g* for 10 min at 4 °C, and then stored at −80 °C before analysis. The liver was perfused with saline to remove residual blood, rapidly excised, rinsed in ice cold saline, blotted dry, weighted, sectioned for analyses and stored in liquid nitrogen. The aortic tissues were then processed as described below.

Following blood collection and liver removal, the intact aorta was first perfused with phosphate buffered saline containing 1 mmol/l $CaCl_2$ and 15 mmol/l glucose for 5 min, then with 0.1 mmol/l sodium cacodylate buffer pH 7.4 containing 2.5 mmol/l $CaCl_2$, 2.5% paraformaldehyde and 1.5% glutaraldehyde for the fixation of the vasculature. The aorta was carefully dissected and processed as previously described (Auger et al., 2002), lipids being stained in Oil red O. An image acquisition and analysis system (ImageJ, Scion Corporation, Frederick, MD) incorporated in an Olympus microscope was used to capture and analyse the total Oil Red O stained area of each aortic arch. The area covered by foam cells (aortic fatty streak area or AFSA) was expressed as a percentage of the total area.

Plasma total cholesterol (TC) and HDL cholesterol (HDL-C) were determined by commercially available enzymatic methods (respectively Nos. CH 200 and CH 203, Randox Laboratories Ltd., Crumlin, UK) on a Pentra 400 automated analyser (HORIBA ABX, Montpellier, France). Plasma very low- + low-density lipoprotein cholesterol (referred to as « non-HDL-C in the data tables) was precipitated with phosphotungstate reagent and HDL-C was measured in the supernatant.

The liver was homogenised in 5 vol of 0.15 M KCl buffer (pH 7.4) and the homogenate was spun at 13,000*g* for 15 min at 4 °C. The supernatant was stored at −80 °C prior to the assay of glutathione peroxidase (GSHPx) and superoxide dismutase (SOD) activity on a Pentra 400 analyser. GSHPx activity was measured by the method of Randox (Randox Laboratories Ltd., Crumlin, UK) using a commercial kit (Ransel, No. RS505). Superoxide dismutase (SOD) activity was determined using a Randox kit (Ransod, No. SD 125).

To extract and analyse livers by HPLC–PDA–MS^2, the livers from two hamsters from each feeding group were combined and homogenised in 2 ml of methanol/water (v/v) containing 5% formic acid and 20 mM sodium diethyldithiocarbamate using an Ultraturrax homogeniser. The resultant homogenate was shaken continuously for 30 min before being centrifuged at 2000*g* for 20 min. The supernatant was decanted and the pellet re-extracted twice. The three supernatants were combined and reduced to dryness *in vacuo*. The extract was dissolved in 25 μl methanol in 475 μl aqueous 1% formic acid and loaded onto an activated 2 g Sep–Pak C_{18} cartridge (Waters, Milford, MA, USA) which was washed with 4 ml acidified water (pH 3.0) before elution with 4 ml methanol containing 1% formic acid. The methanolic eluates were reduced to dryness and resuspended in 50 μl methanol in 950 μl aqueous 1% formic acid before analysis for anthocyanin and flavan-3-ol metabolites by HPLC–PDA–MS^2 using single and selected ion monitoring.

2.6. Statistical analyses

Data are shown as the means ± SEM, $n = 10$ measurements/group. Tea and berry juices samples were analysed in triplicate.

Statistical analysis of the data was carried out using the Stat View IV software (Abacus Concepts, Berkeley, CA, USA) by one-way ANOVA followed by Fisher's Protected Least Significant Difference test. Differences were considered significant at $p < 0.05$.

3. Results

3.1. Phenolic compounds in berry juices and teas

Twenty seven phenolic compounds were detected in the bilberry juice (Table 1) with the 13 anthocyanins comprising 599 nmoles/ml of a total flavonoid and phenolic content of 744 nmoles/ml. The juice also contained 76 nmoles/ml of gallic acid and smaller quantities of flavan-3-ols and a number of flavonols in low concentrations. The major components in the raspberry juice were anthocyanins (164 nmoles/ml), principally cyanidin-3-sophoroside and cyanidin-3–2^G-glucosylrutinoside, and the ellagitannins, lambertianin C and sanguiin H-6 (Table 2). The strawberry juice contained much lower overall levels of flavonoids and phenolics, 181 nmoles/ml (Table 3), than the bilberry and raspberry juices. The main constituents were pelargonidin-3-glucoside (91 nmoles/l) and a *p*-coumaric acid hexose conjugate (46 nmoles/l) (Table 3).

The compositions of the two teas are summarised in Table 4. Both green and black tea contained higher amounts of phenolic compounds than the juices, with 2894 and 2285 nmoles/ml, respectively for green and black tea. The main green tea constituents were catechins which comprised a group of eight flavan-3-ols, accounting for 2414 nmoles/ml with the major component being (−)-epigallocatechin (921 nmoles/ml). Black tea contained much lower concentrations of catechins (52 nmoles/ml) than green tea, but a large amount of theaflavins and thearubigins (1839 nmoles/ml) that were not present in green tea. Both teas also contained broadly similar levels of chlorogenic acids and a diverse array of flavonols.

3.2. Effects of berry juices and teas on fatty steak deposits

Fig. 1A shows the effects of bilberry, raspberry and strawberry juice consumption on aortic fatty streak deposits in hamsters fed a high-fat diet for 12 weeks. In the control animals, which ingested water rather than juice, fatty streaks covered 21.2 ± 2.7% of the aortic wall. The extent of these deposits when juices or teas were administered to hamsters, were dramatically and significantly lower with respect to controls (all $p < 0.001$ when compared to water control). The aortic fatty streak area was 4.5 ± 0.5% for the group fed with bilberry juice, 2.4 ± 0.5% with strawberry juice, 1.1 ± 0.2% with raspberry juice and finally 0.75 ± 0.13% and 1.40 ± 0.31% for green and black tea, respectively. Representative pictures of fatty streak deposits are presented in Fig. 2.

3.3. Effects of berry juices and teas on circulating cholesterol and hepatic antioxidant enzymes

The lower fatty streak deposition in juice and tea hamster groups was not accompanied by lower circulating cholesterol levels (total cholesterol, HDL-cholesterol and non-HDL-cholesterol were not significantly different between all groups; not shown here) but was associated to a reduced activity of liver antioxidant defense system in hamsters fed antioxidant rich beverages in comparison to controls (Fig. 1B and C). Teas induced a greater inhibition in the antioxidant enzymes compared to berry juices. Analysis of liver extracts by HPLC-mass spectrometry operating in selected ion and selected reaction monitoring mode did not detect the presence of any flavonoids or phenolic compounds derived from the teas or berry juices despite the hamsters being fed the supplements for a period of 12 weeks.

4. Discussion

Daily consumption of each of the test beverages for a 12-week period resulted in a substantially lower fatty streak deposition in the arteries of the hamsters compared to water-treated controls, with stronger effects for green tea and raspberry juice (Figs. 1A and 2). This marked limitation of the onset of atherosclerosis was not associated with any significant change in plasma cholesterol profile.

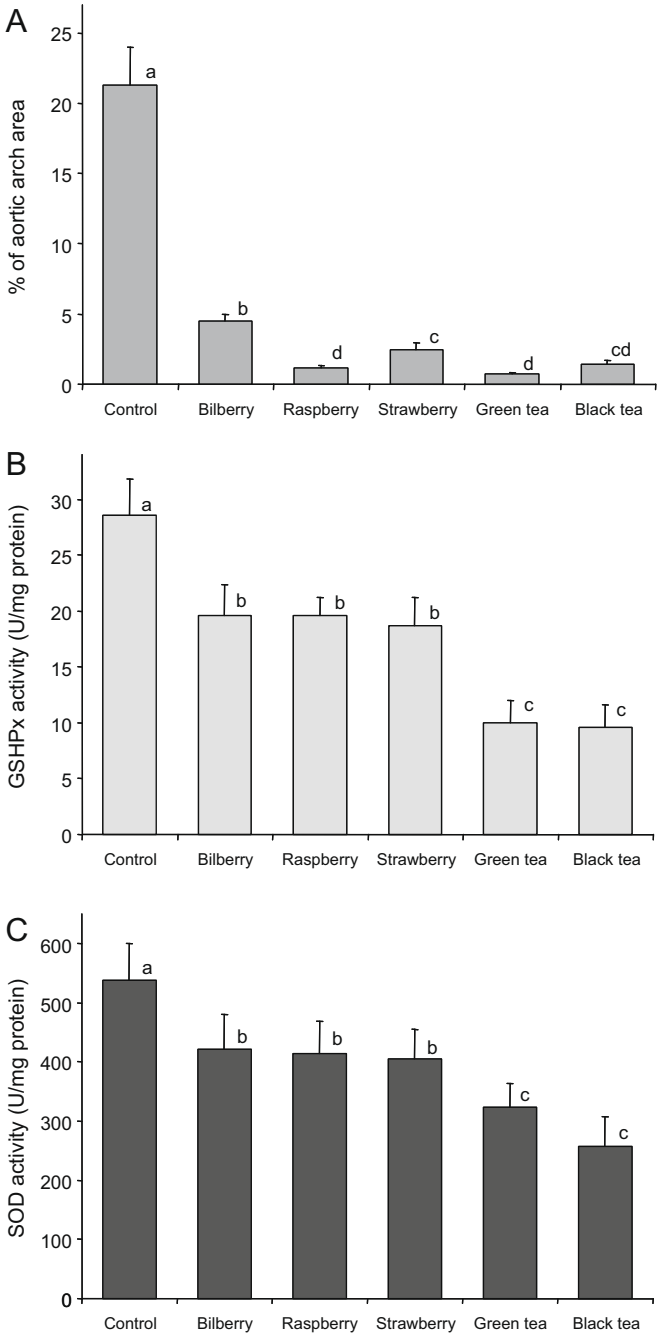

Fig. 1. Effects of dietary treatments on aortic fatty streak area and hepatic antioxidant enzymes activities. Mean values expressed as (A) a percent of aortic area ± SEM (n = 10) for aortic arch area, and as units per mg of hepatic proteins ± SEM (n = 10) for (B) SOD and (C) GSHPx activity. Bars with different letters are significantly different (p < 0.05).

The observation that the plasma cholesterol profile did not change among groups of hamsters (Table 5) is in keeping with the work of Andrews et al. (1995) that demonstrates that absolute cholesterolaemia is not pivotal in determining the aortic fatty streak deposition. These results thus strengthen the hypothesis that oxidation of LDL, more than their plasma level, must be implicated in the pathogenesis of atherosclerosis (Breinholt, Lauridsen, & Dragsted, 1999). This can explain, at least in part, the effects observed on aortic atherosclerosis after antioxidant juices and tea consumption.

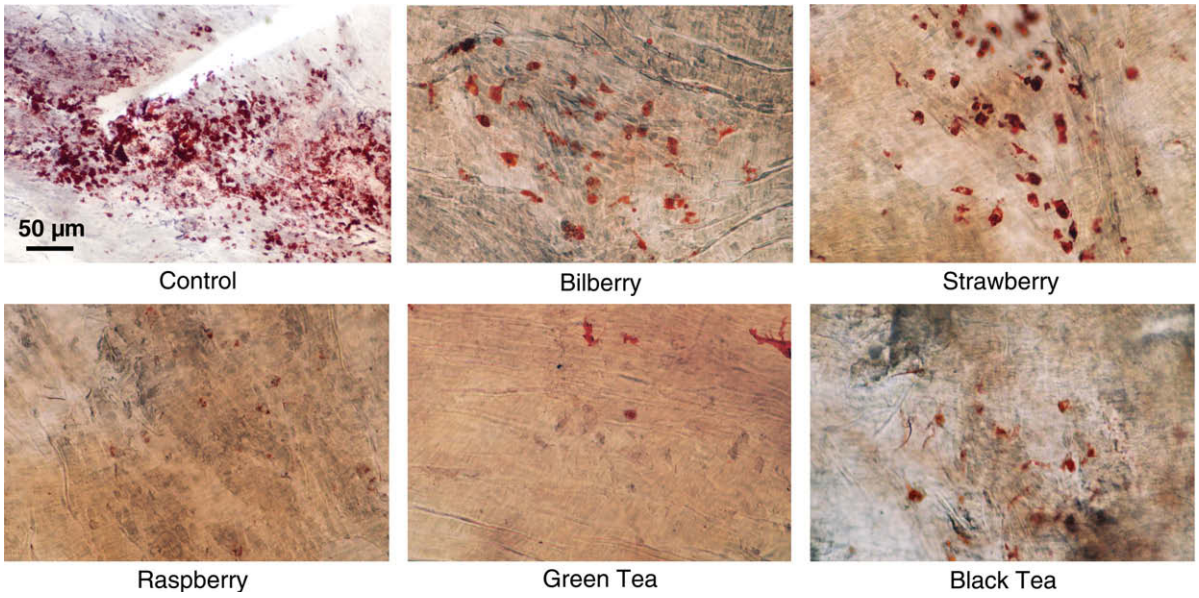

Fig. 2. Photomicrographs of hamster aortic arches after 12 weeks on an atherogenic diet (control) and 12 weeks on an atherogenic diet supplemented with either strawberry juice, bilberry juice, raspberry juice, green tea or black tea. The micrographs are examples of the aortic arch surface covered by lipid inclusion in the intima with lipids coloured red using Oil Red O stain. Quantifications of fatty streaks are summarised in and Fig. 1A. All micrographs have the same scale.

There are reports that consumption of fruit juice and green tea both increase the activity of hepatic antioxidant enzymes (Lin et al., 1998; Young et al., 1999). This contrasts with the findings of the present study where berry juice and tea consumption lowered hepatic GSHPx and SOD activities (Fig. 1B and C), and agree with previous results in hamsters receiving either pure catechin, quercetin or resveratrol (Auger et al., 2005) or phenolics from purple grape, apple, purple grape juice and apple juice (Décordé, Teissèdre, Auger, Cristol, & Rouanet, 2008). One explanation for this down regulation is that it is a consequence of dietary antioxidants being able to scavenge oxygen radicals and thus reduce the need for enzymatic endogenous antioxidants.

The prevention of fatty streak deposition by berry juice and tea consumption does seemingly involve mechanisms allowing the possibility of phenolic compounds to induce local antioxidant effects which cannot be ruled out. Recent data suggests that dietary phenolics can modulate inflammatory pathways, hence reducing the severity of local inflammation (Rahman, Biswas, & Kirkham, 2006). The pathogenesis of atherosclerosis has been linked to the occurrence of inflammatory processes inside the arterial wall during the initiation of lesions (Call, Deliargyris, & Newby, 2004). Compounds derived from the ingested phenolics could, therefore, delay the progression of atherosclerosis by inhibition of arterial wall inflammation.

Endothelial dysfunction is also associated with the increased production of the vasoconstrictive peptide endothelin-1, which has been linked with chronic inflammation of the arterial wall (Feletou & Vanhoutte, 2006; Schiffrin, 2005). Endothelin is also related with the onset and development of atherosclerosis, with atherosclerotic plaques containing an increased endothelin concentration (Bacon, Cary, & Davenport, 1996). Moreover, endothelin-1 production is induced by oxidised LDL, which in turn can recruit macrophages and monocytes in the arterial wall (Schiffrin, 2001). Endothelin, thus, plays a pivotal role in development of diseases related to vascular function. As demonstrated by Corder et al. (2006), phenolic compounds, principally procyanidins, are able to reduce the production of endothelin-1 by endothelial cells. The green tea polyphenol (−)-epigallocatechin gallate is also reported to reduce endothelin expression (Spinella et al., 2006). Inhibition of endothelin-1 over-expression is, therefore, a further potential mechanism for the observed protective effects of juice and tea consumption.

Tea antioxidants, in particular catechins, act either as activators or inhibitors of signal transduction kinases interfering with multiple pathways of signal transduction in cardiovascular relevant cells (Stangl, Dreger, Stangl, & Lorenz, 2007). Arguably, this could explain the strong effect of green tea with respect to the other beverages in this study.

The fact that the five beverages, which reduced the onset of atherosclerosis, contained a very different spectrum of phenolics implies that a wide variety of compounds may be bioactive and that the observed preventive effects may be due to the influence of several constituents working either independently or in tandem. What compounds enter the circulatory system, reduce the arterial fatty streaks deposition and the activity of hepatic SOD and GSHPx remains to be determined. Analysis of the livers of hamsters after 12 weeks plus an overnight treatment between last feed and sacrifice showed no trace of either the parent compounds from the beverages or their glucuronyl-, methyl- or sulfo-metabolites, indicating that they do not accumulate in these tissues, at least in detectable quantities.

In conclusion, we have demonstrated that berry juices and teas fed to hamsters under atherogenic diet are able to facilitate a very strong inhibition of aortic fatty streaks deposition. These effects are physiologically relevant as they were induced by a daily supplement equivalent to 275 ml of beverage consumed on a daily base by a 70 kg human. The features and progression of the lesions observed in the hamster model of atherosclerosis are morphologically similar to atheromatous lesions observed in humans. The hamster is therefore considered to be a good animal model to study the formation of atheromas in humans (Yamanouchi et al., 2000). It is also of interest to note while both bilberry and strawberry juices prevent aortic lipid deposition in hamsters, blueberry, a close relative of bilberry, and strawberry extracts both bring about improvements in neuronal function and behaviour in a rodent model of accelerated aging (Shukitt-Hale, Carey, Jenkins, Rabin, & Joseph, 2007).

Carotid atherosclerosis is associated with aortic atherosclerosis (Shimizu et al., 2003) and the intima-media thickness of the common carotid artery has been shown to predict coronary events and

is, therefore, a non-invasive predictor of future ischemic stroke incidence (Chambless, Folsom, Clegg, Sharrett, & Shahar, 2000). Thus, polyphenol-rich berry juices and green and black tea intake may be of significant relevance to clinical and public health.

Conflict of interest statement

The authors declare that there are no conflicts of interest.

(*E*,*E*)-α-farnesene synthase (MdAFS1)
Volatile compounds

ABSTRACT

Volatile compound production was studied in terms of biosynthetic gene expression in apple ('Tsugaru'). To this end, we first analysed the endogenous and emitted volatiles in the skin of ripened apple fruit. GC–MS and GC analyses suggested that the boiling point of the endogenous compounds in apple skin is an important determinant of the composition and amount of emitted volatiles. Since esters and (*E*,*E*)-α-farnesene are the major endogenous volatiles in apple, key biosynthetic genes were isolated from apple skin and their expression patterns were analysed with ethylene biosynthetic genes. During fruit development, the onset of alcohol acyltransferase (*pMdAAT*) expression in the skin, which is responsible for ester biosynthesis, coincided with the accumulation of *1-aminocyclopropane-1-carboxylate synthase* (*MdACSs*, *MdACS5B*) mRNA. Thereafter, *pMdAAT* expression remained at a high level, even when no *MdACS* transcripts were observed. On the other hand, the accumulation of (*E*,*E*)-α-*farnesene synthase* (*pMdAFS1*) transcripts in the skin was associated with the expression of *MdACSs* and *1-aminocyclopropane-1-carboxylate oxidase* (*MdACO1*). After harvest, the inhibition of *pMdAAT* expression in 1-methylcyclopropene (1-MCP)-treated apple skin was incomplete. In contrast, the expression of *pMdAFS1* was repressed by 1-MCP treatment concomitant with considerable inhibition of ethylene production. These results suggest that *pMdAFS1* expression is controlled by ethylene, whereas *pMdAAT* expression is developmentally regulated in the skin of 'Tsugaru'.

1. Introduction

Volatile compounds are one of the factors that determine apple (*Malus* × *domestica*) fruit quality (Kondo, Setha, Rudell, Buchanan, & Mattheis, 2005). Apples emit a complex mixture of volatile compounds including alcohols, esters, aldehydes, ketones, and sesquiterpenes (Dimick & Hoskin, 1983). The major aromatic compounds in apples are volatile esters (Brackmann, Streif, & Bangerth, 1993; Olías, Sanz, Rios, & Perez, 1992). Esters are, associated with the 'fruity' attributes of a fruit's flavour and, are important aromatic components in many ripened fruits (Aharoni et al., 2000). Esters are derived from amino acids and fatty acids (Dixon & Hewett, 2000). Alcohol acyltransferase (AAT), a BAHD enzyme superfamily, is a key enzyme in ester biosynthesis, catalysing the final step in ester formation by linkage of an acyl moiety from acyl-CoA to the appropriate alcohol (Fellman, Miller, Mattison, & Mattheis, 2000). Studies have reported that apple *AAT* (*MdAAT*) is expressed at a later stage during fruit ripening (Defilippi, Kader, & Dandekar, 2005; Souleyre, Greenwood, Friel, Karunairetnam, & Newcomb, 2005), and studies based on *in situ* hybridization suggested that *MdAAT2* is primarily located in the fruit skin (Li et al., 2006). MdAAT is able to use a range of alcohols and CoA acids to produce the range of esters found in apple fruit (Souleyre et al., 2005). Apart from esters, apples also produce a large amount of (*E*,*E*)-α-farnesene (Girard & Lau, 1995), a sesquiterpene that is biosynthesized via the mevalonate pathway (Pechous & Whitaker, 2004). The products of (*E*,*E*)-α-farnesene oxidation can induce superficial scald disorder, an important disease in the apple industry; several studies have conducted comparative analyses of (*E*,*E*)-α-farnesene biosynthesis in resistant and susceptible cultivars (Lurie et al., 2005; Pechous, Watkins, & Whitaker, 2005; Tsantili, Gapper, Arquiza, Whitaker, & Watkins, 2007). (*E*,*E*)-α-farnesene synthase (AFS), encoded by *MdAFS1* in apple, is a key enzyme in (*E*,*E*)-α-farnesene biosynthesis, catalysing the conversion of farnesyl diphosphate to (*E*,*E*)-α-farnesene in the final steps of sesquiterpene biosynthesis (Pechous & Whitaker, 2004).

Ethylene is a key regulatory molecule for ripening and senescence and it is thought to regulate fruit ripening by coordinating

the expression of many genes, which are responsible for chlorophyll degradation, carotenoid synthesis, conversion of starch to sugars, cell-wall modulation, and so on (Theologis, 1992). It is well-known that volatile biosynthesis is also regulated by ethylene. Kondo et al. (2005) showed that chemical inhibition of ethylene action suppresses volatile production. Moreover, several studies show that the genes responsible for volatile biosynthesis are regulated by ethylene. For example, an antisense experiment with *MdACO1* shows that *MpAAT1* and *MdAFS1* were expressed only after exogenous ethylene application in *MdACO1*-antisense apple transformants (Schaffer et al., 2007).

To date, research aimed at identifying the volatiles and their biosynthetic regulation in apple (e.g. Young, Chu, Lu, & Zhu, 2004) has focused on the relationship between the emitted volatile compounds and their related gene expression, despite the fact that the quality and quantity of endogenous volatiles may influence the emitted volatiles such as in petunia (Oyama-Okubo et al., 2005) and that gene expression should be directly related to endogenous, rather than emitted, volatiles in apple, because the genes function in the tissues in which endogenous volatiles biosynthesis took place. In addition, information regarding the volatile biosynthesis in 'Tsugaru' apple is not available, despite being a major cultivar in Japan. Therefore, in this study, we investigated the emitted and endogenous volatiles and the expression of *pMdAAT*, *pMdAFS1* and ethylene biosynthetic genes in 'Tsugaru' apple skin to gain insight into the regulatory mechanism underlying volatile compound production via ethylene action in this cultivar. To this end, we analysed the emitted and endogenous volatiles using capillary gas chromatography–mass spectrometry (GC–MS) and GC. Furthermore, we analysed the expressions of *pMdAAT*, *pMdAFS1*, apple *1-aminocyclopropane-1-carboxylate synthase* (*MdACSs*), and apple *1-aminocyclopropane-1-carboxylate oxidase* (*MdACO1*) in 1-methylcyclopropene (1-MCP)-treated skins as well as during fruit development. On the basis of the results, we discuss the possible regulation of volatile compound production via ethylene action in 'Tsugaru' apple skin.

2. Materials and methods

2.1. Plant materials

Fruit of 'Tsugaru' apple (pale red cultivar) was obtained from an orchard at the National Institute of Fruit Tree Science in Morioka, Japan. In this area, the commercial harvest time is mid-September for 'Tsugaru'. The mature fruit of 'Tsugaru' apple was harvested about one week after the commercial harvest. Fruits were also periodically harvested from young fruitlet to mature stages, which corresponded to 16, 37, 60, 79, 102 and 116 days after full bloom (DAFB). The last harvesting date of 116 DAFB corresponds to about one week after commercial harvest. The mature fruits were used for the GC–MS and GC analyses. The entire skin, including 1 mm of the cortical tissue, was collected. The collected skin was immediately frozen in liquid nitrogen, and stored at −80 °C until used for RNA isolation. In a preliminary experiment, the specificity of skin preparation was confirmed by the specific expression pattern of a MYB transcription factor gene (*MdMYBA*), which is responsible for anthocyanin accumulation in apple skin (Ban et al., 2007).

For 1-MCP treatment, 'Tsugaru' fruits were harvested at the preclimacteric stage (3 days before commercial harvest). Fruits without injury were selected and temporarily stored at 4 °C for 16 h before being transferred to 24 °C. 1-MCP treatment was carried out essentially as described by Tatsuki and Endo (2006). Fruits were placed in 117 l plastic containers and treated with 1.0 μl l^{-1} 1-MCP (SmartFresh™, AgroFresh, Inc., Spring House, PA, USA) for 24 h at 25 °C. As a control, fruits were left in the air for 24 h at 25 °C. All fruits were then stored for 5 days at 25 °C. Following ethylene measurement, the skins were collected and stored at −80 °C for RNA isolation.

2.2. Determination of ethylene concentration

Ethylene was measured by placing each fruit in a sealed desiccator (about 1,500 ml) for 1 h at 25 °C. A 1.0 ml sample of the gas was then withdrawn with a syringe and injected into a gas chromatograph (GC-14B, Shimadzu, Kyoto, Japan) equipped with a flame ionisation detector. Activated alumina (60–80 mesh) in a glass column (2.0 mm i.d. × 2 m) was used with helium as the carrier gas at 100 kPa pressure. The column, injector, and detector temperatures were 60, 80 and 200 °C, respectively.

2.3. Extraction of the emitted and endogenous volatiles

We used three fruits for extraction of the emitted and endogenous volatiles. The weights of fruits were 410.56, 369.37 and 441.11 g, respectively. The extraction of the emitted and endogenous volatiles was conducted with three biological replicates from three fruits. The emitted volatile compounds were collected by the headspace method (Oyama-Okubo et al., 2005). Mature apple fruits were separately placed in Tedlar Bags (5000 ml volume, GL Science, Tokyo, Japan). A constant stream of air (approx. 500 ml min^{-1}) was filtered through activated charcoal and then piped through the bag, and the volatiles were collected for a 1 h period using Tenax-TA (150 mg, GL science) traps. The relative humidity in the bags was approximately 50%. The emitted volatile compounds were extracted four times from the Tenax-TA traps using pentane and diethyl ether (5 ml each) alternately (Oyama-Okubo et al., 2005). After the addition of ethyl decanoate (20 μg) as an internal standard, the extract was dehydrated with anhydrous sodium sulphate and concentrated to about 15 μl at 40 °C in a water bath.

For analysis of the endogenous volatiles, the fruit skins from the three fruits were separately harvested after collecting the emitted volatile compounds. Extraction of the endogenous volatiles from the skins was carried out essentially as described by Kondo, Oyama-Okubo, Ando, Marchesi, and Nakayama (2006). The skin (5 g) from each sample was ground with a mortar and pestle in liquid nitrogen until a fine powder was obtained. The samples were then extracted twice with pentane (10 ml each) in a microwave oven (700 W) for 20 s. Ethyl decanoate (20 μg) was added as an internal standard. Each extract was then dehydrated with anhydrous sodium sulphate and concentrated to about 15 μl at 40 °C in a water bath.

2.4. GC–MS and GC analyses

The compounds were identified and quantified by GC–MS and GC analyses, respectively. GC–MS analysis was performed using an Agilent 6890N gas chromatograph coupled to an Agilent 5973N Mass Selective Detector (Agilent Technologies, Wilmington, DE, USA) (Kondo et al., 2006; Oyama-Okubo et al., 2005). The GC was equipped with a splitless injector and a DB-WAX capillary column (0.25 mm i.d. × 30 m, 0.25 μm film thickness). The column oven temperature was kept at 45 °C for the first 2 min, then increased by 3 °C min^{-1} to 220 °C and maintained at 220 °C for 10 min. The injection, interface, and MS source temperatures were 250, 280, and 250 °C, respectively. Helium was used as the carrier gas at 50 ml min^{-1}. GC analysis was performed using an Agilent 6850 gas chromatograph (Agilent Technologies) monitored by a flame ionisation detector. The analytical conditions were the same as those described above for GC–MS. Identification of compounds was confirmed by comparison of collected mass spectra with those

in the NIST02 library provided with the GC–MS software. The amount of each compound was calculated by comparison with the peak area of the internal standard. Only reproducible peaks within three biological replicates were extracted as data for analysis.

2.5. Isolation of the partial AAT and AFS genes from 'Tsugaru'

To isolate the partial fragment of *MdAAT* (*pMdAAT*), total RNA was extracted from mature fruit skin using the hot borate method (Wan & Wilkins, 1994). First-strand cDNA was synthesized using a SMART RACE cDNA Amplification Kit (Clontech, Palo Alto, CA, USA) and was then used as the template for amplification of the fragments. Reverse transcription-PCR (RT-PCR) was carried out with forward (5′-CGCATCCAGTAACCAGTCAA-3′) and reverse (5′-TGAGGTCGCCCTCTTAGTACC-3′) primers designed based on the sequences of *MpAAT1* (Souleyre et al., 2005) and *MdAAT2* (Li et al., 2006). Each reaction was performed in a total volume of 10 μl containing 20 ng of cDNA, 200 μM dNTPs, 1 mM $MgCl_2$, 3 pmol of each primer, 2 U of KOD plus (TOYOBO, Osaka, Japan), and 1× PCR buffer (TOYOBO). After pre-heating at 94 °C for 2 min, the tubes were subjected to 35 cycles of 94 °C for 15 s, 57.5 °C for 30 s, and 68 °C for 1.5 min. The products were then cloned into pCR-Blunt using a Zero Blunt PCR Cloning Kit (Invitrogen, San Diego, CA, USA) and sequenced. In contrast, the partial cDNA of *MdAFS1* (*pMdAFS1*) was identified from a subtracted cDNA library constructed using 'Tsugaru' fruit skin (Ban et al. unpublished data); consequently, we were able to use the clone directly. The sequences of *pMdAAT* (411 bp) and *pMdAFS1* (486 bp) have been deposited in the DNA Data Bank of Japan (DDBJ) under accession numbers AB370229 and AB370228, respectively.

2.6. RNA gel blot analysis

Total RNA was isolated from the skins of 1-MCP-treated fruit and during fruit development using the methods described above. Total RNA (5 μg) was electrophoresed on a 1.2% agarose/formaldehyde gel then blotted onto a nylon membrane (Hybond-N, Amersham Biosciences, Piscataway, NJ, USA) by capillary transfer. The insert DNAs in the identified cDNA clones (*pMdAAT* and *pMdAFS1*), the full-length *MdACS* cDNAs; *MdACS1* (accession number U89156), *MdACS3* (U73816), *MdACS4* (Kim, Silverstone, Yip, Dong, & Yang, 1992), *MdACS5A* (AB034992) and *MdACS5B* (AB034993), and apple *ACO* (*MdACO1*, X61390) were labelled with digoxigenin-dUTP (Roche Diagnostics, Mannheim, Germany) using M13 forward and reverse primers by PCR. Prehybridization, hybridization, washing, and detection were carried out according to the methods of Ban et al. (2007). Notably, our probe for *pMdAAT* contained the conserved region in *MpAAT1* (Souleyre et al., 2005), *MdAAT2* (Li et al., 2006) and *MdAAT3* (Zhu, Rudell, & Mattheis, 2008). Therefore, at least these signals could be detected under our conditions.

3. Results

3.1. Components of the emitted and endogenous volatiles in the skin of mature apple fruit

Emitted volatile compounds were first analysed using intact fruits. Twelve emitted volatiles were detected in mature 'Tsugaru' apple (Table 1). The total amount of emitted volatiles was 8.23 ng g^{-1} fresh weight (FW) of fruit. Esters were the predominant compound, accounting for 84.83% of the total emitted volatiles. Among the esters, hexyl 2-methylbutanoate and 2-methylbutyl acetate were predominantly detected. (*E*,*E*)-α-farnesene was also detected, but its content was 12-times lower than the ester content. Next, since volatile compounds are primarily synthesized in the skin (Knee & Hatfield, 1981), the endogenous volatiles in the skin were analysed. Fourteen endogenous volatiles were detected in the mature 'Tsugaru' apple skins (Table 1). The total amount of endogenous volatiles was 15,455.08 ng g^{-1} FW of skin. (*E*,*E*)-α-farnesene was the predominant compound, accounting for 65.1% of the total endogenous volatiles. Esters were also detected as endogenous volatiles; however, their content was about two times lower than the (*E*,*E*)-α-farnesene content. Among the esters, hexyl 2-methylbutanoate was predominantly detected. Nine compounds were detected in both the emitted and endogenous samples, including hexyl 2-methylbutanoate, 2-methylbutyl acetate, and (*E*,*E*)-α-farnesene. Conversely, a number of compounds were detected only in either the emitted or the endogenous samples.

3.2. Relationship between the boiling points and emission ratios

For the nine compounds that were detected in both the emitted and endogenous samples, the logarithm of the ratio of emitted to endogenous amounts was plotted against the boiling point (Fig. 1). The compounds included in the analysis were 2-methylbutyl acetate, butyl butanoate, hexyl acetate, butyl 2-methylbutanoate, hexyl propanoate, hexyl 2-methylbutanoate, hexyl butanoate, butyl hexanoate, and (*E*,*E*)-α-farnesene. Our results show a nearly linear negative correlation between the emission ratio and boiling point of each compound.

3.3. Expression of pMdAAT, pMdAFS1 and ethylene biosynthetic genes

Since esters and (*E*,*E*)-α-farnesene were the major endogenous volatiles in 'Tsugaru' apple skin, expression analysis of their biosynthetic genes and ethylene biosynthetic genes was conducted

Table 1
Composition of the emitted and endogenous volatiles in mature 'Tsugaru' apple.

Compounds[a] (boiling point)	Emitted		Endogenous	
	(ng g^{-1} FW fruit)	(%)	(ng g^{-1} FW skin)	(%)
Ester	6.98 ± 0.45[b]	(84.83)	4573.65 ± 951.24	(29.59)

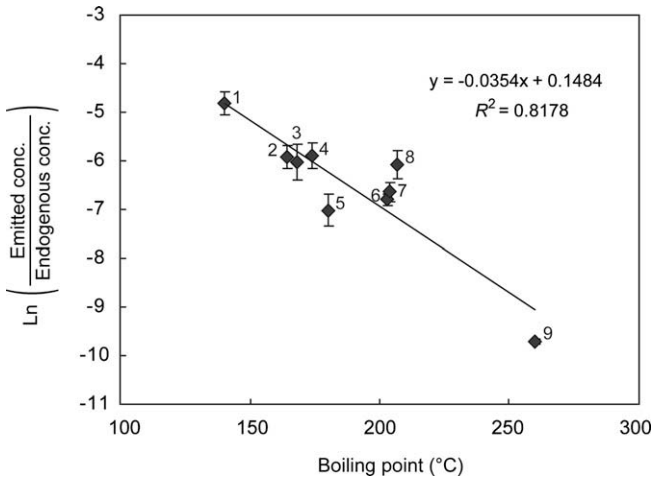

Fig. 1. Relationship between the boiling point and the natural logarithms of the ratios of emitted to endogenous concentrations of volatile compounds in mature 'Tsugaru' apple. 1,2-Methylbutyl acetate (boiling point, 140 °C); 2, Butyl butanoate (164 °C); 3, Hexyl acetate (168 °C); 4, Butyl 2-methylbutanoate (174 °C); 5, Hexyl propanoate (180 °C); 6, Hexyl 2-methylbutanoate (203 °C); 7, Hexyl butanoate (204 °C); 8, Butyl hexanoate (207 °C); and 9, (*E*,*E*)-α-farnesene (260 °C). Bars indicate the SE.

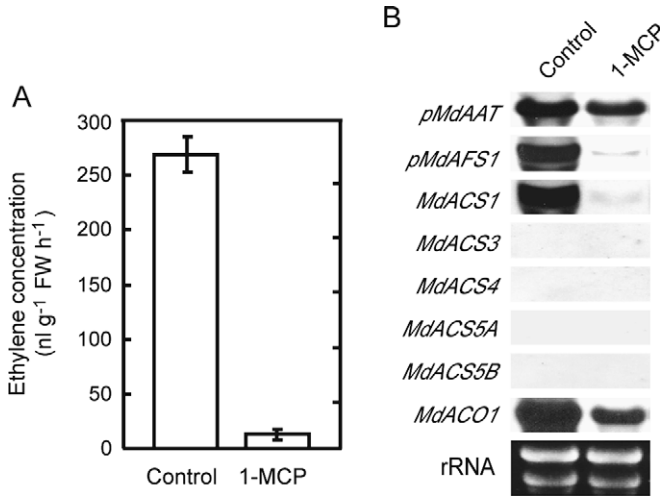

Fig. 3. Effect of 1-MCP on ethylene production (A) and the expression of *pMdAAT*, *pMdAFS1*, *MdACSs*, and *MdACO1* (B) in 'Tsugaru' at 5 days after treatment. 1-MCP was applied to fruits at the pre-climacteric stage (3 days before commercial harvest). The ethylene concentration is shown as the mean ± SE (n = 5). Ethidium bromide staining shows equal loading of rRNA.

using RNA isolated from fruit skins at different developmental stages. The transcript of *pMdAAT* was first detected at 16 DAFB, and its level increased continuously during fruit ripening, peaking at 116 DAFB (Fig. 2). *pMdAFS1* mRNA was abundant at 116 DAFB but rare at 16 DAFB. Ethylene production during fruit development was not monitored in this study. Instead, expressions of *MdACS*s and *MdACO1* were investigated using the same fruit skins because it is generally accepted that the expression level of *ACS* completely corresponds to ethylene production during fruit ripening (Dal Cin et al., 2007; Itai et al., 1999). *MdACS3*, *MdACS4*, and *MdACS5A* were not expressed at any stage in 'Tsugaru' (Fig. 2). However, *MdACS1* mRNA was detected at 116 DAFB. Furthermore, *MdACS5B* transcripts were observed at 16 and 37 DAFB. On the other hand, *MdACO1* mRNA was detected in young fruitlet (16 DAFB) and ripe fruit stages (102 and 116 DAFB). *MdACS5B* and *MdACO1* expression in young fruitlet (16 DAFB) might contribute to a system I ethylene (McMurchie, McGlasson, & Eaks, 1972), although this hypothesis is not yet confirmed.

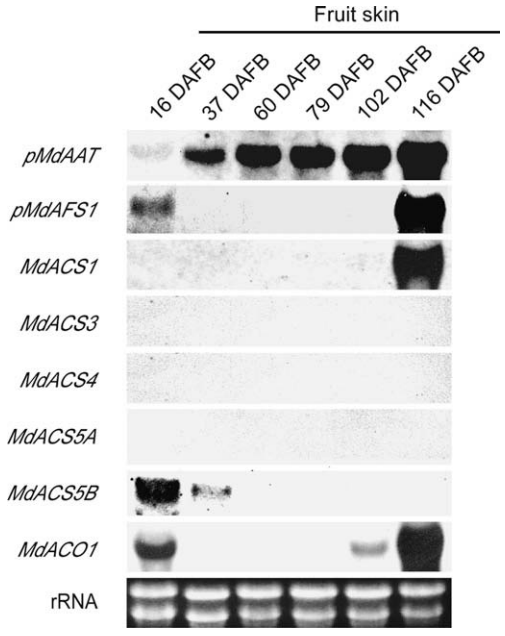

Fig. 2. RNA gel blot analysis of *pMdAAT*, *pMdAFS1*, *MdACSs*, and *MdACO1* in 'Tsugaru' fruit skin during fruit development. Ethidium bromide staining shows equal loading of rRNA.

To further investigate the regulation of *pMdAAT* and *pMdAFS1* by ethylene after harvest, ethylene action was inhibited by 1-MCP in the fruit after harvest. Treatment with 1-MCP effectively inhibited ethylene action at 5 days after treatment (DAT) (Fig. 3A). When the expression of *pMdAAT* and *pMdAFS1* was analysed, *pMdAAT* underwent only a minor change at 5 DAT; its expression was only slightly affected by ethylene signalling inhibitor (Fig. 3B). In contrast, *pMdAFS1* expression was notably inhibited by 1-MCP at 5 DAT. When expression analysis of the genes in the ethylene biosynthetic pathway was conducted, *MdACS1* expression clearly corresponded to ethylene production, whereas *MdACO1* did not tightly correspond to the amount of ethylene in 1-MCP-treated apple skin. Except for *MdACS1*, expression of *MdASC3*, *MdACS4*, *MdACS5A* and *MdACS5B*, was not detected in the skins from harvested apple.

4. Discussion

In this study, we intended to clarify the physiological regulation of volatile compound production in terms of biosynthetic gene expression and ethylene production in 'Tsugaru' apple skin. To this end, we first analysed the endogenous and emitted volatiles in the skin of ripened apple fruit, because it is generally believed that volatile production consists of two steps, endogenous production and evaporation of the endogenous volatile compounds (Oyama-Okubo et al., 2005). We, therefore, measured the composition and amount of both emitted and endogenous volatiles. As for emitted volatiles, 'Tsugaru' displayed esters and (*E*,*E*)-α-farnesene as major volatiles, which is comparable to other cultivars (e.g. Fellman et al., 2000) (Table 1), but the composition and concentration of emitted volatiles other than these major compounds in 'Tsugaru' were not identical to other cultivars. Interestingly, the composition and amount of emitted volatiles was distinct from that of the endogenous volatiles (Table 1). For example, (*E*,*E*)-α-farnesene was a major component of the endogenous samples, but its composition was largely reduced in the emitted samples. Evaporative properties such as the boiling point of volatile compounds may contribute

to floral scent in *Petunia axillaries*, and a negative correlation between the emitted/endogenous ratio and boiling point has been suggested (Kondo et al., 2006; Oyama-Okubo et al., 2005). Accordingly, we also considered the boiling points of the identified compounds. In general, those compounds with a lower boiling point tended to be emitted at higher levels (Table 1), indicating that the differences in composition and amount between the endogenous and emitted volatiles in apple skin might be partly ascribed to the different boiling points of the substances. In addition, the linear negative correlation between the emission ratio and boiling point also suggests the importance of the boiling point in determining emitted volatiles (Fig. 1). On the other hand, a number of compounds were detected either as emitted or endogenous volatiles only; i.e., acetic acid, hexanoic acid, and acetophenone were detected only as emitted volatiles but undetected as endogenous volatiles. Since the endogenous volatiles present in other tissues were not measured in this study, the possibility that these compounds were derived from the flesh and core tissues cannot be ruled out. Conversely, hexyl hexanoate, 2-methylbutanoic acid, and (*E*)-2-hexenal were not detected as emitted volatiles despite their high concentrations endogenously. It is worth noting that (*E*)-2-hexenal has a relatively low boiling point (146 °C); however, it was not detected as emitted volatile, indicating that unknown factor(s) other than boiling point may be involved in this process. Similar results were observed in *P. axillaries* (Kondo et al., 2006). Thus, it is difficult to show a clear-cut reason(s) for the relationships between emitted and endogenous volatiles possibly due to the involvement of many factors, such as enzyme and temperature in this process. It could, however, be suggested that the composition and amount of the emitted volatiles largely depend on the endogenous volatile compounds and their boiling points in apple.

Since GC–MS and GC analyses showed that the production of endogenous compounds is important for volatile production, we analysed the expression of volatile biosynthetic genes and ethylene biosynthetic genes to elucidate the regulatory process of endogenous volatile biosynthesis via ethylene action. Esters and (*E*,*E*)-α-farnesene were the major endogenous volatiles in apple skin. Therefore, we isolated their key biosynthetic genes, *pMdAAT* and *pMdAFS1*. During fruit development, *pMdAAT* expression was first detected at 16 DAFB, concomitant with abundant *MdACS5B* mRNA. After that, *pMdAAT* transcript levels were increasing towards 102 DAFB, even when no *MdACS* transcripts were observed. On the other hand, *pMdAFS1* expression paralleled that of *pMdACS*s; high or low expression at the fruitlet or ripe stage coincided with the expression of *MdACS5B* and *MdACS1*, respectively. Although we did not measure ethylene production during fruit development, a positive correlation has been shown between ethylene biosynthesis and *ACS* expression as suggested by Dal Cin et al. (2007) and Itai et al. (1999). Accordingly, one might suppose that *pMdAFS1* expression should have been detected at 37 DAFB because of the apparent existence of *MdACS5B* mRNA. However, *MdACO1* expression could not be detected at 37 DAFB. Therefore, we assume that ethylene cannot be synthesized at this stage, possibly due to the lack of an *MdACO1* signal (i.e., the final step in ethylene biosynthesis). Thus, onset of *pMdAAT* expression may be triggered by ethylene because of the concomitant expression of *pMdAA*T and *MdACS5B*. This hypothesis is not yet clarified. However, *pMdAAT* expression after 16 DAFB could be developmentally regulated in this cultivar. In contrast, ethylene may regulate *pMdAFS1* expression at the transcriptional level, as previously reported (Pechous & Whitaker, 2004; Schaffer et al., 2007). 1-MCP treatment also showed the incomplete inhibition pattern of *pMdAAT* and concomitant repression pattern of *MdAFS1* with ethylene production (Fig. 3), which supports our aforementioned assumption.

Recently, Zhu et al. (2008) suggested that *MdACS3* was responsible for the expression of *MdAAT1* and *MdAAT2* during ripening processes, since *MdACS3* was always detected throughout ripening processes in 'Golden Delicious'. In our study, only the signal for *MdACS5B* was apparent at 16 and 37 DAFB. No other *MdACSs* transcripts were detected during ripening processes until mature stage at 116 DAFB in which only *MdACS1* transcript was detected. Meantime, *pMdAAT* expressed stably throughout the ripening processes (Fig. 2). Moreover, Zhu et al. (2008) also suggested that *MdACS3* elicited the *MdAAT1* expression when ethylene action was inhibited by 1-MCP, since both *MdACS3* and *MdAAT1* expression were not repressed by 1-MCP treatment. However, in our study, only *MdACS1* transcript was detected at 5 DAT of 1-MCP treatment, and its expression was largely inhibited by 1-MCP concomitant with the large reduction of ethylene production, whereas *pMdAAT* expression underwent only a minor change (Fig. 3). Furthermore, if *pMdAAT* is truly ethylene-regulated gene in 'Tsugaru', similar expression pattern as those for *MdAFS1* should be expected both before and after harvest (Figs. 2 and 3). On the other hand, Defilippi et al. (2005) found small increment of *MdAAT* transcript level during fruit development in transgenic apple trees with suppressed ACC or ACO activity. This indicated that *MdAAT* expression can be induced even under negligible ethylene level conditions. Based on this observation, Defilippi et al. (2005) hypothesized that regulatory mechanisms other than ethylene action may be involved in the regulation of *MdAAT* during fruit development. Similar observation was reported in melon; in the transgenic melon with antisense-*ACO*, whose ethylene production was highly reduced, *CM-AAT1* transcription was not completely suppressed during fruits development (Yahyaoui et al., 2002). Therefore, based on our results and the previous observation of the transgenic plants (Defilippi et al., 2005; Yahyaoui et al., 2002), the expression of *pMdAAT* is regulated by developmental factors rather than ethylene in 'Tsugaru', although ethylene may trigger the onset of *pMdAAT* expression possibly due to the coexistence of *MdACS5B*, *MdACO1* and *pMdAAT* transcripts at 16 DAFB (Fig. 2). Since the cultivar used in this study ('Tsugaru') is different from those examined by Defilippi et al. (2005, 'Greensleeves') and by Zhu et al. (2008, 'Golden Delicious'), the possibility of the different regulatory mechanism of *MdAAT* in the different apple cultivars, needs to be further elucidated in the future.

Taken together, our results indicate that: (i) the boiling point of endogenous compounds is an important determinant of the composition and amount of emitted volatiles and (ii) *pMdAFS1* expression is controlled by ethylene, whereas *pMdAAT* expression is developmentally regulated in the skin of 'Tsugaru'. Our data could provide further insight on the mechanisms of volatile production in apple skin.

Acknowledgements

We thank Dr. Masatoshi Kondo (University of Tsukuba, Japan) and Dr. Miho Tatsuki (National Institute of Fruit Tree Science, Japan) for their valuable suggestions regarding our experiments. We are also grateful to Dr. Benjamin Ewa Ubi (Ebonyi State University, Nigeria) for his critical reading of our manuscript.

ABSTRACT

In order to obtain basic data necessary for the utilisation of aerial parts from *Platycodon grandiflorum* as a functional substance in Korea, the antioxidant activities of solvent fractions from the ethanol extract of *P. grandiflorum* aerial parts were examined. The butanol fraction from *P. grandiflorum* showed the most potent antioxidant activities in each assay, showing 91.31% in the DPPH radical scavenging method, 99.62% in the ABTS radical scavenging method, 7.84% in the reducing power method, and 1.29% in the FRAP method at a concentration of 10 mg/ml. The DPPH, ABTS, reducing power, and FRAP assay indicated that the butanol fraction of aerial parts of *P. grandiflorum* was the most potent radical-scavengers and reducing agents compared to the other two extracts. Therefore, our study verified that the butanol fraction has strong antioxidant activities which are correlated with its high level of phenolics, particularly luteolin-7-O-glucoside and apigenin-7-O-glucoside. This extract of *P. grandiflorum* aerial parts can be utilised as an effective and safe source of functional food materials such as natural antioxidants.

1. Introduction

Platycodon grandiflorum is a perennial grass that grows autogenously in Korea, and the northeastern region of China and Japan. The roots of *P. grandiflorum* (Korean name, 'Doraji', Japanese name, 'Kikyo', and Chinese name, 'Jiegeng'), which belongs to the Campanulaceae family, have been used as either a food material or a traditional oriental medicine in Korea (Lee, Hwang, & Lim, 2004). It has been used more often for food than for medicinal purposes since old times. In the Korean traditional medicine, it has been shown that *P. grandiflorum* is good for cough, phlegm, sore throat having a close relation to a pulmonary disorder, amusia, dysuria, diarrhoea, tenesmus and the like (Lee et al., 2004). The roots of *P. grandiflorum* are used as a traditional material of kimchi, and pickled fresh roots are consumed to prevent obesity in Korea and China. Moreover, the roots of *P. grandiflorum*, as one of the most important traditional herbal medicines are used for functional resources on hyperlipidemia, hypertension, and diabetes in Korea (Xu, Zheng, & Sung, 2004). In some studies, its immunopharmacological effects have been studied (Nagao, Matsuda, Namba, & Kubo, 1986), and some active compounds, such as the triterpenoid saponin (Fu et al., 2007) have been identified. Several researches even extended the cultivation period of *P. grandiflorum* to 22 years using a patented method (Lee, 1991), and reported that its aqueous extracts were effective in preventing hypercholesteroleamia, hyperlipidemia, and CCl_4-induced hepatotoxicity (Lee & Jeong, 2002). Recently, it was reported that *P. gradiflorum* had effects on the protection of the liver against acetaminophen in mice (Lee et al., 2001), anti-inflammatory (Kim et al., 2001), anti-lipidemic (Zheng, He, Ji, Le, & Zhang, 2007), anti-hypercholesteroleamic (Zhao et al., 2006), and antiobesity properties (Zhao, Harding, Marinangeli, Kim, & Jones, 2008). However, antioxidative activities from aerial parts of *P. grandiflorum* have not previously been reported.

Reactive oxygen species (ROS) such as hydrogen peroxide (H_2O_2), singlet oxygen ($^1O_2$), superoxide anion radical ($\cdot O_2^-$), hydroxyl radical ($\cdot OH$) are generated from the auto-oxidation of lipids, as well as reactive nitrogen species (RNS) (Aruoma, 1996; Singh, 1989). Formations of these excess ROS and RNS by UV irradiation, smoking and drug metabolism are likely to damage several cellular components such as lipids, proteins, nucleic acid, and DNAs through oxidation or nitration processes (Sawa, Akaike, & Maeda, 2000). In addition, these reactive oxygen species cause inflammation or lesions on various organs and are associated with various degenerative diseases, including cancer, ageing, arteriosclerosis, and rheumatism (Choi, Choi, Han, Bae, & Chung, 2002; Squadrito & Pryor, 1998).

Edible plants contain a wide variety of chemicals that have potential antioxidant activity. The best known phytochemical antioxidants are traditional nutrients, such as β-carotene, ascorbic acid, and α-tocopherol. However, there is growing evidence that a significant portion of the antioxidant capacity of many edible plants is due to the phytochemicals other than the traditional vitamins (Cao, Sofic, & Prior, 1996). Recently, researchers have sought to isolate powerful and non-toxic natural antioxidants from edible plants not only to prevent autoxidation and lipid peroxidation,

but also to replace synthetic antioxidants. In this respect, the research into the determination of the natural antioxidant source is very important to promote public health. Since the antioxidant activities of extract of *P. grandiflorum* aerial parts have not previously been reported, the objectives of the present study were to assess various antioxidative activities and identify the antioxidant active compounds of *P. grandiflorum* aerial parts which are normally wasted during frequent pruning in order to obtain the possibilities for functional foods. In line with the efforts to balance the conservation of biodiversity and encouraging controlled exploitation of plant resources for economic gains, especially in biopharming, wastage of valuable resources should be minimised.

2. Materials and methods

2.1. Chemicals

Folin–Ciocalteu's reagent, 1,1-diphenyl-2-picrylhydrazyl (DPPH), 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid (ABTS), potassium persulfate, potassium ferricyanide, trichloroacetic acid, ferric chloride, sodium acetate, 2,4,6-tripyridyl-S-triazine, α-tocopherol, ascorbic acid, and all solvents used were of analytical grade and purchased from Sigma Chemical Co. (St. Louis, MO, USA). The aerial parts of *P. grandiflorum* were collected from Jinju, Korea in September, 2007, and were authenticated by Institute of Agriculture and Life Sciences, Gyeongsang National University where voucher specimens were maintained. The plant samples, including stem, flower and leaves, were washed and oven-dried at 45 °C.

2.2. Extraction from the aerial parts of P. grandiflorum

Each solvent fraction of freeze-dried *P. grandiflorum* aerial parts (60 mesh particle size) was obtained as follows. Powdered *P. grandiflorum* aerial parts (100 g) were suspended and extracted with 400 ml of ethanol at 80 °C for 2 h. The extracts were filtered through Whatman No. 2 filter paper (Whatman International Limited, Kent, England) and evaporated to dryness. The dry materials were re-dissolved in 200 ml of distilled water. The solution was consecutively portioned in a separatory funnel with the equivalent amount of chloroform, butanol and water. Each fraction was concentrated in a vacuum evaporator (Eeyla NE, Tokyo Rikakikai Co., Ltd., Tokyo, Japan) at 40 °C. The water filtrate was frozen and lyophilised. The fractions were place in a glass bottle and stored at −20 °C until used. The lyophilised fractions were re-dissolved in ethanol to a concentration of 10 mg/ml.

2.3. DPPH free radical-scavenging activity

This was carried out according to Blois method with a slight modification (Blois, 1958). Briefly, a 1 mM solution of DPPH (Sigma Chemical Co., St. Louis, MO, USA) radical solution in ethanol was prepared, and then 4 ml of this solution was mixed with 1 ml of extract solution in ethanol containing 0.075–10 mg/ml of dried extract; finally, after 30 min, the absorbance was measured at 517 nm (UV-1201, Shimadzu, Tokyo, Japan). This activity was given as percentage DPPH scavenging that is calculated as

$$\%\text{DPPH scavenging} = [(\text{control absorbance} - \text{extract absorbance})/(\text{control absorbance})] \times 100$$

2.4. $ABTS^{\cdot+}$ radical-scavenging activity

$ABTS^{\cdot+}$ was dissolved in water to make a concentration of 7 mmol/l. $ABTS^{\cdot+}$ was produced by reacting the ABTS stock solution with 2.45 mmol/l potassium persulfate (final concentration) and allowing the mixture to stand in the dark at room temperature for 12–16 h before use. For the test of samples, the $ABTS^{\cdot+}$ stock solution was diluted with phosphate-buffered saline 5 mmol/l (pH 7.4) to an absorbance of 0.70 at 734 nm. After the addition of 1.0 ml of diluted $ABTS^{\cdot+}$ to 10 μl of sample, the absorbance reading was taken 5 min after the initial mixing (Fellegrin, Ke, Yang, & Rice-Evans, 1999). This activity is given as percentage $ABTS^{\cdot+}$ scavenging that is calculated as.

$$\%\ ABTS^{\cdot+}\text{scavenging activity} = [(\text{control absorbance} - \text{extract absorbance})/(\text{control absorbance})] \times 100$$

2.5. Reducing power

This was carried out as Oyaizu's study (Oyaizu, 1986). Briefly, extracts in 1 ml of appropriate solvents were mixed with 2.5 ml of phosphate buffer (0.2 M, pH 6.6) and 2.5 ml of potassium ferricyanide $[K_3Fe(CN)_6]$ (1%), and then the mixture was incubated at 50 °C for 30 min. Afterwards, 2.5 ml of trichloroacetic acid (10%) was added to the mixture, which was then centrifuged at 3000 rpm for 10 min. Finally, 2.5 ml of the upper layer solution was mixed with 2.5 ml distilled water and 0.5 ml $FeCl_3$ (0.1%), and the absorbance was measured at 700 nm (UV-1201, Shimadzu, Tokyo, Japan).

2.6. The ferric reducing ability of plasma (FRAP) assay

The FRAP assay developed by Benzie and Strain (Benzie & Strain, 1996). In short, 1.5 ml of working, pre-warmed 37 °C FRAP reagent (10 vol of 300 mmol/l acetate buffer, pH 3.6 + 1 vol of 10 mmol/l 2,4,6-tripyridyl-S-triazine in 40 mmol/l HCl + 1 vol of 20 mmol/l $FeCl_3$) was mixed with 50 μl of test samples and standards. This was vortex mixed and the absorbance at 593 nm was read against a reagent blank at a pre-determined time after sample-reagent mixing. The test was performed at 37 °C and a 0–4 min reaction time window was used.

2.7. Determination of total phenolics

The total phenolics were determined by the spectrophotometric method (Kim, Jeong, & Lee, 2003). In brief, a 1 ml portion of appropriately diluted extracts was added to a 25 ml volumetric flask containing 9 ml of deionised distilled water. Reagent blank using deionised distilled water was prepared. One ml of Folin–Ciocalteu's phenol reagent was added to the mixture and then shaken. After 5 min, 10 ml of a 7% Na_2CO_3 solution was added with mixing. The mixed solution was then immediately diluted to volume (25 ml) with deionised distilled water and mixed thoroughly. After 90 min at 23 °C, the absorbance was read at 750 nm. The standard curve for total phenolics was made using gallic acid standard solution (0–100 mg/l) under the same procedure as above. The total phenolics in aerial parts of *P. grandiflorum* were expressed as milligrams of gallic acid equivalents (GAE) per 100 g of dried sample.

2.8. Quantification by HPLC

Phenolic compounds were measured at 280 nm using an Agilent HPLC (1100 series, Agilent Co., USA). Separation was achieved with a TSK gel column ODS-80Tm (4.6 mmΦ × 15 mm). The mobile phase consisted of water with 0.1% acetic acid (A) and methanol with 0.1% acetic acid (B). The linear gradient was 0–100% (B) in 60 min, at a flow rate of 1.0 ml/min and the injection volume was 20 μl. Compounds were detected by monitoring the elution

at 280 nm. Identification of the phenolic compounds was carried out by comparing their retention times to those of standards. Content of phenolic compounds was expressed in mg/g extract.

2.9. Statistical analysis

All data were expressed as mean ± SD. Analysis of variance was performed by the ANOVA procedures. Duncan's new multiple-range test was used to determine the difference of means, and $P < 0.05$ was considered to be statistically significant.

3. Results and discussion

3.1. Scavenging effect on DPPH radical

The radical-scavenging activities of the fractions from aerial parts of *P. grandiflorum* were estimated by comparing the percentage inhibition of formation of DPPH radicals by the extracts and those of α-tocopherol and ascorbic acid. It was found that the radical-scavenging activities of the positive control and various solvent extract increased with increasing concentration (Fig. 1). The ability to scavenge DPPH radicals of various solvent extracts from *P. grandiflorum* was in the order of butanol fraction (90.63%) > chloroform fraction (58.68%) > water fraction (28.49%) at the concentration of 5 mg/ml. An almost linear correlation between DPPH radical-scavenging activity and concentrations of polyphenolic compounds in various vegetable and fruits have been reported (Pyo, Lee, Logendra, & Rosen, 2004). This indicates that DPPH radical-scavenging activities of all extracts from aerial parts of *P. grandiflorum* were related to the amount of antioxidant extracted from aerial parts of *P. grandiflorum* by various solvents. These results revealed that the butanol fraction from aerial parts of *P. grandiflorum* has free radical scavengers, acting possibly as primary antioxidants.

3.2. Scavenging effect on $ABTS^{\cdot+}$ radical

All fractions from aerial parts of *P. grandiflorum* exhibited $ABTS^{\cdot+}$ radical-scavenging activities to different extents in a concentration-dependent manner; although the activity levels of all of the tested samples were lower than that of α-tocopherol and ascorbic acid.

The butanol fractions from aerial parts of *P. grandiflorum* exhibited the highest radical-scavenging activities when reacted with the $ABTS^{\cdot+}$ radicals (Fig. 2). In contrast, the chloroform and water extracts only showed low activities; approximately 4–7 times lower than the butanol fraction. Fig. 2 presented a steady increase in the percentage inhibition of the $ABTS^{\cdot+}$ radicals by the butanol fraction from aerial parts of *P. grandiflorum* and maximum inhibition was achieved above 10 mg/ml. The water extract showed a percentage inhibition of less than 50% at the highest concentration studied (10 mg/ml). In addition, the chloroform fraction from aerial parts of *P. grandiflorum* did not show a leveling off at the highest concentration; however, its radical scavenging effects were much less than the butanol fraction.

3.3. Reducing power

In the reducing power assay, the presence of reductants (antioxidants) in the samples would result in the reducing of Fe^{3+} to Fe^{2+} by donating an electron. The amount of Fe^{2+} complex can be monitored by measuring the formation of Perl's Prussian blue at 700 nm. Increasing absorbance at 700 nm indicates an increase in reductive ability. Fig. 3 shows the dose–response curves for the

Table 1
Total phenolics content of various solvent extracts and phenolic compounds content of butanol extract from the crude ethanol extract of *P. grandiflorum* aerial parts.

Samples	Content (mg/100 g fraction)
Fractions	
Chloroform	615 ± 32[a]
Butanol	9482 ± 325
Water	494 ± 18
Butanol fraction	
Chlorogenic acid	1214 ± 93
Luteolin-7-O-glucoside	2304 ± 219
Apigenin-7-O-glucoside	1994 ± 72
Luteolin	687 ± 53
Apigenin	151 ± 12

[a] Data are means ± SD of triplicates.

reducing powers of all extracts from aerial parts of *P. grandiflorum*. It was found that the reducing powers of all the extracts also increased with the increase of their concentrations. The various solvent fractions from aerial parts of *P. grandiflorum* exhibited a good reducing power of 3.11, 7.84 and 1.45 at 10 mg/ml, respectively. This data suggested that butanol fraction has a remarkable ability to react with free radicals to convert them into more stable non-reactive species and to terminate radical chain reaction.

3.4. Determination by FRAP assay

In this assay, extracts were used in a redox-linked reaction whereby the antioxidants present in the sample act as the oxidants. Reduction of the ferric-tripyridyltriazine to the ferrous complex forms an intense blue colour which can be measured at a wavelength of 593 nm. The intensity of the colour is related to the amount of antioxidant reductants in the extracts. The trend for ferric ion-reducing activities of different fractions from aerial parts of *P. grandiflorum* in the present study is shown in Fig. 4. For chloroform, butanol, and water fractions, the absorbance clearly increased due to the formation of the Fe^{2+}-TPTZ complex with increasing concentration. The highest reducing activity was for the butanol fraction, compared to those of the other fractions (Fig. 4). Similar to the results obtained from the DPPH to ABTS assay, the butanol fraction showed relatively strong ferric ion-reducing activity. Chloroform and water fractions showed lower ferric ion-reducing activities.

Some authors have reported similar correlations between polyphenols and antioxidant activity measured by various methods (Awika, Rooney, Wu, Prior, & Cisneros-Zevallos, 2003). A strong correlation between the mean values of the total polyphenol content and FRAP deserves detailed attention, because it implies that polyphenols in aerial parts of *P. grandiflorum* are capable of reducing ferric ions.

3.5. Total phenolics

The Folin–Ciocalteu's assay is a fast and simple method to rapidly determine the content of phenolics in samples. Phenolics or polyphenols are secondary plant metabolites that are present in every plant and plant product. Many of the phenolics have been shown to contain high levels of antioxidant activities. The total phenolic content of the three fractions from the ethanol extract of *P. grandiflorum* aerial parts are presented in Table 1. The butanol fraction exhibited the highest total phenolics content (9482 mg GAE/100 g fraction). It is approximately 15-fold more than the chloroform fraction (615 mg GAE/100 g fraction) and 19-fold more than the water fraction (494 mg GAE/100 g fraction).

3.6. Analysis of butanol fraction by HPLC

Since the butanol fraction exhibited the strongest antioxidant activity, it was subjected to further analysis by HPLC. The butanol fraction contained a variety of phenolic compounds (Fig. 5). By comparing the retention time of these compounds with those of standards, five phenolic compounds were identified (Table 1).

Furthermore, the HPLC results (Fig. 5, Table 1) indicated that luteolin-7-O-glucoside (2304 mg/100 g fraction) was the predominant compound in this extract, followed by apigenin-7-O-glucoside (1994 mg/100 g fraction). Flavonoids, and phenolic acids are important contributing factors to the antioxidant activity of the human diet. Based on the results for the phenolic composition of the butanol fraction from aerial parts of *P. grandiflorum*, we can conclude that these compounds (particularly luteoline-7-O-glucoside and apigenin-7-O-glucoside) may contribute to the antioxidant activities of the butanol extract. The activity of the butanol

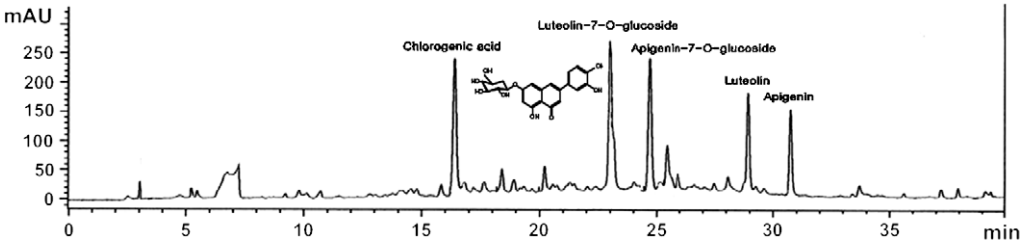

Fig. 5. HPLC chromatograms of the butanol fraction from the ethanol extract of *P. grandiflorum* aerial parts.

fraction is attributed to these phenolic compounds and in particular to luteolin-7-O-glucoside and apigenin-7-O-glucoside.

4. Conclusions

The results obtained in this work are noteworthy, not only with respect to the antioxidant activities of the butanol fraction of *P. grandiflorum* aerial parts, but also with respect to its content of a variety of phenolic compounds. The activity of this extract is attributed to these phenolic compounds and in particular to luteolin-7-O-glucoside and apigenin-7-O-glucoside. Since luteolin-7-O-glucoside is the predominant phenolic compound detected in the butanol extract, the safety of luteolin-7-O-glucoside for use as an antioxidant agent is very important. Consequently, our results presented that the butanol fraction of *P. grandiflorum* aerial parts which are normally wasted during frequent pruning has very strong antioxidant activities, and suggested that the extract can be utilised as an effective and safe antioxidant source, although the antioxidant activities of butanol fraction were lower than that of α-tocopherol and ascorbic acid.

Off-flavours
HS-SPME
Sensory analysis
Volatile compounds

ABSTRACT

The present study focused on the development of a sensory evaluation system, using a quantitative descriptive analysis (QDA) scheme, to define the sensory attributes of boiled potato slices. A HS-SPME–GC–MS technique for a rapid determination of volatile components in boiled potatoes was also investigated. In addition to the mechanism of generation of off-odours and off-flavours in boiled potatoes (POF), the effects of the use of food additives after cooking were examined. POF formation, analysed by both sensory evaluation and HS-SPME, demonstrated an oscillating mechanism of formation of volatile compounds, probably related to enzymatic lipid oxidation and hydroperoxide generation. In particular, POF were strongly correlated with the presence of 2-pentenal, 2-hexenal, 2-heptenal, 2-pentylfuran and 2-decenal. In all, about 50 compounds were detected by HS-SPME technique. Treatment with ascorbate or citrate, after cooking and before storage, did not prevent the formation of off-flavours, in contrast to sodium pyrophosphate. Potassium meta-bisulphite prevented POF formation, but caused the creation of other off-flavours detected by a trained panel.

1. Introduction

Potatoes (*Solanum tuberosum*), originating from the Andes Mountains about 8000 years ago, have widely spread to the rest of the world as a result of their nutritional properties and their adaptability to different climate conditions. The year 2008 was declared the "International Year of the Potato" to highlight the importance of potatoes as a fundamental food resource and to promote the development of sustainable potato-based systems; such actions aim to ensure food security for the increasing world population and also contribute in protecting natural resources (http://www.potato2008.org/en/index.html).

Potatoes may be served in a variety of ways: fried, steam cooked, baked or boiled, with inter-changeable preferences in different regions. Boiled potatoes have a flavour that is rather weak, but which is typical and clearly distinguishable from that of raw or cooked potatoes, and is one of the most important qualitative criteria in assigning different potato varieties to a fresh or processed food market. Volatile compounds responsible for the flavour of boiled potatoes are created by typical chemical precursors of raw tubers, which are characterised by different flavours (Petersen, Poll, & Larsen, 1998).

More than 140 volatile compounds have been identified in boiled potatoes (Ulrich, Hoberg, Neugebauer, Tiemann, & Darsow, 2000), whereas over 250 have been found in baked potatoes (Whitfield & Last, 1991) due to the high temperature and long cooking time that cause the degradation of the large compounds. Different potato varieties, cultivation techniques, storage and cooking methods, in addition to the extraction and the analytical techniques employed, have identified a broad set of aromatic compounds in boiled potatoes, which are quite variable and not always in agreement in different publications (Petersen, Poll, & Larsen, 1999, 2003; Petersen et al., 1998; Ulrich et al., 2000).

The typical aroma of boiled potatoes is mainly due to the presence of essential compounds such as methional and various pyrazines (Ulrich et al., 2000) produced by the Maillard reaction and Strecker degradation. Moreover, lipoxidase (lipoxygenase and lipoperoxidase) enzymes oxidise the fatty acids in boiled potatoes. Palmitic, linoleic and linolenic acids represent more than 90% of the total fatty acids in potatoes (Galliard, 1973), thus creating numerous aldehydes (Josephson & Lindsay, 1987; Petersen et al., 1998).

As reported by Petersen et al. (1999), during storage of boiled potatoes there is production of cardboard-like off-flavours within a few hours from preparation, that is due to lipid oxidation; such compounds, in fact, are strictly related to the presence of oxygen. This problem is particularly significant for the production of potato-based foodstuffs that are stored in modified atmosphere. Under these conditions, the creation of off-flavours slows but does not stop completely. Moreover, the production of volatile components also varies as a function of the amount of oxygen inside the packaging and the permeability of the latter to atmospheric gases. Such reactions may reduce the shelf life of ready-to-eat or ready-to-cook products that contain boiled potatoes.

To the best of our knowledge, the extraction techniques widely employed for the separation of aromatic compounds from boiled potatoes are the Lickens-Nickerson method, Dynamic Headspace (DH) and solid–liquid extraction. Over the years, the Lickens-Nickerson method has been performed with numerous variations from the original version (Buttery, Seifert, & Ling, 1970; Mutti & Grosch, 1999; Nursten & Sheen, 1974; Ulrich et al., 2000), but it is essentially based on steam distillation of volatile compounds at high temperatures for extended times. Due to the analytical conditions required, this process may lead to the creation of new aromatic substances, especially during extended treatments. The extraction is performed with dedicated equipment and assures good detection limits.

The DH technique is based on stripping of volatile components with a flow of inert gas (e.g. N_2, He) and their subsequent adsorption by polymers. Quantitative extraction is granted by high temperatures, such as those employed by Salinas, Hartman, Karmas, Lech, and Rosen (1994), which extracted the aromatic compounds from cooked and reconstituted dehydrated potatoes at 100 °C for 1 h, or by extended treatments such as those of Josephson and Lindsay (1987) who performed an extraction for 15 h at 21 °C. Under these conditions, enzymatic reactions may take place and synthesise ex novo aromatic components that were not present before the extraction.

The extraction procedure has been employed in several works by Petersen et al. (1998, 1999, 2003) to investigate the volatile fraction of potatoes. However, if the aromatic compounds in boiled potatoes are extracted with an organic solvent, a large quantity of sample has to be analysed due to the small concentration of aromas in the food matrix. Moreover, the extraction technique frequently leads to the separation of non-volatile chemical compounds that interfere with the analysis and increase the detection limits.

In 1990, headspace solid-phase microextraction (HS-SPME) has been introduced by Arthur and Pawliszyn as an alternative to the DH technique as a sample preconcentration method prior to chromatographic analysis. In addiction to the analysis of pollutants in water, this method has been applied to various food flavour analyses, and its suitability in qualitative and quantitative analysis of the volatile fraction of virgin olive oil has been frequently reported (Baccouri et al., 2008; Vichi, Pizzale, Conte, Buxaderas, & Pez-Tamames, 2003). It has moreover been used in the analysis of oxidation products of refined vegetable oils (Jelen, Obuchowska, Zavirska-Wojtasiak, & Wasowicz, 2000) and milk, where it demonstrated better precision, accuracy, repeatability and linearity of response than DH (Marsili, 1999).

The objectives of the present research were to perform a sensory evaluation system, using a quantitative descriptive analysis (QDA) scheme, to define the odour, flavour and texture features of boiled potato slices, and to develop a HS-SPME–GC–MS method for a rapid determination of volatile components in boiled potatoes. We also investigated the mechanism of generation of off-odours and off-flavours in boiled potatoes, with particular attention to the effects of treatment with food additives after cooking.

2. Experimental

2.1. Samples

Potatoes (*Solanum tuberosum*) of the Marabel variety were harvested in July and stored for three months at controlled temperature and relative humidity. Potato dry matter was 19.94% at the moment of analysis. From the initial stock of potatoes, only average size tubers (150–180 g) were selected.

All tubers were washed with tap water to remove soil residue before manual peeling. The central portion of each tuber was divided into 5–6 slices (5 mm thickness), and the rest of the tuber was rejected in order to obtain slices with a similar size. About 6.5 kg of potatoes slices were boiled in 24 L of tap water for 12 min. After boiling, slices were split in groups (W, AA, CA, PP, MB) and subjected to various treatments (immersion in hot water or in food additive solutions), as shown in Table 1. Slices were then cooled for 10 min at room temperature (22 °C), put in open PET containers, stored in refrigeration conditions (at a temperature of 5 °C and air exposed) until obtaining thermal equilibrium with

the temperature refrigeration (30 min at 5 °C) or for different times (2, 4, 6, 8, 10, 24 h at 5 °C), before extraction and analysis of the volatile fraction.

W samples, after boiling, were immediately immerged in hot water (80 °C) for 1 min (water/potatoes, 3:1).

WA0j: HS-SPME–GC–MS analysis of volatile compounds was carried out at 70 °C, without the addition of an enzymatic inhibitor to the extraction solution.

WA0i: during volatile compound extraction, carried out at 70 °C, NaCl was added to the extraction solution to inhibit enzymatic reactions.

WA0: volatile components extraction was performed at 37 °C with the addition of NaCl to the extraction solution.

WA2, 4, 6, 8, 10, 24 samples were obtained using the same extraction conditions of WA0 (temperature: 37 °C, inhibitor: NaCl), but were stored, respectively, for 2, 4, 6, 8, 10 and 24 h at 5 °C, before analysis.

After boiling, samples AA24, CA24, PP24, MB24 were immediately immerged, respectively, in ascorbic acid, citric acid, sodium acid pyrophosphate and meta-bisulphite solutions (3 g/L) for 1 min at 80 °C (solution/potatoes, 3:1). Each of these food additives was of commercial grade (CHIMAB S.p.A., Padova, Italy). After immersion, all further steps were the same as for sample W24 (storage: 24 h at 5 °C, HS-SPME extraction temperature: 37 °C, enzyme inhibitor: NaCl).

2.2. Sensory analysis

Quantitative Descriptive Analysis (QDA, Stone & Sidel, 1992; Stone, Sidel, Oliver, Woolsey, & Singleton, 1974) was carried out in the laboratory of sensory analysis at the "Campus of Food Science" at the University of Bologna. A panel of 12 judges, with experience in sensory evaluation of different foods, were trained to carry out QDA of boiled potatoes.

The best features for sensory description of boiled potatoes (attributes) were developed during a focus session. Then, additional six training sessions were held to enhance the ability of each panel member to recognise and quantify the descriptors previously stated.

Standard solutions of some descriptors were used to calibrate the panelists, when reference compounds were not available the descriptors learning and alignment procedure was realised without reference standards, as described by Sulmont, Lesschaeve, Sauvageo, and Issanchou (1999).

Based on repeatability and reproducibility of panel results only some attributes were judged during evaluation of potato samples. The descriptors "Other off-odours" and "Other off-flavours" were defined as defected odours and flavours different from the cardboard-like ones. Judges could identify the qualitative nature of the defects perceived and quantify them, using their personal lexicon developed in previous sensory evaluation experiences. The descriptors were evaluated on a continuous scale from 1 to 9 points. A score of 1 indicated no detectable perception, whilst 9 indicated maximum perception. The repeatability of each descriptor was also determined. Only the eight judges with the best analytical capacity (and best repeatability) were selected to perform the sensory evaluation described in Table 1.

A specific and standardised test was performed for sensory evaluation of boiled potatoes: the slices of boiled potato were cut into quarters, and each piece was served to the assessors in plastic dishes. Sensory analysis was made in individual booths equipped with red light to avoid any influence of potato colour on sample judgment; older samples, in fact, could have been identified from fresh samples as they had a paler pulp. After tasting each sample, the judges rinsed their mouth with water. Each sample cited in Table 1, except for WA0j and WA0i, was analysed four times.

A cardboard-like off-odour descriptor was also analysed on all sample purees immediately after HS-SPME extraction of volatile compounds, as described in paragraph 2.3.

Values of the median of sensory data and the robust standard deviation were calculated (Giomo, 2000).

2.3. HS-SPME–GC–MSD analysis

Potatoes slices (about 200 g for each sample) were put in a 1000 mL bottle and homogenised with 500 mL of NaCl 0.30 M using an Ultraturrax. The extraction solution was at a temperature suitable to bring the homogenate to 37 °C.

The bottle was closed with a silicon cap and then introduced in a heating bath at 37 °C for 10 min. After this step, the silicon cap was perforated with the divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS, 50/30 μm, coating 2 cm) fibre holder (Supelco Ltd., Bellefonte, PA, USA) and equilibrated for 10 min, with the heating bath kept at 37 °C. Finally, the fibre was exposed for 30 min and immediately desorbed for 3 min at 250 °C in the gas chromatograph.

After removing the fibre from the bottle, each sample puree (2 repetitions) was immediately smelled by the panel judges directly from the bottle of extraction, and the cardboard-like off-odour perception was evaluated using the same scale of the other descriptors analysed during QDA.

Volatile compounds were identified and peak area was integrated by gas chromatography coupled to quadrupolar mass-selective spectrometry using an Agilent 6890 N Network gas chromatograph and an Agilent 5973 Network detector (Agilent Technologies, Palo Alto, CA, USA). Analytes were separated on a ZB-WAX Phenomenex column 30 m × 0.25 mm ID, 1.00 μm film thickness. Column temperature was held at 40 °C for 10 min and increased to 200 °C at 3 °C min^{-1}. The ion source and the transfer line were set to 175 °C and 280 °C, respectively. Electron impact mass spectra were recorded at 70 eV ionisation energy in the 20–250 amu mass range (2 scan/sec). Volatile compounds present in boiled potatoes were tentatively identified basing on computer matching against commercial libraries (NIST/EPA/NIH Mass Spectral Library 2005) as well as our laboratory-made spectral library of pure substances, Kovats retention indices (KI) and literature data. Retention indices were calculated for each compound using homologous series of C9–C19 n-alkanes (Van Den Dool & Kratz, 1963).

As the aim of the present work was to compare the use of the different additives and storage times, and thus absolute quantification was not necessary, data are reported as peak areas.

2.4. Statistical analysis

Data were analysed using Statistica 7.0 (Statsoft Inc., Tulsa, OK, USA) statistical software. The significance of differences at 5% level amongst means was determined by one-way ANOVA using Tukey's test. The data were also analysed by principal component and classification analysis to determine the correlation between the analyses and demonstrate differences between samples.

3. Results and discussion

Developing a QDA test is particularly complex, owing to intense training of assessors and the availability of artificial standards to calibrate the attributes. In this investigation, thanks to a high number of panel trainings, it was possible to get optimal repeatability of the attributes used, as shown in Table 2. As previously defined, the 10 attributes evaluated were the most repeatable between those developed during the focus session; particular attention was given to off-flavour and off-odour attributes generated during

Table 2
Description of the attributes evaluated during quantitative descriptive analysis of boiled potato slices.

Attribute	Definition	Standard employed to train the panel	Mean CVr% of attribute
Typical odour	Typical fragrance or aroma of boiled potatoes as perceived by the nose from sniffing through the external nares (Lawless and Heymann, 1998)	Solutions of Quest Aroma of boiled potatoes	10.5
Cardboard-like off-odour	Defected odour, characteristic of oxidised milk, perceived by sniffing boiled potatoes slices (Amerine, Pangborn, & Roessler, 1965)	Potatoes at different ageing degree	9.0
Other off-odours	Other defected odours perceived by sniffing boiled potatoes samples.	Not employed	3.7
Hardness	Force required dividing the potato in two parts by the front teeth (Thygesen, Thybo, & Engelsen, 2001)	Potatoes (variety Marabel) at different cooking degree	6.7
Mealiness	How mealy/crumbly the potato is felt in the mouth after chewing (Thygesen et al., 2001)	Potatoes (variety Innovator) at different cooking degree	13.9
Adhesiveness	Force required removing the potato sticking to teeth and palate after chewing (Thygesen et al., 2001)	Not employed	12.7
Sweetness	Sweet taste perceived during chewing of boiled potatoes slices	Sucrose aqueous solutions. Potato samples cooked in solutions at different sucrose concentration	8.7
Typical flavour	Typical boiled potato retronasal smell originated in the mouth via transportation of the stimulus molecules up to the back of the nasopharynx and into the region of the olfactory receptors (Lawless and Heymann, 1998)	Potato samples cooked in solutions at different Quest aroma concentrations.	9.4
Cardboard-like off-flavour	Defected retronasal smell, similar to the characteristic defected odour of oxidised milk, perceived after deglutition of boiled potato slices (Amerine et al., 1965)	Not employed	3.2
Other off-flavours	Other defected retronasal smell perceived after deglutition of boiled potatoes slices	Not employed	2.6

sample ageing, as also described by Petersen et al. (1999). The results of sensory analysis of boiled potato samples is reported on Table 3; PCA of the same data is shown in Fig. 1. For all sensory analyses, the CVr% were less than 20%, and were thus considered acceptable for sensory data (data not shown).

In the present work, the Marabel variety was used due to its marked tendency to develop off-flavours and rancidity (Thybo, Christiansen, Kaak, & Petersen, 2006).

As seen in Table 3, boiled potatoes analysed only a few minutes after cooking (WA0) presented a typical odour that was very high and no cardboard-like off-odour was detected. Hardness, mealiness and adhesiveness were 5.6, 5.5 and 5.1, respectively. Sweetness was 3.3, and typical flavour and off-flavours had a trend similar to the correspondent values of odour attributes.

WA0 and WA2 were very similar (Fig. 1), whilst at increasing storage times (4, 6, 8, 10 and 24 h) typical odour, typical flavour, off-odours and off-flavours changed, whereas the other characteristics evaluated did not vary considerably. Off-odours and off-flavour did not increase linearly during storage: they reached a maximum value after 6 h of storage (WA6), further decreased after 8 and 10 h (WA8 and WA10) and finally increased again after 24 h of storage (WA24). Typical odour and typical flavour have a complementary tendency.

The off-odour and off-flavour concentration of samples WA2,4,6,8,10,24 might be explained by a kinetic mechanism involving the formation of hydroperoxides during the first hours of storage, their increase with time and finally their transformation to yield aldehydes that are responsible for potato off-flavour (POF). Due to air exposure during refrigeration, some volatile components evaporate, and a decrease in POF in samples WA8 and WA10 was observed. The increase of off-odours and off-flavours after 10 h storage, in our view, may be due to further oxidation of the remaining lipid portion.

Volatile compounds are generated by enzymatic and chemical oxidation of the lipid fraction of boiled potatoes, which takes place on the surface of the food in contact with oxygen. Autooxidation reactions of linoleic and linolenic acids create hydroperoxides which are then broken with the formation of volatile compounds responsible for off-flavours. As reported on literature, the generation of hydroperoxides from food fatty acids is not linear during the time, because when a limit concentration is reached, the bimolecular interaction of hydroperoxides and the decomposition of secondary oxidation products leads to the increase of compounds with a great impact on flavour, like aldehydes, esters and other degradation products (Frankel, 1982, 1985).

Hydroperoxides may be cleaved also by enzymatic reactions catalysed by lipoperoxidase creating further off-flavours. Owing to the reproductive functions of the potato tubers, enzymatic activity is very high; its inhibition at elevated temperatures is not immediate, and it proceeds step-by-step and at lower temperatures during the initial stages of cooking. As a result, enzymatic reactions are accelerated. The consequences of these mechanisms

Table 3
Quantitative descriptive analysis results of boiled potato slices. Data presented is the median of 16 values (8 judges and 2 replicates); in brackets CVr% are reported.

Attributes	WA0	WA2	WA4	WA6	WA8	WA10	WA24	AA24	PP24	CA24	MB24

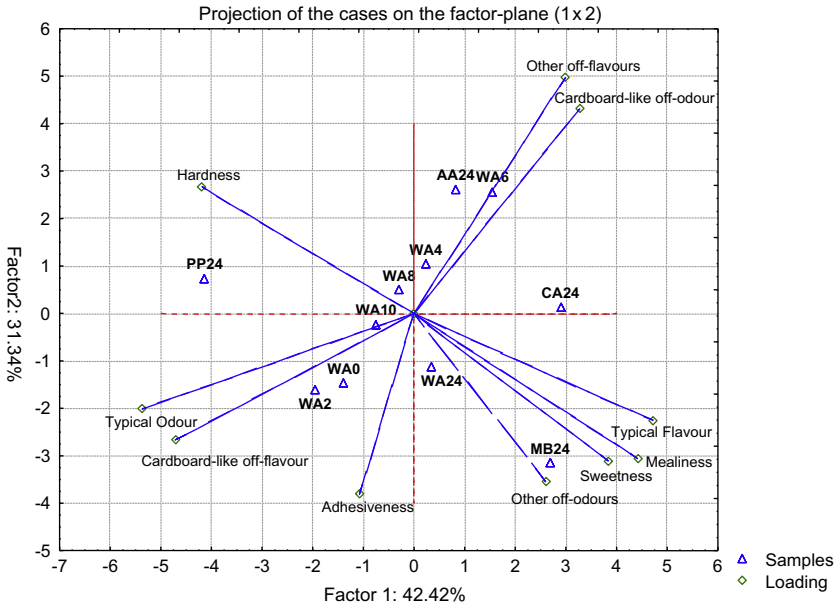

Fig. 1. Principal component analysis of sensory analysis results of boiled potato slices.

are the slow release of volatile components from the food matrix during the successive analytical phases. Another enzymatic mechanism that may be involved is the partial inactivation of potato enzymes, which continue to undergo oxidation even after boiling from atmospheric oxygen (Grosch, 1987; Lercker, Bortolomeazzi, & Pizzale, 1998; Lercker, Capella, & Conte, 1984; Selke, Frankel, & Neff, 1978).

Samples treated with different food additives and stored for 24 h (AA24, CA24, MB24 and PP24) are distant from either WA0 (analysed immediately after cooking) or WA24 (analysed after 24 h of storage without addition of food additives), as shown in the factorial plane of Fig. 1. These results indicate that the additives used do not allow the characteristics of boiled potato slices to remain unchanged, and determine a different evolution of sensorial attributes, with respect to those promoted by different storage times.

AA24 sample has a cardboard-like off-flavour and off-odour that was more intense than the control sample WA24. CA24 sample also differed substantially from WA24, mainly for the presence of other off-flavours defined by the panel judges as "dry", "hay", "biting", which were likely generated by the pH change induced by employing the food additive. These results demonstrate that neither ascorbic acid nor citric acid had any antioxidant effects on the lipid fraction of boiled potatoes, a finding that may be related to their hydrophilic nature, which does not allow them to protect the lipid portion. Moreover, it seems that these acids do not inhibit the activity of oxidative enzymes, which appears higher owing to a pH shift towards more favourable values.

The addition of potassium meta-bisulphite seems to prevent the creation of cardboard-like off-flavour and off-odour. In fact, whilst sample MB24 did not present such attributes, but had other negative characteristics described by the panel members as "beast" and "putrid". These features may be correlated with the capacity of meta-bisulphite to increase the reduction potential and create reduced molecules, with sulphhydryl functional groups.

Sample PP24 was interesting as it had no defects in flavour, odour or taste, but compared to the other samples it was harder and had a lower mealiness. The absence of off-flavours is probably due to the increase of the reduction potential of the system, and it is still unknown if these effects are due to direct inhibition of enzymatic processes. Textural changes in boiled potatoes, in our opinion, are probably due to the creation of a large number of interactions between calcium ions and wall cell pectins, with an increase in calcium pectate and subsequent hardness of boiled potato slices.

These results highlight that further research is needed to explain the reaction mechanisms of additives in boiled potatoes.

During preliminary tests (data not shown), the solid–liquid extraction technique described by Petersen et al. (1999) was applied, but the GC–MS chromatographic traces obtained did not present any significant peaks that were distinguishable from the limits of detection. Differences between our application of the solid–liquid extraction and those reported in literature include the variety of potatoes used (Marabel *vs*. Bintje) and the analysis of slices and not whole tubers. The apparently discrepant results we obtained might be due to the high surface/volume ratio of boiled potatoes, which enable a greater dispersion of volatile compounds, either during the cooking phase or during storage before analysis. However, in our opinion, the solid/liquid extraction technique has the disadvantage of extracting too many interferents that increase the limit of detection. For these reasons, potato slices evaluated by QDA were also analysed by HS-SPME–GC–MS to determine volatile compounds.

HS-SPME extraction was chosen since it is very fast and utilises small amounts of sample. Moreover, it does not extract interferent compounds. Volatile compound analysis by HS-SPME was able to characterise different potatoes samples very well, and in particular those treated with different food additives. Fig. 2 shows the PCA biplot of potato samples and the most representative volatile compounds identified by HS-SPME. Factor analysis was used to determine which variables had greater factor loadings or weights, with those having a value greater than 0.70 being considered significant. Principal components analysis identified two factors that explain 90.69% of the variance: factor 1 explains 63.33% of the variance, whilst factor 2 represents 27.36%. The variables most closely associated with factor 2 were *n*-hexyl acetate, hexyl butanoate and hexyl hexanoate. 2-Pentenal, 2-hexenal, 2,4-heptadienal, 2-heptenal, 2-pentyl furan, 2-nonenal, 2,4 decadienal, and 2-decenal were significantly associated with factor 1.

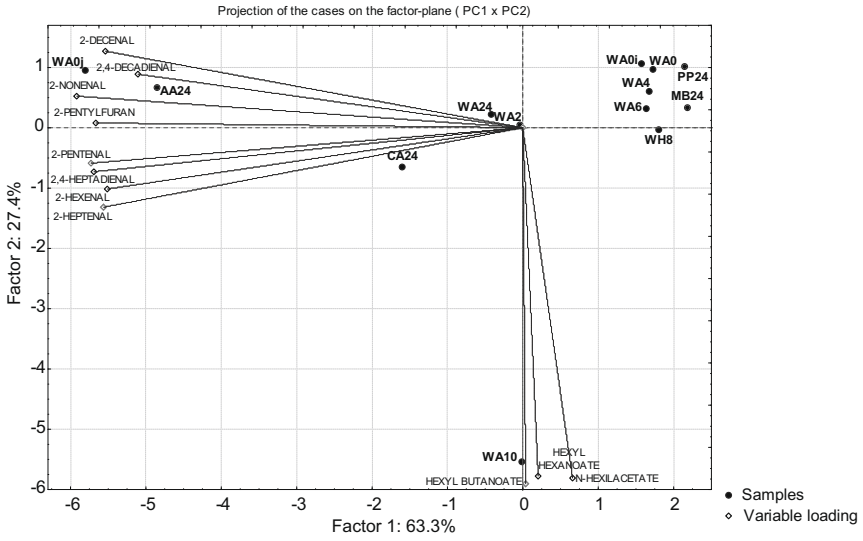

Fig. 2. Principal component analysis of solid-phase microextraction gas chromatography–mass spectrometry analysis results of boiled potato slices.

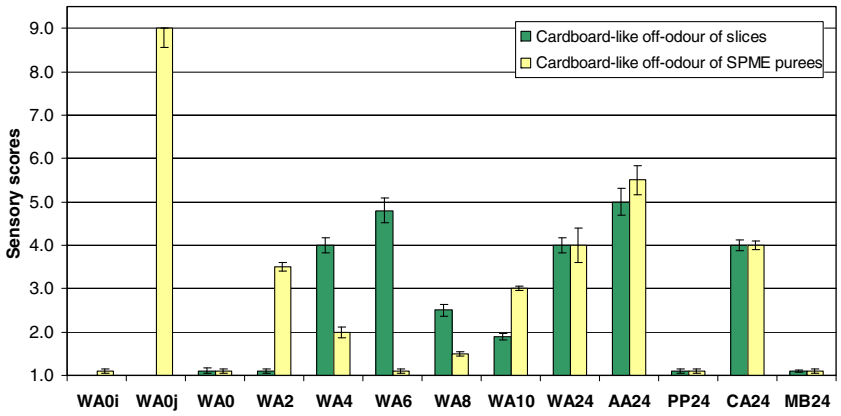

Fig. 3. Quantitative descriptive analysis of cardboard-like off-odour on boiled potato slices and potatoes pureed immediately before solid-phase microextraction analysis.

Samples WA0j and WA0i were analysed to verify the enzymatic production of volatile compounds during the analysis. WA0j, which was extracted with an aqueous solution without enzymatic inhibitor, had an elevated content of aldehydes, probably created by enzymatic processes before and during the adsorption on the fibre. WA0i sample, in contrast, which was extracted with NaCl 0.25 M at the same temperature as WA0j (70 °C), was not substantially different from WA0, which was extracted at 37 °C. In our opinion, this result highlights that temperature does not significantly influence the analysis, and that the oxidation reactions which take place during extraction are exclusively enzymatic. For these reasons, before analysing the volatile fraction in boiled potatoes, it is fundamental to inactivate the enzymatic fraction during the extraction.

In other experiments (data not published), the use of different adsorption temperatures (35, 37, 45, 55 and 70 °C) resulted in aromatic profiles that were very similar, with the same differences in absolute contents of volatile components, but not in the relative ones. In the present work, the temperature selected for absorption of the fibre was 37 °C, which simulated as much as possible that of the human mouth.

In addition, the cardboard-like off-odour attribute was evaluated directly from sample purees after fibre exposure, as described in paragraph 2.2, and the results were compared to those of the same attribute (cardboard-like off-odour) of boiled potatoes slices (Fig. 3). Several differences between slices and purees of the same samples may be noted. WA2 sample slices, which did not have either off-odour or off-flavour, when mashed, showed an increase in these attributes. On the other hand, WA6 had higher POF in slices, which was not detected in the puree. It is likely that this phenomenon was due to the preparation of the puree, which included shredding and homogenising boiled potatoes with NaCl 0.25 M in an aqueous solution at a suitable temperature to bring the system to 37 °C. It is evident that the analyses employed influences the volatile compounds profile.

The presence of cardboard-like off-odour in slices and purees was not seen for all samples, but for slices a trend of this attribute was observed. It did not show linear variations during storage from 2 to 24 h, but there was a maximum of perception at different times for slices and purees that demonstrated peroxide kinetics, as previously assumed.

Good agreement between the sensory evaluation of puree and HS-SPME–GC–MS analysis of volatile compounds was found, as reported below.

As stated by Petersen et al. (1999), the off-flavour of boiled potatoes is mainly due to 8 characteristic aldehydes (reported in thick type in Table 4). In this investigation, we confirmed previously reported results and found a greater number of oxidation products correlated with cardboard-like off-odours and off-flavours. These samples were characterised by the presence of 2-pentenal, 2-hexenal, 2-heptenal, 2-pentylfuran and 2-decenal.

Table 4
Headspace-solid-phase microextraction gas chromatography–mass spectrometry analysis of volatile compounds of potato slices. Different letters in the same row indicate statistically significantly differences (Honestly Significant Differences or HSD by Tukey $p < 0.05$). Values are expressed as peak area integration value (ion abundance x time). Compounds in bold are those identified by Petersen et al. (1999) as responsible for POF generation. Compounds in italics are employed to describe samples in PCA.

* Volatile compounds tentatively identified only with mass spectra libraries search.

Whilst other compounds like *n*-hexyl acetate, hexyl butanoate, hexyl hexanoate were formed during storage, they were not however correlated with the perception of oxidised flavour. Their appearance was slow in samples stored for 2, 4, 6 and 8 h, was rapid after 10 h and finally reduced in samples stored for 24 h, even in presence of food additives.

POF in sample WA10 were higher than those in WA2, probably as result of the different volatility of the compounds present. For example, esters are created slowly at low temperatures by condensation of an alcohol with an acid, but since their volatility is very high, their decrease over time is reasonable.

HS-SPME–GC–MS analysis confirmed the efficiency of some food additives in preventing the formation of POF. As an example, sample PP24 did not show significant differences with respect to WA0, whilst CA24 and AA24 samples had a high content of aldehydes that could be responsible for POF. AA24, in particular, had a content of aldehydes that was similar to those of the sample extracted at 70 °C without food additives (WA0j). These results confirm a promoting effect on the formation of aldehydes, in agreement with data obtained by sensory evaluation of boiled potato slices.

Sample MB24, however, did not have cardboard-like off-flavour and, as illustrated on Fig. 2, was not well represented by factor 1. Therefore, it did not contain significant quantities of the aldehydes responsible for cardboard-like off-flavour. By GC analysis, it was shown that this sample did not have a volatile profile that differentiated it from the samples without defects. These results are in contrast with those of sensory evaluation, which identified off-odour and "beast-like" off-flavour. The reason for this discrepancy may be related to the characteristics of HS-SPME analysis as it does not detect these chemical compounds.

Finally, in the samples analysed in the present study, about 50 different compounds were identified, although no pyrazines were detected, in disagreement with previous reports. This is probably due to the low limits of detection of the method used.

4. Conclusions

In this study, it was found that the POF formation could be due to lipoxidase activity and was strongly correlated with a high content of 2-pentenal, 2-hexenal, 2-heptenal, 2-pentylfuran and 2-decenal. During storage of boiled potato slices many other volatiles were produced, and about 50 compounds were detected by the HS-SPME technique in samples treated under different conditions. In particular, the use of some commonly used food additives led to some interesting effects on potato slices: ascorbic acid and citric acid did not prevent the formation of POF, but actually enhanced it. Potassium meta-bisulphite prevented POF formation and caused the formation of other off-flavours. The best additive was sodium pyrophosphate, and potato slice flavour was almost unchanged during storage.

Acknowledgements

The authors would like to thank all the panel members, L. Alessandrini, C. Antico, S. Barbieri, M. Bonoli, A.U. Mattioli, F. Pasini, B. Rossetti and V. Verardo for their valued help in sensory evaluation. We are also grateful to A. Cardinali for technical assistance.

Antioxidant capacity
Chilling and frozen storage

ABSTRACT

The effect of conventional and microwave pasteurisation on the main bioactive compounds of grapefruit juice and their stability during 2 months' refrigerated and frozen storage was evaluated. Ascorbic acid (AA), vitamin C and organic acids were analysed by HPLC, whereas total phenols and antioxidant capacity (%DPPH) were measured by spectrophotometry. The results showed that conventional treatment led to a significant decrease in citric acid (from 1538 to 1478 mg/100 g) and AA (from 36 to 34.3 mg/100 g), whilst microwave pasteurisation preserved these compounds. Frozen storage maintained AA and vitamin C, especially in treated samples. Frozen non-treated samples and conventional pasteurised ones preserved about a 75% and 20% of the total phenols and antioxidant capacity, respectively, whilst in frozen microwave pasteurised juices this preservation was of 82% and 33%. From these results, the use of microwave energy may be proposed as an alternative to traditional heat pasteurisation in order to preserve the natural organoleptic characteristics and essential thermolabile nutrients of grapefruit juice.

1. Introduction

Evidence from a large number of epidemiological, *in vitro* and *in vivo* studies has shown that the consumption of citrus fruit is generally good for the health and contributes to the prevention of degenerative processes, particularly lowering the incidence and mortality rate of cancer and cardio and cerebro-vascular diseases (Poulose, Harris, & Patil, 2005). Citrus juice is an important dietary source of bioactive compounds, whose beneficial health effects are ascribed, in part, to its high content of ascorbic acid. Vitamin C is a natural antioxidant that may inhibit the development of major oxidative human reactions. In addition to the well-known vitamin C, citrus juice also contains phenolic compounds which contribute to their antioxidant capacity and that may produce beneficial effects by scavenging free radicals (Xu et al., 2008). Vinson and Bose (1988) emphasised the importance of ascorbic acid as a natural component in citrus juice where other natural compounds present in the juice, such as flavonoids, increase the bioavailability of this acid. On the other hand, organic acids, including citric, tartaric and malic acids in citrus juice are important components which contribute to flavour attributes and are usually used as "fingerprints" to detect the quality of the juice and accomplish its authentication (Cen, Bao, He, & Sun, 2007). High concentrations of organic acids and low pH in most fruits are critical for the preservation of derivative products. They also help to stabilise ascorbic acid and anthocyanins (Wang, Chuang, & Ku, 2007).

Nowadays, consumers demand the maximum preservation of the endogenous sensory, nutritional and health related qualities of fruit products. Traditional heat pasteurisation of citrus juices is necessary in order not only to destroy microorganisms and reduce pectin methylesterase (PME) enzymatic activity, but it also leads to detrimental changes in the quality (Elez-Martínez, Aguiló-Aguayo, & Martín-Belloso, 2006). The colour and flavour are different from those of freshly squeezed juice and there is also a decrease in the number of biochemical compounds. PME inactivation is important because this enzyme catalyses pectin degradation and alters the colloid stabilizing power of the pectin, which imparts the favourable appearance and mouth feel to orange juice. As PME is more resistant to heat than microorganisms, thermal treatments are focussed on the inactivation of this enzyme. The search for new technologies that cause minimum damage to the organoleptic and nutritional characteristics may be considered as an alternative to conventional thermal juice pasteurisation. In this sense, the use of microwave energy seems to cause smaller changes in the fruit quality attributes (Nikdel, Chen, Parish, MacKellar, & Friedrich, 1993). Several studies have successfully been carried out into the microwave pasteurisation of fruit juices, as it preserves the natural organoleptic characteristics of the juice and reduces the time of exposure to energy, with the subsequently lower risk of losing

essential thermolabile nutrients (Cañumir, Celis, Brujin, & Vidal, 2002).

The aim of this work was to characterise the main bioactive compounds (vitamin C, total phenol, organic acids) and their relative contribution to the antioxidant capacity of freshly squeezed grapefruit juice and assess the effect of conventional and microwave pasteurisation on these compounds and their antioxidant capacity. Their stability during 2 months' refrigerated and frozen storage was also evaluated.

2. Materials and methods

2.1. Raw material

For this work, grapefruits (*Citrus paradise* var. Star Ruby) from the city of Murcia were purchased from a local supermarket. Grapefruits were selected on the basis of a similar degree of ripeness (ratio °Brix/acidity ≈ 4) and apparent fruit quality (firmness, size, colour and absence of physical damages). Fruit was processed in the laboratory immediately after being purchased.

2.2. Treatments

Freshly squeezed (FS) grapefruit juice was extracted through a domestic squeezer (Braun Citromatic Pulp Control MPZ6), filtered using a sieve (light of mesh diameter 1 mm, Cisa 029077, 1 series) and immediately processed. To obtain conventional pasteurised juice (CP) samples of 40 ml were heated in glass tubes in a thermostatic water bath (Precisterm, Selecta, Spain) operating at 95 °C. In this way, the juice took 80 s to reach 80 ± 2.5 °C and it remained at this temperature for 11 s. In the case of microwave pasteurised juice (MP), samples of 20 ml were heated in 25 ml glass tubes at 900 W for 30 s using a microwave (Moulinex 5141 AFW2, Spain). Treated samples were immediately cooled in ice-water till juice reached 30 °C. Both processes were previously optimised to reach ≈10% of fresh juice pectimethylesterase (PME) residual activity.

2.3. Enzymatic determinations

2.3.1. Pectin methylesterase (PME) activity measurement

PME activity in grapefruit juice was measured using the Kimball (1999) method. Briefly 10 ml of grapefruit juice and 40 ml of 1% peel citrus pectin dissolution (60% degree of esterification, Fluka Biochemika, Switzerland) containing 0.02 M NaCl, previously tempered to 30 °C in a thermostat bath, were mixed and kept in continuous agitation. NaOH was used to adjust the resulting solution to pH 7.7 (Consort C830 pH meter, Belgium) and then 100 µl of 0.05 N NaOH were immediately added. The exact time needed to lower the pH back to 7.7 by enzyme's action was then measured. As it is a first order reaction, the enzyme activity (A) can be calculated according to the concentration of acid produced using Eq. (1).

$$A = \frac{(V_{NaOH}) \times (N_{NaOH})}{(t_R) \times (W_{sample})} \quad (1)$$

where V_{NaOH} is the NaOH volume used in the titration (ml), N_{NaOH} is the normality of the NaOH solution used (mEq ml^{-1}), t_R is the reaction time (min) and W_{sample} is the weight of the sample (g).

The percentage of residual enzyme activity (RA) was defined as indicated by Eq. (2):

$$RA = 100 \times \frac{A_t}{A_0} \quad (2)$$

where A_t and A_0 were the enzyme activities of treated and untreated samples, respectively. A_t and A_0 were determined immediately after processing to avoid the effects of storage time.

2.3.2. Polyphenoloxidase (PPO) activity measurement

PPO activity was measured by spectrophotometry. The enzyme was extracted from grapefruit juice using the method of Valero, Varón, and García-Carmona (1988) modified by Rapeanu, Van Loey, Smout, and Hendrickx (2006). Briefly 100 µl of clarified juice were added to 1 ml substrate (0.1 M cathecol in McIlvaine buffer, pH 5) and the increase in absorbance at 400 nm at 25 °C was recorded automatically for 30 min (Thermo Electron Corporation, USA). One unit of PPO activity was defined as a change in absorbance at 400 nm min^{-1} ml^{-1} of enzymatic extract. Enzyme activity was calculated from the linear part of the curve. The percentage of residual enzyme activity was calculated using Eq. (2).

2.3.3. Peroxidase (POD) activity measurement

POD activity in grapefruit juice was measured using the method described by Cano, Hernández, and De Ancos (1997) with some modifications made by Elez-Martínez et al. (2006). Briefly 10 ml of sample were homogenised with 20 ml 0.2 M sodium phosphate buffer (pH 6.5) and centrifuged (15,000 rpm, 20 min) at 4 °C (P-Selecta Medifrigar BL-S, Spain) to obtain the enzymatic extract. POD activity was assayed spectrophotometrically by placing 2.7 ml 0.2 M sodium phosphate buffer (pH 6.5), 0.2 ml *p*-phenylenediamine (10 g kg^{-1}), 0.1 ml hydrogen peroxide (15 g kg^{-1}) and 0.1 ml of enzymatic extract in a 1 cm oath cuvette. The oxidation of *p*-phenylenediamine was measured at 485 nm and 25 °C using a Thermo Electron Corporation spectrophotometer (USA). POD activity was determined by measuring the initial rate of the reaction, which was computed from the linear portion of the plotted curve. One unit of POD activity was defined as a change in absorbance at 485 nm min^{-1} ml^{-1} of enzymatic extract. The percentage of residual enzyme activity was calculated using Eq. (2).

2.4. Analytical determinations

2.4.1. Soluble solids

Total soluble solids were estimated as °Brix with a refractometer (Abbe Atago 89553 by Zeiss, Japan) at 20 °C.

2.4.2. pH

To determine the pH, a Consort C830 pH meter (Belgium) with a penetration electrode was used.

2.4.3. Organic acids

HPLC (Jasco, Italy) was applied to the quantitative determination of citric (CA), malic (MA) and tartaric acid (TA) according to Cen et al. (2007). Samples were centrifuged at 10,000 rpm for 15 min and filtered by 0.22 µm membrane. HPLC method and instrumentation was: Ultrabase-C18, 5 µm (4.6 × 250 mm) column (Spain); mobile phase 0.01 mol/l potassium dihydrogen phosphate solution, volume injection 20 µl, flow rate 1 ml/min, detection at 215 nm at 25 °C. Standard curves of each reference acid (Panreac, Spain) were used to quantify the acids.

2.4.4. Ascorbic acid and total vitamin C

Ascorbic acid (AA) and total vitamin C (ascorbic acid + dehydroascorbic acid) were determined by HPLC (Jasco, Italy). To determine the ascorbic acid (Xu et al., 2008), 1 ml sample was extracted with 9 ml 0.1% oxalic acid for 3 min and immediately filtered before injection. The procedure employed to determine total vitamin C was the reduction of dehydroascorbic acid to ascorbic acid, using DL-dithiothreitol as the reductant reagent (Sanchez-Mata, Cámara-Hurtado, Diez-Marques, & Torija-Isasa, 2000; Sánchez-Moreno, Plaza, De Ancos, & Cano, 2006). A 0.5 ml aliquot sample was taken to react with 2 ml of a 20 g/l dithiothreitol solution for 2 h at room temperature and in darkness. Afterwards, the same procedure as that used for the ascorbic acid method was performed. The HPLC

method and instrumentation was: Ultrabase-C18, 5 μm (4.6 × 250 mm) column (Spain); mobile phase 0.1% oxalic acid, volume injection 20 μl, flow rate 1 ml/min, detection at 243 nm and at 25 °C. AA standard solution (Panreac, Spain) was prepared.

2.4.5. Total phenols

The extraction of total phenols (Tomás-Barberán et al., 2001) consisted of homogenising 35 g of the sample (T25 Janke and Kunkel turrax) for 5 min with 40 ml of methanol, 10 ml of HCl and NaF to inactivate polyphenol oxidases and prevent phenolic degradation. The homogenate was centrifuged (10,000 rpm, 10 min, 4 °C) to obtain the supernatant. Total phenols (TF) were quantified by using the method reported by Selvendran and Ryden (1990) and Benzie and Strain (1999) based on the Folin–Ciocalteu method. Absorbance was measured at 765 nm in a UV–visible spectrophotometer (Thermo Electron Corporation, USA). The total phenolic content was expressed as mg of gallic acid equivalents (GAE) (Sigma–Aldrich, Germany) per gram of sample, using a standard curve range of 0–800 mg of gallic acid/ml.

2.4.6. Antioxidant capacity

Antioxidant Capacity was assessed using the free radical scavenging activity of the samples evaluated with the stable radical DPPH·, as described by Sánchez-Moreno, Plaza, and De Ancos, Cano (2003). Briefly, 0.1 ml of grapefruit juice sample was added to 3.9 ml of DPPH· (0.030 g/l, Sigma–Aldrich, Germany) in methanol. A Thermo Electron Corporation spectrophotometer (USA) was used to measure the absorbance at 515 nm at 0.25 min intervals until the reaction reached a plateau (time at the steady state). The changes in absorbance were measured at 25 °C. Appropriately diluted juice samples were used on the day of preparation. The percentage of DPPH· (%DPPH·) was calculated as Eq. (3):

$$\%\mathrm{DPPH}^{\cdot} = \frac{(A_{\mathrm{control}} - A_{\mathrm{sample}})}{A_{\mathrm{control}}} \quad (3)$$

where A_{control} is the absorbance of the control and A_{sample} the absorbance of the sample.

2.5. Storage conditions

Samples (FS, CP and MP) were stored immediately after treatment in sterile polypropylene packages and kept in darkness at 4 and −18 °C during a period of 60 days.

2.6. Statistical analysis

Significant differences between treatments and storage time were calculated by means of the analysis of variance (ANOVA). Differences of $p < 0.05$ were considered to be significant. Furthermore, a correlation analysis between antioxidant activity and all the studied components with a 95% significance level was carried out. All statistical analyses were performed using Statgraphics Plus 5.1.

3. Results and discussion

Pectimethylesterase (PME) residual activity detected in samples after thermal treatments was 12.04% ± 3.86% and 10.07% ± 0.63% in CP and MP, respectively. These are intermediate values in the 0–18% range found by Snir, Koehler, Sims, and Wicker (1996), who carried out the heat treatment at 70 °C for 5 min. Nevertheless, they are high enough to obtain good quality products with a convenient cloud stabilisation, which will be kept under refrigeration conditions with low level bacteria growth. According to studies performed by Sentandreu, Carbonell, Rodrigo, and Carbonell (2006), PME had a greater heat resistance than microorganisms.

As in some studies of fresh orange juice carried out by other authors (Cano et al., 1997), analyses of freshly squeezed and pasteurised grapefruit juice did not show PPO activity. According to Dziezak (1993), citric acid, which is an important component of grapefruit juice, provokes the copper quelation present in this enzyme, disabling the activity of the PPO.

With regard to the POD activity of fresh grapefruit juice, the obtained result (5.2 ± 0.2) was similar to values found in the bibliography for citric juices (Cano et al., 1997). In CP, an inactivation of 94.3% ± 0.7% was reached, which in the case of MP was 88.1% ± 0.3%, showing the significant differences that exist between them.

Table 1 shows the physicochemical and compositional parameters of freshly squeezed grapefruit juice, conventional pasteurised juice and that which has been microwave treated. In general, FS obtained for this work presented the characteristic physicochemical parameters shown in the bibliography for grapefruit juice (Moraga, Moraga, Fito, & Martínez-Navarrete, 2009). As was observed, neither pasteurisation process affected °Brix, at a range between 9.9–10.1, or pH (2.92–3). Similar results were found by Kim and Tadini (1999), who showed that temperature and holding time had no effect on pH and °Brix of conventional pasteurised juice. These quality parameters are important as they are closely related with the stability of the bioactive compounds in fruit products (Sánchez-Moreno et al., 2006). A significant ($p < 0.05$) decrease in CA and TA content was observed in the pasteurisation treatments of the juice; the citric acid content was less affected when microwaves were applied to pasteurised juice. In no case did the pasteurisation treatment influence the malic acid content. Cañumir et al. (2002) studied the effect of microwaves comparing them with conventional pasteurisation in apple juice and they observed that total acidity tended to increase when microwave pasteurisation was used, whereas the pH tended to be lower.

Vitamin C is used as reference in different industrial processes since its presence ensures a high nutritional quality of the final product due to its easy degradation (Klimczak, Malecka, Szlachta, & Gliszczynska, 2007). The initial values of ascorbic acid and vitamin C in the fresh juice were similar, 36.0 ± 0.1 mg/100 ml and 34.0 ± 1 mg/100 ml, respectively. This is the AA grapefruit value obtained by Leong and Shui (2002). No significant differences between AA and vitamin C content were observed, as reported by other authors (Plaza et al., 2006). Vitamin C shows great thermal stability at the low pH of citrus fruits (Sánchez-Moreno et al., 2003) and in fact it was not affected by the treatments applied in this case. The conventionally pasteurised juice presented the lowest, statistically significant ($p < 0.05$) ascorbic acid content. In this

Table 1
Mean values (with standard deviation) of °Brix, pH, CA, MA, TA, AA, vitamin C, TP and %DPPH in freshly squeezed (FS), conventional pasteurised (CP) and microwave pasteurised (MP) juice.

	FS	CP	MP
°Brix	9.9 (0.1)^{a}	10.1 (0.1)^{a}	10.1 (0.1)^{a}
pH	3.00 (0.01)^{a}	2.98 (0.01)^{a}	2.92 (0.01)^{b}

The same letter in superscript indicates homogeneous groups in the same physico-chemical property and treatment during storage (temperature, *T* and time, *t*) established by the ANOVA ($p < 0.05$).
In columns: FS, freshly squeezed juice; CP, conventional pasteurised juice; MP, microwave pasteurised juice.

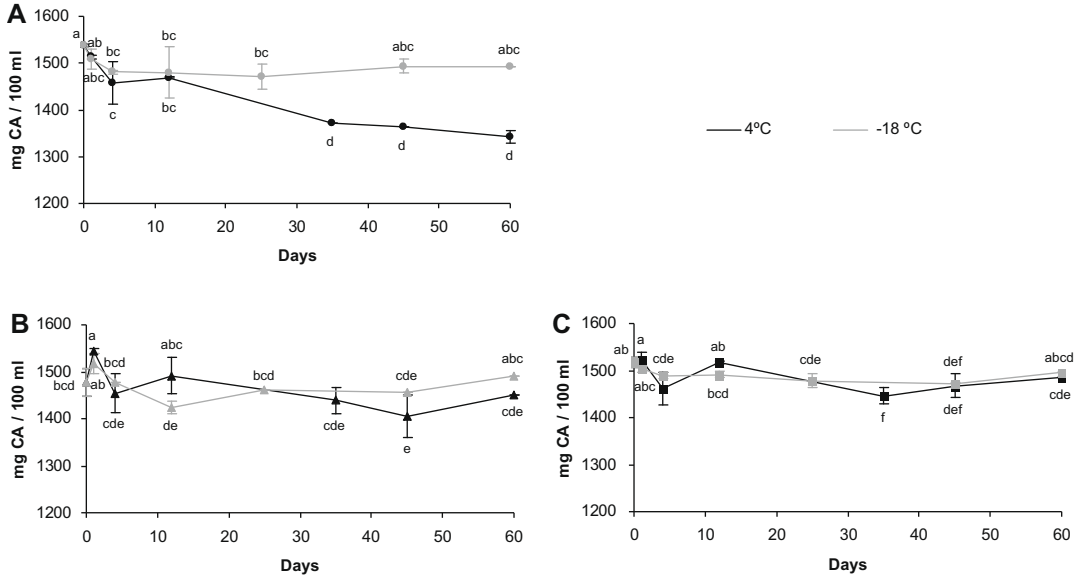

Fig. 1. Evolution of citric acid (CA) of FS (A), CP (B) and MP (C) grapefruit juices stored at 4 and −18 °C for 2 months. Letters indicate homogeneous groups established by the ANOVA ($p < 0.05$).

sense, the obtained results were the expected ones, since according to Vadivambal and Jayas (2007), ascorbic acid retention is superior in the microwave treatment than in the traditional one. In this respect, in order to diminish the impact on quality provoked by processing the juice, it would be preferable to apply microwave pasteurisation since a greater proportion of this compound is preserved.

Total phenols and %DPPH of FS were similar to the values found for orange juice by other authors (Klimczak et al., 2007). Pasteurisation provoked a significant ($p < 0.05$) decrease of the total phenol content and %DPPH. This decrease was similar in both treatments, producing a total phenol and %DPPH loss of 14.64% and 40%, respectively. Studies performed on other fruits, for example strawberry (Klopotek, Otto, & Bohm, 2005), demonstrate that there is a relationship between the decrease of antioxidant capacity, ascorbic acid, phenol content and anthocyanins and the processing necessary to obtain pasteurised juice. In general, the obtained results are comparable to those observed for citrus juices by other authors (Klimczak et al., 2007; Xu et al., 2008). In this case, antioxidant activity seems to be more related to total phenols than to ascorbic acid.

Table 2 shows the °Brix and pH obtained for fresh and pasteurised samples stored in refrigeration and freezing conditions for 2 months. From the statistical analysis and the evolution of the values, it can be stated that °Brix remained stable for all the samples, affected neither by storage conditions nor by storage time. Nevertheless, there is a general increase in pH, with no observed differences between the samples stored at 4 °C and those kept at −18 °C.

Fig. 1 shows that, in refrigeration conditions, the citric acid content of all the samples remained stable for the first 24 h, but sharply and significantly ($p < 0.05$) decreased during the next 3 days. After 12 days, the CA continued to decrease significantly in FS but remained constant in MP and CP. No significant decrease in CA was observed throughout storage at −18 °C.

As Fig. 2 shows, the storage conditions (refrigeration and freezing) affected the malic acid content of all the samples in the same way: the MA content remained constant for the first 25 storage days. Then, there was a significant ($p < 0.05$) drop in the content

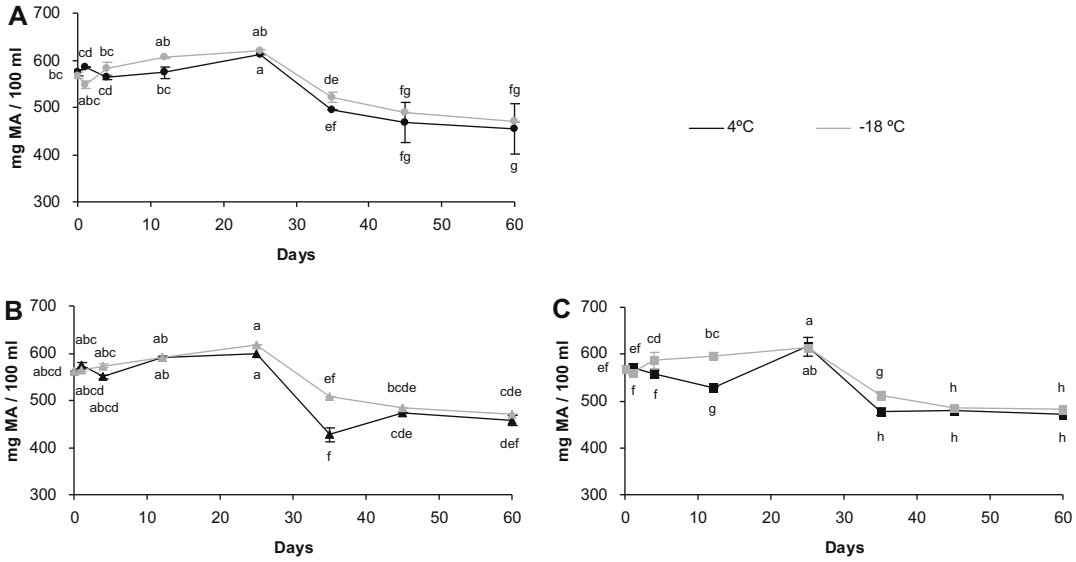

Fig. 2. Evolution of malic acid (MA) of FS (A), CP (B) and MP (C) grapefruit juices stored at 4 and −18 °C for 2 months. Letters indicate homogeneous groups established by the ANOVA ($p < 0.05$).

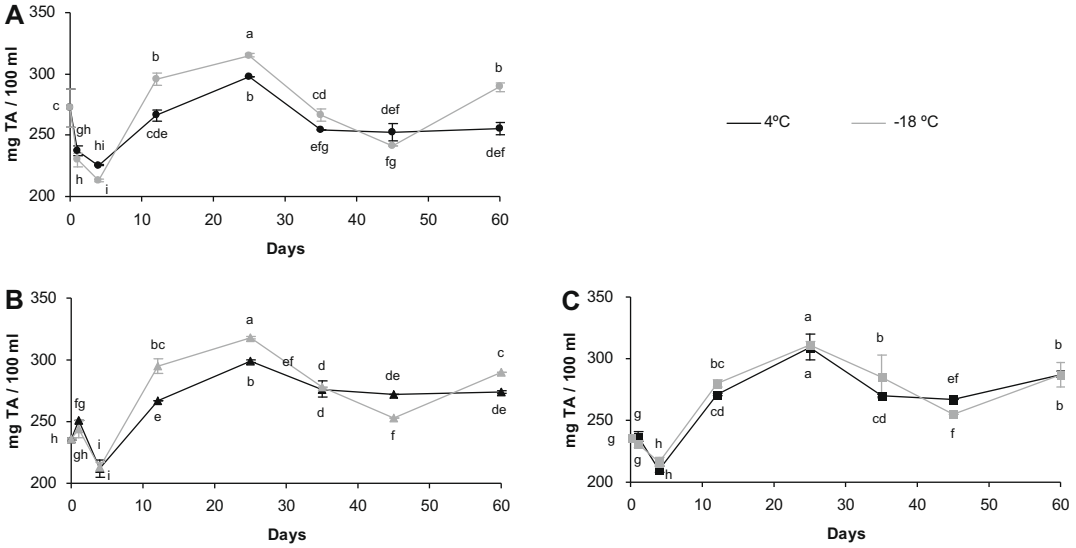

Fig. 3. Evolution of tartaric acid (TA) of FS (A), CP (B) and MP (C) grapefruit juices stored at 4 and −18 °C for 2 months. Letters indicate homogeneous groups established by the ANOVA ($p < 0.05$).

which, once again, stabilised till the end of the storage. With regards to the TA content (Fig. 3), a significant ($p < 0.05$) decrease took place during the first 4 days, with a subsequent recovery. There were no clear differences observed between the TA stability of the different samples and under differing storage conditions.

The evolution of the ascorbic acid content of grapefruit juices stored at 4 and −18 °C for 2 months is presented in Fig. 4. In general, the AA content of all juice samples studied behaved in a similar way whether under refrigeration or freezing conditions and no significant ($p < 0.05$) changes were observed till 12 days of storage. From this moment on, the samples stored under frozen conditions seem to maintain the AA content till the end of storage, whilst in the refrigerated juice the proportion of this component decreased significantly ($p < 0.05$). In this respect, from an industrial point of view, it would be advisable to freeze the pasteurised juice, for example, in the case of overproduction (Gil-Izquierdo, Gil, & Ferreres, 2002). According to the published data, the content of AA in different juices decreases during storage, depending on temperature, oxygen and light access (Klimczak et al., 2007). The degradation of AA follows both aerobic and anaerobic pathways. The oxidation of ascorbic acid occurs mainly during the processing of citrus juices, whereas anaerobic degradation, which is particularly observed in thermally preserved citrus juices, mainly appears during storage (Burdulu, Koca, & Karadeniz, 2006). For instance, Polydera, Galanou, Stoforos, and Taoukis (2004) reported that thermally pasteurised juice (80 °C, 60 s) showed 72% AA retention after 1 month at 5 °C. With regards to our CP and MP samples, 75% and 78% AA retention was reached after 25 days refrigeration, respectively, whereas in freezing conditions the retention was 84% in CP and 85% in MP. The loss of ascorbic acid during storage might be a quality indicator and a critical factor for the shelf life of some products, such as citrus juices (Plaza et al., 2006).

Fig. 5 shows the vitamin C evolution of grapefruit juices stored for 2 months at 4 °C and −18 °C. In the CP and MP juice samples,

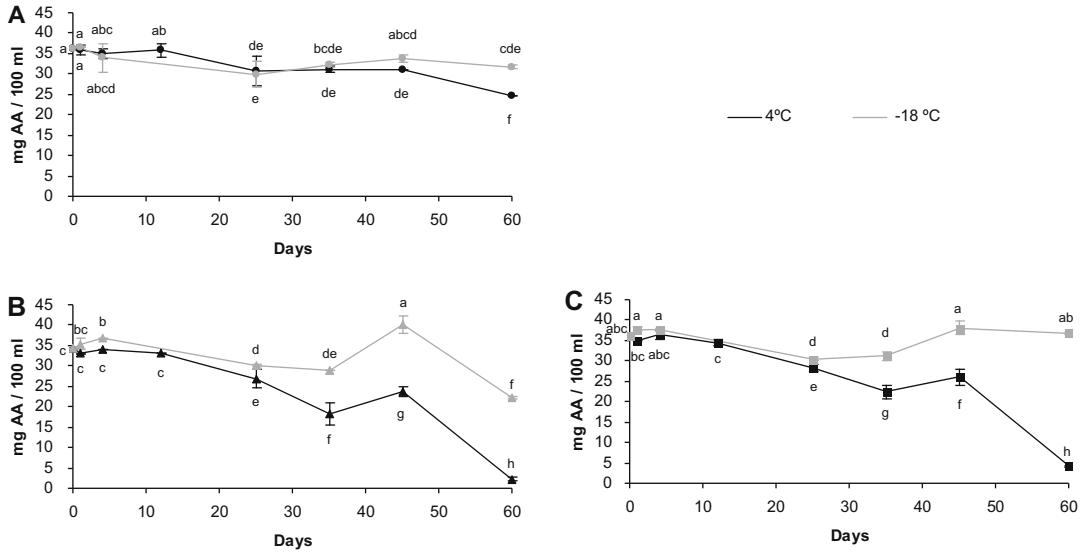

Fig. 4. Evolution of ascorbic acid (AA) of FS (A), CP (B) and MP (C) grapefruit juices stored at 4 and −18 °C for 2 months. Letters indicate homogeneous groups established by the ANOVA ($p < 0.05$).

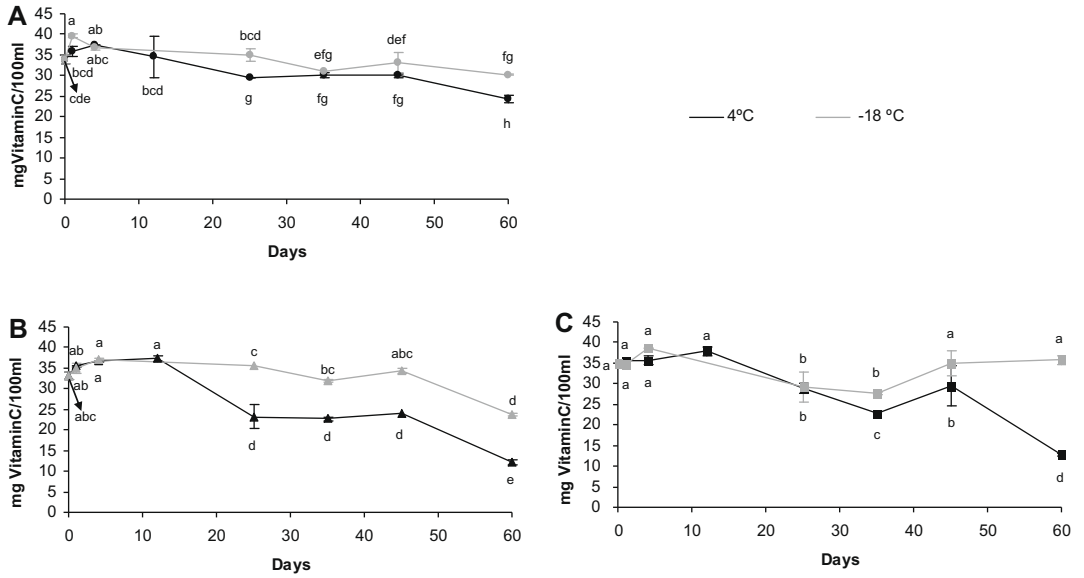

Fig. 5. Evolution of vitamin C of FS (A), CP (B) and MP (C) grapefruit juices stored at 4 and −18 °C for 2 months. Letters indicate homogeneous groups established by the ANOVA ($p < 0.05$).

the vitamin C content behaved in a similar way whether under refrigeration or freezing conditions and no significant ($p < 0.05$) changes occurred till 12 days in the case of CP samples and 25 days in the case of MP samples. From this moment on, under frozen conditions, the vitamin C content of CP samples suffered a significantly ($p < 0.05$) smaller decrease than that of refrigerated juice. In the case of frozen MP samples, this component remained stable whereas it dropped under refrigerated conditions.

At the end of the refrigerated storage, there were some significant ($p < 0.05$) differences observed between the AA and vitamin C content in pasteurised samples. As other authors suggest, the changes observed in the ascorbic acid concentration of the samples stored under refrigeration, suggest the continuation of the oxidative degradation reactions of ascorbic acid to other oxidised forms such as dehydroascorbic acid, which also presents biological activity as vitamin C (Rusell, 2004). The mechanism for enzyme degradation could be direct, by ascorbic acid oxidase, or indirect through polyphenoloxidase, cytochrome oxidase or peroxidase (Belizt & Grosch, 1997). This could be the reason why the values of vitamin C were higher than those of AA at the end of storage of treated samples.

During the storage time studied (Fig. 6), storage temperature seems not to affect FS phenol content since it evolved in a similar way whether stored under refrigeration or frozen, whereas PT significantly ($p < 0.05$) diminished till 25 days, after which it remained constant. In this way, Tavirini, D'Innocenti, Remorini, Massai, and Guidi (2008) reported that phenols did not change in kiwifruits stored for 2 months at 0 °C, but they observed a significant rise after a long storage (6 months at 0 °C) which further increased after a week at ambient temperature. In CP and MP refrigerated samples, the phenol content significantly ($p < 0.05$) diminished after day four, whilst under freezing conditions, the evolution of TP was constant.

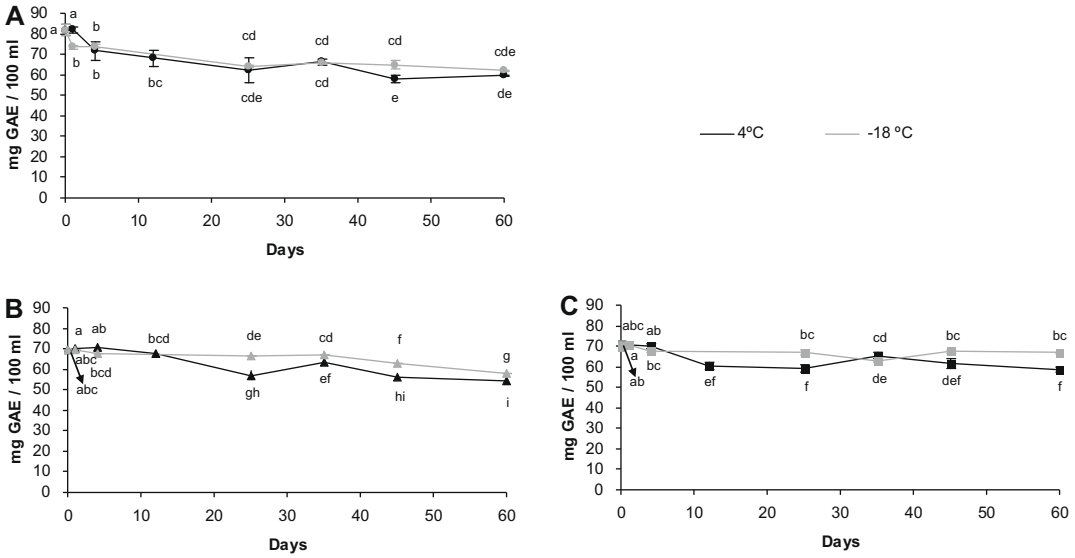

Fig. 6. Evolution of total phenols (mg GAE / 100 ml) of FS (A), CP (B) and MP (C) grapefruit juices stored at 4 and −18 °C for 2 months. Letters indicate homogeneous groups established by the ANOVA ($p < 0.05$).

The same letter in superscript indicates homogeneous groups established by the ANOVA ($p < 0.05$).
In columns: FS, freshly squeezed juice; CP, conventional pasteurised juice and MP, microwave pasteurised juice.
In rows: CA, citric acid; MA, malic acid; TA, tartaric acid; AA, ascorbic acid; TP, total phenols.

As can be observed in Fig. 7, the antioxidant capacity of both thermally treated grapefruit juices was affected by the storage conditions in a similar way. On the other hand, the antioxidant capacity of both the chilled and frozen fresh juice decreased during the first 24 h of storage. From 24 h of storage on, the FS sample evolved in a similar way to pasteurised juices, regardless of storage conditions and till the end of the study. In general, the %DPPH of all the samples decreased throughout the storage. Frozen stored MP samples had a significantly ($p < 0.05$) greater antioxidant capacity at the end of the period.

In Table 3, the variation of components due to treatment and 60 days of storage can be observed. These values were calculated as the difference of each compound in fresh or treated juice at the end of storage related to fresh juice and referred to 100 g of fresh juice. In general, frozen juices showed the smallest losses. The greatest losses were produced in FS refrigerated samples, except in the cases of AA and vitamin C, which were in greater proportions in CP refrigerated samples. When frozen, the vitamin C and AA content of the pasteurised samples remained the highest. Nevertheless, the studied bioactive compounds in the frozen MP juices maintained a greater stability and the smaller observed losses in antioxidant capacity point to this fact.

As regards to organic acids, refrigerated FS samples showed the greatest significant ($p < 0.05$) loss in CA (−12.64%). No significant ($p < 0.05$) differences were observed for the other acids in the rest of the samples and storage conditions (mean value of the loss is 3.58%, 18.18% and 3.06% for CA, MA and TA, respectively). AA and vitamin C were more stable when the samples were frozen, especially in the case of microwave-treated samples. Nevertheless, in refrigerated samples, FS juice contained the greatest amount of these compounds. In both cases, the greatest loss was observed in CP samples. Neither treatment nor storage temperature affected total phenols and antioxidant activity significantly ($p < 0.05$), except in the case of frozen MP samples which showed the lowest significant ($p < 0.05$) loss of TP (−18.35%) and %DPPH (−67.1%).

In order to explain the influence of the different compounds quantified in this study on the antioxidant capacity of the samples, correlation statistical analyses were performed. Only TA showed a negative Pearson's correlation coefficient with %DPPH (−0.5258, $p < 0.05$). Total phenols played a mayor role in the antioxidant capacity of grapefruit juices (0.8389, $p < 0.05$), followed by the vitamin C (0.7216, $p < 0.05$), ascorbic acid (0.5563, $p < 0.05$), malic acid (0.5548, $p < 0.05$), citric acid (0.4785, $p < 0.05$). Other studies (Bahorun, Luximon-Ramma, Crozier, & Aruoma, 2004) confirm the existence of a positive relationship between the phenolic content of a fruit and its antioxidant capacity. Fruits with high antioxidant activity generally contain a great quantity of antioxidant substances, especially phenolic compounds and specifically flavonoids (Tavirini et al., 2008).

4. Conclusion

Contrary to conventional treatment which leads to a significant decrease in CA and AA in grapefruit juice, microwave treatment preserved these compounds. Moreover, frozen microwave pasteurised juices better preserved total phenols and antioxidant capacity when compared with fresh or conventional pasteurised ones and maintained the amount of AA and vitamin C, especially in pasteurised samples. Therefore, the use of microwave energy offers a good alternative to conventional pasteurisation.

ABSTRACT

Lettuce (*Lactuca sativa*) is an important leafy vegetable consumed fresh or in salad mixes. We have compared the functional food properties of selected commercial red and green lettuce varieties grown under field conditions. Both lettuce cultivars were extracted with water at biological (38 °C) and room temperatures (22 °C) at pH 2. The residues from each extraction were further extracted, sequentially with methanol and ethyl acetate. The extracts were evaluated for their *in vitro* lipid peroxidation (LPO) and cyclooxygenase enzyme (COX) inhibitory activities. Amongst the extracts tested, all three extracts of red lettuce showed higher LPO and COX-1 and -2 enzyme inhibitory activities than did the green lettuce extracts. Red lettuce contained a single anthocyanin, cyanidin-3-*O*-(6″-malonyl-β-glucopyranoside) (**1**), which immediately converted to cyanidin-3-*O*-(6″-malonyl-β-glucopyranoside methyl ester) (**2**) and cyanidin-3-*O*-β-glucopyranoside (**3**) under laboratory conditions. Anthocyanins **1** and **2** inhibited LPO by 88% and 91.5%, respectively, at 0.25 μM concentration. Also, they inhibited COX-2 enzyme by 78.9% and 84.3% and COX-1 by 64% and 65.8%, respectively, at 5 μM. The chicoric acid (**4**), amongst other phenolics, such as quercetin glucoside, ferulic and caffeic acids, isolated from both green and red lettuce, showed 85.6%, 45.6% and 94% of LPO, COX-1 and -2 enzyme inhibitions at 50 μM, respectively. This is the first report of the LPO, COX-1 and -2 enzyme inhibitory activities of compounds **1**, **2** and **4**. The variation of phenolics in the red and green lettuces, and specifically the lack of anthocyanins in green lettuce, might account for the higher biological activity obtained with the red variety in our study.

1. Introduction

Numerous studies have shown a correlation between the consumption of fresh fruits and vegetables and their health benefits. Epidemiological studies have further demonstrated the relationship between dietary habits and disease risk and established that food has a direct impact on health. Lettuce, *Lactuca sativa*, is an important dietary leafy vegetable that is primarily consumed fresh or in salad mixes due to its perception as being amongst healthier foods (Dupont, Mondi, Willamson, & Price, 2000). A number of lettuce varieties have been investigated recently and reported to contain phenolic compounds with antioxidant activities (Llorach, Martinez-Sanchez, Tomas-Barberan, Gil, & Ferrers, 2008; Rice-Evans, Miller, Bolwell, Bramley, & Pridham, 1995). The health benefits of lettuce have also been attributed to the presence of Vitamin C, phenolic compounds and fibre content (Nicolle & Cardinault et al., 2004; Nicolle & Carnat et al., 2004. In folk medicine, lettuce seeds are used in the treatment of asthma, cough and as an analgesic.

In 2006, over 4,338,000 metric tons of lettuce plants were harvested from over 306,600 acres with a total value of over $2 billion. Iceberg, romaine and leaf lettuces represented 61%, 18% and 21% of the total national production (by weight), respectively. Despite a relatively small proportion of the total production (21%), leaf lettuce, including red and green types, continues to have the highest value. In 2006, leaf lettuce was valued at $8,451/acre compared to $5,596/acre and $7,016/acre for iceberg and romaine types, respectively. Iceberg lettuce is so far the most common lettuce used (especially in fast food restaurants). The antioxidant phenolics in lettuce vary amongst varieties due to growing practices, processing and storage conditions (Baur, Klaiber, Koblo, & Carle, 2004). Currently, red lettuce is popular in salad mixes due to its anthocyanin content that contributes to the higher value it fetches compared to the green lettuce (Gazula, Kleinhenz, Scheerens, & Ling, 2007). The increased demand of fresh vegetables associated with health benefits has led to an increase in the quality, quantity and variety of produce available to the consumer. Various approaches, involving

doi:10.1016/j.foodchem.2009.04.119

environmental, cultural and management practices, have been used to enhance the quality of lettuce, specifically in the areas of phytochemical contents and health-promoting attributes (Kleinhenz, French, Gazula, & Scheerens, 2003).

Anthocyanins are water-soluble phenolic glycosides that colour fruits, flowers, vegetables and cereals. Apart from imparting colour to plants, anthocyanins exhibit an array of health-promoting benefits. We have reported that anthocyanins isolated from various plants inhibited lipid peroxidation (LPO) and cyclooxygenase (COX) enzymes (Mulabagal, Van Nocker, DeWitt, & Nair, 2007; Seeram, Cichewez, Chandra, & Nair, 2003; Tall, Seeram, Zhao, Nair, & Meyer, 2004; Wang, Nair, & Strasburg, 1999). The ability of anthocyanidins to inhibit LPO and COX enzymes has also been reported (Seeram & Nair, 2002). Both anthocyanins and anthocyanidins stimulated insulin release by rodent pancreatic β-cells (INS-1 832/13) *in vitro* (Jayaprakasam, Vareed, Olson, & Nair, 2005). Also, a purified anthocyanin mixture from *Cornus mas* fruits has demonstrated an ability to ameliorate obesity and insulin resistance in C57BL/6 mice fed a high-fat diet (Jayaprakasam, Olson, Schutzki, Tai, & Nair, 2006). In another *in vivo* study, anthocyanins up-regulated the adipocyte-specific gene and genes involved in lipid metabolism (Tsuda, Ueno, Kojo, Yoshikawa, & Osawa, 2005; Tsuda et al., 2004).

Although red lettuce costs more than green lettuce, it is becoming very popular amongst consumers. This is probably due to its red colour and its association with better health as in the case of red fruits and berries. Therefore, in this study, we have compared both green and red lettuce, using *in vitro* bioassays and chemical composition studies and evaluated their functional food advantages.

2. Materials and methods

2.1. Materials

Seeds of green (Var. North Star) and red lettuce (Var. Cherokee) were purchased from Siegers Seeds Company (Holland, MI). The COX-1 enzyme was prepared from ram seminal vesicles purchased from Oxford Biomedical research, Inc. (Oxford, MI). The COX-2 enzyme was prepared from prostaglandin endoperoxide-H synthase-2 (PGHS-2)-cloned insect cell lysate. Solvents used for isolation and purification were of ACS grade and purchased from Sigma–Aldrich Chemical Co., Inc. (St. Luis, MO). Positive controls, t-butyl hydroquinone (TBHQ), butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), used in the anti-oxidant assay, were purchased from Sigma Chemical Company.

2.2. Equipment

Samples were homogenised using a Kinematica CH-6010 (Roxdale, ON, Canada) homogenizer and centrifuged (model RC5C, Sorvall Instruments, Hoffman Estates, IL) at 10,000*g* for 20 min at 4 °C. The NMR (^{1}H & ^{13}C) experiments were recorded on Varian INOVA (300 MHz) and VRX (500 MHz) instruments. The chemical shifts were measured in DMSO-*d6* and CD_3OD/DCl solutions and are expressed in δ (ppm). Fractionation of anthocyanin was carried out on a XAD-2 column (500 g, Amberlite resin, mesh size 20–50; Sigma Chemical Co., St. Louis, MO) and purified on a C-18 MPLC column (350 × 40 mm). Anthocyanin detection was carried out with a Waters 2010 HPLC system (Waters Corp.) equipped with Empower Software, Shodex Degasser, Auto sampler (Waters 717) and a Photodiode Array Detector (Waters 996). HPLC analysis was carried out by using a Capcell Pak column (DyChrom, Santa Clara, CA) C-18 column (150 × 4.6 mm i.d.; 5 μm particle size). Preparative HPLC purification of anthocyanin was carried out by using a Capcell Pak (DyChrom, Santa Clara, CA) C-18 column (250 × 4.6 mm i.d.; 5 μm particle size).

2.3. Plant material

Lettuce transplants were produced in the greenhouse using 72-cell flats filled with commercial greenhouse potting mix. At the two-leaf stage, the seedlings were transplanted to the field. Field experiments were conducted at Michigan State University Horticulture Teaching and Research Center. The lettuce seedlings were transplanted on raised beds covered with black plastic mulch and drip-irrigated using two staggered rows per bed. Spacing was 30 cm between the rows and 30 cm between plants inside each row. The plants were grown in the absence of any pesticide.

2.4. LC/MS analysis

Samples were analysed on a Surveyor HPLC system equipped with a diode array absorbance detector (DAD), measuring at 520 nm, and an autosampler cooled to 4 °C (Thermo Finnigan, San Jose, USA). An Agilent Zorbax SB C-18 column, 150 × 2.1 mm, i.d.; 5 μm particle size (Agilent, USA), was used and solvent elution consisted of a gradient system over 50 min of methanol (1% acetic acid) and H_2O (1% acetic acid) at a flow rate of 0.19 ml/min. The linear gradient system started from 5% methanol (1% acetic acid) and 95% of H_2O (1% acetic acid) to 95% methanol (1% acetic acid) and 5% of H_2O (1%) at 50 min. The column was maintained at 25 °C. After passing through the flow cell of the DAD, eluate was directed to a LCQ Advantage ion trap mass spectrometer fitted with an Eelectrospray Interface (ESI). Analyses utilised the positive ion mode (*m/z* $M + H^+$) for detection of anthocyanins. Preliminary analyses were carried out using full scan, data-dependent MS/MS scanning from *m/z* 250 to 1000. The capillary temperature was set at 275 °C and the sheath and auxiliary gas at 45 and 0 units/min, respectively. The source voltage was 4 kV. MS/MS and fragmentation were carried out with 50% energy.

2.5. Extraction of lettuce

Fresh leaves of red lettuce (1.2 kg) were blended and extracted at 22 °C with acidic water (0.1% HCl, 1 l 3×) and centrifuged. Supernatants were lyophilised to get water extract (19.1 g). The residue was further extracted with methanol (500 ml 3×), followed by ethyl acetate (500 ml 3×) and the organic extracts evaporated to dryness under reduced pressure. The yields of methanol and ethyl acetate extracts were 7 and 0.2 g, respectively. Similarly, green lettuce (300 g) leaves were blended and extracted with acidic water (200 ml 3×) and the water-soluble portions were centrifuged and lyophilised (3.4 g). Residue was extracted further with methanol (100 ml 3×), followed by ethyl acetate (100 ml 3×) and the resulting extracts evaporated under vacuum to afford 0.3 and 0.4 g of dried extracts, respectively.

To mimic *in vivo* conditions, another extraction was carried out at 38 °C and pH = 2. Red lettuce leaves (350 g) were blended with acid water (0.1% HCl, 300 ml 3×) and allowed to stand at 38 °C and pH = 2 for 4 h. The mixture was then centrifuged and the supernatant lyophilised to yield a powder (14.7 g). The residue was then extracted sequentially with methanol (200 ml 3×) and ethyl acetate (200 ml 3×). The yields of methanol and ethyl acetate extracts from this procedure were 4.9 and 0.8 g, respectively. The green lettuce leaves (200 g) were also extracted in a similar manner (75 ml 3×), followed by methanol (75 ml 3×) and ethyl acetate (75 ml 3×) to afford 3.4, 0.3 and 0.4 g of dried extracts, respectively.

2.6. Purification of anthocyanin from red lettuce

The crude extract (14 g) from red lettuce was dissolved in 200 ml of water and fractionated by an XAD-2 column (35 × 6 cm) according to the published procedure (Nair, 2002). The resin with adsorbed anthocyanins was then washed with water (2 × 1 l). The water fraction was lyophilised (4.9 g). The adsorbed anthocyanin was eluted with acidic methanol (1% HCl, 2 × 1 l), concentrated at reduced pressure (35 °C) and lyophilised to yield a dark red residue (8.5 g). An aliquot of this residue (3 g) was purified further by a C-18 MPLC column (350 × 40 mm) using water:methanol (1% HCl) as the mobile phase under gradient conditions, starting with 80% H_2O. Five fractions, I (H_2O:MeOH, 80:20, 250 ml); II (H_2O:MeOH, 70:30, 200 ml); III (H_2O:MeOH, 60:40, 200 ml); IV (H_2O:MeOH, 60:40, 200 ml) and V (H_2O:MeOH, 50:50, 500 ml) were obtained. All fractions were evaporated under vacuum and analysed by HPLC for purity and anthocyanin content. Based on HPLC, Fraction II contained pure cyanidin-3-*O*-β-glucopyranoside (**3**, 12 mg) as confirmed by NMR studies (Vareed, Reddy, Schutzki, & Nair, 2006).

Fraction IV (75 mg) showed two peaks by HPLC and was further purified by preparative HPLC using Capcell Pak (4.6 × 250 mm, 5 μm). The solvent system consisted of solvent A (water-trifluoroacetic acid (TFA) 99.99:0.1 v/v) and B (water–acetonitrile–acetic acid–TFA, 50.4%, 48.5%, 1%, 0.1%, v/v/v). The linear gradient began at 80% A and 20% B, was allowed to reach 40% A and 60% B in 26 min, and then reverted back to the initial condition of 80% A and 20% B in 30 min, where it remained for 20 min. The flow rate was 1 ml/min. The peaks detected at 520 nm (Fig. 3b) were collected, evaporated to dryness and characterised by NMR spectral methods as cyanidin-3-*O*-β-glucopyranoside (**3**, 6 mg), cyanidin-3-*O*-(6″-malonyl-β-glucopyranoside (**1**, 28 mg) and the methyl ester of cyanidin-3-*O*-(6″-malonyl-β-glucopyranoside (**2**, 15 mg). It is important to note that anthocyanins **2** and **3** are conversion products of anthocyanin **1** (Fig. 3a) produced during purification in the presence of acidic methanol. The structures of anthocyanins **1, 2** and **3** were further confirmed by comparison of NMR and mass spectral data with those of published data (Andersen & Fossen, 1995; Vareed et al., 2006).

2.7. Isolation of bioactive compounds from red and green lettuce

The MeOH extract (3.6 g) of red lettuce prepared at 38 °C was subjected to a silica gel MPLC column (350 × 40 mm) and eluted with $CHCl_3$ and mixtures of $CHCl_3$ and MeOH with increasing polarity. The fractions were analysed by TLC and similar fractions were combined to give fractions A (0.28 g, $CHCl_3$:MeOH; 9:1), B (0.75 g, $CHCl_3$:MeOH; 8:2), C (1.3 g, $CHCl_3$:MeOH; 7:3) and D (0.9 g, $CHCl_3$:MeOH; 1:1). Fraction A showed a single spot on TLC, using hexane and EtOAc (8:2) as mobile phase, and was characterised as linoleic acid (15 mg). Purification of Fraction B by silica gel TLC using hexane and EtOAc mixtures as the mobile phase gave a yellow solid, quercetin (22 mg). The compounds yielded from Fraction C by silica gel MPLC purification, followed by crystallization, were ferulic (7 mg) and caffeic acids (11 mg). The purification of fraction D by silica gel TLC gave a yellow solid, chicoric acid (**4**, 6 mg). The structures of all compounds were confirmed by comparison of NMR spectral data with those of published data (Bilia, Ciampi, Mendez, & Morelli, 1996; Dutta, Mazumdar, Mishra, Dastidar, & Park, 2007; Maeda et al., 2006; Zhang, Mills, & Nair, 2003).

Methanol extract of green lettuce (300 mg), prepared at 38 °C, was also purified by silica gel MPLC, as in the case of red lettuce extract. Fractions were collected in 5 ml aliquots and analysed by TLC. Fractions that showed identical TLC profiles were combined to obtain fractions I (78 mg, chloroform:methanol, 9:1), II (40 mg, chloroform:methanol, 8:2), III (80 mg, chloroform:methanol, 6:4) and IV, (90 mg, chloroform:methanol, 1:1). Fraction I contained primarily chlorophylls and was kept aside. Further purification of fractions II–IV by silica gel MPLC and preparative TLC resulted in the isolation of linoleic acid (12 mg), quercetin glucoside (20 mg), and chicoric acid (**4**, 15 mg), respectively. Structures of the isolates were confirmed by comparison of NMR and mass spectral data with those of published data (Bilia et al., 1996; Dutta et al., 2007; Maeda et al., 2006; Zhang et al., 2003).

2.8. Lipid peroxidation inhibitory assay

Lettuce extracts, pure anthocyanins and compounds were tested *in vitro* for their abilities to inhibit the oxidation of large unilamellar vesicles (LUV's), according to published procedure (Arora & Strasburg, 1997). Peroxidation was initiated by addition of 20 μl of $FeCl_2$–$4H_2O$ (0.5 mM) for positive controls and test samples. Fluorescence was measured at 384 nm and the decrease of relative fluorescence intensity with time indicated the rate of peroxidation. Extracts were assayed at 100 ppm, anthocyanins at 0.25 μM and compound **4** at 25 μM concentrations. Positive controls t-butyl hydroquinone (TBHQ), butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), used in the anti-oxidant assay, were tested at 10 μM. Water extracts and pure anthocyanins were assayed as solutions prepared in water. Compound **4** and methanolic extracts were assayed as solutions prepared in DMSO.

2.9. Cyclooxygenase enzyme inhibitory assay

All the lettuce extracts, anthocyanins and other phenolics were tested for their COX-1, and COX-2 enzyme inhibitory assay accord-

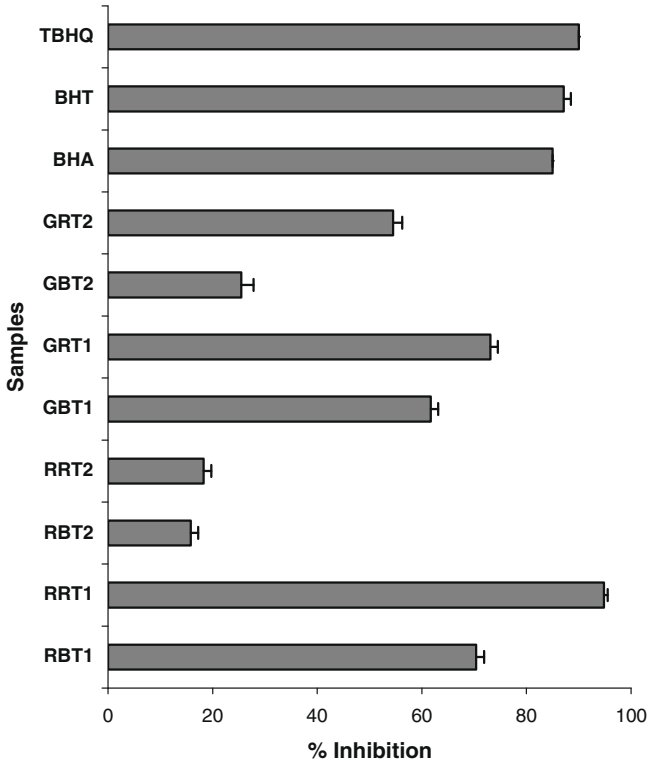

Fig. 1. Lipid peroxidation inhibitory activities of green and red lettuce extracts tested at 100 ppm (RBT1, RRT1: red lettuce water-extracts at 38 °C and 22 °C; RBT2, RRT2: red lettuce methanolic extracts of the residue from water extraction at 38 °C and 22 °C; GBT1, GRT1: green lettuce water-extracts at 38 °C and 22 °C; GBT2, GRT2: green lettuce methanolic extracts of the residue from water extraction at 38 °C and 22 °C). Positive controls BHA (butylated hydroxyanisole), BHT (butylated hydroxytoluene) and TBHQ (t-butyl hydroquinone) were tested at 10 μM in DMSO. Vertical bars represent the averages of two experiments ± SD.

ing to the previously published procedure from our laboratory (Vareed et al., 2006). COX-1 enzyme was prepared from ram seminal vesicles whereas; COX-2 enzyme was prepared from insect cell lysate. The rate of oxygen consumption during the initial phase of the enzyme-mediated reaction, with arachidonic acid as substrate, was measured using a Model 5300 biological oxygen monitor (Yellow Spring Instruments Inc., Yellow Spring, OH). Aspirin (60 μM), Celebrex (26 nM), Vioxx (32 nM) and Arcoxia (120 nM) were used as positive controls. Extracts were assayed at 100 ppm, anthocyanins at 5 μM and compound **4** at 50 μM concentrations. Water extracts and pure anthocyanins were assayed as solutions prepared in water. Compound **4** and methanolic extracts were assayed as solutions prepared in DMSO.

3. Results and discussion

Although the production of red lettuce is increasing, consumers still pay a higher price for red lettuce than for green lettuce. This is probably due to the health benefits attributed to the red colour, such as by anthocyanins, in red lettuce. This assumption and price difference prompted us to compare the functional food qualities, using *in vitro* bioassays, of commercial red and green lettuce grown under field conditions.

For comparison, green and red lettuces were extracted sequentially with water and methanol under laboratory conditions (22 °C). The resulting extracts were then assayed for lipid peroxidation (LPO) and cyclooxygenase enzyme (COX) inhibitory activities at 100 ppm. Amongst the extracts tested, the water extract of red lettuce prepared at 22 and 38 °C inhibited LPO by 94.8% and 70.4%, respectively, (Fig. 1). Similarly, water extracts of green lettuce prepared at 22 and 38 °C gave 73.1% and 61.7% of LPO inhibition, respectively, at 100 ppm (Fig. 1). The COX enzyme inhibitory assays for red and green lettuce extracts were performed by using COX-1, and -2 isozymes. The water and methanol extracts of red lettuce, prepared at 22 and 38 °C, inhibited COX-2 enzyme by 89.7%, 84.9% and 87.8%, 72.2%, respectively, (Fig. 2). The water

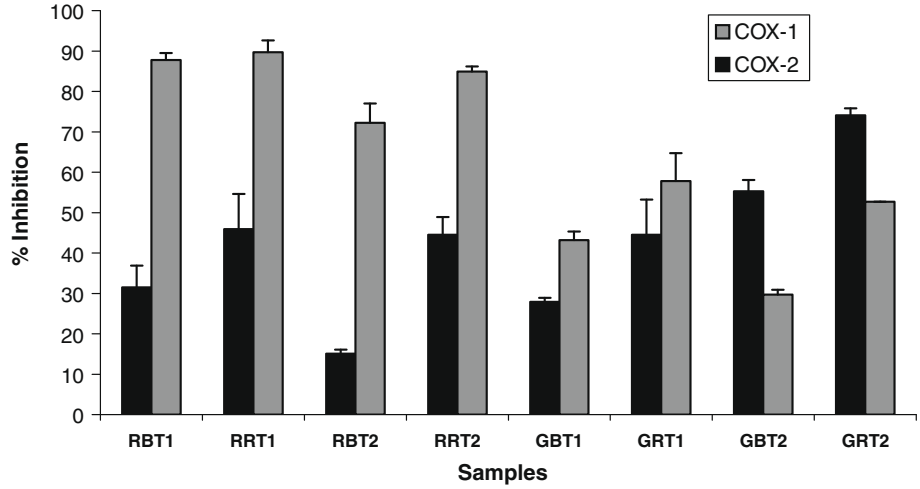

Fig. 2. *In vitro* COX-1 and COX-2 enzyme inhibitory activities of red and green lettuce extracts at 38 °C and 22 °C (RBT1, RRT1: red lettuce water-extracts at 38 °C and 22 °C; RBT2, RRT2: red lettuce methanolic extracts of the residue from water extraction at 38 °C and 22 °C; GBT1, GRT1: green lettuce water-extracts at 38 °C and 22 °C; GBT2, GRT2: green lettuce methanolic extracts of the residue after water extraction at 38 °C and 22 °C). The extracts were tested at 100 ppm. Vertical bars represent the averages of two experiments ± SD.

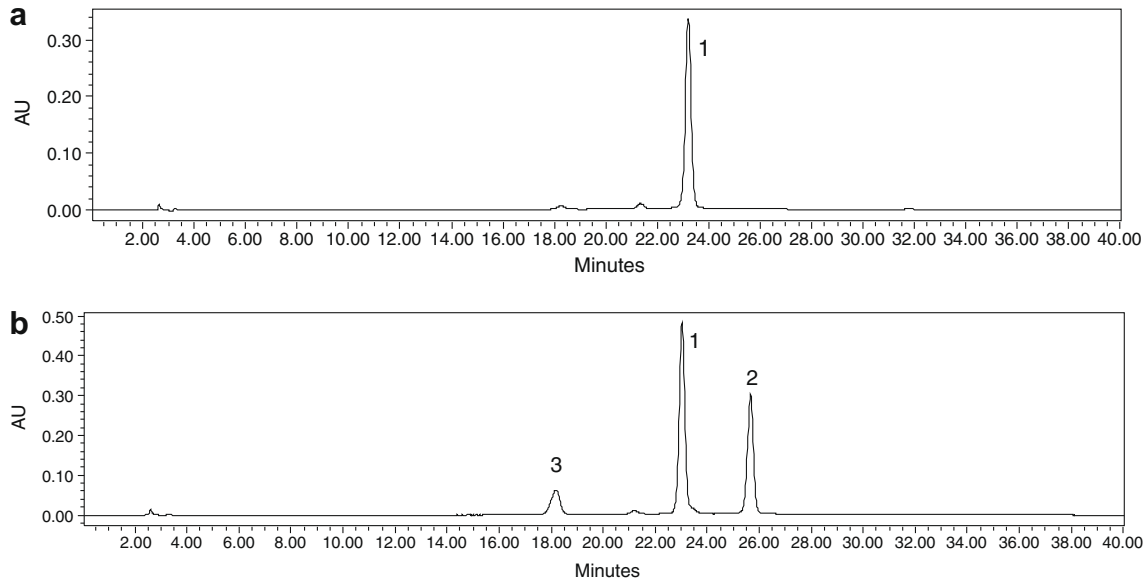

Fig. 3. (a) HPLC profile of anthocyanin in red lettuce, variety "Cherokee". Peak 1. (cyanidin 3-*O*-(6″-malonyl-β-glucopyranoside) and (b) HPLC profile of anthocyanins in the extract of red lettuce stored at room temperature for 1 h. Peak 1. (cyanidin 3-*O*-(6″-malonyl-β-D-glucopyranoside); Peak 2. (methyl ester of cyanidin-3-*O*-(6″-malonyl-β-D-glucopyranoside) and Peak 3. (cyanidin-3-*O*-β-D-glucopyranoside).

extracts of red lettuce, yielded at 22 and 38 °C, were similar in their COX-2 enzyme inhibition at 100 ppm test concentration. Water and methanol extracts of green lettuce prepared at 22 °C inhibited COX-2 enzyme by 57.8% and 52.7%, respectively, at 100 ppm (Fig. 2). Interestingly, the methanol extract of green lettuce showed 74.1% of inhibition against COX-1 enzyme (Fig. 2). Although the activity seems to be higher at 100 ppm for extracts prepared at 22 °C, the percentage weight of extracts obtained at 38 °C treatment was 3-fold higher than that of extracts at 22 °C. Therefore, the overall biological activity of fresh lettuce on a per gramme basis is higher at *in vivo* temperature than under laboratory conditions.

The primary difference between red and green lettuce is in their anthocyanin contents. Since the water extract of the red lettuce showed higher biological activity and contained anthocyanin, we have characterised the anthocyanin in the red lettuce variety studied. The HPLC profile of the extract showed only one anthocyanin, when analysed immediately after extraction, and it was characterised as cyanidin-3-*O*-(6″-malonyl-β-glucopyranoside (**1**) (Fig. 3a). However, purification or storage of the extract results in the methylation or loss of the malonic acid moiety to yield anthocyanins **2** and **3** (Figs. 3b and 4). Anthocyanins were purified using XAD-2 resin, C-18 MPLC followed by HPLC. During this process, anthocyanin **1** was converted to anthocyanin **2** (cyanidin-3-*O*-(6″-malonyl-β-glucopyranoside methyl ester) and then finally to **3** (cyanidin-3-*O*-β-glucopyranoside) (Figs. 3b and 4). The structures of anthocyanin **1** and its conversion products were elucidated by NMR and mass spectral analysis. The data were in agreement with the published spectral data of anthocyanins **1** and **2** (Andersen & Fossen, 1995). The isolation and characterisation of the acylated anthocyanins **1** and **2** from commercial red lettuce variety "Cherokee" are here reported for the first time.

The reported isolation of several anthocyanins from fruits with LPO and COX enzyme inhibitory activities (Mulabagal et al., 2007; Seeram et al., 2003; Tall et al., 2004; Wang et al., 1999), prompted us to evaluate similar biological activities of anthocyanins **1** and **2** isolated from red lettuce. Based on our experience with cyanidin-3-*O*-glucoside (**3**) and related anthocyanins, we tested **1** and **2** for LPO and COX enzyme inhibitory activities. The biological activities observed were similar to all three anthocyanins (Figs. 5 and 6). The positive controls used in the LPO assay were BHA, BHQ and TBHQ and were tested at 10 μM concentration. Similarly, anti-inflammatory drugs, Arcoxia (128 nM), Aspirin (60 μM), Celebrex (26 nM) and Vioxx (32 nM) were used as positive controls in the COX assay. Anthocyanins **1** and **2** inhibited COX-2 enzyme by 78.9% and 84.3%, respectively, when tested at 5 μM (Fig. 6). Both anthocyanins inhibited COX-1 enzyme by 64% and 65.8%, respectively, when tested at the same concentration (Fig. 6). Excellent LPO and COX inhibitory activities of anthocyanin **3** have recently been reported from our laboratory and hence were not repeated in this study (Mulabagal et al., 2007). This is the first report of the LPO, COX-1 and -2 enzyme inhibitory activities of anthocyanins **1** and **2**. Also, the activity of anthocyanins in red lettuce accounts for the higher activity observed for red lettuce than for green lettuce.

We have also analysed the methanolic extracts of red and green lettuce for bioactive principles. The red lettuce extract was fractionated by a silica gel MPLC column, using chloroform and mixtures of chloroform and methanol with increasing polarities. Low polar fractions yielded a fatty acid, linoleic acid, and a flavanone, quercetin. Medium and high polar fractions were purified to yield phenolic acids, caffeic, ferulic and chicoric (**4**) acids. The structures of these compounds were determined by comparison of NMR and mass spectral data with those of the published spectral data (Bilia et al., 1996; Dutta et al., 2007; Maeda et al., 2006; Zhang et al., 2003). This is the first report on the isolation of phenolic acids from red lettuce variety 'Cherokee'.

The purification of the methanolic extract of green lettuce resulted in the isolation of linoleic acid, quercitin glucoside, and chicoric acid (**4**). The majority of the extract contained chlorophyll, along with these compounds in minor quantities. Also, linoleic acid is considered as an essential dietary ingredient, with antioxidant

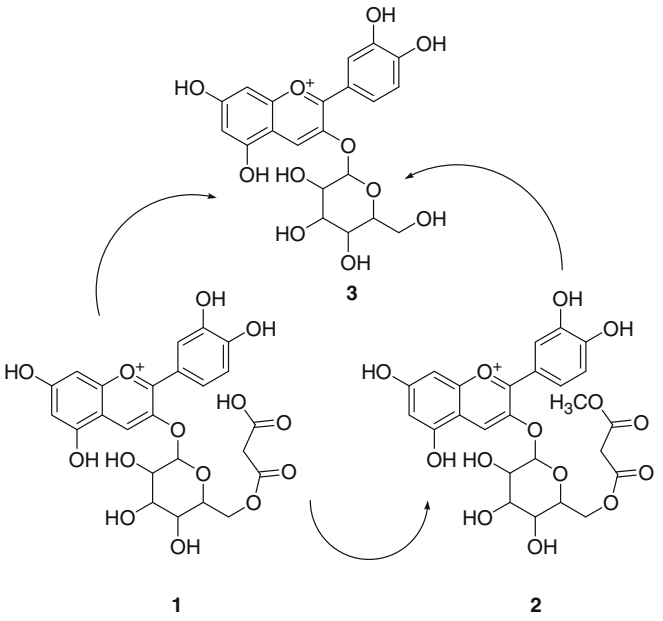

Fig. 4. Structure of anthocyanin **1** (cyanidin-3-*O*-(6″-malonyl-β-D-glucopyranoside), **2** (cyanidin-3-*O*-(6″-malonyl-β-D-glucopyranoside methyl ester) and **3** (cyanidin-3-*O*-β-D-glucopyranoside).

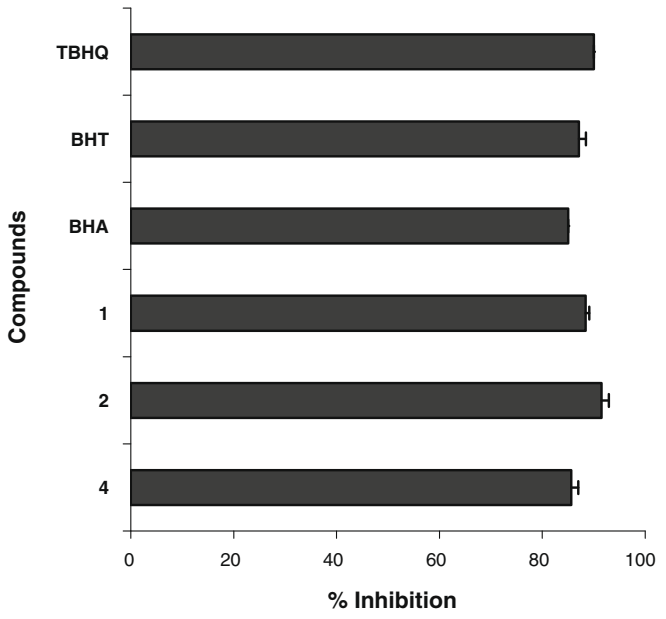

Fig. 5. Lipid peroxidation inhibitory activity of compounds **1** (cyanidin-3-*O*-(6″-malonyl-β-D-glucopyranoside), **2** (cyanidin-3-*O*-(6″-malonyl-β-D-glucopyranoside methyl ester) and **4** (chicoric acid). Compounds **1** and **2** were tested at 0.25 μg/ml. Compound **4** was tested at 50 μM. Positive controls BHA (butylated hydroxyanisole), BHT (butylated hydroxytoluene) and TBHQ (t-butyl hydroquinone) were tested at 10 μM concentration. The percent inhibition was calculated with respect to solvent control (DMSO) and values represent means ± SD ($n = 2$). Activity of anthocyanin **3** (cyanidin-3-*O*-β-D-glucopyranoside) was reported earlier from our laboratory (Mulabagal et al., 2007).

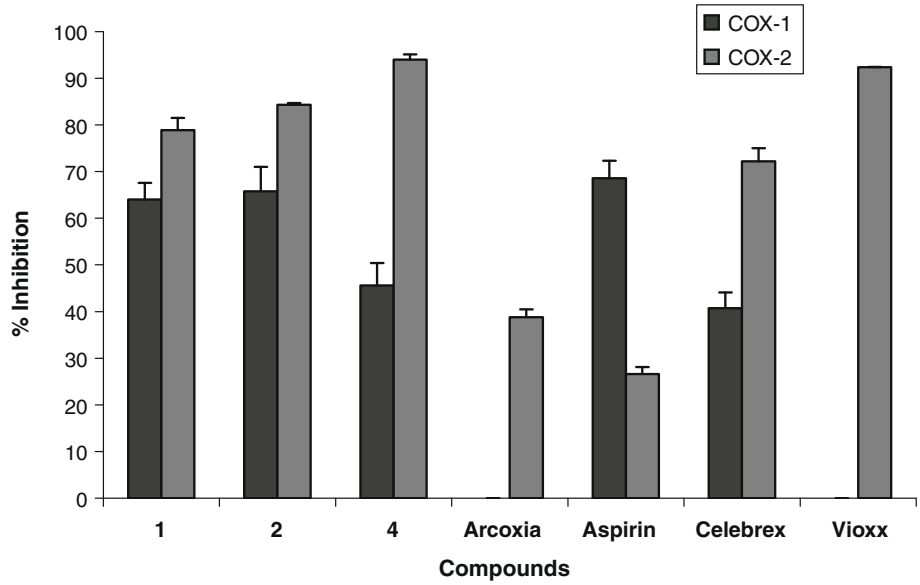

Fig. 6. *In vitro* COX-1 and COX-2 enzyme inhibitory activities of compounds **1** (cyanidin-3-*O*-(6″-malonyl-β-D-glucopyranoside at 0.25 μM), **2** (cyanidin-3-*O*-(6″-malonyl-β-D-glucopyranoside methyl ester at 0.25 μM) and **4** (chicoric acid at 50 μM) and positive controls, Arcoxia (128 nM), Aspirin (60 μM), Celebrex (26 nM) and Vioxx (32 nM). Vertical bars represent the averages of two experiments ± SD. Activity of anthocyanin **3** (cyanidin-3-*O*-β-D-glucopyranoside) was reported earlier from our laboratory (Mulabagal et al., 2007).

and anti-inflammatory properties (Henry, Momin, Nair, & Dewitt, 2002). Isolation of quercetin, caffeic acid, chicoric acid and anthocyanins was reported from other varieties of lettuce (Nicolle & Cardinault et al., 2004; Nicolle & Carnat et al., 2004; Romani et al., 2002). The chicoric acid (**4**), isolated from both green and red lettuce, showed 85.6%, 45.6% and 94% of LPO, COX-1 and -2 enzyme inhibitions at 50 μM, respectively. Other phenolic compounds, monocaffeoyltartaric acid, dicaffeoyltartaric acid, 5-caffeoylquinic acid, caffeoylmalic acid and 3,5-di-*O*-caffeoylquinic acid, have also been reported from lettuce and their contents may vary according to harvesting period (Sobolev, Brosio, Gianferri, & Segre, 2005). This is the first report of the LPO, COX-1 and -2 enzyme inhibitory activities of chicoric acid (**4**) (Figs. 5 and 6).

Most green vegetables contain large quantities of the green pigment chlorophyll. Previous studies from our laboratory have demonstrated that chlorophyll, quercetin and quercetin glucoside inhibited COX-1 and COX-2 enzymes (Reddy, Alexander-Lindo, & Nair, 2005; Vanisree, Alexander-Lindo, DeWitt, & Nair, 2008) *in vitro*. Studies have shown that chicoric acid had antioxidant activity (Thygesen, Thulin, Mortensen, Skibsted, & Molgaard, 2007) and inhibited the replication of HIV virus in tissue culture (Lee, Shin, Lee, & Lee, 2007). From the present study, it is clear that the biological activities observed for the methanolic extracts of red and green lettuce are due to the presence of phenolic compounds.

4. Conclusions

Our results have shown that both red and green lettuce had strong antioxidant and anti-inflammatory activities. However, the anthocyanin in red lettuce may be considered as an additional source of biological activity, based on a number of *in vitro* and *in vivo* experiments suggesting its health-beneficial activities. Our results also demonstrated the difference in biological activities between green and red lettuce due to the variation in phenolic composition. Higher amounts of phenolics, including the anthocyanin, present in red lettuce, may indicate that consumption of red lettuce may provide better health-benefits than green lettuce.

ABSTRACT

The root of *Panax notoginseng* has been shown to change its saponin composition upon steaming. This study examines the effects of different steaming times and temperature on notoginseng root for saponin composition and anticancer activities. Steaming decreased the content of notoginsenoside R1, ginsenosides Rg1, Re, Rb1, Rc, R2, Rb3 and Rd, but increased the content of Rh1, Rg2, 20*R*-Rg2, Rg3 and Rh2. Steaming significantly influenced the transformation of Rg3. The amount of ginsenoside Rg3, an anticancer compound, was 5.23-fold greater in root steamed for 2 h at 120 °C than at 100 °C, and 3.22-fold greater when steamed for 4 h than for 1 h at 120 °C. For anticancer effects, the extract of steamed root significantly inhibited proliferation of SW-480 human colorectal cancer cells. The IC_{50} of the steamed extract for 1, 2, 4 and 6 h at 120 °C was 259.2, 131.4, 123.7 and 127.1 μg/mL, respectively; the effect of unsteamed extract was low. Flow cytometric analysis demonstrated that the apoptotic cell induction rates of SW-480 cells were 56.3% and 64.4% with 150.0 and 200.0 μg/mL extract steamed for 6 h. Compared with Rg1 and Rb1, only Rg3 had a significant antiproliferative effect.

1. Introduction

Panax notoginseng belongs to the family of flowering plants known as the Araliaceae. Notoginseng root is used in traditional Chinese medicine to remove blood stasis, stop bleeding, relieve swelling and alleviate pain. The root is the principal component in Yun-Nan-Bai-Yao, a formula used to stop bleeding, decrease inflammation, and relieve pain, and it is the main component of other traditional formulas for coronary heart disease such as Fu-Fang-Dan-Shen-Pian (Compound Salvia Tablet) and Guan-Xin-Dan-Shen-Pian (Guanxin Danshen Tablet) (Commission, 2005). Notoginseng root is also used to treat hyperlipemia and chronic infectious hepatitis (Wang, McEntee, Wicks, Wu, & Yuan, 2006). Based on the US Dietary Supplement Health and Education Act (DSHEA) of 1994 (103rd Congress, 1994), herbal medicines and food supplements, including notoginseng, were classified as dietary supplements. Thus, in the US health food market, notoginseng tea or capsules are being sold as over-the-counter dietary supplements.

Saponins are the main active constituents in notoginseng root (Wang, McEntee et al., 2006). The alcohol extract of the root, which contains 12.4% of saponins, shortened bleeding time and had better haemostatic effects than no treatment or treatment with lipophilic extract or placebo (White, Fan, Song, Tsikouris, & Chow, 2001). The saponin extract of notoginseng also had haemostatic effects when applied externally (White, Fan, & Chow, 2000). Saponins from notoginseng increased the blood flow of the coronary arteries (Huang et al., 1999) and decreased the consumption of oxygen by heart muscles (Chen et al., 1983). So far 59 saponins have been identified in notoginseng root (Wang, McEntee et al., 2006). These saponins have a dammarane structure: 35 belong to the protopanaxadiols (PPD) group, and 24 belong to the protopanaxatriols (PPT) group, and include ginsenosides, notoginsenosides, and gypenosides. Ginsenosides Rg1, Rb1, Rd, and notoginsenoside R1 are considered the major saponins in the root. These saponins, with the exception of R1, are also found in Asian ginseng (*P. ginseng*) and American ginseng (*P. quinguefolius*) (Wang, Mehendale, & Yuan, 2007). Oleanane-type

saponins in Asian and American ginseng, however, have not been found in notoginseng.

In Korea, processed Asian ginseng is called red ginseng. Red ginseng's ability to inhibit lung tumour induced by urethane and/or 9,10-dimethyl-1,2-benzanthracene (DMBA) has been reported (Yun, Yun, & Han, 1983). Subsequently, other reports of ginseng's anticancer activity after different processing methods were published (Keum et al., 2000; Kim et al., 2000; Kitts, Popovich, & Hu, 2007; Popovich & Kitts, 2004). Pharmacological tests attributed the anticancer activity to the derivatives of the primary ginsenosides naturally generated by intestinal bacteria or by acid hydrolysis (Bae, Han, Kim, & Kim, 2004), not by the primary ginsenosides themselves. Some experiments (Wang, Zhao et al., 2007) suggested that the number of sugar moieties, and the differences in the substituent groups affect anticancer activity. This information may be useful for evaluating the structure–function relationship of other ginsenosides and their aglycones and for development of novel anticancer agents. For example, 20(*R*)-dammarane-3β,12β,20,25-tetrol and 20(*S*)-protopanaxadiol had significant dose-dependent effects on apoptosis, proliferation, and cell cycle progression (Wang, Zhao et al., 2007). Steaming Asian or American ginseng transformed original ginsenosides into anticancer compounds (Nam, 2005; Wang, Zhang et al., 2006; Wang, Aung et al., 2007).

Notoginseng root, too, has been shown to have anticancer activity (Konoshima, Takasaki, & Tokuda, 1999; Wang, Xie et al., 2007), and steaming it can increase its anticancer activity (Wang, Xie, 2007). However, the steaming parameters that affect saponin content and anticancer activities in notoginseng have not been systematically evaluated. The aim of this study was to analyse the influence of different steaming temperatures and duration on changes in saponin content of notoginseng root and to correlate the observed changes to antiproliferative activities in SW-480 human colorectal cancer cells.

2. Materials and methods

2.1. Cell lines, chemicals and biochemicals

SW-480 human colorectal cancer cells were purchased from American Type Culture Collection (Manassas, VA). All solvents were of high-performance liquid chromatography (HPLC) grade (Fisher Scientific, Norcross, GA). Milli Q water was supplied by a water purification system (US Filter, Palm Desert, CA). Standards for ginsenosides Rb1, Rb2, Rc, Rd, Re and Rg1 were obtained from the Indofine Chemical Company (Somerville, NJ); for ginsenosides Rb3, Rg2, Rg3, Rh1, Rh2 and 20(*R*)-ginsenoside Rg2 (20*R*-Rg2), from the Delta Information Center for Natural Organic Compounds (Xuancheng, Anhui, China). All standards were of biochemical-reagent grade and at least 95% pure as confirmed by HPLC. Plastic materials were purchased from Falcon Labware (Franklin Lakes, NJ). Trypsin, Leibovitz's L-15 medium, foetal bovine serum (FBS), and penicillin/streptomycin solution were obtained from Mediatech Inc. (Herndon, VA). A CellTiter 96 Aqueous One Solution Cell Proliferation Assay kit was obtained from Promega (Madison, WI). An Annexin V-FITC Apoptosis Detection kit was obtained from BD Biosciences (San Diego, CA).

2.2. Plant material and preparation of the extract

The roots of *P. notoginseng* were obtained from Wenshan, Yunnan, China. The voucher samples were deposited at the Tang Center for Herbal Medicine Research at University of Chicago.

Notoginseng root was pulverised, passed through a 40 mesh screen and was steamed at 100 °C for 2 h, or at 120 °C for 1, 2, 4 and 6 h. The steamed samples were frozen for 2 h before being lyophilised.

For the HPLC analysis, dried steamed notoginseng samples were pulverised, and 0.5 g of the ground unsteamed or steamed samples was extracted with 100% methanol in a Soxhlet extractor for 8 h while the water bath was maintained at 85 °C. The extracts were concentrated *in vacuo*, transferred into a 25 mL volumetric flask, and diluted to the desired volume with methanol; the solutions were stored at −20 °C until HPLC analysis.

For the *in vitro* anticancer studies, 10 g of dried powders of unsteamed or steamed notoginseng were extracted with 200 mL of 70% ethanol for 4 h; the water bath was maintained at 90 °C. When cooled, the solution was filtered with P8 filter paper (Fisher Scientific, Pittsburgh, PA) and the filtrate was collected. The residue was extracted with 100 mL of 70% ethanol once more and then filtered while the solution was cooled. The filtrates were combined, and the solvent was evaporated *in vacuo*. The dried extract was dissolved in 100 mL of water and then extracted with water-saturated *n*-butanol. The *n*-butanol phase was evaporated under vacuum and then frozen for 2 h and lyophilised.

2.3. HPLC analysis

The HPLC system included a Waters 2965 instrument (Milford, MA) with a quaternary pump, an automatic injector, a photodiode array detector (Model 996), and Waters Millennium 32 software for peak identification and integration.

HPLC conditions: Prodigy ODS (2) column, (5 μ, 3.2 × 250 mm; Phenomenex), with a guard column, (5 μ, 3.2 × 7.5 mm; Phenomenex). Solvent system: A – MeCN, B – H_2O; Gradient 17.5–21% over 20 min, 21–26% over 3 min, 26% A for 19 min, 26–36% A over 13 min, 36–50% A over 9 min, 50–68% A over 9 min, 68–80% A over 2 min, 80% A for 3 min, 80–17.5% A over 5 min, 17.5% A for 6 min. Flow rate: 1 mL/min; Injection volume: 20 μL; DAD conditions: 202 nm. The linearity of this method was assayed by analysing standard solutions in the range of 2–400 μg/mL for notoginsenoside R1 and 12 other ginsenosides. Calibration curves were constructed from the measured peak areas and the related amount of ginsenosides.

Notoginsenoside R1, ginsenosides Rb1, Rb2, Rb3, Rc, Rd, Re, Rg1, Rg2, 20*R*-Rg2, Rg3, Rh1, and Rh2 identified in extract samples were identified by comparison of their retention times with those obtained from the chromatograms of mixed ginsenoside standards. The content of saponins in each sample was calculated using standard curves of notoginsenoside and ginsenosides.

2.4. Cell culture

SW-480 human colorectal cancer cells were grown in the Leibovitz's L-15 medium supplemented with 10% FBS and 50 IU penicillin/streptomycin in a humidified atmosphere at 37 °C. When the cells were in the late log/early plateau phase (with about 90% of the surface area covered) and healthy and free of contamination, the cell culture medium was removed. After the cells were washed with PBS to remove any trace of serum that would inactivate trypsin, the PBS was discarded. One millilitre of trypsin was added to a 25 mL flask to break the cell–cell and cell–substrate links. Fresh culture medium containing serum (5 mL) was then added to inactivate the trypsin in the cell suspension. After pipetting this suspension, a single-cell suspension was prepared. The cell suspension was then counted for accurate cell density. An aliquot of the cell suspension was placed into a new 25 mL flask with the full amount of cell culture medium (10 mL) required for the flask size. The medium was then changed if necessary until the next subculture.

2.5. Cell proliferation analysis

Unsteamed or steamed notoginseng root extracts, and ginsenosides, were dissolved in 50% ethanol and then stored at −20 °C before use. Cells were seeded in a flat-bottomed 96-well plate with a multichannel pipet (1×10^4 cells/well). After 24 h, the medium was removed and 200 μL of fresh culture medium was added to each well. Various concentrations of extracts were added to the wells. The final concentration of ethanol in tested groups was 0.5%. Controls were exposed to culture medium containing the same quantity of ethanol without drugs. All experiments were performed at least in triplicate.

At the end of the drug exposure period (48 h), the medium was removed from all wells and 100 μL of fresh medium and 20 μL of CellTiter 96 aqueous solution was added to each well. CellTiter 96 aqueous solution is composed of a tetrazolium compound, 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulphophenyl)-2*H*-tetrazolium, an electron-coupling reagent (phenazine methosulphate), and buffer. When the solution contacts viable cells, it is bioreduced by dehydrogenase enzymes in metabolically active cells into a formazan product. The quantity of formazan product, measured by the amount of absorbance at 490 nm, is directly proportional to the number of living cells in culture. The plate was then incubated for 1 h in a humidified atmosphere at 37 °C; 60 μL of medium from each well were transferred to an ELISA 96-well plate, and the absorbance of the formazan product at 490 nm was measured. The blank was recorded by measuring the absorbance at 490 nm with wells containing medium but no cells. Results were expressed as per cent of control (ethanol vehicle set at 100%).

2.6. Apoptosis assay using flow cytometry

Annexin V is a Ca^{2+}-dependent phospholipid-binding protein that binds strongly to phosphatidylserine residues on the cell membrane. In a normal cell, these residues are on the inner surface of the membrane and therefore inaccessible to annexin V. In the early stage of apoptosis, the phosphatidylserine residues are translocated to the outside of the cell at which point the cells die. Cell apoptosis can be assayed by flow cytometry after staining with annexin V (Vermes, Haanen, Steffens-Nakken, & Reutelingsperger, 1995). Cells were seeded in 24-well tissue culture plates. After culture for 2 days, the medium was changed and notoginseng extracts were added. After treatment for 48 h, cells floating in the medium were collected. The adherent cells were detached with trypsin. Then culture medium containing 10% FBS (and floating cells) was added to inactivate trypsin. After being pipetted gently, the cells were centrifuged for 5 min at 600*g*. The supernatant was removed, and cells were stained with annexin V-FITC. Untreated cells were used as control. Cells were analysed immediately after staining using a FACScan flow cytometer (Becton Dickinson, Mountain View, CA) and FlowJo software (Tree Star, Ashland, OR). For each measurement, at least 20,000 cells were counted.

2.7. Statistical analysis

Data are presented as mean ± standard deviation (SD). A one-way ANOVA was employed to determine whether the results had statistical significance. In some cases, Student's *t*-test was used

3. Results and discussion

3.1. Effects of temperature on notoginseng constituents

Typical HPLC chromatograms of saponin standards, and unsteamed and steamed notoginseng root are shown in Fig. 1. The content of 13 ginsenosides in steamed notoginseng is shown in Table 1. Compared to unsteamed notoginseng, in root steamed at 100 °C for 2 h, the total content of confirmed saponins decreased slightly from 68.70 to 59.50 mg/g. Among the main saponins, ginsenoside Rg1 decreased from 23.17 to 19.90 mg/g, and Rb1 decreased from 26.90 to 21.28 mg/g; notoginsenoside R1 decreased from 6.78 to 5.48 mg/g; ginsenoside Rg3 increased from 0.33 to 0.90 mg/g. At 120 °C for 2 h, total ginsenoside content decreased to 35.56 mg/g. Rg1 was 4.16 mg/g; Rb1, 8.46 mg/g; notoginsenoside R1, 1.01 mg/g; Rg3, 4.70 mg/g. The changes in saponin content in notoginseng (Fig. 2) were the same as those in American ginseng berry (Wang, Zhang et al., 2006); total saponin content was reduced significantly, while Rg3 increased significantly.

Processing red ginseng with heat inactivates catabolic enzymes that deteriorate antioxidant-like substances, which inhibit formation of lipid peroxide (Nam, 2005). Steaming ginseng at temperatures higher than 100 °C enhanced biological activity (Kim et al., 2000). In our study total saponin content decreased at 120 °C, but ginsenoside Rg3, a recognised active anticancer reagent (Mochizuki et al., 1995), was increased by more than three-fold at 2 h compared to notoginseng root steamed at 100 °C for 2 h. This change shows that the chemical properties of steamed notoginseng root can markedly influence its pharmacological properties.

3.2. Effects of steaming duration on notoginseng root constituents

Typical HPLC chromatograms of notoginseng root steamed at 120 °C for 4 h are shown in Fig. 1C. The content of 13 ginsenosides in steamed notoginseng root is shown in Table 1. Compared to unsteamed notoginseng, in root steamed at 120 °C for 1, 2, 4 and 6 h, the total content of confirmed saponins significantly decreased from 68.70 to 43.74, 35.56, 32.07 and 32.78 mg/g, respectively. After steaming for 4 h, total saponin content was not shown to be significantly different, but notoginseng R1 and ginsenosides Rg1, Re, Rb1, R3, Rb2, Rb3 and Rd decreased during the steaming process. After 4 h of steaming, R1, Re, Rc, Rb2, Rb3 and Rd, were difficult to detect in the chromatogram (Table 1). On the other hand, ginsenoside Rg3, which is a trace saponin in unsteamed notoginseng root, significantly increased during the steaming process (Fig. 1C). The peak areas of four ginsenosides, Rh1, Rg2, 20*R*-Rg2, and Rh2, and two other peaks that could not be identified for lack

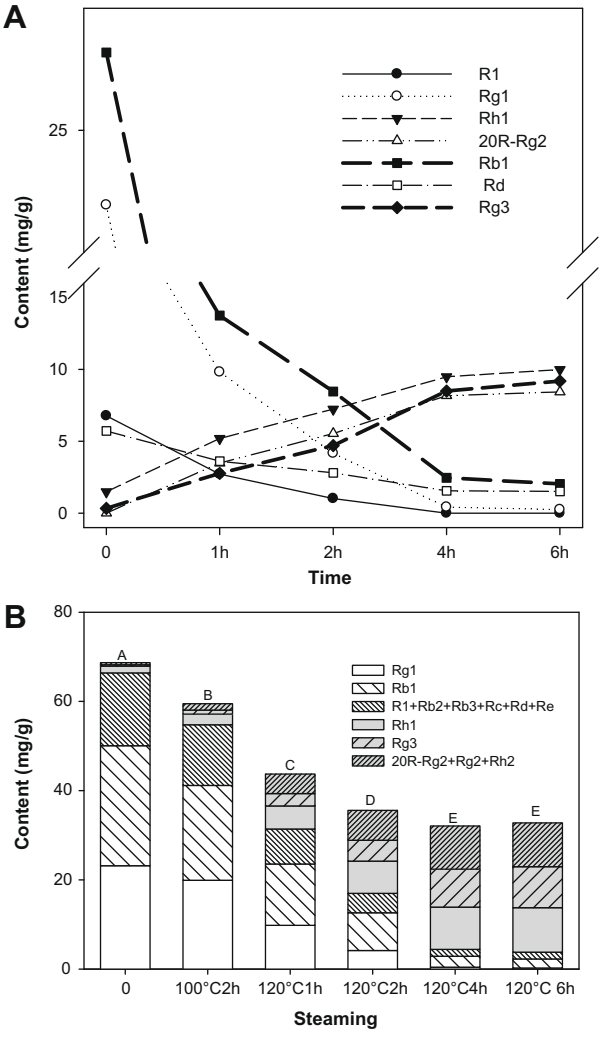

Fig. 2. Saponin content in steaming notoginseng root. The content of (A) typical ginsenosides was changed during the steaming at 120 °C: notoginsenoside R1, ginsenoside Re, Rc, Rb2 and Rb3 disappear as steaming time increases, ginsenosides 20*R*-Rg2, Rh1, and Rg3 significantly increase; and (B) the total ginsenoside content also was changed and with a significant difference between unsteaming and steaming at 100 °C for 2 h, at 120 °C for 1, 2, 4 and 6 h (not between steaming at 120 °C for 4 and 6 h) by multiple comparison [using analysis of least significant difference (LSD) and shortest significant ranges (SSR)].

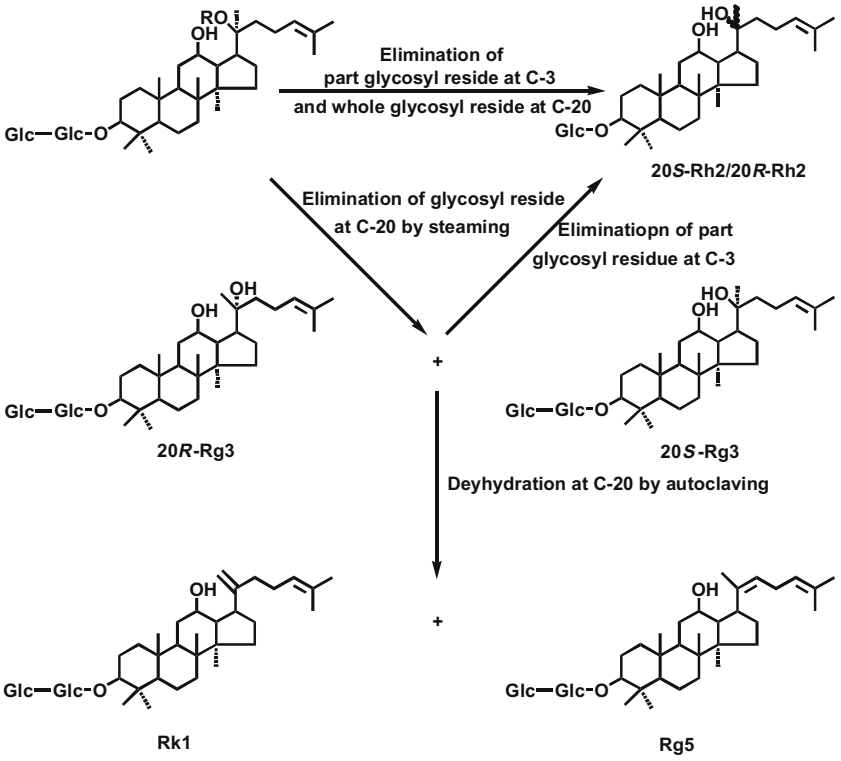

Fig. 3. Proposed saponin transformation in notoginseng root after steaming.

of standards were significantly increased. These two unidentified peaks may be derivates of ginsenoside Rg3, and based on their chromatographic pattern and previous isolation from steamed notoginseng, could be ginsenosides Rk1 and Rg5 (Fig. 3) (Lau, Seo, Woo, & Koh, 2004; Liao, Wang, Zhang, & Yang, 2008).

In some experiments Rk1 (Park et al., 2002) and Rg5 (Park et al., 2002; Yun, 2003) had more anticancer activity than did Rg3. Yun (2003) indicated that Asian ginseng may be a non-organ-specific cancer-preventive agent and the effect of *P. ginseng* could be attributed to ginsenosides Rg3, Rg5 and Rh2. In an MTT assay using SK-Hep-1 hepatoma cancer cells, the GI_{50} (the concentration that inhibits growth by 50%) of Rk1 and Rg5 was 11 and 13 μg/mL, respectively, lower than that of 41 μg/mL for Rg3.

The identity of the confirmed saponins following heating is shown in Fig. 2A. Ginsenoside Rb1 (26.91 mg/g) and Rg1 (23.17 mg/g), the main constituents in notoginseng root, were influenced significantly by steaming temperature and duration. After steaming at 120 °C for 1 h, Rb1 and Rg1 decreased 51.1% and 41.4%, respectively; after 6 h they decreased from 13.75 and 9.8 mg/g to 2.02 and 0.24 mg/g, respectively. Notoginsenoside R1, ginsenoside Rd and Re also decreased with time during steaming (Fig. 2A). Compared to the unsteamed root containing 6.78 mg/g of R1, steaming from 1 to 4 h decreased its content from 2.71 mg/g to undetectable; Rd was decreased from 5.71 mg/g in unsteamed root to 3.6 mg/g after steaming for 1 h and to 1.5 mg/g after 6 h; Re changed from 3.29 mg/g in the unsteamed root to 1.26 mg/g after steaming for 1 h and to undetectable after 4 h (Table 1 and Fig. 2A).

The levels of ginsenosides Rh1, 20*R*-Rg2, and Rg3, on the other hand, significantly increased during the steaming process (Fig. 2A). Rh1 increased from 1.49 mg/g in unsteamed notoginseng root to 5.19 mg/g after steaming for 1 h and to 9.99 mg/g after 6 h; 20*R*-Rg2 was undetectable in unsteamed root and after 1 h steaming was increased to 3.48 mg/g, and after 6 h to 8.43 mg/g; Rg3 increased from 0.33 mg/g to 2.77 and 9.19 mg/g, respectively. Steaming duration changed total saponin content from 49.1% in

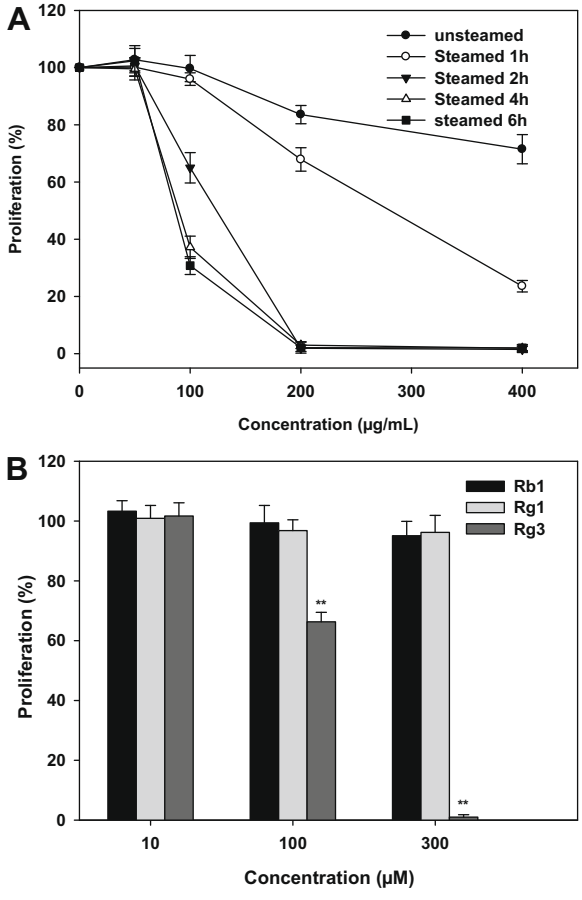

Fig. 4. Percentage of proliferation of SW-480 human colorectal cells treated for 48 h with (A) extract of unsteamed notoginseng or notoginseng steamed for 1–6 h, and (B) three ginsenosides. Statistical significance (**) was set at $p < 0.01$.

notoginseng root after steaming for 2 h, to 81.5% after 4 h, and to 84.2% after 6 h. The differences were not significant when steaming duration was longer than 4 h.

Ginsenoside Rg3 has been found to inhibit the growth of tumour cells (Mochizuki et al., 1995). Rg3 can be obtained via biological transformation or chemical synthesis (Bae et al., 2004), but the process is complicated and the yield is limited. The chemical structure of ginsenoside Rg3 is (3β,12β)-12,20-dihydroxydammar-24-en-3-yl 2-*O*-β-D-glucopyranosyl-β-D-glucopyranoside, and it may be naturally derived from other ginsenosides that are glycosylated at C-20 (S) as shown in Fig. 3. Shibata, Ando, and Tanaka (1966) obtained Rg3 following mild acidic hydrolysis of ginsenosides Rb1, Rb2 and Rc, and it can be isolated from white ginseng (Kaku & Kawashima, 1974) and red ginseng (Kitagawa, Yoshikawa, Yoshihara, Hayashi, & Taniyama, 1983). Rg3 content is lower in white ginseng than in red ginseng, which is produced by steaming at a temperature of 100 °C. When steaming temperature was increased to 120 °C, ginsenoside Rg3 was increased significantly compared to steaming at 100 °C. The result was similar to steaming American ginseng at 120 °C (Wang, Zhang et al., 2006; Wang, Aung et al., 2007), except that the main substrate was slightly different. Ginsenoside Rb1 may be the parent moiety of Rg3 as it is one of the main constituents in notoginseng root with structural similarity.

3.3. Effects of steamed notoginseng root extract on human colorectal cancer cells

The active principal constituents of notoginseng include saponins, polysaccharides, flavonoids, and volatile oils (Wang, McEntee et al., 2006). Investigations of the anticancer activity of notoginseng have focused on the same saponins from red ginseng: ginsenoside Rg3 and Rh2. Extracts from notoginseng root unsteamed or steamed at 100 °C for 2 h or at 120 °C for 1, 2, 4 or 6 h were tested for their effects on SW-480 human colorectal cancer cells (Fig. 4).

SW-480 cells treated for 48 h with an unsteamed, alcohol extract of notoginseng root at concentrations of 50–400 μg/mL showed no significant antiproliferative effects. In notoginseng root steamed for 1, 2, 4 or 6 h, IC_{50} was 259.2, 131.4, 123.7 and 127.1 μg/mL, respectively. Steaming significantly increased the anticancer effect of notoginseng root. At the lower concentration, cell growth was significantly inhibited when steaming lasted for more than 2 h (Fig. 4A).

To confirm the exact constituent responsible for antiproliferation, Rb1 and Rg1, major constituents in unsteamed notoginseng root, and Rg3, a major constituent in steamed notoginseng root, were tested for antiproliferative effects on human colon cancer cells. At concentration of 300 μM, Rb1 and Rg1 inhibited proliferation by <5%, whereas the same concentration of Rg3 inhibited proliferation by approximately 99% antiproliferative effect on SW-480 cells.

Whereas unsteamed root contained approximately 0.33 mg/g ginsenoside Rg3, when steamed for 6 h, the Rg3 content was 9.19 mg/g and produced maximum inhibitory effects on cell proliferation. Steamed notoginseng root may possess other active components besides Rg3 to inhibit the proliferation of SW-480 cells. For example, at a concentration of 100 μM (78.5 μg/mL), ginsenoside Rg3 itself inhibited cell proliferation by 33.7%; however, the extract inhibited cell proliferation by 69.2% at 100 μg/mL (Fig. 4). Further study should examine the potential role of ginsenosides Rk1 and Rg5 in the ability of extract to inhibit cancer cell proliferation.

3.4. Effects of steamed notoginseng root extract on cancer cell apoptosis

Apoptosis is essential in the homeostasis of normal tissues of the body. Apoptosis is a process of programmed cell death

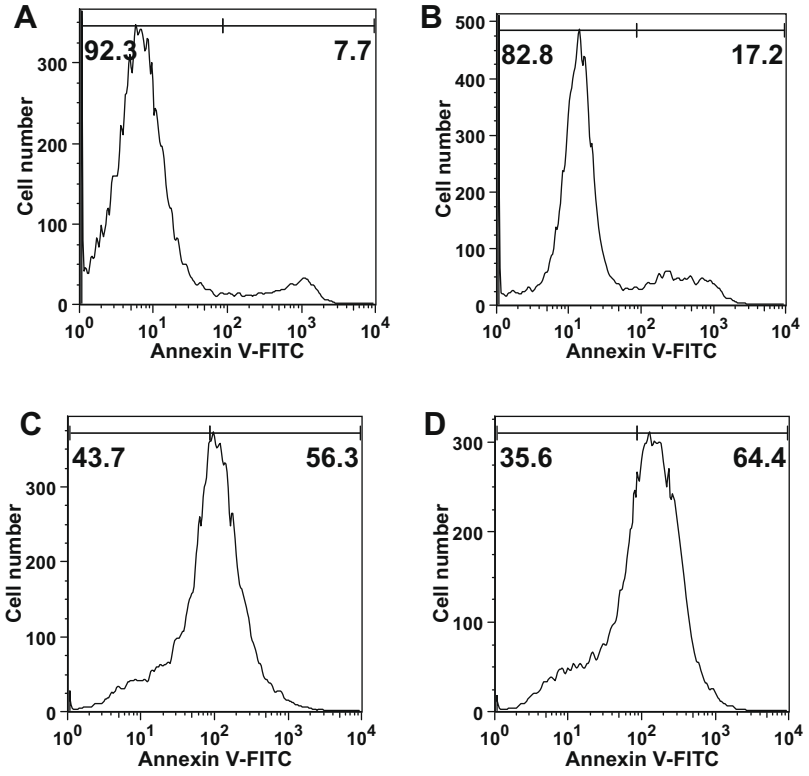

Fig. 5. Apoptotic induction activities of extract from notoginseng root steamed at 120 °C for 6 h on SW-480 human colorectal cells (treated for 48 h). A: unsteamed (control); B: 0.1 mg/mL; C: 0.15 mg/mL; D: 0.2 mg/mL.

through the activation of an intracellular pathway. The pathway produces pathogenomic cellular changes distinct from cellular necrosis. The processes of neoplastic transformation, progression and metastasis alter normal apoptotic pathways. Chemotherapeutic agents exert their cytotoxic activity by indirectly engaging apoptosis. Most chemotherapeutic agents, radiation, immunotherapy, and cytokines induce cancer cell death via the apoptotic pathway (Lowe & Lin, 2000). Compounds found in botanical products such as ginsenosides have been suggested as cancer-preventive agents because of their apoptotic effects (Yun et al., 1983).

In SW-480 cells treated for 48 h with either 0.2 mg/mL of extract from notoginseng root unsteamed and or with 0.10, 0.15 and 0.20 mg/mL of extract from the root steamed for 6 h, cell apoptosis rate was 7.7, 17.2, 56.3 and 64.4%, respectively (Fig. 5). Cells stained with annexin V-FITC dye showed apoptosis mainly in the earlier stage, confirming that decreased cell number may be due to apoptosis and increasing cell death. The exact mechanism still awaits elucidation. The most compelling links between apoptosis and treatment sensitivity in human cancer cells take place with adjuvant chemotherapy. Botanical products boost the immune system to decrease chemotherapy-induced side effects (Wong et al., 2005). American ginseng berry extract has been tested for reduction of gastric side effects induced by cisplatin (Wang, Luo et al., 2007). Anticancer agents induce apoptosis, and disruption of apoptotic programs can reduce treatment sensitivity; anticancer agents with distinct primary targets that induce apoptosis through similar mechanisms and mutations produce multi-drug resistance (Lowe, Ruley, Jacks, & Housman, 1993). Steamed notoginseng extract may become a new adjuvant chemotherapeutic reagent in case of drug resistance.

Induction of apoptosis in SW-480 cells by treatment extract from steamed notoginseng root is similar to results of experiments with steamed American ginseng root or berry (Wang, Zhang et al., 2006; Wang, Aung et al., 2007), but steamed notoginseng root has a higher dose-dependent potency. This difference may be the result of the higher accumulations of various compounds or of different ratios of ginsenoside derivatives with higher bioactivities from processing. Derivates of ginsenoside Rg3 have shown potential for inhibition of cancer cells (Bae, Han, Choo, Park, & Kim, 2002) or for hydroxyl radical scavenging activity (Kang et al., 2007). The relationship between transformation and activities of saponins needs further investigation.

In this study, the equivalent concentration of ginsenoside Rg3 presented lower inhibition *in vitro* than notoginseng root extract at lower dosage. In our previous reports, notoginseng root extract enhanced the actions of two chemotherapeutic agents, 5-fluorouracil and irinotecan on HCT-116 human colorectal cancer cells and may decrease the dosage of 5-FU needed for colorectal cancer treatment (Wang, Luo et al., 2007). Whether the saponins themselves in steamed notoginseng root convey a mutual additive or synergistic effect is not known.

4. Conclusions

There was a significant difference in ginsenoside content after steaming notoginseng root. No differences were observed in total ginsenoside content and antiproliferative effect between steaming treatment for 4 h and 6 h. After steaming, ginsenoside Rg3 content increased significantly, an increase that was partially responsible for the increase in anticancer activity. On the other hand, ginsenoside Rh2 content was increased only slightly by steaming. Thus, some other active anticancer components, in addition to Rg3 and Rh2, may form in notoginseng root extract after the steaming process.

Inducible nitric oxide synthase
Cyclooxygenase-2

ABSTRACT

Inflammation can cause various physical dysfunctions. *Punica granatum* Linne (pomegranate), a high phenolic content fruit, is widely used as an antipyretic analgesic in Chinese culture. Pomegranate has shown potential nitric oxide (NO) inhibition in LPS-induced RAW 264.7 macrophage cells. Moreover, pomegranate (100 mg/kg) significantly decreased carrageenan-induced mice paw edema for 1, 3, 4, and 5 h. Therefore, column chromatography combined with *in vitro* bioassay-guided fractionation was used to isolate the active anti-inflammatory components from the pomegranate. Punicalagin (**1**), punicalin (**2**), strictinin A (**3**), and granatin B (**4**) were obtained with yields of 0.093%, 0.015%, 0.003%, and 0.013%, respectively. All these hydrolysable tannins inhibited NO production and iNOS expression in RAW 264.7 cells. Among them, **4** showed the strongest iNOS and COX-2 inhibitory effects, and exhibited these effects in the inhibition of paw swelling and the PGE_2 level in carrageenan-induced mice. Taken together, we suggest that **4** could be used as a standard marker for the anti-inflammatory effect of pomegranate.

1. Introduction

Punica granatum Linne, pomegranate (Punicaceae), a common fruit in the Mediterranean and Iran, is widely used for therapeutic formulae, cosmetics, and food seasoning. Pomegranate, also easily acquired from traditional medicine markets, was usually used as an astringent agent (Alper & Acar, 2004), for eliminating parasites (Mudzhiri, 1954; Raj, 1975) and as an antipyretic. The pharmacological functions of pomegranate include antioxidation (Lansky & Newman, 2007), anti-tumour (Khan, Afaq, Kweon, Kim, & Mukhtar, 2007; Lansky & Newman, 2007), anti-hepatotoxicity (Kaur, Jabbar, Athar, & Alam, 2006), anti-lipoperoxidation (Reddy, Gupta, Jacob, Khan, & Ferreira, 2007) and anti-bacteria properties (Menezes, Cordeiro, & Viana, 2006). In hematology, pomegranate could reduce the common carotid intima-medium thickness, thus lowering blood pressure and decreasing low-density lipoprotein (LDL) oxidation and the incidence of heart disease (Aviram et al., 2002, 2004). In our previous studies, we found that extract from the dried peel of the pomegranate could significantly inhibit NO production. Hence, we suggested pomegranate contains the anti-inflammatory activity components.

In the last few years, many important functions of fresh fruits and vegetables have been reported, and they are now recognised as being good sources of natural antioxidants (Joseph, Shukitt-Hale, & Lau, 2007), such as grapes, apples, and guavas. The antioxidants can prevent lipid peroxidation, and DNA and protein damage. Polyphenols have been acknowledged to have health-beneficial effects, owing to derived products such as flavonoids, tannins, coumarins, and lignans. According to recent reports, the pomegranate is rich in polyphenols, including mainly ellagitannins, gallotannins (punicalin, punicalagin, pedunculagin, punigluconin, granatin B, and tellimagrandin I) (Satomi et al., 1993) and anthocyanins (delphinidin, cyanidine and pelargonidin) (Noda, Kaneyuki, Mori, & Packer, 2002). However, the correlation between the phytochemicals and the anti-inflammatory properties of the dried peel of the pomegranate has not been investigated. Therefore, this study aimed to clarify the anti-inflammatory activities of pomegranate and its active components.

Inflammation, the first physiological defense system in the human body, can protect against injuries caused by physical wounds, poisons, etc. This defense system, also called short-term inflammation, can destroy infectious microorganisms, eliminate irritants, and maintain normal physiological functions. However, long-term over-inflammation might cause dysfunctions of the regular physiology, i.e., asthma and rheumatic arthritis.

We used *in vitro* and *in vivo* models to confirm the anti-inflammatory activity of pomegranate. Lipopolysaccharide (LPS)-induced RAW 264.7 murine macrophages were used in the *in vitro* study, and carrageenan-induced paw edema in mice served as the *in vivo* study. LPS can induce several cytokines, such as prostaglandins and nitric oxide (NO), which are involved in pro-inflammatory processes. NO can kill bacteria and viruses and is also an important

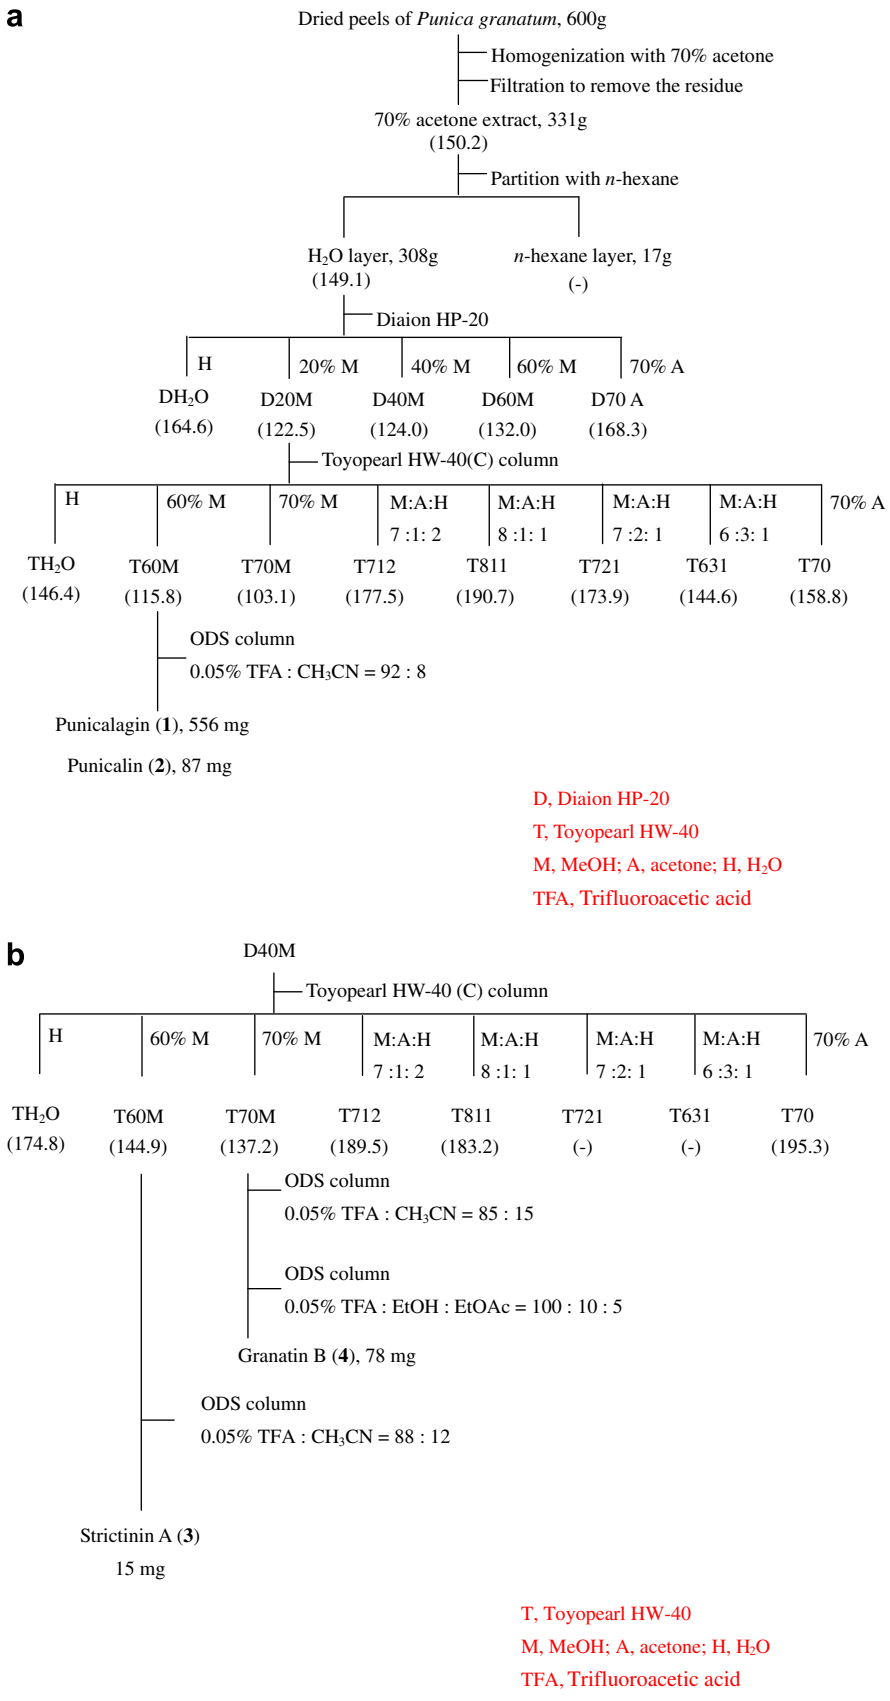

Fig. 1. Isolation flowchart of *Punica granatum* L. using anti-inflammation bioassay-guided fractionation. Numbers in the parentheses were the IC_{50} values (μg/ml) of NO inhibition. All test fractions displayed less than 10% cytotoxicity at 200 μg/ml, except D20M, D40M, D20M –TH_2O, and D20M – T60M. The IC_{50} values of the test sample exceeded 200 μg/ml.

mediator of vasodilatation; but too much NO might cause hypotension or septicemia (Moncada & Higgs, 2006). Prostaglandins have many physiological activities, such as inducing inflammation. Many tissues acutely or chronically generate excess NO and prostaglandin E_2 (PGE_2) by the overexpression of inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2) in the presence of various inflammatory stimulators. RAW 264.7 cells induced by LPS can produce the overexpression of NO and PGE_2, and their regulatory proteins, iNOS and COX-2. Therefore, we used this strategy, combined with chromatography, to isolate the active components, and we used carrageenan-induced paw edema in mice to confirm the *in vivo* anti-inflammatory effects of pomegranate.

2. Materials and methods

2.1. Chemicals

Dimethyl sulphoxide (DMSO), lipopolysaccharide (LPS), 3-(4.5-dimethylthiazol -2-yl) 2.5-diphenyltetrazolium bromide (MTT), indomethacin, *N*-nitro-L-arginine methyl ester (L-NAME), and the other chemicals were purchased from Sigma Industries (St. Louis, MO, USA). Dubecco's modified Eagle medium (DMEM), fetal bovine serum (FBS), antibiotics, and glutamine were purchased from GIBCO BRL (Grand Island, NY, USA). Diaion HP-20 gels were bought from Mitsubishi Chemical Industry (Tokyo, Japan). Western blotting was performed using an antibody specific to mouse. iNOS (sc-650), anti-COX-2 (sc-1745), and anti-GAPDH (sc-32233) were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA).

2.2. Sample preparation

Test solutions of pomegranate were prepared by dissolving pomegranate in 10% DMSO, which was then stored at 4 °C and used within 1 month. Serial dilutions of test solutions with culture medium were prepared before the *in vitro* assays.

2.3. Determination of total phenols

The total phenol content was determined by the Folin-Ciocalteu method. Pomegranate extract was dissolved in distilled water and mixed with the Folin-Ciocalteu reagent and 7.5% aqueous Na_2CO_3 solution. After standing for 5 min at 50 °C, the absorbance was measured at 600 nm in an ELISA reader. The amount of total phenol was expressed as gallic acid equivalents (GAE, μg gallic acid/mg sample) through the calibration curve of gallic acid. The calibration curve ranged from 7.8 to 250 μg/ml (R^2 = 1) (Dudonné, Vitrac, Coutière, Woillez, & Mérillon, 2009).

2.4. Determination of the total flavones content

The total flavanol content was determined by the vanillin assay. Vanillin was dissolved in 80% H_2SO_4 to prepare the vanillin reagent. Pomegranate extract was dissolved in the distilled water and mixed with the vanillin reagent. After standing for 15 min at room temperature, the absorbance was measured at 530 nm in an ELISA reader. The amount of total flavanol was expressed as catechin equivalents (CE, μg catechin/mg sample) through the calibration curve of catechin. The calibration curve ranged from 7.8 to 250 μg/ml (R^2 = 1) (He, Liu, & Liu, 2008).

2.5. Determination of NO produced from LPS-induced RAW 264.7 cells

RAW 264.7 cells, a murine macrophage cell line, was obtained from American Type Cell Culture (ATCC no. TIB-71; Rockville, MD, USA). Cells were cultured in DMEM supplemented with 10% FBS, 1% L-glutamine, and 1% penicillin-streptomycin, and maintained at 37 °C and 5% CO_2. RAW 264.7 cells (4.0×10^5 cells/ml) were seeded in 96-well plates and then co-treated with LPS (500 ng/ml) and the test samples. After 18 h, the NO production was determined by mixing the culture supernatant with Griess reagent, and the absorption was detected in an ELISA reader at 530 nm. Anti-inflammatory activity was presented in terms of the NO production inhibition percentage. The viability of RAW 264.7 cells was detected by the MTT assay (Tseng, Lee, Chen, Wu, & Wang, 2006).

2.6. Isolation of polyphenols from P. granatum

Dried pomegranate peels (600 g) were purchased from a traditional Chinese medicine store in Taipei, pulverised and filtered through a 20# mesh. Pulverised peels were then homogenised with 70% aqueous acetone (3 L × 4) and the homogenate was then filtered. The filtrate was concentrated by evaporation under reduced pressure (*ca.* 40 °C) and further freeze-dried to yield the 70% acetone extract (330 g, yield 55%). The 70% acetone extract was dissolved in water and then partitioned with *n*-hexane to remove the non-polar compounds. The aqueous layer was chromatographed over a Diaion HP-20 gel column (9.5 × 40 cm) with stepwise aqueous MeOH ($H_2O \rightarrow 20\%$ MeOH → 40% MeOH → 60% MeOH → 70% acetone). Column chromatography was combined with an NO inhibition assay to clarify the bioactive fractions. We found that the 20% MeOH (D20M) and 40% MeOH (D40M) fractions of the Diaion column exhibited greater NO inhibition. Furthermore, the D20M fraction was chromatographed on a Toyopearl HW-40 (C) (Tosoh Bioscience, Montgomeryville, PA, USA) gel column (2.5 × 40 cm) and eluted stepwise with $H_2O \rightarrow 70\%$ MeOH → MeOH–acetone–H_2O (8:1:1, v/v/v) → MeOH–acetone–H_2O (7:2:1, v/v/v) → MeOH–acetone–H_2O (6:3:1, v/v/v) → 70% acetone. The 70% MeOH (D20M –T70M) eluate was applied to an ODS column (0.05% trifluoroacetic acid:CH_3CN, 92:8) and HLB® extraction cartridges (Waters, Milford, MA, USA) to yield punicalagin (556 mg, **1**) and punicalin (87 mg, **2**). The D40M fraction was chromatographed on a Toyopearl HW-40 (C) gel column (2.5 × 40 cm) and eluted stepwise with $H_2O \rightarrow 70\%$ MeOH → MeOH–acetone–H_2O (8:1:1, v/v/v) → MeOH–acetone–H_2O (7:2:1, v/v/v) → MeOH–acetone–H_2O (6:3:1, v/v/v) → 70% acetone. The 60% MeOH eluate (D40M –T60M) was purified on an ODS column with 0.05% trifluoroacetic acid–CH_3CN (88:12) to obtained 15 mg of strictinin A (**3**). The

Compound	LPS-induced RAW 264.7 macrophage cells			Free radical-scavenging activity
	NO inhibition[a]	iNOS activity[b,c]		$ONOO^-$ scavenging[c]
	IC_{50} values (mM)	NO inhibition (%)	Cytotoxicity (%)	SNP clearance (%)
1	69.8	15.7 ± 0.4	35.5 ± 0.7	24.7 ± 6.4
2	78.6	46.7 ± 7.0	67.6 ± 1.4	30.7 ± 1.0
3	63.1	25.4 ± 2.4	45.8 ± 1.1	32.3 ± 0.0
4	33.6	14.8 ± 1.0	41.7 ± 0.7	29.5 ± 0.7
L-NAME[d]	–	46.4 ± 2.9	7.5 ± 1.6	–

Results are expressed as the mean ± SD of three experiments.
[a] Co-treatment of LPS and each test compound for 18 h and no cytotoxicites were found in these IC_{50} values.
[b] RAW 264.7 cells were stimulated with 1 μg/ml LPS and incubated overnight.
[c] Each test compound was 100 μM.
[d] L-NAME was used as positive control and its concentration was 400 μM.

70% MeOH eluate (D40M – T70M) was purified on an ODS column with 0.05% trifluoroacetic acid–CH_3CN (85:15) and 0.05% trifluoroacetic acid–EtOH–EtOAc (100:10:5, v/v/v) to obtain 78 mg of granatin B (**4**) (Fig. 1). The structures of these four compounds were identified by nuclear magnetic resonance and the purity of each compound (>99.0%) was confirmed by high-performance liquid chromatography. The formulae and molecular weights of punicalagin (**1**), punicalin (**2**), strictinin A (**3**), and granatin B (**4**) are $C_{43}H_{28}O_{30}$ (MW 1048.7), $C_{34}H_{22}O_{22}$ (MW 782.53), $C_{43}H_{28}O_{30}$ (MW 634.46), and $C_{41}H_{28}O_{27}$ (MW 952.66), respectively.

2.7. Determination of NO radical-scavenging activity

Sodium nitroprusside (SNP) is a stable NO donor. We used SNP as an NO donor to evaluate the direct NO radical clearance of samples. The SNP solution was prepared with H_2O. Test solution was added to the sample volume of SNP solution (50 mM). The mixture was incubated at 37 °C, for 5 h. Then, we took the supernatant (1, mixed it with the Griess reagent, and read the absorption on an ELISA reader at 530 nm (Bor, Chen, & Yen, 2006).

2.8. iNOS activity assay in LPS-induced RAW 264.7 cells

Initially, RAW 264.7 cells were pre-stimulated by 1 μg/ml LPS for 24 h to activate the iNOS. Then, cells were collected and washed twice with PBS to remove the excessive LPS, and the activated RAW 264.7 cells (4.0×10^5 cell/ml) were seeded in 96-well plates. Crude extract and active components were immediately added to the cells. The 96-well plate was incubated at 37 °C overnight. The NO detecting method was the same as previously described. We used *N*-nitrol-arginine methyl ester (L-NAME, 400 μM), a specific inhibitor of NO synthase enzyme, and as the positive control.

2.9. iNOS and COX-2 expression assay in LPS-induced RAW 264.7 cells

Total cellular protein was extracted with a RIPA solution (radioimmuno-precipitation assay buffer) at −20 °C overnight. We used BSA (bovine serum albumin) as a protein standard to calculate equal total cellular protein amounts. Protein samples (15 μg) were resolved by denaturing sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) using standard methods, and then were transferred to nitrocellulose (Hybond-PVDF) membranes by electroblotting and blocking with 1% BSA. The membranes were probed with the primary antibodies (iNOS, COX-2 and GAPDH) at 4 °C overnight, washed three times with PBST, and incubated for 1 h at 37 °C with alkaline phosphatase-conjugated secondary antibodies. Then, we used an NBT/BCIP commercial kit (Gibco) as the visualising agent. The intensity of the bands was quantified by computer-assisted image analysis using AlphaInnotech Digital Imaging Systems. Western blotting results are representative of three independent experiments for every data point.

2.10. Model of 1% carrageenan-induced paw edema in ICR mice

Male ICR mice weighing 25 ± 2 g were bought from the National Science Council, Taipei, Taiwan, and maintained at 21 ± 2 °C with food and water *ad libitum*. They were kept on a 12-h light/12-h dark cycle. All mice used in this experiment were cared for according to

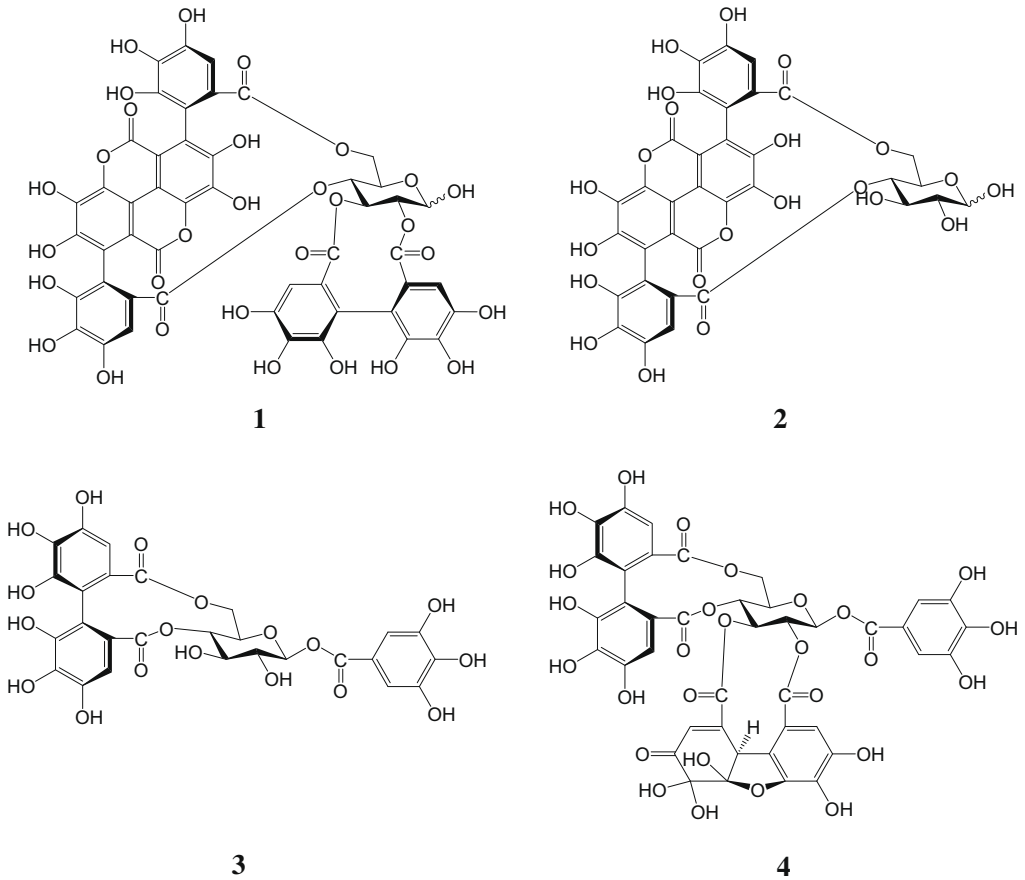

Fig. 2. Structures of the four hydrolysable tannins, punicalagin (**1**), punicalin (**2**), strictinin A (**3**), and granatin B (**4**), isolated from *Punica granatum* L.

the Ethical Regulations on Animal Research of our university. Edema in the left hind paw of the mice was induced by injecting 50 μl of 1% (w/v) carrageenan into the subplantar region. The perimeter of the paw was measured 1 h before the carrageenan injection and after 1–6 h, using calipers. One hour before the injection, the pomegranate (100 mg/kg), the active component (2.5 and 10 mg/kg), and indomethacin (10 mg/kg, as a positive control) were given orally, while the control group was given distilled water. The blank group was injected with normal saline and given distilled water. Each group consisted of five animals. After 6 h, mice were sacrificed and the serum collected for the PGE_2 measurement (Tseng et al., 2006).

2.11. Measurement of PGE_2 production

Serum and cell culture mediums were determined the PGE_2 concentrations by the PGE_2 ELISA kit (Amersham Pharmacia Biotech, Buckinghamshire, UK).

2.12. Statistical analysis

The data are presented as mean and standard deviation (SD). Significance was calculated using the Student's *t*-test. Differences were considered significant for $p < 0.05$.

3. Results

3.1. Polyphenols isolation from P. granatum L.

The phytochemical components of the 70% acetone extract of pomegranate peels were screened using the Folin-Ciocalteu method and vanillin assay. The screening found that pomegranate was rich in total phenol and flavanol (471.0 ± 32.0 μg gallic acid equivalent/mg in total phenol and 257.0 ± 19.6 μg catechin equivalent/mg in total flavanol).

The NO inhibition bioassay-guided fractionation flowchart of pomegranate is shown in Fig. 1. These four hydrolysable tannins, punicalagin (**1**), punicalin (**2**), strictinin A (**3**), and granatin B (**4**), were isolated from D20M and D40M of the pomegranate fractions, with stronger inhibition of NO production; the yields were 0.093%, 0.015%, 0.003% and 0.01%, respectively.

3.2. NO inhibitory effects of four hydrolysable tannins

The NO inhibitory effects of **1**–**4** were measured in LPS-induced RAW 264.7 cells for 18 h. We collected the culture medium to detect the NO levels using the Griess reaction. Compounds **1**–**4** showed less than 10% cytotoxicities in LPS-induced RAW 264.7 cells for 18 h. Compound **4** displayed a more potent NO inhibition

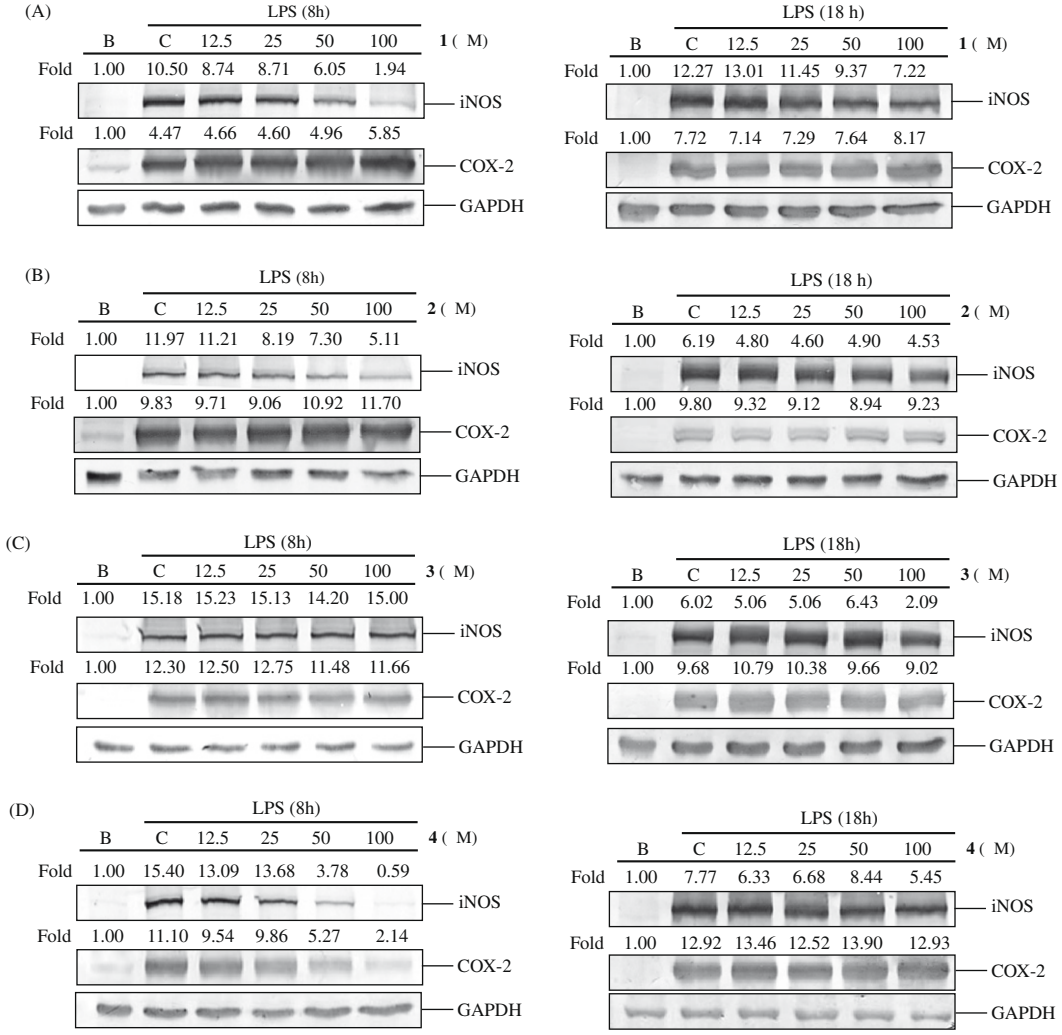

Fig. 3. Inducible NOS and COX-2 expression of punicalagin (A), punicalin (B), strictinin A (C) and granatin B (D) induced by LPS (500 ng/ml) in RAW 264.7 cells for 8 and 18 h. (B) Non-LPS-induced group. (C) Solvent control group (H_2O). GAPDH was used as an internal control to identify equal amounts of protein loading in each lane. The intensity of the iNOS and COX-2 protein was examined by densitometrus analysis, and expressed as the ratio of iNOS/GAPDH and COX-2/GAPDH. Data from three separate experiments were used, and the picture for one of which is shown.

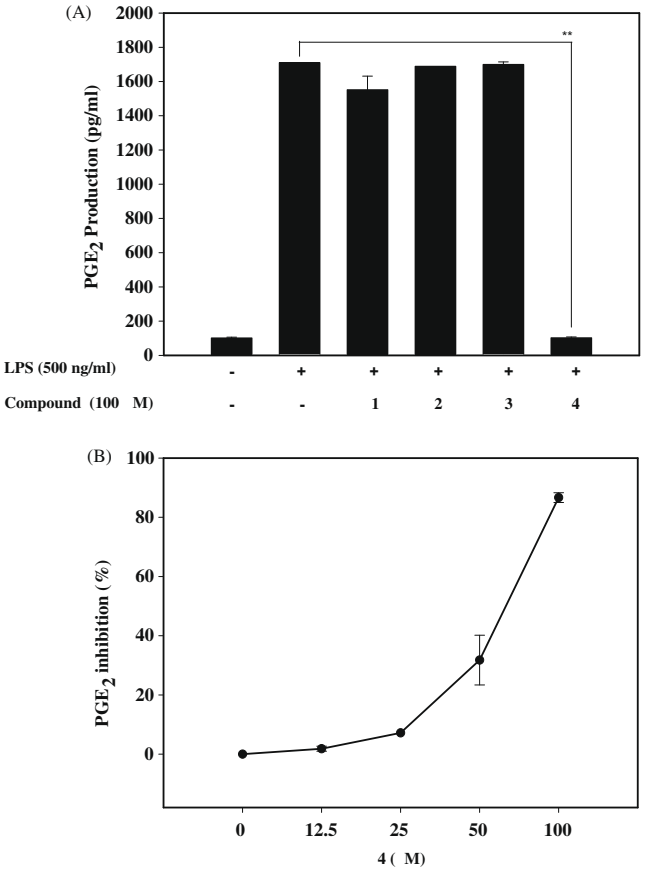

Fig. 4. Prostaglandin E_2 production of **1**–**4** (A) and a series dose–response curve of **4** (B) induced by LPS-induced RAW 264.7 cells for 8 h. $^{**}p < 0.001$. $n = 3$ All data were expressed as the mean ± SD.

in LPS-induced RAW 264.7 cells for 18 h than did the others, and its IC_{50} value was 33.6 μM (Table 1).

Nevertheless, we would like to clarify whether these hydrolysable tannins had NO radical-scavenging activity or not. SNP was used as an NO radical donor to evaluate the NO-scavenging activity of these four hydrolysable tannins. As shown in Table 1, the four hydrolysable tannins did not significantly exhibit SNP clearance at 100 μM.

3.3. iNOS expression and activities of four hydrolysable tannins in LPS-induced RAW 264.7 cells

Based on the above data, we suggest that the NO inhibition effects of the four hydrolysable tannins could be brought about through the influence of iNOS protein expression or activity. The iNOS protein expression in LPS-induced RAW 264.7 cells for 8 and 18 h were observed by Western blot assay. As shown in Fig. 3, the four hydrolysable tannins displayed dose-dependently inhibitory effects on the iNOS expression at 12.5–100 μM. In addition, the 8 h group expressed more significantly iNOS inhibitory effects than the 18 h group. Therefore, these four hydrolysable tannins could decrease the iNOS protein expressions from the early stage (8 h) to the late stage (18 h). Taken together, **1**–**4** significantly decreased the iNOS expressions in LPS-induced RAW 264.7 cells, and **4** was the strongest among them.

On the other hand, RAW 264.7 cells were pretreated with LPS for 24 h to observe the iNOS activity inhibition of these four hydrolysable tannins. As seen in Table 1, L-NAME acted as a positive control and displayed significant iNOS activity inhibition at 400 μM. However, these four hydrolysable tannins had no iNOS activity inhibitory effects and even exhibited cytotoxicity at 100 μM. Hence, these four hydrolysable tannins inhibited NO production through directly decreasing the iNOS protein expressions.

3.4. COX_2 and PGE_2 inhibitory effects of four hydrolysable tannins

The COX-2 and PGE_2 inhibitory effects of these four hydrolysable tannins were evaluated in LPS-induced RAW 264.7 cells for 8 and 18 h. As shown in Fig. 3, Compound **4** inhibited COX-2 protein expression in dose-dependent (Fig. 3) and PGE_2 productions (Fig. 4A) more significantly than the others after treatment with LPS for 8 h. Moreover, **4** inhibited PGE_2 productions in a dose-dependent manner, and the IC_{50} value was 66.22 ± 9.4 μM (Fig. 4D). However, COX-2 protein expression of LPS-induced RAW 264.7 cells was not inhibited after treatment with the four hydrolysable tannins for 18 h (Fig. 3). Hence, we suggested that **4** could inhibit COX-2 and PGE_2 production in the early stage (8 h) because there was less COX-2 expression at that stage, but in the late stage (18 h), COX-2 expression reached a stable state, so **4** had difficulty inhibiting its expression.

3.5. Inhibitory effect of pomegranate and 4 on carrageenan-induced paw edema in ICR mice

Carrageenan-induced paw edema in ICR mice was used to evaluate the *in vivo* anti-inflammatory model. We used indomethacin, a common non-steroidal anti-inflammatory drug (NSAID) as a positive control. Mice were treated with pomegranate (100 mg/kg) or indomethacin (10 mg/kg) 1 h before carrageenan induction, and had detected paw edema for 6 h. Results showed that carrageenan significantly induced paw edema during the entire experiment in the control group (Table 2). Pomegranate significantly reduced paw edema by more than 50% at 1–5 h after the carrageenan injection, and had even greater potential paw edema inhibitory effects than indomethacin.

Table 2
Effects of pomegranate and granatin B on the paw perimeter of carrageenan-induced mice paw edema.

Group	Time after injection of carrageenan (h)					
	1	2	3	4	5	6
Control	1.74 ± 0.30	1.41 ± 0.17	1.41 ± 0.23	1.21 ± 0.13	0.92 ± 0.16	0.88 ± 0.08
Indomethacin (10 mg/kg)	0.70 ± 0.35*	0.90 ± 0.34*	0.79 ± 0.33*	0.72 ± 0.15*	0.75 ± 0.09*	0.62 ± 0.19*
Pomegranate (100 mg/kg)	0.86 ± 0.10*	0.60 ± 0.07**	0.59 ± 0.28*	0.42 ± 0.30*	0.4 ± 0.36*	0.34 ± 0.50
*Granatin B (**4**)*						
2.5 mg/kg	1.08 ± 0.13*	0.84 ± 0.20*	0.77 ± 0.07**	0.75 ± 0.17*	0.63 ± 0.03*	0.59 ± 0.15*
10.0 mg/kg	0.98 ± 0.40*	0.89 ± 0.19*	0.68 ± 0.29*	0.50 ± 0.41*	0.23 ± 0.52*	0.48 ± 0.26*

Values were presented as the mean ± SD of the increasing mice paw edema (mm) of four animals for each group.
* $p < 0.05$.
** $p < 0.001$ were presented as significantly different from the control.

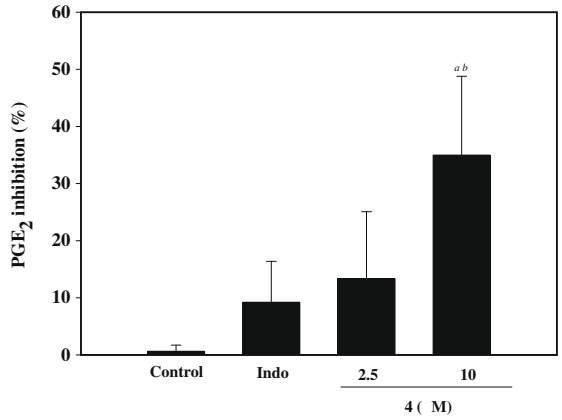

Fig. 5. Prostaglandin E_2 concentrations of **4** on carrageenan-induced mice paw edema for 6 h. Indomethacin served as a positive control and 10 mg/kg dosage used. [a]$p < 0.01$. The p value was calculated by comparison with the control group. [b]$p < 0.05$. The p value was calculated by comparison with the indomethacin group ($n = 3$). All data were expressed as mean ± SD.

Since **4** showed the strongest COX-2 and iNOS inhibitory effects in the *in vitro* study, we examined the *in vivo* anti-inflammatory effect of **4**. We found that **4** (2.5 and 10 mg/kg) could significantly and dose-dependently reduce paw edema, and the inhibitory abilities of the higher dose (10 mg/kg) were the same as that of the indomethacin (Table 2). In addition, **4** had more significant PGE_2 inhibitory effects than the indomethacin at 6 h (Fig. 5).

4. Discussion

Pomegranate has been used for centuries as a therapeutic agent for the treatment of inflammatory diseases. According to current reports, pomegranate is a polyphenol-rich fruit, and showed potential as an anti-inflammatory, anti-oxidative and anti-cancer agent in several experimental models (Shukla, Gupta, Rasheed, Khan, & Haqqi, 2008). Chemical analyses have also shown that the phenol compounds of pomegranate contain significantly high levels of hydrolysable tannins, such as punicalin, punicalagin, pedunculagin, punigluconin (Dudonné et al., 2009). Therefore, we used an NO inhibition assay combined with column chromatography to determine which components in pomegranate would have effective anti-inflammatory activity. In this paper, four hydrolysable tannins, punicalagin (**1**), punicalin (**2**), strictinin A (**3**), and granatin B (**4**), were isolated from pomegranate by bioassay-guided fractionation. Each of them displayed a dose-dependently and significantly inhibitory effect on NO production in LPS-induced RAW 264.7 cells (Table 1). Furthermore, granatin B (**4**) more strongly inhibited PGE_2 production and COX-2 expression in LPS-induced RAW 264.7 cells than the others.

Structure–activity relationships (SAR) of natural products have been found to influence the various pharmacological functions, such as antioxidant and anti-inflammation activities. Up to the present, over 3000 kinds of tannins have been identified, chiefly as secondary metabolites in green plants. Tannin is involved in a large proportion of phenolic derivatives in plants and is divided into two types: hydrolysable and condensed tannins. Many possible permutations are offered by substitution and conjugation, and this could explain why so many tannin derivatives occur naturally (Fylaktakidou, Hadjipavlou-Litina, Litinas, & Nicolaides, 2004). Based on the structural similarities of these four hydrolysable tannins, we divided them into two groups. One was punicalagin (**1**) and punicalin (**2**) and the other was strictinin A (**3**) and granatin B (**4**) (Fig. 2). Among them, **1** and **2** were previously recognised as inhibitors of the pro-inflammatory for anti-edematogenic activity on carrageenan-induced paw edema in rats (10 mg/kg) (Lin, Hsu, & Lin, 1999). However, there is no scientific evidence that **3** and **4** have anti-inflammatory activities. In this study, we first found that both **3** and **4** had potential NO inhibitory effects in LPS-induced RAW264.7, and that **4** was the better one (Table 1). Moreover, **4** showed the strongest COX-2 and iNOS inhibitory effects in an *in vitro* assay, and significantly reduced paw edema and PGE_2 inhibitory effects in an *in vivo* assay.

Dehydrohexahydroxydiphenoyl (DHHDP), a substitution in C-2 and C-3 of **4**, was the difference between **4** and **3**, and probably played an important role in anti-inflammation. In related investigations, tannins with DHHDP units invariably had strong anti-inflammatory and anti-oxidant activity. (Feldman, 2005) Geraniin, a well-documented hydrolysable tannin, has been reported to have excellent NO radical-scavenging and iNOS inhibitory activities (Kumaran & Karunakaran, 2006). Mallotusinic acid and euphorbin E also had potent scavenging effects on DPPH free radicals. (Okuda, 2005) Hence, we concluded once the hydrolysable tannins had the DHHDP group, they would appear to have better anti-inflammatory activities.

Many studies have demonstrated that the massive production of NO and PGE_2 *via* the pro-inflammatory proteins iNOS and COX-2 played an important physiological role in inflammation. Evidence has shown that NO production was initiated by treating LPS for 8 h and reached a stable state for 18 h, and that COX-2 expression began at 6–8 h and reached the maximal level at 16–24 h. (Caughey, Cleland, Penglis, Gamble, & James, 2001; Reher, Harris, Whiteman, Haiand, & Meghji, 2002). Therefore, we used two treatment times (8 and 18 h) to measure the anti-inflammatory effects of these hydrolysable tannins, because of the different mechanism and production time of these inflammation mediators (COX-2, iNOS, etc.). On the basis of the above results, we found that **4** could significantly decrease NO and PGE_2 production through inhibiting iNOS and COX-2 expression. Little NO production was found in LPS-induced RAW 264.7 for 8 h. NO was released from the process of converting L-arginine to L-citruline by iNOS, while NO was initially produced at 8 h and reached the maximum level at 18 h; therefore, NO production from LPS-induced RAW 264.7 was not detected at 8 h. Unlike NO production, activated COX-2 could convert arachidonic acid to PGE_2 in only 30 min. Hence, the COX-2 and PGE_2 inhibitory effects of **4** from LPS-induced RAW 264.7 at 8 h were stronger than those at 18 h. In summary, we suggest that **4** is an effective anti-inflammatory compound and has dual roles in anti-inflammation, by decreasing PGE_2 production in the early stage and decreasing NO production in the late stage.

In conclusion, **4** not only displayed the best NO inhibitory abilities in LPS-induced RAW 264.7, but also had the strongest PGE_2 inhibitory effects in the *in vitro* and *in vivo* assays. Taken together, **4** could be used as a standard marker compound to determine the potential anti-inflammatory effect of pomegranate.

Phosphorylated starch
Digestibility
Resistant starch
Dietary fibre

ABSTRACT

Phosphorylated wheat starch (PWS) was prepared with sodium trimetaphosphate and sodium tripolyphosphate (99/1, w/w), and the modified starch gave 88.8% total dietary fibre by the Prosky method and 68.7% resistant starch (RS) by the Englyst method. The stability of the phosphate esters in aqueous sodium hydroxide was investigated and related to total dietary fibre and RS contents. The phosphorylated starch was slurried (40%, w/w) at 40 °C for 4 h at pH 9.0, 10.0, 11.0, and 12.0. The phosphorus content of the PWS decreased from 0.37% to 0.29% after treatment at pH 12.0, whereas only a slight decrease in phosphorus content occurred after treatments at pH 9.0–11.0. Despite the 22% decrease in total phosphorus content, total dietary fibre content and RS content of the alkali-treated PWS changed only slightly. ^{31}P nuclear magnetic resonance spectroscopy showed that after the alkali treatment at pH 12.0, cyclic monostarch monophosphate and monostarch diphosphate were not detectable and that the level of total monostarch monophosphate decreased from 0.077% to 0.067%. Conversely, distarch monophosphate increased from 0.17% to 0.20%, of ≈18%. The increase in distarch monophosphate (cross-linking) content after alkali treatment at pH 12.0 probably explained the retention of total dietary fibre and RS contents in the alkali-treated PWS.

1. Introduction

Nutritionally, starches are classified into rapidly digestible starch (RDS), slowly digestible starch (SDS), and resistant starch (RS) on the basis of their digestion rate in humans (Englyst, Kingman, & Cummings, 1992). A low ratio of RDS to the sum of SDS and RS in a starchy food indicates a low glycemic index (Englyst, Englyst, Hudson, Cole, & Cummings, 1999). Foods with a low glycemic index improve satiety (Warren, Henry, & Simonite, 2003) and may help prevent obesity and Type II diabetes (Bjorck, Liljeberg, & Ostman, 2000; Jenkins, Jerkins, Kendall, Augustine, & Vuksan, 2001; Roberts, 2000). RS is desirable for its additional prebiotic effect and can be fermented in the colon to produce short-chain fatty acids, which inhibit the development of colon cancer cells (Brown, McNaught, Andrew, & Morita, 2001; Topping & Clifton, 2001).

Chemical modifications, such as phosphorylation, may be used to change starch functionality and digestibility. Different levels and chemical forms of phosphate esters may give different functionalities to phosphorylated starch. Monostarch phosphate, whose structure is a single phosphate group esterified to a starch hydroxyl, imparts improved appearance, hygroscopicity, solution transparency, swelling, and viscosity at 0.1–0.4% P (Rutenberg & Solarek, 1984; Tomasik & Schilling, 2004). In contrast, distarch phosphate, whose structure is a single phosphate group esterified (cross-linked) to two starch hydroxyls, gives improved thickening properties even at very low levels of phosphorus (<0.04%). Distarch phosphate linkages (cross-links) import paste stability to heat, acid, and shearing (Rutenberg & Solarek, 1984; Tomasik & Schilling, 2004).

Monosubstitution of starch with phosphate groups has been shown to decrease starch digestibility with α-amylase (Janzen, 1969). However, it is the phosphate cross-link that can dramatically decrease starch digestion by α-amylase. A distarch phosphate with a high level of phosphorus content (≈0.4%) is high in RS and total dietary fibre (TDF) content (Woo & Seib, 2002). Distarch monophosphate (DSMP), monostarch monophosphate (MSMP), monostarch diphosphate (MSDP), and cyclic monostarch monophosphate (cyclic-MSMP) have been found in the phosphorylated cross-linked RS (Sang, Prakash, & Seib, 2007). The cross-linking of starch with sodium trimetaphosphate (STMP) and phosphoryl chloride are conducted at alkaline pH, and a reaction mechanism for cross-linking of polysaccharides with STMP has been proposed recently (Lack, Dulong, Picton, Cerf, & Condamine, 2007). Lack and coworkers reacted STMP with methyl α-D-glucopyranoside as a model substance for polysaccharides that are soluble at alkaline pH, and they followed the reaction by high-resolution NMR spectroscopy (^{31}P, ^{1}H and ^{13}C). However, the reaction of starch granules

doi:10.1016/j.foodchem.2009.04.121

with STMP is a two-phase, heterogeneous reaction conducted on starch slurries at concentrations of ~30%. The novelty of our work on the reaction of starch granules with STMP is to determine how slurry pH affects the ratio of mono-substituted (MSMP and MSDP) phosphate esters to cross-linked (DSMP) phosphate esters. In addition, we examine the stability of various starch phosphate esters in aqueous sodium hydroxide at different pH levels, and the effects of the various esters on starch digestibility.

2. Materials and methods

2.1. Materials

Wheat starch (Midsol 50) was obtained from MGP Ingredients Inc. (Atchison, KS). Potato starch was obtained from Avebe America Inc (Princeton, NJ). Sodium trimetaphosphate (STMP), sodium tripolyphosphate (STTP), phosphoric acid (85%), phosphocreatin, tetra sodium ethylenediaminetetraacetate (Na_4EDTA), and deuterium oxide were purchased from Sigma Chemical Company (St. Louis, MO). Thermally stable α-amylase (E-BLAAM; 3,000 Ceralpha Units/mL) and glucoamylase (E-AMGDF; 200 *p*-NP β-Maltoside Units/mL) were purchased from Megazyme International Ireland Ltd (Bray, Ireland). All chemicals were reagent grade.

2.2. General methods

Moisture content was determined by drying at 130 °C for 1 h (AACC, 2000) and phosphorus content was determined by the procedure of Smith and Caruso (1964). Total dietary fibre was determined by the Prosky method (AOAC, 2000) using a TDF assay kit from Megazyme (Megazyme International Ireland Ltd, Bray, Ireland). Starch samples were subjected to sequential enzymatic digestion by heat-stable α-amylase, protease and amyloglucosidase, and the enzyme resistant fraction was counted as TDF.

2.3. Preparation of cross-linked phosphorylated wheat starch (PWS)

Phosphorylated wheat starch was prepared according to the method described by Woo and Seib (2002). Wheat starch (50.0 g, db) was added into water (70.0 g) containing STMP (5.94 g), STPP (0.06 g), sodium sulphate (5.0 g), and sodium hydroxide to pH 11.5. The reaction mixture was stirred at 45 °C for 3 h, after which time reaction pH decreased to 10.8. The reaction mixture was adjusted to pH 6.5 by adding 1 M hydrochloric acid, and the slurry was centrifuged. The sedimented starch was collected and washed with distilled water seven times. The purified product was dried at 40 °C overnight and ground to give ≈50 g of PWS.

2.4. Treatment of PWS with aqueous sodium hydroxide

Phosphorylated wheat starch (50.0 g, db) was slurried in water (70.0 g), and the pH was adjusted to 9.0, 10.0, 11.0, and 12.0 by adding 1 M sodium hydroxide. The slurry was stirred at 40 °C for 4 h, cooled to 25 °C, and adjusted to pH 6.5. The starch was isolated and purified as described previously.

2.5. Conversion of PWS to phosphodextrins for ^{31}P nuclear magnetic resonance (^{31}P NMR) spectroscopy

Phosphorylated wheat starch (1.0 g, db) was added to a 50-ml centrifuge tube containing 2.0 mM calcium chloride (50 mL) at pH 8.2. Heat-stable α-amylase (100 μL) was added, and the tube was heated in a boiling-water bath for 30 min. The α-amylase digestion was repeated after adding another 100 μL of heat-stable α-amylase. The mixture was cooled and adjusted to pH 4.5 then incubated with amyloglucosidase (200 μL) for 1 h at 60 °C. The mixture was adjusted to pH 7.0, centrifuged, and the supernatant was freeze-dried. Recovery of phosphodextrins from the phosphorylated starch was estimated to be greater than 95% by mass balance.

2.6. ^{31}P NMR spectra of the phosphodextrins

The freeze-dried starch digest (≈1.0 g) was dissolved in deuterium oxide (1.0 ml) containing 20 mM EDTA and 0.002% sodium azide, and the pH was adjusted to 8.0 by adding 0.1 M sodium hydroxide. The proton-decoupled ^{31}P NMR data were acquired on a 11.75 Tesla Varian NMR System (Varian Inc., Palo Alto, CA,) operating at 499.84 MHz for ^{1}H and 202.34 MHz for ^{31}P, respectively (Sang et al., 2007). The ^{31}P NMR experiments were performed at 25 °C using a delay of 6 s between pulses with pulse width at 15.0 μs and sweep width at 12,730 Hz. The spectra were processed and analysed with Varian software VNMRJ Version 2.2C. Chemical shifts were reported in δ (ppm) from the reference signal of external 85% phosphoric acid (0.0 ppm).

2.7. In vitro digestion profiles of starch and calibration samples

In vitro digestion of starch and calibration samples were done by a modified Englyst procedure (Sang & Seib, 2006). In the modified method, the digestion with pancreatin was done in the presence of 30 glass beads of 6 mm diameter instead of 5 glass balls of 15 mm diameter, and the shake conditions were 90 strokes/min at a displacement of 25 mm instead of 160 strokes/min at 35 mm displacement. In addition, five times more IU (1112 vs.106–208 IU) of glucoamylase was used than in the original Englyst method. Control samples of potato starch and a 70% extraction hard white wheat flour ('Betty') were used to calibrate the degree of shaking so that the RS in potato starch and wheat flour matched their vivo levels determined in ileostomy patients (Englyst et al., 1999). Percentage of RS was calculated by total starch −% RDS −% SDS.

2.8. Differential scanning calorimetry (DSC)

Starch (≈10.0 mg) and deionized water (≈20 mg) were weighed into a stainless steel pan, and after sealing, the mixture was equilibrated overnight.

Differential scanning calorimeter (Q100, TA Instruments) was used to determine starch gelatinisation parameters with an empty stainless steel pan used as a reference. Starch samples were heated at 10 °C/min from 5 °C to 130 °C, and onset temperature (T_o), peak temperature (T_p), completion temperature (T_c), and enthalpy (ΔH) were calculated from the thermograms.

2.9. X-ray diffraction

X-ray diffraction patterns of the starch samples were recorded on a Philips APD 3520 X-ray diffractometer with Philps XRG 3100 X-ray generator. CuKα radiation at 35 kV and 20 mA, a curved crystal graphite monochromator, and a scanning rate of 2° 2θ/min were used. The degree of crystallinity was estimated from the ratio of the area of peaks to the total area of a diffractogram (Komiya & Nara, 1986).

3. Results and discussion

3.1. Effect of alkaline treatment on total phosphorus content of the PWS

The PWS was produced at 45 °C in a slurry (~35% starch) reaction starting at pH 11.5 and ending at pH 10.8. The purified PWS had a

total phosphorus content of 0.37% (dry basis). Exposure of the purified PWS to sodium hydroxide at pH 9.0 and 40 °C for 4 h caused no significant change of total phosphorus content (Table 1). At pH 10 and 11, only a slight decrease of phosphorus content was noted. However, the phosphorus content was reduced to 0.29% P when the PWS was held at pH 12, indicating that more than 22% of covalently bound phosphate was removed from the starch. Similar results were found when PWS with initial phosphorus of 0.029% P was treated at alkaline pH.

3.2. ^{31}P NMR spectra – effects of alkaline treatment on the chemical forms of the phosphate esters on starch

Repeated digestion of PWS with heat-stable α-amylase gave highly water-soluble phosphodextrins in ~95% yield, and a 50% concentration of those dextrins in D_2O were analysed by proton-decoupled ^{31}P NMR (Sang et al., 2007). Fig. 1A shows that PWS had four types of phosphate esters: cyclic-MSMP, MSMP, DSMP, and MSDP, which had a signal centred at δ 15.9 ppm, δ 3–5 ppm, δ −1 to 1 ppm, and δ −5 and −10 ppm, respectively. No cyclic phosphate or grafted pyrophosphate groups were detected on methyl α-D-glucopyranoside when it reacted with STMP at pH 13.5 → 10 (Lack et al., 2007). The broadening of the ^{31}P signals in Fig. 1A was a reflection of mixed molecules. The amylolytic enzymes do not hydrolyse the glucosidic bonds near phosphate groups (Kasemsuwan & Jane, 1996). Therefore, the various phosphate esters occur on phosphodextrins of different chain lengths, and the ^{31}P-signals of each type ester do not coincide.

The major type of phosphate ester in this sample of PWS was DSMP which showed a broad multiplet of ^{31}P peaks centred at ~0 ppm (Fig. 1). The integrated intensity of the multiplet indicated the modified starch contained 0.17% P as DSMP, or 46% of total phosphate content (Table 1 and 2). The prominence of the DSMP signal in Fig. 1 shows that cross-linking is a major pathway when starch is reacted with STMP in alkali. The second most abundant ester form was MSMP which showed two ^{31}P-signals between δ 3 and 5 and corresponded to 0.077% P (dry starch basis), or 21% of total phosphorus in the modified starch. The peak centred at δ 3.717 ppm, which was 1.04 ppm downfield from the inorganic phosphate peak in the sample, was from the monophosphate ester substituted at C-6 of the D-glucose unit (Lim and Seib, 1994), and the peak at δ 4.584 ppm was from C-3 bound monophosphate. The C-3 and 6 monophosphate peak assignments were confirmed by the spectrum of potato phosphodextrin (Fig. 2), which is known to contain monophosphate esters at C-3 and C-6 on its D-glucose repeat units (Blennow, Bay-Schmidt, Olsen, & Moller, 1998; Haebel, Hejazi, Frohberg, Heydenreich, & Ritte, 2008). The proportions of phosphate bound to the C-6 and C-3 positions of the D-glucose residues in potato starch is approximately 70–80% and 20–30%, respectively, which agrees with the intensities of the peaks in Fig. 2. The peak at 2.677 ppm in Fig. 1was confirmed to be inorganic phosphate (Pi) by spiking the PWS sample with phosphate salt.

It is interesting to note that starch phosphorylation is a key part of starch biosynthesis in potato. Glucan water dikinase catalyses phosphorylation at the C-6 position from ATP, and subsequently, C-3 can be phosphorylated by phosphoglucan water dikinase

Table 1
Total phosphorus contents of phosphorylated wheat starch (PWS) and of PWS after stirring for 4 h at 40 °C in aqueous sodium hydroxide at pH 9.0, 10.0, 11.0, and 12.0.

Samples	*P* (% dry basis)	Change (%)
PWS	0.37 ± 0.002	–
PWS treated at pH 9.0	0.37 ± 0.01	0
PWS treated at pH 10.0	0.36 ± 0.004	3

PWS treated at pH 11.0	7.6 ± 0.2	24.9 ± 1.3	67.4 ± 1.2	86.8 ± 1.3
PWS treated at pH 12.0	9.0 ± 0.1	28.3 ± 0.4	62.7 ± 0.4	86.5 ± 0.9

(Haebel et al., 2008). C-6 bound phosphate was found to have a smaller effect on helix packing than C-3 bound phosphate. The C-6 phosphate group aligns well in one of the double-helix surface grooves (Blennow, Engelsen, Nielsen, Baunsgaard, & Mikkelsen, 2002).

The phosphate ester pattern did not significantly change when the PWS was treated at pH 9–11 and 40 °C, but did show changes when the starch was treated at pH 12.0 (Table 2). Phosphorus signals from cyclic-MSMP and MSDP were not detected in the phosphodextrin after PWS was treated at pH 12.0, suggesting that cyclic-MSMP and MSDP are unstable at pH 12. In addition, at pH 12, C-6 bound monophosphate decreased 38% from 0.043% to 0.027%, while C-3 bound monophosphate increased from 18% 0.034–0.040% (dry matter basis). Apparently at pH 12 some of the C6- phosphate groups are lost by alkaline hydrolysis. The increase of C-3 bound monophosphate may result from the alkaline hydrolysis of cyclic-MSMP or MSDP. Moreover, even though total bound phosphorus content decreased, *DSMP (cross-linked esters) increased* ~18% after the PWS was held at pH 12.0 for 4 h. New DSMP may result from the reaction at pH 12 of MSDP or cyclic MSMP with a hydroxyl on another starch chain. Overall, the stability of phosphate esters at pH 12.0 was in the order: cyclic-MSMP ≈ MSDP < MSMP < DSMP.

3.3. Starch enzyme digestion property

The PWS prepared in this study (12% STMP, initial pH 11.5, 45 °C for 3 h) had a high level of the sum of RS (68.7%) and SDS (24.4%). The digestion profile did not change after the starch phosphate was treated at pH 9.0, 10.0, and 11.0 (Table 3). Treating the PWS at pH 12.0 slightly increased enzyme digestion of the starch. The RS content decreased from 68.7% to 62.7%, but TDF content was little changed (88.8% vs. 86.5%) even though the total phosphorus decreased by 22%. It seems that DSMP is more important at inhibiting enzyme digestion than the total phosphorus substitution. After the starch phosphate was treated at pH 12.0, the amount of cross-linking phosphate esters (DSMP) increased ≈18%, which compensated the 22% loss of total phosphorus.

Total phosphorus content in STMP/STPP modified starch for food applications can not exceed the regulatory level of 0.4% P, dry basis in the USA (CFR, 2001). This study suggests that incubating phosphorus cross-linked starch at pH 12.0 can reduce total phosphorus content without significantly changing its digestion property.

3.4. Thermal properties

Gelatinisation of PWS and the PWS treated at pH 9.0, 10.0, 11.0, and 12.0 were investigated by using DSC. The PWS and the PWS after treatment at pH 9.0 to 12.0 showed an endothermic peak due to starch gelatinisation. No melting of an amylose-lipid peak was observed apparently because the alkaline pH saponifies the lipid and somewhere disrupts that complex (Matsunaga & Seib, 1997). Gelatinisation of the PWS started at 66.0 °C (T_o), peaked at 71.3 °C (T_p), and completed at 81.8 °C (T_c) with an enthalpy of 11.3 J/g (Table 4). No significant differences of gelatinisation properties were found after the phosphorylated starch was treated at pH 9.0 to 12.0. Native starch granules do not start gelatinisation until pH 13.0 in sodium hydroxide (Polzinger, 2003). It appears that the alkaline condition used in this study did not change the crystalline phase of the granular structure.

3.5. X-ray diffraction

The PWS and the PWS treated at pH 9.0 to 12.0 had a typical A-type pattern with strong peaks at 2θ values of 13°, 17°, and 23°. The degree of crystallinity of the PWS and the PWS treated

Table 4
Thermal properties of phosphorylated wheat starches (PWS) and the PWS treated at pH 9.0, 10.0, 11.0, and 12.0, respectively.

Starches	Temperature (°C)			ΔH (J/g)
	T_o	T_p	T_c	
PWS	66.0 ± 0.2	71.3 ± 0.3	81.8 ± 0.4	11.3 ± 0.3
PWS treated at pH 9.0	65.8 ± 0.1	71.1 ± 0.2	81.7 ± 0.2	11.3 ± 0.2
PWS treated at pH 10.0	66.0 ± 0.1	71.3 ± 0.1	82.4 ± 0.2	11.5 ± 0.1
PWS treated at pH 11.0	66.1 ± 0.3	71.3 ± 0.1	82.2 ± 0.1	11.6 ± 0.3
PWS treated at pH 12.0	66.4 ± 0.1	72.0 ± 0.1	81.8 ± 0	11.5 ± 0.3

at pH 9.0, 10.0, 11.0, and 12.0 was 24%, 25%, 24%, 23%, and 23%, respectively, confirming that no change in degree of crystallinity occurred after the PWS was treated at pH 9.0–12.0.

4. Conclusions

Four chemically unique phosphate ester forms were detected by ^{31}P NMR when wheat starch was reacted with STMP and STPP in sodium hydroxide starting at pH 11.5. Approximately half of the total phosphate ester was in the form of cross-linked starch diester. The levels of phosphate esters of starch were stable at pH 9.0, but they began to change at pH 10 and 11. At pH 12, the level of substituted phosphate esters decreased ≈22% but distarch monophosphate esters (cross-linked bonds) increased ≈18%. Even though the total amount of phosphate esters significantly decreased after the starch was treated at pH 12.0, the TDF of the starch barely changed, suggesting that the level of the cross-linked phosphate diesters play a key role in making the phosphorylated starch resistant to α-amylase and amyloglucosidase digestion. More work should be conducted to create reaction conditions that can form more cross-linking bonds so that smaller amounts of chemical reagents are used.

β-Glucosidase

ABSTRACT

The study examined the effects of proteases on the isoflavones during enzymatic hydrolysis of soybean flour. Protease itself did not affect the isoflavones during hydrolysis, whereas the applied conditions and contaminated β-glucosidase in the enzyme could greatly affect the content and composition of isoflavones. Soybean flour hydrolysis by ENZECO Alkaline Protease L-FG at high pH (10) resulted in complete loss of malonylglucosidic and acetylglucosidic conjugates in the hydrolysate. However, these conjugates such as 6″-*O*-malonylgenistin and 6″-*O*-malonyldaidzin remained as the principal compounds accounting for 66.2, 58.3 and 70.5% of the total isoflavones in the Protease M "Amano", Alcalase 2.4L, and neutral enzyme ENZECO Neutral Protease-NBP-L hydrolysates, respectively, compared to that of 57.8% in the original soybean flour. The residue prepared by Protease M contained 10 times higher aglycones than that of soy flour, which was due to the contaminated β-glucosidase activity in the enzyme preparation. Our result showed that β-glucosidase contaminated in Protease M has a unique selectivity compared to that of the purified almond β-glucosidase. Results from the study indicated that hydrolysis of soybean flour may provide another alternative approach to enrich aglycone isoflavones in soybean-containing products.

1. Introduction

Soybeans have been used for centuries as an important part of diet in many Asian countries. Consumption of soybean products has been seen an explosive growth worldwide, driven primarily by the US Food and Drug Administration (FDA) health claim concerning the role of soy protein in reducing the risk of heart disease (FDA, 1999). In addition to protein, isoflavones are also touted as one of the most important components responsible for preventing and attenuating cardiovascular diseases, certain cancers and osteoporosis (Brouns, 2002; Messina 1999; Setchell 1998; Setchell & Cassidy, 1999). The content and composition of aglycones in soy foods are largely decided by the genotype, environment, storage and processing conditions (Coward, Smith, Kirk, & Barnes, 1998; Eldridge & Kwolekm, 1983; Hoeck, Fehr, Murphy, & Welke, 2000; Hou & Chang, 2002; Nurmi, Mazur, Heinonen, Kokkonen, & Adlercreutz, 2002). It is believed that isoflavone aglycones, the predominant form in fermented soyfoods (Coward et al., 1998), display greater bioavailability than their corresponding glycosides (Izumi et al., 2000; Watanabe et al., 1998). Setchell et al. (2002) concluded that isoflavone β-glycosides do not cross the intestine of healthy humans, and their bioavailability requires initial hydrolysis of the sugar moiety by intestinal β-glucosidase for uptake to the peripheral circulation. Attempts have been made to increase purposely the aglycone forms mediated by β-glucosidase or microbial fermentation (Obata et al., 2002; Tsangalis, Ashton, Mcgill, & Shah, 2003; Xie, Hettiarachchy, Cai, Tsuruhami, & Koikeda, 2003).

Enzymatic modifications of soybean proteins are extensively explored to improve protein functionalities, nutritional quality, or produce specific population diets/clinical supplements, or as a flavour enhancer (Aaslyng et al., 1998; Clemente, 2000; Lahl & Braun, 1994; Were, Hettiarachchy & Kalapathy, 1997; Wu & Cadwallader, 2002). Recent studies have shown that soybean-derived peptides may have antihypertension (Wu & Ding, 2001), anti-cancer (Galvez, Chen, Macasieb, & de Lumen, 2001; Hellerstein, 1999), lowering cholesterol (Chen, Chiou, Shieh, & Yang, 2002) and immunostimulation activities (Chen, Suetsuna, & Yamauchi, 1995). Compared with many reports on the effect of enzymes on the functional and biological properties of soybean proteins, there is limited information on the effect of proteases on isoflavones that are associated with many soybean products and ingredients. The objectives of this study were to study the effect of proteases on the content and composition of isoflavones.

2. Materials and methods

2.1. Materials

Nutrisoy 7B flour (Lot# 991201C) was obtained from Archer Daniels Midland Co. (Decatur, IL, USA). Protease M (*Aspergillus oryzae,* Amano Enzyme USA Co., Ltd. Elgin, IL, USA), ENZECO

Neutral Protease-NBP-L (*Bacillus subtilis,* Enzyme Development Co., New York, NY, USA), ENZECO Alkaline Protease L-FG (*B. subtilis,* Enzyme Development Co., New York, NY, USA) and Alcalase 2.4L (*Bacillus licheniformis,* Novozymes North America, Inc., Franklinton, NC, USA) were gifts upon request. Almond-derived β-glucosidase was purchased from Sigma Chemical Co. (St. Louis, MO, USA). Isoflavone standards (daidzin, 6″-*O*-acetyldaidzin, daidzein, genistein, 6″-*O*-acetylgenistin, 6″-*O*-malonylgenistin, genistin, glycitin, 6″-*O*-acetylglycitin and glycitein,) were purchased from LC Labs (Woburn, MA, USA). HPLC-grade acetonitrile, acetic acid and spectranalyzed-grade dimethyl sulphoxide (DMSO) were obtained from Fisher Scientific (Pittsburgh, PA, USA). HPLC-grade water generated by Milli-Q system (Millipore, Bedford, MA, USA) was used for the preparation of the mobile phase.

2.2. Enzymatic hydrolysis of soybean flour

Enzymatic hydrolysis of soybean flour was performed in a temperature- and pH-controlled reaction vessel equipped with a stirrer. Nutrisoy 7B flour was mixed thoroughly using a magnetic stirrer with distilled water into a 5% (w/w, protein/water) slurry. The pH and temperature of the slurry was adjusted to the conditions of individual enzyme, such as 4.5 and 50 °C for Protease M (PM), or 7 and 40 °C for ENZECO Neutral Protease-NBP-L (EN), or 10 and 50 °C for ENZECO Alkaline Protease L-FG (EA), or 8 and 50 °C for Alcalase 2.4L; enzyme was then added at the level of 4% (w/w, on the basis of protein content of the slurry) to initiate the digestion. Temperature was kept stable using a circulating water bath and pH was kept constant during protein digestion with continuous addition of 0.5 M NaOH or 0.5 M HCl if necessary. After 3 h incubation, residue was separated from the slurry after centrifugation at 6,000*g* for 25 min; the residue was re-suspended in 100 mL water and centrifuged under the same condition above. The hydrolysates combined as the resulting clear supernatants and the residues were freeze dried and kept −20 °C till further use.

2.3. Isoflavones extraction

Approximately 0.5 g of soy flour was accurately weighted into a screw cap test tube (125 mm × 20 mm) and was extracted at room temperature for 2 h on a rotary mixer with 10 mL of methanol/acetonitrile/water (4:3:2, v/v/v). After a brief centrifugation (2000*g* for 10 min), a portion of the supernatant was removed with a syringe, filtered through a 0.45-μm filter into a sample vial, and analysed by HPLC.

2.4. Isoflavones analysis

Separation and quantification of isoflavones were performed on a symmetry® C_{18} reverse-phase column (4.6 × 250 mm, 5 μm particle size, Waters, Milford, MA, USA) according to Griffith and Collison (2001) with slight modifications as reported (Wu & Muir, 2008). All samples were run automatically via sample management system at a fixed injection volume of 10 μL on an HPLC Waters™ 2690 Separation Module System (Waters Inc.; Milford, MA, USA). UV absorbance was scanned from 200 to 350 nm using a Model Waters 996 Photodiode Array Detector, and peak area was integrated automatically with the supplied software at 254 nm. The sample compartment temperature and column temperature were kept at 15 and 34 °C, respectively. Column was eluted by a two-solvent system: (A) 0.1% acetic acid in water and (B) 0.1% acetic acid in acetonitrile. The column was held constantly at 15% B for the first 10 min, increased to 35% B over 45 min, then to 55% B over 10 min. The concentration of B was brought back to 15% over 5 min and held for another 5 min before the next run.

Individual isoflavone standards were used for peak identification according to elution time, UV spectra and spiking tests. Isoflavone quantification was based on calibration curves for each of the 10 isoflavone standards; quantification of 6″-*O*-malonyldaidzin and 6″-*O*-malonylglycitin, however, was based on their corresponding glucosides adjusted for the molecular weight difference (Kudou et al., 1991). Each sample was analysed in duplicate and mean values were reported.

2.5. β-Glucosidase activity analysis

β-Glucosidase activity in four proteases was determined according to the method of Grover (1977) by measuring the rate of hydrolysis of *p*-nitrophenyl-β-D-glucopyranoside (pNPG). One unit of the enzyme activity was defined as the amount of β-glucosidase that release 1 μmol of *p*-nitrophenol from the substrate pNPG per milliliter per minute.

2.6. Standard isoflavone incubation

Isoflavone standards (a mixture of 0.2 mg of daidzin, acetyldaidzin, malonyldaidzin, genistin, acetylgenistin and malonylgenistin) were dissolved by 1.0 mL of DMSO and extracted solvent mixture (1:1, v/v), diluted 10 times with 0.2 M acetic acid buffer (pH 4.5). Equal volume isoflavone standard solution was incubated with Protease M "Amano" or with β-glucosidase (15 U) at the same condition used for protein hydrolysis as stated above. Samples (0.6 mL) were taken at various incubation intervals at 0, 0.25, 1, 3, 6 and 24 h and the enzyme was inactivated by adding 0.9 mL of acetonitrile whilst stirring under room temperature. After mixed with 1.5 mL HPLC-grade water, the samples were filtered through a 0.45 μm filter prior to HPLC analysis.

3. Result and analysis

3.1. Isoflavones during protease hydrolysis

Four proteases with different pH optimums were used to study their effects on the isoflavones during hydrolysis. Compared to the soybean flour, the content and composition of isoflavones in both the hydrolysate and resultant residues were significantly affected by the proteases and their associated conditions (Table 1). The resultant residues tended to contain higher amount of isoflavones than those of the hydrolysates; the amount of isoflavones in the Protease M residue was more than three times higher than that of the hydrolysate. With the exception of EA hydrolysis, whose recovery of total isoflavones was only 71.6%, the average recovery of isoflavones after hydrolysis was 91.3%; the lower recovery percentage in EA hydrolysis was probably due to the high pH value (10) applied. Hydrolysis under high pH conditions such as in ENZECO Alkaline Protease L-FG resulted in complete loss of malonylglucosidic and acetylglucosidic conjugates both in the hydrolysate and residue (Table 1). However, these conjugates, such as 6″-*O*-malonylgenistin and 6″-*O*-malonyldaidzin remained as the principal compounds accounting for 66.2% in Protease M hydrolysate, 58.3% in Alcalase 2.4L hydrolysate, 70.5% in ENZECO Neutral Protease-NBP-L (EN) hydrolysate, respectively, compared with 57.8% in soybean flour and 0% in EA hydrolysate (Table 1). It is well known that malonylglucosidic and acetylglucosidic conjugates are the most fragile compounds among these isoflavone chemicals and their stability were vulnerable to environmental factors and processing conditions (Coward et al., 1998; Griffith & Collison, 2001; Kudou et al., 1991). With the exception of EA hydrolysis, there were relative high total amount of malonylglucosidic and acetylglucosidic conjugates left in hydrolysates and residues compared

Table 1
Effect of proteases on the isoflavones (values are the mean of duplicate determinations, expressed in the form of μg aglycone/g of dry weight) distribution in the hydrolysates and their residues.

Enzyme	Alcalase 2.4L		Protease M "Amano"		ENZECO Neutral Protease		ENZECO Alkaline Protease		Flour

[a] Not detected.

with their original values in soybean flour (Table 1). In contrast with the total loss of malonylglucosidic and acetylglucosidic conjugates under extreme pH (10.0) hydrolysis conditions, hydrolysis under mild enzymatic conditions had relatively small influence on the stability of these isoflavones (Table 1). The reaction temperature is 50 °C for both alkaline enzymes, but the pH was 8 in Alcalase 2.4L hydrolysis whereas 10 in ENZECO Alkaline Protease L-FG hydrolysis; these results indicated that the difference in pH played an important role in deciding the stability of the conjugated isoflavones. We previously explained that the high water content and the buffering environment formed during enzymatic hydrolysis might be the reasons for the enhanced stability of conjugated chemicals (Wu & Muir, 2008).

Interestingly, 6″-*O*-malonyldaidzin and 6″-*O*-malonygenistin were no longer the predominant chemicals in the PM residue. There was a large increase in aglycone content in the residue, e.g. the contents of daidzein, genistein and glycitein in PM residue were 604.1, 1012.5 and 95.5 μg aglycone/g compared to those of 37.5, 47.5 and 0 μg aglycone/g in the soybean flour; these three aglycones accounted for 62% of the total isoflavones in PM residue compared to that of 4.7% in soy flour. Similar trend existed in other enzymatic residues where the aglycone fraction accounted for 49.0% in Alcalase 2.4L residue, 44.1% in EA residue and 44.7% in EN residue of the total isoflavone content. The increase in aglycone content in our residues compared favourably with lactic acid fermented soymilk, showing a 63–67% increase in aglycone (Otieno & Shah, 2007). Using β-glycosidase from *Penicillium multicolour*, Xie et al. (2003) reported that the amount of genistein, daidzein, and glycitein in β-glycosidase treated soymeal were increased from 1.23, 1.25, and 1.51 mmol/g to 3.21, 2.02, and 2.12 mmol/g, respectively. Our results suggested that the major portion of aglycones formed during hydrolysis was remained in their residues after centrifugal separation; the residues accounted for 84.1, 90.9 and 73.3% of the total aglycones produced during the hydrolysis of soybean meal by EN, PM and Alcalase 2.4L, respectively.

The increase in aglycone content in EA treated sample could be attributed to the high pH applied in enzymatic hydrolysis; however, the remarkable increase in their aglycones under mild conditions could be attributed to the contaminated β-glucosidase present in these protease preparations rather than the temperature and pH applied during incubation. It was reported that β-glucosidase has superior activity for conversion of isoflavones glycosides to aglycones (Matsuura & Obata, 1993; Xie et al., 2003). β-Glucosidase from microorganisms such as *bifidobacteria* and *lactic acid* bacteria have also been studied in hydrolysing isoflavone glycosides into aglycones (Matsuyama, Setoguchi, Arai, & Kiyosawa, 1990; Tsangalis et al., 2003). Microbially derived protease preparations tend to contaminate more or less amount of β-glucosidase; the activity of β-glucosidase in PM, EN, Alcalase 2.4L and EA were determined to be 18.5, 0.09, 0.03, 0 U/g, respectively. The contaminated β-glucosidase in these bacterial proteases contributed greatly to the isoflavones conversion observed during hydrolysis with the exception of EA. Since the optimal pH for β-glucosidase is acidic pH, it is in a good alignment with the result that PM shows the highest β-glucosidase activity among the enzymes tested. However, the increase in aglycones could not be attributed totally to the conversion of their manyolglucosidic and acetylglucosidic conjugates, since the increase magnitude in daidzein (from 546 μg total aglycones in soy flour to 4207.1 μg total aglycones in hydrolysate and residue) was far greater than the total manyolglucosidic (from 7030.0 in soybean flour to 4483.4 μg total aglycones in hydrolysate and residue) and acetylglucosidic conjugates (from 182.1 to 88.5 μg total aglycones) in PM treated samples; furthermore, a significant higher conversion percentage was observed from glucosidic isoflavones to aglycones than malonylglucosidic and acetylglucosidic conjugates to aglycones. It was calculated that 81.1% of daidzin was converted into daidzein, 78.8% of genistin into genistein, compared with 36.2% of 6″-*O*-malonygenistin into daidzein, 51.4% of 6″-*O*-acetyldaidzin into daidzein, and 37.1% of 6″-*O*-malonygenistin into genistein. These results suggested that the activity of β-glucosidase in PM might have a different enzyme selectivity from the reported β-glucosidase (*P. multicolour*) (Xie et al., 2003).

3.2. Standard isoflavone incubation

In order to address the unique enzyme specificity of β-glucosidase in the Protease M, we tested its activity on authenticated isoflavone standards; purified β-glucosidase from almond was also used for comparison. Fig. 1 shows the chromatograms of these standard isoflavones under different incubation intervals using Protease M or purified almond β-glucosidase. Daidzin was completely converted into aglycone in the first 15 min in both enzymes; genistin was not detected in PM treated samples whereas there was trace amount of genistin left in the β-glucosidase treated samples. Matsuura and Obata (1993) reported that β-glucosidase from soybean had a conversion percentage of 16.9% from genistin to genistein and 14.3% for daidzin to daidzein in soymilk, which was much less than the results we reported. The content of malonyldaidzin decreased gradually with the incubation time; percentage conversion reached 74.5 and 61.1% for PM and β-glucosidase treated samples at 24 h, respectively (Fig. 2). It appeared that

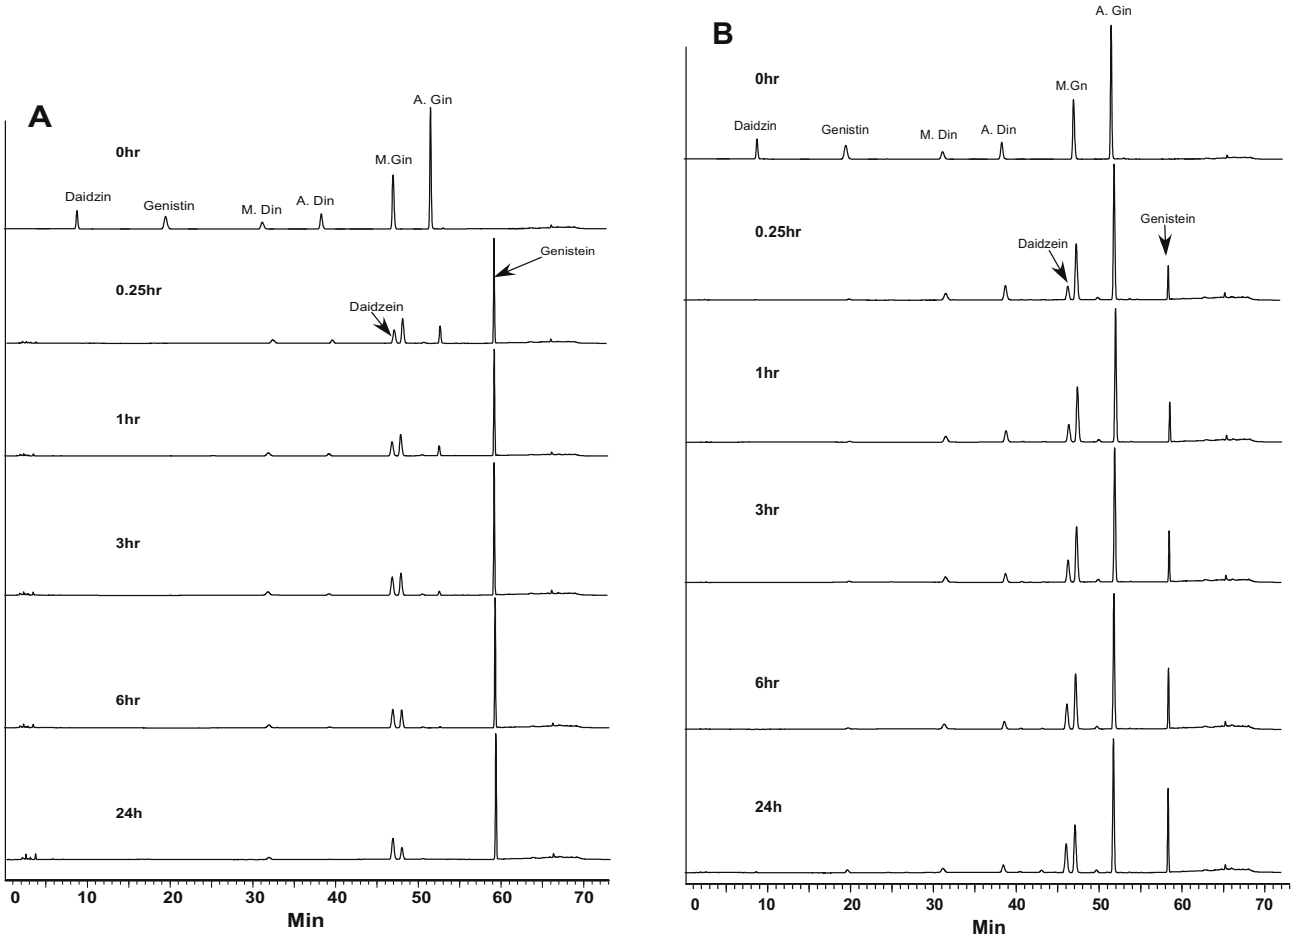

Fig. 1. Chromatograms of standard isoflavones under different incubation intervals with Protease M "Amano" (A) and purified β-glucosidase (B).

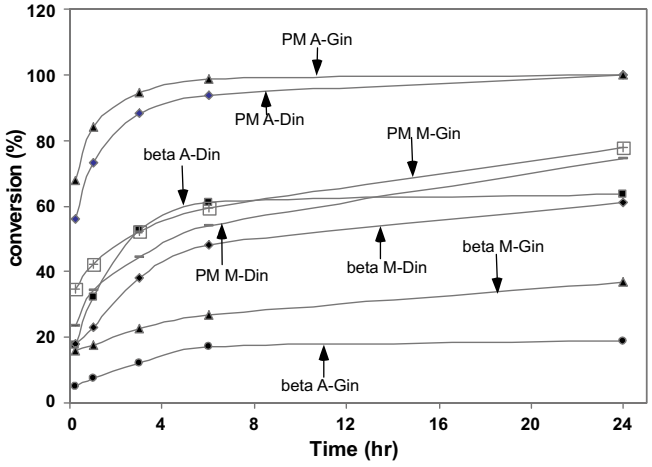

Fig. 2. The conversion percentage of standard isoflavone under various incubation intervals with PM and almond β-glucosidase at the same activity of β-glucosidase. Abbreviations: PM, Protease M "Amano"; β, almond purified β-glucosidase; A-Gin, acetylgenistin; A-Din, acetyldaidzin; M-Din, malonyldaidzin; M-Gin, malonylgenistin.

β-glucosidase from both PM and almond could not convert all malonyldaidzin into daidzein under the condition tested. Generally speaking, acetyldaidzin showed a higher conversion percentage than that of malonyldaidzin (Fig. 2). At 24 h, there was no acetyldaidzin left in PM treated sample whereas there was 36% of acetyldaidzin left in β-glucosidase treated sample. It seemed that β-glucosidase in PM had a higher efficiency than that of almond-derived β-glucosidase and therefore, the conversion percentage from acetylgenistin and malonylgenistin into genistein with PM was higher than that of almond-derived β-glucosidase. The difference between their specificity and efficiency for the conversion of glucosides to aglycones had a great impact on the content of aglycones. Consequently, the contents of daidzein and genistein in PM treated samples were significantly higher than those of almond β-glucosidase treated samples (Fig. 1). The content of daidzein in PM treated sample was 237.1 μg daidzein/mL compared with 156.2 μg daidzein/mL in almond β-glucosidase treated sample at 0.25 h and this difference remained significant within 6 h but not at 24 h incubation. It appeared that the conversion from glucosides to aglycones with PM was higher and faster than that of the almond β-glucosidase (Fig. 2); the greatest conversion happened within 3 h, reached a plateau after 6 h incubation. The content of genistein in PM treated sample increased rapidly to 659.6 μg aglycone/mL at 15 min, compared with 161.4 μg aglycone/mL at 15 min and 356.8 μg glycone/mL at 24 h incubation in almond β-glucosidase.

4. Conclusions

This study showed that protease hydrolysed soybean products contained significant amount of isoflavones, and the content and composition of isoflavones were greatly affected by the applied reaction conditions and presence of β-glucosidase activity in the

commercial protease enzyme. The microbial conversion of isoflavone forms has been reported in soybean products during fermentation efforts to convert conjugated isoflavones into their aglycone forms using bacterial β-glucosidase to develop aglycone-enriched products have been reported (Otieno & Shah, 2007, 2008; Xie et al. 2003). Our results indicated that the β-glucosidase present in commercial protease enzyme preparations has a unique specificity for the conversion of isoflavone chemicals, which was different from almond-derived β-glucosidase. Previous studies also showed that strain-dependent β-glucosidase activity in soymilk (Otieno & Shah 2007, 2008). In addition to β-glucosidase activity, enzyme specificity should be taken into consideration in bioconversion of isoflavones. PM hydrolysis of soybean flours not only resulted in potent bioactive peptides, but also produced a residue with an exceptional high content of aglycones. Our results indicated that protease hydrolysed residues contained more than 10 times higher concentration of aglycones than that of soy flour, thus provided another alternative approach to enrich aglycone isoflavones in soy-containing products. Our further study aims to develop an integrated technology to produce bioactive peptides and enriched aglycone isoflavones from soybean meal. Further research on the purification of the β-glucosidase from the PM preparation is needed to characterise its properties and compare with other sources of β-glucosidase.

ABSTRACT

To observe the neuroprotective effects of marine collagen peptide (MCP) isolated from Chum Salmon (*Oncorhynchus keta*) skin by enzymatic hydrolysis, 20-month-old female C57BL/6J mice were fed with chow diet, 0.22%, 0.44% or 1.32% (wt/wt) MCP diet for 3 months. Comparing with aged control group, the abilities of passive avoidance and spatial memory and learning were significantly enhanced evaluated by step-down test and Morris water maze respectively. Furthermore, the abilities of learning and memory had no significant difference between 0.44% and 1.32% MCP treated groups and young control group. The alleviated oxidative stress, reduced apoptotic neurons, up-regulated expression of brain-derived neurotrophic factor (BDNF) and postsynaptic density protein 95 (PSD95) were observed in MCP treated groups compared with aged control group. Our research revealed that there were no significant difference between 0.44% and 1.32% MCP treated groups and young control group. These findings suggest that MCP could be a candidate for functional food to relieve memory deficits associated with aging.

1. Introduction

Cognitive deficits including learning impairment and delayed amnesia may be caused by age-related deterioration in brain function (Erickson & Barnes, 2003). While the world's population is aging in the 21st century (Kalache, Aboderin, & Hoskins, 2002), a fast growing number of aged people suffer from neurodegenerative diseases, such as Alzheimer's disease (AD) and Parkinson's disease (PD), two of the most common diseases among the elderly that impairs the cognitive ability (Morrison & Hof, 1997).

Mounting evidence suggests that lifestyle factors, especially the diet, may account for the development of chronic diseases, such as cardiovascular disease, diabetes and neurodegenerative disease (Ferrari, 2007). Nowadays, while major dietary intervention has been applied to prevent such diseases as diabetes and heart disease, the potential impact of diet on aging process-associated neurodegeneration has been neglected. Apparently, the potential effect of nutrition on slowing down the neuropathies deserves increasing public concern (Paliyath, 2006). And it is well known that in protein, it is bioactive peptides that act out the biological activity.

Since the first bioactive peptide was revealed by Mellander (1950), the potential physiological functions of bioactive peptides derived from dietary protein have aroused a lot of scientific interest and attention (Korhonen & Pihlanto, 2003; Mellander, 1950). As specific protein fragments, a wide range of activities of bioactive peptides have been described, including antimicrobial, blood pressure-lowering, cholesterol-lowering, antioxidative and immunomodulatory effects, etc. (Hartmann & Meisel, 2007; Miraliakbari & Shahidi, 2008). Moreover, some peptides can influence higher brain functions, such as learning and memory, in humans and animals (McLay, Pan, & Kastin, 2001).

Theoretically, bioactive peptides can be released from dietary proteins through digestion in the gut; the amount of peptides, however, is too small to induce any significant effects. In contrast, enzymatic hydrolysis of dietary proteins offers a rapid and reproducible method for the production of considerable bioactive peptide fractions, and they are likely to become potential health-beneficial-food ingredients or nutraceutical preparations (Hartmann & Meisel, 2007).

During the past five decades, fish proteins were widely studied and their various multifunctional properties were well described (Aneiros & Garateix, 2004; Chavan, McKenzie, & Shahidi, 2001). We still do not know, however, whether bioactive peptides from fish proteins have preventive effect against age-related cognitive decline. It is certain now that oxidative stress can lead to cell and tissue damage, thus resulting in age-related cognitive decline and our previous research demonstrated that bioactive peptides derived from fish skin has antioxidant function in D-galactose induced Sprague-Dawley rats. Hence, it is reasonable to hypothesise that

fish protein may be a valuable source of neuroprotective peptides. The purpose of the present study was to investigate the promnestic effects of Marine Collagen Peptide (MCP), compounds of low molecular weight peptides derived from Chum Salmon (*Oncorhynchus keta*) skin by enzymatic hydrolysis, on the cognition of aged C57BL/6J mice. Despite broadly comparable patterns of cognitive decline with normal aging for males and females, some groups of females may be more vulnerable than males to cognitive dysfunction as they age. Most remarkable is the observation that Alzheimer's disease is two to threefold higher in women than in men after the age of 65 years (Andersen, Launer, & Dewey, 1999; Hebda-Bauer, Luo, Watson, & Akil, 2007). This gender difference persists even after correcting for differences in life expectancy. So, we used female mice in this study. In addition, we intended to explore cellular and molecular mechanisms and how MCP regulates the plasticity of the brain to repair itself in response to the effect of aging. Furthermore, we also wanted to determine whether MCP might become a candidate for functional food or pharmaceutical applications to relieve memory deficits associated with aging.

2. Materials and methods

2.1. Chemicals

Commercial kits used for determination of T-SOD, GSH-Px and TBARS were purchased from Jiancheng Institute of Biotechnology (Nanjing, China). Mouse monoclonal anti-BDNF was purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Rabbit monoclonal anti-PSD95 was purchased from Chimicon (Temecula, CA). ECL plus western blotting detection system was obtained from Amerscham Pharmacia Biotech (Buckinghamshire, England). All other chemicals were reagent grade or the highest quality available from Sigma–Aldrich Co. (St. Louis, MO, USA). MCP was purified by reversed phase chromatography using a 250 × 10 mm C18 column (Phenomenex Inc., Torrace, CA, USA).

2.2. Preparation and identification of MCP

Marine Collagen Peptide (MCP) was derived from the skin of wild-caught Chum Salmon (*O. keta*) (average body weight, 1.47 kg) and donated by CF Haishi Biotechnology Ltd. Co. (Beijing, China). In brief, skin of Chum Salmon was cleaned and the adherent tissue was scraped manually by a scalpel. Then the skin was minced and defatted by vigorous stirring in chill water. The materials were homogenised and emulsified in distilled water, and added into complex protease (3000 U/g protein), which including 7% of trypsin, 65% of papain and 28% of alkaline proteinase, with the constant temperature at 40 °C and pH value of 8, for 3 h. The resultant hydrolysate was centrifuged at 10,000*g* by decanter centrifuge at first, and then it was centrifuged at 15,000*g* by tube centrifuge to get rid of the impurity. After centrifuge, the liquid was subsequently separated through ceramic membrane (200 μm) to purify it. The mineral salt was removed from the liquid through a procedure of nanofiltration at pH 6.5–7.5 with a concentration of solid material between 2.2–2.6 g/100 ml. Then the purified liquid was condensed by cryoconcentration under vacuum at 70 °C with an evaporation rate of 500 kg/h. When the concentration of the condensed liquid was almost 30 Baume degrees, it was decoloured with 12% of active carbon at 75 °C for 1 h, and then got rid of the carbon by filtration. When all the process above was finished, removed most of the water by spray drying with the pressure of 20 MPa at an evaporation rate of 200 kg/h, MCP powder used in the following investigation was obtained.

High-performance liquid chromatography (HPLC, Waters Corp., Milford, MA, USA) of peptide sample was performed using a Phenomenex C_{18} column (10 × 250 mm), which used acetonitrile-0.05 mol/L phosphate buffer (PH 3.2) (10:90) as the mobile phase with a flow rate of 2.0 mL/min and monitored at 208 nm using a Water 486 tunable UV detector. Then the molecular weight distribution of the sample was ascertained by LDI-1700 matrix-assisted laser desorption ionisation time-of-flight mass spectrometry (MALDI-TOF-MS) (Liner Scientific Inc., Reno, NV, USA). In addition, the amino acid composition was further analysed by an H835–50 automatic amino acid analyzer (Hitachi, Tokyo, Japan). The result indicated that the molecular weight distribution of MCP was 100–860 Da. Furthermore, 85.86% of the molecular weight distributed between 300 and 860 Da. So, the main composition of MCP was oligopeptides. The amino acid composition of MCP was shown in Table 1.

2.3. Animals and diet

C57BL/6 J female mice were obtained from the Animal Service of Health Science Center, Peking University. Control animals were fed AIN93M Diet from Vital River Limited Company (Beijing, China). The mice in the experimental groups were fed with 0.22%, 0.44% or 1.32% (wt/wt) MCP in AIN93M diet, respectively. The composition of the AIN93M diet include 20.26% of protein, 4.24% of fat, 25.19% of carbohydrate, 3.60 mg/100 g vitminA, 0.25 mg/100 g vitminD, 44.00 mg/100 g vitminE, 5.00 mg/100 g vitminK, 1.10 g/kg choline chloride and 25.90 g/kg mineral mix. The weight and food consumption were measured every week. No significant differences in diet or weight gain had been found between the un-supplemented aged mice and the old supplemented mice (data were not shown). The young mice were 3 month-old, while aged mice 20 monthly at the start of the experiment. All animals were acclimatised at animal colony facilities in laboratory of animal service of Peking University for at least 1 week before treatment. Mice were housed four to five per cage and provided with MCP-supplemented diet or standard diet for 3 months. All animals were maintained at a constant temperature (23 ± 1 °C) and humidity (60 ± 10%) environment under a 12-h light/dark cycle (light on 07:30–19:30 h) with free access to food and water. Animal treatment and maintenance were carried out in accordance with the Principle of Laboratory Animal Care (NIH publication No. 85–23, revised 1985) and the guidelines of the Peking University Animal Research Committee.

2.4. Behavioral test

2.4.1. Passive avoidance task (step-down test)

A step-down passive avoidance was examined by using apparatus consisted of a box (25 × 25 × 40 cm), a floor with stainless-

Table 1
Amino acid composition of MCP from salmon skin.

Amino acid	No. residues/100 residues
Glycine	23.77

Tyrosine	0.03
Hydroxy proline	7.51

steel grids 2 mm in diameter at 8 mm intervals, and a rubber platform (4 cm diameter, 4 cm height) set on the grid in one corner. Electric stimulation was given through the grid connected with a scrambled shock generator. After 3 months of treatment, an acquisition trial was performed. In this trial, each mouse was placed gently on the platform and allowed to habituate freely for 3 min, and then electric shocks (0.4 mA) were delivered to the grid. If the mouse stepped down from the platform, the electric shock was delivered to the mouse on the grid floor. The cutoff time was 5 min. A retention trial was performed 24 h after the acquisition trial. Each mouse was again placed on the platform. The time (step-down latency) that elapsed until the mouse stepped down from the platform was recorded. If the mouse did not step down from the platform within 300 s, the retention trial was terminated and the maximal step down latency of 300 s was recorded. Each error was counted whenever the mouse stepped down from the platform and the number of errors made within 5 min was recorded.

2.4.2. Morris water maze

The experimental apparatus which used in the Morris water maze test consisted of a circular water tank (120 cm in diameter, 35 cm in height), containing water (24 ± 1 °C) to a depth of 20 cm, which was rendered opaque by adding milk. A platform (4.5 cm in diameter, 19 cm in height) was submerged 1 cm below the water surface and placed at the midpoint of one quadrant. The pool was located in a test room, which contained various prominent visual cues. Each mouse received four training periods per day for seven consecutive days. Before the first trail, each mouse was put on the platform for 10 s, and then it was given 30 s free swim and then was assisted to the platform where it was remained for another 10 s rest. For each trial, mouse was placed in the water facing the wall at one of four starting positions, and the time required for the released mouse to find the hidden platform was recorded. Mouse that found the platform was allowed to remain on the platform for 10 s and then returned to its cage for the inter-trial interval. A mouse failed to find the platform within 90 s was placed on the platform for 10 s at the end of the trial. Latency to escape from the water maze (finding the submerged escape platform), swimming distance and average speed to reach the platform were recorded for each trial.

To measure the strength of the spatial memory, on day 7, a "probe test" was performed, during which, mice were swimming freely for 60 s in the pool without platform. In the "probe test" calculated were: (1) the time (in seconds) spent by mice in the target quadrant in which the platform was hidden during acquisition trails, and (2) the number of times exactly crossing over the previous position of the platform.

Swimming behavior during the test was video-recorded using a commercial VCR and analysed by a PC computer.

2.5. Detection of SOD, GSH-Px and TBARS in serum

Superoxide dismutase (SOD), glutathione peroxidase (GSH-Px) and thiobarbituric acid-reactive substances (TBARS) in serum were examined by reagent kit (Jiancheng Institute of Biotechnology, Nanjing, China). The principles of these kits are as follows. The method which was used to measure SOD employs xanthine and xanthine oxidase to generate superoxide radicals. Activity of GSH-Px was reflected by the speed of enzymatic reaction, in which GSH-Px promote glutathione hormone (GSH) to generate oxidised form glutathione (GSSG). Lipid peroxidation is known to result in formation of malonaldehyde (MDA) and other structurally similar compounds, which react with triobarbitrric acid (TBA) to form TBARS that absorbs at 532 nm. The TBARS levels in serum were expressed as malondialdehyde (MDA) equivalents (Shahidi & Ho, 2007).

2.6. Morphological analysis

After behavioral analyses, five mice in each group were deeply anesthetised with pentobarbital and perfused intracardially with normal saline followed by 4% paraformaldehyde in phosphatebuffered saline (PBS). The brains were removed, post-fixed with the same fixative and cryoprotected with 30% sucrose containing PBS. Sections (10 μm) containing hippocampus were obtained using a rotary microtome (HM505E; MICROM International GmbH, Walldorf, Germany), mounted on slides, and stored at −20 °C until use.

Morphology of the hippocampal was monitored using nissl staining. The slide-mounted brain sections were soaked in cresyl violet solution for 10 min, dehydrated through a graded series of ethanol–water solutions, coverslipped, and analysed under a bright field microscope. Nissl-positive neuronal cell numbers were manually and rigidly counted within the hippocampal pyramidal cell layer (CA1 and CA3 regions and the dentate gyrus). The total cell counts were averaged from at least three sections per animal.

2.7. Western blot analysis

Mice were deeply anesthetised and their hippocampuses were rapidly removed and stored at −80 °C until use. The tissue samples were pooled and lysed in a buffer containing 50 mM Tris–HCl, pH 6.8, 10% glycerol, 2% sodium dodecyl sulfate, and 5% β-mercaptoethanol. 50 μg protein lysate were separated by 8% SDS–PAGE and transferred onto polyvinylidene difluoride (PVDF) membrane. After blocking in a 5% non-fat dry milk solution in washing buffer containing 10 mM Tris (pH7.5), 150 mM NaCl, and 0.05% Tween-20, membranes were incubated overnight at 4 °C with primary antibody (monoclonal anti-BDNF, 1:1000, Santa Cruz Biotechnology, USA; monoclonal anti-PSD95, 1:250, Chemicon, Temecula, CA). After washing three times with TBS, membranes were incubated for 1.5 h with horseradish peroxidase-coupled secondary antibody at room temperature. Following the post-secondary washes, the resulting antigen–antibody-peroxidase complex was detected using the ECL kit (Amersham Pharmacia Biotech) and visualised by exposures of various lengths to Kodak film.

2.8. Statistical analyses

All statistical analyses were performed with the Statistical Package for social sciences for Windows version 11.0 (SPSS Inc. Chicago, IL. USA). Data were expressed as mean ± SEM. Effects on escape latencies and swimming distance in Morris water maze between groups were evaluated using Repeated-measures two-way ANOVA followed by a least significant difference test as a post hoc test. To evaluate other effects of MCP, difference between all groups were compared using one-way ANOVA followed by a least significant difference test as a post hoc test or Dunnett's test. For all statistical tests $p < 0.05$ was considered significant.

3. Results

3.1. Effect of MCP on latency and number of errors in step-down test

One-way ANOVA revealed that the latency and number of errors in step-down test had significant difference among all five groups ($p < 0.01$, $p < 0.05$ respectively). As shown in Fig. 1, aged control showed significantly memory loss with respect to young mice. The error-number increased while latency reduced significantly in aged control with respect to young mice ($p < 0.01$). Treatment with 0.44% and 1.32% MCP prolonged the latency in the testing day compared with aged control ($p < 0.05$). Further-

more, there was no significant latency difference between young mice and 0.44% or 1.32% MCP treated mice. Regarding to mice treated with 0.22% MCP, a reduction in the latency was showed with respect to young control ($p < 0.05$) (Fig. 1A). As shown in Fig. 1B, treatment with 0.44% MCP showed a significant difference in the error-number compared to aged control ($p < 0.05$). No difference was observed between 0.22% or 1.32% MCP supplementation groups and aged control group. Compared with young mice, the error-number in all MCP treated mice had no significant difference.

3.2. MCP improves spatial learning and memory in Morris water maze

Morris water maze is a sensitive method for revealing the impairment of spatial learning and memory. Once animals learn where the hidden platform is located, they can remember the location and swim rapidly to it from any starting point. Both the time taken to reach the platform and the swimming distance traveled were measured. As shown in Fig. 2A and B, the mean latency to find the platform and swimming distance declined progressively during the training days in all animals. However, the aged control demonstrated markedly longer escape latencies and swim-traveling distance than young control group. MCP treatment to aged mice resulted in a significant decrease in escape latency and swim-traveling distance. The main effects for day on escape latency and swim-traveling distance were statistically significantly [$F(5, 370) = 210.32$, $p < 0.01$; $F(5, 370) = 292.22$, $p < 0.01$ respectively]. The main effects for group on escape latency and swim-traveling distance were also statistically significant [$F(4, 74) = 9.71$, $p < 0.01$; $F(4, 74) = 21.38$, $p < 0.01$ respectively]. The day × group interaction was not significant [$F(20, 370) = 0.73$, $p > 0.05$; $F(20, 370) = 1.20$, $p > 0.05$ respectively]. Post hoc test revealed a significant increase in escape latency and swim-traveling distance in aged control mice compared with young control mice and MCP-treated mice ($p < 0.05$). There were no differences between MCP treated and control mice in the swimming speed (data not shown).

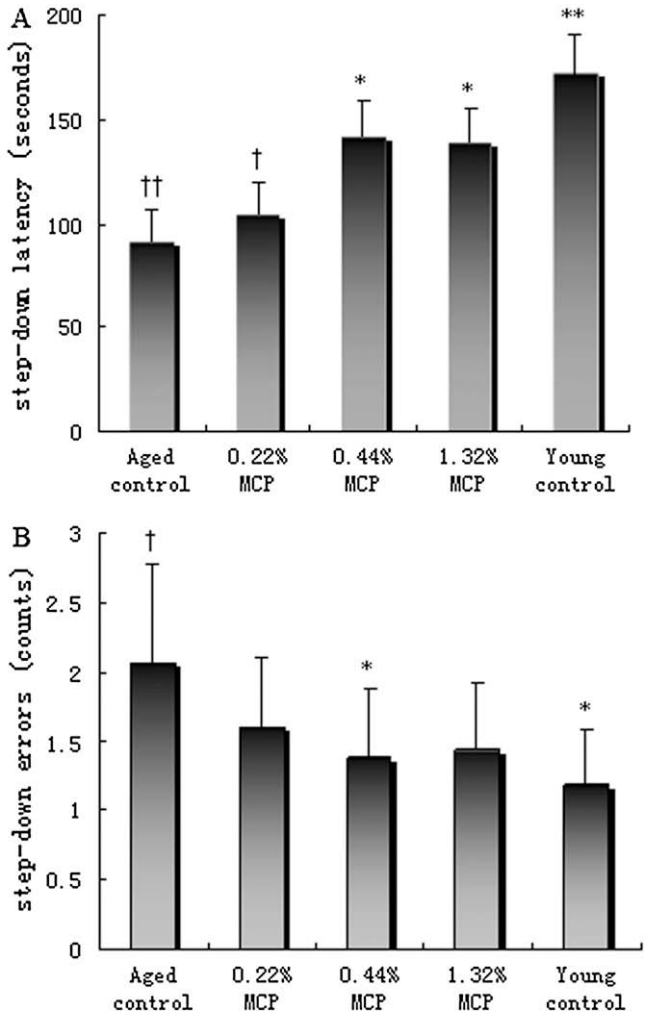

Fig. 1. Effects of MCP on latency (A) and number of errors (B) in step-down passive avoidance test. After daily oral treatment with MCP supplemented diet or standard diet for 3 months, animals were tested in step-down avoidance task. Values were presented as means ± SEMs of 15–16 mice. $^{*}p < 0.05$ compared to aged control mice; $^{**}p < 0.01$ compared to aged control mice; $^{\dagger}p < 0.05$ compared to young control mice; $^{\dagger\dagger}p < 0.01$ compared to young control mice (By Xinrong Pei, Ruiyue Yang, Zhaofeng Zhang, Lifang Gao, Junbo Wang, Yajun Xu, Ming Zhao, Xiaolong Han, Zhigang Liu, Yong Li*).

During the probe test, mice were swimming in the vicinity of the place that contained escape platform during the acquisition trial. There were significant differences on the time spent at target quadrant and number of times crossing over the platform among five groups ($p < 0.01$, $p < 0.05$ respectively). Young mice showed higher precision of the search for the platform as revealed by more time spent at the former platform position and higher number of crossing than aged control mice did (Fig. 2C and D). MCP seemed to restore the lost procedural subcomponent of spatial memory in aged mice, but only the 0.44% MCP had significantly effect on the time spent at target quadrant. On the other hand, 1.32% MCP could increase the number of times crossing over the platform site compared with aged control.

3.3. Effects of MCP on SOD, GSH-Px activities and TBARS level in serum

As regard to activity of SOD, all five groups of animals had significant difference ($p < 0.01$). Compared with young mice, the activity of SOD in serum significantly declined by 33.6% in aged control mice and MCP (0.22%, 0.44% or 1.32%) increased the activities of SOD nearly to 70.9%, 85.7% and 77.3% of the young mice, respectively (Table 2). The dose group of 0.44% MCP reached significant levels ($p < 0.05$) versus aged control.

Analysis on activity of GSH-Px also revealed a significant difference in five groups ($p < 0.01$). The activity of GSH-Px in serum of aged control group mice was significantly lower compared with young control group (Table 2, $p < 0.01$). MCP treatment resulted in an elevation in the activity of this enzyme. The dose group of 1.32% MCP ($p < 0.05$ versus aged control group) had more significant effect than other groups.

Aged control mice showed significant increase in TBARS level compared with the young mice ($p < 0.01$). This increase in TBARS was also attenuated in MCP treated mice.

3.4. Effect of MCP on morphological change in aged mice hippocampus

In order to discuss the neuroprotective effect of MCP, morphological change in hippocampus was observed using nissl staining method. In the young control group, multiple layers of pyramidal neurons with a dense and orderly arrangement were defined easily. However, in the aged control group, pyramidal neurons were less compact than those of young control group. Table 3 numerically expresses nissl positive cells in the CA1, CA3 regions and dentate gyrus (DG) of hippocampus. Measurement of total number in hippocampal CA1, CA3 and DG did not reveal any significant age-related change, although a slight age-related decline was observed. Similarly, no difference was seen in hippocampus between aged control and MCP treated groups.

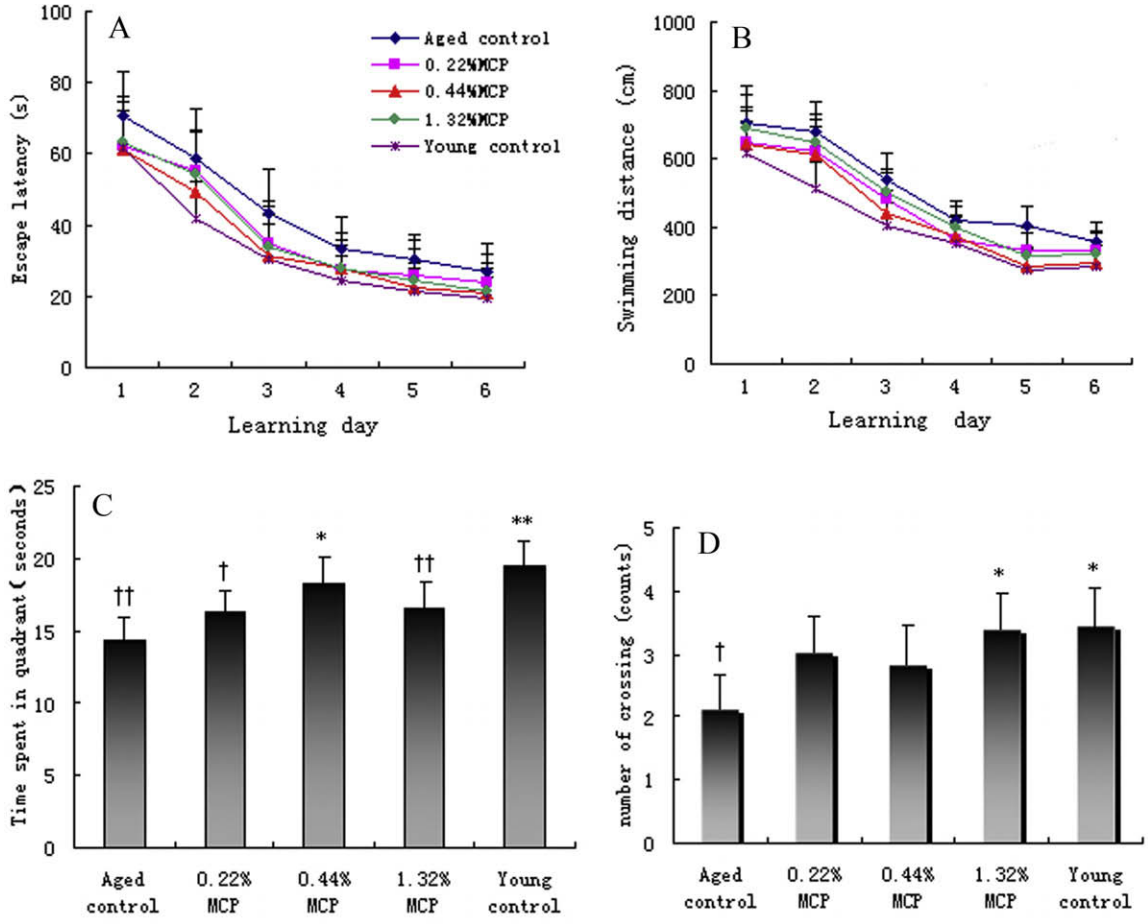

Fig. 2. Effects of MCP on spatial learning and memory of mice in Morris water maze test. The number for aged control group was 15, and 16 for other groups. (A) Escape latency to find the hidden platform. Two-way repeated measures ANOVA revealed statistically significant difference [group, $F(4, 74) = 9.71$, $p < 0.01$, day, $F(5, 370) = 210.32$, $p < 0.01$]. This difference was attributed to the longer latencies of aged control mice (post hoc LSD test $p < 0.01$ vs. all other groups) and shorter latencies of young control mice (post hoc LSD test $p < 0.01$vs. aged control group, $p < 0.05$ vs. 0.22% and 1.32% MCP treated groups). (B) Swimming distance travel to the goal platform. Two-way repeated measures ANOVA revealed statistically significant difference [group, $F(4, 74) = 21.38$, $p < 0.01$, day, $F(5, 370) = 292.22$, $p < 0.01$]. This difference was attributed to the longer distance of aged control (post hoc LSD test $p < 0.01$ vs. all other groups) and shorter distance of young control mice (post hoc LSD test $p < 0.01$vs. all other groups). (C) Presented were means ± SEMs time spent in target quadrant [one way ANOVA using LSD test, $^{*}p < 0.05$ compare with aged control mice, $^{**}p < 0.01$ compare with aged control; $^{\dagger}p < 0.05$ comparing with young control mice, $^{\dagger\dagger}p < 0.01$ comparing with young control mice]. (D) Presented were means ± SEMs numbers of crossing during the "probe test" [one way ANOVA using LSD test, $^{*}p < 0.05$ when compared with aged control mice; $^{\dagger}p < 0.05$ as compare with young control mice] (By Xinrong Pei, Ruiyue Yang, Zhaofeng Zhang, Lifang Gao, Junbo Wang, Yajun Xu, Ming Zhao, Xiaolong Han, Zhigang Liu, Yong Li*).

Table 2
Effects of MCP on superoxide dismutase (SOD), glutathione peroxidase (GSH-Px) and thiobarbituric acid-reactive substances (TBARS) in serum.

Group	*n*	SOD (U/mg protein)	GSH-Px (U/mg protein)	TBARS (MDA nmol/mg protein)
Aged control	8	81.56 ± 23.18††	818.63 ± 116.73††	2.67 ± 0.27††
0.22% MCP	8	87.13 ± 25.02†	874.02 ± 99.31†	2.18 ± 0.24*,†
0.44% MCP	8	105.37 ± 18.22*	886.54 ± 101.01†	1.78 ± 0.33*
1.32% MCP	8	95.00 ± 21.39†	945.14 ± 109.74*	2.31 ± 0.63†
Young control	8	122.87 ± 13.08**	1028.86 ± 161.80**	1.67 ± 0.52**

* $p < 0.05$ compared to aged control.
** $p < 0.01$ compared to aged control.
† $p < 0.05$ compared to young control.
†† $p < 0.01$ compared to young control.

3.5. Effect of MCP on expression of BDNF and PSD95 in hippocampus

As shown in Fig. 3, compared the aged control mice with the young mice, hippocampal BDNF and PSD95 decreased by 30% ($p < 0.01$) and 34% ($p < 0.01$) respectively.

The expression of hippocampal BDNF was significant up-regulated (29%, 26%) in aged mice treated with 0.44% and 1.32% MCP for 3 months ($p < 0.01$, $p < 0.05$ respectively) (Fig. 3). However the difference of hippocampal BDNF expression between aged control mice and 0.22% treated mice had no significant ($p > 0.05$).

The results also indicated that the level of PSD95 was significantly higher (38%) in 0.44% MCP treated mice than that of the aged control mice ($p < 0.01$) (Fig. 3). There was no significant difference of hippocampal PSD95 expression between aged control mice and 0.22%, 1.32% MCP treated mice ($p > 0.05$).

Table 3
Effect of MCP on nissl-positive cell numbers in hippocampal CA1, CA3 regions and DG.

Group	Nissl-positive cells (numbers/mm^2)		
	CA1	CA3	DG
Aged control	7591 ± 1392	5164 ± 665	17822 ± 996
0.22% MCP	7811 ± 1217	5314 ± 857	18302 ± 1292
0.44% MCP	7915 ± 1050	5639 ± 591	18115 ± 1026
1.32% MCP	7050 ± 1149	5505 ± 586	17989 ± 1134
Young control	7972 ± 759	6213 ± 1128	18044 ± 1058

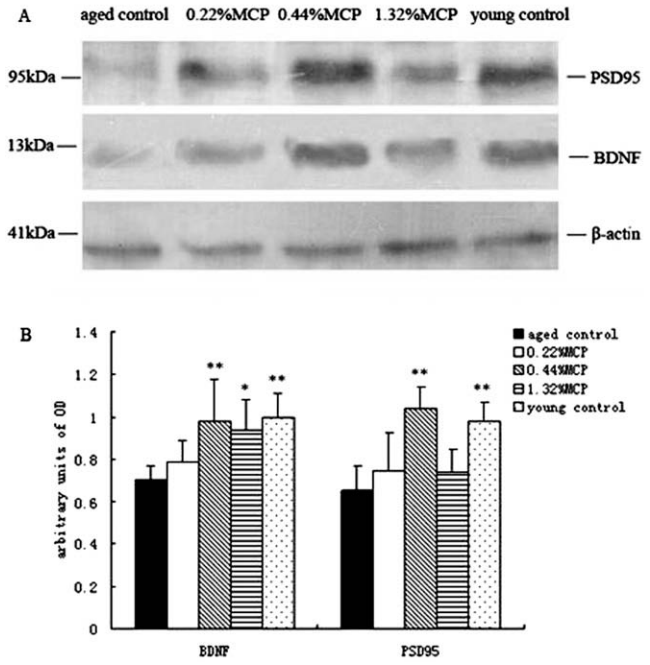

Fig. 3. Immunoblot analysis of BDNF and PSD95 in the hippocampus of the young, aged and MCP-treated mice. (A) Western blot from the aged group showed weak hippocampal BDNF and PSD95 compared with the young mice. Reinforced BDNF and PSD95 expression was observed in the MCP-treated groups, especially the 0.44% MCP treated group. Molecular weight markers (kDa) were shown on the left. (B) Quantitative analysis showed that hippocampal levels of BDNF and PSD95 protein of the young control mice and 0.44% MCP-treated mice were obviously higher than that of the aged mice. $^{*}p < 0.05$, $^{**}p < 0.01$ vs. the aged control group (By Xinrong Pei, Ruiyue Yang, Zhaofeng Zhang, Lifang Gao, Junbo Wang, Yajun Xu, Ming Zhao, Xiaolong Han, Zhigang Liu, Yong Li*).

4. Discussion

Unlike other dietary proteins, fish protein is likely to contain a lot of specific and potent bioactive sub-sequences in nutritional perspective for their competitive and aggressive living conditions (Aneiros & Garateix, 2004). Thus if the potent bioactive compounds were extracted and the functions were revealed, it would open a new perspective for pharmaceutical and functional food development.

MCP, compounds of proline and hydroxyl proline-rich oligopeptides, was derived from Chum Salmon (*O. keta*) skin which usually causes wastage and pollution in fish-processing industry (Kim et al., 2001). The low molecular weight distribution (100–860 Da) and small amounts of free amino acids, fat and carbohydrate, confirmed that the main composition of MCP was oligopeptides. The present study demonstrated that dietary administration of MCP could facilitate acquisition of spatial learning and increase the passive avoidance ability, bringing these to the level observed in young subjects. Furthermore, we found that these results were probably due to the antioxidative activity and protective effect on BDNF and PSD95 expression. To our knowledge, the present study is the first to reveal the neuro-protective effect of MCP on age-related deficit in rodents.

While the exact molecular basis of aging remains uncertain, the increasing accumulated related knowledge suggests that it may be related with the increase of free radical and neuroplasticity loss (Burke & Barnes, 2006). According to Free Radical Theory of Aging, the increase of lipid peroxides and the decrease activities of antioxidant enzymes, such as SOD and GSH-Px, are involved in the course of aging (Ceballos-Picot, Nicole, Clement, Bourre, & Sinet, 1992). The alterations are considered to play important roles in learning and memory deficits. In the present study, the activities of SOD and GSH-Px in serum showed a significant decline in aged control mice compared with young control; moreover, the activities of anti-oxidative enzymes such as SOD and GSH-Px were significantly increased in MCP treated group. As lipid peroxidation may also contribute to the neurotoxicity in mice, the peroxides could be indirectly estimated by measuring TBARS, a measure of lipid peroxidation and widely used as a biomarker of oxidative stress (Shahidi & Ho, 2007; Wanasundara & Shahidi, 1998). An obvious enhancement of the level of TBARS was shown in the aged control mice in this study, and it could be significantly reduced after MCP administration. The results indicate that MCP, to some extent, attenuates the oxidative injury in aging. In other words, the protection of MCP against oxidative stress to brain may be involved in the mechanism of its action to ameliorate the impairments of learning and memory.

Although neuronal cell loss was considered the main cause of learning and memory impairments during normal aging historically, more recent studies of rodents and humans demonstrated that the number of neurons in the hippocampal formation remained stable in aged subjects, irrespective of cognitive status (Calhoun et al., 1998; Rasmussen, Schliemann, Sorensen, Zimmer, & West, 1996). These data indicate that cognitive impairment may occur in aging, independent of neurodegeneration. Our analysis of the morphology of the hippocampal using nissl staining revealed that there was no evidence of aged-induced alterations in aged subjects compared to young control. In line with our observations, Nyffeler also reported that there was no difference in mean total volume of the hippocampus between performance groups as well (Nyffeler, Zhang, Feldon, & Knuesel, 2007). Nyffeler's and our findings support the assumption that aged-related cognitive impairments are not induced by gross morphological changes but rather associated with subtle connectional and synaptic reorganisation within the hippocampal formation (Nyffeler et al., 2007). There is now considerable evidence supporting the view that normal age-related memory deficits can be caused by functional changes, without the occurrence of major neuronal cell loss (Rapp, Deroche, Mao, & Burwell, 2002).

It is well established that brain-derived neurotrophic factor (BDNF), a crucial mediator of neuronal vitality and function, regulates the morphology through acting on both presynaptic and postsynaptic (Suzuki et al., 2004). It is emerging as a major player in neuronal events underlying learning and memory (Castren, Berninger, Leingartner, & Lindholm, 1998). The present study reported that BDNF in hippocampus of aged control group was lower than that of the young group, in agreement with previous data on age-related BDNF expression (Hwang et al., 2006). Furthermore, the results showed that when aged control group compared with 0.44% or 1.32% MCP-treated group, hippocampal BDNF increased by 29% and 26%, respectively. Although no information about how MCP regulates BDNF expression is provided in the present study, the authors think that there are several possible interpretations for MCP increasing BDNF expression: (1) It is well known that the generation of free radicals can lead to cell and tissue damage

paralleled by alterations in the function of the genetic apparatus, resulting in aging and untimely cell death (Droge & Schipper, 2007). MCP is confirmed to have antioxidant function, which can protect cerebral cells and reduce neuron cell apoptosis, therefore enhance the BDNF secretion indirectly or may probably protect the secreted BDNF directly from the oxidant damage. (2) The loss of elasticity and increasing rigidity of the aging vascular are considered as one of the factors leading progressively to severe arteriosclerosis and vascular dementia (Stewart, 2007). Collagen is well proved to improve vascular elasticity and reduce vascular rigidity, consequently increase the blood supply of brain (Bailey, Paul, & Knott, 1998; Silver, Horvath, & Foran, 2001), therefore protect the neuron cells and promote the expression of BDNF. Such effect may be another mechanism of how MCP increases BDNF expression. Despite lacking of direct evidence, the present results suggest that chronic MCP supplementation may prevent age-related learning and memory decline through increasing the expression of BDNF in hippocampus. However, further examinations are needed to elucidate the detail mechanisms on how MCP affects BDNF expression in brain.

BDNF does not only promote neuronal survival and differentiation, but also regulates synaptic transmission and plasticity in the central nervous system (CNS). There is now some considerable evidence indicating that brain has a decreased capacity for plastic response in aging process. Particularly, the hippocampus shows a reduction of synapticplasticity during aging (Teter & Ashford, 2002; Uylings & de Brabander, 2002). Consistent with these data, this study provided evidence for a concomitant decrease in PSD95 protein expression in the hippocampus of the aged mice. Nakata and Nakamura previously demonstrated that the expression of PSD95, a membrane-associated guanylate kinase protein enriched in the postsynaptic density (PSD), was increased upon BDNF addition (Nakata & Nakamura, 2007). Therefore, the PSD95 level in hippocampus was tested using immunoblot analysis in our research. A remarkable decrease in hippocampal PSD95 expression in the aged mice was found in the study, which supported previous reports of reduced PSD expression in aging brain (Head et al., 2007). At the same time, we presented reliable evidence of increasing hippocampal PSD95 of the aged mice receiving MCP administration. Furthermore, our results showed that PSD95 expression changed in an age-dependent manner, and BDNF revealed a similar expression pattern as compared with PSD95 in the hippocampus; also in MCP-treated groups, BDNF level increased in hippocampus accompanied with enhanced PSD95. PSD95 is thought to serve various functions at the synapse, implicate in the regulation of ion-channel function, synaptic activity, and intracellular signaling (Craven, El-Husseini, & Bredt, 1999). Therefore, the increased PSD95 expression induced by BDNF addition may represent a potential molecular substrate by which MCP increases hippocampal synaptic plasticity.

As mentioned above, MCP produced a biphasic effect, of which 0.44% MCP is an optical dose for memory, on the learning and memory in aged mice. This finding is not surprising, because numerous findings indicate that the U-shaped nature of the dose–response curve for the effects of promnestic agents on learning and memory is typical in that low doses have opposite effects from high dose, such as leptin, neuropeptide Y, colostrinin, et al. (Farr, Banks, & Morley, 2006; Flood, Hernandez, & Morley, 1987; Popik, Bobula, Janusz, Lisowski, & Vetulani, 1999).

In conclusion, the present study demonstrates that MCP can facilitate learning and memory in aged mice through reducing oxidative damage in the brain and increasing BDNF and PSD95 expression level. The increase in life expectancy in the 21st century has resulted in an increase in the prevalence of age-dependent diseases such as depression, Alzheimer's disease (AD) and other dementias. It is, therefore, crucial to develop appropriate health care means to deal with age-related neurodegenerative disorders, including cognitive deficits. Considering both the lack and the need of functional food or drugs proven to be effective in improving memory retrieval, the neuroprotective effect of MCP reported here is of vital importance and practical value. Undoubtedly it could be a candidate for functional food or drugs to manage/reduce memory deficits associated with aging.

Canola oil

ABSTRACT

This study was conducted to investigate the effect of dietary alpha-tocopheryl acetate (vitamin E) and oil sources on fish flesh quality characteristics of *Huso huso* during frozen storage. Practical-type diets containing 0 or 250 mg vitamin E kg^{-1} with three lipid sources, fish oil (FO), soybean oil (SO) and canola oil (CO), were fed to *H. huso* for 120 days. Fillet samples were analysed fresh or after storage at −18 ± 1 °C for 12 months. Replacement of FO by SO and CO in diets for *H. huso* significantly altered the fatty acid (FA) profile, which also influenced the FA composition during frozen storage. Dietary vitamin E had a significant effect on muscle vitamin E content and lipid oxidation during storage ($P > 0.05$). Oxidation was reduced for fish fed vitamin E and results showed that dietary vitamin E supplementation can slow down the level of lipid oxidation in *H. huso* muscles during frozen storage.

1. Introduction

The importance of fish oil for human cardiovascular health is well known. The *n*3-polyunsaturated fatty acids (PUFA) are particularly beneficial and fish continue to be their main source in the human diet. Numerous studies over the years have suggested that the dietary consumption of fish/fish oils containing *n*−3 fatty acids may favourably influence a number of biological factors associated with cardiovascular disease (independent of blood-cholesterol lowering) (Abedian-Kenari et al., 2009). However, the *n*−3 fatty acids are highly unsaturated, and therefore, susceptible to oxidation in fish fillets during storage.

It is well established that during freezing and frozen storage, lipid hydrolysis and oxidation leads to a PUFA decrease with an increase of peroxides, which are two of the most important factors contributing to post mortem deterioration of fish meat quality (Pirini, Gatta, Testi, Trigari, & Monetti, 2000). This process is promoted by the abundance of PUFA and high lipid content. Oxidation of lipids initiates other changes that affect the nutritional quality, wholesomeness, safety, colour, flavour, and texture of foods (Shahidi & Wanasundara, 1992).

The use of antioxidants can be an effective way to minimise or delay the oxidation process, retarding the formation of toxic oxidation products, maintaining nutritional quality and prolonging the shelf life of foods (Sau, Paul, Mohanta, & Mohanty, 2004). One way to improve product stability is through dietary supplementation with antioxidants such as vitamin E (DL-α-tocopheryl acetate), which has been reported to improve the stability of fish tissue lipids (Chaiyapechara, Casten, Hardy, & Dong, 2003; Pirini et al., 2000; Ruff, Fitzgerald, Cross, Hamre, & Kerry, 2003; Sant'Ana and Mancini-Filho, 2000; Sau et al., 2004; Yildiz, Şener, & Gün, 2006).

DL-α-tocopheryl acetate, the form of synthetic vitamin E commonly added to fish feed, functions as a lipid soluble antioxidant that protects biological membranes, lipoproteins and lipid stores. Its main function is to protect unsaturated fatty acids against free radical-mediated oxidation (Sau et al., 2004). It is fairly stable during feed storage and only becomes active as an antioxidant after the hydrolysis of the acetate group in the fish's body, and therefore, it is not an antioxidant in the feed (Chaiyapechara et al., 2003).

In the aquaculture industry, marine fish oil (MFO) is the main oil supplement in fish diets to increase their energy content and provide essential fatty acids. A major challenge for future aquaculture production is a stable, predictable and high quality feed supply (Şener, Yildiz, & Savaş, 2005). Due to the decreased availability and increased cost of MFO, there needs to be consideration of the possible replacement with vegetable oils (e.g., soybean and canola oil). At present, partial or total replacement of MFO by vegetable oils in diets for farmed fish such as sturgeon species (i.e., white sturgeon, Xu, Hung, & German, 1993; adriatic sturgeon, McKenzie et al., 1999; and Russian sturgeon, Şener et al., 2005), are practiced without compromising growth, feed efficiency, reproduction or the health of fish. However, it is well known that the dietary fatty acid (FA) profile strongly affects the nutritional quality of the fish (Abedian-Kenari et al., 2009; Sargent, Bell, Bell, Henderson, & Tocher, 1995). Thus, it is important to understand the impact of vegetable oils on quality related characteristics in farmed Beluga sturgeon after ice- or frozen storage.

In recent years the intensive culture of certain sturgeon species has been developed as an alternative to other more traditional fish species such as salmonids and cyprinids. The Beluga sturgeon (*Huso huso*) is an increasingly important aquaculture species in Russia, Eastern Europe, Turkey, Japan and Iran because of the dwindling natural sources for its caviare and meat. This fish is a commercially important fish and is commonly processed into frozen fillets. Although microbial deterioration of fish muscle can be inhibited by frozen storage, as mentioned previously, fish lipids undergo a number of changes that affect the flavour and texture of the flesh (Dragoev, Kiosev, Danchev, Ioncheva, & Genov, 1998). These changes are important since they determine the storage life of the frozen product and are a major consideration in grading the quality of frozen fish. However, to our knowledge, no study has been performed on the effects of vitamin E and frozen storage on the quality of Beluga sturgeon grown using vegetable oils as the principle lipid in their diet.

Therefore, the purpose of the present study was to investigate the effects of vitamin E supplementation, and dietary oil sources on muscle fatty acid composition and flesh quality parameters (mainly lipid oxidation) of Beluga sturgeon during frozen storage (−18 °C). Flesh quality parameters were analysed on day 0 (post-rigor) and during frozen storage (1, 2, 3, 4, 5 and 6 months). Fish were also analysed after long-term frozen storage (12 months) to show whether an altered fatty acid profile due to inclusion of dietary vitamin E and vegetable oils influenced lipid deterioration (peroxide value, PV; free fatty acid, FFA; thiobarbituric acid, TBA; heme iron, HI) and consumer quality indexes [fatty acid (FA) profile; atherogenic index, AI; thrombogenic index, TI; water holding capacity, WHC].

2. Materials and methods

2.1. Feeding trial and fish diets

During 120 days between May and October, the experiments were carried out at the Iranian government's sturgeon hatchery, Shahid Rajaei (Sari, Mazandaran, Iran. Latitude 36° 37′N, Longitude 53° 05′E). The fish were from a genetically homogenous stock obtained from a mesocosm hatchery (land-based pond), weaned and adapted to a compound diet. During the acclimatisation period, fish were fed (five times and 5% of body weight) daily with a semi-moist pellet diet that was provided by a local manufacturer of livestock and aquatic feeds in Mazandaran-Sari (Iran).

Two hundred and seventy Beluga sturgeon juveniles, with near uniform biomass, were selected and distributed randomly into three replicated groups for each treatment in 2000 l fibreglass tanks (18 tanks and 15 fish per tank) for the feeding trials. The initial weight and length of the experimental fish was 209 ± 12 g and 348 ± 11 mm. Fish were reared with an earth bottom and supplied with flowing water constantly overflowing (with a flow rate of around 15 l min^{-1}). The water quality parameters observed during the experimental period were temperature (19–23 °C), oxygen saturation (73–88%), total alkalinity (136 ± 2.11 mg l^{-1} as $CaCO_3$), pH (6.95–7.75) and salinity ⩽ 1 ppt. Tanks were indoors and the light cycle was 16 h light and 8 h darkness.

In the present study, kilka fish oil (FO) rich in eicosapentaenoic acid (EPA, 20:5*n*3) and docosahexaenoic acid (DHA, 22:6*n*3) was chosen as the fish oil, soybean (SO), rich in linoleic acid (LN, 18:2*n*−6) and canola oil (CO) rich in oleic acid (OA, 18:1*n*−9) and α-linolenic acid (ALA, 18:3*n*−3) were chosen as the vegetable oil sources, and DL-α-tocopheryl acetate (Sigma Chemical Co., St. Louis, MO, USA) was used as the antioxidant. FO was provided by a local manufacturer of livestock and aquatic feeds in Mazandaran-Sari and SO and CO were provided by a local manufacturer of vegetable oil extraction (Khazar Yeganeh Oil Seed Co, Agh ghala, Iran). Six experimental fish meal-based diets (practical-type) were formulated by LINDO software-linear programming (LINDO

[f] NFE + crude fibre.

[g] Calculated on the basis of 23.6, 39.5 and 17.2 kJ g^{-1} of protein, fat and carbohydrate, respectively (NRC, 1993).

[h] Vitamin E is supplemented as DL-α-tocopheryl acetate at 250 mg kg^{-1} diet. Analysed vitamin E contents in control diets of FO, SO and CO were found to be 18.2, 41.7 and 28.3 mg kg^{-1} diet, respectively.

Systems Inc., Chicago, IL, USA) to have similar protein and lipid by adding of FO, SO or CO. DL-α-tocopheryl acetate was added to the basal diet (dietary oil treatment) at the expense of small amounts of cellulose to provide the desired quantity of 250 mg kg^{-1}. The basal diet without the addition of DL-α-tocopheryl acetate is referred to as the control diet.

The dietary treatments were randomly assigned to the experimental tanks. All diets were prepared in the aquatic nutrition laboratory of Tarbiat Modares University, Noor (Iran). The experimental diets' ingredient composition is presented in Table 1 and the fatty acid profile of the initial fish, oil used and the diets is presented in Table 2. The diets were stored in airtight freezer bags at −18 ± 1 °C until used. All groups of fish were fed their respective diet by hand to visual satiety (visual observation of first feed refusal). The fish were fed the experimental diets five times a day at 8, 12 16, 20 and 24 h for 120 days.

At the end of the feeding trials, all fish in each tank were collected and immediately killed in a tank containing fresh water and ice (hypothermia), and transferred to the laboratory within ~2 h in foamed polystyrene, self-draining boxes with a suitable quantity of flaked ice (the ice/fish ratio was 3:1, w/w). After passing into rigor, fish were washed with potable water, and then eviscerated manually (head and skin were not removed). During preparation, fish were kept in ice and the process was carried out at room temperature (~14 °C). The samples from each trial group were separately packed into a black nylon bag (un-vacuumed) then transferred to an air-blast freezer and kept at −18 °C for different times (0 or fresh, 1, 2, 3, 4, 5, 6 and 12 months). At the time designated, samples were randomly chosen from every group and were subjected to chemical analysis. Before analysis, samples were thawed (in the original bag) in a refrigerator (Yakhsaran, Tehran, Iran) at 3 ± 1 °C for approximately 10 h.

Table 2
Fatty acid profile of the initial fish (*Huso huso*), oils (fish, soybean and canola oil) and of the experimental diets.[a]

Fatty acid	Initial fish[b]	Oils			Experimental diets

[e] Polyunsaturated fatty acids: C18:2*n*6 + C18:3*n*3 + C20:4*n*6 + C20:4*n*6 + C20:5*n*3 + C22:6*n*3.
[f] Total unsaturated fatty acids: ∑MUFA + ∑PUFA.

2.2. Chemical analysis

2.2.1. Sampling procedure

For the chemical analyses, a slice sample (about 15 g in front of the dorsal fin) was taken for water holding capacity (WHC, %) analysis as described by Pastoriza, Sampedro, Herrera, and Cabo (1998) and the rest was homogenised (without skin and backbone), twice, in a meat blender (SAYA, Model: Promeat W-1800, Tehran, Iran) for around 2 min and sieved through a 4 mm mesh. In the present study, PV, FFA, TBA, HI and WHC were analysed for all sampling occasion, but the FA profile, lipid quality index and vitamin E content were only analysed on 0 (fresh), and at 6 and 12 months.

An initial sample of 12 fish was taken at the start of the experiment to determine baseline levels for proximate compositions, FA profile and vitamin E in muscle (without separation of white and dark muscle). After passing into rigor, fish were washed with potable water, and then headed, gutted, skinned, deboned and filleted manually, using a new sterile scalpel for each fish within 30–45 min, on both sides. The right side was used for the proximate composition assays and the other side was used for determination of FA profile and vitamin E content. The same day, the fillets were homogenised, twice, in a meat blender and immediately analysed for proximate compounds, FA profile and vitamin E content. The preparation process was carried out at room temperature (19 ± 3 °C).

2.2.2. Proximate analysis

The proximate composition at the start and also at the end of the feeding trials were done according to the procedures of the Association of Official Analytical Chemists (AOAC, 2005). Moisture, ash, crude fibre, protein and fat contents were assayed by methods 934.01, 920.153, 973.18, 954.01 and 991.36, respectively. Moisture was determined by drying the samples in an oven (Heraeus, D-63450, Hanau, Germany) at 105 °C to constant weight; ash was determined by incineration in a muffle furnace (Isuzu, Tokyo, Japan) at 600 °C for 3 h; crude fibre was determined by the acid detergent fibre (ADF) method (Fibertec System1010 Heat Extractor, Höganäs, Sweden); crude protein was determined by the Kjeldahl method (N × 6.25) using an automatic Kjeldahl system (230-Hjeltec Analyzer, Foss Tecator, Höganäs, Sweden); crude fat content was measured by gravimetry after extraction with petroleum ether using an automatic Soxtec device (FOSS, Soxtec™ 2050, Höganäs, Sweden); Nitrogen Free Extracts (NFE) was calculated following the formula below and NFE plus fibre was expressed as carbohydrate:

$$\text{Nitrogen Free Extract (NFE)} = 100 - (\text{Crude Protein} + \text{Crude Lipid} + \text{Fibre} + \text{Ash} + \text{Moisture})$$

$$\text{Carbohydrate} = \text{NFE} + \text{Fibre}$$

2.2.3. Analysis of vitamin E, heme iron and lipid (lipid extraction, PV, FFA, TBA, FA profile, AI and TI)

Vitamin E content of fish muscle and feed samples was determined by high-performance liquid chromatography (HPLC)

according to the extraction procedure of Liu, Scheller, and Schaefer (1996), and Vitamin E content was reported as mg kg^{-1} of muscle or feed. Total heme iron (ppm) was determined using the method of Clark, Mahoney, and Carpenter (1997). PV, expressed as meq of peroxide oxygen kg fat^{-1}, and FFA, expressed as % of oleic acid, were determined according to Egan, Kirk, and Sawyer (1981) on the extracted lipids obtained from homogenised fish by the Bligh and Dyer (1959) procedure. The TBA was determined according to Kirk and Sawyer (1991) method. The colour development was measured at 532 nm by using a UV–vis spectrophotometer (JENWAY 6305, Germany). The TBA value was expressed as mg malonaldehyde (MA) kg^{-1} of fish flesh. Total lipids in the diets and the fillets were extracted from a homogenised sample using the methodology described by Folch, Lees, and Sloan-Stanley (1957) and the extracted lipids were used for the FA profile analysis in diets and fish sample, and was done on the extracted lipids as previously described (Abedian-Kenari et al., 2009). Briefly, FA methyl esters were obtained by transmethylation using 20% BF_3 in methanol (Merck, Darmstadt, Germany). They were analysed by gas liquid chromatography (GLC) on a Phillips GLC-PU4400 (Phillips Scientific, Cambridge, United Kingdom), equipped with a fused silica capillary polar column (BPX70, 60 m × 0.32 mm ID, 0.25 μm film thickness, SGM, Victoria, Australia), and a flame ionisation detector (FID). The carrier gas was helium and the split ratio was 1:20. A thermal gradient from 160 to 230 °C at 45 °C min^{-1} was used with the injector and FID temperatures at 240 and 280 °C, respectively. The relative quantity of each FA was determined by measuring the area under the peak corresponding to a particular FA (% of total FA). The total quantity of identified FA was similar between sampling times (90–94%).

The lipid quality indices, i.e., the atherogenic index (AI) and the thrombogenic index (TI), were calculated according to Ulbricht and Southgate (1991) on the basis of fatty acid percentages including the saturated, monounsaturated fatty acids (MUFA) and PUFA:

$$AI = [12:0 + 4(14:0) + 16:0]/[MUFA + n-3PUFA + n-6PUFA]$$

$$TI = [14:0 + 16:0 + 18:0]/[0.5MUFA + 0.5(n-6PUFA) + 3(n-3PUFA) + (n-3PUFA/n-6PUFA)]$$

2.3. Statistical analysis

Descriptive statistics of the analysis results were calculated for each treatment. All data were subjected to one-way analysis of variance (ANOVA) to test the effects of experimental diets. The data were tested for homogeneity of variances at a significant level of $P < 0.05$ by the One-Sample Kolmogorov–Smirnov Test and probability values less than 0.05 were considered as statistically significant. Paired sample *t*-test was used for mean comparison of dietary vitamin E within dietary oil sources. Excel and SPSS version 13.5 (SPSS Inc., Chicago, IL, USA) computer programs were used for data manipulations and statistical analysis.

3. Results and discussion

The proximate compositions of the measured edible portions (muscle) of *H. huso* fed experimental diets are shown in Table 3. Slight changes were observed for some measured components ($P < 0.05$). Muscle lipid content in fish fed the SO diet (with or without vitamin E) was greater than other dietary groups. Conversely, the muscle protein content was lower in fish fed the SO diet compared with all other treatments, but statistical analysis did not show significant differences ($P < 0.05$). This relationship between muscle protein and lipid content has been observed in previous study with Russian sturgeon (Şener et al., 2005) and salmonids (Bell et al., 2001). On the other hand, dietary lipids and the retention of lipids, particularly in fillets, are parameters often discussed in connection with quality. In farmed fish the fatty acids as well as other fillet lipids may be altered by feeding (Bell et al., 2001), so controlled diets can be used to manipulate the FA profile of tissue lipids.

Vitamin E content in fillets from the fish fed the experimental diets is shown in Fig. 1. Dietary vitamin E had a significant effect on the α-tocopherol content of fish muscle ($P < 0.05$). At the end of the feeding trial, the supplemented fillets were 17.7, 19.4 and 17.9 mg kg^{-1} muscle, respectively, for FO, SO, and CO. Results from the present study are consistent with previous studies where the dietary supplementation of vitamin E increased the concentration of tocopherol in the edible tissues of fish (Chaiyapechara et al., 2003; Jitinandana, Kenney, Slider, Kamireddy, & Hankins, 2006; Pirini et al., 2000; Sau et al., 2004; Yildiz et al., 2006). During frozen storage, muscle α-tocopherol content decreased in all feeding groups ($P < 0.05$) and the highest reduction was observed for the FO + E diet (about 60% reduction). Decreased α-tocopherol content during frozen storage has been reported in rainbow trout (Jitinandana et al., 2006).

DL-α-tocopheryl acetate did not affect the FA composition of the feed ($P > 0.05$). For this reason, the data presented in Table 2 are the mean values of each dietary group with and without supplementation. In addition, DL-α-tocopheryl acetate did not affect the FA composition of the fresh muscle ($P > 0.05$, Table 4). This observation is supported by Jitinandana et al. (2006) and Yildiz et al. (2006) who also found that dietary vitamin E did not affect fish muscle FA composition. The FA profile also confirms that the

Table 3
Mean concentrations (% dry weight basis except for % moisture) of proximate constituents in the Beluga sturgeon, *Huso huso*, reared on different diets.[A]

Proximate constituent	Initial fish	Dietary treatment					
		FO	SO	CO	FO + E	SO + E	CO + E
Muscle							
Moisture	74.7 ± 1.10a	72.5 ± 1.37	72.1 ± 2.31	73.1 ± 1.85	72.9 ± 1.50	71.5 ± 1.78^{b}	72.4 ± 0.76
Crude lipid	20.3 ± 1.74	24.9 ± 1.05	27.1 ± 2.15	24.8 ± 1.27	24.5 ± 1.69	26.9 ± 1.72	25.1 ± 0.50
Crude protein	70.4 ± 2.56	70.6 ± 0.96	69.3 ± 1.88	70.4 ± 1.01	70.1 ± 0.96	68.9 ± 1.86	70.6 ± 0.52
Ash	4.37 ± 0.85	4.07 ± 0.16	4.19 ± 0.21$_{x}$	4.50 ± 0.17$^{ab}{}_{x}$	4.31 ± 0.17	5.07 ± 0.24$^{a}{}_{y}$	3.97 ± 0.22$_{y}$

Different superscripts a, b & c indicate significant ($P < 0.05$) differences between all dietary treatments (irrespective of dietary vitamin E and oil source) and different subscript x & y indicate significant ($P < 0.05$) difference between the diet with vitamin E within a single dietary oil source.
[A] See Table 1 for diet abbreviations.

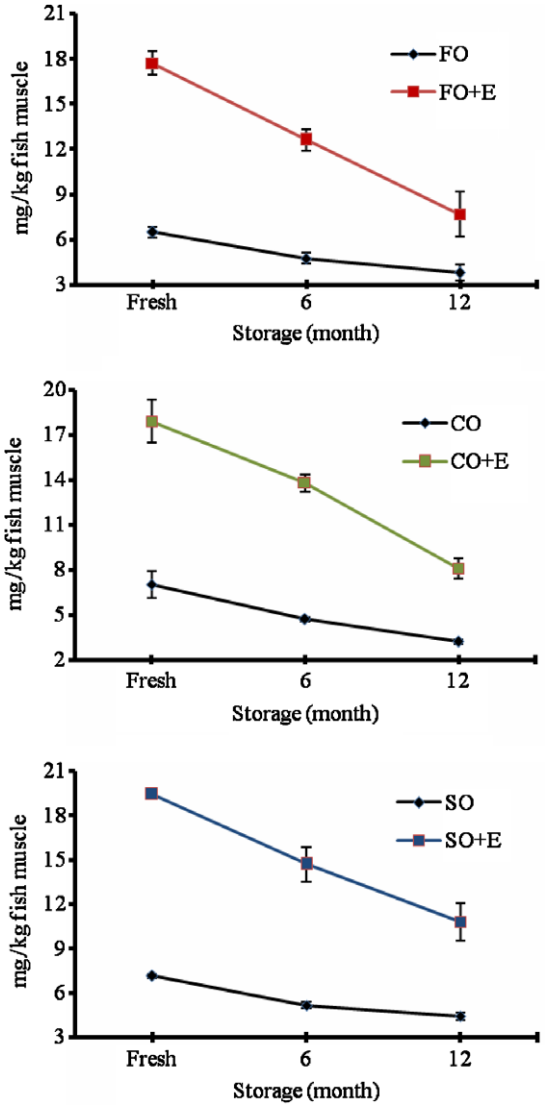

Fig. 1. Muscle vitamin E content (mg kg^{-1} muscle) of Beluga sturgeon, *Huso huso*, fed the experimental diets at 0 (fresh), 6 and 12th months frozen storage. See Table 1 for diet abbreviations.

assimilation patterns of dietary fatty acids in fish muscle reflect the content of the dietary lipid sources. This correspondence with diet content is not only related to the high presence of C16:0, C18:1*n*−9 and C_{18} PUFAs, but also to the high percentage of *n*−3 HUFA (EPA and DHA), which are definitely of exogenous origin. As shown in Tables 2 and 4, feeding sturgeon with diets rich in C_{18} PUFA (SO, CO diets) resulted in relatively good levels of EPA and DHA in the fish muscle. These results showed that *H. huso* have the ability to de-saturate and elongate C_{18} PUFA to EPA and DHA. This is in agreement with the obtained results on other sturgeon fish (Deng, Hung, & Conklin, 1998; Şener et al., 2005; Xu et al., 1993;). Furthermore, with the exception of the SO group, the *n*3/*n*6 ratio obtained from the present study was within the recommended ratio (1:1–1:5) for a healthy human diet (Osman, Suriah, & Law, 2001), but it was lower than that of the other cultured sturgeons [(4.26 for *Acipencer* spp.; 6.74 for *A. naccarii* × *A. baerii* (hybrid); and 4.94 for *H. huso* (reported by Abedian-Kenari et al., 2009)]. In the present study, the major fatty acids found in *H. huso* were palmitic (16:0), oleic acid (OA, 18:1*n*−9), linoleic acid (LN, 18:2*n*−6) and DHA, which is in agreement with the results of Abedian-Kenari et al. (2009) on *H. huso* at different ages.

In this trial fish fed supplemented diets with vitamin E had less significant variation in FA composition in comparison to the control diets during frozen storage at 18 ± 1 °C (Table 4). The FA composition of the muscle underwent slow changes during frozen storage. Fish muscles had higher concentrations of total SFA at 12 months compared to day 0 (fresh) for all dietary treatments ($P < 0.05$). The MUFA levels of the fillet were similar during the 12 months of storage ($P > 0.05$). The *n*−3/*n*−6 ratio of the fillet was the highest on day 0 and the lowest on month 12 ($P < 0.05$). The EPA and DHA levels decreased significantly from day 0 to month 12 ($P < 0.05$), but this reduction was less with the vitamin E treatments. The same trends during storage were observed by Jitinandana et al. (2006) and Yildiz et al. (2006) for rainbow trout fed different levels of dietary vitamin E, but similar results were not observed by Pirini et al. (2000), who found dietary vitamin E supplementation had no affect on general fatty acid composition, MUFA and PUFA content of experimental fish during storage.

Lipid nutritional quality and the AI or TI values are inversely related (Ulbricht & Southgate, 1991). In the present study the lipid quality indices (AI and TI) showed significant variation during frozen storage, but were lower in fish fed diets containing vegetable oils ($P < 0.05$, Table 4). These results showed that the use of vege-

Table 4

[A] Different superscripts a, b & c indicate significant ($P < 0.05$) differences between each dietary treatments (irrespective of dietary vitamin E). See Table 2 for fatty acid abbreviation and equations.
[B] Atherogenic index.
[C] Thrombogenic index.

table oils in *H. huso* diet is effective in reducing the SFA, AI and TI, with consequent benefits on the nutritional quality for human consumption. In this regard, Abedian-Kenari et al. (2009), reported AI and TI values of 0.465–0.698 and 0.441–0.486 for *H. huso* at different ages, respectively.

Lipid deterioration is the main cause of shortened shelf life of fish (mainly in fatty fish) due to progressive oxidation (PV and TBA) and enzymatic hydrolysis (FFA) of unsaturated fatty acids and as mentioned previously, the use of antioxidants is an effective way to minimise or delay these reactions. The activity of an antioxidant can be estimated by quantitatively determining primary (PV) or secondary (TBA) products from the autoxidation of lipids or by monitoring other variables, such as accelerated oxidation studies and model systems tests (Shahidi & Wanasundara, 1992).

In the present trial, though the fat content in Beluga sturgeon was similar (Table 3) in all the dietary groups, the degree of lipid oxidation was different (Fig. 2, $P < 0.05$). The differences in lipid oxidation possibly resulted from the different FA compositions. The inclusion of vegetable oils in fish diet reduces lipid peroxidation in fish muscle (e.g., Atlantic salmon, Regost, Jakobsen, & Rørå, 2004; and red hybrid tilapia, Ng & Bahurmiz, 2009), and thereby might enhance the sensorial attributes of the flesh for human consumption. In the present work, replacement of FO by SO and CO decreased lipid oxidation irrespective of vitamin E supplemen-

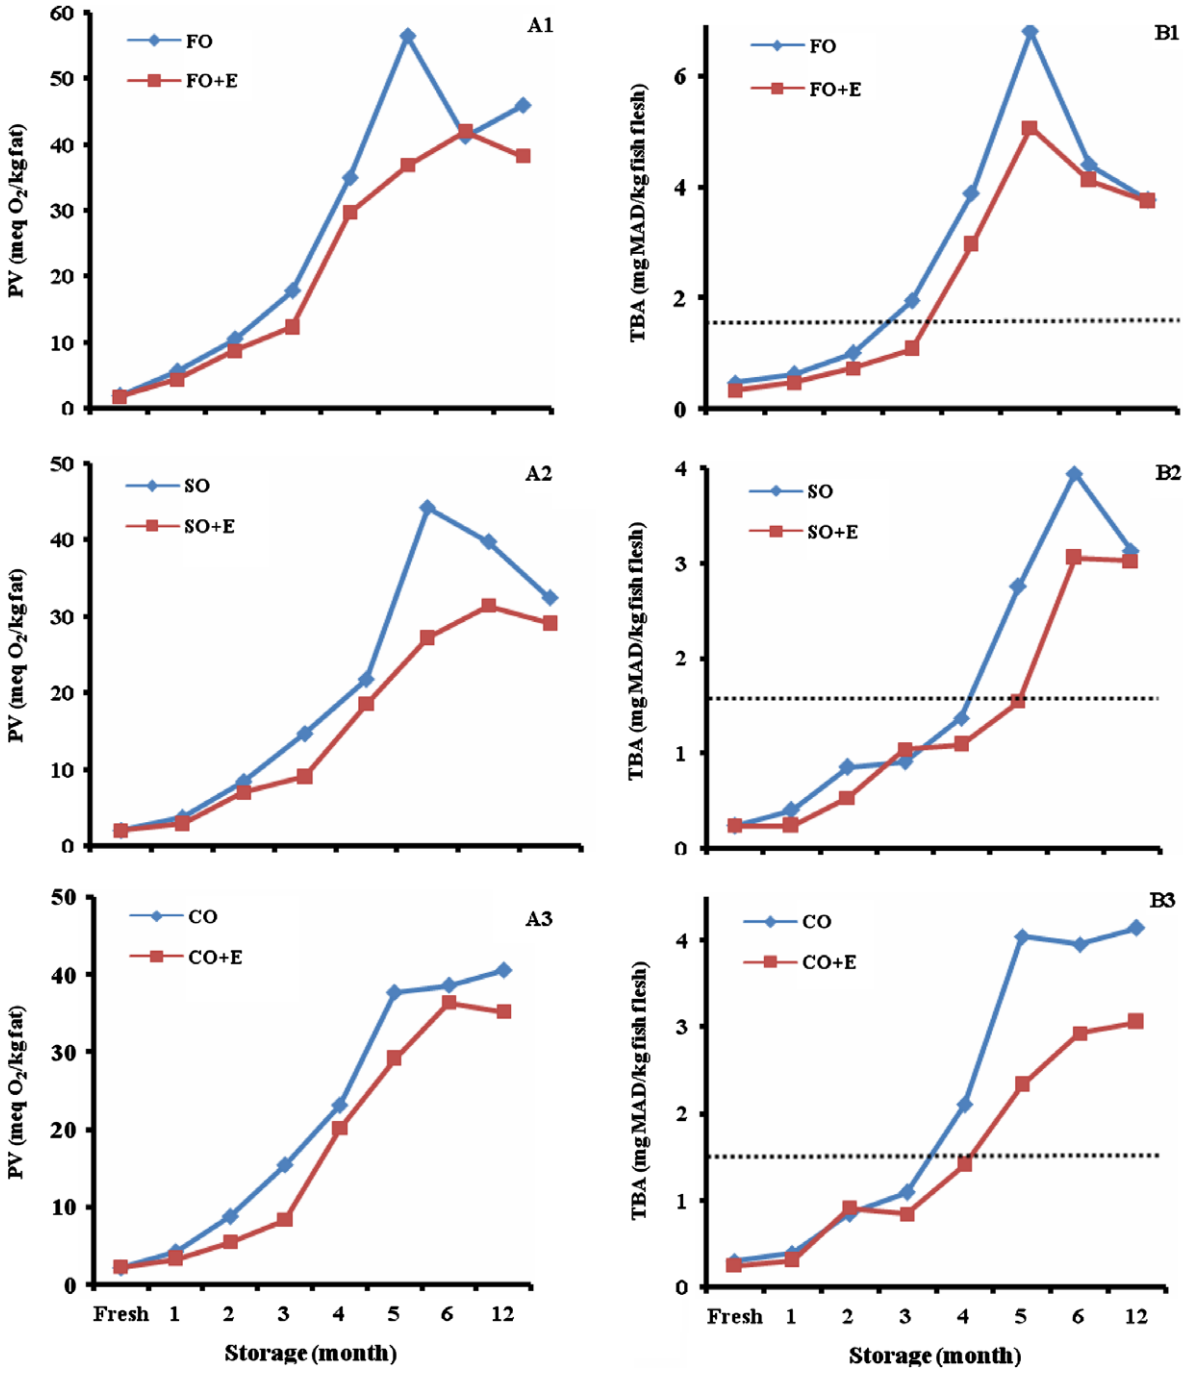

Fig. 2. Muscle peroxide value (PV. A1–3) and thiobarbituric acid (TBA, B1–3) levels of Beluga sturgeon, *Huso huso*, fed the experimental diet for 120 days during frozen storage at −18 °C. See Table 1 for diet abbreviations. (The dotted line represent limit acceptance. Error bar not shown.)

tation (Fig. 2). In addition, the deposition of tocopherols and tocotrienols in diets containing vegetable oil enhanced oxidative stability.

As shown in Fig. 2, the PV and TBA levels were found to be low in all vitamin E groups ($P < 0.05$) throughout the storage period, but as frozen storage time lengthened, PV and TBA levels gradually increased. This may be related to the loss of vitamin E (Fig. 1) that was caused by lipid peroxidation (Yildiz et al., 2006). In addition, it is significant that the Beluga sturgeon used in this study were stored at −18 °C and protected from light, capable of starting lipid oxidation, by a dark sheet of plastic. These conditions most likely contributed to the inhibition of lipid degradation even at low vitamin E concentrations. Frigg, Probucki, and Ruhdel (1990) indicated that when the α-tocopherol concentration in rainbow trout fillet increased to approximately 20 μg g^{-1} then fillet oxidation in fish tissue was effectively prevented. A similar effect of dietary vitamin E concentration in reducing fillet lipid oxidation was observed in rainbow trout (Chaiyapechara et al., 2003; Jitinandana et al., 2006; Yildiz et al. 2006), pacu (Sant'Ana and Mancini-Filho, 2000) and sea bass (Pirini et al., 2000). Since vitamin E prevents the development of rancidity, vitamin E levels and TBA values could be used as indices for fish quality evaluation. However, Auburg (1993) reported that TBA values may not give the actual rates of lipid oxidation since malondialdehyde can interact with other components of fish such as nucleosides, nucleic acids, proteins, amino acids, phospholipids and other aldehydes that are end-products of lipid oxidation. According to a sensory study of various fresh and frozen fish by Ke, Cervantes, and Robles-Martinez (1984), fish flesh with TBA greater than 21 μmol MDA kg^{-1} (1.51 mg MDA kg^{-1}) should be considered rancid and unacceptable. It is important to note that the TBA level for the SO group observed in this study reached this level later than the FO and CO groups (with or without dietary vitamin E).

DL-α-tocopheryl acetate did not affect lipid hydrolysis (FFA), WHC and HI (Fig. 3, $P > 0.05$). For this reason, the data presented in Fig. 3 are the mean values of each dietary oil group. As shown in Fig. 3, progressive development of lipid hydrolysis was observed ($P < 0.05$) during frozen storage but there was no significant differences among experimental diets. These results showed that even the low temperature (−18 °C) could not stop lipid hydrolysis. As a result of the hydrolysis, the original fish lipid structure is destroyed. In the process, significant amounts of FFA are released. They can then be included in the lipid oxidative processes started by free radicals, metal ion initiators, different enzymes or light. This finding is in agreement with that of Dragoev et al. (1998) who found progressive lipid hydrolysis ($P < 0.05$) in carp and mackerel during frozen storage.

The WHC of the muscle is an important flesh quality property of fish, since water is essential for maintaining good texture properties (Ng & Bahurmiz, 2009). Protein denaturation during frozen storage can cause loss of WHC in thawed fish. In the present study muscle WHC in the experimental fish was fairly stable and gradually decreased ($P > 0.05$) as the frozen storage time increased. Although no significant variation was found between the dietary groups ($P > 0.05$), there was a tendency for *H. huso* fed the SO diet to have a higher WHC during the frozen storage. The observed difference in WHC between *H. huso* fed the FO diet and *H. huso* fed vegetable oil diets seemed to be related to the unsaturated FA (Regost et al., 2004), but this aspect needs further investigation. Published reports on the effects of dietary oil on the WHC of fish are limited, and the results are often contradictory. Regost et al. (2004) reported significant differences in WHC in fillets of Atlantic salmon fed different dietary oils. Contradictory results were reported on the red hybrid tilapia by Ng and Bahurmiz (2009), who reported that WHC was not influenced by the dietary oil source, which is in agreement with the results of the present study.

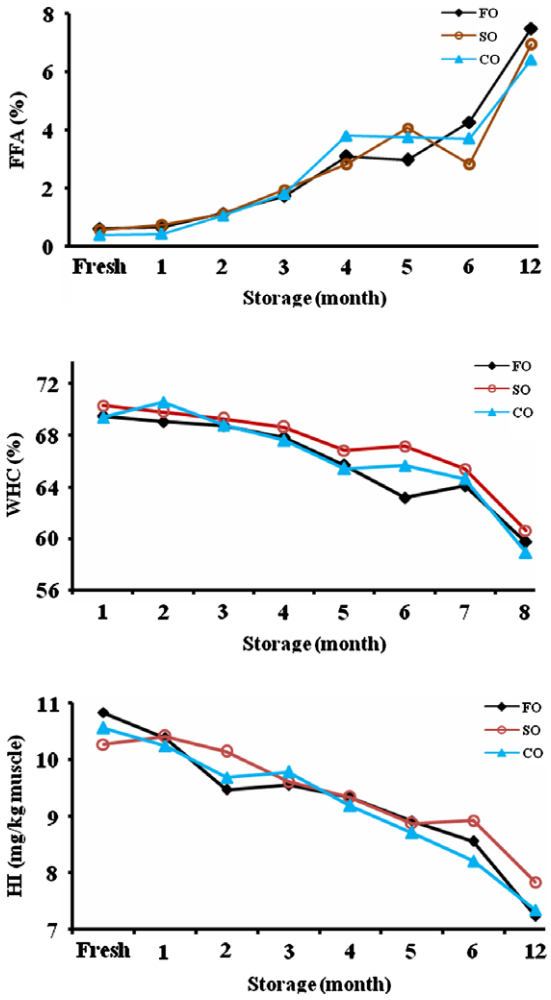

Fig. 3. Muscle free fatty acid (FFA), water holding capacity (WHC) and heme iron (HI) during frozen storage (−18 °C) of Beluga sturgeon, *Huso huso*, fed experimental diets (error bar not shown). See Table 1 for diet treatment.

In the present study, the HI decreased with increasing storage time ($P < 0.05$). Transition metal ions, notably iron, are important in the generation of free radicals that can initiate lipid peroxidation. During storage and processing of fish, heme complexes may have been destroyed and "free" iron released, the latter being considered as the main catalyst of the lipid peroxidation processes in muscle (Dragoev et al. 1998). In the present study, significant correlations were observed between HI values and lipid oxidation for all samples. The results corroborates the experimental findings of Dragoev et al. (1998).

4. Conclusion

This study showed that although proximate composition of Beluga sturgeon, *H. huso*, is not influenced by dietary oil sources. The muscle FA profiles reflected dietary FA profile. Also, there were no significant effects of dietary DL-α-tocopheryl acetate on proximate composition and FA composition of fish muscles. Muscle α-tocopherol content of fish fed diets supplemented with DL-α-tocopheryl acetate increased. The increased muscle α-tocopherol concentration allowed this antioxidant to perform its antioxidant role during storage. Reduced muscle α-tocopherol content was observed during frozen storage fillets compared with fresh fillets. Feeding DL-α-tocopheryl acetate at 250 mg kg^{-1} to *H. huso* for 120 days before slaughter improved the quality of frozen fillets by slowing down

the level of lipid oxidation and would justify the cost of supplementing with vitamin E. It is important that cultured *H. huso* maintain its level of $n-3$ HUFA in the edible flesh and preserve other aspects important to human acceptability i.e., colour, taste, texture during frozen storage. Therefore, further studies are necessary using other levels of vitamin E supplementation in fish dietary to further reduce lipid oxidation during long-term frozen storage. In addition, future study about the effect of such supplementation and also vegetable oil inclusion in *H. huso* diet on FA composition in the liver, histological aspects on intestine and muscle, different size and age fish, and enzymatic activities should be conducted to confirm the results found in this study.

Acknowledgements

This study has been financed jointly by *Tarbiat Modares University*, Tehran, Iran and *Mazandaran Livestock and Aquatic's Feed Co*., Sari, Iran. The authors thank the "University Research Deputy" and the general manager of the company for their support. We sincerely thank Prof. Joe M. Regenstein, from the Department of Food Sciences, Cornell University, USA, and Prof. Barbara Rasco, from the Department of Food Science, Washington State University, USA, for their critically reading of the manuscript and for making a number of helpful suggestions. We are also grateful to Seyedeh Hakimeh Hosseini, Reza Tahergorabi, Hoshang Fayazi and Ali Bagheri for their assistance with the chemical measurements.

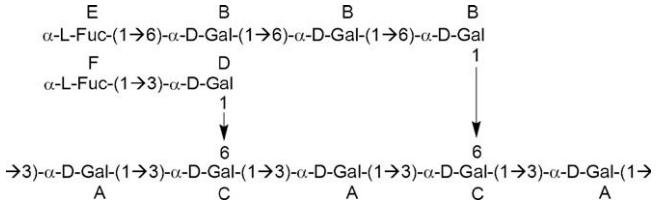
Inflammation

ABSTRACT

Poria cocos has recently been commercially used to formulate nutraceuticals and functional foods in Taiwan. In this study, *P. cocos*, was cultured and polysaccharides were extracted, followed by fractionation with size-exclusion column chromatography to give a water-soluble 1,6-branched 1,3-α-D-galactan (PC-II). The predominant monosaccharide was galactose after complete hydrolysis of the polysaccharide. The chemical structure was characterised by a monosugar analysis, along with ^{1}H, ^{13}C, and 2D nuclear magnetic resonance spectroscopy, including NOESY and HMBC experiments for linkage and sequence analysis. This polysaccharide is composed of a high-galactose-type undecasaccharide repeating unit with the following structure:



PC-II showed no toxicity to endothelial cells (ECs) and dose-dependently suppressed production of the interferon (IFN)-γ-induced inflammation marker, IP-10. However, PC-II showed no effect on cancer cell cytotoxicity or antiangiogenic activity. These results suggest that PC-II may play roles in regulating the anti-inflammatory process.

1. Introduction

Mushrooms constitute a flavourful and nutritious food group. They contain all of the essential amino acids. Mushrooms have long been used in oriental herbal traditions, and also as dietary supplements and natural cosmetics (Kaneno et al., 2004). *Poria cocos* (called *fu ling* in Chinese) is a medicinal fungus of the family *Polyporaceae* that grows on the roots of old, dead pine trees. It has been used in traditional Chinese medicine for many centuries. *P. cocos* has not only long been utilised to treat a wide variety of diseases, but also has recently attracted the attention of the pharmaceutical industry. Traditionally, it has been used to treat diabetes, dysentery, chronic fatigue syndrome, diarrhea, dizziness, edema, insomnia, kidney problems, nervousness, urination problems, and weakness. *P. cocos* is commercially available and is popularly used in the formulation of nutraceuticals, tea supplements, cosmetics, and functional foods in Asia. Chemical compounds found in *P. cocos* include triterpenes (Tai, Akira, Tetsuro, Tohru, & Yasuhiro, 1995; Yasukawa et al., 1998) and β-pachyman, a polysaccharide composed of β-pachymarose, pachymic acid, and poricoic acid. Recently, a growing body of evidence has indicated that *P. cocos* exhibits anticancer (Chen & Chang, 2004; Huang, Yong, Zhang, Cheung, & Kennedy, 2007; Jin et al., 2003), anti-inflammatory (Ukiya et al., 2002), and immunomodulating (Lee & Jeon, 2003) effects. The bioactivities of polysaccharides are related to their physical and chemical properties, such as the monosaccharide composition,

doi:10.1016/j.foodchem.2009.04.126

molecular weight, degree of branching, glycosidic linkages and substituents. For example, a linear 1,6-α-D-glucan from *P. lobata* shows antioxidant activity when the 2-*O*, 3-*O* and 4-*O* positions are sulfated (Cui et al., 2008); a mucilage, 1,4-β-D-glucomannan, from *Dendrobium huoshanense*, which exhibits cytokine-secretion activity, is 2-*O* and 3-*O* acetylated (Hsieh et al., 2008). In addition, a number of physicochemical properties, such as solubility, primary structure, molecular weight, extent of branching by side-chain substituents (Bohn & BeMiller, 1995), and the charge on the polymer, may influence the biological activities (Vetvicka & Yvin, 2004).

Since *P. cocos* is commercially available and is popularly used in Asia, it is worthwhile to fully characterise its activities. Use of cultured mycelia as metabolic factories, instead of whole fruiting bodies, can circumvent problems associated with inappropriate targeting and provide the opportunity to fine-tune the biosynthetic pathway. Polysaccharides isolated from different sources (fruiting bodies, mycelia, and biomass-free broth) differ somewhat in structure, composition, and physiological activities. It is also worthwhile to elevate the total polysaccharide production from the culturing system with a scalable method for pharmaceutical applications. Thus, cultured mycelia of *P. cocos* were used in this study. In nature, polysaccharides occur as mixtures of heterogeneous cellular components (Kim et al., 2003), and it is first necessary to isolate, purify, and structurally characterise these polysaccharides. In this study, the purification and partial characterisation of polysaccharides from an *in vitro* culture system of *P. cocos* were performed. A novel polysaccharide structure of a 1,3-α-galactan (denoted PC-II) from fractionated polysaccharides of cultured mycelia of *P. cocos* is reported. The overall objective of this study was to examine the structure and functions of PC-II from *P. cocos*. The results indicated that the biological properties of PC-II may play roles in regulating the anti-inflammatory process.

2. Material and methods

2.1. Poria cocos

Poria cocos (BCRC 36022) was purchased from the Bioresource Collection and Research Center, Hsinchu, Taiwan.

2.2. Isolation of polysaccharides

Polysaccharides were isolated from a 49 day-old culture of *P. cocos* (Cheng, Lin, Lur, Chen, & Lu, 2008).

2.3. Fractionation of polysaccharides by gel filtration column chromatography

Forty milligrammes of the lyophilised polysaccharide-containing preparation were dissolved in 3 ml of a buffer, containing 150 mM NaCl and 10 mM NaH_2PO_4, at pH 6.8, and analysed on a column of Fractogel BioSec 80 × 1.5 cm (Merck, Darmstadt, Germany) which had been equilibrated with the buffer mentioned above. The eluted fractions (2.8 ml/tube) were assayed for hexose by the phenol-sulphuric acid method (Zevenhuizen, Scholten-Koerselman, & Posthumus, 1980), and the absorbance at 488 nm was recorded.

2.4. Molecular weight and homogeneity determination

Molecular weight determination of the polysaccharide PC-II was determined by the same system as described in Section 2.3. A calibration curve was constructed using a dextran series (Sigma, Saint Louis, MO, USA) containing average molecular weights of 5 mg each of 69.8, 40.0, and 10.5 kDa (kilo-Daltons) in 3 ml of the buffer stated above. The regression equation was made between the log [Mw] (Y) and the fraction number (X) as $Y = 10.55–0.17X$; $R^2 = 0.9860$. Homogeneity of PC-II was confirmed by high performance size exclusion chromatography with an evaporative light scattering detector (HPSEC–ELSD) (Shimadzu, Kyoto, Japan) equipped with a TSK-GEL G-3000PW_{XL} 7.8 × 300 mm column (Tosoh, Tokyo, Japan) eluted with isocratic 100% de-ionised H_2O at a flow rate of 1 ml/min.

2.5. Compositional analysis of PC-II

Acid hydrolysis of PC-II and determination of monosaccharides composition were carried out according to Cheng et al. (2008). Monosaccharides were identified by comparing retention times of sample peaks with those of standards. Quantification of each monosaccharide was carried out by integration of the chromatographic peak on a PeakNet system (Dionex, Sunnyvale, CA, USA). Standards of monosaccharide were dissolved in Q-water. Myo-inositol, sorbitol, fucose, galactosamine, glucosamine, galactose, glucose, and mannose were obtained from Sigma. Sodium hydroxide solution was obtained from Fisher Scientific (Pittsburg, PA, USA).

2.6. One-(1D) and two-dimensional (2D) nuclear magnetic resonance (NMR)

Six milligrammes of PC-II sample was deuterium-exchanged in D_2O, lyophilised, and redissolved in 0.5 ml of D_2O. 1D ^1H (500 MHz), ^{13}C (125 MHz), and 2D NMR spectra of PC-II were recorded on a Varian Unity 500 MHz NMR spectrometer in D_2O (99.9%, Cambridge Isotope Laboratories, Andover, MA, USA) at 25 °C with a Varian 5 mm ^1H–$^{19}F/^{15}N$–^{31}P PFG switchable broadband probe. Chemical shifts were referenced to the HDO (δ_H 4.78) and acetone-d_6 (δ_C 30.89) resonances at 25 °C as the internal standards. 2D DQF-COSY (double-quantum filter correlation spectroscopy), HSQC (heteronuclear single quantum coherence), and HMBC (heteronuclear multiple-bond correlation) spectra were obtained using the standard pulse sequence. TOCSY (total correlation spectroscopy) spectra were recorded with a mixing time of 100 ms and relaxation delay of 2 s. The NOE (nuclear Overhauser enhancement) spectrum was obtained from the standard 2D ^1H–^1H ROESY spectra.

2.7. Endothelial cells culture

Human vascular endothelial cells (ECs) were maintained in Dulbecco's modified Eagle's medium (DMEM, Invitrogen, Carlsbad, CA, USA) supplemented with 2 mM L-glutamine and 10% heat-inactivated fetal bovine serum (FBS) (Life Technologies, Kibbutz, Israel). The cells' viability and the number of cells were determined by the trypan blue dye-exclusion method (Raimondi et al., 2006).

2.8. Determination of cells viability

To assess cell viability, the alamar blue (AB) assay (dye purchased from Biosource International, Nivelles, Belgium) was used as previously described (Fatokun, Stone, & Smith, 2008). At the end of each treatment period, a final concentration of 10% v/v AB was added to each well. Plates were incubated at 37 °C for 6 h prior to measuring the absorbance at 540 and 595 nm wavelengths using a spectrophotometric plate reader (DYNEX Technologies, Chantilly, VA, USA). The ratio of surviving cells is shown as the percentage of untreated control cells.

2.9. Matrigel EC tube formation assays

Matrigel (12.5 mg/ml) was thawed at 4 °C, and 50 μl were quickly added to each well of a 96-well plate and allowed to solidify for 10 min at 37 °C. Once solidified, wells were incubated for 30 min with ECs (25,000 cells/well). After adhesion of the cells, the medium was removed and replaced with fresh medium supplemented (or not) with PC-II and then incubated at 37 °C for 18 h. The growth tubes were visualised with an inverted microscope at a magnification of 10×.

2.10. Transient transfection and promoter activity assay

To evaluate the gene expression alternation of IP-10, a full-length IP-10 promoter construct with a reporter gene (luciferase) conjugation was purified using an EndoFree Plasmid Maxi Kit DNA Purification System (Qiagen, Valencia, CA, USA). Transfection to introduce these constructs into cells was performed by the LipofecTAMINE method (Invitrogen, CA, USA), and a pSV-β-galactosidase plasmid was co-transfected to normalise the transfection efficiency. When promoter activity is turned-on, luciferase will be translated in the cells and the activity of luciferase detected by its substrate equals the promoter activity of the target gene. Besides, β-galactosidase can be detected by its substrate and represents the same amount of cells in each test. In brief, ECs were plated onto 6-well plates at a density 1×10^5 cells/well and grown overnight. Cells were co-transfected with 2 μg of each promoter construct and 1 μg of the pSV-β-galactosidase plasmid for 5 h by the LipofecTAMINE method. After transfection, cells were recovered with 10% FBS medium with vehicle (DMSO) or drugs for 24 h. Luciferase and β-galactosidase activities were assayed using the assay systems according to the procedures of the manufacturer (Promega, Madison, WI, USA). Luciferase activity was normalised to β-galactosidase activity in cell lysates and was expressed as the average of three independent experiments.

2.11. Detection of IP-10 protein release

Levels of IP-10 secreted into the culture supernatant collected from ECs after interferon (IFN)-γ stimulation, with or without pretreatment with PC-II, were determined using a sandwich enzyme-linked immunosorbent assay (ELISA) kit (R&D Systems, Minneapolis, MN, USA) according to the manufacturer's instructions. Supernatants, as pools of triplicates, were collected and stored at −20 °C prior to use in the ELISA. Concentrations of secreted IP-10 were determined using ELISA readers from BioSource (Camarillo, CA, USA).

2.12. Statistical analysis

The data are presented as means ± standard error (SE), and n represents the number of experiments. In bar graphs, SE values are indicated by error bars. Statistical analyses were carried out with Student's unpaired t-tests when applicable; p values of <0.05 were considered significant.

3. Results

3.1. Characterisation of polysaccharides from cultured mycelia of P. cocos

Polysaccharides were isolated according to the methodology previously described and their profiles were evaluated into I (26–34), II (35–38), III (39–41), IV (41–47) and V (48–54), and the estimated Mn values (average molecular weight) of the five

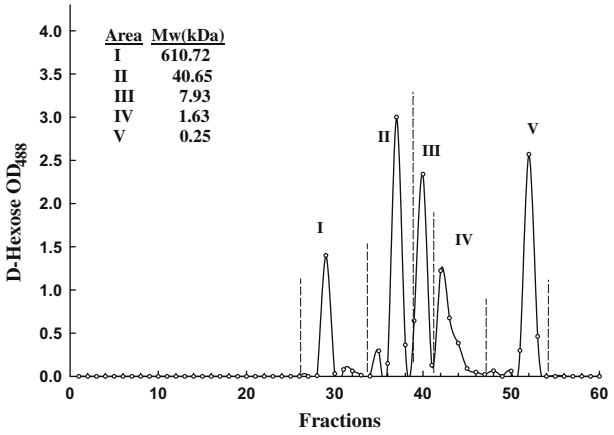

Fig. 1. Gel filtration profile of polysaccharides of *P. cocos*.

polysaccharide populations were determined to be 610.7, 40.7, 7.9, 1.6, and 0.3 kDa for fractions I–V, respectively, using a dextran series (Sigma) containing average molecular weights of 69.8, 40.0, and 10.5 kDa as standards (Fig. 1). In addition, HPSEC on a TSK-GEL G3000PW$_{XL}$ coupled with an ELSD was utilised as an alternative approach to evaluate the homogeneity of PC-II. The consistent retention time (18.3 min) and the peak symmetry double-confirmed that only one sample existed in PC-II (data not shown).

Compositional analysis showed that myo-inositol, sorbitol, fucose, galactosamine, glucosamine, galactose, glucose and mannose were the neutral sugars in the polysaccharide of *P. cocos* (Table 1). Galactose was the predominant species in fractions I, II, and IV.

3.2. 1D and 2D NMR

3.2.1. General

To enhance the quality of spectra and avoid the undesired line broadening effect arising from the high viscosity of the polysaccharide, the PC-II sample was diluted in D_2O to a concentration of 1.2×10^{-2} g cm^{-3} to diminish the intermolecular interaction. The ^{1}H and ^{13}C NMR spectra of PC-II are shown in Fig. 2. The completely assigned spectrum of the polysaccharide, given in Table 2, was derived from 2D DQF-COSY, TOCSY, NOESY, HSQC, and HMBC NMR spectra.

The ^{1}H NMR spectrum (Fig. 2A) of PC-II contained four signals of six embedded anomeric protons at δ 5.02, 4.95, 4.92 and 4.90. The sugar residues were designated as follows: δ 5.02 for residues A and D, δ 4.95 for residues E and F, δ 4.92 for residue B, and δ 4.90 for residue C (Table 2), according to the decreasing chemical shifts of the anomeric protons. The four low-field signals with the *galacto* configuration all appeared as singlets ($^3J_{1,2}$ < 3 Hz) and represent sugars with the α-anomeric configuration. The ^{13}C NMR spectrum (Fig. 2B) contained signals for three anomeric carbons at δ 98.0–102.5, one CH_3–C group (C-6 of Fuc) at δ 15.8,

Table 1
Sugar composition of the fractionated polysaccharide (PS) of *Poria cocos*.

PS (μmole/g)	I	II	IV	V
Myo-inositol	13.8 ± 1.15	6.26 ± 0.23	9.98 ± 0.12	18.5 ± 0.58
Sorbitol	6.29 ± 0.11	3.14 ± 0.07	–	0.67 ± 0.02
Fucose	35.6 ± 2.32	44.4 ± 1.44	33.1 ± 0.36	17.8 ± 0.38
Galactosamine	55.9 ± 0.36	3.94 ± 0.03	–	8.22 ± 0.29
Glucosamine	67.9 ± 0.32	–	–	6.31 ± 0.65
Galactose	104 ± 6.99	159 ± 0.05	35.1 ± 1.99	11.0 ± 0.05
Glucose	47.2 ± 1.57	0.94 ± 0.08	3.69 ± 0.12	2.25 ± 0.18
Mannose	77.4 ± 0.08	16.5 ± 0.13	6.80 ± 0.03	5.36 ± 0.48

one signal for the unsubstituted hydroxymethylene carbon at δ 61.3 (C-6 free), and one substituted hydroxymethylene carbon at δ 66.7 (C-6 glycosylated). As judged by the absence from the ^{13}C NMR spectrum of signals within δ 82–88, all sugar residues were in the pyranose form.

The ^{1}H and ^{13}C chemical shifts of the PC-II sample were fully assigned (Table 2), based on 1D ^{1}H, ^{13}C (Fig. 2), ^{13}C, DEPT-135, ROESY, 2D COSY, TOCSY (data not shown), HSQC (Fig. 3A), and HMBC (Fig. 3B) NMR experiments. The HSQC spectrum showed correlations between four α-^{1}H signals and three ^{13}C signals in the anomeric region, representative of five anomeric protons in the repeating unit. Integration of the H-1 signals and those in the HSQC spectra for residues A–F gave a ratio of around 3:3:2:1:1:1 (residues A–F, respectively), suggesting that the PC-II repeating unit is a high-galactose-type undecasaccharide.

3.2.2. Assignment of residue A

The COSY spectrum showed stepwise connectivities from the H-1 signal at δ 5.02 to H-2 at δ 3.98, H-3 at δ 3.67, H-4 at δ 3.58, H-5 at δ 3.81, and H-6a at δ 3.66, indicative of an α-pyranosyl moiety. The HMBC spectrum (Fig. 3B) demonstrated correlations between H-4 at δ 3.58 and C-3, C-5, and C-6 signals at δ 73.6, 70.5, and 61.3, respectively. In addition, the C-3 and C-5 signals demonstrated $^{3}J_{C,H}$ correlations with H-1 at δ 5.02, and the C-4 signal at δ 67.0 showed correlations with δ 3.98 (H-2), 3.81 (H-6b), and 3.67 (H-3). After the protons had been identified, the chemical shifts of their corresponding carbons were readily determined (Table 2) from the HSQC spectrum (Fig. 3A) between the carbon and proton in C–H pairs. The carbon and proton chemical shifts with a downfield-shifted carbon signal at δ 73.6 (C-3) indicated a 3-substituted α-pyranoside. Since galactose was the predominant monosaccharide identified by the monosaccharide analysis, and the absolute configuration of D for galactose was assumed as the natural occurring polysaccharide, residue A was a 3-substituted α-D-Gal residue, specifically α-D-galactopyranoside.

3.2.3. Assignment of residue B

Using similar approaches, the complete proton and carbon chemical shifts of the spin system beginning from the H-1 signal at δ 4.92 (residue B) was obtained (Table 2). The TOCSY spectrum

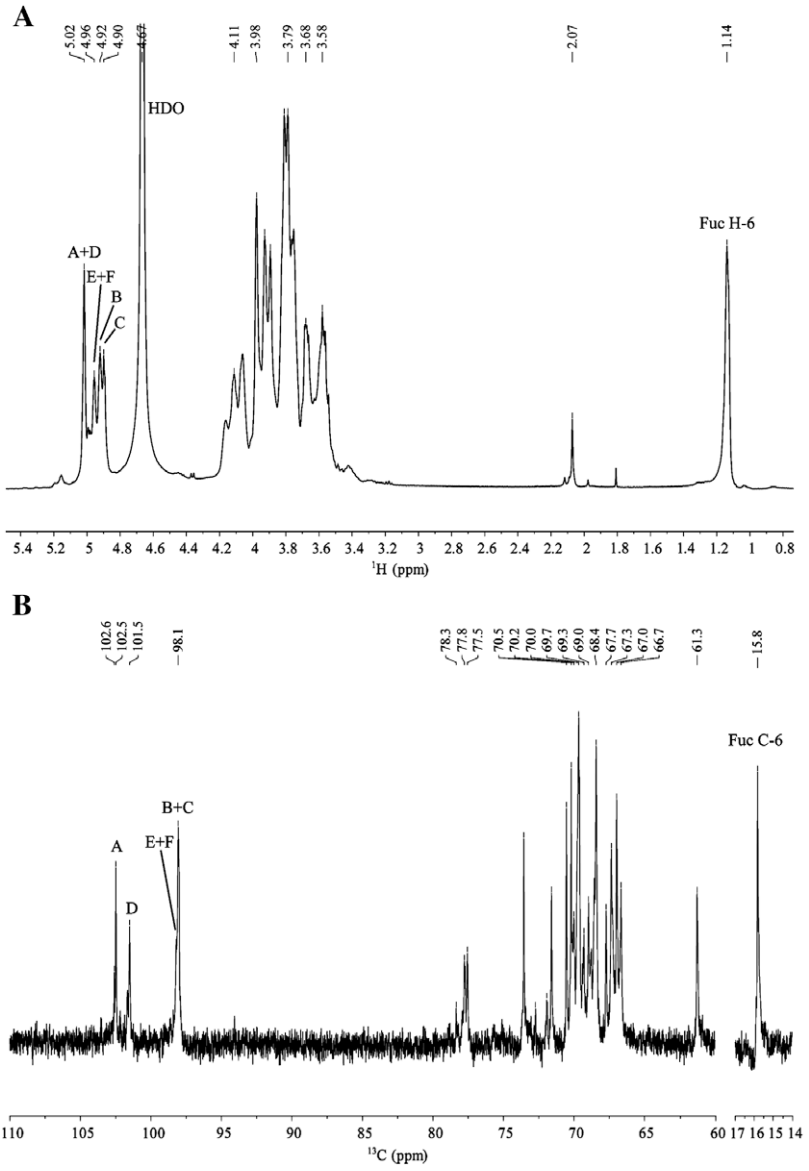

Fig. 2. ^{1}H and ^{13}C nuclear magnetic resonance spectra of 1,6-branched 1,3-α-D-galactan PC-II from *Poria cocos* in D_2O at 25 °C. Anomeric protons and carbons are labelled A–F. The chemical shifts are shown in δ ppm.

Table 2
^{1}H and ^{13}C chemical shift data of the monosaccharides constituting (1,3)-α-D-galactan PC-II from *Poria cocos*.

Residue	$^{1}H/^{13}C$					
	1	2	3	4	5	6
A	5.02	3.98	3.67	3.58	3.81	3.66 (a), 3.81 (b)
α-D-$Gal_{5,02}$	102.5	70.2[a]	73.6	67.0	70.5	61.3
B	4.92	3.93	3.75	3.8	3.81	3.88 (a), 3.59 (b)
α-D-$Gal_{4,92}$	98.1	69.9	68.4	67.0	70.2	67.0
C	4.90	4.06	3.91	4.11	3.79	3.82 (a), 3.59 (b)
α-D-$Gal_{4,92}$	98	69.5	77.5	69.0	70.2	66.7
D	5.02	3.88	3.75	3.58	3.98	3.66 (a), 3.81 (b)
α-D-$Gal_{5,02}$	101.5	67.0	77.8	67.0	70.2	61.3
E	4.95	3.59	3.98	3.89	4.08	1.14
α-L-$Fuc_{4,95}$	98.2	67.7	70.5	71.6	67.3	15.8
F	4.95	3.88	3.75	3.89	4.08	1.14
α-L-$Fuc_{4,95}$	98.2	67.0	69.7	71.6	67.3	15.8

showed connectivities from the H-1 signal at δ 4.92 to H-2 at δ 3.93 and H-3 at δ 3.75, from H-3 to H-4 at δ 3.80 and H-5 at δ 3.81, and from H-5 to H-6b at δ 3.59, one of the 6-substituted pyranosyl proton signals. Their corresponding ^{13}C chemical shifts were readily assigned from the HSQC spectrum (Fig. 3A) between the carbon and proton of C–H pairs (Table 2). The HMBC spectrum showed correlations of δ 98.1 (C-1) with δ 3.75 (H-3), and of δ 68.4 (C-3) with δ 3.93 (H-2) and 3.81 (H-5). The DEPT-135 spectrum showed a substituted hydroxymethylene carbon at δ 67.0, indicative of a glycosidic linkage on C-6. Accordingly, residue B was identified as a 6-substituted α-D-galactopyranoside.

3.2.4. Assignment of residue C

The complete proton and carbon chemical shifts of residue C, beginning from the peak at δ 4.90 (H-1), were obtained using the aforementioned approaches (Table 2). Signals for H-2, H-3, H-4, and H-5 were determined by cross peaks in the HMBC spectrum, including C-2 to H-1, C3 to H-4 and H-5, and C4 to H-5. The COSY spectrum demonstrated a correlation between δ 4.11 (H-4) and 3.82 (H-6a). Their corresponding ^{13}C chemical shifts were assigned, based on C–H pairs in the HSQC spectrum. From the downfield-shifted ^{13}C signals at δ 77.5 (C-3) and the substituted hydroxymethylene carbon at δ 67.0 (C-6), as confirmed by the DEPT-135 spectrum, residue C was assigned as 3,6-disubstituted α-D-galactopyranoside.

3.2.5. Assignment of residue D

The complete proton and carbon chemical shifts (Table 2) of the spin system beginning from the peak at δ 5.02 (residue D) was obtained from 2D TOCSY, ROESY, and HMBC. The TOCSY spectrum demonstrated correlations of H-1 at δ 5.02 with H-2 at δ 3.88, H-5 at δ 3.98, and H-6a at δ 3.81. The ROESY spectrum showed the correlations between the peaks at δ 5.02 (D H-1) and 3.88 (D H-2), indicative of the α-configuration. The HMBC spectrum revealed correlations between C-2 and H-4, and between C-3 and H-5, and the assignments of H-2 and H-3 were therefore confirmed. From the downfield-shifted ^{13}C signal at δ 77.8 (C-3), residue D was a 3-substituted α-D-galactopyranoside.

3.2.6. Assignment of residues E and F

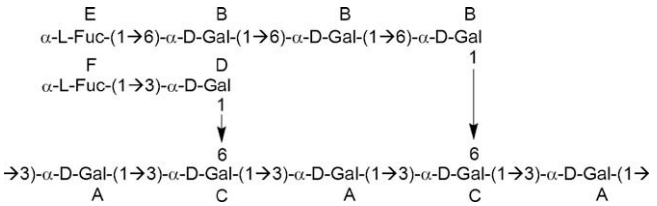
The TOCSY spectrum showed stepwise connectivities from the H-1 (E and F) signal at δ 4.95 to F H-3 at δ 3.75, H-5 at δ 4.08, and H-6 at δ 1.14 (*d*, *J* = 1.35 Hz), indicative of a 6-deoxy-sugar. The HMBC spectrum showed correlations between H-6 at δ 1.14 and the peaks at δ 71.6 and 67.3, indicative of C-4 and C-5 peaks, respectively. In addition, correlations between the peaks at δ 98.2 (C-1) and 3.59, 3.75, and 3.88, and between the carbon signal at δ 67.7 (E C-2) and 3.89 (H-4), and between δ 70.5 (E C-3, $^{1}J_{C,H}$ to E H-3 at δ 3.98) and 3.59 (E H-2) resulted in the assignment of H-2 (E: δ 3.59; F: δ 3.88) and H-3 (E: δ 3.98; F: δ 3.75) signals. The ROESY spectra demonstrated correlations between the signals at δ 4.95 (E H-1) and 3.75 (F H-3), and between δ 3.75 and 4.08 (E and F H-5), indicative of H-3 (δ 3.75) and H-5 (δ 4.08) signals. Furthermore, the COSY, TOCSY, ROESY, and HMBC spectra showed correlations between the signal at δ 1.14 (H-6) and the peak at δ 4.08, which also confirmed the assignment of H-5. Both the carbon and proton chemical shifts (Table 2) are typical of a 6-deoxyhexopyranose. Since L-Fuc was the only sugar identified by the monosaccharide analysis (Table 1), residues E and F were assigned as the fucose residue, specifically as α-L-fucopyranoside. Minor differences were observed in the H-2 and H-3 signals, while their carbon signals were almost identical.

3.2.7. Assignment of remaining residues

After the ^{1}H and ^{13}C spectra for residues A–F had been virtually completely assigned, the sequence of the glycosyl residues in the undecasaccharide was determined by the observed inter-residue connectivities shown in the ROESY and HMBC spectra. ROESY connectivities were observed between A H-1 (and the overlapping D H-1 signal) and the three signals of A H-2, C H-3, and C H-6, indicative of A(1 → 3)C and D(1 → 6)C linkages. Moreover, the ROESY spectrum demonstrated inter-residue correlations between C C-1 and A H-3, and between B C-1 and B H-6, indicative of C(1 → 3)A and B(1 → 6)B linkages. These linkages were further supported by the inter-residue $^{3}J_{C,H}$-connectivities observed in the HMBC spectrum. In the anomeric carbon atom resonance region of the HMBC spectrum, correlations were seen between F C-1 and D H-3, between E C-1 and B H-6, and between F C-1 and D H-6, respectively indicative of F(1 → 3)D, E(1 → 6)B, and F(1 → 6)D linkages.

In the ^{13}C NMR spectra, C-3 signals of residues A, C, and D ranged from δ 73.6 to 77.8, indicative of 1,3-α-D-galactan (Moule, Galbraith, Cox, & Wilkinson, 2004; Vinogradov, Korenevsky, & Beveridge, 2003; Stroop, Xu, Retzlaff, Abeygunawardana, & Bush, 2002) and dissimilar to that of 1,3-β-galactan, 1,3-β-glucan and 1,3-α-glucan at δ 83.0 (Leon de Pinto, Martinez, Ludovic de Corredor, Rivas, & Ocando, 1994), 86.0 (Wang et al., 2004), and 82.0 (Huang & Zhang, 2005; Huang et al., 2007), respectively.

After a comprehensive analysis of the aforementioned 1D and 2D NMR spectral studies of PC-II summarised in Table 2, a putative undecasaccharide repeating unit for the neutral 1,6-branched 1,3-α-D-galactan was depicted as the following structure:



The main skeleton of the repeating unit is composed of three A residues and two C residues, and the two branches F–D and E–B–B–B are both connected to the C residues.

3.3. Toxicity of PC-II

To evaluate the toxicity of PC-II toward EC viability, an alamar blue (AB) assay was performed. The sensitivity and evaluation protocol of AB assay is now well recognised as better than the MTT assay used in our previous study. After ECs had reached confluence, the medium was changed to serum-free medium. Serial dilutions of PC-II were used to assay the toxicity toward ECs for 24 h. PC-II showed no toxicity toward ECs up to a concentration of 250 μg/ml (see Supplementary Table 1).

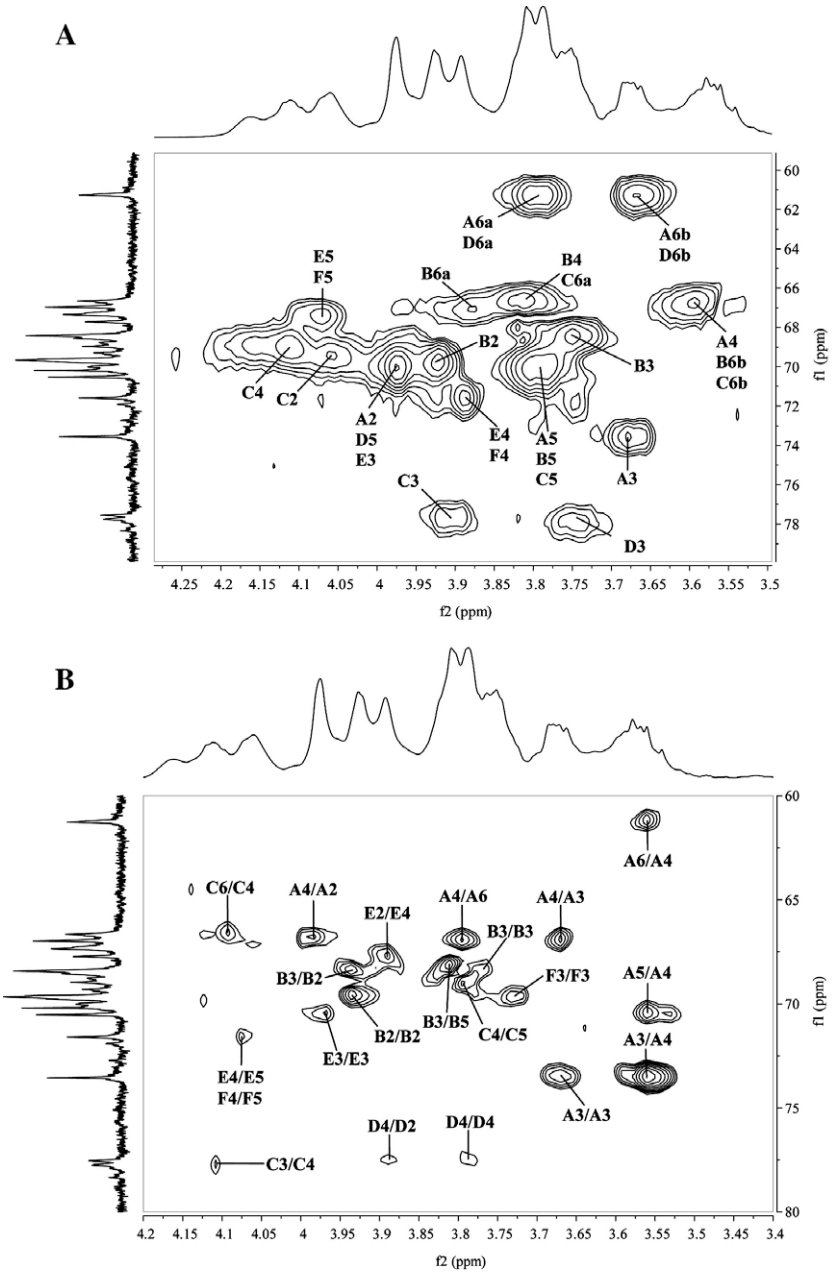


Fig. 3. 2D HSQC (A) and HMBC (B) nuclear magnetic resonance spectrum of 1,6-branched 1,3-α-D-galactan PC-II from *Poria cocos* in D_2O at 25 °C. (A) Cross-peaks marked by capital letters indicate $^1J_{CH}$ correlations. (B) Cross-peaks marked by capital letters indicate $^1J_{CH}$, $^2J_{CH}$, and $^3J_{CH}$ correlations from C to H atoms in selected ranges (^{1}H: 3.4–4.2 ppm; ^{13}C: 60–80 ppm).

3.4. Influences of PC-II on IFN-γ-induced IP-10 secretion

The inhibitory effects on IP-10 protein release and promoter activity induced by IFN-γ, stimulated by PC-II, were evaluated. As shown in Fig. 4A, IFN-γ treatment of ECs increased IP-10 protein release. PC-II pretreatment of ECs suppressed IFN-γ-induced IP-10 protein release in a dose-dependent manner. However, in the IP-10 promoter activity assay, PC-II pretreatment showed no influence on IFN-γ-induced IP-10 promoter activities (Fig. 4B). This result indicates that PC-II might play a role in regulating inflammation.

3.5. Influences of PC-II on cancer cell cytotoxicity

To study the effects of PC-II on cancer cell cytotoxicity, four cancer cell lines were used, including MCF-7 (breast cancer), H460 (lung cancer), HT29 (colon cancer), and CEM (leukemia cancer). Serial dilutions were evaluated for their cytotoxic effects on these four cancer cell lines in the same way as described in the viability assay (see Supplementary Table 2). PC-II exhibited no cytotoxic effect on cancer cells.

3.6. Influences of PC-II on EC tube formation

To study the effects of PC-II on angiogenesis, an *in vitro* Matrigel tube formation model was used. Serial dilutions were evaluated for their effects on VEGF-induced angiogenesis, as revealed by tube formation on Matrigel (see Supplementary Fig. 1). PC-II exhibited no inhibitory effect on EC tube formation compared to VEGF-treated control cells.

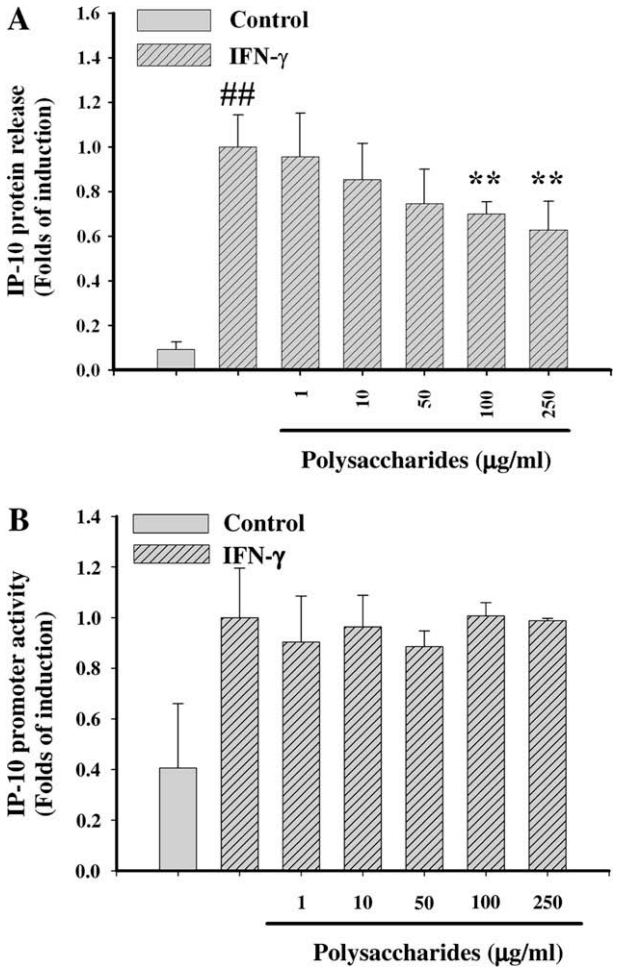

Fig. 4. Influences of PC-II on interferon (IFN)-γ-induced IP-10 secretion. (A) Effects of PC-II on IFN-γ-induced IP-10 protein release from ECs after being pretreated with PC-II at the indicated concentrations for 3 h, followed by IFN-γ (10 ng/ml) stimulation for 24 h. IP-10 protein release into medium is expressed as pg/mg of total protein and is presented as the mean ± SE from three independent experiments. $^{\#\#}p < 0.01$ vs. the control; $^{**}p < 0.01$ vs. IFN-γ treatment. (B) Effect of PC-II on IP-10 promoter activity in ECs. Luciferase activity (represents promoter activity) was normalised to β-galactosidase activity in cell lysates and was expressed as an average of three independent experiments.

4. Discussion

For the species studied in this report, *P. cocos*, a number of polysaccharides have been identified, including a 1,3-β-glucan (Chen, Xu, Zhang, & Kennedy, 2009), 1,3-α-glucan (Lin et al., 2004; Huang & Zhang, 2005), 1,3-α-glucan with 1,6-branches (Kanayama, Adachi, & Togami, 1983), and 1,6-α-glucan (Zjawiony, 2004). In this article, we report the isolation and identification of a 1,3-α-D-galactan with 1,6-branches and an α-L-fucosyl terminal from cultured mycelia of *P. cocos*, and this is the first report of an 1,3-α-galactan from *P. cocos*. The skeleton of 1,3-α-galactosyl moieties has also been found in a number of bacteria, such as *Shewanella* spp. MR-4 (Vinogradov, Kubler-Kielb, & Korenevsky, 2008) and *Streptococcus pneumoniae* type 1 (Stroop et al., 2002). In addition, a fucogalactan with 1,6- and 1,4,6-α-D-galactosyl skeleton and 2-β-galactosyl and 2-α-fucosyl side chains, which elicited the release of TNF-a and NO from murine macrophages, has also been isolated from a mushroom *Sarcodon aspratus* (Mizuno et al., 2000).

In addition to the structure of PC-II, composed of a 1,3-α-D-Gal main skeleton and 1,6-α-D-Gal side chains, at a ratio of 1:1, another possible structure composed of α-1,6- and α-1,3 interlaced D-Gal main skeleton with 1,3-α-D-Gal side chains was also proposed and analysed. However, the strong correlation between C C-1 and A H-3 and the weak correlation between B C-1 and C H-6 in HMBC spectra eliminated the possibility. Besides, for the minor mannose composition of PC-II (at a ratio of 1:10 to galactose) in Table 1, five signals of the 1,4-β-mannosyl moiety (Hsieh et al., 2008) were observed in the 2D HSQC (Fig. 3A) and HMBC (Fig. 3B) NMR spectra, including δ 4.99/101.6 (H-1/C-1) 3.64/71.0 (H-3/C-3), 3.82/77.9 (H-4/C-4) and 3.54/72.4 (H-5/C-5). However, weak 1D NMR signals and insufficient HMBC evidence of the 1,4-β-Man impeded further assignment of this moiety to the putative structure.

Inflammation is a general phenomenon in many diseases. IFN-γ is one of the major mediators which predisposes ECs toward inflammatory/immunological responses. In this study, pretreatment with the PC-II dose-dependently inhibited IFN-γ-induced inflammatory gene IP-10 protein release (Fig. 4A). However, PC-II showed no inhibitory effect on IP-10 promoter activity (Fig. 4B). Furthermore, the profiles and toxicity of PC-II were first evaluated. PC-II showed no toxicity to ECs, indicating the safety of the use of this fungus (see Supplementary Table 1). This result indicated that the effect of PC-II on IP-10 expression was regulated at the translational and not at the transcriptional level and thus it may participate in regulating inflammatory-related diseases.

Polysaccharides are known to have anticancer and antiangiogenic activities (Cheng, Huang, Chang, Wang, & Lu, 2005), and this formed the rationale for investigating the effects of polysaccharides from *P. cocos* on these two processes. Because VEGF is an angiogenic inducer which induces proliferation, migration, and differentiation of ECs, we investigated the effects of PC-II on VEGF-induced EC tube formation on Matrigel. As a result, PC-II did not inhibit VEGF-induced EC tube formation (see Supplementary Fig. 1). In addition, PC-II exhibited no cytotoxic activities on cancer cells (see Supplementary Table 2). Therefore, related diseases due to the anti-inflammatory property of PC-II remain for further elucidation. Furthermore, in comparison with our previous study that extracts from *Fomitopsis pinicola* (Cheng et al., 2008), PC-II from *P. cocos* in this study showed less potency than did *F. pinicola* both in Matrigel tube formation and IP-10 release inhibition. Nevertheless, the purpose of this study is to demonstrate the novel structure we discovered in *P. cocos* and its biological functions. Besides the functions we tested in this study, there may exist other biological functions, and this requires further investigation.

In conclusion, we report a novel polysaccharide of cultured *P. cocos* with 1,6-branched 1,3-α-D-galactan structure and an anti-inflammation function of the fractionated polysaccharide (PC-II). Further investigations on optimisation of the submerged culture to achieve the demands of commercial-scale mycelial and polysaccharide production are required.

Amino acids

ABSTRACT

An investigation into the amino acid profiles of unfermented and fermented cocoa nibs, as well as process-line cocoa nibs (P-LCN) and processed cocoa cake samples (PCCS) was carried out. In the unfermented cocoa nibs, Glu (128 mg/g crude protein i.e. 128 mg/gcp) was the most abundant amino acid whilst the most concentrated essential amino acid in the same sample was Leu (72.2 mg/g crude protein); in the fermented cocoa nibs, a similar trend was observed, with respective values of Glu (153 mg/gcp) and Leu (62.4 mg/gcp). Lys (181 mg/gcp) was most abundant amino acid in P-LCN and Ile (63.3 mg/gcp) was the second most abundant; also, in PCCS, Lys (52.7 mg/gcp) was the most abundant amino acid but Asp (43.7 mg/gcp) was the second most abundant. The total amino acid content was (mg/gcp), 641 (unfermented nibs), 708 (fermented nibs), 635 (P-LCN) and 368 (PCCS), with corresponding essential amino acids of 300, 287, 478 and 185 (all with His), respectively. Based on whole hen's egg, the limiting amino acids for the samples were: Ser (unfermented nibs), Met (fermented nibs), Ala (P-LCN) and Val (PCCS), whereas under provisional amino acid scoring pattern, they were: Met + Cys (unfermented nibs), Met + Cys (fermented nibs), Thr (P-LCN) and Val (PCCS). Prolonged and high heat treatments appeared to have reduced the essential amino acids of the PCCS as compared to the P-LCN. Significant differences existed between contents of essential amino acids and non-essential amino acids at $p < 0.05$ in unfermented cocoa nibs, fermented cocoa nibs and P-LCN.

1. Introduction

Cocoa bean was the foremost Nigerian foreign exchange earner before the advent of crude oil and it is currently in the second position after petroleum. The annual production in Nigeria is about 165,000 metric tonnes (MT) (Akinyeye, 1999). A small percentage of the annual production is processed, locally, to cocoa butter and cocoa cake, whilst the bulk is exported. The cocoa beans of commerce are the seeds of the tree –*Theobroma cacao* (Linnaeus), properly harvested, fermented and dried. It originated from Latin America about 500 years ago and thence to Europe, from where it was introduced to other parts of the world (International Cocoa and Commodities Organisation, 2000). Cocoa bean is an oil seed, just like palm kernel, groundnut, sesame seed or any of the other oilseeds. However, it is rarely processed in the same way as the other oil seeds in order to get the oil. The reason for this is probably due to the unique physicochemical characteristics of the beans and its constituents, especially the fat. The Aztecs (of Mexico) prepared the first cocoa drink called "Chocolatl" about 500 years ago (Minife, 1989). This chocolate drink was prepared from a mixture of ground, roasted whole beans or "nibs" and sugar. The drink was extremely rich because of the high fat content. The richness of the beverage made the Aztecs believe that the cocoa tree was of divine origin, hence the name – "Theobroma" meaning, *food for the gods.* The drink has aphrodisiac properties and was held in high esteem as a nuptial aid.

To obtain cocoa, the harvested pods are fermented, by naturally occurring bacteria and yeasts to eliminate their natural, bitter, astringent quality, during which the seeds are cured and roasted. The clean kernels obtained after the removal of the shell, called cocoa nibs, are manufactured into various products. The larger percentage of the nibs is fat, removed by pressure, and is called cocoa butter which is used in fine soaps and cosmetics and in medicine for emollients and suppositories. The residue is ground to a powder (cocoa) and used for beverages and flavouring. Chocolate is a product in which the cocoa butter has been retained. Cocoa products have a high food value because of the large proportion of fat, carbohydrates, and protein. Cacao is classified in the division Magnoliophyta, class Magnoliopsida, order Malvales and family Sterculiaceae.

Cocoa products are eaten mainly because they are liked, by young and old, owing to their attractive flavours and appearance which give pleasure in eating (Minife, 1989). The nutritional parameters of cocoa are determined largely by the chemical composition of the material. The energy contribution to daily diets is dependent on the quantum of proteins, carbohydrates and fats in the cocoa product and its corresponding digestibility coefficient (Minife, 1989). Cocoa powder is mainly used for low calorie food products. The minerals present in cocoa powder are important

doi:10.1016/j.foodchem.2009.04.127

for their nutritional value. Olaofe, Oladeji, and Ayodeji (1987) and Olaofe and Onajeta (1986) reported on the quality parameters of cocoa beans from Nigeria, as well as on cocoa-based beverages of different brands consumed in the Nigerian market. The level of fermentation, degree of alkalisation, roasting and fat content determine the colour and flavour of cocoa products. Fermentation helps to generate proper aroma and reduce the level of acetic acid, which causes off-flavour in chocolate. The pH of cocoa liquors prepared from well fermented and dried West African beans is around 5.5 whilst those of unfermented or poorly fermented beans are 5.0 or less (The Biscuit, Cake, Chocolate, and Confectionary Alliance (BCCCCA), 1996). Cocoa is added to cigarettes for flavour enhancement. It also contains various psychoactive compounds, such as theobromine, caffeine, serotonin, histamine, tryptophan, trytamine, tyramine, phenylethylamine, octopamine and anandamide (Rambali et al., 2002). The levels of these compounds in added cocoa in cigarettes are thus critical to curtail possible addiction to cigarette smoking. Theobromine and theophylline, as well as caffeine, all found in this plant, are used as a diuretic, stimulant and also, in modern medicine, as an antiasthmatic (Morgan, 1994).

There is, at present, scanty information on the amino acid profile of cocoa beans and the effect of farm and industrial processing on their relative concentrations. This study attempts to evaluate the amino acid composition of dried unfermented and fermented cocoa beans from a major cocoa-producing town in south-west Nigeria vis-à-vis that of the in-process cocoa nibs and processed cocoa cake from a major cocoa processing industry in Nigeria. The effects of fermentation and heat treatment during the course of milling are to be evaluated. Direct processing of the same batch of beans collected from the selected farm location could not be conducted because of the enormous quantity required for batch processing. Consequently, heterogeneous samples of beans supplied, from different locations (thoroughly mixed together to a representative sample), were used for evaluating the effect of heat treatment during milling. This means the analyses were on four samples in two major groups; they are fermented and unfermented samples from the same farm in Aisegba Ekiti and this is the Forastero Amazonian Group (Opeke, 1992); the second group is the factory sample group consisting of the process-line cocoa nibs (P-LCN) and the processed cocoa cake samples (PCCS). The factory samples (P-LCN and PCCS) came from a blend of cocoa beans from different sources of the same species, which is the Forastero Amazonian Group.

2. Materials and methods

2.1. Materials

Cocoa bean seeds were collected from fully ripe pods harvested from some cocoa trees in a farm plantation located at Aisegba Ekiti in Ekiti State of Nigeria in December 2007, during the main crop season. The harvested beans were divided into two portions immediately after they were taken out of the pods. Whilst the first portion was directly sun-dried in open air, the second portion was fermented by a heaping method, using plantain leaves to cover the beans for 6 days before sun-drying. The dried beans were deshelled, dry-milled and labelled as unfermented and fermented nibs, respectively. These formed the group one samples. Similarly, in-process cocoa beans (heterogeneous) of indefinite source, and kibbled cake were collected from the production floor of Co-operative Cocoa Products Limited, Akure, Ondo State, Nigeria in December 2007, for comparative analysis.

The process-line cocoa nibs (P-LCN) were prepared from blended, cleaned and destoned dried cocoa beans from the factory's cleaner/destoner machine. The processed cocoa cake sample (PCCS) was a product that resulted from further processing of the P-LCN. The processes involve microwave heating of the beans at a temperature range of 90–100 °C for a period of about 15 min on a vibratory bed (this makes the cocoa bean shell puff for easy winnowing), automated roasting (at temperature range of 90–100 °C for about 20 min in a rotary evaporator), refining to over 98% fineness to obtain cocoa liquor (masse) which is further heat-treated at 80–90 °C for about 12 h in storage tanks. The liquor is later fed in batches of about 200 kg sizes into a steam-jacketed vacuum mixer, where liquor homogenisation and further heating takes place for about 10 min before final pressing to obtain cocoa butter and cocoa cake. The final heating and homogenisation are used to take the liquor from about 80 °C to about 105 °C and to ensure maturation of the liquor. This also further ensures a final rapid evaporation of residual moisture to <1% in the cocoa liquor and guarantees acceptable sterilisation of the liquor. The pressed cake is kibbled mechanically to obtain smaller sizes of the cocoa cake solid, otherwise called processed cocoa cake samples (PCCS). The factory samples were labelled process-line cocoa nibs (P-LCN) and processed cocoa cake samples (PCCS), respectively. These formed the group two samples.

2.2. Sample treatment

The samples were homogenised and ground to fine powder, using a Mouliness blender. The ground portions were kept in plastic rubbers in the freezer (−4 °C) pending analysis. The values reported for each test were averages of two or more determinations.

2.3. Determination of crude protein

Nitrogen was determined by the micro-Kjeldahl method, as described by Pearson (1976) and the percentage nitrogen was converted to crude protein by multiplying by 6.25.

2.4. Determination of amino acids

The amino acids profile in the cocoa samples was determined using methods described by Adeyeye and Afolabi (2004). The cocoa samples were dried to constant weight. The mass was subsequently defatted, hydrolysed, filtered to remove the humins and evaporated to dryness at 40 °C under vacuum in a rotary evaporator. Each residue was dissolved with 5 ml of acetate buffer (pH 2.0) and stored in a plastic specimen bottle and kept inside the deep freezer pending subsequent analysis. The Technicon Sequential Multisample Amino Acid Analyser (TSM), Technicon Instruments Corporation, New York was used for the analysis. The principle is based on ion-exchange chromatography (IEC) (FAO/WHO, 1991). The equipment is designed to separate free acidic, neutral and basic acids of the hydrolysate. The amount loaded for each sample was 5–10 μl and about 76 min elapsed for each analysis. The column flow rate was 0.50 ml/min at 60 °C with reproducibility consistent within ±3%. The net height of each peak produced by the chart record of the TSM was measured and calculated for the amino acid it was representing. The averages of two determinations were reported. All chemicals used were of analytical grade.

2.5. Estimation of quality of dietary protein

The essential amino acid score was calculated using the following formula (FAO/WHO, 1973): amino acid score = amount of amino acid per test protein (mg/g)/amount of amino acid per protein in reference pattern (mg/g).

Amino acid score (for both essential and non-essential amino acids) was also calculated based on whole hen's egg (Paul, Southgate, & Russel, 1976).

The ratio of total essential amino acid (TEAA) to the total amino acid (TAA), i.e. (TEAA/TAA), total sulphur amino acid (TSAA), percentage cystine in TSAA (%Cys/TSAA), total aromatic amino acid (TArAA), and the Leu/Ile ratios were calculated whilst the predicted protein efficiency ratio (P-PER) was determined using one of the equations developed by Alsmeyer, Cunningham, and Happich (1974), i.e. P-PER = −0.468 + 0.454 (Leu) − 0.105 (Tyr).

Calculations completed were the grand mean, standard deviation, coefficients of variation in percentage, correlation coefficient, regression and F-test, setting the confidence level at 95% (Christian, 1980).

3. Results and discussion

The crude protein levels of the unfermented and fermented samples are shown in Table 1. Also, the crude protein levels in the process-line cocoa nibs (P-LCN) and processed cocoa cake samples (PCCS) are shown in Table 2. The level of crude protein in fermented cocoa bean was 15.2 g/100 g which was better than the value in unfermented cocoa bean (13.6 g/100 g) by 1.58 g/100 g or 10.4%. This meant that the fermentation process had improved the level of the crude protein in the fermented sample compared to the unfermented sample. In the case of the group two samples, P-LCN had a crude protein level of 23.2 g/100 g which was better than the PCCS sample (18.4 g/100 g) by 4.8 g/100 g or 20.7%. This meant that the heat involved in the processing reduced the level of protein. This reduction could have been due to the Maillard reactions which are an interaction between the carbonyl group of a reducing sugar and the free amino acid group from an amino acid or protein. The resulting condensation product is converted by the Amadori rearrangement to the 1-deoxy-2-ketosyl compound. Browning then proceeds along complex pathways, the exact sequence being dependent on pH, temperature, concentration and the identity of the reactants (Muller & Tobin, 1980). However, Ala increased in the PCCS.

The amino acids composition of the unfermented and fermented cocoa nibs is presented in Table 1. The amino acid concentrations were variously distributed amongst the two samples, and this could easily be seen both in the various samples and in the coefficient of variation percentage (CV%). Glutamic acid (Glu) was the most concentrated amino acid amongst the samples: 128 mg/g crude protein (cp) (in unfermented cocoa nibs) and 153 mg/gcp (fermented cocoa nibs). Another acidic amino acid, aspartic acid (Asp), occupied the second position in both samples with values of 100 mg/gcp (unfermented sample) and 82.5 mg/gcp (fermented sample). Cystine (Cys) was the least concentrated, in both samples, with values of 7.8 mg/gcp (unfermented cocoa nibs) and 6.9 mg/gcp (fermented nibs). The fermented cocoa nibs were richer than were unfermented cocoa nibs in the following amino acids: Lys, His, Arg, Ser, Glu, Gly, Ala, Val, Ile, Tyr and Phe, whereas Pro (or one amino acid, 5.88%) was of equivalent level (12.5 mg/gcp in both samples). This meant that the fermented cocoa nibs were 64.7% richer in the amino acids than were the unfermented nibs; whereas the unfermented sample was only better in five (or 29.4%) of the amino acids. Therefore, fermentation improved the amino acid profile of the cocoa nibs. This is particularly true for most of the essential amino acids: Lys, His, Arg, Thr, Val, Ile and Phe. The improvement of amino acid concentration by fermentation followed the trend observed in guinea corn, where steeping of the grains improved the amino acid profile over the raw and germinated samples in Arg, His, Met, Phe, Thr, Val, Ala, Cys, Gly, Pro, Ser, and Tyr (Adeyeye, 2008).

Table 1
Amino acid profiles (mg/g crude protein) of unfermented and fermented cocoa nibs from a farm location.

Amino acid	Unfermented nibs	Fermented nibs	Mean	SD	CV%
Lys*	42.0 ± 0.02	52.6 ± 0.02	47.3	7.50	15.9

[a] Process-line cocoa nibs.
[b] Processed cocoa cake samples.

Our results, in both the unfermented and fermented cocoa nibs, followed the trends in *Cola acuminata, Garcinia kola* and *Anacardium occidentale*, where Glu was the most concentrated amino acid and Asp was the second most concentrated in *C. acuminata* and *G. kola* (Adeyeye, Asaolu, & Aluko, 2007). Our trend in Glu and Asp agreed with the results of Olaofe, Adeyemi, and Adediran (1994) who found that Glu and Asp, respectively, were the first and second most concentrated amino acids in some oilseeds. The differences in the levels of the amino acids in the two samples were shown by the various levels of the CV%; when subjected to the F-test the differences were not significant at $p < 0.05$ since F_c (1.11) < F_t (2.35). Also, the correlation coefficient was high at $r_{0.96}$ and regression (R_c) was 3.51.

Table 2 contains the amino acid profiles for the process-line cocoa nibs (P-LCN) and processed cocoa cake samples (PCCS). In both samples, Lys was the most concentrated amino acid with values of 181 mg/gcp in P-LCN and 52.7 mg/gcp in PCCS; whilst Ile (63.3 mg/gcp) was the second most concentrated in P-LCN, it was Asp (43.7 mg/gcp) in PCCS. The following amino acids were more concentrated in P-LCN than in PCCS (mg/gcp): Lys, His, Arg, Thr, Pro, Cys, Val, Met, Ile, Leu, Tyr and Phe, or 70.6% better in amino acid

concentration. This meant that P-LCN would be a better protein food ingredient than would PCCS. Here some of CV% levels were well above 50.0 and the data, when subjected to F-test analysis, showed that significant differences existed at $p < 0.05$ between the P-LCN and PCCS amino acid profiles, since F_c (6.86) > F_t (2.35). The $r_{0.70}$ was less than the value obtained in Table 1 but the R_c was 12.4 which was much higher than the value in Table 1.

It is interesting to note the high differences in the amino acids, Lys, His, Arg, and Cys between P-LCN and PCCS samples. The availability of some amino acids, for example, Lys, Met, Arg, Try, Cys and His, is often severely impaired when the protein in the food is heated, e.g. in processing, or where it is improperly stored. This impairment occurs when the Amadori rearrangement goes beyond the deoxy-ketosyl stage due to heat treatment. This is particularly serious when intravenous drip fluids containing sugars and proteins undergo Maillard reactions during sterilisation (Muller & Tobin, 1980). Carpenter has used the susceptibility of Lys to heat damage in the presence of moisture as a basis for estimating the extent of the damage (Muller & Tobin, 1980). Although Val may be thermally stable, it may also be possible that it takes part in this type of browning reaction which will definitely reduce its concentration during heat processing.

The processed cocoa cake samples (PCCS) underwent various heat processing unit operations which lasted for 13 h or more. This would have led to a very serious heat effect on the amino acids. Looking critically at Table 2, where the values of P-LCN and PCCS are compared, wide variation existed between the essential amino acids of the two samples. For example, loss of amino acid concentration from P-LCN to PCCS goes thus (mg/g crude protein) Lys, 128 (78.7%); His, 7.3 (62.4%); Arg, 16.9 (36.6%); Thr, 7.2 (45.3%); Cys, 4.5 (29.4%); Val, 36.8 (90.9%); Met, 0.6 (1.40%); Ile, 31.4 (49.6%); Tyr, 1.5 (11.0%) and Phe, 7.0 (32.1%). These values show serious reductions in the available essential amino acids, unlike the non-essential amino acids of the PCCS. Usually, the method used for the amino acid analysis will only detect L-amino acids from animal and plant proteins that do not produce racemisation (White et al., 1973). The reasons for these serious reductions of the amino acids from P-LCN to PCCS would likely be due to Amadori rearrangement that goes beyond the deoxy-ketosyl stage and the formation of D-amino acids which are both due to high and prolonged heat treatment (Fennema, 1985; Muller & Tobin, 1980).

Various parameters are presented in Tables 3 and 4. The total amino acids (TAA) in unfermented cocoa nibs was 641 mg/gcp and it was 708 mg/gcp in fermented cocoa nibs (Table 4) whilst it was 635 mg/gcp in P-LCN and 368 mg/gcp in PCCS (Table 3). The TAA in unfermented cocoa nibs was close to the value of 659 mg/gcp in *A. occidentale* and also the value of TAA in PCCS was close to the value of 356 mg/gcp in *C. acuminaa* (Adeyeye et al., 2007). The level of TAA in fermented cocoa nibs was close to the values of 703–917 mg/gcp of dehulled samples of African yam bean (Adeyeye, 1997). The total non-essential amino acids (TNEAA) for the samples were (mg/gcp): 341 (unfermented nibs), 421 (fermented nibs) – see Table 3, 158 (P-LCN) and 183 (PCCS) – see Table 4. The TNEAA of 341–421 mg/gcp was close to the value of 327–454 mg/gcp in African yam bean (Adeyeye, 1997) and also to 323 mg/gcp in *A. occidentale* (Adeyeye et al., 2007). However, in the composition of the total essential amino acids (TEAA), there was a reversal of concentration which followed this pattern (mg/gcp, with His): 478 (P-LCN) > 300 (unfermented nibs) > 287 (fermented nibs) > 185(PCCS). On a percentage basis, this trend was not consistent amongst the samples. The percent TNEAA ranged between 53.3% (unfermented nibs) and 59.5% (fermented nibs) with a low value of CV% (7.77) (Table 3); from Table 4 it ranged from 24.8% (P-LCN) to 49.8% (PCCS) with a high value of CV% (64.8). The % TEAA (with His) ranged between 75.2% (P-LCN) and 50.2% (PCCS) with CV% of 28.2 (Table 4). These results showed that the industrial processed cake was again lower in the TEAA than in the process on line by a wide margin. The total neutral amino acids (TNAA) levels were close in (mg/gcp); 228 (unfermented nibs), 235 (fermented nibs) but low in P-LCN (74.8) and PCCS (87.2).

The TEAA in melon and gourd oilseeds with respective values of 534 mg/g and 536 mg/gcp (Olaofe et al., 1994) were reportedly higher than all of our values, that ranged between 185 mg/gcp and 478 mg/gcp; with the exception of 478 mg/gcp (P-LCN), all of our EAA values were lower than those in soybean (444 mg/gcp) (Kuri, Sundar, Kahuwi, Jones, & Rivett, 1991). Our present samples were either close to or lower than the following TEAA levels (mg/gcp): pigeon pea (452) (Nwokolo, 1987), pumpkin seed (396)

Table 3
Concentrations of essential, non-essential, acidic, neutral, sulphur, aromatic (mg/g crude protein) of unfermented and fermented cocoa nibs.

* See Table 2.

(Aisegbu, 1987), cowpea (426) (Olaofe, Umar, & Adediran, 1993) and *Cajanus cajan* (436) (Oshodi, Olaofe, & Hall, 1992). This meant that unfermented nibs, fermented nibs and PCCS protein in the samples were of lower quality than those in cowpea, soybean and pigeon pea. However, whilst Cys was 0.0 mg/gcp in melon, pumpkin seed and gourd seed (Olaofe et al., 1994) and 11.3 mg/gcp in *A. occidentale*, 2.5 mg/gcp in *G. kola* and 4.5 mg/gcp in *C. acuminata* (Adeyeye et al., 2007), it was (mg/gcp): in unfermented nibs (17.7), fermented nibs (14.9), P-LCN (19.6) and PCCS (14.5). Generally, most of our results were better in many of the amino acids (essential and non-essential) than was pumpkin seed (Olaofe et al., 1994).

Whilst it is known that cystine can spare part of the requirement for methionine, FAO/WHO/UNICEF (1985) does not give any indication of the proportion of total sulphur amino acids that can be met by Cys. For the rat, chick and pig, the proportion is about 50% (FAO/WHO, 1991). Most animal proteins are low in cystine; in contrast, many vegetable proteins, especially the legumes, contain substantially more Cys than methionine. Thus, for animal protein, Cys is unlikely to contribute more than 50% of the total sulphur amino acids (FAO/WHO, 1991). For our samples, the percentages of Cys in total sulphur amino acids were: 44.1% (unfermented nibs), 46.3% (fermented nibs) – see Table 3; 78.1 (P-LCN) and 74.5 (PCCS) – see Table 4. Whilst the Cys/TSAA% in unfermented and fermented nibs followed the trend in *G. kola* (37.8%) and *C. acuminata* (44.3%) (Adeyeye et al., 2007), as well as in animals: 36.3% (*Macrotermes bellicosus*) (Adeyeye, 2005a), 25.6% (*Zonocerus variegatus*) (Adeyeye, 2005b), 35.5% (*Archachatina marginata*), 38.8% (*Archatina archatina*) and 21.0% (*Limicolaria* sp.) (Adeyeye & Afolabi, 2004), the Cys/TSAA% in P-LCN and PCCS followed the trend in *A. occidentale* (50.5%) (Adeyeye et al., 2007), coconut endosperm (62.9%) (Adeyeye, 2004), raw guinea corn (58.9%), steeped guinea corn (72.0%) and germinated guinea corn (71.1%) (Adeyeye, 2008). This meant that, whilst both unfermented and fermented cocoa nibs behaved like animal proteins under these conditions, the P-LCN and PCCS behaved like plant proteins. FAO/WHO (1973), states that Cys may supply up to one-third of the need for total sulphur amino acids whilst tyrosine may also supply up to one-third of the need for total aromatic amino acids.

The predicted protein efficiency ratios (P-PER) were better in the unfermented (3.55) and fermented (2.55) cocoa nibs than in the P-LCN (2.47) and PCCS (2.02) samples. The experimentally determined PER usually ranged from 0.0 for a very poor protein to a maximum possible of just over 4 (Muller & Tobin, 1980). These results showed that P-LCN and PCCS would likely be less utilised in the body than would the other two samples.

The Leu/Ile ratio values ranged as follows: 3.37 (unfermented nibs), 2.13 (fermented nibs), 0.75 (P-LCN) and 1.16 (PCCS). From Table 1, the level of Leu was more than twice that of Ile in unfermented and fermented nibs whilst, in Table 2, the level of Leu was just above one half that of Ile in P-LCN and slightly above Ile in PCCS. It has been suggested that an amino acid imbalance from excess leucine might be a factor in the development of pellagra in sorghum consumption (FAO, 1995).

High Leu in the diet impairs tryptophan and niacin metabolism and is responsible for niacin deficiency in sorghum eaters (Belavady, Srikantia, & Gopalan, 1963) . This leads to the hypothesis that excess Leu in sorghum is aetiologically related to pellagra in sorghum-eating populations (FAO, 1995). The study of Krishnaswamy and Gopalan (1971) suggested that Leu/Ile balance is more important than dietary excess of Leu alone in regulating the metabolism of Try and niacin and hence the disease process. Experiments in dogs have shown that animals fed sorghum proteins (with less than 110 mg/gcp of Leu) did not suffer from nicotinic acid deficiency (Belavady & Udayasekhara Rao, 1979). None of our samples had levels of Leu up to 110 mg/gcp.

Table 5 contains the amino acid scores, based on the provisional amino acids, for the unfermented and fermented cocoa nibs whilst Table 6 contains the scores of P-LCN and PCCS, based on the same formula. In Table 5, the limiting amino acids for both unfermented and fermented cocoa nibs were Met + Cys with respective values of 0.51 (unfermented nibs) and 0.43 for fermented nibs. The entire CV% was low and no significant differences existed between the two samples at $p < 0.05$ (F-test). Therefore, in order to fulfil the day's needs for the EAA in unfermented cocoa nibs, 100/51 or 1.96 times as much unfermented nibs would have to be eaten when it is the sole protein in the diet; in fermented nibs, it would be 100/43 or 2.33 times the protein level. In Table 6, Thr was the limiting

Table 5
Essential amino acid scores of the unfermented and fermented cocoa nibs based on provisional amino acid scores.

Amino acid	Unfermented nibs	Fermented nibs	Mean	SD	CV%

Phe	0.56	0.71	0.43	0.29
Try	–	–	–	–

amino acid in P-LCN (0.40) and Val in PCCS (0.05); their correction values would be 2.50 times the protein in P-LCN and 20 times in PCCS. There were CV% levels of 124 (Val), 77.4 (Lys) and 46.2 (Ile) and significant differences existed between the P-LCN and PCCS samples at $p < 0.05$ when subjected to F-test analysis.

Table 7 contains the amino acid scores of the four samples based on whole hen's egg amino acid profile. Serine was the limiting amino acid in unfermented nibs (0.30), Met in fermented nibs (0.25), Ala in P-LCN (0.028) and Val in PCCS (0.032). The respective corrections would then be 100/30 or 3.3 (unfermented nibs), 100/25 or 4.0 (fermented nibs), 100/2.8 or 35.7 (P-LCN) and 100/3.2 or 31.3 (PCCS) times the protein of each sample where they serve as the sole protein sources.

The data obtained for TNEAA, TEAA and EAA scores were all subjected to the F-test as follows: TNEAA/TNEAA, TEAA/TNEAA and EAA score/EAA score for the pairs of unfermented/fermented nibs and P-LCN/PCCS setting the $p < 0.05$ (Christian, 1980). The following results were obtained. In unfermented/fermented cocoa nibs, TNEAA/TNEAA $F_c < F_t$ and in P-LCN/PCCS result was $F_c < F_t$, results not significantly different; in TEAA/TNEAA in unfermented nibs, $F_c > F_t$; in fermented nibs, $F_c > F_t$, in P-LCN, $F_c > F_t$ meaning all the values were significantly different but, in PCCS, $F_c < F_t$; hence results were not significantly different. For the EAA score/EAA score, in unfermented/fermented nibs, $F_c < F_t$, but not significant; for P-LCN/PCCS, $F_c > F_t$, and results were significantly different at $p < 0.05$.

In conclusion, the findings of this study showed that there was a more positive build up of AA in fermented nibs than in unfermented nibs. In the processing, about 40% of the AA was destroyed; this might have resulted from the series of reactions involving amino acids, nitrates and antioxidants during the heat processing of cocoa. Finally, more cake (PCCS) would be required for complementation/fortification than would have been used if the unprocessed nibs were to be used. Also the differences observed in the fermented and unfermented samples (group one) and P-LCN and PCCS (group two) could be due to planting material, climate, varieties, application of fertiliser, heat treatments and storage between the group one and two samples.
